

Figure 5: Seismic fragility curves of the vehicle subsystem for the Tirothea-Domokos Railway Bridge (x- and y-direction)

Fragility Curves (X-direction) – Bridge System & Coupled Bridge-Vehicle System

Fragility Curves (Y-direction) – Bridge System & Coupled Bridge-Vehicle System

Figure 6: Seismic fragility curves of the bridge subsystem with and without VBI consideration (a,b) and of the coupled train-bridge system with VBI consideration for the Tirothea-Domokos Railway Bridge (x- and y-direction)

Respectively, VBI consideration was found to reduce the seismic fragility of the bridge system and both the longitudinal and transverse direction, compared to the relevant without

the train movement and VBI consideration. The reduction is greater for the higher limit states and the transverse direction of the bridge and is consistent with the previous comment regarding the effect of VBI on the seismic fragility of components, since series connection is assumed for the estimation of the bridge system's fragility.

The seismic fragility of the vehicle subsystem, i.e. the probability of damage related to the exceedance of the limit state defined for running stability, dynamic bridge performance and running safety, are presented for LS1 to LS3 (same with LS4) in Figure 5. The consideration of the aforementioned limit states in the frame of the coupled system analysis and the derivation of relevant fragility curves is obviously critical, based on Fig.6 (c). The seismic fragility of the coupled vehicle-bridge system for both the longitudinal and transverse direction is obviously higher for all the damage states when the limit states related to the vehicle performance are considered in the frame of fragility analysis (accounting for series connection between subsystems). Therefore, it was found crucial to account for VBI and for limit states related to the vehicle performance for the estimation of the coupled systems' fragility since the system is practically coupled and the train safety, stability, etc affects the total performance. However, for resilience, restoration and loss assessment, all the subsystem and component fragility curves should be considered.

6 CONCLUSIONS

A novel methodology for fragility analysis of the coupled vehicle-bridge system is presented herein, accounting for the fragility of subsystems (vehicle and bridge). Limit state thresholds are defined at component and subsystem level and the probabilistic framework is applied, analyzing the coupled system on the basis of a co-simulation technique. A fully parameterized, software is developed including a tailor-made module for vehicle analysis (multibody system), the use of an open-source software for bridge analysis and a module developed for fragility analysis based on the proposed framework. The methodology and framework proposed are applied to a representative, simply supported bridge of the Greek railway network, providing the coupled systems' fragility curves. The most important conclusions from the application of the methodology to the case study bridge are summarized below:

- The seismic fragility of critical bridge *components* is decreased for the case that VBI is considered, mainly for higher limit states. The latter is attributed to the differentiation of the dynamic characteristics of the bridge due to VBI resulting in a different earthquake response, also related to the structural system and the properties (ductility, inelastic performance, etc.) of the components.
- VBI consideration was found to reduce the seismic fragility of the *bridge system* and both the longitudinal and transverse direction, compared to the relevant without the train movement and VBI consideration. The reduction is greater for the higher limit states and the transverse direction of the bridge.
- The seismic fragility of the coupled vehicle-bridge system for both the longitudinal and transverse direction is higher for all the damage states when the limit states related to the vehicle performance are considered. Therefore, it was found crucial to account for VBI and for limit states related to the vehicle performance for the estimation of the coupled systems' fragility.

ACKNOWLEDGEMENTS

The authors would like to thank ERGOSE SA & METESEISM SA for providing access to the data (drawings, technical reports) of the case study bridges.

This project has received funding from the Hellenic Foundation for Research and Innovation (HFRI) and the General Secretariat for Research and Innovation (GSRT), under grant agreement No 617”

Abstract

The application of precast post-tensioned segmental (PPS) bridge piers is growing in order to reduce global damages through rocking motion of the segments when subject to lateral excitations. However, local damages still exist in form of concrete spalling and crushing at the compression zones when one segment rocks on top of the underlying segment. Hence, this work will address reduction of these local damages in PPS piers through confinement of concrete segments by glass-fibre reinforced polymer (GFRP) tubes and use of elastic layers between segments at the joints. To achieve this goal, a robust Finite Element (FE) model is first developed in ABAQUS software, and is experimentally validated using the existing literature. The cyclic behaviour of the experimentally-validated FE model is then determined. It was found that the GFRP tubes and elastic layers significantly reduce local damages of PPS piers at the joints.

Keywords: Precast Post-Tensioned Segmental Piers, Glass-Fibre Reinforced Polymer, Finite Element Model, Elastic Layer, Cyclic Loading.

1 INTRODUCTION

Bridges are one of the crucial components of any transport network and any small disruption in their functionality can result in enormous economic damages and life losses. In particular, lateral excitations such as earthquake, can cause severe damages in bridge structures. Conventional cast-in-place (CIP) reinforced concrete (RC) piers are constructed monolithically with the bridge deck, and experience permanent damages in form of plastic hinges during

severe earthquake loadings. One of the most effective solutions to avoid any plastic hinge, widely considered by researchers in accelerated bridge construction (ABC) [1], is precast post-tensioned segmental (PPS) piers [2]. In ABC, the concrete segments are manufactured offsite with higher quality, and then transferred to the construction site to be assembled. Additionally, the construction process is expedited, and environmental pollution is reduced. The rocking mechanism of the segments and self-centering effect of the post-tensioned tendon decrease the residual deformation of the PPS piers [3].

On the other hand, application of fibre reinforced polymer (FRP) material is growing in concrete piers due to its high stiffness and resistance against corrosion, weathering, and chemical attacks [4,5]. Using FRP around concrete piers enhances their performance by adding extra confinement to the concrete. In existing piers, FRP tubes are used to strengthen the pier, and in design of new piers, FRP tubes increase axial loading capacity of the pier [4]. FRP tubes also prevent the cover concrete from spalling, and significantly increase the ductility and lateral strength of the pier subject to seismic loading events [6]. The FRP tubes have larger flexural strength and higher strength-to-weight ratio compared to steel tubes, and reduce the creep strain of the confined concrete [7,8].

In moderate- and high-seismicity regions, each segment of the PPS piers may still experience local damages at the contact interfaces (e.g. compression zones at the joints) in form of concrete spalling and crushing [4]. This is because of high stress concentration at the joints due to high compressive stresses [9]. To reduce or even eliminate concrete spalling and crushing at the joints, the segments were confined with steel jackets [10,11,12]. However, the steel jackets yield, and thus induce permanent residual deformations in the pier. Therefore, this study adopts a new approach in order to reduce the local damages and a damage-free PPS pier. The current study numerically investigates PPS piers confined with glass fibre reinforced polymer (GFRP) tubes, where elastic layers are used between the segments. To achieve this aim, a robust FE model is first developed and validated. Then, cyclic behavior of the pier is studied to investigate the effects of GFRP tubes around the segments and elastic layers between the segments.

2 NUMERICAL MODELLING

Four PPS specimens are modelled: (1) PPS pier without GFRP tube and elastic layer, P, (2) PPS pier with GFRP tubes, PT, (3) PPS pier with elastic layers, PL, and (4) PPS pier with GFRP tubes and elastic layers, PTL. To study the effects of the flexibility of the elastic layers between the segments, three values of Young's modulus are considered for the elastic layers: 05, 10 and 15 GPa. All the PPS specimens are summarized in Table 1, and the FE models of the PPS piers are shown in Figure 1.

Pier Name	Pier Description	GFRP Tube	Elastic Layer (E_{layer})
P	Without GFRP tube and elastic layer	-	-
PT	With GFRP tubes	✓	-
PL05	With elastic layers	-	✓ (05 GPa)
PL10		-	✓ (10 GPa)
PL15		-	✓ (15 GPa)
PTL05	With GFRP tubes and elastic layers	✓	✓ (05 GPa)
PTL10		✓	✓ (10 GPa)
PTL15		✓	✓ (15 GPa)

Table 1: PPS specimens with different configurations of GFRP tubes and elastic layers.

Figure 1 compares all the PPS pier specimens considered in this study. A 3D FE modelling of the PPS pier is developed in ABAQUS [13]. Figure 2 shows geometric details of the PPS piers. The 3D FE model of the piers is defined with n segments ($n = 6$), of width B ($B = 0.5$ m) and height h ($h = 0.5$ m). To provide the self-centering mechanism under a lateral cyclic loading, an unbounded post-tensioned tendon passes through a duct in the segments, and is fixed to the top of the pier and the bottom of the foundation. The duct has a diameter of 80 mm, and the post-tensioned tendon area is considered 20 % of the segment area [14]. The elastic layers of height of h_L ($h_L = 5$ cm) are used between the segments.

The segments, foundation, and tendon are modelled using eight-node 3D brick elements (C3D8R). The segments, layers, and tendons are deformable solids while the foundation is a discrete rigid element. The GFRP tubes are modelled as shell elements around the concrete segments. To model the joints, the surface-to-surface contact elements are adopted. The tangential friction between the surfaces is taken 0.5 [15]. To model the normal contact between the surfaces, the hard contact is used. To model the unboundedness of the tendon, the frictionless surface-to-surface contact element is adopted between the tendon and the inside face of the ducts, through the segments and layers. The unbounded tendon is embedded in a load stub at the top of the pier and in the foundation.

Figure 1: The FE models of: (a) P, without GFRP tubes and elastic layer, (b) PT, with GFRP tubes, (c) PL, with elastic layers, and (d) PTL, with GFRP tubes and elastic layers.

Figure 2: Geometric details of the piers: (a) P and PT, and (b) PL, and PTL.

To define concrete material of the segments, there are two models in ABAQUS: (i) smeared cracking model, and (ii) damaged plasticity model. The concrete damage plasticity is recommended for concrete piers subject to monotonic, cyclic and dynamic loading as used in this study [13,16]. Figure 3a shows the stress-strain of concrete for both confined (with GFRP tubes) and unconfined (without GFRP tubes) concrete [17]. The concrete's modulus of elasticity, Poisson's ratio, and density are 34.6 GPa, 0.2, and 22 kN/m³, respectively. To simulate the opening between the joints, tension strength of concrete is taken zero. The post-tensioning tendon is modelled by a bilinear elastic-plastic model, shown in Figure 3b. The initial post-tensioning of the tendon is $T_0 = \alpha f_y$, where α is the yield force ratio of the tendon, 0.2, and f_y is yield stress of the tendon. The tendon's modulus of elasticity, yielding stress, Poisson's ratio, and density, 200 GPa, 2000 MPa, 0.3, and 78.4 kN/m³, respectively. To model the GFRP tubes, the elastic behavior of Lamina type is used [13]. To develop the material properties, five constants are required: three shear moduli (G_{12} ; G_{13} ; G_{23}) and two Young's moduli

(E_{11} ; E_{22}). Each shear modulus is taken 3 MN/m^2 , and each Young's modulus is considered 65 GN/m^2 .

3 VALIDATION

The modelling approach, explained in Section 2, is validated through comparing with the experimental results by Palermo et al. [16,18]. The tested pier is composed of one concrete segment of height 1.6 m, and width 0.35 m without any elastic layer or GFRP tubes. The model has two $\phi 12.7$ mm tendons, which pass through a pair of ducts in the segment and are fixed to a load stub at the top of the pier and a foundation at the bottom of the pier, as shown in Figure 5. The post-tensioning force ratio, α , is 0.3, and the compressive strength of concrete, f'_c , is 54.1 MPa. The yield stress, f_y , and ultimate stress, f_u , of the post-tensioned tendons are assumed 1600 MPa and 1870 MPa, respectively. All the details of the modelling and loading are the same with those in the Palermo's test [16]. As Figure 6 shows, the lateral force-drift of the FE model and the test are very compatible, which demonstrates the robustness of the FE model in capturing lateral behavior of post-tensioned rocking piers. This comparison validates the reliable simulating of the models to study the behavior of the PPS piers.

4 ANALYSIS AND RESULT

In this section, the cyclic behaviors of the eight piers, summarized in Table 1, are compared. Figure 7 demonstrates hysteretic response curves of the piers: the base shear, V , versus drift, Δ/H ; Δ is the tip displacement of the pier, and H is the total height of the pier. The results demonstrate different cyclic behavior for each pier. The pier, P, without any tube and layer, demonstrates a sudden reduction in its stiffness as the slope of the hysteretic loops suddenly drops after a few cycles at small drift ratios, less than 1% (Figure 7a). This stiffness re-

duction is due to the concrete spalling and crushing at small drift ratios at the toe of the segments (see Figure 3a). Adding GFRP tubes around the pier's segment, enhances the strength and slightly the ductility of the pier (Figure 7b). However, significant residual drifts are seen, particularly for the last cycles of the loading. Adding elastic layers between the segments slightly affects the strength of the pier, and gives zero-residual drift for the pier (Figure 7c). The simultaneous use of elastic layers and GFRP tubes increases ultimate strength of the pier, and results in zero-residual drift. This is very desirable in a PPS pier as it is intended to be a damage-free pier (zero-residual drifts).

Figure 7: Hysteretic response curves of the piers: (a) P, (b) PT, (c) PL15, and (d) PTL15.

Figure 8 shows hysteretic response curves of the piers with different values of Young's modulus for the elastic layer. It is seen that the models with both GFRP tubes and elastic layers reach higher lateral strength. For the piers, PL and PTL, (Figures 8a and 8b), larger Young's modulus of the elastic layers gives higher lateral strength; The maximum value of base shear for Young's modulus of 15 GPa are 200 and 273.8 kN, for the piers PL and PTL, respectively.

Figure 8: The effect of Young's modulus of the layer on the hysteretic response curves of the piers: (a) PL, and (b) PTL.

Figure 9 shows the stress at the toe of the bottommost joint (base joint), located between the bottom segment and the foundation, for the piers P, PT, PL15, and PTL15. For the pier P, after a few cycles of loading, the concrete crushes at the toe subject to high value of strain (see Figure 3a), and consequently, an abrupt drop is seen in the compressive stress at very small drifts, less than 1% (Figure 9a). Using GFRP tubes around the segments delays the stress drop by adding confinement to the concrete (Figure 9b). Adding elastic layers to the pier eliminates the sudden drop in the compressive strength of concrete (Figure 9c). The pier with both GFRP tubes and elastic layers (Figure 9d) reaches to higher compressive strength for higher values of drift compared to when using elastic layers only (Figure 9c). Figures 10 and 11 show the stress at the topmost, second bottom, and bottommost joints of the piers, PL and PLT. For both piers, the bottommost joint experiences the highest stress and local damage at their toes. The maximum values of stress is obtained for the models with Young's modulus of 15 GPa (PL15 and PTL15).

Figure 9: Compressive stress at the toe of the bottommost joint for the piers: (a) P, (b) PT, (c) PL15, and (d) PTL15.

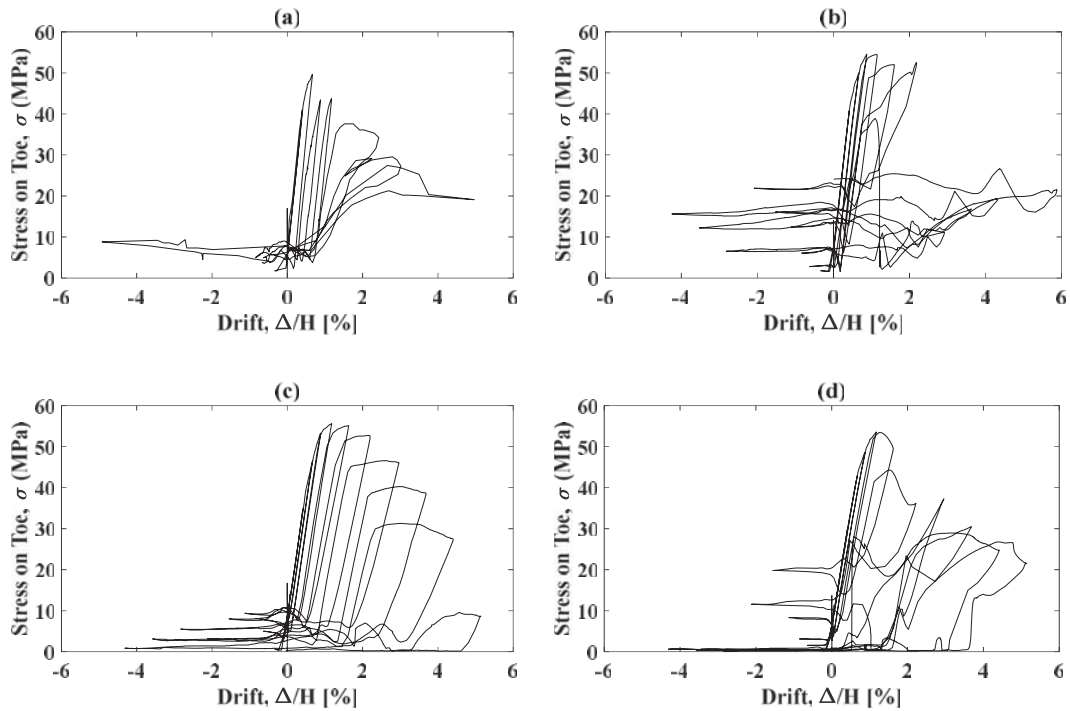

Figure 10: The effect of Young's modulus of the layer on the stress at: (a) the topmost joint, (b) the second bottom joint, and (c) the bottommost joint of the pier PL.

Figure 11: The effect of Young's modulus of the layer on the stress at: (a) the topmost joint, (b) the second bottom joint, and (c) the bottommost joint of the pier PLT.

5 CONCLUSIONS

In this study, the effects of GFRP tubes and elastic layers on local damage of PPS piers were investigated. Hence, an FE model including GFRP tubes around segments and elastic layers in joints between segments were modelled using ABAQUS software.

It is found that elastic layers significantly reduce local damages at the joints, and GFRP tubes improve the results for large drifts. The results also show that GFRP tubes increase strength of the PPS piers, and both elastic layers and GFRP tubes give a zero-residual drift for the pier. These conclusions are very promising in designing a damage-free PPS pier. Hence, elastic layers need to be designed, and experimental tests need to be conducted for further investigation and validation of the proposed strategy.

Keywords: Rigid block-like structures, base active control, active mass damper, pole placement method, rocking motion, overturning.

Abstract. *This paper compares the efficiency of two active control systems based on the same control algorithm in protecting rigid block-like structures from overturning. The control algorithm is the Pole Placement Method that is aimed at transforming the rest position of a rigid block into a stable equilibrium point. The two control systems differ in the position of the actuator driven by the active control algorithm. In the first case, the block is placed on a horizontally translating support that is connected to the ground by an actuator able to provide a controlled displacement. In the second case, a small mass able to run at the top of the block is driven by an actuator capable of applying a controlled displacement. This kind of protection system is commonly called Active Mass Damper. The effectiveness of the two control systems is analysed by comparing the overturning spectra that represent the amplitude of the harmonic excitation able to overturn the block versus its circular frequency. Several simulations have been conducted using different recorded earthquakes to evaluate the performances of the two control methods in the reduction of the rocking angle and the protection from the overturning of the block. The results show the excellent performance of both the considered control systems.*

1 INTRODUCTION

The protection of rigid block-like elements such as obelisks, statues, storage boxes, transformers, cabinets, and racks for both civil and industrial use is a challenging topic for civil engineers. The most common failure of such elements is the overturning caused by base excitation. Different techniques have been proposed to prevent such overturning. The majority of the researchers proposed protection techniques that are based on passive control systems.

For example, in [1, 2], the authors studied the effectiveness of base anchorages. Some papers investigated the efficiency of base isolated systems [3, 4, 5, 6, 7]. Several authors used mass-dampers that have been modeled either in the shape of a pendulum [8, 9, 10, 11] or as a single degree of freedom mass running on the top of the rigid block [12, 13, 14]. Some papers presented the coupling of rigid bodies with inerter devices [15, 16]. Lately, some researchers studied the use of semi-active anchorages [17, 18], and active control techniques [19, 20, 21] to increase the amplitude of base excitation required to topple a rigid block.

This paper compares the efficiency of two active control systems based on the same control algorithm in protecting rigid block-like structures from overturning. The control algorithm is the Pole Placement Method that is aimed at transforming the rest position of a rigid block into a stable equilibrium point. In fact, in the classical rocking equations of rigid blocks based on Housners model [22], the rest position is not an equilibrium point. The two control systems differ in the position of the actuator driven by the active control algorithm. In the first control system, the block is placed on a horizontally translating support. Such support has a mass that is negligible compared to the mass of the block and it is connected to the ground by an actuator able to provide a controlled displacement. This protection system was already studied in [20]. In the second control system, a small mass able to run at the top of the block is driven by an actuator capable of applying a controlled displacement. This protection system is commonly called Active Mass Damper (AMD).

For both methods, the linearized rocking equations are used to derive the control laws. The optimal coefficients of the control laws are selected assuming the overshoot as the key parameter. Both the control systems exhibit a low sensitivity to the geometrical characteristics of the rigid block so that the same optimized control coefficients can be used for a wide class of rigid blocks. The robustness of the two control systems is also investigated by considering the limitations of the control forces and different sampling and delay times.

The effectiveness of the two control systems is analyzed by comparing the overturning spectra that are obtained with and without control. Such overturning spectra provide the amplitude of the harmonic excitation able to overturn the block versus its circular frequency. Several simulations have also been conducted using different recorded earthquakes to evaluate the performances of the two control methods in the reduction of the rocking angle and the protection from the overturning of the block under seismic excitation.

The results show the excellent performance of both the considered control systems. Consequently, since the performances of the control systems are comparable for all the working conditions considered, the choice between the two methods is dictated by the technical and technological aspects of each specific application.

2 ACTIVE CONTROL METHODS

In both the control methods the mechanical system is a rigid block in the shape of a parallelepiped with a height $2h$ and a base $2b$ (Fig. 1). The base dimension orthogonal to the rocking plane has unitary length. The mass of the block is $M = \rho \times 2b \times 2h \times 1.0$, where the mass den-

sity $\rho = 1800\text{kg/m}^3$. The block cannot slide, so its motion is described by only the Lagrangian parameter $\theta(t)$ that is the rocking angle. In the first control method, the block is placed on a horizontally translating support. Such support has a mass that is negligible compared to the mass of the block and it is connected to the ground by an actuator able to provide the controlled displacement $u^B(t)$ (Fig. 1a). In the second control scheme, a small mass m , able to run at the top of the block, is driven by an actuator capable of applying the controlled displacement $u^T(t)$ (Fig. 1b).

The control algorithm used in this paper is the Pole Placement Method (PPM) that is aimed at transforming the rest position of a rigid block into a stable equilibrium point. It is worth observing that, the two rocking equations describing the motion around the two base pivots of a stand-alone rigid block, do not admit the rest position ($\theta(t) = 0$) as an equilibrium point. The PPM algorithm makes the rest position a stable equilibrium point in both the rocking equations.

Figure 1: Active control systems: (a) Base Active Control (BAC); (b) Top Active Control (TAC) or active mass damper.

2.1 Base active control system

Since the active control system applied to the base of the rigid block and based on the Pole Placement Method was already studied in [20], in this subsection only the main governing equations are reported. The system shown in Fig. 1a can be described by the same equations of a stand-alone block with an additional term due to the control device. The control displacement $u^B(t)$ applies an acceleration $\ddot{u}^B(t)$ at the base of the block that works as the external excitation. Hence, it appears in the equations of motion as a contribution added to external acceleration \ddot{x}_g . The equations of motion read

$$\begin{aligned} (J_G + MR^2) \ddot{\theta}(t) + gMR \sin(\alpha_{cr} - \theta(t)) - MR \cos(\alpha_{cr} - \theta(t)) (\ddot{x}_g(t) + \ddot{u}^B(t)) &= 0 \\ (J_G + MR^2) \ddot{\theta}(t) - gMR \sin(\alpha_{cr} + \theta(t)) - MR \cos(\alpha_{cr} + \theta(t)) (\ddot{x}_g(t) + \ddot{u}^B(t)) &= 0 \end{aligned} \quad (1)$$

where g is the gravity acceleration; J_G is the polar momentum evaluated with respect to the mass centre G ; α_{cr} is the value of $\theta(t)$ in which the vertical projection of the mass centre G passes through the base rocking corner; R is the distance between the mass centre G and the base rocking corner.

The control algorithm is obtained by linearising the equations of rocking motion with respect to $\theta(t)$. This assumption leads to an excellent approximation in the case where $\theta(t)$ is very small. This fact occurs in sufficiently tall blocks where θ has to be smaller than the critical angle α_{cr} .

The Pole Placement Method has two main objectives: (i) to vanish the external excitation at each instant and (ii) to make the rest position of the block a stable point. The first objective is achieved by providing a control force opposite to the external one to the system. For the second objective, the rest position of the block can be considered a stable point if the Jacobian matrix is modified in such a way that the eigenvalues have negative real part. The control law $\ddot{u}^B(t)$, representing the control acceleration that the actuator has to apply to the system at each time t reads

$$\ddot{u}^B(t) = \pm g\alpha_{cr} - \ddot{x}_g(t) - \frac{1}{4} \left(4 + q_{22}^2 \right) \vartheta(t) - \frac{g}{\omega_o} q_{22} \dot{\vartheta}(t) \quad (2)$$

where q_{22} is a control coefficient that has to be determined. The sign $(-)$ refers to the rocking motion around the left corner, whereas the sign $(+)$ refers to rocking motion around the right corner.

2.2 Active mass damper system

The equations of motion of the controlled system in Fig. 1b are obtained via a Lagrangian approach

$$\begin{aligned} 0.25 [\theta''(t)(4b^2(m+M) + m(4u(t)(2b+u(t)) + h_m^2 + 8hh_m) + 4h^2(4m+M)) + \\ 4m(2b\dot{\theta}(t)\dot{u}(t) + u(t)(g\cos(\theta(t)) + 2\dot{\theta}(t)\dot{u}(t)) - 2h\ddot{u}(t)) + \\ 4\ddot{x}_g(t)(-\sin(\theta(t))(b(m+M) + mu(t)) - h(2m+M)\cos(\theta(t))) - \\ 2mh_m(g\sin(\theta(t)) + \ddot{u}(t) + \cos(\theta(t))\ddot{x}_g(t))] + \\ bg(m+M)\cos(\theta(t)) - gh(2m+M)\sin(\theta(t)) + J_G\ddot{\theta}(t) = 0 \end{aligned} \quad (3)$$

$$\begin{aligned} 0.25 [\ddot{\theta}(t)(4b^2(m+M) + m(4u(t)(u(t)-2b) + h_m^2 + 8hh_m) + 4h^2(4m+M)) - \\ 2m(4b\dot{\theta}(t)\dot{u}(t) + gh_m\sin(\theta(t)) - 2gu(t)\cos(\theta(t)) + (h_m + 4h)\ddot{u}(t) - \\ 4u(t)\dot{\theta}(t)\dot{u}(t) + 2\ddot{x}_g(t)(2\sin(\theta(t))(b(m+M) - mu(t)) - \\ (2h(2m+M) + mh_m)\cos(\theta(t)))) - \\ bg(m+M)\cos(\theta(t)) - gh(2m+M)\sin(\theta(t)) + J_G\ddot{\theta}(t) = 0 \end{aligned}$$

where $h_m/2$ is the vertical distance between the centre of the small mass m and the top of the block (see Fig. 1b.) Also in this case the control algorithm is obtained by linearising the equations of rocking motion with respect to the variables $\theta(t)$ as

$$\dot{\mathbf{Z}}(t) = \mathbf{A}_1(t)\mathbf{Z}(t) + \mathbf{A}_2 + \mathbf{A}_3\ddot{x}_g(t) + \mathbf{A}_4\ddot{u}^T(t) \quad (4)$$

where $\mathbf{Z}(t) = \left\{ \begin{matrix} \theta(t) & \dot{\vartheta}(t) \end{matrix} \right\}^T$ is the state variables vector and the matrices \mathbf{A}_1 , \mathbf{A}_2 , \mathbf{A}_3 , and \mathbf{A}_4 read

$$\begin{aligned} \mathbf{A}_1(t) = \begin{bmatrix} 0 & 1 \\ \omega_0^2 & \mp \frac{2bm}{J_{A,B}}\dot{u}^T(t) \end{bmatrix}; \quad \mathbf{A}_2 = \begin{bmatrix} 0 \\ \mp \frac{bg(m+M)}{J_{A,B}} \end{bmatrix} \\ \mathbf{A}_3 = \begin{bmatrix} 0 \\ \frac{\omega_0^2}{g} \end{bmatrix}; \quad \mathbf{A}_4 = \begin{bmatrix} 0 \\ \frac{\omega_0^2}{g} - \frac{hM}{J_{A,B}} \end{bmatrix} \end{aligned} \quad (5)$$

where $\omega_0^2 = (hM + (2h + h_m/2)m)g/J_{A,B}$ is the linear frequency associated to the motion of the block and $J_A = J_B$ is the total polar momentum evaluated with respect to one of the base rocking corners. The following control law is assumed:

$$\mathbf{A}_4 \ddot{u}^T(t) = -\mathbf{A}_2 - \mathbf{A}_3 \ddot{x}_g(t) - \mathbf{Q}(t) \mathbf{Z}(t) \quad (6)$$

where $\mathbf{Q}(t)$ is a weighting matrix

$$\mathbf{Q}(t) = \begin{bmatrix} 0 & 1 \\ \omega_0^2 q_{12} & \omega_0 q_{22} \mp \frac{2bm}{J_{A,B}} \dot{u}^T(t) \end{bmatrix} \quad (7)$$

By introducing Eq. 6 into the linearised equations Eq. 4, the linearised controlled system becomes

$$\dot{\mathbf{Z}}(t) = (\mathbf{A}_1(t) - \mathbf{Q}(t)) \mathbf{Z}(t) \quad (8)$$

where the Jacobian matrix of the controlled system $\mathbf{A}_1(t) - \mathbf{Q}(t)$ does not depend on time. The linearised system Eq. 8 admits the rest position $\theta(t) = 0$ as stable equilibrium point if the eigenvalues of the linearised Jacobian matrix are real, negative, and coincident. This fact occurs for the control coefficient $q_{12} = 1/4(4 + q_{22}^2)$.

By expanding Eq. 6, it is possible to observe that the control displacement $u^T(t)$ has to satisfy the following differential equation:

$$\ddot{u}^T(t) \mp c_u(\dot{\theta}) \dot{u}^T(t) \mp c_0 + c_g(\ddot{x}_g) + c_\theta(\theta) + c_{\dot{\theta}}(\dot{\theta}) = 0 \quad (9)$$

where the coefficients in the equation are

$$\begin{aligned} c_u(\dot{\theta}) &= \frac{2bmg}{J_{A,B} - hMg} \dot{\theta}; & c_0 &= \frac{bg^2(M+m)}{J_{A,B} - hMg}; & c_g(\ddot{x}_g) &= \frac{J_{A,B}\omega_0^2}{J_{A,B} - hMg} \ddot{x}_g \\ c_\theta(\theta) &= \frac{1}{4} \frac{J_{A,B}g\omega_0^2}{J_{A,B} - hMg} (4 - q_{22}^2) \theta; & c_{\dot{\theta}}(\dot{\theta}) &= \frac{1}{4} \frac{J_{A,B}g\omega_0}{J_{A,B} - hMg} q_{22} \dot{\theta} \end{aligned} \quad (10)$$

2.3 Ideal and real controlled system

The real working conditions of the controlled system differ from the ideal case because (i) the control accelerations $\ddot{u}^{B,T}$ have to be limited to a threshold value that depend on the characteristics of the actuator, (ii) the control device applies the accelerations $\ddot{u}^{B,T}$ with a delay that depends on the characteristics of the control system, and (iii) the control algorithm is obtained from the linearised equations of motion, hence it works sufficiently well with the nonlinear mechanical system if the smallness of the rocking angle θ can be considered a valid approximation.

It is considered that the actuators can reach the maximum acceleration $\ddot{u}_{max}^B = 0.2g$ and $\ddot{u}_{max}^T = 2.0g$, respectively for the base and the top active control system. Therefore, by taking the moving mass of Fig. 1b $m = \gamma M$, with $\gamma = 0.1$, it follows that the maximum control forces $F_{max}^B = M0.2g$ and $F_{max}^T = m2.0g = \gamma M2.0g$ are equal. In the simulations performed in the paper, it is always considered this threshold value of the controlled accelerations.

As it is known, real control systems suffer of time-delays between the real time and the application of the control displacement. One of the delays is the so-called sampling time δt_c , which measures the time-step between two successive data acquisitions of the state variables necessary to evaluate the control displacement. The other type of delay is the time-delay δt_d , which is related to the speed of the control system and of the actuator to evaluate and to apply

the control displacement to the system. An analysis to evaluate the robustness of the control systems to a variation of the time-delays is performed below.

Both active control systems depend only on the coefficient q_{22} (Eq. 2 and Eqs. 9-10). The search of the optimal value of such coefficient can be usually performed in terms of step response of the system ([23]). In a rigid block system the step input cannot assume any value because the block overturns over a threshold of the base acceleration. Hence, a small constant base acceleration, capable of uplifting the block but not sufficient to overturn it, is considered. The efficiency of the control system can be measured by evaluating the so called *overshoot*. Under a step excitation, the block uplifts, reaches the overshoot, that is the maximum rocking amplitude, and comes back to the rest position, thanks to the control apparatus. A parametric analysis is performed in order to evaluate the overshoot as a function of the sole control coefficient q_{22} , in both the considered control systems. Such parametric analysis provide the same value of the control coefficient $q_{22} = 7$ for both control systems.

3 UPLIFT AND IMPACT CONDITIONS

In order to correctly describe the behaviour of the system, the knowledge of the transition conditions among the different possible phases of motion is needed. The system at hand presents two transition conditions: uplift and impact.

The uplift condition provides the minimum base acceleration a_{up} capable of uplifting the block. It is assumed that the control system works after the beginning of the rocking motion. The minimum value of the horizontal acceleration able to uplift the block can be obtained from the balance between the resisting moment (due to the weight of the block) and the overturning moment (due to the inertial forces).

During the rocking motion, when the rotation $\theta(t)$ approaches to zero, an impact between the block and the support occurs. Consequently, the pivot of the rocking motion changes and it is necessary to evaluate the angular velocity of the block after the impact. Post-impact conditions of the rocking motion can be found assuming that the impact happens instantly, the block position remains unchanged, and the conservation of the angular momentum is imposed.

3.1 Base Active Control system

Since the control system works only after the beginning of rocking motion, the uplift and impact conditions are the same as those of a stand-alone rigid block. The uplift condition reads

$$|a_{up}| \geq \frac{g}{\lambda} \quad (11)$$

where $\lambda = h/b$ is the slenderness of the block. An uplift occurs around the left (right) base corner when $a_{up} > 0$ ($a_{up} < 0$).

The impact condition provides the following restitution coefficient

$$\mu = \frac{\dot{\vartheta}^+}{\dot{\vartheta}^-} = \frac{(J_O - 2bS_y)}{J_O} \quad (12)$$

where J_O is the polar inertia of the block with respect one of the two base corners; $S_y = \pm Mb$ (sign minus in case of re-uplift around the left base corner, sign plus in case of re-uplift around the right corner) is the static moment of the block with respect to a vertical axis passing through one of the two base corners and superscript $(\cdot)^-$ and superscript $(\cdot)^+$ denote pre- and post-impact quantities respectively.

3.2 Top Active Control system

The acceleration able to uplift the system can be found from the balance between the resisting and the overturning momenta as

$$|a_{up}| \geq \frac{(M + m)bg}{Mh + m\left(2h + \frac{h_m}{2}\right)} \quad (13)$$

An uplift occurs around the left (right) base corner when $a_{up} > 0$ ($a_{up} < 0$). By imposing the conservation of the angular momentum before and after an impact, both evaluated respect to the re-uplifting corner, the following restitution coefficient is obtained:

$$\mu = \frac{\dot{y}^+}{\dot{y}^-} = \frac{4\left(J_O - 2bS_y + m\left(-b^2 + 4h^2 + u(t)^2\right)\right) + mh_m^2 + 8h_mh_m}{4\left(J_O + m\left(b^2 + 2bu(t) + 4h^2 + u(t)^2\right)\right) + mh_m^2 + 8h_mh_m} \quad (14)$$

It is worth observing that, if $m = 0$ the uplift and the impact conditions given by Eq. 13 and Eq. 14 becomes the same as those of a stand-alone rigid block.

4 PARAMETRIC ANALYSIS

4.1 Harmonic excitation

An harmonic base excitation is first considered. It reads

$$\ddot{x}_g(t) = A_s \sin(\Omega t) \quad 0 \leq t \leq t_{\max} \quad (15)$$

where $\Omega = 2\pi/T_s$ is the circular frequency of the excitation, T_s is the period of the harmonic cycle, A_s is its amplitude, and $t_{\max} = 10s$ is the maximum time used in the numerical integrations. The assessment of the efficiency of the two control algorithms in protecting the block from the overturning is performed by comparing the results obtained with those of the uncontrolled system. A parametric analysis is performed to obtain overturning spectra, where the overturning amplitude A_s of the excitation is plotted versus the frequency Ω . The single overturning spectrum is obtained for blocks with fixed base $2b$, fixed slenderness λ , and fixed upper limit of the control forces $F_{max}^B = F_{max}^T$ (as explained in Subsection 2.3).

The overturning spectra referring to two blocks with different geometrical characteristics are shown in Fig. 2. Specifically, the spectra in the first row of the figure refer to a block with $2b = 0.4$ m and $\lambda = 5$, whereas the spectra in the second row refer to a block with $2b = 0.6$ m and $\lambda = 7$. Figure 2a shows the spectra of both the blocks obtained for three different couples of time delays and where the Base Active Control (BAC) is used. As can be observed, the spectra obtained for different time-delays are very close to each other. This means that the BAC system manifest a good robustness to time-delays. In Figure 2b the spectra of both blocks with the Top Active Control (TAC) and different time-delays are reported. The results show that the TAC system is more sensible to time-delays than the BAC system. This means that the TAC does not manifest a good robustness to time-delays. However, when the time-delays increase (from the dashed curve to the dotted curve), the distance among the spectra reduces.

Finally, the comparison among overturning spectra with the BAC system, the TAC system, and with No Active Control (NAC) are shown in Fig. 2c. These spectra refer to a fixed couple of time-delays ($\delta t_c = 0.1s$ and $\delta t_d = 0.05s$), that refer to a control apparatus of mean characteristics as in [17] and [18]. As can be observed, both the control systems exhibit a better performance than the case without active control. Nevertheless, the TAC system assures the

best performances in reducing the overturning of the block, since for each frequency Ω of the harmonic excitation the overturning of the block occurs for higher amplitude A_s of the excitation.

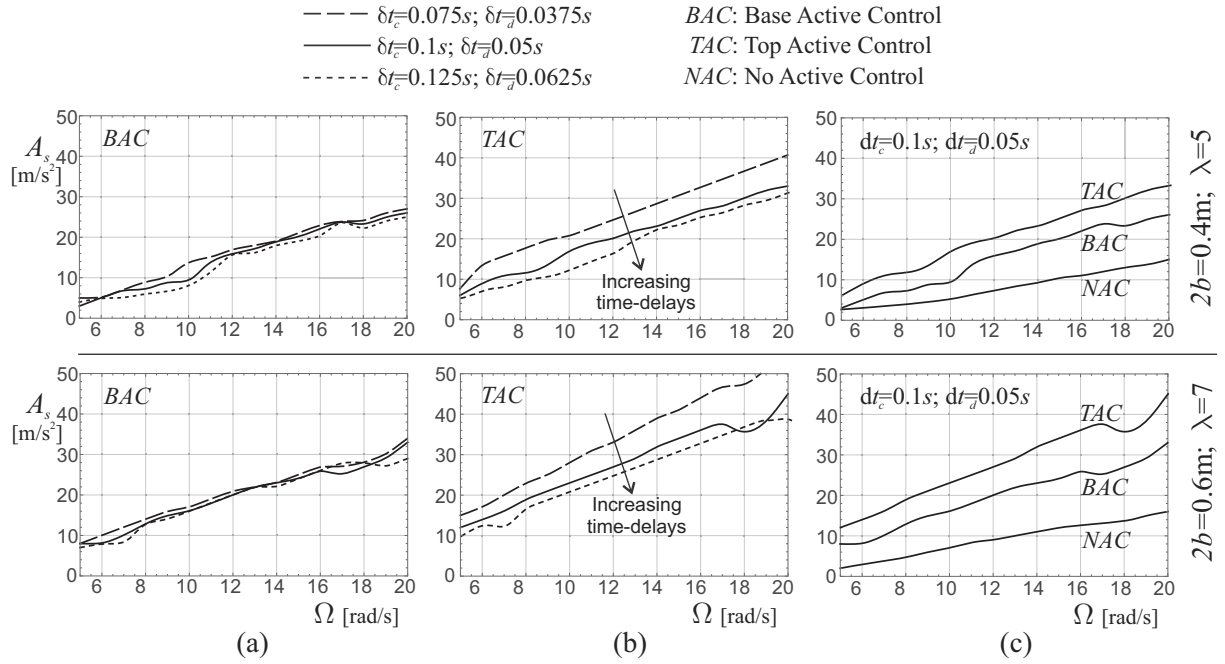

Figure 2: Overturning spectra: (a) spectra of the Base Active Control (BAC) system obtained for different time-delays; (b) spectra of the Top Active Control (TAC) system obtained for different time-delays; (c) comparison among spectra for fixed time-delays ($F_{max}^B = F_{max}^T$, $F_{max}^B = 0.2Mg$, $F_{max}^T = 2.0mg$, $m = \gamma M$, $\gamma = 0.1$).

4.2 Seismic excitation

Two earthquake records are used as seismic input. The earthquake records are

- Kobe, Takarazuka-000 station, ground motion recorded during the 1995 Japan earthquake;
- Parkfield, CO2-065 ground motion recorded during the California earthquake 1966.

Figure 3 shows the time-histories (left graphs) and the pseudo-acceleration elastic spectra (right graphs) of the two earthquake records. The results of the parametric analyses are shown by means of rocking maps that represent the contour plots (for a single seismic record) of the maximum rocking angle in the parameter plane ($2b - \lambda$). The regions where the block overturns (*i.e.*, where the maximum rocking angle is $\theta_{max} = \pi/2$) are colored in dark grey; the regions where the block does not overturn are colored in light grey, and the contour levels represent the maximum values of $\theta(t)$. For each earthquake, the rocking maps of the two control systems and the map obtained without active control are compared. In the analysis, the sampling time and time-delay are assumed as $\delta t_c = 0.1s$ $\delta t_d = 0.05s$, respectively, as in ([17] and [18]).

In Fig. 4 the rocking maps are organized in matrix form. Along the two columns there are the maps of the earthquake records (Kobe and Pacoima), whereas the rows refer to NAC, BAC, and TAC. As can be observed, the active control systems drastically reduce the overturning regions (dark grey regions) with respect to the case without active control. However, the TAC appears to

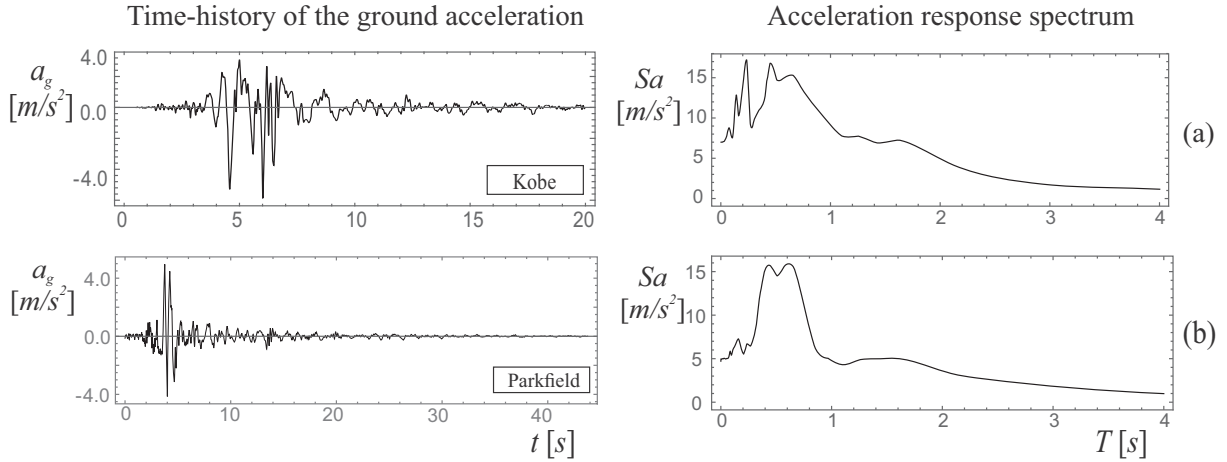

Figure 3: Time-histories (left graphs) and pseudo-acceleration elastic spectra (right graphs) of the earthquakes analysed: (a) Kobe; (b) Parkfield.

be able to extend the safety region (i.e., the regions where no overturning occurs) to the whole parameter $(2b - \lambda)$ plane. In fact, the BAC is not able to protect the block from overturning in the whole parameter plane under Kobe earthquake, as done by the TAC (see maps of the second row in Fig. 4).

Fig. 5 shows sections of the rocking maps that help to understand the efficiency of the control systems in reducing θ_{max} . The sections are identified by paths *I* and *II* in Fig. 4. Specifically, Fig. 5a shows the two section along path *I*, referring to Kobe earthquake, obtained for the Base and the Top Active Control systems. Instead, Fig. 5b shows the two section along path *II*, referring to Parkfield earthquake, obtained for the BAC and the TAC systems. As can be observed, the use of the TAC system generally leads to values of θ_{max} smaller than those obtained by using the BAC system.

5 CONCLUSIONS

The performances in protecting rigid blocks from the overturning of two different active control systems, both based on the same active control algorithm (i.e., the Pole Placement Method), were investigated and compared. In the first control system, the block is placed on a horizontally translating support that is connected to the ground by an actuator able to provide a controlled displacement. In the second control system, a small mass able to run on the top of the block is driven by an actuator capable of applying a controlled displacement. The control algorithm based on the Pole Placement Method acts both vanishing the external excitation at each instant by imposing a control force opposite to the external one and making the rest position of the block a stable point by suitably modifying the Jacobian matrix of the system and its eigenvalues. A preliminary analysis that considers the overshoot as key parameter was performed to evaluate the optimal coefficients of the control law for the two systems. The optimal value of such coefficients weakly depends on the parameters characterizing the mechanical system and is the same for the two different control systems.

The effectiveness of the two control systems was analysed by comparing the overturning spectra that represent the amplitude of the harmonic excitation able to overturn the block versus its circular frequency. Results showed that both control systems significantly improve the behaviour of the rigid block with respect to the case without control. Nevertheless, if on the

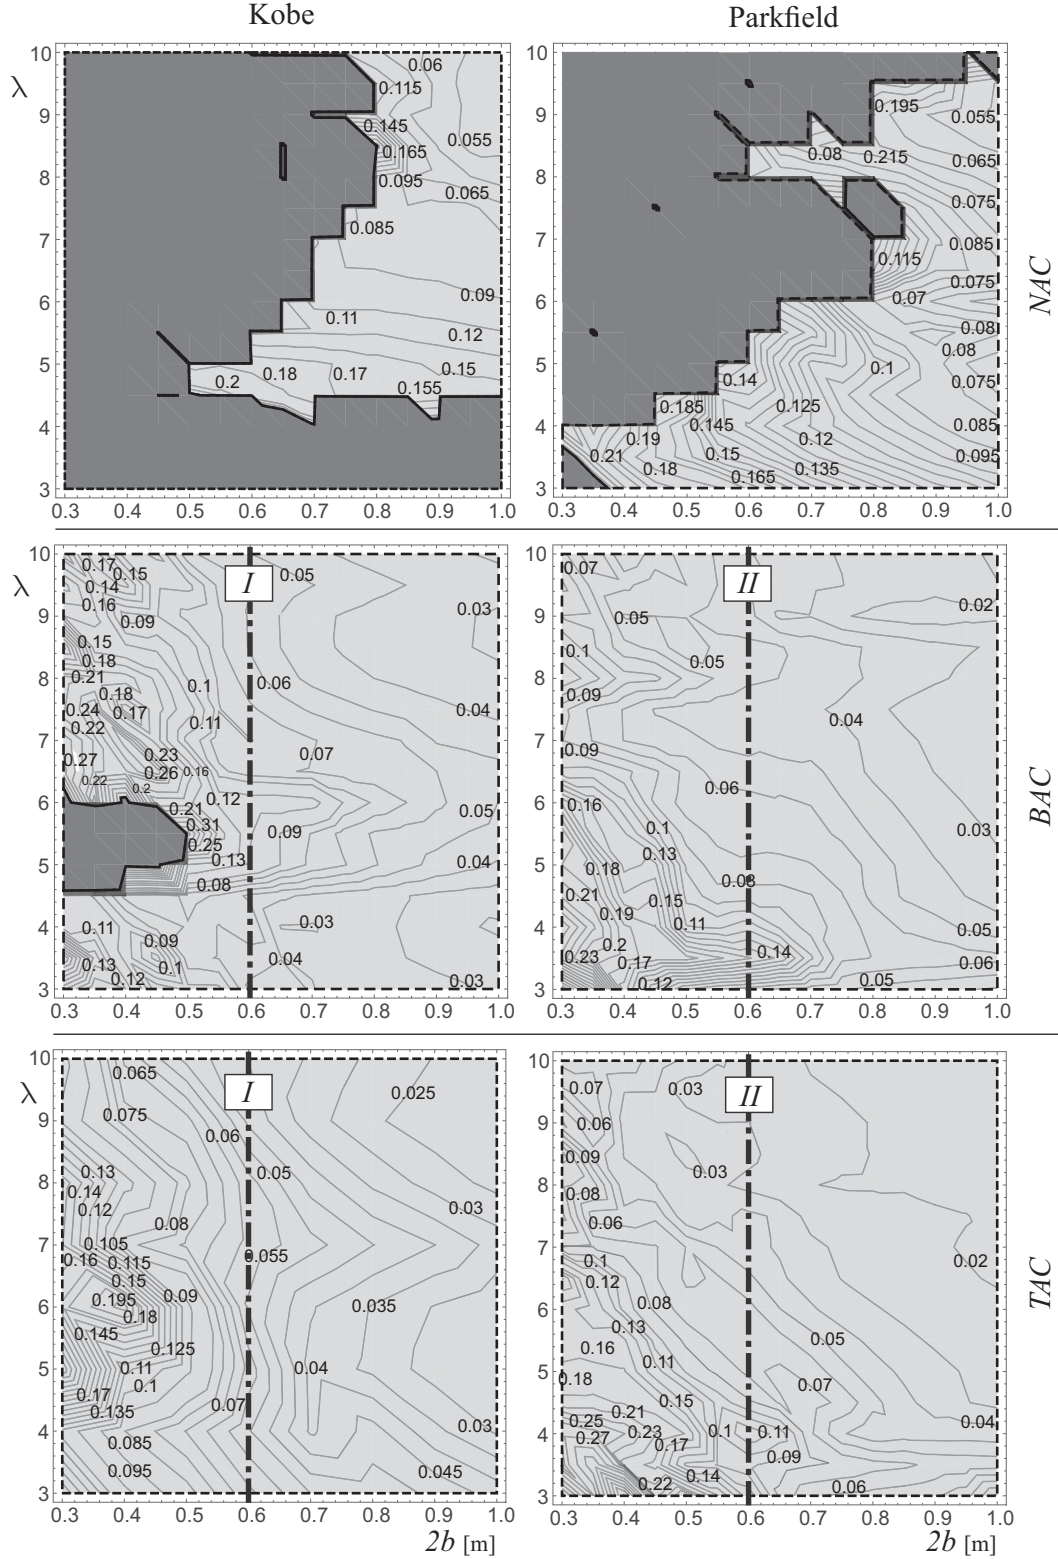

Figure 4: Rocking maps for two different earthquakes (Kobe e Parkfield) and three different configurations: No Active Control (NAC), Base Active Control (BAC), and Top Active Control (TAC).

one hand, the Top Active Control system manifests better performances than the Base Active Control system, on the other hand, this last exhibits an higher robustness to time-delays. Other

Figure 5: Sections of rocking maps for two different earthquakes (Kobe e Parkfield) and two different configurations: Base Active Control (BAC), and Top Active Control (TAC); ($2b = 0.6$ m).

simulations were also conducted using two recorded earthquakes to evaluate the performances of the control methods in the reduction of the rocking angle and the protection from the overturning of the block. The results showed the excellent performance of both the considered control systems. To conclude, since the performances of the control systems are comparable for all the working conditions considered, the choice between the two methods is dictated by the technical and technological aspects of each specific application.

Abstract

This paper presents uniform risk spectra for negative stiffness systems that do not exhibit hysteretic damping, named Negative Stiffness Bilinear Elastic (NSBE) systems. The NSBE oscillator can be used to describe the dynamics of deformable rocking systems with or without restraining systems flexible enough to lead to an overall negative stiffness. It can also be used to describe rocking systems equipped with curved extensions at their base. It has been shown that the response of an NSBE system can be well predicted using the response of a Zero Stiffness Bilinear Elastic (ZSBE) system, which is a bilinear system of constant restoring force. The ZSBE system is a single parameter system; therefore it is simple to construct design spectra for it.

For a wide range of ZSBE system strength values, this paper employs Incremental Dynamic Analysis using 105 ordinary (non-pulse-like, non-long-duration) ground motions to obtain the fragility functions for predefined limit-states of the ZSBE seismic response. Fragility functions per limit-state are convolved with the seismic hazard to compute the Mean Annual Frequency of exceedance (MAF). For this study, the seismic hazard curve for a site at Athens Greece is used as it is obtained via probabilistic seismic hazard analysis. Finally, uniform risk spectra per limit-state are obtained by computing the MAF for all the ZSBE oscillators. These spectra can be used for the design of NSBE systems, including rocking oscillators.

1 INTRODUCTION

Rocking has been proposed as an alternative design method in seismic prone regions because it reduces foundation moments and results in resilient structures [1-19]. Differently from structures designed to yield, rocking systems present negative lateral stiffness after uplift.

The negative stiffness value of the free-standing block is defined by its geometry (Fig. 1). Its negative stiffness, however, can be modified by the introduction of restrainers flexible enough to keep the post-uplift stiffness negative (Fig. 2a) [3, 5, 13, 20-22], or by equipping the blocks with extended curved ends (Fig. 2b) [14, 15]. These solutions increase the maximum displacement the rocking system can achieve before overturning, without affecting its uplifting force. The flexible restrainers also act as a redundant mechanism for the rocking structures, a desired mechanism by practicing engineers.

Figure 1. Free-standing rigid rocking block.

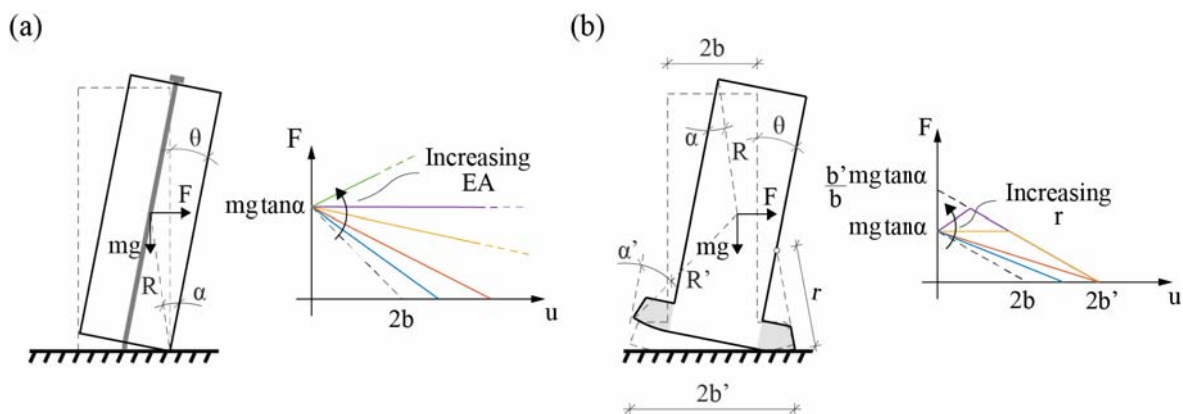

Figure 2. (a) Restrained rigid rocking block, and (b) Curved-base rigid rocking block.

Seismic codes adopt the uniform hazard spectrum concept. The spectrum is constructed using a probabilistic framework and provides seismic actions with a given probability of exceedance. Recently, Luco et al. [23] proposed the Uniform Risk Spectra (URS), which provides seismic actions that results in structures with uniform risk of damage and/or collapse, an indicator much more meaningful for decision makers and users of the designed structure.

Both the uniform hazard spectrum and uniform risk spectrum are useful tools that allow engineers to design structures by only estimating its fundamental period and damping ratio. The elastic spectra, however, cannot be used for designing rocking structures [24]. The inherent negative stiffness of rocking systems would oblige engineers to carry out time-consuming time history analyses when designing such structures.

Reggiani Manzo and Vassiliou [25, 26] have observed that rocking systems having the same uplifting force and being far from their failure point will exhibit roughly equal displace-

ment demand, independently of their post uplift stiffness. Therefore, the displacement of rocking structures of uplift force f_{up} can be computed using as a proxy the displacement of a bilinear oscillator of uplift force f_{up} and infinite displacement capacity (Zero Stiffness Bilinear Elastic (ZSBE) oscillators). This simplification allows the construction of spectra for a range of negative stiffness systems: free-standing rocking frames, restrained rocking frames, or rocking frames with curved ends. Therefore, the design of negative stiffness systems can be accomplished using a spectrum and avoiding time history analysis.

In an attempt to propose a simplified design methodology for negative stiffness systems that also introduces the uncertainty of seismic action, this paper presents uniform risk spectra for rocking structures, using the ZSBE oscillator proxy.

Previous studies have presented fragility curves for rocking structures [27-37], which also consider the random characteristic of seismic actions. These curves, however, were constructed using complex models, or in other cases, considering the classical description of the motion of rocking blocks by its tilt angle. Neither approach allows the construction of a single rocking spectrum that covers all range of systems with negative post-uplift stiffness. On the other hand, the uniform risk spectra proposed herein can be used for any system that presents negative post-uplift stiffness and does not present hysteretic damping.

2 THE ZERO STIFFNESS BILINEAR ELASTIC SYSTEM (ZSBE) AS PROXY FOR NEGATIVE STIFFNESS BILINEAR ELASTIC SYSTEMS (NSBE)

2.1 The Negative Stiffness Bilinear Elastic System

The Negative Stiffness Bilinear Elastic (NSBE) system can describe the dynamics of free-standing (Fig.1), restrained (Fig.2a), and curved-based (Fig.2b) rocking structures, or any other deformable system that presents negative post-uplift stiffness and does not exhibit hysteretic damping.

Fig.3 presents the NSBE oscillator, and its displacement-restoring force relationship. Up until uplift, the system behaves linearly with a positive stiffness (k_{pos}), representing any deformability the system might present before uplifting. After uplifting, the tangent stiffness becomes negative (k_{neg}). The displacement capacity (u_{cap}) is defined not by material failure, but by the displacement where the restoring force becomes negative. Therefore, for an unrestrained rocking column, the displacement capacity is equal to its width.

Figure 3. (a,b) NSBE system; and (c) its displacement-restoring force relationship.

Based on its displacement-force relationship (Fig.3c), the oscillator's equation of motion is:

$$m \cdot \ddot{u}(t) + f_{up} \cdot \frac{u(t)}{u_{up}} = -m \cdot \ddot{u}_g(t), \quad |u(t)| \leq u_{up} \quad (1)$$

$$m \cdot \ddot{u}(t) \pm f_{up} \cdot \left(\frac{u_{cap} - u(t)}{u_{cap} - u_{up}} \right) = -m \cdot \ddot{u}_g(t), \quad |u(t)| > u_{up} \quad (2)$$

The upper sign in Eq.2 corresponds to positive displacements, and the lower sign to negative displacements.

Impact damping is the only source of energy dissipation, implying that the ends of the rocking element are protected from damage [38]. When the system's displacement equals to the uplift displacement (u_{up}), the integration is halted, and its post-impact velocity is calculated by a coefficient of restitution (r_c):

$$r_c = \frac{\dot{u}_{postimpact}}{\dot{u}_{preimpact}} \quad (3)$$

Herein, a coefficient of restitution equal to 0.95 is assumed, corresponding to relatively slender structures.

2.2 The Zero Stiffness Bilinear Elastic System

Fig. 4 presents the displacement-force relationship of the Zero Stiffness Bilinear Elastic (ZSBE) system. The system presents the same equation of motion and assumptions of the NSBE system when its displacement capacity tends to infinity, resulting in a system with zero post-uplift stiffness ($k_{neg} = 0$).

The ZSBE can be used as a proxy for the prediction of the response of the NSBE [25,26]. Hence, studying the response of a ZSBE of a given f_{up} and u_{up} suffices for the description of the response of all NSBE of the same f_{up} and u_{up} , independently of their u_{cap} . Therefore, spectra providing u_{max} of the ZSBE as a function of f_{up} for a given u_{up} can be used for the design of NSBE systems. Fig. 5 presents such a spectrum, extracted from Reggiani Manzo and Vassiliou [26]. It refers to $u_{up}=0.0005\text{m}$ and it gives the median response for a set of ground motions selected and scaled as discussed in [26].

Figure 4. Displacement-restoring force relationship of the ZSBE systems.

2.3 Equal Displacement and Equal Energy Rules for Negative Stiffness Systems

Reggiani Manzo and Vassiliou [25, 26] proposed that the displacement demand of NSBE and ZSBE systems can be related by two different rules: the Equal Displacement rule and the Equal Energy rule.

The Equal Displacement rule assumes that the NSBE and ZSBE system will experience the same displacement demand (Fig. 6a):

$$u_{dem,NS} = u_{dem,ZS} \rightarrow \gamma_{ED} = \frac{u_{dem,NS}}{u_{dem,ZS}} = 1 \quad (4)$$

Figure 5. Design spectrum for negative stiffness systems.

In which, γ_{ED} is the ratio of the displacement demand of the NSBE system ($u_{dem,NS}$) to the displacement demand of the ZSBE system ($u_{dem,ZS}$).

The Equal Energy rule assumes that the displacement-force curves of both systems produce the same work. In other words, it assumes that the shaded areas of Fig. 6b are equal. Therefore, the ratio (γ_{EE}) of $u_{dem,NS}$ to $u_{dem,ZS}$ is:

$$\gamma_{EE} = \frac{u_{dem,NS}}{u_{dem,ZS}} = \frac{u_{cap}}{u_{dem,ZS}} - \sqrt{\frac{(u_{cap} - u_{up})}{u_{dem,ZS}} \cdot \frac{(u_{cap} - 2 \cdot u_{dem,ZS} + u_{up})}{u_{dem,ZS}}} \quad (5)$$

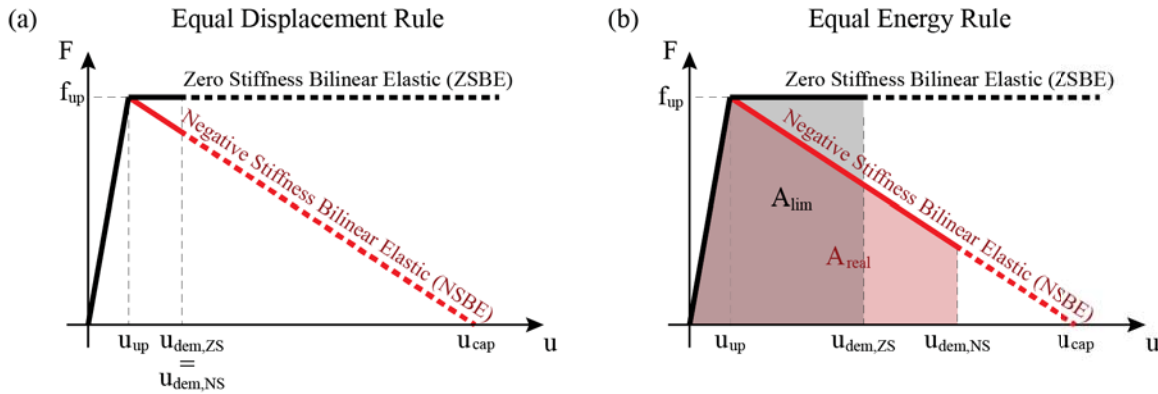

Figure 6. (a) Equal Displacement rule; and (b) Equal Energy rule.

3 PROBABILISTIC FRAMEWORK

Using the ZSBE proxy, the uniform risk spectrum for negative stiffness systems is a plot of the displacement demand of the system as a function of its normalized strength, in which all ordinates of the plot present the same mean annual frequency (MAF) of exceedance (Fig. 7b). It can also be interpreted as an iso-MAF contour plot of the seismic risk surface, which is a 3D plot of the probability of exceeding a displacement demand for a range of systems with different normalized strengths (Fig. 7a).

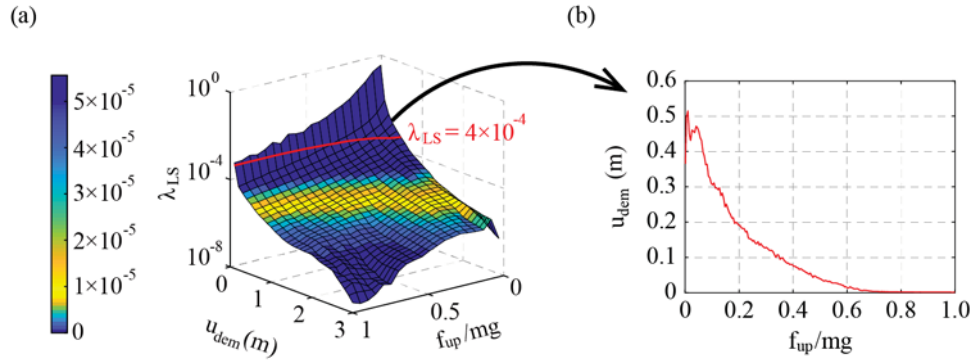

Figure 7. (a) Seismic risk surface with an iso-MAF contour plot highlighted; (b) Uniform risk spectrum.

The calculation of the probability of exceedance, also known as risk assessment, can be performed using the risk integral, the same framing equation of PBEE (Performance Based Earthquake Engineering) framework [39]:

$$\lambda_{LS} = \lambda(EDP > EDP_C) = \int P(EDP > EDP_C | IM) \cdot |d\lambda(IM)| \quad (6)$$

In Eq. 6, λ_{LS} is the mean annual frequency (MAF) of exceeding (i.e., violating) a limit state (LS). $P(EDP > EDP_C | IM)$ is the fragility function, which represents the probability that the engineering demand parameter (EDP) exceeds the capacity threshold of EDP_C associated with LS for any given level of the ground motion intensity measure (IM), and $\lambda(IM)$ is the MAF of exceeding a given value of IM, which can be retrieved from the site-specific seismic hazard curve.

In this paper, the maximum horizontal displacement of the system, or as mentioned before, the displacement demand, was adopted as EDP. Note that Eq.6 gives a single-point of the seismic risk surface. To construct the complete surface, the equation had to be evaluated for several limit states and a range of systems with different normalized uplifting strength. Herein, the probability of exceedance was calculated for 3001 limit states, ranging from 0 to 3m, in steps of 0.001m; and 301 different systems with a normalized strength varying from 0.1 to 1.0, in steps of 0.05.

Based on Eq.6, λ_{LS} combines the structural response and the seismic hazard at the site. The fragility function, or vulnerability analysis, gives us information about the structural response of the system, connecting the EDP to the IM. Given that all results are conditioned on the IM, the IM has to be carefully chosen [40]. The adequate IM for rocking structures, however, is still an open discussion in the engineering community [27–30, 36]. Herein, the peak ground velocity (PGV) was adopted as IM, with further studies pending.

Incremental dynamic analyses (IDA) [41] were carried out to obtain the fragility functions for each predefined limit state and different system. A set of 105 ordinary (non-pulse-like, non-long-duration) ground motions was used in each incremental dynamic analysis. The ground motions were gradually scaled so that their PGV is equal to $\overline{PGV} = [(1:0.5:20), (25:5:200)]$ cm/s, in which \overline{PGV} is the geometric mean of the PGV of the two horizontal components x and y of the individual ground motion:

$$\overline{PGV} = \sqrt{PGV_x \cdot PGV_y} \quad (7)$$

The model considers only planar response. Therefore, the nonlinear dynamic analysis was carried out only for one of the components of each ground motion (arbitrary component); the component was once chosen randomly, and then used for all analyses. After carrying out the analyses for all different scales and ground motions, the fragility function for each limit state

and system can be easily obtained on an EDP-basis or an IM-basis approach [40]. Here, the first was employed where for each IM-step value (stripe) the probability of exceeding the deterministic EDP capacity threshold is calculated as:

$$P(EDP > EDP_c | IM) = \frac{\text{number of records with } EDP > EDP_c}{\text{total number of records}} \quad (8)$$

The second curve necessary for the convolution represented by Eq.6 is the site-specific seismic hazard curve. In this study, a seismic hazard curve for a site at Athens, Greece was assessed via the open source platform OpenQuake [42]. The 2013 European seismic source model [43] was used for the calculations. The site-specific seismic hazard curve for the \overline{PGV} is presented in Fig. 8.

Figure 8. Site-specific seismic hazard curve for \overline{PGV} in Athens, Greece.

At last, after carrying out the vulnerability analysis for all desired systems and limit states, the uniform risk spectrum for a given MAF can be obtained as a cross-section of the seismic risk surface.

4 RISK ASSESSMENT

Herein, uniform risk spectra for quasi-rigid ZSBE systems ($u_{up} = 0.0005$ m), computed using the probabilistic framework of the previous section, is presented.

4.1 Fragility Curves

As the first step of the vulnerability analysis, fragility curves were computed for the different limit states and systems. As mentioned before, the ground motions were gradually scaled in stripes of $\overline{PGV} = [(1 : 0.5 : 20), (25 : 5 : 200)]$ cm/s. A finer discretization for smaller values of \overline{PGV} was necessary because low PGV ground motions might have small overturning potential, but they have large probability of occurrence resulting in significant contribution to the convolution of Equation 6.

Fig. 9 presents the fragility curve obtained using a coarse mesh (ranging from 1 to 100 cm/s, in steps of 5 cm/s) and using the finer mesh for a system with normalized strength $f_{up}/(mg) = 0.15$ and limit state of 9.0 cm. Because the fragility curve is created by a linear interpolation between the values for which the probability was calculated, the coarse mesh cannot capture the peaks and troughs as accurately as the finer mesh. If the risk quantity is

calculated using both fragility curves presented in Fig.9, the one with the coarse mesh overestimates the risk by 12%.

Figure 9. Fragility curves obtained for coarse and fine mesh.

4.2 Uniform Risk Spectra

Fig. 10 presents the uniform risk spectra for negative stiffness systems with 2%, 10%, and 50% probability of exceedance in 50 years, for a site in Athens, Greece. These probabilities correspond to a MAF of 0.0004, 0.0021, and 0.0139 per year, as given by Eq. 9, in which p is the probability of exceedance and T , the number of years considered.

$$\text{MAF} = \frac{-\ln(1-p)}{T} \quad (9)$$

It can be observed that the spectrum with smaller probability of exceedance (2% in 50 years) predicts larger displacement demands, while the spectrum with larger probability of exceedance (50% in 50 years) predicts smaller displacement demands.

The figure also depicts an interesting characteristic: if the curves were scaled by two distinct factors at x- and y-axes, they would collapse into a unique curve. This a very remarkable characteristic that might allow negative stiffness systems to be designed for different performance scenarios using a unique curve.

Figure 10. Uniform risk spectra for negative stiffness systems with 2%, 10%, and 50% probability of exceedance in 50 years, for a site in Athens, Greece.

5 CONCLUSIONS

This paper presented uniform risk spectra for negative stiffness systems, using the ZSBE proxy. It explains in detail the probabilistic framework necessary to construct such spectra, highlighting possible source of errors. It presents uniform risk spectra for three probabilities of exceedance: 2%, 10%, and 50% in 50 years. The uniform risk spectrum, however, can be computed for any given MAF and site, following the framework presented herein.

Interestingly, it seems that the uniform risk spectra for different MAF can be scaled in the x- and y-axes, collapsing to a unique curve. This characteristic would make the design of negative stiffness systems even simpler: one “master” curve could be used to design negative stiffness systems with different displacement capacities for different performance scenarios.

Further studies are still necessary on which is the adequate intensity measure to be adopted for these spectra.

Abstract

Free-standing multidrum stone columns are widespread elements in archaeological areas. The present study aims at investigating the behavior of these elements under seismic excitations. The dynamic behavior of free-standing multidrum columns is greatly affected by geometrical properties, constitutive materials, state of preservation, and amplitude and frequency of the seismic action. The first step of the research involved a wide and detailed survey for the definition of the mean geometrical properties affecting the seismic behavior of these columns in the archeological Pompeii site. To this end, a wide range of grey-tuff columns (103 elements) from four different areas of the site involving private and public areas, were investigated. Then, numerical analyses were carried out based on the Finite Element Method (FEM) to investigate the seismic behavior of such elements. A column from the tetrastyle atrium of Casa del Fauno was selected for the analysis. The house is one of the largest and most visited private buildings at the Pompeii archeological site. The selected column presented deep degradation and needed specific and urgent attention for its assessment. In the following, the detailed survey and the modeling phases of the investigated element are described and the outcomes of the numerical analysis are reported and discussed.

1 INTRODUCTION

Understanding the seismic behavior of typical ancient structures is crucial for the conservation of historical and archaeological assets. In particular, many important Greek and Roman archaeological sites are located in the Mediterranean area which is characterized by a notable seismic activity.

Columns are typical elements of ancient Greek and Roman architecture. In many cases, they were built with dry-overlapped stone pieces, namely the drums, placed above a stylobate, and typically carrying the load transmitted by a stone architrave or a wooden beam. Nowadays, multidrum stone columns are often free-standing elements, i.e. with no axial load except for their self-weight.

When subjected to a seismic motion, the single drums can rock and slide independently or in groups, resulting in a complex and highly non-linear behavior of the whole column. The first systematic and landmark study on the analysis of the rocking response of a single rigid block was proposed by Housner in 1963 [1]. From then, numerous investigations focused on the analysis of the dynamic response of free-standing multidrum columns, by following analytical [2–5], experimental [6,7], or more recent numerical approaches [8–11]. The main findings of these studies can be summarized in the following points: i) when subjected to seismic excitation, multidrum columns show many patterns of the rocking motion, whose number increase with the number of constituent blocks, and continuously move from one of them to another, thus natural modes of vibration in the classical meaning cannot be defined [12]; ii) the dynamic behavior of these elements is extremely sensitive to even trivial changes of the parameters of the structure or seismic input; iii) the slenderness and size of the columns affect their stability, with the higher slenderness, the higher the probability of collapse, and the higher size, for the same slenderness, the higher the stability; iv) low-frequency earthquakes are generally more dangerous than high-frequency ones [2,4,11,13]. Moreover, it was found that this type of structure, if well-preserved, is generally able to sustain notable seismic inputs [8,12]. However, typical forms of degradation can significantly affect the state of preservation and the stability of these elements. These are: material degradation; the presence of cracks; missing portions; deterioration of the contact surfaces among the drums; uneven profile of the column; misplaced drums after their re-erection; permanent relative displacements among the drums caused by past seismic events.

This paper presents a part of a wide study aimed at the investigation of the seismic vulnerability of free-standing multidrum tuff columns at the Pompeii archaeological site. This was a part of a scientific collaboration between the Archaeological Pompeii Park (PAP) and the Department of Structures for Engineering and Architecture (DiSt) of the University of Naples Federico II aimed to support the monitoring of the state of preservation of the columns at the site and the development of programs of interventions. The investigation included 103 columns from four different areas of the site. The first phase of the research involved detailed surveys, archival researches and visual inspections to define the main geometrical properties of the columns and the most common forms of degradation and damage, that may affect their seismic behavior. After that, an analysis of the seismic behavior of such structures was implemented with a column from one of the largest and most visited private buildings at the site, *Casa del Fauno*. Indeed, when the investigation has been started, the selected column presented deep degradation and needed specific and urgent attention for its assessment. The study was carried out based on the Finite Element Method (FEM). Eight seismic records were selected for the analyses, to investigate the influence of different frequencies and amplitudes of the seismic input. The following sections firstly focus on the main geometric characteristics and common forms of degradation of the Pompeian multidrum tuff columns; then discuss the modeling phases of the investigated element and the outcomes of the numerical analyses.

2 FREE-STANDING MULTIDRUM TUFF COLUMNS

According to the results of previous studies, the main geometrical properties and the state of preservation of multidrum columns significantly affect their seismic response [1,12]. Therefore, the following sections present the results of a systematic and detailed survey of a wide number of

multidrum stone columns representative of a typical typology at the Pompeii archaeological site. In particular, free-standing Corinthian and Doric tuff columns were studied.

2.1. Localization of the columns

This part of the investigation involved structures from four different private and public areas of the site: a private house at *Regio VI*, *Casa del Fauno* (CF) and public areas at *Regio VIII*, *Quadriportico dei Teatri* (Q), *Palestra Sannitica* (PS), and *Foro Triangolare* (FT) (Figure 1). Note that the picture related to the *Tetrastyle atrium* of *Casa del Fauno* predates the recent restoration intervention (January 2021), that allowed removing the lateral supporting props shown in the picture.

Tetrastyle atrium, Casa del Fauno (CF), Regio VI, Insula 12.

Quadriportico dei teatri (Q), Regio VIII, Insula 7.

Palestra Sannitica (PS), Regio VIII, Insula 7.

Foro triangolare (FT), Regio VIII, Insula 7.

Figure 1: Research areas.

As shown in Figure 1 several columns are incomplete and in a state of ruins. This was probably related to the fact that throughout the excavation and/or the execution of later interventions certain parts were significantly damaged. In detail, 55 out of 103 columns were complete, i.e. all the parts from the base to the capital stand today, while the other 48 columns were incomplete, i.e. had missing parts. One incomplete column was found at the tetrastyle atrium of the *Casa del Fauno*, for which only the capital was missing. Table 1 reports the total number of investigated columns for each area and the relative numbers of complete and incomplete elements.

Table 1: Number of investigated columns for each area and complete and incomplete elements.

	CF	Q	PS	FT	Total
number of free-standing columns	4	54	19	26	103
number of complete columns	3	28	13	11	55
number of incomplete columns	1	26	6	15	48

2.2. Geometry and state of preservation

The slenderness and the size of a column greatly affect its dynamic response [1,12,13]. The number of constituting drums is also relevant because it affects the energy dissipation due to friction. Literature studies showed that, on hard soil, it is possible to observe the effect of higher stability for a higher number of drums [8,10].

Table 2 summarizes the mean geometric parameters and mass of the investigated complete columns. In particular, Table 2 reports: the total height, H ; the diameter at the base, d ; the aspect ratio, H/d , which is a measure of the column slenderness; the quote of the center of mass, y_{CM} ; the distance from the center of mass of the column to the circumference at the base, R , which is a measure of the column size; the number of drums; the volume; the mass.

Table 2: Main overall characteristics of the complete columns.

	CF	Q	PS	FT
Total height, H [m]	5.74	3.56	3.30	3.99
Diameter at the base, d [m]	0.71	0.49	0.39	0.53
Aspect ratio, H/d [-]	8.09	7.27	8.53	7.50
Quote of the center of mass, y_{CM} [m]	2.79	1.70	1.58	1.88
Distance center of mass - base perimeter, R [m]	2.82	1.72	1.59	1.90
Number of drums	6	5	5	5
Volume, V [m ³]	1.70	0.63	0.37	0.85
Mass, M [kg]	4407	1634	972	2214

The presence of material degradation and damage must be also taken into account for structural modeling since they can significantly alter the dynamic response of a multidrum column. Common forms of degradation and damage were found among the investigated columns at the Pompeii site: the presence of cracks; missing portions; contact surface between the drums reduced by weathering, the presence of invasive and incompatible interventions (see Figure 2).

Figure 2: Most common imperfections, damage and deterioration forms in the columns: the presence of cracks, missing portions, reduced contact surface between the drums (a), (b), (c), invasive and incompatible interventions (b), and (d).

3 INVESTIGATION OF THE SEISMIC RESPONSE OF MULTIDRUM COLUMNS

3.1. Description of the model

The analyses herein presented refer to one column at the *Casa del Fauno*. The analyses were carried out with finite element modeling (FEM), by using the software Abaqus/CAE. Therefore, the column was modeled as an assembly of overlapping deformable blocks, i.e. the drums. The geometric characteristics used in the model are listed in Table 3.

Table 3: Geometrical parameters used in the model.

Free-standing multidrum column at the <i>Casa del Fauno</i>			
	h [m]	d_{inf} [m]	d_{sup} [m]
drum 1	0.55	0.73	-
drum 2	0.99	-	-
drum 3	0.11	-	-
drum 4	0.76	-	-
drum 5	0.17	-	0.66
capital	0.67	0.66	0.66
column	5.72	0.73	0.66

Each drum was modeled as an isotropic and elastic semi-conical solid (Figure 3 (a)) with material properties defined based on information from the technical archive of the Pompeii archeological site (Table 4).

Table 4: Material parameters used in the model.

Grey tuff	
Bulk density, ρ [kg/m ³]	1230
Elastic modulus, E [GPa]	4.5
Poisson ratio, ν	0.25
Coefficient of friction, μ	0.5

The discretization of each drum was performed with 8-node hexahedra elements (Figure 3 (c)). Each drum was partitioned into eight portions, to obtain a regular and correct formation of the meshes (Figure 3 (b)).

Figure 3: The geometric model of a drum: semi-conical solid (a), partition in eight parts (b), and mesh configuration (c).

The contact interaction between two consecutive drums was considered as governed by friction. Thus, it was modeled by adopting the Mohr-Coulomb criterion for the tangential stress along the surfaces, with dynamic coefficient friction equal to the static one (i.e. 0.5). This was consistent with the assumption made in other literature studies showing that the value of the dynamic coefficient friction has a negligible role in the analyses to capture columns seismic behavior [8,13]. Moreover, the hard contact behavior was set for the interaction between the drums in the normal direction, with compressive stress developed on the contact surface between two drums and zero stress when the drums are not in contact. Finally, the interactions between consecutive drums and between the first drum and the base of the column were defined by a “master” surface and a “slave” surface. A boundary condition of fully fixed connection was applied at the base of the column as well as the input seismic signals. Figure 4 shows the geometric assembly of the entire column; the defined interactions between adjacent surfaces; the boundary condition of fully fixed connection at the base; the application of a seismic input at the base; the final numerical model of the column with meshes.

Figure 4: Phases of the modeling process: assembling of the single parts of the column (a); definition of the interactions between adjacent surfaces (b); definition of the boundary condition at the base (c); application of the seismic input at the base (d); final numerical model of the column with meshes (e).

Each analysis involved two steps: the assignment of the geometrical and material properties, interactions and the acceleration of gravity; and the seismic input signal applied at the base of the column. The analyses were performed according to the dynamic implicit method, with the time of each step set equal to 0.005s. This latter was equal to the time step of the selected seismic records.

3.2. Seismic input motions

Eight seismic records with different frequencies and amplitudes were selected for the analyses: i) Irpinia, Italy (1980), recorded at Sturno, close to the epicenter and ii) Irpinia, Italy (1980), recorded at Torre del Greco, about 15km from Pompeii; iii) Molise, Italy (2002), recorded at San Severo, about 50 km from the epicenter; L'Aquila, Italy (2009), recorded at v. Aterno – Centro Valle, close to the epicenter; Kalamata, Greece (1986), recorded at Kalamata; Edessa, Greece (1990), recorded at Edessa; Aigio (1995), recorded at Aigio; Athens, Greece (1999), recorded at Athens. Table 5 reports the intensity measures and frequency content indicator of the seismic input motions selected for the analysis. In particular, the intensity measures PHA, PHV and PHD represent the maximum vector sums of the accelerations, velocities and displacements, respectively, in the two horizontal directions of the seismic records. The predominant period, T_g , was evaluated as the period corresponding to the maximum ordinate of the 5% damped pseudo-velocity spectrum.

Table 5: Intensity measures and frequency content indicator of the seismic input motions selected for the analysis.

Seismic record	PGA	PGV	PGD	PHA*	PHV*	PHD*	T_g [s]**		
	[g]	[cm/s]	[cm]	[g]	[cm/s]	[cm]	E-W	N-S	mean

4 RESULTS AND DISCUSSION

The model of the column of *Casa del Fauno* was excited with the eight selected seismic records. To define the maxim ground acceleration sustained by the column for each seismic input without collapsing, a specific parametric analysis was performed by progressively increasing a scale factor applied to the intensities of the seismic records. Indeed, for each seismic input, the minimum value of the scaling factor leading to the collapse of the column was determined. Table 6 summarizes the outcomes of the analyses in terms of parameters of the seismic input motions leading to the collapse of the column and the number of collapsed drums beside the capital.

Table 6: Parameters of the seismic input motions leading to the collapse of the column.

Seismic record	Scaling factor	PHA [g]	PHV [cm/s]	PHD [cm]	Collapsed parts
Irpinia_Str	0.5	0.17	36	13.9	Capital and 2 drums
Irpinia_TdG	4	0.24	35	28.2	Capital and 4 drums
L'Aquila	1.5	1.16	70	10.2	Capital and 2 drums
Molise	16.8	1.01	41	5.6	Capital and 2 drums
Kalamata	1.1	0.38	42	7.4	Capital and 3 drums
Edessa	3.45	0.38	41	4.2	Capital and 2 drums
Aigio	1.05	0.55	54	9.0	Capital and 2 drums
Athens	3.3	1.24	54	9.5	Capital and 1 drum

The studied column showed different dynamic responses for the different input motions. Seismic motions with the higher predominant periods were found to be more dangerous, leading to the collapse with lower values of PHA, and confirming fundamental conclusions found in previous numerical and experimental studies [11,12]. Indeed, two records of the Irpinia earthquake, characterized by a high value of T_g , led to the collapse with the lowest intensities. Moreover, according to Italian territorial classification [14], the Pompeii site falls in a seismic zone whose acceleration with a probability of exceeding equal to 10% in 50 years ranges between 0.15g and 0.25g. Therefore, considering the maximum vectorial sum, PHA, ranging between 0.21g and 0.35g, only the two records of the Irpinia earthquakes produced PHA at the collapse falling in this range or below it. Figure 5 plots the value of the PHA that produced the collapse of the column for each seismic record, represented by the value of its predominant period, and the range of expected PHA derived by Italian seismic classification.

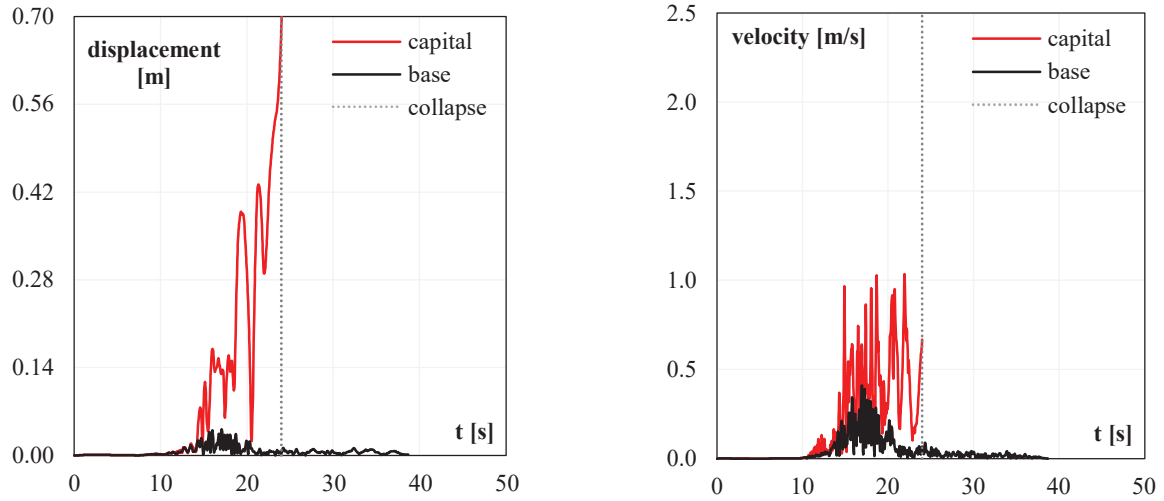

Figure 5: PHA that produced the collapse of the column for each value of the predominant period corresponding to the different seismic inputs and range of expected PHA derived by Italian seismic classification.

The responses were characterized by different combinations of relative sliding and rocking among the drums. As assessed by previous studies [11], low-frequency earthquakes led to prevalent rocking, while high-frequency earthquakes led to significant sliding. Indeed, as an example, Figure 6 shows the displacements and velocities at the capital and base of the column under the Irpinia-Sturno and Edessa records. Figure 7 shows the failure process of the column within the last four seconds until the collapse. Both the records led to the collapse of the capital and two drums. However, the Irpinia-Sturno record initially induced the rocking of the entire column as a single block, then the failure process involved the rocking of the last two drums and the capital without permanent displacements

in the standing part of the column. The second input (i.e. Edessa) induced relative sliding between the drums, other than rocking. Unlike the first case, permanent relative displacements were produced.

5 CONCLUSIONS

This paper presents a part of a wide study focused on the investigation of the seismic stability of multidrum free-standing tuff columns at the Pompeii archeological site. The study involved, at first, extensive surveys and visual inspection aimed at the knowledge of the main geometrical properties and most common forms of degradation of such structures at the site. The study involved 103 grey-tuff columns from four different areas of the site in private and public areas, selected as representative of typical column-type at the site. A study of the seismic behavior of one column from the tetrastyle atrium of *Casa del Fauno* was performed. This structure was selected for the analyses since it showed a high level of degradation and needed specific and urgent actions. The study was carried out based on the Finite Element Method (FEM). The performed investigations led to the following main conclusions:

- A considerable number of the surveyed columns were incomplete with missing parts, while 55 out of 103 columns were completely preserved;
- The main geometrical parameters of complete columns, affecting their seismic behavior ranged between: mean aspect ratio, H/d , 7.27m - 8.53m; mean distance from the center of mass of the column to the base perimeter, R , 1.59m - 2.82m; mean number of drums was equal to 5 or 6;
- Eight seismic records with different frequencies and amplitudes were selected for the numerical analyses aimed at investigating one multidrum column seismic behavior; the minimum scale factors applied to the intensities of the seismic records producing the collapse of the column was determined;
- Two seismic records with the higher predominant periods were found to be most dangerous, leading to the collapse with the minimum critical intensity measures, PHA. These intensity values at the collapse fall into and below the range of expected values derived from the Italian seismic zoning;
- The studied column showed different dynamic responses for the different input motions, with low-frequency records leading to prevalent rocking and high-frequency ones leading to significant sliding and permanent relative displacements among the drums.

Information on the geometrical properties and the state of preservation of typical archaeological multidrum columns are useful for the assessment of the seismic vulnerability of these structural elements. Further research could be performed to assess the effect of different geometrical properties of the structures on their seismic behavior (i.e. slenderness and size of the column and number and size of the drums) and different forms of degradation, particularly considering the presence of cracks, missing portions, eroded surfaces, permanent relative displacements between the drums and/or uneven profile of the column.

Keywords: rocking, lateral flexibility, impact, analytical model.

Abstract. *For rigid rocking models, energy dissipation relies solely on impact. Consequently, the position of the impulse acting on the rocking body determines the magnitude of energy loss and strongly influences the subsequent dynamic response. This paper evaluates the corresponding influence of the location of the vertical impulse on the dynamic behaviour of flexible rocking oscillators. The dynamic behaviour of a rocking flexible oscillator is explored in this study with an impact model that parametrically considers the position of impulse. The influence of the position of impulse on the expected energy loss during impact, and on the overturning stability of the flexible rocking oscillator are then examined. It is shown that the energy loss at impact reduces and the potential for overturning instability increases, for impulses located at increasing distances from the future rocking corner.*

1 INTRODUCTION

The rocking problem of a rigid body was first systematically studied by Housner [1] with the inverted pendulum model (IPM). Several idealisations were made: the rocking body and the support medium are rigid; sliding and complete separation of the body from the support are prevented; the motion is restricted to be planar; dissipation of energy depends exclusively on impact. The impulse forces at impact were assumed to act on the future rocking corner. Consequently, the resulting energy loss can be described as a function of the geometry of the rigid body, and is often quantified with a coefficient of restitution parameter.

The coefficient of restitution arising from the assumption of impulses being applied at the future rocking corner was found to overestimate the energy dissipation during impact by various experimental investigations [2, 3, 4]. Modified values for the coefficient of restitution were used in numerical simulations to achieve a better fit with experimental data. A similar approach was followed for flexible oscillators by Acikgoz et al. [5, 6]. Kalliontzis et al. [7] modified coefficient of restitution in a different way. A new width of the body was adopted by noting the varying location of the instantaneous rocking corner of the rigid rocking body. The coefficient of restitution was obtained by conserving angular momentum with the new future rocking corner. Furthermore, coefficient of restitution was noticed to be velocity-dependent [3, 4, 8].

However, Shenton and Jones [9] noted that conserving angular momentum with a point other than the future rocking corner is not a necessity dictated by mechanics: they hinted the ratio of the impulse at the future rocking corner and the one at the previous rocking corner can be a non-zero value (though a ratio of zero was adopted). Chatzis et al. [8] further extended this observation and quantified the influence of the location of the vertical impulse on the overturning stability of rigid bodies: the future rocking corner was determined to be the least conservative location. These results have later been extended to stacked rocking bodies [10].

The aforementioned publications show that the modelling of coefficient of restitution is of significant importance to model the dynamics of rigid rocking bodies. This paper is devoted to exploring the influence of modelling the coefficient of restitution for the flexible rocking oscillator. In particular, it investigates how the coefficient of restitution is influenced by the position of impulses, and how coefficient of restitution further influences the rocking response.

2 ANALYTICAL MODEL

The model is illustrated in Figure 1(a). There are two masses: the top one is a concentrated mass m with negligible rotational mass moment of inertia at point P; the bottom one is a concentrated mass m_A with mass moment of inertia I_A at point A. The bottom mass takes the form of a rigid ‘U’ structure with a centroid at A; while the top mass is connected to the ‘U’ structure by a spring (with stiffness, k) and a viscous damper (with damping coefficient, c).

The body is symmetrical about a central vertical axis. The half width of the base is denoted by b . The slenderness of the bottom mass, centroid, and top mass are given by α_A , α_{cg} , and α . The height of the corresponding positions are h_A , h_{cg} , and h while their distances to either base corner are given by R_A , R_{cg} , and R , where cg refers to the centre of gravity.

There are three motion phases in this model: full contact phase, rocking around the left corner o’, and rocking around the right corner o. The mechanical constraint for each phase is illustrated in Figure 1(b)-1(d). Two degrees of freedom exist: the rotation of the body θ and the lateral displacement u of the top mass. The system is subjected to horizontal ground accelerations \ddot{x}_g . Based on the mechanical constraints and excitations, the equations of motion for each phase is derived using Newton’s law. They are similar to the ones proposed by Acikgoz

Figure 1: Rocking model and phases.

and DeJong [11], with the difference of the bottom mass at non-zero height.

After obtaining the equations of motion, phase transition rules are defined. There are two types of transition: uplift and impact, with the former indicating a transition from full contact phase to a rocking phase, and the latter a transition from a rocking phase to another rocking phase or to a full contact phase.

During full contact, the reaction forces from the support medium move along the base of the body. Uplift happens when the position of the vertical reaction force coincides with one of the corners of the base. Uplift involves a smooth transition between two phases of motion. In contrast, impact involves impulsive forces and features a non-smooth transition. The horizontal impulse experienced by the top mass is zero, as the spring and damper cannot transmit impulsive forces over an infinitesimally small duration impact. Using this information and noting that angular momentum is conserved around the locus of the impulsive force (located at a distance λb from the future rocking corner) allows the calculation of the post-impact angular velocity $\dot{\theta}^+$. The following equation expresses the coefficient of restitution e which relates pre-impact and post-impact angular velocities (i.e. $\dot{\theta}^+ = e\dot{\theta}^-$) for the body transitioning from a pure-rocking phase to another pure-rocking phase:

$$e = \frac{I_A + m_A h_A^2 + mu(\mp b + u) + b(1 - \lambda)(-m_A b - mb \pm mu)}{I_A + m_A h_A^2 + mu(\pm b + u) + b(1 - \lambda)(+m_A b + mb \pm mu)} \quad (1)$$

Here, the upper sign refers to transitions from rocking around the left corner to rocking around the right corner, and the lower sign refers to vice versa. If e is positive, a new rocking phases follows. A negative value is mechanically inadmissible; in this case, a transition to full contact phase is assumed. For this to occur, $e = 0$ and this implies that λ attains a specific value λ_0 . In the absence of any horizontal impulsive forces applied to the top mass, its post-impact velocity is determined by the conservation of horizontal momentum.

3 INFLUENCE OF IMPULSE POSITION ON ROCKING BEHAVIOUR

3.1 Dimensional analysis

To obtain the effects of the position of impulses on rocking behaviour systematically, dimensional analysis is employed. Single cycle sine and cosine pulses are used as excitations:

$$\ddot{x}_g = \begin{cases} AP(\omega t) & t \leq 2\pi/\omega \\ 0 & t > 2\pi/\omega \end{cases} \quad (2)$$

where \mathbf{P} denotes either sin or cos; A and ω denote the amplitude and frequency of the pulse.

Under the excitations shown in Equation (2), the response of the rocking oscillator can be characterised by Equation (3).

$$(u, \theta) = f(\omega_n, \zeta_n, \alpha, \alpha_A, \omega, A, t, m, m_A, I_A, g, b, \lambda) \quad (3)$$

With 13 parameters and 3 fundamental dimensions involved, the two non-dimensional response parameters can be expressed by $13 - 3 = 10$ non-dimensional parameters according to Buckingham's Π theorem [12]. The chosen three repeating parameters are: p , g and m , while the Π groups are shown in Table 1. Note p is the frequency for rocking ($p = \sqrt{(m + m_A)gR_{cg}/(I_A + m_A R_A^2 + mR^2)}$). Thus, the dimensionless response parameters u/u_{cr} and θ/α_{cg} can be obtained by Equation (4). u_{cr} is a displacement used to nondimensionalise lateral displacement, which corresponds to the critical lateral displacement when an undamped body with a zero bottom mass height uplifts ($u_{cr} = \pm \frac{(m_A/m+1)gb}{\omega_n^2 h}$).

Table 1: Π groups

Π groups	Π_1	Π_2	Π_3	Π_4	Π_5	Π_6	Π_7	Π_8	Π_9	Π_{10}
Quantity	ω_n/p	ζ_n	α_{cg}	α_A	ω/p	$A/(g \tan \alpha_{cg})$	pt	m_A/m	$I_A/(m_A R_A^2)$	λ

$$(u/u_{cr}, \theta/\alpha_{cg}) = f(\omega_n/p, \zeta_n, \alpha_{cg}, \alpha_A, \omega/p, A/(g \tan \alpha_{cg}), pt, m_A/m, I_A/(m_A R_A^2), \lambda) \quad (4)$$

3.2 Coefficient of restitution

The influence of the position of the vertical impulse, as expressed through the value of λ , on the coefficient of restitution can be estimated by evaluating Equation (1) numerically for a chosen rocking body. After defining the Π groups, a stocky but laterally flexible body is chosen to investigate the relationship between the coefficient of restitution, the position of the impulse and lateral displacement of the top mass at the moment of impact. The parameters chosen for the rocking body are given in Table 2. The relationship between e , λ and u/u_{cr} is illustrated in Figure 2 for a range of plausible values.

Table 2: Simulation parameters for investigation of coefficient of restitution

	Π_1	Π_2	Π_3	Π_4	Π_8	Π_9	Π_{10}
Figure 2	2.43	0.05	0.35	0.6	0.47	0.56	[0, 1]

Figure 2(a) shows that e is monotonically increasing with respect to λ . This can be confirmed to be true for all flexible rocking bodies. The partial derivative of e with respect to λ is shown in Equation (5) and is always positive. Thus, the increasing trend is confirmed. Chatzis et al. [8] established that the increase of λ within the expected physical bounds $[0, 2]$ leads to an increased coefficient of restitution for rigid rocking bodies. It is shown the trend is the same for flexible bodies.

$$\frac{\partial e}{\partial \lambda} = \frac{2(m + m_A)b^2(I_A + m_A h_A^2) + 2mm_A b^2 u^2}{[I_A + m_A h_A^2 + mu(\pm b + u) + b(1 - \lambda)(+m_A b + mb \pm mu)]^2} \quad (5)$$

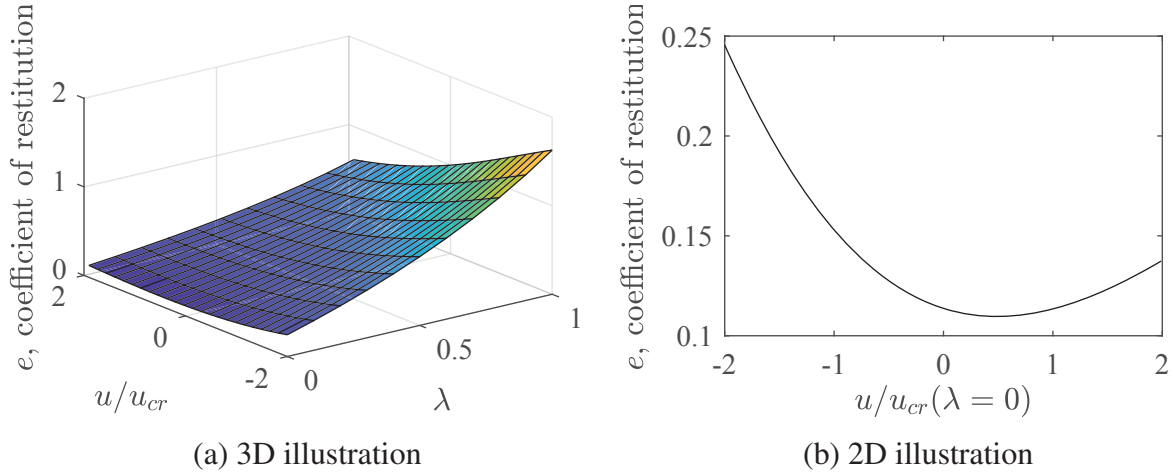

Figure 2: Illustration of the relation between e , λ and u/u_{cr} .

Figure 2(a) indicates the noteworthy influence of lateral deformations u/u_{cr} on the coefficient of restitution e ; while Figure 2(b) further investigates this relationship for an impulsive force locus at the future rocking corner, i.e. when $\lambda = 0$. Coefficient of restitution is clearly not a monotonic function of lateral deformation according to Figure 2(b). The lateral displacement u at impact, can reduce or increase the coefficient of restitution depending on its sign and magnitude.

For the example given in Figure 2, e is greater than 1 in some cases (e.g. $\lambda = 1$, $u/u_{cr} = -2$). However, different from the rigid body scenario, an e greater than 1 does not necessarily mean gaining energy during impact. Similarly, an e smaller than 1 can still lead to increase of energy. Furthermore, e with $\lambda = 0$, $u/u_{cr} = 0$ is much smaller than Housner's coefficient of restitution. This mainly reflects the effect of the absence of horizontal impulse applied at the top mass.

3.3 Stability analysis

A slender body is chosen to examine the influence of the impulse locus on overturning instability. The parameters are presented in Table 3. In the experiment by Espinosa [13], it is noticed $\lambda = 0.3$ is a reasonable value for the specific flat-base steel body placed on a sufficiently-stiff rubber mat. According to this, only three values of λ around 0.3 are included (0, 0.2, 0.4) in the following simulations. Figure 3 shows the stability diagram of a stiffer body; while Figure 4 illustrates that of a more flexible body. For both bodies, a sine and a cosine pulse excitation is applied separately. Each point on the diagram corresponds to the result under a pulse with a specific nondimensional frequency (horizontal axis) and nondimensional amplitude (vertical axis). Three types of results are involved as indicated in Figure 3(a) (annotations are omitted in other figures as the location of different types of results are similar): mode 1 failure (overturning with one or more impacts), mode 2 failure (overturning without impact), safe case (no overturning). It can be seen from all the figures that an increase in λ leads to an expansion of mode 1 failure area.

Table 3: Simulation parameters for stability analysis

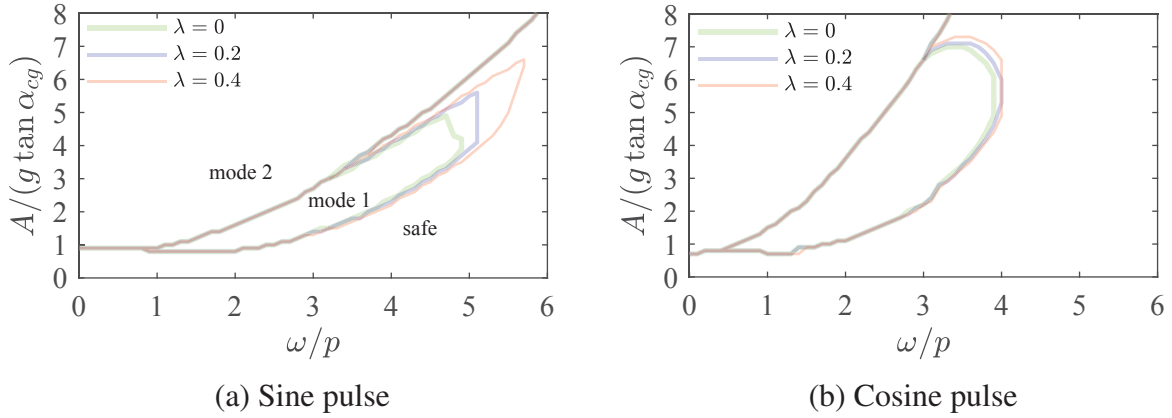

Figure 3: Effects of position of impulse on stability (flexible case).

Figure 4: Effects of position of impulse on stability (stiff case).

The stability of the flexible rocking bodies is less sensitive to the change of λ under cosine pulse excitations. The trends are similar in Figures 3 and 4, indicating that the influence of λ on the stiff and flexible oscillators are qualitatively similar.

The increasing λ leads to more instances of overturning for the investigated flexible bodies, similar to the results obtained for rigid bodies [8]. In the rigid case, a reduced dissipation of energy can be predicted by the increase of λ since it directly determines energy loss. However, both rotational motion and lateral motion need to be considered to estimate energy loss at impact for the flexible body. Thus, a numerical example is chosen to demonstrate the total energy

Figure 5: Time history example.

dissipation. The investigated rocking body is identical to the one shown in Figure 3(a), and its properties are provided in Table 3. The excitation that was considered is a sinusoidal pulse with $\omega/p = 5.3$ and $A/(g \tan(\alpha_{cg})) = 5$.

Figure 5(a)-5(b) show the time histories for rocking angle and total energy, which are all in normalised forms. Note that E_{ref} is the potential energy difference between the unstable and stable equilibrium points of a rigid body with a similar geometry [11]. It can be seen from the inset figure in Figure 5(b) that less energy was dissipated for larger λ , which leads to failure of the rocking body for $\lambda = 0.4$.

To generalise this result further, the total energy dissipation is investigated analytically. The following equation (6) shows the dissipated energy during impact (E_d); while the following equation (7) shows the partial derivative of E_d with respect to e , which is always negative for $e > 0$. Therefore, the dissipated energy is a monotonically decreasing function of e . Since a greater λ invariably leads to a greater e , the dissipated energy also decreases with the rise of λ . Therefore, it is reasonable to postulate that an increase in λ is likely to increase the risk of overturning for most types of excitations.

Nonetheless, due to the coupling between u and θ , it is possible for the rocking body to go directly from rocking into full contact [11]. The energy based considerations above do not account for this behaviour.

$$E_d = -\frac{1}{2}(I_A + m_A R_A^2 + mb^2 + mu^2)(e^2 - 1)(\dot{\theta}^-)^2 \mp mbu(e^2 + 1)(\dot{\theta}^-)^2 \quad (6)$$

$$\frac{\partial E_d}{\partial e} = -[I_A + m_A R_A^2 + m(b \pm u)^2]e(\dot{\theta}^-)^2 \quad (7)$$

It is also possible that a chosen value of λ may lead to an overall increase of the energy of the system during impact. Such values need to be avoided as the system would be gaining energy during impact. Similarly to [10], it is possible for this to happen for values of λ smaller than unity.

4 CONCLUSIONS

- A flexible rocking model and an impact model parametrising the location of the vertical impulse during impact is introduced.

- The effect of the position of the impulse on the coefficient of restitution is analytically and numerically examined, through studying the effect of changing the parameter λ .
- As the vertical impulse moves away from the future rocking corner, less energy is dissipated during impact. This is likely to lead to a higher risk of overturning instability.

Abstract. *This study focuses on structural systems which are particularly attractive for bridge design. Specifically, it investigates the seismic performance of single-column bridges, which are either conventionally designed, with the column monolithically connected with the ground (i.e. fixed-base), or designed with the column-footing system able to uplift and exhibit planar rocking motion during an earthquake. Conventionally designed bridges sustain considerable damage at the column ends after severe earthquakes. Seismic damage often determines whether the bridge remains functional after a seismic event. On the contrary, rocking design implies that a structure under seismic loading performs rigid body rotation around pre-defined pivot points. Thus, in principle, it relieves the structure from excessive deformations and damage. However, rocking isolation is not often applied in bridge engineering practice, mainly due to the lack of thorough understanding of its dynamic (seismic) performance and its potential post-earthquake financial benefits. This paper redirects our attention to the main benefits of rocking design over the conventional (fixed-base) design and conducts a comparative study between the two design methodologies in terms of their seismic losses and resilience in the aftermath of severe seismic hazard scenarios. The analysis reveals the mitigated seismic losses and the remarkable resilience that rocking design offers compared to the conventional (fixed-base) design after all the examined seismic hazard scenarios. The above findings reinforce the potential of the rocking design as an alternative seismic design paradigm for future bridge engineering applications and serve as the basis for a more rational and holistic seismic assessment of single-column rocking bridges.*

1 INTRODUCTION

Conventional bridge seismic design implies the column remains fixed with its foundation, and subsequently with the ground, offering the necessary strength and ductility to the structure to withstand seismic forces and avoid collapse. After severe earthquakes though, such a design concept leads to sustainable seismic damage and, thus, residual displacements. Seismic damage is an important measure of post-earthquake functionality that often dictates whether a bridge remains operational following a seismic event. On the other hand, rocking design allows the structure to uplift and pivot during an earthquake relieving the structure from stresses and subsequently seismic damage. The seminal work of Housner [1] first revealed the benefits of rocking design over the conventional (fixed-base) design after the Chilean earthquake in 1960, and many studies have followed [2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17], among others.

The structural configuration of Fig. 1(a), in which the column is monolithically connected with the ground (i.e. fixed-base), is widely used for bridge design. On the contrary, the configuration of Fig. 1(b) is designed in such a way that the column is monolithically connected with the footing (or base) but the column-base system can detach from the (assumed rigid) ground when subjected to a ground motion. Hence, the rocking structural system of Fig. 1(b) is gaining momentum as an alternative bridge design paradigm, since it combines the benefits of rocking isolation with the merits of the *accelerated bridge construction* method. To illustrate its superior behavior, various studies have compared its seismic performance with the pertinent performance of its fixed-base counterpart [18, 19, 20, 21, 22, 23, 24, 25], and references therein.

This work is motivated by the lack of analytical studies that thoroughly evaluate the post-earthquake performance of the rocking system of Fig. 1. Hence, it extends the well-established performance-based earthquake engineering framework to compare the post-earthquake performance of the conventional design method with the rocking design in terms of: (i) the accumulated seismic (repair) losses, and (ii) the resilience in the aftermath of severe seismic hazard scenarios.

2 ANALYTICAL MODELLING

Fig. 1 illustrates the examined single-column structural systems. Fig. 1(a) shows the conventional (fixed-base) design, while Fig. 1(b) illustrates the rocking column-base system that is designed for bridges. Assuming rigid ground conditions and no sliding at the rocking interface allow the structure of Fig. 1(b) to uplift and pivot during an earthquake exhibiting planar rocking motion. When the rocking structure of Fig. 1(b) remains in full contact with the ground, from a dynamics perspective, it behaves as a single degree-of-freedom system (i.e. similar to the fixed-base structure of Fig. 1(a)). Thus, its motion is captured by the deformation of the column u . After rocking commences, the motion of the rocking structure is captured by both the deformation of the column u and the rocking rotation ϕ of the base [26, 27].

Consider the rocking oscillator of Fig. 1(b) with a concentrated mass m at height h . The column has a total mass of m_c and elastic stiffness of EI uniformly distributed along its length. The rigid base has mass m_b and width $2b$, while its height is considered negligible compared to its width. For simplicity, assume the lumped mass m creates no moment of inertia, while the rigid base creates moment of inertia with respect to its center of mass equal to $I_{m_b} = (1/3) m_b b^2$.

The equations of motion of the rocking oscillator of Fig. 1 can be derived using the general

Figure 1: Single-column bridge: (a) designed conventionally with the column monolithically connected with the ground (i.e. fixed-base); and (b) designed with the column-base system able to uplift and pivot during an earthquake

form of the Lagrange's equation:

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{u}} \right) - \frac{\partial L}{\partial u} = Q, \quad \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{\phi}} \right) - \frac{\partial L}{\partial \phi} = 0 \quad (1)$$

where $L = T - V$, with T the kinetic energy, V the potential energy and Q the generalized force, whose mathematical derivations are omitted herein for brevity (see [25] for more details). While the structure of Fig. 1(b) exhibits planar rocking, the equations that describe its motion are [25]:

$$\begin{aligned} & \left(m + \frac{33}{140} m_c \right) \ddot{u} + \left(m + \frac{11}{40} m_c \right) h \ddot{\phi} = \\ & -C\dot{u} - \frac{3EI}{h^3} u + \left[\left(m + \frac{33}{140} m_c \right) u - \text{sgn}(\phi) \left(m + \frac{3}{8} m_c \right) b \right] \dot{\phi}^2 \\ & -\ddot{u}_g \left(m + \frac{3}{8} m_c \right) \cos \phi + g \left(m + \frac{3}{8} m_c \right) \sin \phi \\ & \left(m + \frac{11}{40} m_c \right) h \ddot{u} + \left[\begin{aligned} & (I_{m_b} + m_b b^2) + m(h^2 + b^2) + mu^2 - \text{sgn}(\phi) 2mbu \\ & + m_c \left(\frac{1}{3} h^2 + b^2 \right) + \frac{33}{140} m_c u^2 - \text{sgn}(\phi) \frac{3}{4} m_c bu \end{aligned} \right] \ddot{\phi} = \\ & - \left(2m + \frac{33}{70} m_c \right) u \dot{\phi} + \text{sgn}(\phi) \left(2m + \frac{3}{4} m_c \right) b \dot{\phi} \\ & + \ddot{u}_g \left[\begin{aligned} & -\text{sgn}(\phi) (m + m_b + m_c) b \sin \phi \\ & - \left(m + \frac{1}{2} m_c \right) h \cos \phi + \left(m + \frac{3}{8} m_c \right) u \sin \phi \end{aligned} \right] \\ & + g \left[\begin{aligned} & -\text{sgn}(\phi) (m + m_b + m_c) b \cos \phi \\ & + \left(m + \frac{1}{2} m_c \right) h \sin \phi + \left(m + \frac{3}{8} m_c \right) u \cos \phi \end{aligned} \right] \end{aligned} \quad (2)$$

whereas when it remains in full contact with the ground, the pertinent equation of motion becomes:

$$\left(m + \frac{33}{140} m_c \right) \ddot{u} = -C\dot{u} - \frac{3EI}{h^3} u - \ddot{u}_g \left(m + \frac{3}{8} m_c \right) \quad (4)$$

where C is the damping coefficient responsible for the energy dissipation while the structure vibrates. \ddot{u} and $\ddot{\phi}$ denote the flexural and angular acceleration, while \ddot{u}_g and g are the ground and gravitational acceleration, respectively.

Rocking initiates when the overturning moment due to the external forces exceeds the restoring moment of the structural system. Therefore, uplift occurs when [25]:

$$\pm h \frac{m + \frac{11}{40} m_c}{m + \frac{33}{140} m_c} \left[\begin{aligned} & C\dot{u} + \frac{3EI}{h^3} u \\ & + \ddot{u}_g \left(m + \frac{3}{8} m_c \right) \end{aligned} \right] \mp \ddot{u}_g \left(m + \frac{1}{2} m_c \right) h - g \left[\begin{aligned} & (m + m_b + m_c) b \\ & \mp \left(m + \frac{3}{8} m_c \right) u \end{aligned} \right] > 0 \quad (5)$$

where the upper sign denotes clockwise (positive) rotations and the lower sign counter-clockwise (negative) rotations.

When during rocking, impact occurs, $\phi = 0$ and energy is lost. Following [28, 29, 25], this work assumes that after impact the rocking structure remains in full contact with the ground and uplifts when Eq. (5) is satisfied. Under this assumption and through conservation of angular momentum, the post-impact flexural velocity \dot{u}^+ can be expressed as [25]:

$$\dot{u}^+ = \dot{u}^- + \frac{I_{mb} - m_b b^2 + m_c \left(-b^2 + \frac{1}{3} h^2 + \frac{33}{140} u^2 \right) + m \left(-b^2 + h^2 + u^2 \right)}{\left(m + \frac{11}{40} m_c \right) h} \dot{\phi}^- \quad (6)$$

where \dot{u}^- and $\dot{\phi}^-$ denote the pre-impact flexural and angular velocity, respectively.

3 RESILIENCE-BASED EARTHQUAKE ENGINEERING ASSESSMENT

To evaluate the seismic performance of a structural system, the Pacific Earthquake Engineering Research (PEER) Center formulated the *performance-based earthquake engineering* (PBEE) framework [30, 31]. The PBEE framework encompasses four steps: (i) hazard analysis, (ii) structural analysis, (iii) damage analysis, and (iv) loss analysis. On the other hand, the resilience-based earthquake engineering (RBEE) framework illustrated in Fig. 2 appears to be a more holistic approach and it is considered as an extension of the PBEE in the design process. Specifically, the RBEE additionally incorporates the post-earthquake functionality and resilience of the structure, which are also important indicators to evaluate its seismic performance.

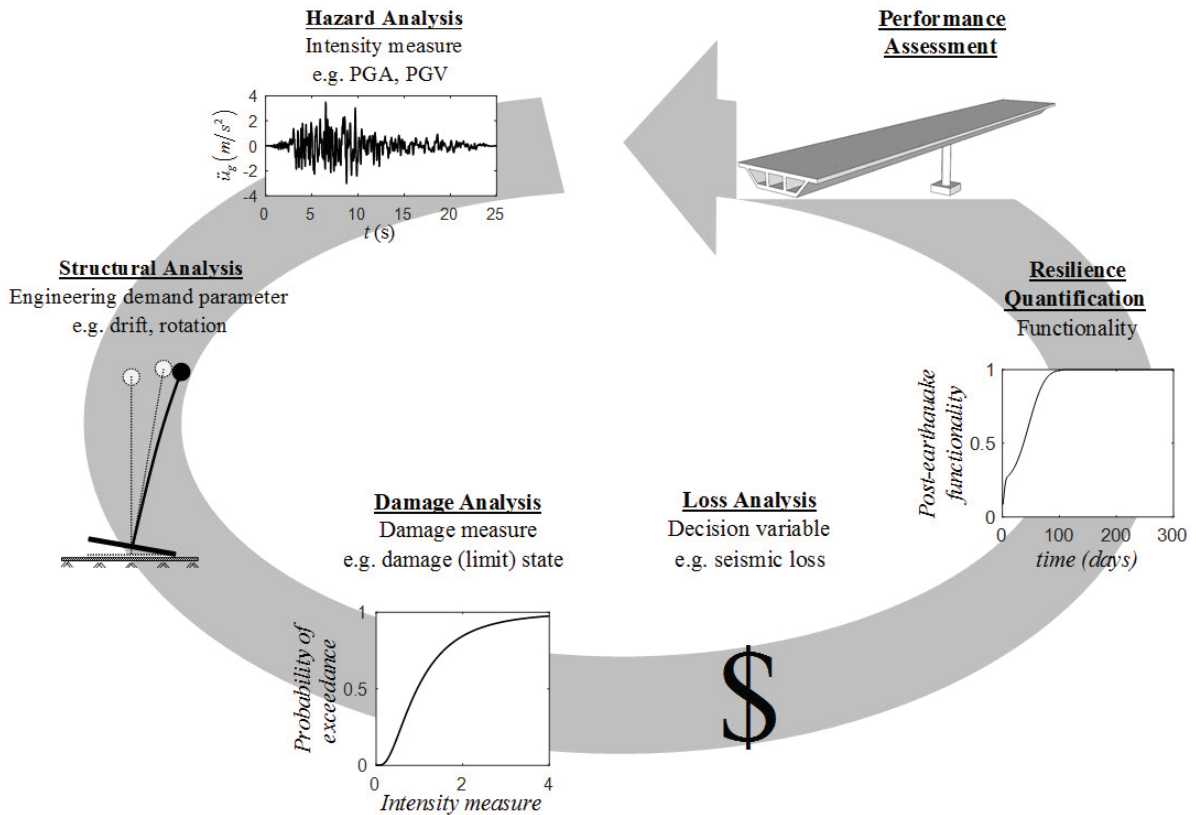

Figure 2: Resilience-based earthquake engineering framework

Figure 3: Hazard curve (in logarithmic scale) for the area of focus after conducting probabilistic seismic hazard analysis

3.1 Hazard Analysis

Assume that the examined structures of Fig. 1 are located in California laying on a strike-slip fault. The minimum and maximum moment magnitudes M_w are taken as 5.5 and 8, respectively, while the shear wave velocity averaged over the top 30 m $V_{s,30}$ is 480 m/s. The Joyner-Boore distance R_{JB} is 5 km. The IM considered herein is the peak ground velocity (PGV) [32, 33]. The PSHA provides a sample of 1,000,000 PGV values of ground excitations that are probable to appear in the area of focus [34]. To connect the earthquake events that are likely to appear in the examined area (i.e. California) with their annual frequency of exceedance, the Gutenberg-Richter recurrence law is adopted: $\log_{10}\lambda_M = 3.94 - 0.89M$, where λ_M is the frequency of the earthquakes with magnitudes greater than M . Fig. 3 plots the hazard curve (in logarithmic scale) that provides the mean annual frequency of exceedance λ_M of every earthquake that is likely to occur in the area of focus characterized by the adopted PGV.

3.2 Structural Analysis

This section investigates the seismic response of the single-column structural systems of Fig. 1. Each structure is considered to be part of a two-span box-girder bridge of total length $L = 60$ m and width $W = 10$ m. Assume that the total mass of the column is $m_c = 0.25m$, while the total mass of the base is $m_b = 0.17m$. The lumped mass m is located at height $h = 8$ m. The rocking structure of Fig. 1(b) has base-width $2b = 4.6$ m and slenderness $\alpha = 0.28$ rad. In addition, the examined structural systems have identical natural frequency $\omega_n = 8p$, where $p = \sqrt{g/R_m}$ is the frequency parameter of the rocking oscillator with R_m being the diagonal distance of the lumped mass from the pivot point (Fig. 1(b)). The damping ratio ζ is taken equal to 5% for the fixed-base oscillator of Fig. 1(a). For the rocking oscillator of Fig. 1(b), this study follows [27, 28] and assumes a constant damping ratio of 5% during rocking and a reduced damping ratio value during full contact (see [27] for further details).

To conduct the structural analysis, appropriate engineering demand parameters (EDPs) need first to be defined. The two EDPs are: (i) the absolute peak flexural deformation $|u_{max}|$ normalized with respect to the height h , and (ii) the absolute peak rocking rotation $|\phi_{max}|$ normalized with respect to the slenderness α .

$$EDP_1 = \frac{|u_{max}|}{h} \quad EDP_2 = \frac{|\phi_{max}|}{\alpha} \quad (7)$$

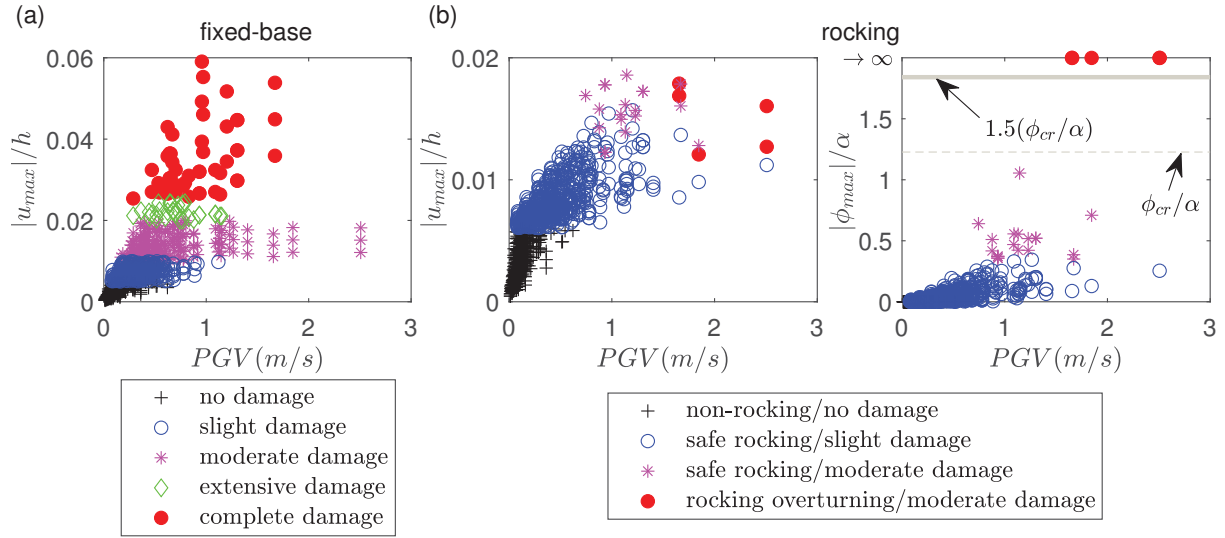

Figure 4: Seismic response analysis of (a) the fixed-base bridge bent of Fig. 1(a), and (b) the rocking bridge bent of Fig. 1(b)

Each of the structural systems of Fig. 1 is subjected to a series of strong ground motions adopted from the Pacific Earthquake Engineering Research (PEER) Center database [35]. The database covers a wide range of both pulse-type and nonpulse-type ground motions with magnitudes $6 \leq M_w \leq 8$ and distance from the fault $R_{rup} \leq 50$ km. To induce higher levels of demand, a scale factor of 1, 1.25 and 1.5 is, respectively, assigned to the accelerograms of the adopted database. Therefore, 960 response-history analyses are conducted for each of the examined structural systems of Fig. 1.

Fig. 4 illustrates the seismic response of both structural systems of Fig. 1. As a first approach, Fig. 4 reveals that uplift considerably reduces the structural deformation $|u_{max}|/h$ and therefore damage at the column. However, it makes the structure prone to excessive rocking rotations $|\phi_{max}|/\alpha$, and thus, overturning. Therefore, Fig. 4 reveals the importance of a proper design for a rocking bridge bent to avoid overturning (or collapse) and at the same time minimize structural damage at the column.

3.3 Damage Analysis

The seismic response of a structure is related to the damage occurred at the structure through appropriate damage measures. When excessive damage occurs, the structure collapses (or overturns for the case of a rocking structure) and subsequently it needs to be reconstructed. This work assumes that damage is occurred only at the column of the structure due to seismic forces. To quantify the seismic damage on the fixed-base structure of Fig. 1(a), this section adopts the damage limit states (or limit values of column damage) proposed by [37, 36], according to which damage is categorized into four levels/states, i.e. *slight*, *moderate*, *extensive* and *complete*. Table 1 presents the damage limits states of the fixed-base structure of Fig. 1(a).

On the other hand, the seismic response of the rocking structural system can be adequately described by three damage limit states. This work adopts the damage limits states proposed in [25], which proposed damage limit states for rocking bridge bents based on equivalence of their flexural deformation ($|u_{max}|/h$) with the pertinent deformation of their fixed-base counterparts. Table 2 presents these damage limits states. In Table 2, u_{cr} is the critical deformation of the column when rocking initiates (i.e. when the condition of Eq. (5) is met), and ϕ_{cr} is the critical

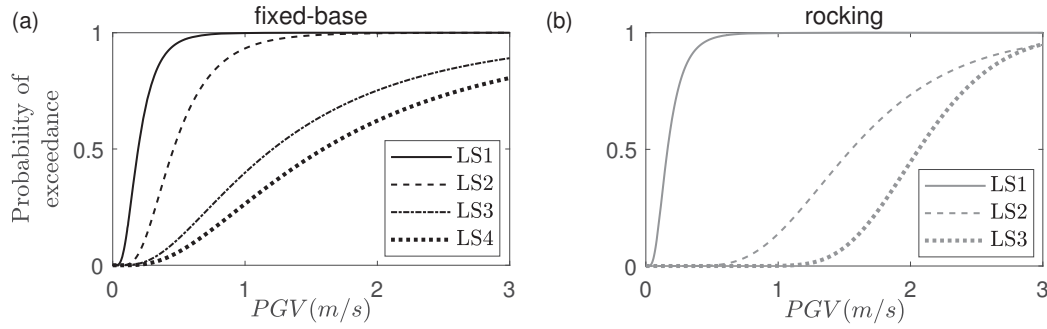

Figure 5: Fragility curves of (a) the fixed-base bridge bent of Fig. 1(a), and (b) the rocking bridge bent of Fig. 1(b) with respect to the adopted intensity measure

rotation for which the structure becomes dynamically unstable [27].

Based on Tables 1, 2, this section employs the *maximum likelihood estimation* approach [38] to estimate the probability of the examined structural systems to exceed the certain damage limit states. Fig. 5 plots the fragility curves of the structures of Fig. 1. Note from Fig. 5 and Fig. 4 that, uplift mitigates both structural deformations and the structure's probability to excessive rocking rotations and thus overturning.

3.4 Loss Analysis

The structural damage of the examined structures of Fig. 1 accumulated in the aftermath of a seismic event is connected with the seismic losses through decision variables such as: (i) the seismic (repair) losses, (ii) downtime, i.e. the time that is required for the bridge to restore its functionality, and (iii) resilience, i.e. the ability of the bridge to sustain a level of functionality

Damage limit state	Capacity limit [36]	Damage description [37]
LS1	$\frac{ u_{\max} }{h} = 0.005$	<i>Slight</i> concrete cracking and spalling at the column. Onset of yielding of the reinforcing bars. Column in operational condition (damage requires no more than cosmetic repair)
LS2	$\frac{ u_{\max} }{h} = 0.010$	<i>Moderate</i> concrete cracking and spalling at the column. Damage to the exposed reinforcing bars. Minimal residual displacements. Column is still operational (column is structurally sound, damage is repairable)
LS3	$\frac{ u_{\max} }{h} = 0.020$	<i>Extensive</i> flexural damage at the column in the form of buckling and/or fracture of the longitudinal reinforcing bars, transverse steel loss, etc. Considerable residual displacements. Column is not operational (column is structurally unsafe, damage is considerable and repairs are immediate)
LS4	$\frac{ u_{\max} }{h} = 0.025$	<i>Complete</i> damage and collapse of the column (column and the whole bridge need to be reconstructed)

Table 1: Damage limit states of the fixed-base bridge bent of Fig. 1(a).

Damage limit state	Capacity limit [25]	Response mode	Damage description [37]
LS1	$\frac{ u_{\max} }{h} = \frac{u_{cr}}{h}$	Rocking initiation	<i>Slight</i> concrete cracking and spalling at the column. Onset of yielding of the reinforcing bars. Column in operational condition (damage requires no more than cosmetic repair)
LS2	$\frac{ \phi_{\max} }{\alpha} = 0.35$	Safe rocking	<i>Moderate</i> concrete cracking and spalling at the column. Damage to the exposed reinforcing bars. Minimal residual displacements. Column is still operational. Damage at the pivot points and the abutments due to rocking motion (column is structurally sound, damage is repairable)
LS3	$\frac{ \phi_{\max} }{\alpha} = 1.5 \left(\frac{\phi_{cr}}{\alpha} \right)$	Rocking overturning	<i>Moderate</i> concrete cracking and spalling at the column. Damage to the exposed reinforcing bars. Minimal residual displacements. Column is still operational. Damage at the pivot points and the abutments due to rocking motion (column is structurally sound, damage is repairable, the column-base system can be reused after the applied repair methods, the whole bridge needs to be reconstructed)

Table 2: Damage limit states of the rocking bridge bent of Fig. 1(b) [25].

for over a period of time.

Seismic losses are defined as the sum of the seismic consequences weighted with their probability of occurrence. Therefore, the expected seismic losses under a given IM can be expressed as [39, 40]:

$$E(l) = \sum_{i=1}^n C_i \cdot P_{LSi|IM} \quad (8)$$

where C_i represents the seismic consequences, e.g. the repair cost associated with the given damage limit state i , and $P_{LSi|IM}$ is the conditional probability of the structure to be at the given damage limit state (see Fig. 5). The seismic consequences associated with the given damage limit states are assumed proportional to the reconstruction cost of the bridge [41, 39]:

$$C_i = RCR_i \cdot c_{rec} \cdot W \cdot L \quad (9)$$

where W and L are the bridge width and length, respectively. c_{rec} is the reconstruction cost, which for the fixed-base structure of Fig. 1(a) is translated into 2,306 \$/m² in present monetary values [42]. RCR_i is the repair cost ratio that corresponds to each damage limit state. The repair cost ratios are expressed as a percentage of the reconstruction cost of the bridge, and differ from damage limit state to damage limit state — the more severe the damage, the larger the repair cost ratio. Tables 3, 4 present the pertinent repair cost ratio values for each damage limit state of the examined structures of Fig. 1.

Damage limit state	Repair cost ratio [37]	Repair methods description [43, 44]	Downtime (days) [37]	
			Mean	Standard deviation
LS1	0.03	Repair slight concrete cracking/spalling at the column (epoxy injection, patch with concrete, etc.)	0.6	0.6
LS2	0.08	Repair moderate concrete cracking/spalling at the column, repair damaged reinforcing bars (patch with concrete, reinforce and recast, etc.)	2.5	2.7
LS3	0.25	Repair extensive concrete cracking/spalling at the column, replace/repair longitudinal/transverse reinforcing bars (reinforce and recast, potential replacement of the column)	75	42
LS4	1	Demolition and reconstruction of the column and the whole bridge	230	110

Table 3: Repair cost ratio and downtime values for each damage limit state of the fixed-base bridge bent of Fig. 1(a).

This study considers nine different seismic hazard scenarios with $T_R = 40, 72, 125, 225, 475, 975, 1,485, 2,475$ and $4,975$ -year return period, which translate into a probability of 71%, 50%, 33%, 20%, 10%, 5%, 3%, 2% and 1%, respectively, that at least one such event will occur in the next 50 years in the area of focus. The hazard curve of Fig. 3 provides the intensities in terms of PGV values that correspond to the adopted seismic hazard scenarios, i.e. 0.37, 0.51, 0.65, 0.83, 1.08, 1.36, 1.53, 1.76 and 2.11 m/s, respectively. Fig. 6 presents a comparison of the examined structural systems in terms of their expected seismic losses accumulated after the considered seismic hazard scenarios. As a first approach, Fig. 6 shows that for all of the examined seismic hazard scenarios, the rocking bridge bent of Fig. 1(b) provides a significant post-earthquake financial benefit compared to its fixed-base counterpart. In particular, even after a severe seismic event (i.e. with $T_R = 4,975$ -year return period), the rocking bridge bent yields seismic losses which correspond to around 50% of the construction cost of the structure — a considerable post-earthquake financial benefit.

Figure 6: Expected (seismic) losses of the examined bridge bents of Fig. 1 in the aftermath of various seismic hazard scenarios

Damage limit state	Repair cost ratio [37]	Repair methods description	Downtime (days) [37, 45]	
			Mean	Standard deviation
LS1	0.03	Repair slight concrete cracking/spalling at the column (epoxy injection, patch with concrete, etc.)	0.6	0.6

3.5 Resilience Quantification

Resilience, as a performance indicator, quantifies the recovery (or restoration) functions of a structural system following a seismic event. These recovery functions depend on the associated damage limit states. For instance, a bridge completely damaged needs more time to restore its functionality compared to a slightly damaged bridge. The resilience of the structural systems of Fig. 1 can be quantified under the investigated time-interval (e.g. $\Delta t = 365$ days) as [46]:

$$R = \frac{1}{\Delta t} \int_{t_0}^{t_0 + \Delta t} Q(t) dt \quad (10)$$

where t_0 indicates the time-instant the seismic event occurs, and $Q(t)$ is time-variant functionality which herein is expressed as [47]:

$$Q(t) = \sum_{i=1}^n FR_i(t) \cdot P_{LSi|IM} \quad (11)$$

where $P_{LSi|IM}$ is the conditional probability of the structure to be at the given damage limit state, and $FR_i(t)$ denotes the functionality restoration process of the structure for each damage limit state. This study models the functionality restoration process of the examined rocking structure as a normal cumulative distribution function corresponding to each damage limit state i [37]:

$$FR_i(t) = \frac{1}{2} \left[1 + \operatorname{erf} \left(\frac{t - \mu_{d_i}}{\sqrt{2}\sigma_{d_i}} \right) \right] \quad (12)$$

where μ_{d_i} and σ_{d_i} represent the mean and standard deviation of the time during which the bridge is under restoration (i.e. downtime). Table 3 presents values mean and standard deviation

Figure 7: Resilience of the examined bridge bents of Fig. 1 in the aftermath of various seismic hazard scenarios under the investigated time-interval of $\Delta t = 365$ days

values of downtime (in days) for the fixed-base bridge bent of Fig. 1(a) proposed by HAZUS [37]. To estimate the corresponding downtime values for a rocking bridge, Mantawy et al. [45] experimentally compared the seismic performance of a rocking versus a conventionally designed (fixed-base) bridge. That study revealed that the construction time of the rocking bridge is, on average, 5 times lower than the construction time of the fixed-base bridge. In other words, when the fixed-base and the rocking bridge bent of Fig. 1 need to be reconstructed (i.e. when LS4 in Table 3 and LS3 in Table 4 are exceeded), the downtime of the rocking structure is considered as 1/5 of the downtime of the fixed-base structure. Table 4 presents the pertinent mean and standard deviation values of downtime for the rocking bridge bent of Fig. 1(b) [25].

Fig. 7 plots the resilience of each structural system and illustrates the dominance of the rocking structure over the conventionally designed (fixed-base) structure after all the examined seismic hazard scenarios. Note that the resilience of the rocking structure starts deteriorating only when a maximum considered earthquake occurs (i.e. with $T_R = 2,475$ -year return period). On the contrary, the resilience of the fixed-base structure is impaired even when a low intensity earthquake occurs (i.e. with $T_R = 72$ -year return period).

In sum, Figs 6, 7 reveal the remarkable financial benefits (i.e. decreased seismic losses and increased seismic resilience) that rocking design offers compared to the conventional fixed-base design, illustrating its potential as a seismic-avoidance design paradigm for bridges.

4 CONCLUSIONS

This work evaluates the seismic performance of structural systems, which are particularly attractive for bridge design. It focuses on single-column bridge bents either monolithically connected with the ground (i.e. fixed-base) or able to uplift and exhibit planar rocking motion during an earthquake. It extends the well-established performance-based earthquake engineering framework to compare the examined structural systems in terms of their accumulated seismic losses and resilience in the aftermath of severe seismic hazard scenarios.

The analysis reveals the considerably mitigated (seismic) losses of the examined rocking structure compared to the pertinent losses of the fixed-base structure, illustrating its potential as an economically feasible design solution. Further, results show that even under an extreme seismic hazard event, i.e. with 1% probability of occurrence in the next 50 years (i.e. $T_R = 4,975$ -year return period), the rocking bridge bent yields financial losses equivalent to 50% of the construction cost of the bridge — a considerable post-earthquake financial benefit. Further, this paper also unveils the remarkable post-earthquake resilience of the examined rocking structure after various seismic hazard scenarios. Importantly, the rocking bridge bent sustains

its resilience at the highest level till a maximum considered earthquake occurs (i.e. with $T_R = 2,475$ -year return period and 2% probability of occurrence in the next 50 years). On the contrary, the resilience of the fixed-base bridge bent is deteriorated even when a low intensity earthquake occurs (i.e. with $T_R = 72$ -year return period and 50% probability of occurrence in the next 50 years). The above findings redirect our attention to the main post-earthquake benefits of rocking design when used as a seismic isolation technique for bridges and pave the way for a more rational and holistic seismic assessment framework of single-column rocking bridges.

Abstract

A storey comprised of free-standing columns that may uplift under ground motion excitations can be regarded as a seismic isolation technique. These columns are referred to the literature as “kinematic bearings” and have been used in Russia and the wider region of the former Soviet Union over the past 40 years. Despite the extensive use of kinematic bearings, there are only limited studies based on the results obtained by the analytical solution of the dynamic response of such structural systems. From this point of view, in the present study the dynamic response of multi-storey structures placed on the top of a kinematic storey is examined. For this purpose an analytical model that describes the dynamic response of such structures is introduced. As long as the curved configuration of the ends of the kinematic bearings can affect the post-uplift stiffness of the kinematic storey, modal analysis is performed and the dynamic properties after the uplift are demonstrated. Subsequently, dynamic time history analyses are performed and the effect of post uplift stiffness of the kinematic storey on the displacement response of the base is investigated. Finally, the seismic demands of the superstructure, as well as their distribution throughout the storeys are examined.

Keywords: Rocking structures; Kinematic bearings; Seismic isolation;

1 INTRODUCTION

The dynamic response of rigid blocks rocking on a rigid ground was first studied by Housner [1], who highlighted the parameters that affect the stability of rigid bodies which can be uplifted under horizontal excitations. Since then, with the recognition of the remarkable properties of the rocking response, various forms of rocking systems have been studied, such as flexible rocking oscillators on solid [2-6] and flexible ground [7, 8], rocking structures on the foundations [9], rocking bridge piers [10-12], rocking frames [13-17], coupled conventional structures with rocking walls [18-20] and seismic isolation by forming a rocking floor at the base [21-24]. Despite the remarkable stability of free-to-rock large-scale systems, the basic requirement for the practical application of rocking systems is the prevention of overturning [25]. Along with the study of free rocking structural systems, the dynamic response of controlled and energy dissipative rocking systems have also been studied. Pre-tensioned tendons [26-29] and energy dissipation mechanisms [30-32] have been implemented onto rocking systems in order to limit the seismic demands and increase the deformation capacity. At the same time, due to the strongly non-linear behavior of the rocking motion, small changes in both the rocking system and the ground motion parameters can lead to large variations in the response, so that the study of the phenomenon under a probabilistic framework yields more reliable conclusions [33]. To this end, various intensity measures have been proposed to describe the influence of ground excitations on the response of rocking systems [34-39].

Although the rocking isolation design strategy has been implemented in a limited number of bridges [40, 41] and tall chimneys [42], hundreds of rocking podium structures (RPSs) have been constructed over the past 40 years in Russia and the wider region of the former Soviet Union [43]. RPSs are comprised of a superstructure placed on the top of a rocking story. The freestanding columns of the rocking story, referred to as "kinematic bearings" in Russian literature, can uplift under earthquake excitations, limiting the earthquake-induced loads on the superstructure. A complete presentation of the application of kinematic bearings in conjunction with energy dissipation mechanisms in Russia is provided by Smirnov et al. [44], while practical recommendations for the design of structures with kinematic foundations can be found in Cherepinskiy's book on kinematic foundations [45].

The first detailed study of the dynamic response of structures seismically isolated using a purely rocking floor at the base, considering that the superstructure behaves like a single degree of freedom elastic oscillator, was carried out by Bachmann et al. [21]. The developed analytical model has also been verified by experiments [22]. Through the analytical model, the forenamed study concentrates mainly on the investigation of parameters related to the stability of such systems, under pulse-type and natural seismic excitations. Based on the sdof model of the superstructure, Bantilas et al. [23] investigated the parameters that affect the elastic demands of RPSs. Later studies of Bantilas et al. [24] highlighted the critical effect of the higher vibration modes on the dynamic response of RPSs consisted of multiple degree of freedom (mdof) elastic superstructure. Due to the coupling between rocking and elastic vibrations, RPSs present a more complex response compared to solely rocking oscillators.

At this point, it should be emphasized that despite the wide use of kinematic bearings, their dynamic response differs from that of purely rocking systems, since the bearing base of the former is configured concave in opposition to the flat base of the latter. The aforementioned configuration of the rocking base results in a rolling response of the kinematic bearing onto the foundation, with positive or negative stiffness, before it starts to purely rock. An analytical model of the dynamic response of rigid bodies rolling and rocking on rigid ground is presented by Bachmann et al. [46] and Bachmann et al. [47].

In the present study an analytical model that describes the dynamic response of multi-storey structures placed on the top of a rocking base comprised of kinematic bearings is presented. As long as the curved configuration of the ends of the kinematic bearings can affect the post-uplift stiffness of the rocking storey, modal analysis is performed and the vibration mode properties after the uplift are demonstrated. In addition, dynamic time history analyses are performed on three typical multi-storey structures using the proposed analytical model. Considering three different rocking columns configurations, the effect of post uplift stiffness of the rocking storey on the response of the base is investigated. Finally, of particular interest are also the determination of the magnitude and the distribution of the seismic demands throughout the storeys of the superstructure. For this purpose the seismic demands of the nine structural systems are also presented.

2 DYNAMIC RESPONSE OF ROCKING PODIUM STRUCTURES

In the present section, the analytical model of the dynamic response of frame structures, seismically isolated using kinematic bearings, is presented. The model is based on the assumption that the superstructure can be described by a mdof elastic oscillator, fixed on the top of a rocking frame comprised of kinematic bearings. The rigid frame consists of a cap beam with mass m_b and N freestanding columns with mass m_c , semi-diagonal length $R = \sqrt{H^2 + B^2}$, rotational moment of inertia around its center of mass I_{cm} , and slenderness $\alpha = \tan(B/H)$. During the dynamic response, the rocking columns are considered to be in contact with the cap beam and the ground, while the friction coefficient at the contact surfaces is large enough to prevent any sliding. The idealization of the model is illustrated in Figure 1(a).

Figure 1: (a) Schematic representation of the analytical model, (b) geometric configuration of a typical kinematic bearing, and (c) static pushover curves of the kinematic storey.

A typical configuration of the kinematic bearings that comprise the rocking storey is presented in Figure 1(b). After the uplift occurrence, the curved extensions at the ends of the rocking columns result in the rolling response of the base storey before it starts to rock purely. With reference to Figures 1(b) and 1(c), the post uplift stiffness during rolling response depends on the radius of curvature r of the extensions, while the wedge's angle β sets the limit between rolling and rocking response. According to Bachman et al. [47], the critical rotation of the rocking storey is given by the following equation:

$$\theta_{cr} = \begin{cases} \arctan \frac{\tan \alpha}{1-2\rho}, & \rho \leq \rho_{cr} \text{ (overturning during rolling)} \\ \arctan \frac{\tan \alpha'}{1-2\rho(1-\cos \beta)}, & \rho > \rho_{cr} \text{ (overturning during rocking)} \end{cases} \quad (1)$$

where $\rho=r/(2H)$ is the non-dimensional radius of curvature of the extensions; $\rho_{cr} = 0.5(1 - \tan \alpha / \tan \alpha')$; $\beta = \arcsin((\tan \alpha' - \tan \alpha)/(2\rho))$; and $\tan \alpha' = B'/H$ (see Figure 1(b)).

The equations of motion of the RPS, as it is depicted in Figure 1 are expressed as follows:

$$A\ddot{\theta} = -B\frac{g}{R}(1+2\gamma+2\eta\gamma) - C\left(\frac{\alpha_g}{R}(1+2\gamma) - \frac{2\eta\gamma V}{M_{tot}R}\right) - D\dot{\theta}^2 \quad (2)$$

$$\mathbf{M}\ddot{\mathbf{u}}_t + \mathbf{C}\dot{\mathbf{u}}_t + \mathbf{K}\mathbf{u}_t = -\mathbf{M}\delta\alpha_g + \mathbf{K}\delta\mathbf{u}_b + \mathbf{C}\delta\dot{\mathbf{u}}_b \quad (3)$$

where A, B, C, and D are the coefficients listed in Table 1 for rolling and rocking response; γ is the mass ratio of the cap beam (m_b) divided by the total mass of rocking columns (Nm_c); η is the mass ratio of the superstructure (M_{tot}) divided by the mass of cap beam (m_b); α is the slenderness of rocking columns; \mathbf{u}_t , $\dot{\mathbf{u}}_t$ and $\ddot{\mathbf{u}}_t$ are the displacements, velocities, and accelerations of the mdof oscillator with respect to the undeformed configuration of the system (see Figure 1(a)); \mathbf{K} and \mathbf{C} are the stiffness and damping matrices of the mdof oscillator, respectively; δ is the influence vector of the ground motion ($\delta=1$); α_g is the ground acceleration; and \mathbf{u}_b and $\dot{\mathbf{u}}_b$ are the cap beam displacement and velocity, respectively. The base shear of the superstructure (V) is given by:

$$V = \delta^T \mathbf{K}(\mathbf{u}_t - \delta\mathbf{u}_b) + \delta^T \mathbf{C}(\dot{\mathbf{u}}_t - \delta\dot{\mathbf{u}}_b) \quad (4)$$

* $\bar{I}_o = I_o/(m_c R^2)$ and I_o is the rotational inertia of the column with respect to the pivot point.

† The upper and lower signs define rolling/rocking around the right ($\theta>0$) and left ($\theta<0$) pivot points.

Table 1: Coefficients of the rocking storey equation of motion.

Until uplift occurs, the rocking base is assumed to remain inactive ($\theta = \dot{\theta} = 0$). Thus the superstructure behaves as a fixed base mdof oscillator, and the equations of motion are given by

Eq. (3), considering $u_b = \dot{u}_b = 0$. When the horizontal overturning actions overcome the restoring forces of the RPS, uplift occurs, and the rocking story starts to roll. The uplift criteria can be summarized as follows:

$$\mp \frac{\alpha_g}{g} \geq \left(1 + \frac{2\eta\gamma}{1+2\gamma}\right) \tan \alpha \mp \frac{2\eta\gamma}{(1+2\gamma)M_{tot}g} V \quad (5)$$

where V is the superstructure's base shear given by Eq. (4) considering $u_b = \dot{u}_b = 0$. The upper and lower signs define rolling initiation around the right ($\theta > 0$) and left ($\theta < 0$) pivot points.

In the particular case where the superstructure is rigid, Eq. (2) and the coefficients of Table 1 results in the equation of motion of rigid rolling and rocking frames[47], whose cap beam mass is equal to the sum of the mass of the superstructure and the mass of the cap beam of the RPS. On the other hand, if $\rho=0$, Eqs. (2) and (3) are equivalent to the equations of motion of pure rocking RPSs [24].

In the rolling/rocking response of rigid blocks, energy dissipation occurs during impact when the tilt angle of the rocking columns reverses the sign. The solution of the impact problem results in the coefficient of restitution of the rocking base, as well as in the post-impact velocities of the floors of the superstructure as follows [24]:

$$c = \left(\frac{\dot{\theta}^+}{\dot{\theta}^-}\right)^2 = \left[1 - 2\sin^2 \alpha \frac{1+4\gamma(1+\eta)}{I_0 + 4\gamma(1+\eta)}\right]^2 \quad \text{and} \quad \dot{\mathbf{u}}_t^+ = \dot{\mathbf{u}}_t^- - \delta 2R \cos \alpha (1 - \sqrt{c}) \dot{\theta}^- \quad (6)$$

where $\dot{\mathbf{u}}_t^-$ and $\dot{\mathbf{u}}_t^+$ are the superstructure's absolute velocity vectors before (-) and after (+) impact, respectively.

Table 2: Linearized matrices of Eq. (7) during rolling and rocking phase.

3 THE EIGENVALUE PROBLEM

In order to obtain the linearized equations of motion of a RPS once uplift occurs, the non-linear terms of Eqs. (2) and (3) expand into Taylor series about the static rest position of the

system ($\theta=0, \dot{\theta}=0, \mathbf{u}_t = \mathbf{0}, \dot{\mathbf{u}}_t = \mathbf{0}$) and the higher order terms are omitted. The linearized equations of motion can be represented as follows:

$$\mathbf{M}_L^{III} \ddot{\mathbf{u}}_L + \mathbf{C}_L^{III} \dot{\mathbf{u}}_L + \mathbf{K}_L^{III} \mathbf{u}_L = -\mathbf{B}_{ag}^{III} \alpha_g(t) \mp \mathbf{F}_L^{III} \quad (7)$$

where $\mathbf{u}_L = [u_{b,R} \ \mathbf{u}_t]^T$ and $u_{b,R}=2R\theta$ is the displacement of the cap beam in direction perpendicular to the diagonal of the rocking columns. The linearized matrices of mass (\mathbf{M}_L), damping (\mathbf{C}_L), stiffness (\mathbf{K}_L) as well as the load vectors (\mathbf{B}_{ag}) and (\mathbf{F}_L) during rolling (I) and rocking (II) are given in Table 2.

The eigenvalues and eigenvectors that correspond to the vibration modes of the superstructure after uplift occurrence, as well as the eigenvalues correspond to the rocking and rolling vibration modes are calculated following the process applied for RPSs consisted of purely rocking columns by Bantilas et al. [24].

4 VIBRATION PRPERTIES

In order to study the modification of dynamic properties of typical structures of one to 10 floors isolated using kinematic bearings, the eigenvalue problem is solved numerically. Superstructures with shear displacement profile are considered. The construction of mass (\mathbf{M}), stiffness (\mathbf{K}) and the damping (\mathbf{C}) matrices is based on the procedure presented by Thermou et al. [48] and has been also applied in RPSs [24]. Assuming that the superstructures are fixed on the top of a typical rocking frame, which consists of rectangular columns ($\bar{I}_0 = 4/3$) of size $R = 1.5$ m, slenderness $\tan(\alpha) = 0.15$ and $\tan(\alpha') = 0.30$, $\gamma = 10$ and cap beam mass m_b equal to the mass of the standard floor m ($\eta = \eta$), the linearized matrices (\mathbf{M}_L), (\mathbf{K}_L), and (\mathbf{C}_L) are constructed. Then, the eigenvalue problem is solved and the dynamic properties ($\omega_{u,i}$ and $\xi_{u,i}$) of the uplifted structures are determined. The amplification factors of the natural frequency ($\omega_{u,i}/\omega_{o,i}$) and damping ($\xi_{u,i}/\xi_{o,i}$) that correspond to the first ($i = 1$) vibration mode of typical superstructures from one to 10 floors ($n = 1 \div 10$) are presented in Figures 2. The amplification of the natural frequency is more intense during rolling phase compared to rocking phase. Regarding the nondimensional radius of the curved extensions, superstructures placed on the top of a rocking base with negative ($\rho=\rho_{cr}$) or zero stiffness ($\rho=0.5$) during rolling present identical modification of their dynamic properties. However, kinematic bearings with positive stiffness ($\rho=1.5$) results in higher values of amplification. Regardless the radius of the curved extensions, the damping amplification factors take lower values compared to corresponding frequency ones.

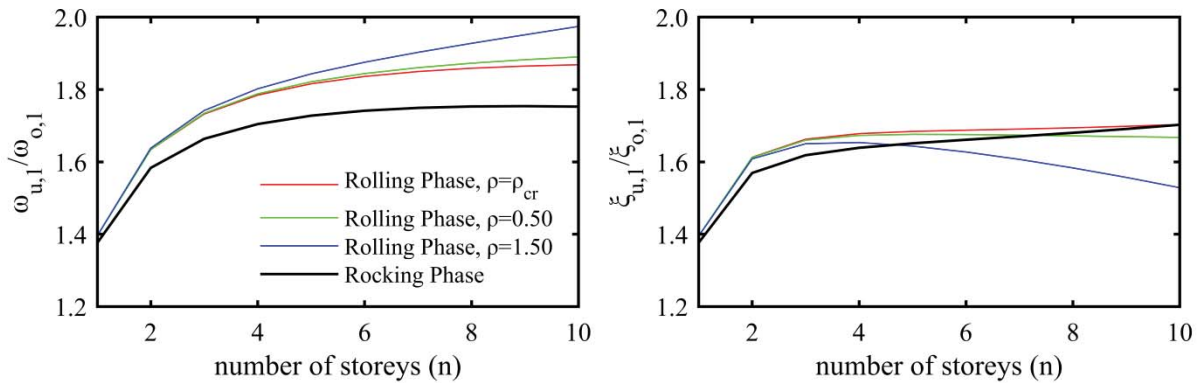

Figure 3: Amplification factors of the natural frequency (left) and damping ratio (right) of the first vibration mode, as a function of superstructure storeys (n) for rocking podium structures.

In Figure 4 (α) the eigenvalues (\bar{p}_{ext}) that correspond to the rolling and the rocking mode for RPSs with columns with nondimensional radius of curvature $\rho = \{\rho_{\text{cr}}, 0.5 \text{ and } 1.5\}$, as a function of size R , are presented. It has to be mentioned that these values correspond to the frequency parameter of the rocking base during rolling and rocking. Moreover, in Figure 4 (β) the frequency parameter during rolling phase is presented as a function of the radius of the curved wedges. The eigenvalues correspond to a six storey superstructure ($n = 6$) with shear deformation profile. In Figure 4 is also depicted, with dashed lines, the frequency parameter (\hat{p}_{ext}) of a rigid rocking frame with cap beam mass is equal to the sum of the mass of the superstructure and the mass of the cap beam of the RPS ($\gamma_{\text{tot}} = \gamma(1 + \eta)$). The frequency parameter \hat{p}_{ext} is given by the following expression:

$$\hat{p}_{\text{ext}} = \hat{p} \sqrt{k_1^*} \quad (5)$$

where \hat{p} the frequency parameter of a rigid rocking frame without curved extensions at the rocking columns; and $k_1^* = 2\rho - 1$ the dimensionless stiffness of the rocking base during rolling.

It is observed that the frequency parameter \bar{p}_{ext} , which is calculated by the modal analysis, is estimated with high accuracy by the frequency parameter \hat{p}_{ext} of the rigid rocking frame, in cases of negative and zero stiffness ($\rho \leq 0.5$) during rolling phase. In case of systems with positive stiffness, the frequency parameter values differ from the analytically calculated parameter, especially for small rocking columns ($R < 1.5 \text{ m}$) with large radius of the curved extensions ($\rho > 1.5$). Moreover, in structural systems with radius of curvature $\rho \leq 0.5$ the frequency parameter take lowers values in rolling than in rocking phase. In the special case where $\rho = 0.5$ (zero stiffness), the frequency parameter take value $\bar{p}_{\text{ext}} = 0$.

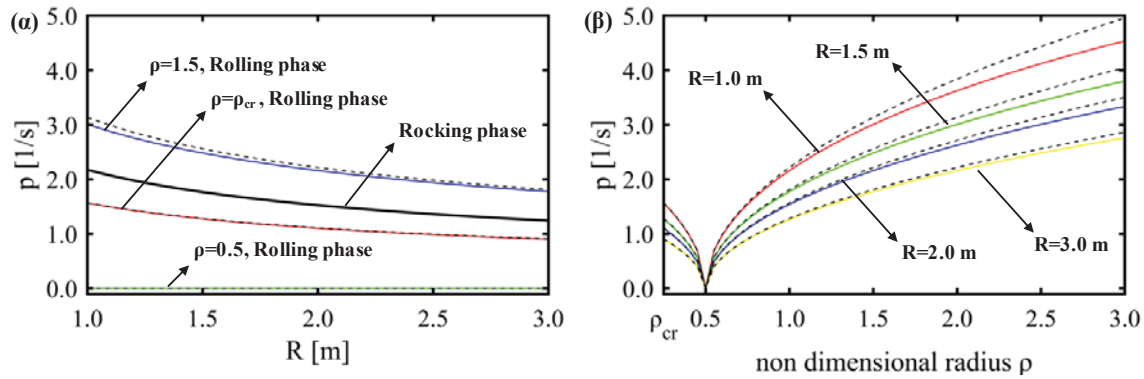

Figure 4: Frequency parameter: (α) as a function of size R and (β) as a function of the wedge's radius (ρ), of a seismic isolated six storey shear structure ($\gamma = 10$, $\eta = 6$, $\tan(\alpha) = 0.15$, $\tan(\alpha') = 0.30$ and $\bar{I}_0 = 4/3$).

The effect of the superstructures flexibility on the frequency parameters is presented in Figure 5 (α) and (β) for negative ($\rho = \rho_{\text{cr}}$) and positive stiffness ($\rho = 1.5$), respectively. The frequency parameter values of isolated shear superstructures with structural features $R = \{1.00, 1.50, 2.00 \text{ and } 3.00\} \text{ m}$, $\gamma = 10$, $\eta = n$, $\tan(\alpha) = 0.15$, $\tan(\alpha') = 0.30$ and $\bar{I}_0 = 4/3$, are illustrated as a function of the number of the floors (n). In dashed lines the frequency parameter (\hat{p}_{ext}) of a rigid rocking frame with curved extensions and beams mass $\gamma_{\text{tot}} = \gamma(1 + \eta)$ is also provided in the Figures. The flexibility of the superstructure do not affect the frequency parameter values in case of negative stiffness systems. However, in systems with positive stiffness during rolling, as the flexibility of the superstructure increases the frequency parameter of the rigid rocking

frame differs substantially from the values of the analytical solution, especially for rocking columns of small size.

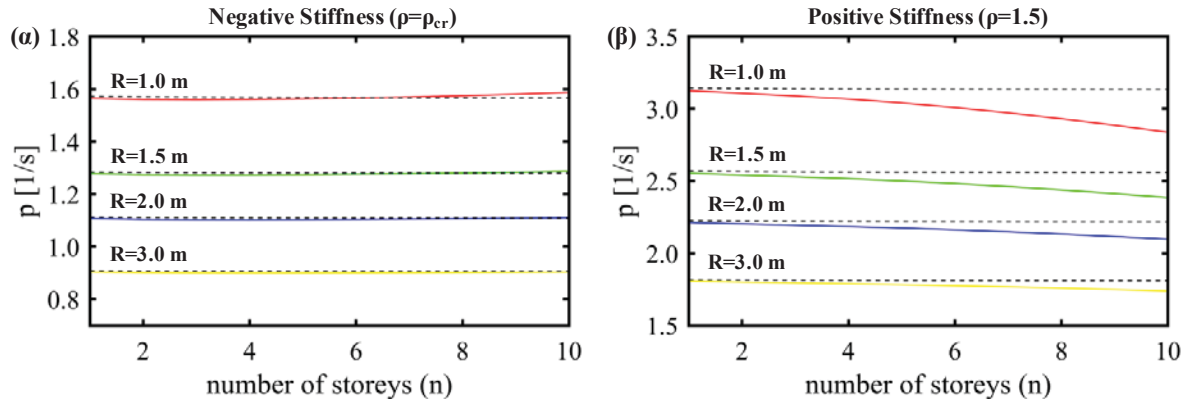

Figure 5: Frequency parameter as a function of the number of the floors (n), of rocking base with (a) negative and (b) positive stiffness during rolling phase.

The vibration mode eigenvectors of a typical three-story RPS ($n = \eta = 3$) isolated using kinematic bearings are presented in Figure 6. Specifically, the vibration modes during rolling phase, considering wedges with nondimensional radius of curvature $\rho = \{\rho_{cr}, 0.5 \text{ and } 1.5\}$, and rocking phase are displayed. The dashed black lines correspond to the full-contact eigenvectors of the superstructure, while the continuous black lines correspond to the horizontal components of the uplifted state eigenvectors of the RPS. The elastic components of the uplifted state eigenvectors are also presented in Figure 6 with continuous red lines. The calculation of the horizontal components of the eigenvectors herein is presented by Bantilas et al. [24].

The vibration mode eigenvectors of the uplifted structures present a compound shape that comprises an elastic component and a rigid body displacement due to the oscillation of the superstructure and the rocking action, respectively. Moreover, during the pure rolling/rocking vibration mode the elastic component eigenvector is negligible. Regardless the radius of the curved extensions the eigenvectors are identical during rolling and rocking phase. In any case, the magnitude of both the rigid body displacements of the uplifted state eigenvectors and the natural frequency amplification factors indicate the coupling between the response of the rocking base and the elastic vibration modes of the superstructure.

5 SEISMIC RESPONSE UNDER NATURAL GROUND MOTIONS

In this section, the seismic response of multi-storey structures seismically isolated using kinematic bearings subjected to natural ground motions is examined. Specifically, the effect of the stiffness of the rocking storey on the overall response of the PRS is investigated. For this purpose, the three sets of ground motions proposed by FEMA P695 [49] are used to perform dynamic time history analyses.

Dynamic time history analysis are performed on three typical shear structures with number of storeys $n = \{3, 6 \text{ and } 9\}$. The fundamental vibration period of the mdof oscillators is assumed to be given by the empirical relation $T_{t,1} = n/10$. Rayleigh damping with critical damping ratio $\xi = 5\%$ for the first two vibration modes is considered for the mdof oscillators. The mass (\mathbf{M}), stiffness (\mathbf{K}) and damping (\mathbf{C}) matrices are constructed based on the procedure applied by Bantilas et al. [24]. Every superstructure is considered to be fixed on the top of a rocking storey comprised of rectangular columns ($\bar{I}_0 = 4/3$) with semi-diagonal length $R = 1.50 \text{ m}$, slenderness $\tan(\alpha) = \{0.10, 0.15 \text{ and } 0.20\}$ and $\tan(\alpha') = 2 \cdot \tan(\alpha)$, and curved extensions

with nondimensional radius of curvature $\rho = \{\rho_{cr}, 0.5 \text{ and } 1.5\}$. Moreover, mass ratios $\eta/T_t = 10$ and $\gamma = 10$ are considered.

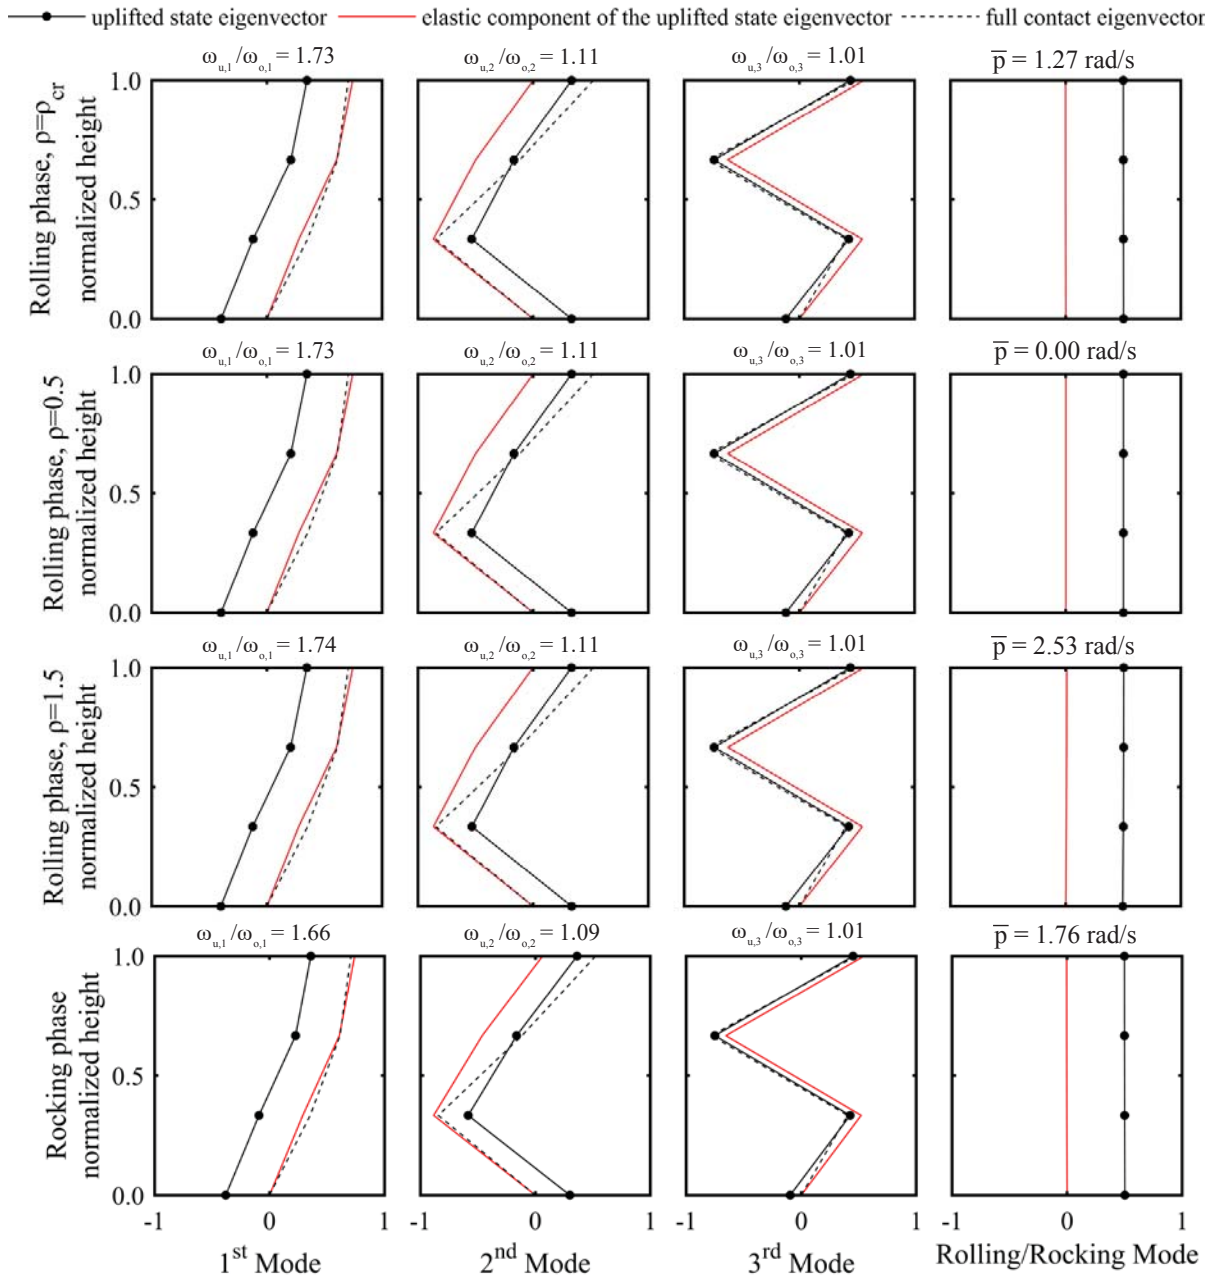

Figure 6: Vibration modes of a typical three-storey rocking podium structure ($\bar{I}_0 = 4/3$, $R = 1.5$ m, $\gamma = 10$, $\eta = 3$, $\tan(\alpha) = 0.15$ and $\tan(\alpha') = 0.30$).

The effect of curvature of the free standing column's curved wedges on the seismic response of the rocking base is presented in Figure 7. Specifically, the maximum rocking response of rocking base with curved extensions $(|\theta_{\max}|/\alpha)_{\text{ext}}$, compared with the response of rocking base without curved extensions $(|\theta_{\max}|/\alpha)_{\text{flat}}$ is displayed. For small rocking rotations $(|\theta_{\max}|/\alpha)_{\text{flat}} < 0.5$ the maximum response is almost identical. In general, the structures with curved extensions present increased stability. Due to the high nonlinearity there are only few cases where the structure without curved extensions develop finite rocking rotations $(|\theta_{\max}|/\alpha)_{\text{flat}} < 1$, while the structure with curved extensions overturns. However, enhanced dis-

placement capacity is achieved using columns with curved extensions. In Table 3 the rocking overturn probabilities of the examined structural systems are listed. It is obvious that rocking columns with curved extensions lead to significantly decreased probabilities of overturn. Moreover, the increase of the stiffness of the rocking base (larger radius of curvature), as well as the increase of the flexibility of the superstructure results in greater stability.

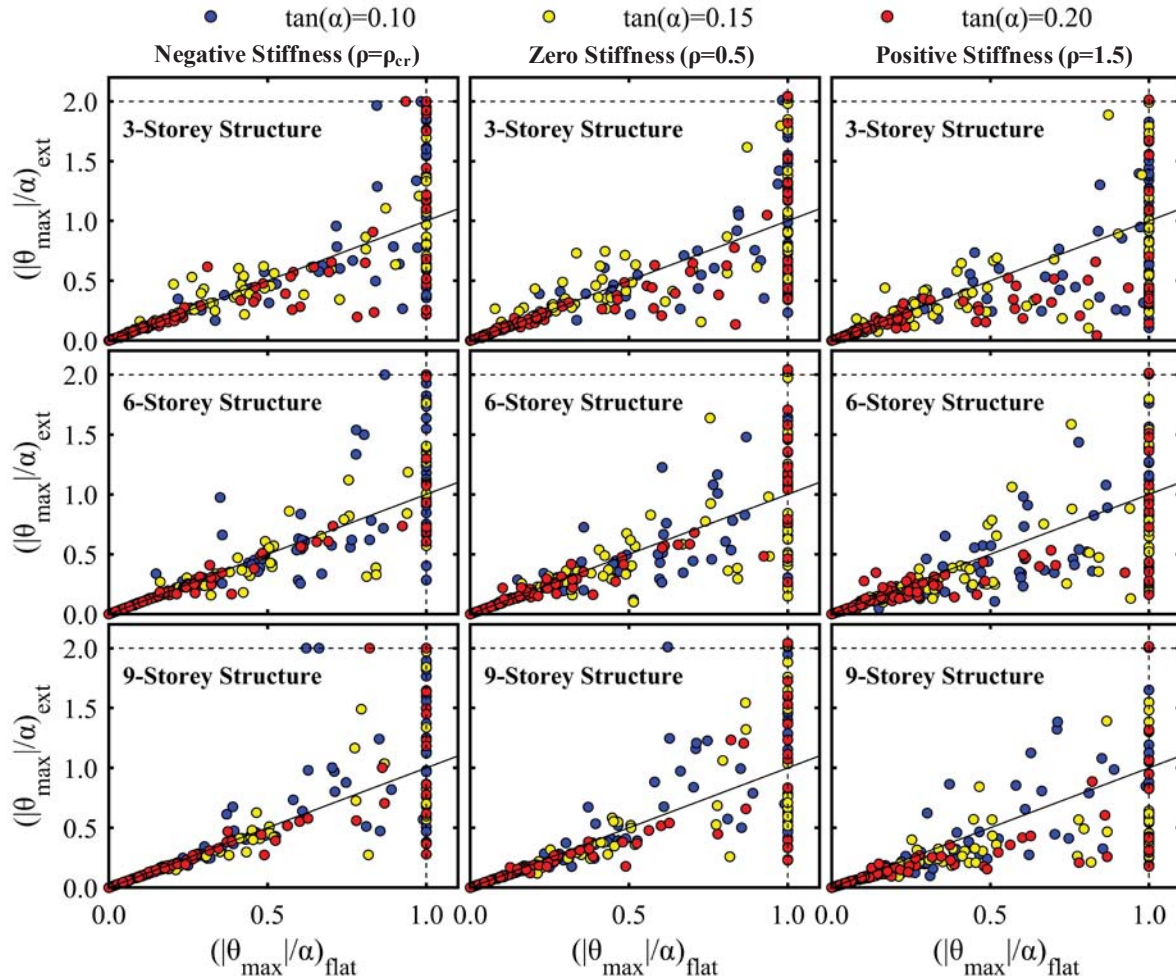

Figure 7: Comparison of the maximum rocking rotations between the isolated systems with $(|\theta_{\max}|/\alpha)_{\text{ext}}$ and without $(|\theta_{\max}|/\alpha)_{\text{flat}}$ curves extensions, under the 100 natural ground motions of FEMA P695.

$\tan(\alpha)$	η	Negative Stiffness ($\rho=\rho_{\text{cr}}$)	Zero Stiffness ($\rho=0.5$)	Positive Stiffness ($\rho=1.5$)	Without Wedges
0.10	3	0.37	0.34	0.29	0.67
	6	0.32	0.33	0.30	0.52
	9	0.31	0.30	0.23	0.49
0.15	3	0.20	0.13	0.09	0.39
	6	0.17	0.13	0.09	0.29
	9	0.16	0.12	0.07	0.25
0.20	3	0.06	0.02	0.02	0.17
	6	0.08	0.02	0.01	0.15
	9	0.03	0.01	0.01	0.13

Table 3: Rocking overturn probabilities of the examined structural systems under the 100 natural ground motions of FEMA P695.

Since rocking initiation, the seismic demands of RPSs present a lower bound of V_{st} [23]. Thus, Figure 8 presents the normalized seismic demands of the podium systems $(V_b/V_{st})_{Pod}$ as a function of the maximum tilt angle of the rocking base $(|\theta_{max}|/\theta_{cr})$. In cases where fairly small rocking rotations are developed $(|\theta_{max}|/\theta_{cr} \approx 0)$, the normalized seismic demands of the superstructure take values $V_b/V_{st} \approx 1$. As the rocking rotation of the base increases, the demands of the superstructure also increase until saturation occurs $(\theta/\theta_{cr})_{sat}$. In order to illustrate the effect of the dynamic characteristics of the superstructure on the elastic response, without a mean to quantify the problem, the seismic demand-tilt angle relationship is summarized in Figure 8 through a bilinear curve. The values of the normalized seismic demands $(V_b/V_{st})_{sat}$ and the critical tilt angle $(\theta/\theta_{cr})_{sat}$ beyond which the slope (k_s) changes, are also presented. It is observed that in cases of kinematic bearings with negative and zero stiffness the seismic demands are stable ($k_s = 0$) for rocking rotations $(|\theta_{max}|/\theta_{cr}) > (\theta/\theta_{cr})_{sat}$. On the other hand, in case of kinematic bearings with positive stiffness the seismic demands increases ($k_s > 0$) beyond $(\theta/\theta_{cr})_{sat}$. Additionally, in case of rocking storey with positive stiffness, increasing the flexibility of the superstructure leads to higher values of the slope coefficient k_s . In all cases, as the stiffness of the superstructure increases, the critical tilt angle $(\theta/\theta_{cr})_{sat}$ increases too, regardless the stiffness of the rocking base.

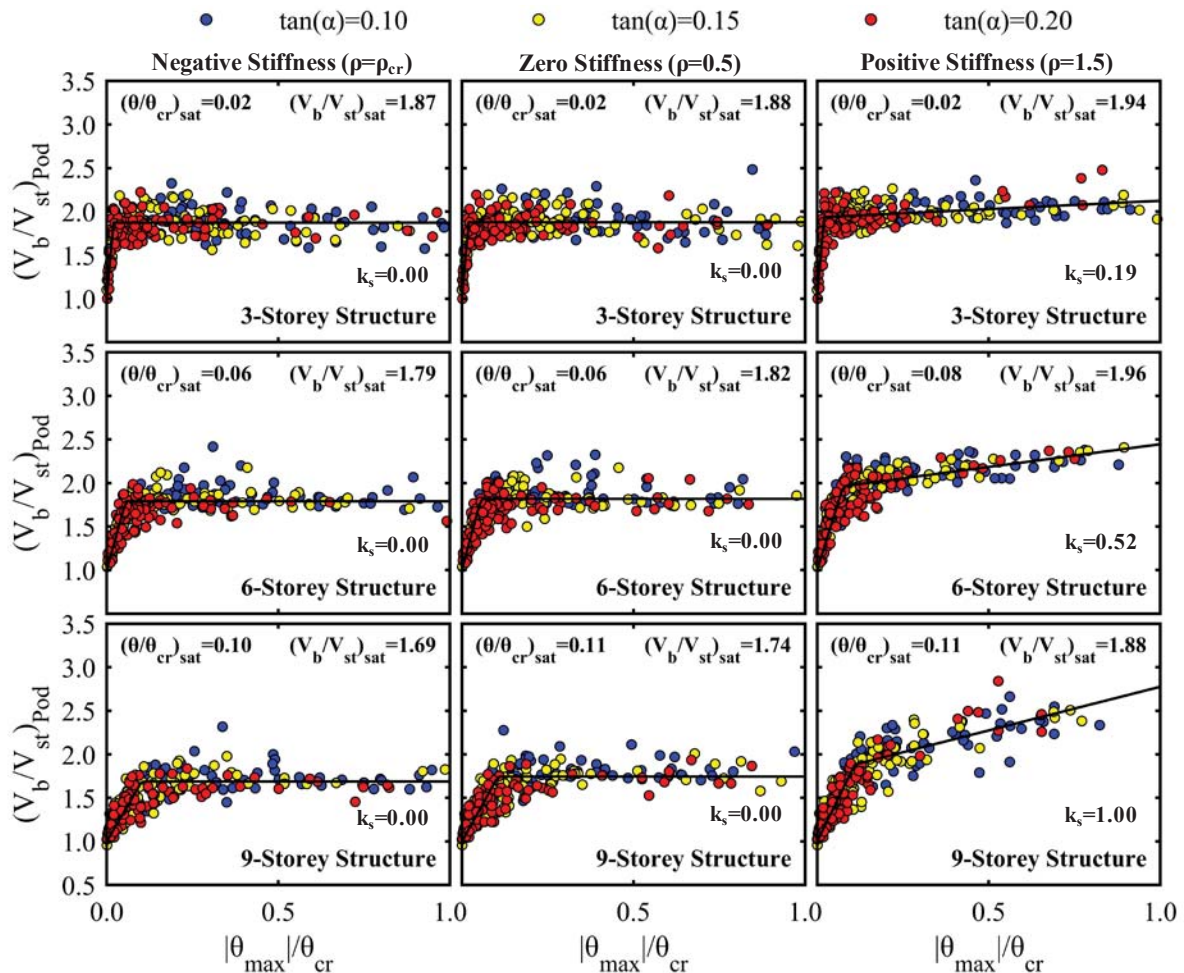

Figure 8: Normalized seismic demands $(V_b/V_{st})_{Pod}$ of the nine multi-storey podium structures as a function of the maximum tilt angle of the rocking floor (θ_{max}/α) .

The effect of the rocking base stiffness on the distribution of the elastic seismic demands throughout the superstructure is also examined. Figure 9 presents the storey shear (V_i) of

structures isolated with kinematic bearings of slenderness $\tan(\alpha) = 0.15$ and $\tan(\alpha') = 0.30$. The black and red lines correspond to the average and maximum values of the storey seismic demands, respectively. In the same figure, the seismic demands of the fixed-base superstructures are presented with dashed lines. The results obtained by ground motions that cause overturning of the rocking base are omitted. In the case of isolated systems, the differences between the mean and maximum values of the storey shear are much smaller than those of the fixed-base systems. Regarding the distribution of seismic demands throughout the superstructure, the maximum shear of the RPSs is developed on the intermediate floors, in contrast to the fixed-base structures in which the maximum seismic demand appears at the base. The completely different distribution pattern of the seismic demands presented by podium structures, regardless the rocking base stiffness, indicates the excitation of higher modes of the superstructure during impact [24]. Moreover, the differences between the mean and the maximum values of the storey shears are lower in cases of zero and negative stiffness than in case of positive stiffness of the base. That fact emerges due to the dependence of the elastic demands on the maximum rocking rotations, in case of rocking base with positive stiffness. Although positive stiffness of the rocking base results in slightly higher values of seismic demands in the superstructure, it should be preferable due to the fact that it significantly decreases the overturning probability.

Figure 9: Average and maximum storey shear profiles (V_i).

CONCLUSIONS

In the present study, the dynamic response of seismic isolated multi-storey structures using kinematic bearings was studied. For this purpose, an analytical model that describes the dynamic response of multi-storey podium structures under rolling and rocking phase of the base was proposed. In addition, the effect of the radius of the curved extensions on the response of the rocking base and the seismic demands of the superstructure was investigated. The conclusions of the present work can be summarized as follows:

1. The uplift of the rocking base results in an increase in both the natural frequency and the damping ratio of the first vibration mode of the superstructure. During rolling phase the dynamic properties amplification depends on the curvature of the columns' curved extensions.
2. The curved extensions of the kinematic bearings results in enhanced stability. Moreover, as the stiffness of the rocking base increases the seismic stability increases too.
3. The magnitude of seismic demands depends mainly on the slenderness of the rocking columns. In case of a rocking base with negative or zero stiffness the seismic demands are independent of the features of the curved extensions. On the other hand, considering rocking base with positive stiffness, the elastic seismic demands depends on the radius of the curved extensions and on the developed displacements of the base.
4. Since rocking initiation, the distribution of the seismic demands throughout the superstructure differs substantially from that of a fixed-base structure, regardless the stiffness of the kinematic bearings.

Abstract

In the present study the effect of impact modeling on the seismic response of multi-storey structures placed on the top of a rocking storey is examined. For this purpose, two impact models are introduced, where the energy dissipation is treated using the angular momentum-impulse theorem combined with different assumptions regarding the post-impact state of the superstructure. The effect of the examined impact models on the dynamic response of nine typical multi-storey podium structures is assessed using synthetic pulse-like ground motion records. The superstructures are divided in three classes based on the lateral displacement profile of their fundamental vibration mode. Thus, the effect of the impact model on the maximum rocking rotations and elastic seismic demands as a function of the superstructure's dynamic properties is investigated. The study concludes that the impact model presents a minor effect on the rocking response of the podium structure. On the contrary, it might substantially affect both the magnitude and the distribution of the seismic demands, especially in cases of stiff superstructures with flexural displacement profile.

Keywords: Rocking structures; Podium structures; Impact model; Synthetic ground motions

1 INTRODUCTION

The dynamic response of rigid blocks rocking on a rigid ground was first studied by Housner [1], who highlighted the parameters that affect the stability of rigid bodies which can be uplifted under horizontal excitations. Since then, with the recognition of the remarkable properties of the rocking response, various forms of rocking systems have been studied, such as flexible rocking oscillators on solid [2-6] and flexible ground [7, 8], rocking structures on the foundations [9], rocking bridge piers [10-12], rocking frames [13-17], coupled conventional structures with rocking walls [18-20]. Regarding the seismic isolation by forming a rocking floor at the base [21-24], the first analytical study was carried out by Bachmann et al. [21]. Subsequently, Bantilas et al. [22] investigated the structural and the ground motion parameters that affect the elastic demands of rocking podium structures (RPSs), while Bantilas et al. [23] examined the effect of the higher vibration modes of multi-storey superstructures on the dynamic response of RPSs.

Due to the strongly non-linear behavior of the rocking motion, small changes in both the rocking system and the ground motion parameters can lead to large variations in the response, so that the study of the phenomenon under a probabilistic framework yields more reliable conclusions [24]. To this end, except of the investigation of the influence of ground excitation characteristics on the dynamic response of rocking systems [25-30], the effect of modeling assumptions on the rocking response is of great interest.

In the rocking response of rigid blocks, energy dissipation occurs during impact when the tilt angle of the rocking columns reverses the sign. Although different models for energy dissipation have been proposed [31-33], Housner's coefficient of restitution [1] has been widely used. Regarding the energy dissipation during impact, various conservation rules have been proposed in order to evaluate the post impact state of a rocking system. In the case of deformable rocking cantilevers, such approaches involve the conservation of the horizontal momentum [34], conservation of the moment of momentum [35] and conservation of kinetic energy at the horizontal direction [6] combined with the assumption that the vertical velocity of the model is completely dissipated. The above conservation rules led to an increase in the elastic demands especially when applied to stiff systems [6, 36]. Due to this fact the conservation of horizontal momentum combined with the assumption that the relative velocity between the deformable oscillator and the base is constant during impact were introduced by Oliveto et al. [36]. Since then, the assumption of constant relative velocity has been adopted by other researchers to study the response of both deformable rocking cantilevers [2-3]. Later studies of Giouvanidis and Dimitrakopoulos [37] prove that the relative velocity of a deformable rocking cantilever before and after the impact does not remain constant.

Regarding the podium structures, assuming instantaneous impact and all the impact forces concentrated at the pivot points, the system can be considered isolated and conservation of angular momentum can be applied. Bachmann et al. [21] and Bantilas et al. [23] examined the response of sdof and mdof RPSs respectively, assuming that the relative horizontal velocity of the superstructure with respect to the cap beam of the rocking frame before and after the impact remains constant. Moreover, Bantilas et al. [22] assumed constant absolute horizontal velocity of the superstructure during impact, in order to investigate the effect of the impact modeling assumption on the response of sdof RPSs. In the present study the effect of the two aforementioned impact assumptions on the response of multi-storey RPSs is investigated. Thus, nine multi-storey RPSs are examined under a set of synthetic pulse-like ground motion records, in order to assess the effect of the energy dissipation model on the response of the rocking base, as well as the elastic seismic demands.

2 DYNAMIC RESPONSE OF ROCKING PODIUM STRUCTURES

In the present section, the analytical model of the dynamic response of frame structures, seismically isolated using a rocking story, is presented. The model is based on the assumption that the superstructure is described by a mdof elastic oscillator, fixed on the top of a rigid rocking frame. The rigid frame consists of a cap beam with mass m_b and N freestanding columns with mass m_c , semi-diagonal length $R = \sqrt{H^2 + B^2}$, rotational moment of inertia around its center of mass I_{cm} , and slenderness $\alpha = \tan(B/H)$. During the dynamic response, the rocking columns are considered to be in contact with the cap beam and the ground, while the friction coefficient at the contact surfaces is large enough to prevent any sliding. The schematic representation of the model is illustrated in Figure 1.

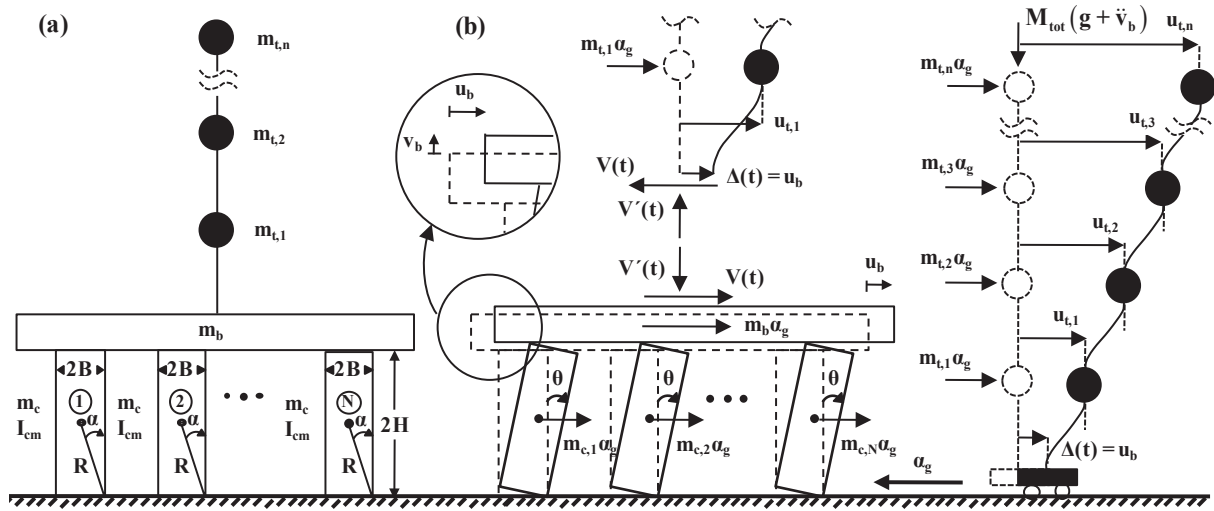

Figure 1: Schematic representation of the analytical model of multi-storey rocking isolated structures (a) and interaction of the rocking base with the superstructure (b).

The analytical presentation of the assumptions related to the model used herein is provided by Bantilas et al. [23]. The equations of motion of the sub-system of the rocking base, as well as the superstructure are given by Equation (1) and (2), respectively.

$$\begin{aligned} & \left[\bar{I}_0 + 4\gamma + 4\eta\gamma \sin^2(\alpha \mp \theta) \right] R\ddot{\theta} = \pm 2\eta\gamma R \sin[2(\alpha \mp \theta)] \dot{\theta}^2 \mp \\ & \mp (1 + 2\eta\gamma + 2\gamma)g \sin(\alpha \mp \theta) - (1 + 2\gamma)\alpha_g \cos(\alpha \mp \theta) + \frac{V}{M_{tot}} 2\eta\gamma \cos(\alpha \mp \theta) \end{aligned} \quad (1)$$

$$\mathbf{M}\ddot{\mathbf{u}}_t + \mathbf{C}\dot{\mathbf{u}}_t + \mathbf{K}\mathbf{u}_t = -\mathbf{M}\delta\alpha_g + \mathbf{K}\delta \underbrace{\left[\pm 2R(\sin(\alpha) - \sin(\alpha \mp \theta)) \right]}_{u_b} + \mathbf{C}\delta \underbrace{2R\cos(\alpha \mp \theta)\dot{\theta}}_{\dot{u}_b} \quad (2)$$

where γ is the mass ratio of the cap beam (m_b) divided by the total mass of rocking columns (Nm_c); η is the mass ratio of the superstructure (M_{tot}) divided by the mass of cap beam (m_b); $\bar{I}_0 = I_0/(m_c R^2)$ and I_0 is the rotational inertia of the column with respect to the pivot point; θ , $\dot{\theta}$ and $\ddot{\theta}$ are the title angle, the rotational velocity and the rotational acceleration of the rocking columns; u_t , \dot{u}_t and \ddot{u}_t are the floor displacements, velocities and accelerations with respect to the undeformed configuration of the system; \mathbf{M} , \mathbf{K} and \mathbf{C} are the mass the stiffness and the damping matrix of the superstructure; δ is the influence vector of the ground motion ($\delta=\mathbf{1}$); α_g is the ground acceleration; u_b and v_b the horizontal and vertical displacements of the center of mass of the cap beam; and the base shear of the superstructure (V) is given by:

$$V = \delta^T \mathbf{K}(\mathbf{u}_t \mp \delta \mathbf{u}_b) + \delta^T \mathbf{C}(\dot{\mathbf{u}}_t - \delta \dot{\mathbf{u}}_b) \quad (3)$$

The terms $\mathbf{K}\delta \mathbf{u}_b$ and $\mathbf{C}\delta \dot{\mathbf{u}}_b$ correspond to the dynamic loads applied to the superstructure due to the continuous displacement of the cap beam of the rocking base. The upper and lower signs in Eqs. (1)-(3) define rocking around the right ($\theta > 0$) and left ($\theta < 0$) pivot points of the rocking columns respectively.

Until uplift occurs, the rocking base is assumed to remain inactive ($\theta = \dot{\theta} = 0$). Thus the superstructure behaves as a fixed base mdof oscillator, and the equations of motion are given by Eq. (2), considering $\mathbf{u}_b = \dot{\mathbf{u}}_b = 0$. When the horizontal overturning actions overcome the restoring forces of the podium structure, uplift occurs, and the rocking story starts to roll. The uplift criteria can be summarized as follows:

$$\mp \frac{\alpha_g}{g} \geq \left(1 + \frac{2\eta\gamma}{1+2\gamma}\right) \tan \alpha \mp \frac{2\eta\gamma}{(1+2\gamma)M_{tot}g} V \quad (4)$$

where V is the superstructure's base shear given by Eq. (3) considering $\mathbf{u}_b = \dot{\mathbf{u}}_b = 0$. The upper and lower signs define rolling initiation around the right ($\theta > 0$) and left ($\theta < 0$) pivot points.

3 IMPACT MODELING

In the present study, in order to evaluate the influence of the adopted energy dissipation model on the elastic response of multi-storey RPSs, two different assumptions regarding the velocity of the superstructure during impact are examined.

Due to the constant relative horizontal velocity (CRV) of the superstructure with respect to the cap beam of the rocking frame before and after the impact assumption, the coefficient of restitution (COR_{CRV}) and post-impact horizontal velocities of the floors of the superstructure are given by Eqs. (5.a) and (5.b), respectively.

$$COR_{CRV} = \frac{\dot{\theta}^+}{\dot{\theta}^-} = 1 - 2\sin^2 \alpha \frac{1 + 4\gamma(1 + \eta)}{I_0 + 4\gamma(1 + \eta)} \quad (5.a)$$

$$\dot{\mathbf{u}}_t^+ = \dot{\mathbf{u}}_t^- - 2R \cos(\alpha) \dot{\theta}^- (1 - COR_{CRV}) \quad (5.b)$$

Additionally, the solution of the impact problem adopting the constant absolute velocity (CAV) assumption results in the coefficient of restitution of the rocking base (COR_{CAV}) as well as in the post impact velocities of the superstructure as follows:

$$COR_{CAV} = \frac{\dot{\theta}^+}{\dot{\theta}^-} = 1 - 2\sin^2(\alpha) \frac{1 + 4\gamma + 4\gamma\eta}{I_0 + 4\gamma + 4\gamma\eta \sin^2(\alpha)} \quad (6.a)$$

$$\dot{\mathbf{u}}_t^+ = \dot{\mathbf{u}}_t^- \quad (6.b)$$

where $\dot{\mathbf{u}}_t^-$ and $\dot{\mathbf{u}}_t^+$ are the superstructure's absolute velocity vectors before (-) and after (+) impact, respectively.

In contrast to the CRV assumption (Eq. 5.b), the CAV assumption (Eq. 6.b) implies that no horizontal impulsive loads are developed on the superstructure which might be crucial for the elastic deformation of the superstructure [36]. In the limit case of an extremely flexible superstructure ($T_t \rightarrow \infty$) the CAV assumption seems well-founded. On the contrary, in the case of a quasi-rigid superstructure ($T_t \rightarrow 0$) the relative velocity between the superstructure and the cap beam cannot change and as a consequence the CRV assumption is more appropriate.

4 SYNTETIC GROUND MOTION RECORDS

Near-fault ground motions often contain distinct velocity and acceleration pulses, caused primarily by the rapture forward directivity effect [38]. The impulsive characteristics of such ground motions are quite destructive for most civil engineering structures [39] as well as rocking systems [1]. Due to the limited number of recorded pulse-like ground motions, the Mavroeidis and Papageorgiou [40] procedure was adopted to generate synthetic ground motions for a wide range of moment magnitude–distance scenarios (M_w – R_e). According to the model, a pulse-like ground motion can be synthesized by properly superimposing low and high-frequency signals that simulate the coherent directivity pulse and the incoherent seismic radiation, respectively.

The low-frequency component of the synthetic ground motion is modeled using the Mavroeidis and Papageorgiou [40] wavelet. In terms of velocity, the closed-form expression of the analytical pulse is given by:

$$v(t) = \begin{cases} \frac{A_p}{2} \left[1 + \cos \left(\frac{2\pi}{\gamma_p T_p} (t - t_0) \right) \right] \cos \left(\frac{2\pi}{T_p} (t - t_0) + v_p \right), & t_0 - \gamma_p \frac{T_p}{2} \leq t \leq t_0 + \gamma_p \frac{T_p}{2} \\ 0, & \text{otherwise} \end{cases} \quad (7)$$

where A_p controls the amplitude of the signal envelope; T_p is the prevailing period of the signal; v_p is the phase; γ_p is a parameter that defines the oscillatory character of the signal ($\gamma > 1$), and t_0 defines the epoch of the peak of the envelope. For every magnitude–distance (M_w – R_e) scenario, a certain low-frequency signal is assumed using the mean values of the Mavroeidis and Papageorgiou pulse parameters (A_p , T_p , v_p , γ_p). The mean values of the parameters v_p and γ_p are 1.93 and 1.83, respectively [41]. Moreover, the mean values of the velocity amplitude (V_p) and the prevailing period (T_p) of the pulse are given by Eqs. (8) and (9) [27]. The envelope parameter A_p of Eq. (7) is calculated using the velocity amplitude and the phase of the signal.

$$\log(V_p) = -5.17 + 1.98 \min(M_w, 7) - 0.14 \min(M_w, 7)^2 - 0.10 \log(R_e^2 + 0.562), \quad V_p \text{ in cm/s} \quad (8)$$

$$\log(T_p) = -2.87 + 0.47 M_w, \quad T_p \text{ in s} \quad (9)$$

The high-frequency component of the synthetic ground motion is modeled using the stochastic method. In this approach, the Fourier amplitude spectrum of a windowed white noise is fitted on a "target" amplitude spectrum $Y(M_w, R_e, f)$. The "target" spectrum is expressed as a product of quantities which represent the earthquake source radiation $E(M_w, f)$, the propagation path effects $P(R, f)$, the site response $G(f)$, and the type of motion $I(f)$. The fitted amplitude spectrum is transformed back to the time domain, yielding the synthetic high-frequency signal. A detailed review of the method can be found in Boore [42]. In the present study, the model parameters of Atkinson and Silva [43] is adopted to generate high-frequency synthetic time histories for different M_w – R_e scenarios.

According to Mavroeidis and Papageorgiou [40], the simulation of a pulse-like synthetic ground motion requires the evaluation of the low and high-frequency components for a given M_w – R_e scenario. Subsequently, the Fourier amplitude spectrum of the high-frequency component is subtracted from that of the coherent pulse. Then, the resulting "residual" amplitude spectrum is transformed back to the time domain by considering that its phase coincides with the phase of the Fourier transform of the high-frequency component. Finally, the "residual" high-frequency signal and the low-frequency component are superimposed, yielding the synthetic pulse-like time history.

In the present study, magnitudes M_w in the range 5.5–7.5 with a step of 0.5 and distances from the fault R_e in the range 5–20km with a step of 2.5 km were considered [27, 28]. For every M_w - R_e scenario, 100 simulations of pulse-like synthetic ground motions were generated using the aforementioned procedure. For the scope of this study a specific low-frequency signal is assumed for every M_w - R_e scenario, using the mean values of the pulse parameters, in order to restrict the ground motion variability and as such to minimize the dependency of the time history analysis results on the characteristics of the signal.

5 EVALUATION OF IMPACT ASSUMPTIONS

The effect of the assumptions regarding the velocity of the superstructure during impact on the response of multi-storey RPSs is examined in the present study. The considered multi-storey podium structures are divided into three classes, based on the lateral displacement profile of the fundamental vibration mode of the superstructure. For this purpose superstructures with flexural, shear and triangular lateral displacement profile are considered (Figure 2). Considering that in typical multi-storey structures the distribution of floor masses is constant and that the fundamental vibration period of the superstructure is $T_{t,1} = n/10$, where n is the number of the floors, the definition of the mass (\mathbf{M}) and stiffness (\mathbf{K}) matrices are defined, given the lateral displacement profile [23, 44]. The damping matrix (\mathbf{C}) of each structure is assumed to be proportional to the mass and stiffness matrices (Rayleigh damping) considering critical damping ratio $\xi = 5\%$ for the first two vibration modes. In total nine different superstructures are examined. Specifically, for every displacement profile superstructures with $n=\{3, 6, 9\}$ floors are considered. All the structures are assumed to be fixed on the top of a typical rocking frame which consists of rectangular columns ($\bar{I}_0=4/3$) of size $R = 1.5$ m, slenderness $\tan(\alpha) = 0.15$, $\gamma = 10$ and cap beam mass m_b equal to the mass of the standard floor m ($\eta = n$).

Figure 2: Lateral displacement profiles of the examined multi-storey structures [44].

The values of the coefficient of restitution as obtained by CAV and CRV assumptions are presented in Figure 3. The only feature of the superstructure that affects the coefficient of restitution is the mass ratio η . The values of the coefficient of restitution obtained by the CAV assumption are much smaller than the corresponding values under the assumption of CRV. Additionally, the superstructure's mass ratio (η) seems to significantly affect the coefficient of restitution under the assumption of CAV. On the other hand the coefficient of restitution under CRV assumption is saturated if the term " $\gamma(1+\eta)$ " of Eq.(5.a) takes values greater than 10. Thus, for typical RPSs with $\gamma=10$, the coefficient of restitution using CRV assumption is identical for $\eta \geq 1$.

Figure 3: Values of the coefficient of restitution, calculated by the two examined assumptions, as a function of the slenderness (α) of the rocking columns for different values of the superstructure's mass ratio (η).

Figure 4 illustrates the responses of three RPSs under free oscillation of the rocking base with initial conditions $\theta_0/\alpha = 0.9$ and superstructure's relative deformation $\mathbf{u}_{t,0} - \delta \mathbf{u}_{b,0} = 0$. The mDOF elastic oscillators correspond to superstructures with $n = \{3, 6 \text{ and } 9\}$ floors and shear displacement profile. The results are presented comparatively between the CAV and CRV impact assumption. The dynamic response of the rocking base is similar in both models. Despite the different values of the coefficient of restitution between the CAV and CAR assumptions, the energy loss during impact is comparable in both models. In the former case energy is dissipated exclusively by the rocking base while in the latter case energy is dissipated by the rocking base and the superstructure. Regarding the response of the superstructure the CAV assumption results in slightly larger elastic deformations.

Figure 4: Response time histories under free rocking oscillations of the rocking base.

The maximum rocking response (θ_{\max}/α) for each of the examined structures considering CRV and CAV assumption, under the set of the synthetic pulse-like ground motions, are presented in Figure 5. It can be observed that the majority of the data follows a trend. However, there are many cases where RPSs considering CRV assumption overturns, while assuming

CAV assumption survives and vice versa. That fact is more intense in case of the 3-storey superstructure. As the flexibility of the superstructure increases, the dispersion between the responses seems to be significantly decreased. However, the displacement profile of the superstructure seems not to affect the developed rocking rotations.

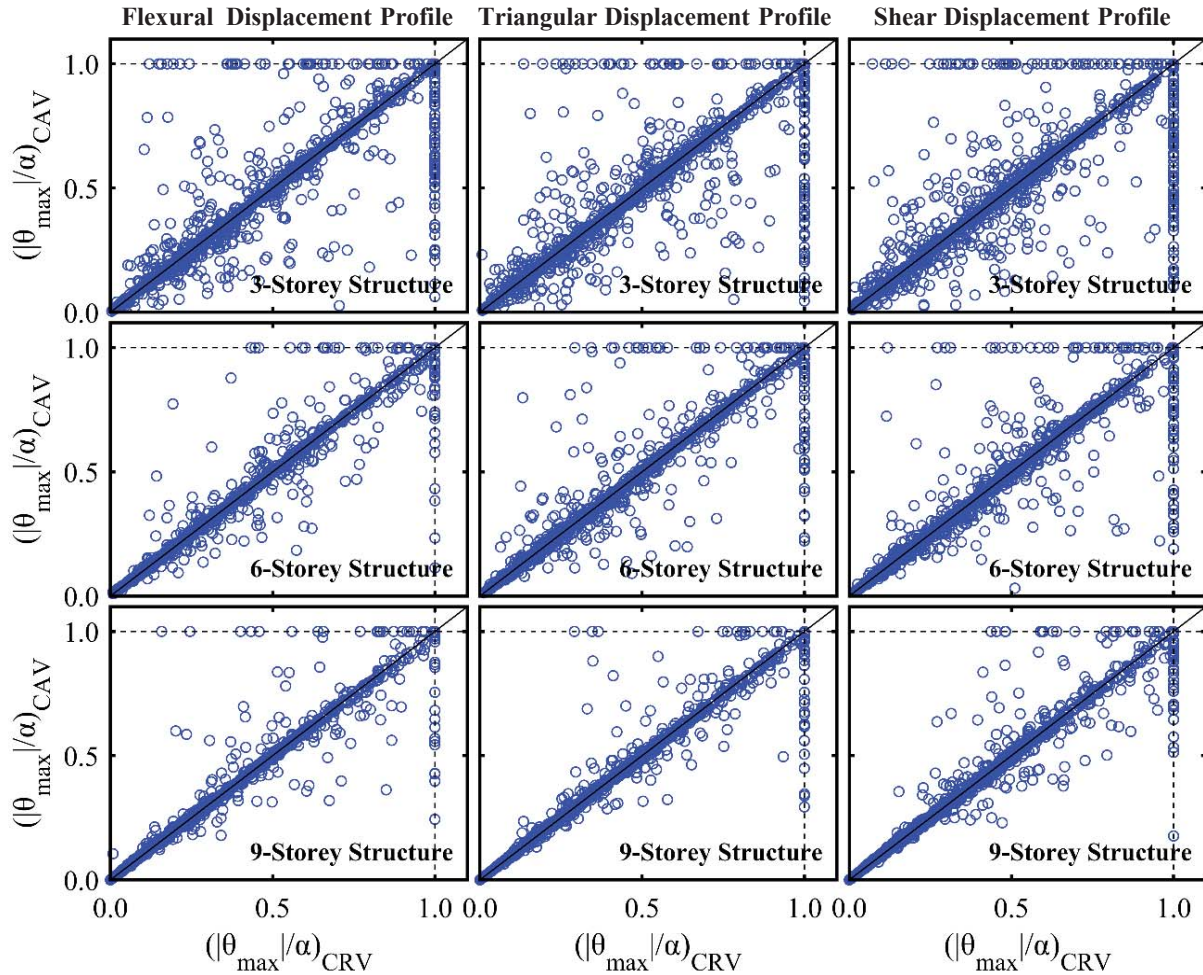

Figure 5: Comparison of the maximum rocking rotation calculated by the CRV and CAV assumption under the pulse like synthetic ground motions.

In order to examine the effect of the adopted assumption regarding the velocity of the superstructure during impact on the elastic seismic demands of mdof oscillators, the maximum shears developed on the multi-storey superstructures are presented in Figure 6. The seismic demands normalized to the horizontal base shear (V_{st}), required to activate the rocking base under static conditions [22], as calculated using both impact assumptions are presented comparatively. The results obtained by ground motions that cause overturning of the rocking base are omitted. As emerged by the results of the tilt angles, the responses of the stiffer superstructure present higher dispersion. Moreover, the displacement profile of the superstructures seems to affect the estimated maximum shear. Specifically, the increase of the effective mass of the superstructure's first mode (from flexural to shear displacement profile) results in higher correlation between the maximum responses obtained by the two energy dissipation models.

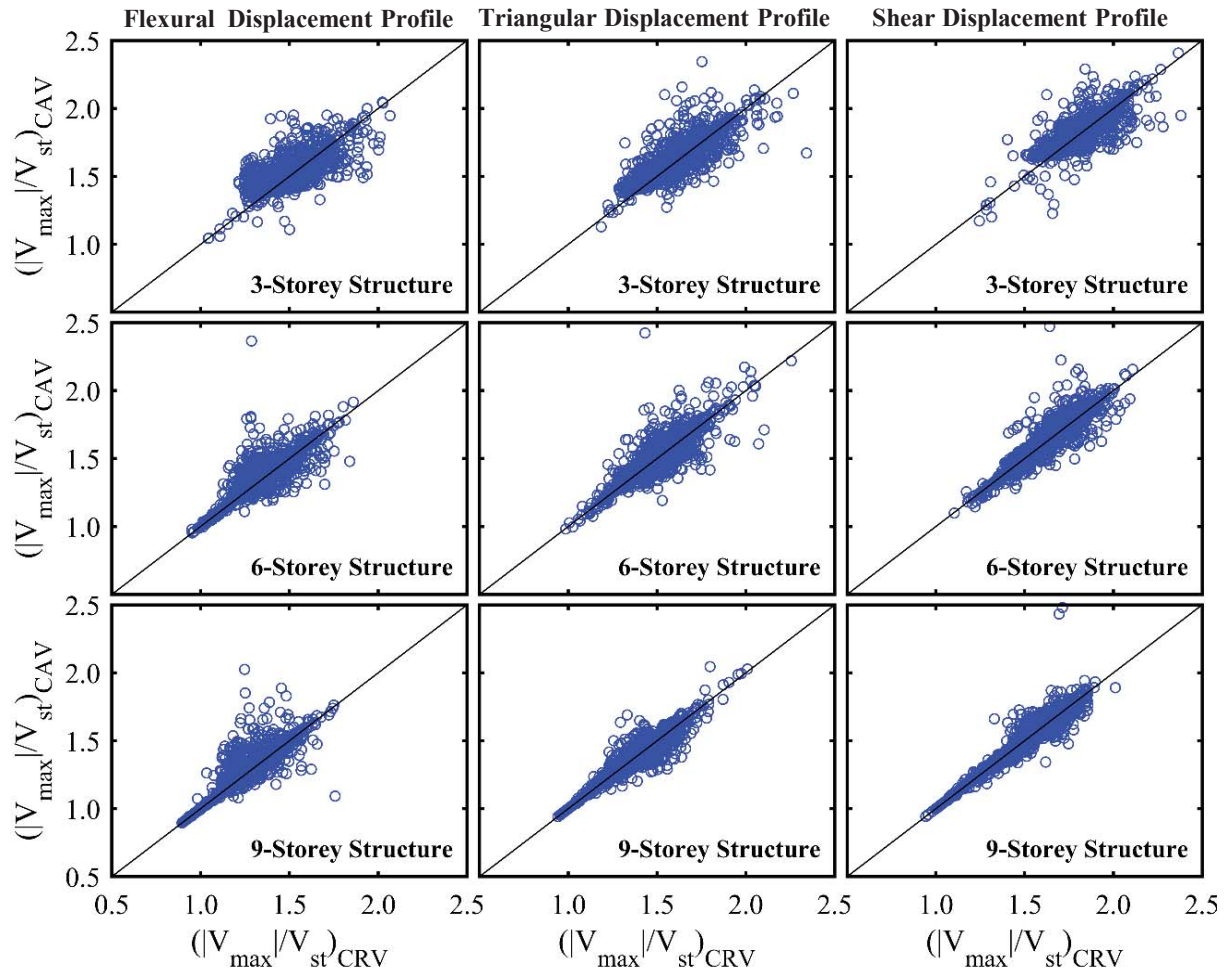

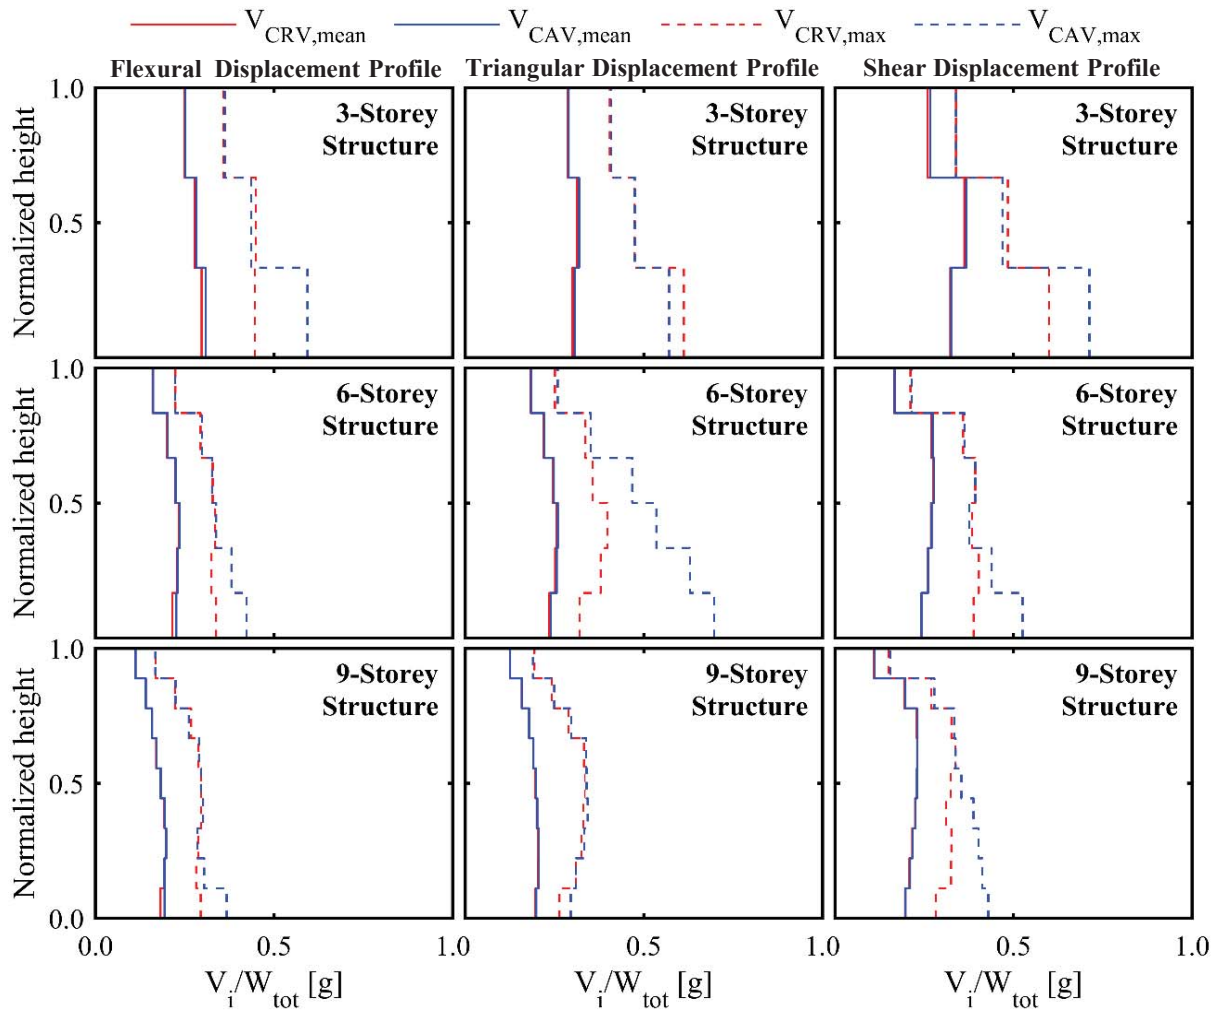

Figure 6: Comparison of the maximum normalized shear calculated by the CRV and CAV assumption under the pulse like synthetic ground motions.

In addition to the seismic demands in terms of maximum shear forces, their distribution throughout the superstructure is also of particular interest. Figure 7 presents the storey shears (V_i) of the nine podium structures. The solid and dashed lines correspond to the average and maximum values of the storey seismic demands, respectively. In the same figure, the seismic demands of the superstructures considering CRV and CAV assumptions are presented comparatively. The results obtained by ground motions that cause overturning of the rocking base are omitted. The differences of the maximum values of the storey shears between the two impact assumptions seems to be important. However, regarding the mean values slight differences are depicted. In general, the CAV assumption results in increase of the shear in the lower floors. In upper floors the shears seems to be identical. The distribution pattern of the mean seismic demands presented by podium structures, regardless the impact assumption, indicates the excitation of higher modes of the superstructure during impact [23].

Figure 7: Average and maximum storey shear profiles (V_i).

In order to statistically assess the effect of the impact assumption on the dynamic response of the RPSs, following Bachmann et al. [45], empirical cumulative distribution functions (ECDFs) are constructed. In Figures 8 and 9 the ECDFs of the maximum rocking rotations of the base, as well as the maximum elastic seismic demands are presented, respectively. In each figure the ECDFs considering both CRV and CAV impact assumption is depicted. Moreover, the 95% confidence interval is reported for the ECDF calculated by the response results assuming CRV assumption. These plots illustrate the probability that the maximum response is smaller than a specific value of the response, in terms of tilt angle of the base ($|\theta_{\max}|/\alpha$) or maximum shear of the superstructure ($|V_{\max}|/V_{st}$).

The ECDFs of the response of the rocking base considering CRV and CAV assumption are almost identical (Figure 8). Thus, statistically the two different assumptions regarding the velocity of the superstructure during impact do not affect the rocking response of RPSs. The effect of the superstructure's flexibility and lateral displacement profile on the response of the base can be observed throughout Figure 8. It has to be mentioned that the ECDFs of the 9-storey superstructure indicate the lack of rocking initiation under a large amount of ground motion excitations ($>15\%$).

Figure 8: Cumulative distribution functions of the normalized maximum tilt angle θ_{\max}/α for the synthetic pulse like ground motions.

In Figure 9 the ECDFs of the maximum superstructure's shear forces are presented. Unlike the response of the rocking base, the ECDFs of the seismic elastic demands considering the two impact assumptions present considerable differences. The variance of the responses is more intense in the 3-storey superstructure. As the flexibility of the superstructure increases the differences are diminished. The differences between the two impact models also tend to decrease as the effective mass of the superstructure's first vibration mode increases. The ECDF by the CAV assumption is inside the confidence interval of the CRV assumption ECDF only in case of the 9-storey superstructure. In general, it is evident that CAV assumption results in increased elastic seismic demands. That fact is more intense in case of stiff superstructures.

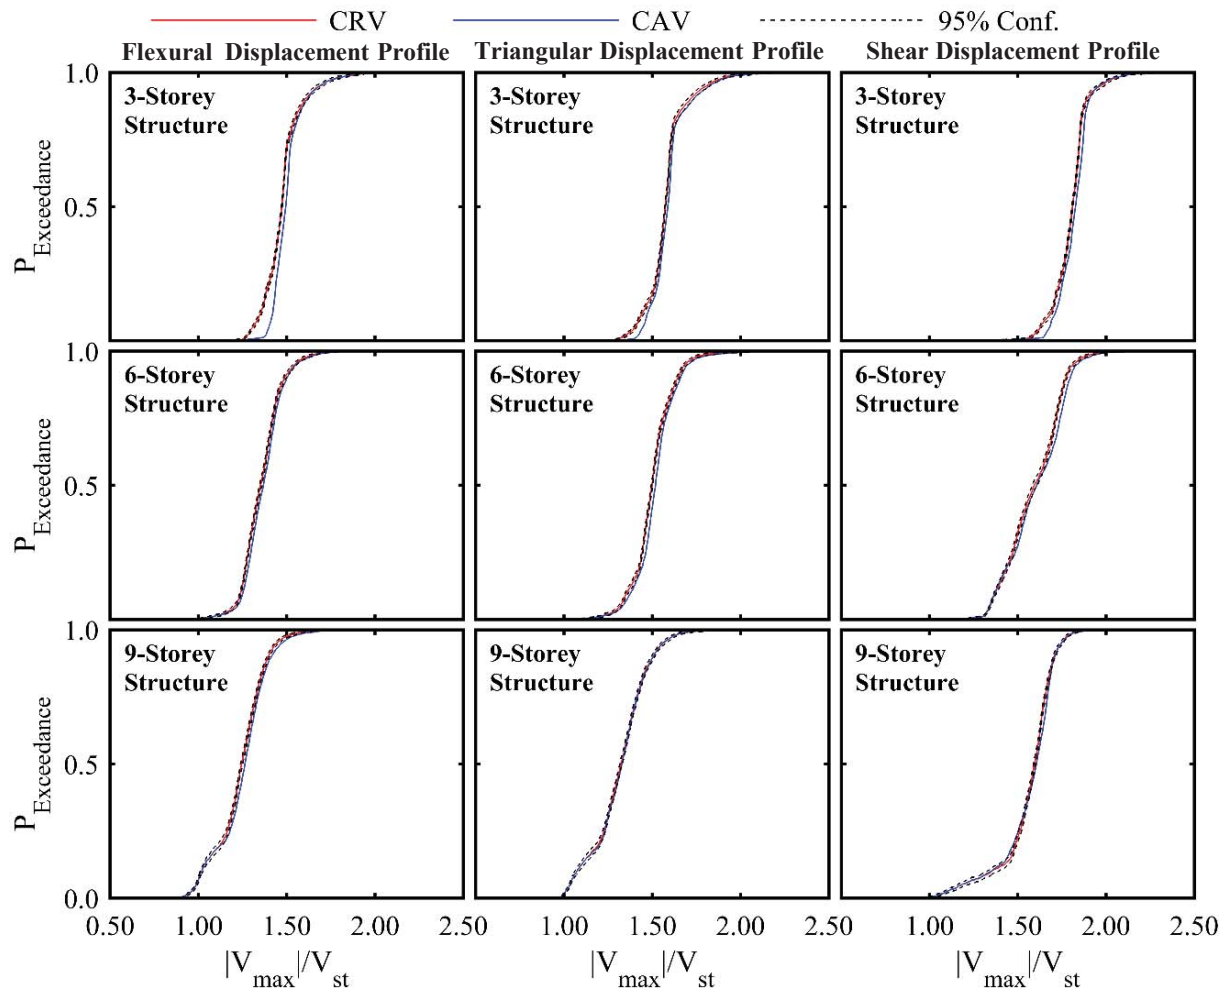

Figure 9: Cumulative distribution functions of the normalized base shear V_{\max}/V_{st} for the pulse like synthetic ground motions.

6 CONCLUSION

In the present study, the effect of the adopted energy dissipation modeling during impact on the response of multi-storey rocking podium systems are examined. Thus, two different assumptions regarding the velocity of the superstructure during impact is examined. Specifically, the assumptions of constant relative horizontal velocity and constant absolute horizontal velocity of the superstructure with respect to the cap beam of the rocking frame before and after the impact were considered.

The response time histories indicate that the assumptions regarding the impact model may result in diverging estimates of the tilt angle, especially in case of stiff superstructures. However, the response of the rocking base in terms of empirical cumulative density functions is not affected by the assumptions regarding the velocity of the superstructure during impact.

The effect of the impact assumption on the elastic seismic demands depends on the stiffness and the lateral displacements profile of the fundamental vibration mode of the superstructure. As the flexibility and the effective mass of the first mode of the superstructure increases, the effect of the two impact assumptions on the superstructure's response tend to be less notable. Examining especially stiff superstructures the CAV assumption results in higher elastic demands.

Abstract

It has been claimed that numerical rocking motion models are not only inaccurate, but that all rocking structures behave unpredictably. This paper revisits the issue of rocking motion unpredictability and explores whether not the response to a single ground motion, but the statistics of the responses to an ensemble of ground motions is predictable.

To this end, a 3D rocking podium structure was constructed and tested on a shake table. A blind prediction contest was organized, where the contestants were invited to predict the CDF of the time-maxima of the responses. There were 13 participant teams that used FEM, DEM and rigid body models.

It was found that several teams were able to predict the CDF with a decent accuracy. Both FEM and DEM can perform well, depending on the input parameters. Hence, it can be concluded that 3D rocking motion is predictable in the statistical sense.

Keywords: Rocking, Blind Prediction Contest, Shake table testing, Model Validation

1 INTRODUCTION

Rocking structures are the ones that can uplift from their base when subject to an earthquake. Such structures attracted the attention of the research community after the powerful 1960 Valdivia (Chile) earthquakes, when Housner presented his seminal work [1] on the dynamics of the archetype rocking block (Figure 1). The rocking block dynamic model is useful because it can also describe the seismic behavior of non-anchored equipment [2-12], masonry structures [13-20], and ancient Greco-Roman and Chinese temples [20-22].

Motivated by the increasing stability of larger rocking blocks with identical aspect ratios, researchers have suggested using rocking as a seismic design strategy because the uplift of the block acts as a mechanical fuse and limits the design forces of both the superstructure and the foundation. The idea is applicable to both buildings [23-25] and bridges [26-40].

However, seismic analysis of rocking structures is not straightforward because, during the uplift, such structures have negative stiffness (in terms of the relation between the lateral force F and displacement u , shown in Figure 1). This is why their seismic response cannot be described by any “equivalent linear” system such as those employed for ordinary yielding structures [41]. Even though attempts to create non-linear spectrum-based methods to present the maxima of the seismic displacement of rocking structures (not related to elastic response spectrum) have been made [43-43], these spectra were created by performing multiple time-history seismic response analyses using Housner’s model. Therefore, Housner’s model is as useful for rocking structures as the elastic SDOF oscillator is for the fixed-base ones.

2 THREE-DIMENSIONAL ROCKING – “WOBBLING” UNDER 2D/3D GROUND EXCITATION

Housner’s model describes planar rocking of a rigid body excited by horizontal excitation. However, many real uplifting structures (e.g., bridges, statues, or ancient temples) would undergo a 3-dimensional motion characterized by simultaneous uplift from the ground (rocking) and change of the contact point with the ground (nutation) without twisting or sliding out of its original position, called “wobbling” in this study. Real uplifting structures may also twist and slide out of their positions, a phenomenon not investigated in this study.

There have been attempts to study wobbling using rigid body analytical dynamics. In [44], the motion of a rigid cylinder under seismic excitation was studied. Other researchers studied the 3D response of ancient conical or cylindrical columns [20, 45-48]. Makris et al. [49] experimentally tested scaled models of uplifting bridges that exhibited wobbling. All the above studies conclude that wobbling motion is present, even under planar initial conditions and/or

Figure 1: Geometric characteristics of a rigid rocking body (a,b); Lateral force-deformation relation of an uplifted rigid rocking body (c).

Figure 2: Cylinder allowed to wobble without twist [56] (Left); Wobbling frame [68] (Right).

under planar ground excitation. Stefanou et al. [50] provided theoretical justification for the above observation.

The 3D behavior of non-cylindrical rocking bodies received attention recently. Konstantinidis and Makris [51] and Zulli et al. [52] studied the rocking motion of a 3D prism. Chatzis and Smyth [53] studied the motion of a 3D prism on a deformable base, taking sliding into account as well as the 3D dynamics of a rigid body with wheels on a moving base [54]. Mathey et al. [55] studied the influence of geometric defects on the 3D response of small-size blocks. They concluded that the blocks with imperfections are less stable than the theoretically perfect ones.

Vassiliou et al. [56] studied a 2DOF rigid cylinder constrained to wobble above its initial position without twisting or sliding, i.e. without stepping out of its original position (Figure 2, left). Subsequently, Vassiliou [57] extended this model to include a slab on top of a set of cylindrical columns (Figure 2, right). This is a model of a wobbling bridge, where the columns are physically constrained to wobble above their initial position without stepping out, under the assumption that wobbling is smooth and sliding on the ground does not occur.

3 STATISTICAL SEISMIC RESPONSE MODEL VALIDATION

A major drawback for rocking seismic response models is that they are not validated - at least not by means of the conventional approach of deterministically comparing the displacement response of the model and the prototype to a given ground excitation. This is further hindered by the fact that the seismic response of a rocking block is particularly sensitive to all of the parameters that define it and as such it has been characterized as “chaotic” (i.e. non-reproducible and non-predictable). In fact, small model parameter perturbations lead to substantially different time-history responses. For this reason, experiments involving seismically or dynamically excited rocking specimens are seldom repeatable.

This lack of validation effectively means that Housner’s model should not be used as its ability to represent the physical reality has not been proven. Consequently, rocking cannot be used as a seismic design strategy, given that the seismic response of such structures would be effectively unpredictable, by analytical or numerical methods.

Bachmann et al. [58, 59] and Del Giudice et al. [60] suggested that the conventional seismic response model validation procedure focused on deterministic reproduction of the experimentally obtained response to a particular ground motion with acceptable accuracy is too strict of a test. Instead, they proposed a weaker, but sufficient, concept of statistical validation of structural seismic response models. This novel model validation procedure comprises two steps. *First*, an experimental benchmark dataset, measuring the recorded dynamic response of the same specimen (or essentially identical specimens) subjected to ensembles of consistently generated and scaled ground motions that represent a given seismic hazard, is developed. *Second*, a model is used to produce a dataset comprising its dynamic responses to the same ground motion ensembles. Validation is conducted by comparing statistical distributions of

the pertinent response quantities of the model and the benchmark using the two datasets. Statistical seismic response model validation is a weak method in that it involves the statistics of model predictions of the response to ensembles of ground motions, rather than predicting the responses to every single ground motion deterministically. Bachmann et al. [58], [59] applied the statistical seismic response model validation procedure to validate the Housner [1] rocking response model. They performed 600 shaking table tests using a well-defined and repeatable uplifting structure as well as 600 numerical simulations for the same tests, and compared both the individual test responses and the statistical aggregates of these responses focused on predicting limit states such as overturning or maximum tilt angle. They showed that the 1963 Housner model passes the weak validation test, even though it fails the strong validation test. Therefore, the Housner model was found to be good enough for the use in the scope of seismic design.

4 WOBBLING SEISMIC RESPONSE BENCHMARK DATASET

Wobbling (three-dimensional rocking without sliding) is even harder to predict than planar rocking. Thus, developing seismic wobbling models is challenging, but is necessary in order to further develop seismic design of rocking structures as well as of non-structural elements, such as equipment, as outlined in the introduction of this paper. Validation of wobbling models is a key step in this development process. To facilitate statistical seismic response model validation of wobbling response models, a series of shake table tests was performed at the University of Bristol to create the benchmark response dataset.

4.1 Specimen Description

The wobbling specimen was designed at ETH Zurich and built in Bristol in the framework of the EU-funded research project SERA [61,62]. It comprises an aluminum slab supported on four wobbling circular structural steel columns resting on the shake table platform (Figure 3). The four columns had a height, diameter and wall thickness of 1000 mm, 244.5 mm and 8 mm, respectively, with a corresponding slenderness (i.e., diameter to height) ratio of $\tan\alpha = 0.2445$ (Figure 4). Note that the size of the wobbling specimen is not representative of the size of a prototype bridge or a prototype podium building. The ground motion excitations used in the

Figure 3: Wobbling specimen on the University of Bristol shake table.

Figure 4: Details of the wobbling specimen.

shake table experiments were scaled to preserve acceleration scaling (as discussed later in this paper) so that the model represents a structure with a height similar to an actual bridge. The intent of the specimen detailing was to mimic the assumptions in Vassiliou's [57] "wobbling bridge" model, namely that the structure is rigid and that the columns wobble without sliding or twisting about their longitudinal axis. Conical end restraints were placed at each end of each column to stop the columns from wobbling out of their original position (Figure 5). After the tests, scratches on the conical restrainers were observed, showing that the columns tried to "climb out" (Figure 5). Aluminum pegs were installed inside the columns (Figure 5) with enough clearance to enable unrestrained wobbling up to overturning, but engage early enough to enable easy recovery of the specimen to its original position after a test that resulted in overturning. Moreover, padded frames were placed under and around the specimen to protect the shake table platform (Figure 3).

4.2 Specimen Excitation Using A Shake Table

The wobbling response of the specimen was induced by a dynamic bi-directional (two orthogonal horizontal components) excitation of its support. This was achieved by placing the specimen on the top of the 6DOF 3 m×3 m shake table of the University of Bristol [63].

4.3 Ground Motions and Scaling

To constrain the uncertainty in the ground motion excitation, ensembles of bi-directional

ground motions were synthesized using a spectral version of the Rezaeian and Der Kiureghian stochastic ground motion model [64-66]). More info on the ground motions used can be found in [61].

Two recorded ground motions, the 1940 El Centro Array #9 record and the 1999 Chi-Chi CHY080 record, were used as the "seed" ground motions for the experimental campaign. Next, two bi-directional (two orthogonal horizontal components) ground motion ensembles, each comprising 100 synthetic ground motions, were generated from the two seed ground motions. These two ground motion ensembles were used to drive the shake table during the conducted tests. Vertical ground motion translational and the three rotational excitations were not considered.

A detailed discussion on the scaling parameters of the tests can be found in [61]: The frequency of the excitations was scaled by a factor of $\sqrt{9.67} = 3.11$, so that the size of the structure in the prototype scale is 9.67 times larger and its height is 9.67m and representative of a typical overpass bridge.

It should be noted that the wobbling specimen is only a distorted model of a prototype structure because the stress similitude is not preserved. Thus, the elastic modulus of the material and the natural frequencies of the prototype are not correctly scaled. In addition, the wobbling specimen columns are not perfectly rigid, as Vassiliou [57] assumes, nor are any realistic foundation condition modelled. However, it has been shown that the deformability of large structures does not qualitatively change their rocking behavior [67-74]. Ultimately, the conducted experiments serve to generate a benchmark dataset for wobbling seismic response model validation and do not aim at representing the nuances of a prototype structure without distortion.

4.4 Motion Measurement

The response of the wobbling specimen was measured using displacement and acceleration sensors.

Figure 5: Conical restraint and an aluminum peg at the bottom of the wobbling specimen column before installation (left). Metal shavings found after the shake table tests showing that the steel column scratched against the conical restrainer during the tests (right).

Figure 6: Marker positions on top of the aluminum slab used for wobbling specimen displacement measurements.

The displacements were measured using an infrared tracking system, with six infrared passive markers installed on the top of the aluminum slab, as shown in Figure 6. The accelerations were measured using three-dimensional accelerometers. These sensors were placed on the shake table platform to record the actually applied excitation.

4.5 Relevant Wobbling Response Quantity

The horizontal displacement of the slab is the relevant response quantity in the created benchmark dataset, which was measured using the markers shown in Figure 6. The following maximum absolute average displacement (MAAD) of the wobbling specimen slab is defined as the relevant measure of the wobbling specimen response:

$$u = \max_t \left(\frac{u_1(t) + u_3(t) + u_4(t) + u_6(t)}{4} \right) \quad (1)$$

where u_i is the Euclidean norm of the horizontal displacement at points M_i of Figure 6, relative to the shake table. Figure 7 plots the Cumulative Distribution Functions (CDFs) of the specimen MAAD (i.e. of u) for the El Centro and the Chi-Chi ground motion ensembles using thick black lines.

5 WOBBLING SEISMIC RESPONSE BLIND PREDICTION CONTEST

Statistical seismic response model validation was conducted for a number of wobbling response models in the scope of a blind prediction contest organized by the Pacific Earthquake Engineering Research center (PEER), the University of Bristol, and ETH Zurich, launched in October 2019 with a prediction submission deadline on November 20th, 2019. The contestants were asked to use their models to predict not the wobbling specimen seismic displacement (Equation 1) to each of the 200 ground motions in the two ground motion ensembles, but the experimental CDFs of the wobbling specimen MAAD u response, as shown in Figure 7 using thick black lines. The as-built geometry of the wobbling specimen and the recorded shake table accelerations were provided to the contestants, but no tests were performed to mechanically characterize the materials of the wobbling specimen (i.e., the steel of the columns and conical restrainers), as these were not essential in terms of affecting the response and use of common modulus of elasticity for steel and aluminum was sufficient.

In the blind prediction contest, for each set of ground motion ensembles, the competing models were ranked according to the maximum vertical distance, i.e. the Kolmogorov-Smirnov (K-S) distance [75], between their predicted and the experimentally obtained CDFs [61]. This paper revisits the ranking by using a different metric to rank the contesting models: Instead of the K-S distance, the models are ranked according to their performance in predicting the median response along each ground motion ensemble. Given that two ensembles of ground motions were used, the average normalized error is taken as a best-fit performance indicator.

Thirteen contestants participated in the blind prediction contest. The models they used can be grouped into three categories, as follows:

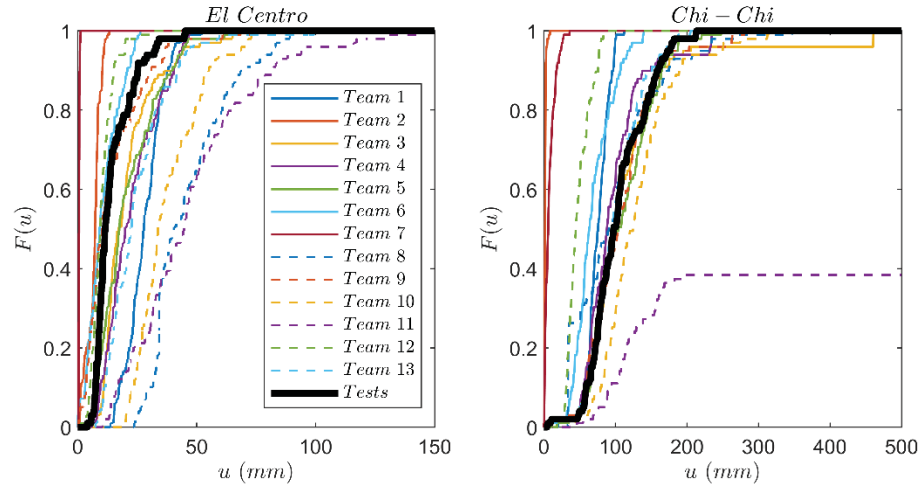

Figure 7: MAAD CDFs obtained from shake table tests (thick black lines) and CDFs of the same response quantity obtained using the 13 contesting models for the El Centro and Chi-Chi ground motion examples.

Table 1. Contestant model ranking based on the error of predicting the median MAAD CDFs

- 8 contestants developed models based on the Finite Element Method (FEM), out of which 4 used ABAQUS [76] (Teams #7, #9, #10, and #12), 2 used SAP2000 [77] (Teams #2 and #4), 1 used Midas GEN [78] (Team #1) and 1 used OpenSees [79] (Team #6);
- 4 contestants used the Discrete Element Method (DEM) to build their models, out of which 3 used 3DEC [80] (Teams #3, #5 and #8), and 1 used Code Aster [81] (Team #13);
- 1 contestant (#Team 11) used Vassiliou's [57] Rigid Body (RB) model (independently, as Vassiliou was one of the contest organizers and did not take part in the contest).

The outcomes of the statistical seismic response validation of the contesting models are shown in Figure 7 and Table 1. Figure 7 graphically compares the predicted wobbling specimen MAAD response CDFs ($F(u)$) to the experimentally obtained wobbling specimen dis-

placement response CDFs. Table 1 ranks the contestant predictions based on the u_{50} distance: Column 1 gives the ranking for the El Centro ensemble, column 2 for Chi-Chi ensemble, and column 3 gives the overall model ranking based on the average normalized u_{50} distance for the two ensembles of ground motions.

Using a different metric than the one used in the blind prediction contest does change the overall ranking. However, the two models that scored the best in term of their K-S distance, continue to score the best in the u_{50} distance: a) The model with the best score is the one submitted by Team #9 (Myron Chiyun Zhong and Constantin Christopoulos from the University of Toronto). They used FE software ABAQUS 6.13 with C3D20R quadratic brick element, with reduced integration. They assumed a coefficient of friction of 0.3 and no Rayleigh damping [82]. The second best model was the one submitted by Team #3 (Daniele Malomo, Anjali Mehrotra, and Matthew DeJong from UC Berkeley). They used Distinct (or Discrete) element software 3DEC. The frictional mechanisms were modeled using a simplified Mohr-Coulomb criterion with tension cut-off [83]. Zero Rayleigh damping was used.

Both FEM and DEM models used in this blind prediction contest performed well or poorly, depending on the modeling parameters. For example, of the two best models, Team #9 developed an FEM and Team #3 used a DEM model. Thus, there is no basis to recommend FEM or DEM to model wobbling structures seismic response. However, it should be mentioned that MAAD CDFs produced by DEM models were close to the experimental benchmark CDFs, except in the case of the model developed by Team #8 which clearly underpredicted the response for the El Centro ground motion ensemble. Similarly, the FEM models of Teams #2 and #7 grossly underestimated the response, as can be seen in Figure 7. This does not mean that FEM models cannot perform well, or that such models would underestimate the response; the FEM model of Team #9 performed the best in all metrics. This is merely an indication that, when it comes to uplifting and rocking structures, modeling decisions should be made with care. This is more important for FEM models, as such models originate from continua, as opposed to DEM models that inherently assume the structure comprises of discrete parts.

The specific Rigid Block model proposed by Vassiliou [57] and used by Team #11 consistently overestimates the response. Hence it is conservative, but not accurate. It should be noted that the Rigid Block model formulation does not include any form of energy dissipation. Apparently, disregarding the energy dissipated in the tests through scratching of the conical restrainers leads to overestimation of the response. Therefore, this model can only be used to obtain conservative estimates of the response.

6 ROLE OF ENERGY DISSIPATION IN MODELING OF WOBBLING RESPONSE

Modelling of energy dissipation in structures is an open problem, not only for rocking structures, but for fixed base structures as well. The widely used Rayleigh model, although numerically convenient (akin to viscous damping in SDOF oscillators), is not validated experimentally and can create implausible forces and moments, especially when the initial stiffness proportional component is included [84-86]. In the wobbling system discussed herein, energy is dissipated mainly through sliding (that created the metal shavings shown in Figure 5) and through radiation damping, through the interaction with the supporting wave transmitting structure [87]. Inherent material damping also exists, but since the stresses are relatively small, this form of energy dissipation is not expected to be significant when compared to the other mechanisms. Therefore, creating a mass and/or stiffness proportional damping matrix clearly has no physical meaning, especially if assigned to all degrees of freedom, including the rocking interface.

Based on the above, it is not a surprise that the best models by Teams #9 and #3 do not use Rayleigh damping and rely only on modelling friction to dissipate energy. On the contrary, Team #1 model that assumed a damping ratio of 1% at 0.05s and 1.5s clearly underestimated the response. Team #4 model used Rayleigh damping, but with damping ratio set to very low values (0.1%), which was low enough not to suppress the response.

Even though the Rayleigh damping model is not suitable for modeling the seismic response of rocking or wobbling structures, this does not imply that the model should not incorporate any energy dissipation. The tests showed that the input seismic energy is dissipated by friction and radiation, and that it should be modelled explicitly. Neglecting energy dissipation completely, like in the Team #11 Rigid Body dynamics model, grossly overestimates the response. The above observations on energy dissipation, corroborate that numerical models should respect the physics of the system, to the extent possible. This is does not hold for Rayleigh damping applied in rocking.

7 CONCLUSIONS

The seismic response of rocking structures is notoriously sensitive to all of the parameters that define it. As expected, numerical models often fail to adequately predict the seismic response of a rocking structure to a single ground motion. Based on this, researchers have claimed that not only are current models inaccurate, but that a numerical model accurate enough to predict the seismic response of rocking structures is not feasible. Hence, rocking is not used as a seismic design approach, and virtually all engineered structures are designed as fixed to the ground.

Along these lines, this paper revisits the issue of seismic response predictability in seismic design. It claims that predicting the response to a single ground motion is too strong of an acceptance test for a model. Instead, the minimum precondition for a valid model to be used in seismic design is the ability to predict the statistical characteristics of the seismic responses to an ensemble of ground motions that are compatible to the seismic hazard of interest. This is a weaker, but sufficient model validation test.

The objective of this study is to answer the question: Are seismic tests of three-dimensional rocking structures predictable using numerical models? To answer the above question in a statistical sense, an experimental campaign has been designed to obtain observations of the seismic response of a rocking podium structure that was able to sustain three-dimensional rocking motion without sliding. A stochastic model was used to generate two synthetic ground motion ensembles that match the physical characteristics of two recorded ground motions. These two ensembles were used to excite a rocking podium structure.

A blind prediction contest was organized to evaluate the ability of several models submitted by the contestants to predict the response of the rocking podium structure statistically. The models were evaluated based on their ability to predict not the time history response to each single ground motion, but the CDF of the maxima of the specimen displacement response time histories. Contestants used FEM, DEM and Rigid Body Dynamics models.

The winning model, developed by means of the FEM, scored the best of all models in terms of its K-S distance from the experimental CDF. This paper shows that it performs the best when a different metric (the median displacement u_{50}) is used to evaluate its performance. However, this is not sufficient to conclude that FEM models were uniformly better than the submitted DEM models, because some DEM submissions were also very accurate, plus some of the least accurate models were FEM. Therefore, both FEM and DEM can perform well or poorly in simulating the wobbling (three-dimensional rocking) seismic response, depending on the parameters used and the assumptions made.

Therefore, it can be concluded that the response of a 3-dimensional rocking structure is predictable in terms of a CDF of the maxima of the time-history responses to a set of ground motions.

In terms of rocking and wobbling seismic response modelling guidelines, this blind prediction contest confirmed that energy dissipation is a key factor that needs to be modelled, though not by means of Rayleigh damping. The models that best predicted the response used zero Rayleigh damping, but modeled energy dissipation directly through friction elements. A model with 0.1% Rayleigh damping that explicitly modelled friction as well also performed relatively well, but a model with 1% Rayleigh damping clearly underestimated the response. The rigid body model which modelled no energy dissipation at all, overestimated the response and should only be used only to obtain conservative wobbling response estimates.

8 ACKNOWLEDGEMENT

This research was conducted under the auspices of the project “Statistical verification and validation of 3D seismic rocking motion models (3DROCK)”, funded by the EU H2020 programme under grant agreement number 730900 [SERA]. Additional funding from ETH Zurich, University of Bristol and the Pacific Earthquake Engineering Research Center, as well as the contribution of the personnel at EQUALS laboratory, University of Bristol, and Erika Donald and Amarnath Kasalanti of PEER Center and UC Berkeley are gratefully acknowledged.

We also acknowledge the participation of the following teams in the blind prediction contest, herein listed alphabetically (not following the team numbering in this paper for reasons of anonymity):

1) Turki Alalawi, Abduaziz S. Al-Hazmi, Majd R. Zain, Jahad I. Al-harbi, Maha M. Hassan, and Mohamed S. Laissy; 2) Yu Bao and Dimitrios Konstantinidis; 3) Shanshan Chen, JingCong Lin, Yanfei Cai, Hanbin Lin, Xiaomin Liang, Jiatun Deng, Haoyun Lin, Lei Zhang, Difang Huang, Zinan Wu, and Xiancai Chen; 4) Ioannis P. Christovasilis, Lorenzo Riparbelli, Dimitris Papaevangelou, Gabriele Pini; 5) Tamás Forgács, Daniel Joó, Sándor Ádány, Vasilis Sarhosis, and José V. Lemos; 6) Jincheng Liu and Xinxin Wei; 7) Royce Liu; 8) Daniele Malomo, Anjali Mehrotra, and Matthew J. DeJong; 9) Yi Peng, Jianian Wen, Zhenlei Jia, Yazhou Xie, Jian Zhang; 10) P. Ravi Prakash, Bora Pulatsu, Nuno Mendes and Paulo B. Lourenço; 11) Chiyun Zhong and Constantin Christopoulos, as well as the 2 participating teams that wished to remain anonymous.

Abstract

Hybrid walls, i.e. rocking walls with additional energy dissipation, represent a valid lateral force resisting system in seismic regions, due to the limited seismic damage experienced by this system and to the self-centering ability provided by unbounded post-tensioned tendons. These systems accommodate the displacement seismic demand by the development of a single gap opening at the wall base.

A sensitivity analysis of the various parameters has been carried out with the purpose to evaluate their influence on the finite element dynamic response of a selected case study. Three types of models are considered in order to describe the behaviour of the wall-foundation interaction: fiber beam elements, compression-only springs and lumped rotational spring. The main parameters investigated are the damping model and damping magnitude, the elastic modulus of the concrete at the wall-foundation interface, the stiffness and number of the compression only springs, the unbonded length of the rebars used as dissipating device and their hysteresis model. The sensitivity analysis was carried out with the OpenSees finite element software and allowed to preliminary address the influence of the selected parameters by comparison with a reference case study.

Keywords: Rocking walls, Nonlinear Static Analyses, Nonlinear Time History analyses, Acceleration Spikes, Steel Dissipators.

1 INTRODUCTION

To reduce the seismic vulnerability of existing buildings it is possible to use different intervention techniques including rocking systems obtained with the insertion of unbonded post-tension cables inside precast structural elements, typically walls or columns [1][2][3][4][5]. These systems are characterized by a bilinear elastic hysterical behavior, that is characterized by a limited ability to dissipate energy in the case of seismic events [6]. For this reason, additional energy dissipation systems are placed [7], including mild steel rebars [8][9], hysteretic devices [10][11], linear and non-linear fluid-viscous damping [12][13] and friction devices [14][15][16] among others. They are defined as hybrid systems and are characterized by a flag-shaped hysterical curve [9].

In these systems the demand for horizontal displacement is guaranteed by the development of a gap at the wall-to-foundation interface [17]. The unbonded post-tension tendons are sized to ensure no residual displacements at the end of the seismic event [18], allowing the structure to be fully operational after the seismic event [19][20][21]. Numerous studies on these systems have proved their performance under both quasi static and dynamic loading [22][7][23][24][25][26][27] and parametric analyses have carried out to highlight the influence of post-tension tendons [28] and dissipative devices [29][30][31].

The present paper focuses on numerical modeling of hybrid walls by investigating the effects of different modeling techniques in dynamic non-linear analyses. The considered rocking wall panel is taken from the DSDM project [32][23][33] in which shake table tests were conducted on a three story half-scale precast concrete structure whose lateral force resisting system consisted entirely on rocking and hybrid walls. Herein, focus is placed on numerical modeling of a single hybrid wall panel and the effects of different modeling techniques in both nonlinear static and dynamic analyses [34][23][17] are investigated. The comparison between the investigated modeling techniques and the experimental tests is carried out in terms of bending moment, rotation at the base and accelerations.

2 SELECTED CASE STUDY

The selected case study considers the hybrid walls adopted as lateral force resisting system for a three-story half-scale precast concrete structure resembling a parking garage tested on the Network for Earthquake Engineering Simulation (NEES) Large High-Performance Outdoor Shake Table at the University of California at San Diego. Detailed information on the test specimen geometry, material tests and loading sequence can be found elsewhere [35][32][23]. The total mass of each floor, considering the tributary mass of the columns, is 36.795ton, 38.999ton and 34.230ton for the 1st, 2nd and 3rd floor, respectively [17]; it is worth noting that a vertical slotted connection between the wall and the floors allowed to transfer only horizontal loads from the floors to the walls.

This work focuses on the study of the single wall panel with additional steel rebars at the wall to foundation interface. The wall panel is 7.010m height, 2.438m long and 0.203m thick. 2 sets of tendons (each of them made by five 12.7mm diameter low-relaxation tendons) are placed on each wall with a total prestressing force in each wall was equal to 642kN. Two longitudinal reinforcing bars are used as hysteretic energy dissipators.

The relevant data for the finite element analyses are reported in Table 1.

Unconfined concrete	
Strength (f_c')	54MPa
Elastic modulus (E_c)	37000MPa
Strain at maximum strength (ϵ_{c0})	0.2%
Ultimate compressive strain	0.55%
Confined concrete	
Strength (f_{cc}')	80.8MPa
Strain at maximum strength (ϵ_{cc})	0.67%
Ultimate compressive strain (ϵ_{cu})	3.77%
Unbonded prestress tendons	
Tendon set	5x0.5" strands
Prestressing force for each tendon set	235.75kN
Unbonded length (ϵ_{cu})	8529mm

Table 1: Summary of the wall properties.

The input motion adopted for the selected case study represent a design basis earthquake for Seattle, i.e. a moderate seismic hazard [32]. It is worth noting that similitude law was not achieved by mass substitution but only by scaling the input ground motions, horizontal acceleration field amplified by 1.855 and ground motions time step compressed by 1.855.

3 FINITE ELEMENT MODELS

The finite element models presented herein represent a single hybrid wall panel. The tributary mass of each floor is modelled as lumped horizontal mass at the wall center line corresponding to the floor height. The foundation is herein assumed as rigid.

Three different types of 2D-models have been developed with the software OpenSees [36]: fiber beam elements model (FM), lumped rotational spring model (RS), and compression-only springs model (MS) (Figure 1). For all the models, a Rayleigh damping with mass proportionality is considered (damping coefficient equal to 0.01).

In the FM model (Figure 1a), different fiber sections are used to capture the hysteretic behavior of the elements. Regular fiber sections are adopted in the wall panel considering non-linear stress-strain relationship for the confined and unconfined concrete and the reinforcing rebars. No fiber elements are placed above the first floor being the response in that region essentially elastic. To simulate the wall-to-foundation rocking interaction, a fiber section with no reinforcing bars and no tensile strength concrete is positioned between the wall base and the ground. Each tendon set is constituted by a truss element fixed at the base and rigidly connected at the top of the wall by rigid elements [37][27].

In the MS model (Figure 1b) the support of the wall is schematized with a series of axial springs acting only in compression to allow separation between the wall and the foundation during rocking. A total of 25 springs has been considered [17]. The elastic stiffness of each spring is calculated as $E_c A/L$, where E_c is the elastic modulus of the foundation, A is the influence area of each spring and L is half the length of the wall. Yielding of concrete in compression is also introduced in each axial spring with a normal bilinear model.

In the RS model (Figure 1c), the wall panel is modeled with an elastic beam with a nonlinear rotational spring connecting the wall base to the ground with a multilinear hysteretic model. The analytical formulations proposed by Restrepo and Rahman [9] is used for the definition of nonlinear properties of the rotational spring. An additional spring was placed in parallel to capture the behaviour of the dissipative devices [9][38][34].

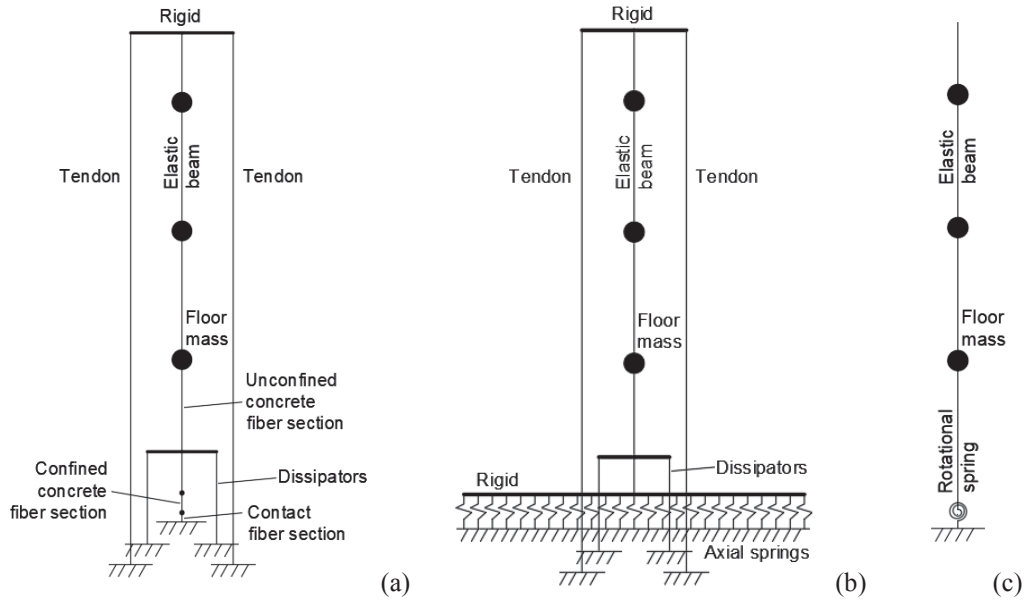

Figure 1: Representation of the 1D elements models: fiber elements, FM, (a), multi-springs, MS, (b), rotational spring, RS, (c).

In all models, the uniaxial material properties of the dissipative device are inserted with the Dodd-Restrepo model [39], with the factor Ω for the Bauschinger effect equal to 1.15. In MS and FB models, each dissipator set is constituted by a truss element fixed at the base and rigidly connected to the wall.

3.1 Sensitivity analysis of the parameters

A sensitivity analysis was conducted to investigate the main parameters affecting the dynamic response of the selected case study: elastic modulus of the concrete at the wall-to-foundation interface, stiffness of the compression only springs, unbonded length of the rebars used as dissipating device and their hysteresis model. For both FM and MS models the effective debonded length is equal to 302mm.

The results of the sensitivity analysis are represented by means of a tornado diagram; Figure 2a shows the variation of the maximum displacement of the 3rd level for FM model, while Figure 2b for MS model.

FM model

MS model

(b)

Figure 2. Tornado diagram for FM model (a) and MS model (b) model.

The parameters that mainly affect the horizontal displacements of the rocking wall are the total unbonded length of the mild-steel rebars and the stiffness of the compression-only springs for MS model (Figure 2b) and the elastic modulus at the rocking interface for FM model (Figure 2a).

4 FINITE ELEMENT ANALYSES RESULTS

In this section, the results of the nonlinear static and dynamic analyses are presented in terms of moment-rotation at the base and relative acceleration on the 3rd floor, both horizontal and vertical. The bending moment is calculated as the product between inertial forces and the distance to the rocking interface.

The nonlinear static results of the considered models are shown in Figure 3, where θ is the rotation at the base, i.e. at the gap developing at the wall-to-foundation interface, V is the shear at the base and W is the half-weight of the model structure equal to 621.3kN [17].

Figure 3: Base shear–base rotation elements models with energy dissipators at the wall-to-foundation interface.

The red line in Figure 3 indicates the bilinear response of hybrid walls [9]. It shows a good approximation to the idealized bilinear response.

Nonlinear dynamic analyses were conducted. The sequence of the actual input ground motions used during the experimental tests is considered. Figure 4, Figure 5 and Figure 6 show the results of the three models, indicating how the models are able to reasonably describe the

global wall behavior. In these figures, the red line indicates the results of the experimental tests, while the blue line indicates the results obtained from the finite element model.

(a)

(b)

Figure 4: Moment-rotation for fiber elements 'FM' (a), multi-springs only-compression 'MS' (b) and rotational lumped spring 'RS' (c) model. Note: in red the experimental test and in blue the numerical results.

Figure 5 shows the horizontal accelerations. The models capture the acceleration trend, but not the exact peak values. These peaks are associated with horizontal acceleration spikes arising when the wall gains horizontal lateral stiffness in the unloading phase [23][40], which happens in proximity of zero-base rotation.

(b)

(c)

Figure 5: Horizontal acceleration [g] for fiber elements (a), multi-springs only-compression (b) and rotational lumped spring (c) model for the hybrid wall. Note: in red the experimental test and in blue the numerical results.

Figure 6 shows the vertical accelerations. The peaks observed arise when the wall base gap closes [23]. A good approximation is obtained compared to the experimental test. Vertical accelerations are not investigated in the RS model.

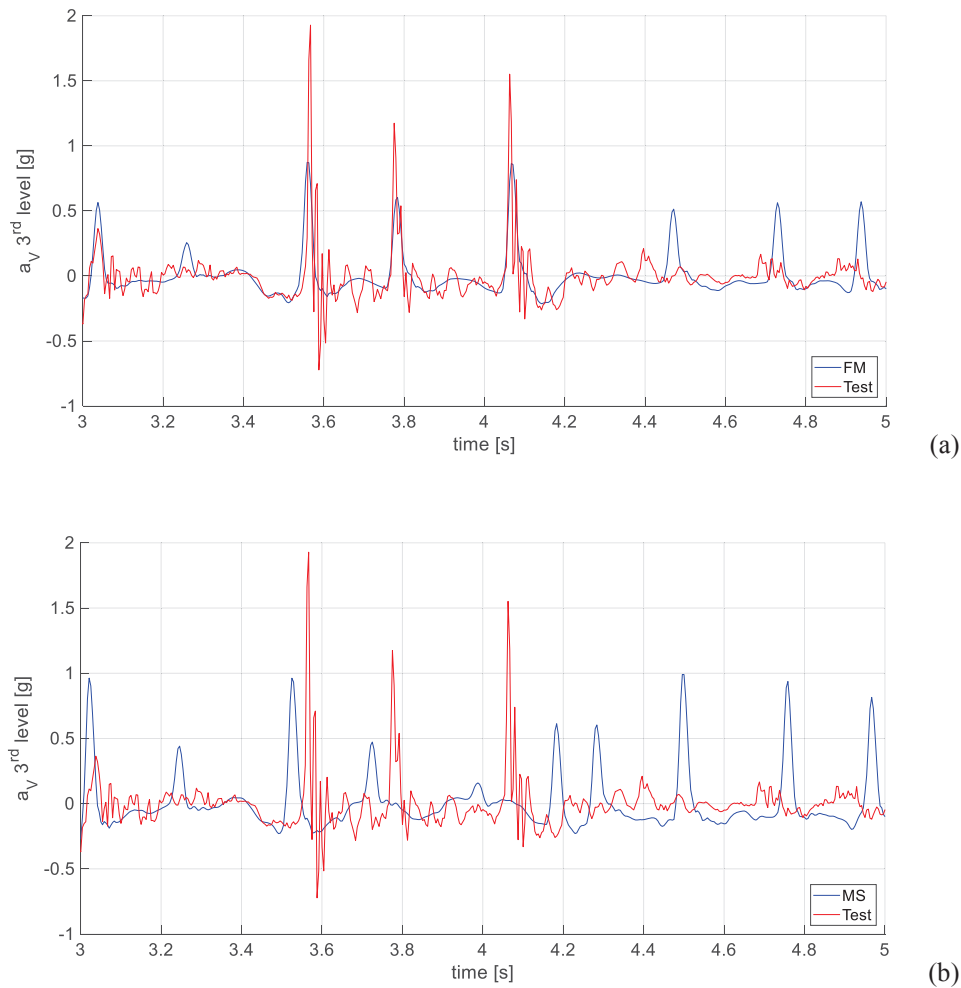

Figure 6: Vertical acceleration [g] for fiber elements (a) and multi-springs only-compression (b) model for the hybrid wall. Note: in red the experimental test and in blue the numerical results.

Overall, the results show how the considered planar models predict quite well the rocking wall behavior in terms of moment-rotation, although significant differences are present close to zero base rotation where horizontal acceleration spikes arise.

5 CONCLUSIONS

In the present paper, the finite element modeling of hybrid walls, i.e. rocking walls with additional energy dissipation, is considered to highlight differences between different modeling techniques: fiber beam elements (FM), lumped rotational spring (RS) and compression-only springs at the base (MS). The dynamic interaction between the wall and the building and the influence of the foundation was not considered. Mass proportional damping formulation is used with a damping coefficient equal to 0.01.

The RS model is the least suitable for capturing the rocking behavior, despite being the easiest to implement model. The sensitivity analysis shows that the main parameters affecting the results in terms of lateral displacements are the stiffness of the compression only springs, the elastic modulus of the concrete at the wall-to-foundation interface in the fiber model, the unbonded length of the mild steel rebars and the amount of damping.

After the sensitivity analysis, a reduced elastic modulus of concrete (0.6 of the elastic modulus of plain concrete) has been considered. The total unbonded length of the energy dissipators are equal to the unbonded length at the wall-to-foundation interface plus six times the value of the diameter of the rebars to account for strain penetration. For the definition of the stiffness of the springs, a value of half length of the wall has been considered.

Regarding nonlinear dynamic analyses, the models provide results qualitatively similar to the experimental test.

Abstract

In seismic regions, more often than never the dogma that bridge columns need to be firmly connected to the ground leads to huge pile foundations that require as much concrete as the superstructure. This is clearly a non-sustainable design method. To reduce the foundation design moment and possibly avoid the piles foundation, it has been proposed to let the bridge columns uplift and rock.

This paper presents quasi-static testing of a 1:5 scale precast restrained rocking bridge column exhibiting negative stiffness. The proposed system is resilient, able to achieve limited to no damage during design earthquakes. It allows prefabrication and quick on-site assembly, which reduces the on-site construction time and traffic impact.

As part of this experimental campaign, quasi-static cyclic tests were carried out on a reinforced concrete column allowed to rock on its interface with the foundation and cap-beam. An unbonded tendon was adopted to restrain the columns. The tendon was connected in series to a Belleville spring system to keep the overall post-uplift stiffness of the system negative. Large drifts lead to stress concentrations at the ends of the columns, therefore they were protected by steel jackets.

The column was subjected to drift ratios up to 15%. The results show that it returned to its original position with negligible to no residual displacement.

Keywords: rocking bridges, Accelerated Bridge Construction, sustainable seismic design, precast bridges

1 INTRODUCTION

Accelerated Bridge Construction (ABC) has emerged as a convenient method to reduce onsite construction time and traffic impact, as well as providing elements of higher quality due to its prefabrication offsite [1–23].

Within ABC two seismic design methods exist: (a) emulating connections of conventional reinforced concrete structures by creating fixed connections of the precast elements with cast in situ concrete or, (b) letting the precast elements rock by adopting dry connections combined with prestressed or posttensioned unbonded tendons passing through the columns. The advantage of the former method is that it results in bridges that behave like the traditional cast in place ones, this it is an established and easily acceptable technology. The advantage of the latter method is that it is more resilient as it presents minimal damage and residual displacement. Some of the techniques developed to emulate connections are: bar coupling [6, 7], pocket and socket connections [5, 10, 21, 23], and grouted duct connections [9, 22, 23].

As an alternative to emulated connections, rocking systems provide the additional advantage of reducing residual displacements and damage after the earthquake event ceases. Priestley and Tao [1] and Stone et al. [2] studied the behavior of precast posttensioned beam columns designed to rock in the connections. Mander and Cheng [13] developed the *Damage Avoidance Design* methodology for bridge piers, introducing the concept of precast posttensioned elements to bridge systems. Following on, Hewes and Priestley [17] and Billington and Yoon [18] also explored the adoption of posttensioned rocking elements to segmental columns.

To control design displacements, researchers proposed introducing energy dissipation devices to the system. Davis et al. [3], Finnson [4], Thonstad et al. [11] and Thonstad et al. [12] conducted an experimental campaign exploring the behavior of prestressed rocking piers with mild reinforcing bars connecting the foundation and column, and/or column and cap beam, which provided energy dissipation. With similar goal, Marriott et al. [20], Guerrini et al. [8], White and Palermo [24] and Mashal and Palermo [14] explored rocking piers equipped with external energy dissipaters.

Sideris et al. [25–27] also proposed a posttensioned segmental column with a rock-dominant connection at the bottom, and intermediate slip-dominant connections, which provided energy dissipation with low damage.

The works mentioned above led to the development of systems with small residual displacements and low damage after a ground motion excitation. Hence, they succeed in the goal of resilience. However, they result in foundation design moments that are on the same order with their plastic design counterparts. These design moments often require huge pile foundations which can comprise up to 50% of the total Reinforced Concrete used in the whole project. Aiming at decreasing the foundation design moments and obtaining a more sustainable system, it has been suggested either to not restrain the bridge columns at all [28–42] or to restrain them with flexible restraining systems [43–46]. In an effort to bring the concept of negative stiffness closer to practice, this paper presents quasi-static cyclic tests of a restrained RC concrete column exhibiting negative post-uplift stiffness. The column is allowed to rock freely on its interface with the foundation, while the cap beam and column are connected through a non-prestressed tendon in series with disc springs.

2 BEHAVIOR OF NEGATIVE STIFFNESS BILINEAR ELASTIC SYSTEMS

Rocking systems of negative stiffness present the Negative Stiffness Bilinear Elastic (NSBE) force deformation loop shown in Fig. 1, and discussed extensively in [30]. Up until uplift the system behaves linearly with a stiffness representing any deformability the system

might present before uplifting. After uplifting, the tangent stiffness becomes negative. The displacement capacity is defined not by material failure, but by the displacement where the restoring force becomes negative. Therefore, for an unrestrained rocking column the displacement capacity is equal to its width. One can increase it by equipping the column with extended curved ends [47–49] or by adopting a flexible restraining system. Herein, a flexible restraining system was adopted for the proposed column.

Figure 1: Characteristic Pushover Curve of a NSBE Oscillator (figure from [30])

3 SPECIMEN DESIGN

In the tests discussed in this paper, the restraining system of the column was designed to double the displacement capacity of the free rocking column, assuming that u_{up} is negligible. The system was composed of an unbonded tendon in series with disc (“Belleville”) springs (Fig. 2). The disc springs were adopted to avoid yielding of the tendon in large displacements.

Figure 2: Specimen

The ungrouted tendon passed through the centerline of the column. One end was anchored in the bottom of the column, providing no connection between the foundation and the column. The other end was anchored above the beam, in series with the disc springs. No prestress loading was applied to the restraining system.

The columns were protected by steel jackets at their ends. The jackets comprised a steel tube welded to a circular end plate. Steel jackets were also used by [11, 14]. However, in the tests discussed in this work, the stresses are expected to be smaller because of the springs.

Steel plates were also fixed to the floor and to the cap beam to avoid damage due to stress concentrations. The plates were equipped with sliding restrainers, which limited the sliding motion of the column. A restrainer was also provided to avoid twisting of the columns. Fig. 2 presents the tested system, in which the elements discussed in this section are identified.

The geometry of the column is shown in Fig. 3-4 and follows from scaling to 1:5 a typical overpass bridge column.

Figure 3: Cap-beam elevation and cross-section (dimensions in mm)

Figure 4: Column elevation and critical cross-sections (dimensions in mm)

3.1 Restraining System

The stiffness of the restraining system (k_{res}) was obtained based on the force deformation curve discussed in [30], under the assumption that the pre uplift deformation is negligible. For small rotations, one can linearize and get the desired stiffness of the restraining system as:

$$k_{res} = \frac{4V}{ab} \cdot \frac{(\lambda - 1)}{\lambda} \quad (1)$$

where V is the total vertical loading acting on the column plus half of its self-weight, α is the slenderness angle of the column (i.e. width to height ratio), $b=257.8$ mm is the diameter of the

column, and λ is the factor by which the displacement capacity of a free rocking column with equivalent slenderness should be increased (i.e. $\lambda = u_{cap}/b$).

The tests were performed under a vertical load $V=52.2$ kN that would correspond to a normalized axial load (ν) of 5% in the columns, which is typical for bridge columns. Then, Eq. (1) gives the target stiffness of the restraining system that would result in doubling the displacement capacity of the column ($\lambda = 2$): $k_{res}=2302$ kN/m. The restraining system was composed of a tendon with nominal cross-section area of 150 mm^2 in series with 11 disc springs of individual deformation capacity of 5.6 mm (Fig. 2). This design gives an overall stiffness of the restraining system of 2613 kN/m until 44 mm axial displacement.

The tendon had threaded sockets at its ends. Therefore, it was anchored in the bottom end of the column, as Detail 1 of Fig. 4 shows. The other end was anchored at the top of the springs with a nut. The tendon was unbonded through its entire length.

3.2 Steel Reinforcement

The column reinforcement was designed to resist the internal moment generated when the column rotates to a displacement equal to $2b=515.6$ mm. It resulted in a longitudinal reinforcement composed of 6 B500B rebars of 8 mm-diameter ($A_s = 3.02 \text{ cm}^2$) distributed uniformly along the circular perimeter of the column. The longitudinal reinforcement was welded on the steel plate at the column ends.

The transverse reinforcement comprised an 8 mm-diameter B500B spiral, which is the minimum according to Eurocode 2 [50] ($A_{sw}/s = 0.022 \text{ cm}^2/\text{cm}$).

3.3 Column steel parts

The steel jackets consisted of a S355 steel tube 3.4 mm-thick, 245 mm-high and 257.8 mm in external diameter. The steel tube was welded in its base to a S355 steel plate 5 mm-thick. The detailing of the steel plate is different in the bottom and top part of the column. In the steel plate placed at the bottom of the column, a threaded steel tube was welded to it for anchoring the tendon. In the top part, a circular annular plate was used to allow casting of the column.

3.4 Slide and twist restrainers

To limit sliding, the steel plates fixed to the ground and to the cap-beam were equipped with sliding restrainers that limited sliding to 5 mm in each direction (Fig. 5).

Figure 5: Schematic illustration of the motion restrainers

3.5 Concrete mix

The columns were casted in-house using a commercial dry mixture of self-compacting concrete of strength class C30/37 ($f_{ck} = 30$ MPa). Although the water/cement ratio suggested in the pack of the dry mixture was initially respected, the concrete workability was not the one expected, and more water had to be added to the mixture.

Three standard cylindrical specimens of 150mm-diameter and 300mm-high were casted to define the strength and Young's modulus of the concrete. The measured mean strength and Young's modulus of the specimen were 45.4 MPa and 30 GPa, respectively.

4 TEST SETUP AND INSTRUMENTATION

The test setup is shown in Fig. 6a. It consisted of two vertical actuators and a horizontal actuator. The three actuators applied forces or displacements to a steel beam, which was connected to the cap-beam with short wide flange steel beams. The steel beam is constrained, and out-of-plane displacement is not allowed.

The setup kept the vertical force applied to the column constant and equal to 52.20 kN, simulating the gravitational loads of the super-structure. The rotation of the cap and steel beam was kept constant and equal to zero. For the cyclic test, the horizontal actuator applied the displacements defined in the loading protocol shown in Fig. 6b. The loading protocol consisted of two consecutive cycles of same drift ratio, followed by a subsequent cycle of 1.25 times the previous drift ratio. In total, the columns were subjected to 18 sets of two cycles each. The loading protocol was based on the American Concrete Institute recommendations. Since the most recent report [51] specifies that the drift ratio must be increased based on the yield strain, the increase of the drift ratios was based on an older report [52].

The displacement of the column and cap-beam were measured by an optical measurement device that tracks the positions of markers fixed in the specimen. The forces and strokes of all actuators were recorded by load cells and lasers installed on them. A load cell was also installed in series with the springs and tendon, recording the forces in the restraining system. Rosettes measured the strain in the steel jacket.

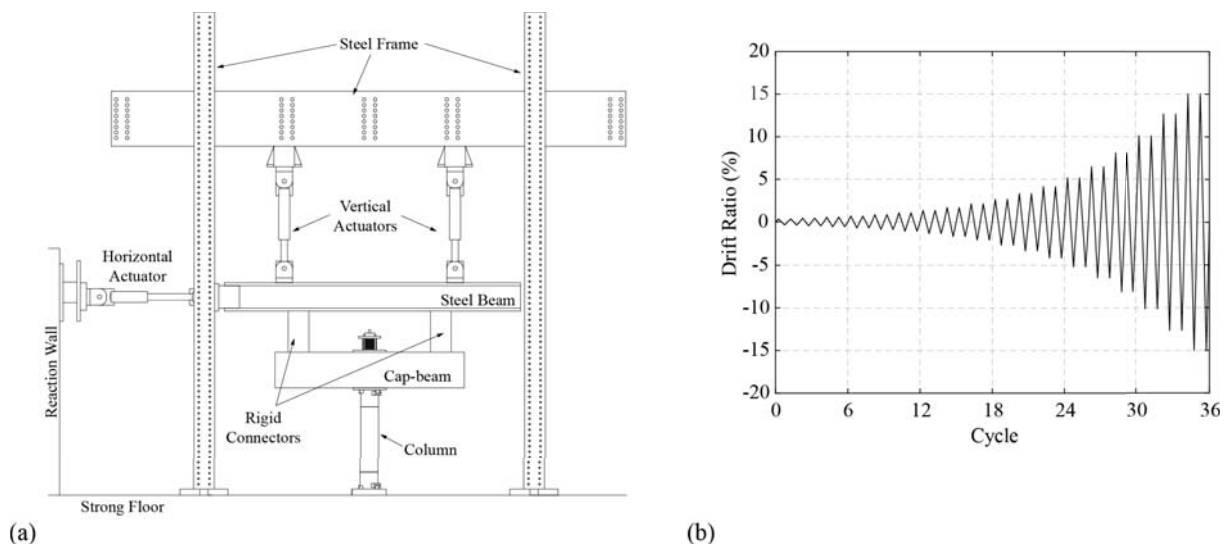

Figure 6: (a) Test setup, and (b) Cyclic time history.

5 FORCE-DRIFT LOOPS

Fig. 7 presents the force-drift response for low drift ratios (up to 1.1%), medium drift ratios (up to 4.2%), and high drift ratios (up to 15%). The drift ratio is defined herein as the ratio between the horizontal displacement of the beam and the height of the column (1450 mm).

Figure 7. Force-drift relation for: (a) low drift ratio, (b) medium drift ratio, and (c) high drift ratio

One can observe that the column presents almost no strength reduction. It is not clear whether the energy dissipation deduced from the area of the loops comes from the column itself or from friction of the set up. More tests are currently performed to quantify the friction of the spring and of the setup itself. In any case, there was only minimal damage in the columns, so it is difficult to imagine a physically plausible way of energy dissipation within the column.

Sliding and twisting of the specimen were limited, but not zero. Both motions could be observed and measured with the optical position trackers fixed in several points of the column and cap-beam. Twisting was negligible. Sliding, however, was observed and it is also depicted in the force-drift relations (Fig.7a-b).

Fig. 8 shows the envelope of the force-drift response. As the protocol defined two cycles per drift amplitude, the envelope for both cycles is plotted. The same plot shows the envelope predicted by rigid body calculations, assuming a rigid column with same dimensions of the tested column (257.8 mm-diameter and 1450 mm-height), constant vertical load of 52.20 kN and restraining system stiffness of 2613 kN/m. The flexibility of the tested system only causes a slight deviation from the rigid body model that is non-negligible only for very small drift ratios, essentially before the column uplifts.

Figure 8: Force-drift envelope

6 OBSERVED DAMAGE

At the end of the test, almost no damage could be noticed at the column (Fig. 9c-d). No cracks or spalling of the column was observed. The top steel jacket, however, presented some minimal damage. The steel plate slightly bent (Fig. 9a) and the steel tube presented a dent (Fig. 9b), as a result of local buckling. Both damages occurred close to the end of the very end of the column, at drift of 12.7%. The bottom steel jacket did not present any damage visually observed, as the contact force there is smaller.

Figure 9: (a) Bending of the steel plate, and (b) dent of the steel tube of the steel jacket at the end of test; (c) column, and (d) overall view of the system at 15% drift ratio.

7 CONCLUSIONS

Negative stiffness restrained rocking columns can be used in bridge design in an effort to reduce the design moment of the foundation and possibly save the piles. Such a system using disc springs in series with a steel tendon as a restraining system was tested to drift ratios up to 15%. Negligible visual damage was observed. Since the force deformation loops did not change during the tests, no strength degradation was observed. Thus the system is resilient.

As the aim of the proposed design approach is to reduce the design moment of the foundation and avoid the huge pile foundations that are often designed in seismic areas, the system contributes to sustainable seismic design.

Abstract

Greece is divided into three seismic hazard zones ZI, ZII, ZIII. In the present research work, the same building in the three seismic zones of Greece is modeled, analysed and dimensioned and then the construction cost of its structural body is estimated. The building modeling was performed in SAP2000 using linear finite elements. The analysis of the building was performed by dynamic spectral analysis methods using the design spectrum of EC8. A ten-storey building with a standard floor plan per floor was used. The purpose of this research paper is through comparative analytical estimation of construction costs to demonstrate whether the cost of construction of the bearing structure of a reinforced concrete building is affected by the area seismic hazard, if this influence is significant and to what extent. Useful conclusions are drawn regarding the influence of seismicity on the construction cost of the load-bearing structure of reinforced concrete buildings.

Keywords: Seismicity, Cost, Reinforced Concrete, Seismic Hazard.

1 INTRODUCTION

One matter that has troubled consultant engineers worldwide is the correct design and detailing of a reinforced concrete (R/C) building [1]–[16]. However, another matter that has troubled engineers is the economical design of a R/C building, as far as the construction cost of the load-bearing structure is concerned. Several studies worldwide have taken place on this matter in order to find the most economical way of designing and detailing the load-bearing structure of structures, whether these structures are buildings [17]–[19], bridges [20]–[24] or other types of structures [25], [26].

2 DESCRIPTION OF BUILDING

The reinforced concrete structure that is simulated and dimensioned in the three seismic zones is a symmetrical ten-storey building, without a basement. The floor plan of the building is 25 m x 25 m, so its area is $E = 625.00 \text{ m}^2$, and is the same for each floor (Figure 1). The height of the ground floor is 4.5 m and the rest of the floors 3 m. In the center of each floor, there is a strong core and two ductile walls around the center of the Y direction.

Figure 1: Floor plan.

The dimensions of the beams' cross sections of the building do not change per floor. The perimeter beams have dimensions 25 cm x 70 cm and the inner ones 25 cm x 60 cm in the X direction and 25 cm x 55 cm in the Y direction, apart from the core where they are also 25 cm x 70 cm. The cross section of the columns varies in height; for the first two floors is 75 cm x 75 cm and then decreases by 5 cm per floor. The thickness of the ductile wall sections varies with height and changes every five floors. On the first five floors, it is 37.5 cm and for the last five it is 25 cm. Enlarged boundary elements are used at both ends of the ductile walls T3 and T10 to avoid lateral buckling of structural walls under extreme seismic actions [27]–[34]. The thickness of the slabs is 15 cm.

3 MODEL DESCRIPTION

The modeling of the load-bearing structure is performed with the program SAP 2000. The ductile walls are modeled through the equivalent frame method (Figure 2). A vertical element is used, equivalent to a column, in the center of the wall, which is connected to the other structural elements with horizontal elements; rigid bodies at the level of the floors, with special properties. These bodies have increased values of their characteristics so that they appear as rigid in relation to the neighboring elements. The nodes at the base of the structure have rigid supports so that the superstructure is not affected by the foundation structure [35], [36].

Figure 2: 3D building simulation.

The construction materials of the load-bearing structure have the following characteristics:

- Concrete quality C30/37
- Steel quality B500C

The modulus of elasticity of concrete is 33 GPa, according to Eurocode 2 [37]. The value of the Poisson ratio is set equal to 0, according to the specifications of Eurocode 2 [37], for cracked sections of reinforced concrete. The beams are modeled as linear finite elements in space, placed on the centroid axis of the structural element. As the diaphragm action of the slabs is ensured, the beams are considered as T or L beams. The columns are modeled as linear finite elements in space, placed on the centroid axis of the structural element, like the beams.

4 DIMENSIONING

4.1 Slabs

All slabs are quadrilateral and are reinforced in both directions and the calculation was done with Czerny tables. The maximum torque at middle of the slabs is $M = 15.80 \text{ kNm}$. Therefore, reinforcement $\emptyset 10/190$ ($A_s = 4,13 \text{ cm}^2$) is placed in the openings of the slabs. The supports that require additional reinforcement are $\Pi 1-\Pi 4$, $\Pi 3-\Pi 6$, $\Pi 9-\Pi 12$, $\Pi 11-\Pi 14$, as well as the core support and so additional reinforcement $\emptyset 10/250$ is placed.

4.2 Beams

The detailing of the beams has been performed in the openings and the supports for the most unfavorable combination and according to the minimum requirements of Eurocodes 2 and 8 [37], [38].

4.3 Columns

Detailing against biaxial bending with axial force is performed according to Eurocode 2 [37]. Similar to the beams, the most unfavorable combinations, the minimum requirements of Eurocodes 2 and 8 [37], [38] and the capacity design were used (Table 1).

ZONE II				
Column	vd	$\mu 1$	$\mu 2$	Reinforcement
K1, K6, K19, 24	-0.07570	0.01544	0.00564	12 \emptyset 25
K2, K5, K20, K23	-0.12780	0.01795	0.00360	12 \emptyset 25
K3, K4, K21, K22	-0.17002	0.01773	0.00281	12 \emptyset 25
K8, K9, K16, K17	-0.16832	0.01783	0.00273	12 \emptyset 25
K7, K10, K15, K18	-0.12499	0.01787	0.00341	12 \emptyset 25

Table 1: Longitudinal reinforcement of ground floor columns of Zone II

4.3 Structural walls

The detailing of the ductile walls has been performed according to the provisions of Eurocodes 2 and 8 (Table 2) [37], [38].

ZONE III				
Structural Walls	vd	μ_x	μ_y	Reinforcement
T1, T2	0.0690	0.1200	0.0043	12 Φ 32
T3, T10	-0.1380	0.1750	0.0160	12 Φ 32
T4, T5	0.2420	0.0805	0.0052	8 Φ 25
T6, T7	0.1200	0.0755	0.0051	8 Φ 25
T8, T9	0.2631	0.0772	0.0052	8 Φ 25

Table 2: Tension reinforcement of ground floor ductile walls of Zone III

5 CONCRETE AND STEEL MEASUREMENTS

The amount of concrete does not change in the three seismic zones, as the dimensions of the elements remain constant. The measurement of the steel reinforcement of the slabs, beams, columns and walls took place after the completion of the detailing for all three seismic zones.

6 ANALYSIS OF RESULTS

6.1 Analysis of concrete results

Figure 3: Percentage of structural elements concrete column compared to the total volume of concrete.

From Figure 3, it appears that the slabs have the largest percentage of the structural elements with a percentage of 51.57%. Then there are the walls with a percentage of 19.81%, the columns with a percentage of 14.63% and finally the beams with a percentage of 13.99%.

6.2 Analysis of reinforcement results for the ground floor

The following Table 3 and Figures 4-11 display the weight of steel of the structural elements of the ground floor for each zone.

Zone	Slab steel (kgr)	Beam steel (kgr)	Column steel (Kgr)	Structural wall steel (kgr)	Sum
Z1	10381.83	6739.43	6391.74	5538.13	29051.13
Z2	10381.83	8028.39	6405.58	7573.54	32389.35
Z3	10381.83	8561.27	7370.15	8784.73	35097.98

Table 3: Weight of steel of structural elements

Figure 4: Total weight of steel of ground floor components for each seismic zone.

Figure 5: Beam steel weight of ground floor for each seismic zone.

Figure 6: Column steel weight of ground floor for each seismic zone.

Figure 7: Wall steel weight of ground floor for each seismic zone.

Figure 8: Percentage increase of total weight of steel of ground floor structural elements per zone.

Figure 9: Percentage increase of beam steel of ground floor structural elements per zone.

Figure 10: Percentage increase of column steel of ground floor structural elements per zone.

Figure 11: Percentage increase of wall steel of ground floor structural elements per zone.

The analysis of the above diagrams shows the following:

- **Transition from ZI seismic acceleration 0.16g, to ZII seismic acceleration 0.24g**
 - Increase of 11.49% of the total weight of steel of all structural elements
 - Increase of 19.13% in the steel weight of the beams
 - Increase of 0.22% in the steel weight of the columns
 - Increase of 36.75% of the steel weight of the walls
- **Transition from ZII seismic acceleration 0.24g, to ZIII seismic acceleration 0.36g**
 - Increase of 8.36% of the total weight of steel of all structural elements
 - Increase of 6.64% in the steel weight of the beams
 - Increase of 15.06% in the steel weight of the columns
 - Increase of 15.99% of the steel weight of the walls
- **Transition from ZI seismic acceleration 0.16g, to ZIII seismic acceleration 0.36g**
 - Increase of 17.23% of the total weight of steel of all structural elements
 - Increase of 21.28% in the steel weight of the beams
 - Increase of 13.28% in the steel weight of the columns
 - Increase of 21.28% of the steel weight of the walls

- **Increase in seismic acceleration**

- Zone I to Zone II $(0.24-0.16)/0.16 = 50\%$
- Zone II to Zone III $(0.36-0.24)/0.24 = 50\%$
- Zone I to Zone III $(0.24-0.16)/0.16 = 125\%$

Figure 12: Percentage of steel of ground floor structural elements of Zone I.

Figure 13: Percentage of steel of ground floor structural elements of Zone II.

Figure 14: Percentage of steel of ground floor structural elements of Zone III.

From the Figures 12-14, it is concluded that:

- Slabs occupy their largest percentage in steel in ZI 35.74%, then in ZII 32.05% and finally in ZIII 29.58%.
- Beams occupy their largest percentage in steel in ZII 24.79%, then in ZIII 24.34% and finally in ZI 23.20%.
- Columns occupy their largest percentage in steel in ZI 22%, then ZIII 21% and finally in ZII 19.78%.
- Structural walls occupy their largest percentage in steel in ZII 25.03%, then in ZIII 23.38% and finally in ZI 19.06%.

7 CONCLUSIONS

In the present work, a ten-storey reinforced concrete building, without a basement, of rectangular conventional floor plan, was analyzed and detailed in the three seismic zones ZI, ZII, ZIII. The following conclusions emerged:

1. As the seismic hazard in the building increases, the largest percentage increase in steel occurs in the seismic walls. Specifically:
 - ZI ($\alpha_g = 0.16g$) \rightarrow ZII ($\alpha_g = 0.24g$) percentage increase 36.75%
 - ZII ($\alpha_g = 0.16g$) \rightarrow ZIII ($\alpha_g = 0.36g$) percentage increase 15.99%
 - ZI ($\alpha_g = 0.16g$) \rightarrow ZIII ($\alpha_g = 0.36g$) percentage increase 36.96%
2. The increase in seismic acceleration:
 - From ZI to ZII is a percentage of 50%, while respectively the increase in the total amount of steel is 11.49%, significantly smaller.
 - From ZII to ZIII is a percentage of 50%, while respectively the increase in the total amount of steel is 8.36%, an even greater difference compared to the previous transition.
 - From ZI to ZIII is a percentage by 125%, while respectively the increase in the total amount of steel is only 17.23%.
3. In a reinforced concrete building designed in accordance with the Eurocodes, seismicity affects the construction cost of the building but certainly the increase in construction costs

is significantly smaller compared to the increase in seismic risk. The increase in the total cost of materials is much smaller than the increase in seismic accelerations.

4. A building may be detailed for a seismic hazard zone greater than that provided for in the respective code, taking into account that there is a difference in construction costs.

Abstract

Most of the existing buildings in seismic prone regions have been built before the publication of modern design provisions against seismic events and progressive collapse. Nonetheless, some studies have highlighted the possible interaction between earthquake resistance and structural robustness, the latter being of interest to either individual extreme hazards (e.g., blast, impact, fire) or interacting hazards (e.g., landslides produced by seismic events). While retrofit strategies to improve the seismic performance of reinforced concrete (RC) structures have been widely investigated since many years, the topic of mitigation strategies against progressive collapse received very little attention. Progressive collapse can be described as a special type of structural collapse that involves several components of the structure as consequence of an initial localised damage. The present study aims at investigating whether and how much seismic retrofitting may improve not only the earthquake resistance but also robustness. A four-storey, five-bay, RC frame building designed according to Eurocode 2 is considered as a case study. The frame was assessed by evaluating: 1) the capacity of the structure to redistribute loads after a local damaging event; 2) the seismic capacity of the structure. Non-linear static analyses, i.e., PushDown and PushOver analyses, were carried out in OpenSees to evaluate the robustness and seismic resistance of the structure, respectively. The progressive collapse capacity was evaluated under two relevant column-removal scenarios, i.e., the sudden loss of an internal and an external column, while the seismic resistance was assessed under two load distributions, i.e., proportional to the first vibration mode and to the inertia masses. Subsequently, the impact of retrofitting with carbon fibre-reinforced polymers on both structural robustness and seismic resistance was evaluated. The use of the retrofit measure allowed, on the one hand, the removal of all the shear failures due to horizontal seismic actions and, on the other hand, to increase the robustness of the structure.

Keywords: Reinforced concrete buildings, structural robustness, retrofit operation, progressive collapse, non-linear static analysis.

1 INTRODUCTION

Some iconic cases, such as the collapse of the Ronan Point Building (London, 1968) [1], the Murrah Federal Building (Oklahoma City, 1995) [2], and the World Trade Centre (New York, 2001) [3] highlighted the high consequences of progressive collapse, in terms of loss of lives and properties, significantly increasing the interest of the research community in this topic [4]. Since the 1940s, many studies focused on this research area, widely investigating various aspects of the problem by performing components [e.g., [5], [6], [7]] and large-scale experimental tests [e.g., [8], [9], [10], [11]], numerical modelling and simulations [e.g., [12], [13], [14], [15], [16], [17]] and investigating several aspects of the design against progressive collapse [e.g., [18], [19]]. These studies allowed to build up an increasing understanding of the structural response in progressive collapse scenarios, along with the definition of possible design strategies. However, design guidelines and codes [[20], [21], [22]] have been introduced only in recent years, and most of the existing buildings worldwide do not incorporate design provisions to achieve structural robustness.

Besides, existing reinforced concrete (RC) structures are often vulnerable to seismic actions, as demonstrated by many events worldwide [e.g., [23]]. However, in the last few decades, there has been a significant effort from the research community in order to address these issues, and many seismic retrofit strategies are currently available and implemented in practice [e.g., [24], [25], [26], [27], [28], [29]].

In contrast, a very limited number of research studies focused on the development and investigation of retrofit strategies to avoid progressive collapse for both RC and steel structures. Among the few studies addressing this problem, Vieira *et al.* [7] experimentally investigated the effectiveness of the Textile-Reinforced Mortar and Near-Surface-Mounted reinforcement techniques when applied for the strengthening of existing RC frames against disproportionate collapse, showing an increase of the ductility by a factor of 1.95. Shayanfar *et al.* [30] numerically investigated the use of several combinations of additional rebars and Carbon Fiber Reinforced Polymer (CFRP) layers for the retrofitting of 2-storey RC frame showing the improved catenary effects and the reduction of vertical displacements. Jinkoo *et al.* [31] investigated the effect of prestressing tendons on the progressive collapse performance of a RC structure by performing non-linear static and dynamic analyses investigating a 6- and a 20-storey RC structure subjected to a sudden column loss scenario.

Although the above-mentioned studies (and a few more) investigate retrofit strategies for progressive collapse resistance, the knowledge level in this field is still very limited and there is a significant need for additional studies in this direction. Moreover, the vulnerability of these structures against multiple hazards offers the opportunity for integrated retrofit strategies that otherwise would often not be economically sustainable if directed toward the improvement of the structural response against a single hazard.

Within this context and given the high vulnerability of RC buildings towards the two considered hazards (*i.e.*, seismic actions and progressive collapse scenarios), the present study investigates the influence of the seismic retrofitting based on the use of CFRP on the structural robustness of a case study RC structure.

2 CASE-STUDY STRUCTURE AND FINITE ELEMENT MODELLING

A five-storey, six-bay by four-bay RC building, designed according to Eurocode 2 [32] and only to gravity loads, and previously investigated by the authors [[33], [34], [35]] was considered for case study purposes (see Figure 1). The building has a constant inter-storey height of 3 m and span lengths along the x - and y -directions equal to 5 m. Columns have a 400×400 mm² square section, whereas beams are 300×500 mm² at each floor. Concrete class C20/25

and steel reinforcement bars B450C were employed in the design. Uniform longitudinal reinforcement consisting of $6\phi 18$ and $8\phi 18$ were used for columns and beams, respectively. The same transverse steel reinforcement of $\phi 18$ stirrups with 200 mm spacing and a concrete cover of 40 mm were used for both beams and columns.

A two-dimensional Finite Element (FE) model of the external frame in x -direction was developed in OpenSees [36]. A spread plasticity approach with displacement-based fibre formulation was used, and each cross-section was discretised in 120 fibres: one hundred fibres relating to the confined concrete (*i.e.*, the concrete core) and twenty for the concrete cover. The stress-strain concrete behaviour was simulated through the uniaxial Kent-Scott-Park concrete model [37] (*i.e.*, ‘Concrete01’ in OpenSees), while a uniaxial bilinear model with kinematic hardening set to 0.01 was adopted to simulate the steel behaviour (*i.e.*, ‘Steel01’ in OpenSees). The characteristic cylinder compressive strength of concrete, f_{ck} , was set to 20 MPa. The characteristic yield strength, f_{yk} , and Young’s modulus of the reinforcing steel, E_0 , were set equal to 450 MPa and 200 GPa, respectively. The loads were applied as concentrated loads on the beams following a discretisation of the structure in which each beam element was subdivided into 5 parts. Masses were concentrated at beam-column intersections while beam-column joints were modelled as rigid. Geometric non-linearities in the form of both large displacements/rotations and P-Delta effects were considered by means of a total corotational transformation.

Figure 1: Reference frame model

3 PROGRESSIVE COLLAPSE ANALYSIS METHODS

The present Section investigates three different strategies for progressive collapse simulations. As shown in Figure 1, two different column removal scenarios were considered, *i.e.*, scenario A1 and A2. Loads were applied according to the accidental load combination, as per UFC [21] guidelines:

$$Q_{bd} = 1.2 DL + 0.5LL \quad (1)$$

where DL and LL indicate the dead and live loads, respectively equal to 3 kN/m^2 and 2 kN/m^2 .

A FE model in Seismostruct [38] was previously developed by the authors [35] for the case study frame, allowing the comparison of the numerical results and increasing confidence in the modelling strategy. The comparison was initially carried out in terms of modal properties showing a good match, *i.e.*, the first vibration periods were 0.35 sec and 0.37 sec for the Seismostruct and OpenSees model, respectively, while the second and third vibration periods

were coincident. A further comparison was carried out investigating the behaviour under the progressive collapse scenarios. In particular, the results of Incremental Dynamic Analysis (IDA) carried out in the previous study [35] were compared with the PushDown Analysis (PDA) carried out in this study. The Dynamic Amplification Factor (DAF) is used in the PDAs in order to simulate the dynamic effects. Figure 2 shows three different approaches used to carry out the PDAs, allowing the identification of the most appropriate one in terms of convergence and analysis' accuracy. The following approaches are evaluated:

- The '*Approach A*' is characterised by two Analyses (see Figure 2(a)). '*Analysis 1*' consists of a standard load control static analysis of the 'undamaged' structure, allowing the definition of the reaction force (R) of the column where the column loss is successively simulated. During '*Analysis 2*' the column removal is simulated by two steps. '*Step 1*', represented in Figure 2(a), allows simulating the presence of the column before the removal. The equivalent upward force F is applied to the frame, which entity corresponds to the vertical load previously detected on that column. In this Step, the gravity loads and the force F, are monotonically increased until the target value. In the following '*Step 2*', represented in Figure 2(a), a downward force F (equal to R in terms of values and opposite in terms of direction) is applied to simulate the column removal. Moreover, the loads on the beams adjacent to the removal are amplified with the DAF. This second set of loads are thus gradually applied.
- The '*Approach B*' is characterised by a single step (see Figure 2(b)), consisting in a displacement control analysis with the application of design loads amplified by the DAF. This approach, differently from '*Approach A*' neglects the initial condition before the collapse but allows an easier implementation of the analysis. In addition, the displacement control strategy allows the convergence of the analysis for larger displacements hence better simulating the catenary effects.
- The '*Approach C*' is characterised by two Steps (see Figure 2(c)). '*Step 1*' represented in Figure 2(c) consists of a standard load control static analysis of the 'damaged' structure with the application of the design loads. In the following '*Step 2*' a displacement control analysis is performed with the design loads amplified by the DAF.

The present Section of the work investigates the intensity of the DAF parameter by the comparison of the results of the PDAs and IDA. For this reason, the DAF was considered unitary during these preliminary analyses.

The results of the PDAs were obtained in terms of α - θ curves, in which α represents the design load multiplier and θ the vertical drift of the control point. Specifically, α was obtained, according to Eq. 2, as the ratio between the sum of the reaction values, relative to the base constraints, and the sum of the loads applied to the structure. The vertical drift was obtained as the ratio between the vertical displacement of the control point, v , and the beam length, L , according to Eq. 3; the control point was coincident with the upper joint of the removed column.

$$\alpha = \frac{\sum_i R_i}{\sum_i R_i(Qbd)} \quad (2)$$

$$\theta = \arctg \frac{v}{L} \quad (3)$$

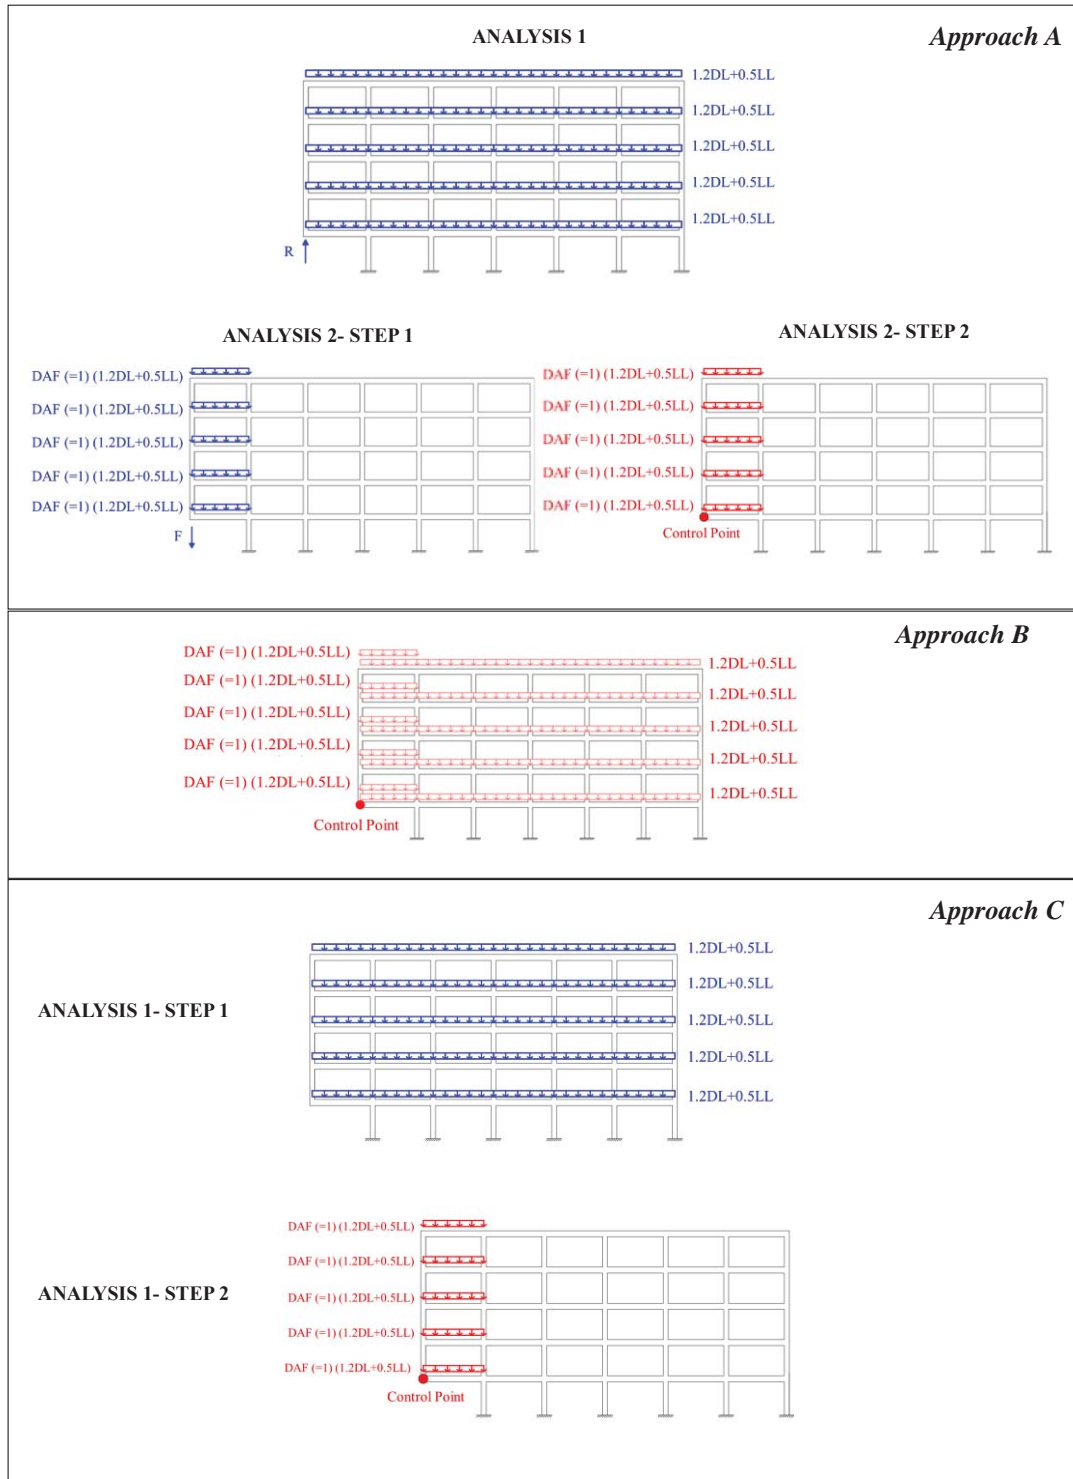

Figure 2: Approaches used for PushDown Analysis (PDA) (scenario A1).

The comparison between PDAs and IDA is shown in Figure 3. Through these results, the specific DAF (DAF_{sp}) was assessed as the ratio between the values of the load multipliers, α , obtained from both analyses, as follows:

$$DAF_{sp} = \frac{\alpha_{PDA}}{\alpha_{IDA}} \quad (4)$$

The results of the PDAs overestimated the design load multiplier, α , overestimating the capacity of the structure. This is related to the lack of consideration of the dynamic amplification during these analyses since the DAF was set equal to 1. However, this preliminary assumption allowed the evaluation of the DAF (DAF_{sp}) based on the results of the PDAs and IDA according to Eq. 4. The DAF_{sp} for the three Approaches and for the two removal Scenarios is shown in Figure 4. Figure 4 shows that Approaches A and C provide DAF values lower than the unit for high values of θ . The Approach B, on the other hand, led to a more realistic estimate of the DAF. Indeed, its value is always higher than the unit for both scenarios up to large vertical drift values and is aligned with DAF values obtained from other studies in the literature [40]. Approach B, with the corresponding value of the DAF, was chosen as the analysis method for the following part of the study. The DAF was set equal to 1.16, corresponding to a value of plastic rotation of 0.03 rads, as suggested by UFC (table 4-1); the yield rotation was calculated based on the recommendations of the Eurocode 8 [39].

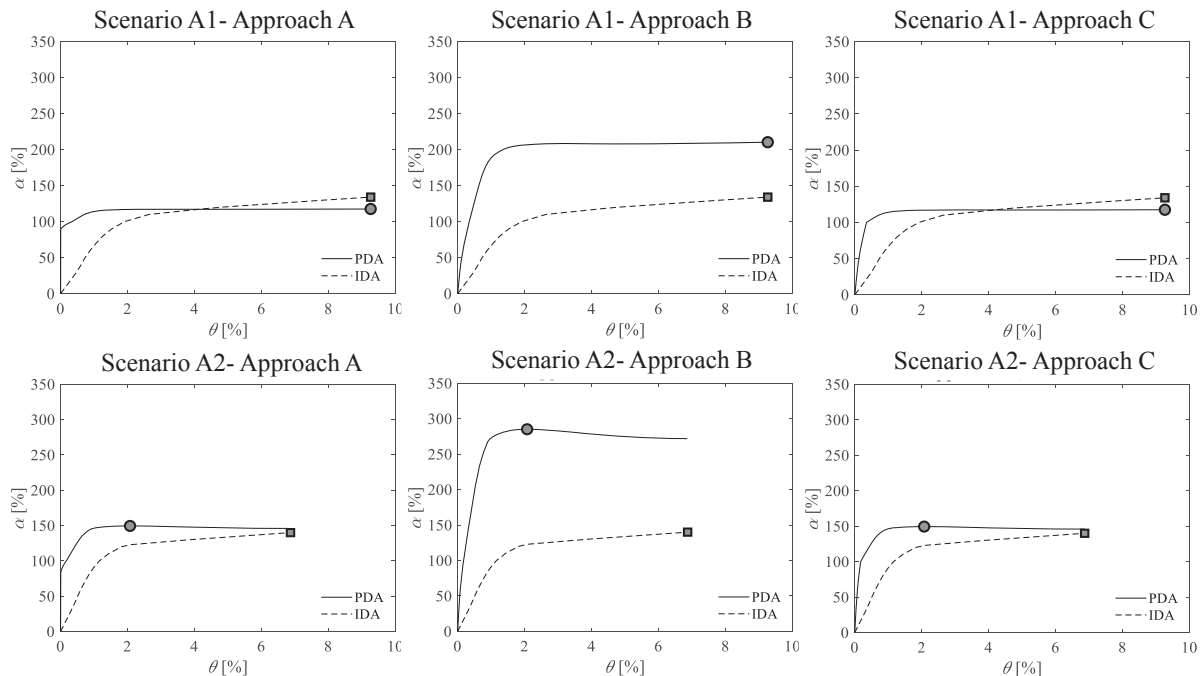

Figure 3: Comparison between PushDown analysis (PDA) and Incremental Dynamic Analysis (IDA).

Figure 4: Dynamic Amplification Factor (DAF) assessment.

4 PROGRESSIVE COLLAPSE AND SEISMIC ANALYSIS

4.1 Progressive collapse resistance assessment

Progressive collapse analyses were carried out to assess structural robustness under the two column-removal scenarios previously discussed and shown in Figure 1. Unlike previous studies [[33], [34], [35]], in which a building perimeter frame was considered, the structural system is herein supposed to be an internal primary frame. This led to an increase of design loads applied on beams equal to 23 kN/m according to Eq. 1.

The α - θ curves for the two scenarios and obtained with the PDAs are shown in Figure 5. For both scenarios, Figure 5 shows that the structure lack of robustness with shear failures of the beams corresponding to α values of 33.05 and 47.61, respectively, for scenarios A1 and A2. The degrading model of Biskinis and Fardis [41] was used for shear checks.

Figure 5: Pushdown analysis results: (a) scenario A1, (b) scenario A2.

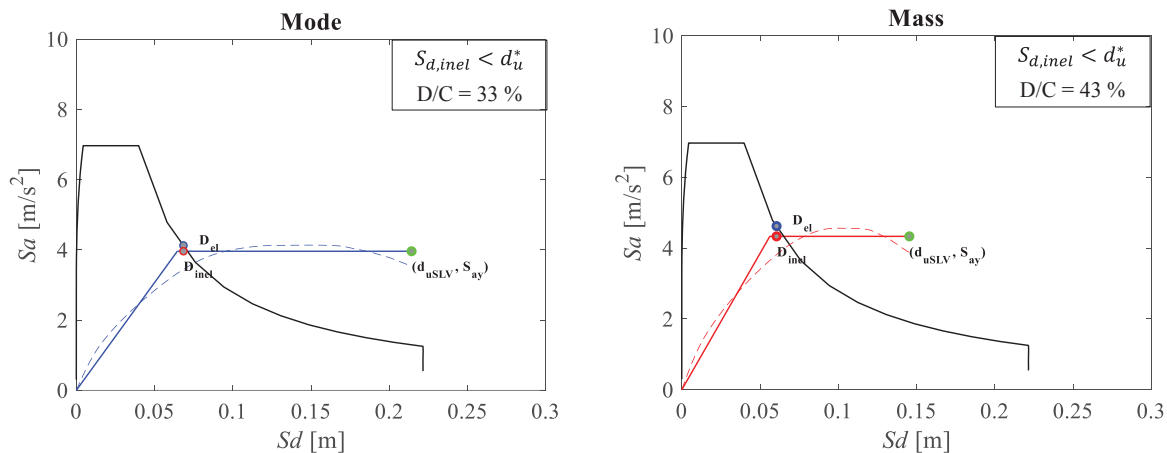

4.1 Seismic safety assessment

In order to evaluate the seismic capacity of the structure, global and local checks were carried out through non-linear static analysis performed according to NTC 2018 [42]. The construction site was coincident with L'Aquila (Abruzzo, Italy), the reference life of the structure, V_R , was 50 years and soil and topographic category were B and T_I , respectively; the PGA was equal to 0,301g. Two different load distribution, such as the MODE and a MASS distribution, were considered. Local checks showed that almost all elements, vertical and horizontal, were subjected to brittle failures, as underlined by the demand/capacity ratios collected in Tables 2 and 3 (Bold values in the tables indicate demand/capacity ratios greater than 1). These checks were carried out step-by-step, and they were performed in correspondence of a single step, *i.e.*, that related to the identified performance point. The global checks compared the required inelastic displacement, $S_{d,inel}$ with the ultimate displacement of the structure, d_u . This comparison was performed in the ADRS plane, allowing the comparison between the demand spectrum and the capacity curve. The intersection between the demand spectrum with the extension of the elastic branch provided the performance point. The results are shown in Figure 6, with the relative demand/capacity ratios.

Floor level	Column Line

5 INFLUENCE OF SEISMIC RETROFITTING ON STRUCTURAL ROBUSTNESS

The analysis results outlined the need to adopt a retrofit measure in order to prevent brittle failures occurring as a consequence of both considered hazards. In this study, the application of CFRP was investigated as it represents a widely used strategy to improve the seismic performances of RC frames. The impact of this retrofit strategy on the structural robustness was successively evaluated. The CFRP were applied differently on vertical and horizontal elements so as to eliminate brittle failures. A single bandage ply was used for the beams, while a different composition was considered for the columns. Five layers of CFRP plies, coinciding with the limit set by CNR-DT 200 R1/2013 [43], were used for the first floor level; three and two layers of plies were used for second and third floor level, respectively, while a single layer of ply was applied for fourth and fifth floor level. The analysis results showed that the application of CFRP allowed the removal of all the shear failures due to the seismic action, obtaining values of demand/capacity ratios lower than the unit.

Additionally, this retrofit measure had a beneficial effect, also improving the structural robustness of the frame under both column removal scenarios, as shown in figure 7. The first brittle failure, for both cases, occurred for a higher multiplier value than in the case of the existing structure. In scenario

A2, the retrofitted structure is able to avoid progressive collapse and at the same time was characterised by little damage, as low drift values were reached. A lower increase of structural performance was observed for scenario A1 where shear failures are observed for α values just above 100% *i.e.*, $\alpha = 101.64$, yet achieving structural robustness under the considered design loads. In this case, however, the activation of the alternative load path required large displacements, *i.e.*, exceeded 10% of vertical drift, corresponding to a damage level significantly greater than in the previous scenario.

Figure 7: Impact of retrofit measure on structural robustness: (a) scenario A1, (b) scenario A2.

6 CONCLUSIONS

In this study, the structural capacity of RC framed structure through a multi-hazard approach was investigated. The impact of a retrofit measure, by the application of Carbon Fibre Reinforced Polymer (CFRP), on structural robustness was assessed. Non-linear static analyses were carried out to evaluate the structure's seismic capacity and its resistance to progressive collapse. The results of the analyses showed the need for retrofitting in order to eliminate brittle failures and to increase the structural capacity. The study also provided some insights into the methodologies for progressive collapse analysis using non-linear static procedures. Three Approaches (*i.e.*, A, B and C) were investigated and compared with the results of non-linear dynamic analysis previously performed on the same case study structure. The following conclusions can be drawn: (i) among the alternative options for progressive collapse resistance assessment, a more realistic estimate of the dynamic amplification factor was obtained with Approach B; (ii) the seismic safety and structural robustness are limited by premature brittle failures and (iii) the use of CFRP as a retrofit measure was efficient for the case study structure, leading to the removal of all the shear failures due to the seismic action. On the other hand, the introduction of this retrofit measure allows obtaining a positive result also in terms of structural robustness.

Keywords: Lateral bracing system, Seismic design, Stochastic optimization, Tall building, Topology optimization.

Abstract. *It is generally presumed that the design of tall buildings is mainly dictated by wind loads rather than seismic actions because of the high flexibility and, therefore, long natural periods. However, slender buildings exhibit a complex dynamic behavior, and the involvement of higher modes can result in higher flexural and shear demands than expected. Overlooking the importance of strength, stiffness, and stability requirements in seismic design of tall buildings can thus lead to excessive damage, large residual deformations, and even failure. In this regard, since pure rigid frames alone are not sufficient to withstand lateral loads, as those due to earthquakes, bracing systems are often introduced to stiffen the steel frameworks of tall buildings. The design of lateral bracing systems, in turn, calls for the selection of a suitable pattern for the diagonals arrangement, which is commonly performed through trial-and-error procedures that can require many iteration cycles. It is too evident that this approach does not neither ensure the convergence towards a design solution able to fulfill all requirements, nor the achievement of an optimal solution that minimizes the consumption of structural material and thus the total construction costs. In this context, topology optimization might represent an effective tool for improving the design of tall buildings under earthquake. Therefore, a topology optimization methodology is here presented to support the selection of the most effective design solution for the lateral bracing systems of tall buildings, in such a way to meet minimum weight requirement while ensuring the highest structural performance. Specifically, a density-based approach is adopted to establish an optimization design procedure able to generate optimal lateral-resisting systems for tall buildings subjected to earthquakes. The optimum design is formulated in terms of minimum compliance, also to facilitate the comparison of the material distribution results with those already available in the literature. Numerical results presented in this work are concerned with two-dimensional case studies, which are envisioned as part of realistic tall buildings.*

1 INTRODUCTION

The introduction of automated optimization approaches has demonstrated great potential in assisting designers to achieve more efficient and advanced structural systems than those obtained using traditional iterative procedures. Specifically, topology optimization has attracted significant attention in the last decades as a robust computational tool for the identification of high-performing design solutions at reduced material consumption. Efficiency and effectiveness of topology optimization for defining bracing systems in multi-story buildings has been widely demonstrated in recent research works, most of which refer to wind loading within deterministic frameworks [1–5].

Although interesting results have been successfully achieved under static loading conditions, slender buildings exhibit a complex dynamic behavior where the involvement of higher modes can result in high flexural and shear demands. To this end, a great effort has been devoted to incorporate the topology optimization problem in a dynamic setting. Previous attempts targeted at enhancing the dynamic performance of structural systems through topology optimization have addressed the maximization of the natural eigenfrequencies of structures under free vibration [6–9] and the minimization of the dynamic compliance [10–12]. Because element-wise design variables operate on both stiffness and self-mass of the continuum domain, the mitigation of the overall dynamic response can be properly performed within a topological optimization approach via density-based formulations. However, it is easy to observe that optimizing the topology of large-scale models, as the case of tall buildings, inevitably involves a huge number of degrees of freedom. Hence, the limitations associated with the use of computationally expensive finite element models have led recently to the implementation of model reduction techniques based on modal decomposition methods [13–15]. In dynamic topology optimization problems, the seismic ground motion is usually modeled as stochastic process using the random vibration theory. In most of the existing works, seismic loading conditions are commonly simulated using a stationary Gaussian-type stochastic excitation whereas the design criterion is concerned with the compliance minimization [16–18] or the strain energy minimization [19].

This paper presents a computational framework for the minimization of the dynamic compliance in linear elastic multi-story buildings subjected to seismic ground motion. The optimization procedure integrates the random vibration theory together with the Solid Isotropic Material with Penalization (SIMP) technique whereas a gradient-based optimizer is employed for updating the design variables. Particularly, the use of the random vibration theory offers several advantages as compared to traditional time-history analyses since it allows to perform iterative optimization procedures at affordable computational cost. Compared to response analysis based on integration schemes in the time domain, in fact, this allows to speed up the optimization routines while accurately identifying the stochastic features of the seismic behavior of the building without performing time consuming Monte Carlo simulations. Finally, numerical examples are presented to demonstrate the influence of the mass modeling on the final topologies. The applicability of the formulation within topology optimization procedures as well as stability and effectiveness of the proposed approach in finding the optimum solutions are discussed with reference to a paradigmatic case study. Mesh independent solutions are monitored by operating a gradual refinement of the mesh structure over the design domain.

2 OPTIMUM DESIGN UNDER DETERMINISTIC CONDITIONS

This work is meant to optimize the lateral loading resisting systems for seismically excited large structures by means of topology optimization. For a better understanding of the optimiza-

tion problem, the topology optimization problem in static and dynamic settings are sequentially discussed henceforth.

For a linear elastic structure with a continuous domain discretized into n_d degrees of freedom and n_f finite elements, the most common topology optimization problem formulation in case of static loads aims at minimizing the compliance of the structural system under volume constraints, that is:

$$\begin{aligned} \min_{\boldsymbol{\rho}} \{ & \mathbf{u}^\top \mathbf{K} \mathbf{u} \} \\ \text{s.t.} & \\ & \sum_{e=1}^{n_f} V_e = V_{max} \\ & \boldsymbol{\rho}_\ell \leq \boldsymbol{\rho} \leq \boldsymbol{\rho}_u, \end{aligned} \quad (1)$$

where V_e is the volume of the generic finite element e within the meshed domain whereas $\boldsymbol{\rho} = \{d_1 \dots \rho_e \dots \rho_{n_f}\}$ represents the set of design variables with lower and upper bounds $\boldsymbol{\rho}_\ell$ and $\boldsymbol{\rho}_u$, respectively. Moreover, \mathbf{K} and \mathbf{u} are global stiffness matrix and static displacements vector, respectively. The constrain in Eq. (1) ensures that the volume of the final optimal solution does not exceed a threshold value equal to V_{max} .

In order to formulate the topology optimization for dynamic problems, a linear viscous elastic structure is assumed according to the Rayleigh damping model:

$$\mathbf{C} = a_0 \mathbf{M} + a_1 \mathbf{K}, \quad (2)$$

where \mathbf{M} is the constant global mass matrix whereas a_0 and a_1 are two positive constants calculated by imposing that the damping ratio ξ_s is the same for the first two modes of the structure. Therefore, the following relationships hold:

$$a_0 = \xi_s \frac{2\omega_1\omega_2}{\omega_1 + \omega_2}, \quad (3a)$$

$$a_1 = \xi_s \frac{2}{\omega_1 + \omega_2}, \quad (3b)$$

where ω_1 and ω_2 are the first two circular natural frequencies of the structure. If the structural system is subjected to a seismic ground acceleration \ddot{u}_g within the time window $[0, t_f]$, then the motion equation reads:

$$\ddot{\mathbf{u}} + \mathbf{M}^{-1} \mathbf{C} \dot{\mathbf{u}} + \mathbf{M}^{-1} \mathbf{K} \mathbf{u} = -\mathbf{r} \ddot{u}_g, \quad (4)$$

where \mathbf{u} are now the dynamic displacements of the structure, \mathbf{r} is the incidence vector and the dots indicate the derivative with respect to time. Formally, the statement of the topology optimization problem for dynamical systems can thus be expressed by rearranging the static compliance problem in Equation (1) as follows:

$$\begin{aligned} \min_{\boldsymbol{\rho}} \left\{ \int_0^{t_f} \mathbf{u}^\top \mathbf{K} \mathbf{u} dt \right\} \\ \text{s.t.} & \\ & \sum_{e=1}^{n_f} V_e = V_{max} \\ & \boldsymbol{\rho}_\ell \leq \boldsymbol{\rho} \leq \boldsymbol{\rho}_u. \end{aligned} \quad (5)$$

3 OPTIMUM DESIGN FOR STOCHASTIC SEISMIC LOADING

The topology optimization problem for structures subjected to stationary stochastic seismic loading is now discussed. The seismic ground motion model is a filtered white Gaussian noise, and the structural system dynamics is described using the state-space representation. Once the covariance matrix of the stochastic response is obtained, the topology optimization problem is presented.

3.1 Stochastic seismic excitation model

Random vibration theory allows to assess the probabilistic response of dynamical systems under random dynamic loads without the need of performing extensive Monte Carlo simulations based on direct integration of the motion equations. This makes random vibration theory especially attractive for topology optimization of large structures under dynamic loads characterized by inherent randomness. Therefore, the seismic ground motion \ddot{u}_g is herein modeled as a stationary filtered white Gaussian noise through the Clough-Penzien filter as follows:

$$\ddot{u}_g = \mathbf{a}_p^\top \mathbf{z}_p, \quad (6a)$$

$$\dot{\mathbf{z}}_p = \mathbf{D}_p \mathbf{z}_p + \mathbf{v}_p W, \quad (6b)$$

where

$$\mathbf{a}_p = \{-\omega_p^2 \quad -2\xi_p\omega_p \quad \omega_k^2 \quad 2\xi_k\omega_k\}^\top, \quad (7a)$$

$$\mathbf{z}_p = \{u_p \quad \dot{u}_p \quad u_k \quad \dot{u}_k\}^\top, \quad (7b)$$

$$\mathbf{D}_p = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -\omega_p^2 & -2\xi_p\omega_p & \omega_k^2 & 2\xi_k\omega_k \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -\omega_k^2 & -2\xi_k\omega_k \end{bmatrix}, \quad (7c)$$

$$\mathbf{v}_p = \{0 \quad 0 \quad 0 \quad -1\}^\top. \quad (7d)$$

where ω_p and ξ_p , ω_k and ξ_k are the filter parameters whereas W is a zero-mean white Gaussian noise having constant power spectral density S_0 . It is evaluated as function of the peak ground acceleration \ddot{u}_g^{max} according to the following relationship:

$$S_0 = \frac{(\ddot{u}_g^{max})^2}{\gamma^2 \left[\pi \omega_k \left(2\xi_k + \frac{1}{2\xi_k} \right) \right]}, \quad (8)$$

where $\gamma = 2.8$ denotes the peak factor, see for instance Liu et al. [20].

3.2 Covariance analysis

By assembling the equation of motion in Eq. (4) and the filter equation in Eq. (6), the state-space representation of the overall dynamics is obtained as follows:

$$\underbrace{\begin{Bmatrix} \dot{\mathbf{z}}_s \\ \dot{\mathbf{z}}_p \end{Bmatrix}}_{\dot{\mathbf{z}}} = \underbrace{\begin{bmatrix} \mathbf{A}_s & \mathbf{H}_p \\ \mathbf{0}_{4 \times 2n_d} & \mathbf{D}_p \end{bmatrix}}_{\mathbf{A}} \underbrace{\begin{Bmatrix} \mathbf{z}_s \\ \mathbf{z}_p \end{Bmatrix}}_{\mathbf{z}} + \underbrace{\begin{Bmatrix} \mathbf{0}_{2n_d \times 1} \\ \mathbf{v}_p W \end{Bmatrix}}_{\mathbf{f}}, \quad (9)$$

where

$$\mathbf{z}_s = \{\mathbf{u} \quad \dot{\mathbf{u}}\}^\top, \quad (10)$$

$$\mathbf{A}_s = \begin{bmatrix} \mathbf{0}_{n_d} & \mathbf{I}_{n_d} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C} \end{bmatrix}, \quad (11)$$

$$\mathbf{H}_p = [\mathbf{0}_{n_d \times 4} \quad -\mathbf{r}\mathbf{a}_p^\top]^\top, \quad (12)$$

while $\mathbf{0}$ is a (square or rectangular) null matrix or vector and \mathbf{I} is the (square) identity matrix, respectively (their size is explicated in the corresponding subscripts, where a single number is used for a square matrix). Given this state-space representation, the response covariance matrix of the resulting linear time-invariant system is defined as follows:

$$\mathbf{R} = \mathbb{E}[\mathbf{z}\mathbf{z}^\top] = \mathbb{E}\left[\begin{Bmatrix} \mathbf{z}_s \\ \mathbf{z}_p \end{Bmatrix} \begin{Bmatrix} \mathbf{z}_s & \mathbf{z}_p \end{Bmatrix}\right] = \begin{bmatrix} \mathbf{R}_{\mathbf{z}_s\mathbf{z}_s} & \mathbf{R}_{\mathbf{z}_s\mathbf{z}_p} \\ \mathbf{R}_{\mathbf{z}_p\mathbf{z}_s} & \mathbf{R}_{\mathbf{z}_p\mathbf{z}_p} \end{bmatrix}, \quad (13)$$

where

$$\mathbf{R}_{\mathbf{z}_s\mathbf{z}_s} = \begin{bmatrix} \mathbf{R}_{\mathbf{uu}} & \mathbf{R}_{\mathbf{u}\dot{\mathbf{u}}} \\ \mathbf{R}_{\dot{\mathbf{u}}\mathbf{u}} & \mathbf{R}_{\dot{\mathbf{u}}\dot{\mathbf{u}}} \end{bmatrix}. \quad (14)$$

The matrix \mathbf{R} , in turn, is the solution of the Lyapunov equation in stationary conditions, which reads:

$$\mathbf{A}\mathbf{R} + \mathbf{R}\mathbf{A}^\top + \mathbf{B} = \mathbf{0}_{2n_d+4 \times 2n_d+4}, \quad (15)$$

where \mathbf{B} is a matrix whose elements are equal to zero except that the element whose index is $(2n_d + 4, 2n_d + 4)$, which is equal to $2\pi S_0$.

3.3 Optimum design under stochastic seismic loads

By applying the mean value operator $\mathbb{E}[\cdot]$ to the objective function \mathcal{F} of the optimization problem formulated in Eq. (5), it can be found that:

$$\mathbb{E}[\mathcal{F}] = \mathbb{E}\left[\int_0^T \mathbf{u}^\top \mathbf{K} \mathbf{u} dt\right] = \int_0^T \mathbf{r}^\top (\mathbf{K} \otimes \mathbf{R}_{\mathbf{uu}}) \mathbf{r} dt, \quad (16)$$

where \otimes is the term-by-term product and $\mathbf{R}_{\mathbf{uu}}$ is the covariance matrix of the structural displacements (i.e., the square block of size $n_d \times n_d$ of the matrix \mathbf{R} in Eq. (14) whose elements index lies between 1 and n_d). Hence, by recalling that a stationary ground motion is here assumed, the topology optimization problem in Eq. (5) can be simplified as follows:

$$\begin{aligned} & \min_{\boldsymbol{\rho}} \{\mathbf{r}^\top (\mathbf{K} \otimes \mathbf{R}_{\mathbf{uu}}) \mathbf{r}\} \\ & \text{s.t.} \\ & \sum_{e=1}^{n_f} V_e = V_{max} \\ & \boldsymbol{\rho}_\ell \leq \boldsymbol{\rho} \leq \boldsymbol{\rho}_u \end{aligned} \quad (17)$$

4 COMPUTATIONAL ISSUES

4.1 Topology design via Solid Isotropic Material with Penalization

The Solid Isotropic Material with Penalization (SIMP) approach is adopted in this work in order to find efficiently the optimal solution for the topology optimization problem formulated in Eq. 17. The computational procedure starts with a spatial discretization of the continuum design domain. The SIMP approach [21] is thus performed by assuming that the design variable is constant over the finite element with a resulting uniform distribution of the structural material. The mechanical properties of each element are determined using a heuristic power-law interpolation that relates the element-wise design variable with the element elastic properties as follows:

$$E_e(\rho_e) = \rho_e^p E_0 \text{ with } \rho_{min} \leq \rho_e(d_j) \leq 1, \quad (18)$$

where E_0 is the elastic modulus of the base material and ρ_{min} is a non-zero minimum value for $\rho_e(d_j)$ that serves at preventing the singularity of the stiffness matrix. A coefficient $p > 1$ is introduced to penalize the presence of intermediate densities in the relaxed setting and steer the solution to discrete integer values (i.e., black-and-white digital image).

It is well recognized that topology optimization problems are especially sensitive to numerical instabilities, which are related to the possible non-existence/non-uniqueness of the optimal solution as well as to the lack of convergence, thereby resulting in some anomalies into the final design. The presence of checkerboarding, mesh dependence and local minima makes the interpretation of the optimal layout unfeasible and should be avoided by adopting a proper regularization scheme. To circumvent the occurrence of such problems, the density-filter proposed in [22] is adopted in the present work. It relies on the convolution product between a filter kernel and the design density vector, which leads to:

$$\rho_e(d_j) = \frac{\sum_{j \in \mathcal{N}_e} H_{ej} d_j}{\sum_{j \in \mathcal{N}_e} H_{ej}}, \quad (19)$$

where H_{ej} are weighting functions defined through a linearly decaying function of fixed-length radius r_{min} . The linear density filter function modifies the densities of the element e to be a function of the design variable d_j and of its neighborhood \mathcal{N}_e .

Because the density variable is assumed to be constant over each finite element, the relationship in Eq. (18) can be implemented for the finite element stiffness matrix by simply scaling it before the global stiffness matrix is assembled. The finite element stiffness matrix is interpolated and expressed in terms of E_0 as follows:

$$\mathbf{K}_e(\rho_e) = E_e(\rho_e) \mathbf{K}_e^0 = \rho_e^p \mathbf{K}_e^0, \quad (20)$$

where \mathbf{K}_e^0 is the finite element stiffness matrix with unit elastic modulus. The adoption of the SIMP approach is particularly beneficial if implemented in iterative algorithms since it allows calculating the finite element stiffness matrices at the beginning of the procedure. For each loop, finite element stiffness matrices are simply updated using the fictitious elasticity modulus E_e and then assembled to solve for the system covariance matrix.

4.2 SENSITIVITY ANALYSIS

The derivative of the objective function f in Eq. (17) with respect to the design variable ρ_e is:

$$\frac{\partial f}{\partial \rho_e} = \mathbf{r}^\top \left(\frac{\partial \mathbf{K}}{\partial \rho_e} \otimes \mathbf{R}_{uu} \right) \mathbf{r} + \mathbf{r}^\top \left(\mathbf{K} \otimes \frac{\partial \mathbf{R}_{uu}}{\partial \rho_e} \right) \mathbf{r}. \quad (21)$$

For this preliminary study, a direct differentiation approach is adopted. The calculation of the derivatives $\partial \mathbf{R}_{uu} / \partial \rho_e$ requires the solution of the following associate stationary Lyapunov equation:

$$\mathbf{A} \frac{\partial \mathbf{R}}{\partial \rho_e} + \frac{\partial \mathbf{R}}{\partial \rho_e} \mathbf{A}^\top + \bar{\mathbf{B}} = \mathbf{0}_{2n_d+4 \times 2n_d+4} \text{ for } e = 1, \dots, n_f, \quad (22)$$

with

$$\bar{\mathbf{B}} = \frac{\partial \mathbf{A}}{\partial \rho_e} \mathbf{R} + \mathbf{R} \frac{\partial \mathbf{A}^\top}{\partial \rho_e}. \quad (23)$$

It is also noted that:

$$\frac{\partial \mathbf{A}}{\partial \rho_e} = \begin{bmatrix} \frac{\partial \mathbf{A}_s}{\partial \rho_e} & \mathbf{0}_{2n_d \times 4} \\ \mathbf{0}_{4 \times 2n_d} & \mathbf{0}_4 \end{bmatrix}, \quad (24)$$

in which

$$\frac{\partial \mathbf{A}_s}{\partial \rho_e} = \begin{bmatrix} \mathbf{0}_{n_d} & \mathbf{0}_{n_d} \\ \mathbf{M}^{-1} \frac{\partial \mathbf{M}}{\partial \rho_e} \mathbf{M}^{-1} \mathbf{K} - \mathbf{M}^{-1} \frac{\partial \mathbf{K}}{\partial \rho_e} & \mathbf{M}^{-1} \frac{\partial \mathbf{M}}{\partial \rho_e} \mathbf{M}^{-1} - \mathbf{M}^{-1} \frac{\partial \mathbf{C}}{\partial \rho_e} \end{bmatrix}. \quad (25)$$

The derivative of \mathbf{C} with respect to ρ_e is calculated as follows:

$$\frac{\partial \mathbf{C}}{\partial \rho_e} = \frac{\partial a_0}{\partial \rho_e} \mathbf{M} + a_0 \frac{\partial \mathbf{M}}{\partial \rho_e} + \frac{\partial a_1}{\partial \rho_e} \mathbf{K} + a_1 \frac{\partial \mathbf{K}}{\partial \rho_e}, \quad (26)$$

where

$$\frac{\partial a_0}{\partial \rho_e} = \frac{\partial a_0}{\partial \omega_1} \frac{\partial \omega_1}{\partial \rho_e} + \frac{\partial a_0}{\partial \omega_2} \frac{\partial \omega_2}{\partial \rho_e}, \quad (27a)$$

$$\frac{\partial a_1}{\partial \rho_e} = \frac{\partial a_1}{\partial \omega_1} \frac{\partial \omega_1}{\partial \rho_e} + \frac{\partial a_1}{\partial \omega_2} \frac{\partial \omega_2}{\partial \rho_e}. \quad (27b)$$

The derivatives of the constants a_0 and a_1 with respect to ρ_e are calculated as follows:

$$\frac{\partial a_0}{\partial \omega_1} = \frac{2\xi_s \omega_2^2}{(\omega_1 + \omega_2)^2}, \quad \frac{\partial a_0}{\partial \omega_2} = \frac{2\xi_s \omega_1^2}{(\omega_1 + \omega_2)^2}, \quad (28)$$

$$\frac{\partial a_1}{\partial \omega_1} = \frac{-2\xi_s}{(\omega_1 + \omega_2)^2}, \quad \frac{\partial a_1}{\partial \omega_2} = \frac{-2\xi_s}{(\omega_1 + \omega_2)^2}, \quad (29)$$

whereas

$$\frac{\partial \omega_1}{\partial \rho_e} = \frac{1}{2\omega_1} \frac{\partial \lambda_1}{\partial \rho_e}, \quad \frac{\partial \omega_2}{\partial \rho_e} = \frac{1}{2\omega_2} \frac{\partial \lambda_2}{\partial \rho_e} \quad (30)$$

are the derivatives of the first two circular natural frequencies of the structure. The terms λ_1 and λ_2 are the first two eigenvalues of the following eigenproblem:

$$\phi_k^\top \mathbf{K} \phi_k = \lambda_k \phi_k^\top \mathbf{M} \phi_k, \quad (31)$$

in which ϕ_k is the k th eigenvector. The derivatives of λ_1 and λ_2 with respect to ρ_e are evaluated as follows:

$$\frac{\partial \lambda_1}{\partial \rho_e} = \phi_1^\top \left[\frac{\partial \mathbf{K}}{\partial \rho_e} - \lambda_1 \frac{\partial \mathbf{M}}{\partial \rho_e} \right] \phi_1, \quad \frac{\partial \lambda_2}{\partial \rho_e} = \phi_2^\top \left[\frac{\partial \mathbf{K}}{\partial \rho_e} - \lambda_2 \frac{\partial \mathbf{M}}{\partial \rho_e} \right] \phi_2, \quad (32)$$

under the assumption of distinct real eigenvalues and the mass orthonormalization condition.

Finally, by virtue of the SIMP method, it is obtained that:

$$\frac{\partial \mathbf{K}}{\partial \rho_e} = \bigwedge_{e=1}^{n_f} \frac{\partial \mathbf{K}_e}{\partial \rho_e} = \bigwedge_{e=1}^{n_f} p \rho_e^{p-1} \mathbf{K}_{e,0}, \quad (33a)$$

$$\frac{\partial \mathbf{M}}{\partial \rho_e} = \bigwedge_{e=1}^{n_f} \frac{\partial \mathbf{M}_e}{\partial \rho_e} = \bigwedge_{e=1}^{n_f} q \rho_e^{q-1} \mathbf{M}_{e,0}, \quad (33b)$$

where \bigwedge stands for standard finite element assembly operator.

5 EFFECTS OF SEISMIC MASS MODELING ON FINAL TOPOLOGIES

In seismic topology design of structural systems, the dynamic load is design-dependent because the inertial load is function of position and value of the structural mass within the domain. In order to obtain objective, reliable, and feasible optimal solutions, a proper modeling of the seismic mass is, therefore, of primary importance and deserves a thorough understanding. Some examples are discussed in such a way to highlight the significance of the mass modeling assumptions on the final topologies.

The reference model is based on a two-dimensional domain with single bay and high equal to 5 m and 15 m, respectively. The inter-story height is equal to 5 m, thereby resulting in three levels along the building elevation. The floors are made of concrete decks and their mass is calculated considering dead and live loads equal to 7.0 kN/m² and 2.0 kN/m², respectively. The design domain is discretized using 4-node quadrilateral Lagrangian (Q4) elements with a uniform thickness equal to 0.15 m and a mesh size 0.25 m \times 0.25 m (which implies a total of 1,200 finite elements). The continuum domain is modeled using steel as building material, with elastic modulus $E_0 = 210$ GPa. The algorithm is executed with constant penalization factor $p = 3$, projection radius $r_{min} = 0.3$ m and initial volume fraction over the Q4 domain equal to 30%. The Rayleigh damping model is assumed with damping ratio equal to 5%. Fixed supports are considered at the base and a symmetry constraint with respect to the centerline is enforced. A seismic ground motion with $\ddot{u}_g^{max} = 0.3g$ is assumed, with $\xi_p = \xi_k = 0.6$, $\omega_p = 1.5$ rad/s and $\omega_k = 15$ rad/s.

A complete system is fully defined by combining the continuum domain with the discrete elements of the gravity load-bearing frame, as already proposed in previous works [2, 23]. The introduction of a non-designable secondary system improves the feasibility of the final solution (e.g., clearer identification of the working points, disappearance of small multiple horizontal elements) and makes the topological results independent from the direct application of the external load on the domain, whether it is static or dynamic. For a deeper understanding of the role of the secondary systems and symmetry constraints on optimal topologies of lateral resisting systems for tall buildings, the reader is referred to the work by Angelucci et al. [15].

For the seismic design of tall buildings, and multi-story buildings in general, the structural mass of the system \mathbf{M} can be decomposed into two contributions $\mathbf{M} = \mathbf{M}_f + \mathbf{M}_\Omega$, where \mathbf{M}_f is the seismic mass of the building components estimated by considering the floor tributary areas and \mathbf{M}_Ω is the mass of the designable lateral resisting system. Nevertheless, it is straightforward to recognize that, in multi-story buildings and especially for concrete slabs, the mass is primarily located at the floor levels and the lateral resisting system contributes only for a small fraction of the overall building mass. Since the seismic excitation produces inertial forces mostly associated with the tributary mass of the building \mathbf{M}_f , the introduction of the

floor mass within the optimizable domain is incorrect from a conceptual standpoint. During the optimization routines, in fact, the dynamic characteristics of the domain representing the lateral resisting system are iteratively updated according to the new material distribution and the inherent structural mass is partially removed. Additionally, it can be demonstrated that when the seismic mass is included in the designable domain, updating the mass arrangement at each iteration slows down the rate of convergence and compromises the stability of the whole topology optimization procedure. Therefore, it is required to allocate the tributary mass within a non-optimizable domain, which remains constant during the optimization routines and expediently relaxes the design-dependency of the tributary mass on the element variables (i.e., $\partial \mathbf{M}_f / \partial \rho_e$ is null). Moreover, since the weight of the bracing members is negligible compared to the mass of the story levels, it is possible to assume a massless optimizable domain in the seismic analysis, without any significant loss of accuracy. The structural mass is thus kept constant during the iterative process, and this allows to state that the final topologies are almost exclusively dependent on the stiffness properties of the continuum elements. Within the scope of this work, the tributary mass is located at each floor level in the horizontal direction only, provided that the dynamic excitation does not include external forces at the nodes in the vertical and rotational degrees of freedom.

Figure 1: Reference models and optimal topologies for different mass modelling: lumped mass at the floor diaphragms (a, b); distributed mass at story levels (c, d); lumped mass at master nodes (e, f).

In the analysis and design of tall buildings subjected to lateral loads, floor slabs are usually assumed to possess high in-plane stiffness, and the assumption of diaphragm constraints reflects quite well the real behavior. This assumption justifies the concentration of the structural mass in a single point at each floor as illustrated in Figure 1a, and allows to further reduce the degrees of freedom of the structural system, thereby simplifying the seismic analysis. However, in case of topology optimization, the introduction of a displacement constraint undermines the objectivity of the final solution because the rigidity/flexibility of the floor diaphragms has a significant influence on the building model. As illustrated in Figure 1b, the optimized layout shows a design-dependent topology, where the diagonal arrangement of the lateral resisting system is affected by the specific location of the tributary mass in the middle of each story level.

Since rigid diaphragm constraints lead to flawed solutions, the effects of floor deformability cannot be disregarded and a reasonable stiffness must be assigned to each floor. Figure 1c illustrates the designable and non-designable domains of the reference model, in which the tributary mass is uniformly distributed at the floor levels. The beams are discretized into smaller ele-

ments, which allows the mass nodes to be coincident with the interior joints of the quadrilateral mesh. The optimal layout presented in Figure 1d results in a K-brace arrangement at the top of the building, due to the development of inertial forces along the line. The top member, in fact, is needed to transfer the load along the bay between the far sided columns. Although correct from a topological standpoint, this solution is theoretically inaccurate since the presence of floor beams at each story level contributes to transmit gravity loads to the vertical members of the unbraced frame. The reference model is thus modified accordingly to reduce the tributary mass to a discrete number of master nodes of the floor system located at the intersections of the secondary system (extreme corners of the quadrilateral mesh in Figure 1e). The resulting topology in Figure 1f shows the optimal solution where theoretical concepts and modeling assumptions are both fulfilled.

Because inertial loads originate at master nodes of the secondary system only and assuming that the auxiliary perimeter framework is not included in the optimizable domain, the final topologies are independent from the master nodes definition. This allows to choose arbitrarily the secondary system bounding the continuum domain. Additionally, the distribution of the seismic mass at a discrete number of nodes suggests the adoption of a reduced-order model during the dynamic analysis of the structural system. Through static condensation, stiffness and mass matrices (and implicitly the damping matrix) of the complete system can be properly reduced to the degrees of freedom of the master nodes.

The demanding computational cost of the dynamic topology optimization process certainly benefits from the sub-structuring technique, where inversion and eigenanalysis of large-size matrices are generally involved. Without any loss of objectivity, the eigenvalue analysis can be performed on the reduced-order system since natural frequencies and modal shapes are defined at the master node locations only.

6 CASE STUDY

The topology optimization problem is solved next to define the lateral resisting system of a multi-story building subjected to ground motion excitation. Particularly, given a stationary-type support excitation described as filtered white Gaussian noise, the optimal material distribution is attained by minimizing the dynamic compliance in the continuum design domain under a volume constraint. The reference model is a regular multi-story building with height and width equal to 40 m and 20 m, respectively. The external skin of the building is split into four panels, such that each façade can be analyzed as a continuous optimizable design domain discretized by using Q4 elements with uniform thickness equal to 0.15 m. A two-dimensional case study is deemed accurate enough. The structure is idealized with fixed supports and symmetry constraints are imposed.

An auxiliary load-bearing framework bounding the continuum domain is designed with bay width and inter-story height equal to 5 m and 4 m, respectively. W8x21 steel cross-sections are preliminary designed to model columns and beams of the unbraced frame, which is considered as a non-designable domain during the optimization process. The frame members are discretized into smaller elements, so that the nodes of the beam-column elements (thick black lines in Figure 2) and those of the Q4 elements (grid area in Figure 2) coincide each other. This operation results in a continuous connection between the discrete frame and the continuum domain throughout height and width of the building. Floor slabs are placed every 4 m. The associated seismic mass is calculated considering gravity loads equal to 9.0 kN/m² and tributary influence areas. The floor mass is lumped at the master nodes at 5 locations for each floor level, corresponding to the intersection of floor beam and column lines (black nodes in Figure

2). The algorithm is executed once again with constant penalization factor $p = 3$, projection radius $r_{min} = 0.3$ m and initial volume fraction over the Q4 domain equal to 30%.

Figure 2: Schematic of the constitutive elements of the numerical model.

The topology optimization is first performed for the reference model with unit mesh size ($1 \text{ m} \times 1 \text{ m}$, resulting in 800 finite elements). The optimal topology is displayed in Figure 3b in terms of filtered design variables. Figure 3c shows the optimal layout obtained when refining the design domain using a mesh size equal to $0.5 \text{ m} \times 0.5 \text{ m}$ (total of 3,200 finite elements). The results clearly demonstrate that the optimal topologies are qualitatively the same, with the possible exception of major differences at the domain boundaries, which become gradually smoother with the mesh refinement. The material distribution within the design domain assumes a precise arrangement composed by two lateral columns and two pairs of full-width diagonal braces. The optimized domain is post-processed to physically appreciate the results of the topology optimization process and correctly identify the location of the working points of brace-to-brace and brace-to-column nodes. It is worth noticing here that the optimal topology does not include the presence of a secondary framed system (which is constituted by intermediate beams and columns), and thus it can be omitted from the final layout. The evolution of the optimal solution during the optimization routines is illustrated in Figure 4 by plotting objective function (dynamic compliance) and constraint function (material volume) values with respect to the number of iterations required until a tolerance of 1% is met (the filled circle marks the convergence). The efficiency of the topology optimization framework is confirmed by the steady convergence as well as the limited number of iterations.

7 CONCLUSIONS

The minimum compliance formulation for the topology optimization of large structures under seismic excitation has been discussed in this work. The huge computational effort required, even for the case of linear elastic systems, has made the adoption of classical time-history dynamic analyses prohibitive. To overcome this challenge and deal with the topology optimization of tall buildings under seismic loads, random vibration theory has been explored in this study. The well-posedness of the optimization problem has been ensured through the adoption of the SIMP approach. A sensitivity analysis of the objective function with respect to the ele-

Figure 3: Reference model of the $40\text{ m} \times 20\text{ m}$ tall building (a), optimal topologies for mesh sizes $1\text{ m} \times 1\text{ m}$ (b) and $0.5\text{ m} \times 0.5\text{ m}$ (c), post-processed refined layout (d).

Figure 4: Objective function (left) and constraint function (right) value for mesh size $1\text{ m} \times 1\text{ m}$.

ment design variables has been assessed analytically to foster the employment of gradient-based methods.

The present study has paid special attention to mass modeling techniques for tall buildings under earthquakes within topology optimization procedures. Numerical examples have been presented to validate the effects of preliminary theoretical assumptions on the final layouts. Finally, a paradigmatic case study has been discussed to demonstrate effectiveness and stability of the proposed framework in finding the optimum solutions. A gradually refined mesh process has been also presented to explore the efficiency of the optimization procedure in avoiding numerical mesh-dependency instabilities.

The findings presented here should be considered as a first attempt toward the development of more sophisticated dynamic formulations within topology optimization frameworks. Further improvements and extensions will be included in future works to identify optimal lateral resisting systems for multi-story buildings subjected to stochastic processes, where fully non-stationary models will be considered to simulate the seismic ground motion more accurately.

Abstract

The historical sites and monuments in Egypt are among the most important in the world and conserving this cultural heritage is crucial. The large damages observed in hundreds of monuments and in the Zoser Pyramid after the Cairo Earthquake in 1992 unveiled the fragility of the Egyptian heritage asset to seismic hazards. This paper aims to investigate the use of the innovative non-invasive vibration control device, the vibrating barrier (ViBa) as a potential strategy to mitigate the effects of the seismic action on the Zoser Pyramid. In this regard, a finite element model of the Zoser Pyramid and surrounding soil has been developed. A pertinent ground motion acceleration induced by the 1992 Cairo earthquake event has been simulated through spectral representation method with power spectral density function defined by seismological data available for Saqqara. Moreover, a reduced-order model is implemented to facilitate the design of the ViBa device. The efficiency of the ViBa is assessed by numerical simulation of the finite element model of the ViBa-Soil-Pyramid system. Results show an evident reduction of the acceleration and stresses on the Pyramid, especially in those areas where the damages have been observed.

Keywords: Vibrating Barriers, Zoser Pyramid, Soil-Structure Interaction.

1 INTRODUCTION

Egypt has an extensive cultural heritage, reaching back more than five thousand years, with a plethora of archaeological sites considered among the most important in the world. The archaeological site of Saqqara, located at a distance of about 20 km from Cairo city, is appraised as the world's most extensive burial ground with monuments of almost every period of ancient Egyptian civilization. In this area, the Step Pyramid of Djoser or Zoser's pyramid is located. It is therefore an important legacy of ancient construction to be preserved.

Although Egypt is a region of small to moderate magnitude earthquakes [1], several events that occurred in the area from the late 1980s, with two main events, the 1992 Cairo earthquake and the 1995 Gulf of Aqaba earthquake, partly damaged the Zoser pyramid that needed of an important restoration activity to avoid the risk of collapse leading to its closure to visitors for a long time [1]. Therefore, it becomes evident that the preservation and conservation of archaeological monuments and sites require unconventional and exceptional seismic analysis and design. Conventional seismic protection systems mainly based on strengthening techniques or local devices such as dampers or seismic isolators are based on structural invasive interventions whose application clearly might risk compromising the historical value of heritage structures such as the pyramid. Those techniques are generally applied to heritage structures as a repairing technique (as done to the Zoser pyramid) rather than as a preventive strategy to mitigate future seismic actions. Ancient monuments, therefore, are left generally unprotected from future catastrophic events due to the difficulty to protect them without altering their historical value.

In this paper, the novel non-invasive seismic passive control device [2] called Vibrating Barrier (ViBa) is proposed as a mean of protection for the Zoser Pyramid. The ViBa is a device buried in the soil and detached from the surrounding structure able to absorb a significant portion of the dynamic energy arising from the ground motion. It exploits the basic principle of the structure-soil-structure interaction introduced in the early 70's [3][4]. To date, several studies on the efficiency of the ViBa have been carried out to mitigate the seismic vulnerability of different structures: Cacciola et al. [5] investigated the potential of ViBa for the seismic protection of monopiled structures, Tombari et al. [6] considered ViBa to mitigate the seismic risk of a nuclear reactor, Cacciola et al. [7] and Andreozzi et al. [8] applied ViBa to control the seismic response of heritage buildings, while the ViBa device was used to protect a large urban area in Coronado et al. [9] as well as a cluster of buildings in Tombari et al. [10]. Therefore, to mitigate the seismic response of the Zoser pyramid, the ViBa device has to be properly designed. In this regard, due to the lack of ground motion records in the area, a stochastic approach following the Boore method [11], has been adopted to determine the power spectral density function of the ground motion at the bedrock underneath the Zoser pyramid. The model has been calibrated using the seismological parameters related to the Cairo 1992 earthquake [12]. The stochastic model has been then used as seismic input for the design of the ViBa device.

Furthermore, a sub-structuring method is proposed in the paper to reduce the large order of the complete system composed of Pyramid and soil and the ViBa. Following this approach, it is possible to optimize the ViBa to minimize the effect of the ground motion on selected-response parameters (e.g. displacement, stresses). Several configurations of ViBas are proposed and their impact on the seismic response of the Pyramid is computed employing a pertinent Monte Carlo Simulation. The efficiency of the ViBa is assessed in terms of mitigation of the peak acceleration of the top of the pyramid and Von Mises stresses over one of the areas that has been damaged during the 1992 Cairo Earthquake.

2 NUMERICAL MODELLING OF ZOSER PYRAMID

The Zoser pyramid is modelled in this study as a stepped solid structure (Figure 1a) with a rectangular base of about $108\text{ m} \times 120\text{ m}$ and a total height of about 63 m . Surveying with a 3D scanner has been carried on to determine the geometry of the Zoser pyramid. Soil investigations have been also conducted at the site. Specifically, samples from the stones inside the site were tested in the laboratory for determining the properties of the materials used in building the pyramid. Moreover, a borehole with a depth of 10 meters was dug to determine the soil properties in Saqqara. The total borehole was limestone or sandy limestone interspersed with layers of silt at the depth of the borehole. No groundwater has been observed during the borehole. Geometrical dimensions of the simplified geometry used in this study pertinent to North and West sections are reported in Figure 1b and 1c, respectively. The Pyramid is made of polished white limestone modelled as an isotropic linear material defined by the elastic modulus, $E_p = 45\text{ GPa}$, Poisson's ratio, $\nu_p = 0.25$ as well as unit density, ρ_p , of 2900 kg/m^3 . The position of the bed-rock has been determined from previous studies available in the literature [13], [14] and it is considered to be located at 35m depth. The soil stratum between the bedrock and the base of the pyramid is assumed homogeneous with a shear wave velocity of 3000 m/sec considering the site investigation undertaken in the first 10m . Material properties used to define the linear elastic behaviour of the soil and Pyramid are shown in Table 1.

Figure 1. Zoser Pyramid, (a) 3D view, (b) North and (c) West sections of the stepped Pyramid

Soil			Pyramid		
$\rho_s\text{ (kg/m}^3\text{)}$	$E_s\text{ (kPa)}$	ν_s	$\rho_p\text{ (kg/m}^3\text{)}$	$E_p\text{ (kPa)}$	ν_p
2200	45×10^6	0.25	2900	45×10^6	0.25

Table 1. Material properties for Soil and Pyramid

Numerical Finite Element models of the fixed-base Pyramid (Figure 2a) and of the full Pyramid-Soil system (Figure 2b) are created through the software SAP2000 by using 8-node elements. A large soil model with lateral free boundaries, 500m far away from each edge of the Pyramid, is considered to mitigate the spurious waves reflected back to the system. Fully fixed restraints are used on the bottom of the soil to simulate the rigid bedrock.

A modal analysis is first carried out for the fixed-base Pyramid model: the first mode, associated with its smallest width (Figure 3a) has a natural frequency of 14.6 Hz , while the second mode, associated with the largest width (Figure 3b) is characterized by the natural frequency of 14.95 Hz .

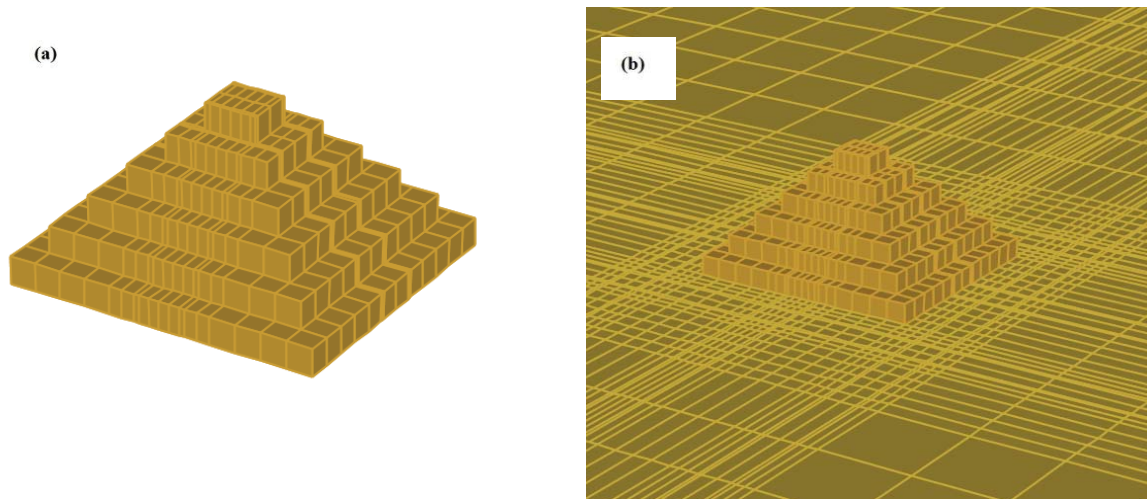

Figure 2. a) Mesh configuration of the fixed-base pyramid and b) soil-pyramid system

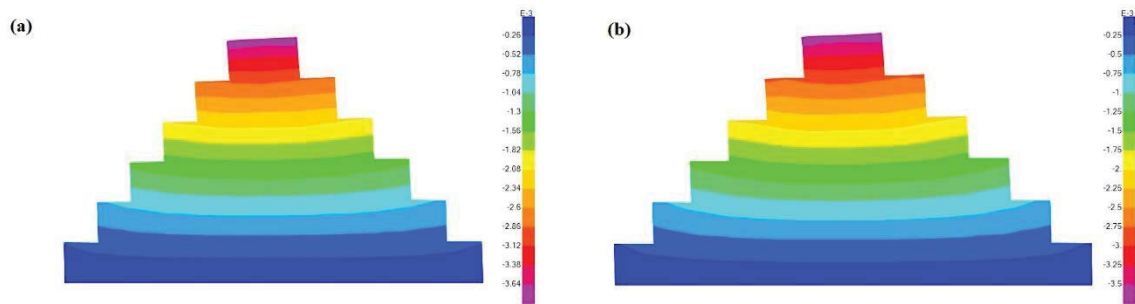

Figure 3. The amplitude of the modal vector for a) the first and b) the second mode of the Pyramid.

Successively, the modal analysis is carried out on the full Soil-Pyramid system to account for the soil-structure interaction effects: the first natural frequency of the pyramid is shifted from 14.6 Hz to 10.54 Hz, while the second natural frequency changed from 14.95 to 10.73 because of the soil flexibility (Figure 4a and b).

Figure 4. The amplitude of the modal vector for a) the first and b) the second mode of the soil-Pyramid system.

3 PROPOSED METHOD FOR THE DESIGN OF THE VIBRATING BARRIERS

To mitigate the seismic response of the Zoser Pyramid, the non-localised system denoted Vibrating Barrier is employed in this section. Figure 5 shows a potential implementation of the Vibrating Barrier to protect the Zoser pyramid.

Figure 5. A potential configuration of the Vibrating Barriers to protect the Zoser pyramid

For a selected configuration, the problem to design the ViBa is therefore reduced to determine the mechanical parameters of the devices so that relevant response quantities (e.g., stresses, accelerations) are reduced.

A reduced-order model capturing the ViBa(s)-Soil-Pyramid interaction is developed to reduce the computational complexity of the optimization problem used to design the ViBa mechanical parameters. Specifically, a sub-structuring method [15], determined in the frequency domain, is used to condensate the Soil-Pyramid system into complex-valued transfer functions and, to reduce the order of the full system to just 2 translational degrees of freedom related to the translational ViBa displacement, X_v and to the displacement, X_f , of its box foundation.

Although the design method proposed in the next section is developed by considering one ViBa device, the approach can be easily extended for any number of ViBas and any possible configuration and location, by adopting the superposition principle.

3.1 A Multi-Step Approach to Evaluate the ViBa-Soil-Structure Interaction

The proposed method consists to subdivide the full domain into 2 partitions: the first subdomain represents the Soil-Pyramid system with any rigid excavations where the ViBas will be installed (Figure 6a); the second subdomain comprises the internal structure of the ViBa contained by the rigid box-foundation resting on a flexible soil medium modelled through soil-foundation impedance functions (Figure 6b). In the design approach proposed in this paper, only the translational degrees of freedom of the ViBa and its foundation, are considered. A 4-step analysis is devised as follows: i) a steady-state analysis of the first subdomain subjected to bedrock ground motion displacement, $U_b(\omega)$, modelled as unitary constant function to derive the foundation input motion of the rigid excavation, $U_{FIM}^V(\omega)$, as well as the normalized displacement in a relevant point of the Pyramid, $U_p^{(1)}(\omega)$; ii) a steady-state analysis of the first subdomain where a unitary displacement, $X_0(\omega)$, is applied to the centre of the rigidity of the excavation (Figure 7) to derive the displacement in a relevant point of the Pyramid, $U_p^{(2)}(\omega)$, as well as the complex-valued soil-foundation impedance, $\tilde{K}_h(\omega)$; iii) an inertial analysis of the ViBa-Soil subdomain where the soil is modelled through the impedance $\tilde{K}_h(\omega)$; and iv)

recovery of the complete displacement of the relevant point of the Pyramid by adopting the superposition principle. It is worth noting the control parameter of the Pyramid can be represented not just in terms of displacements but even stresses, strains, internal forces, or any relevant measure, without compromising the generality of the presented method.

Figure 6. Sub-structuring method: a) Soil-Pyramid System; and b) ViBa-Soil System

Figure 7. Steady-state analysis to condensate the Soil-Pyramid system into transfer functions

3.2 Reduced-Order ViBa-Soil-Pyramid Model Governing Equations

After computing the various complex-valued transfer functions, $U_p^{(1)}(\omega)$ in step i) and $U_p^{(2)}(\omega)$ in step ii), the design of the optimal ViBa parameters is performed on the reduced-order model of step iii) and iv) in which an extremely fast optimization analysis can be implemented. Considering the mechanical system of Figure 6b, the governing equations of the reduced-order model can be written in the frequency domain as follows:

$$\begin{cases} \tilde{K}_V X_V - \tilde{K}_V X_f - \omega^2 M_V X_V = 0 \\ (\tilde{K}_h + \tilde{K}_V) X_f - \tilde{K}_V X_V - \omega^2 M_0 X_f = \tilde{K}_h U_{FIM}^V \end{cases} \quad (1)$$

where the dependencies from the frequency ω have been omitted. Eq. (1) represents a system of algebraic equations in which X_V and X_f , are the unknown ViBa's displacement and foundation displacement, respectively, whilst \tilde{K}_V is the ViBa parameter to be optimized. To perform the optimal design of the ViBa, the complete displacement of the relevant point of the Pyramid, U_p , must be computed by superposition in step iv), as follows:

$$U_p(\omega) = \left(U_p^{(1)}(\omega) + \frac{U_p^{(2)}(\omega)}{X_0(\omega)} X_f(\omega) \right) U_g(\omega) \quad (2)$$

where $U_g(\omega)$ is the Fourier transform of the earthquake ground motion displacement applied at the bedrock. It is worth mentioning that in Eq. (2), the terms within the brackets, $H(\omega) =$

$\left(U_p^{(1)}(\omega) + U_p^{(2)}(\omega) X_f(\omega)/X_0(\omega) \right)$ represents the non-dimensional transfer function $H(\omega) = \frac{U_p}{U_g}$ between the response output of the Pyramid and the input ground motion at the bedrock.

Because of the derivation rule in the frequency domain, $H(\omega) = \frac{U_p}{U_g} = \frac{\dot{U}_p}{\dot{U}_g} = \frac{\ddot{U}_p}{\ddot{U}_g}$.

3.3 Optimal design of the ViBa

The design of the ViBa, once the mass, M_V , is assigned, involves the determination of the optimal value of the internal device, \tilde{K}_V , which can be expressed as $\tilde{K}_V = K_V(1 + i\eta_V)$ with i as an imaginary unit, K_V , real-valued stiffness of the internal device and, η_V as its loss factor.

Therefore, Eq. (2) can be re-written as

$$U_p(\omega, \alpha) = H(\omega, \alpha)U_g(\omega) \quad (3)$$

in which the parameters to be optimised, listed in the design vector $\alpha = [K_V, \eta_V]$, are made explicit in the transfer function. The optimization approach adopted in this paper involves the mitigation of the stochastic response of the Pyramid. Considering a ground motion acceleration modelled as Gaussian zero-mean stochastic process with zero mean, fully defined by the knowledge of the power spectral density function $PSD(\omega)$, it becomes straightforward to extend Eq. (3) by using the Random Vibration Theory, as follows:

$$G(\omega, \alpha) = H^*(\omega, \alpha)PSD(\omega)H(\omega, \alpha) \quad (4)$$

where $G(\omega, \alpha)$ is the PSD function in terms of acceleration at the reference point of the Pyramid and $*$ is the complex conjugate operator.

The largest value of the response in terms of acceleration, $\ddot{u}_{p,ViBa}^{max}$, of the reference point of the Pyramid protected by the ViBa technology, can be derived from Eq. (4) in approximated fashion [8] as:

$$\ddot{u}_{p,ViBa}^{max}(\alpha) \cong \eta_p \sqrt{\int_0^\infty G(\omega, \alpha) d\omega} = \eta_p \sqrt{\lambda_0(\alpha)} \quad (5)$$

where λ_0 is the zeroth-order spectral moment and η_p is the peak factor.

The objective function of the optimization approach determined on the Reduced Order Model (ROM) is defined as follows:

$$\min_{\alpha > 0} (\ddot{u}_{p,ViBa}^{max}(\alpha)) \quad (6)$$

Clearly, other response parameters can be used such as the maximum stress in a specific element or the top displacement. The efficiency of the ViBa device is then measured through the reduction factor in terms of acceleration, $R_{\ddot{u}_p}^{ROM}$, as follows:

$$R_{\ddot{u}_p}^{ROM}(\alpha) = \frac{|\ddot{u}_p^{max} - \ddot{u}_{p,ViBa}^{max}(\alpha)|}{\ddot{u}_p^{max}(\alpha)} \times 100 \quad (7)$$

Therefore, the optimization problem can be written as minimization of the objective function which can be solved with standard iterative algorithms for constrained optimization, such as the derivative-free method [16].

4 NUMERICAL RESULTS

In this study, the method proposed in Section 3 is applied to mitigate the seismic response of the Zoser Pyramid. Three ViBa configurations (hereinafter called, Case 1-2-3), oriented in the North-South (N-S) direction as depicted in Figure 8, are proposed.

Case 1 is represented by one ViBa on the Southern side of the Pyramid realized in a rigid excavation of size 20 m x 20 m x 20 m; in Case 2, one ViBa for each side of the Pyramid is considered; Case 3 considers one ViBa for each side of the Pyramid as in Case 2 but placed inside a larger rigid excavation of 60 m long, 20 wide and 20 m deep. Furthermore, in Case 3, each box-foundation contains three internal vibrating masses supposed to oscillate synchronously.

In every configuration, the excavations where the ViBas are located, are realized at a minimum distance of 15 m from each side of the Pyramid. The box foundation of the ViBa is made of four concrete retaining walls and a matt foundation. The reference point used for the optimization procedure of Section 3, indicated by point 'p' in Figure 8, is selected at the top of the Pyramid. Moreover, an area of interest is to calculate the stresses induced by the seismic event, denoted as representative element (RE) in Figure 8. Because of the damages that the Zoser Pyramid experienced over that area during the 1992 Cairo Earthquake [12], RE is employed on the edge of the pyramid.

Figure 8. Top view of ViBa configurations for Case 1-2-3

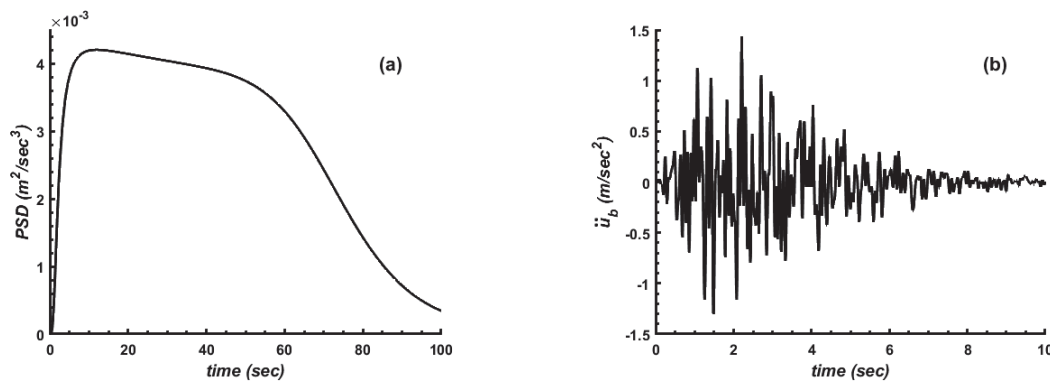

Figure 9. (a) the unilateral PSD function at the bedrock underneath the Zoser Pyramid, (b) a sample of the acceleration time series obtained by the spectral representation method

The unilateral PSD function (Figure 9a) at the bedrock, $PSD(\omega)$, determined using the Boore method [11] and the relevant seismological parameters determined in [12], is used in Eq. (4) of the proposed approach to perform the optimal design of the ViBa. Furthermore, the same PSD function is also used to generate 30 realizations of the time-history acceleration functions using the spectral representation method; these realizations are used to calculate the statistics of the seismic response of the Pyramid before and after being protected by the ViBa technology. A random sample is shown in Figure 9b for illustration purposes.

For each case, the proposed 4-step approach is performed. Results of the steady-state analyses of step i), $U_p^{(1)}(\omega)$, are shown in Figure 10a, while results from step ii), $U_p^{(2)}(\omega)$, are shown in Figure 10b. Also, in step ii) the soil-foundation impedance, $K_h(\omega)$, of Eq. (1) can be computed. In this paper, the static values, $K_h(0)=4320$ GN/m (Case 1-2) and $K_h(0)=8077$ GN/m (Case 3) are used.

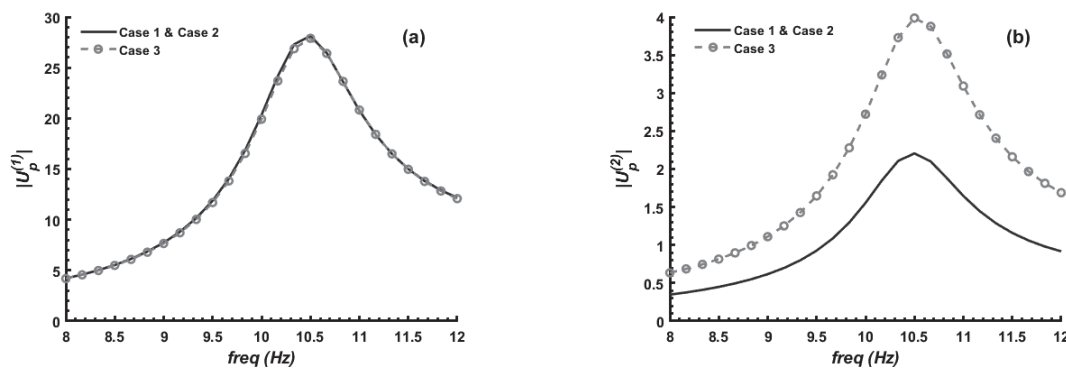

Figure 10. Results of the steady-state analysis in terms of a) $|U_p^{(1)}|$ and b) $|U_p^{(2)}|$ for Case 1-2-3

The optimization problem of Eq. (7) is performed for the 3 cases by considering the total mass of the ViBa devices, M_V , equal to 80% of the Pyramid mass, and by fixing the loss factor, η_V , to 0.1. To minimize the computational effort, a limited range of frequencies from 8 to 12 Hz, hence, around the first natural frequency of the Pyramid, is considered. Optimal parameters computed by using the proposed approach are reported in Table 2.

Case	ViBa 1			ViBa 2		
	M_V/M_p	K_V GN/m	$\eta_{n,V}$	M_V/M_p	K_V GN/m	$\eta_{n,V}$
1	0.8	7190.6	0.1	-	-	-
2	0.4	2394	0.1	0.4	1696	0.1
3	0.4	1883.4	0.1	0.3	1464.2	0.1

Table 2. Optimal design of the ViBa for Case 1-2-3.

Figure 11 shows the results of steady-state analyses in terms of power spectral density functions, $G(\omega) = G(\omega, \hat{a})$ for Case 1-2-3, where \hat{a} is the optimal design vector listing the parameters of Table 2. Results, obtained from the full FEM and ROM, are also depicted for a visual comparison. The reduced-order model with just 2 degrees of freedom captures satisfactorily the response of the full ViBa-Soil-Pyramid system. Furthermore, a comparison with the existing scenario without ViBa is reported with a grey dashed line. It can be seen that the ViBa technology greatly modifies the Pyramid's response by decreasing the total energy experienced by the Pyramid.

Figure 11. Steady-state response of the pyramid for different cases.

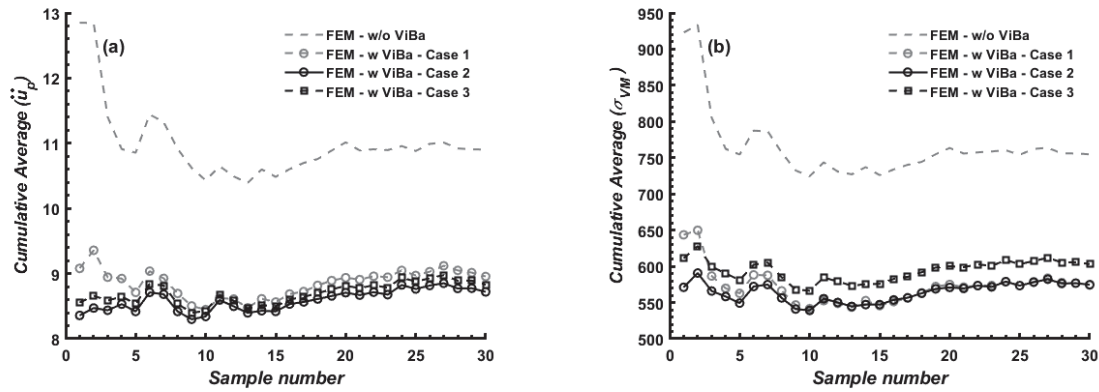

Figure 12. Cumulative average of acceleration recorded at the top of the pyramid (a) and Von Mises Stress (b) recorded at the specific element in respect of the number of realizations.

To assess the effects of the mitigation induced by the ViBa technology on the seismic response of the Pyramid, a modal time-history Monte Carlo Simulation (MCS) is performed by using the $n=30$ generated realizations. The three Cases are compared to the existing scenario of the Zoser Pyramid with no seismic protection. Figure 12 shows the convergence of the results in terms of average acceleration and Von Mises stress at the control point and reference element indicated in Figure 8.

In Figure 13, the mitigating effect of the ViBa technology against the existing scenario without the protection of the ViBa, is shown as acceleration and Von Mises time history functions for Case 1-2-3 for a randomly generated sample.

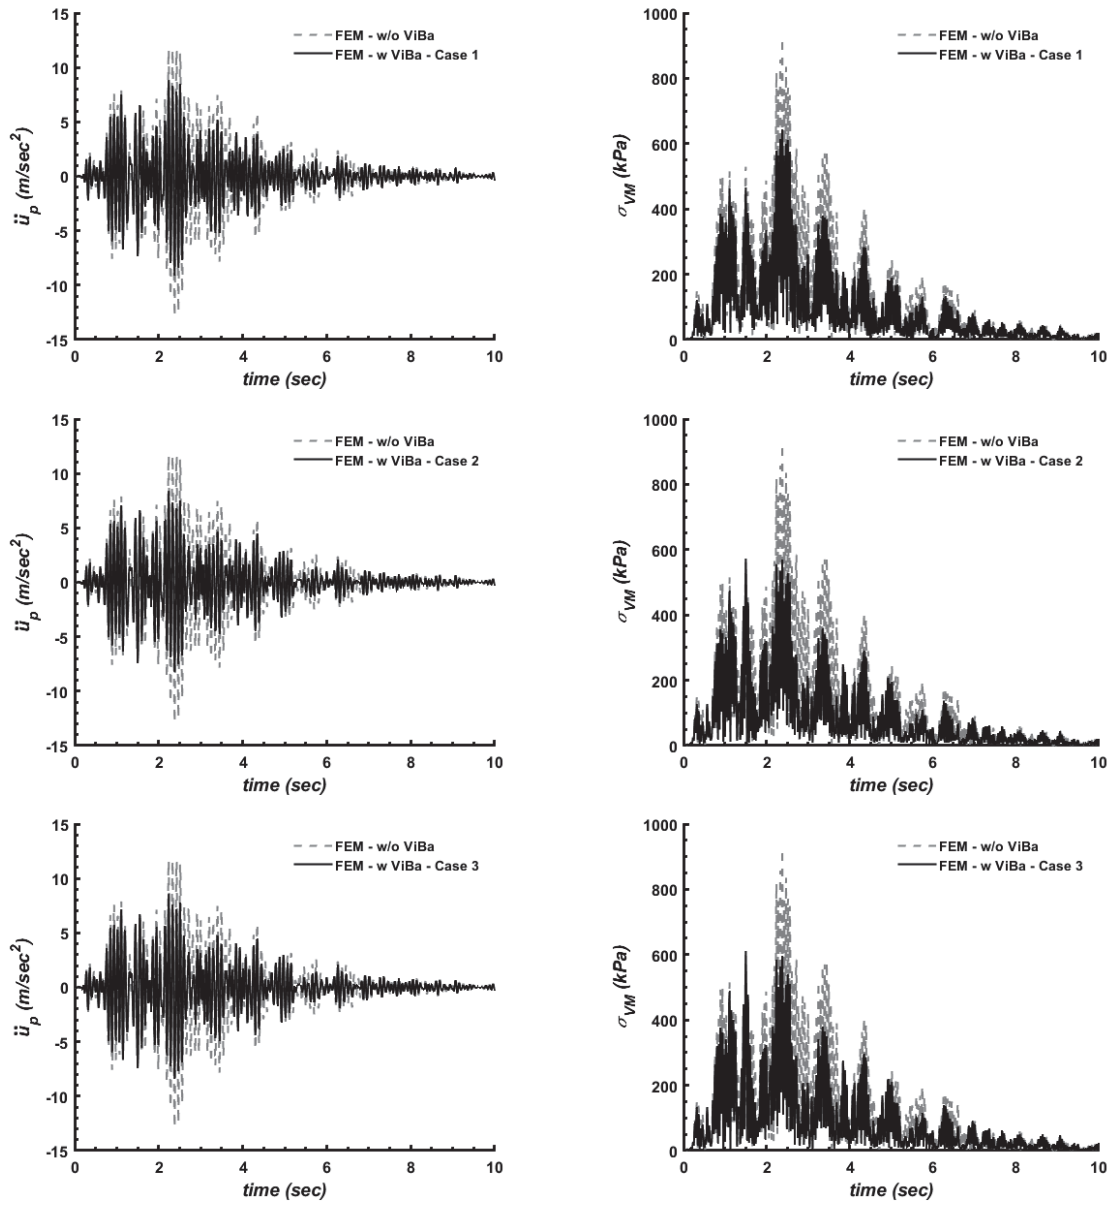

Figure 13. Acceleration time series and Von Mises Stress (σ_{VM}) time series for the top of the pyramid and specified element of the pyramid (RE), respectively, for different cases.

The mitigation of the seismic response is evaluated through a reduction factor in terms of acceleration defined as:

$$R_{\ddot{u}_p}^j = \frac{|\max(|\ddot{u}_p^j(t)|) - \max(|\ddot{u}_{p,ViBa}^j(t)|)|}{\max(|\ddot{u}_p^j(t)|)} \times 100 \quad (8)$$

where $\ddot{u}_p^j(t)$ and $\ddot{u}_{p,ViBa}^j(t)$ are the accelerations computed at the reference point of the Pyramid induced by the j -th realization for the full FEM model, before and after being protected by the ViBa technology, respectively. Therefore, the mean value is expressed as:

$$\bar{R}_{\ddot{u}_p}^{FEM} = \frac{1}{n} \sum_{j=1}^n R_{\ddot{u}_p}^j \quad (9)$$

A further expression of the reduction factor in terms of Von Mises stresses is defined as follows:

$$R_{\sigma}^j = \frac{\left| \max(|\sigma_{VM}^j(t)|) - \max(|\sigma_{VM,ViBa}^j(t)|) \right|}{\max(|\sigma_{VM}^j(t)|)} \times 100 \quad (10)$$

where $\sigma_{VM}^j(t)$ and $\sigma_{VM,ViBa}^j(t)$ are the Von Mises stresses computed at the horizontally central-second row-edge element of the pyramid induced by the j-th realization for the full FEM model, before and after being protected by the ViBa technology, respectively. Accordingly, the mean value is determined as:

$$\bar{R}_{\sigma}^{FEM} = \frac{1}{n} \sum_{j=1}^n R_{\sigma}^j \quad (11)$$

The mitigation induced by the ViBa on the seismic response of the Pyramid is shown in Figure 14a-b for both coefficients determined by Eq. (8) and (10). It is worth noting that the effect of the ViBa is beneficial for most of the events (only a few cases have been observed in which the ViBa was ineffective or slightly detrimental <2%) with a maximum reduction equal to 35 % on the peak acceleration and 39 % on the Von Mises stresses.

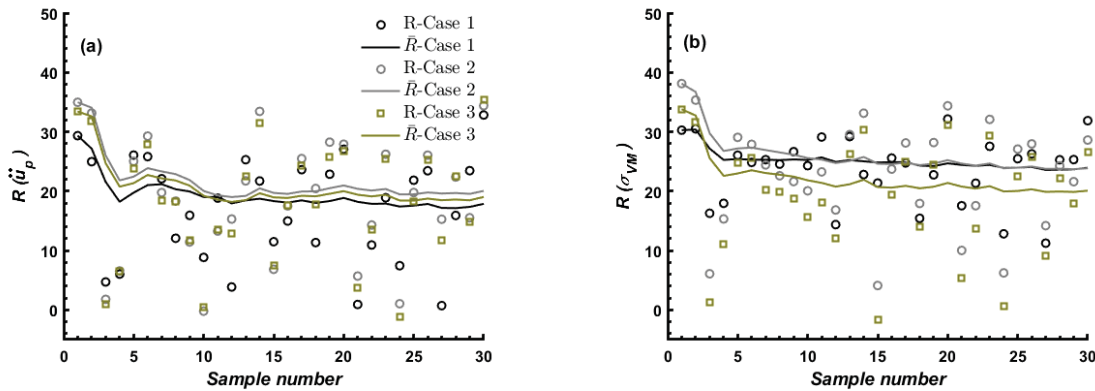

Figure 14. The mitigation provided by ViBa on the seismic response of the Pyramid; (a) mitigation on maximum acceleration, (b) mitigation on maximum Von Mises Stress.

A summary of the results is reported in Table 3 in which the computed averages of Eq. (9) and (11) from the MCS are compared with the target reduction obtained by the ROM through Eq. (7). Therefore, good reductions around 19% on the peak acceleration and about 23% on the Von Mises stress are observed for all three Cases. A slight improvement of the reduction of the peak acceleration is obtained for Case 3 (about 25%) whilst a higher reduction of the stresses on the reference element is obtained for Case 1-2 (about 24%). Remarkably, the three configurations used in this paper do not significantly affect the outcome once the same mass ratio is used, hence, more ViBas with smaller individual masses might be used to efficiently mitigate the seismic response of the Pyramid.

Case	$R_{\ddot{u}_p}^{ROM} (\%)$	$\bar{R}_{\ddot{u}_p}^{FEM} (\%)$	Rel. err (%)	$\bar{R}_{\sigma}^{FEM} (\%)$	Rel. err (%)
1	20.95	17.86	14.75	23.94	-14.27%
2	23.219	20.04	13.69	23.86	-2.76%
3	24.46	19.02	22.24	20.08	17.91%

Table 3. Reduction of the Pyramid response in terms of max acceleration and stresses

It is worth mentioning that the ViBa technology affects the whole behaviour of the Pyramid and not just the investigated control point and reference element. Therefore, the complete contour map of the Von Mises stresses is also shown for a specific instant, $t = 2.38 \text{ s}$, in which the Pyramid experienced the maximum stress at the reference element. Figure 15 shows the distribution of the stresses for the existing situation subjected to the first realization; the maximum stresses occur in the same region where the Pyramid has been largely damaged during the 1992 Cairo earthquake event.

Figure 16 shows the impact of the excavation on the stresses of the Pyramid for Case 1 and 3 for the same realization used for Figure 15. In both cases, the changes in the distribution of the stresses on the Pyramid is minimal, indicating that the excavation on its own cannot reduce the seismic body waves as opposed to the effect of trenches on surface waves (see e.g. [17]).

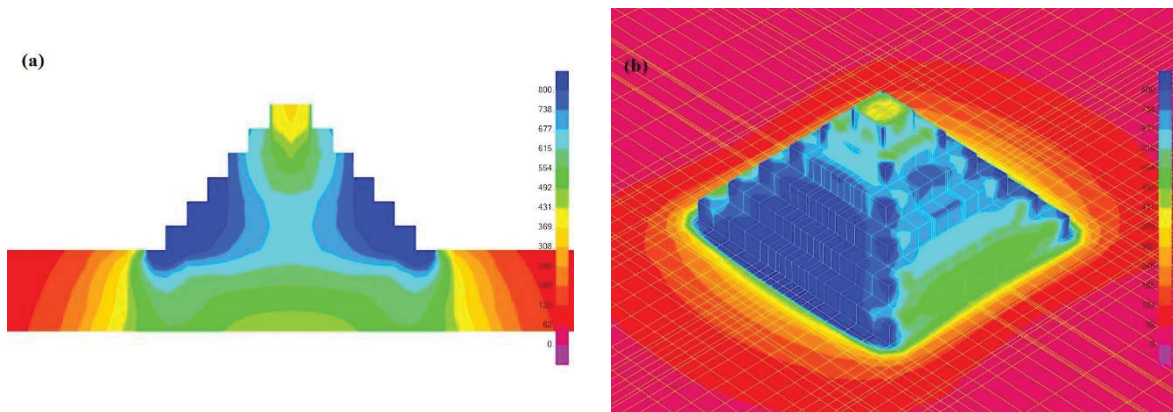

Figure 15. Instantaneous Von Mises stress contour map of a) the central cross-section and, b) the 3D soil-pyramid system for the first generated earthquake.

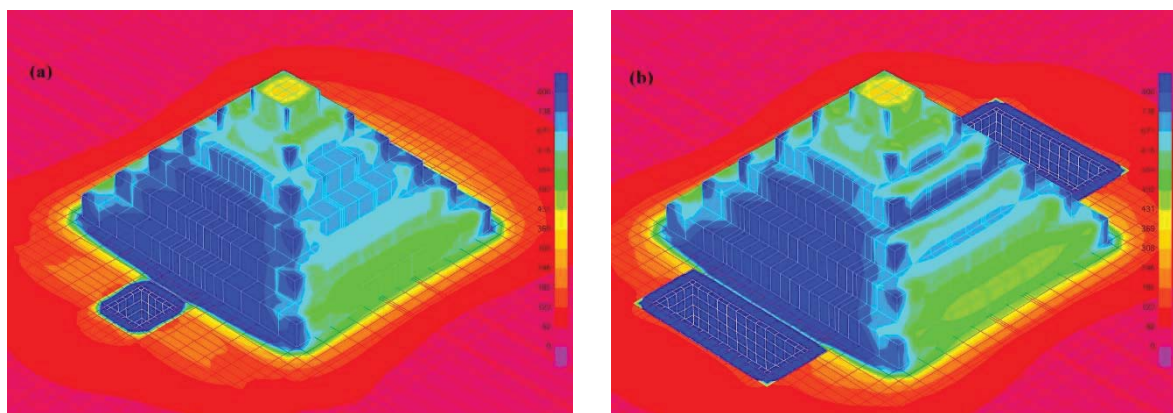

Figure 16. Effect of excavation on the response of the pyramid, (a) small excavation on one side of the pyramid, (b) large excavation on both sides of the pyramid.

Figures 17-18-19 show the response of the Pyramid protected by the ViBa device. As it can be seen, the Von Mises stresses are reduced over a large volume of the Pyramid. Particularly in Case 2, the ViBas have a narrower but greater influence over the central area whilst the large ViBas on Case 3 act in a more uniform fashion.

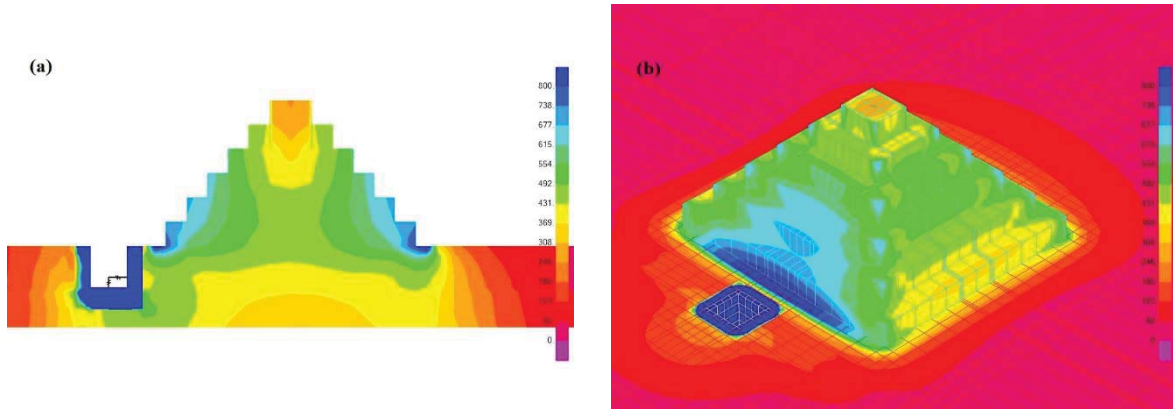

Figure 17. Maximum Von Mises stress contour map in the central cross-section and 3D for case 1 for the first generated earthquake.

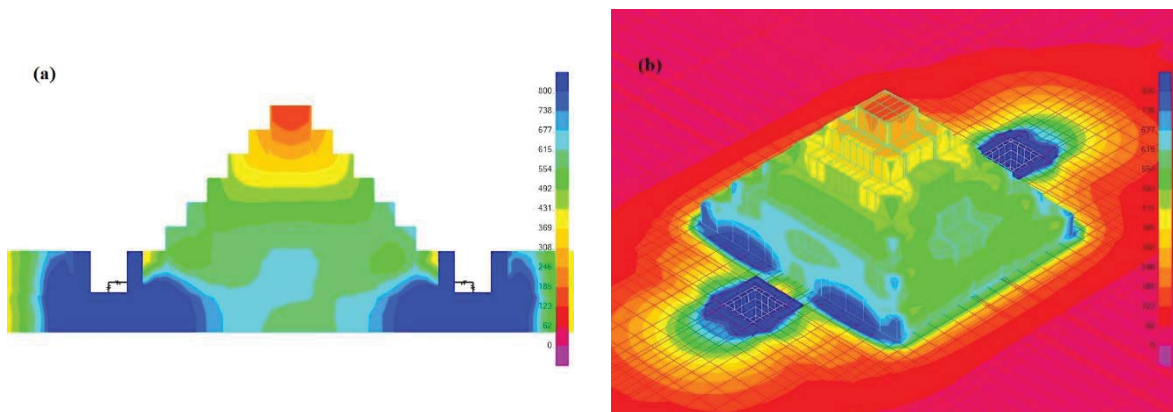

Figure 18. Maximum Von Mises stress contour map in the central cross-section and 3D for case 2 for the first generated earthquake.

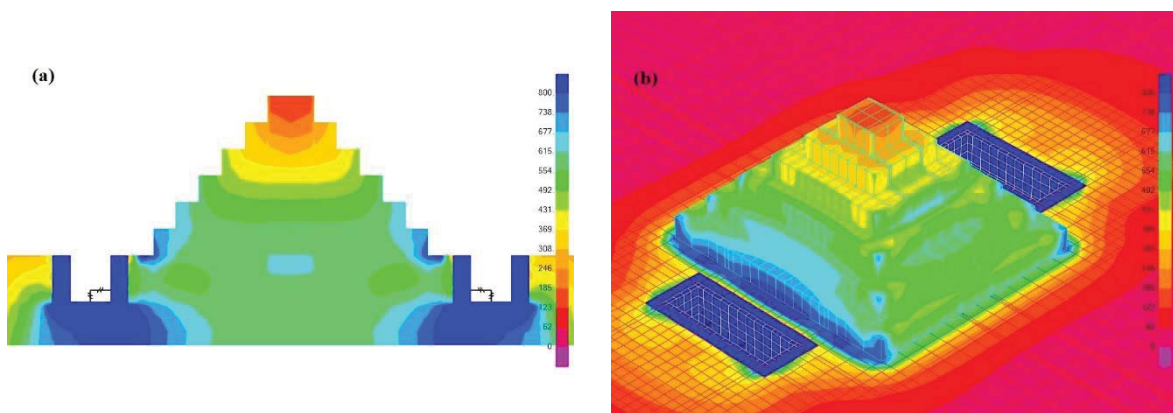

Figure 19. Maximum Von Mises stress contour map in the central cross-section and 3D for case 3 for the first generated earthquake.

5 CONCLUSIONS

In this paper, the innovative non-invasive vibration control technology called Vibrating Barrier has been applied to reduce the seismic response of the Step Pyramid of Zoser. The Pyramid has been severely damaged during the 1992 Cairo Earthquake and to guarantee its preservation, the seismic risk should be mitigated. To reduce the computational complexity of the model during the design stage of the ViBa parameters, a 4-step approach has been proposed to derive a Reduce-Order Model by adopting a sub-structuring technique. Only 2-DOFs capturing the ViBa translations of the internal device and its foundation is required. The result of the inertial analysis is then related to the seismic behaviour of the Pyramid through non-dimensional transfer functions obtained from steady-state analyses on the full FEM Soil-Pyramid system. Because the transfer functions are computed only once, this proposed approach allows performing an optimization analysis on the several parameters of the ViBa through a very fast and robust procedure. By considering a spectral representation of the 1992 Cairo earthquake, the results in terms of peak acceleration and stresses on particular control points have shown a significant reduction of the seismic response of the Pyramid when the ViBa device is used. An average reduction ranging from 20% to 24% has been observed on the Von Mises stresses with maximum mitigation of up to 39%. Remarkably, reductions have been observed in those areas where the damages have been observed. Parametric studies changing the configuration of the ViBa with one or two box-foundations and small and large individual masses were also conducted to assess their impact on efficiency. Whilst results have been obtained with a large overall mass of 80% of the Pyramid mass, the parametric analysis shows that several ViBa devices can be used with smaller masses or by improving its technology through inerters as done in [16]. Therefore, because of the impossibility to use conventional seismic control solutions without affecting its cultural heritage, the ViBa technology can be seen as a viable solution to guarantee the preservation of the ancient monuments as the Zoser pyramid.

Abstract

Nonstructural elements and contents often constitute a large fraction of the economic investment in ordinary buildings. In case of seismic events, damage to nonstructural elements not only contributes to the overall direct material costs but can also significantly impact the indirect costs. The latter are especially affected by earthquake-induced damage if production and business flows depend on proper functioning of such nonstructural components, since consequent downtime costs turn out to be very high. Within this framework, server racks' performance under seismic loading is of interest in the present work. The economic relevance of these nonstructural components requires the implementation of proper design solutions so that their performance under earthquakes can fulfill specific requirements. In this perspective, including isolation devices between server racks and building floors is deemed effective for enhancing the stability of the protected equipment, preserving the computer components' integrity and, minimizing downtime losses. Hence, the present work is meant to optimize a hybrid isolation system for server racks. Specifically, the hybrid isolation device designed for such application combines at least two elastomeric isolators and three sliders, and it is intended for the seismic protection of server racks characterized by different configurations. The objective function is formulated to minimize the accelerations transmitted to server racks and manufacturing cost.

Keywords: Constrained optimization – Cost minimization – Nonstructural elements – Optimum structural design – Server rack – Seismic isolation

1 INTRODUCTION

Nonstructural elements and contents contribute to large part of the initial economic investments in typical buildings, but they often undergo disproportional damage due to seismic actions even if the structure in which they are placed exhibits satisfactory performances [1]. Apart from contributing directly to final material costs after an earthquake, damage to contents housed in most buildings can cause inestimable losses (in case of objects of historical value) or the interruption of production/business flows (when damage occur in industrial equipments, computer servers, etc.) along with extremely high downtime costs. For example, the economic cost due to the five-days of downtime for a single data center following the 1989 Loma Prieta earthquake or the 1994 Northridge and 1995 Kobe seismic events amounted to 5%-10% of the entire rebuilding cost [2]. In this regards, it is opportune to point out that many building contents – such as computer servers or museum artifacts – are acceleration-sensitive, i.e., they are especially vulnerable to damage when subject to high accelerations [3]. In this perspective, there has been growing interest about the use of seismic isolators at the floor level because, in most cases, this can cope efficiently with the need of protecting acceleration-sensitive building equipments under earthquake, provided that the building structure is properly designed against seismic loads. In fact, it is recognized that seismic isolation of server racks would improve business resiliency at a low cost as compared to downtime losses [4].

Within this framework, the present paper proposes a novel design procedure in order to optimize a hybrid isolation system for server racks combining at least two elastomeric isolators and three sliders. The objective function is selected to minimize the accelerations transmitted to the servers placed in the racks as well as the material cost of the isolation system. Design variables include number, compound, and geometric dimensions of the elastomeric elements and slider position. The final optimization problem is then solved using a suitable variant of the differential evolution algorithm [5] to handle the design constraints. The search for the optimal hybrid isolation system is carried out in two phases. The first phase is concerned with the identification of the optimal device to be deployed on all floors of a given building. The standardized optimal design is addressed next in the second phase, in which the design procedure is extended to determine which isolation device is best suited for all floors of the building stock under investigation. The sliders optimal topology is also investigated parallel to that in such a way to minimize the overturning moment. This final design phase is motivated by the fact that standardization and generalization of an industrial device during the development stage are crucial to reduce engineering and production costs. As a matter of fact, they allow to circumvent the redesign phase should any design condition changes and to reduce the costs related to the acceptance tests required in the development stage. Hence, it means no waste of any other devices except the installed ones, thereby saving materials and overall unitary industrial costs.

2 OVERVIEW ABOUT COMMON PRACTICES IN DATA CENTER DESIGN

Most of the world's largest data centers are housed within dedicated one-story buildings, which usually host some offices serving as technical or control rooms. Medium to large data centers are often located within the upper floor of a commercial building. The position of small data centers can vary considerably in terms of, both, building type and location within the host structure. Standard models exist for large data centers placement only, whereas they lack for small to medium-large ones [6].

The distribution of racks in the data center varies significantly, regardless of the size. The most common racks configuration in large data centers is based on rows of racks installed side-by-side with alternating cold aisles and hot aisles [7]. Generally, the rows of racks are placed back-to-back, and all the holes through the rack are blocked off to create barriers that reduce

recirculation and divide hot aisles from cold aisles efficiently [8]. In some cases, hot aisles or cold aisles between two rows of racks are covered with a modular system of cooling containment. This choice reduces the energy cost and concentrates the refrigerated airflow on the rack when the server room is vast or the inter-floor space is large enough compared to the vertical dimension of the racks [9].

Figure 1 – Most common server racks configurations: a) single rack; b) row of racks; c) rows of racks with covered aisle.

The aisle containment system is composed of a series of light aluminum frames that do not have a structural function. Generally, these systems are scalable, and thus there is no a fixed number of racks that compose the covered aisle. Server rooms can host multiple rows of racks and multiple covered aisles.

Data center density is usually measured in terms of W/m^2 or $W/rack$, which represent the electric power consumed per square meter and the electric power consumed per rack, respectively. It means that a low-density data center is characterized by a configuration that consumes few Watts per square meter of the server room. If a data center employs this configuration, then the rows are commonly composed of sparsely populated racks or spaced full single racks [10].

As reported in many guidelines, scalability brings added value to the data center. The scalability requirement implies that the data center can be conceived and built according to a low-density architecture able to meet current needs and to expand for fulfilling higher future demands that require the postponed installation of further infrastructures such as UPS systems, air conditioners, and other racks [10]. This means that the data center layout can eventually evolve during its lifetime, with the possible exception of large and predefined configurations.

It is anticipated that this study addresses the seismic protection of a single rack, whereas the remaining configurations will be considered in future works. The configuration consisting of a single rack device is the most flexible one and facilitates later installations when data center scaling is needed. Some available commercial proposals for server rack seismic isolation are intended for a single item. They are generally modular systems, which means that it is possible to isolate more racks in a row by combining more devices [11–19]. Many other commercial devices propose total raised floor isolation [13,19,20]. Another solution adopted to achieve server rack seismic protection is obtained through the direct introduction of damping to the rack's steel structure or in the raised floor [21,22]. The main guidelines and codes that refer to electronic equipments installed in earthquake-prone areas suggest the use of a cabinet rack that has passed a codified seismic test, usually named "seismic rack" [23–30]. On the other hand, to make a non-conforming cabinet resistant against seismic actions, the installation of a "seismic kit" composed of steel braces is common. Both solutions are meant to enhance the rack resistance and stiffness. Furthermore, technical codes in force indicate that racks in seismic areas have to be anchored to the floor by fasteners together with shear keys. Although these specifications already existed during the 2010 Chile earthquake, the lack of fasteners and shear keys

was common in both new and old buildings [31]. It is worthy highlight that code requirements that target at increasing the system stiffness to reduce the drift generally lead to an increment of the acceleration demands in the electronic components of the racks, thereby amplifying the potential risk of interrupting the business continuity.

3 ANALYSIS OF ELASTOMERIC ISOLATORS

Design rules provided by EN 15129 [32] and EN 1337-3 [33] for seismic actions and static conditions, respectively, are the constraints of the optimization procedure.

The use of slender elastomeric elements is required to ensure a suitable level of isolation for light nonstructural elements. This condition turns out to be very binding for axial loads, since it makes elastomeric elements vulnerable to buckling phenomena. In order to overcome this issue, a hybrid isolation system is adopted, which combines elastomers with at least three sliders that aims at absorbing the axial load. Thanks to these features, elastomeric elements integrity under seismic loads is governed primarily by shear deformability limits. In operating conditions, the racks positioned inside the building are protected against horizontal environmental actions, such as wind. Therefore, only an accidental rotation equal to 0.03 rad and a horizontal force equal to 1 kN are considered during the optimization procedure to account for anthropic interferences. According to EN 15129, the design shear strain $\varepsilon_{q,E}$ due to earthquake-imposed design displacement d_{bd} is given by:

$$\varepsilon_{q,E} = \frac{d_{bd}}{T_q}, \quad (1)$$

where T_q is the total thickness of the active elastomer during shear. The design shear strain calculated using Eq. (1) has to be compared with the maximum shear strain equal to 2.5.

4 SEISMIC ACTION

The floor response spectrum method is a convenient way to find the nonstructural element acceleration on the floor during an optimization procedure because it is less computationally expensive than a time history analysis [34]. The Italian building code (NTC18) floor spectrum formulation [35] is here employed, which demonstrated a good agreement with the Newmark response spectrum derived from a compatible time history analysis.

According to NTC18, the seismic demand on nonstructural elements can be determined by applying a horizontal force F_a defined as follows:

$$F_a = \frac{(S_a \cdot W_a)}{q_a}, \quad (2)$$

where F_a is the horizontal seismic force applied in the center of mass of the nonstructural element, S_a is the maximum dimensionless acceleration, W_a is the weight of the element, and q_a is the quality factor. The following relationship is adopted to determine the acceleration at the j th floor of the structure corresponding to the i th mode:

$$S_{ij} = \varphi_{ij} \Gamma_i S_i(T_i), \quad (3)$$

where $S_i(T_i)$ is the ordinate of the spectrum relative to the i th mode. Herein, Γ_i is the modal participation factor, which is defined by the relationship:

$$\Gamma_i = \frac{\varphi_i^T M \tau}{\varphi_i^T M \varphi_i}, \quad (4)$$

where τ is the drag vector, φ_i is the i th normalized modal shape, and M is the mass matrix.

A ground spectrum for a high seismic risk zone with $a_g=0.26g$ is considered in the present work (Figure 2a). Additionally, it is assumed that the building containing the racks has to undergo slight damage levels or to behave elastically; otherwise, business continuity would be jeopardized in any case. Therefore, the design of the isolation system will not rely on the ductility reserve that the structure would provide by adopting a unit quality factor.

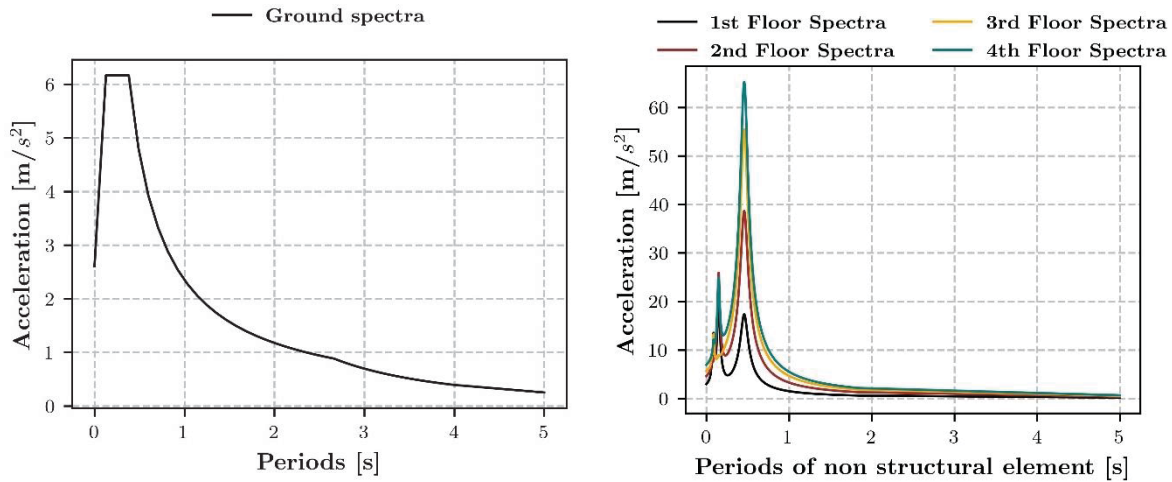

Figure 2 – Reference ground spectrum (left) and floor spectra for a 4-story building (right).

The floor spectra for ten buildings with an increasing number of floors were generated accordingly. As an example, the floor spectra for a 4-story building are shown in Figure 2b. All buildings have a concrete frame structure and $5\text{ m} \times 5\text{ m}$ square floor plan with an inter-floor height equal to 3.5 m. The first frame is replicated to obtain all buildings (Figure 3).

Figure 3 – Stock of buildings under consideration.

5 OPTIMIZATION PROCEDURE

The optimization problem is formulated, taking into account both, integrity of the isolated servers and system cost-effectiveness. Within the present work, the elastomeric isolator's behavior and the seismic actions are evaluated through an iterative search considering the mechanical characteristics of the elastomeric compound and the floor response spectra for each floor. The elastomer's lateral stiffness was calibrated by considering the damping related to the shear deformation calculated through the floor spectral displacement until convergence. The optimization procedure is divided into two phases. In the first phase, the optimum isolation system is identified separately for the ten buildings under consideration (Figure 4). Thus, for each candidate solution generated by the differential evolution algorithm, the iterative procedure required to identify the isolation system's properties was conducted for each floor of the

considered building. In the second phase, all ten buildings are examined simultaneously in the attempt to determine the optimal isolator that complies with all constraints on all floors of all buildings. In this case, the isolator properties were identified for all floors of the ten buildings for each generation. The design variables in the optimization problem are diameter of the elastomeric isolators, rubber height, type of compound, and number of isolators. From these quantities, it is thus possible to derive number of rubber layers and number of steel layers for the isolator. The algorithm employs primary and derived design variables in order to calculate the material cost of the isolation system. The problem constraints are defined in compliance with the design rules in EN 1337-3 and EN 15129. Furthermore, the maximum acceleration at the top of the rack is required to be less than 0.20g, whereas the isolation system period is forced to be larger than 1 s. The limitation about the maximum acceleration transmitted to the servers by the rack is necessary to ensure that the hard disks would remain operational during seismic events.

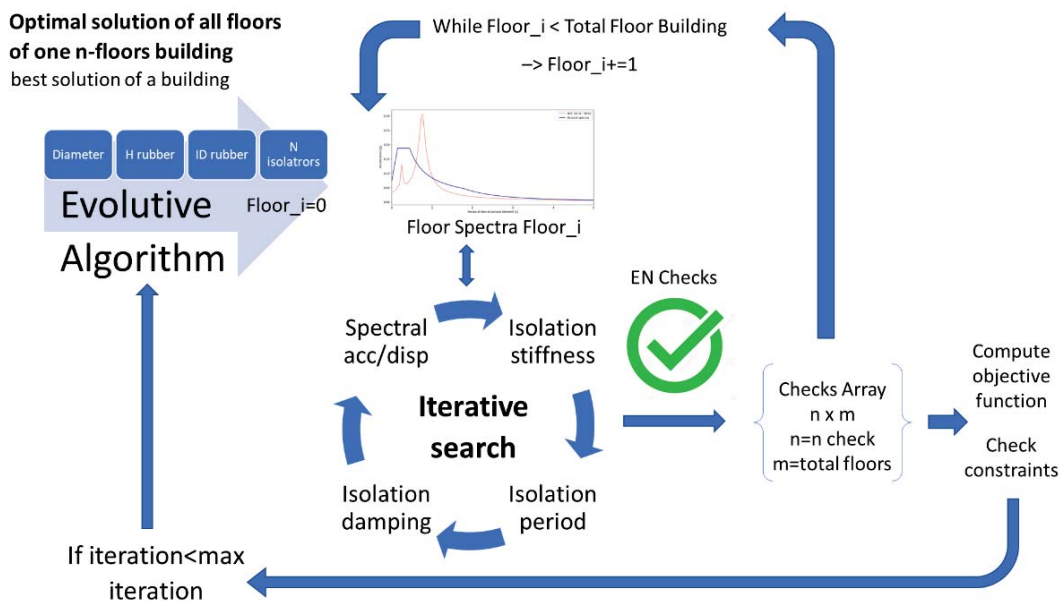

Figure 4 –Workflow of the optimization procedure for a single building

A special $(\mu+\lambda)$ -constrained differential evolution algorithm is adopted to solve the optimization problem. This algorithm uses a robust nature-inspired strategy that focuses on finding the best solution iteratively by checking a set of candidate solutions [36,37]. The objective function of the optimization problem $ObjF$ is formulated as follows:

$$ObjF = \left(\frac{C_{Mat} + C_{Fixed}}{C_{Fixed}} \right) \cdot \gamma_c + Acc_{max} \cdot \gamma_{Acc} \quad (5)$$

where C_{Mat} is the material cost of the isolation system, C_{Fix} are the fixed costs, Acc_{Max} is the maximum acceleration recorded on the floors of each building. The two terms included in the objective function are weighted using two user-defined coefficients (i.e., γ_C and γ_{Acc}). The constrained differential evolution algorithm's iterative strategy runs until the maximum number of fitness evaluations is reached. Meanwhile, the sliders position is optimized to reduce the overturning moment due to the seismic action. The only design variable is the position of the sliders as related to the dimensions of each individual rack. In this case, the optimum design is formulated as a single-objective constrained optimization problem, and the $ObjF$ $f(x_i)$ is calculated as follows:

$$ObjF = \frac{M_{Stab}}{M_{Ov}} \quad (6)$$

where M_{stab} is the stabilizing moment, and M_{ov} is the overturning moment under seismic action.

6 RESULTS

Figure 5a shows the results for all the analyses performed in the first design phase by overlaying the trends in the devices' geometric dimensions with the maximum acceleration values recorded for each building. Figure 5b illustrates the maximum acceleration among all floors of each building, and compare them to the acceleration of a floor-fixed rack. All results are listed in Table 1. A fundamental period equal to 0.33 s is considered for the non-isolated seismic rack [38]. The numerical value of the weights are $\gamma_C=3$ and $\gamma_{Acc}=0.30$ [1/g]. The optimal number of elastomeric devices was found equal to 2 for all cases (it corresponds to the lower bound).

Figure 5 – Results of the optimization performed in the first phase (left) and comparison between maximum acceleration on the isolated rack and that of a fixed-floor rack (right).

Number of floors	Isolator diameter [mm]	Total rubber thickness [mm]	Cost of isolation system [€]	Objective function	Max seismic displacement [mm]	Max acceleration isolated rack [g]
1	37	40	288	1.29	77	0.1354

Table 1 – Results of the optimization procedure in the first design phase.

The second phase of the optimization procedure is performed by assuming the same variables and constraints already employed in the first phase. The results are listed in Table 2.

Finally, the search for the sliders optimal position has been performed alongside the elastomeric elements sizing optimization. The search space area is limited to a single rack size equal to 800 mm × 1000 mm. The minimum number of sliders required for an equilibrium configuration is three. In this study, the 4-slider scheme is also investigated.

7 CONCLUSIONS

This paper has explored the application of the constrained differential evolution algorithm for the optimum and standardized design of a hybrid seismic isolation device for a server rack. The device is designed in compliance with EN 15129 and EN 1337-3. Size of the elastomeric devices and positions of the sliders have been optimized.

The sizing optimization of elastomeric devices allow to draw the following general conclusions:

- the most important seismic demand parameter for the integrity of the elastomeric isolators is the lateral seismic displacement, which increases as the number of floors grows up and ultimately governs the total height of the device;
- the isolator diameter is almost constant for all buildings under consideration and is close to the lower bound of the search space;
- the optimum design of the isolation system performed taking into account all buildings simultaneously leads to the same results carried out considering the tallest building only, which therefore rules the whole design because of the largest value of the seismic demand.

As regards the sliders position, an intuitive layout is obtained for the configuration consisting of 4 devices, whereas the optimal arrangement for 3 devices is less predictable.

The optimization of the isolation system has been here performed through a constrained differential evolution algorithm. This numerical technique was able to reduce the total computational time and to provide a better solution as compared to a parametric analysis-aided approach. Therefore, the constrained differential evolution algorithm proved to be suitable for this optimization problem.

The design procedure herein proposed will be further extended in future works so as to enable the optimization of the other racks configurations typically encountered in data centers.

Abstract

Mass damping is a well known principle for the reduction of structural vibrations and applied in tall building design in a variety of configurations. With mass usually small (around 1% of building mass), the properly “tuned” mass damper (TMD) shows great effectiveness in reducing wind vibrations, but minor advantages under earthquake excitations.

The above limitation can be surpassed by utilizing relatively large mass TMD. For this purpose, two different solutions are here proposed. In both cases, the idea is to separate the building into two or more parts, thus allowing for a relative motion between them, and activating the mass damping mechanism.

In the first solution, the building is subdivided along elevation into an upper and a lower structure, separated by means of an intermediate isolation system (IIS). In the second solution, by revisiting the classical mega-frame typology, the exterior full-height structure provides the global strength and stiffness, and secondary structures, extending between two transfer levels, are physically detached from the main structure at each floor and isolated at transfer level.

Simplified lumped-mass models are developed for illustrating the dynamic behaviour of the two solutions and carrying out parametric analyses. Procedures for deriving optimum values of design parameters are also proposed and compared to the parametric study.

Keywords: mass damping, motion based design, vibrations control, tall buildings, Mega Sub-structure Control System, Intermediate Isolation Systems.

1. INTRODUCTION

Mass Damping (MD) is nowadays a consolidated passive strategy, widely applied in tall building design since 1976 (John Hancock Tower in Boston) for mitigating structural vibrations and improve serviceability and occupant comfort [1]. A Tuned Mass Damper (TMD) is an auxiliary device attached to the main structure, consisting in a mass, spring, and damper. While TMDs with relatively small mass are very effective for reducing wind-induced response, they are not equally interesting under earthquake excitations [1 - 4].

In order to improve their seismic effectiveness, large mass TMDs can be utilized. With this choice, in fact, the system becomes most robust against deviations from design parameters and less dependent on the earthquake frequency content and the impulsive character of the seismic input [5]. This large mass can be obtained by converting a part of the structure into a huge mass damper, also appointed as non-conventional mass damper [5 - 9], thus combining control and structural functions. For this purpose, two different solutions are here proposed, by separating the building into two or more parts that vibrate out of phase and, thus, activate the mass damping mechanism.

In the first solution, the building is divided into two substructures, a lower and an upper structure, separated by means of a flexible horizontal disconnection, the isolation system, thus realizing an Intermediate Isolation System (IIS, Figure 1a). This configuration is widely utilized in Japan, where more than 60 buildings have been already realized [10], both for the seismic design of new buildings [11 - 17], and retrofit of existing buildings by means of vertical addition [13, 14]. While the IIS represents an extension of the Base Isolation System (BIS), its dynamics is more complicated due to the flexibility of the lower structure. In fact, the isolated upper structure behaves like a base isolated structure and as a large mass TMD for the lower structure [5 - 9, 18 - 26].

In the second solution, starting from the classical mega-frame typology for tall building structures [27 - 29], the building is subdivided in an exterior primary megastructure that provides the global strength and stiffness, and several interior secondary substructures, extending between two transfer levels, physically disconnected from the main structure at each floor and isolated at transfer level. Therefore, a Mega Substructure Control System (MSCS, Figure 1b) is realized, in which each isolated substructure behaves like a base isolated structure and the mass damping mechanism is activated by allowing the relative motion between the substructures and the main structure. This approach has been firstly proposed by Feng and Mita in 1995 [30], and then developed by the same authors [30 - 32] and by other researchers in a variety of solutions [34 - 45].

Figure 1: (a) Intermediate Isolation System (IIS) and (b) Mega-Substructure Control System (MSCS).

Both the mass damping solutions can be preliminary analysed by means of a simplified two-degree of freedom lumped mass model (2DOF MD, Figure 2b). For the Mega Substructure Control System, the main system accounts for the exterior megastructure, while the absorber globally represents the internal secondary substructures; instead, for the Intermediate Isolation System, the main and secondary system respectively refers to the lower structure and isolated upper structure. It is worth recalling that the IIS is generally analysed by means of a 3DOF model, accounting the DOFs

of the lower structure, the isolation system, and the upper structure. However, for evaluating its global dynamic behaviour, a 2DOF model can be adopted by satisfying the following two requirements: the upper structure is rigid with respect to the isolation system [46, 47], and the higher modes coupling is avoided [25, 48, 49].

In the present paper the dynamic behaviour of the two solutions is explored by carrying out parametric analyses on the simplified lumped mass model. The authors also propose procedures for deriving optimum values of the mass damper's design parameters, by minimizing the displacement amplitude of the main system under white noise. Finally, the optimal procedures are compared to the parametric study.

2. OPTIMIZATION PROCEDURE FOR NON-CONVENTIONAL MASS-DAMPING (MD) CONFIGURATIONS

Non-conventional mass-damping (MD) configurations utilising isolation system, such as Mega Substructure Control Systems and Intermediate Isolation Systems, can be preliminary analyzed by means of a simplified two degree-of-freedom (2DOF) lumped mass model, as depicted in Figure 2b. The first oscillator represents the main system with mass, stiffness, and damping coefficients named as m_1 , k_1 , and c_1 , while the second oscillator represents the absorber (or secondary system) with mass, stiffness, and damping coefficients named as m_2 , k_2 , and c_2 .

Figure 2: (a) simplified SDOF FB model, (b) simplified 2DOF MD model.

The equations of motion of the 2DOF MD model are:

$$\begin{cases} m_1 \ddot{x}_1 + c_1 \dot{x}_1 + k_1 x_1 - c_2 (\dot{x}_2 - \dot{x}_1) - k_2 (x_2 - x_1) = -m_1 \ddot{x}_g \\ m_2 \ddot{x}_2 + c_2 (\dot{x}_2 - \dot{x}_1) + k_2 (x_2 - x_1) = -m_2 \ddot{x}_g \end{cases} \quad (1)$$

being x_1 and x_2 the relative displacements of the two oscillators with respect to the ground and \ddot{x}_g the ground acceleration.

By considering the stochastic nature of earthquake, the ground acceleration \ddot{x}_g is modelled as a stationary Gaussian random process characterized by zero mean and white noise power spectral density $S_{\ddot{x}_g}(\omega) = S_0$, in which there is no statistical correlation on what happens in two subsequent instants t_0 and $t_0 + \tau$. Although it is neglected the dependency on the excitation frequency content, this process seems to be acceptable in an initial design phase, [e.g. 5].

For the 2DOF MD model shown in Figure 2, the optimization procedure provided by the authors is based on the minimization of the variance of the response x_1 , $E[x_1^2]$ given by:

$$E[x_1^2] = S_0 \int_{-\infty}^{+\infty} |H_1(\omega)|^2 d\omega \quad (2)$$

where $H_1(\omega)$ is the transfer function of the displacement of the main system expressed in the frequency domain ω and obtained by means of the Fourier Transform of the linear differential equations (1) as a function of some dimensionless parameters:

$$H_1(\omega) = \frac{-i\omega^3 B_3 - \omega^2 B_2 + i\omega B_1 + B_0}{\omega^4 A_4 - i\omega^3 A_3 - \omega^2 A_2 + i\omega A_1 + A_0}, \quad (3)$$

where the coefficients $B_1 - B_3$ and $A_1 - A_4$ are:

$$\begin{aligned} B_0 &= -\nu^2 \omega_1^2 (1 + \mu); & A_0 &= \nu^2 \omega_1^4 \\ B_1 &= -2\xi_2 \nu (1 + \mu) \omega_1 + 2\xi_1 \omega_1; & A_1 &= 2\xi_2 \nu \omega_1^3 + 2\xi_1 \nu^2 \omega_1^3 \\ B_2 &= -1; & A_2 &= \omega_1^2 + (1 + \mu) \nu^2 \omega_1^2 + 4\xi_1 \xi_2 \nu \omega_1^2 \\ B_3 &= 0; & A_3 &= 2\xi_2 \nu \omega_1 (1 + \mu) + 2\xi_1 \\ & & A_4 &= 1 \end{aligned}$$

and $\mu = m_2/m_1$ is the mass ratio, $\nu = \omega_2/\omega_1$ is the tuning ratio, ω_1 and ω_2 are the natural circular frequencies while $\xi_1 = c_1/(2m_1\omega_1)$ and $\xi_2 = c_2/(2m_2\omega_2)$ are the damping ratios of the main and secondary system, respectively.

The ranges of values selected for the non-dimensional parameters, covering a wide range of civil engineering applications, are: $\mu =]0, 2]$, $\nu =]0, 2]$, $\xi_1 = [0, 0.1]$, $\xi_2 = [0, 1]$.

By applying the Cauchy's residue theorem, the integral (2) can be analytically obtained [50, 51], leading to the following expression of $E[x_1^2]$:

$$E[x_1^2] = \frac{\pi S_0 \left(\frac{(A_2 A_3 - A_1 A_4) B_0^2}{A_0} + A_3 (B_1^2 - 2B_0 B_2) + \frac{(A_1 A_2 - A_0 A_3) B_3^2}{A_4} + A_1 (B_2^2 - 2B_1 B_3) \right)}{-A_0 A_3^2 + A_1 (A_2 A_3 - A_1 A_4)} \quad (4)$$

The square root of $E[x_1^2]$ is provided in Figure 3a and b, respectively for a damping ratio ξ_1 equal to 0 and 0.05. Each triplet of charts refers to mass ratios equal to 0.01, 0.1, and 1, by assuming unit values of the spectral density S_0 and the circular frequency ω_1 . From Figure 3 it can be noticed that, by increasing the damping of the first oscillator for the same value of mass ratio, the variance of x_1 is reduced, highlighting the beneficial effect of ξ_1 in reducing the response of the main system. Instead, by increasing the mass ratio for the same value of ξ_1 , the number of couples ξ_2 - ν characterized by the same variance increases, leading to lower dependance of the response on the design parameters, and thus, to a major robustness of the system.

The minimization of the variance $E[x_1^2]$ (4) is implemented by imposing that its gradient is null with respect to the tuning ratio ν and the damping ratio ξ_2 , i.e.:

$$\begin{cases} \frac{\partial E[x_1^2]}{\partial \nu} = 0 \\ \frac{\partial E[x_1^2]}{\partial \xi_2} = 0 \end{cases} \quad (5)$$

The optimal values of the tuning ratio ν_{opt} and the damping ratio $\xi_{2,\text{opt}}$, obtained from Eq. (5), are presented in graphical form in Figure 4 by varying the damping ratio ξ_1 and considering the range of validity of the mass ratio μ equal to 0 – 1. In particular, the optimal tuning ratio decreases, and the optimal damping ratio increases, by increasing the mass ratio. From Figure 4 the effect of the first damping ratio on the trend of the optimal parameters can be also evaluated. While the distance between the optimal tuning curves becomes significant for ξ_1 equal to 0.05 and 0.1, with scatters up to 44% for medium-high mass ratios (Figure 4a), in terms of optimal damping curves, only for $\xi_1 = 0.1$ and for mass ratios approaching to 1, considerable scatters, up to 56%, are obtained (Figure 4b).

Depending on project specific considerations, related to both architectural/functional and constructive aspects, as well as to structural and dynamic requirements, the values of the optimal pa-

parameters cannot always be simultaneously adopted. In order to account these cases, starting from the optimizing conditions of Eq. (5), a single design variable is assumed, either the tuning ratio ν_{opt} or the damping ratio $\xi_{2,\text{opt}}$, while the other variable and the mass ratio are assumed as design data.

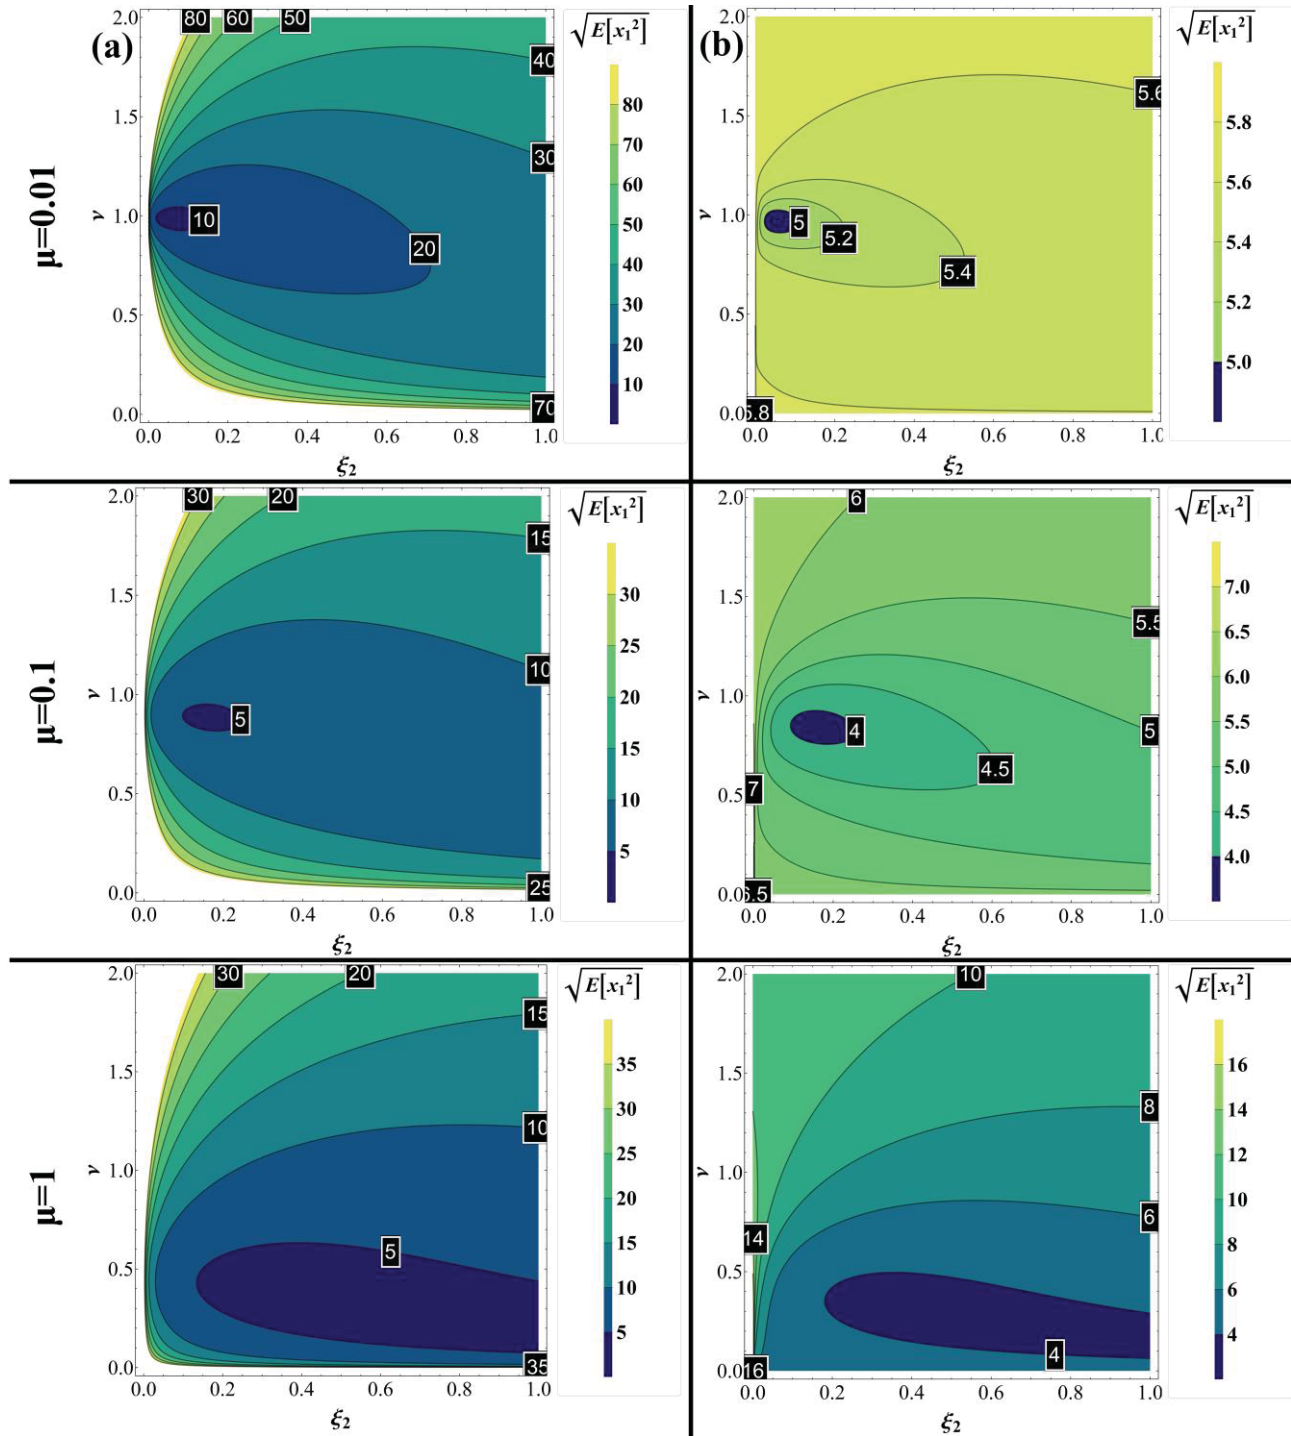

Figure 3: Response displacement of the main system: (a) first column $\xi_1 = 0$, (b) second column $\xi_1 = 0.05$.

Also for these optimization procedures, the values of the optimal parameters are provided in graphic form (Figure 5), by assuming the damping ratio ξ_1 equal to 0.05.

It is worth emphasizing that the first procedure proposed in this paper represents the generalization of the optimization algorithm implemented by [52]. In fact, by neglecting the damping of the main system, Warburton [52] imposes the minimization of the variance of the main system subjected to a white-noise input, with respect to ξ_2 and ν , thus analytically deriving optimal parameters.

Additionally, by considering a single design variable, ξ_2 or ν (Figure 5), the optimization method degenerates into the procedure proposed by [30], when the damping ratio of the main structure is assumed equal to 0 and ξ_2 is set equal to $(2m_2\omega_1)^{-1}$.

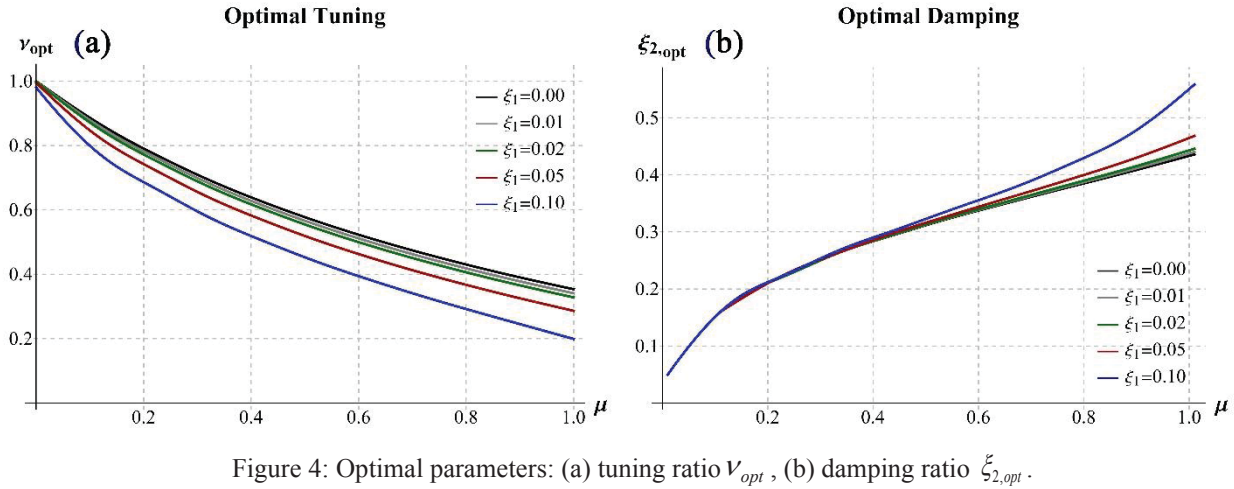

Figure 4: Optimal parameters: (a) tuning ratio ν_{opt} , (b) damping ratio $\xi_{2,opt}$.

3. PARAMETRIC ANALYSIS

A wide parametric analysis is carried out for analysing the dynamic behaviour of non-conventional MD configurations and their potential benefits in reducing the seismic response of tall buildings, by adopting the simplified 2DOF model defined in the previous section 2 (Figure 2b). In particular, the dynamic characteristics of the MD models (periods and participating masses) are derived from classical modal analyses of the undamped system, while the complex eigenvalue problem has been solved in the state space for accounting the effect of the non-proportional damping. Then, response spectrum analyses are carried out by considering the complex modal superposition methods, in order to derive the base shear and displacement demands. Finally, time history analyses are performed for highlighting the effect of the seismic input (frequency content, duration, etc.), for discussing the effectiveness and robustness of the system, and for comparing different procedures of optimization.

3.1. Simplified models and design parameters

A 40-story tall building is adopted as a reference for the fixed-base (FB) single-degree of freedom model, by assuming the mass m_1 equal to 80000 kNs²/m and the damping ratio ξ_1 equal to 0.05. Three baseline SDOF FB (Figure 2a) models are defined by varying the fundamental vibration period T_1 , thus accounting for different structural solutions, from very rigid (*e.g. stiff diagrid structures or diagonalized mega-frame*) to more flexible structural systems (*e.g. moment resisting frames or frame tubes*). In particular, the fundamental vibration periods T_1 are assumed equal to 1.62 s, 2.5 s, 3.5 s.

The design parameters adopted for exploring the dynamic behaviour of the controlled 2DOF MD configurations (Figure 2b) are the mass ratio μ , the isolation period T_2 , and the damping ratio of the isolation system ξ_2 , which vary in the following ranges:

- $T_2 = 0.05 - 10$ s (50 values);
- $\mu = 0.1, 0.5, 1.0, 1.5$;
- $\xi_2 = 0.05 - 0.5$ (26 values).

Hence, by varying all the design parameters, a total of 15600 models have been generated.

It is worth observing that, while some values of the mass ratios and of the isolation periods are not realistic, they are considered herein to fully characterize the behaviour of the system and provide a comprehensive view of its potential applications and limitations. The range for the damping ratio ξ_2 has been chosen considering different isolation systems, composed either by high damping rubber bearings or by natural rubber bearings plus viscous or hysteretic dampers.

3.2. Non-proportional damping and complex mode superposition method

In the controlled MD configurations, the structural damping ξ_1 is assumed equal to 0.05 while the damping of the isolation system ξ_2 varies between 0.05 and 0.50. Structures with very different values of damping ratios represent non-proportional (or non-classical) damped system, characterized by complex-valued natural modes. In this case, the off-diagonal terms in the damping matrix \mathbf{C} cannot be neglected, since the system does not satisfy the Caughey and O' Kelly identity: $\mathbf{C}\mathbf{M}^{-1}\mathbf{K} = \mathbf{K}\mathbf{M}^{-1}\mathbf{C}$ (with \mathbf{M} , \mathbf{K} , and \mathbf{C} the mass, stiffness and damping matrices) [53]. Furthermore, when \mathbf{C} is an arbitrary symmetric positive-definite matrix, the expansion in terms of the eigenvectors for the undamped system and real modal coordinates does not lead to uncoupled modal equations. Therefore, rather than working with a second-order equation, it is more convenient to transform the equations of motion into a set of first-order equations involving complex modal coordinates and complex state eigenvectors, and working in the state space [54].

In the response spectrum analyses carried out in the following section, the complete-quadratic-combination (CQC) rule is utilized in order to obtain the maximum responses associated to each degree of freedom. Being the system non-classically damped, the method described by Sinha and Igusa [55] is utilized in order to consider the complex-valued nature of the vibration mode shapes. Therefore, the maximum system response, R , is given by:

$$R = \sqrt{\sum_{i=1}^n \sum_{j=1}^n B_i B_j \rho_{ij} R_i R_j} \quad (6)$$

with n the number of the considered vibration mode; B_i and B_j real-valued participation factors; R_i and R_j spectral displacements; ρ_{ij} real-valued modal correlation factors. The participation factors and modal correlation factors depend on the vector that defines which DOF is being considered; therefore, they assume different values when evaluating the response of each floor, differently to what is done in the case of CQC rule for classically damped systems, where these parameters are fixed quantities [56].

3.3. Response spectrum analysis (RSA)

Response spectrum analyses (RSA) are carried out on all the simplified MD and FB models by utilizing the acceleration response spectrum defined by the Eurocode 8 [57] for the design earthquake, characterised by 10 % probability of exceedance in 50 years (475 years Return Period).

The spectrum is depicted in Figure 6a, for $a_g = 0.35$ g, soil type B ($S = 1.2$; $T_B = 0.15$ s; $T_C = 0.5$ s; $T_D = 2$ s), damping ratio equal to 0.05. The complex mode superposition method proposed by Sinha and Igusa [55], briefly recalled in section 3.2, has been used to consider the complex-valued nature of the vibration mode shapes. In Figures 6b and 7 the results of the analyses are firstly presented for the case of $\xi_2 = 0.30$; then the effect of the damping ratio of the isolation system is evaluated in Figure 8.

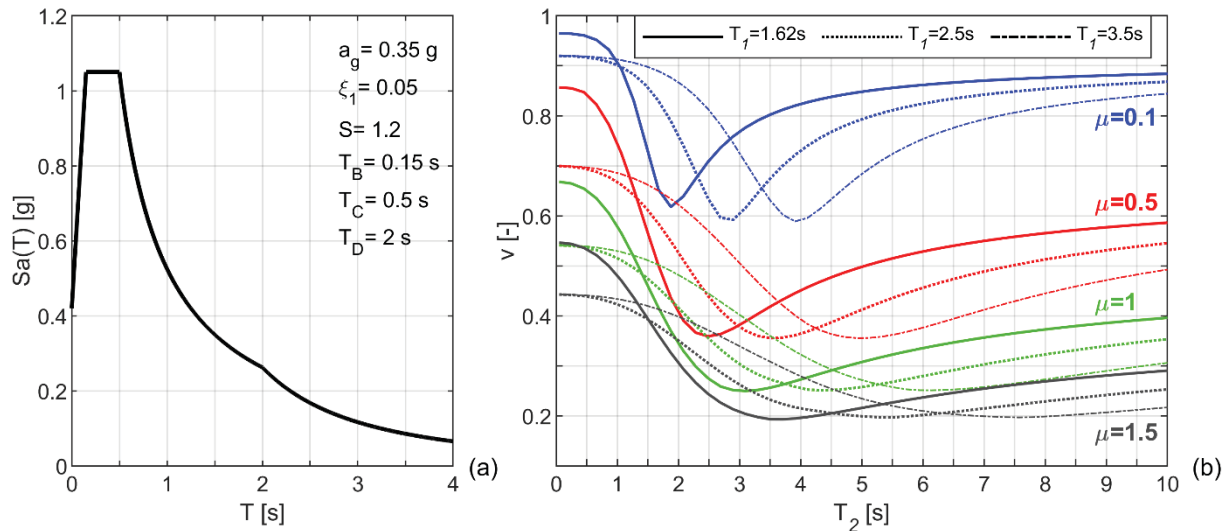

Figure 6: (a) EC8 elastic acceleration response spectrum, (b) base shear ratio v vs. T_{ISO} . for $\xi_2 = 0.30$.

The Figure 6b depicts the base shear ratio between the base shear controlled MD configuration and the uncontrolled FB counterpart, i.e. $v = V_{MD}/V_{FB}$, as a function of the isolation period T_2 . From the chart, it can be immediately observed that the base shear ratio v is always less than one, approximately between 0.95 e 0.85 for $\mu=0.1$, between 0.85 e 0.50 for $\mu=0.5$, between 0.68 e 0.30 for $\mu=1$, between 0.55 e 0.20 for $\mu=1.5$, showing significant reduction by increasing the mass ratio.

Considering the trend of v for each mass ratio, three behavioural zone can be clearly identified. The *first zone* (e.g. very small values of T_2) corresponds to the largest values of v , since the two parts are rigidly connected, thus no relative motion is allowed and no mass-damping mechanism arises. In particular, the first mode is the mode of the main structure, which activates all the mass of the system and, due to the presence of the secondary system, shows a period slightly elongated with respect to the uncontrolled baseline counterpart. Therefore, the base shear assumes values slightly lower than the FB counterpart and the ratio becomes less than one. The *second zone* (e.g. very large values of T_2) shows base shear ratios that reach the relevant mass fractions of the primary system $m_1/(m_1+m_2)$. In particular, the dynamic behaviour of the system tends to a condition of “perfect isolation”, with the masses of the two systems almost completely decoupled, and the first and second mode respectively corresponding to the mode of the secondary and main system. The *third zone* (e.g. intermediate values of T_2) presents the minimum values of v , thanks to maximum exploitation of the mass damping mechanism. In this zone, the first and second modes are still the modes of the secondary and primary system. However, the interaction between the two parts leads to a transfer of a fraction of the main system’s mass from the second to the first mode, with a consequent significant reduction of the ratio v .

In Figure 7 the shear ratio charts (v - T_2) for three values of T_1 (1.62, 2.5, 3.5 s) are coupled to the analogous charts depicting the displacement of the primary system in the MD configuration normalized to the FB counterpart, i.e. $d = d_{I,MD}/d_{I,FB}$, and the deformation in the isolation system δ_2 , as a

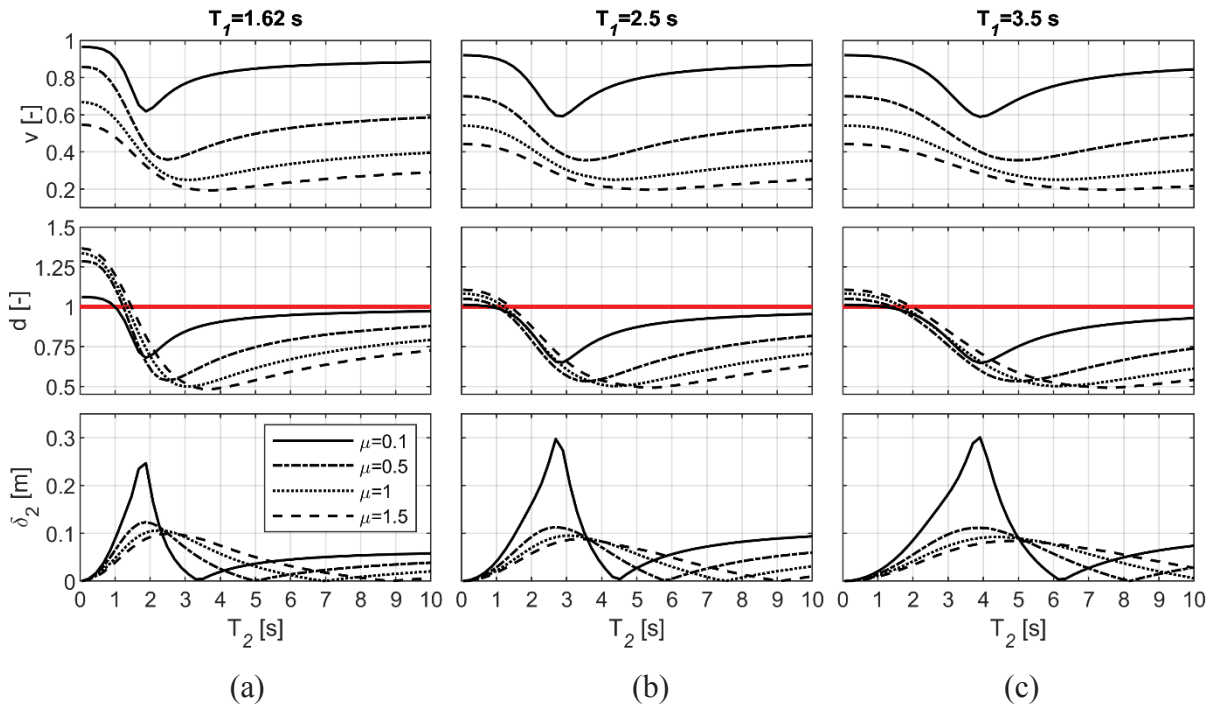

Figure 7: Ratios v , d , and relative displacement δ_2 for $\xi_2 = 0.30$: (a) $T_I = 1.62$ s, (b) $T_I = 2.5$ s, (c) $T_I = 3.5$ s.

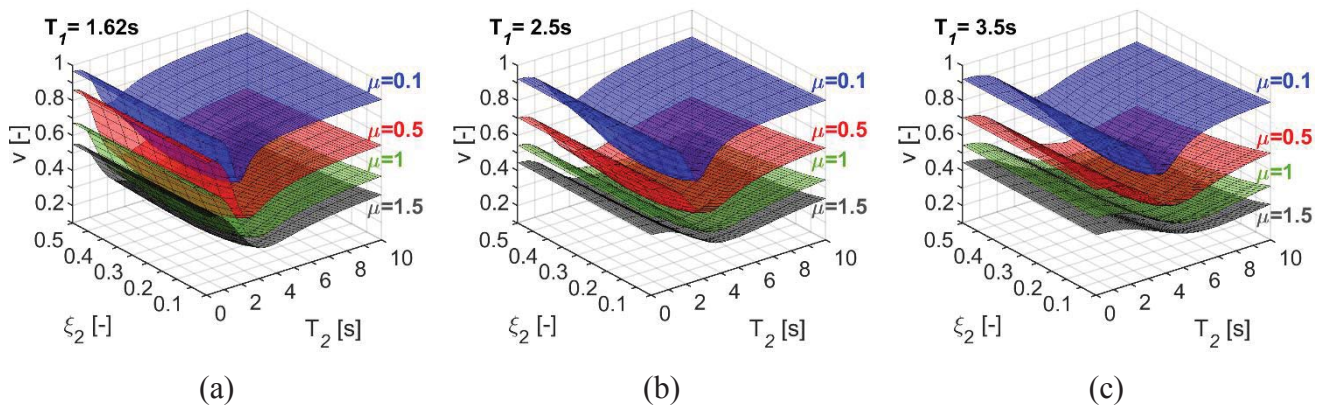

Figure 8: Base shear ratio v as a function of ξ_2 and T_2 for (a) $T_I = 1.62$ s, (b) $T_I = 2.5$ s, (c) $T_I = 3.5$ s.

function of T_2 . Quite trivially, it can be observed that the minimum values of v and d are obtained for the same value of T_2 , which also corresponds to the maximum deformation in the isolation system.

For the three baseline models, Figure 8 provides the trend of the shear ratio v as a function of the isolation period T_2 and the damping ratio ξ_2 , for each value of the mass ratio μ . It can be observed that, in the third zone of “perfect isolation”, the shear ratio v is reduced by increasing T_I , therefore the effect of ξ_2 becomes more significant for more flexible baseline models and isolation systems. In the second zone in which the mass damping mechanism is maximized and the primary and secondary systems are strongly coupled, the minimum values of v are obtained for values of ξ_2 between 0.2 – 0.4, as discussed in detail in the following section.

3.4. Comparison between the results of optimal procedures and of the parametric analysis

In this section the optimal values of the parameters v e ξ_2 derived from the results of the RSA are compared to the ones calculated by means of the optimal procedures provided in section 2. For the sake of brevity, only the results obtained for the MD controlled configuration characterized by $T_I = 1.62$ s and $\mu = 1$ are presented in the following.

In particular, six optimal configurations are defined and named as A, B, C, D, FM, W. The solution A represents the optimal configuration that gives rise to the minimum values of the base shear, and of the displacement of the primary system, obtained through the RSA. The solutions B and C are derived by assuming respectively ξ_{2opt} or v_{opt} from the optimal procedures of section 2, while the other one is retrieved from the parametric analysis (Figure 5); the solution D is entirely derived through the optimization procedure, i.e. the optimal values of both parameters are simultaneously considered (Figure 4). The solutions FM and W are derived by adopting the optimal parameters of the procedures suggested by Feng and Mita [30] and Warburton [52], respectively. The values of the optimal parameters, of the corresponding two complex modal damping ratios η_1 and η_2 , as well as of the shear ratio v , of the six solutions are reported in Table 1. It can be observed that, the solutions A and B provide the minimum shear ratio v , equal to 0.25, while the other solutions show values of the shear ratio varying between 0.28 and 0.34.

3.5. Time history analyses

In order to assess and compare the response of the six controlled configurations under real seismic inputs, time history analyses are carried out on the relevant MD and FB models. A set of ten records registered during real earthquakes is used and scaled by means of the software SeismoMatch [58], by checking the closeness of their average response spectrum to the target elastic spectrum (provided in Figure 6a) in the period range 0.05 - 4 s. Data of the ten scaled ground motions and corresponding acceleration response spectra, with the average spectrum, are given in Figure 9.

Earthquake name	Date	Comp.	PGA [g]
ethq1	Imperial Valley	18/05/1940	S00E 0.425
ethq2	Taft	21/07/1952	S69E 0.482
ethq3	Hachinohe	16/05/1968	NS 0.490
ethq4	Loma Prieta	17/10/1989	NS 0.511
ethq5	Northridge	17/01/1994	S90W 0.547
ethq6	Kobe	17/01/1995	000 0.571
ethq7	L'Aquila	04/04/2009	EW 0.472
ethq8	Chile	27/02/2010	NS 0.437

ethq10	Amatrice	24/08/2016	EW 0.617

Figure 9: Major data and acceleration response spectra of the scaled acceleration records.

The results of the analyses are here provided in Figures 10 and 11 in terms of base shear, relative displacements, floor absolute accelerations, by comparing the six controlled configurations and each MD configuration to the FB counterpart.

The Figure 10 depicts for each optimal solution the average peak response registered during the ten acceleration histories in terms of some response parameters. These parameters express the response of the controlled configuration normalized to the uncontrolled counterpart, considering the base shear, v , the relative displacement, d , and absolute acceleration, a , of the primary structure. The remarkable effectiveness of the controlled configurations emerges in terms of all the response parameters. In fact, the shear ratio v varies between 0.194 and 0.345, the displacement ratio d between 0.388 and 0.689, and the acceleration ratio a between 0.553 and 0.726. In particular, the solution B provides the maximum reductions, with values very close to the ones of the solution A, while the solution FM shows the minimum reductions and thus it represents the less efficient solution. The average envelopes of the peak displacements and absolute accelerations, obtained from the time history analyses of the controlled configurations and baseline structure, are shown in Figure 11. From the graphs it can be observed that, for all the optimal solutions the average values of story drift and absolute acceleration in the MD models are reduced with respect to the FB uncontrolled structure. The solutions A and B are confirmed the most effective in reducing the seismic response of the primary system.

4. SUMMARY AND CONCLUSIONS

In the present paper, the authors investigate the dynamic behaviour of mass damping (MD) configurations utilising isolation system, such as Mega Substructure Control Systems and Intermediate Isolation Systems, by preliminary adopting simplified lumped mass 2-DOF models. By considering a stochastic approach, the seismic acceleration is modelled as a white noise and the variance of the displacement of the first degree of freedom is minimized in the first instance with respect to both design variables, i.e. the tuning ratio and the damping ratio of the secondary system and secondly with respect to only one of these two variables. Furthermore, in order to validate this general proce-

ture, a wide parametric analysis is carried out on simplified lumped mass models and the potential benefits of such systems in reducing the seismic response of tall buildings is examined.

In particular, by selecting a 40-story tall building and by varying the mass ratio, classical and complex modal analyses show three different dynamic behavioural zones as a function of the isolation period: the first zone is characterized by a “fixed-base” behaviour, in the second zone the interaction between the two masses gives rise to the mass damping effect, while in the third zone for very long isolation periods, the two structural parts are almost dynamically decoupled.

Then, response spectrum analyses with complex modal superposition methods are performed, with the aim to compare the base shear and the displacement demands with the fixed-base counterpart simplified SDOF model. More in detail, a significant reduction of the seismic demand on the main system is observed when large mass ratios are adopted for the whole range of the isolation period, thus confirming the structural robustness of such systems. Finally, time history analyses are implemented for underlining the effects of the seismic input (amplitude, frequency content, duration, etc.) and for comparing the results of different procedures of optimization, both those proposed in the present work and those of existing literature.

Abstract

Diagrids are tubular structural systems made up of mega-diagonals arranged in a triangular or tetrahedral pattern, which are placed all over the external surface of the building and usually span across several floors. In the last two decades, diagrids have experienced a remarkable development as efficient structural systems in tall building design and construction. This was mainly due to their high lateral stiffness, capability to realize complex-shaped structures and obtain impressive aesthetic results, flexibility of the external diagonals' layout, etc. The structural analysis of these systems is usually carried out by the Finite Element Method (FEM) or by numerical calculations based on simplified assumptions. Recently, we developed a matrix-based method (MBM) to perform the structural analysis of diagrid systems under static forces. The MBM was then coupled with an analytical formulation developed in the past years by some of the authors, the so-called General Algorithm (GA), in order to study the structural response of an external diagrid tube coupled with an internal shear wall under lateral and torque static actions. The study allowed to investigate the influence of the diagonal inclination on the lateral and torsional flexibility of the diagrid-core system. In the past years, the analytical formulation of the GA was also made suitable to analyze the response of three-dimensional tall building in the dynamic regime. In this contribution, we show new results regarding the dynamical behavior of an external diagrid structural system coupled with an internal shear wall, as obtained from the GA calculations. Modal analysis was carried out in order to obtain the natural frequencies and mode shapes of the tall building, and the influence of the diagonal inclination on the results was also investigated. Moreover, by applying different harmonic oscillations at different frequencies at the base of the building, the damped dynamical response of the different diagrid-core systems was investigated.

Keywords: diagrid, matrix-based method, general algorithm, dynamic analysis, analytical method.

1 INTRODUCTION

In the last decades, the field of tall buildings has undergone a major development due to the introduction of new structural systems able to resist lateral loads very efficiently [1]. Among these, diagrid systems have been exploited worldwide due to their high lateral stiffness and aesthetic potential. The diagrid is a tubular structure placed over the external surface of the building, made up of inclined mega-diagonals [2,3] or tetrahedral configuration [4] which are designed to withstand both lateral and vertical loads. Therefore, in diagrid structures the conventional vertical columns are completely removed from the external tube, as the gravitational loads can be directly transferred to the ground via the mega-diagonals.

Besides the conventional application of Finite Element (FE) calculations, a variety of analytical and simplified methodologies have been proposed in the last years for the structural analysis of diagrid systems under lateral loads. All these methods usually rely on the following basic assumptions: (1) the deformation mechanism of the building is governed by the axial elongation and shortening of the mega-diagonals, (2) the stress-strain relationship of the diagonals lies within the linear elastic regime, and (3) the floor slabs of the building remain plane after deformation. Based on these assumptions, Moon et al. [5] developed a stiffness-based methodology for the structural analysis and preliminary design of rectangular diagrid tubes under horizontal forces. Mele et al. [6] proposed a hand-based method for the calculation of axial stresses in the diagonals under both lateral and vertical loads. Liu and Ma [7] suggested a modular method for the structural analysis of arbitrary polygonal diagrid tubes, where the shear and bending stiffness of the diagrid modules were analytically calculated.

More recently, we developed a stiffness-based approach based on matrix calculus, which was called the matrix-based method (MBM), for the analysis of generic diagrid systems [8]. The MBM is based on the direct calculation of the global stiffness matrix of the diagrid, by considering the kinematic and equilibrium equations at the level of the rigid floors. The MBM allows to perform very quickly the structural analysis of diagrids under both lateral, vertical and torsional actions. Furthermore, the MBM has been recently integrated within a more general semi-analytical framework, the so-called General Algorithm (GA). The GA has been developed by some of the authors in the last decades and allows to investigate the structural behavior of three-dimensional buildings made up of several vertical resisting elements, such as frames, tubes and shear walls [9-12]. Very recently, we have inserted the MBM within the GA environment in order to perform the structural analysis of an external diagrid tube coupled with internal shear walls [13].

One of the main interesting features of diagrid structures is that their structural response is significantly affected by the layout of external diagonals. This means that the diagonal layout can undergo optimization processes, finding the optimal diagonal arrangement to optimize certain responses of the building. Moon [14] has early shown that there exists an optimal inclination of the external diagonals able to minimize the lateral building deflection under horizontal loads. Various diagonal layouts have been proposed in the following years and the corresponding building efficiency under lateral loads has been investigated [15-18]. Attention has also been paid to torsional actions and the role that these might have in the parametric investigation of the diagrid structural response [13].

In this contribution, we make use of the MBM coupled with the GA in order to investigate how the dynamic response of an external diagrid tube coupled with an internal closed-section shear wall changes according to a change in the inclination of the external diagrid diagonals. The natural frequencies and fundamental mode shapes of the building are extracted by solving the multi-degree-of-freedom (MDOF) unforced undamped equations of motion. The analysis of the natural frequencies and mode shapes of the buildings with different inclinations of the

diagonals reveals the influence of the diagrid geometry on the overall dynamic response of the system. Furthermore, the damped dynamic response of the diagrid-core structure is also studied under the application of harmonic oscillations of the base of the building. Comparisons between the obtained maximum displacements, velocities, accelerations, inter-story drifts and base shear values are finally made.

2 METHODOLOGY

As shown in [13], the MBM can be coupled to the GA in order to carry out the structural analysis of a diagrid-core system under lateral and torsional static actions. More details about the basic assumptions and the applications of the MBM and the GA can be found in [8-13]. In the GA environment the building is assumed to be subjected to two horizontal forces (along the horizontal X and Y axes) and one torque moment (around the vertical Z axis) acting at the level of the floor centroids. It follows that the total number of DOFs in the GA is equal to $3N$, N being the total number of floors.

In this paper, the MBM-GA framework has been adapted in order to investigate the dynamic response of a diagrid-core system. First of all, the natural frequencies and fundamental mode shapes of the building are evaluated according to the MDOF undamped unforced equations of motion. Then, we apply harmonic oscillations at various frequencies at the base of the building and solve the dynamical problem based on the MDOF forced oscillations in presence of damping.

The first problem can be formulated in simple mathematical terms via the following matrix relationship related to the modal eigenvalue-eigenvector solution:

$$(\mathbf{K} - \omega_n^2 \mathbf{M}) \mathbf{u}_n = \mathbf{0} \quad (1)$$

where \mathbf{K} and \mathbf{M} represent the stiffness and mass matrix of the structure, \mathbf{u}_n is the mass-weighted eigenvector associated to the n -th mode shape ($n = 1, 2, \dots, 3N$) and ω_n is the angular frequency associated to the n -th mode of vibration. The angular frequency ω_n is related to the vibrational frequency f_n and period of vibration T_n by $\omega_n = 2\pi f_n = 2\pi/T_n$. More details about the calculation of the stiffness matrix \mathbf{K} and mass matrix \mathbf{M} can be found in [9,11]. After the construction of these matrices, equation (1) immediately yields the natural frequencies and mode shapes of the structure.

After evaluating the fundamental vibrational features of the diagrid-core building (frequencies and mode shapes), we also want to investigate the dynamic response of the structure under the application of harmonic oscillations at the base of the structure. This can be done by considering the complete dynamic equation, which includes the contribution of inertia, damping, elastic and external forces:

$$\mathbf{M}\delta''(t) + \mathbf{C}\delta'(t) + \mathbf{K}\delta(t) = \mathbf{F}_{\text{ext}}(t) \quad (2)$$

where \mathbf{C} is the damping matrix of the structure, $\mathbf{F}_{\text{ext}}(t)$ is the vector of external dynamic forces and $\delta''(t)$, $\delta'(t)$ and $\delta(t)$ represent the vectors of floor accelerations, velocities and displacements (the apex ' stands for the time-derivative). One can then separate the spatial and temporal contribution within the dynamic displacements $\delta(t)$, as $\delta(t) = \mathbf{U}\mathbf{p}(t)$, where \mathbf{U} is the matrix whose columns contain the time-independent mode shapes \mathbf{u}_n obtained from equation (1) and $\mathbf{p}(t)$ is the vector containing the time-dependent principal coordinates associated to each mode shape. Hence, we obtain:

$$\mathbf{M}\mathbf{U}\mathbf{p}''(t) + \mathbf{C}\mathbf{U}\mathbf{p}'(t) + \mathbf{K}\mathbf{U}\mathbf{p}(t) = \mathbf{F}_{\text{ext}}(t) \quad (3)$$

Multiplying each term of equation (3) by \mathbf{U}^T and remembering that, due to the mass-normalization of \mathbf{U} , $\mathbf{U}^T \mathbf{M} \mathbf{U} = \mathbf{I}$ and $\mathbf{U}^T \mathbf{K} \mathbf{U} = \mathbf{\Omega}$, \mathbf{I} being the identity matrix and $\mathbf{\Omega}$ the matrix containing the eigenvalues ω_n^2 on the diagonal and zero outside, it follows that:

$$\mathbf{p}''(t) + \mathbf{U}^T \mathbf{C} \mathbf{U} \mathbf{p}'(t) + \mathbf{\Omega} \mathbf{p}(t) = \mathbf{U}^T \mathbf{F}_{\text{ext}}(t) \quad (4)$$

The problem can now be decoupled with respect to each individual mode n if one assumes that the matrix $\mathbf{U}^T \mathbf{C} \mathbf{U}$ is diagonal, with diagonal elements equal to $2\xi_n \omega_n$, where ξ_n represents the damping ratio associated to the n -th mode of vibration. Then, one finally obtains the set of $3N$ scalar equations whose unknowns are the temporal principal coordinates $p_n(t)$:

$$p_n''(t) + 2\xi_n \omega_n p_n'(t) + \omega_n^2 p_n(t) = \mathbf{u}_n^T \mathbf{F}_{\text{ext}}(t) \quad (5)$$

Since we apply harmonic oscillations at the base of the building, the vector of external forces $\mathbf{F}_{\text{ext}}(t)$ can be simply written as $\mathbf{F}_{\text{ext}}(t) = \mathbf{M} \mathbf{u}_g''(t) = \mathbf{M} \mathbf{u}_g'' \sin(\omega_g t)$, where \mathbf{u}_g'' is the vector associated to the ground acceleration and ω_g the angular frequency of the ground oscillation. The solution of the single-degree-of-freedom (SDOF) equation of motion (5), with the application of the initial resting conditions, leads to:

$$p_n(t) = e^{-\xi_n \omega_n t} \left[A_n \cos(\omega_{d,n} t) + B_n \sin(\omega_{d,n} t) \right] + C_n \cos(\omega_g t + \phi_n) \quad (6)$$

where $\omega_{d,n} = \omega_n \sqrt{1 - \xi_n^2}$ is the reduced frequency of the n -th mode of vibration due to its damping, and the coefficients A_n , B_n , C_n and ϕ_n take the following form:

$$\begin{cases} A_n = -C_n \sin(\phi_n) \\ B_n = \frac{\xi_n \omega_n A_n - C_n \omega_n \cos(\phi_n)}{\omega_{d,n}} \\ C_n = \frac{\mathbf{u}_n^T \mathbf{M} \mathbf{u}_g''}{\omega_n^2 \sqrt{(1 - \beta_n^2)^2 + (2\xi_n \beta_n)^2}} \\ \phi_n = -\arctan\left(\frac{2\xi_n \beta_n}{1 - \beta_n^2}\right) \end{cases} \quad (7)$$

where $\beta_n = \omega_g / \omega_n$ is the ratio between the angular frequency of the external excitation and the one associated to the n -th mode shape. Once all the $3N$ principal coordinates are evaluated from equations (6-7), the displacements of the structure $\delta(t)$ are immediately obtained as $\delta(t) = \mathbf{U} \mathbf{p}(t)$. Known the time-dependent displacements of the building floors one can easily find the velocities $\delta'(t)$ and accelerations $\delta''(t)$ by single and double time-differentiation. The inter-story drifts can also be evaluated directly from the vector $\delta(t)$. Finally, the total time-dependent base shear $V(t)$ is calculated by summing all the horizontal elastic forces at the level of the floors, which can be computed as $\mathbf{F}_{el}(t) = \mathbf{K} \delta(t)$.

The analytical procedure described in the above paragraphs is applied to a tall building made up of an external steel diagrid tube coupled with an internal closed-section concrete core. Figure 1a shows the dimensions (in meters) of the building plane, while figure 1b reports the six different lateral views by considering six different inclinations of the external diagonals [13]. The building has 40 stories and the inter-story height is equal to 4 meters, leading to a total height of the building of 160 meters. The internal core is a 9 m \times 9 m closed-section shear wall made of concrete (Young's modulus of 30 GPa) and 0.80 m thick. The ex-

ternal diagonals are made of steel (Young's modulus of 210 GPa) and their cross-sectional area is equal to 0.1 m^2 [13]. The different diagonal inclinations of the models (figure 1b) range from 32.6° (model 1) up to 81.1° (model 6). The mass of the structure is calculated assuming a dead load for the floors equal to 7 kN/m^2 . Finally, the damping ratio ξ_n is considered equal to 0.05 for all the modes of vibration.

Figure 1: Building geometry: (a) floor plan; (b) lateral views. From Lacidogna et al. [13].

3 RESULTS AND DISCUSSION

Table 1 shows the first ten values of the natural frequencies (in Hz) arising from the MDOF unforced oscillation problem reported in equation (1) for the six models. The letters X, Y and Z in the parentheses describe the predominance direction of the mode shape: X and Y refer to lateral oscillations of the building along the X and Y direction, respectively, while T means that there is a not negligible contribution due to the torsional rotation of the building.

As can be seen, due to the symmetry of the building (figure 1a), the first two modes involve lateral oscillations along the X and Y axis at the same frequency for all models. The absolute value of this fundamental frequency is found to be maximum (0.364 Hz) for model 3 and minimum (0.243 Hz) for model 1. The first frequency of model 4 (0.362 Hz) is close to that of model 3, whereas the first frequencies of models 2 (0.321 Hz), 5 (0.339 Hz) and 6 (0.320 Hz) lie in between. Since higher frequencies are associated to stiffer responses, these results reflect a feature already found from the static analysis performed in [13], i.e. model 1 (the one with the shallowest diagonals) has the lowest lateral rigidity, whereas models 3 and 4 (with diagonal inclinations around 70°) are the stiffest under lateral loads.

For higher mode numbers an important torsional contribution is found to appear associated with displacements of the structure along the Y direction. It is interesting to notice how the first mode shapes involving significant torsional rotations are found at the fifth mode for models 1 and 2 and at the third mode for the other models. Moreover, the fundamental frequency values associated to these first torsional oscillations are found to decrease as the number of the model increases, i.e. it is maximum for model 1 (2.313 Hz) and it decreases up to the minimum value for model 6 (1.186 Hz). Again, since higher frequencies correspond to stiffer responses, these results show that increasing the diagonal inclination of the diagrid leads to higher torsional flexibility, as already shown by the static analysis reported in [13].

Mode number	Model 1	Model 2	Model 3	Model 4	Model 5	Model6
1	0.243 (X)	0.321 (X)	0.364 (X)	0.362 (X)	0.339 (X)	0.320 (Y)
2	0.243 (Y)	0.321 (Y)	0.364 (Y)	0.362 (Y)	0.399 (Y)	0.320 (X)
3	1.499 (X)	1.857 (Y)	1.581 (Y+T)	1.442 (Y+T)	1.243 (Y+T)	1.186 (Y+T)
4	1.499 (Y)	1.857 (X)	1.834 (X)	1.746 (Y)	1.539 (Y)	1.458 (Y)
5	2.313 (Y+T)	2.105 (Y+T)	1.834 (Y)	1.746 (X)	1.539 (X)	1.458 (X)
6	4.115 (X)	4.777 (Y)	4.432 (Y+T)	4.200 (Y+T)	3.688 (Y+T)	3.520 (Y+T)

10	7.879 (X)	8.641 (X)	7.834 (Y+T)	7.508 (Y+T)	6.961 (Y+T)	6.820 (Y+T)

Table 1: Natural frequencies (in Hz) of the diagrid-core system depending on the diagrid diagonal inclination.

After evaluating the natural dynamic response of the diagrid-core system, various harmonic oscillations at different frequencies are applied to the base of the building and the dynamic structural response examined as obtained from equations (2-7). The time-dependent acceleration applied at the base of the building is of the form $u_g'' \sin(\omega_g t)$, being $u_g'' = 0.03 \text{ m/s}^2$ the maximum ground acceleration in the X direction and $\omega_g = 2\pi/T_g$ the ground angular frequency, with T_g varying in the range $0.01 \text{ s} - 8 \text{ s}$. Figures 2-6 show the results in terms of maximum story displacement, maximum story velocity, maximum story acceleration, maximum inter-story drift and maximum base shear, respectively, as a function of the applied ground oscillation period T_g and diagrid model.

Figure 2 shows that each diagrid-core system exhibits the largest value of the lateral displacement when the period of the ground oscillation matches the fundamental period of vibration of the building. With reference to the frequency values reported in table 1, this is found to occur when T_g is approximately equal to 4.1 s, 3.1 s, 2.8 s, 2.8 s, 2.9 s, and 3.1 s for models 1, 2, 3, 4, 5 and 6, respectively. Therefore the high peaks in the graphs of figure 1 refer to resonance phenomena related to the first modes of vibrations of the diagrid-core system. Clearly, adopting different diagonal inclinations makes the position of this resonance peak to translate horizontally with respect to the variable T_g , as the fundamental frequency of vibration of the system changes (table 1). It is also interesting to notice that the amplitude of this resonance peak is maximum for model 1 (blue curve), while it reaches a minimum value for models 3 (orange curve) and 4 (purple curve). This result is again in agreement with the above-mentioned fact that models 3 and 4 are indeed the most rigid ones against lateral forces, whereas model 1 is the most flexible. Therefore, the maximum dynamic displacements of the building floors are the highest for model 1, lowest for models 3 and 4, and exhibit intermediate values for models 2 (red curve), 5 (green curve) and 6 (light blue curve).

Figures 3 and 4 report the corresponding spectra of maximum story velocities and accelerations, respectively. Again, we find the largest resonance peaks in correspondence of the fundamental periods of the structure. However, in these cases we also start to see additional resonance peaks at lower periods (higher frequencies). The velocity response spectrum shows secondary resonance peaks around $0.5 - 0.7 \text{ s}$ (figure 3), which correspond to the activation of the second lateral vibrational modes (table 1). These secondary peaks are also found in the acceleration response spectrum (figure 4).

This spectrum is also found to exhibit tertiary resonance peaks around $0.2 - 0.3 \text{ s}$, which correspond to the resonance conditions along the third modes of vibration along the X direction (table 1). The amplitudes of the resonance peaks in the velocity spectrum (figure 3) exhibit similar trends of those reported in the displacement spectrum (figure 2), but here the

difference between the peaks corresponding to the different diagrid models is reduced. In the acceleration spectrum (figure 4), the amplitudes of the fundamental resonance peaks get somewhat inverted, since model 1 is the one experiencing the lowest acceleration, whereas models 3 and 4 are the ones undergoing the highest value. This is mainly due to the fact that, being models 3 and 4 the stiffest ones, they are not highly deformable but can undergo high accelerations due to their stiffer response.

Figure 2: Maximum story displacement of the diagrid-core system.

Figure 3: Maximum story velocity of the diagrid-core system.

Figure 4: Maximum story acceleration of the diagrid-core system.

Figure 5 shows the maximum inter-story drifts depending on the diagrid-core model and the value of the ground oscillation period T_g . As can be seen, this spectrum strictly resembles the one of absolute displacements. However, in this case a somewhat clearer occurrence of the second resonance peaks at 0.5 – 0.7 s can be observed.

Figure 5: Maximum inter-story drift of the diagrid-core system.

Finally, figure 6 reports the maximum value of the total shear at the base of the building obtained for each oscillation period T_g and each diagrid-core model. In this case, three clear resonance peaks can again be observed, in analogy with the acceleration spectrum reported in figure 3. From the graph of the base shears, it can be seen that model 1 is the one absorbing the least amount of elastic force, as it is already known to be the most flexible under lateral loads. On the other hand, since the other models are stiffer, they exhibit a higher value of the base shear. These results reflect the fact that, under dynamic excitations, there is a general trade-off between the displacement-based and force-based demand. Stiffer structures obviously lead to lower displacements but they usually are required to withstand higher amounts of force. On the other hand, more flexible solutions undergo larger displacements but they are less loaded. However, this is also strongly affected by the frequency of the external excitation. Large dynamic responses, with high dynamic amplifications, are obviously generated if the excitation frequency is close to the fundamental ones of the structure. Conversely, if we are far from the resonance condition, the dynamic response of the building might lead to low values of the displacements as well as elastic forces.

Figure 6: Maximum base shear of the diagrid-core system.

4 CONCLUSIONS

In this contribution we presented the analytical investigation of the dynamic response of a diagrid-core system for tall buildings. For this purpose, a matrix-based method (MBM) was employed within the framework of a General Algorithm (GA). For a set of diagrid-core systems with different inclinations of the external diagonals, the analytical formulation allowed to quickly evaluate the natural frequencies and mode shapes of the structure, as well as the damped response under harmonic oscillations at different frequencies. The semi-analytical formulation led to the investigation of the maximum values of the story displacements, velocities and accelerations under the external excitations, as well as the inter-story drifts and generated base shears.

It was found that diagrid solutions with very shallow diagonals lead to the highest lateral flexibility and lowest torsional deformability. Conversely, the lowest lateral flexibility was found for diagonal inclinations close to 70° . These diagrid solutions led to the lowest values of lateral displacements, but they were the ones experiencing the highest amount of elastic shear force in resonance conditions. Conversely, the most flexible solutions (with very shallow diagonals) were found to undergo the highest dynamic displacements, but experienced the least amount of elastic force. From these considerations, it follows that the dynamic response of a diagrid-core tall building strongly depends on the geometry of the external diagrid tube. However, great attention must also be paid to the fundamental frequency of the external excitation. When far from resonance conditions, each structural solution might have its advantages in terms of minimizing the lateral displacements and generated elastic forces.

Abstract

Slender structures as lighting poles and telecommunication towers are usually very sensitive to wind effects due their dynamic characteristics and due to their notable exposure to wind forces. Wind-induced forces produce fluctuating stress, which, despite the assessment of dynamic properties and the study of the environmental conditions, can lead to damage accumulation and consequent collapse of these structures. Careful attention to wind forces has, therefore, to be paid for these typologies of structures, since several damages have been attributed to fatigue issues. It is well known that damping and structural frequencies play a fundamental role in the structural response under wind loads; in fact, an increase of damping would lead to remarkable beneficial effects on the dynamic response of these structures. This paper focuses the attention on a mathematical model of a damped gyroscopic device conceived as a dynamic stabilizer for such slender structures; the proposed mechanical device allows for an increase of structural damping with a consequent improvement of dynamic performances of the tower subjected to wind loads. A parametric study for different mechanical properties of the gyroscopic device has been conducted in the present paper aiming to assess the effectiveness of the proposed apparatus for different configurations of the proposed device.

Keywords: Monopole towers, Slender structures, Gyroscopic stabilizer, Frequency increment, Damping increment.

1 INTRODUCTION

The Monopole towers are slender structures usually employed for supporting communication devices or lighting poles. It is generally recognized that these structures are very sensitive to wind effects and to uncertainties related to wind forces and to structural dynamic features [1, 2]. In past years, the authors have studied the dynamics of the monopole towers [3], among wind sensitive structures, ensuring the presence of specific design problems related to the definition of wind load and the dynamic characteristics of the structure as shown in [4, 5]. Dynamic performances of these structures are therefore strongly affected by environmental conditions and by dynamic and geometrical properties of these structures [6, 7].

Proper assessment of environmental conditions (ground roughness, exposition, orographic placement) combined to dynamic structural characteristics of the mast, is an important topic since these factors deeply affect the structural dynamic behavior of these systems [3, 7, 8]. However, despite the assessment of dynamic characteristics and the examination of the environmental conditions, cautious attention to fatigue problems has to be paid for this typology of slender structures e.g. [7-9].

Gyroscopic systems have been always studied in automotive and in mechanical systems [10-14]; moreover, the interaction between the beam and gyroscopic devices has been studied by several authors for examining their dynamic behavior [15-18] moreover recently gyroscopic devices were applied as structural isolation device in seismic engineering [19].

This paper proposes a direct integration approach for simulating the structural interaction between the gyroscopic device and the vertical mast of the tower, utilizing a mathematical model of the gyroscopic device applied to lumped mass mast model already developed by the author in a previous paper [20], in the present work, a parametric study performed on mechanical properties of the gyroscopic device has been performed, aiming to assesses and to optimizes the performances of the proposed device.

The principal component of the gyroscopic system is a rotating mass, having a horizontal angular momentum Ω perpendicular to the mast axis; the rotating mass is connected to the vertical shaft by a mechanical system provided with rotational damped spring system, which allows relative rotations (in the horizontal plane) between the vertical shaft and the rotating mass. The gyroscopic system reacts to the mast horizontal oscillations by coupling its vibrations with the relative rotation of the gyroscopic device, consequently transferring the energy from the mast to the damped gyroscopic device [11].

Results show that the gyroscopic stabilizer allows, for an increasing of the natural frequency of the system, as confirmed by Yamanaka [21] and Carta et al. [17, 19] and for a remarkable increasing of damping of the tower; which, plays an important role in the reduction of wind-induced vibrations amplitude of slender structures [22-24]. The study demonstrates that the effectiveness of the device depends on the mechanical properties of the gyroscopic device which have to be properly set in order to optimize the efficiency of the proposed apparatus.

2 BACKGROUND MATHEMATICAL MODELS AND BENCHMARK SYSTEM

The present approach is based on the dynamic equilibrium equations of the gyroscopic lumped system with gyricity Ω described by D'Eleuterio [11] and on the hypothesis of the continuous Euler-Bernoulli beam dynamic equation; in the present work, the structural damping of the mast is not taken into account. The proposed formulation is valid for a gyroscopic device positioned at the elevation H_Q of the mast, the equation considers the bending mo-

ments M_{uu} , M_{vv} and of the torsional moment M_{ww} of the mast acting on the gyroscopic device. In case of small oscillations dynamic equation of the lumped gyroscopic device can be written as:

$$\begin{aligned} J_{\Omega,11}\ddot{\alpha} + C_{\alpha}\dot{\alpha} + K_{\alpha}\alpha + M_{ww}^{do} - M_{ww}^{up} &= -\Omega\dot{v}' \\ J_{\Omega,22}\ddot{v}' + M_{uu}^{do} - M_{uu}^{up} &= \Omega\dot{\alpha} \\ J_{\Omega,33}\ddot{u}' + M_{ww}^{do} - M_{ww}^{up} &= 0 \end{aligned} \quad (1)$$

Where u and v respectively indicate displacements in the horizontal and transversal direction, the dot \cdot indicates time derivative, the superscripts ' indicate derivative with respect to the vertical axis w and the superscripts up and do indicate the position “up” and “down” of the cross-section respect to the position of the gyroscopic device. According to above-mentioned hypotheses and after a proper static matrix condensation dynamic equilibrium of the undamped free vibrations of the system can be written in matrix form as:

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{0} \quad (2)$$

Figure 1: Monopole tower with gyroscopic device: (a) Schematic of the structure, (b) Generalized lumped mass model, orientation and displacements.

Where \mathbf{M} , and \mathbf{K} represent respectively the $2N \times 2N$ mass and stiffness matrix of the system depicted in Fig.1 $\ddot{\mathbf{x}}$ and \mathbf{x} symbolize respectively generalized accelerations and displacements vectors of the $2N$ degrees of freedom (DOF) of the structure in the two directions u and v , being N the number of lumped masses of the system.

Accounting on the further DOF α of the gyroscopic device and according to above mentioned hypotheses Eq.1 and Eq.2 [20], can be conveniently combined as a function of a non-dimensional time $\tau = \bar{\omega}_0 t$ and converted to non-dimensional displacements $\chi_j = x_j / D$ in a matrix forma as:

$$\mathbf{M}_n \chi'' + \frac{C_{\alpha}}{M_0} \mathbf{C}_n \chi' + \bar{\omega}_0^2 \mathbf{K}_n \chi = \mathbf{K}_{n,\Omega}(\chi, \chi') \quad (3)$$

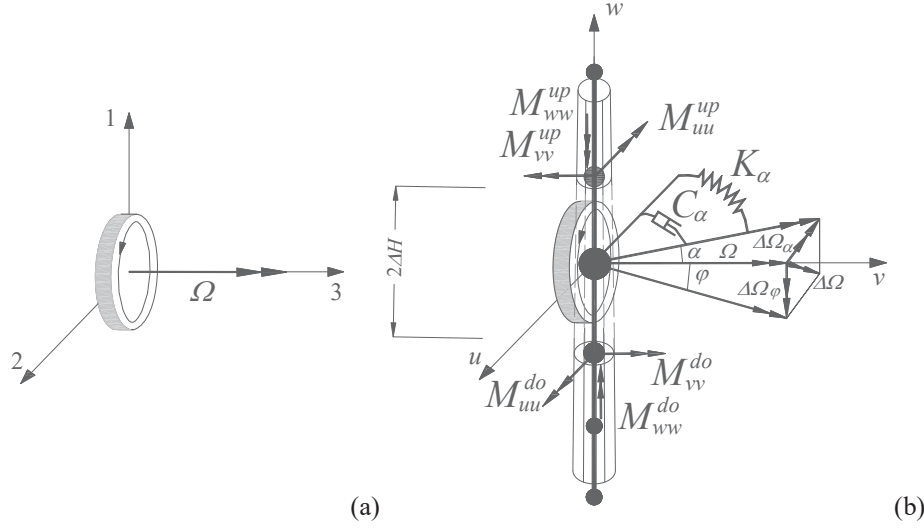

Figure 2: (a) Rotating mass with the local reference axes, (b) schematic of the gyroscopic device placed on the mast.

Where \mathbf{M}_n , \mathbf{C}_n and \mathbf{K}_n represent respectively the normalized mass damping and stiffness $(N+1) \times (N+1)$ matrix of the system depicted in Fig.1, were the additional DOF present in the matrices is due to the further DOF α of the gyroscopic device and $\bar{\omega}_0 = \sqrt{k_0/M_0}$ is the reference pulsation of a single DOF with reference mass M_0 and stiffness $k_0 = 3EI/H^3$, $\mathbf{M}_n = \mathbf{M}/M_0$, \mathbf{C}_n and $\mathbf{K}_n = \mathbf{K}/M_0$ represents respectively the normalized mass matrix, damping matrix and stiffness matrix of the system. The quantities χ'' , χ' and χ are respectively the unknown non-dimensional vectors of the generalized accelerations, velocities and displacements with respect to the dimensionless time τ , $C_\alpha = 2\bar{\omega}_0 J_\alpha \zeta_\alpha$ is the damping coefficient of the of the gyroscopic device with stiffness K_α , inertia $J_\alpha = J_{\Omega,11}$, undamped pulsation $\bar{\omega}_\alpha = \sqrt{k_\alpha/J_\alpha}$ and damping ratio ζ_α . Normalized undamped pulsation of the gyroscopic device can therefore written as function of the reference system pulsation $\bar{\omega}_0$ as $\alpha_\alpha = \bar{\omega}_\alpha/\bar{\omega}_0$ [20].

As it can be noticed from an examination of Eq. (1), displacements in the u - w plane do not involve the gyricity of the system, moreover, given the hypothesis of a lumped mass model having their barycenter coincident with the mast shear center cross-section; displacement u (in the u - w plane) can, therefore, considered decoupled from the remaining degrees of freedom of the structure [25]. The model described in section 2.1 with $2 \times (N+1)$ DOF, can be consequently reduced to a $N+1$ DOF system for proper boundary conditions which does not involve displacements in the u - w plane. Accounting of the above-mentioned hypotheses the lumped mass model with the gyroscopic device will be treated in the following as a $N+1$ DOF system.

To assess the effectiveness of the proposed apparatus, numerical integration of the discrete dynamic equations has been conducted, similar verification approaches were already utilized by the authors in [20, 26-28].

3 NUMERICAL RESULTS

The prototype of the proposed gyroscopic device applied to the lumped mass system depicted in Fig. 1 is examined in this section. Without any loss of generality, the lumped masses are constant and equally distributed in the shaft with $m_i=m$; in order to perform a parametric study, generalized properties of the system are defined as a function of the reference system having mass M_0 (mass of upper platform), stiffness k_0 (stiffness of a cantilever beam with height H and flexural stiffness EI), reference pulsation $\bar{\omega}_0$.

The gyroscopic system has been placed in the N -1- th mass of the lumped mass model with $N=16$. The considered structure is a slender lighting pole typically utilized for illumination of large areas, sizes and structural properties are shown in Table 1:

H (m)	ρ_{mast} (kg/m)	M_0 (kg)	D (mm)	z_Ω (m)	EI (N×m ²)	N (-)	Δz (m)	m (kg)	$\bar{\omega}_0$ (rad/s)
22	71.47	687.9	211.2	20.6	3.07e+7	16	1.37	98.27	1.88

Table 1: Structural properties of the monopole tower and of the corresponding lumped mass model.

Generalized properties of the gyroscopic system (refer to Table 2) are defined as a function of the structural characteristics of the mast, therefore non-dimensional magnitudes defining the gyroscopic device are: the mass ratio $\mu_{M,\Omega}=M_{\Omega,TOT}/M_0$ (respect to the reference mass M_0), the radius of gyration ratio $\mu_{\rho,\Omega}=\rho_\Omega/D$ (respect to mast diameter D), so that $J_{\Omega,p} = M_0\mu_{M,\Omega}(D\mu_{\rho,\Omega})$ and $J_{\Omega,11} = J_{\Omega,22} = 0.5J_{\Omega,p}$. Mechanical properties of the gyroscopic apparatus as stiffness k_a , damping coefficient C_a , damping ratio ζ_a , pulsation $\bar{\omega}_a$ and normalized pulsation α_a are illustrated in Table 2.

$\mu_{M,\Omega}$ (-)	$M_{\Omega,TOT}$ (kg)	M_Ω (kg)	m_Ω (kg)	$\mu_{\rho,\Omega}$ (-)	ρ_Ω (m)	$J_{\Omega,p}$ (kg×m ²)	$J_{\Omega,11}=J_{\Omega,22}$ (kg×m ²)	K_a (N×m)	C_a (N×m×s)	ζ_a (-)	$\bar{\omega}_a$ (rad/s)	α_a (-)
0.10	68.79	67.15	0.82	1.42	0.30	6.14	3.07	-	11.66	10	0.19	0.10

Table 2: Mechanical properties of the gyroscopic device.

It must be noted that the presence of the mass of the gyroscopic device affects the global behavior of the original structure, is therefore important to reduce as much as possible the additional mass of the gyroscopic device $M_{\Omega,TOT}$ and its radius of gyration ρ_Ω which respectively influence the structure natural frequency and its aerodynamic behavior. Therefore, careful attention must be paid for the design of the gyroscopic apparatus especially regarding the additional mass increment for possible buckling effects and frequency reduction and its size for a suitable aerodynamic design. Equation 3 has been solved by fourth-order Runge-Kutta algorithm [34] which requires appropriate initial boundary conditions at $\tau=0$ selected to examine the dynamic response of the first mode by imposing zero velocities and initial displacements in the y - z plane, proportional to linear eigenvector Φ of the structure without gyricity ($\Omega=0$) according to a preselected amplitude parameter $\delta = y/D$.

Fig. 3. First vibration mode of the examined lumped mass model for $\mu_{M,\Omega}=0.10$, without gyricity ($\Omega=0$).

Free vibrations corresponding to the first mode of the dynamic system with the gyroscopic device are illustrated in Fig. 4. Fig. 4a shows normalized displacements x/D of the top of the tower and angular rotations α of the gyroscopic device acting with gyricity $\Omega=\omega J_{\Omega,p}$ ($\omega=180$ rad/sec) for different stiffness K_α of the spring device. Results illustrate the effectiveness of the proposed device in increasing the total damping of the mast, low values of stiffness K_α involve higher values of angular rotations α (refer to Fig. 4b), which in turn allow higher equivalent damping ratios ζ_Ω of the tower. As can be observed by the inspection of Fig. 4a, the effectiveness of the device increases with the decreasing of the device spring K_α , which allows (for a constant gyricity Ω) the maximum effectiveness for $K_\alpha=0.01$, by an inspection of Fig.4b, it must be noted that a further decreasing of the K_α would led, as expected, to unacceptable angular rotations which it would not satisfy the hypotheses of small oscillations on which Equation 1 is based.

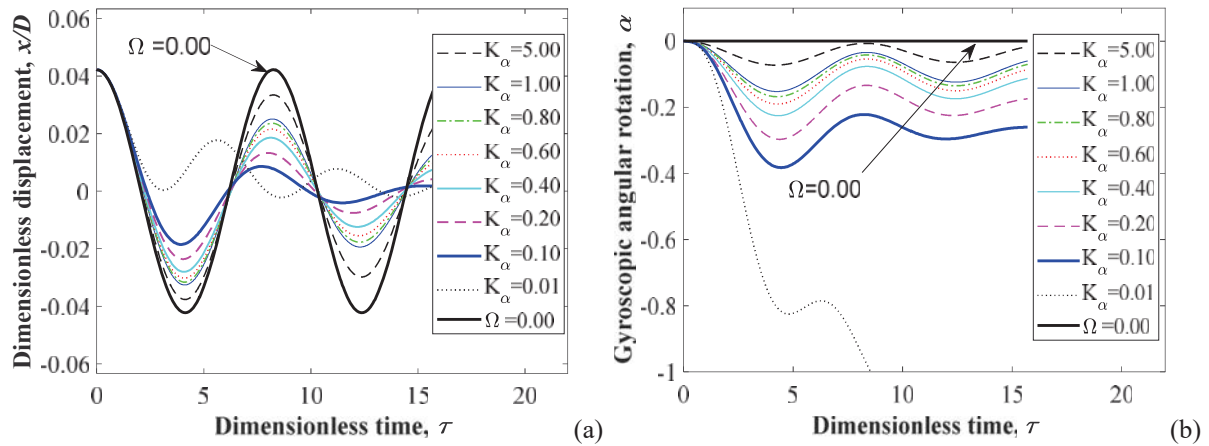

Figure 4. Time history analysis of the free vibrations of the first mode of the tower with $\mu_{M,\Omega}=0.10$, $\mu_{p,\Omega}=1.42$, corresponding to an amplitude parameter $\delta=y/D=0.20$ with constant gyricity $\Omega=\omega J_{\Omega,p}$ ($\omega=180$ rad/sec) for different stiffness of the gyroscopic device spring K_α : (a) normalized horizontal displacements y/D of the N -th point and (b) rotations α of the gyroscopic device.

The results of Fig.4 are corroborated by the data illustrated in Fig.5. which show an increasing of α_Ω and of ζ_Ω with the decreasing of the spring stiffness K_α . The effectiveness of the proposed gyroscopic device acting with the same gyricity, is therefore directly connected to the spring stiffness K_α .

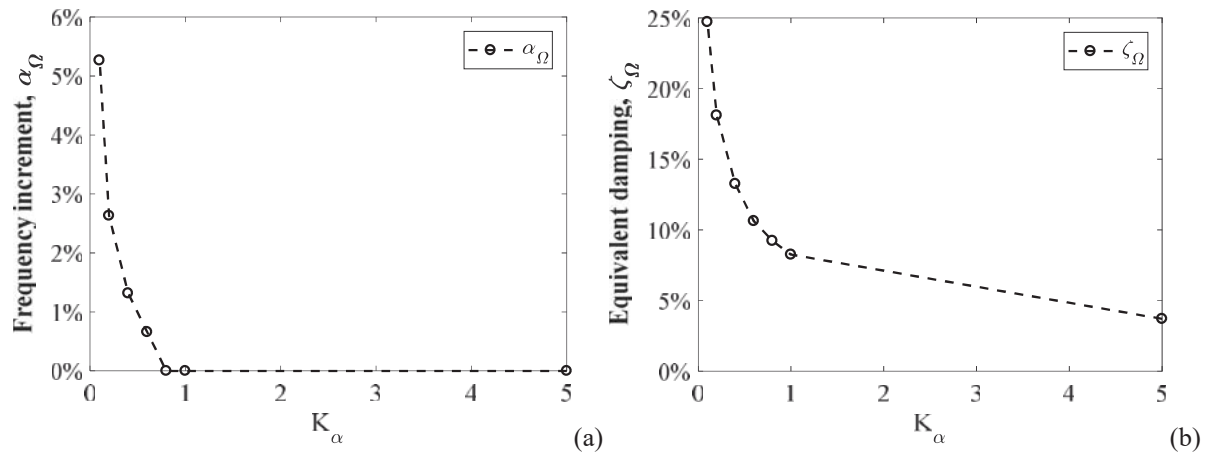

Figure 5. Parametric analysis as function of the stiffness of the gyroscopic device spring K_α for the first mode of the tower with $\mu_{M,\Omega}=0.10$, $\mu_{p,\Omega}=1.42$, $\delta=y/D=0.20$ and constant gyricity $\Omega=\omega J_{\Omega,p}$ ($\omega=180$ rad/sec), (a) Normalized damped frequency α_Ω and (b) equivalent damping ζ_Ω of the tower.

4 CONCLUSIONS

This paper investigated the effects of a prototype of a gyroscopic device installed in slender monopole tower. Results show that the presence of the device allows for an increase of the frequency and for a remarkable increase of damping of the tower; the effectiveness of the device depends on its mechanical properties. A further parametric study assesses and optimizes the performances of the gyroscopic device as a function of the angular spring stiffness K_α which connects the gyroscope to the mast. Results illustrate that stiffness spring K_α can be considered a key parameter for adjusting and setting the mechanical properties of the gyroscopic device.

Abstract

The application of dynamic vibration absorbers (DVA) to Wind Turbine (WT) towers has the potential to significantly improve the damping of the tower and the nacelle dynamic responses, thus increasing the reliability of WTs. The Tuned Mass Damper (TMD) is considered a benchmark for vibration absorption of WT. However, its effectiveness is limited by the requirement of large masses, in association to its installation location. Thus, an alternative concept is introduced, which is based on a novel passive vibration absorption configuration, the extended KDamper concept. The KDamper is essentially an extension of the conventional TMD, introducing appropriate negative stiffness (NS) elements. Instead of increasing the additional mass, the vibration absorption capability of the KDamper can be increased by increasing the value of the NS element. Therefore, the KDamper always indicates better isolation properties than a TMD with the same additional mass. In this paper, the performance of these concepts is examined for increasing the damping of WT towers. A constrained optimization procedure is presented, from which the optimal design parameters are obtained. Although both concepts present a good behavior, the KDamper-based design significantly increases the effective damping of the WT tower, retaining the additional masses in reasonable ranges.

1 INTRODUCTION

Wind power continues its rapid growth worldwide and as a result, wind farms are likely to comprise a significant portion of the total production of wind energy. The high-quality wind resource and the proximity to load centres make wind energy a compelling proposition. The WWEA predicts that offshore wind farms of 150GW will operate in the EU by 2030, contributing 14% of the EU's total electricity consumption. However, the above prediction is very ambitious. In recent years, several failures have been recorded in existing wind turbines (WT). It is estimated that the structural failure (tower, foundation) of the installed WT amounts up to 10% [1]. In addition, the structural and foundation costs are excessively high, reaching up to 17% for land based (onshore) and fixed bottom offshore WT.

From the above comments, and according to the International Energy Agency [2], it emerges as top priority to enhance research to avoid WT structural failures. A way to extend the feasibility of Wind Turbine towers is by means of structural control.

The concept of a resonant damper, like a Tuned Mass Damper (TMD) is among the approaches that have received the most attention in the literature. The principal of the TMD system [3] is the degradation of the dynamic response of the system through energy transfer to a system of an additional mass, designed with optimum characteristics and adapted in a suitable position in the structure [4,5]. Active [6,7] and semi-active [8–12] TMD have been examined thoroughly in the latest year, enhancing the damping performance of the passive TMD. The downside of such designs is that their performance is directly (or obliquely) depended by the accuracy of the actuators output, which over time can have an alternation in its performance. In addition, the essential limitations of all the aforementioned TMD-related concepts, are related with the location and the selected mass of these devices. TMD should be installed at the top of the tower or inside the nacelle in order to be effective, and is associated with large additional masses, which constitutes a major limitation, since additional mass is highly undesirable at the top of the WT. In addition, a slight alteration in the system parameters can alter the TMD tuning and reduce the system performance [13].

In this paper, the (extended) KDamper is intervened between the nacelle and the WT tower. The KDamper, introduced in [14], is essentially an extension of the TMD, by incorporating appropriate negative stiffness (NS) elements. Instead of increasing the additional mass, the vibration isolation capability of the KDamper can be increased by the NS, overcoming the sensitivity problems of TMDs as the tuning is mainly controlled by the NS. Thus, the KDamper always indicates better isolation properties than a TMD with the same mass, finding numerous applications for vibration absorption in structural systems [15–24]. Although the KDamper incorporates a NS element, it is designed to be statically and dynamically stable.

Section 2 of the paper presents the dynamic model of the WT tower. The developed model is an assemblage of prismatic beam elements with sway DoFs considered to be the dynamic ones. In order to verify the validity and the efficiency of the developed model, a set of simplified analyses were conducted and compared with a commercial software package based on FEM. The aerodynamic load is taken into account by generating artificial basic wind velocities following the corresponding regulations of EC1 and applying it at the WT following the procedure described in [25]. Section 3, presents the optimization procedure for the EKD. The independent design variables are presented, and proper limitations and constraints are imposed on the design variables and the system main dynamic responses, based on the proposed constrained engineering-criteria driven optimization procedure. In section 4, the numerical results are presented, where the effectiveness of the EKD is verified. A comparison with a conventional TMD (2% mass) confirms that the EKD manages to significantly increase the effective damping of the WT tower, and thus mitigate the WT dynamic responses, with small

additional masses and a realistically designed configuration. In section 5, the conclusive remarks are presented, based on the nonlinear dynamic responses of the controlled WT tower with the proposed VCS and the comparison with the conventional TMD.

2 MATHEMATICAL MODELLING OF WIND TURBINE FOUNDED ON MONOPILE FOUNDATION

2.1 Dynamic Model of WT with Monopile Foundation

An onshore wind turbine (WT) tower of length l_t and variable tubular cross-section $A_t(x)$ is examined, as presented in Figure 1. The tower supports the NREL baseline 5MW nacelle and rotor [26,27]. In order to account the inertial forces applied by the mechanical parts (nacelle, rotor, and blades) an additional concentrated mass m_{top} is added at the top of the tower [27]. The WT is founded on a monopile of length l_p of cylindrical cross-section A_p . The monopile is embedded in a layered Winkler type soil profile represented by a Kelvin-Voigt element (i.e. elastic spring - dashpot parallel configuration $k_s - c$).

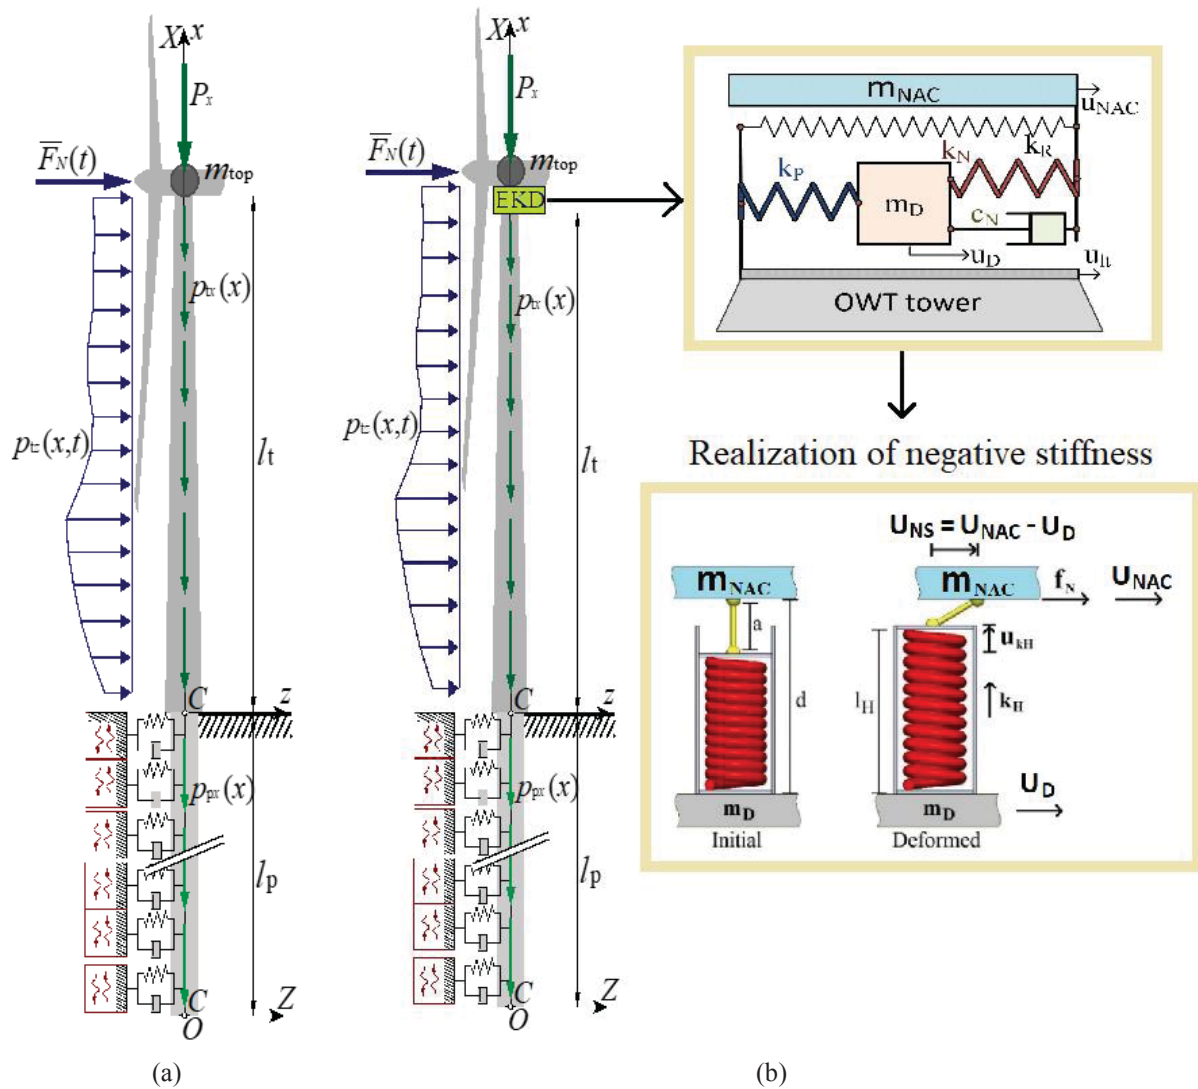

Figure 1: Wind turbine tower of variable cross section founded on monopile foundation. (a) Uncontrolled structure, and (b) controlled structure with EKD at the top of the WT tower.

The transient nonlinear dynamic response analysis of the tower-pile system is investigated through a *Beam of Variable Cross Section* over a *Beam on Winkler Foundation* formulation accounting for both kinematic and inertia interaction. Considering large displacements and employing the second Piola-Kirchhoff stress tensor, the geometrically nonlinear equations of motion of the WT are obtained as follows:

$$\begin{bmatrix} \mathbf{M}_t & \mathbf{0} \\ \mathbf{0} & \mathbf{M}_p \end{bmatrix} \begin{Bmatrix} \ddot{u}_t \\ \ddot{u}_p \end{Bmatrix} + \begin{bmatrix} \mathbf{C}_t & \mathbf{0} \\ \mathbf{0} & \mathbf{C}_p \end{bmatrix} \begin{Bmatrix} \dot{u}_t \\ \dot{u}_p \end{Bmatrix} + \begin{bmatrix} \mathbf{K}_t(x) & \mathbf{K}_{tp}(x) \\ \mathbf{K}_{pt}(x) & \mathbf{K}_p(x) \end{bmatrix} \begin{Bmatrix} u_t \\ u_p \end{Bmatrix} = \begin{Bmatrix} F_t(x) \\ F_p(x) \end{Bmatrix} \quad (1)$$

where (\cdot) denotes differentiation with respect to the time t . Moreover, $[M_t]$, $[M_p]$, $[C_t]$ and $[C_p]$ are the matrices of mass and damping of the WT tower and monopile, respectively. $[K_t]$, $[K_p]$ and $[F_t]$, $[F_p]$ are the nonlinear stiffness matrices and force vectors containing the geometrically nonlinear terms, while $\{u_t, u_p\}^T$ denotes the vector of unknown nodal displacements. By introducing a vibration control system (VCS) at the top of the tower, the tower related matrices of Equation 1 are modified as:

$$[\mathbf{M}_t] = \begin{bmatrix} [\mathbf{M}_s]_{N \times N} & [\mathbf{0}]_{N \times n} \\ [\mathbf{0}]_{n \times N} & [\mathbf{0}]_{n \times n} \end{bmatrix} + \begin{bmatrix} [\mathbf{M}_{n,a}]_{N \times N} & [\mathbf{0}]_{N \times n} \\ [\mathbf{0}]_{n \times N} & [\mathbf{M}_{n,d}]_{n \times n} \end{bmatrix}_{(N+n) \times (N+n)} \quad (2.a)$$

$$[\mathbf{K}_t] = \begin{bmatrix} [\mathbf{K}_s]_{N \times N} & [\mathbf{0}]_{N \times n} \\ [\mathbf{0}]_{n \times N} & [\mathbf{0}]_{n \times n} \end{bmatrix} + \begin{bmatrix} [\mathbf{K}_{n,a}]_{N \times N} & -[\mathbf{K}_{n,b}]_{N \times n} \\ -[\mathbf{K}_{n,c}]_{n \times N} & [\mathbf{K}_{n,d}]_{n \times n} \end{bmatrix}_{(N+n) \times (N+n)} \quad (2.b)$$

$$[\mathbf{C}_t] = \begin{bmatrix} [\mathbf{C}_s]_{N \times N} & [\mathbf{0}]_{N \times n} \\ [\mathbf{0}]_{n \times N} & [\mathbf{0}]_{n \times n} \end{bmatrix} + \begin{bmatrix} [\mathbf{C}_{n,a}]_{N \times N} & -[\mathbf{C}_{n,b}]_{N \times n} \\ -[\mathbf{C}_{n,c}]_{n \times N} & [\mathbf{C}_{n,d}]_{n \times n} \end{bmatrix}_{(N+n) \times (N+n)} \quad (2.c)$$

where $[M_N]$ is the $N \times N$ mass matrix of the uncontrolled WT tower with N DoF while $[M_n]$ indicates the $n \times n$ mass matrix of the VCS. Similarly, $[C_N]$ and $[K_N]$ are the Rayleigh damping matrix and the condensed stiffness matrix corresponding to the sway DoF. The expressions of the matrices in Equation 2 depend on the VCS of choice (TMD, EKD).

2.2 Wind Loads

In this paper, the aerodynamic load is taken into account by employing a basic wind velocity at the altitude of 10 m, V_b and applying the corresponding regulations of (*EN 1991 - Wind actions*, 2010). Moreover, in order to account the wind velocity fluctuation at the altitude of l_t , an artificial velocity time history is generated by applying the procedures presented in [29–32] assuming a standard deviation σ . The total concentrated force exerted on the top of the tower is computed as in [27]. Apart from the concentrated force applied on the top of the steel tower due to operation of the turbine, an additional distributed loading along the tower height is taken into account due to the fact that a portion of wind forced is exerted directly on the tower. The spatial and time distribution of this loading is obtained by employing the procedures of (*EN 1991 - Wind actions*, 2010) and of the studies [29–31]. The basic wind velocity that is employed has corresponding standard deviation $V_b = 27.0$ m/s with $\sigma = 3.30$ m/s ($V_m(120m) = 39.93$ m/s). The rotor is assumed to develop a constant angular velocity $\Omega_{bl} = 12.1$ rpm, while all the necessary blade profile characteristics are retrieved from [26,32]. Figure 2.a presents the mean wind velocity, and Figure 2.b the time history of the evaluated total forces $\bar{F}_N(t)$ for the aforementioned basic wind velocity ($V_b = 27.0$ m/s, $\sigma = 3.30$ m/s).

Figure 2: (a) Wind velocity at the top of the WT tower, and (b) total concentrated force exerted on the top of the WT tower $\bar{F}_N(t)$.

3 IMPLEMENTATION OF VIBRATION CONTROL SYSTEMS

3.1 VCS Considered

The first vibration mitigation approach is based on the classical TMD. The additional mass (m_D) of the TMD is attached at the top of the WT tower or inside the nacelle, using a positive stiffness element and a linear damper (k_D , c_D). This concept is employed as a benchmark because it has received the most attention in the literature due to the simplicity of its implementation. The main drawback of this option is the need for large additional masses, in order for the TMD to achieve significant effective damping, as will be observed in the numerical results. The parameters of the TMD configuration are presented below:

$$\mu_D = m_D / m_{top} \quad (3.a)$$

$$\omega_D = 2\pi f_D = \sqrt{k_D / m_D} \quad (3.b)$$

$$\zeta_D = c_D / (2\omega_D m_D) = c_D / (2\sqrt{k_D m_D}) \quad (3.c)$$

The TMD tuning frequency is selected to equal to the fundamental frequency of the primary structure $f_D = f_l$. The damping ratio affects the transferred vibrating energy to the oscillating mass of the TMD, and the TMD stroke. As the damping ratio decreases, more energy is transferred to m_D , as the oscillating mass has an increased stroke. As a result, the TMD is more effective. However, the TMD stroke is upper bounded due to the geometrical limitation that the oscillating mass is placed at the top of the tower. For this reason, the damping ratio is selected to be equal to 10% in order to be as effective as possible, and at the same time realistic. The mass of the TMD is be equal to 2%, an extreme value selected only for comparison reasons.

In this paper, an extended version of KDamper [21], will be employed at the top of the WT in order to protect the WT tower from environmental vibrations (wind), as presented in Figure 1. The additional mass, m_{top} , of the nacelle, rotor and blades is no longer rigidly attached to the WT tower but is mounted on an extended KDamper device. In this concept, the additional oscillating mass of the EKD (m_D) is connected with the nacelle with a negative stiffness element and a linear damper (k_{NS} , c_{NS}), and with the steel tower with a positive stiffness element (k_{PS}), and the steel tower is connected with the nacelle with a positive stiffness connection (k_R). This way, the EKD aims to isolate the vibrations of the nacelle from the steel tower. In

addition, the EKD aims to increase the effective damping of the WT tower compared to the TMD with the same additional mass, as it has been proven that the KDamper always presents an improved dynamic behavior as compared to the TMD.

The configuration of the extended KDamper (EKD) implemented at the top of the WT tower is illustrated in Figure 1. The positions regarding the EKD are presented below:

$$\mu_D = m_D / m_{top} \quad (4.a)$$

$$k_D = k_{NS} + k_{PS} \quad (4.b)$$

$$\omega_D = 2\pi f_D = \sqrt{k_D / m_D} = \sqrt{\frac{k_{NS} + k_{PS}}{m_D}} \quad (4.c)$$

$$k_0 = k_R + \frac{k_{NS}k_{PS}}{k_{NS} + k_{PS}} \quad (4.d)$$

$$\omega_0 = 2\pi f_0 = \sqrt{k_0 / (m_D + m_{top})} = \sqrt{\left(k_R + \frac{k_{NS}k_{PS}}{k_{NS} + k_{PS}}\right) / (m_D + m_{top})} \quad (4.e)$$

$$\zeta_{NS} = c_{NS} / (2m_D\omega_D) = c_{NS} / (2\sqrt{k_D m_D}) \quad (4.f)$$

where μ_D is the EKD additional mass ratio. In order for the proposed configuration to be realistic, the design of the EKD concept foresees variation in all the stiffness elements to ensure that the system remain statically and dynamically stable:

$$(1 - \varepsilon_R)k_R + \frac{(1 - \varepsilon_{PS})k_{PS}(1 + \varepsilon_{NS})k_{NS}}{(1 - \varepsilon_{PS})k_{PS} + (1 + \varepsilon_{NS})k_{NS}} = 0 \quad (5)$$

Assuming that the m_D , and the values of the stability factors ε_{NS} , ε_{PS} , and ε_R are supposed known, the stiffness elements k_{PS} and k_R , result from Equations (4.e, 5) as a function of f_0 , and k_{NS} . Therefore, the independent design variables sought in the optimization are:

1. the nominal frequency f_0 ;
2. the value of the negative stiffness (NS) element k_{NS} ;
3. the value of the damping coefficient c_{NS} ;

For the optimization process, the Harmony Search (HS) algorithm, a novel metaheuristic algorithm is used [33].

3.2 Optimal Design of EKD

Having established the nonlinear equations of motion Equation 1 for the controlled WT, the next objective is to determine the optimal EKD parameters in order to attain the best possible vibration control strategy. The objective function and the constraints are selected from the geometrically non-linear time domain responses, are described below:

- i. Assign values to the known parameters (initial guess).
 - a) EKD is implemented at the top of the WT tower, and as a result the additional oscillating mass is desired to be the minimum possible. Thus, m_D varies in the range [0.1 0.5] %, one order of magnitude lower as compared to that of the TMD.
 - b) The stability factors of the k_{PS} , k_R are conservatively selected as 5%. The variation of the NS element k_{NS} , is selected equal to 10%, as indicated in [21].

- ii. Set the objective function (OF) as the minimization of the relative displacement of the WT tower. (obtained from geometrically nonlinear dynamic analysis)

$$\min: u_{top}^{Rel} = u_{l_t} - u_{l=0} \quad (\text{OF}) \quad (6)$$

- iii. Set the geometrical constraint regarding the relative displacement of the oscillating mass of the EKD and the top of the WT tower. The upper limit is equal to half of the top tower diameter.

$$u_D^{Rel} = u_D - u_{l_t} \leq D_{top} / 2 \quad (\text{Constraint 1}) \quad (7)$$

- iv. To ensure the effective operation of the WT. another geometrical limitation regarding the relative displacement of the nacelle and the top of the WT tower is set:

$$u_{Nac}^{Rel} = u_{nac} - u_{l_t} \leq 0.5 \text{ m} \quad (\text{Constraint 2}) \quad (8)$$

- v. Set an upper limit for the damping coefficients c_{NS} with respect to the superstructure mass. This constraint is based on previous works [47] as well as on manufacturing restrictions:

$$c_{NS} \leq 1000 \text{ kNs} / \text{m} \quad (\text{Constraint 3}) \quad (9)$$

- vi. Set an upper limit for the NS per 1 *tn* of structure mass [14]:

$$k_{NS} \geq -50 \text{ kN} / \text{m} \quad (\text{Constraint 4}) \quad (10)$$

- vii. The nominal frequency f_0 of the SBA varies in the range $[0.1 \text{ } 5] \text{ Hz}$, (Constraint 5).

Finally, the limits of the free design variables are: a) nominal frequency $f_0 \text{ (Hz)}$ $[0.1 \text{ } 5.0]$, b) value of the NS element $k_{NS} \text{ (kN/m)}$ $[-20000 \text{ } -1]$, and c) damping coefficient $c_{NS} \text{ (kNs/m)}$ $[1 \text{ } 1000]$. As for the parameters inherently involved in the HS algorithm, the commonly used values in relative literature are employed: HMS=75, HMC=0.5, and PAR=0.1.

4 NUMERICAL APPLICATION

4.1 Considered WT tower and monopile systems

In this section, the NREL baseline 5-MW nacelle and rotor, supported by a steel tower of 120 m height is examined. This choice is made due to the fact that is widely used in the literature as a benchmark option for vibration control of WT towers. The key properties of the wind turbine and the steel tower are listed in Table 1 and Table 2 respectively.

As far as monopile system is concerned, a steel tubular pile of constant cross section ($E_p=2.1 \times 10^8 \text{ kN/m}^2$, $\rho_p=7.8 \text{ tn/m}^3$, $\nu_p=0.3$, $G_p=8.0769 \times 10^7 \text{ kN/m}^2$, $l_p=30.0 \text{ m}$, $D_p=5.0 \text{ m}$, $t_p=0.08 \text{ m}$) is considered. The undrained shear strength of the soil profile is assumed to follow a parabolic distribution with depth with mean $S_u=60 \text{ kPa}$, , mass density $\gamma=1 \text{ tn/m}^3$ and modulus of elasticity $E=1800S_u$. The whole structure is subjected to the action of its total weight (including mechanical parts). More specifically, a distributed axial load along the length of the structure and a concentrated axial force at its top are applied, which are evaluated according to the corresponding masses.

4.2 Nonlinear dynamic model verification

In order to verify the validity and the efficiency of the developed formulation, a set of simplified analyses were conducted and the obtained results were compared with those obtained from the commercial software package SOFiSTiK [34] based on FEM. More specifically, in Table 3, the first 5 eigenperiods of vibration, are presented using SOFiSTiK, and are com-

pared with those obtained from a FEM solution employing 24 prismatic beam elements for the tower and 60 for the monopile. Furthermore, the response of each tower configuration is examined performing a simplified linear static analysis, applying a concentrated force at the top of the tower. Table 3 presents the static deflections X_{top} at the top of the WT tower obtained from the developed model of the WT tower as compared with the aforementioned FEM solution, using SOFiSTiK software. It can be observed that the validity of the developed model of the WT tower is verified, as both the values of the WT eigenperiods and the static deflection of the top of the WT tower are in a very good agreement.

	Eigenperiods (sec)					Static deflection at the top of the tower X_{top} (m)
	T1	T2	T3	T4	T5	
Present Study	4.315	0.727	0.243	0.122	0.076	1.225
SOFiSTiK	4.310	0.726	0.246	0.128	0.081	1.233

Table 3: Eigenperiods of the WT tower, and static deflection at the top of the tower under static analysis.

4.3 Dynamic responses

The design parameters selected for the TMD system are $\mu_D=2\%$, $\zeta_D=10\%$, and $f_D=f_I$, where f_I is the fundamental frequency of the primary structure. Regarding the EKD system, the selected additional mass is equal to $\mu_D=0.1\%$, 20 times lower as compared to that of the TMD, and the stability factors ε_{NS} , ε_{PS} , and ε_R are selected as 10%, 5%, and 5%, respectively. The optimal EKD parameters obtained following the procedure presented in Section 3.2, are presented in Table 4.

Fixed values		Independent design variables			Resulting stiffnesses	
m_D (tn)	$\varepsilon_{NS}, \varepsilon_{PS}, \varepsilon_R$ (%)	f_0 (Hz)	k_{NS} (kN/m)	c_{NS} (kN/m)	k_R (kN/m)	k_{PS} (kN/m)
0.403	10, 5, 5	0.3664	-9089.7	511.69	13057	54275

Table 4: Optimal EKD parameters.

The dynamic response of the WT tower relative displacement is presented in Figure 3.a, for the uncontrolled WT, as well as the controlled WT with a conventional TMD (2%), and the proposed EKD (0.1%) implemented at the top of the WT. It is observed that due to the nature of the external load, the first peak of the dynamic response is not affected by either system, however, the 2nd peak is greatly reduced with the EKD system. As a result, the effective damping of the controlled system is significantly increased. In order to calculate the exact value of the effective damping, the initial and the controlled structures are subjected to a free vibration with initial conditions, as illustrated in Figure 4, and more specifically to that of the first modal eigenform of the uncontrolled structure. The effective damping is then calculated with the following logarithmic rule:

$$\ln \left[\frac{u_{top}^{Rel}(t)}{u_{top}^{Rel}(t+T)} \right] = \frac{2\pi\zeta_{eff}}{\sqrt{1-\zeta_{eff}^2}} \quad (1)$$

where T is the time between two consecutive peaks of the dynamic response, and u_{top}^{Rel} is the top tower relative displacement. The effective damping of the initial structure, the TMD and the EKD systems are 2.67 %, 2.98 %, and 8.36 %. The TMD system slightly increases the effective damping, while the EKD system has more than 3 times the initial effective damping.

Figure 3: (a) Dynamic response of the WT tower top relative displacement of the initial, the TMD and the EKD systems. (b) Additional oscillating mass relative to the tower displacement of the TMD and EKD systems.

Figure 4: Free vibration of the top WT tower of the initial uncontrolled structure, the TMD system, and the EKD. The initial displacement conditions imposed are according to the first modal eigenform of the initial WT.

Finally, the relative displacement of the additional oscillating mass of the TMD and EKD systems, is presented in Figure 3.b. The additional mass of the EKD has a stroke more than one order of magnitude smaller, as compared to that of the TMD. More specifically, the peak of the additional mass stroke is 1.11 m with the TMD system, and 0.076 m with the EKD system.

5 CONCLUSIONS

In this paper, a novel passive vibration absorption and damping concept, the extended KDamper, is examined for improving the WT tower dynamic behavior and increasing the effective damping. A wind turbine of 5MW supported by a steel tower of 120 m founded on a monopile was analyzed under a horizontal aerodynamic load due to the wind. The developed nonlinear dynamic model is an assemblage of prismatic beam elements, the validity of which is verified based on a comparison with a commercial software package on FEM. The aerodynamic load is taken into account by generating artificial basic wind velocities applying the corresponding regulations of EC1, Part1,4. The proposed vibration control system (VCS) is designed based on a constrained optimization procedure, that accounts for geometrical, con-

structional and manufacturing limitations. Based on the performed nonlinear dynamic analysis, the following conclusive remarks can be made:

- i. The proposed nonlinear dynamic model is effective and efficient in implementing VCS for vibration control of WT.
- ii. The employed additional mass is significantly lower (0.1%, 0.403 *tn*) as compared to a conventional TMD (2%, 8.6 *tn*).
- iii. The EKD increases the effective damping (8.36 %) of the WT tower more than 3 times compared to the initial WT (2.67 %), while the TMD system achieves only a slight increase (2.98 %).
- iv. The additional mass stroke in the EKD is in the order of a few centimeters (7.6 *cm*), overcoming the fundamental disadvantage of the TMD that requires large strokes, more than 1 *m*.

Abstract. *Adaptive façades can be a solution to many urban aspects such as sustainability and energy efficiency. Along these lines, a parametric analysis has been conducted to investigate the geometrical reconfigurations of the proposed adaptive solar shading system, the daylight performance with Rhinoceros and the plugins Grasshopper and ClimateStudio as well as the structural behaviour with Karamba3D. A skeleton structure synthesized by GFRP bending-active elements and stabilized by a secondary system of cables with variable length and a PTFE tensile skin leads to a lightweight modular structure with embedded actuation. The control system is capable of flexible patterns and multi-stages of open, semi and close configurations for different sun shading effects, depending on the changeable weather conditions and the relative response required in every part of the façade. The mechanism recalls a Class-2 Tensegrity system with springed hinges, where the rigid members and the hinges are substituted by lamellas, which can be bend by controlling the length of the cables. Furthermore, the ever-changing modular structure, especially to the plethora of different configurations, results in an aesthetically pleasing and organic dynamic filter for a tall building. Further research can be carried out about the wind load, how the structure can be naturally wind-resistant, and convective factors triggered by air movements between the façade and the building itself.*

1 INTRODUCTION

Adaptive building envelope design may provide a real-time process of reconfiguration on a daily and seasonal basis enlivening the environmental performance of the building and enhancing the end-users' internal comfort. A viable design for adaptive shading systems is necessary, especially when the building sector absorbs 40 % of the total energy use, even greater than the transport and industry sectors [1]. Current numerical studies evaluate the performance of external shades by scoping the impact of them with regard to the building envelope and the indoor environment [2-6]. Different typologies of shadings such as overhangs, vertical fins, horizontal shading, egg-crate shading, perforated screens and exterior blinds are giving potential opportunities for energy savings and improvement of indoor environment.

The sustainability role of the external shading elements can be further extended by means of adaptability either following environmental spaces and user needs or increasing the efficiency and optimizing the materials in order to reduce energy consumptions [7]. The effectiveness of kinetic façades in terms of energy savings is demonstrated in [8] with three existing buildings, Al Bahar Towers, Council House 2 and Q1 Headquarters Building. Adaptive folding shading systems placed externally on the Al-Bahar Tower in Abu Dhabi obtain different configurations, in order to regulate solar radiation and maximize the energy savings on cooling. In tracking the sun position, the kinetic system applied on the western façade of the Council House 2 in Australia provides full shading while minimizing the electricity consumption by 85 %. Following the sun path with three different configurations by the motorized swivel vertical louvers of the Q1 Headquarters Building in Germany, the adaptive external shading system succeeds in minimizing the electricity consumption, glare, as well as maximizing the heat gain and natural air ventilation.

A systematic analysis for daylight performance of an adaptive façade shading system integrated on a multi-storey office proves that rotation of the external shades and inclination of the slats may considerably influence the indoor daylight performance. Furthermore, shades can control the amount of incoming solar radiation and block the solar heat gain admitted into the open-space offices, while their impact on the air indoor temperature is significant by reducing the overheating and cooling loads [9-10]. Indoor environment is related to the comfort of the occupants and inevitably affects the well-being, productivity and consequently provokes the economic benefit. For example, the rising demand for lighting energy is also associated with the visual discomfort. Adaptive façade systems can lower the thermal load of the building by blocking the sunlight effectively, while daylight can be used properly during the day enhancing occupant comfort [11].

Adaptive sun shading systems can meet the changing solar radiation and provide an optimal shading as well as maximization of the daylight use [12]. Relevant adaptive and kinetic systems that reflect principles of embedded actuation and meditated to sustainable issues, functionality and aesthetics considerations are presented in this paper. An experimental prototype in full-scale of a tensegrity structure is actuated in obtaining a responsive behavior through adjustment of tension members and actuators [13]. In this context, a conceptual development of an adaptable structure aiming at structural simplicity and reduced energy consumption during the reconfiguration is presented in [14]. The proposed actuation method conveys the ability to the structure to obtain different geometrical reconfigurations. The methodology approach of the responsive skylight modules leading to the integration of architectural kinetic elements and computational devices is presented in [15]. Design requirements of the project are the optimization of the thermal and daylighting conditions. The prototype system is based on tensegrity principles incorporated with photovoltaic panels in its structure.

A similar approach on adaptive tensegrity architecture mimics the dynamics of a blinking sail as a dynamic sun-screen harvesting device presented in [16].

The current research project refers to the design and analysis of adaptive bending-active modules for a tensile solar shading system using as a case study the SFB1244 demonstrator tower located in the campus Vaihingen of the University of Stuttgart in Germany. A synergistic architectural and engineering approach of the adaptive bending-active modules leads to the design of a high efficiency envelope system with improved load-bearing performance. Essentially, the goal was to increase energy efficiency by controlling the light transmission and thus provide energy savings on cooling, heating and lighting demands. The characters of lightness, aesthetic quality and utilization flexibility were the most important to consider at the beginning of the designing process. The software used for the parametric analysis include Rhinoceros and Grasshopper for the 3D modeling, ClimateStudio for the daylight analysis and Karamba3D for the structural analysis; both ClimateStudio and Karamba3D work in the Rhino/Grasshopper environment. The daylight simulations were carried out on different days and times throughout the year, to test the response and effectiveness of the various configurations that the adaptive system is capable of, using the parameterization of the Grasshopper model.

2 DESIGN

2.1 Adaptive bending-active modules

The first idea was to use tensegrity for the mechanism of each module - specifically, a Class-2 tensegrity system for the vertical ribs of the shells, consisting of two cable-controlled rigid bars connected by a springed hinge. This approach, though, would have required a change of shape through approximation; this is why, at the end, the bending-active approach was chosen. This approach could keep the structure in the lightweight range, providing almost the same mechanism and the possibility of keeping the shape just as it was designed. The bending-active solution for the module mechanism recalls the bow-and-string principle; the original frame of bending-active elements consisted of a single vertically oriented bow in the middle. This disposition was eventually modified (as shown in Figure 1) to have two vertical elements instead, spaced enough to have a more even area distribution of the membrane.

Figure 1: Adaptive bending-active system.

Each sun-shielding module is 2,00m wide and 0,90m tall, and its shape allows for each row to aesthetically interlock with the previous ones, with a 1,00m horizontal offset. The modules open and close by being constrained to the horizontal plane (identified with the midpoints of each row) by controlling the length of cables.

Glass Fiber Reinforced Polymer (GFRP) was chosen as the material for the bending-active frame; this material allows good behavior on long-term deformation cycles and a very high strength-to-weight ratio. Architectural Polytetrafluoroethylene (PTFE) was chosen as the material for the membrane; the resin-painted fiberglass has excellent properties for a second skin facade, thanks to its weather resistance and self-cleaning behavior.

2.2 Reconfigurations and integration to the Demonstrator

The system is designed to flexibly work in various sunlight conditions, thanks to the ability of each module to change in configuration to a certain degree, from completely closed to completely open. This is possible thanks to the GFRP skeleton of each module, stabilized by cables and a PTFE membrane. The embedded actuation system, controlled by sensors, makes it possible to have different sun shading (and aesthetic) effects, visible as gradients on the façade throughout the day (as shown in Figure 2).

The connection with the Demonstrator tower is realized through a steel space grid-like structure that gives the needed support to the panels and keeps the whole system lightweight, without obstructing the view from and to the building.

Figure 2: Gradients in the adaptive configuration model.

3 STRUCTURAL ANALYSIS

The structural analysis was originally intended to be carried out in SAP2000; in order to do that, the 3D model had to be assembled in GeometryGym, a software that works in the Rhino/Grasshopper environment and helps exporting the model to SAP2000, thanks to the controlled IFC conversion of the files. The issues had with such a work outline were in the double curvature of the shell elements. Said software works best when synthesizing big models, deconstructing them in smaller parts; when the mathematical conversion needed, from the Grasshopper boundary representation to a mesh, interests smaller elements with tighter toler-

ances it becomes a problem. The approximation was excessive and it resulted in troubles related to the bijective individuation of points; this was especially an obstacle for the external forces and support placement. The ideal solution was to control the degree of approximation of the curvature of each element through a software that was closer to the Grasshopper native environment. For this reason, in the present work, it was decided to carry out the analysis in the Rhino environment with Karamba3D; this software made it possible to better control the approximation of the original shape, for both the frame and the membrane. The membrane was meshed, and its area was used for the wind load; its support was the frame, deformed, while the supports of the frame itself were placed in the intersection between the central vertical and horizontal elements. The support structure was designed as a space grid structure, in order to be well distributed and light in both aesthetic and structural terms, while allowing for the full movement of each module.

3.1 Wind load

The main loads considered were self-weight and wind load; the latter was calculated from the local legislation and the Eurocodes. The obtained wind load was related to a wind speed of 81km/h; this was the worst-case scenario, and in Stuttgart this condition is very rare (less than 30 hours per year). Another scenario was taken into account, imagining the request of the client to have the structure designed for 50km/h and 60km/h (wind conditions still rare for the city), to consider the advantages in terms of lightness and economy at the expense of having the façade closed when said wind velocities are reached. Tangential wind was also considered.

3.2 Results

After having the model assembled in Karamba3D, a strict hierarchy was followed in the relationship between each element of the façade, so to have their structural behavior connected just as expected in working conditions. A nonlinear analysis was needed, because of the bending-active approach used; after solving using the specific analysis tool, the ModelView tool allowed the visualization of displacements (Figure 3) and stress on each of the models. A specific set of tools was placed on the Grasshopper canvas to get the axial stress results on each element. The highest displacements measured on the module frame were 2,83mm at the extremes, without considering the stabilizing effect of the steel cables. The highest value of tension measured on the support system is 0,61 kN, while the highest value of compression is 0,43kN.

Figure 3: Karamba3D result window.

3.3 Support system sections

Following positive outcomes related to buckling, displacement and axial stress tests, the profiles chosen for the original wind condition (81km/h) were the EN10210 33,7x3,2mm with circular section. The provided results for a lower wind condition (60km/h) have led to a thinning of the profile section, now the circular EN10210 26,9x3,2mm, which leads to increased lightness and economic convenience.

4 DAYLIGHT ANALYSIS

The daylight analysis was carried out in ClimateStudio; the chosen days for the simulations were the two solstices and the two equinoxes, and for each day the hour chosen was 9:30 am, 12:30 am and 15:30 pm.

All materials have been assigned to each element of the 3D model. Three case studies have been considered in this project: the bare structure, fully open configuration and adaptive configuration.

4.1 Parameterization

The parameterization of the façade allowed each corner to independently open and close, causing a dynamic gradient on each side of the building. By changing the corner values in order to follow the sun position at a certain time, the ideal overall configuration was researched each time (as shown in Figure 4 for March 20th, 15:30). Issues with the model were related to the cable slits, excessively large, and the BRep approximation from Grasshopper to ClimateStudio, that caused some light to creep in. The solution was to reduce the slits and to mesh the entire façade, so the software could read it properly.

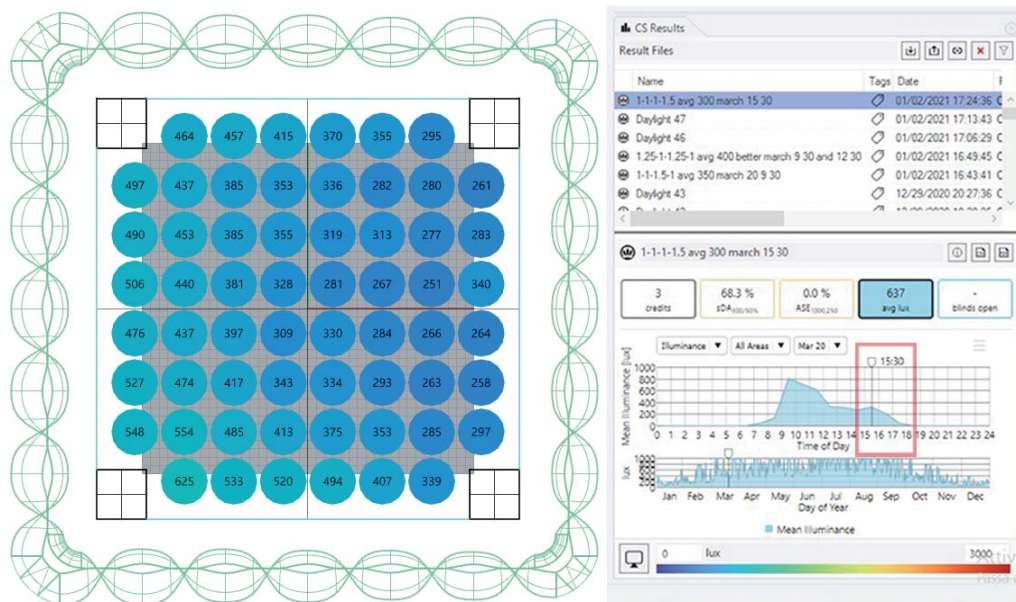

Figure 4: ClimateStudio test environment.

4.2 Results

The results (Figure 5) show that the adaptive configuration always respects the ideal lux range (350–450), with peak values hardly over 500; the completely open configuration has worse results, especially during the cold months. The worst condition is, by far, the bare

structure, with average peak values of over 600lux. Furthermore, the façade shows its dynamic aesthetic value the most when following the sun position in the adaptive configuration.

Figure 5: Daylight simulation results (21st of December).

5 CONCLUSIONS

5.1 Overall results

The designed adaptive façade proved to be very effective in its dynamic sun-shielding behavior, providing the right amount of daylight even when most exposed to the sun radiation. The structure, including the support system, is lightweight and thin, which is convenient for both its cost and aesthetic value. Furthermore, the sculpted feel given to the building helps create a sense of dynamism and the character of the façade becomes the character of the building.

5.2 Further considerations

The structure, especially the support system frame, can benefit from form-finding approaches aimed at optimizing the mass and geometry distribution of its elements. Furthermore, a tensegrity solution for the same space grid can be researched.

Form-finding can also be used for the modules, to consider a change of shape related to the dynamic action of the wind in any configuration. This requires a new parameterization and the use of accessory tools in the Grasshopper environment.

Abstract

Tensegrity concepts are common in nature and are recognizable, e.g., in every cell, in the microstructure of the spider silk, and in the pattern of bones and tendons for control of locomotion. This work deals with the formulation of a tensegrity model of spider dragline silk fiber at the mesoscale through a multi-domain network approach with tensegrity architecture. The fiber is described as a multi-walled tube formed by coaxial cylindrical networks of beta-sheet crystals (crystalline domains) and polypeptide (amorphous) chains (noncrystalline domains). The given model generalizes a previous one recently appeared in the literature and paves the way to the optimal design of innovative biomimetic fibers with tensegrity architecture.

Keywords: Tensegrity, Spider Silk, Multiscale Modeling, Tensile Response.

1 INTRODUCTION

Tensegrity principles are common in nature and exist, e.g., in every cell, in the micro-structure of the spider silk, and in the arrangement of bones and tendons for control of locomotion. The present study deals with the formulation of a tensegrity model of spider dragline silk fiber at the mesoscale through a multi-domain network approach [1],[2] with tensegrity architecture [3].

The fiber is described as a multi-walled tube made of coaxial cylindrical networks of β -sheet crystals (crystalline domains) [4] and polypeptide (amorphous) chains (noncrystalline domains) [5]. Each tube is composed of a network of helical-shaped elements, loaded in tension (or strings) [6] and circumferential elements, loaded in compression (or bars).

The strings correspond to domains of amorphous chains attached to crystalline domains at their extremities, while the bars reproduce the compressive stiffening effect that is played by beta-sheet plated crystals in the circumferential direction, when the fiber is longitudinally stretched [3],[6]. Radial links transfer the compressive stresses from one tube to another.

2 MESOSCALE MECHANICAL MODELING OF A SPIDER SILK FIBER

We now illustrate the mechanical behavior of the dragline silk fiber at the mesoscopic scale through a multi-domain network approach [1],[2] with tensegrity architecture [3]. The fibre is described as a multi-walled tube made of coaxial cylindrical networks of β -sheet crystals (crystalline domains) [4] and polypeptide (amorphous) chains (noncrystalline domains, see Fig. 1) [5]. Each tube consists of a network of helical-shaped elements loaded in tension (or strings) [6] and circumferential elements loaded in compression (or bars). The strings are used to model amorphous chains attached to crystalline domains at their extremities, while the bars are introduced to simulate the compressive stiffening effect of the β -sheet plated crystals in the circumferential direction, when the fibre is stretched along its direction [3],[6]. Radial links reproduce the stresses of compression from one tube to another. The different tubes forming the fibre model describe the homogenised properties of different sections of the core of the fibre. It is indeed largely accepted in the up-to-date literature that the outer lipid, glycol and skin layers minimally contribute to the overall mechanical response of the fibre [6]-[8].

We now focus the attention on the response of the fibre under an isochoric longitudinal stretching deformation, which stretches the fibre up to an engineering strain $\hat{\epsilon} = (\ell - L)/L$, where L denotes the unstretched length of the fibre, and ℓ denotes the stretched length. If we consider that the volume of the fibre remains constant under stretching, as it is written in many experimental studies (refer, e.g., to [9],[10]), the length variation along the longitudinal axis occurs in association with a radial contraction of the fibre. The radial engineering strain $\hat{\epsilon}_r = (r - R)/R$, where R is the radius of the fibre in the unstretched configuration, and r is the stretched radius, is related to the longitudinal strain $\hat{\epsilon}$ through

$$\hat{\epsilon}_r = \frac{1}{\sqrt{1+\hat{\epsilon}}} - 1 \quad (1)$$

Fig. 1: Triple-walled tensegrity model of a portion of the dragline silk fiber at the mesoscopic scale: (a) overall views; (b) exploded view of the different walls. The red members are strings or tendons while the blue members are bars or struts.

We characterise the initial elastic response of the strings forming the multiwalled model in Fig. 1 through the following Young modulus:

$$E_s^{(1)} = x E_a + (1 - x) E_b, \quad (2)$$

where E_a is the elastic modulus of β -sheet crystal domains, E_b is the initial (pre-yielding) elastic modulus of the noncrystalline domanins and x is the volume fraction of β -sheet crystals within the strings.

The generic string yielding occurs when the engineering strain $\hat{\epsilon}_s$ of the element reaches a threshold value $\hat{\epsilon}_{s_y}$. The mechanical response of the string in the post-yielding regime is described through the following incremental Young modulus:

$$E_s^{(2)} = x E_a + (1 - x) E_c, \quad (3)$$

where E_c denotes the post-yield tangent modulus of the noncrystalline domains.

We consider that the bars are characterized by a constant compressive modulus equal to E_a , being not affected by yielding phenomena.

Both the strings and the bars of the model (Fig. 1) are considered as rods with rectangular cross section with width b and thickness t . By considering the strings of the i -th wall, we consider $b = b_{s_i} = L_{b_i}$, where L_{b_i} refers to the initial (undeformed) length of the circumferential bars, and t denotes the radial dimension t_i of the layer. Considering the circumferential bars of the i -th wall, we assume $b = b_{b_i} = s_c/10$ and $t = t_{b_i} = t_{s_i}$, where s_c indicates the longitudinal spacing of such elements. Finally, for what concerns the radial bars we assume $b = b_r = L_{b_r}$ and $t = t_r = s_c/10$. The geometrical and mechanical parameters that describe the proposed model (Fig. 1) are provided in Table 1. Such properties are imported from Refs. [6]-[7] for what concerns the radial dimensions of the layers forming a dragline silk fibre with overall diameter of $5 \mu\text{m}$. The mechanical properties of the fibre elements are instead the following (elastic modulus of the β -sheet crystals and mechanical properties of the links connecting the crystalline domains, in pre- and post-yielding conditions).

wall	d (nm)	t (nm)	L_b (nm)	x	E_a (GPa)	E_b (GPa)	$\hat{\varepsilon}_{s_y}$ (%)	E_c (MPa)

Table 1. Geometrical and mechanical properties of the model in Fig. 1.

3 TENSILE RESPONSE

The use of the properties in Table 1 leads us to predict the engineering and true stress-strain curves illustrated in Fig. 2. The engineering stress $\hat{\sigma}$ is obtained by dividing the total pulling force acting on the fibre by the initial cross section area \hat{A} . The true stress σ is related to the engineering stress through the equation $\sigma = (1 + \hat{\varepsilon})\hat{\sigma}$, while the true strain ε is related to the engineering strain through $\varepsilon = \log(1 + \hat{\varepsilon})$ [12].

4 CONCLUDING REMARKS

We have illustrated a multi-walled generalization of the tensegrity model recently proposed for the spider dragline silk fiber. The different tubes forming the fiber model describe the homogenized properties of different sections of the core of the fiber. It is indeed largely accepted in the recent literature that the outer lipid, glycol and skin layers contribute very little to the global mechanical behavior of the fiber [6]–[8].

The presented model generalizes the one proposed in [9] and paves the way to the optimal design of innovative biomimetic fibers with tensegrity architecture.

Abstract. *The design of buildings with a limited environmental impact and improved energy efficiency is nowadays of fundamental importance to face the challenge of reducing pollution and saving natural resources, without giving up comfort, indoor air quality and well-being. In fact, it is well known that the building industry is one of the largest consumers of material and energy resources and, among the many parts that make up a building, façades are responsible for a huge energy exchange with the surrounding environment. Therefore, both the research world and industry are very interested in effective solutions for smart and climate adaptable façades. A variety of concepts and solutions, which are competing with each other, have indeed already been developed. However, the field is not yet mature and an increase in emerging and innovative solutions is expected and requires future research and further challenges to be addressed. Recent studies have paid attention to the mechanics of folding sunscreens made with origami panels activated by stretching or releasing strings, following the tensegrity design philosophy. The present contribution is aimed at promoting innovative technological solutions based on the study of new models for foldable façade modules, paying attention to geometric patterns, deployability and mechanical properties.*

1 INTRODUCTION

One of the main challenges that contemporary architecture and civil engineering have to face is the construction of sustainable buildings with high energy efficiency, capable of limiting their environmental impact by minimizing the pollution they produce and the consumption of natural resources. It is well known, in fact, that the building industry is among the largest consumers of material resources and energy, accounting for about 40% of final energy consumption in the European Union (EU) [1]. Sustainability is thus among the main objectives of Horizon 2020 [2], the EU program for research and innovation. The challenge of the EU is maintaining the current standards of living while decreasing the energy dependence on fossil fuels and reducing CO₂ emissions by between 80% and 85% compared to 1990 [3].

Since the energy consumption of buildings is mostly related to air conditioning and domestic hot water, electricity and gas [4], increasing importance has been given to the concept of energy efficient buildings (EEBs), able to guarantee a condition of well-being inside, minimizing the use of non-renewable energy sources, through the integration of “active” and “passive” typological solutions. Among the many parts that make up a building, façades are responsible for a huge energy exchange with the surrounding environment. Hence, to save energy, the building envelope must perform more than the simple function of separating the external space from the inside, with insulation. The envelope is thus assigned the task of regulating the energy flow related to the passage of heat, the transmission of light and solar radiation and minimizing energy consumption due to air conditioning. Therefore, both the research world and industry are very interested in effective solutions for smart and climate adaptable facades. A variety of concepts and solutions, as for instance double envelope systems, which are considered with increasing interest in the EEB design [5, 6], have indeed already been developed. However, the field is not yet mature and an increase in emerging and innovative solutions is expected and requires future research and further challenges to be addressed [7]. Recent studies have paid attention to the mechanics of folding sunscreens made with origami panels activated by stretching or releasing strings, following the tensegrity design philosophy [8]. Glazing systems with morphing capabilities controlled by pairs of superelastic cables reversibly actuated against each other have also been considered, where superelasticity is also exploited to improve the structural behavior of the façade system subjected to wind loads [9]. The possibility of harvesting energy under the action of wind loads or partially recovering energy from the folding/unfolding mechanism has also been considered in the literature [10].

The present paper, which is focused on dynamic solar screens and shading systems for façades improving energy performance of buildings, is organized as follows. In Sect. 2, we briefly report about two of the existing state-of-the-art dynamic solar shading systems. Then, Sect. 3 is devoted to the operating principles of tensegrity structures and the possible advantages in using them as building envelopes. Basics on dynamics and foldability of tensegrity are reported in Sect. 4. Finally, some remarks given in Sect. 5 conclude the paper.

2 STATE OF THE ART OF DYNAMIC SOLAR FAÇADES

The present section is devoted to a brief description of two significant examples of adaptive dynamic façades, that indeed constitute the state of the art of contemporary architectural research about the building envelope, that, over time, has been transformed from a static and energetically passive element into a dynamic, permeable, and selective interface, designed to adapt to changes in external environmental conditions and positively affect the thermo-hygrometric and environmental parameters that guarantee comfort of users. Both examples are interesting,

modern reinterpretations of the traditional, wooden shading façades, the so-called “mashrabiyas” [11], common in Arab culture. Mashrabiyas are able to filter the light and control the air flow to reduce the temperature and increase the humidity of the internal environments of a building.

The first example we consider is the building of the Institut du Monde Arabe (IMA). Located in Paris, France, the building of the IMA, designed by Jean Nouvel, Pierre Soria, Gilbert Lezénés and Architecture Studio, has become a fundamental reference for dynamic façades. In particular, the rectangular, south-west façade of IMA is a lattice made up of square modules equipped with motorized steel diaphragms, connected to photosensitive sensors. The diaphragms open and close every hour to regulate the amount of natural light that enters the building, resulting in a dynamic shading system. It is emphasized in [12], to which we refer for further details, that the adaptive façade of the IMA exemplifies the strengths and limitations of mechanically operated designs.

The second example is the adaptive dynamic façade of the Al Bahar Towers, located in Abu Dhabi, where the climate is very hot and humid, especially in the summer, with up to 100% humidity and temperatures that reach 50°C, thus making a cooling system an equipment of paramount importance for buildings. The cooling of the glass façades of the buildings is guaranteed by a system of panels activated by low consumption electric linear actuators and which dynamically responds to the position of the sun during the day. The result is a scalable hexagonal shading device that acts as a solar barrier. This shading system allows the building to reach and maintain optimal thermo-hygrometric well-being, protecting the inhabitants from the glare of the sun rays and, at the same time, guaranteeing the right privacy. The shading system is based on modules made of six panels, coated in polytetrafluoroethylene (PTFE), mounted on a supporting structure made up of duplex stainless-steel frames [13, 14].

3 TENSEGRITY SOLAR FAÇADES

The design of active solar façades may exploit the advantages of tensegrity paradigm, that leads to light, deployable and foldable structures. If well designed, the core module quickly becomes scalable and is capable of being replicated to generate large-scale patterns.

Among the many different possible definition of “tensegrity”, the most widely accepted [15] is that can be given by quoting words by Motro [16], i.e. “tensegrity system is a system in a stable self-equilibrated state comprising a discontinuous set of compressed components inside a continuum of tensioned components.”

Theoretical and experimental studies [17] have highlighted that lightness, modularity, synergy, self-stability, fractal properties, enantimorphism, distributability and foldability are typical characteristics of tensegrity structures.

In particular, foldability makes tensegrity structures useful in many applications in which transport and storage must be considered. For instance, in the field of extra-terrestrial applications, transport costs, lightness of materials and optimization of the available space are of paramount importance [16].

The tensegrity structural paradigm can be exploited at different levels in the design of EEBs, since tensegrity assemblies are minimum mass structures able to carry many different load conditions, including compressive, tensile (under given stiffness constraints) and torsional loads without yielding and instability phenomena [18–20].

Thanks to their special ability to act as extremely light systems with “morphing” abilities [8, 21–24], tensegrity structures allow designing dynamic solar screens leading to a limited use of materials accompanied by a low level of energy consumption. A tensegrity reinterpretation of

the system adopted in Al Bahar Towers is considered in [8, 25].

Furthermore, tensegrity-based dynamic façades can also be exploited to harvest energy from the environment, by converting mechanical energy stored in strings into electrical energy [10, 21, 26] or from solar panels, that can be endowed in the structure and modeled as special rigid members [21, 27].

Finally, tensegrity lattices may be designed to operate as multi-scale actuators, capable of transferring energy through compact solitary waves thanks to their highly non-linear dynamic behavior [28–31].

4 DYNAMICS AND DEPLOYABILITY

This section illustrates a model for the numerical simulation of the dynamics of tensegrity systems. The procedure, already applied to solar façades in [32], with appropriate changes generalizes that presented in [33, 34] to account for the presence of wind forces [10, 35, 36].

Let us assume that the tensegrity structure is composed of n_n frictionless nodes, n_b straight, uniform, rigid bars, and n_s elastic strings, which carry only tensile forces.

The positions of nodes $\mathbf{n}_i \in \mathbb{R}^3$, $i \in [1, \dots, n_n]$, and external forces acting on them are respectively stored in node and load matrices

$$\mathbf{N} = [\mathbf{n}_1 \quad \mathbf{n}_2 \quad \cdots \quad \mathbf{n}_i \quad \cdots \quad \mathbf{n}_{n_n}] \in \mathbb{R}^{3 \times n_n}, \quad (1)$$

$$\mathbf{W} = [\mathbf{w}_1 \quad \mathbf{w}_2 \quad \cdots \quad \mathbf{w}_i \quad \cdots \quad \mathbf{w}_{n_n}] \in \mathbb{R}^{3 \times n_n}. \quad (2)$$

By calling \mathbf{b}_i and \mathbf{s}_i the vectors connecting the end nodes of the i^{th} bar and i^{th} string, respectively, and \mathbf{r}_i the position vector of the center of mass of the i^{th} bar, all of them are grouped in matrices

$$\mathbf{B} = [\mathbf{b}_1 \quad \mathbf{b}_2 \quad \cdots \quad \mathbf{b}_i \quad \cdots \quad \mathbf{b}_{n_b}] \in \mathbb{R}^{3 \times n_b}, \quad (3)$$

$$\mathbf{S} = [\mathbf{s}_1 \quad \mathbf{s}_2 \quad \cdots \quad \mathbf{s}_i \quad \cdots \quad \mathbf{s}_{n_s}] \in \mathbb{R}^{3 \times n_s}, \quad (4)$$

$$\mathbf{R} = [\mathbf{r}_1 \quad \mathbf{r}_2 \quad \cdots \quad \mathbf{r}_i \quad \cdots \quad \mathbf{r}_{n_b}] \in \mathbb{R}^{3 \times n_b}. \quad (5)$$

Let us introduce the connectivity matrices of bars $\mathbf{C}_B \in \mathbb{R}^{n_b \times n_n}$, cables $\mathbf{C}_S \in \mathbb{R}^{n_s \times n_n}$, and centers of mass $\mathbf{C}_R \in \mathbb{R}^{n_b \times n_n}$. The generic $(i, j)^{\text{th}}$ entry of \mathbf{C}_B (or of \mathbf{C}_S) takes values -1 or 1 , if \mathbf{b}_i (or \mathbf{s}_i) is directed away from, or toward node j^{th} , respectively, or 0 if \mathbf{b}_i (or \mathbf{s}_i) does not touch node j . Similarly to \mathbf{C}_B and \mathbf{C}_S , matrix $\mathbf{C}_R \in \mathbb{R}^{n_b \times n_n}$ is a connectivity matrix. Its i^{th} row stores the bar \mathbf{b}_i and its $(i, j)^{\text{th}}$ entry takes values $1/2$, if \mathbf{b}_i touches node j , or 0 , otherwise [37]. The connectivity matrices allows rewriting Eqns. (3)–(5) as

$$\mathbf{B} = \mathbf{N} \mathbf{C}_B^T, \quad (6)$$

$$\mathbf{S} = \mathbf{N} \mathbf{C}_S^T, \quad (7)$$

$$\mathbf{R} = \mathbf{N} \mathbf{C}_R^T. \quad (8)$$

The matrix equation of motion of a tensegrity system is written as [38]

$$\ddot{\mathbf{N}} \mathbf{M} + \mathbf{N} \mathbf{K} = \mathbf{W}, \quad (9)$$

where \mathbf{N} and \mathbf{W} have been already defined by Eqn. (1) and Eqn. (2), respectively, $\ddot{\mathbf{N}}$ stands for the second derivative of \mathbf{N} with respect to time, \mathbf{M} is the mass matrix and \mathbf{K} is the stiffness

matrix. The last two are computed as

$$\mathbf{M} = \frac{1}{12} \mathbf{C}_B^T \hat{\mathbf{m}} \mathbf{C}_B + \mathbf{C}_R^T \hat{\mathbf{m}} \mathbf{C}_R \in \mathbb{R}^{n_n \times n_n}, \quad (10)$$

$$\mathbf{K} = \mathbf{C}_S^T \hat{\gamma} \mathbf{C}_S - \mathbf{C}_B^T \hat{\lambda} \mathbf{C}_B \in \mathbb{R}^{n_n \times n_n}, \quad (11)$$

where $\hat{\mathbf{m}} \in \mathbb{R}^{n_b \times n_b}$ and $\hat{\gamma} \in \mathbb{R}^{n_s \times n_s}$ are diagonal matrices. The generic entry $(i, i)^{\text{th}}$ of $\hat{\mathbf{m}}$ is the mass m_i , $i \in [1, \dots, n_b]$ of the i^{th} bar, while entry $(i, i)^{\text{th}}$ of $\hat{\gamma}$ stands for the force density γ_i , $i \in [1, \dots, n_s]$ along the i^{th} string, given by

$$\gamma_i = \max \left[0, K_i \left(1 - \frac{L_i}{s_i} \right) \right] + \gamma_{ci}, \quad (12)$$

where K_i , L_i , and $s_i = \|\mathbf{s}_i\|$ are the axial stiffness, the rest length, and the current length of the string, respectively, and γ_{ci} is the damping force density, computed as

$$\gamma_{ci} = \begin{cases} c_i \frac{\dot{s}_i}{s_i}, & \text{if } s_i \geq L_i, \\ 0, & \text{otherwise.} \end{cases} \quad (13)$$

The diagonal matrix $\hat{\lambda} \in \mathbb{R}^{n_b \times n_b}$ in Eqn. (11) collects force densities in bars and is given by

$$\hat{\lambda} = -\frac{1}{12} \left[\dot{\mathbf{B}}^T \dot{\mathbf{B}} \right] \hat{\mathbf{m}} \hat{\ell}^{-2} - \frac{1}{2} \left[\mathbf{B}^T (\mathbf{W} - \mathbf{S} \hat{\gamma} \mathbf{C}_S) \mathbf{C}_B^T \right] \hat{\ell}^{-2}, \quad (14)$$

where $\hat{\ell}^{-2} \in \mathbb{R}^{n_b \times n_b}$ is a diagonal matrix, whose entries are $\ell_k^{-2} = \|\mathbf{b}_k\|^{-2}$, and $[\mathbf{A}]$ is a matrix keeping the diagonal terms of the generic square matrix \mathbf{A} , while all the off-diagonal entries are set to zero.

The stiffness matrix \mathbf{K} is not constant, being a function of time and the mechanical variables \mathbf{N} , $\dot{\mathbf{N}}$, and $\hat{\gamma}$, i.e. $\mathbf{K} = \mathbf{K}(t, \mathbf{N}, \dot{\mathbf{N}}, \hat{\gamma})$.

The numerical integration of Eqn. (9) is made by employing the algorithm described in [33, 34], which is based on fourth-order Runge-Kutta schemes.

As a basic module of a façade one can consider the deployable structure reported in Fig.1, which is a tensegrity system of class 6, meaning that the maximum number of bars concurring in each node is at most 6 (see the classification introduced in [18]).

5 CONCLUDING REMARKS

The present contribution aims to promote innovative technological solutions to design shading façades of energy efficient buildings through tensegrity systems, which can also be exploited as actuators to orient solar panels and as devices to harvest the wind-generated energy.

Recent studies have paid attention to the mechanics of tensegrity sunscreens activated by stretching or releasing strings, also exploring the possibility of wind energy harvesting. Glazing systems, with morphing capabilities, actuated with superelastic strings have also been considered in literature.

Future research in the field of tensegrity structures will focus on the possibility of using composite materials to design of dynamic shading façades, also using rapid prototyping of different architectural shapes through 3D and 4D printing technologies, at laboratory and full scales.

In conclusion, lightness, controllability and even the high artistic value of tensegrity structure are distinguished characteristics that can be exploited in the near future applications to building façades. Research in the field of tensegrity applied to buildings must necessarily take into account functionality and eco-sustainability.

Figure 1: Schematic view of a foldable class 6 sunscreen tensegrity system: nodes are depicted as white disks (as n_i and n_j); red colored members are strings (as the generic s_h); black colored members are bars (as b_k); yellow disks (as r_k) stand for centers of mass of bars.

Abstract. *In recent years, the nonlinear response of tensegrity systems has attracted increasing attention in the study of mechanical metamaterials. It has been shown in the literature that geometry and prestress of an elastic tensegrity structure can be designed to obtain different behaviors: stiffening, softening, and snap-through behavior in statics; propagation of solitary waves in dynamics. However, the realization of tensegrity systems is challenging, because of their prestressed state and the presence of tension-only cable members. A design method for periodic lattices with null prestress and no cables is here proposed, in which the repeating unit is at, or close to, a tensegrity configuration, maintaining the nonlinear types of response aforementioned. These structures can be realized by conventional additive manufacturing techniques, while the static and dynamic response can be predicted by means of stick-and-spring models.*

1 INTRODUCTION

Nonlinear mechanical metamaterials have been the subject of numerous studies aimed at discovering and exploiting new structural architectures with unprecedented properties [1–3]. Among lattice metamaterials, tensegrity periodic lattices have been found to possess a peculiar types of behavior, owing to the highly nonlinear mechanical response of the constituting tensegrity units, and to the fact that such response can be tuned by changing their geometry or prestress level [4–12]. In particular, in [4, 5], the nonlinear static and dynamic response of the triangular tensegrity prims (T3) was examined. In [6, 7], it was shown that a T3 can feature a stiffening or a softening response to applied loads in dependence of its aspect ratio. In [8], two distinct regimes of bistability have been highlighted in a case study. In [9, 11], the impact dynamics of tensegrity columns was investigated, finding that such periodic structures support the propagation of solitary waves. In addition, it was shown in [10] that such solitary waves can be either compression or rarefaction waves according to the geometry of the repeating unit. In [12], compression compact waves were obtained in numerical simulations of tensegrity beams in two- and three-dimensions.

While tensegrity units have a rich collection of mechanical responses which are attractive for applications, prototyping and realization of tensegrity metamaterials are challenging, since they are largely composed of tension-only prestressed cables [13]. Taking the cue from the study reported in [14], where bistable lattices with tensegrity architecture were designed, fabricated at the microscale using multiphoton lithography, and subsequently subjected to loading-unloading compression testing, in this work we aimed at showing that similar structures can be realized at higher scales with relatively inexpensive additive manufacturing techniques, such as fused deposition modeling (FDM), in order to obtain lattice metamaterials with customizable nonlinear response, possessing no cables and no prestress. We considered one of the systems analyzed in [14], a double-T3 structure, and we fabricated it by FDM after redesigning its geometry. More specifically, the system was conceived as a compliant mechanism by realizing nodal member connections as flexible hinges [15, 16]. The fabricated structure was then subjected to compression testing for determining its static response. The results of this test were used to validate a Stick-and-Spring reduced-order model of the structure [17, 18] and its predictions. The validated model was then used to perform impact dynamics simulations on lattice columns composed of T3 units.

This paper is organized as follows. After outlining the basic properties of tensegrity systems which can be inherited by tensegrity-like lattices in Section 2, the additive manufacturing process and compression testing results are described in Section 3. Afterward, the reduced-order Stick-and-Spring model, and the results of corresponding static and dynamic simulations are presented in Section 4, while our concluding remarks follow in Section 5.

2 NONLINEAR LATTICES WITH TENSEGRITY ARCHITECTURE

Tensegrity structures are prestressed pin-connected frameworks composed of cables and bars, which in many instances possess internal mechanisms stabilized by their prestress state. In these cases, the mechanical response is mainly geometrical, that is, it is associated to large configuration changes. The two-bar system depicted in Fig. 1(a) exemplifies this situation. In the reference configuration (in black in Fig. 1(a)), the two bars are aligned and subjected to a tensile prestressing axial force. The relation between the vertical load F and the corresponding displacement δ is well approximated by a cubic whose slope in the origin, $\tan \alpha$, is directly proportional to the prestressing axial force, while a stiffening effect can be observed when F

increases.

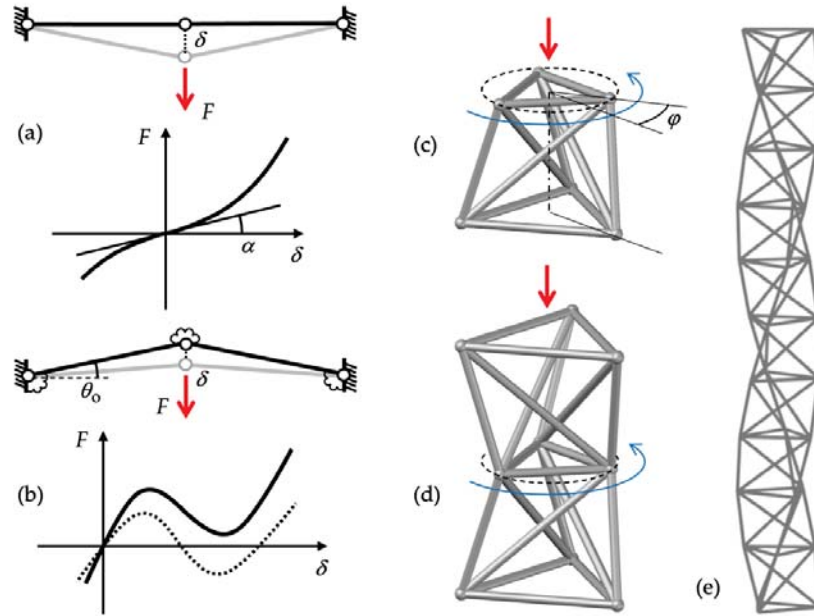

Figure 1: Nonlinear lattices with tensegrity architecture. Two-bar systems with stiffening response (a). Two-bar system with snapping response (b). Single unit (c) and double unit (d) subjected to a vertical load. Column composed of several units (e).

For the two-bar system in Fig. 1(b), the reference configuration is slightly misaligned and unstressed, with each bar inclined by an angle θ_0 . Bars are inflexible and unshearable, while remaining elastically extensible, and additional angular linearly elastic springs respond to changes in angle at nodes. Such angular springs account for the fact that the fabricated structures are monolithic, and bars nodal connections are realized as compliant hinges. If the elastic constant of rotational springs is null, this system constitutes a classic example of bistable snapping system (dotted curve in the F -vs- δ plot in Fig. 1,b). When the elastic constants take positive values in a certain range, the system has just one stable configuration in absence of loads, while retaining a snapping response (solid curve in the F -vs- δ plot in Fig. 1,b).

Figure 1(c) shows a truss unit shaped as a T3 tensegrity system subjected to a vertical load, and the associated deformation mode, in which a relative rotation between the top and bottom bases occurs. The properties of such system depend on the initial twist angle φ between the top and bottom bases. When $\varphi = \pi/6$, the system behaves similarly to the two-bar system in Fig. 1(a) with null prestress [4]. When $\varphi = \pi/6 + \theta_0$, with $\theta_0 < 0$ a small overtwist angle, the system behaves similarly to the two-bar system in Fig. 1(b). Figure 1(d) shows a truss shaped as a double T3 system, obtained by assembling together two mirror images of the unit shown in Fig. 1(c) [14]. In this way, under a vertical force, the relative rotations between the bases of the units compensate each other, and in the resulting deformation mode, the top and bottom bases undergo just a vertical relative displacement, and only the middle base rotates. Several units can be assembled together in columns (Figure 1,e) so as to realize periodic lattices supporting the propagation of solitary or compact waves [12, 14].

3 ADDITIVE MANUFACTURING AND EXPERIMENTAL TESTING

The geometry of the double unit is shown in Fig. 2 (left, center). The top and bottom triangular bases are inscribed in circles of radius $a = 40$ mm, while $b = 30$ mm is the corresponding radius for the middle triangle. Each unit has height $h = 60$ mm, and overtwist angle $\theta_0 = -7$ degrees. Nodes were realized as spheres of diameter $d_s = 6$ mm; the bars forming the bottom, middle, and horizontal triangles are realized with a solid circular cross section of diameter $d_b = 4$ mm. The bars placed between the top and middle triangles, and between the middle and bottom triangle, are subdivided into three segments: the bar main body, with same cross section as mentioned above, and two terminal links to form the connections with nodal spheres. The terminal links have a solid circular cross section of diameter $d_l = 2.2$ mm, and net length $l_l = 4.7$ mm.

Figure 2: Geometry of a double unit and fabricated sample.

Test samples were fabricated by FDM using the UltimakerTM S5 dual extruder 3D printer, employing the Ultimaker Cura slicing software. The material chosen for the samples is polylactic acid (PLA Tough Ultimaker), while polyvinyl alcohol (PVA Ultimaker) has been used as water-soluble support material for fabrication. Figure 3(a) displays the fabrication process preview and main setup parameters in Cura, while Figure 3(b) shows one sample immediately after the fabrication process.

After removal of the supporting material, samples were subjected to a quasi-static displacement-control compression test. An Instron 4482 testing machine, equipped with a 10 kN load cell, was employed to carry out the experiments, setting a testing speed of 1 mm/min. Data were collected with an acquisition frequency of 20 Hz, while the test was recorded with a camera sampling rate of 60 fps at 1080 p resolution. The recorded motion of the structure and the force-vs-displacement curve depicted in Fig. 4 confirm the expected snapping behavior of the double unit.

Figure 3: Fabrication preview display in Ultimaker Cura (a), and sample before removal of the supporting PVA (b).

Figure 4: Compression testing results: force-vs-displacement curve.

4 NUMERICAL SIMULATIONS

We consider a Stick-and-Spring model [17, 18] in which bars are extensible but otherwise undeformable, behaving as axial springs, and equipped with angular springs responding to changes in angle between pairs of adjacent bars. Figure 2 (left) shows the location of such angular springs (green arcs, symmetric copies not shown). The axial spring constants for the bars of the horizontal triangles are computed as EA/l_f , with E the Young's modulus, A the cross-sectional area, and l_f their fabrication length (inter-nodal distance). For the remaining bars, equivalent

axial spring constants are computed considering each of them composed of three springs in series, corresponding to the three segments (two terminal links and the central bar body) they are divided in, taking into account cross-sectional area and length of each segment. Angular springs account for the bending stiffness of the terminal links, and their spring constants are computed as EJ/l_l , with J the inertia moment of the cross section and l_l the link fabrication length.

Figure 5: Test-vs-simulation results comparison.

Displacement-control numerical simulations were carried out in a regime of large displacements and rotations by imposing the vertical relative displacement between the top and bottom bases, and by computing the balancing nodal forces applied to them. In calculations, we considered the value $E = 1820$ MPa for the Young's modulus, as given in the Ultimaker PLA Tough specifications. Figure 5 compares simulation results to experimental ones, and it can be observed that the simulated curve follows the experimental one qualitatively when nominal values of the geometric parameters are considered. By adjusting slightly simulation parameters, setting $\theta_0 = -7.25$ degrees, $d_l = 2.5$ mm, $l_l = 5.0$ mm (nominal values, $\theta_0 = -7.00$ degrees, $d_l = 2.2$ mm, $l_l = 4.7$ mm), the simulated curve can be brought to be almost superposed to the numerical curve.

Impact dynamics simulations were carried out on arrays composed of several units with constant base radius a (Fig. 1,e), by integrating the equations of motion written for Stick-and-Spring model [18], considering nodal lumped masses $m = 0.01$ kg. Figure 6 shows simulation results for an array of 20 units, in which the rightmost base is fixed, while the leftmost base is imposed a longitudinal velocity $v_0 = 2$ m/s, and an angular velocity about the longitudinal axis $\omega = 150$ rad/s, so as to trig the snapping of the leftmost unit. The nodal speed v_n at each triangular base is represented in Fig. 6 at three time instants, showing a localized wave propagating along the array.

5 CONCLUSIONS

In this work, we showed that lattice metamaterials with tensegrity architecture and a highly nonlinear behavior can be effectively fabricated by simple additive manufacturing techniques, such as FDM, and that these types of nonlinear lattice units can constitute the building blocks of three-dimensional arrays with a customized mechanical response. In particular, we redesigned the double unit with snapping behavior studied in [14] by reducing bars cross section near

Figure 6: Impact dynamics simulation on an array of 20 units: profile of the nodal speed (m/s).

the nodes, so as to obtain an easy-to-model compliant mechanism. Fabricated samples were subjected to compression tests which confirmed the snapping behavior. The static response of the double unit was accurately simulated by calibrating a Stick-and-Spring numerical model. Such calibrated model was then employed for predicting the dynamical response of an array of several units subjected to impact loading, confirming that these type of systems support the propagation of solitary or compact waves, and that they can be realized by additive manufacturing techniques. These results can be extended to other types of tensegrity architectures and fabrication techniques to widen the range of mechanical behaviors achievable by lattice meta-materials.

Keywords: Local Resonance, Timoshenko Beam, Dynamic-Stiffness Matrix, Contour-Integral Algorithm

Abstract. *A dynamic-stiffness matrix approach is presented for locally-resonant Timoshenko beams with a periodic array of viscously-damped multi-degree-of-freedom resonators. First, an exact dynamic condensation of the resonator degrees of freedom is pursued, expressing the resonator reaction forces in terms of the deflections of the attachment points via pertinent frequency-dependent stiffness terms. On this basis, a direct integration deriving from the theory of generalized functions provides the exact dynamic-stiffness matrix of the beam, whose size is 4×4 for any the number of resonators and degrees of freedom within the resonators. The dynamic-stiffness matrix is used to calculate the complex eigenvalues of the beam by a recently introduced contour-integral algorithm, without missing anyone. Further, it provides the transmittance for an insight into the elastic wave attenuation properties of the beam.*

1 INTRODUCTION

A great deal of attention was devoted in the last decade to the concept of locally-resonant (LR) beams, i.e. beams coupled with a periodic array of resonators with one or multiple degrees of freedom (DOFs). Indeed, as a result of the periodic resonance induced by the resonators, these beams exhibit considerable mitigation properties of elastic waves over so called frequency band gaps, whose position and amplitude determined by mass, stiffness and mutual distance of the resonators. The typical model of LR beam adopted in the literature involves Euler-Bernoulli or Timoshenko continuous beams coupled with mass-spring subsystems modelling the resonators. Several numerical studies confirmed by experimental results were published in this respect [1, 2, 3, 4, 5, 6, 7, 8, 9].

Here, the focus is on LR Timoshenko beams, when viscous damping is present within the resonators. The exact dynamic-stiffness matrix (DSM) of the beam is obtained with size 4×4 for any the number of resonators and DOFs within the resonators using, for this purpose, (1) a dynamic condensation of the DOFs within the resonators to express their reaction forces in terms of pertinent frequency-dependent stiffness terms and (2) a direct integration of the beam motion equations based on the theory of generalized functions. The DSM is used to compute the complex eigenvalues of the beam by a recently introduced contour-integral algorithm. The interest in the proposed approach is twofold. The dynamic-stiffness formulation involves a reduced number of variables compared with a standard finite-element (FE) approach while the contour-integral algorithm proves successful in evaluating all complex eigenvalues, without missing anyone, with remarkable computational efficiency. Additionally, the dynamic-stiffness matrix allows a straightforward evaluation of the transmittance of the beam, for an insight into its elastic wave attenuation properties due to local resonance.

2 DYNAMIC-STIFFNESS MATRIX FORMULATION

Consider the beam in Figure 1 under harmonic loads $p_v(x, t) = f_v(x)e^{i\omega t}$ and $p_\phi(x, t) = f_\phi(x)e^{i\omega t}$. Using generalized functions, the motion equations in the frequency domain are:

$$GA \left(\frac{\bar{d}^2 V}{dx^2} + \frac{\bar{d}\Phi}{dx} \right) + \rho A \omega^2 V + \sum_{j=1}^N R_j \delta(x - x_j) + f_v = 0 \quad (1)$$

$$EI \frac{\bar{d}^2 \Phi}{dx^2} - GA \left(\frac{\bar{d}V}{dx} + \Phi \right) + \rho I \omega^2 \Phi + f_\phi = 0 \quad (2)$$

where bar means generalized derivative and R_j is the reaction force of the j^{th} resonator, given as

$$R_j = -k_{eq}(\omega)V(x_j) \quad (3)$$

In Eq. (3), $k_{eq}(\omega)$ is the frequency-dependent stiffness of the resonator, which can be obtained from its motion equations by an exact dynamic condensation in the frequency domain. For instance, for a mass-spring-dashpot resonator

$$k_{eq}(\omega) = \frac{(k + i c \omega) m \omega^2}{k + i c \omega - m \omega^2} \quad (4)$$

where k , c and m are the spring stiffness, damping coefficient and mass of the resonator. Analytical expressions for the frequency-dependent stiffness are available also for various types of multi-DOF resonators, see ref. [1].

Figure 1: LR Timoshenko beam with 1-DOF viscous resonators.

The solution is built observing that Eqs. (1)-(2) can be reverted to two decoupled 4th order differential equations only, whose general form is:

$$\frac{\bar{d}^4 Z}{dx^4} + p_1 \frac{\bar{d}^2 Z}{dx^2} + p_2 Z + p_3 = 0 \quad (5)$$

In Eq. (5), symbol Z stands for either V (deflection) or Φ (rotation); symbols p_1 and p_2 are defined as

$$p_1 = \left(\frac{\rho EI \omega^2}{G} + \rho I \omega^2 \right) / EI \quad (6)$$

$$p_2 = \left(\frac{\rho^2 I \omega^4}{G} - \rho A \omega^2 \right) / EI \quad (7)$$

and p_3 denotes the following functions:

$$p_3 = \begin{cases} \frac{1}{GA} \left(\frac{\bar{d}^2 q}{dx^2} + \frac{\bar{d}^2 f_v}{dx^2} \right) + \left(\frac{\rho \omega^2}{EGA} - \frac{1}{EI} \right) (q + f_v) - \frac{1}{EI} \frac{\bar{d} f_\phi}{dx} & \text{if } Z = V \\ -\frac{1}{EI} \left(\frac{\bar{d}^2 f_\phi}{dx^2} + \frac{\rho \omega^2}{G} f_\phi + \frac{\bar{d} f_v}{dx} + \frac{\bar{d} q}{dx} \right) & \text{if } Z = \Phi \end{cases} \quad (8)$$

Recognize that f_v and f_ϕ in Eq. (8) the spatial load functions in Eqs. (1)-(2) while q depends on the reaction forces R_j in Eq. (1), i.e.

$$q = \sum_{j=1}^N R_j \delta(x - x_j) \quad (9)$$

The solution of Eq. (5) is

$$Z = Z_{om} + \sum_{j=1}^N R_j J_{Z,j} + \tilde{Y}_Z^{(f)} \quad (10)$$

whose details are given in Appendix A for brevity.

Now, using $Z = V$ given by Eq. (10) for $V(x_j)$ in Eq. (3), it is noticed that every reaction force R_j depends only on the 4 integration constants $c_{i,0}$ involved in Z_{om} and the reaction forces R_k at $x_k < x_j$. This means that all the reaction forces R_j can be expressed as functions of $c_{i,0}$, providing the frequency response function (FRF) vector $\mathbf{Y}(x, \omega)$

$$\mathbf{Y}(x, \omega) = \mathbf{W}(x, \omega) \mathbf{c}_0 + \mathbf{Y}^{(f)}(x, \omega) \quad (11)$$

In Eq. (11), \mathbf{W} is a 4×4 matrix involving the solution of the homogeneous equation associated with Eq. (5), $\mathbf{c}_0 = [c_{1,0} \ c_{2,0} \ c_{3,0} \ c_{4,0}]^T$, $\mathbf{Y}^{(f)}$ is a 4×1 load-dependent vector. Elements in \mathbf{W} and $\mathbf{Y}^{(f)}$ are available in analytical form, see Appendix A for conciseness; in particular, here they are given for arbitrary polynomial loading functions f_v and f_ϕ . Vector \mathbf{c}_0 in Eq. (11) is derived by enforcing the beam boundary conditions (B.C.), i.e.

$$\mathbf{B}\mathbf{c}_0 = \mathbf{e} \rightarrow \mathbf{c}_0 = \mathbf{B}^{-1}\mathbf{e} \quad (12)$$

where \mathbf{B} and \mathbf{e} are a 4×4 matrix and 4×1 vector, built from \mathbf{W} and $\mathbf{Y}^{(f)}$ computed at $x = 0$ and $x = L$. The inverse matrix \mathbf{B}^{-1} takes a closed analytical form, as shown in ref. [10]. Hence, replacing Eq. (12) for \mathbf{c}_0 in Eq. (11) provides an analytical expression for the FRF vector $\mathbf{Y}(x, \omega)$ of the beam in Figure 1, which can be implemented in any symbolic software package.

Eq. (11) is an exact analytical expression for the FRF vector $\mathbf{Y}(x, \omega)$. It holds for any number of resonators and DOFs within the resonators, any loads and positions of the loads relative to the resonators, with significant advantages w.r.t. to the FE method where the mesh has to be chosen depending also on the applied loads.

Here, Eq. (11) is used for two purposes. First, Eq. (11) is used to build the exact DSM $\mathbf{D}(\omega)$ of the beam, adopting the method in ref. [10]. Specifically, the procedure provides $\mathbf{D}(\omega)$ in exact analytical form and its size depends only on the number of DOFs at the beam ends, regardless of the number of resonators and number of DOFs within the resonators. Second, Eq. (11) can be used to calculate the transmittance of a cantilever beam [11, 12]. In this case, being $V_g e^{i\omega t}$ the harmonic deflection at the clamped end $x = 0$, $V(x)$ in Eqs.(1)-(2) is the beam deflection relative to the ground and transverse load $f_v = \rho A \omega^2 V_g$ is included in Eq. (1); accordingly

$$R_j = -k_{eq}(\omega)(V(x_j) + V_g) \quad (13)$$

while the B.C. are

$$V(0) = 0 \quad \Phi(0) = 0 \quad M(L) = 0 \quad T(L) = 0 \quad (14)$$

Using Eq. (13), changes to matrix \mathbf{W} and vector $\mathbf{Y}^{(f)}$ reported in Appendix A for Eq. (11) are simple. The transmittance is $|V(L) + V_g|/V_g$.

3 CONTOUR-INTEGRAL ALGORITHM FOR EIGENVALUE CALCULATION

Computing the complex eigenvalues for the LR Timoshenko beam under study, without missing anyone and with the required accuracy, is a particularly challenging task since several modes are expected to be close to each other, as a result of local resonance [17, 18, 19].

Specifically, the eigenvalues are calculated by the following key steps [17, 18, 19]:

1. Select a circle $\Gamma = \gamma_0 + \rho_0 e^{i\theta}$ on the complex plane with center γ_0 , radius ρ_0 and $0 \leq \theta \leq 2\pi$.
2. Compute two complex random source matrices \mathbf{U} and \mathbf{V} with dimensions $n_0 \times L_0$, being n_0 the size of the DSM $\mathbf{D}(\omega)$ and L_0 the number of source vectors in \mathbf{U} and \mathbf{V} .
3. Calculate the shifted and scaled moments \mathbf{M}_k using a N_0 -point trapezoidal rule:

$$\mathbf{S}_k = \frac{1}{N_0} \sum_{j=0}^{N_0-1} \left(\frac{\eta_j - \gamma_0}{\rho_0} \right)^{k+1} \mathbf{D}(\eta_j)^{-1} \mathbf{V}, \quad k = 0, 1, \dots, 2K-1$$

$$\mathbf{M}_k = \mathbf{U}^H \mathbf{S}_k$$

where $\eta_j = \gamma_0 + \rho_0 \exp 2\pi i(j + 1/2)/N_0$ for $j = 0, 1, \dots, N_0 - 1$, K is the maximum moment degree assumed for the moment and \mathbf{U}^H denotes the Hermitian transpose of \mathbf{U} .

4. Construct of the Hankel matrices $\hat{\mathbf{H}}_{KL_0}$ and $\hat{\mathbf{H}}_{KL_0}^< \in \mathbb{C}^{KL_0 \times KL_0}$ so that:

$$\hat{\mathbf{H}}_{KL_0} = [\mathbf{M}_{i+j-2}]_{i,j=1}^K \quad \hat{\mathbf{H}}_{KL_0}^< = [\mathbf{M}_{i+j-1}]_{i,j=1}^K$$

5. Carry out a singular value decomposition of $\hat{\mathbf{H}}_{KL_0}$.
6. Eliminate small singular value components $\sigma_i < \epsilon \cdot \max_i \sigma_i$, set \tilde{m} as the number of remaining singular value components ($\tilde{m} < KL_0$) and build $\hat{\mathbf{H}}_{\tilde{m}}$ and $\hat{\mathbf{H}}_{\tilde{m}}^<$ extracting the principal submatrix with maximum index \tilde{m} from $\hat{\mathbf{H}}_{KL_0}$ and $\hat{\mathbf{H}}_{KL_0}^<$, that is

$$\hat{\mathbf{H}}_{\tilde{m}} = \hat{\mathbf{H}}_{KL_0}(1 : \tilde{m}, 1 : \tilde{m}); \quad \hat{\mathbf{H}}_{\tilde{m}}^< = \hat{\mathbf{H}}_{KL_0}^<(1 : \tilde{m}, 1 : \tilde{m})$$

7. Calculate the eigenvalues ζ_j of the linear pencil:

$$\hat{\mathbf{H}}_{\tilde{m}}^< = \zeta \hat{\mathbf{H}}_{\tilde{m}}$$

8. Compute the eigenvalues

$$\omega_j = \gamma_0 + \rho_0 \zeta_j, \quad j = 1, \dots, \tilde{m}$$

The algorithm captures all the eigenvalues ω_j falling within the selected circle Γ , including multiple ones [17, 18, 19]. Circles of increasing radius and centred at the origin can be considered to explore the whole complex plane and calculate all the requested eigenvalues.

The accuracy of the algorithm is determined by the selection of the parameters K , L_0 , N_0 . The maximum moment degree K can be set at least equal to $N_0/4$ [20], while the minimum number of source vectors L_0 is such that $\sigma_{\min}/\sigma_1 < \epsilon$ with small $\epsilon > 0$; the number of quadrature points N_0 determines the quadrature error and can be set in advance.

The eigenfunction associated with every eigenvalue can be derived as non-trivial solution of the eigenvalue problem involving the DSM $\mathbf{D}(\omega)$, as evaluated for that eigenvalue [10].

4 NUMERICAL APPLICATION

Focus on the cantilever LR Timoshenko beam with 1-DOF resonators in Figure 2. Parameters of the beam are: $E = 30 \times 10^9 \text{ N m}^{-2}$; $G = 11.53 \times 10^9 \text{ N m}^{-2}$; $\rho = 2500 \text{ kg m}^{-3}$; $a = 0.125 \text{ m}$, $N = 8$ is the number of the resonators, $L = 1.0 \text{ m}$ is the beam length. Further, the parameters of the resonators are $k = 1 \times 10^5 \text{ N m}^{-1}$, $c_1 = 0.01 \text{ N s m}^{-1}$, $m_1 = 0.1 \text{ kg}$.

Table 1 shows the first 13 complex eigenvalues, as computed from the proposed DSM approach via the contour-integral algorithm, along with the corresponding ones obtained by a standard FE model, implemented in ABAQUS employing a two-node shear-deformable linear FE for every beam segment between two resonators. Specifically, $K = 20$, $L_0 = 30$ (with $\epsilon = 10^{-10}$) and $N_0 = 700$ are selected for the implementation of the contour-integral algorithm (to calculate every eigenvalue, regardless of its position on the complex plane), while an automatic multi-level substructuring eigensolver is used in ABAQUS. The results in Table 1 are in excellent agreement, confirming the accuracy of the DSM approach. Further, the eigenvalue calculation via contour-integral algorithm is very expeditious, with savings up to 30 % – 40 % with respect to the eigenvalue calculation in ABAQUS.

5 CONCLUSIONS

Here, a DSM approach has been presented to calculate complex eigenvalues and frequency response of LR Timoshenko beams, featuring a periodic array of viscously-damped multi-DOF resonators. The approach relies on an exact dynamic condensation of the resonator DOFs and a direct integration approach based on the theory of generalized functions, which provide the exact DSM of the beam with size 4×4 for any number of resonators and DOFs within the resonators. The DSM has been used to evaluate the complex eigenvalues, without missing anyone, by a contour-integral algorithm of remarkable accuracy and, additionally, to evaluate the transmittance of the beam.

6 Appendix A

This Appendix contains various formulas and expressions referred to in the main text.

In Eq. (10), Z_{om} is the solution of the homogeneous differential equation associated with Eq. (5), i.e.

$$Z_{om}(x) = \sum_{i=1}^4 c_{i,0} \alpha_i e^{\lambda_i x} \quad (15)$$

where $c_{i,0}$ are integration constants, λ_i are

$$\lambda_{1,2} = \mp \left(\left(-p_1 - \sqrt{p_1^2 - 4p_2} \right) / 2 \right)^{1/2} \quad (16)$$

$$\lambda_{3,4} = \mp \left(\left(-p_1 + \sqrt{p_1^2 - 4p_2} \right) / 2 \right)^{1/2} \quad (17)$$

and the coefficients α_i are

$$\alpha_i = \begin{cases} 1 & \text{if } Z = \Phi \\ -\frac{GA\lambda_i}{\rho A \omega^2 + GA\lambda_i^2} & \text{if } Z = V \end{cases} \quad (18)$$

Further, $J_{Z,j} = J_Z(x, x_j)$ in Eq. (10) is the particular integral of Eq. (5) that is associated with the Dirac's delta $\delta(x - x_j)$ and its derivatives (see Eq. (8) and Eq. (9)). Based on the approach in ref. [16], $J_Z(x, x_j)$ can be obtained via direct and inverse Laplace Transforms of Eq. (5), on setting $f_v = f_\phi = 0$ in p_3 given by Eq. (8). Specifically, $J_V(x, x_j)$ is

$$J_V(x, x_j) = -(\sqrt{2}GA\Sigma_1)^{-1} [B \sinh(C(x - x_j)) + D \sinh(E(x - x_j))] \mathcal{H}(x - x_j) \quad (19)$$

for

$$\begin{aligned} B &= \left(\sqrt{2}C \right)^{-1} [\Sigma_1 + \Sigma_2 - 2(GA)^2] \\ C &= ((\Sigma_1 - \Sigma_3) / (2EI GA))^{1/2} \\ D &= -\left(\sqrt{2}C \right)^{-1} [\Sigma_1 - \Sigma_2 + 2(GA)^2] \\ F &= -(\Sigma_1 + \Sigma_3) / (2EI GA)^{1/2} \\ \Sigma_1 &= [(EI)^2(\rho A)^2\omega^4 + 2EIGA\rho A\omega^2 (2GA - I\rho\omega^2) \\ &\quad + (GA)^2 I^2 \rho^2 \omega^4]^{1/2} \\ \Sigma_2 &= GAI\rho\omega^2 - EI\rho A\omega^2 \quad \Sigma_3 = GAI\rho\omega^2 + EI\rho A\omega^2 \end{aligned} \quad (20)$$

being $\mathcal{H}(x) = 1$ if $x > 0$ and $\mathcal{H}(x) = 0$ if $x < 0$. Also, $J_\Phi(x, x_j)$ is:

$$J_\Phi(x, x_j) = -GA\Upsilon_1^{-1} \{ \cosh[S_1(x - x_j)] - \cosh[S_2(x - x_j)] \} \mathcal{H}(x - x_j) \quad (21)$$

$$\begin{aligned} S_1 &= ((\Upsilon_1 - \Upsilon_2)/(2EI GA))^{1/2} \\ S_2 &= (- (\Upsilon_1 + \Upsilon_2)/(2EI GA))^{1/2} \\ \Upsilon_1 &= \{ \rho\omega^2 [(A EI)^2 \rho\omega^2 + 2AEIGA (2GA - I\rho\omega^2)] \\ &\quad + (GA I)^2 \rho\omega^2 \}^{1/2} \\ \Upsilon_2 &= AEI\rho\omega^2 + GAI\rho\omega^2 \end{aligned} \quad (22)$$

Finally, $\tilde{Y}_Z^{(f)}(x)$ in Eq. (10) is the particular integral of Eq. (5) that is associated with the loading functions f_v and f_ϕ and their derivatives (see Eq. (8)), given as

$$\tilde{Y}_Z^{(f)}(x) = \int_0^L \tilde{J}(x, \xi) f_Z(\xi) d\xi \quad (23)$$

Based on Eq. (8), f_Z in Eq. (23) is

$$f_Z = \begin{cases} \frac{1}{GA} \left(\frac{d^2 f_v}{dx^2} \right) + \left(\frac{\rho\omega^2}{EGA} - \frac{1}{EI} \right) f_v - \frac{1}{EI} \frac{d f_\phi}{dx} & \text{if } Z = V \\ -\frac{1}{EI} \left(\frac{d^2 f_\phi}{dx^2} + \frac{\rho\omega^2}{G} f_\phi + \frac{d f_v}{dx} \right) & \text{if } Z = \Phi \end{cases} \quad (24)$$

and $\tilde{J}(x, \xi)$ is

$$\begin{aligned} \tilde{J}(x, \xi) &= \sqrt{2} \mathcal{A}_1^{-1} (\mathcal{A}_2^{-1} \sinh(2^{-1/2} \mathcal{A}_2(x - \xi)) \\ &\quad - \mathcal{A}_3^{-1} \sinh(2^{-1/2} \mathcal{A}_3(x - \xi))) \mathcal{H}(x - \xi) \end{aligned} \quad (25)$$

$$\begin{aligned} \mathcal{A}_1 &= (p_1^2 - 4p_2)^{1/2} \\ \mathcal{A}_2 &= (-p_1 - \mathcal{A}_1)^{1/2} \\ \mathcal{A}_3 &= (-p_1 + \mathcal{A}_1)^{1/2} \end{aligned} \quad (26)$$

Notice that $\tilde{J}(x, \xi)$ is the particular integral of Eq. (5) acted upon by $p_3 = \delta(x - \xi)$; its form (25) is obtained, again, by applying direct and inverse Laplace Transforms to Eq. (5).

Keywords: metamaterials, Seismic isolators, Tensegrity, Shape memory alloys.

Abstract. *The class of nonlinear metamaterials with tensegrity architecture is particularly interesting, since the mechanical behavior of such systems can be effectively adjusted by acting on internal and external prestress, as well as the usual controls of geometry, topology, and mechanical properties of the members. This work is focused on the development of 3D versions of the tensegrity braces (T-braces) recently proposed in the literature. The examined structures are aimed at forming novel seismic isolators, reinforcing seismic-resistant frames of steel and reinforced concrete buildings, as well as introducing the energy dissipation mechanisms of masonry walls, floor slabs, and junctions between seismic-resistant structures. This technology consists of lightweight and high-strength systems with re-centering capabilities formed by a variety of tensegrity systems. The tensegrity bracing systems incorporate superelastic shape memory bars/wires acting as pre-tensioned dissipative elements. The struts are prevented from buckling through the internal pretension of the braces via self-stress, and/or by contrasting them against the elements of the structure (external pre-tension). Using fractal geometry concepts, such systems can be designed through bio-inspired self-similar divisions of tensegrity brace modules to enhance both the energy dissipation capacity and the buckling resistance of the bracing system. Their development will significantly impact currently available techniques for the seismic protection of masonry and framed structures.*

1 INTRODUCTION

A novel area of research has emerged over the last few years regarding the highly non-linear dynamics of mechanical metamaterials formed by assembling tensegrity units and lumped masses [4]. Experimental and theoretical studies have shown that the geometrically non-linear response of several tensegrity units may gradually change from stiffening to softening, depending on mechanical, geometrical, and prestress variables. Such behavior, which can be dynamically tuned, supports highly-controllable bandgap and solitary wave dynamics. For this particular reason, various tensegrity devices are being designed also for seismic protection [5]. A Tensegrity System is defined as a set of rigid bodies (subject to compression) that can be stabilized (therefore balanced) by a set of cables (or tense elements), in the absence of external forces [6]. The strings are in pretension and that pretension helps the system to be in equilibrium. There are several known examples of tensegrity structures, for example in nature (the bone-tendon system), in the art (for aesthetic beauty), in architecture (for their properties). These structures are nowadays usually referred to as “mechanical metamaterials”. It has been found that linear elastic meta-materials can exhibit peculiar behaviors in the dynamical regime, like, e.g., negative effective elastic moduli, negative effective mass density, phononic band gaps, to name just a few examples [7]. The seismic response of strongly non-linear meta-materials has been particularly investigated in this article. The tensegrity structures can be 3D printed it is the system comprises of the bars and the strings. The strings are in tension and bars in compression. When we try to change the position, the strings experience some forces which put more compression on the bars and the strings face more tension. These systems which are useful in dissipating the seismic energy are called passive energy dissipation devices. Various designs were studied before adopting the scissor-Jack design (SJD) by replacing the viscous damper with the SMA wires [6]. The reason behind SJD is it has magnification factors substantially greater than unity. Toggle-brace-damper (C & d) systems can also achieve the magnification factor greater than the unity. Viscous dampers used in these systems are pretty heavy [8] -[9]. To reduce the weight and to enhance the amplification, shape memory alloy (SMA) wires have been used in the current version of seismic devices. These SMA wires act as energy dissipators inside the braces because of their shape memory effect and super-elastic effect without having major deformation [11]. When stretched, the energy is dissipated in a considerable amount [12]- [14]. Further SMA effect of the wire amplifies the even infinitesimal movement in bars thus acting as sensors for energy dissipation device. In this article, two different types of seismic systems have been described one is named a 2D bracing system and another is 3D bracing system. In addition to the design, the experimental analysis of the 2D and 3D braces has been discussed in the next sections. It has been seen that 3D braces are far more efficient in terms of stability and dissipation because of the out-of-plane energy dissipation and the SMA effect of the strings [10].

2 Materials and methods

The key focus of this study was on the design and development of an anti-seismic system based on SMA wires. Furthermore, as discussed above, SMA wires have been used as restitution components instead of liquid viscous dampers to serve as passive energy dissipation (PED) equipment. The dissipation in this system is solely elastic due to the peculiar nature of the SMA wires. In this study, two types of bracing systems have been studied, namely the 2D bracing system (Figure. 1) and the 3D bracing system. In the 2D bracing method, the SJD model was used as shown in Figure 1 and was studied for its effectiveness. It was able to dissipate energy,

but some limitations were observed. To overcome these drawbacks, particularly instability, less energy dissipation compared to the 3D brace model, and amplification, a 3D tensegrity bar model has been developed and theoretical results discussed in the following sections.

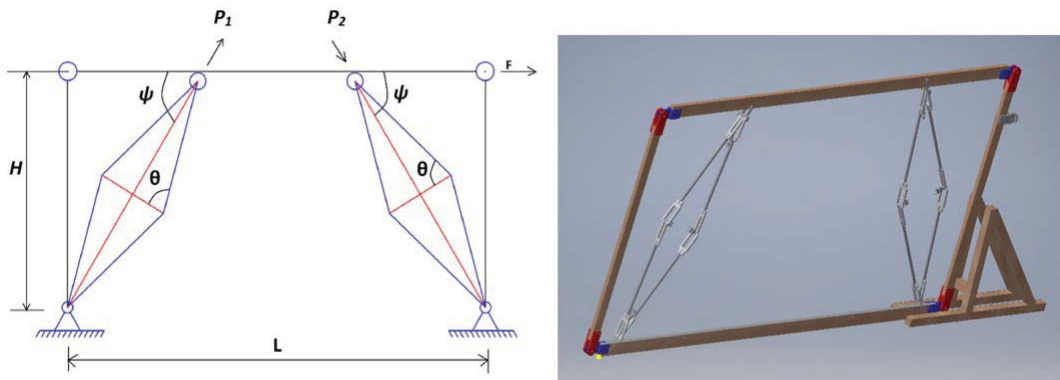

Figure 1: SMAD braces inserted into a frame structure

3 Anti-seismic response of developed 2D bracing system

After the design and development of the 2D tensegrity bar, theoretical tests were performed to access the necessary information. In Figure. 2 of Ref. [3] the amplification properties of the 2D tensegrity bar have shown and quite high amplification has been seen. In this system of braces, the system can achieve extreme position, unlike the liquid viscous dampers. Further, displacement in both the directions i.e, lateral and longitudinal directions has been seen, which makes it a better energy dissipation device by dissipation a fair amount of energy. In this, u and v represent the longitudinal and the lateral displacements of the framework. In a special case of $u/v = \tan\theta$, β approaches to 0 i.e, $\beta \rightarrow 0$, which signifies the negligible displacement from reference or original configuration. The variation of u/v with θ for different values of β is depicted in ref [3]. where u and v , denote the longitudinal and the transverse displacements of the structure respectively.

Also, in Figure 3 of Ref. [3], the experimental and theoretical results were obtained and compared. It can be observed that the experimental and theoretical results are nearly identical. It is worth noting that minute residual strains are observed at unloading (not greater than 0.03 max) in experimental conditions.

4 Anti-seismic response of developed 3D bracing system

As discussed in previous sections, the extension to this work by designing a novel 3D tensegrity brace has been provided (see Figure. 2). Both physical and constitutive models have been developed and tested to characterize the force-displacement behavior of the bracing system. Due to the 3D shape of this configuration, it is possible to obtain a tensegrity element with increased stability towards out-of-plane buckling, and more effective in terms of energy dissipation. Researchers have found that triangular cross-section is by far the most effective configuration for a tensegrity element, where $N=3$ [10].

Next, we show some numerical simulations of a 3D tensegrity bracing system, which enabled us to characterize its force-displacement response to cyclic loading (Fig. 3). In Figure. 4) it is displayed the geometric layout of the tested bracing. For further information about the

Figure 2: 3D model of the tensegrity bracing

Figure 3: Mechanical loading cycle.

numerical implementation which was used for these simulations please refer to [15].

An initial pre-strain is introduced in the SMA wires (State A), prior to the implementation of the mechanical loading cycle, shown in Figure. 3. In Figure. 5 we show a compilation of the stress-strain-temperature responses of the SMA wires acting as ties in the 3D tensegrity bracing, during the imposed loading cycle. We assume isothermal conditions during the mechanical cycle, for an ambient temperature of 20 °C. Finally, in Figure. 6 we show the force-displacement plot for the proposed 3D tensegrity bracing, during the mechanical loading. Due to the fact that the horizontal (cables 1) and vertical (cable 2) ties are working in phase opposition, it is possible to obtain a wide superelastic hysteresis, highlighting the great energy dissipating capabilities of the proposed system.

5 CONCLUSIONS

In present work a novel method of developing seismic bracing systems with tensegrity architecture has been shown. Computational calculations of 2D and 3D tensegrity braces have been carried out to prove the effectiveness of the proposed systems. This research work is an extension of previous research focused on the development of a 2D PED device with tensegrity architecture incorporating SMA wires, which is a competitive alternative to viscous damper systems. SMA effects of the restitution elements has been proved to be very effective in terms

Figure 4: 3D numerical model of the tensegrity bracing (3D view and top view).

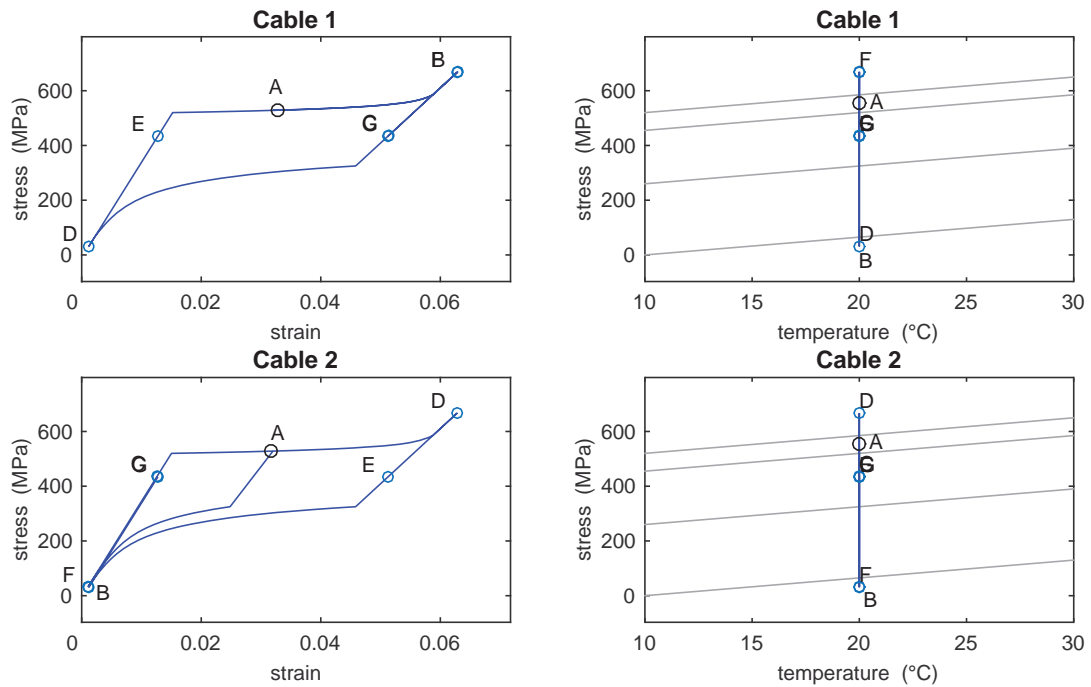

Figure 5: Stress-strain-temperature response of the SMA ties.

Figure 6: Force-displacement responses of a model frame reinforced with symmetrical SMAD braces.

of the displacement amplification factor and the energy dissipation capacity, because of the super-elastic properties of the SMA wires without experiencing permanent deformations. A 3D tensegrity bracing has been developed to multiply the existing effectiveness, such as energy dissipation and the stability of the bars. It has been seen from the theoretical results published in Ref. [3] that the amplification factor of the 2D brace is enhanced when the SMA wires are incorporated. In addition, in the case of the 3D brace, it is possible to obtain even more important energy dissipation features with additional lateral buckling restraints, as shown in the Figure. 6. The non viscous nature of the SMA wires makes the system lightweight and provide the opportunity to achieve extreme positions of the bar i.e., when the aspect angle is nearly 90 degrees. These features of the tensegrity bracing system would be very effective in technical applications, and indeed future steps are being taken to develop real scale models to be validated against experimental results by using various other meta materials and polymer materials and techniques [16]-[19].

Abstract

The widespread use of composite materials has led to the development of characteristics identification methods for composite materials. This paper presents an inverse technique based on genetic algorithms to reconstruct material stiffness properties of composites from dispersion relations of three fundamental modes of guided Lamb waves (A_0 , SH_0 and S_0). The discrepancy between the mesoscopic dispersion relations computed for a textile composites and the macroscopic dispersion characteristics computed for a tentative set of elastic moduli defines the objective function. The proposed scheme is presented to obtain the elastic moduli of unidirectional carbon fibre reinforced polymer composite. The results show that the proposed method can effectively inverse the dispersion curves to get mechanical properties of composites.

Keywords: Textile composites, Guided Lamb wave, Dispersion relations, Genetic Algorithm

1. Introduction

Carbon fiber composite materials have been widely used in modern industries due to the characteristics of high specific strength and high specific stiffness [1, 2]. Different types of damage can occur in composites structures, which potentially leads to catastrophic failure of the whole system. Therefore effective and reliable Non-Destructive Evaluation (NDE) and Structural Health Monitoring (SHM) techniques are of utter importance to develop. Various algorithms were developed for damage identification, including time-of-flight, time reversal, migration technique, tomography and phased-array beamforming [3, 4, 5, 6]. All of the above algorithms require prior knowledge of elastic moduli particularly in anisotropic materials.

The traditional tests for determining the elastic properties of materials are generally expensive and time-consuming. Over years, non-destructive techniques have been done to identify the elastic constants of composite plates as these techniques are robust and quick to perform, especially guided wave technique [7, 8]. The use of guided wave for material characterization yields a frequency-dependent behaviour of the waves that can be used in inverse identification procedures. Different parameters, such as wave velocity [9], group delay curves [10], wavenumber [11], and dynamic displacement response [12] are used to identify the elastic constants in the inverse process.

The solution of dispersion relations is the premise of the inversion process. Methods such as SAFE [13, 14, 15], or WFE [16, 17, 18] using macroscale modelling are extremely efficient to compute the dispersion relations of laminates as long as the elastic moduli are known for each individual layer. The methodology presented in [18] provides a reduced formulation for WFE approach which in itself is a hybridization between periodic structure theory and finite elements. This methodology, while revealing itself to provide accurate dispersion predictions, needs much more computational resources than a macroscale model. Given that macro is superior to meso in terms of the computational time, but from the perspective of accuracy, it is opposite. Therefore, there is considerable motivation to bridge them. The approach proposed in this manuscript takes advantage of the accuracy of the methodology for computing dispersion relations in complex textile composites from [18] and the efficiency of the SAFE method to compute the dispersion characteristics of macroscale laminate models.

Different inversion procedures have been used to identify the elastic constants of composite plates [12, 19, 20, 21]. Balasubramaniam [19] was the first to employ genetic algorithms (GAs) for inverting unidirectional composite

material elastic moduli with significant success. The advantage of GAs over other search algorithms is that GAs do not need an initial guess but rather a valid search space; GAs are also robust and avoid entrapment at local minima. Neural network techniques have also been applied in solving inverse problems [12, 20]. More recently, a Bayesian identification technique based on finite element modelling and the properties of propagating waves in multilayered structures is proposed, which overcomes the limitations of ill-conditioning and non-uniqueness associated with the conventional approaches [21]. Considering the advantages of GAs, GAs are adopted in this paper.

The paper is structured as follows. In Sec. 2, the proposed methodology is thoroughly described. In Sec. 3, the scheme is validated using a simple orthotropic plate structure. Finally, Sec. 4 provides concluding remarks.

2. Inverse methodology based on a genetic algorithm

In this section, the GA is used to determine the elastic moduli of a material from its dispersion relations. A schematic representation of the elastic moduli identification framework based on the GA method is shown in Fig. 1. The mesoscale model based on modified WFE approach [18] is used to calculate the mesoscale dispersion characteristics, which is regarded as the input of an inverse algorithm. The macroscale model based on SAFE method is used to calculate the iterative dispersion relations. The GWs-based identification of elastic properties is realized through the minimization of an objective function, which is built on the relative discrepancies between the dispersion characteristics computed using the mesoscale model and the SAFE method for a tentative set of elastic moduli at the macroscale. The GA procedure iteratively updates the sets of elastic moduli in the SAFE formulation in order to minimise the objective function as presented in [22]. The iteration terminates when the stopping-conditions are fulfilled; these can be when the value of the objective function for a tentative set of elastic moduli overcomes a threshold or after completing a predefined number of iterations.

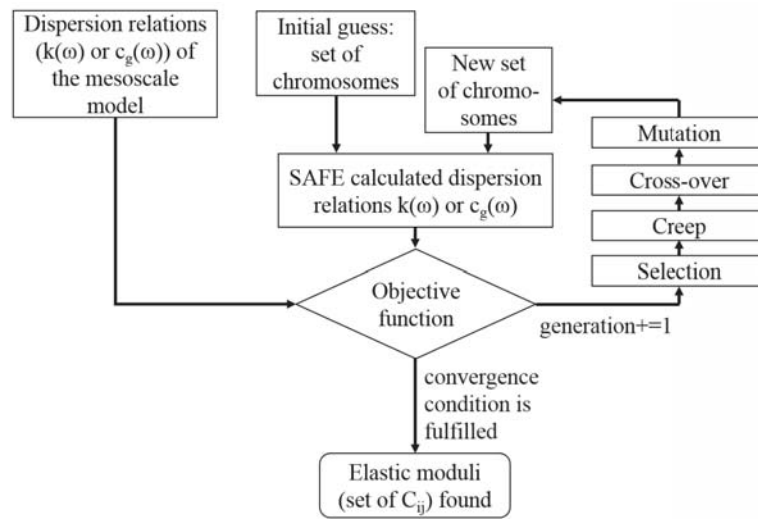

Figure 1: Schematic representation of the elastic moduli (C_{ij}) identification framework based on a genetic algorithm. The starting point for the optimization process are the nine statically determined mechanical moduli for the textile composite. The mesoscale wave propagation properties computed through a modified WFE scheme are compared to the macroscale SAFE estimations incorporating the mechanical moduli. The moduli are updated iteratively until the mesoscale and macroscale wave propagation properties converge.

In this study, a chromosome is a set of nine elastic moduli (also called C_{ij}) describing the stiffness matrix of the homogenised orthotropic material. Each individual modulus is a gene. A set of multiple chromosomes is called a population, as depicted in Fig. 2.

2.1. Initialisation of the homogenisation process

Although it is not necessary for attaining convergence, using an initial guess allows for speeding up the process (that is given that the initial guess is not far from the solution). Since the material is modelled to obtain its mesoscale

Figure 2: Chromosomes incorporating the elastic moduli of an orthotropic textile layer. Multilayer structures can be considered with the size of chromosomes varying accordingly. Nine independent elastic moduli are included for each layer. These moduli are injected within a macroscale SAFE calculation and results are compared against the mesoscale derived wave dispersion properties.

dispersion characteristics, it is convenient to use its effective elastic moduli obtained by static virtual testing (method detailed in [23, 24, 18]) as initial guess but not necessary. A small set of chromosomes of the initial population is set equal to the initial guess while the rest of the population is randomly generated from a small neighborly interval whose median value is the initial guess.

2.2. Objective function

The objective function defines the discrepancy between the mesoscopic dispersion relations computed for a textile composite and the macroscopic dispersion characteristics computed for a tentative set of elastic moduli. It is noted that any property directly related to the dispersion characteristics of the structure (i.e. the computed wavelength, wavenumber of wave speed) can be employed within the objective function in Eq. (1) with such correlated quantities being expected to provide the same effective properties. The identification of the optimal set of elastic moduli is realised through the minimisation of this objective function. The mesoscale dispersion relations are input to the GA procedure and are not updated while the macroscale dispersion curves are computed iteratively using the SAFE method for each updated set of elastic moduli. Different types of dispersion characteristics can be used for comparison: the wavenumber or the group velocity displayed in Fig. 3 are two possibilities. While the group velocity values are traditionally used [25, 26, 27] for GA-based homogenisation methods (for the simple reason that this parameter is straightforward to obtain experimentally), the wavenumber parameter is also a good candidate. In this study, the wavenumber is used to explore more possibilities.

The error function to be minimised is the Mean of the Relative Error (MRE) for each point of an individual dispersion curve and is written as follows:

$$\text{MRE}(\theta) = \sum_{i=1}^n \left| \frac{\lambda_i^{\text{meso}}(\theta) - \lambda_i^{\text{macro}}(\theta)}{\lambda_i^{\text{meso}}(\theta)} \right| / n. \quad (1)$$

with λ the dispersion parameter which is hereby taken as the computed wavelength (equivalently the phase velocity) of the considered wave mode. Moreover θ the angle of propagation of consideration and n the number of compared data points.

The relative error function is computed separately for the three fundamental modes (S_0 , SH_0 and A_0) and in a few directions of propagation. The objective function is set to the maximum of any of these values, thus minimising all modes simultaneously. All modes have to be considered as it would be useless to obtain a set of moduli that reconstructs one mode only considering that results will be employed within wave interaction with damage modelling or multiple ray reflection modelling where wave conversion phenomena are predominant. Using the sum of all relative errors has been considered but revealed itself to slow down the optimisation process. It is noted that while the formulation is globally applicable to frequency ranges including higher order modes, this study focuses on matching

Figure 3: Dispersion relations (group velocity plotted in blue and wavenumber in red) of the three first modes in the x -direction of propagation for a plate constituted of an orthotropic material. Comparisons on the sensitivity of both parameters are provided in Sec. 3 to determine which is best for this application. (—) A_0 , (---) SH_0 , (...) S_0 .

the dispersion characteristics within the range where only fundamental Lamb wave modes propagate, since this is the range typically employed for damage identification.

2.3. Selection and genetic operators

Selection of the portion of existing population to breed. The fitness function is directly derived from the objective function and determines the likeliness of a chromosome to be selected for the next generation. The selection process can be visualised as a roulette wheel in which each chromosome covers an area of the wheel proportional to its probability to be selected. The chromosomes for the next generation are selected one by one by turning the wheel. All generations population contain an equal number of chromosomes thus a chromosome with a high probability of selection might be selected more than once to be passed on to the next generation.

Creeping operation. A creeping operation is performed on each new candidate solution. A threshold is established and a random number is generated. If the random number exceeds the threshold then the considered set of elastic moduli is randomly scaled in the range of $[1-\delta_{creep}, 1+\delta_{creep}]$, δ_{creep} being the creep amount. Using this approach also allows for a search outside the search space.

Single-point crossover of parent chromosomes. Some of the selected chromosomes mate through the crossover process to create new offspring whose genes are a combination of its parent's genes. The crossover rate defines the number of parent chromosomes to be selected for cross-over. Two parent chromosomes are 'cut' at a single random crossover point and their genes are interchanged.

Mutation of parent chromosomes. Finally some of the chromosomes are mutated to avoid stagnation of the solution to a local minima. The mutation rate defines the number of genes to be mutated and their positions across the chromosomes are selected randomly. The genes selected for mutations are each replaced by a newly generated one.

3. Case studies

To show the applicability of the method, it is firstly performed on a simulated orthotropic plate whose theoretical elastic moduli are known. Its dispersion characteristics are computed using the WFE method similarly to the way it would for a textile composite. In the following subsections, the elastic moduli are approximated using two different approaches to validate and compare them. The approach called 'brute-force' with the ambitious task of reconstructing all nine parameters at once is adopted here.

3.1. Brute-force approach

The thickness of the plate and the density of the material are fixed (0.5 mm and 3212 kg/m^3) as known and the nine elastic moduli presented in Table1 in the ‘theoretical’ column are sought. These moduli represent a unidirectional carbon fibre reinforced polymer composite whose fibre arrangement makes it slightly non-transverse isotropic. Table1 shows the results obtained for five different runs of the GA and the percentage of error to the theoretical value. In order to validate the method, a random set of elastic moduli was used as initial guess for each run. The crossover and mutation rates are both set to 0.1, the creep amount is set to 0.3 and the generated population size is 50 chromosomes. The algorithm is launched considering the wavenumber dispersion relations for five runs. Parallel computing is performed on a 4 cores and 8 Gb RAM system and the algorithm is coded in Python language.

Generations	-	103	118	286	222	222
Time (h)	-	25	30	59	49	46

Table 1: Results of the GA for five independent runs for the reconstruction of the elastic moduli of an orthotropic material whose real moduli are displayed on the left-hand side, when $k(\omega)$ is considered.

The results are displayed for the wavenumber approach in Table1. It can be observed that this methodology, while providing a realistic order of magnitude for the elastic moduli, yields strong relative error for many of them ($> 10\%$). Some elastic moduli such as C_{11} and C_{66} however, are in all five runs approximated with a very low relative error ($< 2\%$), while C_{44} and C_{55} are approximated with a tolerable error ($< 6\%$). One can conclude that these parameters are extremely sensible in comparison to the others.

Trying to optimise nine coefficients at once is a very ambitious task and the convergence is obtained after many generations (at least 100) as seen in Fig. 4.a, and thus is computationally taxing. Moreover, only two elastic moduli are reconstructed with good accuracy and two more with a relatively low error. One can conclude that this approach is neither time efficient, nor yields accurate results. However, the objective function value is smaller than 1% at convergence for each of the runs. This indicates that even though the correct solution was not found, at least a solution does exist. Therefore, there is a considerable motivation to employ the sensitivity of each individual mode to the different moduli to optimise a reduced number of parameters at once in the future work.

Figure 4: Value of the objective function as a function of the generation for the five GA independent runs for the reconstruction of the elastic moduli of the orthotropic material. $k(\omega)$ is considered. Convergence is observed for all runs after 290 generations. 100 generations were needed for at least one run to converge. The horizontal red line is plotted at 1% of error.

4. Conclusions

The GA is presented to reconstruct material stiffness properties of composites based on dispersion characteristics of Lamb wave in this paper, which combines the advantages of WFE and SAFE. Case study has been selected to illustrate the strengths of proposed approach. While the brute-force approach showed that the dispersion relations have a very low sensitivity to some of the moduli if considered altogether. A sensitivity study is therefore hereby performed in order to uncover the effect of each parameters to be optimised on the dispersion relations in the future.

Abstract

Hybrid prognosis combining both the physical knowledge and data-driven techniques has shown great potential for damage prognosis in structural health monitoring (SHM). Current practices consider the physics-based process and data-driven measurement equations to describe the damage evolution and the mapping between the damage state and the SHM signal (or the feature extracted from SHM signal), respectively. However, the bias between the measurements predicted by data-driven equation and the actual SHM measurements, arising from uncertainties like damage geometries and sensor placement or noise, can lead to inaccurate prognosis results. To account for this problem, this paper adopts a methodology typically applied for sensor fault diagnosis, and develops a new hybrid state space model with a bias parameter included into the state vector and the measurement equation. Particle filter (PF) serves as the estimation technique to identify the state and parameters relating to the damage as well as the bias parameter, and RUL can be predicted by the PF estimates and physics-based process equation. The numerical study about the fatigue crack growth shows the new model together with PF can provide satisfactory estimation and prediction results in case of bias in the measurement model.

1 INTRODUCTION

Prognostic is the process of predicting the future state and the remaining useful life (RUL) of a component or system. In the last decades, a great variety of damage prognosis techniques have been developed in SHM depending on the availability of physics knowledge and data. From the perspective of how the prognosis models are formulated, they can be distinguished into physics-based [1-3], data-driven [4-8] and hybrid methods [9-13]. Physics-based methods utilize specific mechanistic knowledge and theories to formulate a pure physics-based model, which describes the structural degradation phenomena as well as the links between the damage states and the SHM measurements. On the other hand, data-driven methods, resorting to data-driven modelling techniques such as neural networks [6] and Markov chains [8], attempt to use amounts of data to build the relationship between the internal degradation behaviour and the external observations. Hybrid methods, taken as a combination of the two above methods, usually consider the physics-based process and data-driven measurement equations to describe the damage evolution and the mapping between the damage state and measurement, respectively.

The right method (or model) should probably be case specific, as each type of method has its pros and cons [14, 15]. However, given the uncertainties arising from the complex structural degradation behaviour, the environment effects and the sensor health conditions [16, 17], both the deterministic physic-based and data-driven models are unable to provide an accurate prognostic result. A well-acknowledged strategy for both the physics-based [1-3] and data-driven methods [6, 8] to improve their prognostic performance is to set the parameters within the corresponding models as unknown components to be updated by a state estimation technique, such as particle filter (PF) given its good performance in nonlinear and non-Gaussian problem. On the other hand, this strategy is not fully exploited in hybrid methods, where the parameters in physics-based process equation are usually taken as unknown variables to be estimated by PF, while the parameters relating to the data-driven measurement equation are not [11, 18, 19].

The relationship between the damage state and the SHM measurement should probably vary in different specimens of same structure [9] due to the uncertainties mentioned above. As a consequence, the bias between the measurements predicted by data-driven measurement equation, often derived from training data, and the measurements from testing specimen is unavoidable. In this context, the measurement equation, that fails to be online updated or take the bias into account, will lead to inaccurate damage estimation [20] and prognosis [9] in case of large-level bias. Only a few studies relating to hybrid prognosis [9, 13] field attempt to solve this bias problem, where an additional measurement system is adopted to collect or calculate the true damage state and to update the measurement equation.

The bias between the predicted measurements and the actual measurements can be regarded as a typical sensor fault, which can be detected, localized and identified by adding a parameter representing a bias in both the process and measurement equations for estimation [21-23]. It has been verified that this bias can have little effect on the estimation of other state components

when it can be accurately estimated by a state estimation technique [22, 23]. However, such idea, that has been validated for the sensor fault diagnosis problem [21-23] and the state estimation considering bias [22, 23], has not been used for hybrid damage prognosis.

This paper develops a new particle filter-based hybrid prognosis framework that combines the methods from sensor fault diagnosis and current hybrid prognosis investigations. The process equation is formulated resorting to the physical law describing damage propagation and a bias parameter, while the measurement equation representing the relationship between the damage state and the measurements is built by a polynomial fitting function and the bias parameter. Then, PF is used to estimate the damage state, damage parameters and the bias parameter. Finally, the future states and, consequently, the RUL can be estimated on the basis of the process equation and the estimated damage state and parameters.

The rest of this paper is organized as follows: Section 2 introduces the traditional and new models as well as the prognosis framework. The numerical validation is discussed in Section 3. Finally, Section 4 concludes this paper with some topics for future work.

2 DAMAGE PROGNOSIS FRAMEWORK

Particle filter-based damage prognosis framework generally has three main steps, namely, (i) formulating a state space model, (ii) estimating the unknown state components using PF and (iii) calculating the future state and RUL by the PF estimates and the physic-based process equation.

2.1 Traditional and new models

Current PF-based prognosis investigations in SHM usually have the hybrid state space model formulated as

$$\begin{cases} \mathbf{z}_k = \begin{bmatrix} \boldsymbol{\theta}_k \\ x_k \end{bmatrix} = \begin{bmatrix} \boldsymbol{\theta}_{k-1} + \boldsymbol{\omega}_{\theta(k)} \\ f(x_{k-1}, \boldsymbol{\theta}_k, \omega_k) \end{bmatrix} \\ y_k = h(x_k) + v_k \end{cases} \quad (1)$$

where $f(\cdot)$ is the physics-based function describing the evolution of the damage state, and $h(\cdot)$ is a function mapping the relationship between the damage state and the measurement, the subscript k is the time step, \mathbf{z} represents the state vector, y is the output that is given by the measurement system, such as strain [11] and guided wave [9, 10], $\boldsymbol{\theta}$ includes evolution parameters and x is the state relating to the damage (hereafter focusing on crack damage), ω and $\boldsymbol{\omega}_{\theta}$ are the process noises, v is the measurement noise.

The relationship between the damage extent and measurement will inevitably vary in different specimens of same structure [9], due to the uncertainties like damage geometries and sensor error, which means the bias between the measurement predicted by a data-driven measurement equation derived from some specimens and the actual measurements from another one is typically unavoidable. Inaccurate estimation [20] and prognosis [9] may occur in case of large-level bias. Inspired from the sensor fault diagnosis investigations [21-23] and hybrid prognosis studies [9, 10, 13], a novel hybrid state space model is thus developed with the bias parameter b included as

$$\begin{cases} \mathbf{z}_k = \begin{bmatrix} \boldsymbol{\theta}_k \\ x_k \\ b_k \end{bmatrix} = \begin{bmatrix} \boldsymbol{\theta}_{k-1} + \boldsymbol{\omega}_{\boldsymbol{\theta}(k)} \\ f(x_{k-1}, \boldsymbol{\theta}_k, \omega_k) \\ b_{k-1} + \omega_{b(k)} \end{bmatrix} \\ y_k = h(x_k) + b_k + v_k \end{cases} \quad (2)$$

where ω_b is the process noise for the parameter b . This model can provide satisfactory estimated damage state and parameters, because the bias between the output calculated from the function $h(\cdot)$ and the actual measurement y can be on-line estimated by the parameter b , as will be validated in Section 3.4.

2.2 Particle filter and RUL prediction

Particle filter serves as the state estimation technique in this study, due to its good performance in nonlinear and non-Gaussian problem.

Figure 1 Sampling importance resampling (SIR) particle filter [24]

The sampling importance resampling (SIR) PF [25] with systematic resampling, as presented in Figure 1, is used in this study, and it consists of the three steps, i.e.,

- (i) draw N_p particles $\{\mathbf{z}_k^i: i = 1, 2, \dots, N_p\}$ from the prior probability density function (PDF) $p(\mathbf{z}_k|\mathbf{z}_{k-1})$,
- (ii) calculate the weight w_k^i by the likelihood function $p(\mathbf{y}_k|\mathbf{z}_k^i)$ as

$$w_k^i \propto p(\mathbf{y}_k|\mathbf{z}_k^i) \quad (3)$$

and assign its normalized form \tilde{w}_k^i to each particle \mathbf{z}_k^i ,

- (iii) Resample for $\{\mathbf{z}_k^i: i = 1, 2, \dots, N\}$ using particle weights.

In addition, the kernel smoothing method [26] is adopted for the parameters $\boldsymbol{\theta}$ due to its good performance in current investigations [3],

$$\boldsymbol{\theta}_k^i = \sqrt{1 - h^2} \boldsymbol{\theta}_{k-1}^i + (1 - \sqrt{1 - h^2}) \hat{\boldsymbol{\theta}}_{k-1} + \boldsymbol{\omega}_{\boldsymbol{\theta}(k)}^i \quad (4)$$

where $\hat{\theta}_{k-1}$ are the means of the samples.

The prediction for future state and RUL is summarized in Table 1. At each time step k , the posterior PDFs of the state and parameters are adopted to calculate the future evolution of the particles. The RUL of each particle can be defined when its future state reaches a predefined threshold.

Initialization: set $\{x_k^{i,0} : i = 1, 2, \dots, N_p\}$ as $\{x_k^i : i = 1, 2, \dots, N_p\}$
For $i = 1 : N_p$
$j = 0$
While $x_k^{i,j} < l_{th}$
Calculate the future state $x_k^{i,j+1}$ by $x_k^{i,j+1} = f(x_k^{i,j}, \theta_k^i)$
$j = j + 1$
End
$RUL_k^i = \Delta N j$
End

Table 1 Calculation of future state and RUL at time step k

3 APPLICATION

3.1 Crack growth and measurement

The crack growth data, as presented in Figure 2(a), are created by Paris' law with parameters as in Table 2.

$$x_k = x_{k-1} + e^{\omega_k} C (F \Delta S \sqrt{\pi x_{k-1}})^m \Delta N \quad (5)$$

where x is the crack length, the subscript k means the k -th time step, ΔN , ΔS and F represent the load cycle increment, the applied fatigue stress range and the crack shape function, respectively, C and m are two empirical values governing damage progression and $\omega \sim \mathcal{N}\left(-\frac{\sigma^2}{2}, \sigma^2\right)$ is the unbiased log-normal process noise with standard deviation σ . The crack length 35 mm is set as the threshold for damage prognosis.

Initial crack length x_0	Parameter C	Parameter m	Noise ω
15 mm	$1.1994 \times 10^{-14} \text{ mm/cycle(MPa}\sqrt{\text{mm}})^{-m}$	3.79	$\mathcal{N}\left(-\frac{0.6^2}{2}, 0.6^2\right)$
Crack shape function F	Applied fatigue stress ΔS	Load cycles ΔN	
1	60 MPa	500	

Table 2 Details for crack growth

Given the difficulty in directly measuring the crack length, current SHM applications usually have advanced measurement system, e.g., guided wave [9, 10], strain gauge [11], adopted for online monitoring to estimate the crack length. In this study, the measurements at different crack

lengths (Figure 2(b)) are created via two steps:

- (i) calculate the measurements without the bias and noise by a polynomial fitting function $h(\cdot)$, representing the relationship between the crack lengths and the SHM measurements

$$h(x_k) = (-0.00001x_k^4 + 0.0025x_k^3 + 0.05x_k^2 + 0.3x_k - 0.4)/40 \quad (6)$$

- (ii) add the varying bias, as given in Eq. (7), and 33dB signal-to-noise ratio white Gaussian noise to the above measurements.

$$b_k = -0.12 \sin\left(\frac{k}{100}\right) + 0.0001k \quad (7)$$

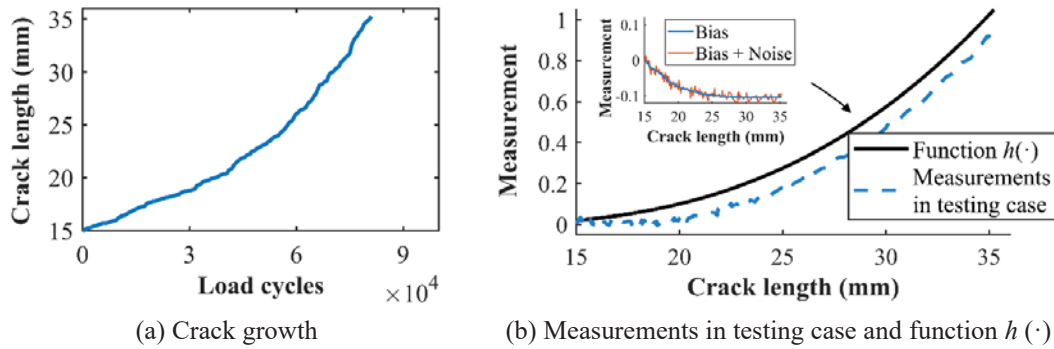

Figure 2 Testing data.

Note: the x -axis for the bias in Figure 2(b) is changed as crack length.

3.2 Formulation of traditional and new models

Given the two parameters C and m will also vary in different specimens, they are taken as unknown variables and added to the state vector to form the traditional augmented state space model as

$$\begin{cases} \mathbf{z}_k = \begin{bmatrix} C_k \\ m_k \\ x_k \end{bmatrix} = \begin{bmatrix} \sqrt{1-h^2}C_{k-1} + (1-\sqrt{1-h^2})\hat{C}_{k-1} + \omega_{1(k)} \\ \sqrt{1-h^2}m_{k-1} + (1-\sqrt{1-h^2})\hat{m}_{k-1} + \omega_{2(k)} \\ x_{k-1} + e^{\omega_k}C_k(F\Delta S\sqrt{\pi x_{k-1}})^{m_k}\Delta N \end{bmatrix} \\ y_k = h(x_k) + v_k \end{cases} \quad (8)$$

where $\omega \sim \mathcal{N}\left(-\frac{\sigma^2}{2}, \sigma^2\right)$ is log-normal process noise with the standard deviation σ [3], while ω_1 and ω_2 are zero-mean Gaussian process noises.

The new hybrid model with a bias parameter included is given as

$$\begin{cases} \mathbf{z}_k = \begin{bmatrix} C_k \\ m_k \\ x_k \\ b_k \end{bmatrix} = \begin{bmatrix} \sqrt{1-h^2}C_{k-1} + (1-\sqrt{1-h^2})\hat{C}_{k-1} + \omega_{1(k)} \\ \sqrt{1-h^2}m_{k-1} + (1-\sqrt{1-h^2})\hat{m}_{k-1} + \omega_{2(k)} \\ x_{k-1} + e^{\omega_k}C_k(F\Delta S\sqrt{\pi x_{k-1}})^{m_k}\Delta N \\ b_{k-1} + \omega_{b(k)} \end{bmatrix} \\ y_k = h(x_k) + b_k + v_k \end{cases} \quad (9)$$

where b is the parameter representing the bias, and ω_b is its process noise.

3.3 Particle filter parameters

All the PF parameters used in this study are reported in Table 3. The strategies about the distributions of initial intervals for C and m and the process noise ω are determined from [3, 11, 12].

Number of particles N_p	STD in likelihood function	h in Kernel smoothing	
2000	0.04	0.1	
Initial distributions for C, m		Initial range for x , mm	Initial value for b
$\begin{bmatrix} C_0 \\ m_0 \end{bmatrix} \sim \mathcal{N} \left(\begin{bmatrix} 1.14e - 14 \\ 3.86 \end{bmatrix}, \begin{bmatrix} 1 \times 10^{-30} & -8 \times 10^{-17} \\ -8 \times 10^{-17} & 0.01 \end{bmatrix} \right)$		$x_0 \in (14.5, 15.5)$	$b_0 = 0$
Distributions of process noises $\{\omega, \omega_1, \omega_2, \omega_3, \omega_4\}$ for x, C, m, b			
x, ω	C, ω_1	m, ω_2	b, ω_3
$\mathcal{N} \left(-\frac{0.04^2}{2}, 0.04^2 \right)$	$\mathcal{N}(0, (1 \times 10^{-17})^2)$	$\mathcal{N}(0, 0.003^2)$	$\mathcal{N}(0, 0.008^2)$

Table 3 PF parameters.

3.4 Results from estimation and RUL prediction

Figures 3 (a) and (b) present the estimation results using traditional model. The estimated crack length remains close to the true values until reaching about 17 mm, when the bias grows large enough to hamper damage estimation, as visible in Figure 2. The narrow confidence boundaries after about 6×10^4 load cycles show the existence of a poor particle diversity. In addition, the samples of the parameters C and m also fail to accumulate around the true values. The observation that the bias between the output of the measurement equation and the actual measurement will lead to inaccurate estimation is confirmed in [9, 20]. Figures 3 (c), (d) and (e) present the estimation results using the new model with included bias parameter. The estimated crack length, C and m are noticeably more accurate than those in Figures 3 (a) and (b), as the bias is correctly identified by the PF and is taken into consideration for the estimation for the other state components. Moreover, given the presence of measurement noise and the difficulty in estimating the time-varying parameter, the bias parameters from the 3×10^4 to 7×10^4 load cycles are not accurately estimated, which leads to less accurate estimation for crack length at these load cycles.

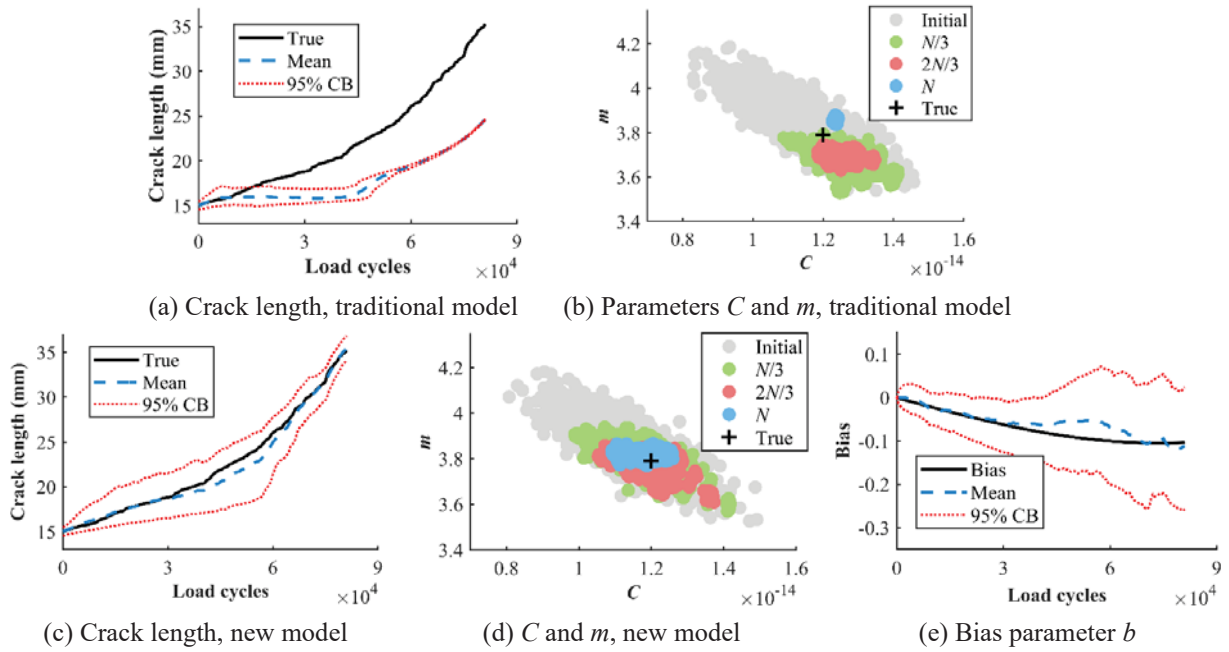

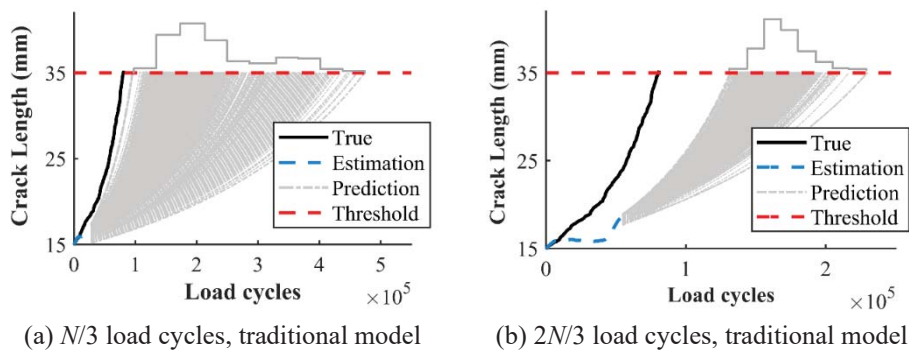

Figure 3 Estimation using traditional and new models

Figures 4 (a)(b) and (c)(d) present the prediction for future states at some selected load cycles using the traditional and new models, respectively. The grey dotted lines are the crack length trajectories predicted by the particles at the selected load cycles, and the grey histogram at the end of life (identified as a critical crack length) is the RUL posterior PDF. Figures 5 (a) and (b) present the RUL predictions using the traditional and new models, respectively, along with their 95% confidence boundary. The predicted states and RULs from the new model always keep close to the true values, while those from the traditional model don't. It can be concluded that the new model can provide more accurate estimation and prognosis results within a PF framework than the traditional model, for which the bias existing between the measurement equation and the actual observation prevents a correct estimation.

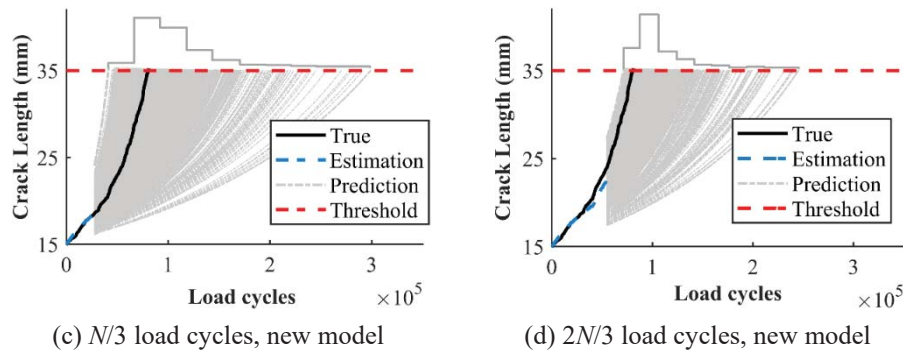

Figure 4 Prediction at two selected load cycles from traditional and new models.

Figure 5 RUL Prediction from traditional and new models.

4 CONCLUSIONS

The bias between the measurements predicted by any data-driven measurement equation and the actual SHM measurements is unavoidable in hybrid prognostic investigations, which might lead to inaccurate prognostic results. Combining the ideas from sensor fault diagnosis and hybrid prognosis, this paper proposes a new hybrid state space model that always includes an adaptive bias parameter in both the state vector and measurement equation. The numerical study proves the new model can provide accurate estimation and prognosis for crack length when the bias can be accurately estimated. Our future work intends to validate this framework by experimental study.

DISPERSION ANALYSIS OF BULK ACOUSTIC WAVES IN PIEZOELECTRIC MEDIA DISCRETIZED BY ENERGY- ORTHOGONAL FINITE ELEMENTS

Francisco J. Brito Castro

Departamento de Ingeniería Industrial, Universidad de La Laguna
Calle Méndez Núñez 67-2C, Santa Cruz de Tenerife 38001, Spain
e-mail: fjbrito@ull.edu.es

Abstract

This contribution studies the propagation of bulk acoustic waves in piezoelectric media discretized by the finite element method. The element elastic and dielectric stiffness matrices are split into basic and higher order components which are related to the mean and deviatoric components of the element strain and electric fields, respectively. This decomposition is applied to the total energy of the finite element assemblage. By a dispersion analysis the higher order total energy is related to the total energy error for the propagating waves. An averaged correlation is proposed as an error indicator for the finite element vibration eigenmodes in piezoelectric solids.

Keywords: energy-orthogonal stiffness, numerical dispersion, piezoelectric media, vibration eigenmodes.

1 INTRODUCTION

It is well known that the wave scattering at boundaries creates an interference field that, if composed solely of waves of frequency equal to a natural frequency of the bounded medium, takes the form of a standing-wave field which is an eigenmode of the continuum [1]. For homogeneous piezoelectric solids, whose three dimensions are comparable, this standing-wave field could be considered essentially composed of propagating quasi-longitudinal and quasi-shear bulk acoustic waves. In this case the goal of determining the finite element mesh required to accurately represent a given number of eigenmodes could be approached by analysing the effect of the spatial discretization over the propagation of such bulk acoustic waves in unbounded media. This effect becomes apparent by observing the dispersive behavior of the waves, a phenomenon that is not present in the physical system [2]. This contribution extends the author's previous research about homogeneous isotropic elastic solids [3].

The piezoelectric media covered in this research include PZT (Lead zirconate titanate ($\text{Pb}(\text{Zr,Ti})\text{O}_3$)) piezoceramics [4]. These are transversely isotropic and they behave the same as crystals in class Hexagonal (6mm). The poling direction is supposed along the Z-axis. The material constants for the piezoceramics selected (PZT-5H, PZT-8 and PZT-5A) can be found in reference [5]. Also PMN-PT (Lead magnesium niobate-lead titanate ($\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{-PbTiO}_3$)) <001> poled single crystals are covered [6]: the single crystal PMN-30PT from reference [7], and the commercial grade single crystals PMN-31PT and PIN-PMN-PT (TRS X2B and TRS X4B) from TRS Technologies Inc. [8] have been selected. These single crystals exhibit Tetragonal (4mm) symmetry in macroscopic material properties. See Appendix 1 for the material constants of the PZT piezoceramics and PMN-PT single crystals selected.

An enlightening discussion about PZT piezoceramics and PMN-PT single crystals in the context of sonar applications can be found in reference [9].

1.1 Finite element formulation

In a lossless piezoelectric medium discretized by the finite element method the equations of equilibrium governing its linear dynamic response for time-harmonic waves will be [10],

$$\begin{pmatrix} \mathbf{K}_{uu} - \omega^2 \mathbf{M} & \mathbf{K}_{u\phi} \\ -\mathbf{K}_{\phi u} & \mathbf{K}_{\phi\phi} \end{pmatrix} \begin{pmatrix} \mathbf{x} \\ \boldsymbol{\phi} \end{pmatrix} = \begin{pmatrix} \mathbf{F} \\ \mathbf{Q} \end{pmatrix}, \quad \mathbf{K}_{\phi u} = \mathbf{K}_{u\phi}^T; \quad \begin{matrix} \mathbf{x} = \tilde{\mathbf{x}} \exp(-i\omega t), & \mathbf{F} = \tilde{\mathbf{F}} \exp(-i\omega t) \\ \boldsymbol{\phi} = \tilde{\boldsymbol{\phi}} \exp(-i\omega t), & \mathbf{Q} = \tilde{\mathbf{Q}} \exp(-i\omega t) \end{matrix} \quad (1)$$

where: \mathbf{M} , consistent mass matrix; \mathbf{K}_{uu} ($\mathbf{K}_{\phi\phi}$, $\mathbf{K}_{u\phi}$), elastic (dielectric, piezoelectric) stiffness matrix of the finite element assemblage; $\tilde{\mathbf{x}}$ ($\tilde{\mathbf{F}}$, $\tilde{\boldsymbol{\phi}}$, $\tilde{\mathbf{Q}}$), column matrix containing the complex amplitude of the nodal displacements (external loads, electric potentials, free electric charges); $\omega = 2\pi/T$, circular frequency; T , period of wave; t , time.

The total energy will be equal to the sum of pure elastic energy and pure electric energy [11],

$$E^M = \frac{1}{2} \text{Re}[\mathbf{x}^T] \mathbf{K}_{uu} \text{Re}[\mathbf{x}] \quad (a) \quad E^E = \frac{1}{2} \text{Re}[\boldsymbol{\phi}^T] \mathbf{K}_{\phi\phi} \text{Re}[\boldsymbol{\phi}] \quad (b) \quad (2)$$

At element level

$$\begin{aligned} \mathbf{K}_{uu}^e &= \int_{V_e} \mathbf{B}_u^T [\mathbf{C}^E] \mathbf{B}_u dV \quad (a) & \mathbf{K}_{\phi\phi}^e &= \int_{V_e} \mathbf{B}_\phi^T [\boldsymbol{\epsilon}^S] \mathbf{B}_\phi dV \quad (b) \\ \mathbf{K}_{u\phi}^e &= \int_{V_e} \mathbf{B}_u^T [\mathbf{e}]^T \mathbf{B}_\phi dV \quad (c) & \mathbf{K}_{\phi u}^e &= \int_{V_e} \mathbf{B}_\phi^T [\mathbf{e}] \mathbf{B}_u dV \quad (d) \end{aligned} \quad (3)$$

where: \mathbf{B}_u (\mathbf{B}_ϕ), matrix relating the strain components (gradient of electric potential) to the nodal values of displacement (electric potential); \mathbf{C}^E , elasticity matrix evaluated at constant electric field; $\boldsymbol{\epsilon}^S$, dielectric matrix evaluated at constant mechanical strain; \mathbf{e} , piezoelectric matrix.

If the matrices \mathbf{B}_u and \mathbf{B}_ϕ are partitioned into mean and deviatoric components,

$$\begin{aligned} \mathbf{B}_u &= \bar{\mathbf{B}}_u + \mathbf{B}_{u,d}; \quad \bar{\mathbf{B}}_u V^e = \int_{V_e} \mathbf{B}_u dV, \quad \mathbf{B}_{u,d} = \mathbf{B} - \bar{\mathbf{B}}_u \quad (a) \\ \mathbf{B}_\phi &= \bar{\mathbf{B}}_\phi + \mathbf{B}_{\phi,d}; \quad \bar{\mathbf{B}}_\phi V^e = \int_{V_e} \mathbf{B}_\phi dV, \quad \mathbf{B}_{\phi,d} = \mathbf{B} - \bar{\mathbf{B}}_\phi \quad (b) \end{aligned} \quad (4)$$

the matrices Eq. (3a) and Eq. (3b) would be respectively decomposed as addition of basic and higher order components,

$$\begin{aligned} \mathbf{K}_{uu}^e &= \mathbf{K}_{uu,b}^e + \mathbf{K}_{uu,h}^e; \quad \mathbf{K}_{uu,b}^e = \bar{\mathbf{B}}_u^T [\mathbf{C}^E] \bar{\mathbf{B}}_u V^e, \quad \mathbf{K}_{uu,h}^e = \int_{V_e} \mathbf{B}_{u,d}^T [\mathbf{C}^E] \mathbf{B}_{u,d} dV \quad (a) \\ \mathbf{K}_{\phi\phi}^e &= \mathbf{K}_{\phi\phi,b}^e + \mathbf{K}_{\phi\phi,h}^e; \quad \mathbf{K}_{\phi\phi,b}^e = \bar{\mathbf{B}}_\phi^T [\boldsymbol{\varepsilon}^S] \bar{\mathbf{B}}_\phi V^e, \quad \mathbf{K}_{\phi\phi,h}^e = \int_{V_e} \mathbf{B}_{\phi,d}^T [\boldsymbol{\varepsilon}^S] \mathbf{B}_{\phi,d} dV \quad (b) \end{aligned} \quad (5)$$

In this case it is said that the element stiffness matrices are formulated in energy-orthogonal form [12]. The decomposition in Eq. (5) holds for the complete model,

$$\mathbf{K}_{uu} = \mathbf{K}_{uu,b} + \mathbf{K}_{uu,h} \quad (a) \quad \mathbf{K}_{\phi\phi} = \mathbf{K}_{\phi\phi,b} + \mathbf{K}_{\phi\phi,h} \quad (b) \quad (6)$$

For a stationary wave the amplitudes of nodal displacements and electric potentials are real-valued vectors in Eq. (1). Then, from Eq. (2a) and Eq. (2b), the period-averaged elastic and electric energies for the discretized domain will be, respectively,

$$\bar{E}^M = \frac{1}{4} \tilde{\mathbf{x}}^T \mathbf{K}_{uu} \tilde{\mathbf{x}} \quad (a) \quad \bar{E}^E = \frac{1}{4} \tilde{\boldsymbol{\phi}}^T \mathbf{K}_{\phi\phi} \tilde{\boldsymbol{\phi}} \quad (b) \quad (7)$$

By introducing Eq. (6) into Eq. (7), the basic and higher order period-averaged energies will be obtained. The latter components will be

$$\bar{E}_h^M = \frac{1}{4} \tilde{\mathbf{x}}^T \mathbf{K}_{uu,h} \tilde{\mathbf{x}} \quad (a) \quad \bar{E}_h^E = \frac{1}{4} \tilde{\boldsymbol{\phi}}^T \mathbf{K}_{\phi\phi,h} \tilde{\boldsymbol{\phi}} \quad (b) \quad (8)$$

2 DISPERSION ANALYSIS

The unbounded piezoelectric domain is discretized by a regular mesh of finite elements. Two different isoparametric finite elements with consistent mass matrix are considered: the hexahedron with twenty nodes and brick geometry HE20, Fig. 1, and the pentahedron with fifteen nodes and right prismatic isosceles geometry PE15, Fig. 2 [13]. The nodal lattice formed by the finite element assemblage has four and five nodes per unit cell, respectively. Different meshes with the same element volume can be selected by the aspect ratio parameter, $0 < \gamma \leq 1$; the skew angle, $0 \leq \beta < 90^\circ$ (only HE 20 element); and the distortion-Z parameter, $\varepsilon > 0$.

For uniform plane harmonic bulk waves at the continuum piezoelectric medium, the displacement vector field and the electric potential field will be, respectively,

$$\mathbf{u} = A^u \hat{\mathbf{a}} \exp(i\kappa \mathbf{n} \cdot \mathbf{r}) \exp(-i\omega t) \quad (a) \quad \phi = A^\phi \exp(i\kappa \mathbf{n} \cdot \mathbf{r}) \exp(-i\omega t) \quad (b) \quad (9)$$

where: A^u and A^ϕ , amplitudes of the wave; $\hat{\mathbf{a}}$, polarization vector; \mathbf{n} , wave normal, unit vector indicating the direction of the wave propagation; \mathbf{r} , position vector; $\kappa = 2\pi/\lambda = \omega/c$, wave number; λ , wavelength; c , phase velocity at the continuum medium.

The wave normal has the components $n_1 = \cos\phi \sin\theta$, $n_2 = \sin\phi \sin\theta$ and $n_3 = \cos\theta$, where: ϕ , azimuthal angle, $0 \leq \phi \leq 180^\circ$; θ , polar angle, $0 \leq \theta \leq 180^\circ$, Fig. 1.

The polarization vectors and phase velocities are solution of the stiffened Christoffel equation, which is expressed in abbreviated subscript notation [14],

$$(l_{iK}(C_{KL}^E + [e_{Kj} n_j][n_i e_{iL}]) / (n_i \varepsilon_{ij}^S n_j)) l_{Lj} \hat{a}_j = \rho c^2 \hat{a}_i, \quad i, j = 1, \dots, 3; \quad K, L = 1, \dots, 6 \quad (10)$$

where the non-null values of l_{iK} are: $l_{11} = n_1$, $l_{15} = n_3$, $l_{16} = n_2$, $l_{22} = n_2$, $l_{24} = n_3$, $l_{26} = n_1$, $l_{33} = n_3$, $l_{34} = n_2$, and $l_{35} = n_1$.

Figure 1: Piezoelectric domain discretized by a regular mesh of HE20 elements and unit cell with four nodes. Polarization vectors.

Figure 2: Piezoelectric domain discretized by a regular mesh of PE15 elements and unit cell with four master nodes (m) and one slave node (s).

By solving the eigenproblem Eq. (10), three mutually orthogonal waves at the continuum medium are computed, Fig. 1: ($\hat{\mathbf{a}}_{SS}$, c_{SS}), slow quasi-shear wave, SS; ($\hat{\mathbf{a}}_{FS}$, c_{FS}), fast quasi-shear wave, FS; and ($\hat{\mathbf{a}}_L$, c_L), quasi-longitudinal wave, L.

Then, the electric potential at the continuum medium can be computed for each wave,

$$A^\phi = A^u (n_i e_{iK} l_{Kj} / (n_i \epsilon_{ij}^S n_j) \hat{\mathbf{a}}_j), \quad i, j = 1, \dots, 3; \quad K = 1, \dots, 6 \quad (11)$$

For the displacement vector field Eq. (9a) and for the electric potential field Eq. (9b), the densities of period-averaged pure elastic energy and period-averaged pure electric energy at the continuum medium can be respectively computed by the equations [14]

$$\bar{E}_0^M = \frac{1}{4} \omega^2 (A^u)^2 l_{Ki} C_{KL}^E l_{Lj} \hat{\mathbf{a}}_j / c^2 \quad (a) \quad \bar{E}_0^E = \frac{1}{4} \omega^2 (A^\phi)^2 n_i \epsilon_{ij}^S n_j / c^2 \quad (b) \quad (12)$$

2.1 Characteristic equations

The characteristic equations can be found assuming harmonic waves Eq. (9) with different amplitudes in each node of the unit cell,

$$\tilde{\mathbf{u}} = A_j^u \hat{\mathbf{a}} \exp(i\kappa \mathbf{n} \cdot \mathbf{r}) \quad (a) \quad \tilde{\phi} = A_j^\phi \exp(i\kappa \mathbf{n} \cdot \mathbf{r}) \quad (b); \quad j = 1, \dots, N \quad (13)$$

where: N , number of nodes per unit cell.

Inserting the solutions Eq. (13) into the homogeneous part of Eq. (1), the characteristic equation for each node of the unit cell is yielded by equilibrium of nodal forces into the direction of the particle displacement [15],

$$\mathbf{F}_K^{uu} \cdot \hat{\mathbf{a}} - \omega^2 \mathbf{F}_M \cdot \hat{\mathbf{a}} + \mathbf{F}_K^{u\phi} \cdot \hat{\mathbf{a}} = 0, \quad -F_K^{\phi u} + F_K^{\phi\phi} = 0 \quad (14)$$

By considering Eq. (14) for each node of the unit cell, a homogeneous system of $2N$ algebraic equations is formed,

$$\begin{pmatrix} \mathbf{a}^{uu}(m, \phi, \theta, \boldsymbol{\alpha}) + \varpi^2 \mathbf{b}^{uu}(m, \phi, \theta, \boldsymbol{\alpha}) & \mathbf{a}^{u\phi}(m, \phi, \theta, \boldsymbol{\alpha}) \\ \mathbf{a}^{\phi u}(m, \phi, \theta, \boldsymbol{\alpha}) & \mathbf{a}^{\phi\phi}(m, \phi, \theta, \boldsymbol{\alpha}) \end{pmatrix} \begin{pmatrix} \mathbf{A}^u \\ \mathbf{A}^\phi \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \end{pmatrix} \quad (15)$$

$$m = b\kappa/\pi = 2b/\lambda, \quad \varpi = (2b/c)\omega \quad (16)$$

where: m , dimensionless wave number, $0 < m < 1$; b , half of the element size; ϖ , dimensionless frequency of the discretized piezoelectric medium; $\boldsymbol{\alpha} = (\gamma, \beta, \varepsilon)$ form parameter for HE20 mesh, or $\boldsymbol{\alpha} = (\gamma, \varepsilon)$ form parameter for PE15 mesh.

In this procedure both the global stiffness matrices and the global mass matrix have been expressed in a suitable form,

$$\mathbf{K}_{xx} = \rho c^2 (2b) \mathbf{K}_{xx}^0 \quad xx = (uu, u\phi, \phi u, \phi\phi), \quad \mathbf{M} = \rho (2b)^3 \mathbf{M}^0 \quad (17)$$

The homogeneous system of $2N$ algebraic equations Eq. (15) can be reduced to a homogeneous system of N equations by static condensation [16]. So, from Eq. (15),

$$(\mathbf{a}^{uu} + \varpi^2 \mathbf{b}^{uu}) \mathbf{A}^u + \mathbf{a}^{u\phi} \mathbf{A}^\phi = \mathbf{0} \quad (a) \quad \mathbf{A}^\phi = -(\mathbf{a}^{\phi\phi})^{-1} \mathbf{a}^{\phi u} \mathbf{A}^u \quad (b) \quad (18)$$

Inserting Eq. (18b) into (18a), the condensate system of characteristic equations is formed,

$$(\mathbf{a}^{uu} - \mathbf{a}^{u\phi} (\mathbf{a}^{\phi\phi})^{-1} \mathbf{a}^{\phi u} + \varpi^2 \mathbf{b}^{uu}) \mathbf{A}^u = \mathbf{0} \quad \Leftrightarrow \quad \mathbf{Z} \mathbf{A}^u = \mathbf{0} \quad (19)$$

2.2 Dispersion equations

The system of homogeneous algebraic equations given in Eq. (19) has a non-trivial solution only if the matrix \mathbf{Z} is singular; that is, $\det[\mathbf{Z}] = 0$. Then it is yielded the following polynomial equation which is called the characteristic frequency equation for the plane wave propagation,

$$\sum_{r=0}^N c_r(m, \phi, \theta, \boldsymbol{\alpha}) \varpi^{2r} = 0, \quad c_N = 1 \quad (20)$$

It is an important fact that the N zeroes of a polynomial of degree $N \geq 1$ with complex coefficients depend continuously upon the coefficients [17]. Thus, sufficiently small changes in the coefficients of a polynomial can lead only to small changes in any zero. However, if the zeros are numerically computed, there is no simple way to define a function which takes the N coefficients (all but the leading 1) of a monic polynomial of degree N to the N zeroes of the polynomial, since there is no natural way to define an ordering among the N zeroes. In the case of the HE20 mesh, for which the polynomial Eq. (20) is quartic, the above difficulty has been

overcome by computing the zeroes in closed form as functions of its coefficients. Then, the components

$$\varpi_k = \varpi_k(m, \phi, \theta, \alpha), \quad k = 1, \dots, 4 \quad (21)$$

will be continuous functions precisely defined. They are called the dispersion equations.

Substituting Eq. (21) into Eq. (19), the displacement wave amplitudes corresponding to the nodes of the unit cell are yielded for each dispersion equation. Then, by Eq. (18b), the corresponding electric potential amplitudes are recovered.

To find the zeros of a polynomial equation as functions of its coefficients beyond the quartic equation is a very difficult mathematical problem [18]. Then, for the mesh PE15 which has five nodes per unit cell, if the zeros of Eq. (20) are numerically computed, the above mentioned ordering difficulty could be a problem. In this case, by considering the initial condition,

$$\lim_{m \rightarrow 0} \varpi_1(m, \phi, \theta, \alpha) = 0 \quad (22)$$

it is proposed to compute the first dispersion equation by a reduced unit cell obtained by a procedure of exact dynamic condensation [16].

Assume that the total nodes at the unit cell are categorized as master nodes (m) and slave nodes (s), where the number of master nodes is four and the number of slave nodes is one, Fig 2. With this arrangement, the system of characteristic equations Eq. (19) may be partitioned as

$$\begin{pmatrix} \mathbf{Z}_{mm}(q) & \mathbf{Z}_{ms}(q) \\ \mathbf{Z}_{sm}(q) & \mathbf{Z}_{ss}(q) \end{pmatrix} \begin{pmatrix} \mathbf{A}_m^u \\ \mathbf{A}_s^u \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ \mathbf{0} \end{pmatrix}, \quad q = \varpi^2 \quad (23)$$

From Eq. (23) the relation of wave amplitudes between the master and slave nodes may be obtained as

$$\mathbf{A}_s^u = -\mathbf{Z}_{ss}^{-1}(q) \mathbf{Z}_{sm}(q) \mathbf{A}_m^u \quad (24)$$

Then, by back-substituting, the system of characteristic equations of the reduced unit cell is obtained as

$$\mathbf{Z}_R(q) \mathbf{A}_m^u = \mathbf{0}, \quad [\mathbf{K}_R(q) + q \mathbf{M}_R(q)] \mathbf{A}_m^u = \mathbf{0} \quad (25)$$

Then, from Eq. (25), the reduced form of the characteristic frequency equation is obtained

$$q^4 + c_{3R}q^3 + c_{2R}q^2 + c_{1R}q + c_{0R} = 0, \quad c_{rR}(m, \phi, \theta, \alpha, q), \quad r = 0, \dots, 3 \quad (26)$$

The first dispersion equation is computed by the following iterative procedure:

Set by Eq. (22) the initial value $q_{i1} = 0$.

Do for $0 < m < 1$, step Δm

1. Compute the coefficients $c_{rR}(m, \phi, \theta, \alpha, q_{i1})$ of Eq. (26).

2. Compute the zero q_1 of the quartic polynomial Eq. (26).

Do while $(|q_1 - q_{i1}|/q_1) \geq \delta$

1. Refresh initial value $q_{i1} = q_1$.

2. Compute the coefficients $c_{rR}(m, \phi, \theta, \alpha, q_{i1})$ of Eq. (26).

3. Compute the zero q_1 of the quartic polynomial Eq. (26).

End do

3. Substituting q_1 into Eq. (25) to compute the wave amplitudes at the master nodes.

4. Substituting q_1 into Eq. (24) to compute the wave amplitudes at the slave nodes.
5. Refresh initial value $q_{i1} = q_1$ for the next step.

End do

It must be recall the equality of the energy and group velocities for bulk acoustic waves in a lossless piezoelectric medium [19], and the equality of the normal component of the group velocity and the phase velocity at the anisotropic continuum [20]. Then, the indicators of numerical dispersion for the phase velocity and the normal component of the group velocity are yielded for each dispersion equation. From Eq. (16),

$$e_p = c_p/c = (2\pi)^{-1} \varpi/m \quad (a) \quad e_{gn} = c_{gn}/c = (2\pi)^{-1} \partial \varpi / \partial m \quad (b) \quad (27)$$

The range of dimensionless wave number values where each dispersion equation represents the propagation of acoustic waves in the discretized medium will be called the acoustical branch of the dispersion equation. In order to determine the acoustical branches the following constraint conditions are imposed,

$$A_1^u = 1, \quad A_j^u(m, \phi, \theta, \alpha) > 0 \quad j = 2, \dots, N \quad (a) \quad (\partial \varpi / \partial m)_{\phi, \theta, \alpha} > 0 \quad (b) \quad (28)$$

In molecular physics the condition Eq. (28a) is called the restriction of the lattice spectrum to the acoustical branch [21]. By considering Eq. (27b), the constraint condition Eq. (28b) imposes that the normal component of the group velocity or energy velocity must have the wave direction. The preliminary constraint condition $\dim[\mathbf{N}(\mathbf{Z})] = 1$, over the dimension of the null space of matrix \mathbf{Z} for the HE20 mesh, or $\dim[\mathbf{N}(\mathbf{Z}_R)] = 1$ for the PE15 mesh, must be imposed in order to Eq. (28a) would be a meaningful constraint condition. For each dispersion equation only the acoustical branch will be considered.

2.3 Energy at the unit cell

From Eq. (2), Eq. (16) and Eq. (17), the densities of period-averaged elastic and electric energies at the unit cell are computed,

$$\begin{aligned} \bar{E}^M &= \frac{1}{2} \rho(\omega/\varpi)^2 C \int_0^1 \text{Re}[\tilde{\mathbf{x}}^T \exp(-i2\pi\tau)] \text{Re}[\tilde{\mathbf{F}}_{uu}^0 \exp(-i2\pi\tau)] d\tau \quad (a) \\ \bar{E}^E &= \frac{1}{2} \rho(\omega/\varpi)^2 C \int_0^1 \text{Re}[\tilde{\boldsymbol{\phi}}^T \exp(-i2\pi\tau)] \text{Re}[\tilde{\mathbf{F}}_{\phi\phi}^0 \exp(-i2\pi\tau)] d\tau \quad (b) \end{aligned} \quad (29)$$

where: $\tau = t/T$, $0 \leq \tau \leq 1$, dimensionless time; $\tilde{\mathbf{F}}_{uu}^0$ and $\tilde{\mathbf{F}}_{\phi\phi}^0$ are column matrices of forces at the nodes of the unit cell; $C = 1$ for the HE20 mesh, $C = 2/(3)^{1/2}$ for the PE15 mesh.

From the decomposition in Eq. (6), the above computed densities of period-averaged energies Eq. (29) can be partitioned as addition of basic and higher order components. Then, the percentage of period-averaged higher order total energy can be defined as

$$e_h = (\bar{E}_h^M + \bar{E}_h^E) / (\bar{E}^M + \bar{E}^E) = \bar{E}_h / \bar{E}, \quad e_h = e_h(m, \phi, \theta, \alpha) \quad (30)$$

From Eq. (29) and Eq. (12), the percentage indicator of total energy error associated with the spatial discretization that is introduced by the finite element model is defined as

$$e_T = ((\bar{E}^M + \bar{E}^E) / (\bar{E}_0^M + \bar{E}_0^E)) - 1 = (\bar{E} / \bar{E}_0) - 1, \quad e_T = e_T(m, \phi, \theta, \alpha) \quad (31)$$

From Eq. (30) and Eq. (31), a mapping between the total energy error and the percentage of higher order total energy can be also computed,

$$e_T = e_T(e_h, \phi, \theta, \alpha) \quad (32)$$

2.4 Substitute wave field

It is clear that the harmonic acoustic waves cannot be exactly captured by a regular mesh of finite elements HE20 or PE15. This fact is a consequence of the element interpolation which is quadratic. A substitute wave field [22] or alias field [13] has been obtained in the discretized unbounded medium by performing a dispersion analysis in terms of allowable polarizations of the continuum. The substitute wave field is obtained by collocating Eq. (13a) and Eq. (13b) in each node of the unit cell. The assumption of different amplitudes is introduced because the equation of equilibrium is different for each node. The analysis yields the relative wave amplitudes and the dispersion relation under which the alias field may propagate in the discretized medium. The alias wave field will be

$$\tilde{\mathbf{u}}^a = \sum N_{s,i} \tilde{\mathbf{u}}_i, \quad \tilde{\phi}^a = \sum N_{s,i} \tilde{\phi}_i \quad (33)$$

where: $\tilde{\mathbf{u}}_i$, the values of Eq. (13a) at the nodes; $\tilde{\phi}_i$, the values of Eq. (13b) at the nodes; $N_{s,i}$, the nodal shape functions.

By computing the wave amplitude distortion, the discretization error of the wave field Eq. (33) can be decomposed as addition of interpolation and pollution errors [23].

2.5 Numerical research

For the waves and media considered the indicators Eq. (27), Eq. (30) and Eq. (31) are computed versus dimensionless wave number for different meshes and directions of wave propagation. Five meshes having the same element volume will be considered for each of the elements analyzed. Specifically, for HE20 element, Fig. 1:

Q1: square section; $\gamma = 1$, $\beta = 0$, $\varepsilon = 1$.

Q2: rectangular section with aspect ratio 1:2; $\gamma = 1/\sqrt{2}$, $\beta = 0$, $\varepsilon = 1$.

Q3: skewed section; $\gamma = 1$, $\beta = 45^\circ$, $\varepsilon = 1$.

Q4: distorted in the poling Z-direction with aspect ratio 2:1; $\gamma = 1$, $\beta = 0$, $\varepsilon = 2^{1/3}$.

Q5: distorted in the poling Z-direction with aspect ratio 1:2; $\gamma = 1$, $\beta = 0$, $\varepsilon = 1/2^{1/3}$.

and, for PE15 element, Fig. 2:

T1: triangular section of equilateral geometry; $\gamma = 1$, $\varepsilon = 1$.

T2: triangular section of right geometry; $\gamma^2 = 1/(3)^{1/2}$, $\varepsilon = 1$.

T3: triangular section with angle of 30° opposite to the base; $\gamma^2 = 1/(3)^{1/2} \tan 75^\circ$, $\varepsilon = 1$.

T4: distorted in the poling Z-direction with aspect ratio 2:1; $\gamma = 1$, $\varepsilon = 2^{1/3}$.

T5: distorted in the poling Z-direction with aspect ratio 1:2; $\gamma = 1$, $\varepsilon = 1/2^{1/3}$.

Given the mesh and the piezoelectric medium, the dispersion analysis is numerically carried out by a step of $\pi/36$ for the azimuthal and polar angles, and a step of $1/10000$ for the dimensionless wave number. As result the indicators Eq. (27), Eq. (30) and Eq. (31), are computed as finite sets of values. An example of the indicators Eq. (30) and Eq. (32) is shown in Fig. 3. It is observed that Eq. (30) and it is deduced that Eq. (31) both vanish as dimensionless wave number goes to zero; that is, as the mesh is refined and in the limit of long waves. It must be remarked that the behavior of the higher order total energy as dimensionless wave number goes to zero is a consequence that both the strain field and the electric field inside each element becomes uniform. That is, given the mesh, in the limit of long waves, the density of total energy

approaches to zero more slowly than its higher order component; and, given the wavelength, as the solution converges on account of mesh refinement, the density of total energy is increasingly dominated by its basic component.

Investigating the relationship between the total energy error and the percentage of higher order total energy Eq. (32), it can be observed from Fig. 3 that both variables could be related by a cubic function for moderate values of the higher order total energy,

$$e_T = [A(\phi, \theta, \alpha) * e_h + B(\phi, \theta, \alpha)] * e_h^2 \quad (34)$$

For each of the waves (SS, FS, and L) and piezoelectric media considered in this research, an averaged correlation between the total energy error and the percentage of higher order total energy is sought by computing averaged values for the coefficients A and B .

First, two reference values of the percentage of higher order total energy are selected,

$$HE20: e_{h1} = 0.10 \quad e_{h2} = 0.20; \quad PE15: e_{h1} = 0.075 \quad e_{h2} = 0.15 \quad (35)$$

Figure 3: Percentage of higher order total energy versus dimensionless wave number and versus percentage of total energy error. PMN-30PT, MESH Q4, L-WAVES, $\phi = 45^\circ$.

Then, by Eq. (30) and Eq. (32), the reference values related of dimensionless wave number and percentage of total energy error are respectively computed,

$$m_{1,2} = m_{1,2}(\phi, \theta, \alpha), \quad e_{T1,2} = e_{T1,2}(\phi, \theta, \alpha) \quad (36)$$

The mean value of each reference dimensionless wave number, and the root mean square value (based on the L_2 -norm) and the sup-norm value [24] of each reference total energy error are next computed on the range of propagation angles,

$$\begin{aligned} m_{1,2}^M(\alpha) &= \frac{1}{\pi^2} \int_0^\pi \int_0^\pi m_{1,2} d\phi d\theta \quad (a) \quad e_{T1,2}^{RMS}(\alpha) = \sqrt{\frac{1}{\pi^2} \int_0^\pi \int_0^\pi |e_{1,2}|^2 d\phi d\theta} \quad (b) \\ e_{T1,2}^{SUP}(\alpha) &= \sup \{|e_{1,2}(\phi, \theta, \alpha)| : 0 \leq \phi, \theta \leq \pi\} \quad (c) \end{aligned} \quad (37)$$

Consistent with the discrete analysis carried out, the integrals in Eq. (37a) and Eq. (37b) are numerically computed. Mean values of the indicators of numerical dispersion for the phase velocity and the normal component of the group velocity Eq. (27) have been also computed. Detailed values are presented in the Appendix 2 attached to this manuscript.

As a next step, the values computed in Eq. (37a) and Eq. (37b) are mesh-averaged,

$$\begin{aligned}
HE20: \quad \overline{m_{1,2}^M} &= \frac{1}{5} \sum_{j=1}^5 m_{1,2}^M(Q_j) & HE20: \quad \overline{e_{T1,2}^{RMS}} &= \frac{1}{5} \sum_{j=1}^5 e_{T1,2}^{RMS}(Q_j) \\
PE15: \quad \overline{m_{1,2}^M} &= \frac{1}{5} \sum_{j=1}^5 m_{1,2}^M(T_j) & PE15: \quad \overline{e_{T1,2}^{RMS}} &= \frac{1}{5} \sum_{j=1}^5 e_{T1,2}^{RMS}(T_j)
\end{aligned} \tag{38}$$

The results of Eq. (38a) and Eq. (38b) are displayed in Table 1 and Table 2, respectively, for each of the piezoelectric media and waves investigated. Similar mesh-averaged values of the indicators of numerical dispersion for the phase velocity and the normal component of the group velocity Eq. (27) have been also computed, Table 3.

From Table 1 and Table 2, it is deduced that the mesh-averaged root mean square values of the first and the second reference percentage of total energy error roughly correspond, in an averaged sense, to six and four elements per wavelength, respectively. In such averaged sense, the total energy error of the quasi-longitudinal waves is greater than the one of the quasi-shear waves. An opposite behavior is shown by the indicators of numerical dispersion. It is deduced from Table 3 that the numerical dispersion of the quasi-shear waves is greater than the one of the quasi-longitudinal waves.

Table 1: Mesh-average of the mean values of the first and second reference dimensionless wave number.

Finally, by the mesh-averaged reference values of total energy error Eq. (38b), the averaged values of the coefficients A and B for the cubic correlation Eq. (34) can be computed,

$$\overline{e_{T1,2}^{RMS}} = [\overline{A} * e_{h1,2} + \overline{B}] * e_{h1,2}^2 \tag{39}$$

Then the averaged correlation between the total energy error and the percentage of higher order total energy will be yielded

$$e_T^{RMS} = (\overline{A} * e_h + \overline{B}) * e_h^2, \quad 0 < e_h \leq e_{h2} \tag{40}$$

3 MODAL ANALYSIS

As application it is explored the use of the averaged correlation Eq. (40) as a reference to apply the higher order total energy as an indicator of discretization error for the finite element vibration eigenmodes. These ones are the solution of the eigenproblem obtained by considering the homogeneous part of Eq. (1) and assuming stationary waves. In condensed form [10],

$$\mathbf{K}^* \tilde{\mathbf{x}}_j = \omega_j^2 \mathbf{M} \tilde{\mathbf{x}}_j, \quad \mathbf{K}^* = \mathbf{K}_{uu} + \mathbf{K}_{u\phi} \mathbf{K}_{\phi\phi}^{-1} \mathbf{K}_{\phi u}^T \quad (a) \quad \tilde{\boldsymbol{\phi}}_j = \mathbf{K}_{\phi\phi}^{-1} \mathbf{K}_{\phi u}^T \tilde{\mathbf{x}}_j \quad (b) \quad j = 1, \dots, n \quad (41)$$

$$\tilde{\mathbf{x}}_i^T \mathbf{K}^* \tilde{\mathbf{x}}_j = \delta_{ij} \omega_j^2 \quad i, j = 1, \dots, n \quad (42)$$

where: ω_j and $(\tilde{\mathbf{x}}_j, \tilde{\boldsymbol{\phi}}_j)^T$ are the finite element natural frequencies and eigenvectors.

Table 3: Second mesh-averaged reference values of the indicators of numerical dispersion.

Eq. (41a) and Eq. (41b) are solved by LAPACK routines [25]. By considering the relation of \mathbf{K} -orthogonality Eq. (42) for the condensed eigenproblem Eq. (40a), and taking into account Eq. (41b) and Eq. (7), it can be yielded the following expression for the modal total energy

$$\frac{1}{4} \tilde{\mathbf{x}}_j^T \mathbf{K}_{uu} \tilde{\mathbf{x}}_j + \frac{1}{4} \tilde{\boldsymbol{\phi}}_j^T \mathbf{K}_{\phi\phi} \tilde{\boldsymbol{\phi}}_j = \frac{1}{4} \omega_j^2 \rightarrow \bar{E}_j = \frac{1}{4} \omega_j^2, \quad j = 1, \dots, n \quad (43)$$

The error for the modal total energy computed with the discretized piezoelectric domain is estimated by a reference model that will be obtained by dividing each element of the actual mesh into eight elements. The modal total energy computed with the actual model and the one computed with the reference model will be compared for each eigenmode by

$$TEE = (\bar{E}/\bar{E}^{REF}) - 1, \quad TEE = (\omega/\omega^{REF})^2 - 1 \quad (44)$$

The modal total energy error Eq. (44) will be compared with a proposed total energy error indicator which is computed either by averaging the correlation Eq. (40) for the slow and fast quasi-shear waves, or by the correlation Eq. (40) for the quasi-longitudinal waves,

$$TEES(PHE) = \frac{1}{2}(e_{T,SS}^{RMS} + e_{T,FS}^{RMS}) \quad (a) \quad TEEL(PHE) = e_{T,L}^{RMS} \quad (b), \quad 0 < PHE \leq e_{h2} \quad (45)$$

where PHE is the percentage of higher order total energy computed with the actual model.

From Table 2, the following inequality is clearly fulfilled,

$$TEES(PHE) < TEEL(PHE) \quad (46)$$

Finally, by taking into account Eq. (7), the percentage of modal electric energy will be also computed with the actual model,

$$PEE = \bar{E}^E / (\bar{E}^M + \bar{E}^E) \quad (47)$$

It must be remarked that, for plane bulk acoustic waves, Eq. (47) would be an accepted definition of electromechanical coupling coefficient from energy consideration [26].

3.1 Numerical research

Two test problems discretized by the HE20 element have been analyzed, Fig. 4: a piezoelectric cantilever bimorph connected in parallel configuration made of PZT-5A ($L = 16$ mm, $b = 3$ mm, $t = 2$ mm) [27, 28], and a piezoelectric cube laterally clamped made of PZT-5H or, alternatively, PMN-30PT single crystal ($L = 1$ mm) [29]. A piezoelectric disk laterally clamped, discretized by the PE15 element, is also analyzed, Fig. 5 ($R = 12$ mm, $t = 6$ mm). The piezoelectric disk is made of PZT-8 or, alternatively, PIN-PMN-PT single crystal. In each test problem the electrodes are shorted and their mechanical effects are neglected.

Figure 4: Piezoelectric cantilever bimorph and cube laterally clamped discretized by the HE20 element.

Since the piezoelectric bimorph has two planes of symmetry, which are XY and YZ , the modes can be computed by idealizing one quarter of it and applying four combinations of boundary conditions on the two planes for symmetric motion (S) and for antisymmetric motion (A), see details in reference [30]. In this test problem, the swaying modes in the Z -direction (AS) and the torsion modes about the Y -axis (AA) have been computed, Table 4.

Figure 5: Piezoelectric disk laterally clamped discretized by the PE15 element.

Similarly, since both the piezoelectric cube and the piezoelectric disk have three planes of symmetry, which are YZ , XZ and XY , the modes can be computed by idealizing one eighth of them, and applying six combinations of boundary conditions on the three planes for symmetric motion (S) and for antisymmetric motion (A). Also see details in reference [30]. In both test problems, the antisymmetric and symmetric longitudinal modes in the Z -direction (SSA and SSS), the antisymmetric and symmetric swaying modes in the Y -direction (SAA and SAS), and the antisymmetric and symmetric torsion modes about the Z -axis (AAA and AAS) have been computed. The results are displayed in Tables 5-16.

For each test problem it is selected the set of consecutive eigenmodes for which the following condition is fulfilled: $0 < PHE \leq e_{h2}$ (see Eq. (35)).

Table 6: PMN-30PT cube laterally clamped. Proposed total energy error indicator TEEL versus total energy error computed by mesh halving TEE. Modes SS (S) and SS (A).

From Tables 4-16 it is deduced that the percentage of higher order total energy decreases as the mesh is refined. Then, it is verified that this energy component behaves as a modal error indicator, which is in accordance with the numerical dispersion analysis.

From Tables 4, 5, 7, 9, 11, 13 and 15 it can be deduced that, for the solids made of PZT piezoceramics, the proposed total energy error indicator based on S-waves Eq. (45a) and the

total energy error computed by mesh halving Eq. (44) generally exhibit a similar evolution pattern as the modal order increases. Also, the proposed total energy error indicator Eq. (45a) generally overestimates the total energy error computed by mesh halving Eq. (44). Clearly, by the proposed total energy error indicator based on S-waves Eq. (45a), the accuracy of the finite element eigenmodes could be confidently verified in order to select a cutoff modal order given an upper bound for the total energy error close to one per cent.

The above behavior for the solids made of PZT piezoceramics could be expected based on the heuristic that, given the natural frequency, both the percentage of higher order total energy and the spatial discretization error should be mainly influenced by the error induced by the slowest quasi-shear waves which have the shortest wavelengths.

Table 7: PZT-5H cube laterally clamped. Proposed total energy error indicator TEES versus total energy error computed by mesh halving TEE. Modes SA (S) and SA (A).

From Tables 5-16, it can be deduced that the modal total energy errors computed by mesh halving for the solids made of PMN-PT <001> poled single crystals are significantly greater than the ones computed for the solids made of PZT. This behavior is similar to the dilatational locking phenomenon that is most commonly associated with nearly incompressible isotropic materials, i.e., with those for which the Poisson's ratio approaches one-half very closely [13].

From Tables 6, 8, 10, 12, 14 and 16 it can be deduced that, for the solids made of PMN-PT single crystals, only the proposed total energy error indicator based on L-waves Eq. (45b) overestimates for some eigenmodes the total energy error computed by mesh halving Eq. (44); however, by the proposed total energy error indicator based on L-waves Eq. (45b), an upper bound for the total energy error generally can be satisfactorily estimated for the set of eigenmodes selected. Clearly, for the PMN-PT solids, the modal total energy error should be mainly influenced by the error induced by the quasi-longitudinal waves. Both for PMN-30PT cube and for the PIN-PMN-PT disk laterally clamped, the total energy errors computed by mesh halving, for the eigenmodes selected, generally can be accepted for all practical purposes from the engineering point of view.

4 CONCLUSIONS

For piezoelectric media discretized either by the energy-orthogonal twenty-node hexahedral finite element or by the energy-orthogonal fifteen-node pentahedral finite element, by a dispersion analysis of plane harmonic bulk waves, an averaged correlation between the percentage of higher order total energy and the total energy error is yielded in each case both for the quasi-longitudinal waves and the quasi-shear waves. The use of such correlations as reference to apply the higher order total energy as an error indicator for the finite element vibration eigenmodes in piezoelectric solids is explored. As noteworthy conclusions:

- For PZT piezoceramics discretized by regular meshes the numerical research reveals that, by the correlation based on quasi-shear waves, the accuracy of the finite element eigenmodes can be confidently verified in order to select a cutoff modal order given an upper bound for the total energy error close to one per cent.

- For PMN-PT <001> poled single crystals a phenomenon similar to the dilatational locking could affect the accuracy of the eigenmodes computed. In this case, the correlation based on the quasi-longitudinal waves will be more accurate than the one based on the quasi-shear waves. An upper bound for the total energy error generally can be satisfactorily estimated for the set of eigenmodes selected.

Keywords: Periodic systems, rank minimization heuristics, optimization-based material design, log-det heuristics, reduced-order modeling.

Abstract. *A new class of performance functions for dispersion design of 1D periodic discrete systems using matrix rank is considered, and its regularization using existent log-det heuristics is proposed. As an input, the desired dispersion dependency of a branch is used. The design space is defined by a finite set of continuous parameters such as mass or stiffness constants. The mass and stiffness matrices are assumed to depend linearly on these parameters. Ideally, the representative dynamic stiffness matrix is singular at every point of the desired branch. Instead, the sum of ranks for the representative dynamic stiffness matrix evaluated at several discrete points is minimized using a surrogate log-det objective. This approach avoids ordering or tracking of eigenfrequencies and reduces the design problem to a sequence of quadratic programming problems. The considered periodic discrete systems are simplified objects for method development with a future goal of dispersion design of acoustic metamaterials. Also, a combination with reduced-order techniques is conceptually tested.*

1 INTRODUCTION

Dispersion design in acoustics seeks a material or a system that interacts with acoustic waves in desired manner. Typical examples of desired behavior are prohibiting wave propagation in a specific frequency range via stopping bands in metamaterials and elimination of reflected waves with anechoic tiles. Usually, these designs are realized as an array of repeating heterogeneous cells. Different options are available for manufacturing heterogeneous cells and they can use solid-solid, solid-liquid or solid-air interfaces. Each cell can be described by a large number of design parameters, which makes finding the design a challenging problem.

A common approach is to introduce a performance function that relates the design variables to desired performances and to use it in a gradient-based optimization or integer programming, see examples for maximizing relative band gap in [2] or design of self-collimating materials in [10]. Unfortunately, the common performance functions are implicit functions of dynamic equilibrium equations and their sensitivities are sometimes difficult to obtain, see [13] and references herein. Alternative integer programming approaches need very large number of iterations, e.g. of genetic algorithms. In this contribution a new class of performance functions based on matrix rank is proposed and discussed. An advantage of using matrix rank is that several explicit surrogate functions for rank approximation are available simplifying computation of the performance functions and their sensitivities.

The problem of minimizing the rank of a matrix is known to be computationally hard, see [12, 7.3] and it is attributed to be NP-hard in general case [11]. Fortunately, several available heuristics can efficiently solve it. These heuristics rely on different tractable relaxations of the problem, e.g. a nuclear norm minimization, weighted norm minimization or minimization of the logarithm of the determinant [4, 5, 9]. Tractable means here that one quadratic function minimization or SVD per an iteration step is required and the number of such iterations is affordable. Unfortunately, these heuristic methods guarantee the minimum rank solution only in case of well-conditioned equality constraints on the matrix, see the proof in [11]. Various numerical experiments show a satisfactory quality of the solutions obtained by the heuristics for applications as low-rank matrix completion [5, 9], low-order system realization [5] and lowest-dimension embedding of points in Euclidean space [5]. However, these methods are not wide spread for design in vibration or acoustic systems so far. An example in [1] uses rank minimization for reducing dispersion error in spatial discretizations of reciprocal mass matrices. Therefore, exploring rank minimization formulations in dispersion design is promising.

For simplicity, examples here are limited to 1D periodic undamped systems consisting of point masses and springs. Only continuous parameters for mass and stiffness constants are used. Constraints are applied only on upper and lower limits of parameter values.

The contribution is organized as follows. First, equations of motion for a repetitive patch are introduced and a rank minimization objective is formulated in Section 2. A log-det heuristic is applied to the rank minimization problem and two illustrative algebraic examples are discussed in Section 3. A combination of log-det heuristic with the reduced-order techniques is described and illustrated with one algebraic example in Section 4. A numerical example for a uniform back-bone mass-spring chain with a side branch at every second mass element are considered in Section (5). Conclusions are presented in Section 6.

2 EQUATION OF MOTION AND RANK MINIMIZATION OBJECTIVE

The equations of motion for an infinite periodic mechanical system can be formulated in different ways, see a comprehensive textbook [3]. Here, a form following [8] is considered for

1D case. The representative patch of the periodic structure is assumed to have n_{rep} unknown amplitudes denoted as $\tilde{\mathbf{U}}$. These amplitudes satisfy equations

$$\mathbf{Q} (\mathbf{K}(\mathbf{s}) - \omega^2 \mathbf{M}(\mathbf{s})) \mathbf{S}(k) \tilde{\mathbf{U}} = \mathbf{0}, \quad (1)$$

where ω and k are the angular frequency and wavenumber, \mathbf{K} and \mathbf{M} are the stiffness and mass matrix. Herein, affine dependence of the stiffness and mass matrix on n_s parameters \mathbf{s} is assumed with

$$\mathbf{K}(\mathbf{s}) = \mathbf{K}_0 + \sum_{j=1}^{n_s} \mathbf{K}_j s_j, \quad \mathbf{M}(\mathbf{s}) = \mathbf{M}_0 + \sum_{j=1}^{n_s} \mathbf{M}_j s_j. \quad (2)$$

These matrices are assembled for the periodic cell and a layer of neighboring elements. The periodic boundary conditions are enforced via a shift matrix \mathbf{S} whose entries on the slave side are proportional to the phase shift $\exp(ik \cdot \Delta x)$ along the lattice vector for the periodic cell Δx . The matrix \mathbf{Q} filters degrees of freedom of the representative patch $\tilde{\mathbf{U}}$ from the total model. Thus, the equation of motion as in equation (1) allows us to define the representative dynamic stiffness matrix (RDSM) with

$$\mathbf{A}(\mathbf{s}, k, \omega) = \mathbf{Q} (\mathbf{K}(\mathbf{s}) - \omega^2 \mathbf{M}(\mathbf{s})) \mathbf{S}(k). \quad (3)$$

We denote with $\mathbf{A}_j := \mathbf{A}(\mathbf{s}, k_j, \omega_j)$ the RDSM evaluated at a specific frequency-wavenumber pair (k_j, ω_j) . Solvability of the equation of motion (1) at a frequency-wavenumber pair requires that the corresponding RDSM is singular or it has a deficit of rank with

$$\text{rank } \mathbf{A}_j < \dim(\mathbf{A}_j) = n_{\text{rep}}, \quad j = \overline{1, n_w}, \quad (4)$$

where n_w is the number of sampled frequency-wavenumber pairs. Inspection of all n_w inequalities is still a hard problem. Instead, a *good* solution is sought that minimizes the *sum of the ranks* of RDSM for all pairs j with respect to parameters \mathbf{s} . Such a sum now defines the objective of the dispersion design. This sum is equal to the product $(n_{\text{rep}} n_w)$ at an initial value of parameters \mathbf{s}_0 . During the optimization process, for certain values of the parameters \mathbf{s}_k the rank of some of the matrices $\mathbf{K}_{\text{dyn,rep}}(\mathbf{s}_k, \omega_j, \mathbf{k}_j)$ reduces to $(n_{\text{rep}} - 1)$ meaning that exactly one branch of the dispersion relation crosses the prescribed frequency-wavevector pair (ω_j, \mathbf{k}_j) . Reduction of the rank to $(n_{\text{rep}} - 2)$ or less would require that more than one branch of the dispersion relation crosses the prescribed frequency-wavevector pair, i.e. two or more waves can propagate with the same wavenumber and frequency, but a different mode. Such a multiple crossing is possible but it does not significantly influence the design for a sufficiently large number of target pairs per branch. Therefore, reduction of the objective increases the number of the frequency-wavevector pairs at which the designed material follows the wanted dispersion behavior. Thus, this objective can estimate the *quality of the design*.

To bring the objective to a concise form, let us define the rank identity for a block diagonal matrix with

$$\sum_{j=1}^{n_w} \text{rank } \mathbf{A}_j = \text{rank } \text{diag}_{j=\overline{1, n_w}}(\mathbf{A}_j) \quad (5)$$

is valid for any set of square matrices \mathbf{A}_j . Here, an operator diag denotes a constructor of a block diagonal matrix from a list of rectangular matrices. Finally, the objective reads

$$J(\mathbf{s}) = \text{rank } \text{diag}_{j=\overline{1, n_w}}(\mathbf{A}_j). \quad (6)$$

The latter problem is still an affine rank minimization problem. Affinity easily follows from the definition of individual subblocks of the objective matrix. Recasting leads to

$$\begin{aligned} \text{diag}_{j=\overline{1, n_w}}(\mathbf{A}_j) &= \text{diag}_{j=\overline{1, n_w}}(\mathbf{Q}(\mathbf{K}(\mathbf{s}) - \omega_j^2 \mathbf{M}(\mathbf{s})) \mathbf{S}(k_j)) \\ &= \text{diag}_{j=\overline{1, n_w}}\left(\mathbf{Q}\left(\mathbf{K}_0 + \sum_{l=1}^{n_s} \mathbf{K}_l s_l - \omega_j^2 \left[\mathbf{M}_0 + \sum_{l=1}^{n_s} \mathbf{M}_l s_l\right]\right) \mathbf{S}(k_j)\right) = \mathbf{B}_0 + \sum_{l=1}^{n_s} \mathbf{B}_l s_l, \end{aligned} \quad (7)$$

where matrices $\{\mathbf{B}_l\}_{l=0}^{n_s}$ are defined

$$\mathbf{B}_l = \text{diag}_{j=\overline{1, n_w}}(\mathbf{Q}(\mathbf{K}_l - \omega_j^2 \mathbf{M}_l) \mathbf{S}(k_j)). \quad (8)$$

3 HEURISTIC RANK MINIMIZATION

Herein, a focus on log-det heuristics is made because of its simplicity and robustness. The rank minimization problem stated above is solved approximately by log-det heuristics from [5]. A substantial difference to the original method is due to complex entries of the RDSM matrices. These complex entries originate from the shift matrix \mathbf{S} even for the case without damping. The original rank minimization algorithm is valid for real semi-definite matrices. To bring our problem to an appropriated shape, a matrix \mathbf{X} is introduced with

$$\mathbf{X} = \text{diag}_{j=\overline{1, n_w}}(\mathbf{A}^H(\mathbf{s}, \omega_j, k_j) \mathbf{A}(\mathbf{s}, \omega_j, k_j)) \quad (9)$$

where superscript \square^H denotes Hermitian transpose (the conjugate transpose). The resultant matrix is a Hermitian positive semi-definite matrix, which is sufficient for the original log-det heuristics. The rank of matrix \mathbf{X} coincides with the objective function (6), but dependency on the free parameters is quadratic. A similar trick is used in [1] for dispersion error minimization on a regular spatial grid of finite elements. Now, a rank minimization problem (RMP) is formulated for matrix \mathbf{X} with

$$\mathbf{s}^* = \arg \min_{\mathbf{s} \in \mathcal{K}} (\text{rank}(\mathbf{X})), \quad (10)$$

where \mathcal{K} denotes an admissible convex set for parameters \mathbf{s} . Rather than solving a RMP, a *log-det smooth surrogate* for $\text{rank}(\mathbf{X})$ is used

$$\mathbf{s}^* = \arg \min_{\mathbf{s} \in \mathcal{K}} (\log \det (\mathbf{X} + \delta \mathbf{I})), \quad (11)$$

where $\delta > 0$ is a small regularization constant and \mathbf{I} is as the identity matrix. Despite complex entries of the matrix \mathbf{X} , the determinant of a Hermitian positive definite matrix $(\mathbf{X} + \delta \mathbf{I})$ is real and positive. Therefore, the objective function above is real and the optimization problem well defined. Here, we follow the paper [5] and reduce the optimization to a series of quadratic programming problems. First, a Taylor expansion of the objective function in the vicinity of the current value \mathbf{X}_k is carried out

$$\log \det(\mathbf{X} + \delta \mathbf{I}) \approx \log \det(\mathbf{X}_k + \delta \mathbf{I}) + \text{trace}(\mathbf{W}_k(\mathbf{X} - \mathbf{X}_k)), \quad (12)$$

where $\mathbf{W}_k = (\mathbf{X}_k + \delta \mathbf{I})^{-1}$ denotes the weighting matrix. The weighting matrix is evaluated numerically. Thus, the linearization of the surrogate function (12) has only a dependence on design parameters in the second factor $(\mathbf{X} - \mathbf{X}_k)$. The algorithm is illustrated in Box 1. The linearization of objective leads to real-valued Hessian H_{jl} and real-valued linear part f_j with

$$H_{jl} = \text{Re} [\text{trace}(\mathbf{W}_k(\mathbf{B}_j^H \mathbf{B}_l))] \quad f_j = \text{Re} [\text{trace}(\mathbf{W}_k(\mathbf{B}_j^H \mathbf{B}_0))] \quad (13)$$

Algorithm 1 Algorithm for dispersion design based on log-det heuristic proposed in [5].

```

Computation with double precision leads to tiny imaginary parts in the coefficients. Therefore, taking the real part is necessary.

The presented above algorithm is illustrated now with two algebraic examples. Both example use double precision arithmetic and a value of the regularization parameter $\delta = 10^{-3}$.

Algebraic example 1. First, a real-valued example is considered, where Hermitian transpose and usual transpose coincide. Find values of two parameters $\mathbf{s} = [s_1, s_2]$ within an admissible set $\mathcal{K} = [0, 1] \times [0, 1]$ that minimize the rank of a square matrix $\mathbf{X} \in \mathbb{R}^{4 \times 4}$ given as

$$\mathbf{X} = \mathbf{A}^T \mathbf{A}, \quad \mathbf{A} = \mathbf{B}_0 + s_1 \mathbf{B}_1 + s_2 \mathbf{B}_2 \quad (14)$$

with affine representation of matrix \mathbf{A} with matrices \mathbf{B}_i defined as

$$\mathbf{B}_0 = \begin{bmatrix} 5000 & 20 & 1/3 & 1/3 \\ 20 & 5/4 & 1/3 & 1/4 \\ 1/3 & 1/3 & 1/3 & 1/3 \\ 1/3 & 1/4 & 1/3 & 1/4 \end{bmatrix} \quad \mathbf{B}_2 = \begin{bmatrix} -1 & -1 & -1 & -1 \\ -1 & 0 & -1 & 0 \\ -1 & -1 & -1 & -1 \\ -1 & 0 & -1 & 0 \end{bmatrix} \quad \mathbf{B}_3 = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & -2 & 0 & -2 \\ 0 & 0 & 0 & 0 \\ 0 & -2 & 0 & -2 \end{bmatrix}. \quad (15)$$

This RMP has the global minimum

$$\mathbf{A} \left(s_1 = \frac{1}{3}, s_2 = \frac{1}{8} \right) = \begin{bmatrix} \frac{224973482}{9} & \frac{885118}{9} & 0 & 0 \\ \frac{885118}{9} & \frac{3490}{9} & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \Rightarrow \text{rank}(\mathbf{X}) = \text{rank}(\mathbf{A}^T \mathbf{A}) = 2. \quad (16)$$

The log-det surrogate function shown in Figure 1 has its global minimum very close to the global minimum of the original problem. The global minimum is observed at the cross-section of two valleys where deficit of rank is one. Decreasing the regularization parameter would make the valley flanks steeper but it does not change qualitatively the shape of the objective function. The evolution of the surrogate objective over iterations is also shown in Figure 1. Convergence

Figure 1: Surrogate objective function $\log \det (\mathbf{X} + \delta \mathbf{I})$ for the algebraic example with a regularization $\delta = 10^{-3}$ (left). Convergence of the surrogate objective (right) from starting value $[1/6, 1/12]$.

is achieved from starting value $[1/6, 1/12]$ to the rank-2 solution

$$\mathbf{X}^*(s_1=0.333328, s_2=0.125539) \approx \begin{bmatrix} 2.5e7 & 9.83e4 & 0.0264 & 0.00515 \\ 9.83e4 & 388.0 & 1.09e-4 & -9.72e-4 \\ 0.0264 & 1.09e-4 & 1.11e-9 & -1.13e-8 \\ 0.00515 & -9.72e-4 & -1.13e-8 & 2.32e-6 \end{bmatrix} \quad (17)$$

with two lowest eigenvalues below 10^{-5} within ten iterations.

Algebraic example 2. The second algebraic example treats a complex-valued square matrix $\mathbf{X} \in \mathbb{C}^{3 \times 3}$ depending on two parameters $\mathbf{s} = [s_1, s_2]$ within an admissible set $\mathcal{K} = [0, 1] \times [0, 1]$. Hermitian semi-positive matrix \mathbf{X} is defined as

$$\mathbf{X} = \mathbf{A}^H \mathbf{A}, \quad \mathbf{A} = \mathbf{B}_0 + s_1 \mathbf{B}_1 + s_2 \mathbf{B}_2 \quad (18)$$

with matrices \mathbf{B}_i defined

$$\mathbf{B}_0 = \begin{bmatrix} 5/4 & 1/3 & -1/12 + i/3 \\ 1/3 & 1/3 & i/3 \\ -1/12 + i/3 & i/3 & -5/12 \end{bmatrix} \quad (19)$$

$$\mathbf{B}_2 = \begin{bmatrix} 0 & -1 & 1-i \\ -1 & -1 & -i \\ 1-i & -i & 2 \end{bmatrix} \quad \mathbf{B}_3 = \begin{bmatrix} 0 & -1 & 1-i \\ -1 & -1 & -i \\ 1-i & -i & 2 \end{bmatrix}. \quad (20)$$

This RMP has the global minimum

$$\mathbf{A} \left(s_1 = \frac{1}{3}, s_2 = \frac{1}{8} \right) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \Rightarrow \text{rank}(\mathbf{X}) = \text{rank}(\mathbf{A}^H \mathbf{A}) = 1. \quad (21)$$

Log-det heuristic approximates this solution within ten iterations $s_1 = 0.334057$, $s_2 = 0.126277$ from starting value $[1/6, 1/12]$

$$\mathbf{X}^* = \begin{bmatrix} 0.995 & -0.000721 + 0.00000133i & -0.00182 - 0.000722i \\ -0.000721 - 0.00000133i & 0.00000157 & (1.33 + 0.247i)e - 6 \\ -0.00182 + 0.000722i & (1.33 - 0.247i)e - 6 & 5.62e - 6 \end{bmatrix}. \quad (22)$$

and it demonstrates work of the log-det heuristic for a Hermitian semi-positive matrix.

4 COMBINATION WITH REDUCED-ORDER TECHNIQUES

Increasing size of the representative patch increases rapidly cost of evaluation of the coefficient of quadratic programming problem in (13). Therefore, reducing dimension of the final RMP is very important. Here, a naive projection of the problem onto a reduced basis $\Phi \in \mathbb{C}^{n_{\text{rep}} n_w \times n_r}$, $n_r \ll n_{\text{rep}} n_w$ is proposed in form

$$\bar{J}(\mathbf{s}) = \text{rank}(\Phi^H \mathbf{X}(\mathbf{s}) \Phi). \quad (23)$$

Accuracy and efficiency of the reduced problem depends strongly on the reduced basis. Ideally, it should contain the kernel of the matrix \mathbf{X} at the solution point \mathbf{s}^* and have comparable dimension. Practically, using few consequent eigenmodes of \mathbf{A} at the initial approximation \mathbf{s}_0 is possible and used herein. Formally, this reduce basis can be written in block-diagonal format with

$$\Phi = \text{diag}_{j=\overline{1, n_w}} \left([\text{eig}(\mathbf{A}_j(\mathbf{s}_0))]_{:, n_l \dots n_u} \right), \quad (24)$$

where eig is an operator returning in columns eigenmodes in ascending order w.r.t. real part and an operation $\square_{:, n_l \dots n_u}$ returns columns $\overline{n_l}, \overline{n_u}$ of a matrix. This construction of the reduced basis yields the reduced dimension

$$n_r = n_w(n_u - n_l + 1) \quad (25)$$

The surrogate log-det function for the rank is computed in the same manner as for the full problem. Finally, a following minimization problem is solved

$$\mathbf{s}^* = \arg \min_{\mathbf{s} \in \mathcal{K}} (\log \det (\Phi^H \mathbf{X}(\mathbf{s}) \Phi + \delta \mathbf{I})), \quad (26)$$

where the dimension of identity matrix is adjusted to n_r .

We expect that the influence of reduced-order technique is two-fold. First, the dimension of the problem significantly reduces. Second, the conditioning of the matrix $\Phi^H \mathbf{X}(\mathbf{s}) \Phi$ is better than for full matrix $\mathbf{X}(\mathbf{s})$, which helps log-det heuristic to converge faster and allows lower values of the regularization parameter δ . However, checking these two hypothesis goes beyond the contribution.

Algebraic example 3. This example uses setup of algebraic example 1. The influence of the reduced basis on the quality of the solution is studied in for two reduced bases

$$\Phi_1 = \begin{bmatrix} 0 & 0 \\ 0 & 1/5 \\ 1 & -1 \\ 1 & 1 \end{bmatrix}, \quad \Phi_2 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ -1 & 0 \\ 0 & -1 \end{bmatrix}. \quad (27)$$

The former basis is very close to the kernel of the matrix \mathbf{X} at the solution point

$$\ker(\mathbf{X}) = \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ 1 & -1 \\ 1 & 1 \end{bmatrix}. \quad (28)$$

The surrogate objective function for the reduced basis Φ_1 is shown in Figure 2 (left). It has a global minimum close the exact one. The surrogate objective function for the reduced basis Φ_2 does not depend on the parameters and it cannot be used. It is an example of extremely unfavorable choice of the reduced basis. Convergence to a solution $s_1 = 0.333337$, $s_2 = 0.125002$ is obtained within 10 iterations. Evolution of the objective during iteration process is shown in Figure 2 (right). The absolute values of objective for the reduced problem are different the full one, which is also clear from comparison of Figure 2 and 1.

Figure 2: Surrogate objective function $\log \det (\Phi^H \mathbf{X}(\mathbf{s}) \Phi + \delta \mathbf{I})$ for the algebraic example with a regularization $\delta = 10^{-3}$ using the reduced basis Φ_1 (left). Convergence of the reduced surrogate objective (right) from starting value $[1/6, 1/12]$.

5 NUMERICAL EXAMPLE

A mechanical example illustrates performance of the proposed approach. A periodic system with a uniform back-bone mass-spring chain and a side branch at every second mass element is shown in Figure 3. Dimension of the representative patch is five, while seven continuous parameters define system properties. The mass and stiffness constants in the back-bone are fixed. Three mass and four stiffness parameters of the side branch can be varied within ranges given in Figure 3. Stiffness parameters are denoted with letter β to avoid any confusion with the wavenumber denoted with letter k .

The aim is to obtain a dispersion design with an almost *constant frequency branch*, which also provides a near to zero group velocity. Five target wavenumber-frequency pairs are used

Figure 3: Setup for a periodic discrete system. Overall view on 1D linear mass-spring system with side branch (left) and a zoom in a repetitive structure with topology, parameters and their ranges (right).

with

$$n_w = 5, \quad ak_j = \frac{\pi j}{n_w + 1}, \quad \omega_j = 1.58, \quad j = \overline{1, n_w}, \quad (29)$$

where $2a$ is the physical length of repetitive structure, as shown in Figure 3. At these pairs, the RDSM should be singular and it is achieved by minimizing the rank of the corresponding matrix via log-det heuristic. Three starting value sets for design parameters are listed in Table 1. The regularization parameter $\delta = 3 \cdot 10^{-8}$, convergence tolerance $\epsilon = 10^{-10}$ and maximum 15 iterations is used in the log-det heuristic.

A solution is obtained after 15 iterations and the final values are given in Table 1. Reduction of the surrogate objective over iterations is given in Figure 4. These curves have very steep initial phase. Eventually, they flatten and come to saturation. If the convergence tolerance ϵ for the increment of parameter vector is not reached then the algorithm iterates until the maximum iteration number is reached.

Case	β_1	β_2	β_3	β_4	m_1	m_2	m_3
Starting values, set I	1.000	1.300	.6000	.1000	1.000	2.000	1.200
Starting values, set II	1.000	.5000	.6000	.1000	.5000	1.000	1.200
Starting values, set III	.3000	.5000	.6000	.1000	.5000	2.000	2.000
Result, set I	1.098	.3000	.3009	.3245	.4443	.5395	.2848
Result, set II	1.089	.3000	.3001	.2883	.4359	.5731	.2676

Table 1: Starting and final values for dispersion design parameters of the periodic discrete systems.

Figure 5 illustrates the dispersion behavior for the obtained system for starting set I and III. Result obtained with set II is very similar to one obtained for set I. The obtained system satisfies the desired property of having a constant frequency branch for initial set I and II. Notably, this branch is crossed by another branch and it is formed by third frequency for wavenumbers $ak < 2.02$ and fourth frequency otherwise. Information about the order of frequencies was not specified in the algorithm. Such a behavior illustrates the advantage of the proposed approach over standard methods, where the objective is formulated with respect to a specific frequency. Solution obtained from the starting set III is different and it satisfies the rank deficit condition only at four out of five points.

Figure 4: Convergence of the surrogate objective for initial parameter set I (left) and set III (right).

Figure 5: Dispersion behavior of the designed periodic discrete system with prescribed constant frequency $\omega = 1.58$. Initial and final dispersion behavior for initial parameter set I (left) and set III (right).

Reduced-order technique presented in Section 4 is now applied to dispersion design problem. Dimension of the original system is $n_w n_{\text{rep}} = 25$. Here, three eigenmodes in span $n_l = 2$ and $n_u = 4$ per sampling pair is used. Thus, the problem is reduced to the size $n_w(n_u - n_l + 1) = 15$ as explained in equation (25). This reduction is not drastic and it only served to check algebraic correctness of the approach.

Similar results are obtained for three starting parameter sets, see Table 1 and Figure 6. For all initial sets, third branch crosses all target pairs and these solutions are considered as satisfactory.

The considered example is undetermined, i.e. it has seven parameters and five conditions to be fulfilled. It is not a surprise that more than one solution is inside the admissible set \mathcal{K} and they are obtained with the proposed approach. It is also clear that the influence of starting approximation and algorithm setting is significant.

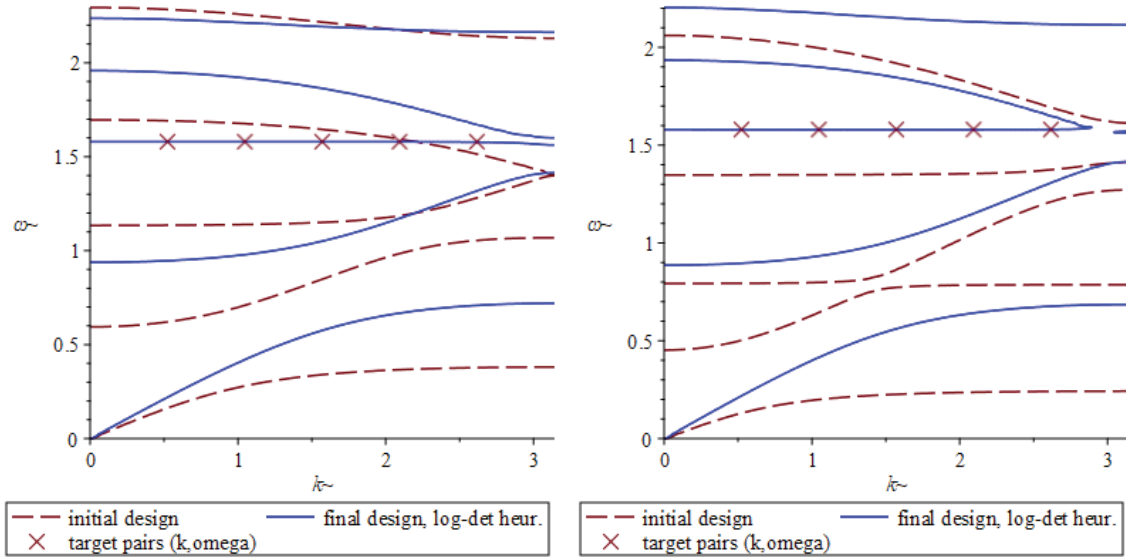

Figure 6: Dispersion behavior of the designed periodic discrete system with prescribed constant frequency $\omega = 1.58$. Initial and final dispersion behavior for initial parameter set II (left) and set III (right) obtained with reduced-order technique.

6 CONCLUSIONS

This contribution considers a special problem of design of 1D periodic discrete systems whose dispersion branch matches a prescribed dependency. For this problem, a new class of performance functions is proposed that explicitly depends on the design variables and does not require tracking of eigenmodes. This performance function is derived in several steps. First, a match to a dispersion branch is collocated in few discrete wavenumber-frequency pairs. Second, this match at discrete pairs is understood as the deficit of the representative dynamic stiffness matrix's rank. Thus, sum of these ranks is identified as a possible performance function and its reduction means quality improvement of the design. Third, the latter rank minimization problem is solved using log-det heuristics. Here, a modification for a case of square complex-valued matrices is proposed. Fourth, the log-det heuristics reduces the problem to a series of quadratic programming problems. The coefficients of the objective quadratic function are obtained here for the case of affine dependency of the mass and stiffness matrices on the free parameters.

Combining the proposed approach with reduced-order techniques is shortly discussed and a version of the reduced basis is proposed.

This approach is illustrated with several algebraic examples and one mechanical example. First algebraic example demonstrates the basic features of the rank minimization using log-det heuristic. Second algebraic example confirms the extension of the log-det heuristic for Hermitian semi-positive matrices. Third algebraic example demonstrates validity of projection-based reduction for rank minimization problems. Finally, a mechanical periodic system is considered and the concept of the dispersion design using log-det heuristic is demonstrated.

Further efforts may be focused on extending the approach to damped systems (achieving so-called metadamping [7]) and exploring the method for larger or multidimensional systems. Also, finding further explicit performance functions for different types of target dispersion behavior is of high scientific interest.

Keywords: Preconditioner, modal frequency response, iterative solver, complex eigenvalue problem

Abstract. *In frequency response analysis, it is of interest to simulate the dynamic response of a system for many excitation frequencies. In order to accelerate the calculation, the system is first transformed to modal space by calculating a limited set of eigenvectors and eigenvalues. In this way, the number of degrees of freedom can be reduced from e.g. 50 million to 50,000. However, due to the existence of structural and viscous damping, the system matrix in modal space is dense in a general case.*

In this work, a method to generate a preconditioner for the solution of modal frequency response is proposed. First, a decomposition of the system matrix at one excitation frequency is performed using a direct method (e. g. LU decomposition). In a second step, this decomposition is modified for different excitation frequencies in an efficient way, by using a complex eigenvalue problem. Although the modified decomposition is no longer exact, it has excellent characteristics to be used as a preconditioner in an iterative method. Using a complex eigenvalue problem and a decomposition update has already been proposed in [1] for a direct solution method. However, in this work, the focus is on an iterative method.

By making use of the structure of the system matrix, it is possible to split the product \mathbf{Ax} in the iterative solver in multiple parts to iterate many right hand sides (for equal or different excitation frequencies) at once. In this way, the iterative solver can make use of dense matrix-matrix multiplications, using BLAS Level-3 [6], which results in better performance.

1 INTRODUCTION

In modern finite element software (e.g. PERMAS [9]), an important problem is the calculation of the response of a system subject to harmonic loading. The system can represent a large finite element model such as a car (see figure 1), an aircraft or a ship. It is also important in the design of machine tools [3], spaceflight [4] or in acoustic analysis [5]. The dynamic response is calculated with frequency response analysis. This analysis is performed for many (e.g. 1000 or more) excitation frequencies. The solution at each excitation frequency requires the solution of a linear equation system with millions of unknowns in modern applications. In order to speed up the calculation, the dynamic system is typically transformed to modal space. This is achieved by calculating a limited number of eigenvalues and eigenvectors of the original system. The quality of the transformation depends on the dimension of the modal space, e.g. the number of calculated eigenvalues. !

Figure 1: Porsche 996, by courtesy of Dr. Ing. h.c. F. Porsche AG

In modal space, the mass and stiffness matrix are diagonal matrices, which is very convenient for the frequency response analysis. However, a finite element model also often contains damper elements or structural damping, which results in dense damping matrices in modal space. Kim and Benninghof [1] noted, one of the two dense matrices can be diagonalized in modal space by solving another complex eigenvalue problem. However, one dense matrix remains. If this matrix is of low rank, the inverse can be updated easily with the Woodbury matrix identity as noted by Kim and Bennighof. However, if the viscous damping matrix has full rank, there is no advantage in doing this.

In this work, an idea is presented to solve this problem with an iterative solver, where the inverse of the system matrix at a reference frequency is calculated and this solution is modified by solving a complex eigenvalue problem, similar to the work by Kim and Bennighof. The iterative solver could be a purely iterative method (e.g. Jacobi iteration) or a more sophisticated method like GMRES [2].

2 THEORY

In frequency response, the solutions $\tilde{\mathbf{x}} \in \mathbb{C}^n$ to the equation

$$\left(-\omega^2 \tilde{\mathbf{M}} + i\omega \tilde{\mathbf{D}} + i\tilde{\mathbf{H}} + \tilde{\mathbf{K}}\right) \tilde{\mathbf{x}} = \tilde{\mathbf{A}}(\omega) \tilde{\mathbf{x}} = \tilde{\mathbf{b}} \quad (1)$$

for different $\omega \in \mathbb{R}$ have to be calculated. $\tilde{\mathbf{M}} \in \mathbb{R}^{n \times n}$ is the mass matrix, $\tilde{\mathbf{D}} \in \mathbb{R}^{n \times n}$ is the viscous damping matrix, $\tilde{\mathbf{H}} \in \mathbb{R}^{n \times n}$ is the structural damping matrix and $\tilde{\mathbf{K}} \in \mathbb{R}^{n \times n}$ is

the stiffness matrix. In addition, on the right hand side, there is a loading vector $\tilde{\mathbf{b}} \in \mathbb{C}^n$. i represents the imaginary unit. The matrices $\tilde{\mathbf{M}}$, $\tilde{\mathbf{K}}$, $\tilde{\mathbf{D}}$ and $\tilde{\mathbf{H}}$ are symmetric in most cases, but they may also include rotational effects or special elements, that result in a non-symmetric problem. In this work, only the symmetric case is considered. Furthermore, it is assumed that the matrices $\tilde{\mathbf{D}}$ and $\tilde{\mathbf{H}}$ are positive semi-definite.

In modal frequency response, a generalized eigenvalue problem for $\tilde{\mathbf{K}}$ and $\tilde{\mathbf{M}}$ is solved for a limited number of eigenvalues m and the system is transformed to modal space. Using a transformation matrix Φ , we can transform the matrices to modal space: $\mathbf{M} = \Phi^T \tilde{\mathbf{M}} \Phi$, $\mathbf{D} = \Phi^T \tilde{\mathbf{D}} \Phi$, $\mathbf{H} = \Phi^T \tilde{\mathbf{H}} \Phi$, $\mathbf{K} = \Phi^T \tilde{\mathbf{K}} \Phi$. The load is transformed as $\mathbf{b} = \Phi^T \tilde{\mathbf{b}}$ and the displacement vector is $\mathbf{x} = \Phi^T \tilde{\mathbf{x}}$. Finally we arrive at the following equation system in modal space:

$$(-\omega^2 \mathbf{M} + i\omega \mathbf{D} + i\mathbf{H} + \mathbf{K}) \mathbf{x} = \mathbf{A}(\omega) \mathbf{x} = \mathbf{b}. \quad (2)$$

The transformed system has a diagonal mass matrix \mathbf{M} , a diagonal stiffness matrix \mathbf{K} and a dense viscous damping matrix \mathbf{D} and a dense structural damping matrix \mathbf{H} . The system size is reduced from $n \times n$ to $m \times m$. In this work, this system is investigated to be solved with an iterative method. In general, iterative methods need a preconditioner to converge within an acceptable number of iterations.

3 PRECONDITIONING

In order to judge the quality of the preconditioner, the convergence criterion of a purely iterative solver is used, because it is very simple and easy to understand. The equation $\mathbf{A}\mathbf{x} = \mathbf{b}$ is iteratively solved using a preconditioner \mathbf{P} . This means that every eigenvalue λ of $\mathbf{I} - \mathbf{P}^{-1}\mathbf{A}$ must fulfill

$$|\lambda(\mathbf{I} - \mathbf{P}^{-1}\mathbf{A})| < 1. \quad (3)$$

It is desirable to construct a preconditioner that works for k values $\omega_1 < \omega_i < \omega_k$. First, a reference circular frequency ω_{ref} with $\omega_1 < \omega_{\text{ref}} < \omega_k$ is selected and a direct solution method (e.g. LU decomposition) is used to calculate the inverse of $\mathbf{A}_{\text{ref}} = \mathbf{A}(\omega_{\text{ref}})$. However, this reference inverse is insufficient as a general preconditioner and it must be modified to adapt it to each individual circular frequency ω_i as will be seen later.

The idea consists of approximating the difference between $\mathbf{A}(\omega)$ and $\mathbf{A}(\omega_{\text{ref}})$ with a matrix \mathbf{S} and an ω -dependent scalar factor $f(\omega)$. This approximation of $\mathbf{A}(\omega) \approx \mathbf{P} = \mathbf{A}(\omega_{\text{ref}}) + f(\omega) \mathbf{S}$ is taken as preconditioner.

In general, the difference between $\mathbf{A}(\omega)$ and $\mathbf{A}(\omega_{\text{ref}})$ can be expressed as

$$\begin{aligned} \mathbf{A}(\omega) &= \mathbf{A}(\omega_{\text{ref}}) + ((\mathbf{A}(\omega) - \mathbf{A}(\omega_{\text{ref}}))) \\ &= \mathbf{A}(\omega_{\text{ref}}) + (-\omega^2 + \omega_{\text{ref}}^2) \mathbf{M} + i(\omega - \omega_{\text{ref}}) \mathbf{D} \end{aligned} \quad (4)$$

In this work, only an approximation of the mass matrix is considered. The reference matrix \mathbf{A}_{ref} is modified with the mass matrix \mathbf{M} , multiplied with a scalar function $f(\omega)$.

$$\mathbf{A}(\omega) \approx \mathbf{A}(\omega_{\text{ref}}) + (-\omega^2 + \omega_{\text{ref}}^2) \mathbf{M} = \mathbf{A}(\omega_{\text{ref}}) + f(\omega) \mathbf{M} = \mathbf{P} \quad (5)$$

The expression is now transformed as follows,

$$\begin{aligned} \mathbf{P}^{-1} &= (\mathbf{A}_{\text{ref}} + f(\omega) \mathbf{M})^{-1} = (\mathbf{A}_{\text{ref}} (\mathbf{I} + \mathbf{A}_{\text{ref}}^{-1} \mathbf{M} f(\omega)))^{-1} \\ &= (\mathbf{I} + \mathbf{A}_{\text{ref}}^{-1} \mathbf{M} f(\omega))^{-1} \mathbf{A}_{\text{ref}}^{-1} \end{aligned} \quad (6)$$

Next, we solve a complex eigenvalue problem of $\mathbf{A}_{\text{ref}}^{-1} \mathbf{M} = \mathbf{Q} \mathbf{\Lambda} \mathbf{Q}^{-1}$. We can now replace $\mathbf{A}_{\text{ref}}^{-1} \mathbf{M}$ with an orthonormal eigenvector matrix \mathbf{Q} and the eigenvalue diagonal matrix $\mathbf{\Lambda}$:

$$\begin{aligned} \mathbf{P}^{-1} &= (\mathbf{A}_{\text{ref}} + f(\omega) \mathbf{M})^{-1} = (\mathbf{Q} \mathbf{Q}^{-1} + f(\omega) \mathbf{Q} \mathbf{\Lambda} \mathbf{Q}^{-1})^{-1} \mathbf{A}_{\text{ref}}^{-1} \\ &= \mathbf{Q} (\mathbf{I} + f(\omega) \mathbf{\Lambda})^{-1} \mathbf{Q}^{-1} \mathbf{A}_{\text{ref}}^{-1}. \end{aligned} \quad (7)$$

This expression for \mathbf{P}^{-1} is quite interesting, because first the right hand side is multiplied with the reference inverse $\mathbf{A}(\omega_{\text{ref}})^{-1}$ and then with the eigenvector matrices \mathbf{Q} and a diagonal matrix, that is different for each ω . With the definitions $\mathbf{U} = \mathbf{Q}$, $\mathbf{V} = \mathbf{Q}^{-1} \mathbf{A}_{\text{ref}}^{-1}$ and $\mathbf{G}(\omega) = (\mathbf{I} + f(\omega) \mathbf{\Lambda})^{-1}$, we can write this as

$$\mathbf{P}^{-1} = (\mathbf{A}_{\text{ref}} + f(\omega) \mathbf{M})^{-1} = \mathbf{U} \mathbf{G}(\omega) \mathbf{V}. \quad (8)$$

As can be seen, the only term that is ω -dependent is \mathbf{G} , which is a diagonal matrix. In the next section, it will be shown that this preconditioner can be evaluated in a very efficient manner.

However, first, the preconditioner quality is discussed. GNU Octave [7] is used for the evaluation of the eigenvalues. A matrix \mathbf{A} of the size $m = 100$ is selected, which corresponds to 100 modes calculated. The stiffness matrix \mathbf{K} is the identity matrix in modal space. The mass matrix \mathbf{M} is also diagonal and we set the value of \mathbf{M} equal to $M_{ii} = 1/i^2$, which corresponds to circular eigenfrequencies $\omega_i = i$. Furthermore symmetric, positiv semi-definite matrices are chosen for \mathbf{H} and \mathbf{D} . The eigenvalues of \mathbf{H} and \mathbf{D} are set to be randomly equally distributed between 0 and d_{max} or h_{max} , respectively. In addition, we select a reference frequency $\omega = 50$ and look at the absolute largest eigenvalue between $\omega = 0$ and $\omega = 100$. Depending on the seed of the random generator, the eigenvalues of $\mathbf{I} - \mathbf{P}^{-1}(\omega) \mathbf{A}(\omega)$ look slightly different, but the general picture is as seen in figure 2 and 3.

Figure 2: Plot of the absolute largest eigenvalue of $\mathbf{I} - \mathbf{P}^{-1}(\omega) \mathbf{A}(\omega)$ for two different preconditioners, inverse only and inverse with mass matrix modification. $d_{\text{max}} = 1.0 \times 10^{-4}$

Figure 3: Plot of the absolute largest eigenvalue of $\mathbf{I} - \mathbf{P}^{-1}(\omega) \mathbf{A}(\omega)$ for two different preconditioners, inverse only and inverse with mass matrix modification. $d_{\max} = 1.0 \times 10^{-2}$

Using these definitions for \mathbf{M} , \mathbf{D} , \mathbf{H} and \mathbf{K} , figures 2 and 3 show the absolute largest eigenvalue of $\mathbf{I} - \mathbf{P}^{-1}(\omega) \mathbf{A}(\omega)$ for different values of d_{\max} . As can be seen in the figure, at $\omega = \omega_{\text{ref}}$, the absolute largest eigenvalue is zero as expected. The inverse is - of course - the perfect preconditioner. For other frequencies the absolute largest eigenvalue is monotonously rising with ω . If only the inverse at the reference circular frequency ω_{ref} is taken as preconditioner, it can be seen that the absolute largest eigenvalue is rising quickly, depending on damping d_{\max} . The higher the damping, the better the inverse for neighbouring frequencies. If the inverse is modified with the above mentioned approach, the largest absolute eigenvalue is rising much more slowly and remains below or equal to 1 in the investigated interval. Even in cases, where the inverse-only preconditioner rises quickly as seen in figure 2, the absolute largest eigenvalue of the modified inverse stays below 1. The reason for this will be investigated in future work.

4 IMPLEMENTATION

In order to use this formulaton, it is useful to have an efficient evaluation of the product $\mathbf{A}(\omega) \mathbf{x}$ and the application of the preconditioner. The matrix is defined as

$$(-\omega^2 \mathbf{M} + i\omega \mathbf{D} + i\mathbf{H} + \mathbf{K}) \mathbf{x} = \mathbf{b}. \quad (9)$$

In an iterative solver, the desired value is the residual \mathbf{r} with

$$\mathbf{r} = \mathbf{b} - (-\omega^2 \mathbf{M} + i\omega \mathbf{D} + i\mathbf{H} + \mathbf{K}) \mathbf{x}. \quad (10)$$

This can be rearranged to

$$\mathbf{r} = \mathbf{b} + \mathbf{M}\mathbf{x}\omega^2 - i\mathbf{D}\mathbf{x}\omega - i\mathbf{H}\mathbf{x} - \mathbf{K}\mathbf{x}. \quad (11)$$

By defining the matrix

$$\mathbf{\Omega} = \begin{bmatrix} \omega_1 & 0 & \cdots & 0 \\ 0 & \omega_2 & \ddots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & \omega_q \end{bmatrix} \quad (12)$$

and assembling q right hand sides

$$\mathbf{B} = [\mathbf{b}(\omega_1) \quad \mathbf{b}(\omega_2) \quad \cdots \quad \mathbf{b}(\omega_q)], \quad (13)$$

it is possible to calculate residuals for multiple right hand sides with different ω_i at once instead of calculating each vector \mathbf{x} with a different $\mathbf{A}(\omega)$. With the iteration vectors

$$\mathbf{X} = [\mathbf{x}(\omega_1) \quad \mathbf{x}(\omega_2) \quad \cdots \quad \mathbf{x}(\omega_q)] \quad (14)$$

the \mathbf{R} can be expressed as

$$\mathbf{R} = \mathbf{B} + \mathbf{MX}\mathbf{\Omega}^2 - i\mathbf{DX}\mathbf{\Omega} - i\mathbf{HX} - \mathbf{KX}. \quad (15)$$

The preconditioner is applied to the residual \mathbf{r} in order to get an increment on \mathbf{x} :

$$d\mathbf{x} = \mathbf{P}^{-1}\mathbf{r} = \mathbf{UG}(\omega)\mathbf{Vr}. \quad (16)$$

The diagonal matrix $\mathbf{G}(\omega)$ can be converted to a column vector \mathbf{g} . Next, preconditioner vectors for multiple right hand sides can be assembled to form a matrix

$$\mathbf{G}_R = [\mathbf{g}(\omega_1) \quad \mathbf{g}(\omega_2) \quad \cdots \quad \mathbf{g}(\omega_q)]. \quad (17)$$

In other words, just like the product $\mathbf{A}(\omega)\mathbf{x}$, also in this case multiple vectors can be iterated at once:

$$d\mathbf{X} = \mathbf{P}^{-1}\mathbf{R} = \mathbf{U}(\mathbf{G}_R \odot (\mathbf{VR})). \quad (18)$$

Here \odot symbolizes the Hadamard product [8]. The Hadamard product is a entry-wise multiplication of matrices. Both matrices must have the same dimension. The total operation count per iteration and vector is a bit higher than compared to the case, where each vector is iterated with the assembled matrix. However, modern CPU architecture is limited by memory bandwidth and the proposed method can make full use of the CPU as only dense matrix multiplication are performed. These can be efficiently performed with Level-3 BLAS [6], for example. A benchmark test case will be performed in future work.

5 CONCLUSIONS

In this work, the construction of a preconditioner for modal frequency response has been presented. The inverse of the system matrix is calculated at a reference frequency with a direct solution method (e.g. LU decomposition). The decomposition is modified by first solving a complex eigenvalue problem. By solving a complex eigenvalue problem, the frequency specific modification information is limited to diagonal matrices. These diagonal matrices can be transformed to a column vector and efficiently evaluated by performing a Hadamard product with the iteration vectors. The absolute value of the eigenvalues of $\mathbf{I} - \mathbf{P}^{-1}\mathbf{A}$ are below or equal 1, if the reference frequency is in the middle of the interval of interest. The absolute largest eigenvalue of $\mathbf{I} - \mathbf{P}^{-1}\mathbf{A}$ is slowly rising from zero at the reference frequency to 1 at the integration bounds.

Abstract

High-rise buildings with unusual shapes and high-technological systems are commonly used by companies to represent their economic power. In many cases, equipment consisting of LED screen walls is frequently not compatible with wind-induced displacements and accelerations experienced at high floors. The aim of the research work is to design and optimize a control device for response reduction of a prismatic room equipped with LED screen walls on all sides. The control system is a passive sliding device located at the base of the room disconnecting the LED supporting frame from the building's floor. Fragility analysis is carried out to compute the probability of exceeding predetermined displacements and acceleration thresholds with and without the control system.

Keywords: Video walls, high-rise building, wind-induced vibration, wind tunnel tests, base isolation.

1 INTRODUCTION

The wind induced vibration is an important topic for high-rise building with unusual shape because torsional effects and large oscillation along and across wind may affect the occupants' comfort largely discussed in literature [1-7]. A few information and recommendations are given by codes and literature for non-structural elements inside buildings that can be severely damaged and therefore can influence costs of construction and maintenance. This is the case of LED screen walls which are used to disseminate entertainment messages and information. They are sensitive to the floor wind induced vibration that can give significant deformation to the wall and a consequent malfunctioning or collapse.

The LED screen walls operation is frequently not compatible with wind-induced displacements and accelerations experienced at high floors in high-rise buildings. The proper functioning of these high-technological devices can therefore require the installation of local control systems to reduce wind induced vibrations.

In this paper, the wind-induced response of a LED video screen room was reduced by means of passive control system consisting in a base isolated floor which disconnects the substructure from the building. The probability of exceeding predetermined displacements and acceleration thresholds with and without the control system was investigated through fragility analysis based on the PEER integral equation [8-10]. This allows to consider all the possible sources un uncertainties involved in the problem, like those related to wind load characterization, structural modeling and analysis and damage occurrence [11-14]. Calculation was computed on the high-rise building illustrated in Fig.1 and discussed in Section 3. Metti un riferimento ad un tuo articolo precedente

2 PROBABILITY-BASED DESIGN APPROACH

The proposed methodology for the design of video screen rooms inserted in high-rise buildings accounts for randomness in the load characterization, the structural response estimation and the damage occurrence and exploits the PEER (Pacific Earthquake Engineering Research) equation [8, 9]. The annual probability of exceeding a selected level of damage is computed as follows:

$$P_f\left(\frac{Z}{H}, DS\right) = \int \int P(DS|EDP) f\left(EDP|IM, \frac{Z}{H}\right) f\left(IM|\frac{Z}{H}\right) dEDP dIM \quad (1)$$

where DS is the selected damage state; EDP is the engineering demand parameter associated to the i -th DS ; $P(DS|EDP)$ is the fragility curve, i.e. the complementary cumulative distribution function (CCDF) evaluated for the specific $EDP(DS)$ under investigation; the term $f(IM|Z/H)$ represents the probability density function (PDF) of the intensity measure (IM), i.e., the reference mean wind speed evaluated at Z/H ; the term $f(EDP|IM, Z/H)$ represents

the probability density function (PDF) of the selected *EDP* conditional on the value of IM. This probability is evaluated by considering the *N* experimental realizations of the structural response components (*EDP*) evaluated from the FE model.

The *EDP* are associated to the lateral deformation of a video component (i.e. with and without isolation system); the hammer effect on the corner (i.e. with and without isolation system); acceleration-dependent damages on mechanical components (i.e. with and without isolation system); the achievement of the maximum allowable stroke of the base isolation system.

3 THE CASE STUDY

3.1 The structural setup

The case study structure is a 300 m high building with 138×138 m footprint. The building has 60 floors above ground and interstory height of 5.00 m [15]. It is assumed that inside the building a technological equipment is inserted consisting in LED screens joined to one another to reproduce screen walls on the lateral surfaces of the room, on the ceiling and on the floor. The screens are supported by a pultruded GRP-Tubes substructure (Fig.2) that is pinned to the building floors. A Finite Element Model of the substructure has been built, using frame and shell elements to perform dynamic analyses.

Fig. 2 Numerical model of the pultruded GRP-Tubes substructure

3.2 Wind tunnel setup

The floors' accelerations obtained from wind tunnel tests on a 1:400 reduced scale aeroelastic model of the tall building are used to evaluate the response of the substructure. Accelerations were acquired on an aeroelastic model with a sampling frequency equal to 1000 Hz for a time length equal to 180 s. At the prototype scale it corresponds to a time step equal to 0.05 s and a time length equal to 9000 s (i.e. 15 intervals 10 minutes long). Figure 3 shows a picture of the

test model during experiments. The model was equipped with 6 mono-directional accelerometers fixed on 6 floors. The main frequency of the aeroelastic model was equal to 5.86 Hz and the structural damping ratio was around 2%. The wind velocity profile was assumed equal to the Terrain IV given by [16].

Figure 3: Test model during experiments.

Figure 4 shows the relative peak displacements at the corner of the substructure illustrated in Fig.2. Results illustrated in Fig.4 suggest that after the 30th floor and for a wind speed bigger than 40 m/s at the building top, the substructure's displacements and accelerations are not compatible with the proper functioning of the video screens. Indeed, to avoid damage to video wall components, the relative displacements should be contained within a few millimeters. Therefore, it can be suitable equipping the substructure with devices able to reduce the video room response, to avoid damage and ensure proper operating conditions.

Figure 4: Relative (δ) peak displacements as a function of wind velocity (U) and height above ground (z/H) at corner of the substructure.

3.3 The base isolation system

To reduce the wind-induced vibration response, a passive control system is designed, consisting in a base isolated floor which disconnects the substructure from the building. The behavior of the base isolation devices has been modeled by a bilinear force-displacement hysteretic model, with K_s being the stiffness associated to the second branch. The model consists of a spring and a slider and it is similar to devices used for the protection of industrial equipment [17]. The period of the system is defined as $T=2\pi(M/K_s)^{0.5}$ where M is the structure's mass and K_s represents the spring's stiffness.

Figure 5 shows the results of the parametric analysis on the variation of the device's period T and the friction coefficient μ for the case $z/H=1$ and $U = 111.8$ m/s, in terms of relative displacements δ (Fig. 5). The period T varies with the change of K_s , whose interval of investigation ranges from 0.18 to 2793 kN/m. Three different values of the friction coefficients $\mu = 0.1$, $\mu = 0.3$, $\mu = 0.5$ are considered. From the figure it is possible to observe that the relative displacements (δ) are closely reduced with respect to those obtained without the isolation system.

Figure 5: Corner's relative displacements δ as a function of the period T of the base isolation device.

3.4 The damage limit states

The main objective of the present paper is the evaluation of the probability-based performance of a video wall room integrated in a high-rise building by accounting for the occurrence of damages associated to the video components with and without a base isolation system. Hence, four different DS are considered (Table 1): the lateral deformation of a video component; the hammer effect on the corner; acceleration-dependent damages on mechanical components; the achievement of the maximum allowable stroke of the base isolation system.

The isolator has the capacity of providing the restoring force (given by the spring) and the capacity of limiting the maximum displacements (given by the friction force originated at the slider). Consequently, a force is transmitted to the structure equal to the combination of the friction force, due to the friction of the slider, and the reaction force of the spring as a function of the stiffness of the spring.

Table 1 Damage limit states and thresholds considered for the design of the video wall room.

Type of damage (DS)	Classification	<i>EDP</i>
DS1: Lateral deformation of a video component	Non-structural	Δ
DS2: Hammer effect on the corner	Non-structural	δ
DS3: acceleration-dependent damages on mechanical components	Non-structural	a
DS4: achievement of the maximum allowable stroke of the base isolation system	Structural	ΔL

In Table 1, Δ and a represent the absolute displacement and acceleration of the video's supporting structure, δ is relative displacement of two orthogonal faces of the supporting structures, ΔL refers to the base isolation system's stroke.

4 EVALUATION OF DAMAGE PROBABILITY

The calculation of $P_f(\frac{Z}{H}, DS)$ defined in Eq. 1 can be summarized according to the following steps:

1. Select the damage state DS and evaluate the corresponding fragility curve $P(DS|EDP)$ by means of a lognormal distribution. The selected values of μ and σ are reported in Table 2.
2. Evaluate the PDF of mean wind speed annual maxima $f(IM|Z/H)$ at the reference height Z/H according to [18] for suburban terrain, which is compatible with the mean wind profile of the wind tunnel tests.
3. Evaluate the maximum structural response component EDP for each realization of the experimentally recorded acceleration, i.e., 15 values.
4. Assess the PDF of EDP by means of a GEV distribution that gives the best fitting of the experimental values.
5. Repeat steps 4-5 for all possible IM values to find P_f by sampling.

Table 2 Fragility curves: mean values and standard deviations [14].

Parameters	Δ	δ	a	ΔL
μ	0.01 m	0.002 m	0.5 g	0.1 m
σ	0.5	0.5	0.6	0.5

5 NUMERICAL RESULTS

Figure 6 shows the annual damage probabilities P_f of DS1, DS2, DS3 and DS4, as a function of the height above ground z/H for video wall room integrated in a high-rise building by accounting for the occurrence of damages associated to the video components with and without a base isolation system. Reductions of more than 50% are noticeable at the top floor for DS1, DS2 and DS3. It is worth noticing that higher values associated to $z/H=0.83$ are due to relevant peak accelerations recorded during the wind tunnel tests. For this reason, the damage probability associated to DS4, which represent the exceeding of the maximum stroke of the base isolations system, is significant only for $z/H=0.83$.

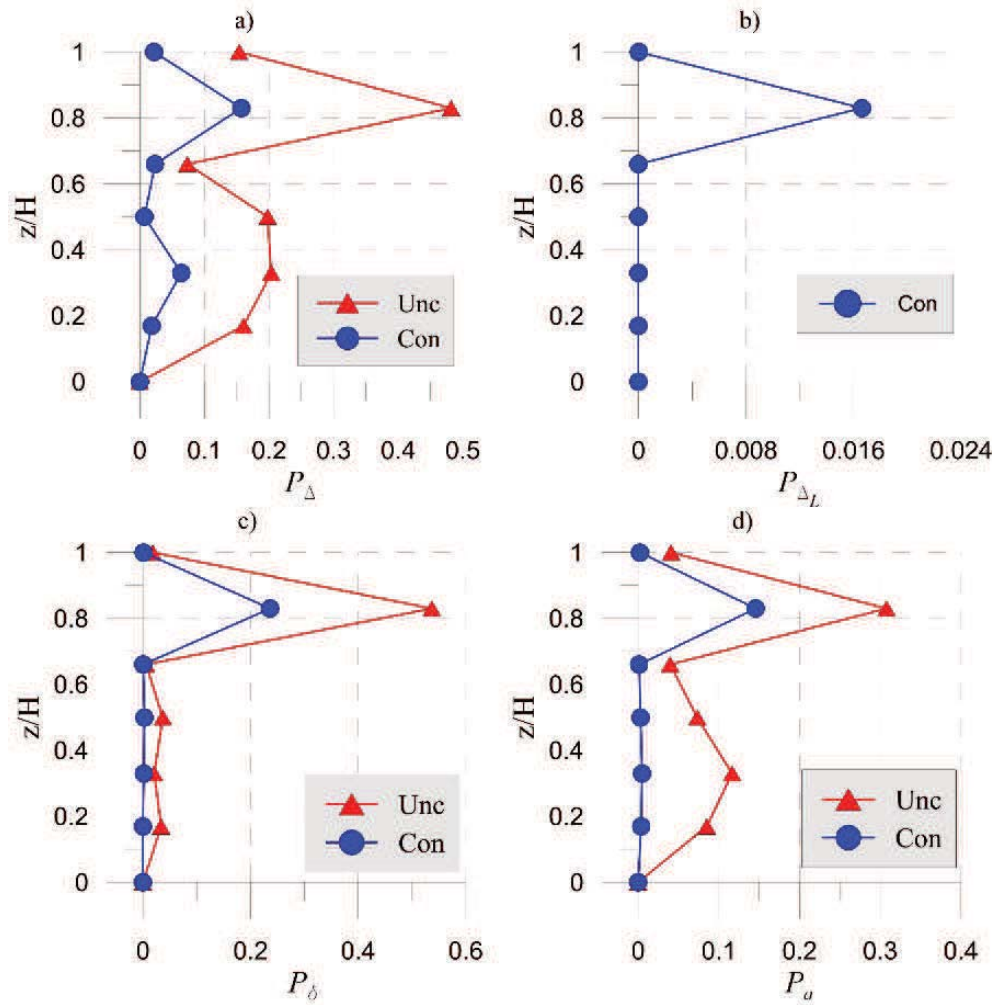

Fig. 6 Annual damage probability as a function of the floor height z/H varying between 0 and 1 with (Con) and without (Unc) the base isolation system: a) DS1; b) DS4; c) DS2; d) DS3.

6 CONCLUSIONS

The paper investigates the behavior of a base isolation system calibrated to increase the reliability of non-structural elements affected by wind induced acceleration at building's floors. A probabilistic framework for fragility assessment has been developed whose main features are:

- numerical simulations are carried out on a FE model of the video room by using the floors' accelerations measured during aeroelastic wind tunnel tests on a scaled model of the high-rise building .;
- uncertainties associated with the experimental assessment of the wind-induced accelerations and with the structural modeling and the damage estimation are considered;
- the parameters of the base isolation system with hysteretic non-linear behavior are calibrated as a function of location along the building height to avoid the excessive lateral deformation of the video components, the hammer effect at the corner, the acceleration-related damage and the exceedance of displacement limits of the isolation devices;
- the isolation system performance was discussed through a fragility analysis to compute the probability of exceeding predetermined displacements and acceleration

thresholds with and without the control system. It was observed that on the building top the reliability was increased of more than 50%.

7 ACKNOWLEDGEMENTS

A special thanks to the H-Sign srl company to sponsoring this research, to Prof. Giuseppe Piccardo and Dr. Andrea Freda for their advice and assistance during the experimental tests in the DICCA Wind Tunnel of the University of Genoa. Mr. Davide Perazzetti is grateful for his support during the model construction. Prof. Giuseppe Maddaloni, Prof. Antonio Occhiuzzi and Prof. Andrea Prota are gratefully acknowledged for their support during the experimental model dynamic identification through shaking table experiments at the University of Napoli Federico II, Italy.

Abstract

Fragility curves are a well-established tool to define probabilistically the vulnerability of an asset to a prescribed hazard. The majority of previous studies have investigated the seismic fragility of structures and infrastructures. Nonetheless, recent disasters have highlighted the need to assess the vulnerability of aging bridges to gravity loads. Based on existing data from the literature and novel data from some real case studies, the present work presents analytical fragility curves of Italian bridges to traffic loads. The class of simply supported, beam-type, prestressed concrete bridges constructed between 1960 and 1980 was considered, given that those structures are the most recurrent type of existing Italian bridges. Then, a fragility analysis was performed through a fully automated procedure implemented in MATLAB. Geometric, material and load parameters were defined as random variables considering their probability distribution and correlation through either univariate or multivariate models. Structural fragility was evaluated with respect to the limit state of collapse. The output of this study can be of interest to engineers and decisions makers who must manage existing bridges, considering their probability of collapse under traffic loads and eventually limiting their use before structural retrofitting.

Keywords: Prestressed concrete bridges; traffic loads; fragility; collapse limit state.

1 INTRODUCTION

Structural safety of existing bridges is involving the worldwide engineering community during the last years due to recent casualties. In the aftermath of the Polcevera bridge collapse in Genoa in 2018 [1], an increasing attention has been paid towards safety evaluation and monitoring of existing bridges with a service life approaching to or even exceeding 50 years. This trend also led to new Italian guidelines for classification, safety checks and monitoring of existing bridges issued by the High Council of Public Works in April 2020 [2]-[4]. During the last years, overloads, collisions, flood and environmental degradation caused more than 80% of the total collapse cases [5]–[7][7]. Furthermore, the structural assessment and retrofiting of existing bridges is urgently needed also because of aging and material deterioration, lacking or ineffective maintenance, and climate change in multi-hazard environments involving both human-related and natural events.

The study of existing bridges should take into account the following points:

- (i) Traffic load conditions have been changing over time, i.e. different traffic loads were prescribed during original design in comparison with current code provisions.
- (ii) Materials adopted in the past are not compliant with modern building codes and may be affected by significant variability and deterioration.

In this study, the structural fragility of a class of existing Italian bridges subjected to traffic loads is studied according to code-conforming capacity models and analysis procedures [8][8]. The most important properties of the bridge decks were probabilistically modelled based on available data, randomly sampled via Monte Carlo technique, and propagated through structural analysis. Fragility analysis was fully implemented in MATLAB software [9][9], providing the conditional probability of collapse given the intensity level of code-conforming traffic loads.

2 METHODOLOGY

This study aims to define the vulnerability of existing Italian bridges subjected to code-compliant traffic loads. Previous studies investigated the seismic fragility of bridges, but recent disasters highlighted the need for a comprehensive investigation on their vulnerability to human-induced loads. A class of simply supported, beam-type, prestressed concrete (PC) bridges was considered, since they represent more than 90% of the total bridge population in Italy [10][10]. Previous studies [10][10]–[12][12] also reported that the time frame 1960–1980 is the period when the highest number of bridges were built due to Italian economic growth and infrastructure development. In those decades, a relevant part of the Italian road network was built. Based on available data collected by the authors on real case-study bridges, the period 1970–1980 was chosen in order to carry out the fragility analysis of existing bridges. Figure 1 outlines the methodology used in this study to assess the vulnerability of existing bridges to traffic loads, the distribution and design values of which was defined according to the Italian building code [8][8].

The material, geometric and load uncertainty models were defined in order to generate a set of case studies through a Monte Carlo simulation. Demand and capacity analysis were carried out and the performance level of each model was calculated. The counted fragility was evaluated applying a frequentist approach. A lognormal distribution function was then fitted to fragility points in order to obtain fragility curves.

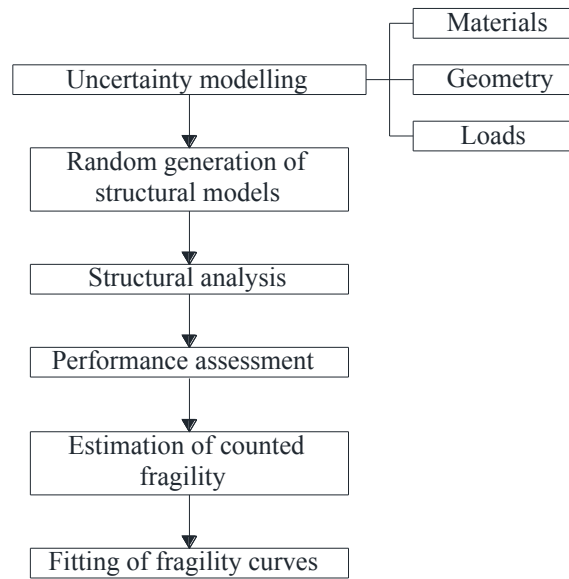

Figure 1: Flowchart of fragility analysis.

3 UNCERTAINTY MODELLING

Random variables (RVs) included both geometric and material properties. Based on [10][10] and some real case-studies, a subset of RVs were modelled through probability distributions, whereas other RVs were assumed to be statistically dependent upon the former RVs according to regression models. To that aim, the authors examined:

- geometric properties of 14 bridges built in the period 1960 to 1980;
- experimental data on mechanical properties of concrete (100 data), mild reinforcing steel (65 data), and prestressing steel (21 data) of bridges dating back to the period 1970–1980.

Case-study bridges have different locations in Italy and were built by different construction companies to be representative of the selected class of bridges. In the following sections, probability distributions and regression models are described.

3.1 Material properties

The database of material properties was based on laboratory test results of real case-studies collected by the authors. Figure 2a shows three alternative probability distributions fitted to experimental data to model the uncertainty in concrete compressive strength f_c , namely normal, lognormal and Weibull distribution. Based on best fitting, the lognormal distribution with mean value of 38.5 MPa and coefficient of variation (CoV) of 11.4% was assumed.

The same procedure was applied to derive a probability distribution for the yield strength f_y of mild steel (Figure 2b). Best fitting produced a lognormal distribution with a mean value and CoV equal to 436 MPa and 6.4%, respectively.

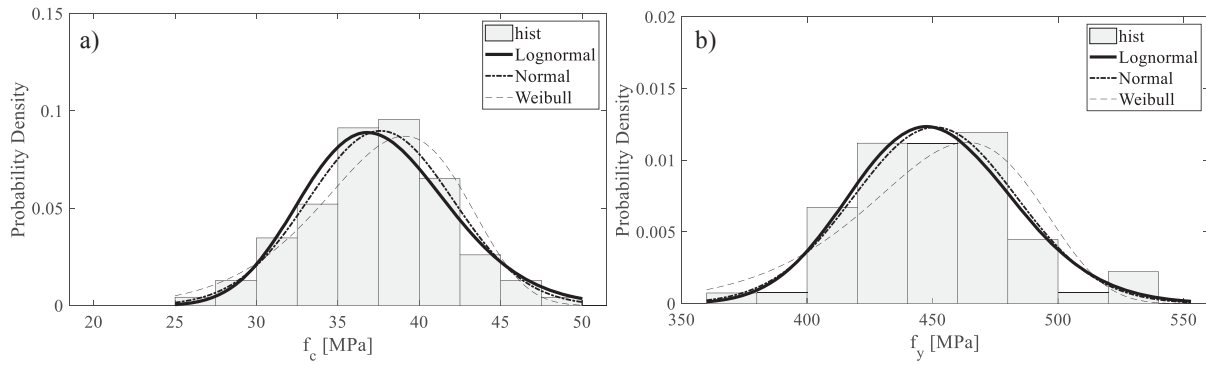

Figure 2: Probability distributions for (a) concrete compressive strength and (b) yield strength of mild steel.

A probability distribution was also fitted to experimental data on the conventional yield strength of prestressing steel $f_{p,01}$ (i.e., the tensile stress associated with a residual strain of 0.1%). A limited amount of data was collected by the authors and data were fitted by a lognormal distribution (Figure 3) with a mean value and CoV equal to 1665 MPa and 2.5%, respectively. These statistics agree well with different studies available in the literature (e.g., [13][13]–[15][15]).

Figure 3: Probability distribution for conventional yield strength of prestressing steel.

The weight per unit volume of reinforced concrete (RC) was modelled through normal distribution with mean and CoV equal to 25 kN/m³ and 5%, respectively, in order to account for the variability of permanent loads (G_{1k}). Non-structural permanent loads (G_{2k}) were modelled via a normal distribution with mean value and CoV equal to 2 kN/m² and 10%, respectively.

3.2 Geometry

Geometric properties were defined for simply-supported PC bridge decks built between 1960 and 1980. The cross sections of the deck and longitudinal girders are shown in Figure 4, highlighting the most relevant geometric properties considered in the analysis.

Figure 4: Cross sections of the bridge deck and longitudinal girder.

The span length (L) and width (W) of the deck were assumed as main independent RVs. Based on both literature [10][10] and case studies, the histogram of the bridge span length was derived. Approximately half of the existing bridges have a length between 30 m and 35 m, as depicted in Figure 5. A lognormal distribution was assumed, with a mean value equal to 33.2 m and $\text{CoV} = 13.6\%$. The distribution was truncated at 15 m and 45 m to obtain realistic values of the bridge length in subsequent probabilistic simulation.

Figure 5: Probability distribution of girder span length.

Regarding the deck width W , a probability mass function (PMF) with three values equal to 8.5, 12.25 and 16 m having the same probability of occurrence was assumed. The slab thickness (denoted by s) was modelled through a uniform distribution with a mean value and CoV equal to 0.25 m and 12%, respectively, in the range [0.2 m, 0.3 m].

The transverse reinforcement ratio ρ_{sw} (A_{sw}/p , where p is the distance between stirrups) and prestressing ratio of the tendons $\sigma_{sp}/f_{p,01}$ were considered as additional independent RVs. The former was modelled through a uniform distribution between 300 mm²/m (corresponding to 8-mm-diameter stirrups with 330mm spacing as per minimum code requirement) and 1130 mm²/m (corresponding to 12-mm-diameter stirrups with 200 mm spacing as maximum recorded value). The prestressing ratio was modelled in two different ways: (i) uniform distribution between 40% and 60%, (ii) PMF with 3 equally probable values equal to 40%, 50% and 60%. In this study, degradation of prestressing steel was not taken into account. The residual stress levels σ_{sp} take into account average values of relaxation loss due to concrete creep, shrinkage and relaxation of steel under tension [17][17].

The set of independent RVs is listed in Table 1, providing their distributions, mean μ and CoV.

Random variable	μ or discrete values	CoV [%]	Distribution
f_c [MPa]	34.70	24.40	Lognormal
f_y [MPa]	436.00	6.40	Lognormal
$f_{p,01}$ [MPa]	1665.00	2.50	Lognormal
L [m]	33.20	13.60	Lognormal
W [m]	8.50 – 12.25 – 16.00	-	PMF
s [m]	0.25	12.00	Uniform
ρ_{sw} [mm ² /m]	715.00	34.00	Uniform
$\sigma_{sp}/f_{p,01}$ [%]	50.00	12.00	Uniform
$\sigma_{sp}/f_{p,01}$ [%]	40.00 – 50.00 – 60.00	-	PMF
γ_c [kN/m ³]	25.00	5	Normal
G_{2k} [kN/m ²]	2.00	10	Normal

Table 1: Distributions and statistics of independent random variables.

3.3 Correlation models

Based on case-studies, regression models were developed in order to model RVs conditioned upon independent RVs. The following dependent variables were considered:

- number of longitudinal girders, n_b ;
- height of longitudinal girder, H_b ;
- area of girder cross-section, A_b ;
- width of girder top flange, B_{sup} ;
- distance of equivalent total prestressing area from top of girder cross-section, d_{sp} ;
- geometric ratio of prestressing steel ρ_{sp} multiplied by d_{sp} , $\rho_{sp} \cdot d_{sp}$.

In Table 2, the regression models used in this study are listed together with their coefficient of determination R^2 and boundaries.

RV	Regression model	R^2	Lower bound	Upper bound
$n_b (W)$	$n_b = 0.33 \cdot W$	0.51	2	8
$H_b (i_b, L)$	$H_b = 0.28 \cdot \frac{W}{n_b} + 0.03 \cdot L$	0.81	$H_b \geq L/20$	3.2 m
$A_b (H_b)$	$A_b = 0.43 + 0.06 \cdot H_b^2$	0.84	-	-
$B_{sup} (H_b) (G_{1k})$	$B_{sup} = 0.34 \cdot H_b + 0.02 \cdot G_{1k} - 0.02 \cdot H_b \cdot G_{1k} + 0.002 \cdot G_{1k}^2$	0.71	-	1.2
$d_{sp} (H_b)$	$d_{sp} = 0.98 \cdot H_b$	0.97	-	-
$d_{sp} \cdot \rho_{sp} (L)$	$\rho_{sp} \cdot d_{sp} = 8.16 \cdot 10^{-5} \cdot L + 1.85 \cdot 10^{-5} \cdot L^2$	0.88	$0.007 d_{sp}$	-

Table 2: Regression models

The following deterministic variables were assumed:

- concrete cover equal to 0.03 m;
- girder web equal to 0.2 m;
- bottom flange thickness equal to 0.3 m;
- geometric ratio of longitudinal reinforcing mild steel equal to 0.1%;

- Young's modulus of steel equal to 200 GPa.

4 STRUCTURAL ANALYSIS

The first stage of structural analysis consisted in the modelling of loads on the bridge deck. Self-weight of deck components was evaluated according to G_{1k} , sectional area of longitudinal girders and their effective width w_{eff} (which was equal to i_{beam}). Non-structural permanent loads were obtained according to G_{2k} and w_{eff} .

Traffic loads were defined according to the Italian building code [8][8] and Eurocode 1 – Part 2 [16][16]. The number of lanes adopted in the present study is either two or three, depending on the randomly generated geometry of the deck in order to maximize the strength demands on the edge girders (i.e., bending moment at mid-span or shear force at girder ends). The deck cross section was assumed to be rigid, according to design calculations at the time of construction and Engesser formulation [18][18]. The structural analysis procedure was implemented in MATLAB [9] in order to automatically define traffic load distributions which maximize bending moment and shear force on the edge girder.

Flexural and shear capacity models were also programmed in MATLAB to evaluate the collapse capacity of the edge girder as representative of the deck structural behaviour. The ultimate limit state (ULS) of the deck was thus defined as the attainment of either flexural or shear capacity in the edge girder.

The flexural capacity of the girder was evaluated on the basis of the following assumptions:

1. Plane cross section and perfect steel-concrete bond after flexural deformation;
2. maximum compressive concrete strain equal to 0.35%;
3. uniform stress distribution and zero tensile strength of concrete;
4. mild and prestressing steel with elastic-perfectly plastic behaviour and unlimited ductility;
5. yielded steel (i.e., to be checked in all cases after neutral axis is found).

Mild steel was defined through its geometric ratio ρ_s (e.g., 0.1%). The flexural capacity M_r of girder cross section was basically predicted through sectional analysis at ULS.

The shear capacity V_r of the girder was evaluated by enveloping three different capacity models provided by current codes ([8][8], [17][17]). The first model describes the capacity of a RC member in cracked conditions without shear reinforcement. The second model adopted in this study applies to PC beams in uncracked conditions. The third model applies to cracked RC beams with internal stirrups based on a strut-and-tie resisting mechanism.

5 COLLAPSE FRAGILITY OF CASE-STUDY BRIDGES

Fragility analysis was based on Monte Carlo sampling of independent RVs, which allowed the random generation of 10,000 model realizations based on their probability distributions. Regression models were then used to generate statistically dependent variables, considering the model error of each regression equation. The magnitude of traffic loads was defined through an intensity measure (IM) denoted as α and defined as the ratio between the incremental and design first-lane tandem load, i.e. $\alpha = Q_1/Q_{1d}$ with $Q_{1d} = 600$ kN. Structural analysis of each set of 10,000 deck models was carried out under varying α from 0 to 2.5 with step of 0.1. For each deck model, both flexural and shear capacities were computed.

The output of fragility analysis was the conditional probability of exceeding ULS given IM. The maximum demand-to-capacity ratio (DCR) between flexural DCR ($DCR_f = M_e/M_r$) and shear DCR ($DCR_s = V_e/V_r$) was assumed as limit state function. Accordingly, ULS was assumed to be attained or exceeded if DCR was equal to or greater than unity. Fragility was thus defined as follows:

$$P[DCR \geq 1 | IM = im] \quad (1)$$

After that counted fragilities were computed over the whole range of IM levels, fragility curves were fitted through a lognormal distribution.

Fragility curves associated with flexural and shear failure modes were initially derived separately, considering either discrete values (Figure 6a) and uniformly distributed values (Figure 6b) of prestressing ratio. In Figure 6, the lower x -axis indicates the selected IM chosen (i.e., α), whereas the upper x -axis provides the corresponding the first-lane tandem load Q_1 . Figure 6 shows the higher fragility of the existing Italian bridges under study in terms of flexural failure. Indeed, the median value η of the flexural fragility curve is lower than that of the shear fragility curve, regardless of the prestressing ratio. This means that the attainment of ULS is governed by flexural failure. As shown in Figure 6(a), shear fragility significantly reduces under increasing prestressing ratio. Table 3 outlines the median value, dispersion β (i.e., the logarithmic standard deviation) and R^2 of each fragility curve, evidencing that the lognormal distribution fits very well the fragility points as demonstrated by R^2 very close to unity.

Figure 6: Fragility curves associated with flexural and shear failure modes: (a) discrete distribution of prestressing ratio; (b) uniform distribution of prestressing ratio.

Failure mode or limit state	η	β	R^2
Flexural failure	1.69	0.31	0.99
Shear failure ($\sigma_{sp}/f_{p,01} = 40\%$)	2.04	0.23	
Shear failure ($\sigma_{sp}/f_{p,01} = 50\%$)	2.30	0.23	
Shear failure ($\sigma_{sp}/f_{p,01} = 60\%$)	2.57	0.24	
Shear failure ($\sigma_{sp}/f_{p,01}$ uniformly distributed)	2.30	0.24	
ULS	1.68	0.30	0.99

Table 3: Fragility parameters corresponding to flexural failure, shear failure, and ULS.

Figure 7 shows the fragility curve of the case-study bridges for the limit state of collapse, which is almost totally overlapped to that associated with flexural failure mode. However, the median value and dispersion are slightly different from those related to the flexural fragility curve because of a very rare occurrence of shear failure in some model realizations. Table 3 shows that the selected bridges have a median collapse traffic load equal to 1.68 times the design load, with a dispersion $\beta = 0.30$. It is also found that the conditional probability of collapse under design traffic load (corresponding to $\alpha = 1$) is $4.4 \cdot 10^{-2}$. Further studies are needed to assess the unconditional failure probability of collapse, namely, the failure probability derived as a convolution of fragility and traffic load hazard.

Figure 7: Collapse fragility curve of case-study bridges.

6 CONCLUSIONS

This study aimed at evaluating the fragility of existing Italian, simply supported, beam-type, prestressed concrete bridges. A fragility analysis procedure was implemented in MATLAB software to generate a set of 10,000 random samples of bridge deck models and carry out their structural performance assessment. The procedure starts considering a set of variables, including independent variables modelled through probability distributions, dependent variables evaluated through regression models, and deterministic variables. Assuming code-conforming traffic-load models, each bridge model was randomly generated according to Monte Carlo sampling technique and was analysed under incremental loading to detect the attainment of both flexural and shear failure modes. In this regard, three alternative capacity models were considered to predict shear resistance of edge longitudinal girders.

The fragility of Italian existing bridges was calculated by assuming the scale factor α of traffic loads as intensity measure IM, which was gradually incremented from 0 to 2.5. The demand-to-capacity ratio DCR was considered as limit state function, hence identifying the occurrence of flexure or shear failure modes. These latter were first probabilistically assessed separately and then considered altogether to develop the collapse fragility curve of the selected bridges. The large number of random samples allowed the estimation of collapse fragility according to a frequentist approach.

Analysis results show that the case-study bridges are significantly more vulnerable to flexural failure than to its shear counterpart. In addition, shear fragility reduces under increasing prestressing ratio.

On the basis of these outcomes, it can be inferred that flexural behaviour has a remarkable effect on the vulnerability of the considered class of existing bridges. These preliminary results suggest a prioritization scheme for structural retrofitting of existing bridges against traffic loads.

Abstract

Life-cycle cost analysis (LCCA) is used as a decision-making tool in the design phase to predict the expenses required over the lifetime of the bridge. The application of LCCA to bridges allows to consider different types of uncertainties such as those on loads, resistances, degradation and on the numerical modelling and structural response analysis. In this context, the present paper proposes a general framework for bridges' LCCA under multiple hazards based on the use of the PEER equation. It allows to account for the random nature of hazards and for structural and modelling uncertainties, considering in a unified manner different hazards concurring to damage occurrence. The approach is for the first time applied to cost and fragility analysis of bridges subjected to fatigue, highlighting the possibility of treating the problem of fatigue damage estimation with an approach similar to the one currently adopted for damage induced by other hazards, like earthquake and wind. Starting from the knowledge of the traffic load model, the gross vehicles weight is assumed as intensity measure (IM) and a fatigue damage index calculated through the Palmgren-Miner's rule is adopted as engineering demand parameter (EDP). The damage accumulation is evaluated by considering the time dependency of the fatigue damage index. The framework is applied to the case study of a composite steel-reinforced concrete multi-span roadway bridge located in central Italy. The evolution over time of the probability of failure and the life-cycle costs due to fatigue damage induced by heavy traffic loads are investigated.

Keywords: Life cycle cost, PEER equation, multi hazard analysis, fatigue damage.

1 INTRODUCTION

The correct definition of a life-cycle cost model for a bridge requires the preliminary selection of the limit states that could lead to bridge damage or collapse. The loads acting on the bridge are of different nature (earthquake, wind, traffic, degradation) and each one of them can lead to the achievement of more than one limit state. The main limit states which are taken into consideration in bridges are usually the achievement of the ultimate strength for bending and shear, the achievement of the serviceability limit states of deformation and stresses and the achievement of fatigue limit state [1]. In case of long-span bridges, aeroelastic limit states may also become important [2].

In this context, the fragility and cost assessment must be done exploiting a probabilistic approach to account for the random nature of hazards and for structural and modeling uncertainties, also considering in a unified manner different hazards concurring to damage occurrence. [3]. Several studies have addressed the problem of evaluating the expected life cycle cost of structures [4,5,6], including design applications of the main structure [7] and/or auxiliary damping systems [8,9,10], which is related to the probability of failure calculated through the PEER convolution integral [11] or through a reliability analysis based on the calculation of the reliability index [12].

The objective of this paper is the estimation of lifetime costs of roadway bridges with specific focus on costs related to fatigue damage. The paper presents a general and comprehensive methodology accounting for multiple-hazards and several limit states, exploiting the PEER convolution integral to compute the probabilities of failure related to life-cycle costs. The application of the PEER equation is subordinate to the definition of a hazard curve for each type of load (i.e. earthquake, traffic) and to the selection of the engineering response parameters characterizing the damage limit states (forces, deformations, tensions and accelerations). The limit state conditions are expressed through fragility functions which lead to the determination of the probability that a damage threshold is exceeded [13].

The proposed framework is particularized to the case of bridges subjected to fatigue damage. The estimation of fatigue-related probability of failure using the PEER framework is a novelty in the scientific literature and allows to insert the evaluation of fatigue-damage induced costs in a comprehensive and unified framework for life-cycle cost assessment of bridges.

2 METHODOLOGY FOR LCCA OF BRIDGES

2.1 General LCCA methodology in case of multiple-hazards

The general formulation of the expected value of the total cost in the lifetime of a bridge, considering several hazard types and limit states at the same time, can be expressed through the following expression:

$$E[C(L_t)] = C_0 + \sum_{t=1}^{L_t} \left[\frac{C_m(t) + C_i(t)}{(1+r)^t} + \sum_{h=1}^H \sum_{j=1}^J \sum_{s=1}^S \frac{E[C_{j,s,h}(t)]}{(1+r)^t} \right] \quad (1)$$

where $E[.]$ denotes the expected value operator; L_t is the lifetime of the bridge expressed in years; J is the total number of the considered limit states; S is the total number of analyzed sections; H is the total number of the considered hazards; C_0 is the initial cost of the bridge that includes the costs for design, testing, construction, terrain purchase and safety burdens; $E[C_{j,s,h}]$ is the expected value of the cost of the j -th limit state being reached in the s -th section of the bridge and due to the h -th hazard, including cost of damage and repair; C_m is the maintenance cost per year; C_i is the inspection cost per year; r is the discount rate.

The total expected normalized cost is evaluated through normalization of the Eq. (1) with respect to the initial cost C_0 as follows:

$$c(L_t) = E \left[\frac{C(L_t) - C_0}{C_0} \right] = \sum_{t=1}^{L_t} \left[\frac{c_m(t) + c_i(t)}{(1+r)^t} + \sum_{h=1}^H \sum_{j=1}^J \sum_{s=1}^S \frac{E[k_{j,s,h}(t)]}{(1+r)^t} \right] \quad (2)$$

where $c_m = C_m / C_0$, $c_i = C_i / C_0$ and $k_{j,s,h}$ can be defined as follows:

$$k_{j,s,h} = \begin{cases} \frac{c_j P_{j,s,h}}{C_0} & \text{if } P_{j,s,h} < \bar{P} \\ \frac{c_r}{C_0} & \text{if } P_{j,s,h} = \bar{P} \end{cases} \quad (3)$$

where c_j is the failure cost related to the j -th limit state, c_r is the repair cost per unit length, \bar{P} is the probability threshold beyond which the repair cost is required and $P_{j,s,h}$ can be evaluated by using the PEER convolution integral, as follows:

$$P_{j,s,h} = \int \int P(DS|EDP) f(EDP|IM) f(IM) dEDP dIM \quad (4)$$

where IM is the intensity measure related to the h -th hazard; EDP is the engineering demand parameter at section s ; DS is the damage state associated to the achievement of the j -th limit state; $P(DS|EDP)$ is the fragility curve (the complementary cumulative distribution function of DS conditioned to the occurrence of EDP); $f(EDP|IM)$ is the probability density function (PDF) of EDP conditional on IM; $f(IM)$ is the PDF of IM.

The earthquake and the traffic are the main hazards stressing a bridge. For seismic risk assessment, it is necessary to conduct a probabilistic analysis considering the site where the structure is located, the possible presence of nearby faults and the different magnitudes associated with the return period. By knowing this information, it is possible to determine the hazard curve that shows the variation of IM parameter versus the annual average of exceedance. In the earthquake case, the intensity measure (IM) can be defined as the spectral acceleration, the peak ground acceleration or the magnitude. The engineering parameters demand (EDPs) can be represented by internal forces, deformations, displacements or accelerations. The use of an EDP is specifically related to the analyzed limit state. For example, in the case of piers it is possible to use as EDP the displacement of the piers, which is closely linked to the bending and shear stresses that occur due to the seismic event.

2.2 LCCA methodology for bridges subjected to fatigue limit state

In this Section, the methodology is particularized to the LCC analysis of bridges subjected to fatigue damage due to traffic load.

The proposed methodology adopts as IM the gross vehicle weight (GVW). The traffic hazard curve, whose first derivative is the $f(IM)$ in the PEER equation, is specific for the analyzed bridge and represents the annual relative frequency of vehicles passages as a function of the GVW. It can be obtained following two different procedures:

1. exploiting information provided by the National Standards that give the annual traffic composition;
2. using monitoring data obtained from a Weight-In-Motion (WIM) system capable of detecting the total weights and the number of the vehicles that annually pass through the bridge.

The proposed methodology adopts the fatigue damage index (D) calculated through the Palmgren-Miner's rule, as EDP [14]:

$$D = \sum_i \frac{n_i}{N_i} \quad (5)$$

where n_i is the number of cycles associated with the stress range $\Delta\sigma_i$ and N_i is the corresponding cycles to failure obtained from the S-N Wöhler curve [15]. The time histories of the internal forces and the corresponding stresses at the analyzed sections are determined from the knowledge of the influence line of each type of vehicle and using the rainflow cycle counting method [16].

Exploiting Eq. (4) it is possible to determine the annual probability of exceeding the fatigue limit state due to traffic load. The following steps are carried out for the computation of the PEER equation:

- partition of the GVW range, available from WIM data or from National Standards, in a set of intervals. Knowing the annual number of passages corresponding to the vehicles comprised in each subinterval, it is possible to determine a relative frequency diagram of GVW which is used to obtain the probability distribution of GVW, i.e., $f(\text{IM})$ (Figure 1 (a));

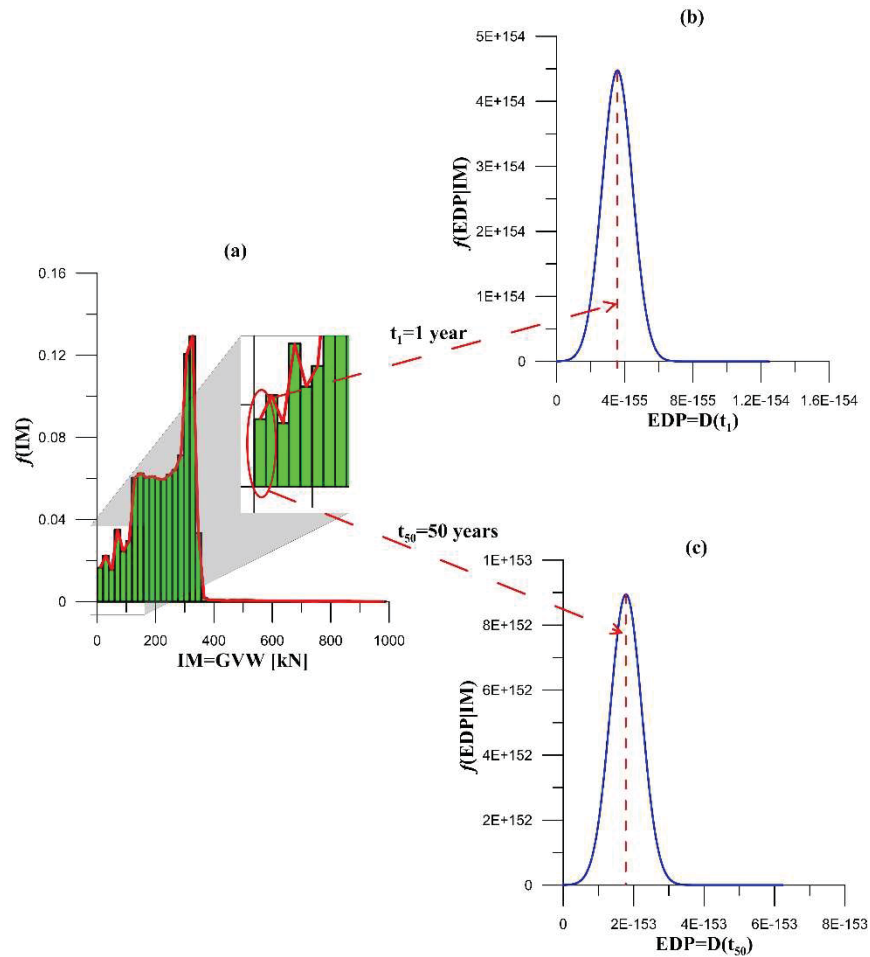

Figure 1. Probability density function of IM (a), probability density functions of EDP for different operating years: $t_1 = 1$ year (b) and $t_{50} = 50$ years (c).

- for each k -th subinterval of GVW, a damage index D_k is computed as the sum of the damage indices of the vehicles belonging to the k -th subinterval, exploiting Eq. (5). D_k is assumed as the mean value of the EDP conditional on IM, $f(\text{EDP}|\text{IM})$. A normal distribution is adopted for $f(\text{EDP}|\text{IM})$, with mean value equal to D_k and a coefficient

of variation (COV) taken from literature, accounting for uncertainties in traffic load model characterization and response parameters estimation (Figure 1 (b-c)). To account for damage accumulation over time, the probability distribution of EDP is modified over years. In particular, for each k -th subinterval of GVW, the mean value of D at time t_i , is obtained as the sum of $D_k(t_{i-1})$ and $D_k(t_i)$. Moreover, if the traffic model is constant with time $D_k(t_{Lt}) = L_t \cdot D_k(t_1)$;

- definition of the fragility curve $P(DS|EDP)$; the fatigue damage occurs when the damage value D (calculated through Eq. (5)) equals its critical value D_{crit} :

$$D_{crit} - D = 0 \quad (6)$$

Due to the random nature of fatigue damage, D_{crit} can be considered as a random variable with mean value equal to unity. Therefore, the fragility curve is determined by defining an uncertainty on the critical damage value distributed with a log-normal distribution, as shown in Figure 2.

Figure 2. Fragility curve.

3 THE CASE STUDY

The proposed framework has been applied to a continuous steel-concrete composite highway bridge located in central Italy. The structure is 570 meters long and includes 10 spans of varying lengths, represented in Figure 3. The cross section consists of two double-T welded steel girders. The PEER convolution integral is calculated on 57 sections, uniformly spaced every 10 meters over the bridge length. The detail category considered for the fatigue limit state is a continuous longitudinal weld between the web and the flange of the girder.

Figure 3. Schematic representation of the bridge with the indication of the analyzed cross sections.

3.1 Hazard model

For the evaluation of the fatigue limit state it is necessary to probabilistically characterize the traffic model through the hazard curve. For the sake of demonstrating the influence of the traffic model on the LCCA results, the analyses have been carried out considering two different types of traffic hazard curves:

- the first hazard curve has been constructed from traffic data obtained from a WIM monitoring system located along the Interstate 80, Iowa, USA, known to the authors from a separate research study. The traffic hazard curve has been defined experimentally by choosing as the parameter that describes the load the GVW according to its annual frequency of exceeding. The traffic hazard curve obtained from WIM data is shown in Figure 4 (a);
- the second hazard curve has been obtained considering the Fatigue Load Model 4 used by the European Technical Standard (Eurocode 1 – Part 2) [17] for the estimation of fatigue damage on bridges (Figure 4 (b)). The Eurocode provides, for each one of the five vehicles specified in Fatigue Load Model 4 and for a specific type of road, the weight of the single axles and the percentage of the number of passages with respect to the total number of annual passages. The IM is the GVW calculated as the sum of the weights of the individual vehicle axles provided by the Eurocode. The total number of vehicles is assumed equal to the one provided by the WIM system, to consider the effect of the sole traffic distribution, being equal the traffic intensity.

Figure 4 Traffic hazard curve obtained from WIM system (a) and from Eurocode (b).

It is assumed that the annual composition of traffic does not change over time, so the PDF(IM) is the same for all years. On the other hand, the value of the EDP changes over time due to the accumulation of damage.

3.2 Fatigue damage assessment

The calculation of the damage index D is done through Eq. (5), where n_i is determined from WIM data in case of use of the monitoring system while n_i is defined as a percentage of the total number of vehicle passage in the case of adoption of Eurocode Fatigue Load Model 4. In both

cases, in addition to providing information regarding the total weight of the vehicles, the weight distribution of the axles and their spacing are provided. This information is necessary for the determination of the influence line which allows to evaluate the time histories of the internal forces and the corresponding stresses at the analyzed sections. The stress ranges are determined by the rainflow method [16] and the corresponding cycles to failure obtained from the S-N curve.

The damage index D calculated for each range of GVW is assumed to have a normal distribution with a $COV=0.25$. The uncertainty assumed on the Palmgren-Miner damage accumulation rule (D_{crit}) is assumed to be lognormal distributed with mean 1.0 and $COV=0.3$ [18].

Figure 5 shows the probability of exceeding the fatigue limit state over time of one of the most critical bridge sections (no. 43, at the midspan of the 8th span), calculated by Eq. (4). Figure 5 (a) represents the probability calculated from the hazard traffic curve obtained from the WIM system and Figure 4 (b) shows the probability referred to the hazard traffic curve obtained from the Eurocode. The increase in probability over time is due to the accumulation of damage caused by the passage of vehicles across the bridge.

Figure 5 Probability of exceeding the fatigue limit state over the lifetime of the bridge in section no. 43 obtained using traffic model from WIM system (a) and from Eurocode (b).

3.3 Life-cycle cost analysis

LCCA is carried out by applying Eqs. (2-3). The initial cost C_0 is taken from design documentation [12]. The maintenance cost C_m is considered as a percentage of the initial cost of the bridge. The annual percentage value is assumed to be equal to 1% [19]. The unit c_j can be computed as a percentage v of the initial cost C_0 [12], as follows:

$$c_j = v C_0 \quad (7)$$

while the repair cost c_r is taken as the 10% of c_j ($c_r = 0.1 c_j$). The coefficient v is taken to be equal to 1.1 to account for demolition and disposal costs [12]. The annual inspection cost is defined through the price list of Italian National Autonomous Roads Corporation (ANAS) [20]. The cost items are summarized in Table 1 and Table 2.

Cost item	Cost
C_0 [12]	€ 4.084.801
C_m [19]	€ 40.848,01
C_i [20]	€ 11.439,65
c_j [12]	€ 4.493.281,10

Table 1: Costs of the bridge.

C_i	Cost
Inspection of bridges and viaducts [20]	15.52 €/m
Inspection of piers [20]	235.75 €/pier

Table 2: Inspection Costs.

The discount rate is assumed equal to $r = 0.05$ and the threshold of the probability beyond which a repair intervention is required is 10^{-2} [21].

Figure 6(a) illustrates the expected life cycle cost over time of the bridge normalized with respect to the initial construction costs (Eqs. (2-3)) and Figure 6(b) shows the corresponding cumulated probability of failure as a function of time by comparing the case in which the hazard traffic curve is obtained from the monitoring system and when it is obtained from the Eurocode. In the case of Eurocode, it can be noted the cost increase associated to the attainment of the probability threshold.

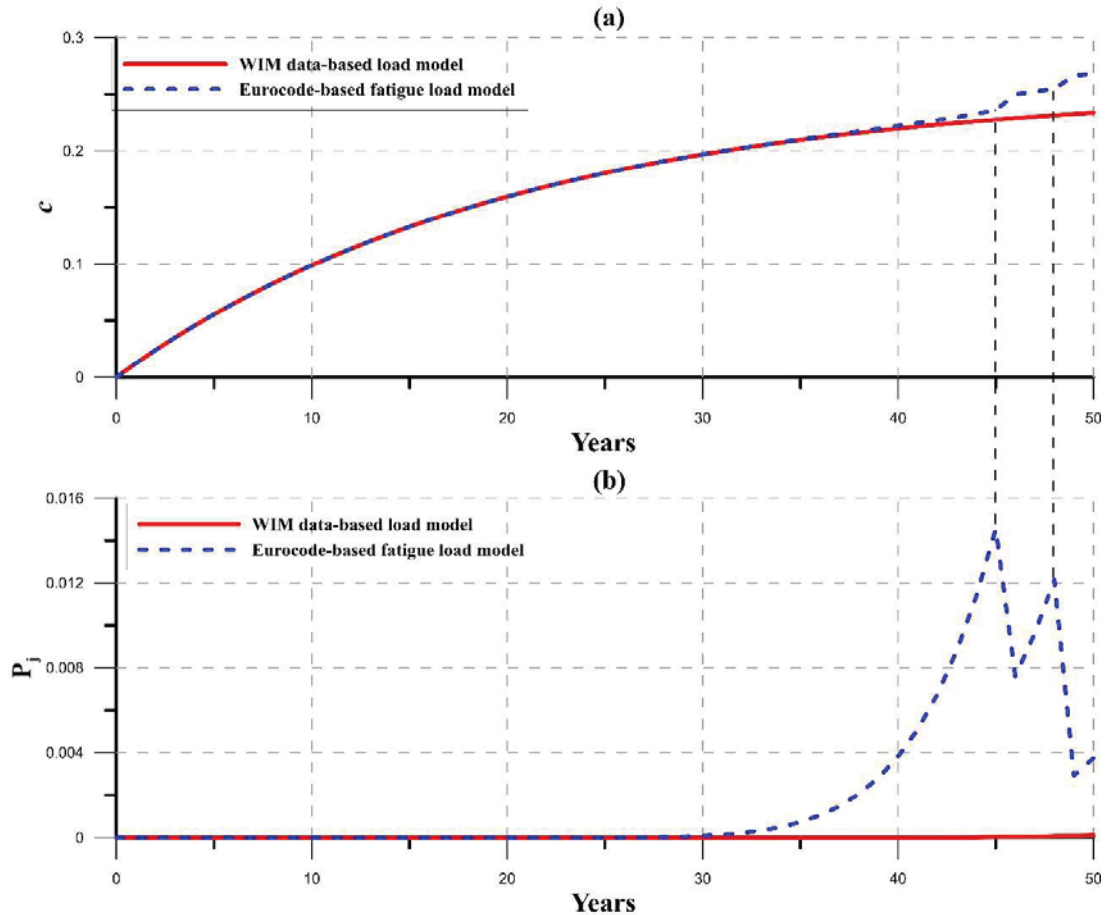

Figure 6 Expected normalized costs over the lifetime of the bridge (a) and the related probability (b).

Since the choice of the probability distributions of EDP and D_{crit} significantly influence the expected costs, parametric analyses have been carried out on the variations of the COVs of EDP and D_{crit} . Figures 7 (a) and 7 (b) show the normalized expected cost, evaluated for different values of COV of EDP (0.25, 0.5 and 0.8) for D_{crit} lognormally distributed with mean 1.0 and $COV = 0.3$, for the case of Eurocode-based fatigue load model and WIM-based monitoring data load model, respectively. Figures 7 (c) and 7 (d) represent the normalized expected cost, evaluated with mean 1.0 and for different values of COV of D_{crit} (0.1, 0.2 and 0.3) and for a fixed value of COV of EDP equal to 0.8, for the case of Eurocode-based fatigue load model and WIM-based monitoring data load model, respectively. It is visible from Figures 7 (a-b) that the expected cost increases over time and is greater when the uncertainty on the EDP is equal to 0.8. On the other hand, Figures 7 (c-d) show that the cost is higher when the uncertainty on COV of D_{crit} equals 0.3.

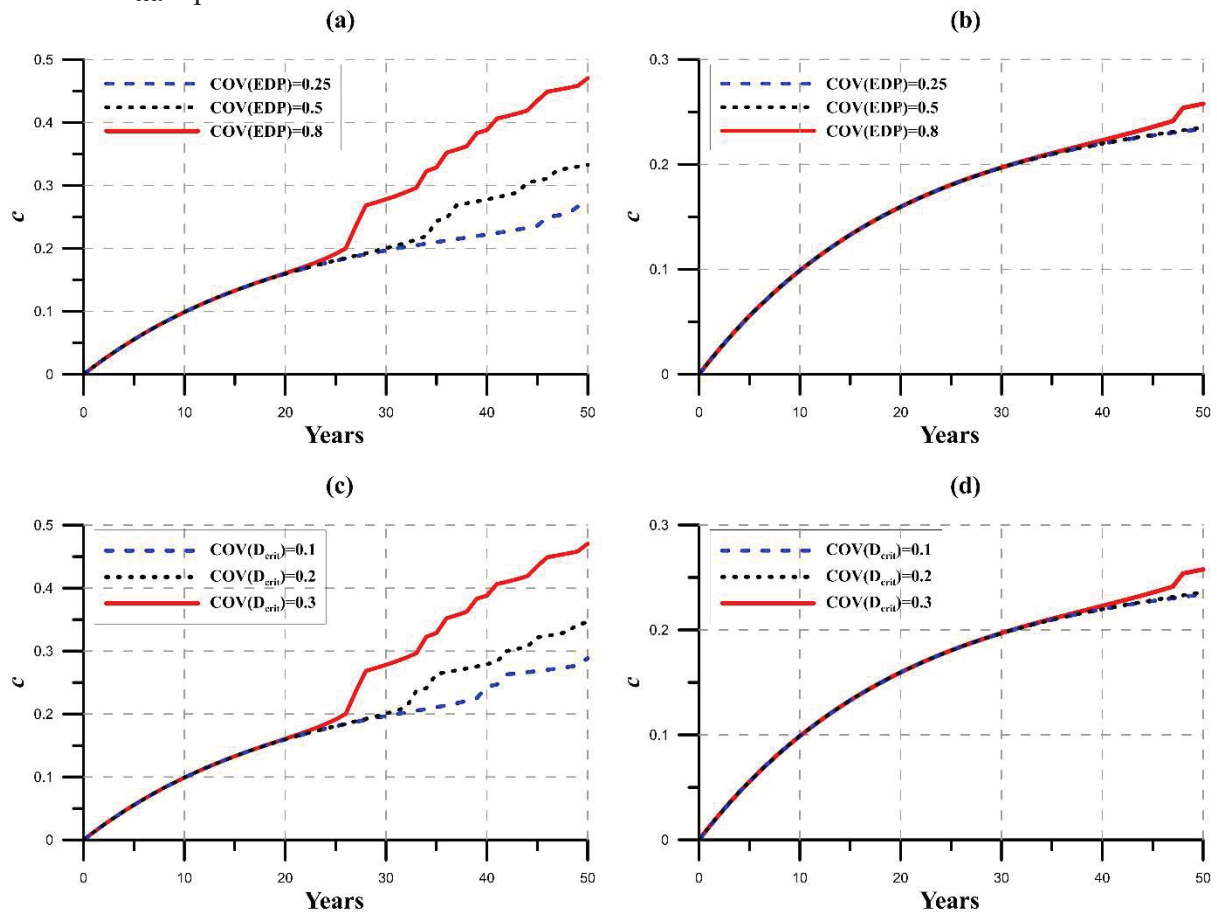

Figure 7 Expected normalized costs over the bridge's lifetime for different values of COV of EDP (a-b) and D_{crit} (c-d).

Figure 8 shows the results in terms of expected normalized costs (a-b) and the corresponding trends of the fatigue failure probabilities (c-d) considering COV of EDP equal to 0.8 (mean value equal to D) and D_{crit} equal to 0.3 (mean value equal to 1.0). Figures 8 (a-c) are obtained with the Eurocode-based fatigue load model and Figures 8 (b-d) are obtained with the WIM data-based load model. In both cases it is possible to observe that the costs increase when the probability threshold is reached, as there is the need for a repair action. From results, it can also be noted that the Eurocode-based hazard traffic curve overestimates the cost with respect to the case in which the hazard curve is obtained from WIM data.

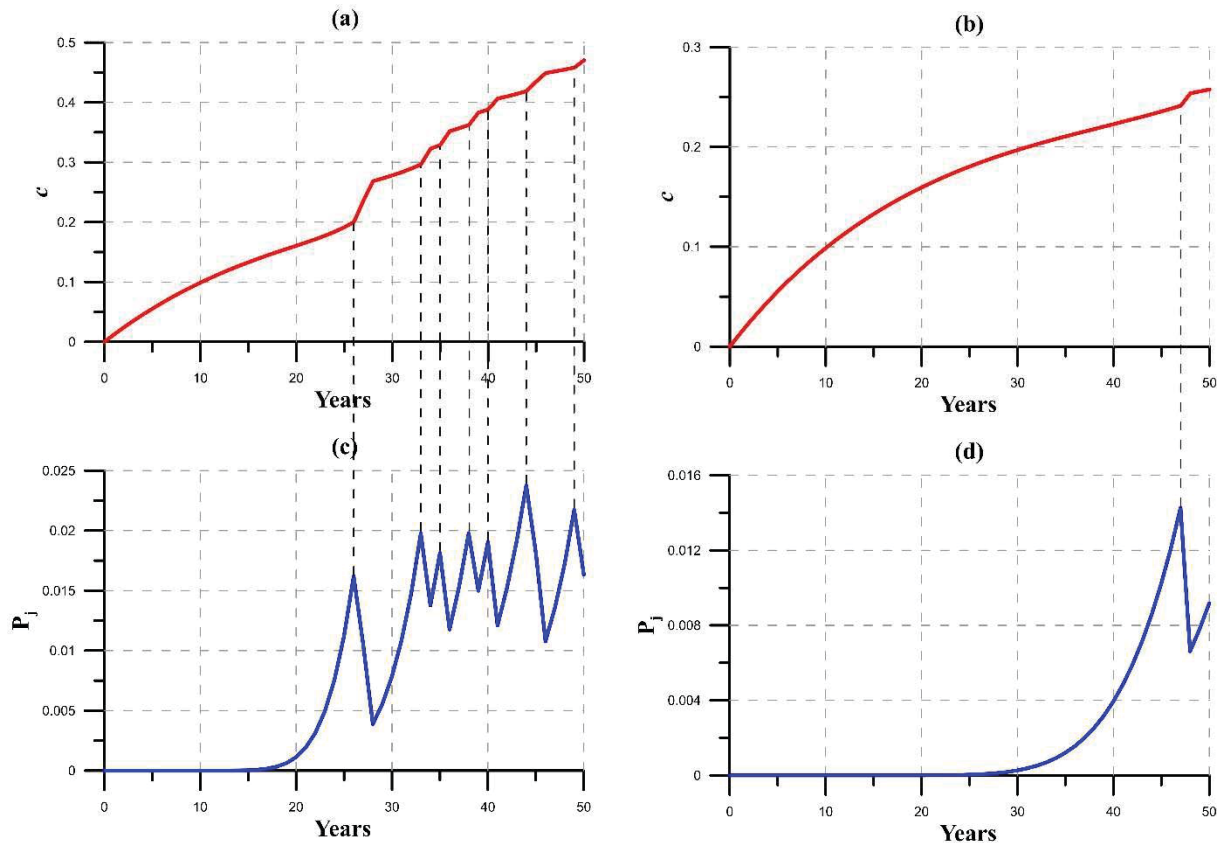

Figure 8 Expected normalized costs over the lifetime of the bridge (a-b) and the respective trends of the probabilities (c-d).

4 CONCLUSIONS

In this paper a general methodology for the computation of the expected total life-cycle cost of bridges is proposed, based on the PEER equation for failure probability estimation. The approach is for the first time applied to cost and fragility analysis of bridges subjected to fatigue, highlighting the possibility of treating the problem of fatigue damage estimation with an approach similar to the one currently adopted for damage induced by other hazards, like earthquake and wind. Starting from the knowledge of the traffic load model, the gross vehicles weight is assumed as IM and the fatigue damage index calculated through the Palmgren-Miner's rule is adopted as EDP. The damage accumulation is evaluated by considering the time dependency of the fatigue damage index.

The framework was applied to a continuous steel-concrete composite highway bridge located in central Italy by evaluating the fatigue limit state from the traffic loads defined by the Eurocode and obtained through a WIM monitoring system, for different probability distributions of the EDP and for different fragility models. The comparison between the fatigue failure probabilities and the life-cycle costs obtained with the two traffic models highlighted that the Eurocode-based hazard traffic curve overestimates the cost with respect to the case in which the hazard curve is obtained from WIM data, encouraging the adoption of traffic monitoring systems for a correct damage estimation.

Keywords: Mixed Wind Load Climates; Layered Stochastic Approximation Monte-Carlo Method; Wind Directionality; Life-cycle Cost Analysis.

Abstract. *This paper extends the existing formulation for life-cycle cost analysis (LCCA) of tall buildings subjected to synoptic, mixed wind load climates. This situation arises, for example, if the site is characterized by the presence of both tropical cyclones and extra-tropical depressions. A parametric study is conducted to examine the dependence of building's intervention cost, due to wind-induced damage, on the building height. Special attention is paid to the influence of wind load directionality, enabled by the modeling of the joint probability of mean-wind speed and direction using an angular-linear model. Furthermore, the Layered Stochastic Approximation Monte-Carlo (LSAMC) method is implemented for fragility analysis, as an alternate, surrogate approach compared to the standard Monte-Carlo simulation via physical building model. The results of the LSAMC simulations are validated by Monte-Carlo sampling. The study demonstrates that the LSAMC method is eligible for wind-induced fragility analysis while simultaneously achieving a remarkable reduction in computing time.*

1 INTRODUCTION

Tall buildings tend to oscillate in the along-wind, across-wind and torsional directions under the effect of dynamic wind loads, arising from variable pressure distribution on the building surface [1]. Due to the aleatory nature of the wind flow, efficiently quantifying wind loads can be problematic for structural design. Great efforts have been devoted to the estimation of wind load effects in the presence of uncertainties [2, 3, 4]. Adapted from performance-based design that was introduced for seismic engineering, the field of performance-based wind engineering (PBWE) has been introduced as an efficient approach that accounts for various uncertainties, inherent in the interactions between structures and wind loads. PBWE has been implemented for a wide range of structures and extreme wind phenomena; examples include low-rise, light-frame wood structures subjected to hurricanes [5], tall buildings [6, 7, 8], long-span bridges [9, 10], and various structures affected by non-stationary wind loads (e.g. tornadoes, thunderstorms) [11].

At the core of the PBWE is the uncertainty evaluation and fragility determination. Uncertainty sources may incorporate wind turbulence, structural deterioration and experimental conditions, used for wind load estimation. Some of these factors are aleatory, e.g. wind turbulence, and thus cannot be eliminated, while uncertainties related to experiments can be minimized by improving testing facilities and protocols. The concept of “fragility” is used to examine likelihood of failure occurrence contingent on the prescribed uncertainties. In practice, the fragility is expressed as the exceedance probability of a predefined performance objective, conditional on a variable (e.g. mean wind speed) describing the intensity of the demand on the structure. Performance objectives are described as limit-state conditions by a resultant structural effect, for example, in tall buildings the top-floor lateral drift and acceleration for a serviceability limit state and the internal stresses in a corner column for an ultimate limit state.

Currently, Monte-Carlo simulation is widely used for the assessment of fragility because it is applicable to any structural, physical model and it is simple to implement. However, an entrenched problem that the Monte-Carlo-based approach faces is that the process requires the generation of a large number of realizations and, consequently, is time consuming and computationally expensive. To overcome this limitation, attempts have been made by using sophisticated techniques [12] and improved algorithms, e.g. the Layered Stochastic Approximation Monte-Carlo (LSAMC) method [13]. The LSAMC method is based on the Stochastic Approximation algorithm [14]; it can derive the statistics of the performance objective indicator, expediting the procedure for fragility evaluation while preserving fidelity. The objectives of this paper are to: (i) describe the results of a parametric study implementing LSAMC-based fragility analysis for a benchmark tall building with variable heights and (ii) investigate the dependency of life-cycle cost assessment on the building height within the PBWE framework [15].

2 BACKGROUND THEORY

2.1 Multi-directional aerodynamic response of tall buildings

Capitalizing on the frequency-domain random vibration analysis for estimating wind-induced loads and structural response of tall buildings, a linear, quasi-steady model for multi-directional wind analysis allows a practitioner to simultaneously examine vibrations in along-wind, across-wind and torsional directions [16]. Multi-directionality is necessary for dynamic analysis because wind load effects are multi-directional. Furthermore, several studies [15, 17] demonstrate that there is a strong correlation between the local building orientation, another factor that influences directionality effect, and the structural performance.

For a linear elastic building subjected to turbulent wind loads with a mean-wind, horizontal incidence angle Ψ , the PSD of the generalized quasi-steady buffeting forces is

$$S_{Q_b Q_b}(n) = \iint_0^h \frac{\rho^2 D^2}{4} \bar{U}(z_1) \bar{U}(z_2) \Phi^T \mathbf{C}^* \begin{bmatrix} S_{uu}(n, z_1, z_2) & 0 \\ 0 & S_{vv}(n, z_1, z_2) \end{bmatrix} \mathbf{C}^{*,T} \Phi dz_1 dz_2 \quad (1)$$

where

$$\mathbf{C}^* = \begin{bmatrix} \cos \Psi & -\sin \Psi & 0 \\ \sin \Psi & \cos \Psi & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 2C_D(\Psi) & C'_D(\Psi) - C_L(\Psi) \\ 2C_L(\Psi) & C'_L(\Psi) + C_D(\Psi) \\ 2DC_M(\Psi) & DC'_M(\Psi) \end{bmatrix} \quad (2)$$

In the previous equations, $S_{Q_b Q_b}$ is the PSD matrix of the generalized buffeting forces; ρ is the air density; D is a reference floor-plan dimension (usually in the across-wind direction at $\Psi = 0$); $\bar{U}(z)$ is the mean wind speed profile evaluated at height z ; Φ is the mode shape matrix of the structure that can lead to inter-modal coupling arising from non-uniplanar, complex structural modes shapes; $C_D(\Psi)$, $C_L(\Psi)$, $C_M(\Psi)$ is the aerodynamic coefficients of drag force, transverse (lift) force and torque about z , respectively; $C'_D(\Psi)$, $C'_L(\Psi)$, $C'_M(\Psi)$ are the corresponding derivatives with respect to Ψ ; $S_{uu}(n, z_1, z_2)$ is the cross spectral density function of the along-wind turbulence component, evaluated at elevations z_1 and z_2 , and $S_{vv}(n, z_1, z_2)$ is the across-wind turbulence component. The cross-spectral density function between the two turbulence components is omitted due to a weak correlation. Furthermore, a set of dimensionless “model curves” in Eq. (3)–Eq. (4) are utilized to facilitate the parametric study of wind loads, extracted from HFFB wind tunnel tests [18].

$$\frac{n S_{Q_x Q_x}(n)}{\left(\frac{1}{2} \rho \bar{U}^2(h) D h\right)^2} = \frac{a_D f}{1 + b_D f^{c_D}} \quad (3)$$

$$\frac{n S_{Q_y Q_y}(n)}{\left(\frac{1}{2} \rho \bar{U}^2(h) D h\right)^2} = \frac{a_L f}{1 + b_L f^{c_L}} + d_L f^2 \exp \left[- \left(\frac{f - e_L}{f_L} \right)^2 \right] \quad (4)$$

2.2 Brief introduction to PBWE analysis

A general procedure for PBWE [19] analysis is summarized in Fig. 1, which describes the key steps that are usually involved in the assessment for structural design. The evaluation of each of the joint probability density functions (PDFs) represents a particular step: $f(IM)$ for site and structure-specific hazard analysis, $f(SP)$ for structural characterization, $f(IP|IM, SP)$ for interaction analysis, $f(EDP|IM, IP, SP)$ for structural analysis, $f(DM|EDP)$ for damage analysis and $f(DV|DM)$ for loss analysis. When the performance related to a decision variable DV is expressed by a limit state, which can be associated with an EDP (e.g. the top-floor lateral drift), the procedure of PBWE assumes $DV = EDP$ and can be concisely summarized in Eq. (5) below, where $G(\cdot)$ is a complementary cumulative distribution function (CCDF).

$$G(EDP) = \iiint G(EDP|IM, IP, SP) f(IP|IM, SP) f(IM) f(SP) dIM dIP dSP \quad (5)$$

Figure 1: PBWE flowchart, reproduced from [19]. *IM*: intensity measures; *SP*: structural parameters; *IP*: interaction parameters; *EDP*: engineering demand parameters; *DM*: damage measures; *DV*: decision variables.

3 NOVEL, LSAMC-BASED SIMULATION METHOD

3.1 Wind load modeling in mixed wind climates

A parametric angular-linear distribution model [20] can be employed for the description of mean-wind speed and direction at a reference height (e.g. building's rooftop). Based on the marginal distributions of the two random variables (speed and direction), the general form of the joint PDF is given by Eq. (6), where the two marginal PDFs are combined using a third angular PDF $g(\zeta)$.

$$f_{V,\theta}(v, \theta) = 2\pi g(\zeta) f_V(v) f_\theta(\theta) \quad 0 \leq v < \infty, 0 \leq \theta, \zeta < 2\pi \quad (6)$$

In the previous equation, $g(\zeta) = 2\pi[F_\theta(\theta) - F_V(v)]$ and $F_\theta(\theta)$, $F_V(v)$ are the marginal CDFs of the wind direction and wind speed, respectively. The Gumbel distribution can be used to model the magnitude of wind speeds (annual maxima) for non-hurricane winds, and a Weibull distribution for hurricane winds, specified in Eq. (7) and Eq. (8), respectively. For the corresponding wind direction, a model based on a mixture of von Mises distributions [21], as expressed in Eq. (9) below, enables the inclusion of several prevailing wind directions.

$$f_V(v; \mu, \gamma) = \frac{1}{\gamma} \exp \left\{ - \left[\frac{v - \mu}{\gamma} + \exp \left(- \frac{v - \mu}{\gamma} \right) \right] \right\} \quad (7)$$

$$f_V(v; k, \lambda) = \frac{k}{\lambda} \left(\frac{v}{\lambda} \right)^{k-1} \exp \left[- (v/\lambda)^k \right] \quad (8)$$

$$f_\theta(\theta) = \sum_{j=1}^{N_m} \frac{\omega_j}{2\pi I_0(\kappa_j)} \exp [\kappa_j \cos (\theta - \mu_j)] \quad (9)$$

In Eq. (9), N_m is the number of components in the mixture model; ω_j are the nonnegative weights for each component that must satisfy the condition $\sum_{j=0}^{N_m} \omega_j = 1$; $I_0(\kappa_j)$ is the modified Bessel function of the first kind and order zero, evaluated at a nonnegative quantity κ_j ; μ_j is the mean directions for each prevailing wind [21].

For a site that is subjected to more than one type of extreme wind events, the wind modeling is better achieved by separately examining each meteorological phenomenon, thus yielding a comprehensive probabilistic description of the local wind environment [22]. This study examines a local wind climate typical of the Mid-Atlantic coast of the United States of America that

is subjected to both extra-tropical depressions and hurricanes. Therefore, the joint CDF of the annual maxima of the wind speed and direction, is formulated as:

$$F_m(v, \theta) = F_H(v, \theta)F_{NH}(v, \theta) \quad (10)$$

where $f_m(v, \theta)$, $f_H(v, \theta)$, $f_{NH}(v, \theta)$ are the joint PDFs of the annual maximum mean-wind speed and direction in mixed, hurricane and non-hurricane wind climates, respectively; $f_H(v)$, $f_{NH}(v)$ are the marginal PDFs of the magnitude of the maximum mean-wind speeds for hurricane winds and non-hurricane winds; $f_H(\theta)$, $f_{NH}(\theta)$ are the marginal PDFs of the corresponding directions, respectively.

$$\begin{aligned} f_m(v, \theta) &= \frac{\partial^2 F_m(v, \theta)}{\partial v \partial \theta} \\ &= f_H(v, \theta)F_{NH}(v, \theta) + f_H(v)f_{NH}(\theta) + F_H(v, \theta)f_{NH}(v, \theta) + f_H(\theta)f_{NH}(v) \end{aligned} \quad (11)$$

where $f_m(v, \theta)$, $f_H(v, \theta)$, $f_{NH}(v, \theta)$ = the joint PDFs of annual maximum wind speed and direction in mixed, hurricane and non-hurricane wind climates, respectively; $f_H(v)$, $f_{NH}(v)$ = the marginal PDFs of the magnitude of the maximum speeds for hurricane winds and non-hurricane winds; and $f_H(\theta)$, $f_{NH}(\theta)$ = the marginal PDFs of the corresponding directions, respectively.

3.2 Structural failure probability and LCCA

The objective of the fragility analysis is to estimate the probability that a specific *EDP*, conditional on the examined *IM*, exceeds a preselected threshold. Following previous studies, the *EDP* is chosen as the lateral rooftop drift; the vector *IM* consists of two random variables, the mean wind speed at the building rooftop, \bar{U}_h , and the corresponding mean wind direction, $\bar{\theta}$. Structural fragility can be explicitly expressed by Eq. (12), where d_j is the preselected threshold for the *j*-th *EDP*. In this study, the threshold for the lateral drift of a building can be set as 1/400 of the building height [23]. Note that the obtained fragility is a fragility surface, allowing for the assessment of the multi-directionality effect induced by the wind.

$$f_j(v, \theta) = P(EDP_j > d_j | \bar{U}_h = v, \bar{\theta} = \theta) \quad (12)$$

Having obtained the joint PDF of intensity measures $f(IM)$ and the fragility, the structural failure probability with respect to the *j*-th *EDP* can be estimated by Eq. (13). Finally, the annual probability of *j*-th *EDP* exceeding the preselected threshold is described by Eq. (14) [24].

$$P_{j,\text{event}} = \int_0^{2\pi} \int_0^\infty f_j(v, \theta) f_{V,\Theta}(v, \theta) dv d\theta \quad (13)$$

$$P_{j,\text{annual}} = 1 - \exp(-\nu P_{j,\text{event}}) \quad (14)$$

In Eq. (14) ν is the average annual number of occurrences in the local mixed climate. Assuming independence between hurricane and non-hurricane incidents, ν is estimated as the summation of the annual rate of hurricane landfall and the number of monthly maximum non-hurricane wind speeds occurring in any one year.

Capitalizing on the quantification of structural failure probability, the LCCA can be implemented to predict damage-induced monetary losses over the structural life-time (with *t* unit

time in years). The normalized, expectation of the relative intervention (maintenance, repair, retrofitting, etc.) cost $C_E(t)$, adapted from the cost function in [25], can be calculated as:

$$C_E(t) = \mathbf{E} \left[\frac{C(t) - C_0}{C_0} \right] = \mathbf{E} \left[\sum_{i=1}^{N(t)} \sum_{j=1}^k \epsilon_j e^{-\lambda t_i} P_j \right] \quad (15)$$

In the previous equation, $\mathbf{E}[\cdot]$ denotes the expectation operation; $C(t)$ is the expected total cost induced by damages; C_0 is the initial construction cost of a structure; $0 \leq t_i \leq t$ is the random variable describing the time when the i -th hazard occurs; $\epsilon_j = C_j/C_0$ is a normalized relative cost of the j -th limit state being violated at time t_i calculated as the ratio of the expected intervention cost related to the j -th limit state, C_j , to the initial cost; λ is the constant discount rate, which places more weight on hazards occurring closer to the completion date of the structure over those that are not; $P_j = P_{j,\text{annual}}$ is the failure probability of the j -th limit state, i.e. the probability that intervention relating to the j -th limit state is desired; k is the total number of limit states considered; $N(t)$ is the number of wind occurrences, which is a function of ν during the lifetime.

3.3 LSAMC method

Similar to the idea of the Latin Hypercube sampling, the LSAMC method uses the layered sampling of random variables within a Monte-Carlo simulation environment. As proposed by [13], the key steps of the LSAMC method include: (i) dividing the range of each random variable into a finite number of adjacent non-overlapping equally-probable intervals; (ii) constructing a subspace of the random variables for each iteration, consisting of one of the equally-probable intervals for every random variable; (iii) feeding the subspace to the standard Stochastic Approximation algorithm, which has the form of Eq. (16), to find one root of the examined problem subjected to perturbation. Iterating through all the possible subspaces of the original random variables set yields a sequence of roots to the perturbed problem; this allows to approximate the effects of the noises in a structural system through statistical moments derived from the root sequence. By contrast, the "exact" values are determined by a standard "brute-force" Monte-Carlo simulation.

$$\begin{aligned} \hat{\mathbf{x}}_{k+1} &= \hat{\mathbf{x}}_k - a_k \mathbf{Y}_k \\ \mathbf{Y}_k &= \mathbf{g}(\hat{\mathbf{x}}_k) + \mathbf{e}_k(\hat{\mathbf{x}}_k) \end{aligned} \quad (16)$$

In the previous equation, $\hat{\mathbf{x}}_k$ is the estimate of the root \mathbf{x} at the k -th iteration; \mathbf{Y}_k is the noisy measurement at the k -th iteration; $\mathbf{g}(\cdot)$ is the general vector-valued function from which the root-finding equation $\mathbf{g}(\mathbf{x}) = \mathbf{0}$ is constructed; \mathbf{e}_k is the noise introduced by the input of the k -th iteration; a_k is the gain sequence controlling the step size, which is subject to the convergence conditions $\sum_{k=0}^{\infty} a_k = \infty$ and $\sum_{k=0}^{\infty} a_k^2 = 0$. Eq. (17) utilizes recommended values of the gain sequence [14], where α is a constant belonging to the range $(0.5, 1]$ and a , A are a strictly positive constant and a nonnegative constant, respectively.

$$a_k = \frac{a}{(k + 1 + A)^\alpha} \quad (17)$$

The main advantage of the LSAMC method is the avoidance of time-consuming, computationally-expensive Monte-Carlo simulations. However, it is worth noting that the advantage could be

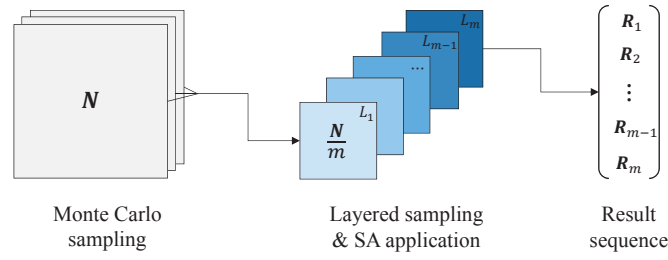

Figure 2: Key steps of the LSAMC method (workflow).

lost if the number of the random variables included were large. To illustrate the potential of the LSAMC method, the reduction of computing time achieved by the LSAMC method, in the case of two input random variables, can be as large as 88% compared to brute-force Monte-Carlo simulation for a monopole tower structure under wind loads [13].

4 NUMERICAL APPLICATION

In this section, the application of the proposed LSAMC-based simulation to a set of variants of a benchmark tall building is discussed. The LSAMC method is employed for the fragility analysis and the estimation of P_j in Eq. (15). Furthermore, dependency of the life-cycle cost variable $C_E(t)$ in Eq. (15) on the variable building height is examined.

4.1 Description of reference building structure and its variants

Based on the benchmark tall building model of the Commonwealth Advisory Aeronautical Research Council (CAARC), a set of building variants is parametrically constructed. The variants share the same structural parameters (floor plan dimensions, unit mass and mass moment of inertia, etc.) as the CAARC building, except for the building height h , which is set to vary as $h \in \{100, 150, 200, 250, 300\}$ [m]. The structural properties of the benchmark CAARC building are listed in Table 1.

Table 1: Structural properties of the original benchmark CAARC building.

Quantity	Unit	Values
Height h_0	[m]	183.0
Depth D	[m]	45.7
Width B	[m]	30.5
Unit-height mass m	[kg/m]	2.23×10^5
Unit-height mass moment of inertia I_m	[kgm ² /m]	5.62×10^7
Lateral-mode fundamental freq. $n_{0,x}, n_{0,y}$	[Hz]	0.20
Torsional-mode fundamental freq. $n_{0,z}$	[Hz]	0.40
Structural damping ratio $\xi_{0,x}, \xi_{0,y}$	—	0.01

For simplification, the fundamental lateral-mode frequencies of the building variants are modifications of the original values, $n_{0,x}$ and $n_{0,y}$ in Table 1, inversely proportional to the building height, as expressed by Eq. (18) below. The torsional-mode frequency is not modified. In addition, all mode shapes are assumed as dimensionless, monotonic functions, linearly varying

along the building height.

$$n'_{0,i} \approx \frac{h_0}{h} n_{0,i} \quad (i = x, y) \quad (18)$$

4.2 Modeling of site wind climate

The buildings are assumed to be located in Miami, Florida (USA) where hurricanes are frequent. To evaluate the probability distribution of the hurricane wind speed and direction (at landing), a total number of 20 019 synthetic hurricane records, simulated in the Miami region over a period of 20 000 years [17], are utilized. The angular-linear model for the hurricane wind is obtained by fitting a Weibull model to the magnitudes of the wind speed and a two-component mixture of von Mises model to describe the corresponding directions of the approaching storm; the $g(\zeta)$ function in (6) is modeled as a two-component von Mises mixture model. The resultant joint PDF of the hurricane mean wind speed and direction, evaluated at the rooftop of the original CAARC building with $h = 183$ m, is illustrated in Fig. 3, which is characterized by two peaks. The predominant peak corresponds to the high probability of winds coming from the east coast and the Atlantic Ocean, whereas the secondary peak is linked to the westerly winds, originating from the Gulf of Mexico and crossing the peninsula.

Figure 3: Joint PDF of the mean wind speed and direction for hurricane winds (Miami, Florida, USA) at the reference elevation of the original CAARC building, $h = 183$ m.

For the non-hurricane winds, the joint PDF of the mean wind speed and direction is obtained by using wind record data collected at an offshore buoy station near the Miami site. The data can be accessed by the National Oceanic and Atmospheric Administration (NOAA) [26]. In order to eliminate the influence of hurricanes, the Atlantic hurricane tracking database, HURDAT2 [27], is used to manually remove the buoy data records related to days when a hurricane approaches within a 500 km radius of the building site. In particular, the monthly maxima of the gust speed and the corresponding direction are selected from the filtered buoy data records to form a non-hurricane extreme wind dataset. The averaging time interval of the speed is transformed from 3600 seconds to 600 seconds for consistence with hurricane wind data. By fitting a Gumbel distribution to the magnitudes of the wind speeds and likewise a two-component von Mises mixture model to describe the directions, the joint PDF for the non-hurricane wind speed and direction, is illustrated in Fig. 4; quantities are also evaluated at the rooftop of the original

CAARC building with $h = 183$ m. Fig. 4 indicates that easterly winds, coming from the sea, play a prominent role in the local non-hurricane climate.

Figure 4: Joint PDF of the mean wind speed and direction for non-hurricane winds (Miami, Florida, USA) at the reference elevation of the original CAARC building, $h = 183$ m.

The joint PDF of the wind in the mixed climates can be consequently estimated from the Figs. 3 and 4 through Eq. (11). Since an analytical form of the CDF for the von Mises distribution is unavailable, the joint CDFs $F_H(v, \theta)$ and $F_{NH}(v, \theta)$ are found through numerical integrations. The joint PDF is plotted in Fig. 5. It is clear that the compound joint PDF combines features of the two separate PDFs related to both hurricane and non-hurricane climate.

Figure 5: Joint PDF of the mean wind speed and direction for the mixed wind climate of Miami, Florida (USA) at the reference elevation of the original CAARC building, $h = 183$ m.

4.3 Characterization of uncertainty in the wind loads

As an example, this study analyzes uncertainty propagation due to experimental wind load errors by considering a parameter denoted by ΔC_D ; this quantity describes the deviation of experimentally estimated drag coefficient C_D from an average, measured value at a particular incidence angle, i.e., $\Delta C_D = C_D(\Psi) - \mathbf{E}[C_D(\Psi)]$. Data points of the drag coefficients are extracted from wind tunnel tests on a rigid, scale model of the original CAARC building [18];

eleven incidence angles are tested with $\Psi \in \{0^\circ, 5^\circ, 10^\circ, 15^\circ, 30^\circ, 45^\circ, 60^\circ, 75^\circ, 80^\circ, 85^\circ, 90^\circ\}$. Experimental data points of C_D along with a Fourier series fitting are illustrated in Fig. 6.

Figure 6: Drag coefficients C_D measured at various incidence angles, reproduced from [18].

Figure 7: Histogram of the dimensionless uncertainty parameter ΔC_D .

Assuming that ΔC_D , collected from all the measured data points, is independent of Ψ and that ΔC_D is identically distributed for different angles, a suitable distribution model can be determined through Kolmogorov-Smirnov goodness-of-fit test. A normal distribution, parameterized by a mean value of 1.000 and a standard deviation STD of 0.077, can adequately describe the empirical histogram (and distribution) of the ΔC_D in Fig. 7.

4.4 Structural fragility analysis

Both the standard brute-force Monte-Carlo simulation and the LSAMC method are employed. For the LSAMC method, the number of equally-probable subsets is 10; the parameters of the gain sequence are set as $a = 10$, $A = 0$, $\alpha = 0.95$. Structural fragilities against the limit state of rooftop lateral drift are illustrated in Fig. 8; fragility curves related to mean incidence angle $\Psi = \{0^\circ, 45^\circ, 90^\circ\}$ are exclusively shown for the sake of brevity. The LSAMC results, represented by dashed, non-solid lines, are very close to those found by brute-force Monte-Carlo method plotted as solid lines. By comparing the fragility curves corresponding to different building heights, it is concluded that the wind speed required to reach the prescribed

performance limit ($h/400$) decreases as the building height increases, indicating that a higher building is more sensitive to wind-induced damage as the limit state is probabilistically violated at a lower wind speed.

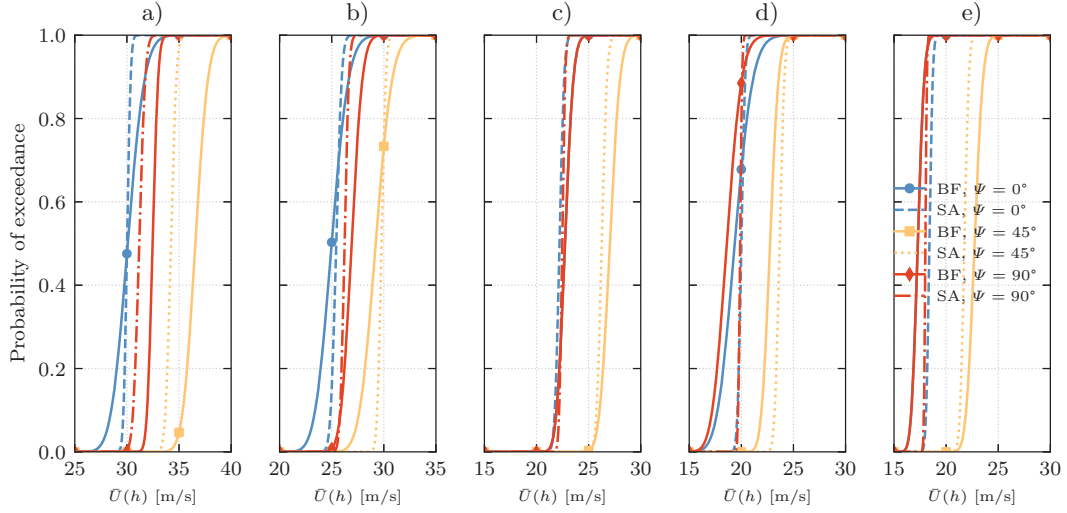

Figure 8: Fragility curves against the limit state of lateral drift with uncertainty parameter ΔC_D : a) $h = 100$ m, b) $h = 150$ m, c) $h = 200$ m, d) $h = 250$ m, e) $h = 300$ m (BF=brute force, SA=LSAMC).

Fig. 9 depicts the fragility surface of the CAARC building variant of height $h = 200$ m; other examples of fragility surface for other building variants can be similarly derived and, thus, are not included. The fragility surface is generated by linear interpolation among the fragility curves (Fig. 8) related to the eleven incidence angles. As shown, the fragility surface has an irregular, “ragged” shape, which is attributed to the directionality of the wind load. In Fig. 8c, the curves corresponding to different incident wind directions seem to shift back and forth along the horizontal axis, because the wind-induced force is directional, thus leading to a variation of fragility even for a same performance objective (EDP).

Figure 9: Fragility surface of the CAARC building variant of height $h = 200$ m.

4.5 Expected relative lifetime cost analysis

Fragility surfaces are used to calculate the failure probability and the expected lifetime cost. According to the Eq. (15), the relative intervention costs due to wind-induced damage, associated with nonstructural failures on the building façade and triggered by disproportionate lateral drift, is $\epsilon = 0.02$ and the discount rate is $\lambda = 0.05$. Numerical values have been calibrated according to previous studies [15, 17]. Using the above results of the joint PDF of the mean wind speed and direction in mixed climates and the fragility surfaces, the expected relative lifetime intervention costs due to failures associated with lateral drift are illustrated in Fig. 10. The maximum relative lifetime cost (asymptotic value as t tends to 100 years) is observed for the building variant of height $h = 300$ m and is approximately a quarter of the initial cost, while the minimum relative lifetime cost is found for the building with height $h = 100$ m, which is roughly 2% of the initial cost. This remark suggests a superlinear relationship between building height and expected relative lifetime cost (i.e. a superlinear increment of $C_E(t)$ with height). This behavior can be associated to two aspects. First, due to the wind profile the wind loading on a higher building is generally larger, thus causing larger-magnitude, wind-induced vibrations; second, as discussed in the previous section, a higher building is more slender and exhibits greater sensitivity to wind loads of same intensity because of the concurrent decrement of fundamental frequencies. Consequently, the probability of exceeding the lateral drift limit state and damage is superlinearly higher in a taller building, e.g. $h = 300$ m, vs. $h = 100$ m in Fig. 8.

Figure 10: CAARC building variants: expected relative, lifetime intervention cost due to wind-induced damage, associated with nonstructural failures on building façade and triggered by disproportionate lateral drift.

5 CONCLUSIONS

This study examined the comprehensive application of the novel LSAMC method in the context of PBWE. Special attention was paid to lifetime intervention cost analysis. A parametric study was conducted, examining a set of variants of the benchmark CAARC building with equal floor-plan dimensions but variable heights. The LSAMC method was used to estimate structural fragilities; results were compared against standard Monte-Carlo simulation. The LSAMC method is adequate for the fragility analysis. The life-cycle cost assessment revealed a superlinear relationship between asymptotic, expected relative cost and building height; this trend can be ascribed to the reduction in structural stiffness and the increase in the sensitivity to wind-

induced resonant response. This study confirmed the particular significance of nonstructural facade damage caused by wind for operations and maintenance of a high-rise building.

Keywords: Transfer learning, Bayesian model updating, Model Class Selection, Surrogate model, Damage classification, Continuous monitoring.

Abstract. *The identification of high-fidelity surrogate models for real-time updating based on continuous monitoring data, is an emerging and challenging topic in the structural system identification of historical structures with a special focus on damage identification and structural health monitoring. Indeed, the protection of the historical and cultural heritage aimed at developing cost-effective and long-lasting dynamic monitoring systems in regions characterized by high seismic risk, has received a growing attention in civil engineering. A dynamic monitoring system is usually composed by a selected number of sensors installed in strategic positions within the building which enable a continuous assessment of the structural conditions over time. Then, the observation of the recorded data allows to identify any variations due to possible damages, i.e. novelty detection, which is classified as unsupervised learning. The basic idea behind the present paper is to transfer knowledge from data to updated numerical models with varying levels of complexity developed from the engineering judgment in order to detect and localize damage in a probabilistic manner, moving on to semi-supervised learning. In order to accomplish this challenging task, a transfer Bayesian-based learning (TBL) methodology is proposed by means of model class selection. For the purpose, different classes of FE (finite elements) models, with a low level of complexity, are preliminary defined in such a way to reproduce the structural dynamic behavior as a function of damage-dependent mechanical characteristics (such as average elastic moduli) of pre-selected regions within the structure. Such regions, designated as damage-sensitive, are defined on the basis of nonlinear static analyses and/or Engineering judgment. Then, the large amount of measured data is periodically used for the automatic Bayesian model selection procedure, i.e., the inverse problem to derive the posterior statistics of the uncertain parameters over the space of the FE models classes. For verifying the proposed methodology, an iconic monumental palace, located in Gubbio, Italy, named Consoli Palace which has been monitored by the Authors since 2017, is used. The dynamic monitoring system, updated in July 2020, comprises 12 uniaxial accelerometers installed at different levels within the building.*

1 INTRODUCTION

The non-destructive nature and the relatively low economic impact of the technology make SHM particularly suitable for the detection of structural damages suffered by monumental structures. Nowadays, the most common procedure in civil SHM concerns the data acquisition and feature extraction (system eigenfrequencies and modal shapes) through signal processing [20], while damage identification problems can be classified as a five-level hierarchical approaches [9]: (i) detection; (ii) localization; (iii) classification ; (iv) assessment; (v) prediction. On the one hand, variations over time (novelty detection) in the dynamic response of an healthy structure can be associated to material's damage and deterioration [26], with a special attention to proper techniques able to remove the environmental effects such as temperature and humidity [14] and the different sources of uncertainties related to SHM can be accounted for by means of Bayesian statistical frameworks [28, 1, 27]. On the other hand, long-term monitored data and labeled features able to define the meaning of novelties detection to localize, classify, assess and eventually predict damage are usually not available. Indeed, only a few recent contributions deal with long-term SHM data and damage detection so far [4, 3, 23, 2, 12].

In this context, SHM-based technologies are encompassing machine learning (ML) techniques [18, 17, 24], devoting the attention to the semi-supervised learning paradigm, which allows the use of large amount of monitoring data with and without descriptive labels [5, 6]. The process of prioritizing the acquired data can be accomplished by using numerical models, i.e. precalibrated surrogate models [11, 10], in order to transfer knowledge from the trained model to the data and build a labeled training set. Such methods can be classified as transfer learning (TL) techniques [21, 9, 19].

The present work presents a TBL methodology based on long-term monitoring data aimed at evaluating the possible damage of monumental structures in a probabilistic way. In this framework, TL concepts allow to compensate the lack of labeled structural data, especially in the case of damage occurrence, by means of a trained surrogate model, which is used as a formal prior belief for damage assessment. Then, a Bayesian-based procedure allows to associate a probability of damage occurrence.

The effectiveness of the proposed methodology is demonstrated by making use of a real complex historical masonry building as a case study, the Consoli Palace located in Gubbio, near Perugia, in Italy. The structure has been monitored by the Authors since 2015. The continuous monitoring data are used for the Bayesian-based updating of specific mechanical properties of some pre-selected damage-sensitive regions by means of non-linear static analysis (NLSA) and Engineering judgment (EJ). A trained surrogate model allows to reconstruct different classes of FE models, with a low level of complexity, i.e., depending on a single uncertain parameter. The results show the advantage of having long-term monitoring data on the correct estimation of the uncertain parameters' distribution enabling informed model-based decisions and providing a basis to mitigate the risk of a false alarm. The rest of the paper is organized as follows. Section 2 presents the proposed methodology. Section 3 presents the case study. Section 4 summarizes numerical results. Section 5 concludes the paper.

2 THE PROPOSED METHODOLOGY

The proposed methodology, designated as TBL, schematically represented in Figure 1, embraces different consequential steps which can be summarized as follows:

1. Start continuous SHM.

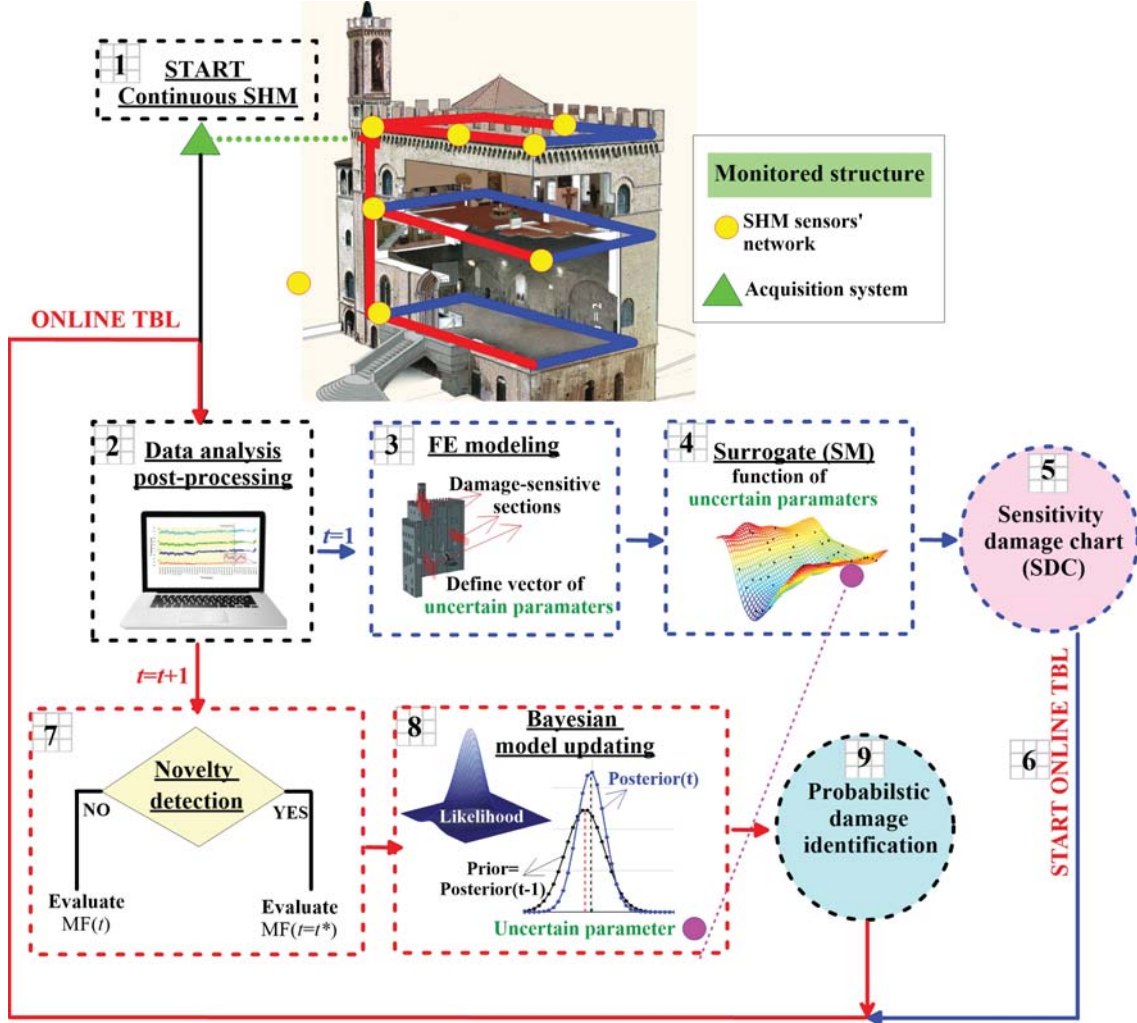

Figure 1: The proposed TBL methodology.

2. Data analysis and post-processing consisting of acquiring data from the monitoring system (acceleration data, temperature information, crack amplitudes) and post-processing data continuously over time to estimate the modal features (MF), such as natural frequencies f_i^{exp} , mode shapes Φ_i^{exp} and damping coefficients ζ_i^{exp} associated with each natural vibration mode.
3. If $t=1$, where the term t stands for discrete time (days): FE modeling and evaluation of damage-sensitive regions. The calibration process consists of solving the following optimization problem:

$$\mathbf{Y}^{\text{opt}} = \arg \min_{\mathbf{Y}} \sum_{i=1}^M p_1 \eta_{f,i}(\mathbf{Y}) + p_2 \eta_{\Phi,i}(\mathbf{Y}) \quad (1)$$

where M is the number of vibration modes; $\mathbf{Y} = \{\mathbf{Y}_1, \dots, \mathbf{Y}_u, \dots, \mathbf{Y}_U\}$ is the vector collecting the n^{th} parameter to be calibrated with N total number of uncertain parameters; p_1 and p_2 are the weights of the objective function; $\eta_{f,i}(\mathbf{Y}) = |f_i^{\text{exp}} - f_i^{\text{FEM}}|/f_i^{\text{exp}}$ and $\eta_{\Phi,i}(\mathbf{Y}) = 1 - \text{MAC}_i(\mathbf{Y})$ are the frequency-based and mode shape-based residual func-

tions, where the term MAC_i refers to the Modal Assurance Criterion (MAC) between the i^{th} experimental Φ_i^{exp} and numerical Φ_i^{FEM} mode shape.

With the main objective of selecting j^{th} damage-prone regions $\mathcal{R} = \{\mathcal{R}_1, \dots, \mathcal{R}_j, \dots, \mathcal{R}_N\}$ with $j = 1, \dots, N$, both EJ and NLSA are used. Then, each region is considered as an homogeneous portion of the structure in terms of material and, consequently, potential damage. Hence vector $\mathbf{X} = \{k_1, \dots, k_j, \dots, k_N\}$ is defined, collecting the multipliers of the Young moduli (k_j) of all the elements comprised in each region, with $0 \leq k_j \leq 1$.

4. Calibration of the surrogate model as a function of \mathbf{X} . For the present paper, the Kriging model is used, whose effectiveness in spatial interpolation was demonstrated in previous works by the Authors [11]. According to the Kriging model, the FE model-based data \mathbf{X} can be numerically interpolated by considering a regression model \mathcal{F} , i.e., the deterministic component, and an approximation error α , i.e., the stochastic component [15]:

$$y(\mathbf{X}) = \mathcal{F}(\beta, \mathbf{X}) + \alpha(\mathbf{X}) \quad (2)$$

where β are the regression parameters of \mathcal{F} . The approximation error α is assumed as a random process with zero mean and covariance $\text{cov}(X_i, X_j) = \sigma^2 \mathcal{R}(\boldsymbol{\theta}, X_i, X_j)$, with σ^2 variance of $\mathcal{F}(\beta, \mathbf{X})$ and \mathcal{R} the matrix of stochastic-process correlations with components $r(\boldsymbol{\theta}, X_i, X_j)$, where $\boldsymbol{\theta}$ are the correlation parameters.

5. Construction of the SDC, i.e., a graphical chart able to directly associate a stiffness reduction to each frequency/MAC decay for the selected damage-prone region.
6. if $t > 1$: novelty detection on a daily basis t , i.e. daily average values of MF. If a novelty is detected, i.e., a frequency or MAC anomaly, increase the frequency of the modal tests on a hourly basis $t = t^*$, i.e., $\text{MF}(t^*)$.
7. Bayesian model updating of the uncertain parameters by means of the surrogate model. Assuming that the identified model parameters k_j are statistically independent [13, 4], the surrogate model $\text{SM}(\mathbf{X})$ can be subdivided in j surrogate models with a low level of complexity, depending on k_j , i.e., $\text{SM}(k_j)$. Hence, the t - and k_j -dependent posterior probability density function (PDF) can be evaluated as follows:

$$p(k_j | \mathbf{d}, t) = c \cdot p(\mathbf{d} | k_j, t) \cdot p(k_j | \mu(t-1)) \quad (3)$$

where $c = 1 / \int p(\mathbf{d} | k_j, t) p(k_j | \mu(t-1)) dx$ is a normalizing factor called the evidence of the $\text{SM}(k_j)$; $p(\mathbf{d} | k_j, t)$ is the likelihood function that quantifies the agreement between the measured data \mathbf{d} and the surrogate-based data; $p(k_j | \mu(t-1))$ is the prior PDF of k_j function of the mean value of the posterior k_j evaluated at $t-1$.

More in depth, the likelihood function $p(\mathbf{d} | k_j, t)$ is modeled as a Gaussian distribution with zero mean [13, 4] as follows:

$$p(\mathbf{d} | k_j, t) = \frac{1}{\left[2\pi \prod_{i=1}^M (\sigma_{f_i} \sigma_{\Phi_i})^2 \right]^{(MD)/2}} \exp \left(-\frac{1}{2} \sum_{m=1}^D \sum_{i=1}^M J_i^{\text{err}}(k_j, d_k, t) \right) \quad (4)$$

where index $i = 1, \dots, M$ refers to the reference parameter associated to the i^{th} vibration mode; index $k = 1, \dots, D$ represents the number of measured data collected in the vector \mathbf{d} ; $J_i^{\text{err}} = (\sigma_{f_i})^{-2} e_{f_i}^2(\mathbf{X}, \mathbf{d}) + (\sigma_{\Phi_i})^{-2} e_{\Phi_i}^2(\mathbf{X}, \mathbf{d})$ is the measure of the fit function (error function) which quantifies the discrepancy between the experimental data and the FE model results with σ_{f_i} , σ_{Φ_i} standard deviations associated to the i^{th} natural frequency and vibration mode, $e_{f_i} = f_i^{\text{exp}} - \hat{f}_i(\mathbf{X})$ and $e_{\Phi_i} = 1 - MAC_i$.

Finally, it is noteworthy that, theoretically, the prior distribution acts as a regulator in the Bayesian-based model updating process and the more the number of data increases, the less new data influences the updating process. This aspect can be counter-productive, especially in the case of possible damage occurrence. Hence, the co-variance of the prior distribution is assumed as known, while the mean value μ is updated step by step, given the evidence of the knowledge acquired at the previous step.

8. Probabilistic damage identification which consists of calculating the probability P_j^{dam} that the updated j^{th} parameter k_j^{up} in a possibly damaged state is reduced from the undamaged state k_j^{ref} [4, 25]:

$$P_j^{\text{dam}} = P(k_j^{\text{up}} \leq (1 - \bar{k}_j)k_j^{\text{ref}} | \mathbf{d}^{\text{ref}}, \mathbf{d}^{\text{dam}}) = F\left(\frac{(1 - \bar{k}_j)k_j^{\text{ref}} - k_j^{\text{up}}}{\sqrt{(1 - \bar{k}_j)^2 \sigma_{k_j^{\text{ref}}}^2 + \sigma_{k_j^{\text{up}}}^2}}\right) \quad (5)$$

where $F(\cdot)$ is the standard Gaussian cumulative distribution function; $\bar{k}_j \in [0, 1]$ is the damage threshold selected for the j^{th} damage-prone region and quantifies the reduction of k_j^{ref} ; $k_j^{\text{ref}} = 1$ is the reference undamaged state. The possible outcomes of Eq. (5) are summarized in Table 1, where P_j^{al} is defined as probability alarm threshold.

No.	Outcome	P_j^{dam}	Meaning
1	$k_j^{\text{up}} = (1 - \bar{k}_j)k_j^{\text{ref}}$	$P_j^{\text{dam}} = 0.5 = P_j^{\text{al}}$	the damage threshold is reached
2	$k_j^{\text{up}} > (1 - \bar{k}_j)k_j^{\text{ref}}$	$P_j^{\text{dam}} < 0.5$	the damage threshold is not reached
3	$k_j^{\text{up}} < (1 - \bar{k}_j)k_j^{\text{ref}}$	$P_j^{\text{dam}} > 0.5$	the damage threshold is exceeded

Table 1: Possible outcomes of Eq. (5).

Additionally, in order to capture a possible damage occurrence, the damage factor DF is introduced and defined as follows:

$$DF = \frac{k_j^{\text{ref}} - k_j^{\text{up}}}{\bar{k}_j} \quad (6)$$

From Eq. (6) it is possible to obtain $DF=0$ if $k_j^{\text{up}} = k_j^{\text{ref}}$ and $DF=1$ if $k_j^{\text{ref}} - k_j^{\text{up}} = \bar{k}_j$. If $DF>1$, it means that k_j^{up} is strongly reduced with respect to the threshold \bar{k}_j , which is a sign of a possible high level of damage for region j or a possible false alarm due the lack of consistency with a damage in the j^{th} region. Hence, the case of $DF>1$ needs to be carefully checked in real world in order to avoid false alarms.

3 THE CASE STUDY: THE CONSOLI PALACE

The Consoli Palace is a medieval building with a rectangular plan and a height of 60 meters above the square level, located in Gubbio, Umbria, central Italy. With reference to Figure 2, three structural components can be identified: a central body; a loggia, connected to the main structure along the south wall; a bell tower. The architectural style of each façade (East and West side), is characterized by round arched windows and merlons in the rooftop. The load-bearing walls have a thickness of about 1.2 m and they are connected through horizontal masonry vaults. The Palace is built in calcareous stone masonry with a regular and homogeneous texture.

Figure 2: The Consoli Palace, located in Gubbio, Umbria, central Italy.

3.1 The SHM system

The monitoring system (Figure 3) was installed and activated by the Department of Civil and Environmental Engineering of University of Perugia in July 2020. Data are stored every 30 minutes with an acquisition sampling frequency of 40 Hz. The SHM system is characterized by:

1. No. 1 NI CompactDAQ-9132 data acquisition system to which sensors A1-A12, C1-C2 and T1-T2 are wired;
2. No. 1 wireless gateway to which sensors C3,C4,T3-T6 are connected;
3. No. 12 PCB393B12 unidirectional accelerometers A1-A12, differently oriented, installed at the 3rd (A7, A8 and A9), 5th (A4, A5 and A6), roof level (A1, A2, A3, A11 and A12) and wired to the acquisition system through NI 9234 acquisition module;
4. No. 4 S-series linear variable transducers (LVDTs), denoted as C1-C4. Sensors C1-C2 are wired to the acquisition system by means of a NI 9219 acquisition modules;
5. No. 6 temperature sensors T1-T6.

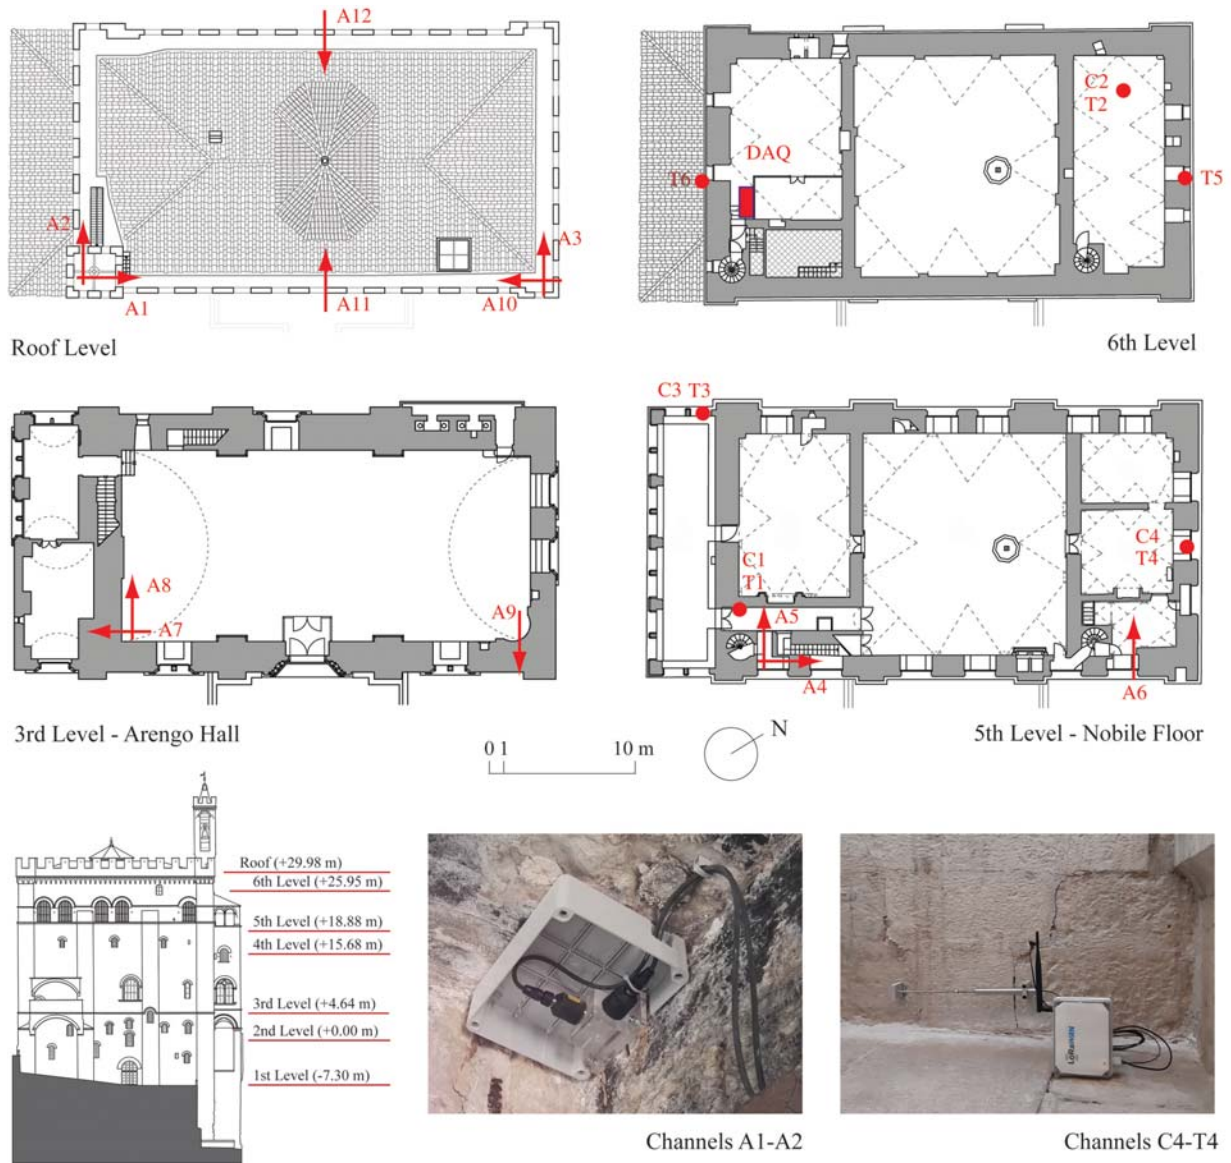

Figure 3: Continuous monitoring configuration.

For the numerical simulations, data stored between July 20th 2020 and December 21th 2020 are used. The training period is set between July 20th 2020 and November 15th 2020). Environmental effects are removed by using Multiple Linear Regression (MLR) by means of the least-angle regression (LAR) algorithm [8], which allows to efficiently select the predictors. It is worth noticing that a training period of 1 year would be more appropriate in order to effectively remove environmental effects.

3.2 FE model

According to Sect 2, step 3, a 3D FE model of the structure has been built and calibrated within the Abaqus environment [22] in order to reproduce local and global modes of vibration identified at $t = 1$. The masonry of the Palace is modeled by means of tetrahedral elements with isotropic materials. The well known concrete damage plasticity (CDP) model is assigned to reproduce the non-linear behavior and the assumed mechanical parameters are summarized as follows [16]:

- parameter which regulates the shape of the yield surface $K_c = 0.667$ (Lubliner criterion);
- eccentricity term $e = 0.1$;
- ratio between the ultimate compression strength in biaxial stress states and in uniaxial conditions $r = 1.16$;
- viscosity parameter $\nu = 0.002$.

Table 2 illustrates the principal vibration modes of the Consoli Palace: Fx1 is a global flexural mode along the x direction ; Fy1 is a global flexural mode along the y direction; L1 is a local mode which pertains to the bell tower; T1 is a global torsional mode. The x and y directions develop along the longer side and the shorter side of the Palace, respectively. The relatively low quality of model calibration, i.e., values of MAC lower than 0.8, has been already discussed in [14, 7].

Mode Fx1	Mode Fy1	Mode L1	Mode T1
			
$f_1 = 2.35 \text{ Hz}$ $MAC_1 = 0.98$	$f_2 = 3.05 \text{ Hz}$ $MAC_2 = 0.76$	$f_3 = 3.46 \text{ Hz}$ $MAC_3 = 0.64$	$f_4 = 4.17 \text{ Hz}$ $MAC_4 = 0.97$

Table 2: FE model-based frequencies and MAC of principal vibration modes.

3.3 FE model-based damage prone regions

Damage-prone regions are selected by means of NLSA and EJ. More in detail, each selected region allows to define a one-parameter dependent model. The different models (1-6) are described in Table 3.

Model No.	Region	Description	Uncertain Parameter	Source
1	R1	Loggia	k_1	EJ
2	R2	Crack pattern x	k_2	NLSA
3	R3	Crack pattern y	k_3	NLSA
4	R4	Bell tower	k_4	EJ
5	R5	Staircase	k_5	EJ
6	R6	main façade's degradation	k_6	EJ

Table 3: The different model selected by means of NLSA and EJ.

In particular: R1 represents the poor connection exerted between the loggia and the central body of the Consoli Palace (Figure 4a); R2 represents the crack pattern resulting from NLSA along x direction capable of reproducing the existing pattern, especially along the south wall

(Figure 4b); R3 refers to the crack pattern resulting from NLSA along the y direction (Figure 4c); R4 pertains to the bell tower (Figure 4d); R5 represents a possible damage to the principal staircase (Figure 4e); R6, which represents degradation of the exterior texture of the main façade of the building (Figure 4f) due to climate-induced material aging [7].

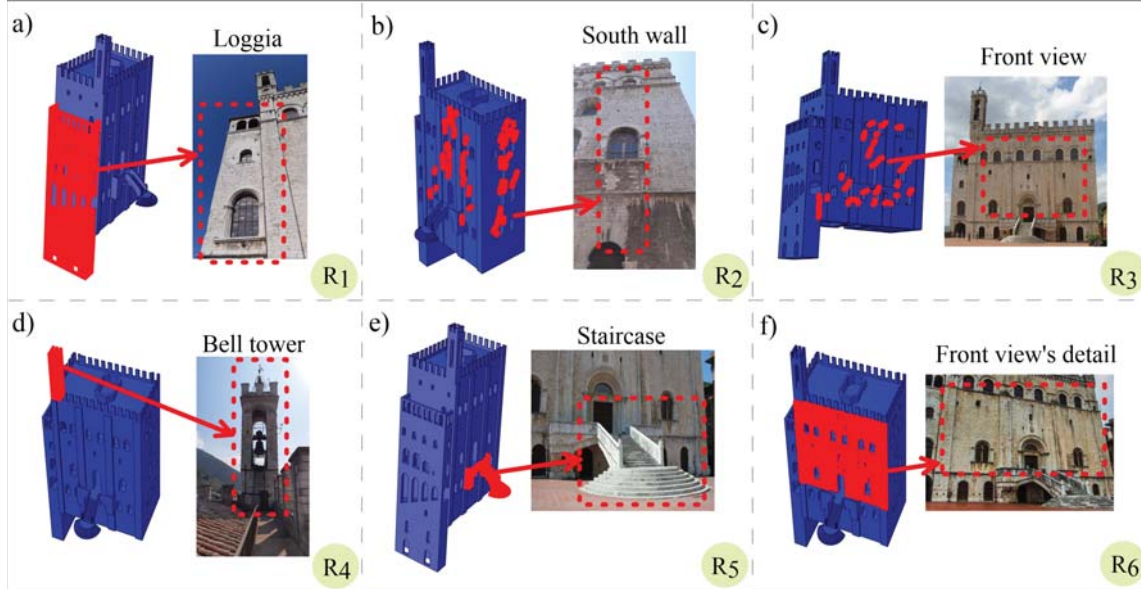

Figure 4: Selected damage sensitive areas with reference to both FE model and real structure: a) R1, the loggia; b) R2, crack pattern y ; c) R3, crack pattern x ; d) R4, the bell tower; e) R5, the staircase; f) R6, the façade degradation.

As reported in Table 3, in such areas, the multipliers of the Young's moduli (k_1, \dots, k_6) assigned to the isotropic material of each region are assumed as uncertain.

In order to calibrate the surrogate model, a total number of 500 samples (N_s) are randomly simulated for the uncertain parameters collected in vector \mathbf{X} . The correspondence between both frequencies and mode shapes is quantified by calculating the coefficient of determination R^2 and the function $J_{MAC} = 1/N_s \sum_i (1 - MAC_i)$ by comparing the FE and the Kriging models, respectively. Values of R^2 and J_{MAC} are summarized in Table 4. From the Table it can be noted

Parameter	Vibration modes			
	Fx1	Fy1	L1	T1
R^2	0.9833	0.997	0.999	0.9968
J_{MAC}	0.0142	0.0015	0.0156	5.85E-5

Table 4: Values of R^2 and (J_{MAC} associated with the calibrated surrogate model.

that the surrogate-predicted frequencies and mode shapes (Kriging estimate) well fit the corresponding FE values.

4 NUMERICAL RESULTS

The SM-based sensitivity damage chart SDC, which relates frequency and MAC values with the uncertain parameters for each Model, is depicted in Figure 5. On the one hand, due to the observed frequency decay, Fx1 (flexural mode along the x direction) appears as the most

damage-sensitive vibration mode for damage-prone regions R2 and R5, Fy1 (flexural mode along the y direction) for R1, R3, R4 and R6, L1 (local mode which pertains to the bell tower) for R4 and R6, and T1 (torsional mode) for R1 and R2. On the other hand, it can be observed that MAC variations can be considered negligible for all damage-prone regions except for R1 and R4. Indeed, a reduction of k_1 provokes a modification in the local L1 mode shapes and a reduction of k_4 induces a huge reduction of Fy1 and L1 MAC values.

Finally, a damage scenarios (Table 5), designated as DII, is selected for the numerical analyses

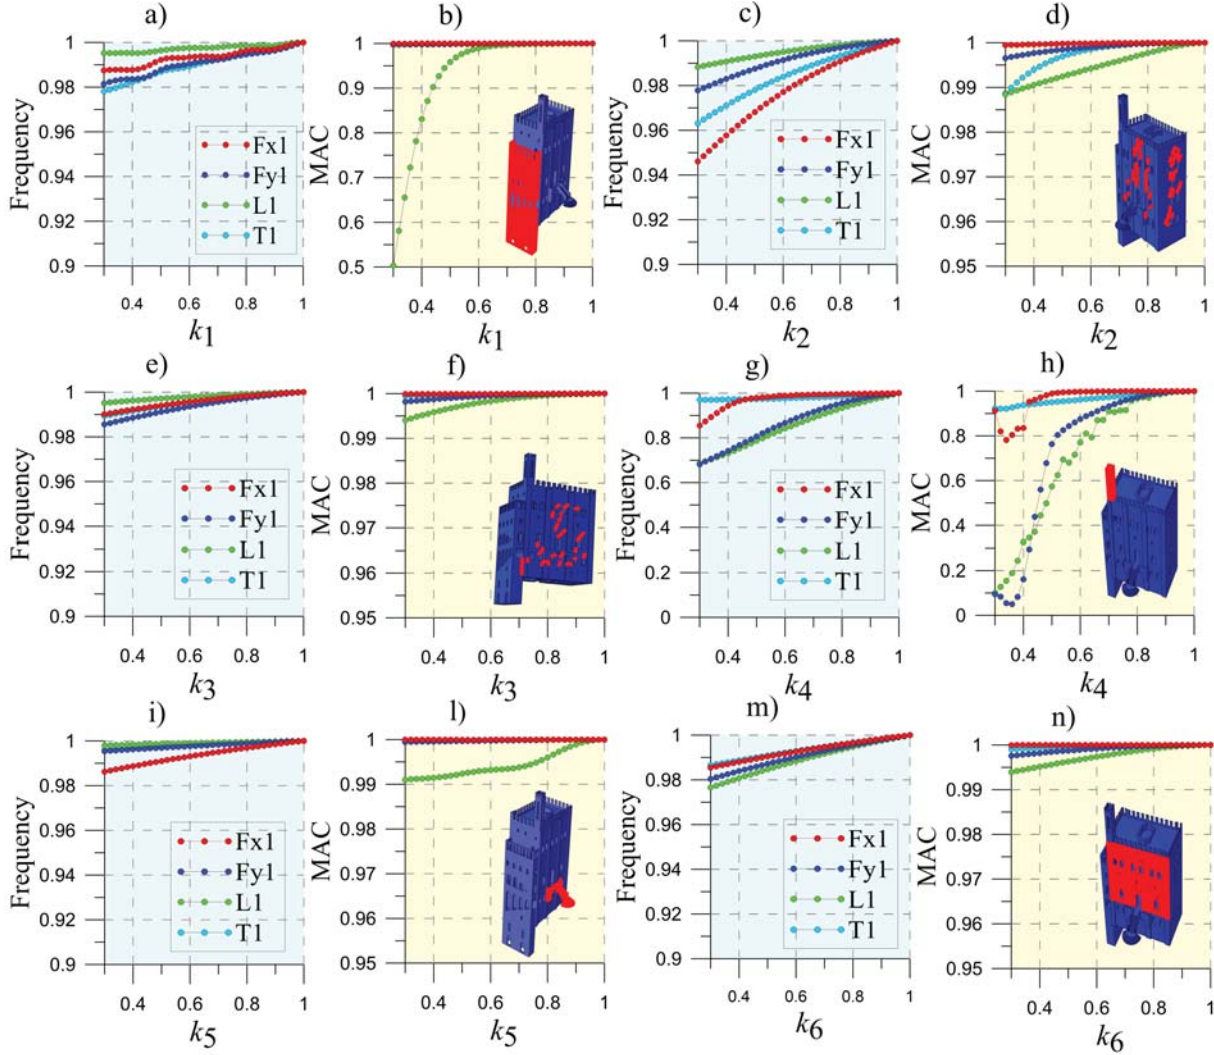

Figure 5: SDC for frequency and MAC decays: a)-b) R1; c)-d) R2; e)-f) R3; g)-h) R4; i)-l) R5; m)-n) R6.

by artificially simulating the frequencies decays (reported in Table 5) extracted from the SDC of region R2 in correspondence with the value of $k_2 = 0.3$, while MAC decays are negligible.

Following, the main results of the Bayesian model updating are summarized by simulating damage scenario DII. The uncertain parameter k_2 is updated once the model is trained, i.e., starting from November 15th 2020. From that moment on, the monitored data are gathered together in subgroups of daily data-sets (t) in order to perform the Bayesian model updating continuously over time on a daily basis. The first 20 days are considered as undamaged. Then, a damage scenario is simulated and the frequency of the model updating is incremented on an hourly basis (t^*), as described in Sect. 2.

Damage scenario	Uncertain parameter						Frequency decays			
	k_1	k_2	k_3	k_4	k_5	k_6	Fx1	Fy1	L1	T1
DII	1	0.3	1	1	1	1	0.054	0.022	0.012	0.037

Table 5: Values of k_j representing the different damage scenarios and corresponding frequency and MAC decays (%).

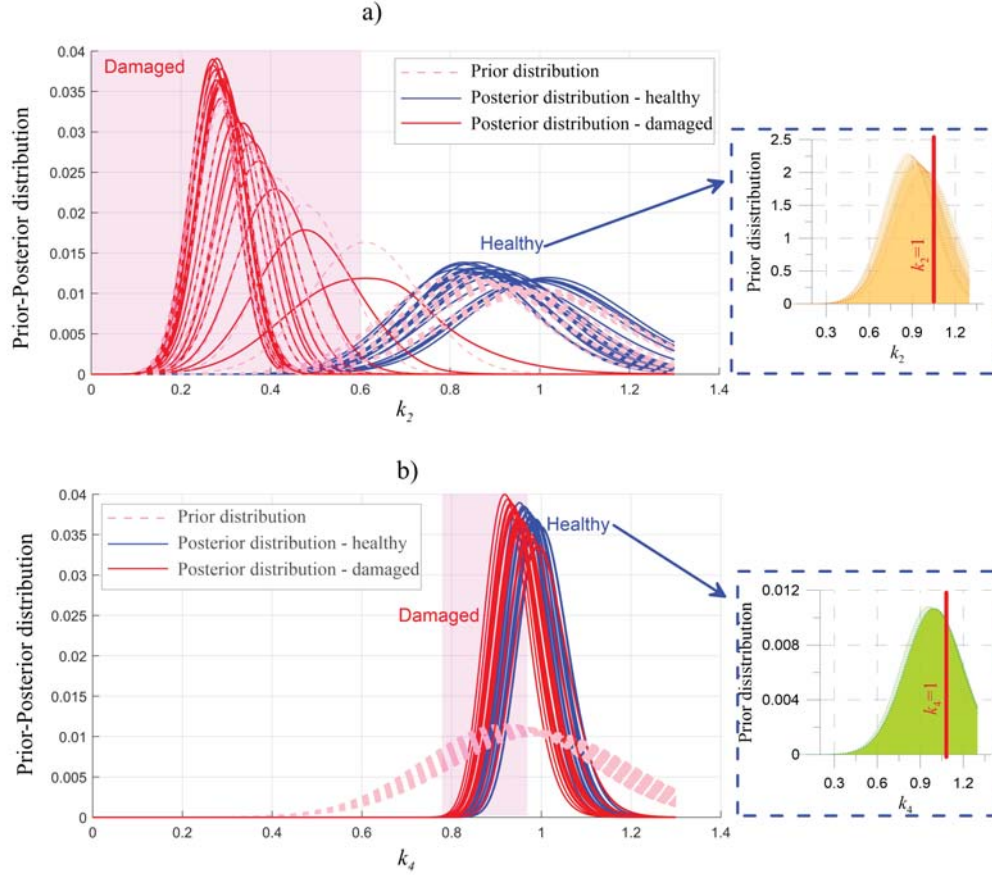

Figure 6: Bayesian-based prior and posterior distributions by simulating damage scenario DII for $k_2 = 0.3$: a) R2; b) R4.

Results in terms of prior and posterior distributions for k_2 and k_4 , when DII is simulated, are depicted in Figures 6a)-b). From the results it can be observed that the posterior distributions associated to the uncertain parameters k_2 and k_4 in the undamaged time period present a fluctuation of the mean value of k_j between about 0.9 and 1. This aspect can be related to the fact that k_j is sensitive to the slight variations which can daily occur in the frequency and, eventually, MAC tracking as confirm by the SDC. This sensitivity to changing environmental conditions can be considerably reduced by considering an appropriate training period, i.e., 1 year. Moreover, consistently with the SDC, the occurrence of a damage for region R2 is clearly highlighted by a translation of the posterior curves towards reduced values of the selected uncertain parameter k_2 (Figure 6a). In detail, it can be observed that the Bayesian-based procedure is able to tracing back to the simulated damage scenario associated to R2, i.e., $k_2^{\text{up}} \approx 0.3$. However, as expected, the simulation of DII barely affects k_4 (bell tower) in the damaged state (Figure 6b), since the mean value of the posterior distribution doesn't significantly change between healthy and damaged conditions.

As concerns the probabilistic damage identification, Figures 7a)-f) illustrate the updated values

of the uncertain parameters k_j^{up} over the number of updates, while Figures 7g)-n) show the trend of DF vs P^{dam} , when simulating the occurrence of damage scenario DII. According to the SDC, the simulated frequency decays are reported in Table 5. The values of \bar{k}_j selected for the eval-

Figure 7: Time series of k_j^{up} over the number of updates by simulating the occurrence of the damage scenario DII (Table 5 for each damage-prone region, with the indication of P^{al} and \bar{k}_j : a) R1; b) R2; c) R3; d) R4; e) R5; f) R6.

uation of DF and P^{dam} are the following: a) R1: $\bar{k}_1 = 0.7$; b) R2: $\bar{k}_2 = 0.7$; c) R3: $\bar{k}_3 = 0.7$; d) R4: $\bar{k}_4 = 0.4$; e) R5: $\bar{k}_5 = 0.7$; f) R6: $\bar{k}_6 = 0.7$. Region R4 pertains to the bell tower and a reduction of the bell tower's stiffness corresponding to 40 % ($k_4 = 0.6$) is assumed sufficient to simulate a damage occurrence. From the Figures it can be noted that P^{al} is reached for region

R2, as expected, and for region R5. This result is consistent with the SDC-based results, since both regions R2-R5 can be designated to damage when a frequency decay of mode Fx1 occurs. The case of R5 deserves a particular attention and needs to be checked in the real-world structure with the main objective to avoid a false alarm. Indeed, after a certain number of updates (see the multiple points in the damaged area), P^{dam} tends to 1, DF approaches 1 and k_5^{up} faces up to $1 - \bar{k}_5$. This fact is due to the higher sensitivity of k_5 to small variations associated to Fx1. On the contrary, the remaining regions exhibit a smaller probability of being damaged, which is consistent with the simulated scenario.

5 CONCLUSIONS

The present paper has presented the numerical results of a transfer learning Bayesian methodology in the context of integrated SHM aimed at the probabilistic damage assessment of monumental structures.

The case study building is the Consoli Palace, located in Gubbio, Umbria (Italy), which has been monitored by the Authors since 2015 with an enhancement of the SHM sensors' network in 2020. The dynamic behavior of the Palace is reproduced on a calibrated FE model and NLSA in conjunction with EJ enabled to pick damage-sensitive regions within the structure. Then, each selected region allows to define a one-parameter dependent model, i.e., the multiplier of the Young's Modulus assigned to the isotropic material associated with each region. The surrogate modeling has been performed by using the Kriging model in order to define the region-dependent SDC as a prior knowledge of possible damage. Finally, a real time Bayesian model updating of the selected uncertain parameters has been developed in order to continuously identify the probability of damage occurrence over the selected regions. The main advantages and innovations of the proposed approach concern:

- the use of real-time long-term monitoring data within the context of Bayesian TL where the surrogate modeling allows real-time data;
- the use of damage factors and damage probabilities enabling informed model-based decisions and providing a basis to mitigate the risk of a false alarm.
- the use of NLSA to generate estimates of potentially vulnerable structural regions alongside with EJ.
- the possibility to continuously identify the probability of damage occurrence over time in a timely manner.

Abstract

Surrogate models, including neural network (NN), machine learning, and Kriging, are used in various fields to reduce the computational demand of risk assessment and uncertainty analysis. In civil engineering applications, surrogate models are usually trained on synthetic data generated with numerical simulation models, which might yield approximate responses and significant computational burdens. Post-disaster reconnaissance observations represent an alternative source of data that could be used to train a surrogate model without the need for numerical models. However, the limited number of reconnaissance observations available in the literature might yield challenges, such as unbalanced data distributions. This paper presents a surrogate-based approach for seismic-induced damage prediction, where post-earthquake reconnaissance data are exploited to train a NN model. The approach is demonstrated on steel liquid storage tanks. Field data from past earthquake reconnaissance reports are first collected. Then, features representative of tank characteristics, seismic hazard parameters, and seismic-induced damage are extracted. A traditional two-layers NN model is built to map the relationship between tank characteristics, seismic hazard parameters, and seismic-induced damage. To tackle the challenge of unbalanced dataset, a cascade NN approach is proposed. In the cascade approach, two NN models are employed to predict the damage level of the steel tanks. The first NN returns a binary classification of the tank damage (i.e., damage, no damage). If the tank results damaged, a second NN identifies the level of damage (i.e., minor, severe, collapse). The performance of traditional and cascade NN approaches is compared using different metrics. Results demonstrate that the cascade NN strategy leads to more accurate damage predictions than the traditional NN approach.

1 INTRODUCTION

Performance-Based Design (PBD) is gaining prominence in the civil engineering community [1]. PBD allows to holistically evaluate a structure for potential risks and engage building owners in cost-effective risk-mitigation strategies [2-4]. It follows that risk assessment is a key component of PBD, as it enables the estimation of the probability of occurrence of a certain damage state, considering a variety of hazard scenarios [1,5]. Typically, the performance of civil structures is assessed through nonlinear numerical models (e.g., finite element models), which permit the evaluation of the structure's response beyond the elastic regime [2,6,7]. However, the computational demand of high-fidelity numerical simulation models, coupled with the necessity to simulate the structure under a large number of hazard and uncertainty scenarios, makes risk assessment a computationally demanding, if not impractical task.

Data-driven surrogate models [8-10], including neural network (NN), Kriging, and machine learning, have been proposed to reduce the computational burden of risk assessment [11,12]. Surrogate models, or metamodels, are simplified mathematical relationships trained based on input/output observations to represent the physical system under consideration. In civil engineering applications, metamodels have been used to replace computationally expensive numerical models for uncertainty and risk analyses. For example, Sudret and Mai [13] employed polynomial chaos expansion to generate fragility curves of a 3-story structure subjected to seismic hazard. Later, Gidaris *et al.* [14] developed a Kriging surrogate model for seismic risk assessment of civil structures. The authors exploited the metamodel to construct fragility functions of a 4-story building under stochastic ground motions and uncertain structural parameters. Recently, Micheli *et al.* [15] proposed a multiple-surrogate models framework for risk assessment of wind-excited tall buildings. The proposed framework exploits a set of Kriging surrogates to reduce the computational demand of risk assessment of high-rise structures subjected to wind load time histories. A drawback of using surrogate models for civil structures is the necessity to generate input/output observations to train the metamodel. Synthetic input/output observations are usually derived from numerical simulation models, which might lead to approximate responses. Furthermore, when the response of the structure is highly nonlinear, a large data pool might be required to train a reliable surrogate model [15-17], yielding a significant computational burden. A solution to this drawback could be to extract input/output observations directly from field data [18]. In this context, post-disaster field reconnaissance reports could be a valuable source of information, enabling a realistic representation of damage mechanisms and hazard characteristics. However, the use of post-disaster reconnaissance observations presents some challenges. For example, the limited number of records available could yield unbalanced datasets, eventually reducing the accuracy of the surrogate model.

This paper investigates a surrogate-based approach for damage assessment of civil structures, where the metamodel is trained based on reconnaissance observations. The approach is demonstrated on aboveground, cylindrical, steel liquid storage tanks subjected to seismic hazard. The seismic risk of storage tanks is significantly higher than ordinary structures, as damage to liquid storage tanks could cause irreparable consequences to built and natural environments, including the release of hazardous materials, uncontrolled fires, and soil contaminations [19-21]. In the proposed approach, features representative of tank characteristics (e.g., diameter, height, thickness, liquid level) and seismic excitation parameters (e.g., peak ground acceleration, magnitude) are extracted directly from reconnaissance reports, along with the corresponding damage levels. Then, a surrogate model consisting of a two-layers NN is built to map the relationship between inputs (i.e., tank and hazard features) and output (i.e., damage level). To tackle the unbalanced dataset challenge, a cascade approach is proposed,

where two NN models are employed to estimate the damage level of steel tanks. The first NN exploits a binary classification to guess if the tank is damaged or not. If the tank results damaged, a second NN identifies the damage level between minor damage, severe damage, and collapse. The accuracy of the NNs is assessed on a testing dataset using different performance metrics, such as accuracy, precision, and recall. The performance at predicting seismic-induced damage of the traditional two-layers NN and the cascade NN models is compared.

The remainder of the paper is organized as follows. First, the collected post-earthquake reconnaissance data are described. Then, traditional and cascade NN approaches are introduced. After, the metrics employed to quantify the performance of the NNs are discussed. Finally, the damage prediction capability of traditional and cascade NNs is compared.

2 METHODOLOGY

2.1 Dataset Description and Features Extraction

In this study, post-earthquake reconnaissance observations are employed as data pool for training a NN model. Such observations were derived from existing post-earthquake reconnaissance report [22] and survey [23]. Both anchored and unanchored cylindrical steel tanks were taken in consideration. Features representative of tank and seismic hazard properties were extracted and used as inputs of the NN models described in Section 2.2. Tank features include geometric characteristics, such as diameter (D), height (H), shell thickness (t), and height of the liquid at the moment of the earthquake (H_L). Peak ground acceleration (PGA) and magnitude (M) were selected as seismic hazard features. For some of the tanks, the thickness was not documented in the post-earthquake report in reference [22]. The thickness of these tanks was estimated based on the work of Cortes and Prinz [24]. Similarly, for some earthquake events, the PGA was not reported, and it was estimated based on the location of the tank and the corresponding ground motion records [25]. The material properties of the steel tanks were not enclosed in the reports. Therefore, yielding stress and modulus of elasticity of steel were assumed to be the same for all tanks and were not included between the input variables. A total of $n = 247$ aboveground, cylindrical, steel liquid storage tanks observations were collected. Table 1 reports the statistics of the dataset, while Figure 1 (a) shows a schematic representation of a storage tank, including the features selected to represent tank and seismic hazard characteristics.

	Min.	Max.	Mean	Standard dev.
Diameter, D (m)	2.0	83	22	14.3
Height, H (m)	3.0	45	11	4.0
Thickness, t (m)	0.001	0.098	0.01	0.01
Liquid height, H_L (m)	0.0	44	10	8.4
Magnitude, M	5.5	8.4	7.0	0.64
Peak ground acc., PGA (g)	0.02	2.0	0.41	0.40

Table 1: Statistics of the dataset.

A description of the damage reported by each tank was also retrieved from the reconnaissance reports [20, 21], along with the corresponding values of tank and seismic features. The

steel tanks experienced various types of seismic-induced damage, including elephant foot buckling, roof damage, shell buckling, and complete collapse [20, 21]. The damage types were assembled in four main classes: class 0, no damage; class 1, minor damage; class 2, severe damage; and class 3, collapse. Minor damage includes damage to the seal, minor roof damage, damaged valves, and, in general, damage that requires simple repairs. Severe damage comprises elephant foot buckling, shell buckling, local buckling caused by roof collapse, and floor plate rupture. Collapse is intended as the tank's total failure, or widely spread damage that necessitates the replacement of the tank. Note that, if more reconnaissance observations become available, additional damage mechanisms could be included and the damage classes may be further refined. Figure 1 (b) shows the distribution of the steel tank observations among the four damage classes, where n_0 represents the number of data in class 0, n_1 in class 1, n_2 in class 2, and n_3 in class 3, respectively. Figure 1 demonstrates that the dataset is severely skewed toward one class only, with the majority of data lying in class 0, and a smaller number of observations belonging to class 3. Such an unbalanced dataset could cause poor performance of traditional NN models, as the majority of the NN algorithms available in the literature were developed considering a balanced data distribution [26].

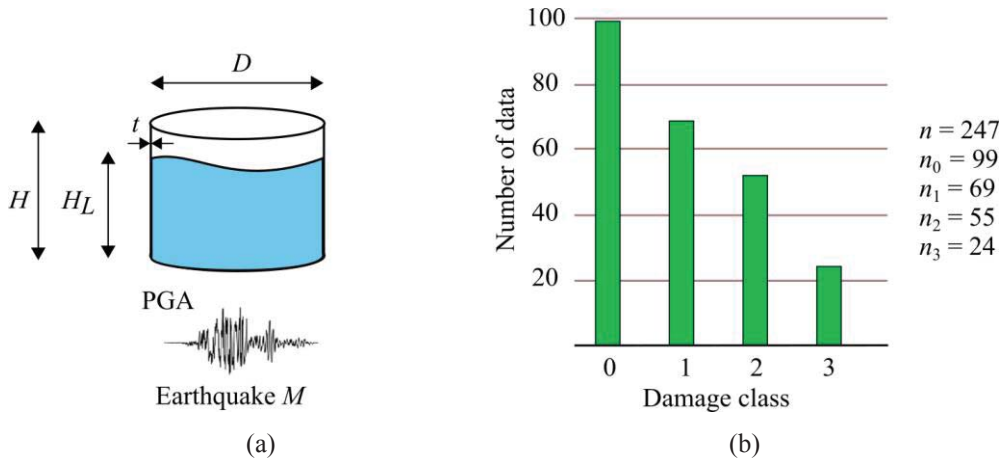

Figure 1: (a) Schematic representation of an aboveground, cylindrical, steel liquid storage tank and input variables; (b) distribution of the data among the four damage classes.

2.2 Neural Network for Damage Prediction

A traditional two-layers NN is first used to map the relationship between tank and seismic hazard characteristics (i.e., inputs) and the corresponding damage class (i.e., output). The NN is composed of a hidden and an output layer, with sigmoid and softmax activation functions, respectively. Figure 2 illustrates a representation of the NN architecture. In the figure, k_1 and k_2 indicate the number of neurons in the hidden and output layers, respectively. The NN has six inputs, corresponding to tank and seismic hazard features, and one output, representing the damage class. The output of the NN can be expressed as [27]:

$$y = g(f(\mathbf{w}_1 \mathbf{x} + \mathbf{b}_1)) \mathbf{w}_2 + \mathbf{b}_2$$

where \mathbf{x} is the input vector, \mathbf{w}_1 and \mathbf{w}_2 are the hidden and the output layers' weights, \mathbf{b}_1 and \mathbf{b}_2 are the hidden and the output layers' biases, f and g are the sigmoid and softmax activation

functions, respectively. The weights and biases are tuned based on the training dataset using a gradient backpropagation algorithm [27].

Figure 2: Neural Network configuration.

To tackle the unbalanced dataset issue (Figure 1 (b)), a cascade NN approach is proposed as an alternative for seismic-induced damage prediction. Instead of a single NN, the cascade approach employs two consecutive NN algorithms to estimate the damage class experienced by a steel tank as a function of the input variables. The first NN is trained based on a binary classification of the data among class 0 (no damage) and class 1 (damage). Note that in the binary classification, all the damaged tanks are lumped in class 1, independently of the type of damage they experienced. A second NN classifies the type of damage among classes 1, 2, and 3, eliminating the data in class 0, and thus, the source of unbalance. Both NN models have the same inputs (tank and seismic hazard features), but different outputs and number of training data. The proposed approach is schematically represented in Figure 3 (a).

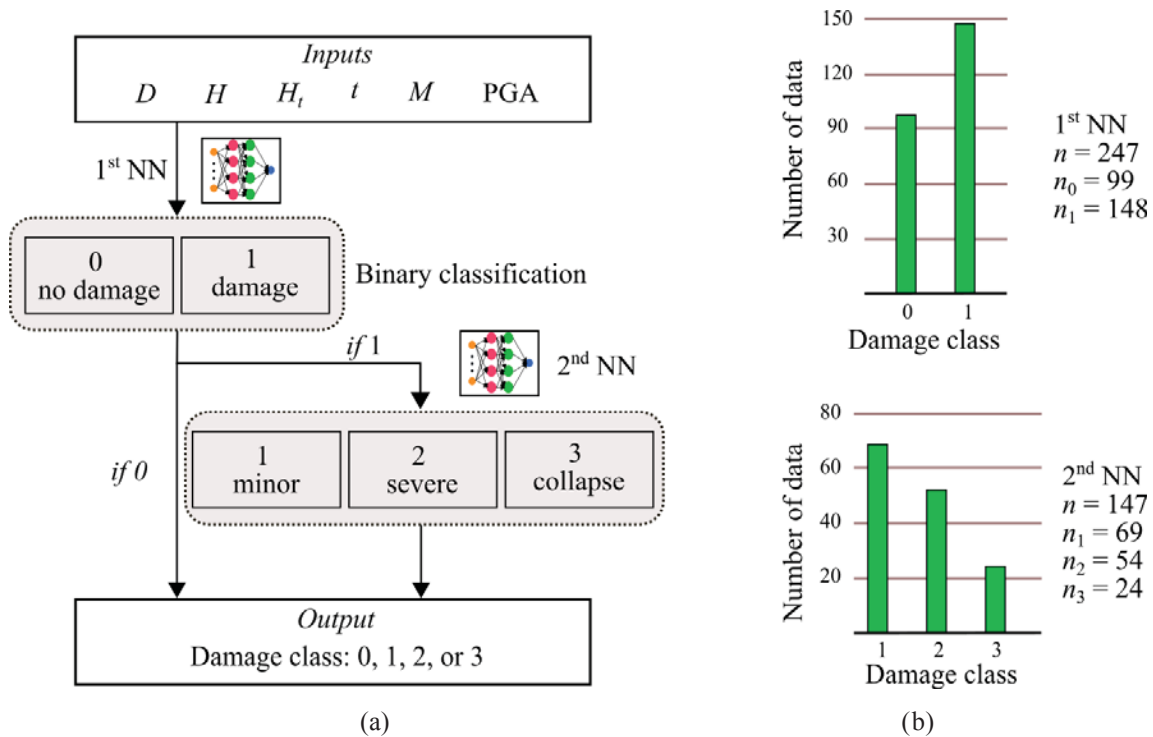

Figure 3: (a) Cascade neural network representation; (b) data distribution among damage classes for the 1st and the 2nd NN models in the cascade approach.

It is worth noting that the cascade approach uses the dataset described in Section 2.1, where data were first rearranged in the binary classification damage/no damage. Then, for training the second NN, data belonging to class 0 were eliminated, leaving only observations lying in classes 1, 2, and 3. The distribution of the data among different damage classes is reported in Figure 3 (b) for the two NN models. Furthermore, the architecture of the two NNs of the cascade approach is the same as the one shown in Figure 2.

2.3 Performance Metrics

The effectiveness of both traditional NN and cascade NNs approaches at predicting the damage experienced by steel liquid storage tanks subjected to seismic hazard is assessed on a testing subset. Specifically, the tank dataset composed of n observations is divided into three subsets: training, validation, and testing. The training data (size $n_{tr} = 70\% n$) is used to train the NN models. The validation subset (size $n_{val} = 15\% n$) is employed to validate the models, while the testing subset (size $n_{ts} = 15\% n$) is exploited to test the prediction capability of the NNs. The performance of the NNs at predicting the damage class in correspondence with the testing data is taken as an indication of the model's performance on unseen data.

		n	n_{tr}	n_{val}	n_{ts}
Traditional	NN	247	173	37	37
	1 st NN	247	173	37	37
Cascade	2 nd NN	147	103	22	22

Table 2: Dataset sizes for the traditional NN and cascade NN models.

The performance of the NNs is evaluated using different metrics, including precision, recall, and accuracy. The precision can be defined as the percentage of damage cases correctly assigned by the NN. The recall represents the percentage of the true damage classes correctly predicted by the algorithm, also referred to as true positives. The accuracy is defined as the ratio between the number of correct predictions and the total number of observations. Precision and recall can be computed for each class, while accuracy is a global performance metric.

3 RESULTS AND DISCUSSION

3.1 Neural Network

The two-layer NN model described in Figure 2 was trained to predict the damage class experienced by the tanks between 0 (no damage), 1 (minor damage), 2 (severe damage), and 3 (collapse) with the dataset described in Section 2.1 and reported in Figure 1(b). MATLAB Toolbox [28] was used to build, train, and test all the NN models developed in this study. The number of neurons k_1 and k_2 were selected iteratively to maximize the accuracy on the validation subset and set as $k_1 = 40$ and $k_2 = 3$. The values of weights and biases obtained from the training process can be found in reference [29]. Note that the trained NN model can be employed to predict the damage level of steel tanks with characteristics lying in the ranges reported in Table 1 only.

Precision, recall, and accuracy for training, validation, and testing datasets are reported in the confusion matrices in Figure 4. Each element of the confusion matrix C_{ij} indicates the

number of data known to be in class i and predicted in class j . The diagonal elements in green are the damage classes correctly guessed by the NN model, while the off-diagonal elements in red are the categories predicted incorrectly. The confusion matrices also contain precision and recall for each class, along with overall accuracy of the model.

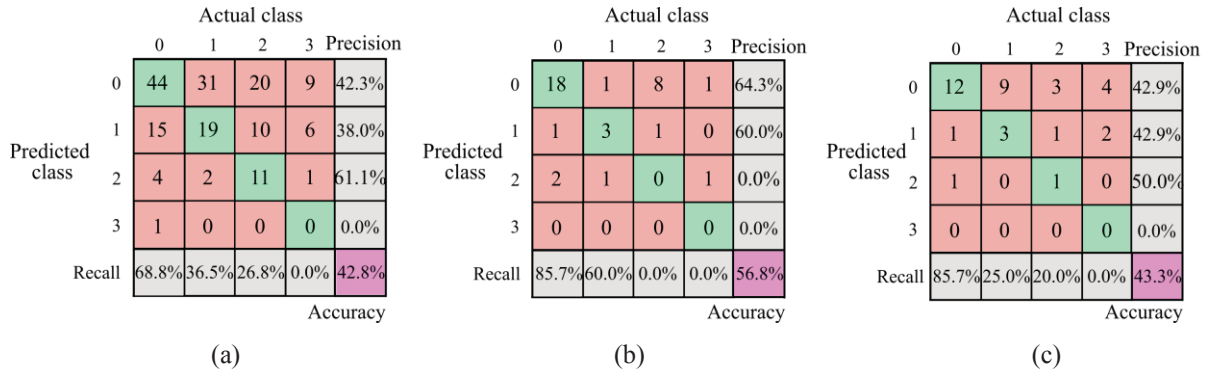

Figure 4: Confusion matrix for the traditional NN: (a) training, (b) validation, and (c) testing datasets.

Results in Figure 4 indicate a relatively poor performance of the NN at predicting the damage classes, with an average accuracy of 47.6% (accuracy averaged over training, validation, and testing datasets). Looking at recall and precision, it can be observed that the simplest class to predict is class 0, where the majority of the data is concentrated. The lowest values of precision and recall correspond to class 3, which corresponds to the class with the smallest number of observations available (Figure 1(b)). The poor performance of the NN can be attributed to the unbalance in the distribution of the data, which are severely skewed toward class 0. In particular, Figure 4 (a) shows that a very small number of data were used to train the NN in class 3, which might translate to poor accuracy of the model over both validation and testing datasets, as demonstrated by Figure 4 (b) and (c).

3.2 Cascade Neural Networks

In the cascade approach, two NN models were built and employed to classify the damage level of steel tanks, following the procedure summarized in Figure 3 (a). The first NN model was trained to predict the binary damage classification 0 (no damage) and 1 (damage) based on the data distribution reported in Figure 3 (b). The second NN was trained to identify the damage level of the tank between class 1 (minor damage), class 2 (severe damage), and class 3 (collapse). For both NN models, the number of neurons was selected iteratively as $k_1 = 10$ and $k_2 = 3$, while weights and biases values can be found in reference [29]. Figure 5 illustrates the confusion matrices for the first NN, while Figure 6 reports the second NN results.

Results in Figures 5 and 6 show that both NN models yield similar performance, with an average accuracy of 73.4% for the first NN and 71% for the second model. For the first NN, the highest values of precision are reached in class 1, while the largest recall correspond to class 0 in training and validation datasets, and class 1 in the testing subset. On the other hand, results in Figure 6 show that class 1 seems to be the simplest class to predict with the second NN model, corresponding to relatively high values of precision and recall over training, validation, and testing datasets.

A cross-comparison between the performance of the traditional and the cascade NN approaches demonstrate that the cascade NNs are 51.7% more accurate than the single NN. This

could be attributed to the more balanced distribution of the observations among different damage classes in the cascade approach. Overall, the performance of the models in terms of recall and precision varies with the damage class under consideration, with the highest values attained by the two cascade NN models. Based on the overall accuracy and the fair performance at identifying different damage classes, the cascade NN approach is recommended as the method to use to estimate the damage level of steel storage tanks as a function of tank and seismic hazard characteristics.

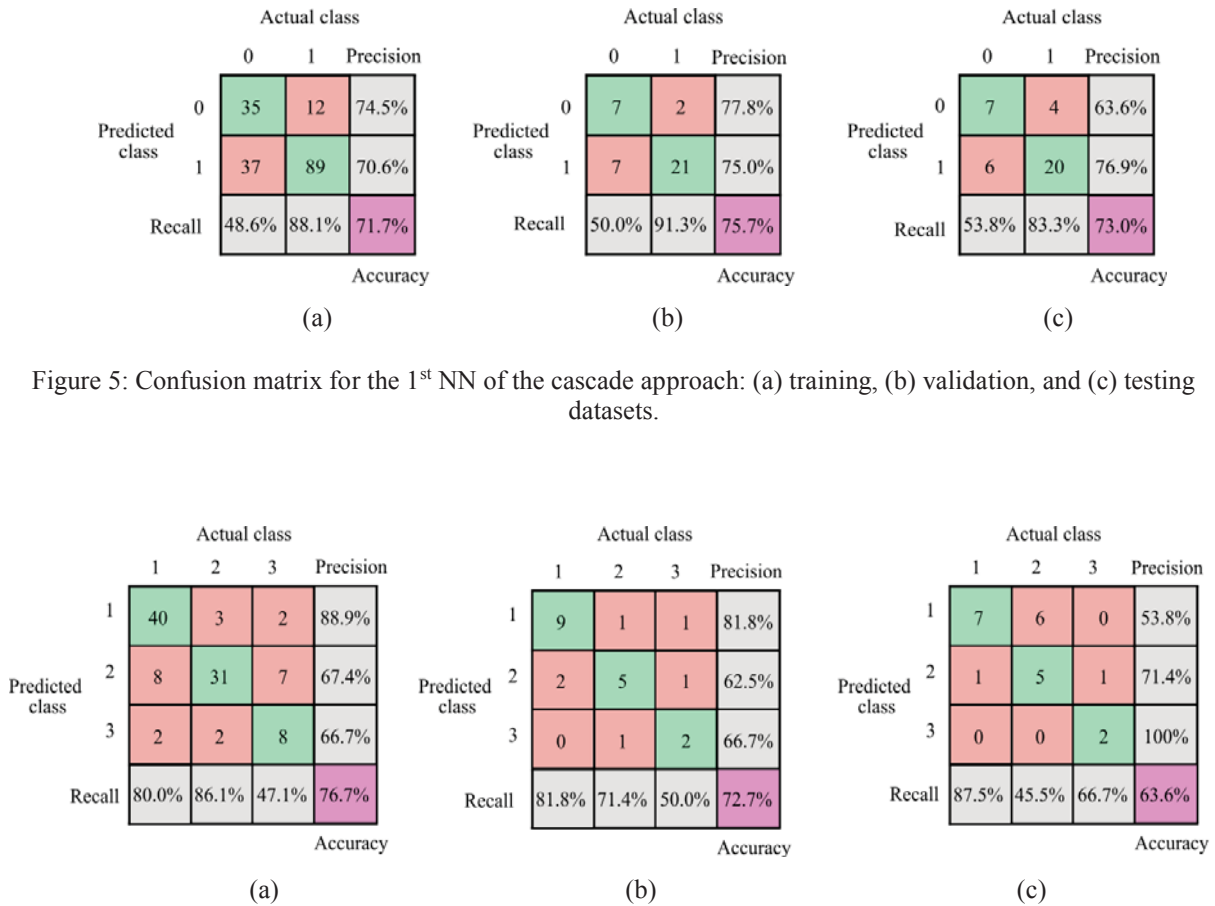

Figure 5: Confusion matrix for the 1st NN of the cascade approach: (a) training, (b) validation, and (c) testing datasets.

Figure 6: Confusion matrix for the 2nd NN of the cascade approach: (a) training, (b) validation, and (c) testing datasets.

4 CONCLUSIONS

In this paper, an NN-based approach for damage prediction of aboveground, cylindrical, steel liquid storage tanks was investigated. In the proposed method, data were derived from post-earthquake reconnaissance reports and surveys. Features representative of tank and seismic hazard characteristics were extracted from the reconnaissance reports, along with a description of the corresponding damage modes. The different types of damage were initially classified into four classes, ranging from no damage to collapse. The limited number of reconnaissance observations available in the literature yielded an unbalanced dataset, with the majority of the data skewed toward one class. First, a traditional two-layers NN was constructed to infer the unknown relationship between tank and seismic features (inputs of the

NN model), and corresponding damage class (output). Then, to tackle the unbalanced dataset challenge, a cascade NN approach was proposed, where two NN models were utilized to guess the damage class of the tanks. The first NN was trained based on a binary classification of the reconnaissance observations (i.e., damage, no damage). If the tank resulted in the damage class from the first model, a second NN refined the damage guess between minor damage, severe damage, and collapse. The performance of traditional and cascade NN methods was assessed with different metrics, such as accuracy, precision, and recall.

Results demonstrated that the cascade NN approach led to a better performance than the conventional NN model, with an average accuracy of 73.4% for the first and 71% for the second NN models. On the other hand, the traditional NN yielded a relatively poor performance, with an average accuracy of 47.6%. The values of recall and precision vary with the damage class under consideration. Overall, the two NNs in the cascade approach resulted in the largest values of both precision and recall compared to the traditional model. The enhanced performance of the cascade NNs can be attributed to the more balanced distribution of the data relatively to the traditional NN dataset.

Overall, the paper showed that the cascade NN approach could be a viable alternative to traditional NN models, in particular when unbalanced datasets are available, such as for post-disaster reconnaissance observations. Nevertheless, the accuracy of the cascade NN models could to be further improved by increasing the number of training data or using different data learning algorithms. Future investigations will entail exploring different machine learning algorithms, applying other techniques to solve the issue of imbalanced data, and integrating the cascade NNs into a seismic risk assessment framework for steel liquid storage tanks.

Abstract

Building floor accelerations recorded during earthquakes represent valuable data which contribute to the improved understanding of structural dynamic behavior and the state of the art and practice. After recording, all accelerations are considered to be “raw” (or unprocessed, uncorrected, unfiltered), and need to be processed before they can be used. In practice, the most common approach is to apply the conventional high- and low-pass filtering methods. However, some records cannot be corrected in such a manner and remain practically useless. The problems which may occur when conventional filtering methods are applied are: (1) inability to distinguish frequencies of noise and signal, (2) change of noise characteristics in time, and (3) a need to estimate and pre-select the parameters of a chosen filter function. These issues can be avoided if wavelets are used for signal processing. In mathematical terms, wavelets are finite wave-like functions which are able to capture local changes, and are used to transform a signal into a representation which shows its properties in the time-frequency domain. Such transformation is known as a wavelet transform. The continuous wavelet transform (CWT) was applied to recordings obtained from a 3-storey reinforced concrete building shake table test performed at the E-Defense facility in Kobe, Japan. It was demonstrated that the CWT represents a useful tool for the visual interpretation of the energy localization in the time-frequency domain, and that there is a large potential for the CWT application in earthquake engineering.

Keywords: Wavelet, Transform, Acceleration, Noise, Filtering.

1 INTRODUCTION

Accelerations recorded during earthquakes provide valuable data which can be utilized in various analyses to contribute to the expansion of knowledge and the improvement of the states of the art and practice. After they are recorded, all accelerations are considered to be “raw” (or unprocessed, uncorrected, unfiltered). So, in order to make them applicable, they need to be processed (i.e. “corrected”). In practice, the most common approach is to apply conventional high- and low-pass filtering methods. However, some records cannot be corrected in such a manner, and they practically remain useless.

An overview of the conventional filtering methods’ shortcomings can be found elsewhere [1] and will not be discussed here in detail. Nevertheless, the main problems which usually occur are: (1) an inability to distinguish frequencies of noise and signal, (2) the change of noise characteristics in time, and (3) a need to estimate and pre-select the parameters of the chosen filter function. These issues are avoided if wavelets are used for signal processing, and this fact was recognized by researchers and engineers [2, 3]. In mathematical terms, wavelets are wavelike functions that satisfy certain requirements, and they are used to transform a signal into a representation which shows the information of the signal in a more useful form. Such transformation is known as a wavelet transform, which is basically a convolution of the wavelet with the signal [4].

Analysis of a signal by using a wavelet transform starts with the selection of a single wavelet, usually referred to as an “analyzing” or “mother wavelet”. Wavelets are manipulated by translation (i.e. movement along the time axis) and dilation (i.e. stretching or compressing), and they are used to decompose the signal into a series of basis functions of the finite length. Understanding the concepts of the scale-varying basis functions is key to understanding wavelets [5]. In a way, roughly speaking, the process can be seen as the “time-frequency” decomposition of the signal, where “modes” represent individual parts of the signal. The essential difference between the wavelet transform and the well-known Fourier analysis is that the former can distinguish localized events at different times at the same frequency [6]. There is a wide selection of wavelets that can be used in practice, and they can roughly be divided into real and complex ones. The choice of wavelet depends on the signal properties and the purpose of analysis. The most commonly used wavelets are Haar, Daubechies, Mexican Hat, Morlet, Meyer, Morse (some of these are shown in Fig. 1), and information about them is widely available in the literature.

Figure 1: Often used wavelets: (a) Daubechies of order 4, (b) Mexican hat, and (c) Morlet.

This paper provides an insight into the practicality and possible benefits of using wavelets for raw acceleration processing. The paper is written from a practical point of view rather than in a mathematical manner, though the following two sections cover fundamental mathematical terms related to the continuous and discrete wavelet transforms. The benefits of the application of wavelets in the processing of acceleration records will be highlighted to encourage their usage in engineering practice.

2 CONTINUOUS WAVELET TRANSFORM

As previously noted, a function must fulfil certain criteria in order to be classified as a wavelet. These are: (1) its energy is finite, (2) it has a zero mean, and (3) the Fourier transform must be both real and vanish for negative frequencies for complex wavelets [4]. If the mother wavelet is denoted as $\psi(t)$, the continuous wavelet transform (CWT), $T(a,b)$, is defined as:

$$T(a,b) = \frac{1}{\sqrt{a}} \int_{-\infty}^{+\infty} \psi^* \left(\frac{t-b}{a} \right) f(t) dt \quad (1)$$

where $f(t)$ is a signal function, and a and b denote the dilation and translation parameters, respectively. Both parameters are real numbers, and a is always positive. It should be noted that the asterisk denotes that the complex conjugate of the wavelet is used, which needs to be taken into account only when complex wavelets are applied. The plot of $T(a,b)$ against a and b is commonly referred to as “transform plot”.

Integration of the wavelet and signal product described by Eq. (1) represents a convolution. In the sense of its energy, the normalized wavelet function can be written as

$$\psi_{a,b}(t) = \frac{1}{\sqrt{a}} \psi \left(\frac{t-b}{a} \right) \quad (2)$$

and so Eq. (1) becomes

$$T(a,b) = \int_{-\infty}^{+\infty} \psi_{a,b}^* f(t) dt \quad (3)$$

CWTs are operable at every scale, they are performed over a continuous range of a and b , and the wavelet is shifted smoothly over a full domain of the considered signal. There are several advantages in applying the CWT. For example, the movement of wavelet along the signal enables identification of the “coherent structures” within the signal, whereas the Fourier transform does not provide any information on the nature of the signal local features. Also, sudden discontinuities in the signal can be easily identified by the CWT. Furthermore, the selection of $\psi(t)$ can be such that the $T(a,b)$ contains sufficient information for the reconstruction of the signal function $f(t)$, and this is possible by using the inverse wavelet transform. However, it should be mentioned that in the inverse transform the original wavelet function is used, not the conjugate one. Thus, the integration over a range of a scales rather than all a scales makes basic filtering of the original signal possible [4].

Under the assumption that the signal contains a finite energy, the signal’s total energy can be obtained by integrating its squared magnitude

$$E = \int_{-\infty}^{+\infty} |f(t)|^2 dt \quad (4)$$

It is possible to determine the part of the energy corresponding to the particular scale a and location b as

$$E(a,b) = |T(a,b)|^2 \quad (5)$$

Graphical representation of $E(a,b)$ is called “scalogram”, and it provides a useful picture of the non-stationary process nature and energy distribution, which is shown in the application

example later in the paper. It should be noted that scalograms and transform plots have similar forms, which is a consequence of their definitions.

A known issue with the CWT analysis is the so called “edge” or “boundary” effect. It arises from the fact that the signal data set is finite and that it usually needs to be analyzed as a whole. Practically speaking, wavelets extend beyond the signal edges, and the transform is disrupted. In transform plots and scalograms, the region that is potentially affected by the edge effect is called the “cone of influence”. Its extent is proportional to the wavelet width (i.e. it increases linearly with parameter a). However, since logarithmic scale is usually used for a , the cone of influence becomes curved. The extension of the cone depends on the wavelet scale. Unfortunately, the precise way to determine the extent of cone at each scale does not exist, so it is rather a subjective decision. For instance, for Morse wavelets, which are used in the example in this paper, a useful proposal is available in the literature [7].

3 DISCRETE WAVELET TRANSFORM

In order to present the basics of the discrete wavelet transform (DWT), firstly consider Eq. (2), a continuous signal $f(t)$, and the discrete values of parameters a and b , which are linked to each other [4]. Thus, the discretization of the wavelet has the following form:

$$\psi_{m,n}(t) = \frac{1}{\sqrt{a_0^m}} \psi\left(\frac{t - nb_0 a_0^m}{a_0^m}\right) \quad (6)$$

where a_0 is the selected dilation step larger than 1, b_0 is the location parameter larger than 0, and m and n are integers that control the wavelet dilation and translation, respectively.

By considering Eq. (6), the wavelet transform of the signal $f(t)$ becomes

$$T_{m,n} = \int_{-\infty}^{+\infty} \frac{1}{a_0^{m/2}} \psi(a_0^{-m}t - nb_0) f(t) dt \quad (7)$$

In the case of the DWT, the values of $T_{m,n}$ are known as “wavelet coefficients”. In practice, the values of a_0 and b_0 are often chosen to amount to 2 and 1, respectively. These values lead to the so called “dyadic grid” arrangement, a simple and efficient discretization which leads to an orthonormal wavelet basis. By considering $a_0 = 2$ and $b_0 = 1$, Eq. (6) becomes

$$\psi_{m,n}(t) = 2^{-m/2} \psi(2^{-m}t - n) \quad (8)$$

Moreover, it is common to select the discrete dyadic grid wavelets to be orthonormal (i.e. orthogonal to each other) and normalized so that they have unit energy. In other words, the product of each wavelet with all others in the same dyadic system is zero. This way, the information contained in each coefficient $T_{m,n}$ is not repeated elsewhere, which provides the possibility to fully recover the original signal. If Eq. (8) is considered, the DWT can be expressed as

$$T_{m,n} = \int_{-\infty}^{+\infty} \psi_{m,n}(t) f(t) dt \quad (9)$$

The considered signal can be reconstructed from the inverse DWT:

$$f(t) = \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} T_{m,n} \psi_{m,n}(t) \quad (10)$$

Note that for the DWT described by Eq. (9) the transform integral is continuous over the discretized grid. Thus, the summation in Eq. (10) provides the return of the exact signal. It is important to note though that there is a difference between the DWT and the so called discretized CWT, in which the discrete approximation of the transform integral is usually involved, in order to be able to perform its computation. Such computing of the CWT is quite robust, and in practice the fast Fourier transform is used instead.

Finally, the energy of the signal can be determined as

$$E = \int_{-\infty}^{+\infty} |f(t)|^2 dt = \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} |T_{m,n}|^2 \quad (11)$$

4 EXAMPLE OF APPLICATION

In this section an example of application of the CWT is presented, and the application of the DWT may be found in the works of Pan and Kusunoki [2] and Kusunoki et al. [8], who used it to extract the predominant building response for structural health monitoring purposes. The signal that was analyzed is the absolute acceleration at the second floor of a 3-storey reinforced concrete frame building specimen recorded during shake table tests at the E-Defense facility in Kobe, conducted between the 3rd and 7th December 2019. The test was a part of the Tokyo Metropolitan Resilience Project, Subproject C, Theme 2 [9]. Some other recordings from the same building were previously subjected to the CWT by Yeow and Kusunoki [10].

The building properties and the description of ground motions used as input during the test are available in Yeow et al. [11]. For the analysis presented in this paper, the fourth applied motion was considered (denoted as 1.5–2 in [11]). During that input motion the structural response was highly nonlinear. Raw absolute acceleration under consideration is shown in Fig. 2. It was normalized with the respect to its absolute peak value, so it is dimensionless.

Figure 2: Normalized absolute acceleration recorded at the second floor of the considered building.

The CWT was applied to the recorded signal by using the *cwt* function which is integrated in the Wavelet Toolbox of MATLAB R2019b. The analytic Morse wavelet was adopted as the mother wavelet. The reconstruction of the signal was obtained by using the *icwt* function, which inverts the CWT coefficient matrix, by using the same predefined default parameters of the Morse wavelet as the *cwt* function. In order to perform filtering using the *icwt* function the frequency range of interest needs to be specified. This can be obtained using scalogram plots.

The scalogram obtained for the considered record is shown in Fig. 3. The dashed white line marks the cone of influence described earlier. Horizontal and vertical axes show time and frequency in the logarithmic scale, respectively, and the wavelet transform magnitude scale is shown on the right. The interpretation of the scalogram presented in Fig. 3 is quite straightforward. The parts of it in which the magnitude is sizeable are either related to the response of the structure, or to the noise and certain anomalies (e.g. a loose cable moving during shaking).

In the considered case, the influence of the response in the fundamental mode is localized at approximately 1.5 Hz, whereas the influence of the second mode is obvious at 10 Hz. It can be seen that the scalogram can be used for the visualization of modes.

As noted above, in order to perform filtering, it is necessary to select the frequency range of interest. It is usually done intuitively, which may be seen as a limitation of the CWT approach. Herein, the frequency range of 0.2 to 12 Hz was chosen. In this way, the noise at frequencies above 12 Hz was eliminated. A comparison of the raw and corrected accelerations, normalized to their absolute peak values, is shown in Fig. 4. It is obvious that the spikes are eliminated, and that the original signal is successfully recovered.

Figure 3: Scalogram of the considered absolute acceleration record.

Figure 4: Comparison of the raw and corrected absolute accelerations in (a) the interval of 38 to 42 s, and (b) between 41 and 42 s.

The corrected acceleration can be integrated in order to obtain velocity and displacement, but it usually needs to be baseline-corrected first. This known issue is beyond the scope of the paper, and more details can be found elsewhere [1]. Another issue is that wavelets have zero-mean, meaning that the acceleration signal and its integrals (i.e. velocity and displacement) will always eventually return to zero. This poses an issue with obtaining residual deformations, though such issues already exist when obtaining displacements from acceleration data using conventional means [12]. Alternatives such as using Kalman filters could be an option [13, 14], but this is outside the scope of this research and will not be elaborated upon further here.

While not shown here, the DWT approach has been used in literature to extract out the predominant hysteretic response of buildings based on floor acceleration recordings. This is done by: (i) decomposing the acceleration recordings of each floor using the DWT, (ii) obtaining the relative floor acceleration and displacement response for each decomposition level, (iii) simplifying the multi-degree-of-freedom response into an equivalent single-degree-of-freedom response for each decomposition level, (iv) using the equivalent response of each decomposition level to identify which should be eliminated, and (v) re-computing the equivalent single-degree-of-freedom response using the remaining decomposition levels. Examples of the application are available in literature [2, 3, 8].

5 CONCLUSIONS

Wavelet transforms represent an alternative to the conventional high- and low-pass filtering methods, with whose application it is sometimes not possible to correct the acceleration data recorded during earthquakes. Mathematical background of the continuous and discrete wavelet transforms was briefly provided, along with the example of application of the former on the acceleration recorded during the shake table test. Application of the continuous wavelet transform by using the available commercial software was demonstrated, along with interpretation of the scalogram data and discussion on the pros and cons of the approach. Even though the use of wavelet transforms in earthquake engineering started only relatively recently, their large potential is already recognized.

Abstract

Earthquake loadings can cause significant principal stress rotation (PSR) in the sand bed. Even the pure PSR (rotation of principal stress axis with constant principal stress magnitudes) can lead to the build-up of excess pore water pressures and accumulation of plastic strains, thus accelerating sand liquefaction in undrained conditions. This paper conducts the fully coupled finite element simulations of a centrifuge test to investigate the PSR effect under earthquake loadings. The PSR is considered by using a PSR model developed based on an elastoplastic sand model with kinematic hardening and bounding surface concepts. The numerical predictions from the PSR model and base model are compared with the experimental results. The comparative study shows that the PSR model performs better than the base model at capturing the sand responses and liquefactions behaviors. The investigation also finds obvious PSR in the sand bed and demonstrates the importance of considering the PSR effect under earthquake loadings in undrained conditions.

Keywords: Earthquake loading, Principal stress rotation, Elastoplastic model, Liquefaction, Finite element simulation

1 INTRODUCTION

Earthquake loadings can lead to quite complicated stress conditions in the soil bed, such as conditions with principal stress rotation (PSR). Early in 1983, Ishihara and Towhata found that the PSR at fixed principal stress magnitudes can also cause the build-up of excess pore water pressure, the reduction of effective confining pressure and the increase of plastic strain in undrained conditions, which could further accelerate sand liquefaction and lead to catastrophic failure of foundations [1]. Similar conclusion and the importance of considering the PSR were also proposed by other researchers [2-5]. Ignoring the PSR effect can lead to inaccurate computations and unsafe designs. During last decades, numerous experimental and numerical attempts have been made to investigate the earthquake induced soil behaviors, such as VELACS (Verification of Liquefaction Analysis using Centrifuge Studies) [6], LEAP (Liquefaction Experiments and Analysis Projects) [7], etc. Although a number of numerical simulations have been conducted for these projects [7-10], there are few of them focusing on the PSR effect under earthquake loadings.

Therefore, this paper aims to investigate the effect of PSR induced by earthquake loadings in the sand with a series of numerical studies using an elastoplastic constitutive model considering the PSR, which is improved based on a bounding surface model with the critical state theory. The model will be verified in the numerical simulations of geotechnical laboratory tests and then implemented in the finite element simulations of the VELACS centrifuge model test. The numerical predictions from the original base model, the improved PSR model and the experimental results will be compared.

2 THE ORIGINAL BASE MODEL

The bounding surface model proposed by Dafalias & Manzari [11] is chosen as the base model. This model adopts the critical state theory, the kinematic hardening rule and state parameter to represent sand with different initial states. To better illustrate and focus on the PSR effect, the fabric change effect in their original work is not considered in this paper. The basic model formulations are briefly introduced as follows.

The yield surface of the model is given as:

$$f = [(\mathbf{s} - p\boldsymbol{\alpha}) : (\mathbf{s} - p\boldsymbol{\alpha})]^{1/2} - \sqrt{2/3} pm = 0 \quad (1)$$

where \mathbf{s} and $\boldsymbol{\alpha}$ are the deviatoric stress and back-stress ratio tensor, respectively. p is the confining pressure and m represents the radius of yield surface. The normal to the yield surface is given as:

$$\mathbf{l} = \frac{\partial f}{\partial \boldsymbol{\sigma}} = \mathbf{n} - \frac{1}{3} (\mathbf{n} : \mathbf{r}) \mathbf{I} \quad (2)$$

where \mathbf{n} is defined as the normal to the yield surface on the deviatoric plane. \mathbf{r} equals to \mathbf{s}/p and \mathbf{I} is the isotropic tensor. The elastic volumetric strain increment $d\boldsymbol{\epsilon}_v^e$ and elastic deviatoric strain increment $d\boldsymbol{\epsilon}^e$ are given as:

$$d\boldsymbol{\epsilon}_v^e = dp / K \quad (3)$$

$$d\boldsymbol{\epsilon}^e = d\mathbf{s} / 2G \quad (4)$$

The plastic strain increment $d\boldsymbol{\epsilon}^p$ is given as:

$$d\boldsymbol{\epsilon}^p = \langle L \rangle \mathbf{R}; \quad L = \frac{1}{\kappa_p} \left(\frac{\partial f}{\partial \boldsymbol{\sigma}} \right) : d\boldsymbol{\sigma}; \quad \mathbf{R} = \mathbf{n} + \frac{1}{3} D \mathbf{I} \quad (5)$$

where L is loading index and \mathbf{R} represents the direction of $d\boldsymbol{\epsilon}^p$. The plastic modulus K_p and the dilatancy ratio D are given as:

$$K_p = \frac{2}{3} p \left[G_0 h_0 (1 - c_h e) \left(\frac{p}{p_{at}} \right)^{-1/2} \right] \left[\frac{|\mathbf{b} : \mathbf{n}|}{|(\boldsymbol{\alpha} - \boldsymbol{\alpha}_{in}) : \mathbf{n}|} \right] \quad (6)$$

$$D = A_d \mathbf{d} : \mathbf{n} \quad (7)$$

where \mathbf{b} and \mathbf{d} are distances between the back-stress ratio and bounding surface and dilatancy surface back-stress ratio, respectively. $\boldsymbol{\alpha}_{in}$ represents the value of $\boldsymbol{\alpha}$ at the very beginning of each loading stage and requires update when the negative denominator occurs. h_0 , c_h and A_d are model parameters.

3 THE MODIFIED PSR MODEL

In the PSR model, the plastic strain increment is split into two parts—the monotonic strain increment $d\boldsymbol{\epsilon}_m^p$ and the PSR strain increment $d\boldsymbol{\epsilon}_r^p$. The model formulations are briefly introduced here and details can be found in Yang and Yu [12]. The subscript m and r represent monotonic and PSR loading hereinafter. The plastic strain increment is defined as:

$$d\boldsymbol{\epsilon}_m^p = \langle L_m \rangle \mathbf{R}_m = \frac{1}{K_p} \left(\frac{\partial f}{\partial \boldsymbol{\sigma}} d\boldsymbol{\sigma}_m \right) \mathbf{R} \quad (8)$$

$$d\boldsymbol{\epsilon}_r^p = \langle L_r \rangle \mathbf{R}_r = \frac{1}{K_{pr}} \left(\frac{\partial f}{\partial \boldsymbol{\sigma}} d\boldsymbol{\sigma}_r \right) \mathbf{R}_r \quad (9)$$

\mathbf{R}_r represents the direction of PSR strain increment and is given as:

$$\mathbf{R}_r = \mathbf{n} + \frac{1}{3} D_r \mathbf{I}; \quad D_r = A_r (1 - \alpha / \alpha_\theta^b) \alpha \quad (10)$$

where D_r is the PSR dilatancy ratio and A_r is model parameter for the PSR effect on dilatancy. The PSR plastic modulus K_{pr} is given as:

$$K_{pr} = \frac{2}{3} p \left[G_0 h_{0r} (1 - c_h e) \left(\frac{p}{p_{at}} \right)^{-1/2} \right] \left(\frac{|\mathbf{b} : \mathbf{n}|}{|(\boldsymbol{\alpha} - \boldsymbol{\alpha}_{in}) : \mathbf{n}|} \right)^{\xi_r} \quad (11)$$

where h_{0r} and ξ_r are new model parameters for the PSR effect. The final relationship between the stress and strain increments can be derived as:

$$d\boldsymbol{\sigma} = \mathbf{E}^{ep} d\boldsymbol{\epsilon} \quad (12)$$

$$\mathbf{E}^{ep} = \mathbf{E} - B_1 \left[\frac{(\mathbf{E}\mathbf{R})(\mathbf{I}\mathbf{N}_r^*)}{K_{pr} + \mathbf{I}\mathbf{N}_r^* \mathbf{R}_r} - \frac{(\mathbf{E}\mathbf{R})(\mathbf{I}\mathbf{E})}{K_{pr} + \mathbf{I}\mathbf{E}\mathbf{R}_r} \right] - B_2 \left[\frac{(\mathbf{E}\mathbf{R}_r)(\mathbf{I}\mathbf{N}_r^*)}{\mathbf{I}\mathbf{N}_r^* \mathbf{R}_r} - \frac{(\mathbf{E}\mathbf{R}_r)(\mathbf{I}\mathbf{E})}{K_p + \mathbf{I}\mathbf{E}\mathbf{R}_r} \right] \quad (13)$$

$$\mathbf{N}_r^* = 2G \mathbf{N}_r \quad (14)$$

$$B_1 = \left(\frac{\mathbf{I}\mathbf{N}_r^* \mathbf{R}_r}{K_{pr} + \mathbf{I}\mathbf{N}_r^* \mathbf{R}_r} - \frac{K_p + \mathbf{I}\mathbf{E}\mathbf{R}_r}{K_{pr} + \mathbf{I}\mathbf{E}\mathbf{R}_r} \right)^{-1} \quad (15)$$

$$B_2 = \left(\frac{K_{pr} + \mathbf{I}\mathbf{N}_r^* \mathbf{R}_r}{\mathbf{I}\mathbf{N}_r^* \mathbf{R}_r} - \frac{K_{pr} + \mathbf{I}\mathbf{E}\mathbf{R}_r}{K_p + \mathbf{I}\mathbf{E}\mathbf{R}_r} \right)^{-1} \quad (16)$$

where \mathbf{E} is the elastic stiffness and \mathbf{N}_r is defined to project the total stress increment to the PSR direction. It can be seen that the modified PSR model obtained a stiffness tensor independent of stress increments and the linear relationship between the stress and strain increments, thus facilitating its finite element applications in boundary value problems.

4 MODEL CALIBRATION AND SIMULATIONS OF LABORATORY TESTS

The sand used in the VELACS centrifuge model test chosen to be simulated is Nevada sand. Its specific gravity is 2.67 and has maximum and minimum void ratios of 0.887 and 0.511, respectively. Therefore, a series of undrained triaxial tests (N50U1, N60U1002, N60U2501) and rotational shear tests using Nevada sand from Chen and Kutter [13] are adopted to calibrate the model parameters and verify the model. Some typical results are presented in Figure 1 & 2 and model parameters calibrated are listed in Table 1. The first 13 parameters are calibrated using the method proposed by Dafalias and Manzari [11, 14]. The PSR parameters h_{0r} and ξ_r are calibrated by the shear stress-strain relationships in undrained rotational shear tests while A_r is determined from the volumetric responses.

	Constant	Parameters	Value
Base model	Elasticity	G_0	150
		ν	0.25
	Critical state	M	1.45
		c	0.712
		λ_c	0.005
		e_0	0.807
		ξ	0.5
	Yield surface	m	0.05
	Plastic modulus	h_0	5.5
		c_h	0.968
		n^b	0.55
	Dilatency	A_0	0.6
		n^d	3.5
Modified model	Plastic modulus	h_{0r}	0.9
		ξ^r	1.1
	Dilatancy	A_r	0.5

Table 1: Model parameters of Nevada sand used in the numerical simulation.

Figure 1 presents the numerical predicted results along with the experimental results of undrained triaxial tests. The numerical simulations have successfully reproduced the sand responses under undrained monotonic loadings, including the contractive-dilative phase transformation, the peak stress ratio q/p' around 1.45 and the increase of axial strains with deviatoric stresses. It should be noted that there is no difference between the predicted results from the base model and modified PSR model because the direction of principal stresses does not change in the monotonic triaxial tests.

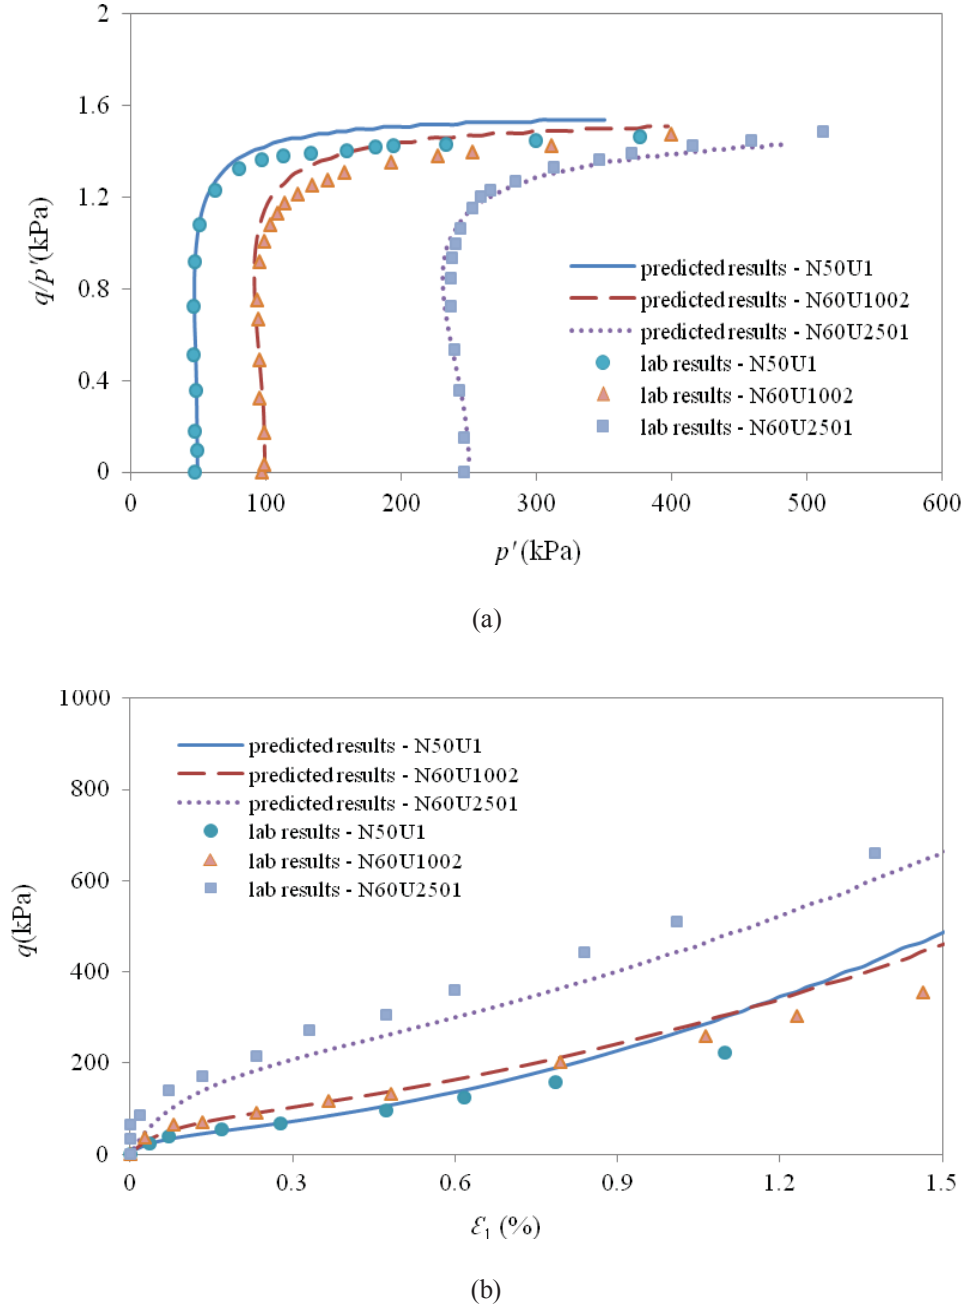

Figure 1: Predicted results and experimental results of stress-strain behaviors for undrained triaxial tests.

Figure 2 shows the numerical predicted results of the undrained rotational shear test from the base model and the modified model, as well as the experimental results. In Figure 2a, the effective confining pressure p' in the predicted results from the modified model reduced to the lowest value of 50 kPa, which agrees well with the experimental results. However, in the predicted results from the base model, both the reduction of p' and accumulation of deviatoric strain were underestimated. In the shear stress-strain behaviors in Figure 2b, the modified model has reproduced the accumulation of shear strain and dramatic shear strain increase in the last few cycles, which indicates the occurrence of liquefaction and agrees well with the experimental results. However, the base model still underestimates the shear strain accumulation because it is not able consider the PSR effect, which is important in cyclic loading conditions such as in the rotational shear test.

5 FINITE ELEMENT ANALYSIS

5.1 Problem definition

Model No.3 in VELACS centrifuge testing project is chosen to investigate the PSR effect and verify the modified model in boundary value conditions under earthquake loadings. The centrifuge model contains a 220 mm deep laminar box deposited with saturated sand, which is further horizontally divided into two layers with the relative density of 40% and 70%, respec-

tively (Figure 3). The soil sample is measured with 7 accelerometers, 10 pore water pressure transducers and 6 displacement LVDT transducers. Horizontal base shaking is then applied to the laminar box.

The numerical simulation is conducted using a fully coupled finite element computer code, which adopts the Hilber-Hughes-Taylor α time integration method and a predictor-multi-corrector algorithm to achieve quadratic accuracy [15]. The model scale gravitational acceleration of 50 g is used in the simulation and 30 seconds is considered in total, as the liquefaction occurs at the majority of the sand bed after 30 seconds.

Figure 3: The front view configuration and the location of measuring instruments for the centrifuge model test.

5.2 Predicted results and comparison with the experimental data

The time histories of excess pore water pressure at typical locations are shown in Figure 4. Generally, the predicted results from the modified model have reached nearly the same peak value as the experimental data and agree well with the experimental results. In contrast, the base model has significantly underestimated the build-up of excess pore water pressures. For example, the peak value of excess pore water pressure from the base model only reached 27 kPa in location P3, which is 15 kPa lower than the experimental data. The stress path in the p' - q space at a typical location is presented in Figure 5. It is obvious that the modified model has brought the soil to liquefaction and captured the critical features such as the zero p' and the butterfly shape stress path in the liquefaction state while the base model only achieved the lowest p' value of 5 kPa and does not reach the liquefaction state. Figure 6 shows the predicted results of the displacement along with the experimental results in typical locations of L1 and L2. It can be seen that there are again significant differences between the predicted results from the two models. The modified model has reproduced the increase of displacement after the base shaking started and generally agrees with the experimental data, although slight overestimation can be observed at location L2 in the last few seconds. However, the maximum displacements in predicted results from the base model are 0.51 mm at location L1 and 1.52 mm at location L2, respectively, which is far from the experimental data. This is because the base model has failed in reproducing the PSR effect and liquefaction behaviors. The comparative study above has demonstrated that it is important to consider the PSR effect as ignoring it can cause the underestimation of the build-up of excess pore water pressure, the decrease of effective confining pressure and the increase of displacement, thus leading to inaccurate computations and unsafe designs.

6 CONCLUSION

This paper presents the numerical investigation of the principal stress rotation under earthquake loadings using an elastoplastic sand model considering the PSR effect, which is improved from a bounding surface model with the critical state theory. The modified model is verified by a series of triaxial and rotational shear tests and then implement in the numerical simulation of a centrifuge model test under earthquake loadings involving the PSR. The predicted results from the base model and the modified model as well as the experimental results are presented and compared. The analysis shows that the base model can reproduce sand responses under monotonic loading conditions without the PSR but in most cases underestimates the build-up of excess pore water pressure, the decrease of effective confining pressure, the increase of displacement and fails to predict the liquefaction under loading conditions involving the PSR, which may lead to unsafe designs. In contrast, the modified PSR model provides much more accurate predictions than the base model as its predictions generally agree well with the experimental results and capture most of critical features of sand behaviors under the PSR. The comparative investigation demonstrates that it is important to consider the PSR effect in the simulation of geotechnical boundary value problems under earthquake loadings.

ACKNOWLEDGEMENTS

This research is supported by Zhejiang Natural Science Foundation, China (Project Code LQ19E090003), National Natural Science Foundation of China (NSFC Contract No. 51708040), and the post doctoral research program (236527) of Zhejiang University of Technology. These supports are appreciated.

Keywords: Seismic assessment, Dynamic analysis, Shear and torsion, Warping, Beam Finite Element.

Abstract. *This work investigates the performance of the enhanced beam Finite Element (FE) formulations proposed in [20] for the dynamic response of frame structures subjected to shear and torsional actions. These formulations introduce enriched kinematic descriptions to describe the out-of-plane deformations of beam cross-sections, in addition to the standard in-plane rigid modes. First model is based on the Vlasov's theory, enriched to include shear induced warping, and is developed according to a displacement-based approach. To this end, additional degrees of freedom (DOFs) are introduced at the two element end nodes and are used to interpolate warping along the element axis, so that the influence of warping restraints at the element boundaries are properly accounted for. Second model is based on the Benscoter's warping theory, also enriched to include shear warping, and is developed according to a mixed formulation free from shear-locking. Third model is the extension of second formulation and considers a general and accurate warping description. Indeed, a variable number of additional DOFs is introduced over the element cross-section and the warping displacement field is interpolated at two levels, along the beam axis and over the cross-section plane.*

Numerical analyses are presented to assess the performances of the three models in describing the seismic response of frame structures, when shear/torsional actions dominate the structural behavior. Results are compared with the solutions obtained from standard beam and more involving shell and brick FE models.

1 INTRODUCTION

Simulation of the mechanical behavior of large scale structures is a challenging task, although significant advances in computer technology were made during the last decades and increasingly accurate computational models were proposed. In particular, civil engineering structures subjected to seismic actions deserve special efforts, as the dynamic response to ground motions is strongly influenced by the material complex nonlinear behavior and multi-axial stress interaction. Many works have focused on the effects of in-plane and out-of plane cross-section deformation modes due to shear and torsional actions and, by employing enhanced beam models, they have proved that these phenomena can significantly reduce the element stiffness, influencing the natural frequencies of the structure [1] and producing local and global buckling under both static [2, 3, 4] and dynamic loading conditions [5]. Despite their considerable accuracy, full generalization of these models and their introduction in numerical codes for the analysis of large scale structures is hard to accomplish. Hence, more demanding two-dimensional (2D) plate/shell or three-dimensional (3D) Finite Element (FE) approaches are often used, although their lower efficiency and high computational cost. The adoption of beam FEs is to now the most convenient choice for the analysis of large scale framed structures. However, standard models are often based on classical rigid cross-section assumption and fail in correctly reproducing the structural response, even more when thin-walled members subjected to shear and torsion are considered.

Starting from the first proposals by Vlasov [6] and Bescoter [7], several enhanced beam theories and numerical models were presented [8, 9, 10, 11]. An extensive review of the first proposals is reported in [12], while more sophisticated formulations were recently developed, to include also effects due to shear forces, e.g. [13, 14, 15, 16, 17, 18]. However, only in few cases these models were focused on the analysis of large structures under dynamic loading conditions, e.g [19].

This work explores the application to dynamic field of the 3D beam FE formulations presented in [20] and originally developed for the static analysis of frame structures subjected to shear and torsional actions. Enriched kinematic descriptions are considered to include out-of-plane deformations of beam cross-sections, in addition to the classical in-plane rigid modes. Hence, warping effects related to both torsion and shear are accounted for.

First model is based on an extended Vlasov's theory that includes both torsional and shear warping and relies on an enriched displacement-based approach that prevents shear-locking [21]. The out-of-plane cross-section displacement field is assumed as the linear combination of three warping functions, a priori defined over the element cross-section, and the generalized cross-section torsional curvature and shear strains. By introducing additional degrees of freedom (DOFs) at the element end nodes, these generalized strains are interpolated along the axis as parabolic and linear functions, respectively. The model is referred to as Enhanced Vlasov Displacement-based Element (EVDE).

Second model is based on Bescoter's warping theory, also enriched to include both torsional and shear warping. As opposed to the first model, warping variables defined along the axis are assumed as independent kinematic quantities from cross-section strains. Hence, a mixed approach is followed, where the warping displacement field is interpolated along the element, together with the generalized cross-section stresses. The model is referred to as Simplified Warping Mixed Element (SWME).

Third model is the general extension of the above latter formulation. Indeed, in addition to the warping displacement interpolation along the element axis, this considers a 2D interpolation

over the cross-section plane, thus allowing for higher order descriptions of the out-of-plane deformations and full coupling of all stress components. The model is referred to as Enhanced Warping Mixed Element (EWME).

Main details of the adopted beam FE models are reviewed, discussing their extension to dynamic field. For EVDE and EWME, detailed derivation of the element governing equations under dynamic effects is reported in [22] and [23], respectively, and is briefly recalled here. More focus is dedicated to the dynamic extension of SWME, which is presented as a simplified case of that proposed for the EWME.

Numerical analyses on a steel L frame and a reinforced concrete (RC) shear wall are presented to assess the performances of the three models in describing the seismic response of the structures, when shear/torsional actions dominate the structural behavior. Elasto-plastic and plastic-damage nonlinear material behavior is considered. Results are compared with the solutions obtained from standard beam and more involving shell and brick FE models.

2 BEAM FINITE ELEMENT FORMULATIONS

The adopted model formulations are described referring to a straight beam with the local intrinsic reference system (x, y, z) , being x the axis parallel to the section centroid locus and y and z two general orthogonal axes lying on the cross-section plane. The element length and the 2D domain of the cross-section are indicated as L and $A(x)$, respectively.

Under the assumption of small displacements and strains, all models introduce the description of the out-of-plane deformations partially removing the classical hypothesis of rigid cross-sections. Hence, displacements $\mathbf{u}_m(x, y, z)$ of the generic point m are defined as the sum of cross-section rigid body motions, $\mathbf{u}_r(x, y, z)$, and warping displacements, $\mathbf{u}_w(x, y, z)$, i.e.:

$$\mathbf{u}_m(x, y, z) = \mathbf{u}_r(x, y, z) + \mathbf{u}_w(x, y, z) = \begin{Bmatrix} u_r(x, y, z) \\ v_r(x, y, z) \\ w_r(x, y, z) \end{Bmatrix} + \begin{Bmatrix} u_w(x, y, z) \\ 0 \\ 0 \end{Bmatrix} \quad (1)$$

Accordingly, three non-zero strain components are introduced, that is the axial elongation $\varepsilon_{xx}(x, y, z)$ and the two transverse shear strains, $\gamma_{xy}(x, y, z)$ and $\gamma_{xz}(x, y, z)$. These are collected in vector $\boldsymbol{\varepsilon}_m(x, y, z)$ and are work-conjugate to the axial, $\sigma_{xx}(x, y, z)$, and shear stresses in the cross-section plane, $\tau_{xy}(x, y, z)$ and $\tau_{xz}(x, y, z)$, collected in vector $\boldsymbol{\sigma}_m(x, y, z)$.

Based on the above assumptions, three enriched beam FE formulations are derived. These are presented in detail in [20] and are summarized in the following, focusing the attention on the warping description hypotheses and the derivation of the element governing equations including inertia effects.

2.1 Enhanced Vlasov Displacement-based Element (EVDE)

The EVDE formulation considers nine DOFs at each of the two end nodes, i and j , of the element, being these the six standard translations and rotations, collected in vectors $\mathbf{u}_{i/j}$ and $\boldsymbol{\theta}_{i/j}$, respectively, and three additional DOFs used to describe cross-section warping, i.e. the end cross-section torsional curvature, $\chi_{xi/j}$, and shear strains, $\gamma_{yi/j}$ and $\gamma_{zi/j}$, collected in vectors $\boldsymbol{\eta}_i = \{\chi_{xi} \ \gamma_{yi} \ \gamma_{zi}\}^T$ and $\boldsymbol{\eta}_j = \{\chi_{xj} \ \gamma_{yj} \ \gamma_{zj}\}^T$ (Figure 1). Hence, the nodal displacement vector is written as:

$$\hat{\mathbf{u}} = \{\mathbf{u}^T \ \boldsymbol{\eta}^T\}^T = \{\mathbf{u}_i^T \ \boldsymbol{\theta}_i^T \ \mathbf{u}_j^T \ \boldsymbol{\theta}_j^T \ \boldsymbol{\eta}_i^T \ \boldsymbol{\eta}_j^T\}^T \quad (2)$$

vectors \mathbf{u}^T and $\boldsymbol{\eta}^T$ collecting the standard and warping DOFs, respectively.

Figure 1: Standard (black) and warping (blue) nodal DOFs for the EVDE

A reference basic configuration is introduced to remove the element rigid body motions and only twelve basic displacements are used to define the element behavior. These are listed in vector $\hat{\mathbf{v}}$, that results as:

$$\hat{\mathbf{v}} = \{u_j \quad \theta_{zi} \quad \theta_{zj} \quad \theta_{xj} \quad \theta_{yi} \quad \theta_{yj} \quad \chi_{xi} \quad \gamma_{yi} \quad \gamma_{zi} \quad \chi_{xj} \quad \gamma_{yj} \quad \gamma_{zj}\}^T = \hat{\mathbf{a}}_v \hat{\mathbf{u}} \quad (3)$$

being $\hat{\mathbf{a}}_v$ the kinematic operator that removes the rigid body motions [20].

To avoid shear locking issues, generalized cross-section displacement interpolation is performed by assuming the two cross-section shear strain fields, $\gamma_y(x)$ and $\gamma_z(x)$, as independent quantities, instead of the bending rotations, $\theta_y(x)$ and $\theta_z(x)$ [21]. Thus, cross-section kinematic vector results as:

$$\hat{\mathbf{u}}_s(x) = \{u(x) \quad v(x) \quad \theta_x(x) \quad w(x) \quad \gamma_y(x) \quad \gamma_z(x)\}^T \quad (4)$$

being $u(x)$, $v(x)$ and $w(x)$ the rigid traslations and $\theta_x(x)$ the rigid torsional rotation. The nodal DOFs introduced permit to express the displacement fields $u(x)$, $\gamma_y(x)$ and $\gamma_z(x)$ as linear functions along the element axis, and $v(x)$, $w(x)$ and $\theta_x(x)$ as cubic polynomials. The relations between $\hat{\mathbf{u}}_s(x)$ and $\hat{\mathbf{v}}$ is written in compact form as:

$$\hat{\mathbf{u}}_s(x) = \hat{\mathbf{N}}(x) \hat{\mathbf{v}} \quad (5)$$

where $\hat{\mathbf{N}}(x)$ is the element shape function matrix containing the polynomial interpolations for the displacement and shear strain fields [20].

By enforcing the cross-section compatibility conditions, the generalized cross-section strain vector, $\hat{\mathbf{e}}(x) = \mathbf{D}(x) \hat{\mathbf{u}}_s(x)$, is introduced, being $\mathbf{D}(x)$ the compatibility differential operator. Vector $\hat{\mathbf{e}}(x)$ collects the axial strain, $\varepsilon_G(x)$, flexural curvatures, $\chi_z(x)$ and $\chi_y(x)$, torsional curvature, $\chi_x(x)$, shear strains, $\gamma_y(x)$ and $\gamma_z(x)$, and additional warping strains, $\zeta_x(x) = \chi'_x(x)$, $\zeta_y(x) = \gamma'_y(x)$, $\zeta_z(x) = \gamma'_z(x)$, related to warping, i.e.:

$$\hat{\mathbf{e}}(x) = \{\varepsilon_G(x) \quad \chi_z(x) \quad \gamma_y(x) \quad \chi_x(x) \quad \chi_y(x) \quad \gamma_z(x) \quad \zeta_x(x) \quad \zeta_y(x) \quad \zeta_z(x)\}^T \quad (6)$$

where the apex denotes the derivative with respect to x . Hence, the following relationship holds between the generalized cross-section strains and the nodal basic displacement vector:

$$\hat{\mathbf{e}}(x) = \hat{\mathbf{D}}(x) \hat{\mathbf{N}}(x) \hat{\mathbf{v}} = \hat{\mathbf{a}}(x) \hat{\mathbf{v}} \quad (7)$$

where $\hat{\mathbf{a}}(x) = \hat{\mathbf{D}}(x) \hat{\mathbf{N}}(x)$ is the cross-section strain compatibility matrix.

According to Vlasov's warping description [6], strain fields $\gamma_y(x)$, $\gamma_z(x)$ and $\chi_x(x)$ are used to describe cross-section out-of-plane displacements. Indeed, displacement field $u_w(x, y, z)$ is defined as the linear combination of assigned 2D warping functions, defined over the cross-section area and collected in vector $\mathbf{M}_\eta(y, z) = \{M_{\eta x}(y, z) \quad M_{\eta y}(y, z) \quad M_{\eta z}(y, z)\}$. These

are associated to torsion and shear along y - and z -directions, respectively, and, thus, are combined by means of the corresponding strain fields, assumed as warping parameters, $\eta_s(x) = \{\chi_x(x) \ \gamma_y(x) \ \gamma_z(x)\}^T$, i.e.:

$$u_w(x, y, z) = \mathbf{M}_\eta(y, z) \eta_s(x) \quad (8)$$

The warping functions $M_{\eta_x}(y, z)$, $M_{\eta_y}(y, z)$ and $M_{\eta_z}(y, z)$ are determined according to the numerical procedure described in [20], which ensures the orthogonality conditions between rigid and warping displacements, as required by Equation (1). Examples of warping functions are depicted in Figure 2 for a S-shaped cross-section.

Figure 2: Warping functions for a S-shaped cross-section related to (a) torsion, $M_{\eta_x}(y, z)$, (b) shear along y -axis, $M_{\eta_y}(y, z)$, and (c) shear along z -axis, $M_{\eta_z}(y, z)$

Accounting for the warping description in Equation (8), material strains are determined as:

$$\epsilon_m(x, y, z) = \hat{\alpha}(y, z) \hat{e}(x) \quad (9)$$

where $\hat{\alpha}(y, z)$ is the cross-section compatibility operator. By enforcing the virtual work principle, the generalized section stresses, $\hat{s}(x)$, are defined as:

$$\hat{s}(x) = \int_{A(x)} \hat{\alpha}^T(y, z) \sigma_m(x, y, z) dA \quad (10)$$

with:

$$\hat{s}(x) = \{N(x) \ M_z(x) \ T_y^p(x) \ M_x^p(x) \ M_y(x) \ T_z^p(x) \ B_x(x) \ B_y(x) \ B_z(x)\}^T \quad (11)$$

being $N(x)$ the axial stress, $M_z(x)$ and $M_y(x)$ the bending moments and $B_x(x)$, $B_y(x)$ and $B_z(x)$ the bi-moments, work-conjugate to $\zeta_x(x)$, $\zeta_y(x)$, $\zeta_z(x)$ [6, 13], i.e.:

$$B_k(x) = \int_{A(x)} M_{\eta_k}(y, z) \sigma_{xx}(x, y, z) dA, \quad \text{with } k = x, y, z \quad (12)$$

Quantities $M_x^p(x)$, $T_y^p(x)$ and $T_z^p(x)$ are the *primary* torsional moment and shear stresses, each resulting as the sum of the corresponding standard stress, $M_x(x)$, $T_y(x)$ or $T_z(x)$, and bi-shear, $M_x^s(x)$, $T_y^s(x)$ or $T_z^s(x)$.

2.1.1 Derivation of the element governing equations

According to the displacement-based formulations [24], element equilibrium equations are derived from the stationarity of a Lagrangian functional, $\mathcal{L} [\mathbf{u}_m(x, y, z), \dot{\mathbf{u}}_m(x, y, z)]$, function of the displacements, $\mathbf{u}_m(x, y, z)$, and velocities, $\dot{\mathbf{u}}_m(x, y, z)$, and expressed as the difference of the element kinetic, $T [\dot{\mathbf{u}}_m(x, y, z)]$, and potential energy, $\Pi [\mathbf{u}_m(x, y, z)]$, that is:

$$\mathcal{L} [\mathbf{u}_m(x, y, z), \dot{\mathbf{u}}_m(x, y, z)] = T [\dot{\mathbf{u}}_m(x, y, z)] - \Pi [\mathbf{u}_m(x, y, z)] \quad (13)$$

Kinetic energy is expressed first in terms of cross-section velocities, $\dot{\hat{\mathbf{u}}}_s(x)$, and then in terms of nodal velocities, $\dot{\hat{\mathbf{u}}}$, as reported in details in [22]. Hence, it finally results as:

$$T (\dot{\hat{\mathbf{u}}}) = \frac{1}{2} \dot{\hat{\mathbf{u}}}^T (\mathbf{m}_r + \mathbf{m}_w) \dot{\hat{\mathbf{u}}} = \frac{1}{2} \dot{\hat{\mathbf{u}}}^T \mathbf{m} \dot{\hat{\mathbf{u}}} \quad (14)$$

where \mathbf{m}_r and \mathbf{m}_w are the element rigid and warping mass matrices related to the inertia effects due to $\mathbf{u}_r(x, y, z)$ and $u_w(x, y, z)$, respectively, while $\mathbf{m} = \mathbf{m}_r + \mathbf{m}_w$ is the total element consistent mass matrix.

Similarly, potential energy is expressed first in terms of cross-section quantities, $\hat{\mathbf{e}}(x)$ and $\hat{\mathbf{s}}(x)$, and then in terms of nodal quantities, $\hat{\mathbf{u}}$ and $\hat{\mathbf{p}}$, this latter collecting in vector \mathbf{p} the standard forces and couples, $\mathbf{p}_{i/j}$ and $\mathbf{m}_{i/j}$, work-conjugate to $\mathbf{u}_{i/j}$ and $\theta_{i/j}$, and in vector β the additional generalized forces, β_i and β_j , work-conjugate to the warping DOFs, η_i and η_j , that is:

$$\hat{\mathbf{p}} = \{\mathbf{p}^T \quad \beta^T\}^T = \{\mathbf{p}_i^T \quad \mathbf{m}_i^T \quad \mathbf{p}_j^T \quad \mathbf{m}_j^T \quad \beta_i^T \quad \beta_j^T\}^T \quad (15)$$

Hence, it results:

$$\Pi (\hat{\mathbf{u}}) = \hat{\mathbf{u}}^T \left\{ \hat{\mathbf{a}}_v^T \left[\int_L \hat{\mathbf{a}}^T(x) \hat{\mathbf{s}}(x) dx - \int_L \hat{\mathbf{N}}^T(x) \hat{\mathbf{q}}_s(x) dx \right] - \hat{\mathbf{p}} + \hat{\mathbf{p}}_{rq} \right\} \quad (16)$$

where $\hat{\mathbf{p}}_{rq}$ is the vector collecting the basic reaction forces due to distributed loads, $\hat{\mathbf{q}}_s(x)$. Under static loading conditions, the element equilibrium equations state that the term in brackets must equal the basic nodal force vector, $\hat{\mathbf{q}}$, work-conjugate to $\hat{\mathbf{v}}$ [20]. Hence, by considering Equations (14) and (16), expression of \mathcal{L} in terms of nodal quantities is obtained as:

$$\mathcal{L} (\dot{\hat{\mathbf{u}}}, \hat{\mathbf{u}}) = \frac{1}{2} \dot{\hat{\mathbf{u}}}^T \mathbf{m} \dot{\hat{\mathbf{u}}} - \hat{\mathbf{u}}^T (\hat{\mathbf{a}}_v^T \hat{\mathbf{q}} - \hat{\mathbf{p}} + \hat{\mathbf{p}}_{rq}) \quad (17)$$

and the element governing equations are derived by enforcing its stationarity as:

$$\frac{d}{dt} \frac{\partial \mathcal{L} (\dot{\hat{\mathbf{u}}}, \hat{\mathbf{u}})}{\partial \dot{\hat{\mathbf{u}}}} - \frac{\partial \mathcal{L} (\dot{\hat{\mathbf{u}}}, \hat{\mathbf{u}})}{\partial \hat{\mathbf{u}}} = \frac{d}{dt} \frac{\partial T (\dot{\hat{\mathbf{u}}})}{\partial \dot{\hat{\mathbf{u}}}} + \frac{\partial \Pi (\hat{\mathbf{u}})}{\partial \hat{\mathbf{u}}} = \mathbf{0} \quad (18)$$

which gives the element equilibrium equations in the form:

$$\mathbf{m} \ddot{\hat{\mathbf{u}}} + \hat{\mathbf{a}}_v^T \hat{\mathbf{q}} + \hat{\mathbf{p}}_{rq} = \hat{\mathbf{p}} \quad (19)$$

Linearization of Equation (19) results as:

$$\mathbf{m} \Delta \ddot{\hat{\mathbf{u}}} + \hat{\mathbf{a}}_v^T \Delta \hat{\mathbf{q}} = \mathbf{m} \Delta \ddot{\hat{\mathbf{u}}} + \hat{\mathbf{a}}_v^T \hat{\mathbf{k}}_v \Delta \hat{\mathbf{v}} = \mathbf{m} \Delta \ddot{\hat{\mathbf{u}}} + \underbrace{\hat{\mathbf{a}}_v^T \hat{\mathbf{k}}_v \hat{\mathbf{a}}_v}_{\hat{\mathbf{k}}} \Delta \hat{\mathbf{u}} = \Delta \hat{\mathbf{p}} \quad (20)$$

where Δ indicates the quantity increment and $\hat{\mathbf{k}}$ is the element tangent stiffness matrix, being:

$$\hat{\mathbf{k}}_v = \frac{\partial \hat{\mathbf{q}}}{\partial \hat{\mathbf{v}}} = \int_L \hat{\mathbf{a}}^T(x) \frac{\partial \hat{\mathbf{s}}(x)}{\partial \hat{\mathbf{e}}(x)} \frac{\partial \hat{\mathbf{e}}(x)}{\partial \hat{\mathbf{v}}} dx = \int_L \hat{\mathbf{a}}^T(x) \frac{\partial \hat{\mathbf{s}}(x)}{\partial \hat{\mathbf{e}}(x)} \hat{\mathbf{a}}(x) dx \quad (21)$$

2.2 Simplified Warping Mixed Element

The SWME formulation considers an arbitrary number of nodes, n_w , located along the element axis (Figure 3), always including end nodes, i and j . At each node, three DOFs are added

Figure 3: Standard (black) and warping (blue) nodal DOFs for the SWME model

and used to interpolate cross-section warping due to torsion and shear. These are collected in vector $\eta_n = \{\eta_{xn} \ \eta_{yn} \ \eta_{zn}\}^T$, where subscript $n = 1, \dots, n_w$ indicates the node number. Hence, the nodal displacement vector is written as:

$$\hat{\mathbf{u}} = \{\mathbf{u}^T \ \boldsymbol{\eta}^T\}^T = \{\mathbf{u}_i^T \ \boldsymbol{\theta}_i^T \ \mathbf{u}_j^T \ \boldsymbol{\theta}_j^T \ \boldsymbol{\eta}_1^T \ \boldsymbol{\eta}_2^T \ \dots \ \boldsymbol{\eta}_{n_w}^T\}^T \quad (22)$$

The element rigid body motions are removed from the standard DOFs, \mathbf{u} , and vector \mathbf{v} , collecting the standard basic nodal displacements, is obtained as follows:

$$\mathbf{v} = \{u_j \ \theta_{zi} \ \theta_{zj} \ \theta_{xj} \ \theta_{yi} \ \theta_{yj}\}^T = \mathbf{a}_v \mathbf{u} \quad (23)$$

being \mathbf{a}_v the standard element compatibility matrix [18]. The total basic deformation displacement vector $\hat{\mathbf{v}}$ reads:

$$\hat{\mathbf{v}} = \{\mathbf{v}^T \ \eta_{x1} \ \eta_{y1} \ \eta_{z1} \ \dots \ \eta_{xn_w} \ \eta_{yn_w} \ \eta_{zn_w}\}^T = \{\mathbf{v}^T \ \boldsymbol{\eta}^T\}^T \quad (24)$$

The SWME model follows a mixed beam formulation [25] where standard generalized cross-section stresses, $\mathbf{s}(x) = \{N(x) \ M_z(x) \ T_y(x) \ M_x(x) \ M_y(x) \ T_z(x)\}^T$, are interpolated along the element axis, by enforcing the equilibrium conditions in strong form, i.e.:

$$\mathbf{s}(x) = \mathbf{b}(x) \mathbf{q} + \mathbf{s}_q(x) \quad (25)$$

being $\mathbf{q} = \{p_{xj} \ m_{zi} \ m_{zj} \ m_{xj} \ m_{yi} \ m_{yj}\}^T$ the vector collecting the basic nodal forces work-conjugate to \mathbf{v} , $\mathbf{b}(x)$ the equilibrium matrix [23] and $\mathbf{s}_q(x)$ the generalized section stress vector due to distributed loads.

In addition, the warping displacement field $u_w(x, y, z)$ is interpolated. To this end, Benscoter's warping description is adopted [7], where, similarly to Equation (8), $u_w(x, y, z)$ is defined as the linear combination of warping functions, $\mathbf{M}_\eta(y, z)$. However, independent warping parameters, $\eta_s(x) = \{\eta_x(x) \ \eta_y(x) \ \eta_z(x)\}^T$, are considered to describe warping variation along x . Hence, by exploiting the additional warping DOFs, η_{xn} , η_{yn} and η_{zn} at the element nodes, polynomial interpolation of fields $\eta_x(x)$, $\eta_y(x)$ and $\eta_z(x)$, respectively, is introduced and Equation (8) is written as:

$$u_w(x, y, z) = \sum_{n=1}^{n_w} N_n(x) \mathbf{M}_\eta(y, z) \boldsymbol{\eta}_n \quad (26)$$

being $N_n(x)$ the Lagrange polynomial shape function associated to node n .

The material strains $\epsilon_m(x, y, z)$ are, thus, determined as:

$$\begin{aligned}\epsilon_m(x, y, z) &= \alpha(y, z) \mathbf{e}(x) + \alpha_\zeta(y, z) \zeta_s(x) + \alpha_\eta(y, z) \eta_s(x) = \\ &= \alpha(y, z) \mathbf{e}(x) + \sum_{n=1}^{n_w} \left[\frac{\partial N_n(x)}{\partial x} \alpha_\zeta(y, z) + N_n(x) \alpha_\eta(y, z) \right] \eta_n\end{aligned}\quad (27)$$

where three contributions are distinguished, the first related to rigid cross-section displacements and the others to warping. Vector $\mathbf{e}(x)$ collects the standard generalized cross-section strains work-conjugate to $\mathbf{s}(x)$ and matrix $\alpha(y, z)$ is the compatibility operator, while vector $\zeta_s(x) = \{\zeta_x(x) \ \zeta_y(x) \ \zeta_z(x)\}^T$ contains the strain quantities assumed as equal to the derivatives of the warping parameters with respect to x (see also Equation (6)). Matrices $\alpha_\zeta(y, z)$ and $\alpha_\eta(y, z)$ are compatibility operators related to the warping field with size 3×3 [20].

The virtual work equivalence, enforced by alternatively assigning a virtual variation to the three fields composing $\epsilon_m(x, y, z)$ [20], leads to the definition of standard, $\mathbf{s}(x)$, and warping, $\mathbf{b}_w(x)$ and $\mathbf{t}_w(x)$, generalized cross-section stresses, that is:

$$\mathbf{s}(x) = \int_{A(x)} \alpha^T(y, z) \boldsymbol{\sigma}_m(x, y, z) dA \quad (28)$$

$$\mathbf{b}_w(x) = \int_{A(x)} \alpha_\zeta(y, z)^T \boldsymbol{\sigma}_m(x, y, z) dA, \quad \mathbf{t}_w(x) = \int_{A(x)} \alpha_\eta(y, z)^T \boldsymbol{\sigma}_m(x, y, z) dA \quad (29)$$

The latter are work-conjugate to $\zeta_s(x)$ and $\eta_s(x)$, respectively, and are equivalent to the *bi-moments* and *bi-shears* introduced in the EVDE model.

2.2.1 Derivation of the element governing equations

The element governing equations are derived from the stationarity of an extended Lagrangian functional, expressed as function of four independent fields, being these the material rigid displacements, $\mathbf{u}_r(x, y, z)$, total strains, $\epsilon_m(x, y, z)$, and stresses, $\boldsymbol{\sigma}_m(x, y, z)$, and warping displacement, $u_w(x, y, z)$, i.e.:

$$\mathcal{L}(\mathbf{u}_r, \epsilon_m, \boldsymbol{\sigma}_m, u_w, \dot{\mathbf{u}}_r, \dot{u}_w) = T(\dot{\mathbf{u}}_r, \dot{u}_w) - \Pi(\mathbf{u}_r, \epsilon_m, \boldsymbol{\sigma}_m, u_w) \quad (30)$$

where dependency of the quantities from spatial coordinates x, y and z is omitted for brevity. The kinetic energy is expressed first in terms of rigid cross-section velocities, $\dot{\mathbf{u}}_s(x)$, being $\mathbf{u}_s(x) = \{u(x) \ v(x) \ \theta_x(x) \ w(x) \ \theta_y(x) \ \theta_z(x)\}^T$, and then in terms of all nodal velocities, $\dot{\mathbf{u}}$ and $\dot{\boldsymbol{\eta}}$, following [23]. This is accomplished by accounting for Equation (26) and by expressing the rigid cross-section displacements and velocities in terms of nodal DOFs as follows:

$$\mathbf{u}_s(x) = \mathbf{N}_s(x) \mathbf{u} + \mathbf{N}_w(x) \boldsymbol{\eta} \quad \text{and} \quad \dot{\mathbf{u}}_s(x) = \mathbf{N}_s(x) \dot{\mathbf{u}} + \mathbf{N}_w(x) \dot{\boldsymbol{\eta}} \quad (31)$$

where $\mathbf{N}_s(x)$ and $\mathbf{N}_w(x)$ are the shape function matrices relating $\mathbf{u}_s(x)$ to the standard and warping nodal DOFs, \mathbf{u} and $\boldsymbol{\eta}$, respectively. These are derived by using the unit load method, described in more detail in [23] for the EWME. Hence, the kinetic energy results as:

$$T(\dot{\mathbf{u}}, \dot{\boldsymbol{\eta}}) = \frac{1}{2} \dot{\mathbf{u}}^T \mathbf{m}_{rr} \dot{\mathbf{u}} + \dot{\mathbf{u}}^T \mathbf{m}_{rw} \dot{\boldsymbol{\eta}} + \dot{\boldsymbol{\eta}}^T \mathbf{m}_{wr} \dot{\mathbf{u}} + \frac{1}{2} \dot{\boldsymbol{\eta}}^T (\mathbf{m}_{ww}^r + \mathbf{m}_{ww}) \dot{\boldsymbol{\eta}} \quad (32)$$

where \mathbf{m}_{rr} , \mathbf{m}_{rw} , \mathbf{m}_{wr} and \mathbf{m}_{ww}^r are the element mass matrices associated to the generalized rigid cross-section velocity $\dot{\mathbf{u}}_s(x)$ and are defined as:

$$\begin{aligned} \mathbf{m}_{rr} &= \int_L \mathbf{N}_s^T(x) \mathbf{m}_s(x) \mathbf{N}_s(x) dx, & \mathbf{m}_{rw} &= \int_L \mathbf{N}_s^T(x) \mathbf{m}_s(x) \mathbf{N}_w(x) dx = \mathbf{m}_{wr}^T \\ \mathbf{m}_{ww}^r &= \int_L \mathbf{N}_w^T(x) \mathbf{m}_s(x) \mathbf{N}_w(x) dx \end{aligned} \quad (33)$$

being $\mathbf{m}_s(x)$ the standard rigid cross-section mass matrix [23], while \mathbf{m}_{ww} is the element mass matrix associated to the warping velocity $\dot{u}_w(x, y, z)$ and is defined as:

$$\mathbf{m}_{ww} = \int_L \begin{bmatrix} N_1(x) \mathbf{m}_{sw}(x) N_1(x) & \dots & N_1(x) \mathbf{m}_{sw}(x) N_{n_w}(x) \\ \vdots & \ddots & \vdots \\ N_{n_w}(x) \mathbf{m}_{sw}(x) N_1(x) & \dots & N_{n_w}(x) \mathbf{m}_{sw}(x) N_{n_w}(x) \end{bmatrix} dx \quad (34)$$

being $\mathbf{m}_{sw}(x)$ the cross-section mass matrix associated to $\dot{u}_w(x, y, z)$, that results as:

$$\mathbf{m}_{sw}(x) = \int_{A(x)} \rho(x, y, z) \mathbf{M}_\eta^T(y, z) \mathbf{M}_\eta(y, z) dA \quad (35)$$

where $\rho(x, y, z)$ indicates the material density.

Similarly, the potential energy is expressed first in terms of the standard cross-section quantities, $\mathbf{u}_s(x)$, $\mathbf{e}(x)$ and $\mathbf{s}(x)$, and warping displacements, $u_w(x, y, z)$, and then in terms of standard cross-section strains and stresses, $\mathbf{e}(x)$ and $\mathbf{s}(x)$, and nodal DOFs, \mathbf{u} and $\boldsymbol{\eta}$. Hence, it results:

$$\begin{aligned} \Pi(\mathbf{u}, \mathbf{e}, \mathbf{s}, \boldsymbol{\eta}) &= \int_V \boldsymbol{\varepsilon}_m^T[\mathbf{e}, u_w(\boldsymbol{\eta})] \boldsymbol{\sigma}_m(\boldsymbol{\varepsilon}_m) dV + \int_L \mathbf{s}^T \{ \mathbf{e}[\mathbf{u}_s(\mathbf{u}, \boldsymbol{\eta})] - \mathbf{e} \} dx + \\ &+ \Pi_{ext}[\mathbf{u}, \boldsymbol{\eta}, \mathbf{u}_s(\mathbf{u}, \boldsymbol{\eta})] \end{aligned} \quad (36)$$

where $\Pi_{ext}[\mathbf{u}, \boldsymbol{\eta}, \mathbf{u}_s(\mathbf{u}, \boldsymbol{\eta})]$ is the external load potential.

By considering Equations (32) and (36), expression of \mathcal{L} results as:

$$\begin{aligned} \mathcal{L}(\mathbf{u}, \mathbf{e}, \mathbf{s}, \mathbf{u}_w, \dot{\mathbf{u}}, \dot{\boldsymbol{\eta}}) &= \frac{1}{2} \dot{\mathbf{u}}^T \mathbf{m}_{rr} \dot{\mathbf{u}} + \dot{\mathbf{u}}^T \mathbf{m}_{rw} \dot{\boldsymbol{\eta}} + \dot{\boldsymbol{\eta}}^T \mathbf{m}_{wr} \dot{\mathbf{u}} + \frac{1}{2} \dot{\boldsymbol{\eta}}^T (\mathbf{m}_{ww}^r + \mathbf{m}_{ww}) \dot{\boldsymbol{\eta}} + \\ &+ \int_V \boldsymbol{\varepsilon}_m^T[\mathbf{e}, u_w(\boldsymbol{\eta})] \boldsymbol{\sigma}_m(\boldsymbol{\varepsilon}_m) dV + \int_L \mathbf{s}^T \{ \mathbf{e}[\mathbf{u}_s(\mathbf{u}, \boldsymbol{\eta})] - \mathbf{e} \} dx + \Pi_{ext}[\mathbf{u}, \boldsymbol{\eta}, \mathbf{u}_s(\mathbf{u}, \boldsymbol{\eta})] \end{aligned} \quad (37)$$

and four element governing equations are derived, by assuming \mathbf{u} , $\mathbf{e}(x)$, $\mathbf{s}(x)$ and \mathbf{u}_w as independent variables, that is by imposing the following four stationarity conditions:

$$\frac{d}{dt} \frac{\partial \mathcal{L}(\mathbf{u}, \mathbf{e}, \mathbf{s}, \mathbf{u}_w, \dot{\mathbf{u}}, \dot{\boldsymbol{\eta}})}{\partial \dot{q}_h} - \frac{\partial \mathcal{L}(\mathbf{u}, \mathbf{e}, \mathbf{s}, \mathbf{u}_w, \dot{\mathbf{u}}, \dot{\boldsymbol{\eta}})}{\partial q_h} = \frac{d}{dt} \frac{\partial T(\dot{\mathbf{u}}, \dot{\boldsymbol{\eta}})}{\partial \dot{q}_h} + \frac{\partial \Pi(\mathbf{u}, \mathbf{e}, \mathbf{s}, \boldsymbol{\eta})}{\partial q_h} = \mathbf{0} \quad (38)$$

with $q_h \equiv \mathbf{u}, \mathbf{e}, \mathbf{s}, \boldsymbol{\eta}$.

For $q_h \equiv \mathbf{e}, \mathbf{s}$, the term related to the kinetic energy vanishes and the resulting equations are those holding for static loading conditions, that is the nonlinear material constitutive law and element compatibility enforced in weak form as:

$$\boldsymbol{\sigma}_m(x, y, z) = \hat{\boldsymbol{\sigma}}_m[\boldsymbol{\varepsilon}_m(x, y, z)] \quad (39)$$

$$\mathbf{v} = \int_L \mathbf{b}^T(x) \mathbf{e}(x) dx \quad (40)$$

By contrast, for $q_h \equiv \mathbf{u}$, η the dynamic equilibrium equations result, related to rigid and warping motions, respectively, and written as:

$$\mathbf{m}_{rr} \ddot{\mathbf{u}} + \mathbf{m}_{rw} \ddot{\mathbf{u}}_w + \mathbf{a}_v^T \mathbf{q} - \mathbf{p}_{rq} = \mathbf{p} \quad (41)$$

$$\mathbf{m}_{wr} \ddot{\mathbf{u}} + (\mathbf{m}_{ww}^r + \mathbf{m}_{ww}) \ddot{\mathbf{u}}_w + \int_L \begin{bmatrix} \frac{\partial N_1(x)}{\partial x} \\ \dots \\ \frac{\partial N_{n_w}(x)}{\partial x} \end{bmatrix} \mathbf{b}_w(x) dx + \int_L \begin{bmatrix} N_1(x) \\ \dots \\ N_{n_w}(x) \end{bmatrix} \mathbf{t}_w(x) dx = \boldsymbol{\beta} \quad (42)$$

where \mathbf{p}_{rq} is the vector collecting the basic reaction forces due to distributed loads, written considering only the twelve standard nodal components, while vectors \mathbf{p} and $\boldsymbol{\beta}$ contain the element nodal forces work-conjugate to \mathbf{u} and η , respectively. These are arranged in the total nodal force vector $\hat{\mathbf{p}}$, resulting as:

$$\hat{\mathbf{p}} = \{\mathbf{p}^T \quad \boldsymbol{\beta}^T\}^T = \{\mathbf{p}_i^T \quad \mathbf{m}_i^T \quad \mathbf{p}_j^T \quad \mathbf{m}_j^T \quad \boldsymbol{\beta}_1^T \quad \boldsymbol{\beta}_2^T \quad \dots \quad \boldsymbol{\beta}_{n_w}^T\}^T \quad (43)$$

Linearization of Equations (41) and (42) is written in compact form as [23]:

$$\underbrace{\begin{bmatrix} \mathbf{m}_{rr} & \mathbf{m}_{rw} \\ \mathbf{m}_{wr} & \mathbf{m}_{ww}^r + \mathbf{m}_{ww} \end{bmatrix}}_{\mathbf{m}} \underbrace{\begin{Bmatrix} \Delta \ddot{\mathbf{u}} \\ \Delta \ddot{\eta} \end{Bmatrix}}_{\Delta \hat{\ddot{\mathbf{u}}}} + \underbrace{\begin{bmatrix} \mathbf{k}_{rr} & \mathbf{k}_{rw} \\ \mathbf{k}_{wr} & \mathbf{k}_{ww}^r + \mathbf{k}_{ww} \end{bmatrix}}_{\mathbf{k}} \underbrace{\begin{Bmatrix} \Delta \mathbf{u} \\ \Delta \eta \end{Bmatrix}}_{\Delta \hat{\mathbf{u}}} = \underbrace{\begin{Bmatrix} \Delta \mathbf{p} \\ \Delta \boldsymbol{\beta} \end{Bmatrix}}_{\Delta \hat{\mathbf{p}}} \quad (44)$$

and gives the definition of the total consistent element mass, \mathbf{m} , and stiffness matrix, \mathbf{k} . Similarly to \mathbf{m} , matrix \mathbf{k} is composed by five contributions. First four, \mathbf{k}_{rr} , \mathbf{k}_{rw} , \mathbf{k}_{wr} and \mathbf{k}_{ww}^r are the element stiffness matrices associated to the generalized rigid cross-section displacement $\mathbf{u}_s(x)$ and are defined as:

$$\mathbf{k}_{rr} = \mathbf{a}_v^T \mathbf{f}^{-1} \mathbf{a}_v, \quad \mathbf{k}_{rw} = \mathbf{a}_v^T \mathbf{f}^{-1} \mathbf{b}_{sw}, \quad \mathbf{k}_{wr} = \mathbf{b}_{ws} \mathbf{f}^{-1} \mathbf{a}_v, \quad \mathbf{k}_{ww}^r = \mathbf{b}_{ws} \mathbf{f}^{-1} \mathbf{b}_{sw} \quad (45)$$

where \mathbf{f} is the standard consistent element flexibility matrix [25] and \mathbf{b}_{sw} and \mathbf{b}_{ws} are the element warping compatibility and equilibrium matrices, respectively [18, 23]. While, \mathbf{k}_{ww} is the element stiffness matrix associated to warping.

2.3 Enhanced Warping Mixed Element

The EWME formulation is the enhanced version of the SWME model. Indeed, a richer warping interpolation is performed in this case, by introducing an arbitrary number, m_w , of DOFs at each of the n_w element nodes. These are located at uniformly distributed points over the cross-section, as depicted in the examples of Figure 4. Hence, vector η_n collecting all DOFs, u_{wnm} , with $m = 1, \dots, m_w$, for node n , now reads as:

$$\eta_n = \{u_{wn1} \quad u_{wn2} \quad \dots \quad u_{wnm_w}\}^T \quad (46)$$

while nodal displacement vector $\hat{\mathbf{u}}$ is arranged as in Equation (22).

As opposed to the SWME, where warping profiles, $\mathbf{M}_\eta(y, z)$, over the cross-section are assigned, for the EWME, warping interpolation involves all three spatial dimensions. Hence, instead of Equation (26), this assumes:

$$u_w(x, y, z) = \sum_{n=1}^{n_w} N_n(x) \left[\sum_{m=1}^{m_w} M_m(y, z) u_{wnm} \right] = \sum_{n=1}^{n_w} N_n(x) \mathbf{M}_\eta(y, z) \eta_n \quad (47)$$

 Figure 4: Examples of EWME warping DOFs for typical cross-sections at element node n

where $\mathbf{M}_\eta(y, z)$ is now a row vector containing 2D Lagrange polynomials $M_m(y, z)$ used to interpolate $u_w(x, y, z)$ over the cross-section plane.

The material strains, $\epsilon_m(x, y, z)$, are expressed in a similar fashion to Equation (27), i.e.:

$$\epsilon_m(x, y, z) = \alpha(y, z) \mathbf{e}(x) + \sum_{n=1}^{n_w} \left[\frac{\partial N_n(x)}{\partial x} \alpha_\zeta(y, z) + N_n(x) \alpha_\eta(y, z) \right] \eta_n \quad (48)$$

although matrices $\alpha_\zeta(y, z)$ and $\alpha_\eta(y, z)$ have, now, size $3 \times m_w$ and contain polynomials $M_m(y, z)$ and their derivatives with respects to y and z [20].

Generalized cross-section stresses playing the role of *bi-moments* and *bi-shears*, $\mathbf{b}_w(x)$ and $\mathbf{t}_w(x)$, are derived as in Equation (29) and all other fundamental relationships and governing equations are obtained through similar derivations performed for the SWME, that lead to formal identical expressions. Complete details of the element formulation are described in [23].

3 NUMERICAL APPLICATIONS

To validate and compare the performances of the adopted beam formulations, two numerical applications are considered. First application simulates the behavior of a steel L frame with beam and column having symmetric cross-sections and subjected to a base earthquake excitation. Second application reproduces the response of a RC U-shaped shear wall under similar loading conditions.

3.1 Steel L frame with flange continuity

The behavior of the steel frame depicted in Figure 5 is analyzed. The specimen is composed by a 4 m long column and 3 m long beam having same I-shaped cross-section geometry. Cross-section orientation is such that flange continuity is obtained at the beam-column connection joint (point C in the figure) and rigid and warping displacements are prevented at the ends of the frame (points A and E). Transverse displacement along y direction of point C is also restrained. Similar specimen was studied in [26, 27] under static loading conditions, while, here, dynamic response to ground acceleration is investigated. To this end, in addition to the mass of the frame, a lumped mass $M = 7645$ kg is considered, applied at mid-span of the beam (point D) and representing the mass of a typical slab supported by the frame. A small vertical eccentricity e is assumed between mass and centroidal axis of the beam, being equal to 0.05 m, that is half of the cross-section width.

Elasto-plastic material response is assumed. Thus, J2 plasticity model with linear kinematic hardening is adopted, with Young's modulus $E^s = 205000$ MPa, Poisson ratio $\nu^s = 0.3$, yielding stress $\sigma_y^s = 150$ MPa and hardening modulus $H_k^s = 0.01 E^s$. Material density is assumed as equal to $\rho = 7850$ kg/m³.

Figure 5: Geometry of the steel L frame with flange continuity.

A uniform mesh made of 10 and 14 FEs for beam and column, respectively, is used to model the frame. For the SWME and EWME, parabolic warping interpolation is assumed along the element axis, i.e. $n_w = 3$. Same order of interpolation is considered for torsional warping in the EVDE, while shear warping is assumed as linear (Equations (5) and (8)). Over the cross-section plane, EWME considers parabolic and cubic warping interpolation along web and flanges, respectively, and linear interpolation across the membrature thickness, i.e. $m_w = 28$, on the basis of the findings reported in [10, 18, 23, 20]. Same interpolation order is used to compute warping profile functions $M_\eta(y, z)$, adopted in the EVDE and SWME.

Figure 6: Steel L frame: deformed shape for mode (a) 1, (b) 2, (c) 3, (d) 4, (e) 5, (f) 6

Fiber discretization is used to compute nonlinear cross-section response, that is to evaluate cross-section resultant forces and stiffness. In this case, fibers are distributed according to the Gauss-Legendre rule, as exact integration of the element torsional stiffness is required to obtain the correct response of the frame. Fiber grid is arranged to have 6 fibers placed along web and flanges and 3 across the membrature thickness.

Table 1: Elastic circular frequency ω_i [rad/s] obtained for the L portal frame

FE type	Mode					
	1 st Flex.	1 st Tors.	2 nd Flex.	3 rd Flex.	2 nd Tors.	4 th Flex.
Shell	10.55	20.03	123.01	140.28	176.37	356.54

SWME	10.48	19.80	123.66	143.35	176.61	358.41
EVDE	10.49	19.87	123.68	143.37	176.28	358.54
Rigid section beam	10.48	9.07	123.64	143.33	84.70	358.27

Figure 7: Steel L frame: circular frequency errors obtained with beam models with respect to the shell solution

For all models, damping ratio is set equal to 2% and introduced through Rayleigh method on the basis of the first two elastic frequencies of the frame [28]. These correspond to the first in plane flexural and torsional natural modes, respectively, as depicted in Figures 6(a) and 6(b). Indeed, Figure 6 shows the deformed shapes for the first 6 elastic modes obtained with a reference model made of 2268 4-node Discrete Kirchhoff Quadrilateral shell elements. The blue and colored configurations indicate the undeformed and deformed shapes, respectively. The circular frequencies ω_i are reported in Table 1 and are compared with the values obtained from the adopted enhanced beam models and with a standard beam model assuming rigid cross-section. For this latter, cross-section torsional inertia is computed according to the thin-walled beam theory and results equal to $J = \kappa_t I_\rho$, being I_ρ the cross-section polar inertia and $\kappa_t = 0.001153$ the correction coefficient. Figure 7 shows the solution differences in terms of percentage error for ω_i with respect to the reference results. As shown, all enhanced beam formulations give similar results that perfectly agree with the shell solution. By contrast, the standard beam model provides incorrect frequency values for the torsional modes. Indeed, this model neglects warping and, thus, warping restraints at the boundaries. Moreover, due to the particular orientation, the

end cross-sections of beam and column that meet at the joint C undergo equal warping profile. As a result, when beam twists, warping of the end cross-section at C produces warping in the column, which twists as well (see, for instance, Figure 6(e)). As opposed to the standard model, in the enhanced beam formulations, the additional nodal warping DOFs placed at the nodes permit to correctly account for boundary restraints. Moreover, mesh connectivity ensures warping continuity between column and beam and, thus, the correct warping transmission at the joint C.

The frame dynamic response is also investigated by applying to the frame the ground acceleration history depicted in Figure 8(a), and considering both linear elastic and elasto-plastic constitutive behavior. Peak ground acceleration results equal to 0.4167 g, where g indicates the gravity acceleration. Figure 8(b) shows the resulting Fourier transform and, thus, indicates the frequency content of the acceleration signal. In the same figure, the green dotted vertical line indicates the value of the first torsional natural frequency of the frame. Ground acceleration is assumed to act in the direction Y transverse to the frame plane. Newmark method [28] is adopted for time integration of the structure global equilibrium equations, with coefficients $\beta = 0.25$ and $\gamma = 0.5$ and time step set equal to 0.001 s.

Figure 8: Base excitation signal: ground acceleration (a) history and (b) Fourier transform

Although mass eccentricity, e , is small, the applied ground acceleration mainly induces torsional deformation of the beam and, due to warping continuity, torsion is transmitted to the column. By contrast, transverse flexural deformation are mainly limited to the beam, as expected, given the assumed boundary restraints. Figure 9 plots the time-evolution of (a) the torsional rotation, θ_x^B , of the column mid-height cross-section, (b) the torsional rotation, θ_x^D , and (c) transverse displacement, v^D , of the beam mid-span cross-section, respectively, under the assumption of linear elastic material. Solid black curves represent the reference solutions obtained with the shell FEs. Red, yellow and blue curves refer to those obtained with the EWME, SWME and EVDE models, respectively. Finally, dotted dark gray curves indicate the response obtained with the standard beam formulations. As observed in the modal decomposition analysis, standard beam model, not considering the boundary warping restraints, provides a significantly more flexible response, as opposed to all enhanced models that perfectly agree with the reference response. In addition, standard model does not account for warping transmission at the joint and, thus, gives null rotations for the column (horizontal line at zero in Figures 9(a)), as opposed to the enhanced beam models that correctly capture the column torsional deformation.

Figure 9: Linear elastic response of the steel L frame: time history of (a) the torsional rotation of the column at mid-height (point B), (b) torsional rotation and (c) transverse displacement of the beam at mid-span (point D)

Figure 10: Nonlinear response of the steel L frame: time history of (a) the torsional rotation of the column at mid-height (point B), (b) torsional rotation and (c) transverse displacement of the beam at mid-span (point D)

Similar results are plotted in Figure 10 for elasto-plastic material response, showing that all enhanced beam formulations correctly simulate the evolution of the plastic effects in the material. Indeed, due to warping constraints, torsion of the members induces significant shear-lag effects and, thus, when ground acceleration reaches the peak value, at almost 1.3 s, axial stress exceeds material yield stress, at both ends and mid-height of the beam. Consequently, plastic strains affect the remaining part of the time-history response. As opposed to the beam model formulations accounting for warping, the standard beam model does not capture shear-lag and shows yielding of the material caused by severe torsional shear stresses acting in the cross-section plane.

Fourier transforms of the beam and column rotation histories, θ_x^B and θ_x^D , are plotted in Figure 11, for (a-b) linear elastic and (c-d) nonlinear material response, respectively. These confirm that main frequency content of the response is associated to torsional deformation mode of the frame. First torsional frequency of the frame is indicated by the green dotted vertical lines.

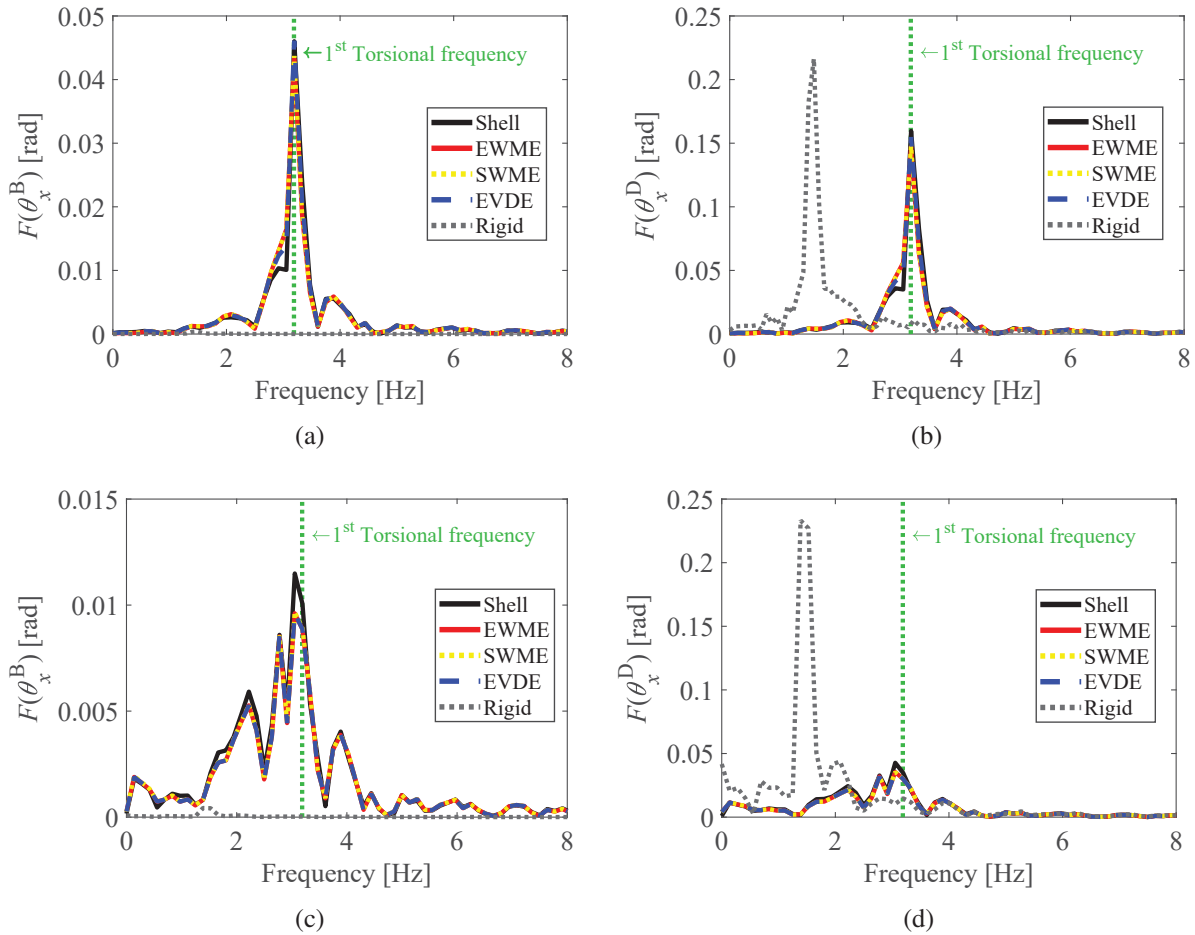

Figure 11: Steel L frame: Fourier transform of the torsional rotation of (a-c) the column mid-height (point B) and (b-d) beam mid-span cross-section (point D), for (a-b) linear elastic and (c-d) nonlinear material response

3.2 RC U-shaped shear wall

To investigate the performances of the presented enhanced beam models describing the interaction between warping and damaging mechanisms, the response of the RC U-shaped shear wall in Figure 12 is analyzed under dynamic loadings. Same specimen was experimental tested

Figure 12: RC U-shaped shear wall: (a) specimen and (b) cross-section geometry (dimensions in cm)

by Pegon et al. [29] under cyclic transverse loads applied at the top slab, while ground acceleration is considered, here, as base excitation, i.e. the same signal reported in Figure 8 but scaled so that peak ground acceleration results equal to 0.8334 g. This is assumed to act in the x direction, parallel to the wall web.

In addition to the weight of the top slab, the wall is vertically loaded by a constant compression force equal to 2000 kN. As a result, a lumped mass $M = 203969$ kg is applied at the top of the wall (at $z = 3.90$ m), representing the mass of the slab and that of the additional vertical load. Concrete density is assumed as equal to $\rho = 2548.42$ kg/m³.

The wall is modeled as a vertical cantilever, where square slabs are assumed to fully prevent warping deformations of the bottom and top cross-sections. A uniform mesh made of 4 FEs is used. For the SWME and EWME, parabolic warping interpolation is assumed along the element axis, i.e. $n_w = 3$. Over the cross-section plane, EWME considers cubic warping interpolation along web and flanges and linear interpolation across the membrature thickness, i.e. $m_w = 24$. Same interpolation order is used to compute warping profile functions $M_\eta(y, z)$, adopted in the EVDE and SWME.

A cross-section fiber discretization is defined so that 9 fibers are placed along web and flanges and 3 across the membrature thickness, while concrete response is reproduced by adopting the damage-plastic model proposed in [18]. Table 2 lists the material parameters, being σ_t and σ_c the uniaxial plastic limit stress in tension and compression, respectively, H_k and H_i the kinematic and isotropic hardening moduli, respectively, Y_{0t} and Y_{0c} the damage thresholds in tension and compression, respectively, k_t , a_t , k_c , a_c and β parameters governing the damage evolution. Young's modulus and Poisson ratio are assumed as equal to $E = 28000$ MPa and $\nu = 0.25$, respectively. The Giuffrè-Menegotto-Pinto model [30] describes the behavior of the steel reinforcing bars, with $E^s = 200\,000$ MPa, $\sigma_y^s = 540$ MPa and $b = 1.0\%$ being the Young's modulus, plastic yield strength and ratio between hardening and elastic stiffness, respectively. The transition coefficient R from the elastic to the plastic state required in the model results from the following parameters: $R_0 = 20$, $a_1 = 18.5$ and $a_2 = 0.15$ and no isotropic hardening is assumed.

(a)

(b)

(c)

Figure 13: Linear elastic response of the RC U-shaped shear wall: time history of the transverse displacement u , along x , of the top slab obtained with (a) EWME (red dotted curve), (b) SWME (green dotted curve) and (c) EVDE (blue dotted curve), compared with the reference brick FE solution (black curves)

Table 2: Material parameters for concrete model in RC U-shaped wall.

σ_t	σ_c	H_k	H_i	Y_{0t}	k_t	a_t	Y_{0c}	k_c	a_c	β
3.3 MPa	30 MPa	$0.8 E$	$0.001 E$	$6.7 \cdot 10^{-5}$	$2.0 \cdot 10^{-5}$	0.8	$4.0 \cdot 10^{-4}$	$2.8 \cdot 10^{-3}$	0.8	0.5

Damping ratio is set equal to 2% and introduced through Rayleigh method [28] on the basis of the first two elastic frequencies of the frame and Newmark method [28] is adopted for time integration of the structure global equilibrium equations, with coefficients $\beta = 0.25$ and $\gamma = 0.5$ and time step set equal to 0.001 s.

Figure 13 shows the evolution of the transverse displacement u , along x , of the top slab, under linear elastic material behavior, for (a) EWME model (red dotted curve), (b) SWME model (green dotted curve) and (c) EVDE model (blue dotted curve). Each response is compared with a reference solution (black curve) obtained with a FE model made by 24480 8-node bricks.

As opposed to the steel portal frame analyzed in Section 3.1, in this test, the asymmetric geometry of the wall cross-section induces significant coupling between shear/bending in the x - z plane and torsional behavior. As a consequence, only the most sophisticated EWME model is able to correctly capture the shear/torsional warping interaction and provide the same solution as that obtained by the brick 3D model. The SWME provides a correct response only for the first 2 s of the history, while it slightly overestimates the wall horizontal displacement for the remaining part. Worse results are obtained with the EVDE, whose response also shows a significant overestimation of the maximum displacements occurring during oscillations. However, if compared with the solution provided by a standard beam model assuming rigid cross-sections, that obtained with the SWME results significantly more accurate, proving that this model can be considered as a good compromise between more sophisticated, but onerous, formulations and simpler, but less demanding, approaches. The standard beam solution is plotted in Figure 14 as gray dotted curve. For this model, shear areas in the x and y directions are set equal to $A_t^x = 0.4286 A$ and $A_t^y = 0.7142 A$, being A the cross-section area, while torsional inertia is assumed as $J = 0.05495 I_\rho$, being I_ρ the cross-section polar inertia.

Figure 14: Linear elastic response of the RC U-shaped shear wall: time history of the transverse displacement u , along x , of the top slab obtained with reference brick FE (black curve) and standard beam (gray dotted curve) solutions

Different trend is observed for nonlinear material behavior. Figure 15 shows the displacement time histories along x of the top slab, obtained by considering the nonlinear response of concrete and steel. Figure 15(a) compares the solution obtained with the EWME (red curve) with the linear elastic response provided by the brick FE model (gray curve). When ground acceleration reaches the peak value, at almost 1.3 s, the wall significantly damages at the base, without collapsing. As a result, structural response with lower frequency content is observed compared to the linear elastic behavior. As expected, higher peak displacements occur in the first part of the history, around the peak acceleration, while lower amplitude oscillations are shown in the remaining part.

Figure 15: Nonlinear response of the RC U-shaped shear wall: time history of the transverse displacement u , along x , of the top slab obtained with (a) EWME (red curve) and (b) SWME (yellow dotted curve), EVDE (blue dashed curve) and standard beam (gray dotted curve)

In this case, all beam formulations, including the standard model, are able to correctly reproduce the wall response, as shown in Figure 15(b). This compares solutions obtained with the other beam models (SWME as yellow dotted curve, EVDE as blue dashed curve and standard beam as gray dotted curve) with the EWME results (red curve). Indeed, after damaging, wall behavior is

mainly governed by the nonlinear hinge that forms at the base and, although shear contribution is not negligible, warping effects become less important.

Fourier transforms of the displacement histories are plotted in Figures 16, using same curve styles of Figure 15. Green dotted vertical line indicates the value of the first elastic natural frequency of the wall involving shear/bending in the x direction, coupled with torsion.

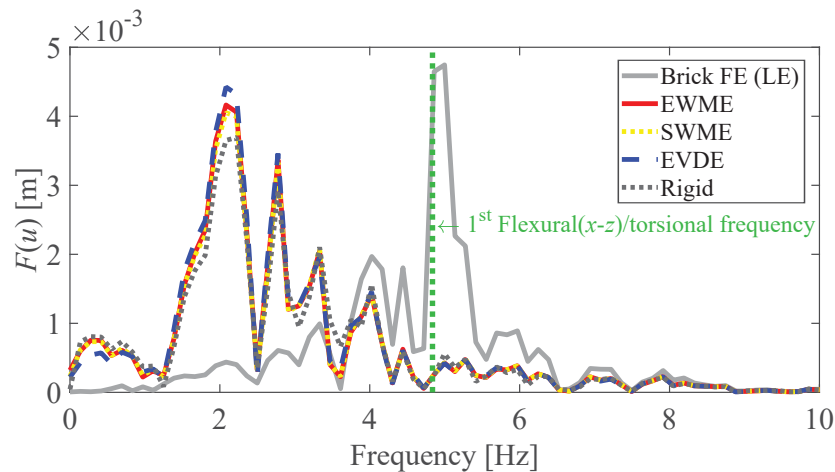

Figure 16: RC U-shaped shear wall: Fourier transform of the transverse displacement histories of the top slab

This plot confirms that, for the nonlinear behavior, natural modes of the wall that are excited by the seismic action are associated to lower frequencies, compared to the linear elastic response, as damage reduces the stiffness of the structure.

The values of the first four elastic circular frequencies ω_i obtained from all models are reported in Table 3.

Table 3: Elastic circular frequency ω_i [rad/s] obtained for the RC U-shaped shear wall

FE type	Mode			
	1 st Flex.(y-z)	1 st Flex.(x-z)/Tors.	1 st Axial.	2 nd Flex.(x-z)/Tors.
Brick	28.24	30.39	181.91	465.05

SWME	29.01	31.60	185.08	510.73
EVDE	29.18	32.61	185.08	542.53
Rigid section beam	28.86	35.32	185.08	205.75

4 CONCLUSIONS

- This paper presented three beam FE formulations for the analysis of frame structures subjected to dynamic shear and torsional actions. These are derived by extending to the dynamic analysis previously proposed enriched models, where kinematic description includes shear and torsional cross-section warping and, thus, coupling between axial/bending and shear/torsional stress components.
- More sophisticated EWME model considers a detailed two-level warping displacement field interpolation. By contrast, SWME model considers pre-defined profile functions

to describe warping variation over the cross-section and interpolates warping along the element axis only, by means of independent quantities, according to Benscoter's theory. Similar assumptions are made in the EVDE model, but warping axis variation is directly linked to torsional curvature and shear strains, according to Vlasov's theory.

- Numerical analyses performed on the steel L frame showed that, when torsional effects dominate the response, standard beam formulations based on rigid cross-section assumption fail in reproducing the correct structural behavior. By contrast, all three enhanced FEs result highly accurate and are preferable to higher order shell/brick FE models for the analysis of large scale structures, due to the lower computational cost these require. This is particularly true for the simplest model of the three, EVDE, which, however, gives satisfactory results only for open symmetric cross-section geometries, as proven in [20]. For closed and/or un-symmetric profiles, SWME model is the best alternative of the set, as this involves a lower number of additional nodal DOFs than EWME.
- Numerical analyses performed on the RC U-shaped shear wall confirm the findings observed for the steel L frame. Linear elastic response predicted with EWME model perfectly matches that evaluated with the 3D brick FE model. Good approximation is also obtained with the SWME model. Instead, major discrepancies are detected with the EDVE formulation, as a consequence of the non-symmetric cross-section geometry. However, tests also showed that nonlinear phenomena due to onset of damage can significantly modify the structural response, making the warping effects less important. As a result, correct structural response may be obtained also with simpler models and even standard formulations.

Abstract

Earthquake-induced pounding among contiguous building structures with insufficient separation distance, common in highly populated areas, may generate large impact forces that can significantly modify the overall dynamic behavior of the intervenient buildings. Serious structural damage or global collapse is among the negative consequences of building pounding. Inelastic behavior is inherent in building structures subjected to moderate to severe seismic excitations. Hence, the consideration of the inelastic behavior of building structures in the occurrence of pounding is extremely important to obtain more realistic results in the study and modeling of these phenomena. To this end, a Matlab-Simulink model was developed to emulate the elastic and inelastic behavior of two lumped mass SDOF structural systems under an earthquake excitation, where pounding is likely to occur. Using a smooth hysteresis model different hysteresis cases will be considered in the inelastic behavior of the structural systems, namely, stiffness degradation, strength deterioration, and pinching effect, arising in cyclic behavior of materials that compose civil engineering structures. A non-linear viscoelastic impact model will be used to assess the magnitude of pounding forces and their relation with the interpenetration depth. It was verified that the consideration of elastic behavior in buildings prone to pounding overestimates the magnitude and number of impacts that the structures experience, and underestimates structural displacements, especially in flexible structures.

Keywords: Building pounding, Earthquake-induced structural pounding, Impact modeling, Inelastic behavior, Hysteretic model.

1 INTRODUCTION

The world has been impacted by numerous earthquake hazard events that cause in a few amounts of time total or partial destruction of built patrimony and human activity, and potential loss of human lives. In this sense, civil and earthquake engineering came along to develop methods of analysis and design of structures, that essentially establish certain requirements to avoid the structure's collapse and minimizing damage to allow possible repair.

The seismic design of structures is primarily based on an elastic analysis to compute the seismic strength of structures. However, non-linear behavior with significant inelastic deformation is generally observed in structures under seismic events. Thus, in more advanced methods of analysis but not exclusively, this non-linear inelastic behavior can be considered in the critical zones, or plastic hinges, which within buildings are commonly located at the beams' ends, emulating in this way its behavior with an appropriate hysteresis model.

One phenomenon that has been recognized and studied for the last three decades gaining increasing importance is earthquake-induced structural pounding between adjacent buildings that are insufficiently separated.

When building pounding is likely to occur, i.e., in a situation where the buildings are very close to each other, leaving insufficient space or gaps between them or even without space, something common in metropolitan cities, great impact forces and acceleration spikes can be generated at the building floors, leading to substantial damage at the vicinity of the impact and in the worst-case scenario, it can cause the complete collapse of the structural system. Besides, and in these conditions, buildings with very different dynamic properties and consequent dynamic behavior will vibrate out-of-phase increasing the possibilities of collisions between buildings under earthquake loads.

It is known that pounding can considerably amplify the structural responses of the buildings, but in some situations, it was also found that can lead to the reduction of lateral displacements. The effects of this phenomenon are very dispersed, some in agreement, others in contradiction, while it can decrease the displacements due to the mutual blocking of the adjacent buildings it can still cause significant local damage.

And due to the high non-linearities in this contact phenomenon, pounding is very difficult to model with high accuracy since it depends on a lot of variables and their relationships. This insurgent phenomenon involves a non-linear relationship between the contact area, pressure, and deformations; local inelastic deformations; propagation of stress waves within the colliding structures; tangential and friction forces; vibrations resulting in thermal and acoustic effects; and other complex situations that makes this phenomenon extremely difficult to model.

Earthquake-induced structural pounding is usually assessed considering that the structures are within the elastic regime. This oversimplification can lead to an overestimation of the magnitude of the pounding forces and can underestimate the displacements that the structures actually experience. Some researchers already addressed this matter ([1], [2]), although additional research is required to further understand the consequences of pounding when inelastic behavior is considered.

The overall dynamic behavior of two SDOF systems with very different dynamic behavior is assessed in the following sections. These systems will represent two building structures under an earthquake excitation, in which the gap between is modified to evaluate its responses when pounding is likely to occur. The elastic and inelastic behavior of the structures will be considered. A smooth hysteresis model will be applied to emulate the non-linear hysteresis of the given structural systems.

The ultimate objective will be the understanding of the influence of the structures' non-linear inelastic behavior in the occurrence of earthquake-induced structural pounding.

2 NON-LINEAR HYSTERESIS MODEL

Hysteresis is a phenomenological concept and thus it is based on experimental data relating an input-output couple. This relationship in the present scope will represent the lateral restoring force in function of the inelastic displacement experienced by the structures.

Hysteresis is regarded as a rate-independent memory effect. However, and in reality, the response of structural systems depends always on the rate of the applied load. When this rate is significant, viscosity must be introduced. In the seismic response of structures, viscosity and hysteresis will contribute to the overall energy dissipated by the structure. Hence, the following equations of motion can be derived for the elastic and inelastic cases, respectively,

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = -m\ddot{x}_g(t) \quad (1)$$

$$m\ddot{x}(t) + c\dot{x}(t) + ak_0x(t) + f_r^*[x(t), \dot{x}(t)] = -m\ddot{x}_g(t), \quad (2)$$

where m is the mass of the structure, c is the viscous damping, k is the elastic stiffness of the structure, $\ddot{x}_g(t)$ is the ground acceleration, $x(t)$ is the structure's displacement, \dot{x} is the structure's velocity, $\ddot{x}(t)$ is the structural acceleration. Parameters k_0 and f_r^* for the inelastic case are, respectively, the initial elastic stiffness and the restoring force comprising the hysteresis stiffness and which depends on the displacements and velocities.

More realistic hysteresis models are essential to accurately characterize an inelastic response analysis of a structural system subjected to dynamic loads, such as seismic excitations. The hysteresis models in the literature can be broadly characterized in polygonal (PHM) and smooth hysteresis models (SHM).

In this study, an SHM is used. This model was initially developed by Bouc ([3]-[6]), modified by Wen ([7], [8]), and further modified by many others ([9]-[12]). The modification used herein is the one developed by Sivaselvan and Reinhorn ([13], [14]).

Figure 1 displays the scheme used in this hysteresis model. This model is capable of simulating different behaviors of a structural system under cyclic loading, viz., strength hardening, the Bauschinger effect, stiffness degradation, strength deterioration, and the pinching effect.

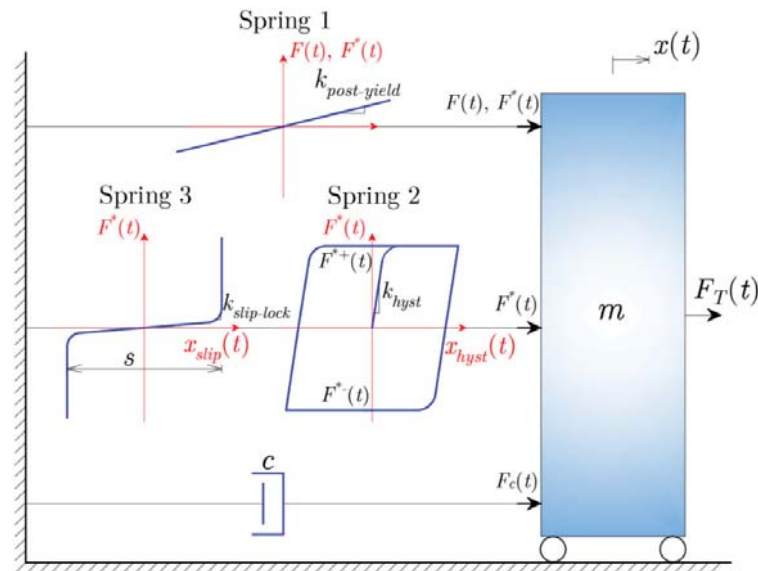

Figure 1: Sivaselvan and Reinhorn's smooth hysteresis model schematic representation.

Three different springs are used within the model: a post-yield spring (Spring 1); a hysteresis spring (Spring 2), and a slip-lock spring (Spring 3).

This modification to the original Bouc-Wen provides a more physical understanding than the previous modifications since the parameters are chosen in such a way to carry a physical meaning. A brief description of the model is presented below based on [14].

Spring 1 and Spring 2 are used in parallel to model post-yield strength hardening, and stiffness degradation, respectively. Hence, upon the application of a load, the springs undergo the same deformation, although they share this force in proportion to their instantaneous stiffness,

$$k = k_{post-yield} + k_{hyst} \quad (3)$$

in which the post-yielding stiffness, $k_{post-yield}$, is represented by a linear elastic spring (Spring 1), and the hysteresis spring, k_{hyst} , is represented by a pure elasto-plastic spring with a smooth transition from the elastic to the inelastic range (Spring 2), that may display degradation phenomena. The linear elastic stiffness and the non-degrading hysteresis stiffness are given by the following expressions, respectively,

$$k_{post-yield} = ak_0 \quad (4)$$

$$k_{hyst} = (1-a)k_0 \left\{ 1 - \left| \frac{F^*}{F_Y^*} \right|^{n_w} \left[\eta_1 \operatorname{sgn}(F^* dx) + \eta_2 \right] \right\} \quad (5)$$

where a is the post to pre-yielding stiffness ratio, n_w controls the smoothness of the transition from elastic to plastic stages, η_1 and η_2 are parameters that control the shape of the unloading curve, F^* and F_Y^* are the portion of the applied force shared by the hysteresis spring and its respective yield value, which are given, respectively, by

$$F^* = (x - x_0)(1-a)k_0 \quad (6)$$

$$F_Y^* = (1-a)F_Y \quad (7)$$

To model stiffness degradation, parameter α is introduced in factor R_K which is a positive parameter with the unity as its possible maximum value. This factor is given by the following expression

$$R_K = \frac{F^* + \alpha F_Y^*}{k_0 x + \alpha F_Y^*} \quad (8)$$

is implemented in the present SHM in the hysteresis spring, in this way only the hysteresis stiffness is modified in the following way

$$k_{hyst} = (R_K - a)k_0 \left\{ 1 - \left| \frac{F^*}{F_Y^*} \right|^{n_w} \left[\eta_1 \operatorname{sgn}(F^* dx) + \eta_2 \right] \right\} \quad (9)$$

To include strength deterioration a rule based on a continuous energy-based degradation, and on a backbone degradation which occurs when the maximum deformation value attained in the past is exceeded and is given by the following expression

$$F_Y^{+/-} = F_{Y0}^{+/-} \left[1 - \left(\frac{x_{\max}^{+/-}}{x_{\text{ult}}^{+/-}} \right)^{\frac{1}{\beta_1}} \right] \left[1 - \frac{\beta_2}{1 - \beta_2} \frac{E_h}{E_{h\text{ult}}} \right] \quad (10)$$

where $F_Y^{+/-}$ is the positive or negative yield force, $F_{Y0}^{+/-}$ is the initial positive or negative yield force, $x_{\max}^{+/-}$ is the maximum positive or negative displacement, $x_{\text{ult}}^{+/-}$ is the ultimate positive or negative displacement, E_h is the hysteresis energy dissipated, $E_{h\text{ult}}$ is the hysteresis energy dissipated when loaded monotonically until the ultimate displacement without any degradation, β_1 is a parameter based on ductility demands, and β_2 is a parameter based on energy demands. The second term on the right side of Equation 10 is related to strength deterioration based on increased deformation and the last term is related to the hysteresis energy dissipated.

The hysteresis energy dissipated can be given in incremental form as follows

$$\Delta E_h = \left[\frac{F + (F + \Delta F)}{2} \right] \left(\Delta x - \frac{\Delta F}{R_k k_0} \right) \quad (11)$$

A “slip-lock” spring (Spring 3) represented in Figure 1 was implemented in the hysteresis model to simulate pinching behavior. The combined stiffness from the three springs can be given as

$$k = k_{\text{post-yield}} + \frac{k_{\text{hyst}} k_{\text{slip-lock}}}{k_{\text{hyst}} + k_{\text{slip-lock}}} \quad (12)$$

where

$$k_{\text{slip-lock}} = \left\{ \sqrt{\frac{2}{\pi}} \frac{s}{F_\sigma^*} \exp \left[-\frac{1}{2} \left(\frac{F^* - F_m^*}{F_\sigma^*} \right)^2 \right] \right\}^{-1} \quad (13)$$

in which s is the slip length, F_σ^* is a measure of the force range over which slip occurs, and F_m^* is the mean force level on either side about which slip occurs, being these three parameters given, respectively, as follows

$$s = R_s (x_{\max}^+ - x_{\max}^-) \quad (14)$$

$$F_\sigma^* = \sigma F_Y^* \quad (15)$$

$$F_m^* = \lambda_s F_Y^* \quad (16)$$

where parameters R_s , σ_s , and λ_s are parameters that control each of the resulting values of the previous three equations.

With the right tuned hysteresis parameters presented in Equations 3 to 16 different hysteretic behaviors can be achieved and replicated, representing different structural systems, elements, or with different materials.

3 IMPACT MODELS REVIEW

As mentioned in the introduction section, structural pounding involves different and complex phenomena that make the problem of earthquake-induced structural building pounding extremely complicated to model.

When modeling structural pounding between buildings it is enough to accurately estimate the magnitude of the pounding forces to understand how these forces will influence the overall dynamic behavior of the intervenient structures. Hence, in the literature two possible ways to model these forces are available: stereomechanics or the classical theory of impact, and the use of impact or contact elements [15].

The first approach is limited to the specification of the initial and final impact velocity states of the colliding rigid bodies (Equations 17 and 18), as well as the applied linear or angular impulse-momentum.

$$\dot{x}_{1,f} = \dot{x}_{1,0} - (1 + CR) \frac{m_2 \dot{x}_{1,0} - m_2 \dot{x}_{2,0}}{m_1 + m_2} \quad (17)$$

$$\dot{x}_{2,f} = \dot{x}_{2,0} + (1 + CR) \frac{m_1 \dot{x}_{1,0} - m_1 \dot{x}_{2,0}}{m_1 + m_2} \quad (18)$$

This approach cannot describe transient stresses or forces and fails to account for local deformations at the contact point of the bodies assuming that a negligibly part of the initial kinetic energy of the system is transformed into vibrations of the colliding bodies [16].

The impact velocities are related to the very important parameter, coefficient of restitution (CR),

$$CR = \frac{\dot{x}_{2,f} - \dot{x}_{1,f}}{\dot{x}_{1,0} - \dot{x}_{2,0}} \quad (19)$$

in which its value represents the energy losses and degree of inelasticity of the collision being directly related with the kinetic energy loss ($-\Delta E_k$) during impact, as follows

$$-\Delta E_k = \frac{1}{2} \left(\frac{m_1 m_2}{m_1 + m_2} \right) (1 - CR^2) (\dot{x}_{1,0} - \dot{x}_{2,0})^2 \quad (20)$$

A coefficient of restitution equal to one represents a perfectly elastic impact and equal to zero represents a perfectly plastic impact. This coefficient is found to be intrinsically correlated with the prior-impact velocity ([16], [17]).

The classical theory of impact is generally not used in structural pounding due to referred limitations. In addition, it neglects the existence of the period of impact failing to directly assess the evolution of the pounding forces during contact [18].

In reality, the period of impact exists and is divided into the approach (compression, loading, deformation) and restitution (unloading, elastic) periods. These periods are explicitly considered in most of the impact models that constitute the second approach available in modeling structural pounding between buildings under seismic excitations.

This approach is essentially based on a penalty method, i.e., when the buildings interpenetrate, the impact element is activated generating the pounding forces that push the structures apart. Considering the unidirectional relative displacements of the colliding structures, the impact element becomes active when

$$\delta(t) > 0 \quad \text{where} \quad \delta(t) = x_1(t) - x_2(t) - \text{Gap} \quad (21)$$

in which $\delta(t)$ is the interpenetration depth of the colliding structures.

These models are compression-only zero-length elements comprising a massless spring and dashpot in parallel. The structures involving large masses can be considered as rigid bodies, having the masses lumped at the stories' levels.

The use of these elements is based on Hertz's theory and oversimplified assumptions that make the analysis of the problem simpler yet less accurate [19].

According to theories of contact mechanics [19], in impact problems, the stress wave propagation will have a significant influence on the distribution of forces within the structure. However, if one can assume that the stress waves will travel through the structures being re-

flected many times before any of them is brought to rest, then the state of stress in the structures at any instant can be considered approximately uniform throughout its length. Thus, the sudden changes in stress associated with the passage of the elastic stress waves within the structure are small compared with the general stress level. This justifies the use of the well-known spring-dashpot element with acceptable accuracy, ignoring the dynamic effects in the structures due to wave propagation and assuming that structural pounding between buildings can be approximately quasi-static if the duration of the impact is long enough to allow stress waves to transverse the length of the body many times.

In addition, the contact area is in general elliptical and is assumed to be small in comparison with the main dimensions of the bodies; deformations are restricted to the vicinity of the impact; contact surfaces are non-conforming, smooth, continuous, and frictionless; and the contact regions are assumed to remain elastic and unaltered after impact events.

During impact, the spring will control the elastic restoring force and deformation, and the dashpot will account for the energy radiated due to impact by wave motion. With these impact models is thus possible to determine with reasonable accuracy the magnitude of the impact forces at any instant during structural pounding between buildings, which is the fundamental information to understand how pounding influences the overall dynamic response of the colliding buildings.

Nonetheless, and cumulative to the oversimplified assumptions, the effectiveness of the impact models largely depends on its parameters, viz., impact stiffness and impact damping ratio. The impact stiffness (k_{imp}) namely depends on the material properties and geometric characteristics of the region of impact, and hence it presents high levels of uncertainties. The impact damping ratio (ξ_{imp}) depends mostly on the coefficient of restitution and is generally derived from energy considerations.

Based on the relations between these parameters several impact models were developed in the literature.

The most basic impact model is the linear elastic model (Figure 2a), comprising only a spring and lacking the ability to account for energy loss during impacts which is inevitable in this kind of phenomenon. The pounding force, $f_P(t)$, can then be determined by the following expression

$$f_P(t) = \begin{cases} k_{imp} \delta(t), & \text{for } \delta(t) > 0 \\ 0 & \text{for } \delta(t) \leq 0 \end{cases} \quad (22)$$

The non-linear elastic model or Hertz's contact model follows Hertz's contact law [20], which describes the static compression between two isotropic elastic bodies according to the previously defined assumptions. It essentially consists of a non-linear spring as represented in Figure 2b. The spring non-linearity is capable of modeling the force-deformation relation more realistically, i.e., the contact area between neighboring structures is expected to increase as the contact force grows, leading to a non-linear stiffness. In other words, the impact force increases with the interpenetration depth to the power of 3/2 [19],

$$f_P(t) = \begin{cases} \beta_{imp} [\delta(t)]^{\frac{3}{2}} & \text{for } \delta(t) > 0 \\ 0 & \text{for } \delta(t) \leq 0 \end{cases} \quad (23)$$

in which β_{imp} is a parameter indicating the non-linear impact stiffness depending on material properties and geometry of the colliding structures. Simplified formulae were developed by Goldsmith [16] to compute the impact stiffness parameters depending on the shape of the colliding bodies.

Alternatively, a linear viscoelastic impact model (also called Kelvin-Voigt model) as represented in Figure 2c, can be used accounting for the energy dissipation during impact ([21], [22]). The pounding force can be computed using the following system of equations

$$f_p(t) = \begin{cases} k_{imp} \delta(t) + c_{imp} \dot{\delta}(t), & \text{for } \delta(t) > 0 \\ 0 & \text{for } \delta(t) \leq 0 \end{cases} \quad (24)$$

where c_{imp} is the damping constant of the pounding contact element computed by the following expression ([22], [23])

$$c_{imp} = 2 \xi_{imp} \sqrt{k_{imp} \frac{m_1 m_2}{m_1 + m_2}} \quad \text{where} \quad \xi_{imp} = \frac{-\ln(CR)}{\sqrt{\pi^2 + [\ln(CR)]^2}} \quad (25)$$

A shortcoming to this model is the tension stress verified at the end of the restitution period, i.e., immediately before separation of the bodies, produces a negative pounding force, pulling the bodies together in the unloading phase not having a physical meaning. This happens since the parallel association in the Kelvin solid means that the total stresses are obtained as the summation of the stresses in the spring and dashpot, i.e., all elements will suffer the same deformation, meaning that the stress-strain curves produced in both periods of impact will have the same damping coefficient. This will produce a uniform dissipation of energy on both periods of impact, which in reality does not happen ([15], [16]). Also, it is observed that the elastic strain energy stored in the first period of impact is released in the second period without major plastic effects, being that most of the energy dissipated is verified to be lost in the approach period, while in the restitution period only a relatively small quantity is observed to be dissipated.

To address and solve these drawbacks some modifications to the Kelvin-Voigt impact model have been developed. Komodromos et al. [24] proposed the following modification

$$f_p(t) = \begin{cases} k_{imp} \delta(t) + c_{imp} \dot{\delta}(t), & \text{for } f_p(t) > 0 \\ 0 & \text{for } f_p(t) \leq 0 \end{cases} \quad (26)$$

Valles and Reinhorn [25], modified the Kelvin-Voigt model by considering the damping term to be activated only for positive velocities during impact which means only activated during the approach period (Figure 2e). The following compact expression was suggested

$$f_p(t) = \left\{ k_{imp} \delta(t) + c_{imp} \dot{\delta}(t) H[\dot{\delta}(t)] \right\} H[\delta(t)] \quad (27)$$

where H is the unit step or Heaviside function. The expressions used to compute the impact damping coefficient and ratio are the same as in Equation 25, and an expression to compute an equivalent coefficient of restitution was derived based on the instant of time of maximum deformation (end of approach period), impact frequency (ω_{imp}), impact damped frequency ($\omega_{d,imp}$), and impact damping ratio

$$CR = \sin(\omega_{d,imp} t_{max}) e^{-\xi_{imp} \omega_{imp} t_{max}} \quad \text{where} \quad t_{max} = \frac{1}{\omega_{d,imp}} \tan^{-1} \left(\frac{\omega_{d,imp}}{\xi_{imp} \omega_{imp}} \right) \quad (28)$$

Mahmoud [26] addressed the drawbacks of the linear viscoelastic impact model by redefining the pounding force depending on the two periods of impact. The author considered a similar approach to Valles and Reinhorn [25] (Figure 2e), and the following equivalent expression was suggested

$$f_p(t) = \begin{cases} k_{imp} \delta(t) + c_{imp} \dot{\delta}(t) & \text{for } \delta(t) > 0, \dot{\delta}(t) > 0 \\ k_{imp} \delta(t) & \text{for } \delta(t) > 0, \dot{\delta}(t) \leq 0 \\ 0 & \text{for } \delta(t) \leq 0, \end{cases} \quad (29)$$

The relationship between the damping ratio and the CR was reevaluated since the energy dissipation properties depend on the damping term, which now is only active in the first period of impact. The author used the same procedure as Jankowski in [27] using energy considerations, arriving at the following expression

$$\xi_{imp} = \frac{1}{\pi} \frac{1 - CR^2}{CR} \quad (30)$$

Ye et al. [28] proposed the following modification to the Kelvin-Voigt model (Figure 2e) at the impact damping coefficient and ratio

$$c_{imp} = \xi_{imp} \delta(t) \quad \text{where} \quad \xi_{imp} = \frac{3 k_{imp} (1 - CR)}{2CR (\dot{x}_{1,0} - \dot{x}_{2,0})}. \quad (31)$$

Pant et al. ([29], [30]) developed a modification on the Kelvin-Voigt impact model (Figure 2e) considering the same expression presented by Mahmoud in Equation 29, by modifying the expression of the impact damping ratio as follows

$$\xi_{imp} = \frac{3 k_{imp} (1 - CR^2)}{2CR^2 (\dot{x}_{1,0} - \dot{x}_{2,0})} \quad (32)$$

Following the research in Mahmoud [26], Mahmoud and Jankowski [31] suggested a further modification to the linear viscoelastic model (Figure 2e) using a different approach to arrive at an improved formula for the impact damping ratio

$$\xi_{imp} = \frac{1 - CR^2}{CR [CR (\pi - 2) + 2]} \quad (33)$$

In the modifications to the Hertz contact model, the lack of energy dissipation properties was addressed by the addition of non-linear damping becoming now a non-linear viscoelastic model. Lankarani and Nikraves ([32], [33]) proposed a contact model considering a non-linear spring using Hertz's law in parallel with non-linear damping in hysteresis form proposed by Hunt and Crossley [34] (Figure 2d) to better represent impacts between mechanical systems. The authors considered the pounding force to be computed as follows

$$f_p(t) = \beta_{imp} [\delta(t)]^n + c_H \dot{\delta}(t) \quad (34)$$

where c_H is the non-linear damping coefficient given by

$$c_H = \mu_d [\delta(t)]^n \quad \text{where} \quad \mu_d = \frac{3 \beta_{imp} (1 - CR^2)}{4 (\dot{x}_{1,0} - \dot{x}_{2,0})} \dot{\delta}(t) \quad (35)$$

in which μ_d is the hysteresis damping factor and $n=3/2$ to represent Hertz's law. Muthukumar and DesRoches ([35], [36]) proposed an impact model, the "Hertzdamp" impact model represented in Figure 2d, using the previous considerations applied to civil engineering structures

$$f_P(t) = \begin{cases} \beta_{imp} [\delta(t)]^{\frac{3}{2}} + c_H \dot{\delta}(t) & \text{for } \delta(t) \geq 0 \\ 0 & \text{for } \delta(t) < 0 \end{cases} \quad (36)$$

where the impact damping ratio is now

$$\xi_{imp} = \frac{3\beta_{imp}(1-CR^2)}{4(\dot{x}_{1,0} - \dot{x}_{2,0})} \dot{\delta}(t) \quad (37)$$

Jankowski [37] proposed a modification to Hertz's non-linear impact model by considering that the non-linear damping component is only active in the approach period (Figure 2f) since it is in this period of the impact that most energy is dissipated. Thus, the pounding force is obtained using the following piecewise function

$$f_P(t) = \begin{cases} \beta_{imp} [\delta(t)]^{\frac{3}{2}} + c_H(t) \dot{\delta}(t) & \text{for } \delta(t) > 0 \text{ and } \dot{\delta}(t) > 0 \\ \beta_{imp} [\delta(t)]^{\frac{3}{2}} & \text{for } \delta(t) > 0 \text{ and } \dot{\delta}(t) \leq 0 \\ 0 & \text{for } \delta(t) \leq 0 \end{cases} \quad (38)$$

The impact element's damping can be considered as an extension of the linear viscoelastic model (modified Kelvin-Voigt) and is obtained with the following expression

$$c_H(t) = 2\xi_{imp} \sqrt{k_{imp} \frac{m_1 m_2}{m_1 + m_2}} \quad \text{where} \quad k_{imp} = \beta_{imp} \sqrt{\delta(t)} \quad (39)$$

The second of Equation 39 can be seen as an effective impact stiffness for a given value of the interpenetration depth. Additionally, Jankowski ([27], [37]) redefined the expression for the damping ratio which is related to the coefficient of restitution since now the non-linear damping is only active in the approach period. To do this the author developed two algebraic expressions (with approximating functions) for the impact damping ratio and then compared them with numerical results to verify its validity. The two expressions are

$$\xi_{imp} = \frac{\sqrt{5}}{2\pi} \frac{1-CR^2}{CR} \quad \text{and} \quad \xi_{imp} = \frac{9\sqrt{5}}{2} \frac{1-CR^2}{CR[CR(9\pi-16)+16]} \quad (40)$$

in which the second was found to provide better approximations. The approximating functions used by Jankowski in [27] served as the base to the procedure adopted by Mahmoud and Mahmoud and Jankowski in [26] and [31], respectively. Also, the results regarding the relationship between the impact damping ratio and the coefficient of restitution in impact models drew attention to the fact that when the coefficient of restitution becomes zero the impact damping ratio should go to infinity. This was addressed by Ye et al. [28] for the modification to the original Kelvin-Voigt that provided the unit value of the impact damping ratio for zero value of the coefficient of restitution, and by the same authors [38] for the modification of the Hertz damp model that gave a finite value for the impact damping ratio for perfectly plastic collisions. Besides, all models corroborated the fact that a coefficient of restitution of one corresponds to the obvious zero value of the impact damping ratio.

Ye et al. [38] then arrived at a more accurate expression to approximate the damping constant given by

$$\xi_{imp} = \frac{8 \beta_{imp} (1 - CR)}{5CR (\dot{x}_{1,0} - \dot{x}_{2,0})} \quad (41)$$

which confirms the aforementioned premises by Jankowski [27] and was then validated through numerical simulations.

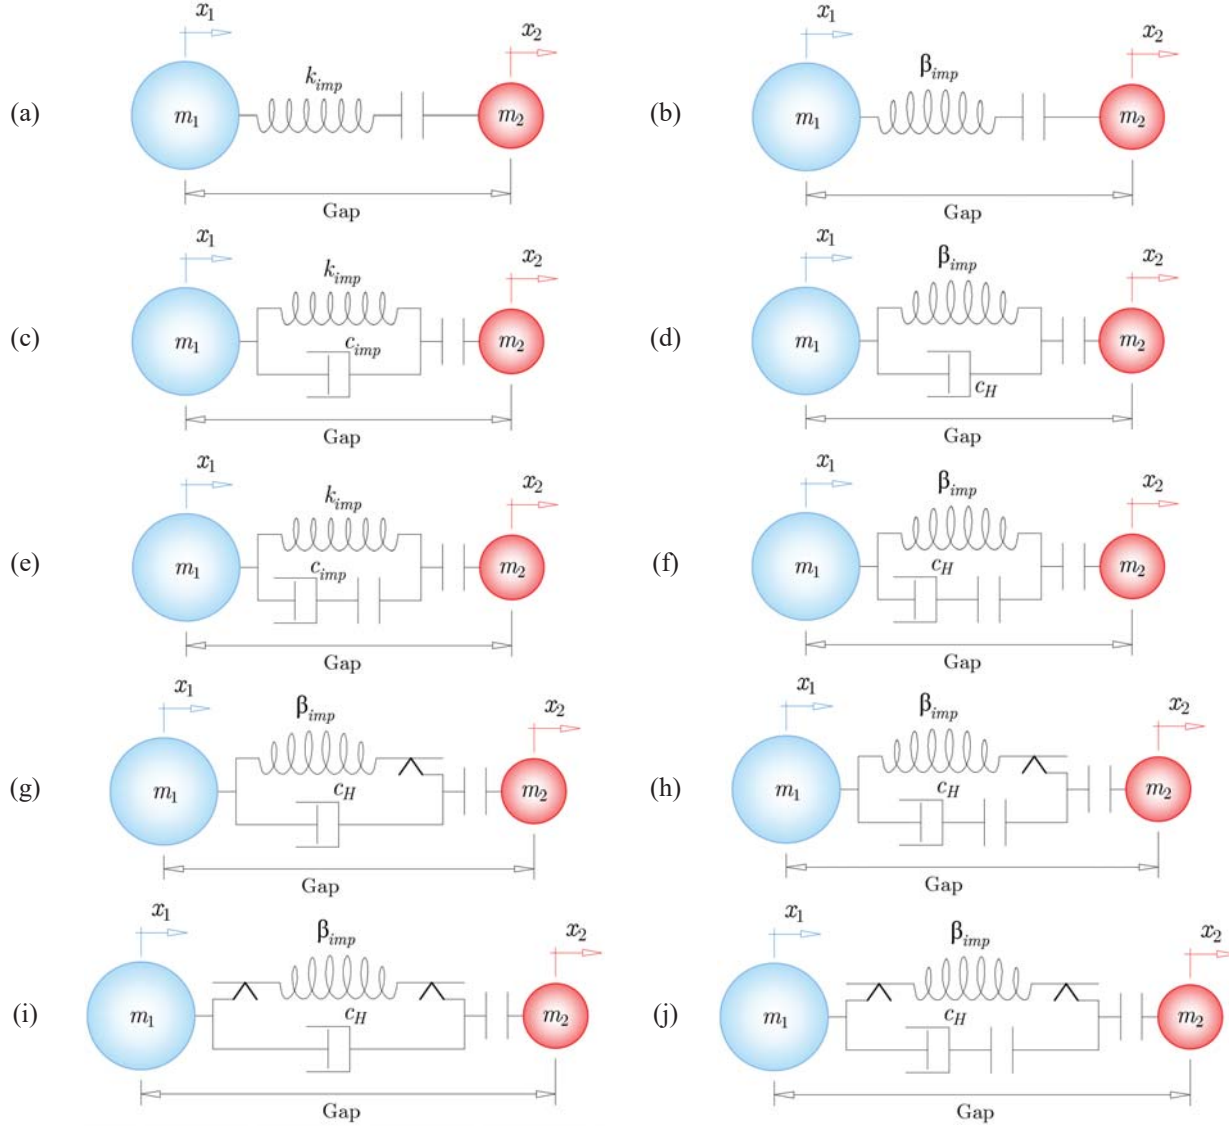

Figure 2: Schematic representation of state-of-the-art impact models.

More recently, Naderpour et al. [39] considered an equivalent expression to Equation 34 and the first of Equation 35 to compute the pounding force between buildings. Ultimately, a new expression for the impact damping ratio for the non-linear viscoelastic model (Figure 2f) related to the coefficient of restitution was obtained by an iterative procedure that attempts to equate the energy dissipated by the non-linear damping in the approach period (translated by the area of the impact hysteresis loop) to the kinetic energy loss (of the stereomechanical impact), resulting in

$$\xi_{imp} = \left[\frac{2}{CR\sqrt{\pi}} (1 - CR^2) \right]^2 \quad (42)$$

A further study by Naderpour et al. [40] suggested a new expression (see Equation 43) for the impact damping coefficient that depends on the prior-impact velocity and coefficient of restitution.

$$c_{imp}(t) = \alpha \frac{CR^\beta \dot{\delta}_{imp}(1-CR)}{\ddot{\delta}(t)} k_{imp} \delta^n(t) \quad (43)$$

Bamer [41] and Bamer and Markert [42], respectively, proposed an extension to the Hertz-damp and Jankowski's non-linear viscoelastic model by including a dry friction element in series with the non-linear spring (Figure 2g and 2h) to address one of the mentioned oversimplified assumptions, the unaltered contact surface which is tacitly known to experience damage and material dissipation caused by numerous and repeated impacts. The authors modified the condition of collision (see Equation 21), first by considering the equivalent condition of collision when $\delta < 0$ (when the Gap is added instead of subtracted) and then by including an additional increase in the gap due to damage, material loss, or plastic deformation, yielding

$$\delta_T(t) = \delta(t) + \delta_s(t) < 0 \quad \text{where} \quad \delta(t) = x_1(t) - x_2(t) + \text{Gap} \quad (44)$$

in which the non-negative parameter δ_s is the additional offset to the position of the initial pounded surface. Three states were then considered within the periods of impact: state 0 refers to the case without impact; state I corresponds to the activation of the impact model satisfying the condition in Equation 44; state II when a limit value of the elastic Hertz's contact force is exceeded (sliding). A constant friction force R obeying Coulomb's friction law is considered based on the material and geometric properties of the colliding surfaces, together with the non-linear damping term. An additional state, state III considered in the case of Jankowski's non-linear viscoelastic model, where the damping term is no longer active in the restitution period. Equations 45 represents, the improved models of Hertz-damp and Jankowski's non-linear viscoelastic model, according to the states defined ([41], [42])

$$f_P(t) = \begin{cases} f_k + f_c & \text{for } \delta_T(t) < 0 \quad \text{and} \quad \dot{\delta}_T(t) < 0 \quad \text{and} \quad f_k < f_R \quad (\text{State I}) \\ f_R + f_c & \text{for } \delta_T(t) < 0 \quad \text{and} \quad \dot{\delta}_T(t) < 0 \quad \text{and} \quad f_k \geq f_R \quad (\text{State II}) \\ f_k & \text{for } \delta_T(t) < 0 \quad \text{and} \quad \dot{\delta}_T(t) \geq 0 \quad (\text{State III}) \\ 0 & \text{for } \delta_T(t) \geq 0 \quad (\text{State 0}) \end{cases} \quad (45)$$

$$\text{where} \quad f_k = \beta_{imp} \left[|\delta(t)| - \delta_s(t) \right]^{\frac{3}{2}}, \quad f_c = c_H(t) \dot{\delta}_T(t), \quad f_R = -\text{sgn}(\dot{\delta}_T(t)) R$$

Later Bamer et al. [43] went further to include in the previous model a decrease in the stiffness depending on the sliding gap which now is divided into two and attributed to each frame. A simple damage curve was then assumed to allow structural damage description. The impact model may then be represented, respectively, for the modified Hertz-damp and Jankowski's non-linear viscoelastic model in Figures 2i and 2j.

Khatami et al. [44] developed an effective formula for the impact damping ratio included in the non-linear viscoelastic impact model (Figure 2f). The authors used a program developed called the Coefficient of Restitution-Velocity-Stiffness (CRVK), which performs several dynamic analyses and solves impact problems. The accuracy of this new formula was assessed based on four different approaches that include energy-based considerations, numerical simulations, and comparisons with experimental results. The expression proposed by the authors is

$$\xi_{imp} = \frac{(1 - CR)}{CR^{(\alpha + 0.204)} + 3.351\pi CR} CR^{0.204} \quad \text{where} \quad \alpha = 1.05 CR^{0.653} \quad (46)$$

Based on the previous studies regarding impact models it is possible to verify that the main modifications are at the parameters impact stiffness and impact damping ratio. These parameters along with the coefficient of restitution, which generally is the only independent variable of the impact damping ratio constitute the core of the impact models and its accuracy depends on how accurate is the estimation of these parameters.

Some experimental tests regarding pounding between structures have been carried out ([17], [45]-[49]) essentially concerning reduced-scale models. These experimental tests motivated several investigations comparing the effectiveness of the previous impact models and other comparisons between them.

For instance, based on different experimental results available in the literature regarding pounding-involved structural responses, Jankowski [37] made comparisons between Jankowski's non-linear viscoelastic model, Kelvin-Voigt model, and Hertz's non-linear model. The author verified that the Kelvin-Voigt and the non-linear viscoelastic model gave the smallest simulation errors in the pounding force time-histories during impact and that further research confirmed that Jankowski's model provided smaller errors in the response time-histories with the structural pounding.

Jankowski and Mahmoud ([15], [17]) performed experimental tests based on dropping different balls of different materials (steel, concrete, timber, and ceramic), and on the impact between reduced-scale models excited by shake tables. The results corroborated with the study addressed in the previous paragraph and revealed that the improved version of the linear viscoelastic model by Jankowski and Mahmoud did not lead to increased accuracy and that the Hertz damp also furnished small errors in the response time-histories of earthquake-induced structural pounding.

Bamer et al. ([41]-[43]) proposed a new strategy using state-of-the-art impact models that includes damage description and failure of the pounding-involved structures. The authors verified through sensitivity analysis the importance of the consideration of the damage state of the adjacent structures.

Khatami et al. [44] compared their impact damping ratio formula with the ones of different impact models in the literature and based on different experimental tests and numerical simulations, presenting the lowest errors and proving its accuracy in the study of earthquake-induced structural pounding.

Still, most of the impact models in the literature lack the ability to emulate structural pounding between three-dimensional structures. The central impact is defined as the collision between two non-rotating objects at a point belonging to a line that connects the two centroids. An oblique impact considering a two-dimensional impact model may be possible to develop to emulate three-dimensional pounding that considers in addition to the two directions of translation of the buildings, their rotation. One good example is the model developed by Polycarpou et al. [50] that considers tangential forces and friction during impact, and the material properties and geometry of the contact area without the need to previously determine the location of the impact. The model proved to furnish good results and close to the results obtained with commercial software.

4 NUMERICAL MODELING

Two adjacent structural systems will be considered in this earthquake-induced structural pounding study, one flexible building, and the other building stiffer as represented in Figure 3.

The structures are assumed to be in shear configuration, and thus can be reduced to lumped mass models with the masses lumped at the floor levels. The structural properties of the representative buildings are considered to be the same as in [15] and are summarized in Table 1.

Figure 3: Representation of the two SDOF structural systems separated by a gap size.

Structural properties	Flexible building	Stiffer building
Mass (kg)	$m_L=75000$	$m_R=3000 \times 10^3$
Stiffness (kN/m)	$k_L=2056$	$k_R=1.316 \times 10^6$
Natural period (s)	$T_L=1.2$	$T_R=0.3$
Damping coefficient (kg/s)	$c_L=39270$	$c_R=6.283 \times 10^6$
Damping ratio (%)	$\xi_L=5$	$\xi_R=5$

Table 1: Structural properties of the adjacent buildings.

Among the different types of building pounding, impacts will be assumed to happen exclusively between floors. The impact model used in this study is the one developed by Jankowski ([27], [37]), the non-linear viscoelastic model which is illustrated in Figure 2f, and so the expressions to be used are Equations 38, 39 and the second of 40. These expressions are then implemented in the equations of motion in Equations 1 and 2, being modified, respectively, for the elastic and inelastic case as follows

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) + f_p(t) = -m\ddot{x}_g(t) \quad (47)$$

$$m\ddot{x}(t) + c\dot{x}(t) + ak_0x(t) + f_r^*[x(t), \dot{x}(t)] + f_p(t) = -m\ddot{x}_g(t), \quad (48)$$

Depending on the structural behavior one of the two previous equations will be solved for each building. The term regarding the pounding force becomes activated when the buildings interpenetrate satisfying Equation 21.

The stiffness of the impact element is usually taken as the same order of magnitude as the axial stiffness of the stiffer story. This parameter depends on the geometry of the impact surfaces, material properties, variable impact velocities, and uncertainties concerning its value arising from these factors [22]. Goldsmith [16] referred that for steel-to-steel impacts the impact stiffness generally takes higher values than concrete-to-concrete impacts. Van Mier et al. [45] experiments reveal that impacts between concrete bodies depend mostly on the contact surface geometry and ranges typically between $40 \text{ kN/mm}^{3/2}$ and $80 \text{ kN/mm}^{3/2}$ (respectively, $1.2 \times 10^9 \text{ N/m}^{3/2}$ and $2.6 \times 10^9 \text{ N/m}^{3/2}$). Cole et al. [51] refer that the impact stiffness is typically set as ten times the stiffness of the larger axial floor.

The values used for the impact stiffness and the coefficient of restitution are, respectively, $2.75 \times 10^9 \text{ N/m}^{3/2}$ and 0.65. These values were provided by Jankowski [37] based on comparisons between numerical simulations using the author's non-linear viscoelastic model and experimental data available in the literature.

The hysteresis parameter values considered for the present study are: $a=0.1$; $\eta_1=\eta_2=0.5$; $\alpha=4$; $\beta_1=0.30$; $\beta_2=0.15$; $\sigma_s=0.2$; $R_s=0.1$; $\lambda_s=0$; $n_W=3$. In addition, the yield force and displacement of the left building are, respectively, $F_{YL}=70 \text{ kN}$, $x_{YL}=3.4 \text{ cm}$, the yield force and displacement of the right building are, respectively, $F_{YR}=7000 \text{ kN}$, $x_{YR}=0.53 \text{ cm}$, and the ductility is $\mu=10$. The values were chosen according to the information furnished in [14] and are intended to be representative of a reinforced concrete (RC) frame, although the values are not the result of direct calibration with experimental data. Hence, for the RC frame a severe stiffness degradation, moderate strength deterioration, and mild to moderate pinching effect.

A Matlab/Simulink [52] model was developed and used to emulate structural pounding between the elastic and inelastic SDOF systems under the El Centro earthquake represented in Figure 4. The simulations were performed for the following values of the gap between the adjacent structures: 0 cm , 3 cm , 5 cm , 10 cm , and 15 cm . To solve the differential equations of motion the Runge-Kutta of 4th order was used with a fixed time step of $5 \times 10^{-4} \text{ s}$.

5 RESULTS AND DISCUSSION

As an example, the following results in form of graphs are presented only for the situations where the buildings have no gap in between and are separated by 3 cm and for the elastic and inelastic structural systems described in the previous section. Nevertheless, and for the purpose of comparisons Table 2 presents the peak responses (displacements, velocities, accelerations, and pounding forces and number of impacts) of both buildings for the different situations of the separation distance and structural behavior cases. It should be pointed out that in the case where the gap is 10 cm and the structural system has inelastic behavior no impacts were verified and so its response is the same as for the case with 15 cm of gap size, thus its results do not explicitly appear in the table.

Hence, Figures 5 to 8 present the displacement and pounding force time-history responses for the 0 cm and 3 cm of gap size and for the elastic and inelastic case. Correspondingly the graphs of Figure 9 present the pounding force vs interpenetration depth cycles for the 0 cm and 3 cm of gap size for the elastic and inelastic case. Figures 10 and 11 present comparisons between the displacements and impact forces time-history responses for the different gap sizes considered (except for the 10 cm for the mentioned reason).

The graphs of Figures 12 and 13 present the hysteresis cycles of the left and right structural systems obtained with the aforementioned hysteresis model for the two gap cases considered, respectively.

Additionally, the acceleration time-history responses are also presented in Figures 14 to 18 for the mentioned cases to assess the acceleration spikes.

Figure 5: Displacements and pounding forces time-history responses for the elastic case of the representative structural systems with no gap in between.

Figure 6: Displacements and pounding forces time-history responses for the inelastic case of the representative structural systems with no gap in between.

The huge differences in stiffness and mass of the structures allow for better conclusions regarding the effects of pounding between these buildings. In general, and as expected, it can be verified for every response considered that the most flexible structure is the most affected, and thus, the most sensitive to the ground motion excitation and the pounding forces.

In general, as the gap between the buildings decreases, the number of impacts increases. No distance between buildings with very different dynamic properties may constitute one of

the worst situations when pounding is likely to occur. This situation presents the biggest number of impacts between the buildings, and the intensity of the pounding forces is closer to the maximum verified in the situation with a 3 cm of gap size.

Figure 7: Displacements and pounding forces time-history responses for the elastic case of the representative structural systems separated by a distance of 3 cm.

Figure 8: Displacements and pounding forces time-history responses for the inelastic case of the representative structural systems separated by a distance of 3 cm.

Attention should be drawn to the acceleration spikes, that in comparison with no pounding display huge percentages of increase. The sudden changes in the velocity response of the

buildings due to impacts cause these short-duration acceleration spikes in the opposite direction that can cause greater damage to the buildings' structures and contents. The graphs of Figures 14 to 17 show these acceleration spikes due to pounding between the building during the seismic hazard event.

Figure 9: Comparison of the displacements and pounding forces time-history responses for the elastic case of the left building for different gap sizes.

Figure 10: Comparison of the displacements and pounding forces time-history responses for the inelastic case of the left building for different gap sizes.

Observing the elastic case (Figure 5, 8, and 9) it can be seen that the mutual blocking of the buildings explains the peak displacement reductions in Table 2. It is known that pounding tends to reduce the inbound structural displacements due to building blocking. Conversely, it tends to increase the rebound displacements. This is evident in the flexible structure as can be seen in Figure 9, although the same cannot be verified in the stiffer building which experiences great reductions in the peak structural displacements (Table 2). In terms of peak velocities, the flexible structure tends to suffer increases (gap sizes of 10 cm and 5 cm), and the stiffer structure only experiences a slight decrease in the case of no separation distance. It should be stated that although there is a reduction in the peak responses when pounding is considered, this is not beneficial since great local damages at the regions of impact are implicitly known and damage in the structures due to structural inelastic behavior should be expected and aggravated due to pounding, as will be discussed in the next paragraphs.

The inelastic behavior of the structural systems has a significant influence on the structural overall dynamic behavior. As can be seen by comparing Figures 9 and 10, the inelastic case experiences fewer impacts and its intensity is also smaller. However, the presence of permanent deformations is inevitable and increases with decreasing gap size. In addition, the rebound displacements are also increased concerning the elastic case, particularly, in the flexible structure for the gap sizes of 0 cm and 3 cm since in the corresponding 5 cm of gap size a reduction is verified. In the case of the stiffer structure, permanent deformations are still expected although much smaller than in the flexible structure, increases were verified in the gap sizes of 3 cm and 5 cm and a decrease in the case with no gap.

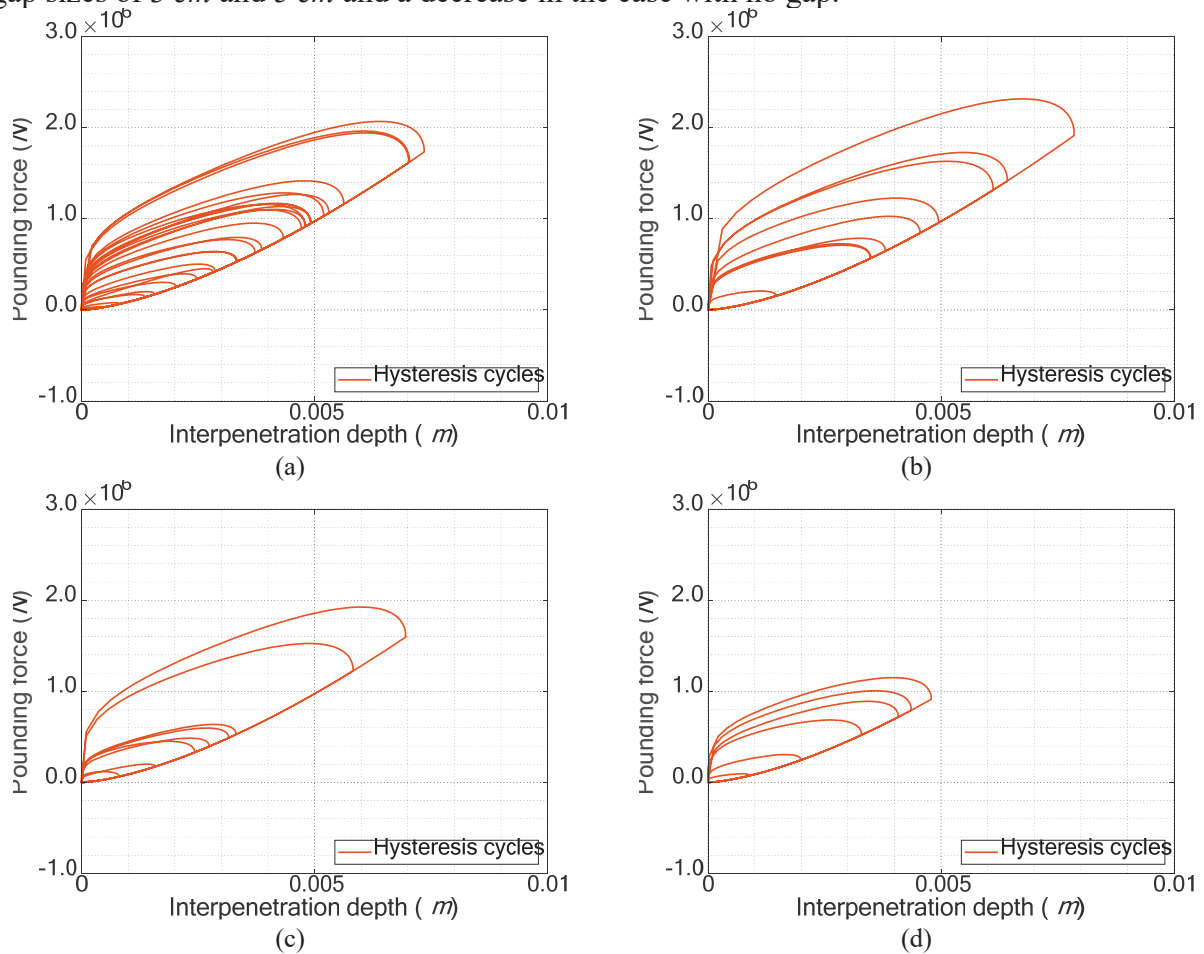

Figure 11: Pounding cycles for the elastic case of the structural systems: (a) 0 cm, (b) 3 cm; and for the inelastic case of the structural systems: (c) 0 cm, (d) 3 cm.

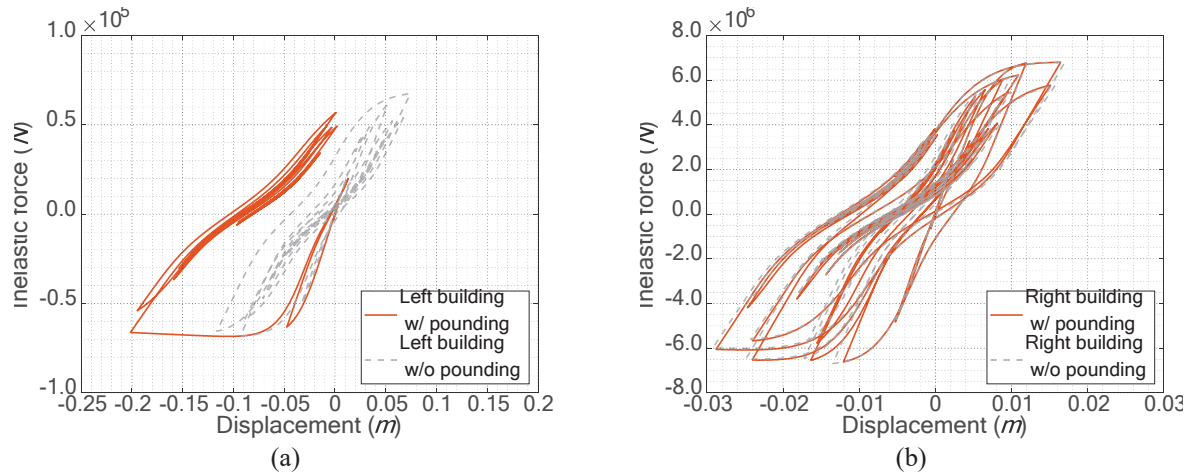

Figure 12: Hysteresis cycles when the structural systems have no gap in between: (a) Left and (b) Right building.

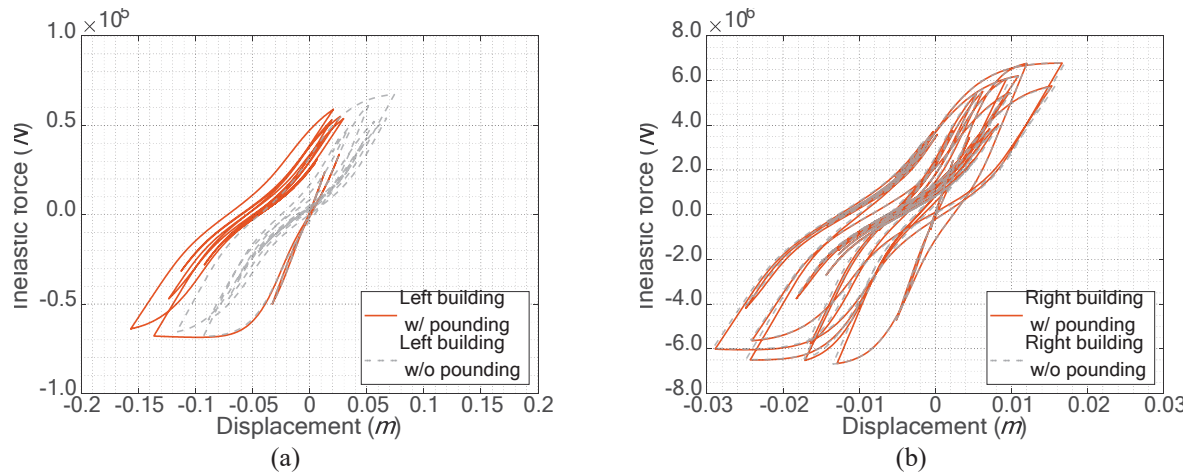

Figure 13: Hysteresis cycles when the structural systems are separated by a distance of 3 cm: (a) Left and (b) Right building.

Figure 14: Acceleration time-history responses for the elastic case of the structural systems with no space in between.

Figure 15: Acceleration time-history responses for the inelastic case of the structural systems with no space in between.

Figure 16: Acceleration time-history responses for the elastic case of the structural systems separated by a distance of 3 cm.

Figure 11 shows the pounding cycles that display the reduced number of cycles and the relatively small magnitude of impacts in the inelastic case. The influence of the gap size when inelastic behavior is considered can also be seen in the graphs of Figures 12 and 13 in which in the right building corresponding to the stiffer structure there is no clear difference between the responses with and without pounding. On the contrary, the flexible structure exhibits clear increases in the rebound displacements and hysteresis energy dissipation as well as the presence of permanent deformations which increase for smaller gap sizes.

Single-degree-of-freedom structural systems with elastic and inelastic behavior were considered in this study and the differences between these were addressed. Although it should be pointed out that further research is required to better investigate this complex behavior with

building pounding that should include more degrees of freedom, three-dimensional analysis including tangential/friction forces, different ground motion excitations, parametric and sensitivity analysis to understand the influence of intervenient input parameters on the output responses, presence of non-structural elements such as infill walls which are common in building structures, and the consideration of different pounding scenarios.

Figure 17: Acceleration time-history responses for the inelastic case of the structural systems separated by a distance of 3 cm.

6 CONCLUSIONS

The present study concerns earthquake-induced structural building pounding considering two SDOF systems with elastic and inelastic behavior. Building pounding can be simulated by the use of impact models which rely on the proper establishment of its parameters. Several analytical expressions were provided to calculate each of the parameters of the impact models which depend essentially on the impact stiffness, impact damping, and coefficient of restitution. The uncertainties regarding these parameters are intrinsically connected with the over-simplified assumptions considered as well as the unknown geometry and material properties of the contact region. Experimental data and parametric sensitivity studies may reduce the level of uncertainties and/or redirect the investigations for particular input parameters to obtain more reliable results.

One of the factors that may influence pounding-involved results is the consideration of the inelastic behavior of the colliding structures. Pounding forces caused permanent damage on the buildings in the rebound direction, especially in the flexible structure, increasing for smaller gap sizes. In addition, it was observed that the inelastic behavior should be considered since the most flexible structure presents higher increases of displacements when pounding is considered, and the acceleration spikes continue to have large peak values. The positive effect is the reduction of the number of impacts and their intensity compared with the elastic case. Hence, the neglect of the structural inelastic behavior may overestimate the magnitude of pounding forces and underestimate the displacement amplitude as well as neglect the permanent deformations that will certainly arise during earthquakes.

Further research is necessary since it is not possible to find a clear pattern or trend in the results concerning the input parameters and the desired output results using only SDOF systems with representative inelastic behavior under a specific ground motion. Future studies should address more degrees of freedom and possibly a three-dimensional spatial model (to account for forces in the tangential direction), calibration of the hysteresis model with experimental data, and the consideration of several different ground motions to validate the presented results as well and contribute with additional information on the matter of earthquake-induced structural building pounding.

Abstract

Earthquake-induced structural pounding between buildings is an insurgent field of investigation since in metropolitan areas it is very common to construct buildings very close to each other leaving small gap distances in between or even no space at all, increasing the likelihood of structural collisions in an earthquake event. These impacts can provoke substantial structural damage or global collapse of building structures. The overall dynamic behavior is thus greatly affected by this phenomenon and so importance should be given in the study of the respective consequences. The most practical and simple approach is to model buildings as SDOF lumped mass models considering elastic behavior. However, it has been verified previously that neglecting inelastic behavior in these situations can lead to significant overestimations of the magnitude and number of impacts between the adjacent structures and underestimations of the displacement responses, especially in flexible structures. In this sense, the influence of inelastic behavior in SDOF structural systems is carried out using a smooth hysteresis model, implemented in a Matlab-Simulink model, for different levels of hysteresis degradation phenomena under cyclic loading. This parametric study will enable a further understanding of the inelastic behavior of structures under pounding forces.

Keywords: Building structural pounding, Earthquake-induced pounding, Impact modeling, Inelastic behavior, Parametric study.

1 INTRODUCTION

Non-linear inelastic behavior and significant damage are usually observed in building structures when subjected to earthquake events.

Loss of human lives, total or partial destruction of built patrimony, and human activity are consequences that seismic design seeks to avoid and in the case of significant structural damage to limit it to permit for possible repair and/or substitution of damaged elements in the structures.

Seismic design of building structures can be performed using linear or non-linear, static or dynamic analysis. When inelastic behavior is considered it is usually assumed to be lumped at beam's ends, critical regions, commonly called plastic hinges that require an adequate structural detail to possess acceptable ductility, while other zones should be kept in the elastic range with overstrength, forming the strong links in the structural system, the case of columns and the middle span of beams. Nevertheless, the behavior of columns should be assessed since, in reality, these elements will suffer some inelastic deformation (due to redistribution of forces within the structure) that should be evaluated by analyzing its lateral restoring forces.

To reproduce this inelastic behavior, the common assumption is to consider for plastic hinges known constitutive behavior translated by a suitable hysteresis model capable of emulating different physical phenomena such as stiffness degradation, strength deterioration, and the pinching effect.

Hence, it is well known and expected that permanent damage will occur under moderate to severe earthquakes. One phenomenon that has been progressively studied over recent years is structural pounding between buildings that have very limited separation distance or no distance at all. Earthquake-induced structural pounding between buildings has revealed significant negative effects that may lead to the global collapse of the structural systems. Large ductility and energy dissipation demands are verified in buildings under earthquake-induced pounding.

To emulate structural building pounding several approaches have been developed and are present in the literature. The simplest approach is the consideration of impact models based on some simplifications and assumptions that capture the essence of the impacts, i.e., its magnitude. This phenomenon is extremely or virtually impossible to emulate with perfect accuracy, being associated with non-linear relationships between the contact area, stresses, and deformations; local inelastic deformations; propagation of stress waves in the involved structures; friction forces; vibrations resulting in thermal and acoustic effects; etc.

Due to these short-duration impulses, i.e., huge forces involving large masses in an incredibly short amount of time, it is known to cause inevitable local and global structural damage and thus, influencing the overall dynamic responses of the colliding buildings.

Thus, this paper intends to analyze how different kinds of hysteresis behaviors may influence the pounding-involved response of buildings under seismic events.

To achieve this the usual approach of assuming two single-degree-of-freedom (SDOF) lumped mass models with very different dynamic behavior is considered. These structural systems are connected by a zero-length element, an impact model.

A smooth hysteresis model is implemented to emulate the non-linear inelastic behavior of the structures.

The elastic case and the inelastic behavior with different levels/cases of hysteresis degradation phenomena under cyclic loading and structural pounding are then simulated using a developed Matlab-Simulink model. The results are then presented in terms of graphs and peak responses to enable a further understanding of the inelastic behavior of building structures under earthquake-induced pounding forces.

2 HYSTERESIS BEHAVIOR CASES

The relationship between the input and the output in the inelastic range is controlled by the rate-independent memory effect concept, that is, a hysteresis operator, that takes in an input function and returns an output function. This phenomenological concept is based on experimental data relating the input-output pair.

The response of structural systems depends always on the rate of the applied load when this needs to be considered viscosity is introduced along with the rate-independent restoring force. Hence, the usual dynamic equation of motion is modified, including the lateral restoring force (in this study) term, f_r^* , that depends on the displacements and velocities of the system, to become

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = -m\ddot{x}_g(t) \Leftrightarrow m\ddot{x}(t) + c\dot{x}(t) + ak_0x(t) + f_r^*(t) = -m\ddot{x}_g(t) \quad (1)$$

where m , k , and c are, respectively, the mass, the elastic stiffness and the viscous damping of the structure, $\ddot{x}_g(t)$ is the earthquake's acceleration, $x(t)$ is the structural displacement, \dot{x} is the structural velocity, and $\ddot{x}(t)$ is the structure's acceleration.

To account for the inelastic behavior several empirical hysteresis models were developed by many researchers and can be broadly categorized into polygonal and smooth hysteresis models. In the present study, a smooth hysteresis model is considered. This model was developed by Sivaselvan and Reinhorn [1] and is a subsequent modification of the original Bouc-Wen model ([2]-[4]).

A schematic representation of the abovementioned hysteresis model is presented in Figure 1 which is capable of simulating different behaviors of a structural system under cyclic loading, viz., strength hardening, the Bauschinger effect, stiffness degradation, strength deterioration, and the pinching effect.

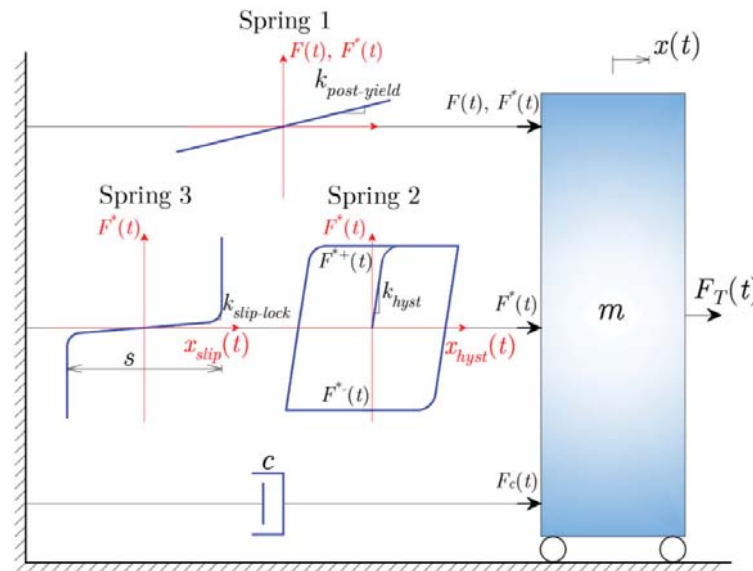

Figure 1: Sivaselvan and Reinhorn's smooth hysteresis model schematic representation.

The following subsections describe the model in [1] and present different hysteresis behavior cases that can be considered depending on the type of structural system and material used for simulation. Three springs define the model and the different hysteresis cases: a post-yield spring (Spring 1), a hysteresis spring (Spring 2), and a slip-lock spring (Spring 3) as can be observed in Figure 1.

2.1 Plain hysteresis

Plain hysteresis behavior is characterized by a case of hysteresis that can account for strength hardening and possess no degradation features. In the present investigation, this will be denominated by Case 0 of hysteresis behavior. This behavior is suitable for well-detailed steel structures, e.g., special moment resisting frames (SMRFs) [5].

Upon the application of a load, the springs 1 and 2 in parallel undergo the same deformation, although they share this force in proportion to their instantaneous stiffness,

$$k = k_{post-yield} + k_{hyst} \quad (2)$$

in which the post-yielding stiffness, $k_{post-yield}$, is represented by a linear elastic spring (Spring 1), and the hysteresis spring, k_{hyst} , is represented by a pure elasto-plastic spring with a smooth transition from the elastic to the inelastic range (Spring 2).

The previous stiffnesses terms, the elastic stiffness, and the non-degrading hysteresis stiffness are given, respectively, by the following expressions

$$k_{post-yield} = ak_0 \quad (3)$$

$$k_{hyst} = (1-a)k_0 \left\{ 1 - \left| \frac{F^*}{F_Y^*} \right|^{n_W} \left[\eta_1 \operatorname{sgn}(F^* dx) + \eta_2 \right] \right\} \quad (4)$$

in which a is the post to pre-yielding stiffness ratio, n_W controls the smoothness of the transition from elastic to plastic stages, η_1 and η_2 are parameters that control the shape of the unloading curve, F^* and F_Y^* are the portion of the applied force shared by the hysteresis spring and its respective yield value.

2.2 Stiffness degradation

Stiffness degradation is considered by the introduction of an additional parameter, R_K , a positive parameter with the unity as its possible maximum value. This factor is given by the following expression

$$R_K = \frac{F^* + \alpha F_Y^*}{k_0 x + \alpha F_Y^*} \quad (5)$$

The stiffness degradation is implemented in the Matlab-Simulink model through the so-called pivot rule [6]. This degradation phenomenon is observed in several structural elements and systems under cyclic loading and occurs due to non-linear geometric effects [7] and the elastic stiffness degrades with increasing ductility [1]. The degree of stiffness decay depends on the characteristics of the structure, e.g., material properties, geometry, ductility capacity, and connection type; and on the loading history, e.g., the intensity in each cycle, number of cycles, and sequence of loading cycles [8].

In the case of reinforced concrete (RC) components under severe cyclic loading, this degradation can be the result of cracking, loss of bond, or interaction with high shear or axial stresses [8]. Reduced stiffness in steel elements can be attributed to the Bauschinger effect [9] and is caused by accumulated damage or fatigue.

This type of hysteresis behavior in this study will be designated as Case 1. Hence, the hysteresis stiffness in Equation 4 is modified by including parameter R_K in Equation 5 which depends on parameter α (measuring the degree of stiffness degradation), as follows

$$k_{hyst} = (R_K - a) k_0 \left\{ 1 - \left| \frac{F^*}{F_Y} \right|^{n_w} \left[\eta_1 \operatorname{sgn}(F^* dx) + \eta_2 \right] \right\} \quad (6)$$

2.3 Strength deterioration

Two main types of strength deterioration can be identified: cyclic strength degradation and in-cycle strength degradation [8]. Cyclic strength degradation refers to the loss of strength and stiffness in subsequent cycles. As for the in-cyclic strength, degradation is characterized by a reduction of strength during the current cycle, leading to a negative stiffness. This type of behavior occurs when a structural component subjected to increasing deformation reaches the capacity boundary. Since a cyclic load-path cannot pass through this limit, the response continues along the boundary until unloading occurs, producing the in-cycle strength degradation.

According to FEMA's report [8], cyclic reduction of lateral strength is based on the increasing inelastic displacement and ultimately on the peak displacement, and on the total hysteresis energy demands of the system translated by the area enclosed by the hysteresis cycles. On the other hand, in-cycle strength degradation along with stiffness degradation may occur due to geometric (P-delta effects) and/or material non-linearities. Material nonlinearities that may cause in-cycle strength degradation include concrete crushing, shear failure, buckling or fracture of longitudinal reinforcement, and splice failures for RC components; and for steel components include buckling of bracing elements, local buckling in flanges of columns or beams, and fracture of bolts, or welds. The first type of deterioration usually specifies this decay in terms of the ductility ratio, and the second is the result of a single level of inelastic displacement imposed many times (along with the cycles), reducing the lateral strength level as the number of cycles increases.

The authors [1] considered in the current model a deterioration rule that reduces the capacity of the backbone curve. This rule of deterioration is based on a continuous energy-based degradation, and on a backbone degradation which occurs when the maximum deformation value attained in the past is exceeded and is given by the following expression

$$F_Y^{+/-} = F_{Y0}^{+/-} \left[1 - \left(\frac{x_{\max}^{+/-}}{x_{\text{ult}}^{+/-}} \right)^{\frac{1}{\beta_1}} \right] \left[1 - \frac{\beta_2}{1 - \beta_2} \frac{E_h}{E_{h\text{ult}}} \right] \quad (7)$$

where $F_Y^{+/-}$ is the positive or negative yield force, $F_{Y0}^{+/-}$ is the initial positive or negative yield force, $x_{\max}^{+/-}$ is the maximum positive or negative displacement, $x_{\text{ult}}^{+/-}$ is the ultimate positive or negative displacement, E_h is the hysteresis energy dissipated, $E_{h\text{ult}}$ is the hysteresis energy dissipated when loaded monotonically until the ultimate displacement without any degradation, β_1 is a parameter based on ductility demands, and β_2 is a parameter based on energy demands. The second term on the right side of Equation 7 is related to strength deterioration based on increased deformation and the last term is related to the hysteresis energy dissipated.

Stiffness and strength degradation will be considered together as Case 2 of hysteresis behavior for the present investigation.

2.4 Pinching effect

The pinching effect is another phenomenon observed in structural components and connections subjected to cyclic lateral load. The name pinching arises from the effect that has on the hysteresis loops. Pinched or compressed hysteresis cycles are obtained by great reductions in stiffness during reloading and stiffness recovery when the opposite displacement is imposed.

This phenomenon is mostly observed in brittle materials, viz., RC elements, timber components, and some types of masonry components. Some connections in steel structures also exhibit this kind of effect. In RC elements, pinching is the consequence of cracks that open when the element deforms in a certain direction. On load reversal, the deformation in the opposite direction closes the cracks and the stiffness is partially recovered. In timber structures, the main cause of pinching is the opening and closing of gaps in bordering elements due to nail pullout. Reinforced masonry also experiences pinching due to the opening and closing of flexural cracks, gaps between the masonry infill and the bordering structural frame, and between plates in steel-end connections [8]. In addition, the degree of pinching essential depends on the material properties, geometry, ductility, and connections of the structure, as well as the loading history, in terms of the intensity and sequence of the loading cycles.

An additional spring (Spring 3) is thus implemented in the hysteresis model to simulate pinching behavior [1]. A “slip-lock” spring is added in series to the hysteresis spring as illustrated in Figure 1. The combined stiffness now becomes

$$k = k_{post-yield} + \frac{k_{hyst} k_{slip-lock}}{k_{hyst} + k_{slip-lock}} \quad \text{where} \quad k_{slip-lock} = \left\{ \sqrt{\frac{2}{\pi}} \frac{s}{F_{\sigma}^*} \exp \left[-\frac{1}{2} \left(\frac{F^* - F_m^*}{F_{\sigma}^*} \right)^2 \right] \right\}^{-1} \quad (8)$$

in which s is the slip length, F_{σ}^* is a measure of the force range over which slip occurs, and F_m^* is the mean force level on either side about which slip occurs, being these three parameters given, respectively, as follows

$$s = R_s (x_{\max}^+ - x_{\max}^-) \quad (9)$$

$$F_{\sigma}^* = \sigma F_Y^* \quad (10)$$

$$F_m^* = \lambda_s F_Y^* \quad (11)$$

where parameters R_s , σ_s , and λ_s are parameters that control each of the resulting values of the previous three equations.

Proper calibration of these hysteresis parameters presented in the present section (in Equations 2-11) can model different hysteresis behaviors depending on material properties and structural systems.

This hysteretic model will be further implemented in this investigation to assess the inelastic behavior of the structures under the earthquake-induced pounding.

Stiffness and strength degradation with the pinching effect will be denoted as Case 3 of hysteresis behavior in the following sections.

3 STRUCTURAL POUNDING MODELING

Structural pounding involves complex phenomena making the problem of earthquake-induced structural building pounding extremely difficult to model with high accuracy. However, in structural pounding, the estimation of the magnitude of pounding forces with satisfactory accuracy is enough to verify its influence on the overall dynamic response of the colliding structures.

Two possible ways of earthquake-induced structural pounding modeling are available in the literature: the classical theory of impact and the use of impact or contact elements [10].

The classical theory of impact fails to describe transient stresses and to account for local deformations at the contact point of the bodies assuming that a negligibly part of the initial kinetic energy of the system is transformed into vibrations of the colliding bodies [11]. Addi-

tionally, it does not consider the existence of the period of impact failing to directly assess the evolution of the pounding forces during collision [12].

The coefficient of restitution (CR) is a parameter derived in the first approach of pounding modeling. This parameter depends on the relative final ($\dot{x}_{2,f} - \dot{x}_{1,f}$) and initial ($\dot{x}_{2,0} - \dot{x}_{1,0}$) impact velocities and represents the energy losses and degree of plasticity of the impact being directly related with the kinetic energy loss during impact. CR is given by the following expression

$$CR = \frac{\dot{x}_{2,f} - \dot{x}_{1,f}}{\dot{x}_{1,0} - \dot{x}_{2,0}} \quad (12)$$

Impact models constitute the second approach to model building pounding, largely used in many investigations to assess the detrimental effects of impacts in building structures. From the consideration of two periods of impact, approach and restitution periods, to the penalty method and establishment of parameters such as impact stiffness and impact damping ratio, the impact models have been widely used providing relative satisfactory accuracy in replicating the pounding forces arising from the contact of buildings during earthquake events. Although, the formulation of these elements is based on Hertz's theory and oversimplified assumptions making the problem simpler yet less accurate.

Among these simplifications, one can mention [13]: the stress wave propagation is neglected and the state of stress in the structures at any instant can be considered approximately uniform. This ignores the dynamic effects in the structures due to wave propagation, assuming that structural pounding between buildings can be approximately quasi-static if the duration of the impact is long enough to allow stress waves to transverse the length of the body many times, justifying in this way the use of spring-dashpot elements; the contact area is in general elliptical and is assumed to be small in comparison with the principal dimensions of the bodies; deformations are restricted to the vicinity of the impact; contact surfaces are non-conforming, smooth, continuous and frictionless; and the contact regions are assumed to remain elastic and unaltered after impact events.

In these compression-only impact models with zero-length, the spring will control the restoring force and deformation, and the dashpot will account for the energy radiated due to impact by wave motion. Hence, these two elements in the model represent the impact stiffness (k_{imp}) which depends on material properties and the contact geometry, and the impact damping ratio (ξ_{imp}) that depends mostly on the CR being derived from energy considerations.

Different impact models have been developed. The simplest model is the consideration of a spring, hence possessing only the elastic part of the impact correspondent to the impact spring and lacking the ability to account for energy dissipation during a collision. Similarly, the non-linear elastic model following Hertz's contact law [14], describes the static compression between two isotropic elastic bodies and is also limited by the lack of energy dissipation during impact. The spring non-linearity is capable of modeling the force-deformation relation more realistically. The impact force increases with the interpenetration depth to the power of 1.5

$$f_p(t) = \begin{cases} \beta_{imp} [\delta(t)]^{\frac{3}{2}} & \text{for } \delta(t) > 0 \\ 0 & \text{for } \delta(t) \leq 0 \end{cases} \quad (13)$$

in which β_{imp} is a parameter indicating the non-linear impact stiffness depending on material properties and geometry of the colliding structures.

The two impact models mentioned in the previous paragraph were the target of many modifications through the years, mostly to correct its drawbacks and increase the accuracy in modeling pounding forces.

A central modification to the linear elastic model was carried out giving rise to the linear viscoelastic or Kelvin-Voigt impact model [15], having now the ability to account for the loss of energy during impact. Pounding forces are thus computed using the following expressions

$$f_p(t) = \begin{cases} k_{imp} \delta(t) + c_{imp} \dot{\delta}(t), & \text{for } \delta(t) > 0 \\ 0 & \text{for } \delta(t) \leq 0 \end{cases} \quad (14)$$

where c_{imp} is the damping constant of the pounding contact element computed by the following expression ([16], [17])

$$c_{imp} = 2 \xi_{imp} \sqrt{k_{imp} \frac{m_1 m_2}{m_1 + m_2}} \quad \text{where} \quad \xi_{imp} = \frac{-\ln(CR)}{\sqrt{\pi^2 + [\ln(CR)]^2}} \quad (15)$$

However, this modification revealed a tensile force at the end of the impact period due to the uniform dissipation of energy on both periods of impact, which in reality does not happen ([10], [11]). This model further suffered different modifications to address this drawback. Komodromos et al. [18] modified the linear viscoelastic model by eliminating the negative force making it zero. Valles and Reinhorn [19], modified the Kelvin-Voigt model by assuming that the damping term is activated only for positive velocities during impact, which means only activated during the approach period. Mahmoud [20] addressed the drawbacks of the linear viscoelastic impact model with the same line of reasoning in [19] but redefining the expression of the impact damping ratio through energy considerations. Ye et al. [21] and Pant et al. ([22], [23]) proposed different modifications providing a different expression for the impact damping ratio. Following the research in [20], Mahmoud and Jankowski [24] suggested a further modification to the linear viscoelastic model using a different approach to arrive at an improved formula for the impact damping ratio.

Hertz's model (Equation 13) was modified by Lankarani and Nikraves ([25], [26]), to address the matter of the lack of energy dissipation properties by including in parallel with the non-linear spring a non-linear damping proposed by Hunt and Crossley [27] to better represent impacts between mechanical systems. Similar to the previous modifications, this model now becomes a non-linear viscoelastic impact model. Muthukumar and DesRoches ([28], [29]) considered the previous model applied to civil engineering structures being designated by the "Hertzdamp" impact model. An important modification to the Hertzdamp model was carried out by Jankowski [30] suggesting that the non-linear damping component becomes active only in the approach period where most energy is dissipated. Figure 2 presents a representation of Jankowski's non-linear viscoelastic model.

Figure 2: Schematic representation of Jankowski's non-linear viscoelastic model.

The pounding force can thus be calculated using the following system of equations [30]

$$f_P(t) = \begin{cases} \beta_{imp} [\delta(t)]^{\frac{3}{2}} + c_H(t) \dot{\delta}(t) & \text{for } \delta(t) > 0 \text{ and } \dot{\delta}(t) > 0 \\ \beta_{imp} [\delta(t)]^{\frac{3}{2}} & \text{for } \delta(t) > 0 \text{ and } \dot{\delta}(t) \leq 0 \\ 0 & \text{for } \delta(t) \leq 0 \end{cases} \quad (16)$$

where the damping coefficient is determined as follows

$$c_H(t) = 2\xi_{imp} \sqrt{k_{imp} \frac{m_1 m_2}{m_1 + m_2}} \quad \text{where } k_{imp} = \beta_{imp} \sqrt{\delta(t)} \quad (17)$$

and the impact damping ratio, which had to be redefined was approached by using two different approximating functions in the process, leading to two expressions from which one was found more accurate and is thus shown below [31]

$$\xi_{imp} = \frac{9\sqrt{5}}{2} \frac{1 - CR^2}{CR[CR(9\pi - 16) + 16]} \quad (18)$$

Further modifications were carried out to the Hertz damp impact model. Ye et al. [32] based on the resulting relationship between the CR and the impact damping ratio developed a new and more rational expression for the damping ratio.

More recent modifications to the core impact models presented in previous paragraphs were carried out, mostly modifications to the relation between the impact damping ratio and the CR, e.g., Naderpour et al. ([33], [34]) and Khatami et al. [35].

A different modification was carried out by Bamer et al. ([36]-[38]) to include damage provoked by repetitive impacts which are known to happen in inelastic impacts translated implicitly by parameter CR. This was made by the inclusion of a dry friction element in series with the non-linear spring from the Hertz damp model or the Jankowski's non-linear viscoelastic model (respectively, [36] and [37]).

Hence, most of the investigations concerning the development of impact models are based on the correct establishment or calibration of the impact stiffness and impact damping ratio. These parameters along with the coefficient of restitution, are the core of the impact models and their accuracy depends on how accurate is the estimation of these parameters. Unfortunately, these parameters are also subjected to great sources of uncertainties, viz., the geometry of the region of impact, material properties, impact velocities, stiffness and mass properties of the involved buildings, etc. These uncertainties may be addressed by performing validation experimental tests and performing parametric sensitivity analysis, which allows for additional information reducing the epistemic error in the models and understanding which parameters are important and relevant to consider and the ones that have no or little influence in the model. Some experimental tests regarding impacts and the calibration of the abovementioned parameters have been carried out ([39]-[43]).

It should be referred that the previous models mostly addressed central impact, i.e., impacts in one direction and a predefined location and geometry of impact. In reality, buildings will have correlated translational and rotational responses which makes the location and geometry of impacts unknown being a more complex model to study. In addition, the neglect of tangential forces and friction constitutes one of the assumptions of the previous models that may have a substantial effect on the overall dynamic response of building structures under earthquake-induced pounding. The work of Polycarpou et al. [44] addressed these situations by using a rational three-dimensional spatial model supported by previous considerations of impact models and by classical theory of contact mechanics considerations.

4 NUMERICAL MODELING PROCEDURE

The numerical models consist of two SDOF systems that can have elastic or inelastic behavior. The inelastic behavior will be considered by four representative cases of frame behavior. The two SDOF systems will represent two buildings with very different dynamic properties and are assumed as lumped mass models as sketched in Figure 3.

Figure 3: Representation of the two SDOF lumped mass models separated by a certain distance.

Table 1 presents the considered dynamic properties of each SDOF structural system according to [10].

Structural properties	Flexible building	Stiffer building
Mass (kg)	$m_L=75000$	$m_R=3000 \times 10^3$
Stiffness (kN/m)	$k_L=2056$	$k_R=1.316 \times 10^6$
Natural period (s)	$T_L=1.2$	$T_R=0.3$
Damping coefficient (kg/s)	$c_L=39270$	$c_R=6.283 \times 10^6$
Damping ratio (%)	$\xi_L=5$	$\xi_R=5$

Table 1: Structural properties of the adjacent buildings.

Equation 1 is modified to include the pounding force according to Equations 16 to 18, becoming now, respectively, for the elastic and inelastic case as follows

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) + f_p(t) = -m\ddot{x}_g(t) \quad (19)$$

$$m\ddot{x}(t) + c\dot{x}(t) + ak_0x(t) + f_r^*[x(t), \dot{x}(t)] + f_p(t) = -m\ddot{x}_g(t), \quad (20)$$

These structural systems will be subjected to a seismic ground motion, the El Centro's earthquake, whose acceleration signal is presented in Figure 4.

Figure 4: NS component of El Centro seismic accelerations - Station: El Centro, CA - Sta9; Imperial Valley-02 [45].

Equation 19 or 20 is used to emulate, respectively, the elastic and inelastic behavior of the considered structural systems. The hysteresis cases presented in section 2 will be considered. Table 2 presents the values considered to account for each case of hysteresis behavior. These values were based on the considerations given in [5].

Case	Hysteresis behavior	α	β_1	β_2	σ_s	R_s	λ_s
0	Plain	50	0	0	1	0	0
1	Stiffness degradation	1	0	0	1	0	0
2	Stiffness and strength degradation	1	0.3	0.3	1	0	0
3	Stiffness and strength degradation with pinching effect	1	0.3	0.3	0.2	0.1	0

Table 2: Non-linear hysteresis parameters for the structural system for different hysteresis behavior cases (in all cases: $\eta_1 = \eta_2 = 0.5$, $n_W = 5$, $a = 0.03$, $F_{YL} = 70 \text{ kN}$, $x_{YL} = 3.4 \text{ cm}$, $F_{YR} = 7000 \text{ kN}$, $x_{YR} = 0.53 \text{ cm}$, $\mu = 10$).

The pounding will be considered between the buildings' slabs and as implicitly mentioned the impact model will be the non-linear viscoelastic model developed by Jankowski ([30], [31]). The impact stiffness and the coefficient of restitution are, respectively, $2.75 \times 10^9 \text{ N/m}^{3/2}$ and 0.65 [30].

A Matlab/Simulink [46] model was developed to simulate structural pounding between the elastic and inelastic SDOF systems subjected to the El Centro Earthquake. The Simulink model is represented in Figure 5 and contemplates the case of structural pounding between SDOF systems. The gap between the adjacent structures was varied: 0 cm, 3 cm, 5 cm, 10 cm, and 15 cm. To solve the differential equations of motion the Runge-Kutta of 4th order was used with a fixed time step of $5 \times 10^{-4} \text{ s}$.

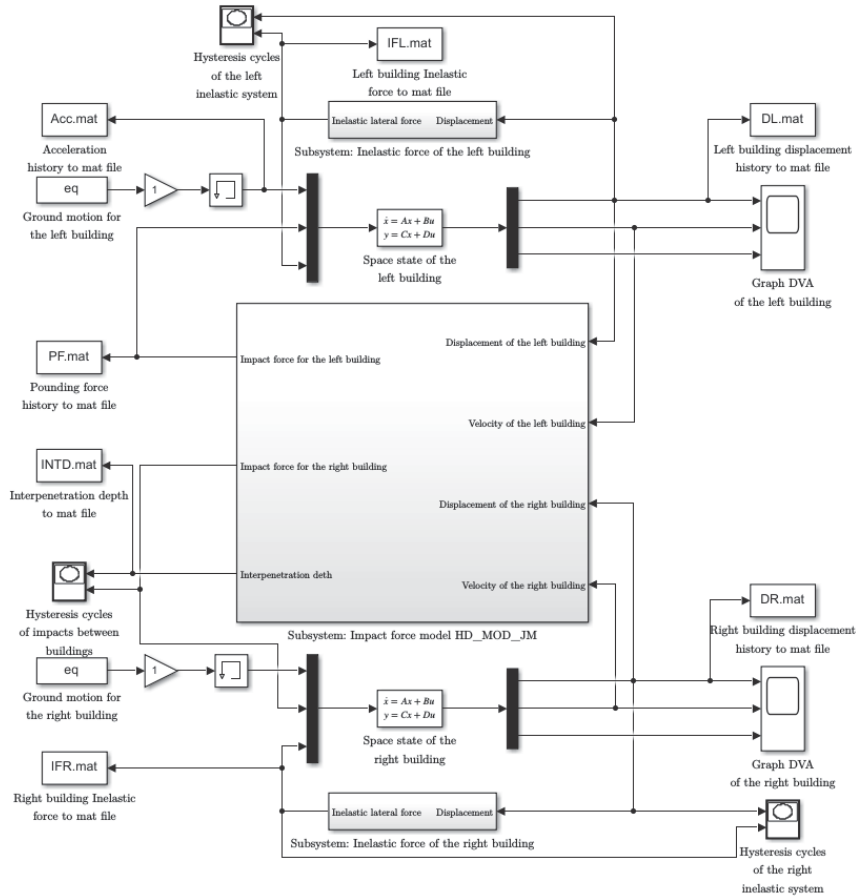

Figure 5: Layout of the macro Matlab/Simulink model using the non-linear viscoelastic impact model modified by Jankowski for pounding between non-linear systems.

5 RESULTS AND DISCUSSION

For convenience, only the results concerning the gap size between the adjacent buildings of 0 cm and 3 cm are presented in graphical form, except for the hysteresis cycles for the four hysteresis cases in which only the worst case was presented, for the case of no gap distance. The graphs of the acceleration time-histories are presented only for case 3 of hysteresis behavior compared with the elastic case for both the gaps of 0 cm and 3 cm. Nonetheless, Table 3 shows the peak values regarding displacements, velocities, accelerations, and pounding forces for each building and for the hysteresis cases considered and every value for the gap size studied. In addition, the number of impacts associated with each case is also presented. The percentages of increase or decrease depending on the cases being compared are shown below the peak values for better comparisons and understanding of the influence of the inelastic behavior in earthquake-induced pounding between buildings.

Attention is drawn to the fact that the gap size of 10 cm when the structural system has inelastic behavior does not appear in Table 3 since it didn't produce any impact and thus the responses are exactly the same as for the gap size of 15 cm.

Figures 6 to 10 present the graphic results regarding the displacement time-histories of the two colliding structures with no space in between and the corresponding resulting pounding forces for the elastic case and the different hysteresis cases considered. In the same way Figures 11 to 15 present the same graphs mentioned but for the gap size of 3 cm.

The graphs of Figures 16 to 20 present relevant comparisons between the displacements and pounding forces histories of the left structure, the most sensible to impacts and the ground motion for the different hysteresis behaviors considered and the elastic case.

The pounding cycles in Figure 21 are presented for both the elastic case and the different hysteresis cases considered.

Figure 22 shows the hysteresis cycles of each colliding building in comparison with the case of no pounding.

Finally, Figure 23 presents the acceleration response histories of both buildings for case 3 of hysteresis compared with the elastic case.

Figure 6: Displacements and pounding forces time-history responses for the elastic case of the representative structural systems with no gap in between.

Figure 7: Displacements and pounding forces time-history responses for the hysteresis case 0 of the representative structural systems with no gap in between.

Figure 8: Displacements and pounding forces time-history responses for the hysteresis case 1 of the representative structural systems with no gap in between.

As expected, it is possible to verify the sensitiveness of the flexible building to both pounding forces and the ground motion. It is clear by the analysis of the results in Figures 6 to 15 that the inelastic cases present fewer impacts and the magnitude of the forces is smaller. However, the amplitude of the inelastic displacements, generally, exceeds the displacements in the elastic case, as can be validated by the peak values presented in Table 3. This is particularly true when the responses involve pounding and for hysteresis cases with degradation fea-

tures. When pinching is considered is possible to verify the largest inelastic displacements and magnitude of the pounding forces.

Analyzing the graphs from Figures 16 to 20 regarding the flexible building, one can verify that the case with no gap presents larger displacements and impact forces, as well as an increased number of impacts.

In the graphs of Figures 7 to 10 and 12 to 20, it is possible to verify the permanent displacements in the rebound direction caused by the action of the ground excitation and aggravated by the impact forces.

Figure 9: Displacements and pounding forces time-history responses for the hysteresis case 2 of the representative structural systems with no gap in between.

Figure 10: Displacements and pounding forces time-history responses for the hysteresis case 3 of the representative structural systems with no gap in between.

Figure 11: Displacements and pounding forces time-history responses for the elastic case of the representative structural systems separated by a distance of 3 cm.

Figure 12: Displacements and pounding forces time-history responses for the hysteresis case 0 of the representative structural systems separated by a distance of 3 cm.

These permanent displacements are most visible in the flexible structure which proves once more the sensitiveness of the flexible building to pounding forces.

The residual displacements increase as the gap between the adjacent structures decreases, and since the number of impacts and its magnitude increases for these scenarios then it proves and supports the influence that the pounding forces have when inelastic behavior is considered. Such a fact would not be noticed when elastic behavior is considered.

Figure 13: Displacements and pounding forces time-history responses for the hysteresis case 1 of the representative structural systems separated by a distance of 3 cm.

Figure 14: Displacements and pounding forces time-history responses for the hysteresis case 2 of the representative structural systems separated by a distance of 3 cm.

It is not clear for which case of hysteresis behavior the unrecoverable displacements are bigger since it also depends on the separation distance between the adjacent buildings. Nevertheless, these tend to be slightly bigger in case 2 of hysteresis behavior, when stiffness and strength degradation are considered.

Observing the graphs of Figure 21 regarding the pounding cycles, it is evident the difference between the magnitude of impacts when elastic and inelastic cases are considered. The number of cycles for the elastic case is also bigger for the inelastic cases. The number of im-

pacts is smaller for the hysteresis case 0 and bigger for the cases where stiffness degradation, strength deterioration, and the pinching effect are considered. In addition, the increase in the gap size decreased the magnitude of impacts as already mentioned by the observation of other graphs. Hence, with a few exceptions within the inelastic cases, case 3 presented slightly higher magnitudes for the impact forces.

The hysteresis loops for the different cases considered and for the scenario of no gap confirm the conclusions withdrawn previously, viz., the presence of permanent deformations in the rebound direction in the left building.

Figure 15: Displacements and pounding forces time-history responses for the hysteresis case 3 of the representative structural systems separated by a distance of 3 cm.

Figure 16: Comparison of the displacements and pounding forces time-history responses for the elastic case of the left building for different gap sizes.

Figure 17: Comparison of the displacements and pounding forces time-history responses for the hysteresis case 0 of the left building for different gap sizes.

Figure 18: Comparison of the displacements and pounding forces time-history responses for the hysteresis case 1 of the left building for different gap sizes.

The hysteresis cycles also reveal that pounding has very little or no effect on the right structure. The hysteresis loops when pounding is considered are almost coincident showing very little deviation from the case with no pounding.

Table 3 also shows that the stiffer structure with inelastic behavior generally presents percentages of increase or decrease of the peak displacement with respect to the case with no pounding, which are approximately zero concerning the hysteresis cases and the gap sizes presenting impacts, viz., 3 cm and 5 cm. The exception is the scenario without space in be-

tween the structures that present an increase of the peak displacement in every hysteresis case. This increase corresponds to the case presented in Figure 22.

Table 3 also shows that in the elastic case the stiffer structure exhibits a reduction of the peak displacements for every gap size when pounding is considered.

Regarding the acceleration responses in Figures 23 and 24, it is possible to verify the reduction of the number and magnitude of the acceleration spikes of both the left and right structures when the inelastic behavior (Case 3 of hysteresis behavior) is considered with respect to the elastic case.

Figure 19: Comparison of the displacements and pounding forces time-history responses for the hysteresis case 2 of the left building for different gap sizes.

Figure 20: Comparison of the displacements and pounding forces time-history responses for the hysteresis case 3 of the left building for different gap sizes.

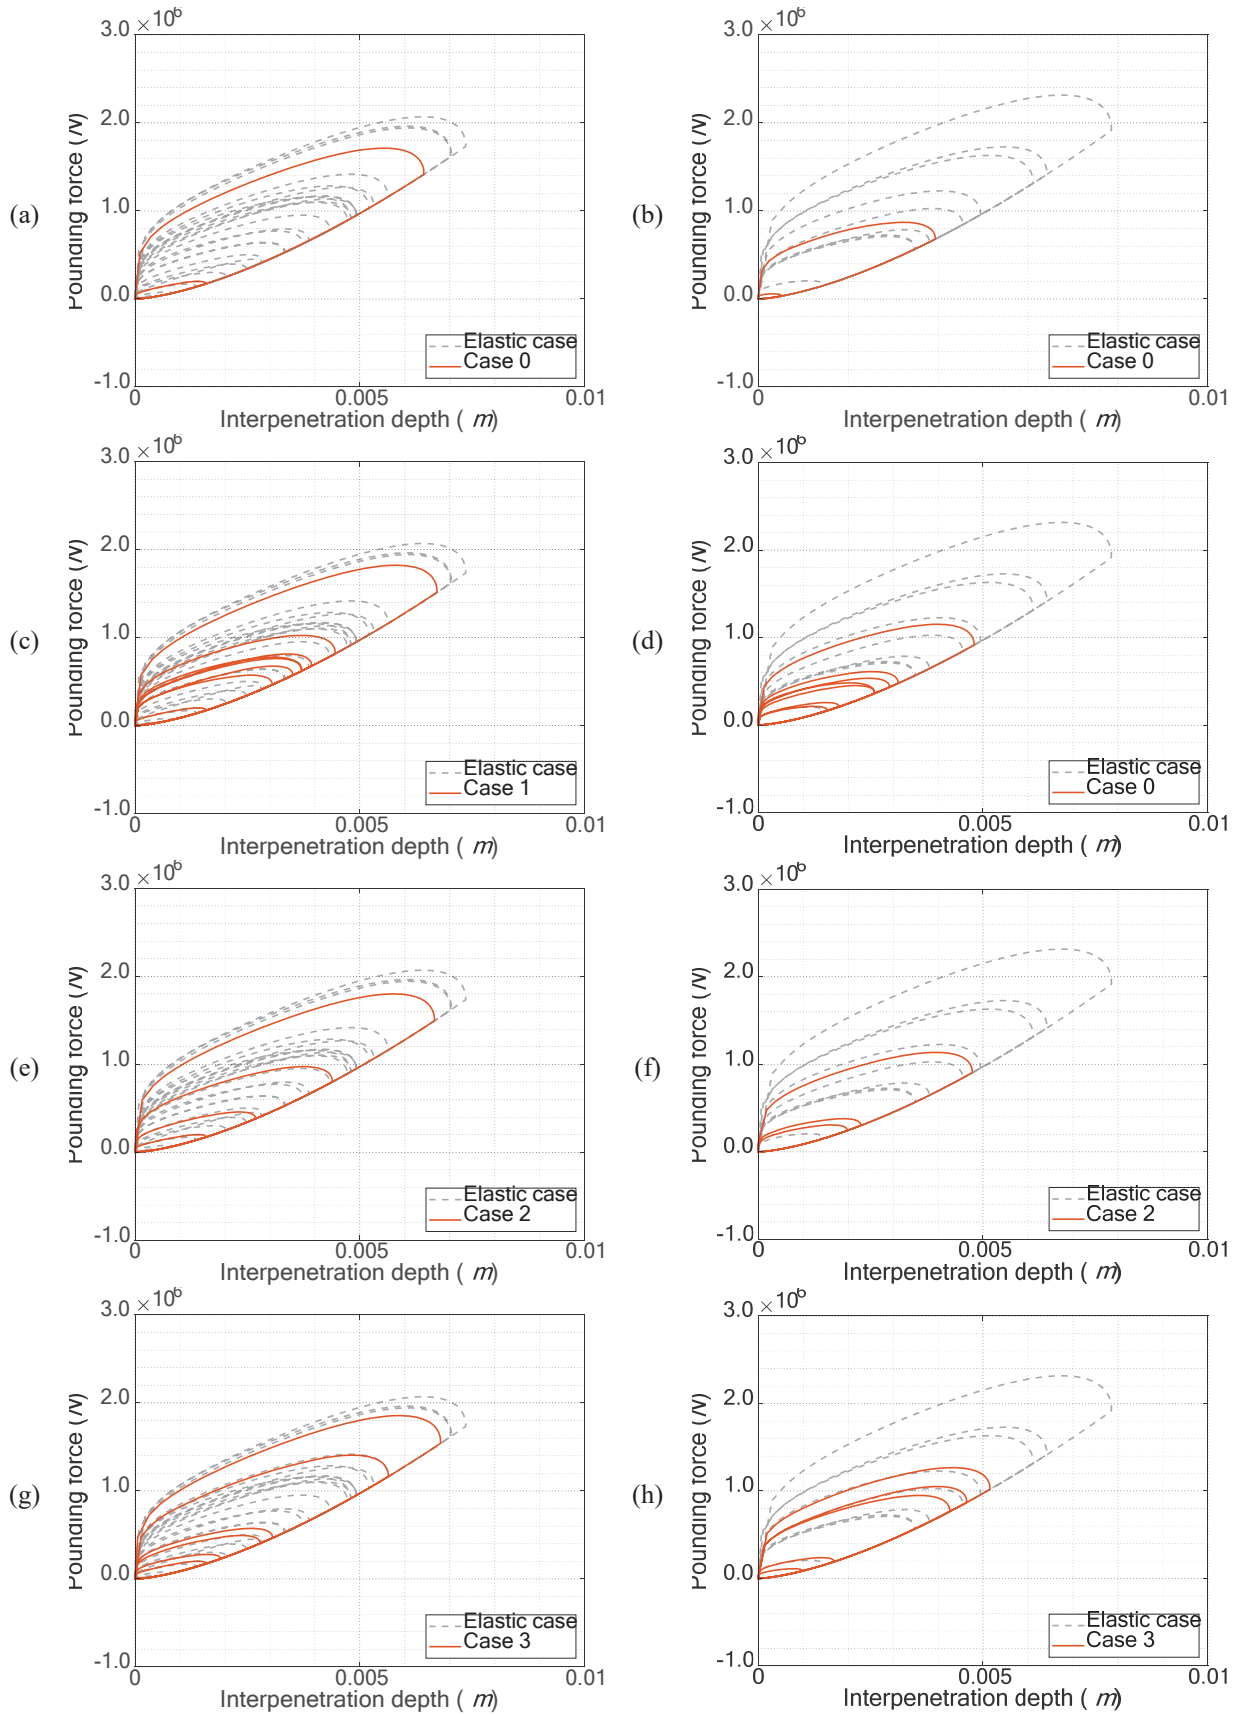

Figure 21: Pounding cycles for the hysteresis cases of the frame structures compared to the elastic case: (a), (c), (e), and (g) 0 cm; (b), (d), (f) and (h) 3 cm.

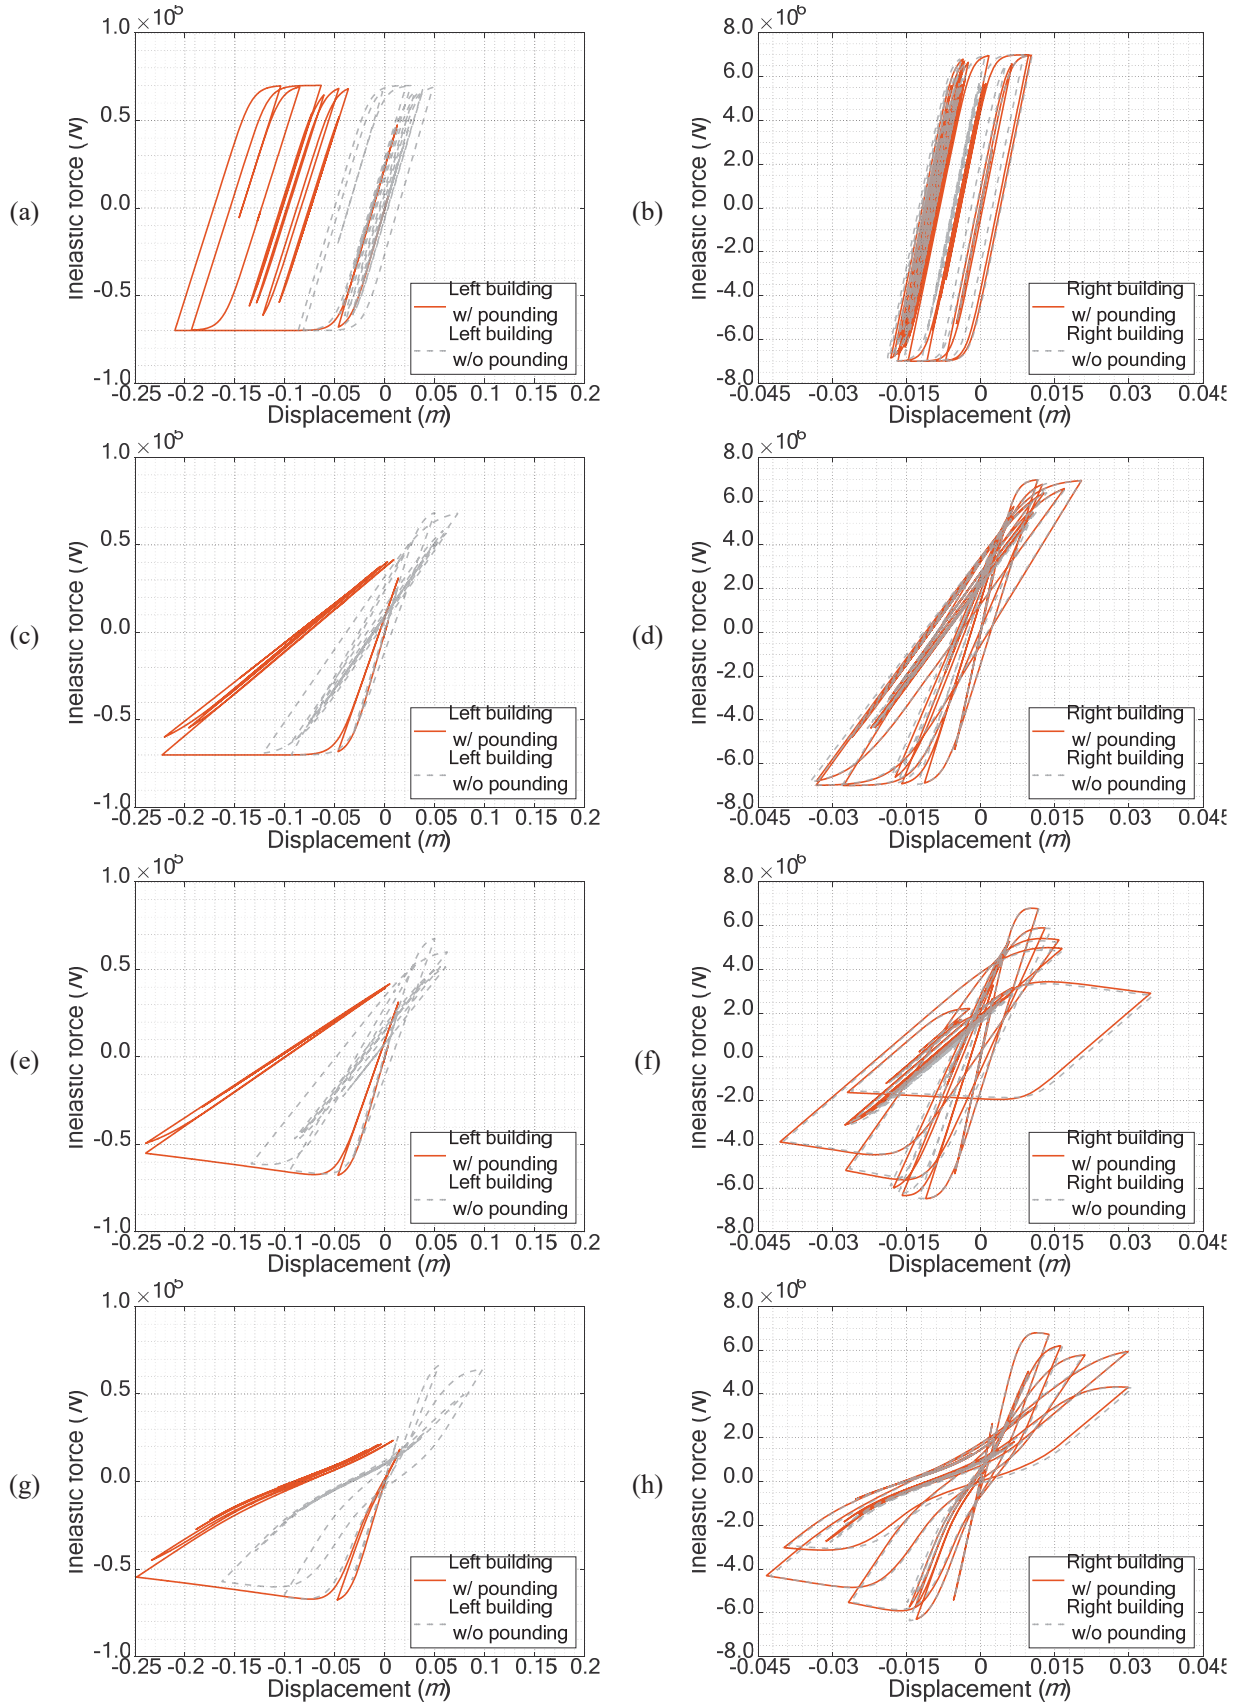

Figure 22: Hysteresis cycles when the structural systems have no gap in between: (a) and (b) Case 0; (c) and (d) Case 1; (e) and (f) Case 2; (g) and (h) Case 3.

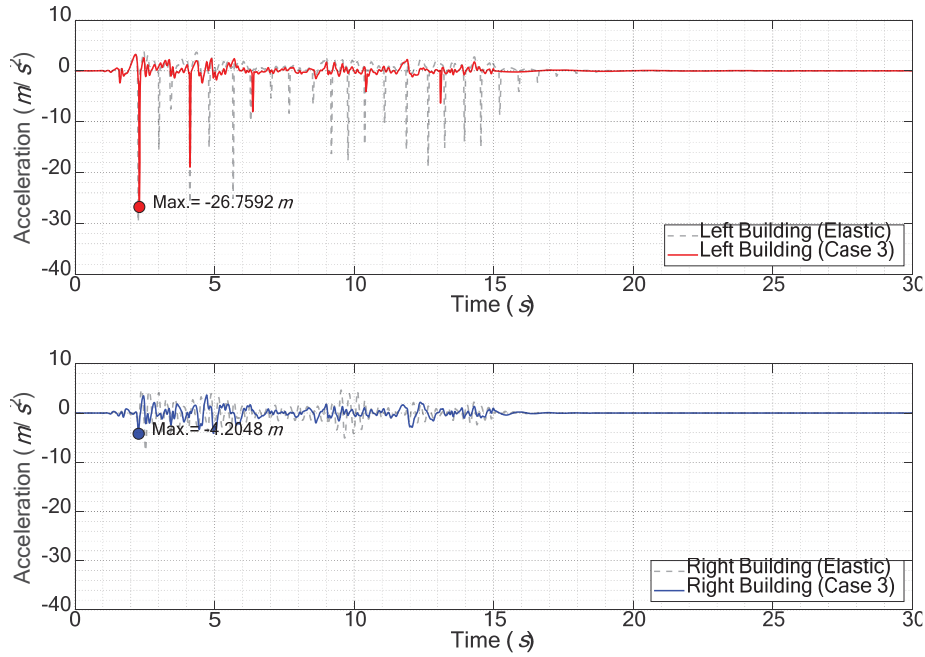

Figure 23: Acceleration time-history responses for the hysteresis case 3 of the structural systems with no space in between.

Figure 24: Acceleration time-history responses for the hysteresis case 3 of the structural systems separated by a distance of 3 cm.

From the peak acceleration values presented in Table 3 with particular emphasis on the flexible structure, it is possible to see the influence of the pounding forces in the large increases of the peak acceleration values for both the elastic and inelastic cases (except for the case 0 cm with 5 cm of gap size that presented no impact – see Figure 17). However, the acceleration spikes are smaller when the hysteresis cases are considered as can be seen in the percentages in green color that present negative values.

6 CONCLUSIONS

Earthquake-induced structural pounding between two SDOF structural systems was investigated. These systems can have elastic behavior or one of the four different types of hysteresis behavior considered with and without degradation features.

Inelastic behavior was found to be very relevant when impacts between the SDOF structures occurred. Ultimately, elastic behavior overestimates the number and magnitude of impact forces and underestimates the displacements and accelerations that the structures might experience. These conclusions are particularly relevant for the case of the flexible structure.

It was found that the amplitude of the inelastic displacements, generally, exceeds the displacements in the elastic case, particularly, when the responses involve pounding and for hysteresis cases with degradation features. Among the hysteresis cases, the case with pinching presented the largest peak displacement and magnitude of the pounding forces for the scenario without space between the structures.

Permanent displacements were verified in the rebound direction, viz., in the flexible structure, caused by the action of the ground excitation and aggravated by the impact forces. These residual displacements increase as the gap between the adjacent structures decreases. Although there is no clear understanding of which hysteresis behavior the unrecoverable displacements are bigger since it also depends on the separation distance between the adjacent buildings. However, these tend to be slightly bigger for the case where stiffness and strength degradation are considered.

The hysteresis cycles revealed that pounding has very little or no effect on the right structure. The hysteresis loops when pounding is considered are almost coincident with the case of no pounding, showing very little deviation from it.

Regarding the acceleration responses, it is possible to verify the reduction of the number and magnitude of the acceleration spikes of both the left and right structures when the inelastic behavior is considered with respect to the elastic case.

This study only comprises SDOF structural systems under a specific ground motion. Further studies should include multiple DOFs, a three-dimensional spatial model, calibration of the hysteresis model with experimental data, and the consideration of several different ground motions to further validate the results presented in this study and add more relevant information to the problem of earthquake-induced structural building pounding.

Abstract. *Virtual sensing enables expansion and transformation of measured quantities from physical sensors into new quantities at unmeasured locations. This allows for estimating the strain and stress in unmeasured locations of a system by transforming the physical sensors (input) into the desired strain and stress response (output). This transformation model can be based on either knowledge of the systems, data from the system, or any combination of these. In this paper, supervised learning and data-driven models are applied to strain estimation of an offshore wind turbine through Principal Component Analysis (PCA). Training data are used to establish the data-driven model that enables a versatile strain estimation that functions well under different wind scenarios than the training data set.*

1 INTRODUCTION

Virtual sensing transforms measured data into other quantities and/or expands the data to unmeasured locations through virtual sensors [1]. We can categorise stress/strain estimation technique as a subcategory within virtual sensing that estimates the full-field stress/strain response of a system [2]. The reader should note that there is unfortunately not a consensus or common terminology in the field of virtual sensing and stress/strain estimation [2].

Stress/strain estimation started in the 1950s with models of analytical relationships between response and strain [3]. In the 1990s, transformation matrices started to replace the analytical relationships with Okubo and Yamaguchi [4] introducing a displacement-to-strain transformation matrix, which is based on data of both strain and displacement. Hjelm et al. [5] used mode shapes to create a transformation matrix - called the modal expansion technique - that enabled full-field strain estimation. The techniques of stress/strain estimation were expanded to include adaptive filters as Papadimitriou et al. [6] introduced the Kalman filter to full-field strain estimation in 2011. In 2016, Maes et al. [7] compared the different techniques of the transformation matrix (modal expansion) and adaptive filters (Kalman filter and the joint input-state estimation algorithm) for strain estimation on an offshore monopile wind turbine and they found the technique to be equal performance-wise. Accounting for the quasi-static response, Iliopoulos et al. [8] fused both accelerometers and strain gauges into the modal expansion technique while Skaftø et al. [9] applied Ritz vectors to the modal expansion technique. Risaliti et al. [10] introduced the augmented extended Kalman filter on a nonlinear system using the implicit equation of motion. Tarpø et al. [11] studied expansions of experimental mode shapes used for stress estimation and they concluded that expansions of mode shapes is equivalent to updating the system model. Nabuco et al. [12] estimated the dynamic full-field strain of an offshore tripod structure during operation with high accuracy. Tarpø et al. [13] proved that the modal expansion technique applies to a subsystem within a nonlinear and time-varying system when the nonlinear and time-varying effects act externally on the subsystem. At the end of the 2010s, machine learning and data-driven models enter the portfolio of stress/strain estimation techniques where Lu et al. [14] applied pattern recognition and Deng et al. [15] applied deep learning to modal expansion.

In this paper, we will study data-driven strain estimation on an operating offshore wind turbine in the Great Belt in Denmark. In general, a data-driven model consists of relationships between input and output of a system and is constructed through training data without any explicit knowledge of the system [16]. Therefore, data-driven strain estimation enables a transformation from physical sensors (input) to strain (output) at locations where temporary strain gauges were placed during the training data. Thus, this form of strain estimation is unextendable to other locations without adding information or new data to the model. This is the main drawback of data-driven strain estimation. Data-driven strain estimation, however, has the advantage over strain gauges in the form of prolonged service life. Strain gauges are known to be unreliable over long-term monitoring - especially in an offshore environment where they are damaged by the corrosive seawater. The service life of the data-driven strain estimation depends on the utilised physical sensors (eg. geophones or accelerometers) and these often have longer service life and are easier to replace than strain gauges. Furthermore, data-driven strain estimation is independent of a system model (often a finite element model) and the accuracy of this model.

In this paper, we utilize training data to construct a data-driven model that can estimate the strain response with high accuracy and reliability. The model works for different wind scenarios than the one from the training data.

2 STRAIN ESTIMATION USING PRINCIPAL COMPONENT ANALYSIS

In this paper, we apply the Principal Component Analysis (PCA) [17] in a supervised learning approach to find a transformation matrix between the displacement (the input) and the strain response of that system (the output) based on training data. Essentially, principal component analysis is a dimensionality reduction of data to set of uncorrelated principal components ordered by contribution [17].

In this technique, we will stack the displacement vector, $\mathbf{y}(t)$, and the strain response, $\boldsymbol{\varepsilon}(t)$, in a vector.

$$\mathbf{y}_c(t) = \begin{bmatrix} \mathbf{y}(t) \\ \boldsymbol{\varepsilon}(t) \end{bmatrix} \quad (1)$$

We estimate the covariance matrix of this stacked response and apply the singular value decomposition on the covariance matrix.

$$\mathbf{U}\mathbf{S}\mathbf{U}^T = \mathbb{E} [\mathbf{y}_c(t)\mathbf{y}_c(t)^T] \quad (2)$$

where \mathbf{S} is a diagonal matrix holding the singular values, \mathbf{U} holds the singular vectors as column vectors, $\mathbb{E}[\cdot]$ denotes the expectation operator, and $(\cdot)^T$ denotes the transpose of a vector or matrix.

We use the singular values, \mathbf{S} , to find the dominating principal components to represent the majority of the response. Then we can create a displacement-to-strain matrix, \mathbf{H} , using the singular vectors corresponding to these dominating singular components. We can estimate the strain response in other data set by the displacement-to-strain matrix.

$$\widehat{\boldsymbol{\varepsilon}}(t) = \mathbf{H}\mathbf{y}(t) \quad (3)$$

We must avoid an ill-posed problem, which requires a redundant sensor network with more physical sensors than included singular vectors in $\widehat{\mathbf{U}}$. Fortunately, we can separate the data into multiple frequency bands and find a set of singular vectors for each band.

3 CASE STUDY

3.1 Quality measures

In the literature or industry, there are no rules or guidelines for an evaluation of virtual sensors. The most common approach is to compare the virtual sensors with a set of reference sensors through different quality measurements. In this paper, we will use two different quality measurements.

3.1.1 Coefficient of determination (R^2)

The coefficient of determination (R^2) [18] is a popular quality measure in statistics and modal validation where a value of one indicates perfect correlation with the same amplitudes.

$$R_i^2 = 1 - \frac{\mathbb{E} [(\boldsymbol{\varepsilon}_i(t) - \widehat{\boldsymbol{\varepsilon}}_i(t))^2]}{\text{Var} [\boldsymbol{\varepsilon}_i(t)]} \quad (4)$$

where $\boldsymbol{\varepsilon}_i(t)$ is the measured strain response for the i^{th} strain gauge, $\widehat{\boldsymbol{\varepsilon}}_i(t)$ is the estimated strain response at the same location, and $\text{Var} [\cdot]$ denotes the variance operator.

Figure 1: Wind turbine near Sprogø and the Great Belt Bridge in Denmark

3.1.2 Normalised error in equivalent stress range

It is important to evaluate stress estimation in terms of the fatigue damage when the estimation is intended for a fatigue analysis. When we have varying stress amplitudes, we must apply cycle counting [19], like rainflow counting [20]. Sometimes, we might prefer to access fatigue damage for variable amplitude loading in the form of a damage equivalent stress range, which leads to the same fatigue damage as all stress cycles [19]. We calculate the damage equivalent stress range for both reference and the estimated as follows

$$\Delta\sigma_{eq} = \left(\frac{1}{n_{cycles}} \sum_{j=1}^{n_{cycles}} \Delta\sigma_j^m \right)^{1/m}, \quad \Delta\hat{\sigma}_{eq} = \left(\frac{1}{\hat{n}_{cycles}} \sum_{j=1}^{\hat{n}_{cycles}} \Delta\hat{\sigma}_j^m \right)^{1/m} \quad (5)$$

where n_{cycles} and \hat{n}_{cycles} are the total number of counted cycles for the measured and estimated signal, respectively, $\Delta\sigma_j$ and $\Delta\hat{\sigma}_j$ denote the stress range from cycle counting, and m is the "slope" of the SN curve. For this paper, we will assume $m = 3$, which corresponds to welded steel structures [19].

The normalised error of the equivalent stress range is given as

$$\eta_i = \frac{\Delta\hat{\sigma}_{eq} - \Delta\sigma_{eq}}{\Delta\sigma_{eq}} \quad (6)$$

Here $\eta_i = 0$ indicates a correct strain estimation in terms of equivalent fatigue damage while a negative value suggests an underestimation and a positive value suggests an overestimation of fatigue damage.

3.2 Wind turbine

The case study is an offshore wind turbine in the Great Belt in Denmark and the model of the wind turbine is a Vestas V90, 3 MW installed on a gravitation foundation, see Fig. 1. The wind turbine is equipped with a sensor network consisting of four Sigicom triaxial geophones

Figure 2: Monitoring campaign during a month with the measured wind speed, wind direction, and the production of power of the wind turbine. The chosen data sets are marked with a line and numbered where the training data set is marked with a green line and the others are marked with red.

attached at the lower part of the tower and two strain gauges located just above the foundation. The monitoring campaign was during a one month period, see Fig. 2, with a sampling frequency of 20 Hz.

To exclude the quasi-static response of the wind turbine, we apply a high-pass filter to all data with a cut-off frequency of 0.2 Hz. We calibrate the geophones using digital correlation [21] and we reduce the tilt effects on the geophones through the vertical geophones [22]. We integrate signals from the geophones into displacement by the integration theorem for the Fourier transformation [23]. Then, the data is divided into 3 frequency bands: 0.2-0.7, 0.7-4.5, and 4.5-10 Hz using complementary filters. These filters are applied to avoid an ill-posed problem for the strain estimation. We applied 40 minutes of training data to the principal component analysis, as explained in Section 2, to generate the transformation matrix for each frequency band. The training data set is marked with green in Fig. 2 and it has a wind direction of 180° and a low power production. The results of the strain estimation is shown in Fig. 3 for the training data sets. This displacement-to-strain matrix is saved as the data-driven model for the strain estimation for the entire monitoring period.

To illustrate the accuracy of the data-driven model, we apply the strain estimation model to three other data sets with different wind direction and power production distributed over the entire monitoring campaign, see the data sets marked with red in Fig. 2. Figs. 4, 5, and 6 show the strain estimation in both time and frequency domain for the three data sets. Finally, Fig. 7 (a) shows the coefficient of determination (R^2), Eq. (4), for all three data sets while Fig. 7 (b) displays the normalised error of equivalent strain range, Eq. (6).

All coefficient of determination values are above 0.965 and the estimated equivalent stress range is within $\pm 7\%$ of the measured one. All these values indicate that the data-driven model estimates the strain response with high accuracy and low uncertainty. Furthermore, strain estimation of the training data has similar quality measurements as the other data sets. This indicates that the displacement-to-strain matrix is versatile and applies to different wind scenarios of wind directions, wind speeds, and power production than the original training data set,

(4), for the estimated and measured strain, and (b) the normalised error in equivalent strain range, Eq. (6), for the estimated and measured strain.

which was constructed from.

4 CONCLUSION

In this paper, a data-driven strain estimation technique was introduced based on principal component analysis and temporary strain gauges. After the creation of the data-driven model, the temporary strain gauges become unessential for the future monitoring of the strain response and they can be removed. The technique was applied to an offshore wind turbine equipped with both triaxial geophone and strain gauges. A single data set was used to generate the data-driven model that could estimate the strain response - using only vibration responses from the geophones - with high precision in other data sets under different wind scenarios. Recapitulating, the virtual sensors were reliable and robust regardless of wind direction, wind speed, and power production of the wind turbine.

Abstract

The design process of a slender structure, such as a wind turbine tower, goes through the analysis of the natural frequency, since it is important that this frequency is away from the frequencies generated by the excitation sources. The simplified analysis models and formulations are an important tool in the frequency evaluation on design phase, even though most formulations consider the structure with constant mass and inertia, which is not the case of wind turbine tower, that have a tapered shape. The main objective of this study is to evaluate the accuracy of the simplified models when applied to structures with variable inertia. The results of the simplified models applied to a small wind tower were compared with the finite element method and experimental results. The large scatter of the simplified method's results, frequencies in the range of 0.8 – 2.12 Hz, emphasizes the importance of a reliable model to evaluate the frequency. The Rayleigh and SDOF reduction methods were found to be accurate in evaluating the first frequency of the investigated tower under consideration.

Keywords: Wind turbine tower, Simplified frequency estimation, Eigenfrequency.

1 INTRODUCTION

Wind energy is one of the sources of renewable energy that has been used by mankind since the dawn of civilization. Recent wind turbine towers (WTT) studies intend to optimize the costs of installation and production, not only for large ones but also for small ones; the later can be used for domestic or specific energy production. The wind turbine tower is a part of the system that affects energy production efficiency, and because of being usually slender and flexible structures, is considered the critical part of the wind turbine since it should support the dead loads of equipment and additional loads caused by wind. There are essentially two types of towers used for this purpose: lattice towers and tapered hollow towers. Tapered hollow towers are usually preferable because they require less implantation area and are aesthetically more pleasant. For modeling these structures, it is necessary the estimate the natural frequency in the lowest sway mode of the structure.

The importance of the natural frequency determination for wind turbine towers design is because it must be away from the frequencies generate by the excitation sources as wind, the rotor (1P) or blade passing (3P-for 3 blades turbines)[1]. For complex structures finite-element computer programs will be used to access this information, however, for cost reduction and in the early design the simplified methods are quite useful.

In literature can be found several methods for frequency estimation, like empirical formulas [2] simplified formulas [1, 3] as well as Rayleigh's method [4, 5]. The tower can be considered as a generalized single-degree-of-freedom structure with a concentrated tip mass on top, that is analyzed with SDOF reduction [5] or through the solution of the transcendental equation. The main problem is that the mass of the rotor and nacelle located on top of the tower is usually neglected, and generally tapered towers have a behavior different from the tubular towers; these are sufficient sources capable of causing certain errors.

The objective of this research work is to analyze the accuracy of simplified models for the determination of the first eigenfrequency of a cantilever metallic hollow tower (used as a small WTT), by evaluating the differences between them and the results obtained by finite-element model analysis in established computational software; still comparing these results, with those of evaluated frequencies from ambient or structural health monitoring vibrations measurements on the real structure. The analysis shows that the main difficulty of simplified formulas is the determination of the mass and moment of inertia that should be used, which can significantly affect the results.

2 SIMPLIFIED MODELS REVIEW

The studies of standard vibratory movements of structures are based on the hypothesis that for small amplitudes of vibration the structures exhibit a linear behavior; that is, the forces of inertia, stiffness and damping are respectively proportional to acceleration, displacement and velocity, defining a linear systems [6]. The equation of motion (on the displacement variable $w(t)$) of an elastic linear undamped system (mass M and stiffness K) in the absence of external forces (Eq.1), leads to the natural frequency f (in Hz) expressed by Eq.2.

$$M\ddot{w}(t) + Kw(t) = 0 \quad (1)$$

$$f = \frac{1}{2\pi} \sqrt{\frac{K}{M}} \quad (2)$$

The simplest way to determine the frequency of a cantilever tower is to consider the structure as a beam with a concentrated mass at the top and with constant stiffness and mass, that is, as a structure with one degree of freedom (SDOF). In such case for towers of height H with constant inertia and constant distributed flexural stiffness EI , the lateral stiffness is calculated by

$$K_L = \frac{3EI}{H^3} \quad (3)$$

According to Ko [1] if the tower is modelled as a SDOF system with a tip mass, using a constant cross-section than the natural frequency is,

$$f = \frac{1}{2\pi} \sqrt{\frac{K_L}{M_{tip} + \alpha M}} \quad (4)$$

where α is the equivalent mass ratio of the tower concentrated at the top. The wind turbine design standard DNV-OS-J101 [7] establishes $\alpha = 0.25$, while the IEC 61400-1 standard [8] indicates that $\alpha = 0.5$; another value of $\alpha = 33/140$ is proposed by Blevins [9].

A different procedure is to model the wind turbine tower as Euler-Bernoulli beam system [10], with distributed mass m and distributed flexural stiffness EI . The governing equation of motion for undamped free vibrations of a uniform Euler-Bernoulli beam [11, 12, 13] is,

$$EI \frac{\partial^4 w(z, t)}{\partial z^4} + m \frac{\partial^2 w(z, t)}{\partial t^2} = 0 \quad (5)$$

and, the clamped-free boundary conditions with a tip mass are,

$$w(0, t) = 0, \quad \left[\frac{\partial w(z, t)}{\partial z} \right]_{z=0} = 0 \quad (6)$$

$$\left[EI \frac{\partial^2 w(z, t)}{\partial z^2} + I_{tip} \frac{\partial^3 w(z, t)}{\partial t^2 \partial z} \right]_{z=L} = 0, \quad \left[EI \frac{\partial^3 w(z, t)}{\partial z^3} - M_{tip} \frac{\partial^2 w(z, t)}{\partial t^2} \right]_{z=L} = 0 \quad (7)$$

Separating the spatial and temporal functions using the method of separation of variables [11], applying Eq. 8 leads to Eq. 9

$$w(z, t) = \Phi(z)\eta(t) \quad (8)$$

$$\frac{EI}{m} \frac{1}{\Phi(z)} \frac{\partial^4 \Phi(z)}{\partial z^4} = -\frac{1}{\eta(t)} \frac{\partial^2 \eta(t)}{\partial t^2} = \gamma = \omega^2 \quad (9)$$

From which, the solution for Eq. 8 can be expressed as follows,

$$\Phi(z) = A \cos\left(\frac{\lambda}{H} z\right) + B \cosh\left(\frac{\lambda}{H} z\right) + C \sin\left(\frac{\lambda}{H} z\right) + D \sinh\left(\frac{\lambda}{H} z\right) \quad (10)$$

$$\eta(t) = E \cos(\omega t) + F \sin(\omega t) \quad (11)$$

where A, B, C, D, E and F are unknown constants and,

$$\lambda^4 = \frac{\omega^2 m H^4}{EI} \rightarrow \omega = \frac{\lambda^2}{H^2} \sqrt{\frac{EI}{m}} \quad (12)$$

The non-trivial solution for $\Phi(z)$ is obtained by the differential eigenvalue problem, using the spatial form of the boundary conditions to find the values of λ [12]. Then the characteristic equation of the system is,

$$1 + \cos \lambda \cosh \lambda + \frac{\lambda M_{tip}}{mH} [\cos \lambda \sinh \lambda - \sin \lambda \cosh \lambda] - \frac{\lambda^3 I_{tip}}{mH^3} [\cosh \lambda \sin \lambda + \sinh \lambda \cos \lambda] + \frac{\lambda^4 M_{tip} I_{tip}}{mH^4} [1 - \cos \lambda \cos \lambda] = 0 \quad (13)$$

If the tip mass is modeled as a point mass, the rotational inertia of the tip mass is negligible, $I_{tip} = 0$. The first root of the characteristic equation is the first natural frequency, calculated by solving Eq. 13.

The main difficulty is to determine the values of m and EI to be used, since the tower has distributed mass and elasticity, i.e., the structure is non-uniform. Nevertheless, this structure can be modeled as a generalized SDOF system and provide an approximate solution. This procedure is called SDOF reduction and consists in creating a SDOF-equivalent system with distributed mass and stiffness, where according to the principle of virtual work, the generalized mass M^* and stiffness K^* can be obtained [6, 13, 14],

$$M^* = M_{tip} + \int_0^H m(z) \Phi^{*2}(z) dz \quad (14)$$

$$K^* = \int_0^H EI(z) \left[\frac{\partial^2 \Phi^*(z)}{\partial z^2} \right]^2 dz - \int_0^H N(z) \left[\frac{\partial \Phi^*(z)}{\partial z} \right]^2 dz \quad (15)$$

Paz [5] recommends the Eq. 16 as a simplified mode shape of the tower,

$$\Phi^*(z) = 1 - \cos\left(\frac{\pi z}{2H}\right) \quad (16)$$

On the other hand, an alternative method to establish the stiffness of the structure is through the linear relationship between the force and displacement Eq.17. But the difficulty with this procedure is that one must know the force and the displacement caused by that force.

$$F = Kx \rightarrow K = \frac{F}{\delta} \quad (17)$$

The displacement can be determined by theoretical calculations or by structural analysis software. Balagopal *et al.* [14] present a simplified model for calculating the displacement at the top considering the application of a unit force on the structure. The procedure defined the cross sectional area of the tower and the moment of inertia are calculated based on ASCE 48-11 [15].

$$K = \frac{1}{\delta_{unit}} \quad (18)$$

$$\delta_{unit} = \delta_{lat} + \delta_{vert} \quad (19)$$

$$I = C d_m^3 e \quad C = 0,403 \quad d_m = (d_t + d_b)/2 \quad (20)$$

$$A = 3,19 d_m e \quad (21)$$

The displacement δ_{unit} is calculated using the following set of equations,

$$\delta_{lat} = \int_0^H \frac{z^2}{E C e (d_t + s_p z)^3} dz \quad (22)$$

$$\delta_{vert} = \int_0^H \frac{M z}{E C e (d_t + s_p z)^3} dz \quad (23)$$

$$M = \delta_{lat} V = \delta_{lat} M_{tip} * g \quad (24)$$

$$s_p = \left(\frac{d_b - d_t}{H} \right) \quad (25)$$

When the law of conservation of energy is used to obtain the differential equation of motion for an undamped system in free vibration, the so-called Rayleigh's method is derived to find the natural frequency, by equalizing the maximum kinetic energy to the maximum potential energy (at different specific instants); but for this, it is necessary to assume a deformed shape. Usually, the shape is determined as that produced by the gravitational loads acting in the direction of the expected displacements [5, 6]. The natural frequency is expressed as,

$$f = \frac{1}{2\pi} \sqrt{\frac{g \sum_i W_i \delta_i}{\sum_i W_i \delta_i^2}} \quad (26)$$

where δ_i is deflection at the coordinate i and W_i is the concentrated weight at this coordinate.

Holmes [2] uses a semi empirical formula for cantilevered tapered circular tower, that was also recommended by the European Convention for Structural Steelwork in 1978, given by

$$f = \frac{\lambda}{2\pi H^2} \sqrt{\frac{E I_b}{m_b}} \quad (27)$$

$$\lambda = 1,9 * \exp\left(\frac{-4d_t}{d_b}\right) + \frac{6,65}{0,9 + (e_t/e_b)^{0,666}} \quad (28)$$

Another simplified expression is presented in the Annex F of EN 1991-1-4 [3],

$$f = \frac{1}{2\pi} \sqrt{\frac{g}{\delta_{w,max}}} \quad (29)$$

where $\delta_{w,max}$ is the maximum displacement (expressed in meters) due to self-weight applied in the vibration direction.

3 TOWER AND INVESTIGATION DESCRIPTION

To determine the natural frequency of a structure, there are three main approaches: theoretical calculation, application of the finite element method (FEM) using robust computational software, and experimental determination on the real structure. In general, the FEM method and the experimental determination show more accurate results, but they are also more expensive to achieve and perform.

To analyze the accuracy of the simplified models in determining the first natural frequency of conical hollow towers, the results of the formulations presented in the literature review are compared to the numerical FEM model and the experimental results.

3.1 Description of the tower

A metal tower 17.8 m height located at the School of Technology and Management of the Polytechnic Institute of Bragança (Portugal), consists of a steel S275 structure with a hexadecagonal section with an outside diameter of 0.5890 m at the base and 0.1954 m at the top, with a constant wall thickness of 4 mm. The tower is fixed to the gravity-base foundation by 16 anchor bolts connected to a flange at the base; the flange has an external diameter of 0.7960 m and a thickness of 20 mm. The main properties of the tower are presented in Table 1, and the geometric plan view configuration is shown in Figure 1.

3.2 Numerical model

The analysis of the structure using the finite element method is performed using the SAP2000 Software. The tower is modeled with the geometry presented above, considering the bottom boundary condition of the type BC1f (CEN, 2010) [3] for the location of the 16 anchor bolts; the top boundary is considered free with the action of a tip mass of 75 kg that corresponds to the weight of the wind turbine. The simulation is performed considering the linear behavior of the material.

3.3 Experimental analysis

To determine the dynamic characteristics of the structure, the experimental modal analysis was carried out using: a data acquisition system composed of NI USB-4431 data acquisition board with 4 input channels, 24-bit ACD resolution, sampling rate from 1 kS/s to 102.4 kS/s, resolution 2.10 mS/s; piezoresistive accelerometer ICP® with a frequency range from 0.5 to 2000 Hz; and a laptop with SignalExpress © software.

Two accelerometers are placed at 1.41 meters high in two distinct perpendicular directions (x and y). The input force is caused by the impact hammer PCB 086b20. The first (and others, if required) natural frequency is defined by the peak-picking technique.

3.4 Summary of analysis

In Table 2 are synthesized the methodologies used in this work for the determination of the WTT fundamental frequency, ranging from several simplified formulations presented in the literature to the numerical model and experimental analysis; some formulas require the use of a software to find the displacement, in which case the FTOOL software was use.

Equation	Stiffness parameters	General parameters	Name/reference
$f = \frac{1}{2\pi} \sqrt{\frac{K_L}{M_{tip} + \alpha M_{tower}}}$	$K_L = \frac{3EI_m}{H^3}$	$\alpha = 0,25$	DNV-OS-J101
		$\alpha = 0,5$	IEC 61400-1
		$\alpha = 33/140$	Blevins, 1979

Table 2: Analysis summary

4 RESULTS AND DISCUSSION

The advantage of using a finite element model is the determination of the mode shapes of the structure, as the fundamental or 1st mode shape shown in Figure 2(a). As mentioned in Paz and Kim [5], the accurate determination of the mode shapes is one of the crucial points for the correct calculation of the frequency by the application of SDOF reduction [5]. Figure 2 (b) compares the FEM mode shape and the approximate mode shape given by Eq. 16.

In relation to the results of the experimental analysis, the power spectra density is presented in Figure 3 (a) for the x-direction and in Figure 3 (b) for the y-direction. As shown, the first natural frequency is coherently evaluated as 1.610 Hz.

Figure 2: Tower mode shapes

Figure 3: Power spectral density

The values obtained by the different methods for the first natural frequency are shown in Figure 4. It is possible to observe a large dispersion of results with relative differences in the order of 50%, in comparison with the experimental value; this is due to the fact that most of the formulations are established for a tower of constant mass and constant inertia per unit length. Although they are simplifications, the problem lies mainly in the definition of the inertia to be used, since it varies cubically.

Figure 4: First natural frequency, by different methodologies

It is observed that the simplified models that present the results closest to the experimental value are the FEM model, the Rayleigh method and the SDOF reduction method; however the first two methods require the use of software, and are more time consuming. The difficulty in applying the SDOF reduction method consists in solving the integrals, but they are easily solved with a graphic scientific calculator; in fact this method presents the best results when analyzing the frequency value and the time taken to calculate it.

Notice that the vast majority of results by different methods underestimate the value of the fundamental frequency, that is, consider the structure more flexible than it really is. This is mainly due to consider the inertia and the mass defined in the first half of the structure (up to $H/2$), and because the tower having a conical or tapered shape its mass is more concentrated near the base. Also the results of the expressions using the displacement value at the top distributed by a simplified model of average diameter in the FTOOL, overestimate the frequency value by about 16%.

5 CONCLUSIONS

The metallic hollow cantilever tapered tower analyzed has the first natural frequency of 1.61 Hz. This frequency can be accurately evaluated by the application of the finite-element model, even though this method is time consuming. The Rayleigh's method also shows accurate result for the WTT analyzed; but the single degree of freedom reduction method is the simplified method that has the best performance, since it is simple and the result is accurate.

The analysis shows that the main difficulty of simplified formulas is the determination of the moment of inertia and mass, which significantly affect the results. The results show large difference between the frequencies analytically evaluated by different methods (with values in a range of 0.8 to 2.12 Hz), some of them with a significant difference from the real natural frequency, and the majority of them underestimate the value of the frequency.

The dispersion of the results reflects the importance of accurate assessment of the structural inertia and mass on the use of simplified methods, for tapered tower with tip mass; nevertheless further investigation, on the accurate estimation of mass and inertia for the tapered towers, should be carried out.

Abstract

Analysis and modeling of structures, under the influence of dynamic loads, is usually carried out through the application of the finite element method (FEM). These analyses are intrinsically dependent on the parameters considered in the model, and the parameters must translate the real properties of the structure so that the model's behavior is reliable as compared with the physical behavior of the structure; for these purposes the model calibration using experimental data aims to improve the uncertainty of model parameters or inaccuracies in modeling.

In the present work a numerical analysis was carried out, on a small wind turbine metallic hollow tower with hexa-decagon section and 17.80m high, applying the finite element theory with SAP2000® software. The FEM model was updated with the frequency results of in-situ vibration tests; to compare the results, two methods Experimental Modal Analysis (EMA) and the Operational Modal Analysis (OMA) were applied in the experimental tests to evaluate the dynamic properties of the tower.

It is noticed that the first frequency of the model without calibration has a value of 2.129 Hz that is 32,2% above the real measured 1.610 Hz; after calibration update, the first frequency of the tower has a value of 1.590 Hz consistent with the results of the vibration tests. The static response of the structure to loading at the top, also shows a significant difference between the uncalibrated and the calibrated model: after calibration there is a 25% increase in displacement at the top of the structure; the compression force is the one with the smaller differences, while the base shear and base moments increased tremendously but maintained the location of points of maximum stresses.

Keywords: Finite element model calibration; Ambient vibration test; Impact hammer test; hollow tapered tower; Small wind turbine tower.

1 INTRODUCTION

Developing and improving sustainable and affordable energy production systems is one of today's engineering concerns. Wind energy is one of the sources of renewable energy that has been recently continuously studied, also with the purpose of optimizing the costs of installation and production. The wind turbine tower WTT is a part of the system that affects production efficiency and is usually a slender and flexible structure; it is considered the critical part of the wind turbine, since it should support the dead loads of equipment and additional loads caused by wind. The wind turbine tower has two crucial functions: supports in the height the rotor nacelle system in the height and transfer the loads' action on the structure to the foundation.

The analysis and modeling of these type of structures, under the influence of dynamic loads, is usually achieved through analytical computational modeling techniques, on the application of the finite element method (FEM). These analyses are intrinsically dependent on the values chosen for the parameters considered in the model, which must translate the real properties of the structure so that the model's behavior is reliable as the physical behavior of the structure.

In complex structures, the model generally consists of some simplification of the structure, but it must adequately represent the real structure; so there is a need to validate the numerical model with test results in real structures, to adjust the parameters used. Adjusting the analytical model using experimental data is known as model calibration in structural dynamics, and aims to improve the uncertainty of model parameters or inaccuracies in modeling.

To determine the dynamic characteristics of a structure, there are two experimental methods accessible: Experimental Modal Analysis (EMA) and Operational Modal Analysis (OMA); and the main difference between these methods, is the need or not for a controlled excitation source. In EMA, it is necessary to know the excitation force and the response of the structure; on the other hand, in OMA only the response of the structure is measured. In fact, for general structures OMA is largely more applied -- as in bridges [1]–[7], tall or quite specific buildings [8]–[11] and towers [12]–[14] – for example through structural health monitoring associated with series of ambient vibration measurements.

In the case of dynamic excitations in towers of major wind turbines, there are several studies in the bibliography that compared analytical and experimental results [15]–[18]; for such it is common to use the NREL 5MW wind turbine as the object of study [19]–[22], and then apply different techniques of dynamic tests and structural monitoring.

However, when it comes to small wind turbines, those that have a rotor swept area smaller than 200 m², comparative studies are limited. Castellani et al. [23] calibrated and updated the parameters of a small wind turbine using the power spectra density, function of major excited frequencies, evaluated with an impact hammer test in a prototype tower for wind tunnel test; but in his work, the main objective was the study of the wind turbine. In the present work a numerical analysis was carried out, on a small wind turbine metallic hollow tower with hexa-decagonal section and 17.80 meters high, applying the finite element method with SAP2000 software and using the results of dynamic vibration tests in the real tower to calibrate the model.

2 DESCRIPTION OF THE TOWER

The analyzed metal tower is located at the School of Technology and Management of the Polytechnic Institute of Bragança (Portugal), consists of a steel structure with the height of 17.81 m, having a hexa-decagonal section with an outside diameter of 0.5890 m at the base and 0.1954 m at the top, and with constant wall thickness of 4 mm. The tower is fixed to the gravity-base foundation by 16 anchor bolts connected to a flange at the base; the flange has an external diameter of 0.7960 m and a thickness of 20 mm.

The designed tower structure has a straight geometric configuration as shown in Fig. 1 (a); but the real tower structure presents an initial out-of-straightness with a total offset of 0.122 m at the top in relation to the axis of the tower, as shown in Fig. 1 (b). The tower is produced from S275 steel whose properties and design characteristics were established in accordance with the Eurocode 3 [24]; considering the thickness $t \leq 4$ mm, the properties are shown in Table 1. The computational simulations using FEM considered the linear behavior of the material.

Yield strength	275	[MPa]
Ultimate strength	430	[MPa]

Table 1 : Steel S275 properties.

2.1 In situ vibration measurement

To determine the dynamic characteristics of the structure two methods were applied in the studied tower: EMA and OMA.

Measurements associated with the experimental modal analysis were carried out using: a data acquisition system composed of NI USB-4431 data acquisition board with 4 input channels, 24-bit ACD resolution, sampling rate from 1 kS/s to 102.4 kS/s, resolution 2.10 mS/s; piezoresistive accelerometer ICP® with a frequency range from 0.5 to 2000 Hz; and a laptop with SignalExpress © software.

Firstly, the dynamic load test was performed with two accelerometers placed at 1.41 meters high in two distinct perpendicular directions (x and y). The input excitation force is caused by the impact hammer PCB 086b20. The first (and others, if required) natural frequency is defined by the peak-picking technique.

The power spectra density (PSD) functions associated with this EMA is presented in Figure 2(a) for the x-direction and in Figure 2(b) for the y-direction.

The average values of the first three eigenfrequencies, in one direction, were obtained: 1.610 Hz for the first natural vibration frequency, 5.990 Hz for the second natural frequency, and 8.010 Hz for the third natural frequency.

As the structure is mainly symmetric, these frequencies for the two measured directions (x and y) are practically considered the same, as is possible to verify in the given PSD's.

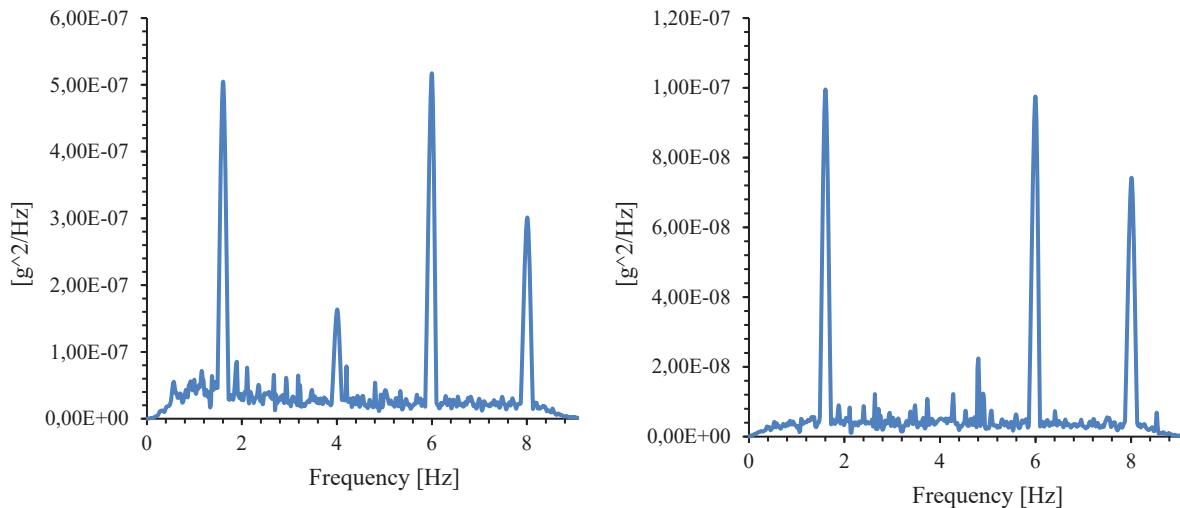

Figure 2 : PSD -- EMA. (a) x-direction, (b) y-direction

The ambient vibration testing associated with OMA was carried out for 20 minutes records, with the same location of the two accelerometers, and was executed three times. During the test, the average wind speed was 1.333 m/s in the SWW direction, with a peak velocity of 4.92 m/s in the S direction. As it is possible to verify in the PSD's presented in Figure 3, the external excitation was not capable to excite all the range of structural frequencies, so it is only possible to determine the first frequency that is congruent with the EMA results.

Figure 3 : PSD -- OMA. (a) x-direction, (b) y-direction

3 NUMERICAL MODEL

The analysis of the structure using the Finite Element Method (FEM) is performed using the SAP2000 software. Initially, the model consists of a straight tower with the geometry presented above, including wind turbine's weight as a static boundary condition corresponding to a concentrated mass at the top of the tower. The boundary conditions assumed in the analysis must be chosen in such a way as to guarantee and achieve a realistic or conservative model of the actual structure. According to Eurocode 3 - Part 1-6 [3] the upper extremity is a free boundary condition (type BC3), and for the first model the lower extremity boundary condition is considered rigid (type BC1r, infinity support for which any type of movement is prevented).

Although FEM is a powerful tool for engineers, some aspects need to be verified carefully and the refinement of the mesh should be checked to avoid unrealistic local behavior; also the mesh should satisfy the so-called patch test. Figure 4 displays the frequency convergence of the model according to the number of elements, so the ideal mesh for the first FEM model divides the tower into 76800 elements; for such first model the converged fundamental frequency was evaluated as 2.12965 Hz.

Figure 4 : Frequency convergence

3.1 Finite element method model updating procedure

The FEM model generally consists of a simplification of the structure, corresponding to some assumptions made, but it must adequately represent the real structure; so there is a need to validate the numerical model with test results in real structures, to adjust the parameters used. The procedure of adjusting the analytical or computational model using experimental data is known as a model calibration or model updating in structural dynamics; it aims to improve the uncertainty of model parameters or inaccuracies in modeling, that originate the uncertainties in simplifying assumptions of the structural geometry, materials, and even of inaccurate boundary conditions [25].

The comparison between the results of the experimental dynamic tests (EMA-OMA), the initial FE model and the updated FE models, are shown in Table 2.

	Experimental	Initial FEM	1 st update	2 nd update	3 rd update
First frequency [Hz]	1.610	2.129	1.732	1.724	1.590
Second frequency [Hz]	5.990	8.881	7.668	6.898	6.330

Table 2 : Results of experimental and analytical modal identification and modification of structure parameters

As the first frequency of the model 2.12965 Hz does not match with the measured 1.61 Hz frequency, the first model update was the inclusion of the flange and the change of the lower boundary condition, applying boundary condition of the type BC1f [26] (only rotation is free) in the location of the 16 bolts. The second updating was the consideration of the out-of-straightness of the tower and the eccentricity of the wind turbine. Even though the frequency is still above the real one, as the structure presents a service ladder and its equivalent mass was not considered in the numerical model, it is responsible for altering the inertia of the structure; so the last change or third updating, was to consider that equivalent mass through a factor. Now the first frequency of the model is the same as the measured one, and the model is considered calibrated. Even though the second frequency is not exact, it is very close and the final upgrade of the initial FE model produced a quite good agreement with the experimental results. The first frequency value shows a reduction about 25% from de non calibrated model to the calibrated one, and in Figure 5 it is possible to observe the change in the form of the mode shapes.

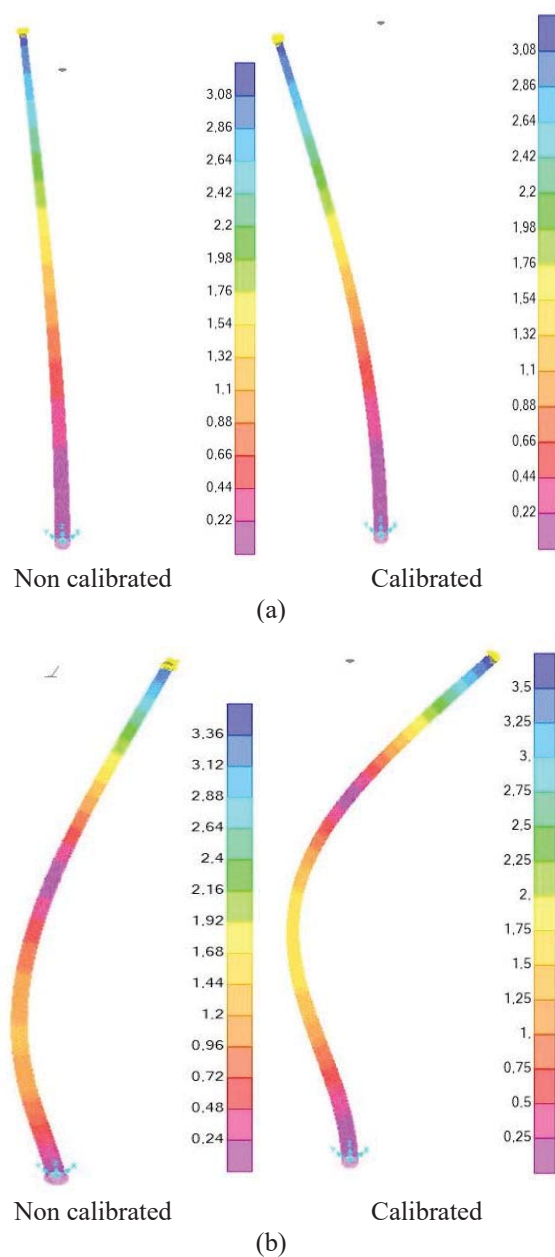

Figure 5 : Changed form of the mode shapes. (a) first mode, (b) second mode

3.2 Static analysis

To evaluate the effects of the calibration upgrading in a static analysis, the external forces acting on the top of the tower that are induced by the wind turbine were determined according to DNV guidelines [27]. For simplification, the wind force acting laterally on the tower was not considered in this analysis.

The aerodynamic drag force produced by the blades on the top of the tower can be predicted by simplified calculations based on the projected area perpendicular to the flow. The rotor loads are expressed by three load quantities: static horizontal airflow (Eq. 1), driving torque (Eq.2) and weight of the rotor.

$$F_0 = 300 \cdot A \quad (1)$$

$$M_{e,nom} = \frac{P_{nom}}{2\pi n_l \eta} \quad (2)$$

where A is the swept area of the rotor in (m^2), P_{nom} is the nominal power of the wind turbine, n_l is the rotor frequency and η the nominal efficiency.

The wind turbine supported by the tower is a Fortis Passat (1.4 kW) and the characteristics are presented in Table 3 including static loads predicted on top of the tower.

Fortis Passat (1.4 kW)			
Gravitational acceleration	g	9.8066	[m/s ²]
Rotor blade radius	r	1.5	[m]
Area of rotor	A	7.65	[m ²]
Rotor mass	m	75	[kg]
Rotor frequency	n_l	3	[Hz]
Nominal power of wind turbine	P_{nom}	1400	[W]
Nominal efficiency	η	0.7	
Calculations			
Static horizontal airflow load	F_0	2295.000	[N]
Driving torque	$M_{e,nom}$	106.103	[N.m]
Eccentricity	e	0.250	[m]
Static load			
Moment about horizontal axis rotor plane	M_x	573.750	[N.m]
Horizontal force along rotor axis	F_y	2295.000	[N]
Moment about axis rotor	M_y	137.934	[N.m]
Vertical force	F_z	-735.495	[N]
Moment about vertical axis	M_z	573.750	[N.m]

Table 3 : Simplified load calculations on top of the tower

The structural analysis results shown in Table 4 for top displacements and generalized stress resultants, before and after model calibration updating and upgrading, indicate the differences between the correct calibrated model and the initial model; the most important differences occur for the maximum base shear force and the maximum and minimum base moments.

	Initial FEM	Final FEM	Difference (%)
First frequency [Hz]	2.129	1.590	-25.32
Top displacement [m]	0.146683	0.196223	25.25
Fmax [kN]	1156.488	1323.539	14.44
Fmin [kN]	-1213.27	-1430.88	17.94
Vmax [kN]	5.676	488.543	8507.17
Mmax [kN.m]	0.101	17.997	17718.81
Mmin [kN.m]	-0.096	-19.497	20209.38

Table 4 : Comparison of results before and after model calibration updating

Figure 6 shows that the points of maximum stresses are the same in both models, however, the intensity of the stress is much larger in the calibrated model.

Figure 6 : Normalized maximum stress. (a) non calibrated, (b) calibrated model.

4 CONCLUSIONS

In this paper, modal testing and finite element model updating of a steel hollow tapered tower were presented. A 3D finite element model of the tower was developed using the SAP2000 software. Dynamic tests were performed using the impact hammer technique and also ambient vibration testing, in order to extract the natural frequencies of the tower. The FEM model was calibrated changing the boundary conditions, but also including some geometric characteristics complemented by better detailing of some uncertain modeling parameters.

Based on the results of this study, the following conclusions can be made with respect to differences in dynamic characteristics: reduction of 25% in the first natural frequency of the tower from the initial FEM model to the final calibrated model, and a reduction of 29% for the second natural frequency; considerable changes in the form of the 1st and 2nd mode shapes. With respect to differences in the static behavior of the structure, results showed: a 25% increase in tower top displacement; the compression force is the one with the smaller differences, with an increase of around 14% to 18% in maximum and minimum values; the major differences in calculated values occur in the base shear and the base moment values, with increases ranging from 8500% to 20200% but maintaining the location of the points of maximum stresses.

These results show the importance and the need of calibrating FEM numerical models to properly represent the real dynamic behavior of the steel structures.

Abstract

The telecommunications sector is a fundamental pillar of today's society. The answer to the need for constant communication is based on a network of structures, that allows the uninterrupted functioning of the communication system. Among these structures of the communication infrastructure are the so-called telecommunications towers, which are fundamental elements for the functioning of the system. Therefore, given the importance and actual demand for these structures, there is a great need for a deep knowledge of their behaviour, to find more economically viable and safer solutions. Since the wind action is in fact the most significant and conditioning for the design of this type of structures, this work focusses on the study of different bracing schemes, which were divided into three groups differing by specific parameters or even locations. Starting from a base or initial model of a lattice tower designed according to Eurocodes (EC1 and EC3), five conceptual tower models were redesigned with different lay-out schemes, but without changing the territorial location and their height and width. These models were analysed and compared to understand how different bracing schemes can affected the wind action determination and what are their consequences on the behaviour of the structures and their design.

Keywords: Lattice towers, wind loading action, EN 1991-1-4, EN 1993-3-1, parametric study on bracing.

1 INTRODUCTION

The development of today's society is also strongly linked to the ease and speed of communication and information sharing, and so it is not difficult to understand the importance of telecommunications towers, commonly present in the urban landscape and elsewhere. These structures, normally of great height, have as main objective the placement of transmission equipment on its top that allows the adequate transmission of signals. With an increasing use of mobile phones and the offer of services such as channel television, there is a greater need for the implantation of these structures to guarantee a good quality of all the services provided [1]. But despite the great importance of telecommunications towers to society, these structures exhibit statistically a higher number of failures when compared with many other structures [2]. Thus, it is essential to understand the behaviour of these structures, so that it is possible to design them as economically viable as possible, but still complying with safety criteria.

This work focusses on the study of different bracing schemes, which can be divided into three groups differing by specific parameters or even locations; a change or modification done to a specific tower parameter causes re-sizing of structural members to satisfy the structural design conditions for the tower wind actions at the implantation site [3]. Starting from a base model of a lattice tower designed according to Eurocodes (EC1 and EC3), conceptual tower models were redesigned with different lay-out of bracing schemes, but without changing the territorial location and the tower height and width. These models were analysed and compared to understand how different bracing schemes can affected the wind action determination and what are their consequences on the behaviour of the structures and their design.

2 DESCRIPTION OF CONCEPTUAL TOWER MODELS

2.1 Initial Tower Model for Reference Comparison

The initial model of the tower, predesigned by the industrial partner Metalgalva - Irmãos Silva SA according to this metalo-mechanical company experience on lattice towers and its industrial production characteristics (including delivery and assemblage at specific locations), consists of a self-supporting lattice tower with a triangular section 100 meters high and 15 meters wide at the base.

The tower can be divided into two distinct tower segments: the first or lower segment, from the base to about two thirds of the height, up to 72.5 meters, uses the K-typology scheme as the main bracing system in elevation along the height; the second or upper segment, in the last 27.5 meters, uses lattice diagonal bracing because this tower segment width is much smaller.

The diaphragms, which constitute horizontal stiffening zones or horizontal bracing systems, are spaced 6 meters apart up to 72.5 meters in height of the first tower segment; in the last 27.5 meters, the diaphragms of the second tower segment are spaced 3 meters apart.

Table 1 indicates the characteristics of the initial tower model; and Figure 1 shows the general 3D layout.

Table 1 : Characteristics of the initial tower model

Total height	100 m
Top width	3 m
Base width	15 m
Number of sub-segments (12+10)	22
Type of profile used	Circular
Steel class	S 355
Ultimate stress (f_u)	510 MPa
Yield stress (f_y)	355 MPa
Elasticity modulus (E)	210 000 MPa
Distortion modulus (G)	81 000 MPa
Poisson coefficient (ν)	0.3
Coefficient of thermal expansion (α)	$12 \times 10^{-6} / ^\circ\text{C}$

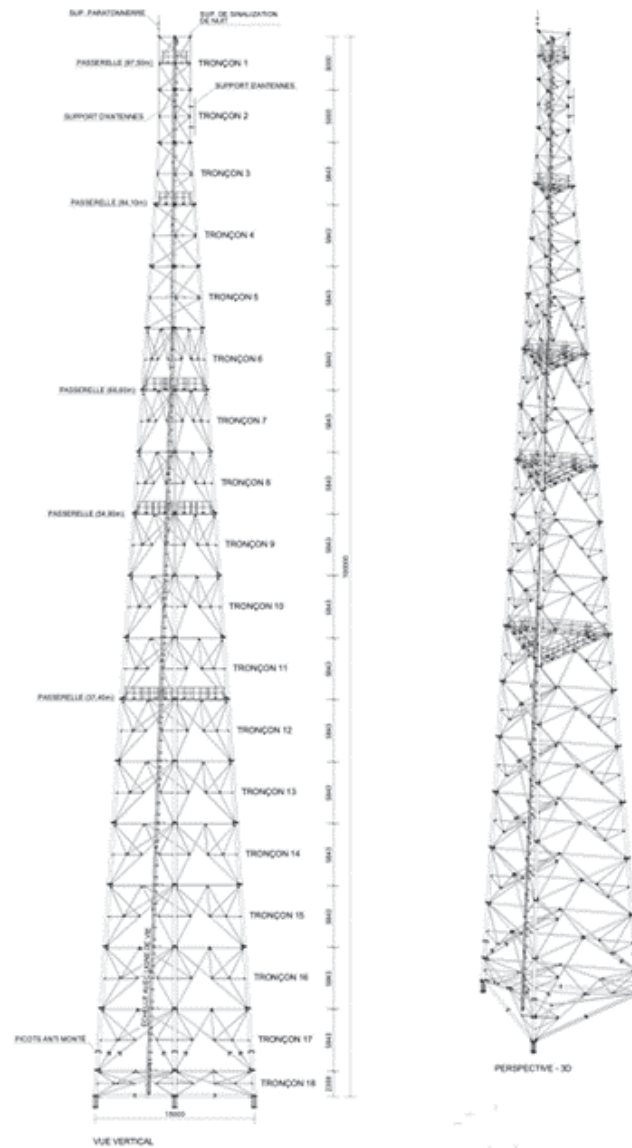

Figure 1 : Initial tower model.

2.2 Tower Model A

This tower model A (shown in Figure 2) is very similar to the initial tower model, the only change occurring in the upper tower segment with a truss system where a new circular profile member was added in the opposite direction to the existing one; therefore, making it a cross (or X) bracing system instead of the diagonal bracing of the initial tower model.

This alteration attributes a greater stiffness to the altered upper tower segment, increasing its torsional stiffness; however, with the addition of the diagonals, the exposure area to wind actions increases.

Figure 2 : Tower model A.

2.3 Tower Model B

In tower model B (shown in Figure 3 (a)), the change made consists of varying the spacing between the horizontal diaphragms bracing system. Such change occurred only in the first third part of the structure, up to 37 meters in height, and the spacing chosen between diaphragm levels is 4 meters.

2.4 Tower Model C

The tower model C (shown in Figure 3 (b)) is like tower model B, but now studying the variation of results for a chosen spacing of 5 meters between horizontal diaphragms in the first 37 meters of the tower structure; so, initial tower model has horizontal diaphragm bracing system with 6 meters spacing, while for tower models B and C, such spacing is of 4 meters and 5 meters respectively.

Figure 3 : (a) Tower model B ; (b) Tower model C.

2.5 Tower Model D

The development of the tower model D aims to analyse the structure's behaviour in case the main bracing system in elevation is altered in the first third part of the structure, up to 37 meters in height, from the original “K” bracing system to a discontinuous bracing system; as shown in Figure 4 (a), this tower model D still presents the continuous horizontal diaphragm bracing system at specific horizontal intersections.

2.6 Tower Model E

The tower model E shown in Figure 4 (b), like the tower model D, also aims to study how some alterations of the bracing system influences the operation of the tower, using another variation of discontinuous main bracing system in elevation. In this model tower E, the main “K” bracing system that exists in elevation in the original tower was replaced entirely up to 72.5 meters in height, by a discontinuous bracing locking system in elevation, but still with continuous horizontal diaphragm bracing system at specific horizontal intersections.

Figure 4 : (a) Tower model D ; (b) Tower model E.

In Table 2 a brief synthesis is given about the six tower models designed and analysed in this parametric study, but still complying with the metal-mechanical company experience on lattice towers and its industrial production characteristics. For each design alternative, emphasis is given to the final total weight of the tower (directly related to costs) and to the exposed area to wind in each tower face or incidence plane to wind.

Table 2 : Final weight and exposed areas, for alternative tower models

Tower label	Total weight of tower (kgf) ; 1 kgf \approx 0.01 kN	Exposed area per face (m ²)
Initial tower model	22354.13	95
Tower model A	23366.31	95.5
Tower model B	29610.04	114
Tower model C	27087.03	108
Tower model D	21928.05	93
Tower model E	21995.66	90

3 WIND ACTIONS ON THE TOWERS

The design guidelines for the regulatory normative of the wind actions on the towers, were the corresponding parts of Eurocodes EC1 and EC3 namely EN 1991-1-4 [4] and 1993-3-1 [5]. Additional comprehensive bibliography used as support were the book chapter of Barros *et al.* [6] and the article of Calostescu [7]. Also the graduation master's thesis of the second co-author [8] details the remaining expressions and calculations.

3.1 Wind velocity and dynamic wind pressure

The tower is located in Zone B mentioned in NP EN1991-1-4/NA [4], to which corresponds a reference wind base velocity of 30 m/s; the adopted orography coefficient was $c_o(z)=1$.

For ground category II, parameters z_0 and z_{min} are respectively $z_0=0.05$ m and $z_{min}=2$ m.

The turbulence coefficient K_f used, was the recommended value of 1. Using specific mass of air $\rho_{air} = 1.25 \text{ kg/m}^3$ – mentioned in clause 4.5 (1) of Eurocode 1 - EN 1991-1-4 [4] – and resorting to the expressions of EC1 [4] and EC3 [5] with respect to characterization of wind actions (by one of the two methodologies in Eurocode annexes), or to the expressions also used in the abovementioned comprehensive bibliography of Barros *et al.* [6] and Calostescu [7], Table 3 can be systematically obtained. The last two columns in this table (calculation procedure of wind actions - step I) present respectively the dynamic wind pressure (in Pa) and the wind peak velocity (in m/s) at 18 section levels (limiting distinct tower panels), in which the towers were discretized along height at specific elevations z (in m) for improving more accurate determination of distributed wind related quantities.

Table 3 : Calculation procedure - step I

Section	z (m)	v_m (m/s)	$C_f(z)$	I_v	q_p (Pa)	V_{peak} (m/s)

18	100	43,325	1,444	0,131	2253,588	60,047

3.2 Wind force coefficient

The coefficient of wind force of a lattice metallic tower C_f , depends on the index of filled parts φ defined as the ratio between the solid area per panel and the area of the panel if it was completely filled. In this determination of the coefficient of wind force required for the calculation of wind actions, it is conservatively assumed that the tower is subjected to a super-critical wind flow. For lattice towers of triangular cross section, made of equilateral triangles, the wind causes the maximum drag when its direction is normal to the face, as [9]. So it is going to be considered in these analyses a null or zero angle of attack, that is the wind acts normal to the face of the tower ($\theta = 0^\circ$) and then the wind incidence factor $K_\theta = 1$.

Table 4 details for the section levels associated with tower panels, the calculation procedure of wind actions - step II: index of filled parts, and corresponding wind force coefficient.

Table 4 : Calculation procedure - step II

18	100	0,153	1,083

3.3 Structural coefficient

For the determination of the structural coefficient $C_s C_d$ the dynamic parameters of the tower were obtained using a finite element method model. The first vibration mode has a frequency very close to unit, so that (in Eurocodes symbology) $n_1=1$; also, for the logarithmic decrement of structural damping, the value $\delta_s = 0.05$ was assumed. The remaining intermediate values necessary for the calculation of the structural coefficients are shown in the following Table 5 through Table 7; for more details, refer to [6] [7] [8].

3.4 Wind forces

The wind forces are calculated using the following equation

$$F_w = c_s c_d c_f q_p(z_s) A_{ref} \quad (1)$$

which was shown in detail and with its used explained, in the third chapter of [8].

In Table 8 are presented the quantities used for the calculation of wind force, the wind force value, and the wind force value per node in each panel; again, for more details, refer to [6] [7] [8].

Table 8 : Calculation procedure - step IV

Section	z (m)	$C_s C_D$	$I_v(z)$	q_p (Pa)	A_{ref} (m ²)	F_w (kN)	F_w per node (kN)
1	2,37	0,706	0,259	850,818	5,466	3,56	1,19

3.5 Wind forces on equipment auxiliary structures

For the calculation of the forces acting on equipment auxiliary structures, an equipment exposed area of 30 m² was allowed in the last 10 meters from the top of the tower. Account was also taken on the existence of an access staircase throughout the height of the tower, as well as 0.30 m of cablings width across the height.

Table 9 shows the values of wind forces in auxiliary structures, and their section level of actuation.

Table 9 : Wind forces on equipment auxiliary structures

7	1,35	0,45
9	1,20	0,40
16	11,8	3,83
17	11,64	3,88
18	11,72	3,91

3.6 Combinations of actions

The combinations of actions used in this parametric study for the ultimate limit state (ULS) are shown in Tables 10-11-12. Tables 10 and 11, detail the conditioning combinations for the determination of generalized forces; and Table 12 details the conditioning combination for the determination of displacements.

Table 13 details the conditioning combination of actions used in this parametric study for the determination of displacements under the serviceability limit state (SLS).

For a better understanding of the combinations detailed, the nomenclature used and its meaning is the following: PP refers to self-weight; Wind_Y+ refers to wind acting along the direction Y+ ; Wind_Y- refers to wind acting along the direction Y- ; Wind_X refers to wind acting along the direction X ; PLAT SW refers to platform self-weight; PLAT LL refers to platform live load.

Table 10 : Combination of actions for ULS – generalized forces (1st combination)

4 ANALYSIS OF RESULTS

Table 14 shows the values of the generalized reactions at the base of the towers, obtained at each tower model analysed in accordance with the ULS combinations of Tables 10 and 11. These generalized reactions are respectively the force reactions in the horizontal base plane (F_x and F_y) and the vertical force reaction F_z ; as well as the two moment reactions M_x and M_y at the base of the towers.

Table 14 : Values of Reactions at the base of the towers for ULS

Tower label	Fx (kN)		Fy (kN)		Fz (kN)		Mx (kNm)	My (kNm)
	Max	Mín	Max	Mín	Max	Mín		
Initial tower model	72	-134	142	-170	1330	-1148	17294	15855
Tower model A	74	-139	148	-176	1401	-1212	18213	16774
Tower model B	77	-142	142	-178	1378	-1144	17914	16041
Tower model C	77	-140	149	-181	1381	-1164	17953	16178
Tower model D	74	-134	144	-171	1321	-1141	17173	15817
Tower model E	71	-131	140	-167	1321	-1141	17173	15772

From the analysis of the results of this parametric study, each tower identity or parameter of change can be easily distinguished. Tower model A has the highest bending moments (M_x and M_y) at the base due to the increase in the wind force because of the increase in the exposure area of this model has been made at the top of the structure, greatly influencing the value of the moments at the base.

In the tower models B and C, the two bending moments at the base are superior to the moments at the base of the initial tower model: for reasons already explained above, and also because the compromise between increased wind action and increased stiffness (due to the resizing) did not prove to be beneficial at this point.

In the tower models D and E, the two bending moments at the base are slightly lower than the moments at the base of the initial tower model: because the action of the wind on these tower models is slightly less than the action of the wind on the original tower, thus generating smaller moments.

Regarding the values of the generalized displacements (lateral displacements and torsional rotation through vertical global axis) in accordance with the SLS combination of Table 13, their results are presented in Table 15 for the top as well as for sections at two-thirds and one-third of the tower height (H).

Table 15 : Values of lateral displacements and rotations, for the SLS

Tower model	Lateral displacement (cm)			Rotation along vertical axis (°)		
	Top	2/3 H	1/3 H	Top	2/3 H	1/3 H
Initial tower	31,1	14,7	3,9	0,526	0,321	0,134
Tower A	32,9	15,6	4,1	0,497	0,351	0,139
Tower B	32	15,2	4,1	0,532	0,327	0,123
Tower C	32	15,1	4	0,531	0,330	0,128
Tower D	31,2	14,8	4	0,523	0,321	0,131
Tower E	32,1	15,5	4	0,529	0,325	0,160

In general, it is observed that the difference in lateral displacements is not significant: of the order of 1 cm in the top section for models A-B-C-E, and 1 mm for model D; much smaller differences at the other tower sections. With regards to rotation along vertical axis, all the tower models have rotation values quite identical, except the top rotation of tower model A; in fact, for this tower model A the maximum rotation is 5% to 7% lower than maximum rotation of the other tower models. This could be expected because the increase of the stiffness of the top third part of the tower structure (above 72.5 m) by adding an additional diagonal member, converting the initial diagonal bracing into a cross X-bracing, leads to an expected reduction of torsional rotations at the top tower levels.

5 CONCLUSIONS

All the proposed tower models were resized or redesigned, leading to changes in the type of circular profile used in various sections and in the total number of elements used. These changes, besides leading to different structural responses when the towers were subject to wind action (as previously explained and analysed), also lead to different costs of the models proposed tower structures. Table 16 shows an estimate of the total weight of each tower and an estimate of the price of each tower, considering a market value for the steel price of around 2.5 euros per kilogram-force of weight.

In view of the foregoing considerations -- both in terms of the generalized reaction values and generalized displacements, and in terms of estimated total cost associated with the studied solutions in this parametric study -- it is thought that, in addition to the original solution associated with the initial tower model structure, the most indicated alternatives may be the tower models D and E.

Table 16 : Cost estimate of the tower models

Tower model	Total weight of tower (kgf) ; 1 kgf \approx 0.01 kN	Cost estimate of tower (Euro)
Initial tower	22354.13	55885.33
Tower A	23366.31	58415.79
Tower B	29610.04	74025.09
Tower C	27087.03	67717.57
Tower D	21928.05	54820.13
Tower E	21995.66	54989.14

Abstract

A large amount of world population lives nowadays in earthen buildings, often constructed only based on construction practice and within earthquake-prone regions. In the recent history, several strong earthquakes had dramatic consequences on these structures, highlighting their significant seismic vulnerability due to multiple reasons, such as poor mechanical properties, poor detailing, and large inertia mass. Several aspects of seismic performance of existing earthen constructions need to be investigated through full-scale experimental testing. In this regard, the present study aims at contributing to the investigation by testing a full-scale adobe masonry wall with a central door-type opening under in-plane lateral loading with cyclic fashion. The mechanical behaviour of materials, specimen's design, loading protocol and instrumentation setup are described. The experimental response curves, observed damage evolution and failure mode are discussed, especially focusing on dissipation capacity of the wall.

Keywords: Full-scale tests; Adobe masonry; Walls; Cyclic tests; Seismic capacity.

1 INTRODUCTION

Unreinforced masonry (URM) structures represented the most popular solution for buildings adopted in many countries up to the last century, when other construction technologies became progressively more common [1]. Thus, a large portion of the existing building stock around the world is made of URM structures, often within high-seismicity regions such as Europe and Pacific Rim countries [2]. Among URM typologies, adobe masonry (AM) represents one of the most ancient and widespread for historical construction as well as currently still used for construction of low-cost dwellings in less developed areas of the world [3-4]. Recently, several reconnaissance missions after strong earthquakes [5-9] revealed the considerable vulnerability of existing URM structures, with severe damages and frequent global collapses resulting in significant losses.

This framework led researchers in increasing interest on the seismic assessment and retrofitting of URM members during last few decades, resulting in numerous experimental investigations. Firstly, these studies were mainly focused on the mechanical behaviour of URM walls representative of masonry piers, on the basis that these latter governed seismic response of the structure, whereas spandrel panels were considered secondary elements [10-11, among many others]. Then, several studies established the key role of spandrel panels in load-carrying capacity under lateral actions [12-13], thus several testing programs were performed on both reduced-scale full-buildings and spandrels. Benedetti et al. [14] presented the experimental results of 24 shaking-table tests on 1:2 scaled models of two-story masonry buildings before and after cracks-repairing and strengthening of spandrels. The as-built specimens were characterized by severe cracks localized on spandrel-panels and showed higher capacity than strengthened ones for which critical damage occurred in the piers resulting in premature collapse. A full-scale prototype of two-story URM building was tested under increasing cyclic lateral load in both as-built and strengthened conditions by Moon and his co-authors [2, 15]. A combined strengthening system was applied to the structure, made of fibre reinforced plastic e post-tensioning devices, proving to be considerably effective in improving original seismic capacity. Bothara et al. [1] performed a shaking-table test on a half-scale model of an existing New Zeland URM structure with two stories, gable walls, inclined roof and slightly eccentricity. The unreinforced test-building was prior shacked along longitudinal direction, then repaired and tested in the opposite direction. Intense rocking and out-of-plane phenomena were observed, especially on gable walls and experimentally-based fragility curves were derived. The results of an experimental campaign on URM spandrels were presented in [16-18]. Specific testing setups were realized in order to reproduce piers constraint effects and properly apply the cyclic lateral loading. Different spandrel configurations were tested showing that their strength and failure modes were governed by the axial load acting along the member. Chourasia et al. [19] carried out quasi-static cyclic tests on full-scale single-room URM building composed of four orthogonal walls connected to a reinforced concrete (RC) slab on top, before and after strengthening by means of RC bands. Typical Indian materials were adopted for masonry. Brittle failure was observed for the unreinforced specimen, with huge diagonal cracks and sliding of RC roof, whereas the repaired one showed substantial strength improvement.

A first example of in-plane cyclic testing on full-sized URM wall with door-opening representative of a structural sub-assembly was reported in [20]. Firstly, monotonically increasing lateral load was applied until damage occurred in the spandrel. Then, this latter was strengthened by means of inorganic reinforced matrix and further cyclic tests were carried out on the wall. Experimental evidence showed that most of the observed damage was localized in the spandrel-panel, whereas rocking of piers governed the hysteretic response, and the

strengthening system was effective in improving lateral response. Knox and his co-authors presented two experimental studies [21-22] focusing on the influence of spandrel panels on the mechanical response of URM structures under in-plane cyclic lateral loads. Pier-spandrel sub-assemblages were tested in [21] in which different failure modes of the whole structure were observed depending on different spandrel's aspect-ratio (namely, height-to-width ratio). The experimental outcomes derived from testing a half-scale two-story perforated (i.e., with multiple door- and window-type openings) URM wall were provided in [22]. The shallow spandrels behaved as coupling beams for masonry piers which were governed by rocking mechanism resulting in an elastic-perfectly plastic response with notable displacement ductility. More recently, an experimental and numerical study was carried out by Choudhury et al. [23] on typical Indian URM buildings. Specifically, the Authors performed cyclic in-plane tests on three different full-scale walls (respectively, with a door in the middle, a window in the centre and a solid wall) and a single-story one-room building, observing combined flexural action and sliding shear. Finally, Howlader et al. [24] experimentally investigated in-plane cyclic response of eight full-scale URM walls with semi-circular arched openings and materials typical of Australian last-century constructions. Specimens were different in terms of dimensions of spandrels and piers as well as imposed vertical loads. The observed lateral load capacity and failure modes were governed by changes in wall geometry.

The experimental study presented in this paper fits in this line of research focusing on the mechanical response of a perforated adobe masonry wall, with a central door-type opening, under quasi-static in-plane cyclic loading. Notice that, currently, no similar experimental studies are available in literature. A proper experimental characterization carried out for the adopted materials, i.e. adobe bricks and mud mortar representative of existing Italian earthen buildings and largely widespread in Sardinia island [25-26], is described according to a multiscale approach. Then, geometry of the wall specimen and details of the experimental program are illustrated. Then, test results are presented and discussed in terms of both observed damage and response curves.

2 EXPERIMENTAL PROGRAM

A full-scale AM wall with a central door-type opening was constructed within the structural laboratory at the University of Naples Federico II. The wall specimen was tested into place under cyclically increasing lateral displacements and constant vertical loading. In the following, a detailed description of material properties is reported according to a multiscale approach, from constituents to the behaviour of the adobe masonry under uniaxial compression and shear. Then, the geometry of the wall specimen, test set-up and monitoring instrumentation along with loading protocol are described.

2.1 Material properties

The wall specimen was made of adobe bricks and mud mortar. Bricks were obtained by reproducing the non-industrial manufacturing process, mainly based on the worker's experience, in compliance with Sardinian construction practice. Local soil, classified as clayey-silty sand, was mixed with water and straw fibres by volume. Specifically, randomly oriented straw fibres with different dimensions were added to a first soil/water mixture. Subsequently, some water or soil was added based on the mixture appearance evaluated by the manufacturer. Then, the final form was achieved by filling a prismatic wood formwork characterized by internal grooved surface and the wet brick was left to dry to the sun. On average, straw fibres had diameter equal to 3 mm, 70 mm length and 0.64% percentage by weight. Density and water content were 2.68 g/cm³ and 27%, respectively. Each adobe bricks was 200×400×100 mm³ in

size. The resulting mean unit weight was equal to 16.80 kN/m^3 with a very limited coefficient of variation ($\text{CoV} = 2\%$). Mud mortar used for masonry joints had same particle size of earth bricks, but no fibres were added to the mixture as typical of Sardinian adobe masonry [25, 27]. Nevertheless, a different amount of water was added during the mixing operations until a 20% optimal water content by volume was reached, in tune with trend from literature [28]. More detailed description of the production process and physical properties can be found in [26].

Mechanical properties of both adobe bricks and mud mortar were derived through uniaxial compression and three-point bending tests. Overall, compressive standard tests [29] were performed on 6 and 36 cubic specimens, respectively for mortar and bricks, from which mean values of compressive strength (f_c) equal to 0.50 MPa ($\text{CoV} = 14\%$) and 1.08 MPa ($\text{CoV} = 36\%$) were derived. Standard three-point bending tests on specimens $40 \times 40 \times 160 \text{ mm}^3$, in compliance with the European standard EN 1015-11 [30], were carried out for assessing tensile properties. In this case, for the adobe bricks test-specimens were extracted from original units, whereas for mortar characterization they were moulded into standard formwork. A total of 8 tests were performed on mud mortar and 36 on adobe bricks. Notice that higher number of experimental tests were systematically conducted for bricks in order to properly taking into account the further source of variability in mechanical response due to straw fibres with respect to mud mortar. On average, tensile strength (f_t) of adobe bricks was 0.56 MPa ($\text{CoV} = 36\%$) whereas a lower value ($f_t = 0.45$) was obtained for mud mortar, as expected due to absence of fibres reinforcement, with CoV equal to 20%. Typical observed failure modes of tested specimens in tension and compression are shown in Figure 1. Furthermore, main materials mechanical properties are summarized in Table 1.

Figure 1: Typical failure modes of material test specimens in tension (a) and compression (b).

Material	f_c [MPa]	f_t [MPa]	E_c [MPa]	E_t [MPa]
Bricks	1.08 (36%)	0.56 (36%)	143 (40%)	69 (29%)
Mortar	0.50 (14%)	0.45 (20%)	47.5 (35%)	20.5 (33%)

* Coefficient of variation reported in round brackets.

Table 1: Main mechanical properties of AM constituents*.

2.2 Experimental characterization of adobe masonry under uniaxial compression and shear

In addition to base materials, associated to bricks and mortar, the mechanical behaviour of the adobe masonry used for construction of the wall specimen was furtherly investigated by testing at the level of the elementary sub-assembly. Specifically, mechanical properties of adobe masonry wallets under compression and shear, respectively, were assessed by means of uniaxial compression and diagonal compression tests.

Uniaxial compression tests were carried out on 8 adobe masonry single-leaf running-bond wallets with size $610 \times 650 \times 200 \text{ mm}^3$, composed of six horizontal courses and 10-mm-thick mud mortar joints. Wallets were subjected to monotonically increasing vertical displacement by means of a universal electro-hydraulic testing machine with a 2000 kN force capacity and total stroke of $\pm 150 \text{ mm}$. In order to achieve uniform distribution of axial stress a rigid steel beam was interposed between machine loading head and top of masonry prism. A load cell was used to measure applied force acting on specimen, whereas the deformations were measured by means of a specific monitoring-system composed of linear variable displacement transducers (LVDTs) installed vertically in the middle of the panel and horizontally along specimen's thickness to monitor splitting phenomena at failure. Normal stress (σ) was derived considering the gross cross-section of the wallet whereas vertical strain (ε) was computed from records of vertical LVDTs.

For all specimens, failure mode was characterized by cracks along compressive isostatic lines, involving both bricks and joints (see Figure 2a,b), and considerable splitting observed within specimen thickness. Resulting stress-strain (σ - ε) curves are reported in Figure 2c. Compressive strength of the adobe masonry ($f_{c,am}$) was equal to 1.32 MPa, on average, slightly higher than bricks, with low dispersion (CoV = 8%). Conversely, larger scatter was recorded for Young's modulus ($E_{c,m}$), evaluated at half peak-stress, the mean value of which was 425.4 MPa with CoV = 25%.

Figure 2: Typical damage state corresponding to compression failure (a,b) and stress-strain response curves (c).

Shear response of AM masonry was assessed by means of diagonal compression tests on seven wallets of total size of $410 \times 1230 \times 1230 \text{ mm}^3$ and running bond configuration. Such specimens were built on specific supports in order to allow for the execution of testing by means of the portable loading set-up depicted in Figure 3a. This latter was composed of a steel closed reaction-system acting as contrast to ejection of the hydraulic-jack interposed on the specimen. The adopted testing set-up was able to reduce either disturbance of wallets due

to transportation to laboratory and preparation time. The testing machine reached maximum load of 500 kN and total stroke equal to ± 75 mm. Double pair of linear variable differential transformers (LVDTs), with 400 mm gauge length, were installed in the middle of masonry external panels to monitoring the deformations along specimen's diagonal. Experimental records were processed according to the American standard ASTM E519-15 [31] in order to derive shear stress and strain (τ - γ). Typical final damage state is reported in Figure 3b. Diagonal-tension failure mode occurred with cracking patterns characterized by wide passing-through diagonal cracks generally involving both joints and bricks. Response τ - γ curves of all tested wallets are shown in Figure 3c. AM specimens were characterised by a pseudo-elastic branch up to peak shear stress followed by limited softening until collapse occurred. Post-peak softening response was considerably different among specimens. Peak shear stress ($\tau_{max,m}$) equal to 0.107 MPa was obtained on average, with limited dispersion (CoV = 7%), whereas the mean value of the initial shear modulus (G_i), assumed as secant at $\tau_{max}/4$, was equal to 185 MPa (CoV = 33%).

Table 2 summarizes strength and stiffness mean properties obtained for elementary AM sub-assembly under axial compression and shear along with their CoV.

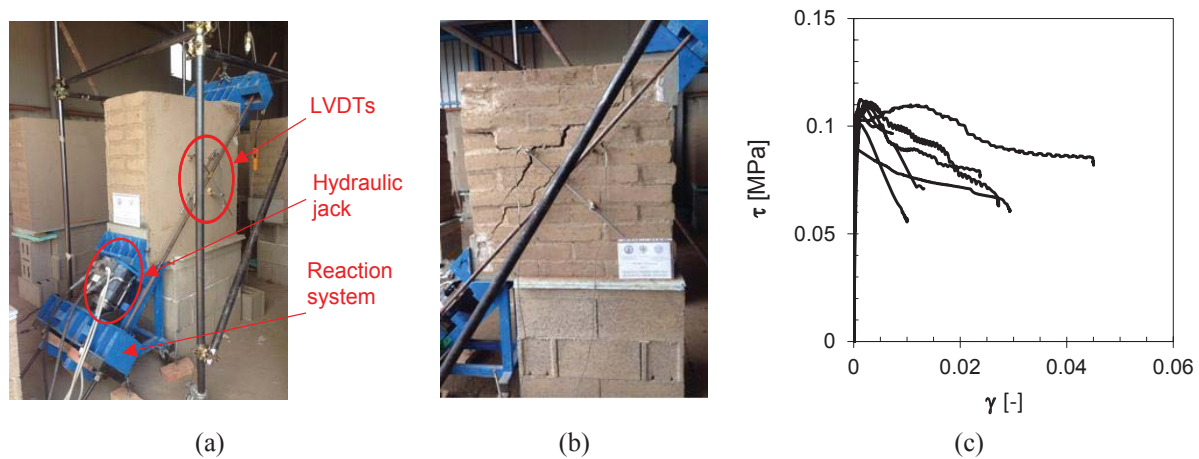

Figure 3: Diagonal compression tests on AM wallets: test set-up (a), typical failure mode (b), τ - γ curves (c).

Statistic	Compressive properties		Shear properties

2.3 Geometry of the specimen

The AM specimens was a full-scale single-leaf masonry wall with a door-type opening in the middle-length (Figure 4). The latter was 1.70 m-long and 2.00 m-high. The two adjacent masonry piers had same opening's dimensions and were interconnected by a spandrel panel with height of 1.00 m. Three masonry layers were built above the piers in order to ensure proper vertical-load distribution. At the spandrel-panel intrados a wooden lintel was installed

with 150 mm anchorage-length within the piers. Therefore, the wall had total height and length equal to 3.60 m and 5.10 m, respectively, and 400 mm thickness.

Figure 4: Frontal and lateral views of the adobe wall specimen (dimensions in m).

2.4 Test set-up and instrumentation

The specimen was erected on a rigid reinforced concrete (RC) beam, acting as wall-foundation. Such basement was anchored to the strong floor of the testing laboratory by means of pre-tensioned high-strength steel rebars. Vertical load on piers, kept constant during the test, was applied by means of two hydraulic jacks (one for each pier). Each hydraulic jack pushed against a steel reaction closed-system made of a rigid short beam, perpendicular to the wall, to which two steel rebars were connected. These latter were hinged to both ends so that any parasite contribution of the test set-up to the overall response of the specimen was prevented. Similarly, spherical hinges were introduced in-between hydraulic jack and the overlying beam. In order to uniformly distributing the vertical load, two rigid I-beam were interposed between hydraulic-jacks and pier tops, on which levelled mortar layers were priorly realized. Horizontal cyclic displacement was applied to the wall top by means of a servo-hydraulic actuator, with a nominal capacity of 1250 kN and ± 25 cm stroke, anchored to a vertical RC contrast. The actuator was equipped with a hinged head, with the aim to accommodate the actual deformed shape of the wall, fixed to a steel collar made of a couple of rigid plates located on the opposite sides of the wall and interconnected each-other by means of six steel bars, slightly pre-tensioned.

Main deformation sources were monitored during the test by means of a proper instrumentation system installed on both front and back sides of the wall specimen. Specifically, on the front side, a total of eight linear variable differential transformers (LVDTs) were installed at the location of critical end sections of the piers and central spandrel element, in order to measure axial displacements due to bending. On the backside, specific vertical LVDTs were mounted piers/foundation interface in order to measure the width of rocking-induced cracks. Those displacement transducers were complemented by two couples of vertical wire potentiometers (PTs) that measured the axial and bending deformations of each pier. Additional PTs were arranged along diagonals of piers and spandrel panel with the aim of monitoring shear deformations. Finally, a horizontal PT was installed at the same elevation of the actuator (i.e., $y = 3055$ mm) and connected to a wall edge.

Figure 5: Test set-up and instrumentation installed on the adobe wall specimen before testing.

2.5 Loading protocol

Load application was performed in two consecutive stages. Firstly, vertical loads were applied on top of piers under force control in order to simulate gravity loads transferred by an ideal floor. After that effective contrast between jacks and piers were obtained, the axial load on piers was monotonically increased according to a force rate equal to 1 kN/s until load value of 88 kN was reached (corresponding to 10% of the mean ultimate load of pier cross sections). Then, such value was kept constant during the second stage of the test when in-plane horizontal cyclic displacement was applied to the wall corresponding to the top of the spandrel, reproducing slab/wall transfer. The cyclic displacement history was composed of increasing displacement blocks of three cycles at a given amplitude peak until failure was observed. The amplitude was increased between consecutive blocks of 5.6 mm. The displacement rate was set at 0.70 mm/s. The cyclic displacement history is shown in Figure 6. A sampling rate equal to 5 Hz was of all instruments to ensure a proper monitoring of deformations during the entire test. The positive orientation was assumed as associated to a pushing action of the actuator. A total number of twelve displacement cycles were imposed on the specimen for a maximum displacement reached equal to 33.6 mm.

Figure 6: Cyclic displacement time history.

3 OBSERVED DAMAGE AND FAILURE MODE

Figure 7 shows the damage occurred to the specimen at the end of the experimental test. Horizontal cracks were observed on both sides of the spandrel panel along different bed joints and extended to the whole length. On the lower part of the spandrel, in the proximity of the lintel, a partially inclined crack was observed towards the left-hand side end. Such a crack pattern is representative of shear failure mode. Overall, a quite moderate damage was observed on the spandrel. Conversely, both piers suffered large cracks on the bottom part. Specifically, sub-horizontal cracks concentrated in the first six/seven masonry layers from the base were firstly observed, subsequently evolving along inclined directions, mainly developed along mortar-joints. Corresponding to peak load condition, vertical cracks were observed within piers thickness due to failure of masonry in the compressed zone. Therefore, bending failure was experienced by the piers. Beyond the peak load, the wide cracks located at the base of the piers caused piers buckling and the experimental test was arrested when significant out-of-plane deformations were identified.

Figure 7: Damages observed on the specimen at the end of the experimental test.

4 RESPONSE CURVES

The horizontal load recorded by the actuator load-cell is plotted against the horizontal displacement measured by the PT positioned at the same height in Figure 8. Globally, the hysteresis curve appears quite symmetrical both in force and displacement for the first three cycles, whereas the fourth group of cycles was slightly asymmetrical due to onset of vertical cracks widening and piers buckling. The maximum horizontal force was reached in the positive orientation and was equal to 86.4 kN, whereas 81.4 kN peak force was recorded in the opposite orientation. By assuming the lateral resisting force as the average of such values ($F_{max} = 83.9$ kN), a load-capacity value equal to approximately 31% of vertical load (apart from the effect of self-weight) was reached by the AM wall. Therefore, an in-plane acceleration-capacity of 0.31g can be assumed for the specimens. The experimental test was stopped during the first cycle of the fifth loading block when a horizontal force of 61.4 kN was attained on the last positive displacement cycle, evidencing approximately a 25% reduction in lateral resistance, for which evident out-of-plane deformations were observed. Regarding the deformation ca-

capacity of the adobe wall, the maximum horizontal displacements reached in the positive and negative orientations of lateral loading were respectively equal to 31.81 mm and 34.50 mm.

Figure 8: Force-displacement (F - d) curve recorded during the experimental test.

The experimental response curve of the AM wall is reported in Figure 9 as backbone of the hysteresis cycles expressed in terms of lateral force versus inter-storey drift ratio (F - IDR), the latter assumed as the measured lateral displacement normalized to the height of the horizontal loading line from the base of the piers. Within the framework of seismic performance-based assessment of masonry structures, establishing a relationship between limit states and observed damage appears crucial for response assessment as well as repair costs. Therefore, on the envelope curve, three performance levels (PLs) were identified representative of significant limit states of the wall:

- elastic limit (PL1), corresponding to diffuse cracks on wall members and herein associated to $0.6F_{\max}$;
- peak condition (PL2), related to lateral peak-load attainment and for which severe damage was observed on the wall (such as, vertical cracks due to rupture of masonry under compression);
- ultimate limit state (PL3), identified when a drop in lateral force equal to $0.2F_{\max}$ was recorded and representative of incipient loss of load-bearing capacity for the wall.

Mean values, between positive and negative directions, of force (F) and inter-storey drift ratio (IDR) corresponding to the above-defined PLs are summarized in Table 3. The AM specimen reached a IDR value higher than 1.00% at failure, significant for a masonry structures, whereas peak condition was attained at about $IDR = 0.61\%$. Finally, the elastic behaviour was overcome at very early stage ($IDR = 0.02\%$).

PL1		PL2		PL2	
IDR	F	IDR	F	IDR	F
[%]	[kN]	[%]	[kN]	[%]	[kN]
0.023	50.3	0.606	83.9	1.043	67.1

5 CONCLUSIONS

In this study, the nonlinear response of a full-scale adobe masonry wall with a central door-type opening to cyclic lateral loading and constant vertical loading has been described. A detailed experimental characterization of masonry constituents, i.e. adobe bricks and mud mortar with peculiarities of existing Sardinian earthen dwellings, and of adobe masonry as a whole was carried out according to a multiscale approach. The geometry of the wall specimen, test set-up, measuring system and loading protocol have been described. Preliminary experimental results on the wall specimen have been discussed. Specifically, observed crack patterns and failure modes have been firstly described; then, damage states were related to the force-drift response by identifying specific performance levels. Based on such discussion, the following remarks can be pointed out:

- The wall specimen reached its lateral strength due to bending failure of masonry piers associated with extensive toe crushing at the base of piers.
- The spandrel panel suffered a relatively moderate damage, mainly due to shear action.
- The ultimate limit state of the wall was characterized by incipient loss of wall load-bearing capacity with visible out-of-plane deformations.
- The in-plane response of the wall was defined by premature cracking and relatively large ultimate inter-storey drift ratio, which was slightly larger than 1%.

Abstract

It is worldwide recognized the importance of assessing the vulnerability of structures in seismic prone zones. Focusing on steel structures, it is well-known that the behavior of beam-to-column connections plays a key role in the seismic response of any moment-resisting frame system. Recently, a research project funded by European Commission investigated the seismic performance of pre-qualified connections through numerical analyses and pseudo-static cyclic testing. From a designer perspective, it is, however, necessary to understand the efficiency of such connections in terms of building performance to take a rational and conscious decision when designing a building. With this in mind, this paper investigates the influence of different beam-to-column connections on the seismic response and vulnerability of medium-rise steel frame structures. The behavior of these structures has been investigated by means of non-linear dynamic analysis for increasing seismic intensity levels using the OpenSeesPy finite element software. The record selection has been carried out through the Average Sa-based method. The building performance has been assessed computing both maximum and residual interstory drifts, as well as fragility curves and absolute acceleration floor response spectra. The last mentioned enables to evaluate the likely damages experienced by acceleration sensitive non-structural elements, giving an additional point-of-view for estimating the building content performance. The outcomes of this study provide useful information for practitioners and designers interested in adopting the new set of pre-qualified connections, clarifying their effects on performance of common buildings and their content.

1 INTRODUCTION

The importance of explicit modeling for beam-to-column connections is well-known and recognized in literature with unanimous consensus [1]. The stiffness and strength of beam-of-column connections could affect both the static and dynamic response of structures, leading to unrealistic or unconservative results if their behavior is not adequately considered. To deal with such an issue, experimental data is necessary in order to study the hysteretic response of the connections and to calibrate numerical models that have to be accurate and computationally efficient at the same time. However, analyzing data available in literature, it appears evident that exhaustive test results on the cyclic response of different typologies of beam-column connections are still missing, which could call for further efforts towards standardization.

Following damage observed after the 1994 Northridge (CA, USA) earthquake to steel structures, some significant efforts have been done by US researchers to investigate the response of a wide set of selected joints, commonly adopted in moment-resisting frames (MRFs). The research outcomes allowed to conceive a specific standard [2] that describes criteria for design, detailing, fabrication, and quality of the set of pre-qualified connections.

Regarding the European context, a recent research project [3] tried to fulfill such gaps. The EQUALJOINTS project [3], funded by the European Commission, aimed at providing a qualification of European beam-to-column joints adopted for seismic design. In order to accomplish such a goal, this project selected a set of common joint configurations and focused on the standardization of design and manufacturing procedures. In particular, bolted haunched, bolted extended stiffened end-plate, bolted extended unstiffened end-plate and welded dog-bone joints were experimentally and numerically studied. From the results of the project, it is possible to obtain the cyclic hysteretic response curves, in terms of moment-rotation relationships, which are useful for the explicit modeling of the behavior of connections when integrated in steel MRFs.

Recent studies also focused on the evaluation of the seismic response of steel MRFs considering the influence of joint behavior by means of numerical analyses [4] and shake-table tests [5].

The present study is meant to provide a further contribution on the evaluation of the influence of the explicit modeling of beam-to-column connections in the seismic vulnerability assessment of steel MRFs; in addition, the results of the undertaken nonlinear dynamic analyses are used here to estimate the seismic demand on non-structural elements (NSEs) via floor absolute acceleration spectra [6].

The consideration of NSEs in performance-based earthquake engineering is of paramount importance since they significantly contribute to economic losses and buildings' functionality issues [7-9]. Indeed, recent earthquakes have shown that earthquake-induced direct (i.e., structural and non-structural damages, deaths) and indirect (i.e., downtime and business disruption) losses might be socio-economically arduous [7].

Regarding the seismic performance assessment, several studies dealt with the selection of the most suitable parameter for measuring the damage of steel MRFs due to seismic actions. Generally, the choice bias for the interstory drift [10,11]. Besides, further studies comprised the computation of performance and fragility functions [12-17] or robustness [18] for steel MRFs.

This study aims to evaluate the influence of beam-column connections in the performance of a MRF steel building by employing fragility curves and interstory drift profiles; moreover, for a non-structural perspective, the connections' influence in the seismic demand on NSEs was assessed through acceleration profiles and floor absolute acceleration response spectra.

2 NUMERICAL MODEL OF THE CASE-STUDY BUILDING

The case-study building is a medium-rise steel MRF structure. The structural layout is presented in Figure 1. The building has 6-floor levels, with an interstory height of 3.0 m and a total height of 18 m. In the X-direction, the lateral stability is provided by a 4-bay MRF (Figure 1a) with all the beams spanning 6 m; contrariwise, the lateral support system in the Y direction is offered by diagonal braces (Figure 1b), located in the two end frames (Figure 1c). In this direction, the bay length is equal to 5 m.

Figure 1: Structural layout: a) moment-resisting frame, b) concentric braced frame, c) plan-view of the building.

The structure was designed in compliance with European standards [19,20] for steel structures under seismic actions. Table 1 reports the profiles assumed for both beams and columns. It should be noted that all the sections are composed of an S355 material, the behavior of which has been simulated by means of a Menegotto-Pinto material model [21]. The choice of the sections and the bay length in the X-direction was made according to the available data from the experimental tests conducted in [3]. The diagonal braces are composed of hollow square sections with a width of 100 mm and a thickness of 10 mm. Following the load analysis, a uniform load equal to 40.5 kN/m and 30.25 kN/m was applied to the main internal and external beams (parallel to X-direction), respectively. At the roof level, the loads applied to the beams are equal to 33.25 kN/m and 16.78 kN/m for internal and external beams, respectively. Secondary external beams (parallel to Y-direction) are supposed to carry infills' weight,

computed and turned into a uniform load equal to 10 kN/m; the same beams at the roof are instead subjected to a load equal to 0.15 kN/m due to the parapet.

From a numerical point of view, the MRF connections were modeled following two different approaches: 1) full-rigid beam-to-column connections, namely Rigid (R) model and 2) explicit modeling of connections. This latter modeling option makes use of the outcomes of EQUALJOINTS [3], and in particular of results corresponding to the bolted extended stiffened end-plate connections, thus leading to the nomenclature of Extended Stiffened (ES) model. It should be noted that the bolted extended stiffened end-plate joint, in practical design, is generally assumed as rigid; therefore, the comparison between the two modeling approaches is consistent and is meant to shed light into the effects produced by basic modeling assumptions made at the design level. To deal with the geometry of the building, and the selected beams and columns, four connections tested in the EQUALJOINTS project were selected. Using the experimental results, the numerical models simulating the beam-column connections were developed using the pinching4 material model [22] available in OpenSeesPy. For illustrative purposes, and to demonstrate the good prediction capability of the calibrated numerical models, Figure 2 reports the numerical-experimental comparison of the hysteretic curves. Assuming the nomenclature adopted in EQUALJOINTS [3], the joint E1-TB-E-C1 (Figure 2a) and E1-XW-P-C1 (Figure 2a) refer to the HEB280-IPE360 and HEB340-IPE360 connection, respectively.

Floor level	Internal column	External column	Internal beam	External beam	Brace
1	HEB500	HEB340	IPE450	IPE360	100x100x10
2	HEB500	HEB340	IPE450	IPE360	100x100x10
3	HEB340	HEB280	IPE450	IPE360	100x100x10
4	HEB340	HEB280	IPE450	IPE360	100x100x10
5	HEB340	HEB280	IPE450	IPE360	100x100x10
6	HEB340	HEB280	IPE450	IPE360	100x100x10

Table 1: Selected sections for columns, beams, and braces.

The beam-to-column connections in the frames along the Y-direction were modeled as pinned. In this direction, only the braces act as lateral load-bearing elements. These members were modeled as truss elements, i.e., they sustain only tension and compression loads. However, due to their propensity for buckling, the braces were modeled with an asymmetric material, which offers a full-strength for the tension load and a partial-strength for the compression load. It should be noted that the partial strength was calibrated in order to permit the brace to reach its critical load.

The three-dimensional numerical models were developed by the finite-element software OpenSeesPy [23]. Both columns and beams were modeled by force-based beam-column elements with two-point Gauss integration for the interior element and two-point Gauss-Radau integration over each plastic hinge length at the element ends [24]. Such an approach permits to capture the material nonlinearity by discretizing the sections in fibers (about 100 fibers, in this study).

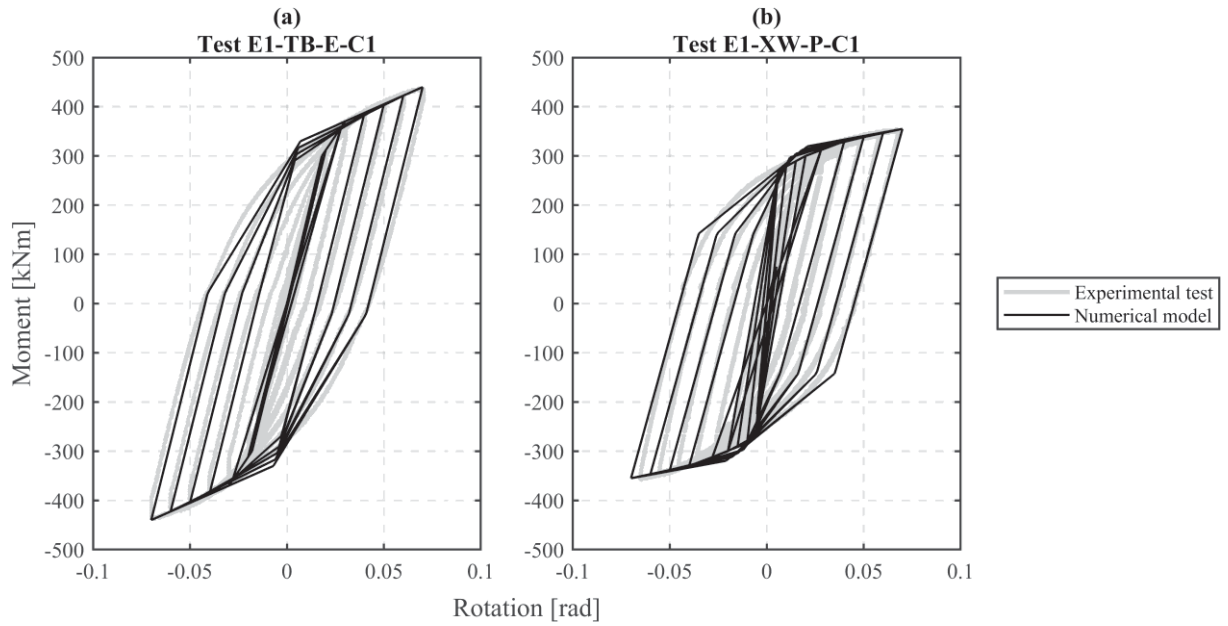

Figure 2: Calibration of the beam-column connection models with the test results provided by EQUALJOINTS [3].

Finally, a modal analysis was performed in order to capture both the free-vibration modes of the building with the two different modeling approaches and obtain essential information for the PSHA and record selection procedure, described in Section 3. Table 2 shows the first six periods of the building obtained from the two modeling approaches. The first, fourth, fifth, and sixth mode are predominantly translational in the X-direction; the second mode is translational in the Y-direction, while the third mode is torsional. Note that these considerations are valid for both R and ES models. As can be observed in Table 2, the actual connections' effect increases the first period by approximately 41%, while minor changes were obtained for the other periods.

Mode	R-model	ES-model	Mode shape
1 st	1.24 s	1.75 s	Translational, X-direction
2 nd	0.96 s	0.96 s	Translational, Y-direction
3 rd	0.71 s	0.77 s	Torsional
4 th	0.60 s	0.60 s	Translational, X-direction
5 th	0.49 s	0.54 s	Translational, X-direction
6 th	0.41 s	0.49 s	Translational, X-direction

Table 2: Free-vibration periods for the R- and ES-model.

In the nonlinear dynamic analyses, a Rayleigh damping model with 2% of critical damping was set for the first and third modes of vibration resulting from each eigenvalue analysis performed.

3 PSHA AND RECORD SELECTION

To obtain a suitable seismic threat for a specific location, a probabilistic seismic hazard analysis (PSHA) should be performed. As it is well-known, the PSHA gives the earthquake rate causing exceedance of any arbitrary ground-motion Intensity Measure (IM) at the site [25]. Therefore, the PSHA provides the seismic actions necessary to perform the structural design and assessment. In this study, the PSHA was performed with the assistance of the

OpenQuake platform [26]. The chosen location to perform the PSHA is the city of L'Aquila, a high seismicity zone in Italy, also tragically known for the catastrophic 2009 earthquake. An average seismic shear-wave velocity from the surface to a depth of 30 m (V_{s30}) equal to 200 m/s was selected, corresponding to a class soil C in accordance with the soil classification proposed in Eurocode 8 [20]. Note that for the PSHA, an appropriate ground motion prediction equation (GMPE) should be selected; in this study, the GMPE proposed by Lanzano et al. [27] has been used, since such equation is the latest revision for shallow crustal earthquakes in Italy.

Return Period [years]	Probability of Exceedance	Limit state
30	81% in 50 years	SLO – Immediate Occupancy
50	63% in 50 years	SLD – Damage Control Range
475	10% in 50 years	SLV – Life Safety
975	5% in 50 years	SLC – Collapse Prevention
2475	2% in 50 years	
4975	1% in 50 years	

Table 3: Return period of the record selection.

The Multiple-Stripe Analysis (MSA) [28] has been used to perform the seismic vulnerability assessment. Therefore, for each stripe, a PSHA has to be performed, varying the IM increasing the return periods. In Table 3, the six return periods (RPs) selected are reported, together with the probability of exceedance and the limit state associated in accordance with the Italian standard [29].

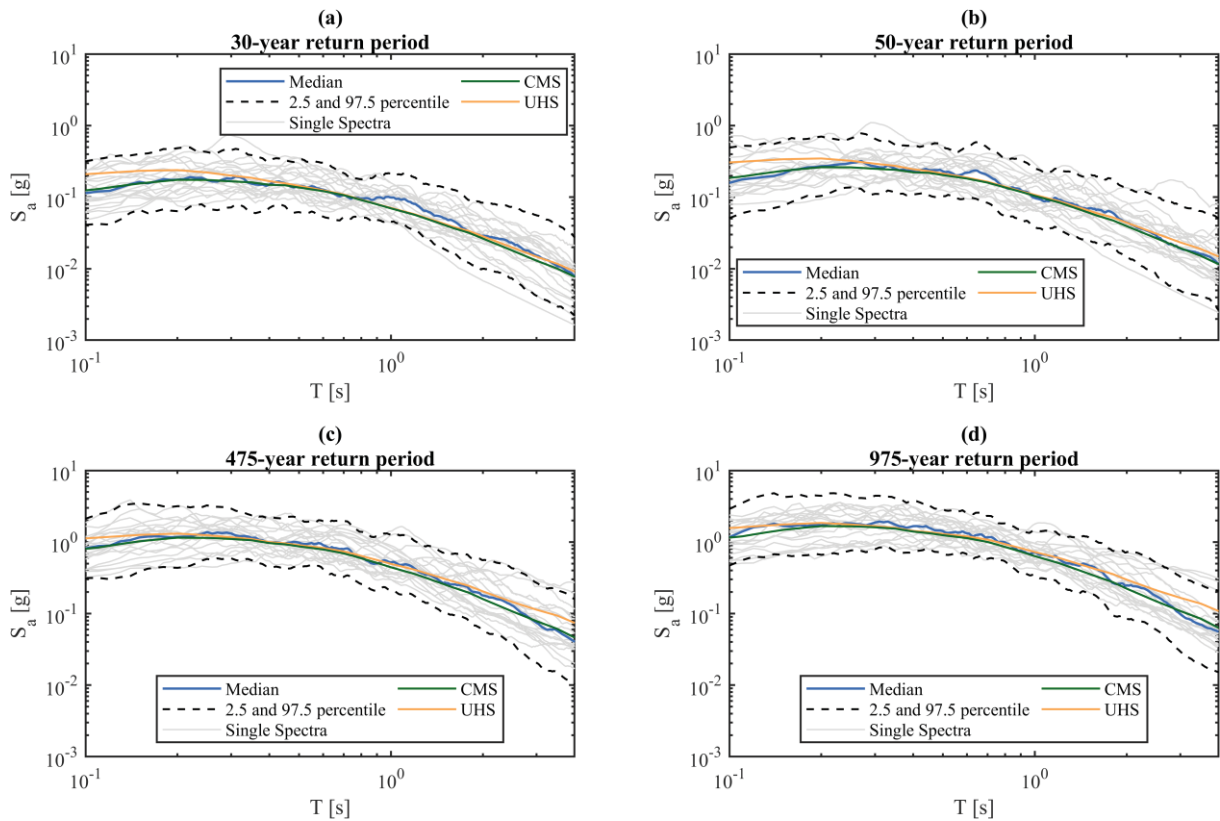

Figure 3: Ground motion spectra for the four selected limit states.

Regarding the choice of the IM and the calculation of the conditional mean spectra (CMS) necessary for the record selection, the average spectral acceleration (AvgSA) was adopted [30]. The AvgSA permits to consider spectral accelerations in a wide range of periods; as suggested by Kohrangi and Bazzurro [30], the calculation of the mean of the log spectral accelerations should be approximately in the range of $0.2T_1$ and $1.5T_1$, where T_1 is the first vibration period of the building. Since in this study there are two models with different first vibration periods, the computation of the range was performed considering the lower first period (1.24s) for the lower bound and the higher first period (1.75s) for the upper bound, leading to a range equal to 0.2s – 2.6s.

For each RP 20 ground motions were selected and, for the return periods associated to the limit state in accordance with the Italian standard [29], depicted in Figure 3 together with Uniform Hazard Spectrum (UHS), the CMS, the median of the selected records, and the median plus/minus the standard deviation, i.e., the 2.5% and 97.5% percentile.

4 STRUCTURAL RESPONSE RESULTS

The MSA is a powerful tool to assess the seismic performance of a structure and, in this case, to investigate the effects of the two considered modeling approaches. The main performance metric considered for steel structures is the interstory drift. Besides, this measure can be discerned in two parts, namely the transient drift and the residual (or permanent) drift. The former one represents the drift experienced during the analysis, and generally, from a performance metric perspective, it corresponds to the maximum drift reached during the whole analysis. Instead, the latter represents the drift in which the structure lies after the dynamic analysis due to permanent deformations caused by the nonlinear behavior of the buckled or yielded components. Therefore, for the sake of completeness, both maximum and residual interstory drifts were recorded.

Moreover, after collecting the accelerations experienced by the case study structures, the floor absolute acceleration response spectra were computed to offer an overview of the differences between the two modeling approaches (R and ES model) in terms of seismic demand on NSEs.

4.1 Interstory drift profiles

The maximum peak interstory drift profiles, for each record, were recorded and are plotted in Figure 4. In particular, Figure 4 shows all the outcomes derived from the six RPs selected and for the two considered configurations. It is worth mentioning that only the results in the X-directions are reported because in the Y-direction pinned connections are assumed. The results in the Y-direction are not discussed also because, from the eigenvalue analysis, it was observed that the different modeling approaches adopted in the two configurations modified the vibration periods but did not affect the global behavior of the structure in terms of modal shapes.

As a general remark, for both R and ES models and for all the RPs, the median peaks drift along the height are concentrated at the fourth and fifth floors. For instance, in the case of life safety limit state (i.e., 475-year RP), the median peak drift occurs at the fourth floor and it is equal to 1.83% for the R model and to 2.61% for the ES model. Similar considerations can be conceived for the other RPs.

As far as the seismic behavior for higher RPs is concerned, both modeling techniques revealed a soft-story mechanism activated between the second and third floors. Therefore, one may deduce that explicit modeling of connections does not change the overall seismic behavior of the structure when subjected to high seismic input.

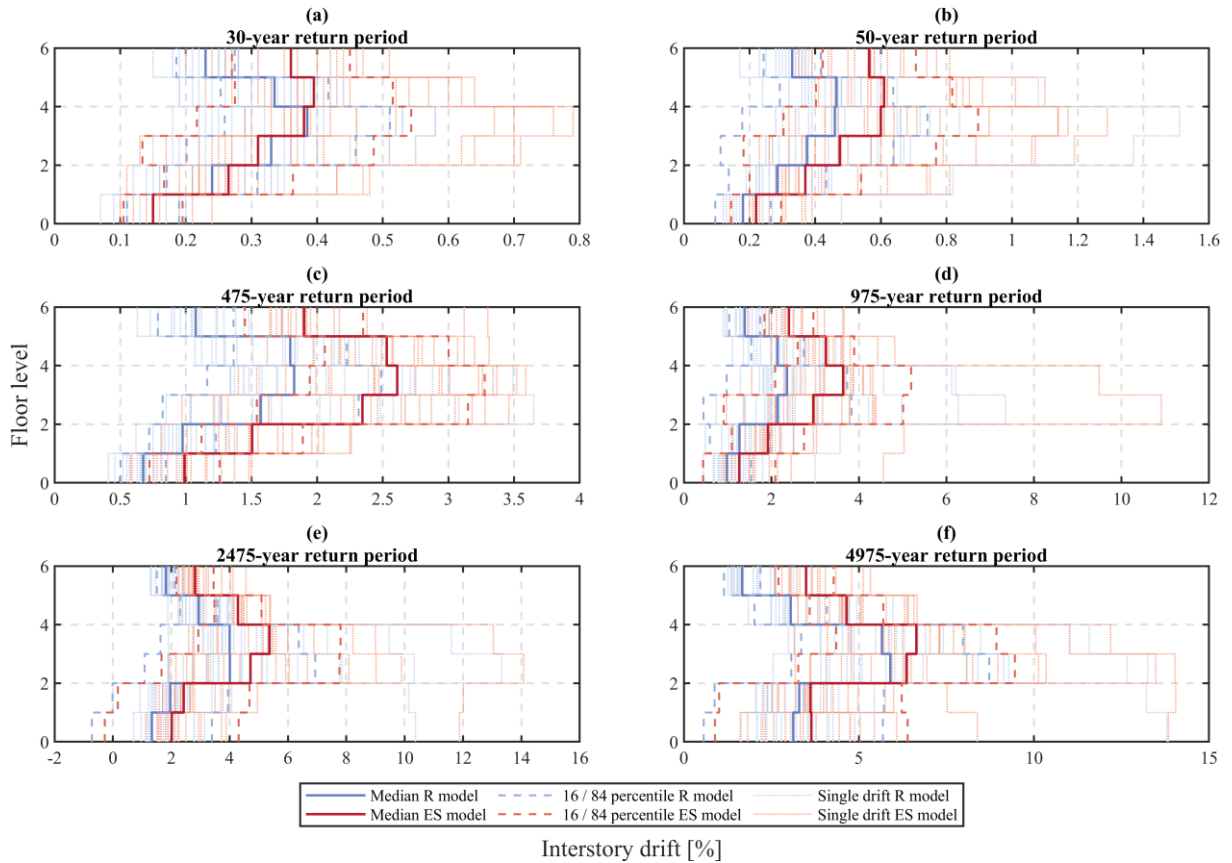

Figure 4: Interstory drift peak profiles for each RP in the X-direction.

However, although the drift trends are quite similar, the inclusion of the actual connections significantly increased the experienced drift values. This is especially true if medium-high RPs are considered. For the 475-year RP an increase of the peak drift equal to 43% is recorded, while for the 975-year RP an increase of 55% is observed. Lower percentage increases of the drifts are instead estimated for the 2475-year and 4975-year RPs, since the experienced drifts present a significant increment of 34% and 17%, respectively. The lower difference of the peak for the two higher RPs (2475-year and 4975-year) is due to the fact that both models, with these RPs, are subjected to large displacements, which induced significant plastic deformation in joints and elements, reducing in turn the stiffness and flattening the dissimilarity between the two structural models. Considering the FEMA-356 [31] interstory drift limitations, the two models behaved quite well. In fact, according to FEMA-356 [31], the maximum drifts are equal to 0.7%, 2.5% and 5% for the immediate occupancy (30-year RP), life safety (475-year RP) and collapse prevention (975-year RP) performance levels, respectively. Only in the case of life safety (Figure 8c) such limits are exceeded since, for the ES model, a maximum peak interstory drift of 2.61% located at the fourth floor is assessed. It is worth mentioning that, although the structure was designed according to EC8 [20], the comparison in terms of maximum interstory drift has been conducted considering the thresholds provided by FEMA-356 [31] because the EC8 [20] only provides some indications for the serviceability limit states.

4.2 Residual drift profiles

The median residual interstory drifts, together with the 16% and 84% percentile and the single drift profiles for each record, are reported in Figure 5. At first glance, it can be noted

that the higher differences between the R and ES models can be appraised for the lower RPs, namely 30- and 50-year RP. In these cases, the increase in terms of residual drifts is around 125% and 280% for the 30- and 50-year RP, respectively. However, considering the first four RPs, it can be noted that the record-to-record variability is considerably higher for the ES model; nevertheless, for the 475- and 975-year RPs, this discrepancy is due to few records with very large residual drift demands.

Overall, both structures behave well with respect to the FEMA-356 [31] limitations. Regarding the immediate occupancy limit state (30-year RP), FEMA-356 [31] indicates a negligible residual drift; in this context, a negligible maximum median value of 0.09% was obtained for the ES model, while an even smaller value was estimated for the R model, i.e., 0.04%. In the case of the life safety limit state (475-year RP), the limitation coincides with 1.0% of residual drift. Again, both models experienced smaller values, i.e., 0.39% and 0.3% for the ES and R models, respectively. Finally, concerning the collapse prevention performance level (975-year RP), a limit of 5% is defined, while the two models did not reach such value, since the maximum median residual drifts corresponded to 0.53% and 0.39% for the ES and R model, respectively.

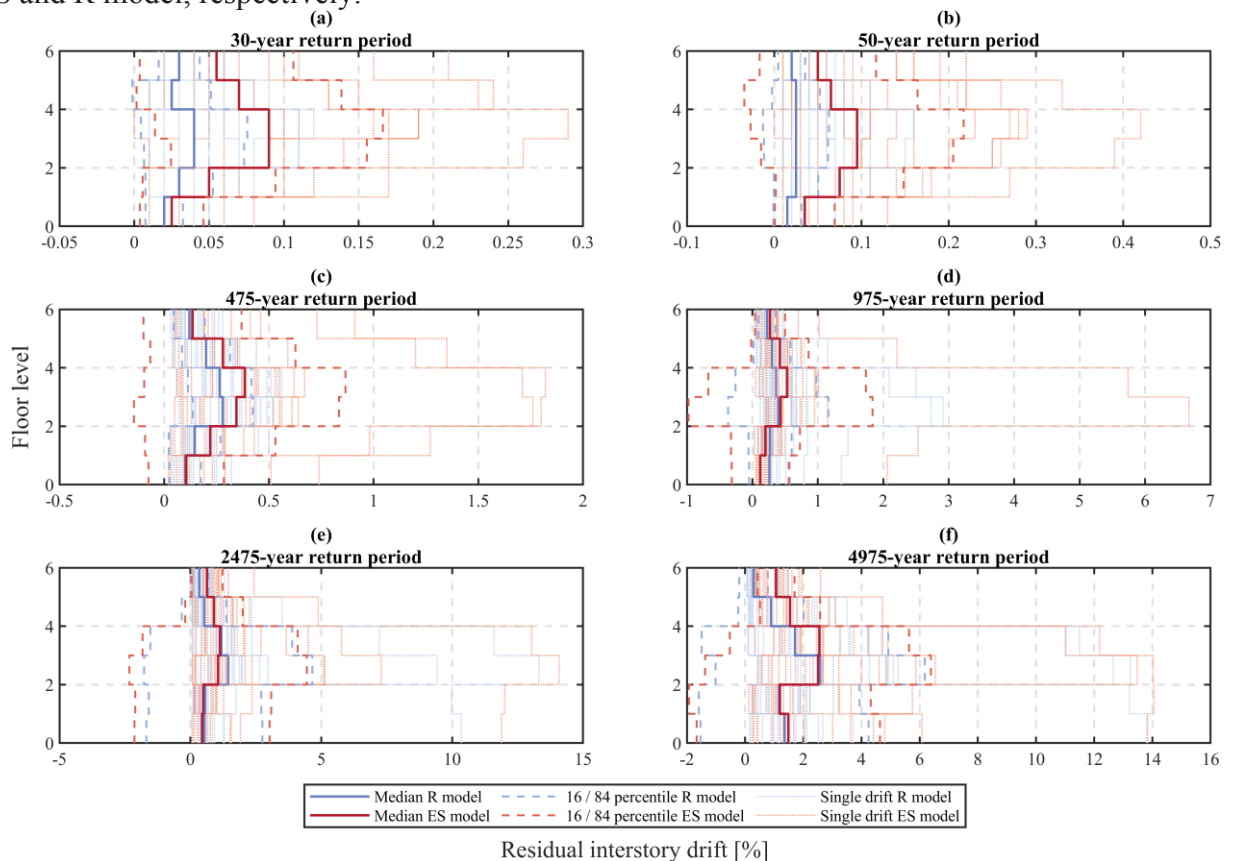

Figure 5: Residual interstory drift peak profiles for each RP in the X-direction.

4.3 Floor acceleration response spectra

Although floor response spectra are generally not considered to assess the structural performance, their evaluation could provide useful information regarding the dynamic response of the building and could also give an insight about the seismic demand at which the NSE installed in the building are prone.

Floor absolute acceleration response spectra were computed for each floor and RP. Figure 6 shows the absolute acceleration floor response spectra related to the roof floor for all the

RPs under investigation. In the first two RPs, namely the 30-year and 50-year RP, distinct peaks can be observed in proximity to the first and fifth (R-model) or sixth (ES-model) free-vibration periods (Figure 6a and 6b). Note that the spectra collected in Figure 6 are related to the X-direction; hence, a peak at the second free-vibration period, which involves masses in Y-direction, is not expected. Considering the differences between the two modeling approaches, it can be inferred that the median peaks in proximity to the sixth and fifth period for the R and ES model reached quite similar values (i.e., 0.8g and 0.66g for the 30-year RP and 1.23g and 1.24g for the 50-year RP, considering the R and ES models, respectively).

As regards the peaks at the first period, the differences are remarkable both in terms of spectral acceleration (0.74g and 0.25g for the 30-year RP and 1.0g and 0.49g for the 50-year RP, referring to R and ES models) and in terms of period shifting. Obviously, the first period elongation was expected for the ES model, as confirmed by the outcomes of the modal analyses performed prior to NLTHAs. For higher RPs, a flattening effect in the first periods can be observed; this phenomenon is quite common and it is due to the nonlinear response of the structures. In all RPs, the absolute acceleration response spectra present significant peaks in proximity to the structures' higher modes. Again, this outcome is not surprising since it is well-known that, in some circumstances, the floor acceleration response spectra are high-mode dominated [32-34]. This behavior is also the consequence of the high fundamental period of the structure, which is associated with lower ground spectral accelerations with respect to the higher modes, although the associated seismic masses are lower.

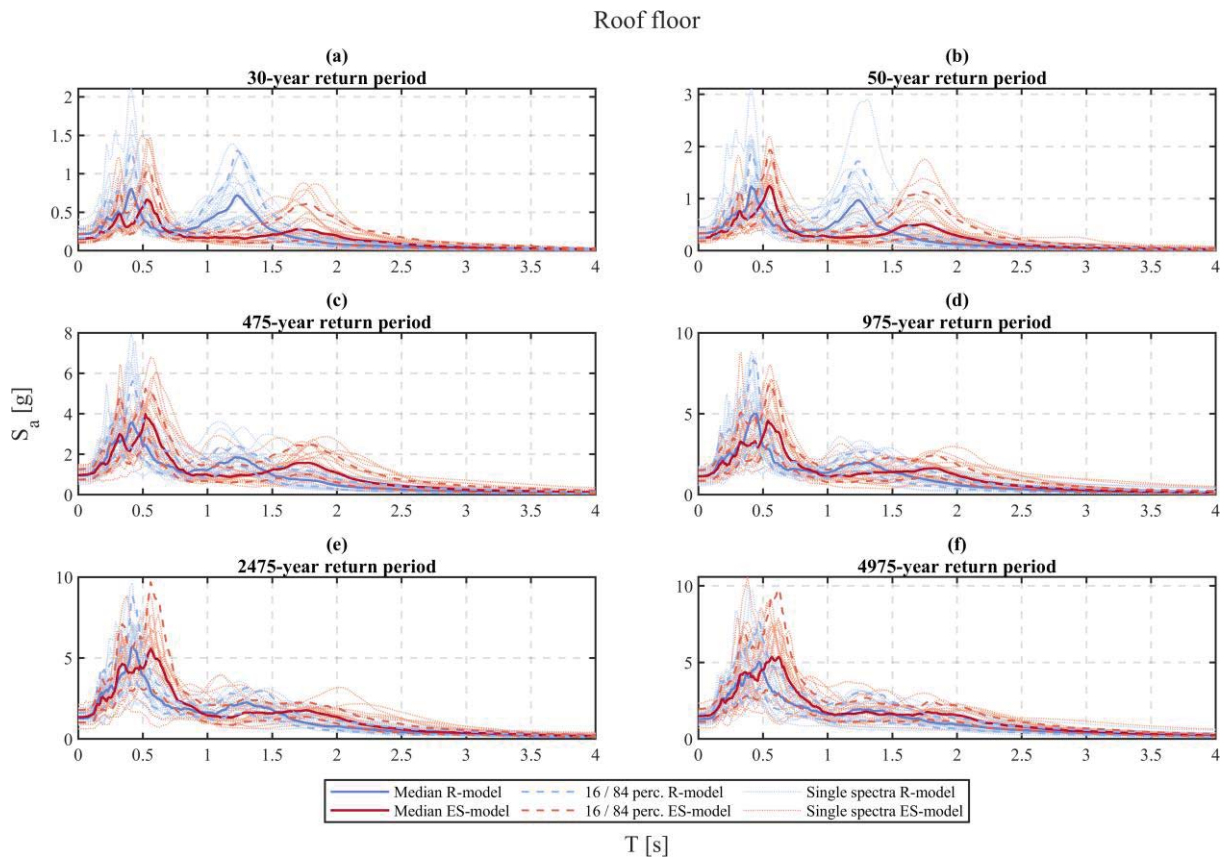

Figure 6: Absolute acceleration floor response spectra at the roof floor for each RP in the X-direction.

5 FRAGILITY CURVES

The calculation of fragility functions was carried out in accordance with the indications provided by Baker [35], in which the fitting technique of the maximum likelihood was suggested. Fragility curves obtained from the NLTHAs are shown in Figure 7; median and dispersion for each curve are also reported.

The limit states were defined following the indications provided by FEMA-356 [31] and already mentioned in the previous sections. FEMA-356 [31], concerning the steel MRFs, suggests adopting a 0.7% transient interstory drift and negligible residual drift for the immediate occupancy limit state; 2.5% transient and 1% residual drift for the life safety limit state and 5% transient or residual drift for the collapse prevention limit state. In addition, a further limit state was considered, namely collapse limit state, in which a limit of 10% transient or residual interstory drift was defined. Therefore, such parameters and thresholds were considered in the fragility curves computation for both models (R and ES model). Note that the curves constructed only refer to the X-direction of the structure.

As can be clearly seen from Figure 7, the ES model (dashed lines) presents a higher seismic vulnerability for most of the limit states. In particular, the median for the attainment of the life safety limit state is equal to 0.34g against a higher value for the R model, i.e., 0.48g. The same applies to the collapse prevention (0.77g versus 0.83g) and collapse (2.06g versus 2.14g) limit states. Only in the case of the immediate occupancy, the median presents identical values (0.09g), although the dispersion is different.

Figure 7: Fragility curves of the case study structure in the X-direction.

A straightforward conclusion can be done from a structural seismic performance perspective, adopting concepts similar to the collapse margin ratio (CMR), i.e. the ratio between the median collapse intensity and the intensity at the collapse limit state. The seismic intensities

(i.e., the AvgSA) for each limit state are 0.05g, 0.37g and 0.54g for the immediate occupancy, life safety and collapse prevention limit states. Therefore, the ratios between the median of each fragility curve and these last intensities are 1.8 (both models) for the immediate occupancy, 1.3 and 0.92 (R and ES model) for the life safety, and 1.54 and 1.43 (R and ES model) for the collapse prevention limit state, respectively. Reflecting the outcomes related to the maximum peak interstory drifts, only in the ES model case for the life safety limit state the ratio fell behind the unity, indicating a dangerous probability of reaching such limit state. This consideration also provides further insights into the importance of an accurate numerical modeling of the beam-column connections.

6 CONCLUSIONS

Past earthquakes demonstrated that, although less attention is generally paid to the seismic performance assessment of steel buildings with respect to, for instance, reinforced concrete and masonry structures, this structural typology could suffer significant damages, both from a structural and non-structural point of view. For this reason, it is of paramount importance to determine suitable models and methods to define the seismic performance correctly. As such, recent researches and projects focused on closing those gaps. In a European context, accurate investigations on pre-qualified joints' seismic behavior for steel buildings were missing until the very last years. Therefore, this study focused on evaluating the influence of the explicit modeling of joints in the structure's seismic performance. The performance metrics considered glanced at both structural and NSEs. Outlining that further research is necessary to define general conclusions for different steel buildings typologies and for all the pre-qualified joints, the outcomes of the analyses conducted in this study are listed in the following:

- The explicit modeling of a rigid joint reduced the structure's overall stiffness; therefore, a significant increment of the interstory drift can be observed. Similar considerations can be made referring to the residual interstory drift.
- The evaluation of the fragility functions, for different performance limit states, pointed out a high vulnerability of the structure if the actual behavior of the joints is explicitly modeled. For the case study structure, only in the case of life safety limit state, for the configuration in which the joints' behavior is modeled, the minimum requirements were not met.
- The shape of the floor absolute acceleration response spectra is significantly affected by the modeling of the joints, in particular for lower return periods. This consideration is of particular interest because the variation of the periods at which the maximum spectral accelerations are observed could significantly modify demand on and, thus, design of NSEs installed in the structure.

Abstract

Due to the vulnerability of reinforced concrete hollow piers subjected to seismic actions, it becomes urgent to assess the expected shear damage and its evolution with the increase of the intensity level. Additionally, the focus of the scientific research dedicated to seismic behaviour of these elements is still reduced, in particular with regard to the limit states of damage and to the economic consequences of repairing and retrofitting the physical damages existing in RC hollow piers subjected to the seismic action. This information is deemed crucial when cost-benefit analysis is concerned for the definition of measures for repair and retrofit of seismic damage.

This paper focus on the issue of damage to hollow piers due to the seismic action, proposing a methodology to characterize the limit states of damage under the perspective of the physical behaviour. It also intends to discuss adequate strengthening strategies and their direct costs, associated with each seismic physical limit state of damage. An extensive review of numerous cyclic experimental works on RC hollow piers will be performed, and in liaison with specialized construction companies, the direct repair costs will be estimated.

Keywords: Repair cost; Shear limit state damage, RC hollow-piers, Non-linear cyclic behaviour.

1. INTRODUCTION

The hollow section piers are often used in high-rise bridges, particularly when it is necessary to ensure high stiffness and simultaneously low weight, thus leading to a more economical construction. Hollow piers can be compared to reinforced concrete walls, however when such components are subjected to high intensity seismic actions can, in certain circumstances, evidence a significant vulnerability associated mainly to the low shear capacity.

Due to the expected vulnerability of these piers, when subjected to seismic actions, it becomes urgent to assess the expected damage and its evolution with the increase of the intensity level. Additionally, it is noted that the focus of the scientific research devoted to seismic behaviour of these elements is still reduced, in particular with regard to damage and to the limit states of damage. This paper focus on the analysis of damages on hollow piers due to the seismic action, proposing a methodology to characterize the limit states of damage under the perspective of the physical behaviour. To establish a correspondence between physical damage states and structural parameters, a set of results of quasi-static experimental tests was analysed, in hollow piers of reinforced concrete subject to cyclic loading [1-3].

An experimental test campaign was conducted in the Laboratory of Earthquake and Structural Engineering (LESE), located at the Faculty of Engineering of University of Porto, where a test setup was developed and that served to several research works on this field of study.

This experimental test campaign consisted of 12 piers, 6 with a squares cross section (PO1) and 6 with a rectangular section (PO2). The square piers have a section of 0.45x0.45m and a wall thickness of 7.5cm. The rectangular piers have a section of 0.90x0.45m also with a wall thickness of 7.5cm. All piers are 1.40m tall and were built with 1/4 scale from the original size. All the piers have different characteristics of materials, arrangement of shear reinforcement or cross areas of reinforcement. Table 1 shows these characteristics of the piers [1-3] and Figure 1 illustrate the reinforcement details. An axial load of 250 kN was considered, that corresponds to a normalized axial force of 0.08.

Designation	Geometry	f_{cm} (Mpa)	Longitudinal Reinforcement		Shear Reinforcement		
			area	f_{sy} (Mpa)	\emptyset (mm)	f_{sy} (Mpa)	Type
PO1-N1	Square	19,8	40 ϕ 8	625	3,8	390	2 legs
PO2-N1	Rectangular	19,8	64 ϕ 8	625	3,8	390	2 legs
PO1-N2	Square	27,9	40 ϕ 8	435	2,6	437	2 legs
PO1-N3	Square	27,9	40 ϕ 8	435	2,6	437	2 legs
PO2-N2	Rectangular	27,9	64 ϕ 8	435	2,6	437	2 legs
PO2-N3	Rectangular	27,9	64 ϕ 8	435	2,6	437	2 legs

2. LIMIT STATES OF SEISMIC DAMAGE

With the analysis of the experimental test it was possible to perform an evaluation of the damages in the columns. The types of damages that were observed correspond to: concrete cracking, concrete spalling and concrete crushing. After quantifying and analysing the damages due to the displacement applied on the top of the column, it was possible to identify several response levels corresponding to the seismic damage limit states. The seismic damage limit states chosen for the present study were those defined by Delgado *et al.* [4]. These seismic damage limit states are in line with other studies and documents, e.g. [5] and [6].

The methodology proposed by Delgado *et al.* [4] defines a total of four damage limit states. The first state of damage corresponds to slight damage. In this state, the damage is barely visible and does not compromise the structural stability. The visible damages are essentially the beginning of cracking, in a small extension and density, concentrated on the lower third of the columns. The second state of damage, referred to as moderate damage, is distinguished from the previous state limit by the increase in cracking. The cracks have reduced openings, smaller than 1mm, being a large part of the typical cracks, shear cracking, which reach a maximum of 1mm of opening. The third state of damage is the state of extensive damage. When a pier reaches this level of damage the element already requires attention and a significant repair. The most visible damages in the piers are the appearance of cracks openings of up to 3 mm and with a high density. In this state of damage the cracks are essentially due to shear in the webs and to bending in the flanges also noting the effect of "shear lag effect". The cracks are evenly distributed over the entire section of the pier. It is also possible to observe some concrete spalling. The ultimate damage state is the collapse. When damage to the pier reaches this level, it is no longer economically and feasible to repair the structural element and its structural safety is seriously compromised. Between this state and the state of extensive damage, there is a significant evolution of damages, with emphasis on the concrete

crushing and an increase of the detachment of the concrete cover. Numerically, this state is defined when the shear stress is higher than the theoretical resistant value or the conventional shear occurs. Figure 2 illustrates the evolution of damage, in the various limit states of damage.

Figure 2: a) Slight damage, b) Moderate damage, c) Extensive damage, d) Collapse.

After defining the several damage states, it is necessary to identify a response parameter capable to translate the evolution of the physical damages of the column in each of the above limit states. Thus, and with the purpose of using a single structural parameter for all limit states, which can be easily evaluated in any numerical model, the drift response parameter was selected. The correspondence between the four previously defined limited states of damage and the drift values was established from the analysis of the experimental tests of the hollow piers, and considering a description of each boundary state. Table 2 translates the drift limit values associated with each physical damage state.

Limit State	Drift (%)
Slight	0.6
Moderate	1.3
Extensive	2.0
Collapse	3.0

Table 2 :Limit states and corresponding drift value.

3. SEISMIC REHABILITATION TECHNIQUES

Currently, there are several techniques for the repair and strengthening of structures, with the aim to ensure the replacement or improving of seismic behaviour and capacity. This study was followed by the approach and characterization of repair techniques proposed in the research project "PRISE - Evaluation of Losses and Seismic Risk of Buildings in Portugal" [7], funded by the Portuguese Foundation for Science and Technology, in which the authors of this study were involved, and as presented in the work conducted by Delgado *et al.* [4]. In this project was built a database of unit repair costs for each repair technique, which includes materials and labour costs, obtained from surveys collected from several construction companies existing in Portugal and specialized in repairing/strengthening these damages. In this study, the costs of the access to the pier to be repaired and other works, were considered.

3.1. Slight Damage

This limit state is characterized by minor or irrelevant, and almost imperceptible visualized damages, with very small cracks, up to 0.5mm of opening. For such pattern, with crack width less than or equal to 0.1mm, three possible repair techniques are identified and may or may not occur together, namely: surface painting; Surface plaster of the piers; Scrub surface with epoxy resin. If the environmental conditions of aggression are zero, no repair is necessary. For crack width between 0.1mm and 0.5mm, the most appropriate repair technique is the injection of epoxy resin.

The painting of the concrete surfaces of the piers must be carried out through water-based monolayer paint scheme. This painting should be done in two coats, with a smooth finish, resistant to the alkalis of the hydraulic binders and complying with the minimum requirements of EN 1504-2 [8]. This painting should be done with elastic paints to prevent further fissure of the piers. The surface plater repair technique consists of a generalized treatment of the cracks at an unspecified location. The same plastering should be done with an adjuvant mortar. The last repair technique, applied on crack width lower than 0.1mm is to scrub the surface with epoxy resin. This technique consists on the application of impregnation product with one coat, resistant to the alkali of the hydraulic binders and fulfilling the minimum requirements of EN 1504-2, [8].

3.2. Moderate Damage

The state of moderate damage is characterized by small cracks in the abutment faces, corresponding to an opening between 0.5mm and 1.0mm. Structural stability is not compromised, and any type of structural intervention is unnecessary. To repair crack openings, the most appropriate repair technique is the injection of epoxy resin, which must comply with EN 1504-5 [9], regarding injections in reinforced concrete structures

3.3. Extensive Damage

In the limit state of extensive damages the crack width is, approximately, between 2mm to 3 mm, and is visible some concrete spalling. When a pier reaches this state of damage it already requires some attention, and needs to be repaired in a short term in order not to compromise the structural stability. For this reason, it is necessary to proceed with a structural reinforcement of the element. The repair technique for the cracks consists of the injection of epoxy resin, respecting EN 1504-5 [9], as previously mentioned. When the pier has cracks and some spalling, it is necessary to proceed with the reconstruction of the piers. With respect to the structural reinforcement of the element this can be realized in three distinct ways: increase of the section with the use of reinforced concrete; Bonding of metal sheets and Pier engagement with carbon fibre blankets (CFRP).

When the piers have some concrete spalling, it is necessary to replace this same concrete. It is first necessary to remove the damaged concrete, to clean and to perform a surface treatment with a needle hammer. Once the degraded concrete has been cleaned, it is necessary to place a new concrete in compliance with EN 1504-2 [8].

One of the most used strengthening techniques is the jacketing with carbon fibre blankets (CFRP). This technique has the advantage of causing a minimal increase of the section and greatly increasing the strength. This technique consists of bonding carbon fibre blankets using epoxy resins and then finishing with a self-adhesive mortar. In this type of strengthening, it is necessary to ensure that the ends are well bonded. Figure 3 illustrates the result of a CFRP-reinforced piers. All of these glues referred to in the previous reinforcements must comply with EN 1504-4 [10].

Figure 3: Pier reinforced with CFRP.

3.4. Collapse

As previously mentioned, the damage limit state corresponding to the collapse is characterized by a large concrete spalling and in which the theoretical resistance is exceeded. Thus, when a pier reaches this state of damage, it becomes economically impracticable to repair. If the demolition operation is not possible, there is no feasible repair techniques and only structural reinforcement is possible, using the reinforcement techniques described above.

4. DIRECT REPAIR COSTS ESTIMATION

After identifying the unit costs associated with the tasks and resources required for each rehabilitation and strengthening technique of the piers, the evolution of the cost according to the response of the structural element was quantified. The pier behavior develops according to its material and geometric characteristics, and the level of seismic action. The drift was considered as the response parameter, thus allowing to estimate the cost of piers rehabilitation for each seismic damage limit state [7]. The quality of the cost estimate for repair or strengthening is very important in the identification of the technique to be adopted. In the case of rehabilitation works, construction presents several sources of uncertainty, due, for example, to the difficulty in performing some of the tasks, making it difficult to quantify the necessary resources, such as man cost and equipment needed in the intervention. However, in this work an estimate of the average costs of the pier rehabilitation was carried out according to its damage limit state and separating the cost by type of work to be carried out, that is, the cost of materials, the cost of labor and cost of access to the pier area to be repaired and other additional works.

4.1. Slight Damage

For the limit state of slight damage, if the cracks have openings less than 0.5mm, the cracked surface must be repaired, corresponding to the pier bottom, in this case approximately equal to the dimension of the cross section. Table 3 illustrates the separation of repair costs according to the type of work to be carried out.

	Average Cost (€)
Material	77
Labors	49
Accessibility and other works	21
Total	154

Table 3 :Pier repair costs for limit state of slight damage.

4.2. Moderate Damage

For the limit state of moderate damage with cracks between 0.5mm and 1mm, the injection of epoxy resin should be used. In this case, about 2/3 of the pier surface is cracked, including the repair costs associated with each task in Table 4.

	Average Cost (€)
Material	112
Labors	98
Accessibility and other works	49
Total	259

Table 4 :Pier repair costs for limit state of moderate damage.

4.3. Extensive Damage

The limit state of extensive damage is characterized by the deteriorating of the state of the structure, with the appearance of large cracks, with openings that can vary between 1 mm and 3 mm, distributed on all sides of the pier, and it is also possible to verify the spalling of the concrete cover. When the pier reaches this state of damage, the surface treatment is not sufficient to guarantee the necessary minimum requirements, thus it is necessary to proceed with a structural reinforcement of the element. Table 5 represents the different costs by type for repair, taking into account an average estimate of the three structural reinforcement techniques namely: increase in section with reinforced concrete, reinforcement with the addition of metallic profiles and reinforcement with carbon fiber blankets (CFRP).

	Average Cost (€)
Material	245
Labors	252
Accessibility and other works	105
Total	602

Table 5 :Pier repair costs for limit state of extensive damage.

4.4. Collapse

Finally, for the limit state of collapse, which is characterized by a large detachment of the covering concrete, its repair is economically unfeasible. Thus, the demolition and construction of a new pier corresponds to the work to be applied in this case. The total cost will reflect all the demolition work on the pier, involving the recycling of all materials, loading, transport

and unloading, as well as the auxiliary tasks necessary for cleaning the site. The cost of building a new pier includes the execution of an identical reinforced concrete pier, including the supply, placement, compaction and curing of the concrete. The total price for demolition and construction of this reinforced concrete pier is around € 699. Table 6 shows the costs separated according to the type of work to be carried out. Unit costs were estimated and validated through contact with specialized construction companies.

	Average Cost (€)
Material	209
Labors	280
Accessibility and other works	210
Total	699

Table 6 : Pier repair costs for limit state of collapse.

4.5. Evolution of structural intervention costs

After analysing the costs of each structural repair and strengthening technique, it is necessary to understand how the cost evolution occurs as a function of the structural response, considering in this case the drift as a response parameter. Thus, it will be possible to quantify the economic weight of each state limit for the repair or strengthening of the piers.

In order to make this analysis more global, it was adopted to represent the evolution of the ratio between the cost of repair and the cost of replacing the pier as a function of the drift, as illustrated in Figure 4, for each Limit State of Damage (LSD). This transfer evolution of damage into costs, provides an important indicator for any cost estimate in hollow section reinforced concrete piers. Additionally, it also allows to assess the impact and efficiency of each repair or strengthening technique. Figure 4 reveals that the repair costs associated with the extensive and collapse damage levels mean that the repair of the structural element is not viable. However, even in the case of slight and moderate damages the respective costs are already quite significant.

Figure 4: Evolution of the repair cost ratio (%) for each LSD/drift.

In the case of this study, for structures that suffered from the impact of an earthquake and therefore in need of rehabilitation, factors such as the type, size of the bridge and how it will be made accessible must be taken into account. The places where structures are found that are damaged by earthquakes are usually difficult to access, and the debris on the site and the size of the structure contribute to a considerable increase in the budget. The piers previously studied are usually implemented in different types of bridges, with different dimensions and which, in terms of accessibility, can vary between easy access, moderately difficult access and difficult access.

5. CONCLUSIONS

In the present study, the evolution of structural damage in hollow reinforced concrete piers (whose behaviour is also representative of reinforced concrete walls) due to the action of earthquakes, with the purpose of defining limit states of damage (LSD), is based on a previous study of the authors of this study Delgado *et al.* [4]. This information was associated with repair and strengthening techniques, which are commonly applied in Portugal. Finally, the respective costs were estimated, which allowed to characterize the evolution of the costs of piers repair and strengthening as a function of the structural response. This work uses the construction techniques and their unit costs established under the PRISE project.

In this study, it was intended to obtain a methodology that is capable of predicting an assessment of the damage to the different piers, and the cost estimation of piers repair and strengthening, allowing to assess, in a simplified way, the cost estimate of the piers rehabilitation with insufficient shear capacity for each limit state of seismic damage. The proposed methodology allows to conclude that the repair of hollow reinforced concrete piers has significant costs even for moderate damage, and the replacement costs for collapse and extensive damage are practically identical. Thus, both from the point of view of costs and seismic safety, this study identifies the urgency of verifying the shear capacity of bridge piers and, in case it is insufficient, proceed to strengthening it in order to avoid the most severe LSD or collapse.

6. ACKNOWLEDGMENTS

Keywords: Seismic retrofitting, friction-based dissipation, Cross-Laminated Timber panels, Reinforced Concrete structures, Sustainability.

Abstract. *The European Union has sponsored the development of a new friction dissipating system, for improving seismic behaviour of existing buildings. The proposed system consists of CLT-elements connected to the external beams of existing reinforced concrete building using steel profiles. Each of the steel profiles consists of two separate plates connected by a friction connection made by preloaded bolts in elongated holes. The authors carried out the experimental testing of the friction connection by estimating the corresponding hysteresis curve. A Duhem-like mechanical model, matching with the experimental results, simulates the cyclic response of the connection. The authors investigate the seismic performance of a structural archetype, a plane RC frame with CLT shear walls equipped with this sort of friction dampers. It is assessed the optimum preload condition to achieve an optimal seismic performance according to the Italian seismic scenario by the fragility assessments. A selected suite of earthquakes is the basis of Incremental Dynamic Analysis (IDA) of the structural archetype, without and with the friction device. The optimum preload of the dissipating systems descends by optimizing the structural performance: maximizing the dissipated energy by preventing damage to the CLT panel and the reinforced concrete frame.*

1 INTRODUCTION

The vulnerability of the existing building entails developing non-invasive retrofitting approaches, based on passive devices [1, 2, 3].

The use of passive devices could be advantageous due to low-invasiveness and reduced installation time [4, 5], compared to more traditional seismic retrofitting strategies [6, 7, 8].

Among them, friction-based dampers have shown great potential, compared to the most diffuse buckling restrained braces and fluid viscous dampers [9, 10]. The performance of friction-based systems is sensitive to dampers' location and the value of the slip forces. The first studies about friction dampers directed on experimental tests and technological development of the friction-based devices with the hysteresis loop's rectangular shape [11], as the Slotted Bolted Connection (SBC) discussed by [12, 13, 14]. Lately, several researchers proposed alternative friction dampers featured by nonrectangular hysteresis curves. Among the others, Clifton et al. [15] introduced the asymmetric sliding hinge joint (SHJ) for steel moment-resisting frames with a nonrectangular hysteresis.

A few investigations dealt with applications of friction devices on timber shear walls. Filiatrault et al. [16] proved the advantage in using friction sliders in timber sheathed shear walls. Loo et al. [17] confirmed the findings by [16]: they applied symmetric slip friction connections to replace the traditional nail plate hold-downs for timber Laminated-Veer-Lumber (LVL) walls. Hashemi et al. [18] extended the study by [17] to Cross-Laminated Timber (CLT) coupled walls and hybrid timber–steel core walls. Recently, Hashemi et al. [19] developed an innovative, resilient slip friction joint (RSFJ) characterized by a nonrectangular hysteresis shape.

The current research focuses on the e-CLT technology, developed on the ongoing multidis-

Figure 1: (a) Proposed friction energy dissipating system; (b) Illustration of a working application.

ciplinary Horizon 2020 research project e-SAFE (Energy and Seismic Affordable rEnovation solutions): an application of Asymmetric Friction Connection (AFC) dampers and CLT panels on existing reinforced concrete structures for seismic retrofitting purposes.

The AFC is an arrangement of five plates, three steel plates and two thinner plates, named shims, assembled using high strength bolts. The AFC were studied by [15]. Primary attempts used brass shims based on the energy dissipation mechanism proposed by [14] for slotted bolted connections. Succeeding studies carried out by [20] extended the SHJ idea to mild steel and aluminium shims. Fresh studies carried out by [21] introduced bisalloy grades 80 and 400 shims.

Figure 2: (a) Possible profile design with front mounted CLT panel; (b) Possible profile design with back mounted CLT panel.

The e-CLT technology consists of the external application of prefabricated Cross-Laminated Timber (CLT) [22, 23, 24] structural panels by connecting them to the RC beams through AFC, see Fig.1 and 2. If moderate earthquakes occur, the dampers rigidly connect the CLT panels to the RC structure, by enhancing the lateral stiffness and strength. During strong ground motions, the friction dampers activate with possible significant energy dissipation. The e-CLT system aims at reducing the storey drift demand and the damage to nonstructural and structural components. The presented retrofitting intervention may combine the e-CLT technology with nonstructural pre-assembled panels made of wooden frames and provided with high-performing windows to replace the existing ones. Not secondarily, structural and nonstructural panels integrate bio-based insulation materials and the desired finishing layer to improve the energy performance and the architectural image of the renovated building [25].

The e-CLT technology comprises the installation of AFC, whose response is mostly driven by Columbian forces. The damper consists of a contacting friction interface clamped by pretension high strength bolts: the friction interface sliding guarantees energy dissipation. The device has two cold-bent steel profiles that connect the CLT panels of two consecutive storeys with the existing interposed RC beam. The upper profile is connected to the RC beam by anchor bolts. The bottom profile is provided with slotted holes and is connected to the upper one by pre-tensioned high strength bolts. Standard timber screws connect both the upper and bottom profile to the CLT panels. The authors present the experimental cyclic response of the considered AFC by addressing the slip force's role for its optimum design.

To the authors' knowledge, a few studies focused on the optimum design of friction-based dampers. The most recent researches examine the optimum design of friction-based dampers installed on structural archetypes through nonlinear dynamic analysis driven by optimization algorithms [26].

So far the most significant achievements about the optimum design of friction-based dampers are:

- Optimum distribution of the friction device and optimum selection of the slip force value can lead to a more than 50% reduction of the inter-storey drift in RC frames. Additionally, a nonuniform distribution of the total slip force along the building's height can further reduce the inter-storey drift [27, 28].

- The optimum slip load values are more affected by the amplitude and frequency of the input earthquakes (e.g. peak ground acceleration) rather than the characteristics of the structure [16].
- [29] derived an empirical equation which predicts the optimum slip load:

$$R = 1.12 e^{-0.11n} \quad (1)$$

where R is the ratio between the average of the slip loads with uniform cumulative distribution and the average shear strengths of the storeys, n is the number of storeys.

The mentioned studies, focused on optimizing slip-forces in friction dampers, required extensive parametric studies, which involved modelling a large variety of structural archetypes. However, the analyses' main drawback stood in the adoption of simplified constitutive models for concrete and the dampers and the modelling of the frames without the infill. The use of an elementary Coulomb-like friction model may be inadequate due to the possible higher slip force during the first cycles. The stability of the hysteresis loop and the magnitude of the friction forces developed by AFC specimens are directly related to the shim material hardness [30]. The presence of the masonry infill affects the seismic performance of RC frames significantly by increasing both the stiffness and resistance, as well as the ductility and pinching phenomena [31].

This paper investigates the performance of the e-CLT technology on an RC frame with masonry infill, which is the primary unit of many existing RC buildings. The main novelties of the research are:

- Discussion of the experimental cyclic response of a novel AFC, included in the e-CLT technology, and presentation of an enhanced Coulomb-like model.
- Investigation of the seismic response of an elementary RC frame equipped with the AFC using the Atan model calibrated on the experimental cyclic response of an RC frame with clay infill. Estimation of the optimum slip-force in the considered system, which yields the minimum displacement drift.
- Comparison between the optimization results with existing empirical formulations useful for preliminary design.

The paper has the following organization. The second section formulates the optimization problem, while the third presents and discusses the experimental tests on the friction-based dampers. The fourth section addresses the modelling choices and the calibration of the hysteresis models for simulating the RC frame and the friction damper. The fifth section discusses the first results obtained from the coupled system, while the sixth section deals with the optimization problem's solution. The last section compares the obtained results to the existing formulations by proposing alternative design approaches.

2 ACTIVATION CONDITION

The preliminary design of friction-based dampers may descend from the definition of their activation condition. The activation identifies the phase when the inertial forces win the connection's slip resistance, and the device starts dissipating energy.

The activation condition definition is crucial: a precocious activation may lead to a non-optimum

exploit of the structure's elastic energy. A late activation determines the safety margin's erosion: the damper may start dissipating when the system has already suffered extensive and critical damage. Therefore, the activation phase must occur just in time to yield the maximum benefits to the structure.

Likely, the activation is not contemporary between all devices, since the structural deformation is not uniform within the structure. Therefore, the activation condition's optimum design is the most crucial task in designing a retrofitting intervention based on friction dampers. The practitioner must design both the slip force and the distribution of the dampers inside the structure.

Let us consider an elementary structural archetype, a plane frame, representing the primary structural unit in an RC frame building. The dampers' activation at the i -th storey occurs when the inter-storey drift exceeds a given threshold.

The authors will focus on estimating the slip force associated with a structural archetype's optimum seismic performance and will neglect to determine the dampers' optimum distribution, which can be the object of future investigations.

Why is the design of the slip resistance a minimum problem? Let us consider the maximum inter-story drift, which is an acknowledged indicator of the damage level in both structural and non-structural elements of RC structures [32]. The displacement drift depends on multiple factors. The authors will consider the sole slip resistance of the damper:

$$d_{\max} = f(F_{s,R}, \mathbf{x}) \quad (2)$$

where d_{\max} denotes the maximum displacement demand, $F_{s,R}$ is the damper slip resistance and \mathbf{x} collects additional variables affecting the maximum drift demand (structural stiffness, e.g.). The following paragraphs explain the presumed evolution of the maximum displacement demand as a function of the slip resistance, qualitatively illustrated in Fig.3.

Figure 3: Qualitative illustration of the trend of the maximum displacement d_{\max} as a function of the slip resistance of the AFC.

The displacement drift is related to the dissipated energy during the seismic excitation. If the damper's slip resistance tends to zero, the structure behaves as if no damper is installed.

$$\lim_{F_{s,R} \rightarrow 0} d_{\max} = d_{\max,c} \quad (3)$$

where d_{\max} is the maximum displacement demand, and $d_{\max,c}$ is the maximum displacement demand of the RC structure without dampers. If the slip resistance tends to infinity (Eq.4), the damper does not activate, and the structure behaves as if no damper is installed and the CLT panel behaves as an additional stiffening element reducing the maximum displacement demand: the slip resistance would be higher than the shear resistance of the RC structure, expressed by a double vertical line in Fig.3.

$$\lim_{F_{s,R} \rightarrow \infty} d_{\max} = d_{\max,c} - d_{CLT} \quad (4)$$

where d_{CLT} is a contribution which lowers the displacement demand due to the additional stiffness of the CLT panel. If the slip resistance increases from the zero value, see Fig.3, the dissipated energy increases. The damper activates when there are low inertial forces. Still, the friction-based device must endure significant displacement to obtain a meaningful energy dissipation. However, the drift should reduce, and the following derivative would be negative:

$$\lim_{F_{s,R} \rightarrow 0} \frac{\partial d_{\max}}{\partial F_{s,R}} < 0 \quad (5)$$

If the slip force is lower than the shear resistance of the structure, the damping device can activate, green region in Fig.3. However, if the slip resistance reduces from the value corresponding to the structure's shear resistance (red area in Fig.3), the expected drift should reduce. The damper may start dissipating when the system did not attain the maximum displacement capacity, thus increasing the dissipated energy and possibly lowering the drift demand. The AFC has larger displacement margin for dissipation. Therefore, the following derivative would be positive:

$$\lim_{F_{s,R} \rightarrow F_{c,R}} \frac{\partial d_{\max}}{\partial F_{s,R}} > 0 \quad (6)$$

where $F_{c,R}$ is the shear resistance of the RC frame. The design of the slip force resembles a minimum problem. Likely, there is a force value which may minimize the drift demand during seismic excitation. The mathematical problem cannot have a closed-form formulation. The optimum performance depends on the expected seismic scenario. Therefore, the authors followed an *a posteriori* approach, conventional in earthquake engineering. They select a set of earthquakes, matching a given design spectrum. Then, they estimated the nonlinear dynamic response of a specific structural archetype by varying the slip resistance in a given range—the minimum of these values obtained from the considered list of earthquakes identifies the optimum solution.

$$F_{s,R,optimum} = \arg \min_{F_{R,s}} d_{\max}(F_{R,s}, a_g) \quad (7)$$

where a_g represents a seismic scenario. The paper aims to solve the minimum problem in a specific structural configuration, representing the anatomical unit of the e-CLT technology.

3 Experimental tests

The authors investigated the cyclic behaviour of the AFC devised for e-CLT technology. The considered setup focuses on the friction damper and does not include CLT elements. The experimental setup consists of a rigid steel frame, namely the columns have a 12.5mm thickness and 100×200mm rectangular section, the bottom profile of the specimen is attached to the right

column, while the top profile is in the central part of the frame and is free to slide, being connected to the actuator of the press. An additional steel cap plate and two aluminium shim layers were inserted between the profiles, to obtain an asymmetrical friction connection. The goal of

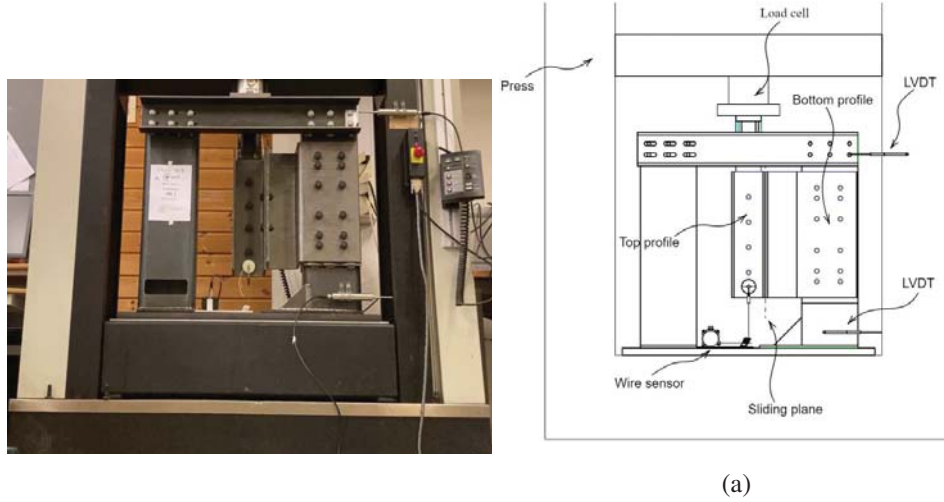

Figure 4: (a) Setup with all measuring instruments mounted; (c) illustration of the setup

the friction connection in the current setup is to have a 30kN sliding force, this threshold originates from the working limit of the press machine and previous FEM models [33]. The preload force in the bolt was set to $F_{P,c} = 36\text{kN}$, which resulted in an experimental slip resistance $F_{s,R} = 29.57\text{kN}$, calculated as [17]. The experimental friction coefficient is calculated as:

$$\mu = \frac{F_{s,R}}{n_s n_b F_{P,C}} = \frac{29.57}{2 \cdot 2 \cdot 36} = 0.21 \quad (8)$$

where $F_{s,R}$ is the experimental slip resistance, $n_s = 2$ is the number of shear surfaces, $n_b = 2$ is the number of the preloaded bolts and $F_{P,c}$ is the preload force in the bolts. Interestingly, the

Figure 5: (a) Experimental hysteresis loop; (b) Force-Time function; (c) Dissipated Energy-time function.

estimation of resistant slip force is not unmistakable. The hysteresis loop does not display an expected rectangular shape. There is a significant increment of the slip resistance in the first few cycles at lower displacements, while it stabilizes at higher displacement to an almost constant value equal to 30kN, as seen in Fig.5. This effect is not negligible, since there is an approximate 56% increment of the peak to the stable value at higher deformations. The modelling of this

phenomenon is mandatory to achieve a reliable prediction of the performance of this system. This aspect is in full accordance with the experimental tests reported by [30]. Specifically, the adoption of an aluminium plate, characterised by low hardness, causes moderately stable loops. The friction coefficient corresponding to the peak force value is, in fact:

$$\mu = \frac{F_{peak}}{n_s n b F_{p,C}} = \frac{47.03}{2 \cdot 2 \cdot 36} = 0.33 \quad (9)$$

This value is in accordance with the findings by [30], who, in the case of aluminium shims, obtained a static friction coefficient of 0.34 and a dynamic of 0.21.

4 MODELLING OF THE COUPLED SYSTEM: RC FRAME, CLT PANEL AND AFC CONNECTION

The authors modelled the hysteretic response of the RC frame in Fig.6(a). Fig.6(b) shows the experimental cyclic response by increasing the displacement at each cycle up to a drift of 2.5 %. The authors reproduced the hysteretic response in Fig.6(b) using the Atan model, presented

Figure 6: (a) RC frame subject to cyclic loading after [31]; (b) Experimental hysteresis loop; (c) Comparison with the Atan model.

by [34], which suits the simulation of mechanical systems with pinching, and both strength and stiffness degradation. It is a hysteresis model based on the arctangent function characterized by the following piece-wise definition:

$$\begin{aligned} 1 - a_1 \arctan(b_1 x - |c_1|) & \text{ if } \{ \dot{x} > 0, x > 0, |x| > q \max(|x(t)|) \forall t \in [0, t] \} \\ 2 - a_2 \arctan(b_2 x - |c_2|) & \text{ if } \{ \dot{x} < 0, x > 0 \} \\ 3 - a_3 \arctan(b_3 x + |c_3|) & \text{ if } \{ \dot{x} < 0, x < 0 \} \\ 4 - a_4 \arctan(b_4 x - |c_4|) & \text{ if } \{ \dot{x} > 0, x > 0, |x| < q \max(|x(t)|) \forall t \in [0, t] \} \\ 5 - a_5 \arctan(b_5 x + |c_5|) & \text{ if } \{ \dot{x} > 0, x < 0, |x| \leq q \max(|x(t)|) \forall t \in [0, t] \} \\ 6 - a_6 \arctan(b_6 x + |c_6|) & \text{ if } \{ \dot{x} < 0, x < 0, |x| \leq q \max(|x(t)|) \forall t \in [0, t] \} \end{aligned} \quad (10)$$

where the six conditional statements identify the transition between the different parts of the hysteresis. A set of three parameters define the arctangent function in each section of the loop: a_i characterise the amplitude of the force, b_i the x axis resolution and c_i the residual displacement. The subscript i varies between 1 and 6. The strength and stiffness degradation descend from the use of an exponential function, like in [35, 36]. The exponential function expresses the force and stiffness degradation as a function of the dissipated hysteretic energy (ϵ). The energy-dependent definition of a_i and b_i is:

$$a_i(\epsilon) = e^{(-\xi_{a_i} \epsilon)} a_0 \quad (11)$$

$$b_i(\epsilon) = e^{(-\xi_{b_i}\epsilon)} b_{0,i} \quad (12)$$

where ξ_{a_i} and ξ_{b_i} are properly calibrated to the degradation of the strength and stiffness respectively. The parameters are $a_0 = \frac{2F_u}{\pi}$ and $b_{0,i} = \frac{k_{0,i}}{a_0}$, where $k_{0,i}$ is the tangent stiffness, and F_u is the ultimate resistance.

Fig.6(c) displays the superposition between the experimental cyclic response of the RC frame and the simulated one using the Atan model with the parameters in Tab.1. The model satis-

Table 1: Parameters of the Atan model for the simulation of the cyclic response of the RC frame in Fig.6.

Parameter	Value
a_0	140.12
$b_{0,1}, b_{0,4}$	0.71
$b_{0,2}, b_{0,3}$	0.32
$b_{0,5}, b_{0,6}$	0.25
c_{1-6}	0.20
ξ_{a_i}, ξ_{b_i}	0.00005
q	0.80

factorily follows the experimental data by exhibiting the expected degradation behaviour. The model's significant stability under dynamic excitation endorsed this model's adoption: it was explicitly conceived to enhance the stability of hysteresis models with pinching, which present several convergence issues due to the stiffness boost in the pinched branches.

Columbian friction mainly drives the cyclic response of the AFC. Therefore, the authors adopted the following definition of the slip force:

$$F_s(\epsilon) = \mu(\epsilon) F_{p,C} \text{sign}(\dot{x}) \quad (13)$$

where $F_s(\epsilon)$ is the slip force, $F_{p,C}$ is the absolute value of the preload force, \dot{x} the velocity of deformation, ϵ is the dissipated hysteretic energy. The definition of the friction coefficient is:

$$\mu(\epsilon) = \mu_0 [\exp(-\xi\epsilon(i)) + 1] \quad (14)$$

where the μ_0 and ξ from an ordinary least squares optimization are 0.33 and 0.00005 respectively. The authors noticed that an exponential function closely follows the strength evolution

Figure 7: Comparison between the experimental data and the Coulomb-like friction model: (a) Hysteresis loop; (b) Force-Time function; (c) Dissipated Energy-time function.

of the AFC. Fig.7 presents the comparison between the experimental data and the Coulomb-like friction model. The model seizes the experimental response, but it exhibits an energy dissipation higher than expected due to the loop's non-rectangular shape due to the corner chirping effect. The authors neglect this phenomenon in the current investigation due to its limited influence on the dissipated hysteretic energy.

4.1 Modeling the coupled system

The assemblage of the RC frame with masonry infill, a CLT wall panel and the AFC represents the structural unit of the e-CLT technology. In the considered system, the CLT panel's in-plane resistance must be higher than the slip resistance of the AFC. The CLT panel increases the RC frame's strength and stiffness, but the sole AFC provides the extra dissipation capacity. Accordingly, a linear elastic behaviour of the CLT is assumed for the modelling of the panel. In the current case, the structural unit consists of the RC frame equipped with a 90mm thick CLT panel, circumscribed by the frame. Likely, the CLT panel behaves like a clamped-clamped beam. Therefore, the lateral stiffness is:

$$k_{CLT} = \frac{1}{\frac{h^3}{12EI} + \frac{1.2h}{GA}} \quad (15)$$

where k_{CLT} is the lateral stiffness, h the panel's height, E the longitudinal elastic modulus, I the cross-section inertia, G the shear modulus, A the cross-section area. The authors adopted the following parameters $E = 11600\text{MPa}$ and $G = 450\text{MPa}$. The assemblage's lateral resistance, F_T , is the summation of the three contributes, conditional of the exceeding of the slip resistance: the resistance of the RC frame F_c , the slip resistance of the AFC F_s and the CLT panel contribute F_{CLT} .

$$F_T(x, \dot{x}, \max(|x(t)|), t, \epsilon) = F_c(x, \dot{x}, \max(|x(t)|), t, \epsilon) + F_{CLT}(x) \quad \text{if } F_T \leq F_s \quad (16)$$

$$F_T(x, \dot{x}, \max(|x(t)|), t, \epsilon) = F_c(x, \dot{x}, \max(|x(t)|), t, \epsilon) + F_{CLT}(x) + F_s(\dot{x}, \epsilon) \quad \text{if } F_T > F_s \quad (17)$$

where x is the top displacement of the frame, F_c is described by the Atan model, F_s by Eqs.(13)-(14), and $F_{CLT} = k_{CLT}x$. Likely, the combination of Eqs.(16)-(17) would simulate the lateral response of the structural unit obtained by assembling the RC frame, the CLT panel and the AFC connection.

5 SEISMIC PERFORMANCE OF THE STRUCTURAL ARRANGEMENT

The inelastic restoring force in Eqs.(16)-(17) participates to the equilibrium of single-degree-of-freedom oscillator (SDOF), representative of the RC frame dynamic response. The equilibrium of a lumped mass above the frame yields the following ordinary differential equation under earthquake excitation:

$$m\ddot{x} + F_T = -m\ddot{x}_g \quad (18)$$

where m is the mass, x the displacement, \ddot{x} the double derivative of x with respect to time, F_T the resisting inelastic force defined in Eqs.(16)-(17), and \ddot{x}_g the ground acceleration. A SDOF system is the most elementary structure. Nevertheless, it is the most meaningful, and the results obtained from this basic structure have universal application. The SDOF model is used to assess the slip force, which guarantees the lowest inter-storey drift. An RC frame represents any

storey distinguished by a prevalent shear-type response. Accurately, any structure is a stand-alone case, but an elementary model's accurate analysis supports a mindful assessment of the optimum ranges to be expected in more complicated structures. In contrast with the previous section, the displacement is unknown and must descend from the numerical integration of the ODE. Precisely, the authors used the explicit fourth-order Runge–Kutta method for the temporal discretization of the approximate solution of the ODE. The optimization of the slip force in AFC descends from an indirect approach. The authors simulated the response of an RC frame equipped with the AFC to a set of 41 earthquakes by varying the value of the slip force in a given range. A list of 41 Italian earthquake records with magnitude M_L ranging between 5 and 6.5, reported in [37, 38], represented the base for generating 41 artificial earthquakes, scaled to the same PGA and optimized to match a given design spectrum. The design spectrum corresponds to the seismic scenario expected in L'Aquila, Italy, according to the National Seismic Code. The algorithm presented by [39] is used to scale the accelerograms to a 0.3PGA, and carry out the analyses based on coherent inputs. The algorithm modifies the frequency content without producing substantial shape modifications. The force slip varied in the range 0-100kN, with a 1kN step. Fig.8 displays the results of the analyses. Fig.8(a) reports the maximum displacement drift due to a single earthquake. Maximum inter-story drift is widely used to evaluate the level of damage to both structural and non-structural elements in RC structures [32]. Fig.8(b) superposes the curves in Fig.8(a) by considering the responses to the 41 earthquakes. The mean and variance of the minima of the curves in Fig.8(b) leads to the normal distribution pictured in Fig.8(c).

Figure 8: (a) Maximum drift of the RC frame from the response to the El Centro earthquake as a function of the slip force; (b) Superposition of the maximum drifts of the considered system under the earthquakes in Tab.??; (c) Half-Normal distribution of the slip force vales corresponding to the minimum drift.

The curves do not exhibit a smooth trend: they are very jagged. Still, despite the oscillation, each curve has a minima range with a concave shape by the minima. Hence, the authors picked the argument corresponding to the lowest value, considered representative of the optimum slip force. There are considerable differences between the curves obtained from different earthquakes. This evidence agrees with the findings by [16]. They observed that the optimum slip load values are more affected by the amplitude and frequency of the input earthquakes (e.g. peak ground acceleration) rather than the structure's characteristics.

Interestingly, the range of local minima gathers by the lower values of the slip force.

Also [29], [40] and [41] observed that the use of friction dampers leads to an optimum range of slip load ratios that, on average, leads to lower inter-story drifts. According to [29], the slip load ratio is the ratio between the slip value and the resistance of the structure without the

passive device. They found the following empirical function for the prediction of the optimum slip force as a function of the number of storeys n :

$$R = 1.12 e^{-0.11n} \quad (19)$$

If there is one storey, the R ratio is almost one. As the number of storeys grows, the R ratio reduces to 0.12. This empirical equation does not agree with the outcomes of this investigation. The R ratio in the considered configuration is $R \approx 0.23$.

According to [29], in the considered case, the optimum slip resistance should be approximately equal to 200kN. Numerous factors are affecting the optimum value of the slip force. Both the RC frame and the AFC dissipate the seismic energy. The energy dissipated by the friction dampers is proportional to both the slip force and the mutual drift. If the slip force is kept low, the dissipated energy increment must descend from the increment in displacement. If the slip force is higher, a lower displacement can generate the same dissipation. However, higher forces cause the device activates when the RC frame has already experienced a significant displacement drift. In the considered system, characterized by strength and stiffness degradation, if the slip force was equal to 200kN, the AFC's benefit was reduced by its tardy intervention.

Still, the RC frame with masonry infill can exhibit more the 50% strength increment to the same structure without infill. If R is the ratio between the slip resistance and the RC lateral capacity without the infill, the findings of this research and those by [29] become coherent, R will approximate one. The masonry infill is determinant for the correct assessment of the optimum slip force.

6 Conclusions

The paper addresses the seismic performance of the e-CLT technology via nonlinear dynamic analysis on an elementary RC frame with masonry infill. The e-CLT technology is a seismic retrofitting solution of existing RC building based on the use of cross-laminated timber (CLT) panels and asymmetric friction connectors (AFC). In an RC frame, one end of the CLT panel is fixed on the lower beam, while the other end is equipped with an AFC, connected to the RC frame's upper beam. The slip force's exceeding in the AFC activates the dissipating device, which possibly contributes to the seismic energy absorption and the reduction of the displacement drift demand. The authors experimented the cyclic behaviour of the AFC and proposed a Coulomb-like model with a friction coefficient dependent on the dissipated hysteretic energy. The experimental data are used to simulate a frame's coupled response with masonry infill equipped with the AFC. The Atan model, which is an empirical hysteresis model proposed by [34], simulates the experimental cyclic response of an RC frame with masonry infill, tested by [31]. The authors tested the frame's response, represented by an SDOF oscillator with a lumped mass on the top, under a set of 41 earthquakes by varying the slip force in a given range. Interestingly, there is a range of minima where the slip force is associated with a significant reduction of the storey drift. The displacement reduction can be higher than 50%. However, as observed by [16], seismic input's nature significantly affects the optimum slip force's value, which exhibits a significant scatter. The mean value of the optimum slip forces found in the considered structure is 45kN, which is approximately the 21% of the shear resistance of the frame. This evidence does not match the findings by [29], who predicted higher optimum slip force values in bare RC structural archetypes with friction dampers; while in the analyses of this paper the RC frame was modelled with its real behaviour including the masonry infill. The masonry infill can add more than 50% increment in strength and stiffness to the same RC frame without infill, in which case the results from this paper would align with [29].

Funding

This paper was carried out in the framework of the "Energy and seismic affordable renovation solutions" (e-SAFE) project, which has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No.893135. Abstract

Recently, timber has gained increasing importance as a structural material, as it offers competitive structural performance and efficient production combined with a significant reduction of the environmental impact. Light-weight timber frames provide an efficient structural solution for wooden multi-storey buildings, in which the wall elements - acting as diaphragms - provide lateral stiffness and resistance to wind and earthquake loads. Light-weight timber frame elements are built up of several components (sheeting, fasteners, frame, support and anchorages), each of them contributing to the total performance of the structure. The current paper presents the outcome of experimental and numerical investigations on a ductile and replaceable supporting and anchoring system for wood shear walls. The aim of the examined novel system is two-fold: (i) to limit the damage of the superstructure under seismic loads by concentrating plastic deformations on the anchoring elements, placed at the base of the building and (ii) to be replaced after getting damaged because of a significant earthquake. The supporting and anchoring detail is made of steel and designed appropriately to behave nonlinear in a ductile manner under severe seismic loads and thus to provide additional energy dissipation. The damage is concentrated on the steel part, which acts as a dissipative mechanism limiting the forces transferred into the timber building. Consequently, the timber members remain undamaged for moderate earthquakes and slightly damaged in case of strong seismic events. A parametric study, using FE models validated based on experimental results, was conducted with the objective to investigate the influence of the geometrical characteristics of the anchorage. Moreover, a built-up anchoring configuration optimized for replaceability was developed and analyzed. Finally, recommendations for applications are provided, as well as the main conclusions of the study.

Keywords: timber shear walls, ductile and replaceable anchoring system, experimental tests, FE-investigation

1 INTRODUCTION

Recently, timber has gained increasing importance as a structural material, as it offers competitive structural performance and efficient production combined with a significant reduction of the environmental impact. Light-weight timber frames provide an efficient structural solution for wooden multi-storey buildings, in which the wall elements - acting as diaphragms - provide lateral stiffness and resistance to wind and earthquake loads. Light-weight timber frame elements are built up of several components (sheeting, fasteners, frame, support and anchorages); each of them contributes to the total performance of the structure.

Rising demand for multi-storey timber buildings leads to new challenges regarding stiffness, strength and ductility - properties responsible for the seismic performance. On the one hand, because of their relatively low structural mass, timber buildings are exposed to lower seismic loads compared to other structural materials. On the other hand, the anisotropic and naturally scattering characteristics of wood material settle the design of timber structures for dissipative behavior a challenging process. Fundamental for the dissipation is the capacity design, which guarantees a reliable and accurate prediction of the nonlinear response of the dissipative elements. Therefore, an innovative support and anchoring system acting as a dissipative element was developed, aiming at improving the seismic performance of light-weight timber frame structures.

Currently, tension ties made of galvanized flat steel represent the common solution for anchoring timber frames to the foundation. These ties are designed for uplift forces only; they are connected to the timber studs by means of screws or nails and to the foundations by anchor bolts. In [1][2], tension ties were investigated and it was found that, although the tested specimens can resist adequate tensile forces and provide ductility redundancies, they are susceptible to sudden failures. The limited predictability of the governing failure mode of the tension ties was confirmed by own tests (Figure 8 b & c). Tlustochowicz [3], compared two different alternative techniques for the transmission of shear and tension forces: either through nailing plates welded to a foundation steel plate or via a HEB profile, which was connected to the studs of the timber wall by glued rods and anchored in the foundation. The specimens with glued rods failed suddenly in the glued interface [4]. The alternative with nailing plates is widely used in timber structures. Sufficient ductility can be provided by adequate number and strength of nails, but sudden block failure of the connectors must be prevented.

In light-weight timber frames, the key component governing the ductility (stiffness and strength as well) is the shear connection between sheathing and frame. The investigated anchoring detail was developed to enhance the ductility and dissipation capability of the structure by adding a dissipative mechanism at the base of the timber wall. The development of the novel anchorage targeted at eliminating the drawbacks of existing solutions, by providing a simple, reliable and replaceable element which, to some extent, also prevents damages to the main timber structure. To this end, the anchorage must provide a stable hysteretic performance in the plastic domain. Additionally, the opportunity to strengthen or substitute the anchorage after a significant seismic event resulting in plastic deformations limited to the anchor system was also taken into account. This concept allows for a rapid restoration of the occupancy of the building after an earthquake.

The novel anchorage examined within the current study is made of steel and is integrated into the corner studs of a timber wall, as shown in Figure 1. It consists of a steel rectangular hollow section (RHS) and a steel plate, welded to the upper flange of the hollow section. The steel plate is used for transferring vertical forces from the slitted timber stud by means of a double shear connection with steel dowels or bolts. The anchoring device is designed to transfer

vertical loads (tension and compression) only. Shear forces are transferred by separate shear keys or angle profiles to the foundation.

The response of the structure to seismic loads can be “controlled” through definition of different performance levels for the proposed anchorages. Following the principles of the modern codes [6], three main performance levels are considered: damage limitation, significant damage and near collapse. By adjusting the elastic limit of the examined anchorage, the performance of the total building can be subdivided into: (i) damage limitation performance level: both superstructure and anchorage respond elastic, (ii) the significant damage performance level (or ultimate limit state): the anchoring device behaves nonlinear and dissipates energy, the timber superstructure remains undamaged or slightly damaged and (iii) near collapse level, damages (nonlinear response) are expected both at the anchorage and at the superstructure.

Figure 1: Innovative ductile and replaceable anchorage for timber shear walls

Crucial point of the developed concept is the capacity design of the detailing. The non-dissipative elements should be designed appropriately to remain elastic, permitting yielding and nonlinear response of the dissipative elements. Material hardening and overstrength of the dissipative elements must be considered. Concerning the tested subassemblies, fasteners, internal steel plate and timber studs were considered as non-dissipative elements. Regarding global systems, depending on the desired performance level, shear walls can also be considered as non-dissipative for specific scenarios.

The reliability of the novel ductile anchorage was investigated experimentally and validated numerically by the Institute of Steel Construction of RWTH University in Aachen, Germany. The investigation was part of a national funded research project (HOLZBEBEN), in which the seismic response of light-weight timber frames was holistically examined including tests on connections details, on wall elements and on a reference structure [7].

2 EXPERIMENTAL INVESTIGATIONS

Two series of experimental tests both monotonic and cyclic were carried out. The aim of the first series (S1) was the investigation of the principle of the novel anchorage and the validation of the numerical models, whereas the target of the following tests (S2) was to examine the performance of the anchorages as parts of a realistic building, including the interaction with the timber members. For comparison reasons also tests on commercial tension ties were executed. Table 1 provides an overview of the tested specimens and their characteristics.

Series	Specimen	Anchorage	Dimensions (b x t x h x d) in mm	Material	Connectors Ø in mm	Loading
S1	M01	novel anch.	200x100x100x6.3	S235	3 x threaded rods 12-8.8	monotonic tension
S1	M01*	novel anch.	200x100x100x6.3	S235	3 x threaded rods 12-8.8	monotonic compression
S1	Z01	novel anch.	200x100x100x6.3	S235	3 x threaded rods 12-8.8	cyclic (ECCS)
S1	Z02	novel anch.	200x100x100x6.3	S235	3 x threaded rods 12-8.8	cyclic (ECCS)
S1	Z03	novel anch.	200x100x100x6.3	S235	3 x threaded rods 12-8.8	cyclic (ECCS)

Table 1: Overview of experimental tests

2.1 Investigation of Series 1

2.1.1. Test set-up and instrumentation

The tests of this series were conducted on a ZwickRoell Z100 testing machine. The specimens were fixed through a bolt on a steel plate, which was rigidly clamped at the testing machine. The loads were transmitted from the machine jack through the timber element using a steel to timber connection.

Firstly, a monotonic tensile test (M01) was performed, in order to define the yield displacement, according to ECCS testing procedure [8]. The determination of the yield displacement is necessary to define the amplitudes for the following cyclic tests (Z01-Z03).

During the tests, the machine jack displacement and the applied load were recorded by the testing machine. In addition, the vertical displacement in the middle of the hollow cross-section (W1), the vertical displacement at the upper corner of the hollow profile (W2) and the relative displacement between the inner steel plate and the timber member (W3) were measured by displacement transducers. During the cyclic tests (Z01-Z03), the inclination of the right and left part of the hollow steel member flange were recorded by inclinometers (N1 and N2). The monotonic and the cyclic tests were conducted in displacement control with a constant speed rate of 0.1 mm/s. The instrumentation configuration is presented in Figure 2.

2.1.1. Results

Regarding the monotonic (M01 and M01*) tests, it was observed, that: (i) the novel anchorage presented significantly different stiffness in tension $K_t = 2.69 \text{ kN/mm}$ and in compression $K_c = 23.92 \text{ kN/mm}$, (ii) in tension the behavior was ductile and a remarkable amount of energy could be dissipated, (iii) no brittle failure occurred despite extreme tensile displacement, and (iv) the high compression stiffness is present, when the system anchorage-stud returns to the initial position and the compression load was transferred by contact between the timber stud

and the flange of the RHS. The response of the anchorage is displayed in Figure 3, whereas the initial stiffness, the yield point (according to ECCS [8]), the dissipated energy and the damping ratio are depicted in Table 2.

Concerning the cyclic tests, it was observed, that the envelope curve is very close to the monotonic curve. Moreover, the anchorage was proved to be capable of dissipating energy and resisting a large number of loading cycles, without significant strength reduction (less than 7.5% as illustrated in Figure 4). In addition, the measurements of inclinometers confirmed, that the anchoring device responded in a symmetric way.

2.2 Investigation of Series 2

2.2.1. Test set-up and instrumentation

After the applicability of the novel anchoring devices was experimentally proven in test-series S1, the anchorages were designed for the shear walls of a multi-storey timber building. In addition, commercial tension ties (HTT31, Simpson Strong Tie [9]), which could be used as a conventional solution for the same building, were selected as reference anchorages. Tensile tests were carried out on one specimen of the innovative anchorage and on two HTT31 specimens. The innovative anchorage was made of steel S355 and its thickness was $t=12.5\text{ mm}$. HTT31 anchoring elements are made of galvanized steel S350GD. According to [9], they can resist $R_{t,c} = 85.1\text{ kN}$ characteristic tensile load. They are considered to be very ductile and capable of dissipating energy and are assumed to provide sufficient dissipation capability for ductility classes DCM or even DCH.

Figure 6: Series 2, test set-up and instrumentation configuration

For the test-series S2 a new test set-up was used, accounting for the increased dimensions and expected loads. The test configuration, the specimens and the instrumentation system are depicted in Figure 6. The instrumentation of the novel anchorage consisted of eight displacement transducers, two of them (d7 and d8) measuring the relative displacement between the internal steel plate and the timber stud. The other sensors (d1 ÷ d6) were measuring the response of the anchorage in terms of displacement at three points (left, right, middle) at the upper and at the lower flange of the hollow profile. The instrumentation of the tension ties included measurement of the relative displacement between steel plate and timber member by displacement transducers d5 and d6 and measuring of the displacement in the middle of the bottom angle part by the transducer d7. In addition, the strains at three characteristic positions along flat steel part

of the ties were measured ($s1 \div s3$), in order to determine, the load distribution to the connectors. In all tests the hydraulic jack load and displacement were measured too.

2.2.2. Results

In Figure 7, the experimental results are presented. The novel device displays no failure until a load of 230 kN (max. load capacity of the hydraulic jack) with a corresponding displacement of about 90 mm . It is obvious, that such displacements are not considered as accepted under seismic loads. The maximum accepted displacement depends on the requirements of each building. Regarding the specimen, it is to underline, that after a displacement of about 40 mm , membrane effects appear and are responsible for the change of inclination. Concerning the HTT31 tension ties, it is to be noted, that their stiffness, calculated according to [14], was close to the suggested values and their capacity about 27% higher than characteristic strength provided in the approval [9]. The results of the experiments are included in Table 3. In addition, it is worth mentioning, that the two HTT31 specimens presented different failure modes (Figure 8: b & c). The first one exposed net cross-section failure in tension, while the second one failed in the bottom part responsible for the connection to the foundation. Both failure mechanisms provided some plastic ductility followed by a sudden drop of resistance. Measurements by strain gauges showed a non-uniform force distribution along the HTT31 and the corresponding fasteners. The measured force decreases from 1 kN (point s3) to 0.67 kN (point s2) and 0.25 kN (point s3) (the values are normalized). Comparing the test configuration of the novel anchorage with the reference anchorage, the main conclusions are: (i) the novel anchorage is slightly stiffer and presents higher strength, (ii) the yield point is clearly identifiable and is about 50% higher (96.01 kN to 62.65 kN), (iii) both anchors are very ductile in monotonic tension however, the novel anchorage has the potential to dissipate significantly more seismic energy by developing stable

Test results	Novel A01	HTT31 A03
Initial stiffness	29.63 kN/mm	27.39 kN/mm
Yield load	96.01 kN/mm	62.65 kN
Yield displacement	3.14 mm	2.42 mm
Max. load	>230 kN	109.17 kN
Max. displacement	>90 mm	19.62 mm
Ductility factor	-	8.1

hysteresis in tension and compression. In general, the examined novel anchorage shows an excellent performance, regarding the decisive properties for the seismic design – stiffness, strength and ductility - compared with a very effective reference tension tie (HTT31).

3 NUMERICAL AND ANALYTICAL INVESTIGATION

Numerical simulations were used to verify and to predict the behavior (load transfer, plastic hinges) of the examined specimens and to extend the study to other parameters (geometry, material properties) allowing for an adjustment of the anchorage to the design situation. The numerical investigations in this study were developed using the FEM software Abaqus Simulia 2018 [12].

3.1 FEM modeling procedure

The numerical models consisted of solid elements and included the rectangular hollow section (RHS), the steel plate, a foundation plate and the connectors, as depicted in Figure 9. The RHS, the steel plate and the foundation plate were modeled with a simplified isotropic bilinear material law for steel S235 and S355, according to the minimum requirements for steel as proposed by Eurocode 3[11]. The material law for the steel to timber connectors is taken from experimental results published in [10]. The timber element was modeled assuming elastic behavior, based on observations from the tests. Regarding the interactions and boundary conditions, the following options were applied: (i) “tie constraint” – for the welded connection between internal steel plate and hollow profile, (ii) “contact interaction” – for the interaction of different model components (bolts-timber, timber - RHS, RHS – foundation plate) in contact. The ‘normal hard contact’ used in the model, allows for separation between the parts and the ‘friction/penalty contact’ for considering friction effects. Sensitivity study for penalty values between 0.01 and 0.25 exposed that the penalty value does not influence the results. Regarding the boundary conditions, the foundation plate was fixed on both transverse edges, which approaches very close the real boundary conditions of the testing machine. The external loading was applied as imposed vertical displacement on the upper surface of the timber stud. For convergence reasons ‘Dynamic Explicit Analysis’, with a smooth step amplitude was selected, considering geometrical and material nonlinearities. The kinetic energy at all stages of the analyses (monotonic and cyclic) remained negligible. Regarding the discretization method, the mesh was adapted to the different components (4 mm for the timber stud and the hollow profile, 1.5 mm for the connectors and 1 mm at the areas of the RHS, where plastic strains were

expected). The element type was linear hexahedral elements type C3D8R. The size of the mesh elements was adapted until the results were independent of the mesh.

Figure 9: Assembled finite element model and discretization

3.2 Calibration of the model

The numerical model was developed with the characteristics described above and was calibrated with the monotonic and pseudo cyclic load – displacement curve from the tests A01 and M01 - M01*. In Figure 10, the results of the test and of the numerical simulation both in tension and compression are compared.

Figure 10: Comparison of response curves: test versus numerical reference model

Taking into consideration the simplified material law, the numerical and experimental results are in good agreement. The differences between the numerical and the experimental results are within an acceptable range for the intended application. In detail, the following deviations between A1 test and simulation are observed: (i) 1.0 % at yield force, (ii) 1.8 % at initial stiffness. Between M01-M01* test and FE model the deviations are: (i) 5.6 % at yield, (ii) 9.49 % at initial stiffness, (iii) 2.9 % at maximum load and (iii) 13.2 % at dissipated energy. The stress and stain distribution of the numerical model, that represented the specimen M01-M01* are displayed at the image series of Figure 11. The distribution of stresses and equivalent strain (PEEQ) illustrates the symmetric response of the anchoring and the sequential formation of plastic zones in the RHS, initially, near the foundation connector and at the sides of the vertical plate and afterwards at both ends of the webs.

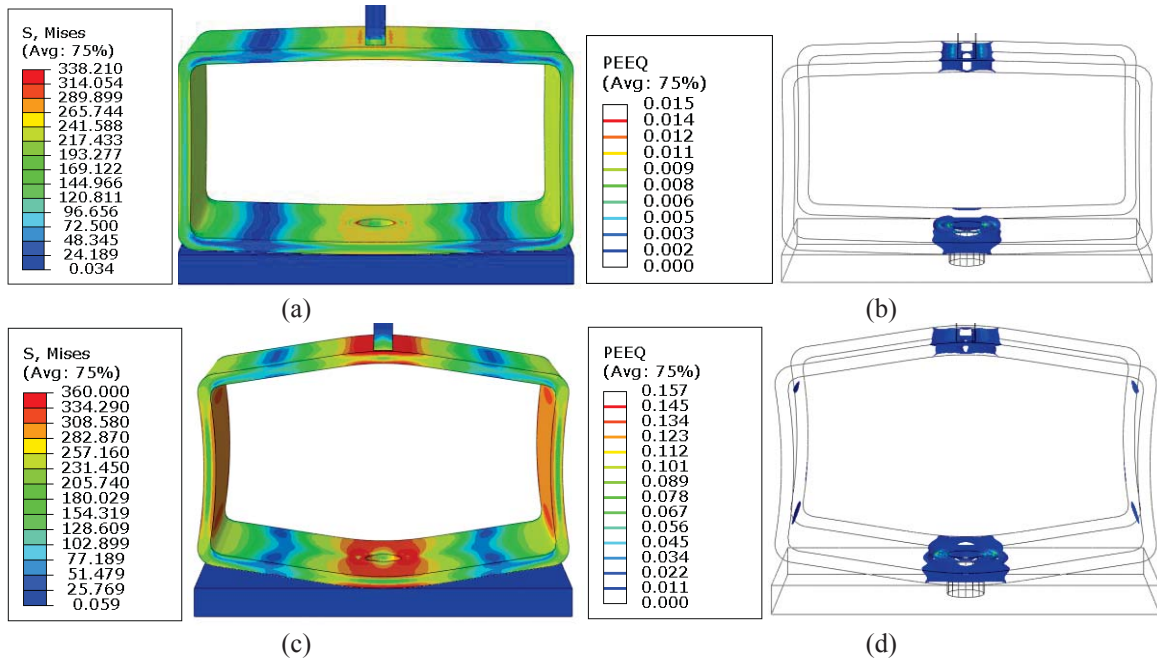

Figure 11: (a) stress distribution $U_2 = 5$ mm, (b) plastic strains at $U_2 = 5$ mm, (c) stress distribution $U_2 = 25$ mm, (d) plastic strains at $U_2 = 25$ mm

3.3 Parametric Study

After the calibration of the numerical models based on the experimental results, a parameter study was performed, in order to investigate the influence of the geometrical characteristics of the novel anchorage. The influence of wall thickness (t), width (w) and depth (d) of RHS was examined by varying separately these parameters in numerical models. As reference the anchorage with the properties as tested in first experimental series is used. The load-displacement curves in tension for various values of (t), (w) and (d) determined by FEM are presented in Figure 13. Furthermore, a simple analytical approach for the determination of the

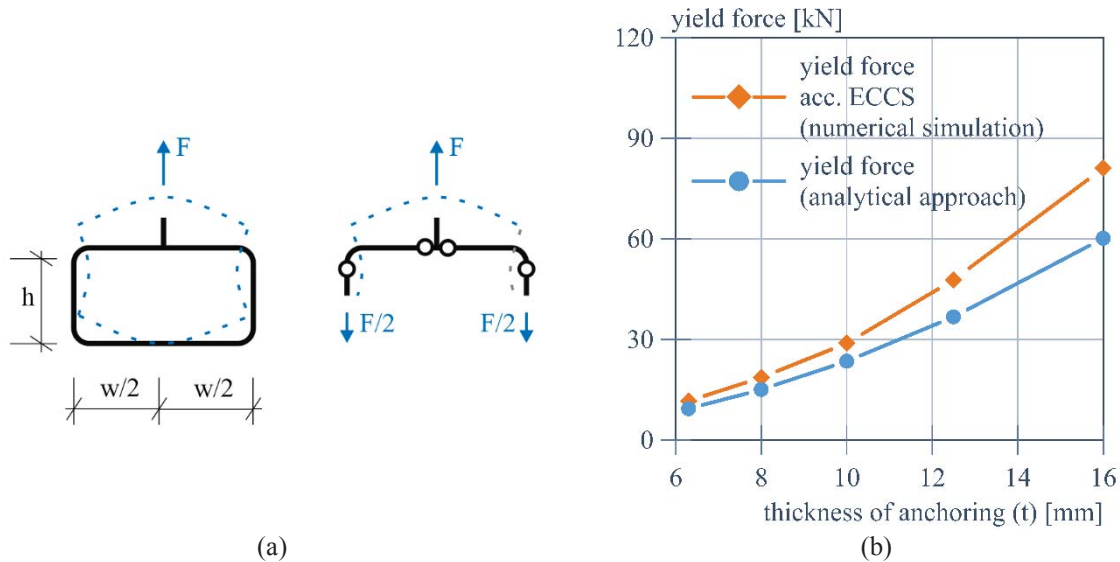

Figure 12: (a) Simplified model for analytical investigation, (b) Influence of thickness on yield force according to numerical and analytical approach

yield force was developed. For the analytical approach, the plastic zones are reduced to plastic hinges Figure 12a. The influence of the thickness on the yield force by the analytical and the

numerical approach is illustrated in the Figure 12b. For the upper part of the plastic mechanism with four plastic hinges, the following equations apply:

$$M_{ex} = F_y \cdot \frac{w}{2} \quad (1)$$

$$M_{ex} = 4 \cdot M_{pl} \quad (2)$$

$$M_{pl} = \left(d \cdot \frac{t}{2} \cdot f_y \right) \cdot \frac{t}{2} \quad (3)$$

Combining the equations (1÷3) allows the calculation of the yield force F_y as function of thickness t , depth d , width w and material (f_y):

$$F_y = \frac{2 \cdot f_y \cdot d \cdot t^2}{w} \quad (4)$$

Parametric studies have shown, that the thickness t has the strongest influence on the initial stiffness, the yield load and the dissipation capacity. The influence of the depth and width variation is less significant, but changes of these parameters allow for a fine-tuning of the anchors, according to the specific structure and loading situation. Finally, the dependency of the dissipated energy on thickness, depth and width of the RHS was examined by FE-analysis. To this end, each of these values was increased by 20% compared to the reference dimensions. The dissipated energy was determined for a loading cycle with a deformation amplitude of 30 mm in tension. It was found that 20% thickness increase ($t = 7.5\text{mm}$) leads to 53% more energy dissipation, 20% increase depth ($d = 120\text{ mm}$) absorbs 19.8% more energy and a 20% wider RHS dissipated 29.3% less energy.

Figure 13: Load-displacement parametric curves of the anchorage (a) wall thickness varying between 6.3 mm to 16 mm, (b) depth varying between 80 mm to 120 mm and (c) width varying between 180 mm to 250 mm

3.4 Optimization for replaceability

One of major aims of the development of the novel anchorage was its replaceability after a significant earthquake. The substitution of dissipating structural parts is always a great challenge, as the existing structure should be temporarily supported and residual forces in the members or details are expected [15][16]. On the other hand, considering the concept of

replaceability in the design and detailing of a structure inherently includes the option of recentering the main structure, under condition that the residual (plastic) deformations are limited to the specific dissipative objects. The introduced innovative anchoring solution can be also designed for disassembling and replacing, as long as the connection of the anchor to the timber studs remains elastic. Also, the main timber structure shall not suffer significant damages. Using the validated numerical models, different alternatives following this concept were investigated. The research focused on built-up members, in which one part only (the lower one in particular) is considered to be dissipative and needs to be replaced. The upper (non-dissipative) part must remain robust and undamaged. After investigating several alternatives, the configuration illustrated in Figure 14a, was selected as the most efficient one. It enables the transfer of gravity forces by contact and simultaneously the lower part (dissipative part) is activated only when uplift forces are present. The investigated hybrid built-up member consists of an outer profile with thickness $t = 16 \text{ mm}$ and width $w = 200 \text{ mm}$. Regarding the internal profile, the dissipative flange was selected as $t = 6.3 \text{ mm}$; the webs are $t = 16 \text{ mm}$ thick as well. The total height of the anchorage remains 100 mm, the steel material is S235 for both the lower and the upper part. The connecting bolts are M16-10.9.

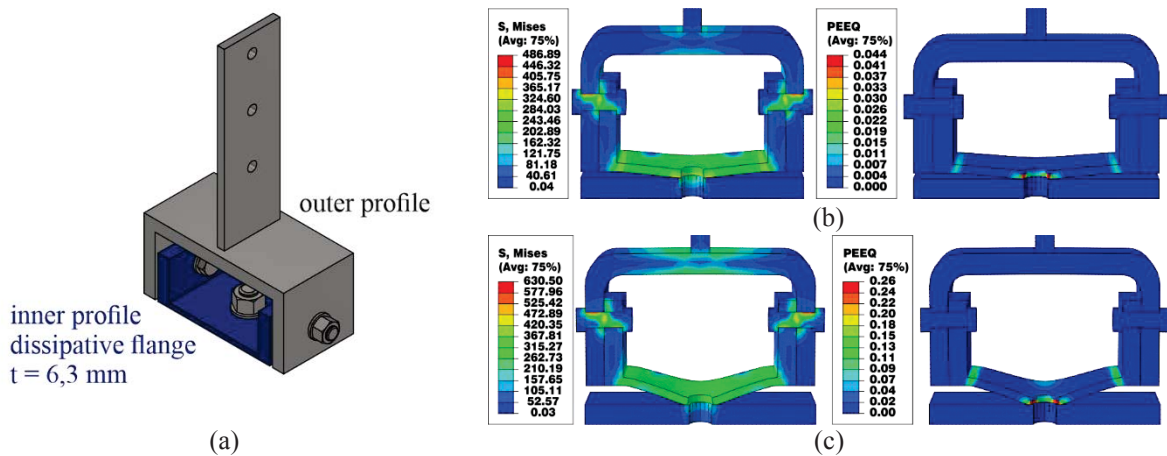

Figure 14: (a) Built up optimized anchoring device, (b) Stress and plastic strain distribution, $U2 = 5 \text{ mm}$, (c) Stress and plastic strain distribution, $U2 = 15 \text{ mm}$

The results of the numerical simulation, plotted in Figure 15, are very encouraging, as the optimized configuration presents a similar initial stiffness to the RHS anchoring configuration with $t = 10 \text{ mm}$ thickness ($K_{t=10} = 14.57 \text{ kN/mm}$) and a performance (yield force and plastic behaviour), which corresponds to the novel RHS anchorage with a thickness between $t = 8 \text{ mm}$ and $t = 10 \text{ mm}$. The plastic hinges form in three regions (around the foundation bolt and at both ends of the dissipative flange), as illustrated in Figure 14 (b & c: plastic strains). The performance limit was estimated to be at an uplift deformation of about 26 mm, where the concentration of strains is significantly beyond those in the reference configuration (RHS). Nevertheless, the ratio between ultimate displacement ($d_u = 26 \text{ mm}$) and yield displacement ($d_y = 1.4 \text{ mm}$) combined with the stable cyclic response without pitching effects (Figure 15b) indicate that the optimized configuration is also capable of dissipating considerable amount of seismic energy. In order to keep the lower part replaceable, the webs of the lower profile must remain elastic, to enable unscrewing the connecting bolts.

Figure 15: Load – displacement curves of the optimized anchoring configuration

4 APPLICATION

For the application of the novel anchors in timber buildings, the stiffness and strength characteristics and relations of the timber superstructure and the anchors need to be considered. The anchors have different stiffness properties in pure compression (e.g., gravity loads govern the force) and if uplift forces (overturning moment governs) are present. In pure compression the elastic stiffness of the anchors is very high, thus having limited influence on the stiffness of the building. The plastic deformations and cyclic energy dissipation are activated as soon as uplift forces appear. In order to avoid damages to the timber building, it needs to be designed using the lateral seismic actions corresponding to the yield force of the anchors. This shall comprise material overstrength and hardening effects of the dissipative part. Also, the transfer of the base shear force to the foundation and of the shear force between the storeys must follow this principle. If designing for deformations on top of the building, the whole horizontal displacement shall be determined considering two components:

- (i) the displacement Δ_1 , which is the sum of the horizontal head displacement of the wall on each floor due to shear loads and depends on the applied shear force on each floor and on the stiffness of the wall and
- (ii) the displacement Δ_2 , which is the result of the rocking effect due to usage of the novel ductile anchorage and depends on the presence of uplift forces and the corresponding stiffness of the anchoring

In order to achieve an optimum seismic performance in combination with limited damage to the building, the following aspects shall be considered:

- anchorage should be equipped with sufficient strength to remain elastic under moderate earthquakes (local damage limitation);
- light timber shear walls should be designed appropriately according to capacity design as non-dissipative elements for the design earthquake, in order to concentrate the damages in the ductile anchoring device;
- the inherently available ductility of the light timber shear walls should be activated only for a near collapse seismic scenario. In such case, lateral deformations may become critical (inter-storey drift, theory 2nd order effects). This can be controlled either by selecting stiffer profiles or by using additional tension ties, which get activated after a certain, pre-defined uplifting displacement.

As horizontal displacements and drifts are decisive for the design of the ductile anchorage, a pushover analysis is recommended for the evaluation of the different performance levels. Finally, the novel anchorage is designed to transfer vertical loads only (uplifting and compression). In order to prevent unintended transfer of base shear forces, slotted holes for the innovative anchorage should be used. Additional shear keys preferably at the middle of the wall, are suggested.

Figure 16: Shear displacements (left), displacement due to rocking effects at the base (right)

5 CONCLUSIONS

The current paper described the results of experimental and numerical investigations of an innovative, ductile and replaceable anchorage for timber shear walls. Aim of the developed device is the protection of the timber superstructure. One additional advantage of the investigated system is its replaceability. The monotonic experimental tests have shown that the anchoring device behaves in a very ductile manner, when uplift forces are present; in pure compression the loads are transferred by contact and the anchor behaves elastically with a high stiffness. Buckling effects under compressive loads should also be taken into consideration. Cyclic tests have proved, that the investigated anchoring can withstand many loading cycles even of high amplitude, without any significant reduction of its strength. Simultaneously a reasonable amount of seismic energy can be absorbed. After validating the numerical models based on experimental results, a parametric study was conducted and proved that the governing parameter for the behavior of the introduced anchorage is the thickness of the profile. Thicker profiles have an increased stiffness, yield force and dissipation capacity. Finally, the examined anchorage was optimized aiming at its replaceability. The most effective solution among several investigated cases was a built-up member, in which only the lower part is dedicated to dissipate energy and must be replaced after a significant earthquake. The achievement of the intended plastic mechanism requires the application of capacity design rules, in order to prevent plastic deformations or damages in the connections to the timber studs and to the parts of the anchorage, which are supposed to remain in the structure.

Abstract

In the region of Groningen (NL), human-induced earthquakes initiated by gas extraction are causing structural damage. In that area, the building stock is mainly composed of unreinforced masonry (URM) buildings with light and flexible timber floors and roofs. Thus, an experimental campaign was arranged for assessing the in-plane response of these diaphragms, and a retrofitting method was developed, consisting of an overlay of plywood panels screwed to the existing sheathing around their perimeter. This light, reversible stiffening measure showed a great increase in the in-plane strength, stiffness, and energy dissipation of the floors. Subsequently, an analytical model was developed, showing very good agreement with experimental results, and enabling the design of retrofitting interventions with this technique. Starting from the formulated model, a user-supplied subroutine was implemented in the finite element software DIANA FEA, allowing to represent the in-plane response of the diaphragms, including their energy dissipation. Finally, the impact of this retrofitting intervention on a case study of an existing building was evaluated by means of nonlinear time-history analyses. The results of numerical analyses show that the user-supplied subroutine accurately describes the in-plane behaviour of the retrofitted timber floors. Besides, the proposed retrofitting technique greatly increases the global seismic performance of the building, compared with both its as-built configuration and to stiffer and less reversible strengthening measures.

Keywords: Timber floors, Seismic Rehabilitation, Retrofitting, Seismic capacity, Masonry.

1 INTRODUCTION

In-plane response of timber diaphragms greatly influences the seismic response of existing unreinforced masonry (URM) buildings. As-built floors are often too flexible to withstand in-plane loads without causing the out-of-plane collapse of the walls. Hence, a proper retrofitting of the diaphragms, as well as an improvement of their connections to the walls, have to be performed. In this framework, several strengthening techniques have been investigated in the recent years [1]-[14], aiming at enhancing the seismic properties of the existing diaphragms. Among these techniques, reversible ones are usually preferred when they are applied to monumental structures, because of their lower impact [15].

Retrofitting interventions on timber diaphragms appear to be urgent and delicate in the region of Groningen, in the northern part of the Netherlands, where earthquakes induced by gas extraction are causing structural damage. The seismic events up to now have been light and have not caused collapses, but according to probabilistic studies, more intense events might occur. In that area, the building stock is mainly composed of URM low-rise buildings with light and flexible timber floors and roofs. This construction typology is widely present and very vulnerable to horizontal loads, because the buildings were not designed to withstand earthquakes, since seismic events were absent until recently. Thus, in 2018-19 a full-scale test campaign, recalled in Section 2, was arranged at Delft University of Technology for assessing the in-plane response of as-built and strengthened timber diaphragms typical of the Groningen area. The retrofitting measure consisted of an overlay of plywood panels screwed to the existing sheathing around their perimeter. This light, reversible strengthening measure showed a great increase in the in-plane strength, stiffness, and energy dissipation of the floors [14].

In this work, the analytical and numerical modelling of the refurbished floors is presented. An analytical model was firstly developed to enable a detailed design of the retrofitting intervention with the proposed strengthening technique. The formulated model, presented in detail in [16] and recalled in Section 3, estimates well the floors' strength, stiffness and energy dissipation, including pinching behaviour.

After these first steps, the impact of this retrofitting intervention in a case study of an existing building was evaluated by means of nonlinear time-history analyses. Three configurations were studied: an as-built one with flexible floors; one where a stiff and not reversible retrofitting intervention was applied, such as the cast of a concrete slab on the existing diaphragms; one where the proposed strengthening method was applied. For the latter case, given the high amount of energy dissipation of floors already at limited in-plane deflection, and their characteristic pinching behaviour, it was important to model in detail their seismic response for fully evaluating the impact of this retrofitting method. For this purpose, starting from the developed analytical model, a user-supplied subroutine was implemented in the finite element software DIANA FEA [17], allowing to represent the global in-plane response of the diaphragms. In this way, it was possible to simulate the nonlinear behaviour of both masonry (already featured by the software) and timber floors. The subroutine implementation is presented in Section 4, while results from the analyses on the case-study building are discussed in Section 5.

2 IN-PLANE EXPERIMENTAL TESTS ON TIMBER DIAPHRAGMS

To gain more insight into the in-plane behaviour of timber diaphragms with Dutch features, an experimental campaign was arranged at Delft University of Technology [14]. The floors were initially tested in their as-built configuration, and then retested after being strengthened with an overlay of plywood panels screwed along their perimeter to the existing sheathing. Prior to testing, portions of diaphragms were extracted from existing buildings in the Groningen area, so that the material properties of the tested samples could be accurately replicat-

ed and representative for the actual floors. Five full-scale samples representing half of a floor were tested in a vertical configuration (Fig. 1): two specimens were tested parallel to the joists (*DFpar-1*, *DFpar-2*) and two perpendicular to them (*DFper-3*, *DFper-4*), the last represented a roof pitch (*DRpar-5*). For the strengthened samples, the same nomenclature was adopted, adding the letter *s* at the end of each specimen name. As can be noticed from Fig. 1, the retrofitted floors exhibited a great improvement in strength, stiffness, and energy dissipation. To facilitate a detailed design of retrofitting interventions by adopting the proposed strengthening technique, an analytical model was formulated, which is presented in the next section. For further details on this experimental campaign, the reader can refer to [14].

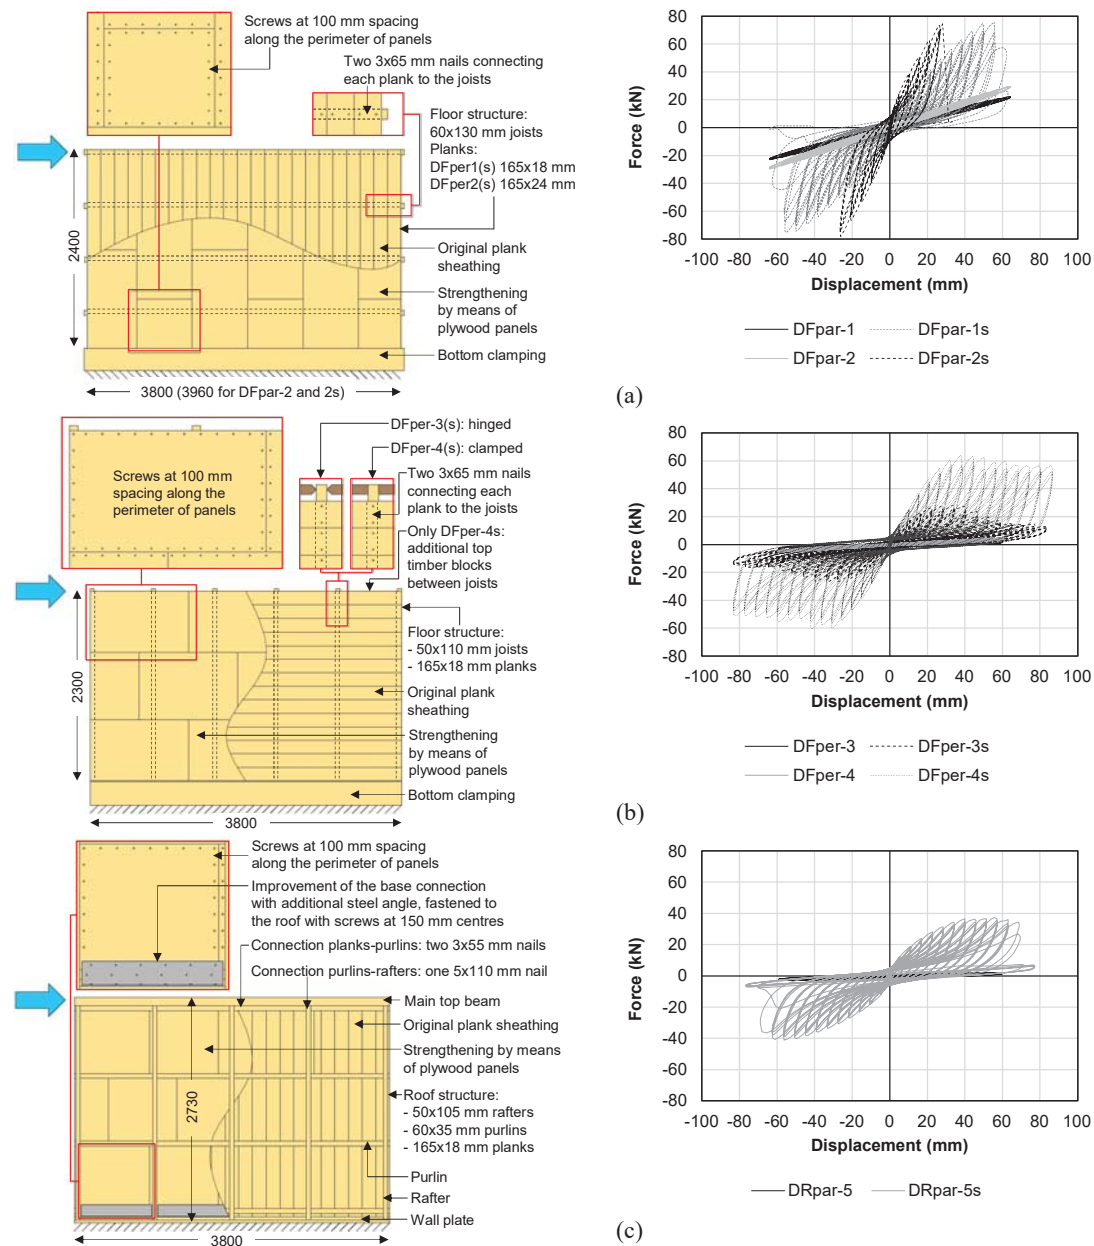

Figure 1: Main characteristics and cyclic in-plane response of the timber diaphragms; floors tested parallel (a) and perpendicular to the joists (b), roof pitch (c) [14].

3 ANALYTICAL MODELLING OF THE STRENGTHENED DIAPHRAGMS

3.1 General

The starting point for the formulation of the model was the evaluation of the load-slip behaviour of the screws fastening planks and plywood panels (Section 3.2). Based on their response, the global in-plane response of the diaphragm was then derived analytically (Section 3.3). The developed calculation model enables a good prediction of the diaphragms' in-plane behaviour [16], as shown in Section 3.4.

3.2 Evaluation of the load-slip behaviour of the fasteners

Besides the experimental campaign on full-scale floors, tests were also performed on fourteen small-size replicates for evaluating the response of the screws connecting plywood panels and planks. These specimens were composed of a plank and a plywood panel portion fastened together by means of two screws (Fig. 2). The samples were tested in shear, under the quasi-static reversed-cyclic loading protocol of ISO 16670 [18]: seven replicates were tested parallel to the main direction of the plank, and the other seven orthogonal to it (Fig. 2a). Similar load-slip curves were obtained between the two loading directions (Fig. 3).

Based on the obtained results, the load-slip response was modelled by means of a combination of a linear and a parabolic branch, representing the initial stiffness and the global behaviour, respectively [16]. A continuous curve was created with an extension of Foschi's load-slip model for nails [19]. With the proposed model, both post-yielding and softening behaviour of the fasteners can be described. The equation of the curve was defined as follows:

$$F_s = (F_0 + a d_s + b d_s^2)[1 - \exp(-K_0 d_s/F_0)] \geq 0; \text{ with } a > 0, b < 0 \quad (1)$$

In Eq. 1, F_s and d_s are the force and displacement of the screw, respectively; F_0 , a and b are the coefficients of the parabola representing the global behaviour, while K_0 is the slope of the line representing the initial stiffness. This curve fits the experimental points with $R^2 = 0.83$ when the panel is loaded parallel to the plank, and with $R^2 = 0.95$ if the force is applied perpendicular to it (Fig. 3). As a failure criterion, the ultimate displacement was considered as the one for which the transferred load drops below 80% of the peak strength during the softening phase, in agreement with the provisions of ISO 16670 [18] and EN 12512 [20]. As a last consideration, a scatter is present in the data points and the backbones, as it is usually observed when analysing tests on timber joints. Yet, since a large number of screws is used in the whole floor, the global behaviour will approach the average trend.

Figure 2: Samples prepared for testing the screws fastening the plywood panels to the existing sheathing: schematic description (a) and example of specimen (b) [16].

With the aforementioned procedure, it is possible to construct the load-slip curve starting from experimental tests, but in order to further generalize the proposed model, a fully analytical estimation of the curve was proposed as well [16]. This generalization was also necessary because some of the full-scale strengthened floors had different characteristics from the small-size replicates: sample *DFpar-2s* featured 24 mm planks, and in specimens *DFpar-2s*, *DFper-3s*, *DFper-4s* screws with a 5 mm diameter were used [14]. Therefore, the parameters K_0 , F_0 , a and b were also estimated according to formulations from standards or literature.

The initial stiffness K_0 was found to be well predicted with the expression provided in [21] for non-predrilled nails, thus $K_0 = 50 d^{1.7}$, with d nominal diameter of the screw.

F_0 can be predicted starting from the knowledge of the maximum force F_{max} determined according to EN 1995 [22] and Johansen's theory [23] for timber-to-timber joints, and with a screw sufficiently slender to develop two plastic hinges. Then, F_0 can be estimated as $F_{max}/8$ (Fig. 4).

To determine the parameters a and b , three points crossed by the parabola have to be identified. The last quantity to be estimated is thus the slip d_{max} of the screw at F_{max} . To this end, firstly the expression of EN 409 [24] can be used for determining the angle α at which the screws' bending moment is evaluated, and adopting for its calculation the shank or inner diameter d_1 of the screw. Secondly, the distance $(b_1 + b_2)$ between the two plastic hinges according to Johansen's theory [23] is determined. By combining these two quantities, the slip at F_{max} can be estimated as $d_{max} = (b_1 + b_2) \tan(\alpha)$ (Fig. 4). The parabola is thus now identified by the three points $(0, F_0)$, (d_{max}, F_{max}) , and $(2d_{max}, F_0)$. Further details on the analytical derivation of the proposed load-slip curve can be found in [16].

Figure 3: Proposed load-slip curve (dashed) in comparison to experimental data points and backbones for the direction parallel (a) and perpendicular to planks (b). The main parameters of the equation are also reported [16].

Figure 4: Comparison between the analytically derived curve and the ones obtained from the experimental data [16]. In the reported equations, the same notation as in EN 1995 [22] and EN 409 [24] is used.

3.3 Prediction of the global response of the retrofitted diaphragms

The floors were retrofitted by screwing plywood panels along their perimeter to the existing sheathing. This type of refurbishment is particularly advantageous, because the screws are placed in such a way that it is possible to identify their specific contribution to the overall resisting mechanism. With reference to Fig. 5, when the strengthened floor is subjected to a horizontal load and the panels are vertically arranged, the force is subdivided among the columns of panels, and the screws are opposing to it with their stiffness. Each column of panels is subjected to rotation and sliding: the rocking behaviour is taken into account by considering the vertical screws, while the (very limited) slip is evaluated through the horizontal screws (Fig. 5). In general, the diaphragms retrofitted with this method can be regarded as very similar to timber shear walls. Therefore, once the load-slip response of the single screw is known, the global behaviour can be predicted by considering equilibrium relations [16].

Figure 5: Determination of the global floors' response from single screws through equilibrium relations [16].

Additionally, the evaluation of energy dissipation was essential, because the strengthened diaphragms proved to provide significant values of equivalent hysteretic damping, of approximately 14-15% [25]. In order to consider this potentially beneficial effect in numerical modelling, an analytical formulation for determining the evolution of pinching cycles was proposed [16].

The pinching behaviour implies the presence of a residual force at zero displacement: this load approximately corresponds to the force causing the very first yielding of the tested sample. In the analytical curve equation, F_0 is the intercept on the y -axis (force) of the parabola representing the global response of the specimens. To capture the very first yielding on the analytical curve, the intercept on the y -axis assumed for the pinching cycle was $2/3F_0$, a value around which the initial slope of the curve starts to change.

Starting from this first intercept, the pinching cycle can be estimated for a certain amplitude identified by a point $(\delta_c, F_c(\delta_c))$ on the curve. As a first step, two lines are determined: one joining the points $(0, 2/3F_0)$ and $(\delta_c, F_c(\delta_c))$, and one crossing the point $(\delta_c, F_c(\delta_c))$ with slope K_0 (Fig. 6, step 1). Then, the bisector of these two lines is found (step 2). In step 3, the remaining part of the cycle is defined: firstly, the line joining $(0, 2/3F_0)$ and the point on the bisector having x -coordinate equal to $\delta_c/2$ is determined; secondly, a line parallel to the former one intersects the branch having slope K_0 , starting from the point $(0, -2/3F_0)$.

In step 4, the whole multilinear cycle is determined, and could already be used for software implementation, as it was exemplified in [16]. The negative part of the pinching cycle (points B', C', D' of Fig. 6) is antisymmetric to the positive one, as is assumed for the backbone curve equation. For a more refined evaluation of both pinching and damping properties of the diaphragms, this multilinear cycle is used in step 5 to construct four exponential branches, smoothening the straight lines, again similarly to Foschi's formulation. The equations of these branches are reported in Section 4.3, in which the implementation of the user-supplied subroutine is presented. A graphical representation of them is given in step 6 of Fig. 6, showing the pinching cycles evolution.

3.4 Comparison between analytical and experimental results

By combining the derived analytical curve and the pinching cycles estimation, the cyclic response of the tested diaphragms was predicted: the reliability of the developed model can now be evaluated by comparing the analytical results with experimental ones. Therefore, this section presents a comparison of the analytical backbone (always depicted in red) and an estimated representative pinching cycle (always shown in dark blue), with the experimental hysteretic cycles (light blue). The results are shown in Figs. 7-9 for a diaphragm tested parallel to the joists (sample *DFpar-1s*, Fig. 7), a floor tested perpendicular to the joists (sample *DFper-4s*, Fig. 8), and the roof pitch (Sample *DFper-5s*, Fig. 9); both the global behaviour and the initial response (up to 20 mm displacement) are displayed. For a more detailed comparison and overview, the reader is referred to [16]. As can be noticed, the analytical model proves to well predict the in-plane behaviour of all diaphragms, also when variations are present with respect to the reference tests on plank-plywood panel joints. In general, the initial stiffness and pinching response are accurately captured by the model, along with strength and displacement at failure of the specimens.

4 NUMERICAL MODELLING OF THE STRENGTHENED DIAPHRAGMS

4.1 General

Given the great improvement in relevant seismic properties of the retrofitted timber diaphragms, it was important to properly model their in-plane response. In this way, the potentially beneficial effect of their energy dissipation, provided at an already limited deflection, could be described. Yet, when considering existing URM buildings with timber floors, the behaviour of the diaphragms is usually simplified in numerical models. Existing or not stiff diaphragms are often modelled as (very flexible) linear elastic orthotropic slabs [26], while after retrofitting them the hypothesis of infinitely stiff diaphragms is frequently assumed, given its compliance with the pushover method [27].

Therefore, the potential energy dissipation of the floors is neglected, and their global in-plane response is not fully considered. However, if it is possible to properly account for both, then an optimized design of the retrofitted diaphragms could be achieved, so that the floors can become an additional source of energy dissipation for the buildings in which they are present. In order to further investigate these aspects, the aforementioned analytical model was implemented in a user-supplied subroutine to be imported in the software DIANA FEA, version 10.4 [17]. This software already featured an advanced nonlinear model for masonry, but lacked suitable materials and constitutive laws for modelling timber floors. In the following sections, the adopted modelling strategy, the subroutine implementation, and its validation are discussed.

4.2 Modelling strategy for timber floors

In order to properly capture the in-plane and out-of-plane behaviour of the diaphragms, while simultaneously implementing the analytical model, a macro-element strategy was adopted (Fig. 10). The floors were modelled by combining linear elastic shell elements, for representing the out-of-plane behaviour under static vertical loads, and nonlinear macro-elements overlapped to them for describing the in-plane behaviour.

These macro-elements consisted of six trusses: four rigid trusses connected to form a quadrilateral, and two nonlinear trusses placed diagonally (Fig. 10), in which the nonlinear in-plane behaviour of the floor was implemented adopting the proposed analytical model. This modelling strategy proved to be accurate and efficient, and was also adopted in past research studies [28], [29]. For the linear elastic orthotropic shells, the flexural characteristics were assigned considering an equivalence between the actual inertial properties of the joists, and those of the slab, so that the same vertical deflection could be achieved.

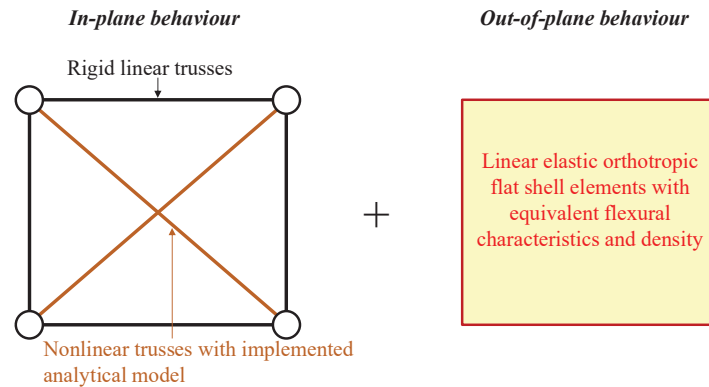

Figure 10: Adopted strategy for modelling in-plane and out-of-plane behaviour of timber diaphragms.

4.3 Implementation of the user-supplied subroutine

In order for the user-supplied subroutine to be compatible with the DIANA FEA environment, the constitutive laws for the diagonal trusses of the macro-elements were implemented adopting the FORTRAN 90 programming language. Two types of input variables are required by the software: user-specified initialization parameters (not changing within the subroutine calculations), and initial state variables (varying during subroutine calculations, e.g. for determining loading and unloading points). As output, DIANA FEA requires user-supplied subroutines to provide the stress-strain relation, to be adopted at every calculation step.

Three relevant parameters for initialization were chosen: the strain ε_{max} at peak stress σ_{max} , the peak stress σ_{max} itself, and the initial elastic modulus K_0 (Fig. 11). These parameters are known, once the retrofitting of the diaphragm is designed through the analytical model, according to the expected seismic loads. Besides, ten initial state variables were adopted, necessary for describing all loading and unloading branches, and their initial value was set to 0. With reference to Fig. 11, these variables are the maximum strains ever reached in tension and compression ($\varepsilon_{t,max}$ and $\varepsilon_{c,max}$, respectively), and the stress-strain coordinates identifying the end of the loading and unloading branches in tension (points $(\varepsilon_{t,l}, \sigma_{t,l})$ and $(\varepsilon_{t,ul}, \sigma_{t,ul})$, respectively) and compression (points $(\varepsilon_{c,l}, \sigma_{c,l})$ and $(\varepsilon_{c,ul}, \sigma_{c,ul})$, respectively). Through these variables, the pinching behaviour during unloading and reloading can be defined. The constitutive laws implemented through the user-supplied subroutine are now presented for the tensile branch only, since the compressive one follows antisymmetric relations.

The material follows the tensile loading branch as long as $\varepsilon > 0$ and $\varepsilon > \varepsilon_{t,max}$, with the constitutive law of Eq. 2 (Fig. 12, blue branch):

$$\sigma = (\sigma_y + a \varepsilon + b \varepsilon^2)[1 - \exp(-K_0 \varepsilon / \sigma_y)] \quad (2)$$

In Eq. 2, $\sigma_y = \sigma_{max}/8$, following the analytical derivation presented in Section 3.2.

Figure 11: Representation of the input parameters for the user-supplied subroutine.

Figure 12: Loading, unloading and reloading branches implemented in the user-supplied subroutine.

After reaching $\varepsilon_{t,max}$, the tensile unloading phase is defined if $\varepsilon > 0$, $\varepsilon < \varepsilon_{t,max}$, and $\varepsilon < \varepsilon_0$, with ε_0 initial strain at the beginning of the current step. In this case, the response is distinguished between the case in which the unloading starts from the envelope curve (at $\varepsilon_{t,max}$, yellow branch of Fig. 12), and when the unloading occurs after a reloading phase (red branch of Fig. 12). In the first case, $\varepsilon_{t,l} \equiv \varepsilon_{t,max}$, and the constitutive law is formulated as (see Fig. 12 for the meaning of the various parameters):

$$\sigma = f_{t,ul} = \sigma_{t,max} - [\sigma_{t,max} - p_{0,ul} - K_4(\varepsilon - \varepsilon_{t,max})] \{1 - \exp[2K_0(\varepsilon - \varepsilon_{t,max})/(\sigma_{t,max} - p_{0,ul})]\} \quad (3)$$

In the second case, instead, the relation is ($\varepsilon_{t,l} \neq \varepsilon_{t,max}$):

$$\sigma = \sigma_{t,l} - (\sigma_{t,l} - f_{t,ul}) \{1 - \exp[2K_0(\varepsilon - \varepsilon_{t,l})/(\sigma_{t,l} - f_{t,ul})]\} \quad (4)$$

Finally, the tensile reloading phase is defined if $\varepsilon > 0$, $\varepsilon < \varepsilon_{t,max}$, and $\varepsilon > \varepsilon_0$, according to the constitutive law of Eq. 5:

$$\sigma = \sigma_{t,ul} + (f_{t,l} - \sigma_{t,ul}) \{1 - \exp[-2K_0(\varepsilon - \varepsilon_{t,ul})/(f_{t,l} - \sigma_{t,ul})]\} \quad (5)$$

with:

$$f_{t,l} = \sigma_{t,max} - [\sigma_{t,max} - p_{0,l} - K_4(\varepsilon - \varepsilon_{t,max})] \{1 - \exp[D \cdot K_3(\varepsilon - \varepsilon_{t,max})/(\sigma_{t,max} - p_{0,l})]\} \quad (6)$$

and:

$$D = 1 + (\varepsilon_{t,max}/\varepsilon_{max})^3 \quad (7)$$

With reference to Eq. 7, the parameter D is a factor accounting for the progressive degradation of the pinching cycles, becoming progressively less stiff when the floor drift increases (Fig. 6, step 6).

4.4 Validation of the user-supplied subroutine

As already presented in section 3.4, the analytical model proved to be accurate for predicting the global in-plane response of the retrofitted timber diaphragms. Since the model was implemented in the user-supplied subroutine, very close results were expected, useful to validate both the subroutine itself, and the adopted modelling strategy for timber diaphragms.

As validation example, a retrofitted timber diaphragm with similar characteristics to sample *DFpar-1s* was modelled. A 4×6 m floor was considered, supported on the long sides, having as in-plane properties an initial stiffness of 10 kN/mm, and a strength of 150 kN activated at 60 mm displacement. The floor featured 60×130 mm joists at a heart-to-heart distance of 500 mm, while the thickness of both plywood panels and planks was 18 mm. The elastic modulus of timber was assumed to be 10000 MPa. On the basis of these characteristics, equivalent input properties were determined for the elements in the numerical model.

The modelled diaphragm consisted of a mesh of 1×1 m macro-elements (capturing the in-plane response), overlapped to flat shell elements (accounting for the out-of-plane behaviour), as shown in Fig. 13. The three initial parameters, required by the user-supplied subroutine for determining the constitutive law of the nonlinear diagonal trusses, can be derived from geometrical considerations. Starting from the whole floor deflection u , the displacement δ of a truss is given by:

$$\delta = (u \cos \alpha)/m \quad (8)$$

where α is the angle between the truss and the loading direction (Fig. 13), and m the number of macro-elements rows parallel to the applied load in half of the floor (in this case, $m = 2$). The shear force $F/2$ is then subdivided among the s trusses in one macro-elements row, and transformed into an axial force N on a single one:

$$N = F/(2 s \cos \alpha) \quad (9)$$

From the knowledge of the geometrical relations for N and δ , also the initial stiffness of the diagonal trusses can be calculated. For convenience, a unitary section was adopted for the truss elements, so that force and stress could be coincident in their values.

The properties of the shell elements were derived by considering an equivalence in flexural properties between the joists and the slab, defining an equivalent elastic modulus E_{eq} :

$$E_{eq} = E_{timber} I_{joists} / I_{slab} \quad (10)$$

where I_{joists} is the sum of the moments of inertia of the single joists, and I_{slab} is the moment of inertia of the slab, defined by attributing to the shell elements a thickness of 36 mm (planks and plywood panels). According to the reference system of Fig. 13, the elastic modulus E_{eq} was assigned to all directions, while the shear moduli were different: a value of 0.1 MPa was assigned to G_{xy} , because the in-plane behaviour was already described by the macro-elements, while $G_{xz} = G_{zy} = E_{eq}/16$ (similarly to an actual timber material). The main material properties assigned to the model are summarized in Table 1. Hinged supports were placed to the two lateral edges parallel to the application of the in-plane load (Fig. 13).

The floor was firstly subjected to a linear static analysis to verify the equivalence in flexural properties between the slab and the joists (Fig. 14a). Both the self-weight and a vertical load of 1.5 kN/m² were applied. Then, two in-plane cyclic analyses were performed, one to assess the global cyclic behaviour (Fig. 14b), and one in which local loops were imposed (Fig. 14c). These analyses were displacement-based, and the displacement was applied at the floor midspan (Fig. 13). Finally, a time-history analysis was conducted (Fig. 14d), subjecting the floor to a scaled seismic signal, representative for the Groningen area.

As can be noticed (Fig. 14), both out-of-plane and in-plane behaviour of the floor are properly captured by the adopted modelling strategy and the implemented subroutine. The deflection under vertical loads proved the correct application of the flexural properties to the shell elements: the obtained displacement was practically coincident with the one calculated analytically by considering the floor joists. With regard to the in-plane response, strength, stiffness, energy dissipation and pinching behaviour are well described in all in-plane analyses, with a response quite close to that of reference sample *DFpar-1s* (Fig. 7a).

Figure 13: Model of the retrofitted diaphragm for the validation of the user-supplied subroutine.

Table 1: Properties adopted in the floor model.

Function	Element type	Property	Value
Macro-elements representing the in-plane behaviour of the floor	Rigid trusses	Elastic modulus E_t (MPa)	10^{10}
		ϵ_{max}	0.01
	Diagonal trusses	σ_{max} (MPa)	12000
		K_0 (MPa)	5520000
Shell elements describing the out- of-plane response of the floor	Shell elements	Elastic moduli E_x, E_y, E_z (MPa)	62000
		In-plane shear modulus G_{xy} (MPa)	0.1
		Shear moduli G_{xz}, G_{zy} (MPa)	3880

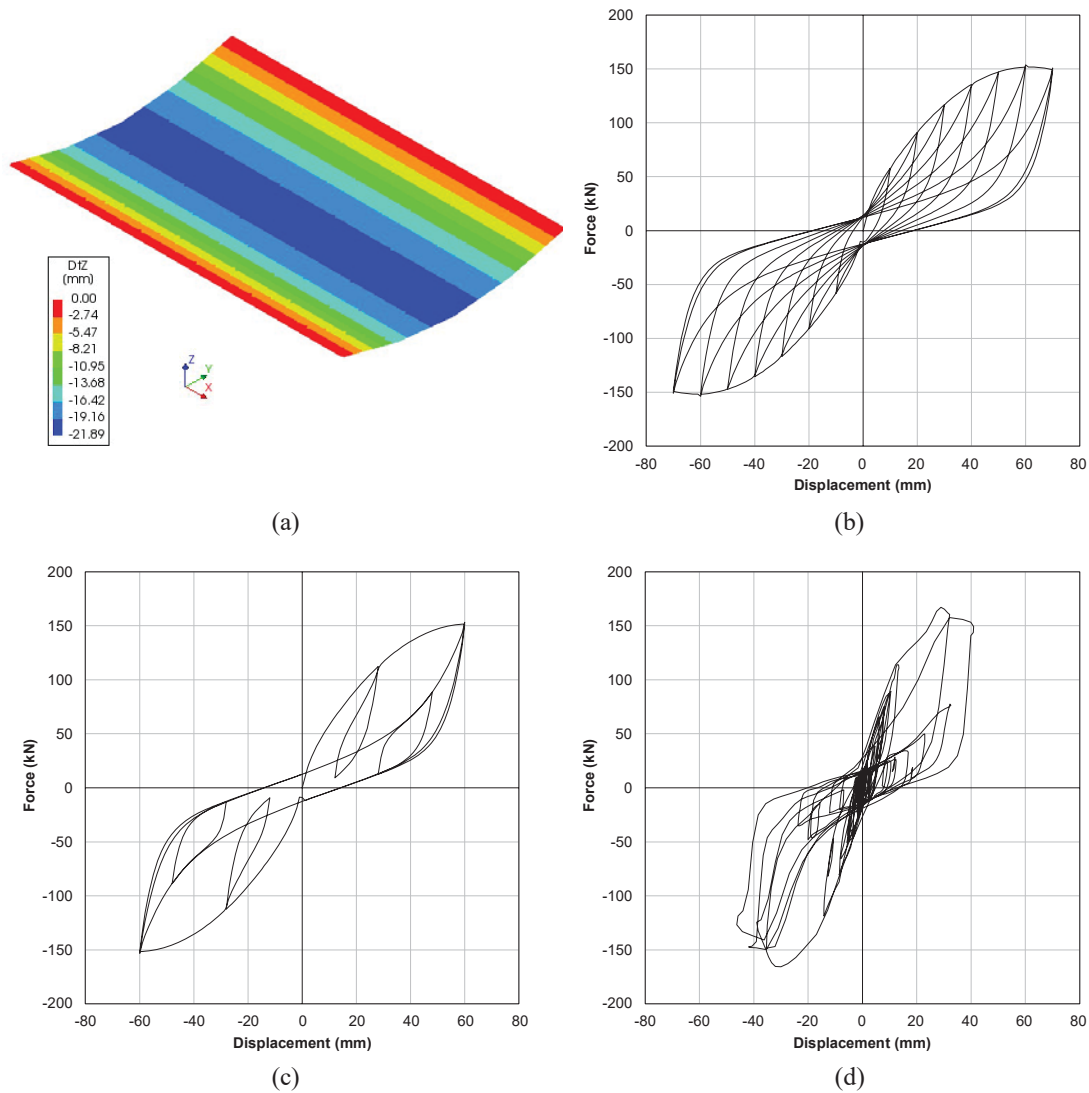

Figure 14: Results from the analyses conducted for the validation of the user-supplied subroutine and the overall modelling strategy for timber floors: out-of-plane static analysis under vertical loads (a); complete displacement-based in-plane cyclic analysis (b); displacement-based in-plane cyclic analysis with local loops (c); in-plane time-history analysis under an induced Groningen earthquake accelerogram (d).

5 CASE STUDY: A MASONRY DETACHED HOUSE WITH TIMBER FLOORS

5.1 Introduction

The implemented user-supplied subroutine opened up the opportunity to analyse the beneficial impact of a dissipative retrofitting of timber diaphragms in an existing URM building. The effect of floors strengthened with plywood panels, and thus with a light, reversible technique, was compared to that of the as-built configuration, and of another not reversible retrofitting measure, widely applied also in the past, and namely the cast of a reinforced concrete slab on the existing diaphragms. Several studies have already shown that the latter retrofitting measure could be detrimental for masonry buildings [28]-[30], and not advisable if the construction is protected or part of the architectural heritage of a certain context [15]. Yet, the

need of stiffening in their plane the existing, inadequate floors, combined with design rules based on the hypothesis of infinitely stiff diaphragms [27], could often result in realizing a concrete slab. This intervention undoubtedly increases the overall seismic masses, but contemporarily improves the static out-of-plane behaviour of the floor, and also the in-plane capacity of walls. After applying these retrofitting measures, or similar ones making the floors almost infinitely stiff, the contribution that is missing is the potential energy dissipation that the floors could provide. If, instead, the diaphragms are strengthened with a dissipative technique, allowing efficient shear transfer and horizontal loads redistribution, and at the same time a controlled deflection, then their role can be quite beneficial. With the adopted retrofitting solution, this advantageous effect can be obtained, and through the user-supplied subroutine it can be evaluated through numerical analyses, fully accounting for the nonlinear in-plane response of the floors.

5.2 Characteristics of the analysed building

A detached house typical of the Groningen area was selected as the case-study building (Fig. 15). This URM low-rise house has a relatively simple structure, but some irregularities are present, such as the position and shape of wall openings, and the thickness of the walls, not constant along the height, with gables featuring a single-leaf wall (100 mm thick) instead of the ground floor double-leaf walls (210 mm thick). Besides, one more single-leaf wall was present, supporting one of the floors approximately at midspan, in correspondence to the staircase (Fig. 15). Three configurations were studied: one represented the as-built house with flexible diaphragms; in the other two, the floors were retrofitted with plywood panels or with a concrete slab. The properties of masonry, reported in Table 2, were assumed to be the same for the three configurations. The adopted values are in line with the characteristics of medium-low quality masonry: these material properties fall on the conservative side with respect to experimental tests performed on both existing and replicated Dutch masonry [31], [32], and were also defined according to calibration studies [33]. Shell elements with the implemented DIANA FEA Engineering Masonry Model [34] were used for modelling the masonry.

For all configurations, nonlinear incremental dynamic analyses were performed, by subjecting the house to seven accelerograms of induced earthquakes retrieved from the seismic database of the Netherlands Normalisatie-instituut (NEN) [35]. The main loading directions x and y were studied separately, therefore a total of 42 analyses were performed. The signals were referred to an average peak ground acceleration (PGA) of 0.17g, and are shown in Fig. 16; a Rayleigh damping of 2% was considered in the analyses. While for walls a density of 2000 kg/m³ was assumed, for the diaphragms the density values included the self-weight of structural elements, a dead load of 1.00 kN/m² (accounting for further elements such as non-structural walls, finishes, plants, pipes), and 30% of the live load, equal to 1.75 kN/m² for Dutch residential buildings [36].

The as-built configuration featured flexible diaphragms: the 4.0×4.6 m floor presented 75×180 mm joists at a heart-to-heart distance of 800 mm; the 4.6×6.8 m floor had 60×160 mm joists arranged at 750 mm heart-to-heart distance; the roof presented 50×105 mm rafters at 900 mm heart-to-heart distance; all diaphragms had 18 mm thick planks. These structural properties were translated in the numerical model by following the modelling strategy for shell elements described in Section 4.2. In this case, because of the very small energy dissipation observed from tests on replicated as-built floors [14], the diaphragms were modelled with linear elastic orthotropic shell elements (thus without overlapping the nonlinear macro-elements), whose properties are reported in Table 3. The in-plane shear moduli of the diaphragms were derived by considering the flexural properties of the planks or the joists [14]. These values would correspond to equivalent shear stiffnesses of 108 to 216 kN/m, and are

thus in line with other similar stiffness estimations for existing floors from literature [3], [4], [7], [8], [11]-[14]. From an in-situ inspection, it was noticed that a timber wall plate surrounded the whole roof, and the floor joists were also connected to this structure. Therefore, a continuous hinged connection was assumed between diaphragms and walls at the floors supports. A continuous connection among masonry walls was assumed as well. In general, the main elements of vulnerability due to the diaphragms flexibility, are related to the lack of seismic load redistribution among the walls in the x direction, and to the very low stiffness of the roof structure in the y direction, with possible local collapses of the north and south wall gables. These issues were confirmed by the observed failures, as discussed in the next section.

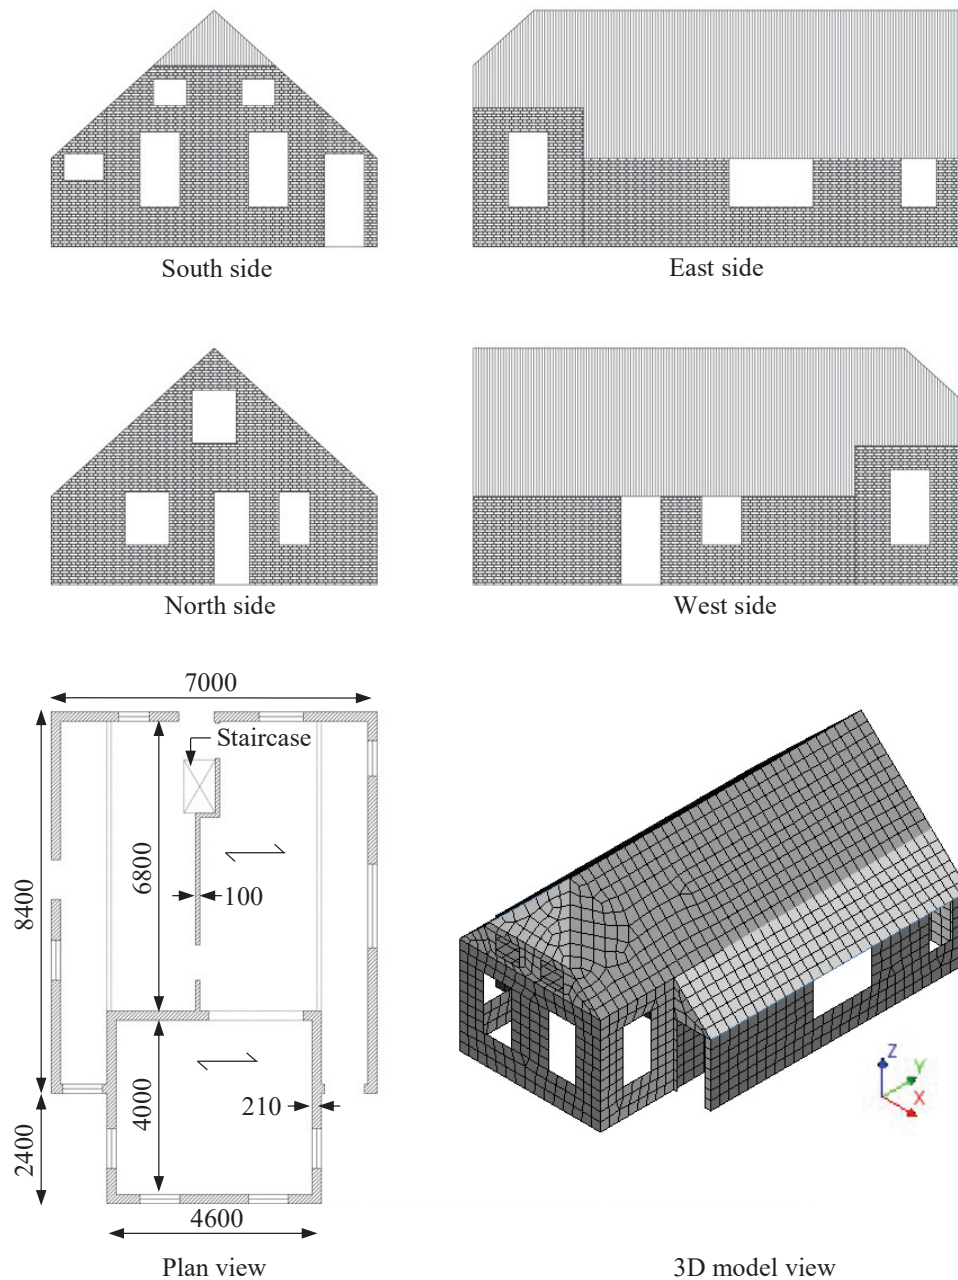

Figure 15: Main properties and geometry of the case-study building.

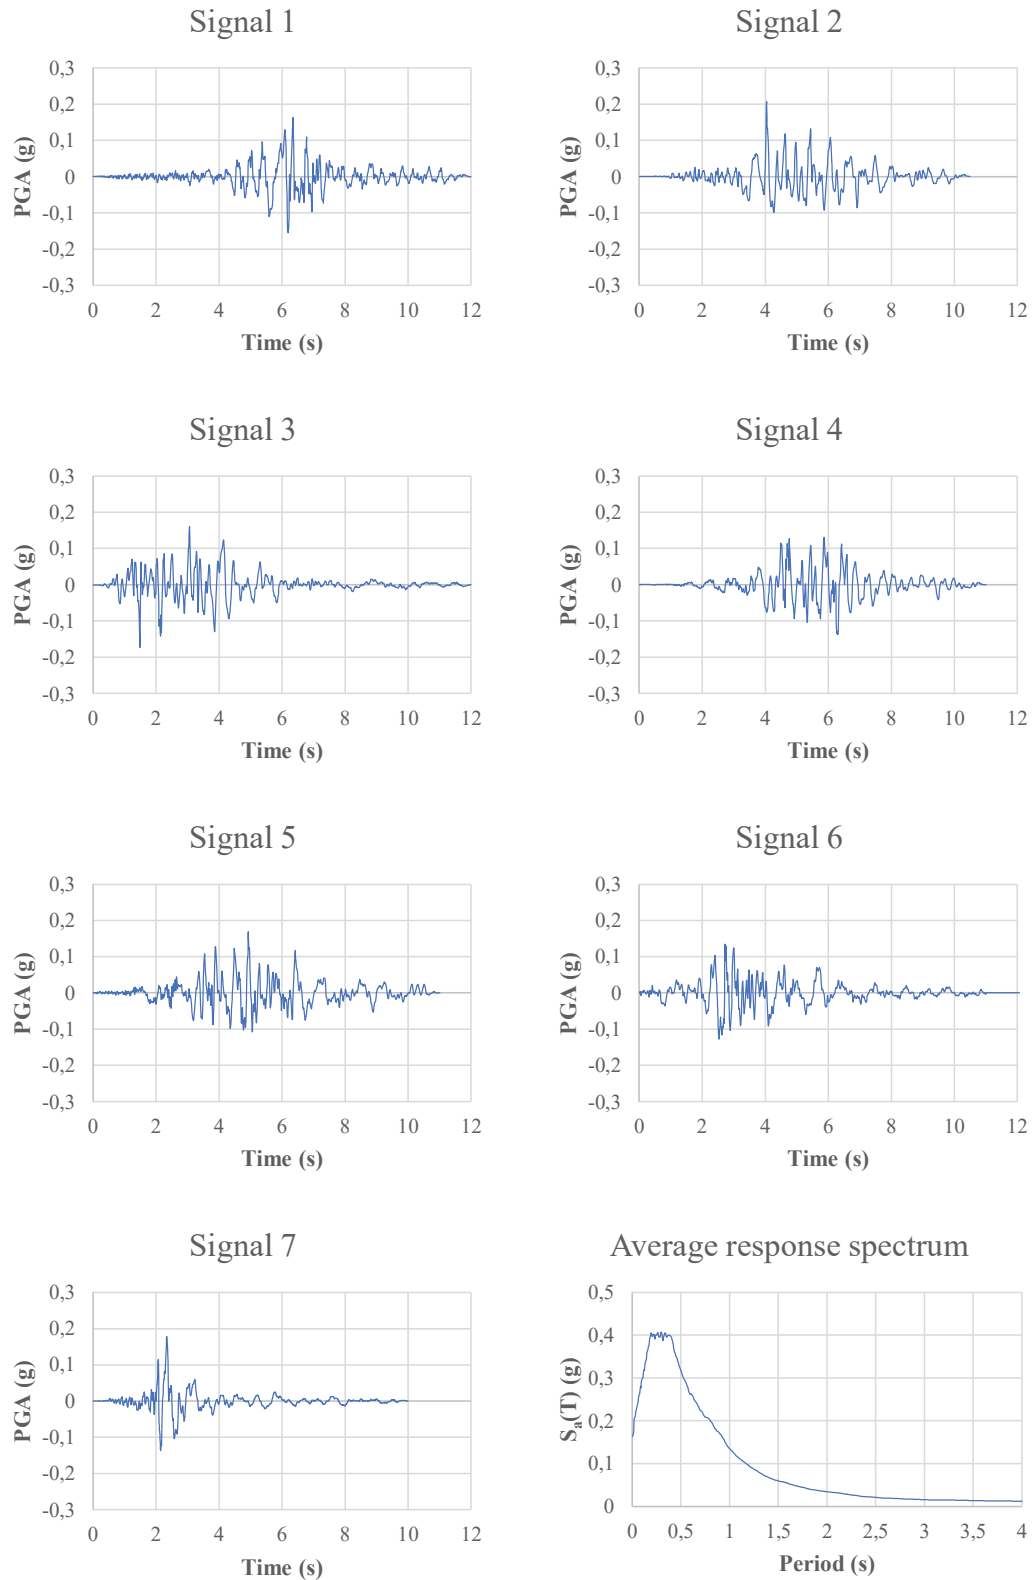

Figure 16: Adopted signals for time-history analyses; their average response spectrum is also reported. Data from NPR 9998 Webtool [35].

The following modelling strategies were adopted for the building with retrofitted floors:

- In the configuration with diaphragms retrofitted by casting a concrete slab on them, the floors were also modelled with linear elastic orthotropic shell elements, having the properties of structural reinforced concrete (Table 4). The thickness of the slab was 50 mm, as it would commonly be realized in practice [1], [6], [27]-[30].
- For the configuration featuring floors retrofitted with plywood panels, the modelling strategy discussed in section 4.2 was adopted: besides the linear elastic orthotropic shell elements, also the nonlinear macro-elements were present. The retrofitting interventions on the diaphragms were designed according to the global in-plane capacity of the piers, and conservative out-of-plane drift limits for the walls. The maximum base shear of the house (approximately 450 kN) was evaluated through a preliminary pushover analysis applied to the configuration with stiff diaphragms, and then the loads at floor and roof level were estimated through the lateral force method. The retrofitting intervention was designed accordingly, providing sufficient strength to activate in-plane failure mechanisms, but at the same time deflection capacity. With regard to this latter aspect, to prevent out-of-plane walls failure, the maximum midspan displacement, at which the diaphragms reached their strength, was fixed at 2% of the out-of-plane walls (or gables, for the roof) height. This value is in line with the 2.5% global drift suggested by New Zealand standards [37], which includes, however, also the displacement contribution of the in-plane walls. The potential stiffening effect of the out-of-plane walls was conservatively not taken into account, also because of the presence of large openings. Besides, use of dry screed made of loose material was assumed. Table 5 reports the properties of the retrofitted diaphragms adopted as input for the numerical model.

Table 2: Properties adopted for masonry shell elements based on [31]-[33].

Property	Value
Young modulus E_x parallel to bed joint (MPa)	1500
Young modulus E_y perpendicular to bed joint (MPa)	2000
Shear modulus G_{xy} (MPa)	800

5.3 Results of the time-history analyses and discussion

The three configurations of the house were subjected to the seven signals shown in Fig. 16, by progressively scaling them until collapse. The results in terms of PGA at collapse of the configurations are presented in Fig. 17. The reference design response spectrum (2475 years return period) for the location of the house (Godlinze) corresponded to an expected maximum PGA of 0.17g; as can be noticed, the as-built configuration already collapsed at this level of intensity under almost all signals, making a retrofitting intervention necessary to increase the seismic performance of the house. Instead, the floors stiffened with a concrete slab greatly improve the capacity of the building, but the best performance is obtained with the plywood panels overlay, in both directions. The latter retrofitting intervention is easily applicable, light, reversible, and provides a beneficial energy dissipation to the diaphragms, improving even more the seismic capacity of the house.

Figure 17: PGA at collapse for the three configurations in the x (left) and y direction (right).

The effect of the diaphragms on the response of the building is represented in Fig. 18: the base shear-displacement curves are reported at collapse, and refer, as a representative example, to signal 1 applied in the x direction (the weakest); the control node for displacement corresponds to the centre of mass of the roof. The as-built configuration shows a very flexible response: the floors undergo large displacements at an already limited signal amplitude, and the in-plane walls are not brought into play. Besides, the crack pattern (Fig. 18a) shows a partial out-of-plane collapse of the 100 mm thick central wall, and of the north gable, probably due to torsional effects.

A very different situation is noticeable with the floors retrofitted with concrete slabs. In this case, the failure of the building is fully related to the in-plane walls, and a beneficial redistribution of horizontal loads is achieved among the various walls; the force-displacement graph also confirms a typical in-plane failure of masonry (Fig. 18b).

A hybrid response between the first two configurations is obtained when the floors are retrofitted with plywood panels: a larger displacement capacity of the diaphragms together with an in-plane failure of the walls is noticeable (Fig. 18c). The crack pattern is similar to that observed for the concrete slab configuration, with a slightly higher amount of damage in the out-of-plane walls, because of the lower stiffness of the floors. Yet, the beneficial dissipative effect of the diaphragms leads to a 30% higher performance of the building in terms of PGA.

The possibility of withstanding more intense earthquakes does not only depend on the lower seismic mass provided by the reversible retrofitting intervention, but also because of its energy dissipation capacity. In fact, first of all, the higher mass of the concrete slab has a beneficial effect on the in-plane capacity of the wall, which is increased due to the larger vertical precompression applied. Secondly, by performing a modal analysis, the fundamental period of the house retrofitted with concrete slabs resulted as 0.1 s, while for the configuration with diaphragms strengthened with plywood panels it was 0.14 s. In both cases, the structure in the elastic phase is stiff, as expected when studying a low-rise masonry building; however, the plateau of the design average response spectrum starts at a period of 0.19 s (Fig. 16). Since the displacement capacity of the diaphragms retrofitted with plywood panels immediately brings into play their nonlinearity (including pinching cycles and energy dissipation), this configuration has a rapid increase of its period, and becomes quickly subjected to the maximum spectral acceleration. When concrete slabs are present, the diaphragms can be regarded as infinitely stiff, thus the response is approximately linear elastic until the in-plane capacity of the weakest wall is reached. The combination of a higher precompression on the walls (and therefore a higher in-plane strength) with a limited displacement capacity, compared to the floors retrofitted with plywood panels, implies a slower evolution of the period due to nonlinearities, and the spectral plateau is reached at a later stage. Nevertheless, the reversible retrofitting still shows a higher capacity, confirming its beneficial dissipative role.

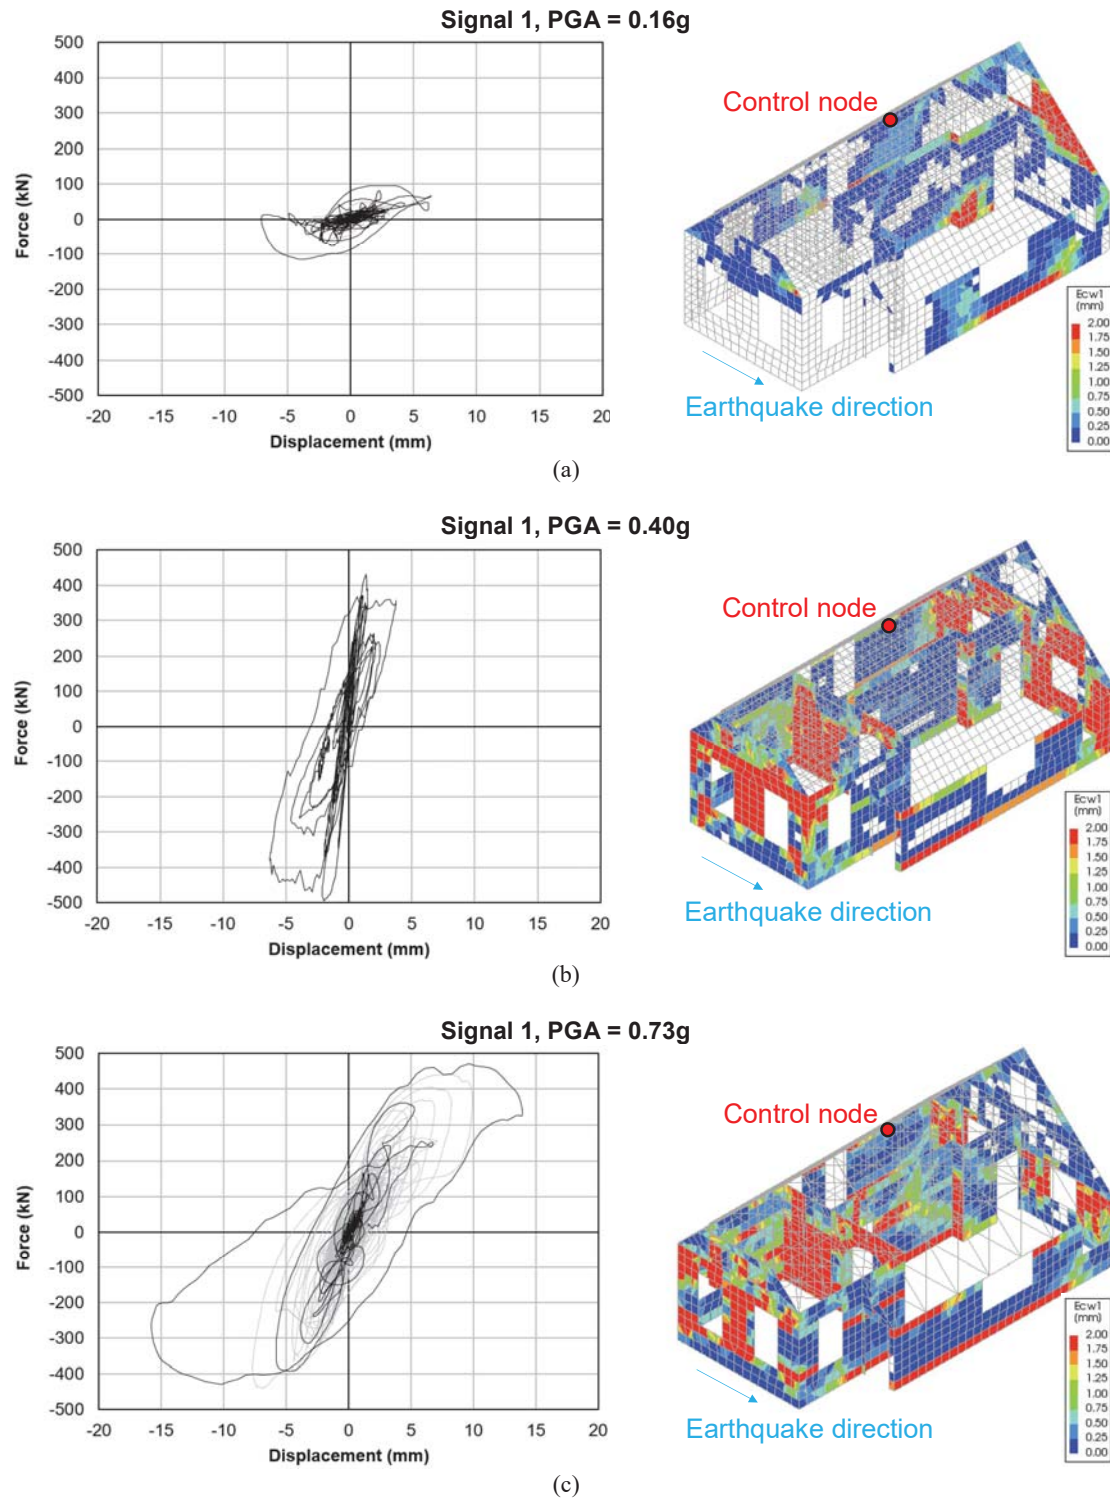

Figure 18: Base shear vs. roof displacement response and crack opening (Ecw1) pattern of the three configurations: as-built (a), floors strengthened with concrete slabs (b), diaphragms retrofitted with plywood panels (c).

The dissipation provided by the floors is further highlighted by Figs. 19 and 20, both showing the positive effect of the plywood panels retrofitting on the response of the building. Fig. 19 compares the in-plane behaviour of the most solicited wall at the collapse PGA for the concrete slab configuration, and the same response with the plywood panels overlay. As can be noticed, in the latter case the wall has not yet reached its capacity, but has just started to behave nonlinearly. Fig. 20 shows the total hysteretic energy dissipated by the structural components of the house: the amount of energy dissipated by the floors is relevant and, especially in the early phase of an earthquake, this can helpfully reduce in-plane loads on the walls.

As last consideration, in [25] a value of equivalent hysteretic damping ratio $\xi = 15\%$ was determined for the diaphragms retrofitted with plywood panels. The difference in PGA at collapse between the configuration with stiff floors and that with the dissipative diaphragms was on average 30% (Fig. 17). This result appears to confirm the obtained 15% damping ratio: if the floors were retrofitted with plywood panels, and for a simplified modelling (e.g. a pushover analysis) they were assumed as stiff, their dissipative contribution could be taken into account by considering an overdamped spectrum reduced by the factor $\eta = [10/(5+\xi)]^{1/2}$ [38]. It is interesting to notice that $\eta = 0.71$ for $\xi = 15\%$, a value suggesting that the collapse response spectrum could indeed correspond to approximately 30% higher spectral acceleration when a dissipative retrofitting of the floors is designed, and in addition to the further nonlinear contribution of the in-plane masonry walls.

Figure 19: Comparison between the in-plane response of the most solicited wall under the application of signal 4 in the configuration having floors strengthened with concrete slabs (left) and with plywood panels (right).

Figure 20: Hysteretic energy vs. time response under seismic signal 1 for the building having floors retrofitted with plywood panels: the dissipative role of the diaphragms is evident.

6 SUMMARY AND CONCLUSIONS

In this work, starting from an experimental campaign on as-built and strengthened timber diaphragms, the analytical and numerical modelling of the retrofitted floors was presented, including an application to a case-study existing building.

The strengthening technique, consisting of an overlay of plywood panels screwed along their perimeter to the existing sheathing, showed a great improvement in strength, stiffness and energy dissipation of the diaphragms. In order to enable the design of the proposed retrofitting method, and to account for the nonlinear and dissipative response of the floors, an analytical model was formulated, starting from the load-slip behaviour of the single screws fastening plywood panels and planks. The analytical model shows good agreement with the experimental results, and can be adopted to determine the relevant seismic properties of the retrofitted diaphragms.

The formulated model opened up the opportunity to implement a user-supplied subroutine in the software DIANA FEA: the subroutine validation demonstrated that an accurate numerical modelling of the in-plane response of the floors can be achieved. Then, the proposed retrofitting intervention was applied to the case-study of an existing building, and the seismic response was compared to both that of the as-built house, and that of a configuration in which the floors were stiffened with concrete slabs. The numerical time-history analyses showed that the diaphragms retrofitted with plywood panels can greatly improve the seismic capacity of the building, mainly because high energy dissipation is provided, and already at limited deflections. This allows to beneficially dampen the in-plane loads on the walls, obtaining the best performance, even in comparison to the configuration retrofitted with concrete slabs.

Therefore, the choice of light, reversible and dissipative retrofitting like the proposed one could be not only a more suitable technique for seismic strengthening of buildings belonging to architectural heritage, but also more beneficial in improving seismic capacity compared to stiffer, not reversible, and less sustainable techniques.

Abstract

Typically, panel-to-panel and panel-to-foundation connection zones in Cross-Laminated Timber (CLT) walls consist of steel-to-timber mechanical connections (hold-downs and angle-brackets) and timber-to-timber contact. While hold-downs and angle brackets are extensively studied in literature, the role of timber-to timber contact is underestimated. The platform constructional technology used for build CLT walls requires that the vertical timber panels compresses the horizontal CLT floors, engaging the orthogonal to grain timber properties in the seismic response.

This paper discusses a new development concerning a theoretical sectional model for CLT panels proposed by the authors in a recent work, where strength of the panels subjected to combined axial force and bending moment was studied accounting for orthogonal to grain timber properties. As advancement, a theoretical moment-curvature model for CLT panels is proposed in this paper and the displacement capacity (i.e., ductility) is investigated. The main parameters which affect the ductile behavior of the panels have been studied by means of parametric analyses, i.e. varying cross-section dimensions, amount of axial force, and hold-downs resistance.

Theoretical results have been also compared with numerical ones derived from a bi-dimensional finite element model developed by the authors and a good matching between the results has been highlighted.

Keywords: CLT panels, Orthogonal to grain compression, Connection Modelling, Theoretical model, Moment-Curvature diagrams.

1 INTRODUCTION

Cross-Laminated Timber (CLT) represents a high efficient engineered mass timber product originated in Austria in the early 1990s. In Europe, CLT panels are one of the most diffused mass timber product used for low and mid-rise residential and non-residential buildings in seismic prone area. It has been estimated that the global annual production of CLT is growing exponentially in Europe, from 25.000 m³ in 1996, up to 1.2 million of m³ in 2020 [1]. Nevertheless, a significant annual increase of the manufactured CLT has been also recorded in the United States, Canada, Australia, Japan and New Zealand [2-4].

Shake-table tests demonstrated the satisfactory seismic behavior of multi-story CLT buildings. They resisted seismic accelerations up to 0.82g for a seven story building [5] and up to 1.52g for a two-story building [6] thanks to their good dissipative behavior. The dissipation is mainly concentrated in the panel-to-panel and in panel-to-foundation mechanical connection zones, generally composed by thin-walled steel plates nailed or screwed to the vertical panels and bolted in foundation, named as Hold-Downs (HDs) and Angle-Brackets (ABs). HDs are devoted to withstand tensile forces produced by the overturning moments, while ABs resist to shear forces. Compression forces, instead, are faced by timber-to-timber or timber-to-foundation contact.

Experimental local tests on mechanical connections aimed at investigating their cyclic behavior highlighted that ductile failure mechanisms can be achieved when properly designed [7, 8]. Contrariwise, brittle failure mechanisms could occur if the requirements for end and edge distances are not respected [9]. Commonly, in timber practice it is assumed that ductile mechanisms are those respecting the Johansen's failure modes [10] also included in Eurocode 5 [10]. Although provided of an appreciable dissipative behavior, such mechanisms entail significant damaging of vertical timber panels making them unusable after the seismic event [12].

In addition to the seismic resistance, modern seismic design approaches based on the Performance-Based Design require that also damaging of structural (and non-structural) components should be prevented or reduced as far as possible. Thus, alternative connection systems based on the 'plug and play' concept have been introduced by researchers [13-15]. They consist of replaceable steel fuses, or other steel-based material, fastened to timber panels which dissipate energy through the cyclic plasticization of the steel parts only, while timber parts remain elastic. Steel parts, which can be substituted after the seismic event, are devoted to prevent the damaging of timber CLT panels and consequently to reduce economical losses for their repairing.

To date, theoretical models for evaluating flexural load-bearing capacity of CLT panels subjected to combined bending and axial force are presented in literature, taking into account the contribution of the HDs and ABs at the base of the panels [16, 17]. Two are the main shortcomings that characterize such methods: *a)* the role of timber-to-timber contact is under evaluated, *b)* no formulation for evaluating the ductility are presented.

Usually, the timber-to-timber contact is modelled considering the parallel to grain direction timber properties [19]. Contrariwise, due to the platform constructional technology used to realize CLT buildings, the perpendicular to grain timber properties (i.e., Young's modulus, ultimate compression strength and strain) are unavoidably involved in the seismic behavior of the panel. In fact, at each story the horizontal CLT floor panels are inserted between two consecutive vertical CLT panels, while at ground level a horizontal timber beam is commonly interposed between vertical panel and foundation (Fig. 1). Conversely, if interposed timber beams are not used and the vertical panels are directly placed on the reinforced concrete foundation, the parallel to grain timber properties must be employed in the calculations.

Nowadays, no specific information relative to the orthogonal to grain compressive behavior of CLT elements are provided in the European standards (with exception for the Austrian National Annex [20]), as well as limited experimental and numerical results can be found in literature [20-22].

This paper deals with a new development of a theoretical sectional model for CLT panels subjected to combined axial force and bending moment, presented by the authors in a recent paper [23]. The method presented in [23] permitted to define the flexural load-bearing capacity of the panels through axial force-bending moment interaction domains. As advancement, a theoretical moment-curvature ($M-\chi$) model for CLT panels is herein presented.

A parametric study aimed at investigating the influence of different factors on the post-elastic displacement capacity of the panels - such as percentage of reinforcement ratio (intended as the contribution provided by HDs in tension), the amount of axial force and the length-to-width ratios of the panel cross-section - has been carried out. Due to the absence of experimental tests, the validity of the proposed $M-\chi$ diagrams has been assessed by comparison with a finite element numerical model of the CLT panels developed by the authors.

The results allowed to investigate the role of the mechanical connections and timber-to-timber contact on the ductile behavior of the panels, highlighting a good matching between theoretical and numerical results. Moreover, the comparative analyses permitted to develop a design-oriented approach for evaluating the ultimate curvature and the ultimate bending moment of the panels through closed-formulas, useful in engineering practice.

Figure 1: Platform constructional technology for CLT buildings.

2 CONNECTIONS MECHANICAL MODEL

With aim of calculating the flexural load-carrying capacity of CLT panels under gravity and horizontal loads, different methods for schematizing the panel to panel and the panel to foundation connection zone are proposed in literature. These methods, extensively compared in [17] and in [12], are mainly based on static equilibrium equations. They assume the hypothesis that CLT panel behaves as a rigid-body with deformations concentrated in the mechanical connections: the overturning moments are faced by HDs (tension) and timber-to-timber contact (compression), while shear forces are resisted by ABs exclusively. Due to buckling, the contribution of HDs under compression is generally disregarded.

Recently, a mechanical model to schematize the connections has been proposed by the authors in [23]. The goal of the method was that of determining the flexural load-bearing capacity of CLT panels and deriving the axial force-bending moment interaction domains. The same model has been employed for deriving moment-curvature diagrams in the present paper, allowing to investigate the post-elastic displacement capacity of the CLT panels with mechanical connections at the base.

The proposed model could be considered as an advancement with respect to the method presented in [16], in which the behavior of panel-to-panel and panel-to-foundation connection zone has been modelled in analogy with Reinforced Concrete (RC) cross-sections: HDs are considered as the tensile-resistant elements which yield in tension, while timber-to-timber contact is assimilated to compressed concrete whose behavior is limited to the elastic field. For timber-to-timber contact, the maximum compression strength is assumed equal to that in parallel to grain direction, while the Young's modulus is that in orthogonal to grain direction. Conversely, for timber-to-RC foundation contact the parallel to grain Young's modulus is considered (while the compression strength remains that in parallel direction).

In the proposed method, instead, both orthogonal or parallel to grain timber properties for panel-to-foundation connections can be used, as a function of constructional technology used at the ground level (i.e., if interposed timber beam between vertical panel and foundation is used or not). While, only the orthogonal to grain contact is assumed for panel-to-panel connections at upper storey.

2.1 Orthogonal to grain compression behavior

Orthogonal to grain compression situations are a direct consequence of the platform constructional technology used to build CLT structures. Under seismic actions, the vertical panel rocks around a pivot point - often not coincident with the corner of the panel - loading in orthogonal to grain direction the CLT timber floors at upper storey or the timber beams at ground floor when present [24] (Fig. 2).

This phenomenon cannot be neglect in evaluating the load-carrying capacity of the panel, because:

- (i) the orthogonal to grain compressive strength $f_{c,90}$ is less than that in parallel to grain direction $f_{c,0}$ ($f_{c,90}/f_{c,0} \sim 1/10$);
- (ii) the Young's modulus in perpendicular direction E_{90} is much less than that in parallel direction E_0 ($E_{90}/E_0 \sim 1/30$);
- (iii) the orthogonal to grain ultimate strain $\varepsilon_{c,90}$ is much higher than in parallel direction $\varepsilon_{c,0}$ ($\varepsilon_{c,0}/\varepsilon_{c,90} \sim 1/10-1/15$).

Although the orthogonal to grain compressive behavior for mono-dimensional elements has been extensively studied and tests procedures codified [25, 26], few are the results available for CLT specimens. Some experimental results on CLT specimens subjected to perpendicular to grain compression loads, with different loads configurations, are presented in [20-22]. Experimental stress (σ)-strain (ε) diagrams are characterized by a first nonlinear elastic branch, followed by a significant perfectly-plastic branch with hardening at the end.

By a theoretical point of view, the shape of the σ - ε diagram can be described by parabola-rectangle constitutive law (Fig. 3). The shape is similar to that of concrete subjected to compression and then, by analogy, the same constitutive law suggested for concrete in the Eurocode 2 [27] has been adopted to describe the orthogonal to grain compressive behavior of timber. The parabolic and the constant branch are described by the following equations, respectively:

$$\sigma = \eta(2 - \eta)f_{c,90,d} \quad 0 \leq \eta \leq 1 \quad (1)$$

$$\sigma = f_{c,90,d} \quad 1 \leq \eta \leq \varepsilon_{c,90,u} / \varepsilon_{c,90,el} \quad (2)$$

where $\eta = \varepsilon / \varepsilon_{c,90,el}$ represents the ratio between the values of strain (ε) included into the interval $[0; \varepsilon_{c,90,el}]$ for eq. (1) and into the interval $[\varepsilon_{c,90,el}; \varepsilon_{c,90,u}]$ for eq. (2); while $\varepsilon_{c,90,el}$ and $\varepsilon_{c,90,u}$ represent the limit elastic and ultimate strain of timber, respectively.

Contrarily to the maximum perpendicular compression strength, whose values are codified also by Eurocode 5 [11], for orthogonal to grain ultimate strain no values are suggested by codes. Experimental studies conducted by Serrano and Enquist [20] and by Brandner [22] on CLT panels under compression shown significant plastic strains, greater than 15-20% at the end of tests.

2.2 Cross-sectional behavior modelling

In this paper, a model for describing the cross-sectional behavior of CLT panels developed by analogy with RC cross-sections is presented. The term ‘section’ indicates the timber-to-timber contact area defined between the vertical and the horizontal timber panels.

In this model, tensile-resistant contributions are provided by hold-downs (*HDs*) exclusively, or combining hold-downs and angle brackets (*ABs*) if both are assumed able to resist tensile forces [7, 9, 28]. Instead, compression forces are totally faced by timber-to-timber or by timber-to-RC foundation contact.

By analogy with RC, three different behavioral stages for the cross-section have been defined (Fig. 4): stage *I*, in which both timber-to-timber contact and tensile-resistant elements behave elastically both in compression and in tension; stage *II*, when the maximum strength into timber-to-timber compressed corner is reached, whereas tensile-resistant elements still work in linear-elastic field (or vice versa); stage *III*, when the orthogonal to grain ultimate strain at compressed corner is attained, while tensile-resistant elements are ‘yielded’.

It should to be highlighted that the proposed theoretical method is of general validity. In fact, failure mechanisms based on (*A*) timber embedding combined with metal fasteners [10, 11] or on (*B*) yielding of metal steel elements (steel plates, steel fuses based on ‘plug and play’ concept, etc.) with timber in elastic field can be both implemented. As already noted in Sect. 1, the failure mechanisms (*B*) are far preferred to avoid permanent damage into timber panels in case of earthquakes and represents a new frontier for low-damage and more sustainable CLT buildings [12, 13].

Figure 4: Normal stress diagrams for the three behavioral stages.

3 THEORETICAL MOMENT-CURVATURE DIAGRAMS

Moment-curvature diagrams represent a useful tool for evaluating the ductile behavior of CLT panels subjected to combined horizontal seismic actions and gravity loads.

The $M-\chi$ cross-sectional behavior has been investigated based on the Euler-Bernoulli hypothesis concerning the conservation of plain transversal cross-sections after the deformation. Moreover, it has been assumed that the mechanical connections fail according to the mechanism type-B only, thus maximum yielding strength and ultimate strain in tension of thin-steel plates (e.g., HDs) are involved in the plastic mechanism. In other terms, a mechanical connection based on a ‘plug and play’ system, or having innovative dog-bone shaped hold-downs presented in [23] has been herein considered. While for the compressed timber the orthogonal to grain direction properties have been taken into account.

On the other side, also failure mechanisms type-A (Johansen’s mechanisms) can be implemented in the proposed model, but with the disadvantage that it is more complex to establish a suitable and reliable value of ultimate strain (axial elongation) due timber-to-steel interaction. In fact, available experimental tests provided only maximum values of axial displacement in timber-to-steel interaction because it is difficult to evaluate the corresponding strain.

Constitutive stress-strain behaviors adopted for timber (Fig. 5a) and steel (Fig. 5b) in this paper are represented in Fig. 5. For timber the parabola-rectangle constitutive behavior has been obtained by using the eqs. (1) and (2), with $\varepsilon_{c,90,u}=5\%$ (assumed as a reasonable value by the authors), $\varepsilon_{c,90,el}=0.75\%$ and design perpendicular to grain compression strength $f_{c,90,d}=2.90$ MPa. The latter has been evaluated considering the spatial dispersion of locally applied compression perpendicular to grain stresses: the increasing coefficient $k_{c,90}$ (in this case equal to 1.50) has been multiplied for the perpendicular compression strength according to [11]. Note that the material properties of the 3-ply CLT panels have been derived from ETA-14/0349 [29], as those corresponding to solid wood of class C24.

For steel, instead, an elastic-perfectly plastic constitutive stress-strain behavior has been adopted, considering steel-type S275 (as defined in Eurocode 3 [30]) with design yielding strength $f_{yd}=261.9$ MPa, yielding strain $\varepsilon_{HD,y}=0.12\%$ and ultimate strain $\varepsilon_{HD,u}=7\%$.

Figure 5: Constitutive stress-strain behavior for (a) timber compressed in orthogonal to grain direction, (b) steel in tension.

3.1 Methodology

Moment-curvature diagrams have been obtained by means of an iterative procedure, schematically represented in the flowchart reported in Fig. 6. The procedure consists of assigning a pair of first attempt values (χ , x_n) - where χ represents the curvature of and x_n the neutral axis depth - for panel to panel or panel to foundation contact cross-section and of verifying, by means of equilibrium conditions, that such assumption is right. In the following is summarized step-by-step the procedure:

- (i) assign attempt values of (χ , x_n);
- (ii) calculation of values of strains (ε) corresponding to the couple (χ , x_n) in each point of the cross-section thanks Euler-Bernoulli hypothesis;
- (iii) calculation of normal stresses associated to these strains from the constitutive stress-strain constitutive behavior adopted for both CLT and HD;
- (iv) determination of both internal compression and the tension resultant forces by integrating the stresses diagram over the cross-sections;
- (v) the supposed values of χ and x_n are right if the translation equilibrium over the cross-section among the internal forces and the applied axial force is satisfied. If it is not satisfied, the procedure must be reiterated by choosing another couple of values (χ , x_n); if it is satisfied, the corresponding moment (M) can be determined through the equilibrium rotation (with respect to the center-of-gravity of the section).

To obtain the entire M - χ diagram, the procedure must be developed for the interval between $\chi=0$ and the ultimate curvature χ_u .

3.2 Parametric analyses results

Based on the iterative procedure, theoretical M - χ diagrams have been obtained. In particular, parametric analyses considering different factors which influence the cross-sectional behavior have been conducted. The investigated parameters are listed in the following:

1. geometrical 'reinforcement' percentage ratio:

$$\rho = \frac{A_{HD}}{A_{CLT}} (\%) \quad (3)$$

where A_{HD} represent the cross-section area of HDs involved in the plastic mechanism, while A_{CLT} is the cross-section area of the CLT panel.

2. Cross- section slenderness ratio:

$$\lambda = \frac{L_p}{B} \quad (4)$$

where L_p represents the panel length, while B the panel width.

3. Dimensionless axial force ratio:

$$\nu = \frac{N_{Ed}}{N_{Rd}} (\%) \quad (5)$$

where N_{Ed} is the acting axial force and N_{Rd} the ultimate strength of the fully compressed section.

In Figure 7 are represented the $M-\chi$ diagrams obtained by varying the geometrical ‘reinforcement’ percentage ratios, from $\rho=0\%$ to $\rho=0.30\%$. To obtain these diagrams, a CLT panel having a slenderness ratio $\lambda=18$ (cross-section with $L_p=2500$ mm and $B=135$ mm) and an axial force ratio $\nu=20\%$ has been considered as representative and however realistic for CLT buildings. As it can be noted in Figure 7, for increasing value of ρ the ultimate moments of the panel increases, whereas the ductility reduces more than 50% passing from $\rho=0\%$ to $\rho=0.30\%$. This means that higher reinforcement percentages (i.e., several HDs) lead the panel toward brittle behavior, in the face of increase of flexural resistance.

On the same diagrams, squared blue dots indicate the curvature corresponding to the HDs which yield in tension ($\epsilon_{HD,y}$), green dots the points in which the timber-to-timber contact attains its yielding strain ($\epsilon_{c,90,y}$), while red triangles the achievement of the ultimate strain of timber compressed in orthogonal to grain direction ($\epsilon_{c,90,u}$). It can be observed that for a wide range of ρ (from 0 to 0.24%) the yielding of HDs in tension precede that of timber in compression, while for ρ greater than 0.24% timber yield before than HD. Moreover, as ρ increases the interval of the first yielding curvature between HDs and compressed timber reduces.

In Figure 8 are represented the $M-\chi$ diagrams for slenderness ratios ranging from $\lambda=10$ to $\lambda=38$, relative to a panel having constant width (B) equal to 135 mm while the panel length (L_p) varies from 150 to 500 mm. The $M-\chi$ diagrams show that as λ increases the ductility decreases, while ultimate moment increases. Also in these diagrams the yielding in tension of the HDs anticipates that of timber stressed in orthogonal to grain compression, whilst the ultimate curvature is attained when the compressed timber reaches the its ultimate strain at the compressed edge.

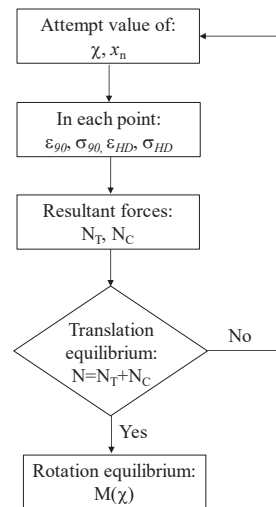

Figure 6: Flowchart of the iterative procedure developed for obtaining the $M-\chi$ diagrams.

In Figure 9 instead are reported the $M-\chi$ diagrams for dimensionless axial forces ratios varying from 0% (pure bending) to 40%. Again, the yielding of HDs precedes that of compressed timber, except for the case having $v=40\%$. This latter finding is convincing, because high values of the applied axial force involves significant orthogonal to grain compression stresses on the cross-section which lead to a 'yielding' of timber before of HDs. For the sake of simplicity, the curve with $v=50\%$ has not been reported in the Figure because resulted quite superimposed with the curve having $v=40\%$: This is reasonable observing the N-M interaction domains: about $v=40-50\%$ the domain varies smooth, such that ultimate moment (which is reached at $v=50\%$) varies little from $v=40\%$ to $v=50\%$ [23]. On the contrary, passing from $v=40\%$ to 50% the ductility reduces further.

Figure 7: Moment-curvature diagrams obtained varying the 'reinforcement' area ratio.

Figure 8: Moment-curvature diagrams obtained varying the cross-section slenderness ratio.

Figure 9: Moment-curvature diagrams obtained varying the dimensionless axial force.

4 COMPARISON WITH THE NUMERICAL MODEL

To assess their effectiveness, theoretical $M-\chi$ diagrams have been compared with those obtained through a numerical Finite Element Model (FEM) developed with the software SAP 2000 v.18 [31]. This required to model both CLT ‘material’ and mechanical connections and to carry-out nonlinear static analysis (e.g., pushover analyses).

4.1 Material modelling

CLT panels have been modelled through a two-dimensional FEM consisting of squared shell elements provided by in-plane shear and flexural stiffness, with a mesh 125x125 mm and thickness equal to those of the panel.

Due to its cross-layered nature, the in-plane behavior of CLT panels has been simulated through an equivalent (indefinitely) elastic orthotropic material. In other terms, only the layers of boards capable of withstanding the internal forces have been assumed as effective with regards to both flexural and shear elastic stiffness (i.e., two external layers for 3-ply vertical panels). Then, Young’s moduli of CLT have been obtained as it in the following:

$$E_L = \frac{n_l}{n_{tot}} E_0 \quad (6)$$

$$E_T = \frac{n_t}{n_{tot}} E_0 \quad (7)$$

where E_L and E_T represent the reduced Young’s moduli in longitudinal and transversal direction, respectively; E_0 the Young’s modulus of raw material, n_l and n_t the number of layer in longitudinal and transversal direction, respectively; n_{tot} the total number of layer of the panel. The same reduction has been also applied to the tangential modulus (G) in both longitudinal and transversal direction. This material modelling gives back an acceptable representation of the material elastic properties, and is frequently adopted in literature [9, 18, 24, 32].

4.2 Connections modelling

Mechanical connections are usually modelled using links, trusses or frame elements having uniaxial or biaxial behavior [9, 18, 23, 33]. In the uniaxial case, HDs and ABs resist only in their primary direction (e.g., HDs in tension and ABs in shear only). In the biaxial case, both HDs and ABs resist to axial and shear forces simultaneously.

In this paper, vertical truss elements are used to model the HDs and the timber-to-timber contact, while frame elements are used for the ABs [23]. Three different elements have been defined to model the connection zones (Fig. 10):

1. HD element, consists of a no-compression truss element devoted to face the tensile forces at the bottom of the CLT panel;
2. AB element, consists of a no-compression frame element devoted to face the shear forces at the bottom of the CLT panel;
3. C element, consists of a no-tension truss element devoted to face the compression at the bottom of the panel.

The nonlinear behavior of the connection elements has been simulated through a lumped plasticity model. An elastic-perfectly plastic axial force (N)-displacement (Δ) behavior for both HD and C elements and an elastic-perfectly plastic shear (V)-displacement (Δ) behavior for ABs have been assumed (Fig. 8). Concerning HDs and ABs, this modelling approach has been considered suitable also in other literature works and then effectively used to perform nonlinear analyses [16, 34]. While for C elements, the elastic-perfectly plastic behavior represents an acceptable approximation of the parabola-rectangle behavior (see Fig 5a).

Due to buckling phenomenon which interests the HDs loaded in compression, their contribution has been disregarded in the model; while both hold-downs and angle brackets have been modelled with biaxial behavior but neglecting the reduction of strength due to axial-shear force interaction [9].

Figure 10: Representative scheme of the connection model.

4.3 Comparisons

In this Section the theoretical M - χ diagrams are compared with the numerical ones. At this stage of the research, only two cases have been analysed and compared: M - χ diagrams obtained by varying reinforcement area ratio (ρ) and the dimensionless axial force ratio (v).

Fig. 11 reports the comparison in terms of reinforcement area ratios. On the graphs are indicated the points corresponding to the first yielding of both HDs and compressed timber and those indicating the attainment of ultimate strain by timber. Numerical curves fit the theoretical ones satisfactorily: the curvature corresponding to first yielding of steel or

compressed timber are best quantified, while ultimate curvature provided by the numerical model resulted greater than the theoretical one.

In Fig. 12, instead, theoretical and numerical $M-\chi$ curves obtained by varying the dimensionless axial force ratios are compared. Also in this case, a good matching between the curves in terms of yielding curvature (provided by steel in tension) is resulted, while ultimate curvature provided by the numerical model is greater than theoretical.

In general, the numerical results confirm the trend that (i) the yielding curvature is ruled by steel in tension, because it precede the ‘yielding’ of timber under compression and that (ii) the ultimate curvature depends on ultimate strain in orthogonal to grain direction of compressed timber.

Figure 11: Comparison between theoretical and numerical $M-\chi$ diagrams by varying the reinforcement area ratios.

Figure 12: Comparison between theoretical and numerical $M-\chi$ diagrams by varying the dimensionless axial force ratios.

4.4 Design-oriented formulas for estimating the ultimate curvature

Both theoretical and numerical analyses proved that yielding in tension of HDs precedes those in compression of timber, and that ultimate curvature of the cross-section is ruled by the ultimate strain of the compressed timber.

In the light of this, it is reasonable to assume as optimal *failure condition* at Ultimate Limit State (ULS) for timber-to-timber contact cross-section those corresponding to HDs yielded in

tension and timber at its ultimate strain ($\varepsilon_{c,90,u}$) in compression (Fig. 13). Based on this assumption, *design-oriented* formulas for evaluating both ultimate curvature and the corresponding ultimate moment of the cross-section have been defined in the following.

With regards the ultimate curvature, a closed- form formula has been obtained starting from a translation equilibrium condition on cross-section between the applied axial force (N_{Ed}) and tensile and compression internal resultants:

$$\beta B x_{n,u} f_{c,90,d} - \sum_{HD=1}^n (A_{HD} \sigma_{HD})_i = N_{Ed} \quad (8)$$

where β represents the filling coefficient of the adopted parabola rectangle normal stress distribution, assumed equal to 0.810 for rectangular cross-section (also according to Refs. [29,36]), B the panel width, $f_{c,90,d}$ the design compression strength of timber in orthogonal to grain direction, A_{HD} the cross-section area of the tensile-resistant element and σ_{HD} the associated normal stress.

The maximum (or ultimate) axial force of the cross-section subjected to pure compression is:

$$N_{Rd} = B L_p f_{c,90,d} \quad (9)$$

where L_p represents the panel length.

Dividing the eq. (8) by eq. (9) the equilibrium translation becomes:

$$\beta \frac{x_{n,u}}{L_p} - \frac{\sum_{HD=1}^n (A_{HD} \sigma_{HD})_i}{B L_p f_{c,90,d}} = \frac{N_{Ed}}{B L_p f_{c,90,d}} \quad (10)$$

They have been defined with the symbols ω and ν the mechanical reinforcement percentage and the dimensionless axial force, respectively:

$$\omega_i = \frac{(A_{HD} \sigma_{HD})_i}{B L_p f_{c,90,d}} \quad (11)$$

$$\nu = \frac{N_{Ed}}{B L_p f_{c,90,d}} \quad (12)$$

Figure 13: Failure condition for the timber-to-timber cross-section at ULS (i.e., stage III).

By introducing ω and ν , the equilibrium translation equation can be written as:

$$\beta \frac{x_{n,u}}{L_p} = \sum_{HD=1}^n \omega_i + \nu \quad (13)$$

In general, the ultimate curvature is given by:

$$\chi_u = \frac{\varepsilon_{c,90,u}}{x_{n,u}} \quad (14)$$

where $\varepsilon_{c,90,u}$ represents the ultimate strain of timber at compressed edge and $x_{n,u}$ the ultimate neutral axis depth. By substituting the eq. (14) in the eq. (13) the ultimate curvature of the cross-section can be expressed with the closed formula:

$$\chi_u = \beta \frac{\varepsilon_{c,90,u}}{L_p \left(\sum_{HD=1}^n \omega_i + \nu \right)} \quad (15)$$

As it can be noted, the eq. (15) is easy of use. It allows to determine the ultimate curvature as a function of mechanical parameters which define the timber-to-timber connection zones without any other additional calculation. Furthermore, the eq. (15) confirms all the findings proved through the Figures 7, 8 and 9: when ω , ν and L_p increase the ultimate curvature decreases. While, if the ultimate strain ($\varepsilon_{c,90,u}$) of compressed timber reduces (increases) also the ultimate curvature reduces (increases) proportionally.

The ultimate moment of the cross-section associated to χ_u is determined through the equilibrium rotation around the center-of-gravity of the cross-section:

$$M_{Rd}(N_{Ed}) = \beta B x_{n,u} f_{c,90,d} (L_p / 2 - k x_{n,u}) + \sum_{HD=1}^n (A_{HD} \sigma_{HD} d_G)_i \quad (16)$$

where $k x_{n,u}$ represent the distance of the internal compression resultant of timber with respect to the compressed edge, with $k=0.40$ and d_G the distance of the i -th tensile resistant element with respect to the center-of-gravity of the section (Fig. 13).

Case	$\chi_{u, th}$ (1/cm)	ω (-)	ν (-)	$\chi_{u, CF}$ (1/cm)	$\Delta(\chi_u)$ (%)

Table 1: Comparisons among ultimate curvature derived by theoretical and closed-form formula obtained by varying the percentage reinforcement area ratio.

In Table 1 and 2 are summarized and compared the values of the ultimate curvature obtained from theoretical model (indicated as $\chi_{u,th}$) with those derived the proposed closed-form formula described by the eq. (15) (indicated as $\chi_{u,CF}$). In particular, Table 1 refers to the ultimate curvature obtained by varying the reinforcement percentage ratios, while Table 2 refers to ultimate curvature obtained by varying the dimensionless axial force ratios. In the same Tables, the percentage differences between $\chi_{u,th}$ and $\chi_{u,CF}$, indicated with the symbol $\Delta(\chi_u)$, are also reported. The results proved that the percentage deviations $\Delta(\chi_u)$ are quite constant and included in the interval 10-15%, thus confirming that the closed-form formula gives acceptable results.

Case	$\chi_{u, th}$ (1/cm)	ω (-)	ρ (%)	$\chi_{u, CF}$ (1/cm)	$\Delta(\chi_u)$ (%)

5 CONCLUSIONS

Despite that CLT constructional technology is widely diffused in many countries, a unified approach for evaluating the flexural load-bearing and displacement capacity of the panel subjected to seismic and gravity loads has not been yet defined. Different theoretical methods are proposed in literature, whose main shortcomings consist of under evaluating the role of compressed timber in the timber-to-timber contact zone and its influence on the ductile behavior of the panels.

This paper presents a novel moment-curvature ($M-\chi$) theoretical model for CLT panels. The method, based on an iterative procedure, allowed to develop the entire $M-\chi$ diagrams and to investigate the ductile behavior of CLT accounting for the orthogonal to grain properties of compressed timber.

The influence of different parameters on the post-elastic displacement capacity of the panels has been investigated through a parametric study. The obtained results proved that: (i) CLT panels are provided of good ductile behavior; (ii) increments of percentage reinforcement ratios, as well as of slenderness cross-section ratios and amount of axial force, induce significant reductions of the panels' ductility, whereas the ultimate moment increases simultaneously; (iii) the yielding curvature is ruled by HDs in tension, while the ultimate curvature depends on timber compressed in perpendicular to grain direction.

To assess the validity of the theoretical $M-\chi$ diagrams, a comparison with a finite element numerical model has been carried out. Theoretical vs numerical results showed a good matching, thus confirming the validity of the theoretical method.

Finally, based on the results achieved with the parametric study, a design-oriented approach for evaluating the ultimate curvature (together with the associate ultimate moment) through a closed-form formula has been presented in the paper. Comparison of the results shown a good accordance of the closed-form formula with the theoretical approach.

Abstract

Repairing stop-splayed scarf-joints in beams or truss-rods is a frequent occurrence in restoring ancient timber structures. Reinforcement of carpentry joints by means of metallic elements as well as unconventional materials is extensively investigated in literature, while timber pegs in timber to timber connections are studied referring mainly to new timber structures.

In the present paper, authors' previous research analysing the mechanical behaviour of stop-splayed scarf joints reinforced with timber pegs has been carried on, focusing on the evaluation of ductility which can be achieved by reinforcement with timber pegs. Moreover, the role of slenderness, the rate between jointed timber thickness and peg diameter is analysed.

An experimental program has been carried out testing in axial tension two samples of fir scarf joints with an ash key: one sample constituted of two simple scarf joints, and one constituted of three scarf joints reinforced with two ash pegs of 20 mm of diameter. Comparing experimental results has allowed to better understand the role played by timber pegs in reinforcement and to evaluate the influence of reinforcement on ductility of reinforced scarf joints behaviour.

Experimental results have also been compared with those obtained in a previous experimental study where an analogous experimental program has been made on smaller scarf joints reinforced with two ash pegs of 8 mm of diameter. So, the role played by slenderness has been focused.

The evaluation of the attained results, even if not exhaustive for a reliable theoretical formulation of timber peg behaviour in reinforcing stop-splayed joints, has allowed the identification of some interesting features, that is stiffness and reinforcement due to timber pegs.

Keywords: stop-splayed scarf joint, reinforcement, timber peg, ductility, slenderness, timber structures.

1 INTRODUCTION

In the field of ancient timber structures restoration, the need of substituting rotten portions of structural elements, preserving the original spatial configuration without modifying their structural behavior is advisable. At this aim, when total or partial substitution of an element is needed, the employment of traditional carpentry joints normally leads to a more conservative approach. In particular, in ancient trusses and floors, taking off the end portions of rafters or beams, damaged by biotic agents often due to high moisture content inside the masonry walls, is sometimes inevitable.

A quite speared methodology of restoration envisages the introduction of new timber elements connected to the standing structure. This connection is generally realized with metallic bolted plates, steel pins, or epoxy resin adhesives. According to their arrangement and geometry, common traditional carpentry joints can be divided in four main types: a) tenon and mortise joints; b) notched joints; c) lap joints and d) scarf joints. These connections are generally fixed or reinforced with metallic connectors, or epoxy resin adhesive, even if some disadvantages may occur such as (i) moisture condensing problems in the interface between timber and steel elements, (ii) questionable aesthetic output in uncovered structures, and (iii) the difficult reversibility of the intervention with resin adhesives [1, 2]. Nowadays an efficient alternative is the use of timber pegs in timber to timber connections. In literature, reinforcement of carpentry joints by means of metallic elements, as well as unconventional materials, is extensively investigated, while fewer papers can be found regarding the employment of timber pegs. In a review paper by Branco and Descamps [3] a state of art is described where many interesting references are quoted concerning the main themes as modelling and simulation of analysis and strengthening of carpentry joints. Moreover, several papers focusing on birds mouth joint [1, 2], mortise and tenon joint [4-6], and dowel joint [7, 8] can be found. A general overview regarding lapped scarf joints is presented by Kunecký et al. [9] in which the stiffness assessment of jointed structural elements for different joint positions and element sizes is investigated. Arciszewska-Kędzior et al. [10] performed both experimental and numerical analyses to study the mechanical behavior of a lapped scarf joint with inclined contact faces and four oak dowels. Sangree and Schafer [11] presented an experimental study on the mechanical behavior of a stop-splayed scarf joint with transverse key. Mechanical tests on four specimens simulating real joints have been performed and the study has been completed using a three-dimensional finite element model created using ABAQUS. Ceraldi et al. [12] analyze the mechanical behavior of stop-splayed scarf joints unreinforced and reinforced with timber pegs and with steel pins, subjected to tension test, to assess the reliability of employing timber fasteners. The role of the fastener inside this tensile-resistant carpentry joint and its contribution in yield strength and stiffness have been investigated. Aira et al. [13] experimentally analyze the structural behavior of halved and tenoned scarf joint subjected to tensile stresses in order to describe the different failure modes. In Perria et al. [14] results of an experimental campaign and an analytical model for the behavior of the halved under-squinted scarf joint are presented. Different aspects that influence the behavior of the connection subjected to pure compression, pure bending and combined compression and bending are analyzed. The stiffness of scarf joints with keys and timber pegs has been investigated and modelled by Fajman and Măca [15], including the role of friction forces, already studied in [16]. An experimental evaluation of traditional scarf joinery behavior in bending can be found in Hirst et al. [17]. More recently, in Karolak et al. [18] a more in-depth analysis on the current state of knowledge related to scarf and splice carpentry joints in flexural elements as well as selected examples of tensile elements is presented.

The rheological behavior of timber to timber joints connected by timber pegs, its modelling and the formulation of corresponding design rules, can be more extensively found in literature

referred to new structures, such as timber frames. Generally, research about timber peg behaviour in simple and double shear plane joints fastened with timber pegs and its theoretical and numerical interpretation aims to the identification of codified design rules, usually starting from those derived from Johansen's theory [19] prescribed for calculating strength capacity of steel fasteners [20-23]. Design rules validated for mortice and tenon joints have been proposed in [24, 25]. Many research, instead, have investigated the role of the different parameters influencing the joint behavior: rate of diameter and timber board thickness [21]; dowel bearing strength [22, 26, 27, 28]; shear and bending of the peg [19, 29, 30, 31]; direction of the load [32]; ductility [21, 33, 34, 35].

In the present paper, authors' previous research analyzing the mechanical behaviour of stop-splayed scarf joints reinforced with timber pegs has been carried on, focusing on the evaluation of ductility which can be achieved by reinforcement with timber pegs.

Ductility describes the ability of a structure to attain large deformation in the plastic range before its collapse. In timber structures, it may predominantly be supplied by plastic behaviour of the connections which are the critical regions for load transfer. There are several definitions of ductility, all related to stress, strain or energy, which may be useful in different situations [34]. For connection design, definitions referring to absolute values of rotation and displacement may be the most applicable [33]. Also, ductility may further be divided into static ductility for constant loads, and dynamic ductility for cyclic loads [33]. Commonly, it is defined as the ratio between ultimate and yield displacement, according to the European code EN 12512 [36] and the Swiss code SIA 265 [37] for timber structures.

Since knowledge of the yield point and ductility of a structure is important in seismic design, their investigation has become more and more of interest within recent years. From structural engineering point of view in general and for timber engineering, there is not a unified definition of the ductility term, nor is there a common understanding on how ductility shall be used in structural design. As a result, several methods have been developed in order to determinate the point of yield and, consequently several measures for evaluating of the ductility of timber structures and connections are obtained. In Northern America is widely used the equivalent energy elastic-plastic method (EEEP); in the European code EN 12512 (CEN method) the 1/6 method is adopted [36]; the 0.5 F_{max} method so as deduced from Karacabeyli and Ceccotto and finally, according to Yasamura and Kawei, the 10-40-90 method are also employed. A detailed description and discussion of those different methods can be found in [33]. According to these approaches, the evaluation of ductility can be carried out on the analysis of the load-displacements diagrams resulting from experimental tests or, alternatively, on approximating curves. This paper is focused on comparing two analysis methods commonly used in determination of yield load and deformation and of failure load and deformation, respectively.

An experimental program has been carried out testing in axial tension two samples of fir scarf joints with an ash key: one sample constituted of two simple scarf joints, and one constituted of three scarf joints reinforced with two ash pegs of 20 mm of diameter. Comparing experimental results has allowed to better understand the role played by timber pegs in reinforcement and to evaluate the influence of reinforcement on ductility of reinforced scarf joints.

Experimental results have also been compared with those obtained in a previous experimental study where an analogous experimental program has been made on smaller scarf joints reinforced with two ash pegs of 8 mm of diameter. So, the role played by slenderness has been focused.

The evaluation of the attained results, even if not exhaustive for a reliable theoretical formulation of timber peg behaviour in reinforcing stop-splayed joints, has allowed the identification of some interesting features, that is stiffness and reinforcement due to timber pegs.

2 EXPERIMENTAL PROGRAM

2.1 Samples and test set-up

The experimental program concerns two samples of stop splayed scarf joints made of fir, (*Abies alba*) with a key made of ash, (*Fraxinus excelsior*), whose dimensions and geometry are illustrated in Figure 1.

Sample A_D20 consists of two unreinforced joints, while sample B_D20 is constituted by three specimens of the same type of sample A_D20 but reinforced with two ash pegs with diameter of 20 millimeters (Figure 1).

Proportions and limit dimensions recommended for traditional configuration of scarf joints, with length three times the height of the cross section, have been assumed in their design.

Figure 1: Specimen geometry of samples A_D20 e B_D20 (dimensions in mm)

Density and parallel to grain compression strength ($\sigma_{c,0}$) of the two employed essences quoted in Table 1 have been experimentally determined in previous research [22, 31] with an average moisture content approximately equal to 12%.

Timber	Density (kg/m ³)	$\sigma_{c,0}$ (MPa)
Ash	652	56.3
Fir	472	39.2

Table 1: Mean values of density and parallel-to-grain compression strength.

Samples have been tested in tension with a universal electromechanical test machine with hydro pump LOSENHAUSENWERK, Mod: UHP 60, electronic control with control unit Zwick Roell, (Figure 2), in displacement control, at a speed of 0.8 mm/min, until a complete loss of bearing capacity was reached.

Figure 2: Test set-up

2.2 Unreinforced sample (Sample A_D20)

Final collapse of an unreinforced scarf joint with a key loaded in tension [32], can occur on the following critical surfaces: (i) compression failure at key contact inclined surface (notch area), (ii) shear failure through the horizontal plane in the heel surface, (iii) combined tension and bending failure at the reduced section above the notch and (iv) compression failure perpendicular to grain of the key (Figure 3).

Figure 3: Failure surfaces of an unreinforced scarf joint with a key

Both specimens of sample A_D20 have failed due to shear stresses through the heel area (Figure 4). Force-displacement diagrams (Figure 5) show that the observed behavior can be schematized with two linear steps: the elastic one, and, after the yielding point, the plastic one, with a relevant hardening. Stiffness, which is governed only by the level of confinement of the key, increases in the plastic phase, due to the enforcement of the key, which has shown no deformation at all after collapse of both unreinforced joints. In specimen 1A_D20 this increase is more than in specimen 2A_D20 as its elastic stiffness is 26% of the plastic one, while that of test 2A_D20 is 35%.

Figure 4: Failure mode of specimens 1A_D20 e 2A_D20

Figure 5: Force-displacement diagrams of sample A_D20

2.3 Sample reinforced with pegs (Sample B_D20)

In addition to the failure mode on the critical surfaces of a scarf joint with key, the reinforced joint can collapse in the single plane shear joint for embedment of the connected parts or failure of the peg in bending or “effective peg shear” failure mode, which is a combination of peg shearing, peg bending and embedding of timber boards [31].

Specimens 1B_D20 e 2B_D20 have both failed due to shear stresses through the heel area, while bending of the peg and embedding in the connected zone have been of little intensity in the first test and absent in the second. The key hasn't shown deformations (Figure 6).

Figure 6: Failure mode of specimens 1B_D20 e 2B_D20

Specimen 3B_D20 has shown a different failure mode as collapse has been determined by embedding of the lower connection, with scarce deformation in the pegs, while the key has been undeformed (Figure 7).

Figure 7: Failure mode of specimen 3B_D20

Comparing force-displacement diagrams for sample B_D20, quoted in Figure 8, it can be noted that only the specimen 2B_D20 doesn't have the ductile phase expected for the presence of the pegs [12], as collapse has been attained without deformations in the peg connection. Nonetheless, while specimens 2B_D20 and 3B_D20 present the same behaviour until the rupture of the first, specimen 1B_D20 differs from both. During the test of specimen 1B_D20, an initial crack developed in the notch area, parallel to the grain. This splitting due to tension perpendicular to the grain induced by compression parallel to the grain of the fibres, has generated a little crack which has not extended to the edge of the joint, as the presence of the peg connections delayed this occurrence, which at the end has induced shear collapse in the heel area.

Figure 8: Force-displacement diagrams of sample B_D20

2.4 Discussion of experimental results

In Table 2 yielding force F_y and maximum force F_{max} values are summarized, together with corresponding displacement. In sample B_D20, due to the presence of the peg, the yielding point has been determined following the American procedure ASTM 5764 [38], consisting in choosing as yield point the intersection of the load-displacement curve with a straight line parallel to the linear phase of the diagram shifted to a distance equal to 5% of fastener diameter.

Specimen	d mm	F_y (N)	u_y mm	F_{max} (N)	u_f mm
1A_D20	20	11664.1	8.1	13514	8.1
2A_D20	20	10025.0	5.6	13129	5.6
1B_D20	20	16507.5	8.3	21227	8.2
2B_D20	20	14701.3	3.8	15959	3.7
3B_D20	20	16590.3	4.4	18340	5.4

Table 2: Force and displacement values for sample A_D20 e B_D20

The reduced number of performed tests doesn't allow choosing a diagram fully representative of each sample behavior; so, with aim of comparing the rheological behavior of the two samples, all the diagrams are together compared in Figure 9.

The reinforcement with timber pegs is resulted efficient as it has induced a considerable increase of yielding and maximum forces values with respect to the unreinforced sample. In fact, sample B_D20 mean values $F_{y,mean}=15933$ N and $F_{max,mean}=18509$ N are 47% and 39% larger than the corresponding values of sample A_D20 $F_{y,mean}=10845$ N and $F_{max,mean}=13322$ N. This enforcement can be ascribed to the interaction between the timber peg and the joint, which has delayed the failure along the typical critical surfaces of the scarf joint. So, a reliable prediction of load-bearing capacity of the reinforced stop-splayed scarf joint depends upon evaluating the amount of load transferred to the joint, inducing the collapse of critical surfaces, as observed in [12].

Figure 9: Comparison of force-displacement diagrams of samples A_D20 and B_D20

The observed rheological behaviors are quite different both in elastic and plastic range. While sample A_D20 shows a linear response in the elastic as well as in the plastic phase, sample B_D20, when deformation appears in the simple shear plane joint constituted by the timber peg connection, shows a stiffer behavior in the elastic phase and a more ductile behavior, in the plastic one. In fact, the overall behavior of the reinforced joint is conditioned by the force distribution among the resisting elements, i.e., the ash key and the added fasteners, which act as damping elements in transferring loads. Moreover, the stiffening effect can be related to the friction forces generated by the contact between the two timber elements, which help hold tight the connection and enhance the level of confinement of the key. The presence of no negligible friction forces when timber pegs are used and the influence of the key on the joint axial stiffness have been already noticed and measured in [11, 15, 16], highlighting that the more the key is confined, the stiffer is the joint behavior.

3 INFLUENCE OF SLENDERNESS ON DUCTILITY

3.1 Ductility

Ductility is related to the ability of a structure to attain large deformations in the plastic range before its collapse and without substantial reduction in strength in specimen loaded in displacement control. There are several definitions of ductility, all related to stress, strain, or energy, which may be useful in different situations. For connection design, definitions referring to absolute values of rotation and displacement may be the most applicable (see [33]).

Commonly, ductility ratio is defined as the proportion of the displacement at failure u_f to the displacement at yielding u_y , so as deduced in the European and Swiss codes [36,37], which is given by:

$$D_f = \frac{u_f}{u_y} \quad (1)$$

An additional definition of the ductility ratio is also based on the displacement u_u at ultimate load F_u and it is represented by the following equation:

$$D_u = \frac{u_u}{u_f} \quad (2)$$

These parameters can be determined from the analysis of the load-displacements graphs resulting from experimental tests. The displacement at yield u_y , with the corresponding yielding load F_y , describes the point where the elastic behavior passes into a plastic behavior. So, in order to estimate ductility, the identification of yield point is necessary and as a yield criterion for timber connections is not well defined, several methods for its determination have been developed [36,37,39,40,41].

In the present paper, Eqs (1) (2) have been used to estimate the level of ductility of the two stop splayed scarf joints samples tested: sample A_D20, unreinforced, and sample B_D20 reinforced with timber pegs. In figure 10, referring to a graph for a specimen of sample B_D20, are identified: F_y as the force at the yield point, determined by the method based on a 5% diameter offset, F_{max} as the maximum value registered and F_u as the ultimate force at the failure point.

Figure 10: Identification of force values for samples B_D20

A summary of load and displacements at the yield and failure points, for the two samples under consideration is given in Table 3.

Specimen	d mm	F_y (N)	u_y mm	F_{max} (N)	u_f mm	F_u (N)	u_u mm	D_f -	D_u -
1A_D20	20	11664.1	8.1	13514	8.1	3593.8	8.21	1.00	1.01
2A_D20	20	10025.0	5.6	13129	5.6	5669.5	5.74	1.00	1.02
1B_D20	20	16507.5	8.3	21227	8.2	9807.7	8.35	0.99	1.00
2B_D20	20	14701.3	3.8	15959	3.7	12944.1	4.15	0.97	1.08
3B_D20	20	16590.3	4.4	18340	5.4	15163.5	8.01	1.23	1.83

Table 3: Determination of the displacements at point of yielding (u_y) and failure (u_f) and ductility ratio based on Eqs (1) and (2).

As can be seen from Table 3, the ductility values show a uniformity of results in unreinforced and reinforced samples, respectively. Also, the mean value of ductility, at the yield point, in-

creases by approximately 6% in the reinforced joint compared to the unreinforced one. Furthermore, the mean ductility value increases if the ultimate displacement is considered. As can be easily seen, in this case the increase in ductility is about 30%. However, evaluating the plastic displacement ($u_f - u_y$) only the reinforced specimen 3B_D20 shows a definite ductile behavior.

3.2 Role of slenderness

The present experimental results have also been compared with those obtained in a previous study [12], where an analogous experimental program has been made on smaller scarf joints, unreinforced sample A_D8, and reinforced with two ash pegs of 8 mm of diameter, sample B_8D (see Figure 11).

Fig. 11. Specimen geometry of samples A_D8 and B_D8 [12] (dimensions in *mm*)

So, the role played by slenderness in reinforcement with timber pegs has been evaluated. In that regard, the slenderness λ is defined as follows:

$$\lambda = \frac{s}{d} \quad (3)$$

where “s” is the smallest thickness of the pegged joint and “d” is the diameter of peg.

The slenderness values of B_D20D and B_D8 are quoted in Table 4:

Specimen	h cm	s cm	d cm	λ
B_D20	140	48	20	2.4
B_D8	100	44	8	5.5

Table 4: Slenderness values for samples B_20D and B_D8

Speci- men	d mm	F _y (N)	u _y mm	F _{max} (N)	u _r mm	F _u (N)	u _u mm	D _f -	D _u -
1A_D20	20	11664.1	8.1	13514	8.1	3593.8	8.21	1.00	1.01
2A_D20	20	10025.0	5.6	13129	5.6	5669.5	5.74	1.00	1.02
1B_D20	20	16507.5	8.3	21227	8.2	9807.7	8.35	0.99	1.00
2B_D20	20	14701.3	3.8	15959	3.7	12944.1	4.15	0.97	1.08
3B_D20	20	16590.3	4.4	18340	5.4	15163.5	8.01	1.23	1.83
1A_D8	8	5849.7	5.9	6070.5	6.7	6058.9	6.72	1.14	1.15
2A_D8	8	6837.6	6.4	7504.61	8.6	4772.2	15.41	1.34	2.42
1B_D8	8	6955.6	4.5	8678.9	12.7	6918.3	14.10	2.83	3.13
2B_D8	8	9264.8	6.9	9486	8.8	9327.0	9.01	1.28	1.31
3B_D8	8	6969.1	4.9	8770	8.5	7945.0	14.73	1.74	3.03

Table 5: Comparison of samples_D8 and samples_D20

Also, the ductility gain obtained reinforcing the scarf joint with timber pegs is larger for the slenderer samples. In fact, for samples_D8, D_f and D_u increase of 57% and 40% respectively with the reinforcement, while for samples_D20 they increase only of 6% and 30%, respectively.

4 CONCLUSION

The reduced dimensions of the tested samples in this step of the research do not allow definitive conclusions about the influence of reinforcing stop-played scarf joints with timber pegs on ductility. Nonetheless, some interesting remarks have been deduced with can guide modeling the reinforced joint behavior.

First of all, the reinforcement with timber pegs is resulted efficient as it has induced a considerable increase of yielding and maximum forces values with respect to the unreinforced sample and it leads to a ductility increase. A fundamental question is given by the reference point: the European code and Swiss code for timber structures set the reference to the displacement at failure, whereas other methods consider the displacement at ultimate load to evaluate the ductility ratio.

Moreover, the observed rheological behaviors are quite different both in elastic and plastic range. While sample A_D20 shows a liner response in the elastic as well as in the plastic phase, sample B_20, when deformation appears in the simple shear plane joint constituted by the timber peg connection, shows a stiffer behavior in the elastic phase and a more ductile behavior, in the plastic one.

Finally, a more sensitive gain in ductility can be observed when the slenderness is low. In particular, according the Eqs (1-2) for samples_D8, D_f and D_u increase of 57% and 40% respectively with the reinforcement, while for samples_D20 they increase only of 6% and 30%, respectively. So, in designing reinforcement with timber pegs checking slenderness is necessary, as one of the parameters orienting the choice of peg diameter to be employed.

Abstract

In Italy, as well as in other earthquake-prone countries, most buildings have been erected without considering the effects of seismic excitation or according to obsolete seismic design provisions. Furthermore, they also suffer from significant structural deficiencies because of the low mechanical characteristics or the natural decay of the materials. The seismic vulnerability of the existing building stock is a serious economic and social concern and the need for retrofitting or rebuilding grows as time progresses. In this framework, this study investigates a newly developed retrofit technique for buildings with RC framed structure. The intervention is realized by means of Cross-Laminated Timber (CLT) panels placed over the exterior walls and connected to the RC structure by friction dampers. The CLT panels provide the existing structure with additional lateral stiffness and strength. The role of the friction dampers is twofold. On one hand they cap the internal forces of CLT panels, thus controlling the reaction forces transmitted to the existing structure and avoiding the failure of CLT panels themselves. On the other, friction dampers dissipate part of the input earthquake energy. The effect of these multiple features could reduce the storey drifts demanded by the earthquake to values compatible with the structure capacity. This paper aims at sounding the impact of the proposed retrofit solution on the response of the RC framed structure to be upgraded. To this end, a one storey RC frame representative of existing RC framed structures designed considering only gravity loads is upgraded by a CLT panel and friction dampers of usual size. The impact of the retrofit intervention is investigated in terms of the achieved increase of stiffness, strength and energy dissipation capacity. The bare RC frame and the frame equipped with CLT panel and friction dampers are modelled in OpenSEES environment. Hence, the nonlinear responses of the two frames are assessed by monotonic and cyclic pushover analyses and the comparison between the results obtained for the bare and the upgraded frame quantifies the expected impact of the proposed retrofit intervention.

Keywords: Existing buildings, RC framed structure, seismic retrofit, CLT, friction dampers.

1 INTRODUCTION

In European seismic countries – such as Italy, Greece, Bulgaria, Turkey, Romania and the Balkan peninsula [1] – the building stock designed without anti-seismic criteria or according to old seismic standards is extremely wide, including mainly masonry or Reinforced Concrete (RC) framed buildings. For instance, in Italy, over 55% of the existing residential buildings was built before the 1970s [2], when seismic regulations were not in force and only gravity loads were considered at the design stage. Moreover, these buildings are over 50 years old, which means that they have reached their nominal service life, exhibiting structural deficiencies mainly due to the naturally decay of the materials originally used.

In this framework, seismic upgrading of the existing buildings is strongly needed, in order to ensure a higher level of safety for inhabitants, meanwhile to reduce the economic losses and environmental harm which could be caused by the damage or collapse of buildings in the event of earthquakes.

With reference to RC framed structures, the current seismic upgrading techniques are aimed at increasing the strength, stiffness, and ductility capacity of the structure and/or reducing the seismic demand. The most common techniques include the strengthening of the existing structural members by traditional materials (i.e. steel, concrete) or innovative ones (fibre-reinforced polymer, textile-reinforced mortar), as well as the addition of new RC shear walls or steel-braced frames. Other techniques include the installation of base isolators or energy dissipation devices. The main drawbacks that limit the wide applicability of these techniques are the excessive costs and time for implementation as well as the high occupants' disturbance. In fact, common strengthening techniques require the temporary downtime of the building and considerable demolition and reconstruction actions, which may affect up to 70-75% of the total construction costs in a new building [3]. Instead, the addition of a new seismic-resistant system requires relevant enlargements and reinforcement of the foundations and is not always possible if located externally to the building.

In order to overcome these drawbacks, newly seismic retrofit techniques need to be investigated, which can be able to meet the current needs of cost-effectiveness, quick installation and reduced users' disturbance. To this purpose, the use of Cross Laminated Timber (CLT) has been recently investigated as an alternative and sustainable solution to increase the seismic performance of the existing buildings, thanks to its high mechanical performance [4]. CLT is a plate-like engineered timber product, commonly composed of an uneven number of timber board layers, which are arranged crosswise to each other at an angle of 90° and quasi rigidly connected by adhesive bonding. The crosswise build-up provides the material high capacity of bearing loads both in-plane and out-of-plane, allowing its use for structural purpose [5].

Strengthening technique based on coupling the infill outer walls of the existing RC framed buildings by CLT panels has been investigated by Sustersic e Dujic [6-7], in view of an integrated retrofitting approach aimed also at increasing the energy efficiency of the buildings. Specifically, they proposed to realize the connection between the panels and the structure through special steel brackets, provided of ductility and energy dissipation capacity. The external application of CLT panels has been recently investigated also within the AdESA project [8], resulting in a real application on a case study characterized by a prefabricated RC structure. Stazi et al. [9] proposed CLT shear walls in replacement of the existing masonry infill walls. In particular, the results of preliminary numerical studies proved that CLT infills allows the RC frame to reach higher lateral stiffness and peak load values compared to common masonry infills. CLT infilled shear walls have been also analysed by Haba et al. [10], who investigated narrow CLT elements bonded to each other and onto the RC frame with epoxy resin, with po-

tential results in terms of stiffness and ductility capacity according to the experimental activities conducted. Then, the use of post-tensioned, dissipative, and re-centering rocking CLT walls located in the external perimeter of the building has been investigated by Sandoli et al. [11]. In this work, nonlinear analyses on a case study showed the considerable effectiveness of this intervention in terms of seismic capacity increase, even using a small number of CLT walls with limited size.

The research on the topic of seismic upgrading of RC frame structures through strengthening CLT panels is still ongoing, and further studies are needed. Additional investigations on connection systems between the CLT panels and the existing structure are also required, in order to make this renovation solution concretely and widely applicable [12]. In this framework, this study investigates an innovative seismic retrofit technology (named e-CLT) for RC framed buildings based on the use of CLT panels placed over the exterior walls and connected to the structure by means of friction dampers [13]. This solution is currently under development within the ongoing multidisciplinary Horizon 2020 innovation project, called e-SAFE (energy and Seismic AFFordable rEnovation solutions), aimed at investigating innovative and combinable integrated retrofitting interventions. In this work, the impact of the e-CLT retrofit intervention on the response of the RC framed building structures is investigated, referring to existing structures designed considering only gravity loads. In the following sections, first the proposed retrofitting system is presented focusing on its components, mechanics, and installation. Hence, a RC frame is designed according to old building regulations and from this a set of single-storey frames with and without e-CLT is derived. The aim is to analyse the seismic response of RC frames upgraded by the e-CLT system, considering the number of CLT panels and friction dampers applied, as well as the contribution/presence of infill walls.

2 SEISMIC UPGRADING BY e-CLT SYSTEM

The e-CLT system is aimed at reducing the drifts demanded by earthquakes and improving the seismic performance of the building for the expected levels of seismic excitation. It consists in the application of CLT panels on the outer side of the existing walls, by connecting them to the RC structure through friction dampers (Figure 1a). The system is conceived so that in occurrence of moderate ground motions, the dampers rigidly connect CLT panels to the RC structure, thus making available additional lateral stiffness and strength that reduce drifts and may protect non-structural elements. Conversely, dampers activate in occurrence of stronger ground motions, thus dissipating part of the input seismic energy. This further resource of the system activated at this seismic excitation level, after cracking of non-structural elements, reduces the damage of structural components and protect the building from collapse. Furthermore, the activation of the dampers defines an upper bound to the force sustained by the CLT panels, thus preventing their failure even under strong ground motions. The installation of CLT panels from the outside of the building minimizes the occupants' disturbance, while maintaining the building operativity.

The mechanical characterization of the proposed friction damper is currently under investigation within the e-SAFE project [14]. The damper is basically made by two steel profiles, which connect the CLT panels of two consecutive floors to the existing interposed RC beam (Figure 1a). One profile (named "anchor profile") is connected to the RC beam by anchor bolts and to the other profile (named "free profile") by slotted holes and pretensioned high-strength bolts. Common timber screws connect both the steel profiles to the CLT panels. The shear force is transmitted from the free to the anchor profile by means of the friction exerted in the contact surface. During an earthquake, when the force transmitted by the damper attains the value

of the friction force, the free profile slides on the anchor one and thus dissipates seismic energy (Figure 1b).

Figure 1: (a) e-CLT system and (b) behaviour of e-CLT system under seismic loads

The e-CLT system is designed also to allow a quick and easy external installation, which can be performed by means of a mobile lifting equipment (cranes, aerial platforms, etc.), proceeding to apply panels from the ground floor to the top of the building. In particular, the anchor profiles of each damper can be pre-assembled on the top of CLT panels off-site, in order to connect directly the panels to the existing RC beams through chemical anchors.

Moreover, the e-CLT system is designed to be combined with energy-efficient solutions, in view of an integrated (seismic and energy) approach to the buildings renovation. More details can be found in [15].

3 CASE STUDY

The case study is a one storey, three-bay RC frame having net height and net width of 3.2 m and 11.1 m, respectively. The columns have cross-section of 30x30 cm and are reinforced by four rebars with diameter of 14 mm, while the beams have cross-section of 30x50 cm and are reinforced by nine rebars with the 14 mm diameter. Both columns and beams have been designed according to the regulations in force in Italy during the 1970s, as well as the construction practices of that period. In particular, the cross-sections size and the steel reinforcements area of the frame members have been designed by means of the allowable stress method [16], considering gravity loads only. Columns have been designed to resist only to axial force, that was evaluated on the assumption of a 4-storey RC frame.

Steel grade Feb38K with a characteristic yield stress $f_{yk}=375$ MPa is assumed for rebars, while the characteristic compressive cubic strength R_{ck} of concrete is assumed equal to 20 MPa (corresponding to cylinder strength f_{ck} equal to 17 MPa).

The case study frame has been analysed considering both the bare and the infilled configuration. Specifically, the infill wall has been assumed made of two leaves of hollow clay bricks (8-cm and 12-cm thick, internally and externally respectively, with an intermediate air cavity), according to the construction techniques used in Southern Italy between the 1950s and 1980s.

Window openings in the infill walls have been considered according to two layouts. In the first and the second layout, openings are assumed in the two lateral bays and in the central one, respectively.

The impact of the e-CLT system on the seismic response of both bare and infilled case study frame has been investigated, considering two different configurations of the seismic retrofit system (configurations 1 and 2 in Figure 2). Specifically, configuration 1 (Figures 2a, c) involves the application of a single CLT panel to the central bay of the frame, while in configuration 2 (Figures 2b, d) the RC frame is retrofitted by 2 CLT panels applied to the lateral bays of the frame.

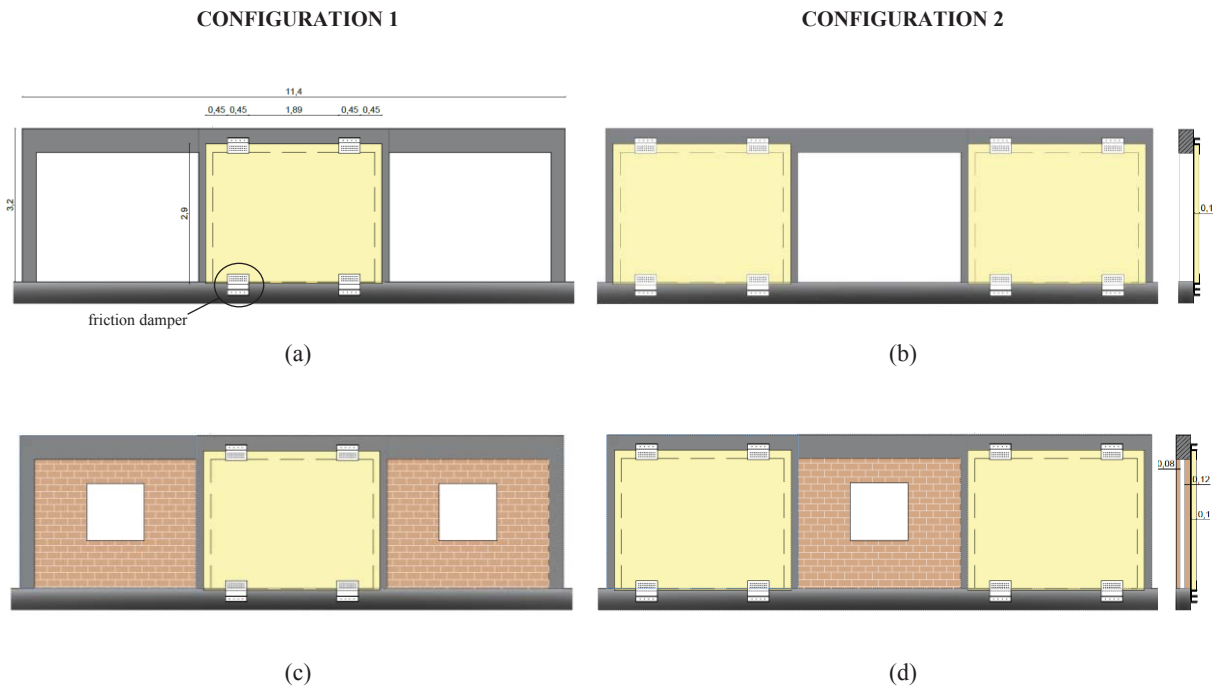

Figure 2: Investigated configurations of the e-CLT retrofitting intervention on the case study frame: (a) bare and (c) infilled frame with e-CLT in configuration 1; (b) bare and (d) infilled frame with e-CLT in configuration 2.

In both configurations, 10-cm thick, 3-ply CLT panels made of C24-class boards are assumed. Each CLT panel is 2.9-m high and 3.7-m wide and is connected to the RC beam by means of two anchor profiles arranged on its top. Two friction dampers connect the bottom of each CLT panel to the foundation of the RC frame. The friction dampers are 450-mm wide and 8-mm thick and are arranged symmetrically each other, at a distance of 0.45 m from the side edge of the panel.

4 NUMERICAL MODELLING

A numerical model has been implemented in OpenSees environment, in order to analyse the nonlinear response of the investigated RC frame at pre- and post-intervention state, considering the configurations described in Section 3.

Figure 3 shows the numerical model schema, referring to a single infilled bay of the case study frame, equipped with CLT panel and friction dampers. The detailed description of the parts the numerical model (RC frame, CLT panel, friction damper and infill) is reported in the following Sections.

Figure 3: Numerical model schema, referring to a single infilled bay of the case study frame at post-intervention state.

4.1 RC frame

Beams and columns of the RC frame have been modelled differently. Specifically, the “beamWithHinges Element” is used for columns. This element consists in a member with a linear-elastic region in the middle and plastic hinges at its ends. The length of the plastic hinges is equal to the depth of the column cross section. Instead, beams where the CLT panels are fixed at post-intervention state are discretized in five elements (elements B₁-B₅ in Figure 3). The intent was to locate along each beam four intermediate nodes (nodes nb₂, nb₃, nb₄ and nb₅ in Figure 3) to connect the beam and the two anchor profiles. The two lateral beam portions (elements B₁ and B₅) and the central one (element B₃) are modelled by the “nonlinear-BeamColumn Element”, a nonlinear force-based beam-column element able to replicate the spread of plasticity along the member. Three and five Gauss integration points are assigned to the lateral and central portions of the beam, respectively. Whereas, the “elasticBeamColumn Element” is used to model the beam portions B₂ and B₄, assuming that plastic hinges form outside of the damper length. Instead, the beams belonging to the span without CLT panels are modelled by nonlinear force-based beam-column elements, with five Gauss integration points.

A fibre cross section is assigned to each plastic zones of nonlinear RC members, considering both the concrete part and steel rebars. The concrete part is divided into fibres having constant 5-mm depth, to which the Mander constitutive law (“Concrete 04” uniaxial material) is assigned. Instead, single fibres enclosed in the cross section are used to model the steel rebars. In particular, an elastic-plastic material with isotropic strain hardening (“Steel 02” uniaxial material) is assigned to steel rebars. The parameters used for the two materials are summarized in Table 1.

Concrete	
Average compressive strength	25 MPa
Strain at maximum strength	0.002
Strain at crushing strength	0.0035
Young's modulus	31,500 MPa
Rebars	
Average yielding strength	380 MPa
Young's modulus	200,000 MPa

Table 1: Material properties of RC frame members.

4.2 CLT panel

The 3-ply CLT panel (layers thickness: 30-40-30 mm) is modelled as an assembly of 10-cm thick “MITC4 Shell Elements”, as shown in Figure 3. In order to model the multi-layer panel layout, an orthotropic and homogenized material is assigned to the cross section of each shell element, according to the reduced cross section method proposed in [17]. This method is based on the reduction of a multi-layer material into a single-layer one by means of specific composition factors, assuming a plane stress state of the timber panel. This assumption is widely adopted to define the material properties of CLT for the needs of seismic modelling, when building nonlinear behaviour is mostly localized in connections [6,18].

The material properties of the homogenized CLT material are reported in Table 2 and are based on the mechanical characteristics of C24-class spruce wood, according to EN 338 [19]. The value of shear modulus was reduced to 500 MPa since generally CLT panels are not glued on their narrow face. For the same reason, the value of Poisson's ratio has been set equal to 0.0 [20].

CLT	
Perpendicular-to-grain Young's modulus (E_{wx})	4622 MPa
Parallel-to-grain Young's modulus (E_{wy})	6748 MPa
Perpendicular-to-grain Young's modulus (E_{wz})	370 MPa
Shear modulus	500 MPa
Poisson's ratios	0.0
Density	420 kg m ⁻³

Table 2: Material properties of CLT panel.

4.3 Friction damper and connection elements

As shown in Figure 1a, the proposed friction damper is made by two steel profiles (i.e. anchor and free profile), which mainly consist of a middle web and two side flanges. The “ShellMITC4 Element” and the “Truss Element” are used to model both these components. Specifically, the web of each profile is modelled by five 8-mm thick shell elements (Figure 3), while the flanges are modelled by truss elements (8-mm thick and 100-mm depth) which connect the edge nodes of the above-mentioned shell elements. An elastic material is assigned to web and flanges of the steel profiles, assuming that they do not yield. The Young modulus of steel ($E_s=210.000$ MPa) is considered for the assigned material.

A “zeroLength Element” is used to connect the adjacent nodes of the anchor profile and “free profile” of each friction damper. In the X direction, an elasto-plastic material with strain kinematic hardening constitutive law (“Steel01” uniaxial material) is assigned to each element, in order to model the sliding movement of the upper profile when the shear force attains the

value of 30 kN. In the Y direction, two of these elements are characterized by a large stiffness, in order to simulate the pretensioned high strength bolts that connect the two steel profiles.

Then, “Two Node Link Elements” are used to model the connection between the friction damper and CLT panel by means of timber screws. An elastic material is assigned to each element, whose stiffness is calculated in accordance with the Eurocode 5 [21] assuming the use of 30 screws for each damper.

The same modeling is used for the anchor profiles on the top of each CLT panel, using “zeroLength Elements” with large stiffness to connect the web to the RC beams, in order to simulate the connection by means of chemical anchors.

4.4 Infill wall

The infill walls are modelled by a pair of diagonal “Truss Elements”, which connect the top of each column with the bottom of the subsequent one (Figure 3). These elements are supposed to have no tension resistance and their force-displacement relationship is calibrated to replicate the shear force-drift relationship of the infill panel, as proposed by Panagiotakos and Fardis [22] and Celarec et al. [23]. This relationship consists of four branches: a first elastic branch up to the first cracking of panel, a second branch with a lower stiffness up to the complete cracking of panel, a degrading branch and a last branch with a residual resistance. The stiffness and the value of the maximum force of each branch are determined according to the equations proposed in [23]. The multi-linear force-displacement relationship thus obtained is then converted into an equivalent stress-strain relationship. The values of stress and strain corresponding to the three corners of the envelope are assigned to the truss member by means of the “Hysteretic” uniaxial material implemented in OpenSees. The force-displacement relationship is first determined for the infill without openings assuming that it is 20-cm thick, as reported in Section 3, the shear cracking strength is equal to 0.28 MPa, while Young modulus and shear modulus are equal to 4130 and 1240 MPa, respectively. The ordinates of this force-displacement relationship have been reduced to 50% for the infill with openings. These relationships define a layout of infills with high mechanical properties. Other two infill layouts are defined reducing the ordinates of the force-displacement relationships of the first layout to 80% and 60%, in order to represent infills with lower mechanical properties and/or window openings having larger size.

5 ANALYSES AND RESULTS

Monotonic and cyclic pushover analyses in displacement control have been carried out both on bare and infilled RC frame at pre- and post-intervention state (Figure 4a). First, a vertical load of 292.5 kN has been applied at the top of the two central columns, a vertical load of 146.25 kN at the top of the two lateral ones, and a uniformly distributed load of 26 kN has been applied on each beam. These loads are consistent with those used to design the frame.

The top horizontal displacement corresponding to the near collapse limit state of the bare RC frame is determined by monotonic pushover analysis. In this case, the top horizontal displacement is increased until in one column the chord rotation has attained its ultimate value determined according to Eurocode 8 – part 1-3 [24]. The cyclic pushover analysis is performed for all the considered frames. The applied top horizontal displacement is cycled according to the loading protocol reported in Figure 4b, where the maximum amplitude is equal to the top displacement corresponding to the near collapse limit state of the bare RC frame. The hysteretic responses of bare and infilled frame are shown in Figures 5 and 6, respectively. Specifically, the seismic response of the masonry infilled frame has been investigated assum-

ing the three different levels of quality of masonry infill, i.e. mechanical properties equal to 100%, 80% and 60% of the reference infill defined in Section 4.4.

Figure 4: (a) Cyclic pushover analysis on bare RC frame equipped with e-CLT in configuration 2 and (b) cycling loading protocol.

Figure 5: Hysteretic responses of the investigated bare frame at pre- and post-intervention state, with e-CLT system in (a) configuration 1 and (b) configuration 2.

The impact of the retrofit by e-CLT system on the seismic capacity of the case study frames has been investigated in terms of the achieved increase of lateral strength, stiffness, and energy dissipation capacity. The lateral strength is assumed equal to the maximum horizontal force sustained by the system during cyclic loading. The lateral stiffness is calculated as the ratio of the lateral strength to the corresponding displacement. Finally, energy dissipation capacity is quantified as the energy dissipated during cyclic loading, which is calculated as the area enclosed by the hysteresis loops.

The hysteretic responses of the bare frame at pre- and post-intervention state (Figures 5a, b) show a considerable increase of the seismic capacity after the application of the e-CLT system. In particular, the lateral resistance of the structure upgraded by the e-CLT in configurations 1 and 2 reaches the values of 231 kN and 300 kN. Compared to the lateral strength of 165 kN at pre-intervention state, the achieved percentage increase is 40% and 82% for configurations 1 and 2, respectively. Furthermore, the application of a single CLT panel equipped with two friction dampers (configuration 1) provides the RC frame with an increase of lateral stiffness and energy dissipation capacity of 93% and 128%, respectively. Instead, by adding

two CLT panels and four friction dampers (configuration 2) the stiffness of the structure increases of 165%, while the energy dissipation capacity of 275%.

Figure 6: Hysteretic responses of the investigated infilled frame at pre- and post-intervention state, with e-CLT system in (a-c-e) configuration 1 and (b-d-f) configuration 2, assuming the mechanical characteristic values of the masonry infill at: (a,b) 100%; (c,d) 80%; (e,f) 60%.

The impact of the e-CLT system on the capacity of infilled frames (Figure 6) is less remarkable, because the infills make the frame stiffer and stronger, and significantly depends on the capacity parameter. As showed by the comparison of the hysteretic responses of the infilled frame at pre- and post- intervention state, the application of CLT panels determines a negligible increase of the lateral stiffness, regardless of the mechanical properties of infills.

The increase of lateral strength is also low, with higher percentage increase for infills with low mechanical properties (increase of 16% and 26.3% in configuration 1 and 2, respectively). However, the introduction of the e-CLT still leads to a significant increase of the lateral residual strength of the RC frame after the infill failure and even a more remarkable increase of energy dissipation capacity. The percentage increase of lateral residual strength achieved by the retrofit with e-CLT in configuration 1 and 2 is about 38% and 77%, respectively. Finally, the percentage increase of energy dissipation capacity achieved for infills with high, intermediate and low mechanical properties is 82%, 89.5% and 98.5% after the application of the e-CLT in configuration 1 and 146%, 162.7% and 182.6% in configuration 2.

6 CONCLUSIONS

This paper investigates the potential impact of an innovative seismic retrofit technology on the response of RC framed structures. This technology, named e-CLT system, consists in the application of CLT panels on the outer side of the existing walls, by connecting them to the RC structure through innovative friction dampers. The friction damper is still under development and here it is idealised with a connection with rigid-plastic cyclic behaviour. The results reported in this work evidence the potential of the e-CLT system in enhancing the seismic performance of existing RC framed buildings considering different features of the buildings to be upgraded (with and without infill walls) and different importance of the retrofit solution (one or two CLT panels with dampers for the one storey, three-bay RC frame considered as case study).

Even the configuration with the single CLT panel, if applied to the bare RC frame, leads to a significant improvement of all the seismically relevant features of the building: lateral strength, stiffness and energy dissipation capacity. In this case, the largest impact is on energy dissipation capacity. Significant is also the impact on lateral stiffness. However, when the e-CLT system is applied to infilled frames, even considering the solution with two CLT panels, the impact on the lateral stiffness is minor. Instead, the improvement achieved in terms of increase of energy dissipation capacity remains significant: for instance, even in the case of the stiffest and strongest considered infill, it was found equal to 82% and 146% for the configurations with one or two CLT panels, respectively. The increase of lateral strength of the infilled frame provided by the e-CLT system is fair.

Based on these results, the e-CLT system appears to be a promising tool for seismic upgrading of RC framed buildings. Its effectiveness is expected to be great in fulfilling the Near Collapse performance objective, which relies mostly on energy dissipation capacity of the structure. Instead, when the improvement of seismic performance is mainly related to the increase of lateral stiffness, as in the case of damage limitation performance objective, the effectiveness of the e-CLT system could be limited when it is applied to infilled frames. In the future, more comprehensive investigation will be performed, based on the experimental mechanical characterization of the proposed friction damper. Furthermore, the effectiveness of the e-CLT system will be also investigated by multi-storey numerical models.

Abstract

The retrofit of existing masonry buildings plays a relevant role in the Italian building context, both for preservation and requalification of the cultural and architectural heritage. Historically, timber has been widely used in unreinforced masonry (URM) buildings, mainly for horizontal structures. In recent years, the use of timber in the retrofit of existing buildings has gained an increasing interest for the improvements of both structural and energetic performances. Indeed, wooden elements present good hygrothermal properties and, thanks to their lightweight and stiffness, they are suitable for the seismic improvement of masonry buildings. The aim of this paper is to numerically investigate the seismic strengthening of existing URM structures by means of cross laminated timber (CLT) panels, evaluating the coupling degree of the timber-masonry integrated system. The investigation was carried out through a finite element modelling. First a parametric local model of a CLT-masonry coupled wall was calibrated with literature experimental data. Then, the study was extended to a XVII-century URM building located in the Italian Alpine region (Roana, Vicenza province). Non-linear static analyses were carried out in order to assess the local and global behavior of the URM-CLT system and its potential benefits. Results suggested a seismic capacity improvement due to shear strength increase and global weight reduction.

Keywords: masonry building, CLT, seismic retrofitting, integrated intervention technique, FEM.

1 INTRODUCTION

The seismic retrofit of existing buildings has gained more and more interest in the Italian context due to the necessity of protecting the cultural and architectural heritage. The great variability of the building typologies and the sustainability requirements lead to the necessity of finding alternative solutions to invasive interventions. As a matter of fact, massive replacements of the wooden floors with RC elements, insertion of RC curbs, etc., within unreinforced masonry (URM) buildings aimed at activating an ideal ‘box-like behavior’, proved to be damaging, by excessively weighing down the structure and leading to local collapses of vulnerable portions of the buildings [1].

These observations led to the need for a more accurate study on the effects of the interventions and the search for innovative methods. Timber structural elements, which were historically used in masonry buildings even for seismic purposes [2][3], present favorable characteristics for some of the problems that characterize conventional reinforcement interventions, such as reduced weight, which permits widespread intervention in the structure with a limited variation of the total seismic mass, and good mechanical properties, often more compatible with URM historical structures. Furthermore, the rapidly evolving of timber technology in recent decades developed more efficient materials, e.g., Cross Laminated Timber - CLT, widening its application field and possibilities.

The intervention described in this paper is addressed to existing URM buildings which need an improvement in terms of structural-seismic capacity, functionality and energetic performances. Based on the effectiveness of URM-CLT coupling walls for shear capacity [4][5] and energetic performances improvement [6], such as the benefits of stiffened timber diaphragms [7][8], an integrated intervention aimed at the insertion of a CLT endoskeleton within a URM structure was designed.

The intervention consists in inserting a CLT structure inside the perimeter walls, substituting the un-strengthened existing floors and inner partitions and assembling a inner core able to bear part of the static and eventual seismic loads. The paper presents the procedure implemented to simulate the intervention. First, a coupled URM-CLT wall was modeled within finite element (FE) software (i.e., DIANA FEA [8]): the model was validated through the comparison with literature studies [10][11] and the influence of FEM parameters involved in the system were evaluated. Following, global models of an existing URM structure and the proposed integrated CLT-URM were created. The CLT nest was designed through a specific software for timber structures ([12]), defining the structural properties such as panel thickness and connection types. Modal and non-linear static analyses were performed, and the results compared.

1.1 State of Art

The CLT technology consists of layered panels of solid timber, in which each layer is oriented perpendicular to adjacent ones. This configuration permits the use of the material for the realization of large boards that can be used for both wall and floor elements, being able to bear both in-plane and out-of-plane loads. Those characteristics make the CLT an efficient and versatile element, which use has spread largely in recent years. CLT products are widely used for new buildings, but in recent years are also gaining attention for the retrofit of existing buildings [4][10][13][14].

One of the most acknowledged intervention consists in coupling CLT panels to masonry walls, thus providing benefits on structural, energetical and architectural fields [6][15]. In this

framework, two main approaches can be adopted, depending on the location of CLT reinforcement panels, at the exterior or interior of walls [4][14], as shown in Figure 1.

Figure 1: Approaches for CLT intervention on existing structures [6]

Particular attention has to be paid to connection systems among the existing structure and CLT elements. Different approaches can be adopted, such as connection at floor levels, taking advantage of existing RC curbs [14], or distributed URM-to-CLT connections realized with screwed joints [16]. The connection system plays a crucial role in the intervention, having to transmit actions from one system to the other and to provide ductility and resistance. However, studies proved that coupling at floors levels, without specific URM-CLT diffused connectors, is enough for shear and displacement capacities improvement of a URM wall [4].

1.2 Case Study

The case-study belongs to a building system known as “Cattedra”, risen in Canove di Roana (Vicenza), in the North-East Italian Alps. The intervention is limited to this original building which dates back to the XVII century. It's a three-story building with a rectangular plan (10m x 13m)(Figure 2). The structure is composed of stone masonry (SB) walls in the lower section, and hollow clay brick (HCB) masonry in the upper one (due to an elevation intervention), while floor and roof structures are RC based.

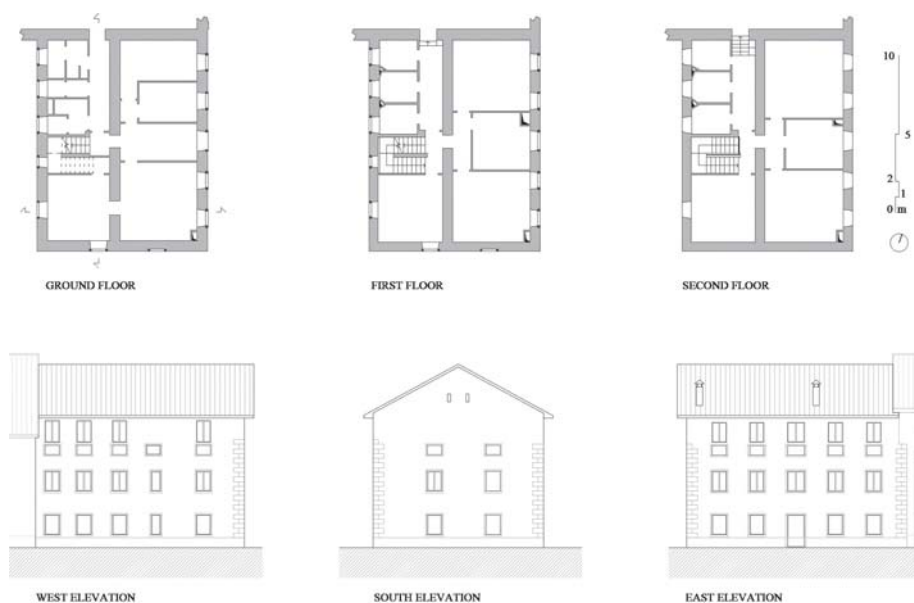

Figure 2: Plans and elevations of the case study.

The intervention concerned the upper stories of the building, excluding the first floor, due to the toned of preserving the existing conditions at this level (Figure 3). Indeed, the intervention consisted of removing the existing floors and roof structures and inserting a CLT nest, connected with the existing URM structure at floor levels. No direct connections were provided between CLT panels and URM walls.

Figure 3: Intervention scheme: a) existing structure, b) demolished parts, c) new CLT nesting structure.

2 COUPLED WALL SIMULATION

The FE modeling of the global structure had to be preceded by the study of a local model, consisting of a 40 cm-thick masonry wall retrofitted with three 6 cm-thick CLT panels (Figure 4). The model was compared and validated with a literature example provided by [10], since the same FE code was used and later subjected to a parametric analysis involving both masonry and CLT systems.

Figure 4: Local FEM model for URM-CLT interaction

2.1 Model Generation

The FEM model was realized with DIANA FEA software [8]. The masonry panel was modeled with 4-noded quadrilateral linear flat shell elements: a macro-modeling approach for material behavior was implemented, and units and mortar properties were merged into a continuum homogeneous material [17]. Physical non-linearities follow the smeared crack approach (*Total Strain Based Crack* in DIANA), in which tensile and compressive behaviors are described by stress-strain curves. Specifically, a linear softening behavior in tension and a parabolic behavior in compression were chosen. CLT panels were modeled with 4-noded quadrilateral linear curved shell. The layered structure of CLT was simplified into a homoge-

neous linear orthotropic material, which elastic properties were calculated according to the analytical approach for composite sections suggested by Eurocode 5 [18]. Table 1 reports the material parameters.

Masonry		CLT	
Elastic Properties		Material Properties	
E	2500 MPa	E_x	9000 MPa
ν	0.25	E_y	4500 MPa
W_{URM}	14 kN/m ³	E_z	1000 MPa
Total Strain Parameters		G_{xy}	821 MPa
f_t	0.01 MPa	G_{xz}	370 MPa
G_t	0.00135 N/mm	G_{yz}	121 MPa
f_c	3 MPa		
G_c	4.8 N/mm		
β	0.01	W_{CLT}	4.5 kN/m ³

Table 1: FEM parameters for masonry and CLT material models (Young's and shear moduli E and G , Poisson's ratio ν , specific weight W , compressive and tensile strength f_c and f_t , compressive and tensile fracture energy G_c and G_t , shear retention factor β).

The panels were externally connected via nodal springs, which represent the tension and shear connections (i.e., hold-down and angle bracket), while 3D line interface elements were introduced to simulate in-plane joints between panels. The CLT panels were connected to the URM wall through 3D surface interface elements. At last, a no-tension non-linear 3D line interface element was modeled, which represents the contact interactions at the base of the panel; this was to simulate base compression and neglect tensile retention during shear loads. Table 2 shows the FE parameters implemented for the connection elements.

Figure 5: Local reference axes for connection elements in FE model.

Connection	Typology	$k_{s,x}$ [N/mm]	$k_{s,y}$ [N/mm]	$k_{s,z}$ [N/mm]
Hold-down	<i>nodal spring</i>	50000	0	0
Angle brackets	<i>nodal spring</i>	0	50000	50000
		$k_{i,x}$ [N/mm ³]	$k_{i,y}$ [N/mm ³]	$k_{i,z}$ [N/mm ³]
in-plane joints	<i>3D line interface</i>	10	0.16	0.16
URM-CLT connection	<i>3D surface interface</i>	1	0.05	0.05

Table 2: FEM parameters for connections: linear spring stiffness k_s and interface stiffness k_i along x , y and z local axes [4].

Pushover analyses were carried out on the URM wall and on the coupled one to evaluate the in-plane response of both systems.

By comparing the capacity curves (Figure 6), no significant differences can be noticed on the elastic branch [4]; this suggests that, in this phase, the response of the reinforced system was still determined by the masonry characteristics. When cracking occurred, an increase both in post-elastic stiffness (and consequently maximum shear) and in the ultimate displacement capacity was observed in the coupled model. These results suggest that the CLT system is more effective in the masonry damaged conditions, leading to a significant increase of system ductility (almost doubled with the CLT panels reinforcement).

The capacity curves compared to the ones provided by the reference case resulted in a good match both in terms of maximum shear resistance and ultimate displacement capacity was detected.

Figure 6: Comparison between FE models of URM and retrofitted walls compared to Giongo et al. [4]

2.2 Parametric Study

A parametric study was performed to assess input parameters and evaluate the incidence of various characteristics on the wall behavior. The investigated parameters involved both masonry and CLT systems, starting from the reference values used in the previously described model. In the *Total Strain Based Crack* model used for masonry, the main uncertainties concern tensile and compressive energy fracture and shear behavior (*rotating crack* and *fixed crack* models); therefore, these parameters were taken in account for the parametric analyses carried out on the URM model (Table 3), which led to the analysis of 9 cases.

			1	2	3
Parameter	G_t [N/mm]	GT	0.012	0.005	0.00135
	G_c [N/mm]	GC	4.8	3.6	2.5
	Shear behavior	S	<i>rotating</i>	<i>fixed</i> $\beta = 0.01$	<i>fixed</i> $\beta = 0.05$

Table 3: Parameters for masonry analyses. Reference parameters cells, used for the previously validated model, are filled in grey.

The obtained pushover curves (Figure 7) revealed that the G_c parameter had low impact on global behavior, presumably because compressive strength of masonry is way higher than tensile one, which play the major role in shear failure. The differences observed for G_t parameter are more evident, as a higher value provided a much higher displacement capacity (+71% on the reference one). An even major influence was noticed for the shear behavior. In particular,

rotating crack model provided a higher ideal yielding point and, consequently, higher shear resistance, while the two fixed crack model curves presented equal elastic branch. However, the higher shear retention factor β led to both higher post-elastic stiffness and ultimate displacement values.

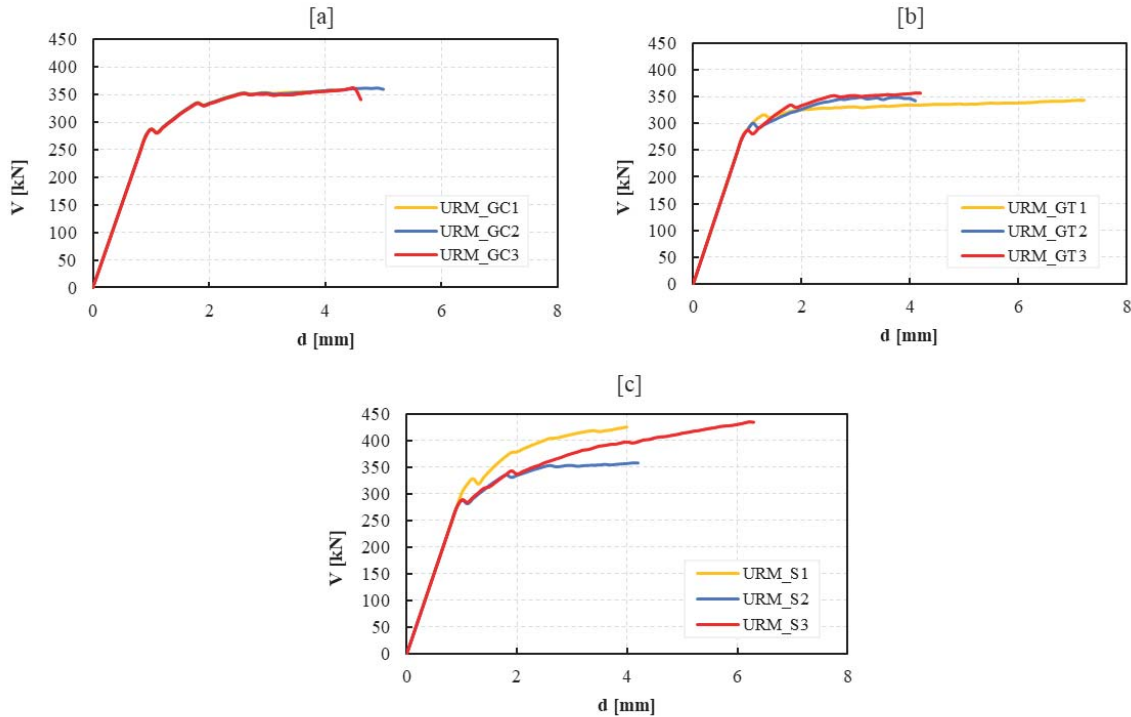

Figure 7: Pushover curves by variation of a) compressive fracture energy G_c , b) tensile fracture energy G_t , and c) shear behavior model

The parameters of the CLT system, i.e., hold-down stiffness, in-plane joints stiffness and panel's thickness (Table 4), were evaluated through 9 cases on the reinforced model.

			1	2	3
Parameter	HD $k_{s,x}$ [N/mm]	HD	10000	20000	50000
	in-plane $k_{i,y}$ [N/mm ³]	K	0.05	0.16	1.5
	panel thickness [mm]	T	60	90	140

Table 4: Parameters for CLT system. Reference parameters cells, used for the previously validate model, are filled in grey.

By comparing the obtained capacity curves (Figure 8), small dissimilarities can be noticed by changing connection type, as both for hold-downs and in-plane joints, with slightly higher shear values reached by the system as elements' stiffness increases. However, differences are not very significant, which suggest that relevant improvements could be achieved by intervening on both connection systems. No major differences were observed with the variation of CLT panel thickness, since the shear behavior of the panel is still ruled by connections in the range of the measured displacements.

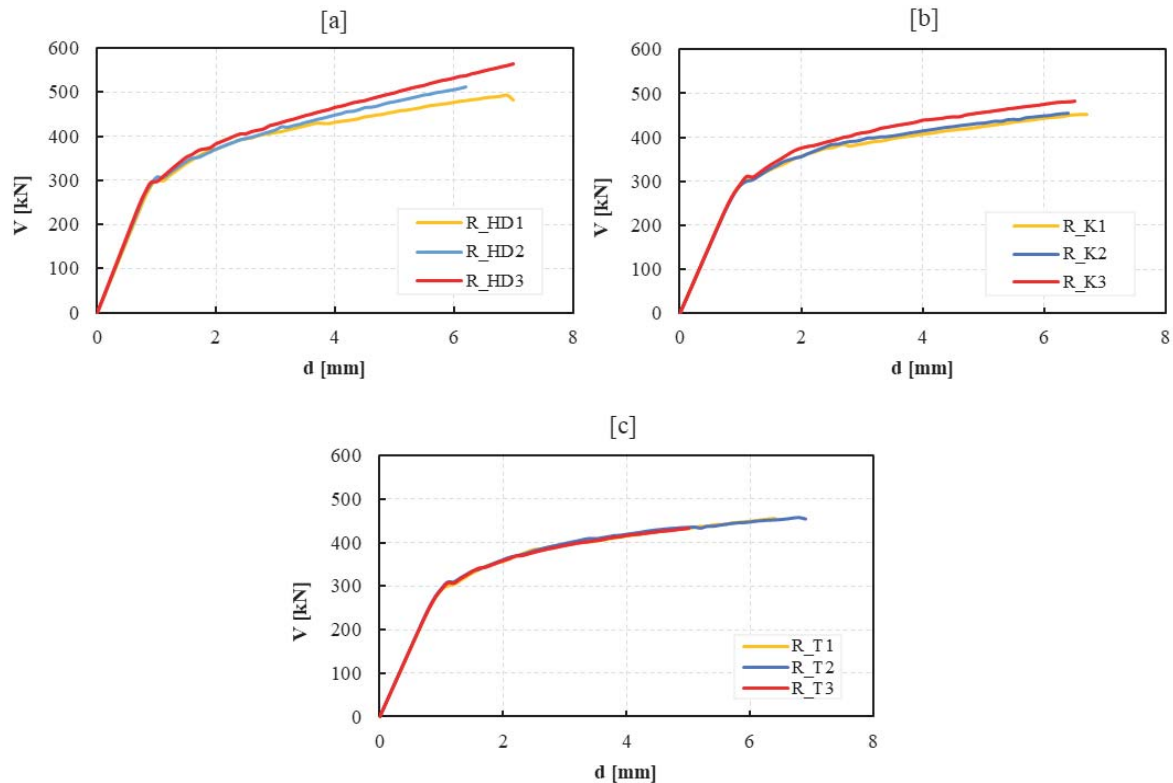

Figure 8: Pushover curves by variation of a) hold-down stiffness, b) in-plane joints stiffness, and c) panel's thickness.

3 MODELING OF THE INTEGRATED INTERVENTION

The extension of the local simulation to a real-scale structure was carried out by assessing a URM case study and then its retrofitted configuration with the endoskeleton integrated solution. FE models within DIANA FEA environment were generated, preceded by the preliminary design and dimensioning of the CLT inner structure.

3.1 Preliminary design of CLT nest

The internal CLT nest was sized by the means of TimberTech Buildings software [12], by assuming the CLT nest as independent from the URM structure. The numerical model was based on the definition of a macro-element for CLT system, which considers the different contributions in deformation and resistance provided by panels and connection elements. The software allows to easily design the structure through pre-defined elements and to verify it by means of linear static and dynamic analyses, for both vertical and horizontal loads. The process led to the definition of three-layered 10 cm panels for walls and five-layered 14 cm and 16 cm panels for the first and the second floor, respectively. Table 5 reports the details of the panels' types.

Element	Material	n. of layers	Thickness [mm]	Layers' thickness [mm]
Walls	Spruce C24	3	100	30 - 40 - 30
First floor	Spruce C24	5	160	40 - 20 - 40 - 20 - 40
Second floor	Spruce C24	5	140	40 - 20 - 20 - 20 - 40

Table 5: CLT panels typology

Tensile and shear connections were sized with reference to the most common commercial typologies. Three types of hold-down and one type of angle bracket were used (Table 6), depending on their location in the structure.

Furthermore, panels were connected through in plane joints, consisting in 6 mm x 80 mm screws, spaced 150 mm and coupled with a 27 mm Laminated Veneer Lumber (LVL) board.

Element	Typology	Connector	n. connectors
HD340	Hold-Down	Nail 4x60mm	20
HD440	Hold-Down	Nail 4x60mm	30
HD540	Hold-Down	Nail 4x60mm	45
AB240	Angle Bracket	Nail 4x60mm	36

Table 6: Hold-down and angle brackets types.

3.2 Global FE model generation

The overall FE study was carried out with DIANA FEA [8]. Firstly, a URM model of the existing structure was created. As in the local model, masonry walls were modeled as 4-noded linear flat shell elements. A *Total Strain Based Crack* material model was chosen, which properties are reported in Table 7. Tensile and compressive strength values were obtained from the Italian seismic code [19][20] following the results of IQM (masonry quality index) analyses carried out for walls [21]. The fracture energy values were chosen by the previous local modal and from multiple values suggested by scientific literature [22], assuming a conservative low tensile fracture energy, close to the brittle behavior.

Figure 9: FEM model of a) URM building and b) CLT nest.

Masonry properties of the retrofitted model did not change since no intervention was provided for masonry, in order to assess directly the benefits of the endoskeleton addition. The CLT structure was modeled in reference to the preliminary design. CLT material properties and connection elements were the same of those of the local FE model (Table 1), i.e., nodal springs for hold-downs and angle brackets and linear interface elements for in-plane joints.

Masonry		
Parameter	SB Masonry	HCB Masonry
E [MPa]	1740	4550
ν	0.25	0.25
w [kN/m ³]	20	14
Tens. function	Linear softening	Linear softening
f _t [MPa]	0.018	0.037
G _t [N/mm]	0.00135	0.0045
Comp. function	Parabolic	Parabolic
f _c [MPa]	1.12	1.85
G _c [N/mm]	4.8	5
β	0.01	0.01

Table 7: Mechanical parameter for masonry type (SB: stone blocks; HCB: hollow clay bricks).

The values for the connections' stiffness were analytically identified according to the European regulations for steel-to-timber fasteners and connectors [18]. As the project did not provide for any connection between the masonry walls and the CLT panels, the 3D surface interface elements were not considered, likewise the layout in [4]. At last, non-linearities were located in the masonry material model only.

Modal and pushover analyses were performed on the URM and the URM-CLT models. Uniform loads in both principal directions were considered for pushover analysis.

3.3 Results

The modal analyses results (Table 8) showed an increase in modal frequencies due to nesting intervention, partly due to the decrease of total mass for the reinforced model (about 25%). The modal participation mass factor also decreases to around 65% for the first two bending modes, in each principal direction. This could be due to the difference in terms of masses and stiffnesses distributions generated by the presence of the endoskeleton only at the second and third floors, whereas the first one remained unchanged.

Mode	URM model			Reinforced model		
	f [Hz]	% mx	% my	f [Hz]	% mx	% my
1	6.147	0.00%	75.55%	7.298	0.09%	66.89%
2	8.052	76.15%	0.00%	8.491	65.66%	0.10%
3	9.787	2.21%	0.01%	10.845	0.56%	0.01%

Table 8: Frequencies and mass participation factors for the first three modes: URM and reinforced (URM+CLT) models.

Pushover analyses results were evaluated in terms of equivalent acceleration at the base, thus normalizing the results to the mass of the model to obtain comparable curves (Figure 10). This comparison shows an increase in maximum equivalent acceleration for the retrofitted model. Differences were more pronounced for Y direction analyses than X direction's ones; this suggests that the intervention could be more effective on the shear capacity of the weaker direction. Ultimate displacement capacity does not get significantly affected instead.

Figure 10: Pushover curves for X e Y directions analyses

Further observations can be made from the contour of tensile strain, where cracks should rise. On the URM model (Figure 11a), damage is mainly located on the piers of the ground floor, while upper levels are less damaged. With the intervention (Figure 11b), the damage involves all stories, thus exploiting the resistant elements along the entire height. Moreover, in the URM model, tensile strains significantly spread in piers and lintels, whereas in the URM-CLT model strains are lumped in piers, i.e., the resistant elements of masonry structures.

Figure 11: Damage patterns for a) URM and b) retrofitted models.

At last, to measure the intervention benefits, seismic safety verifications were carried out according to the Italian code [19], by comparing PGA (peak ground acceleration) values for derived from the capacity curves. The results showed an improvement on the global behavior of the building thanks to the intervention, with an increase of +8.6% and +19.8% in X and Y directions, respectively (Table 9). Further improvements can be obtained, taking into consideration that, currently: i) the intervention is lumped at second and third stories, whereas the first one is the most solicited by uniform mass distribution and, ii) no improving interventions such as injections or joints rebars were adopted for masonry walls.

Direction	URM	URM+CLT	
	PGA _C [g]	PGA _C [g]	Δ PGA _C [%]
+X	0.222	0.241	8.6%
+Y	0.187	0.224	19.8%

Table 9: Near-collapse PGA capacities (PGA_C) and percentage variation between un-strengthened and retrofitted cases.

4 CONCLUSIONS

The modelling of a novel intervention technique for URM buildings was discussed in this paper. The study was carried out both at local and overall scale. The local model, on which parametric analyses were performed showed that:

- the CLT reinforcement is effective on the post-elastic phase of masonry, when cracking occurs and cause a loss in masonry stiffness;
- the timber connections (i.e., hold-down and angle brackets) play a fundamental role in the effectiveness of the system, since they affect its stiffness more than CLT panel thickness.

The local FE model allowed the connections of timber (both panel-to-panel and floor-to-panel) to be calibrated and to be implemented within a global FE model of an existing URM building. Modal and pushover analyses were carried out, on both as-built and retrofitted models. Results suggested that:

- mass reduction due to substitution of RC floors with lighter timber panels induced the increment in mode frequencies;
- retrofitted configuration can bear a higher equivalent acceleration than as-built one;
- the intervention led to a more homogeneous damage pattern, involving more resistant elements than the un-strengthened case;
- the intervention was effective, taking into consideration that it is limited to the second and third floor (demolition of two RC floors and RC roof), and provided an improvement in terms of PGA_C up to 20%.

The results showed that the CLT endoskeleton proposed here is a promising technique to improve the seismic performances of URM buildings. However, further studies need to be carried out to better clarify the effectiveness of the intervention and to extend its field of application.

Abstract

In the last decades, low-damage post-tensioned technologies have been introduced in the field of timber constructions, with the aim to obtain structural solutions able to guarantee, in case of seismic events, not only the safeguarding of human life, but also the rapid re-use of the buildings without permanent damage. To this aim, structural systems based on rocking dissipative timber walls have been conceived, which rocking behaviour is due to the presence of post-tensioning cables, and the dissipative contribution is provided by steel dampers, easily replaceable after an intense seismic event. The paper presents a numerical non-linear model to predict the response of PT-timber walls, particularly useful to support the design. In particular, the geometrical non-linearity due to the rocking behavior of the walls and material non linearities that characterize the dampers, are specifically taken into account. The post-tensioned systems characterized by the single wall configuration with axial dampers are analyzed by considering different initial post-tensioning levels. The proposed numerical modeling strategy has been validated with experimental literature tests, demonstrating its effectiveness in predicting the behavior of post-tensioned walls subjected to cyclic loads.

Keywords: post-tensioning timber walls, dissipative dampers, numerical modelling.

1 INTRODUCTION

In the last two decades, the employment of timber buildings is increasing in seismic prone areas, thanks to the significant evolution of performances of these constructions against seismic actions, mainly due to the development of new technologies [1]. The most common timber buildings are composed of engineered timber walls, i.e. Cross Laminated Timber (CLT) or Laminated Veneer Lumber (LVL), connected to each other and to the foundation through steel connectors, such as angle-brackets, hold-downs, nails, and screws. During a seismic event, the energy dissipation is mainly devoted to connectors, which could be severely damaged [2-5]. Moreover, both internal and external timber walls are load bearing elements, leading to an excessive use of the material and to the impossibility of moving the internal walls, so their position constitutes an architectural constraint. In order to avoid these drawbacks, low-damage post-tensioned (PT) technologies have been introduced [6], which entrust the energy dissipation to rocking timber walls equipped with dampers, whose main advantages are: the re-centering of walls at the end of the seismic motion, additional energy dissipation, and easy replacement of dampers. Since this system is predominantly employed in seismic prone zones, the assessment of a numerical modelling strategy to predict the cyclic behavior of post-tensioned timber walls assumes significant importance within the structural engineering field. Downstream of this brief discussion, the paper presents numerical models to predict the response of PT-timber walls, particularly useful to support the design. In particular, the geometrical non-linearity due to the partial uplift of the walls and material non-linearities that characterize the dissipaters, are specifically taken into account. The responses in terms of horizontal load-displacement curves and post-tensioning (PT) force-displacement curves are presented. The post-tensioned systems characterized by the single wall configuration with axial dampers are analyzed by considering different initial post-tensioning levels. The proposed numerical modelling strategy has been validated with literature experimental tests, demonstrating its effectiveness in predicting the behavior of post-tensioned walls subjected to cyclic loads.

2 LOW DAMAGE TIMBER SYSTEMS

Low damage timber systems arise from the need to guarantee, in case of a critical seismic event, not only the safeguarding of human life, but also the rapid re-use of the buildings without permanent damage. Laboratory tests and numerical investigations highlight that CLT traditional buildings can resist high intensity seismic actions [7]; however, a high-permanent damage in connection steel elements and on timber panels is generally observed. From these observations comes the idea of conceiving a system able to prevent damage to the load-bearing structural elements. In this regard, low damage timber systems were thought to be constituted of timber elements destined to remain in the elastic field during a seismic event, and steel dampers, destined to be severely damaged and then easily replaced. It deals with rocking dissipative walls, which rocking behaviour is due to the presence of post-tensioning cables placed inside cavities in the wall, fixed at the base and anchored at the top of the wall, while the dissipative contribution is due to steel dampers. The dampers can work as axial dampers, positioned at the base of the walls, and/or shear dampers, i.e. connecting adjacent rocking timber elements along elevation [6, 8–12]. The contribution of post-tensioning cables and steel dampers could be simply recognizable by observing a typical flag-shape force-displacement curve of a post-tensioning wall subjected to cycling loading (Figure 1), in which the bilinear envelope is mainly due to the rocking behaviour, controlled by the post-tensioning cables, and the amplitude of the flag is mainly due to the dissipative contribution of the steel dampers. This system takes inspiration from precast post-tensioned concrete elements that

were firstly developed by Stone et al. [13], and then investigated by Priestley *et al.* [14] within a five-story building.

Figure 1: Typical flag-shape force- top displacement (F-Δ) curve of a PT- wall subjected to cycling loading.

To confirm the validity and the growing diffusion of this structural idea, some buildings are recently constructed in New Zealand adopting this innovative solution. Furthermore, it is important to underline that the design of post-tensioned timber buildings is also proposed in the Australian and New Zealand design guidelines [15].

3 LITERATURE EXPERIMENTAL CAMPAIGNS

The firsts experimental campaigns have been performed on Laminated Veneer Lumber (LVL) PT- walls, in reference to single-wall [9] and double [6] systems. In particular, these configurations have been tested with and without dampers to highlight their benefits in terms of dissipative contribution. The dampers employed for the single wall systems are fuse-type dampers [8, 16, 17], which connect the PT wall to the foundation and works along the axial direction. These are characterized by a mild steel round bar placed inside a confining tube, and the space between them is filled with grout or epoxy, which act as a buckling restraint. Instead, the dampers employed for the double-wall systems are U-shape dampers [18, 19] connecting the walls along elevation.

Similarly, Ganey et al. [10] carried out an experimental campaign on single PT- wall systems without damping, and on double walls connected by U-shape dampers, while Massari et al. [11] conducted experimental tests on a single PT-wall system provided by fuse-type dissipaters, but using CLT walls.

Some authors have also proposed a configuration in which the PT- walls are connected to boundary columns by means of dampers [20], ensuring the support to the inter-floor beams connected to the diaphragm. This system avoids the vertical uplift generated by the rocking behaviour that causes vertical displacements incompatible with the diaphragm system, leading to unexpected damage.

In the present paper, the results of the experimental campaign conducted by Sarti et al. [9] was employed to validate the proposed numerical model, which will be presented in the next section. The experimental campaign concerns single wall systems, made of LVL characterized by a modulus of elasticity E_t of 11 GPa. The rocking behavior is entrusted to two post-tensioned steel bars characterized by a diameter of 32 mm, a Young modulus of E_p of 170 GPa, and a yield strength f_{py} of 835 MPa. The dissipative contribution is due to fuse-type dampers characterized by a diameter of 14 mm, a mild steel with a Young modulus of E_s of 200 GPa, and yield stress f_{sy} of 400 MPa. The single wall system has been tested in the various configuration:

- post-tensioned configuration (no dampers), with initial post-tensioning levels of 200 kN, 400 kN, and 600 kN;

- post-tensioned configuration with two couple of fuse-type dampers, with initial post-tensioning levels of 400 kN and 600 kN;
- post-tensioned configuration with four couple of fuse-type dampers, with initial post-tensioning level of 400 kN.

Figure 2 shows the geometric and mechanical characteristics of the experimental setup.

Figure 2: Geometric and mechanical characteristics of the reference experimental setup.

4 NUMERICAL MODELING

In order to predict the response of PT-timber walls, a numerical model was developed, particularly useful to support the design of the described system. The proposed numerical model has been validated on the experimental campaign results conducted by Sarti et al. [9] described in section 3. For the sake of brevity, the comparison between experimental and numerical results will be shown for post-tensioned configurations with two couple of fuse-type dampers, and initial post-tensioning levels of 400 kN and 600 kN.

4.1 Description of the numerical model

The proposed numerical model has been developed in the OpenSees [21], a software framework for simulating the seismic response of structural and geotechnical systems, realized by the Pacific Earthquake Engineering Research Center.

The numerical model of the structural system, shown in Figure 3, accounts for the geometrical and mechanical non-linearities. In particular, the first is due to the rocking behaviour of the system allowed by introducing unilateral constraints at the base, the second is mainly due to the presence of axial dampers simulated by non-linear springs. LVL walls and columns have been schematized with 2D Quadrilateral elements (Quad) associated with an elastic orthotropic material, supposing that timber elements remain in the elastic range.

The PT- bars have been modelled with truss elements, which is associated with an elastic-plastic force-displacement response with an initial imposed strain that simulates the initial post-tensioning level. Furthermore, to capture the rocking behaviour of LVL panels, the unilateral constraints at the base have been represented by inserting zero-length elements, characterized by an elastic no-tension material (gap elements).

For the simulation of the test performed with axial dampers, non-linear springs that simulate their behaviour are included in the model. The two pairs of axial dampers, placed at the base, are simulated with non-linear springs using zero-length elements.

Figure 3: Numerical model.

4.2 Validation of the proposed numerical model

In this section, a comparison between experimental results and numerical simulations is reported in terms of horizontal load/ drift curves and PT-force/ drift curves, by considering the post-tensioned configuration with two couple of fuse-type dampers, with initial post-tensioning levels of 400 kN and 600 kN. The horizontal load/ drift curves are shown in Figure 4(a) and Figure 4 (b) for initial post-tensioning levels of 400 kN and 600 kN, respectively. The monotonic envelopes are characterized by a well-defined bilinear curve, in which the transition point between the first branch and the second one, corresponds to the drift at which the first cable is subjected to an increment of tension due to the wall rocking. The comparison shows a good agreement between experimental and numerical results, in terms of initial stiffness, strength and cyclic behaviour. In this regard, the predicted cyclic behaviour is slightly underestimated, because of the presence of frictional dissipations not included in the numerical model. It is interesting observing that the model is able to capture also the effect of increasing the initial post-tensioning level on the global response of the system: a greater strength characterizes the configuration with the higher PT-level, and it shows a greater re-centering capacity, recognizable by the typical flag shape. Focusing on the behaviour of the PT-bars, these are subjected to an axial deformation make the PT force increase with respect to the initial imposed load, due to the wall uplift. This variation will be higher for the cable close to the wall edge that is uplift. To clarify this behaviour, the numerical wall base uplifts, evaluated at 20 cm from the base, are reported in Figure 5 for various drift levels, where the

position of the cables is drawn in order to perceive their increasing deformation as the drift of the wall increases. It is interesting to highlight that the base uplifts for fixed values of drift are similar for both the post-tensioning levels of 400 kN (Figure 5(a)) and 600 kN (Figure 5(b)), suggesting that the kinematic of the system is almost independent from the initial post-tensioning level. However, it affects the lateral strength of the wall (Figure 4). The good agreement between experimental tests results and numerical simulations is well confirmed also by the comparison in terms of PT force-drift response of the walls for both the initial post-tensioning levels of 400 kN (200 kN for each cable) and 600 kN (300 kN for each cable) reported in Figure 6(a) and (b), respectively. For both the post-tensioning levels, graphs show that the numerical model well captures the PT force variation in both the loading and unloading phases, showing a slight difference for the cable further from the uplifted wall corner.

Figure 4: Horizontal load/ drift curves: (a) initial PT-force of 400 kN and (b) initial PT-force of 600 kN.

Figure 5: Numerical wall base uplift for various drift levels, evaluated at 20 cm from the base: (a) initial PT-force of 400 kN and (b) initial PT-force of 600 kN.

Figure 6: PT-force/ drift curves: (a) initial PT-force of 400 kN and (b) initial PT-force of 600 kN.

CONCLUSIONS

The paper deals with a proposal for a non-linear numerical model, developed in the OpenSees framework, for the prediction of the cyclic response of rocking dissipative timber walls, by virtue of the fact that in the last decade, a diffusion of low damage systems have been observed, so it is particularly important to develop numerical models that can support the design phase. The proposed numerical model specifically considers geometric and material non-linearities associated with the rocking behavior and the entry into the plastic field of the dampers, respectively. A first validation with experimental results from literature is presented here. In particular, the global response in terms of horizontal load-displacement curves and post-tensioning force-drift curves has been investigated, demonstrating its effectiveness in predicting the behavior of post-tensioned walls subjected to cyclic loads with different levels of post-tensioning force.

Further developments will be to verify the numerical model's capability to predict the non-linear response of different experimental tests on various PT wall configurations, also including shear dampers. After the proper validation of the rocking wall numerical model, it will be employed for design purpose in a more complex framework, together with the timber frame structure designed for gravital loading.

Abstract

Southern regions of Europe are characterized by presenting a large number of existing buildings with reinforced concrete (RC) structures with masonry infills. From a structural point of view, they are characterized by one-way RC frames, with poor structural details and masonry infills, contributing to the high seismic vulnerability of these constructions.

Current retrofitting technologies, such as reinforced concrete jacketing of columns, concrete shear walls or FRP wrapping, could be effective but require the occupants' relocation, available perimetral space and legislative constraints. The use of CLT panels, as an innovative retrofitting technique, seems to be a reasonable alternative for existing buildings given their easy and fast assembly, high performance and reversibility.

This paper presents a numerical analysis to evaluate the seismic behavior of masonry-infilled RC portal frames strengthened by an external CLT panel. The 20 cm thick masonry wall was represented by two nonlinear diagonal elements with a multi-linear plastic constitutive law, including a Pivot hysteresis type in the axial direction. On the other hand, the 100 mm thick CLT panel was modeled through an orthotropic elastic shell-element. The study comprises four different connections between the RC frame and CLT panels. These connections are modeled through nonlinear Pivot links in both uplift and lateral directions. Their cyclic response, including degradation parameters, effective stiffness and force-deformation envelope curve, was calibrated based on previous experimental results. Numerical results confirm that CLT panels can be an efficient strengthening solution to increase the initial stiffness, as well as energy dissipation, while decreasing the impact of strength degradation on the response of masonry-infilled RC frames against in-plane quasi-static cyclic loading.

Keywords: RC Frame; Masonry infills; Cross Laminated Timber; Quasi-static Analysis

1 INTRODUCTION

Masonry-infilled reinforced concrete (RC) buildings constitute a significant part of the existing building stock across southern regions of Europe [1]. Consequently, many studies have been conducted to analyze the properties of infilled RC frames, in order to improve their weaknesses and prevent their failure under cyclic loading [2][3].

The presence of infill walls on the bare frame can induce unexpected force distributions that can lead to local failures during intense ground shaking [4]. The main failure modes in masonry-infilled RC frames that have been shown in experimental, analytical, and numerical research works are: corner crushing mode; sliding shear mode; diagonal cracking mode; diagonal compression mode; and the failure of the RC frame [5]. Furthermore, when subjected to seismic loads, RC frames are susceptible to non-ductile failure modes, particularly the frames built according to previous codes and standards [6]. Therefore, seismic retrofitting seems inevitable. Some of the available retrofitting techniques aim to directly strengthen the masonry infill, besides an improvement of the RC frame structure. Indeed, there is a wide range of retrofitting techniques that are divided into two general approaches: structure-level retrofit and member-level retrofit [7].

Cross-laminated timber (CLT) panels are a combination of several crosswise-stacked lumber boards that confer high in-plane stiffness. These panels allow fastening the construction work and can contribute to meet societal goals in terms of environmental sustainability, improving the energy performance of buildings, while reducing CO₂ emissions of construction. Sustersic et al. [8] introduced CLT as a seismic retrofitting method for infilled RC buildings by developing a three-step over strengthened connection. This study showed that longer CLT panels are more efficient than shorter segments under seismic forces for a better bending behavior.

On the other hand, Stazi et al. [9] showed that RC frames strengthened by CLT can reach higher lateral stiffness and peak load values than masonry-infilled RC frames. In both cases, the use of prefabricated timber panels improves the energy efficiency of the building by reducing global energy demand up to nearly 60% [10].

Experimental evaluations have shown that the connection used to connect panels and the main RC structures play a crucial role in the overall seismic response, given their nonlinear behavior that promotes energy dissipation [11][12]. Considering this fact, special attention should be given to their design and assessment.

The present work studies the response of strengthened RC frame under cyclic loadings with a special focus on strength degradation, stiffness deterioration, ductility and energy dissipation. A one-story one-bay infilled reinforced RC frame is used as a case study, where its seismic response is improved through a collaborative CLT panel. Four different connections between the CLT panel and RC frame, are evaluated by adopting distinct properties to nonlinear link connection elements. It is worth noting that these properties were defined based on tests results obtained through previous experimental campaigns [13][14][15]. The masonry infill is represented by an equivalent diagonal element, consisting on a macro-modeling procedure that exploits the multi-linear plastic link element with Pivot hysteresis law, available in SAP2000 NL software [16]. Moreover, the CLT panel is represented by the Homogenized-Orthotropic-plane stress-reduced cross-section (HOBS) approach [17].

2 DESCRIPTION OF THE INFILLED RC FRAME

The RC frame employed here, representing the actual building practice in Portugal, was built and tested at the University of Minho's laboratory in the 2/3 scale RC frame by Silva et al. [13]. Figure 1 shows the geometry and reinforcement scheme.

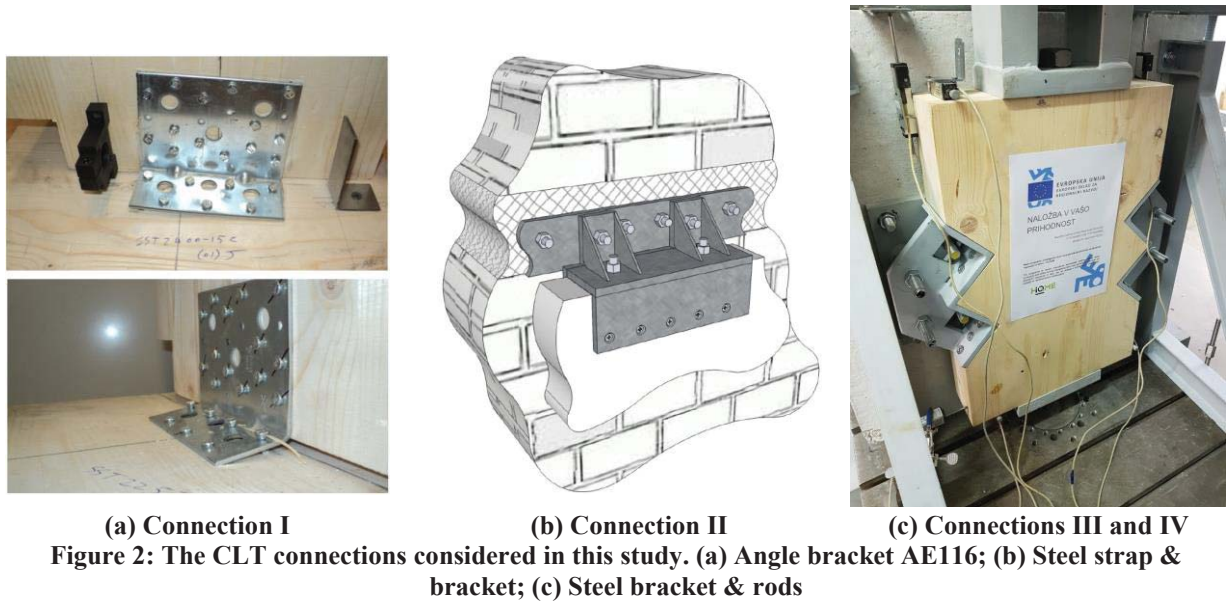

Figure 1: RC frame used in this study, (a) Geometry, (b) Reinforcement scheme (Silva et al. [13])

The frame length and height are 2575 mm and 1770 mm, respectively. Beam and column sections are 270×60 mm and 160×160 mm, respectively. The masonry infill was built with 294x187x140mm bricks with vertical perforation, using murfor RND 0.5 100 reinforcement in every two rows, and murfor L +100 anchors to connect the infill to the RC frame at the same level of reinforcements. The rebars used in the RC frame and masonry infill are an A400NR, and A500NR, respectively. The concrete of the RC elements is from the C55/67 class. For laying of masonry units, an M10 mortar is employed. The thickness of the horizontal joints is assumed to be 0.5 cm. More details can be found in Silva et al. [18].

3 CLT PANEL AND CONNECTIONS

The CLT panel has a thickness of 97 mm, comprising three layers with thicknesses 35, 27, and 35 mm. The panel's mechanical properties, including moduli of elasticity and shear modulus, are determined according to standard EN 338 [19] and DIN 1052 [20], while the Poisson coefficients are obtained according to Bodig et al. [21].

Four different connections were considered in this study. The first (Figure 2 (a)) consists of a prefabricated mechanical connector, angle bracket AE116, widely used in the CLT structures [14]. The second one, Figure 2 (b), comprises three parts: a steel strap and steel threaded rods connecting to the beams, a steel bracket connected to the panel through self-tapping screws, and a steel plate connecting the steel strap with the steel bracket. The first two are designed to behave essentially elastic, whereas the last part is designed with a controlled failure, ductility and energy dissipation. This connection was developed and characterized by Sustersic [15]. The third and fourth connections, developed by Sustersic [15], adopt a newly designed angle bracket and two steel threaded rods with a length of 50 mm and grade rods of 4.6 and 8.8, respectively (Figure 2 (c)). The connections of Figure 2 (a) were selected because they represent a common in CLT buildings, while the remaining ones have presented an adequate response under cyclic loading both for sliding (shear) and uplift (tension) motions [15]. It is important to mention that the availability of experimental tests [14][15] allows calibrating numerical models, increasing the reliability of their results.

4 MODELLING METHODOLOGY

4.1 Characteristics of RC plastic hinges

The RC frame is represented through linear elastic frame elements with plastic hinges at their ends that concentrate the nonlinear behavior of the beam-column joints. These plastic hinges whose properties are obtained according to Eurocode 8 (part 3) provisions [22] are governed by the Pivot hysteresis model, available in SAP2000 NL software [16]. The Pivot's coefficients are then adjusted in order to obtain an agreement between the numerical model and the test results from Silva et al. [13], in terms of the envelope curve, as shown in Figure 3.

Figure 3: Experimental/analytical cyclic response of the selected RC frame from Silva et al. [13]

4.2 Characteristics of the masonry infill

The confined masonry infill is represented with two diagonal multi-linear link elements following the Pivot hysteresis law. The parameters of the links, including Pivot coefficients and Force-Deformation envelope definition, along with plastic hinges assigned to RC joints, are obtained after a calibration process based on the test data available in Silva et al. [10]. Figure 4 allows evaluating the response of the masonry infilled RC frame under cyclic loading

and verifying the agreement between the numerical model and the experimental data in terms of force-displacement curves. The accuracy of the method is satisfactory in terms of the envelope curve, while the model is not accurate enough in terms of unloading stiffness.

Figure 4: Experimental/analytical cyclic response of the selected infilled RC frame from Silva et al. [13]

4.3 Characteristics of connections between the CLT and frame

The connections between the CLT panel and the RC frame are represented by multi-linear plastic link elements that are governed by the Pivot hysteresis law. The force-deformation definition and Pivot's coefficients are obtained by a calibration process based on the experimental campaign developed by Matos et al. [14]. For connection I (angle bracket AE116), Figure 5 allows the numerical and experimental results of cyclic tests, for both lateral (a) and uplift (b) motions, in terms of force-deformation curves. In turn, Figure 6 presents the tension and shear response of an over strengthened connection (II), according to the experimental results obtained by Šušteršič [15]. The connections III and IV, presented in Figure 2 (c), were tested for loads applied in horizontal and vertical directions. In this regard, Figure 7 shows the behavior in shear for both numerical and experimental responses under cyclic loads for connections III (4.6 grade rods) and IV (8.8 grade rods).

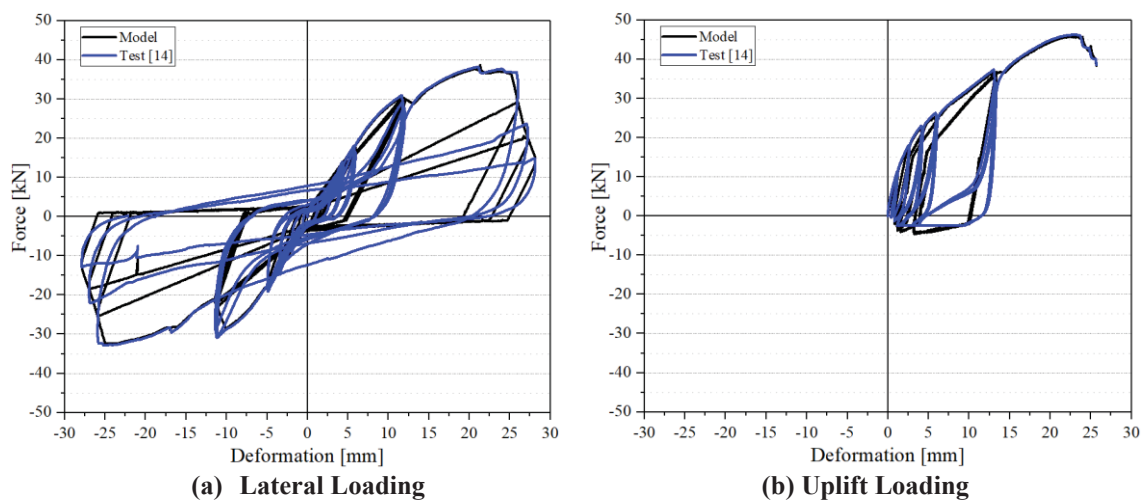

Figure 5: Experimental/analytical cyclic response of the first connection I

Figure 6: Uplift and Lateral force versus deformation in connection II [15]

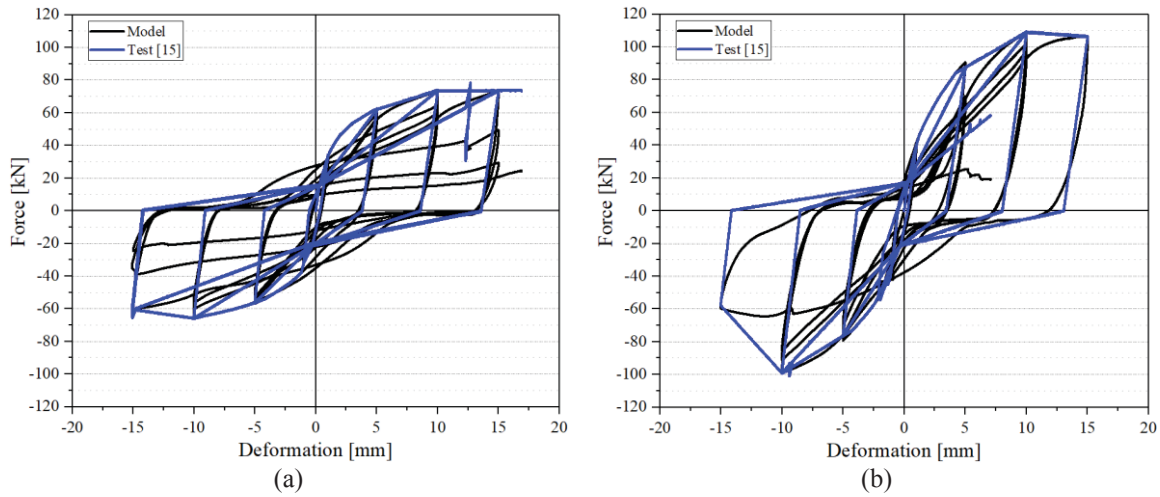

Figure 7: Experimental/analytical cyclic response, (a) Connection III, (b) Connection IV

4.4 Simulation of the infilled frame strengthened by CLT

The CLT panel and connections are simulated separately in this study. The panel is discretized according to the homogenized-orthotropic-plane stress-reduced cross-section method. The modeling approach adopted considered the three-layered panel as a single-layer shell element [17], based on reduction coefficients that result in a simplification, which requires less computational efforts, where most of the attention must be paid to connections modeling. Their correspondent links, divided into two sliding and uplift springs, can be distributed along panels' borders (beams and columns) or concentrated in four positions (corners). Considering the latter, in which the upper and lower beams corners are linked to the panel so that the end of connections is set to the end of beams, all springs are attributed by multi-linear plastic link elements.

The loading pattern applied in the experimental campaign [10] followed FEMA 461 [14], in which the displacement is applied throughout 16 steps, starting from 0.5 mm, and ending in 75 mm. Each step is repeated two times except for the first one, which is repeated six times. The numerical study adopts the same loading pattern as the experimental work.

5 NUMERICAL RESULTS

In this section, one can evaluate the structural responses, under cyclic loading, obtained through the numerical modes used to represent the distinct connection schemes under study. The behavior is evaluated in terms of base shear versus top displacement, dissipated energy, and ductility factor.

5.1 Force-displacement response of frames

Figures 8-11 present the force-displacement responses of the bare frame, the bare frame strengthened by CLT, infilled frame, and infilled frame strengthened by CLT, subjected to cyclic loading considering the four CLT connections.

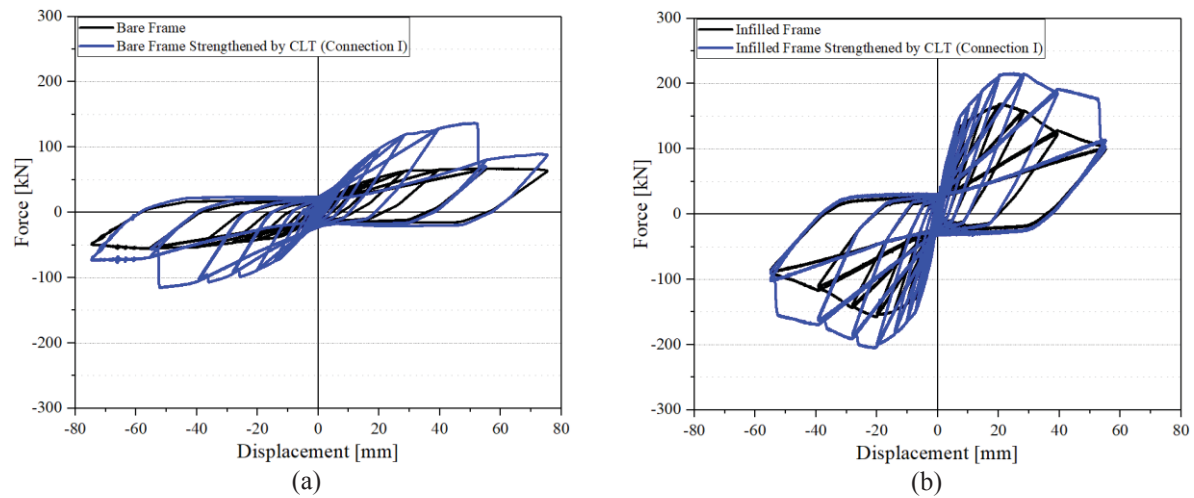

Figure 8: Force-displacement response considering connection I: (a) Bare frame and bare frame strengthened by CLT; (b) Infilled frame and infilled frame strengthened by CLT

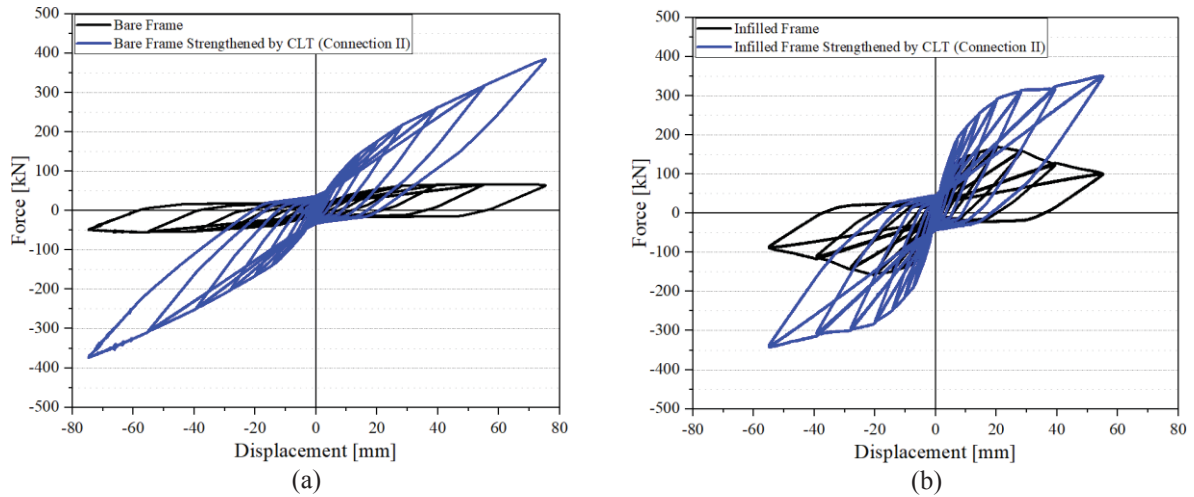

Figure 9: Force-displacement response considering connection II: (a) Bare frame and bare frame strengthened by CLT; (b) Infilled frame and infilled frame strengthened by CLT

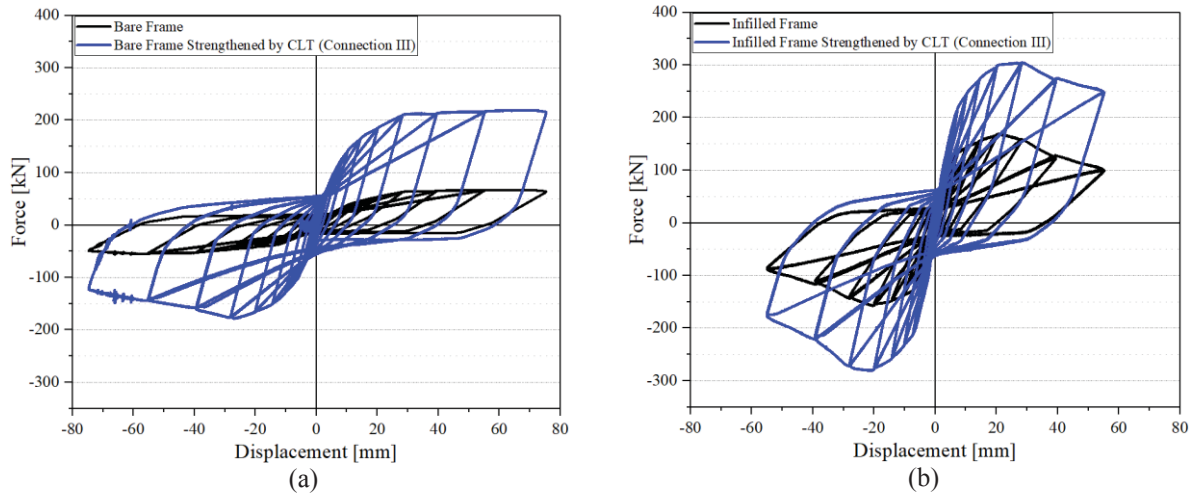

Figure 10: Force-displacement response considering connection III: (a) Bare frame and bare frame strengthened by CLT; (b) Infilled frame and infilled frame strengthened by CLT

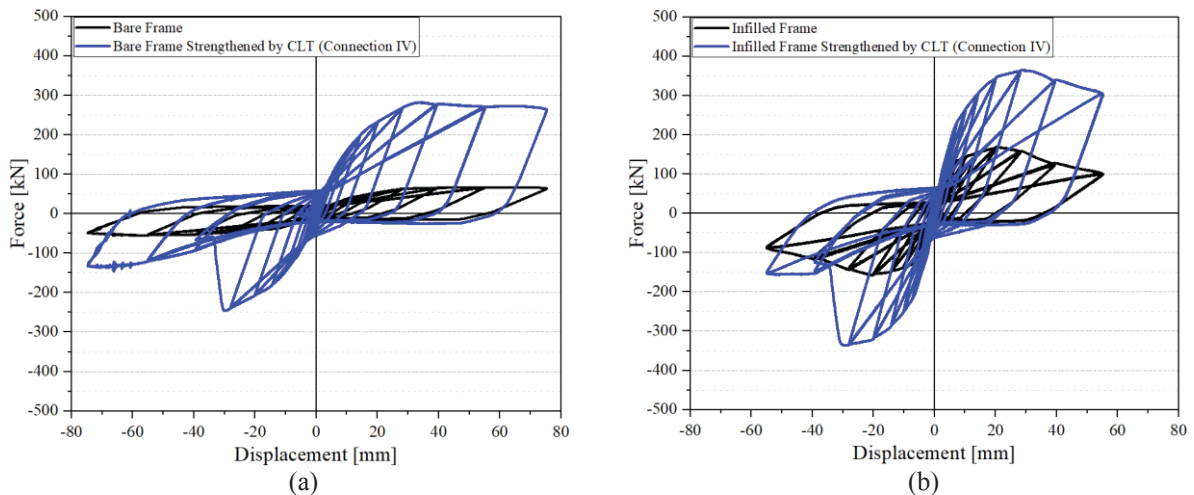

Figure 11: Force-displacement response considering connection IV: (a) Bare frame and bare frame strengthened by CLT; (b) Infilled frame and infilled frame strengthened by CLT

The oversized connection II makes 473% and 107% improvement in the maximum capacity of the bare frame and infilled frame, respectively. In this joint, unlike others, no strength degradation is observed for both bare and infilled frame strengthened. On the other hand, connection I has an increase of 104% and 27% in the strength capacity of the bare and infilled frame, respectively, which seems negligible compared to connection II, while the pinching effect as an index for evaluating energy dissipation is the same as previous. Figures 10 and 11 show the substantial ability of connections III and IV to dissipate energy, even more than connection II, although these connectors are simpler and then cheaper than three-part connection II, indicating that more efficient joints associating seismic reliability are possible at a lower cost. Connection IV shows about 30% and 15% improvement in strength capacity for bare and infilled frames, respectively, which is not satisfactory enough based on the differences in their rod strength. In other words, it proves that the geometry of connection, such as plate's thickness, number of rods and their size, makes a more contribution to modifying seismic properties of structures.

With regards to Figures 8-11, it is proved again that infills generally improve the post-elastic behavior of bare frames with increasing maximum strength and dissipating more seismic energy despite the fact that the ultimate strength stays almost unchanged. Comparing the

results of the bare frame strengthened by CLT panel and those of infilled frame, a result is that the bare frame strengthened by CLT has higher seismic performance than the infilled frame due to the considerable potential shown to increase the energy dissipated, the initial stiffness, unloading and reloading stiffness, load carrying capacity, and decreasing strength/stiffness degradation.

It should be pointed out irregular responses in two opposite loading directions, as shown in Figure 11, due to unequal inelastic behavior in tension and compression.

In summary, Figure 12, through the backbone curves obtained from the cyclic analysis, compares the strengthening effect of the CLT panel connected to the RC frame considering four different connections. The comparisons are divided into two cases: bare frame (Figure 12 (a)) and masonry-infilled frame (Figure 12 (b)).

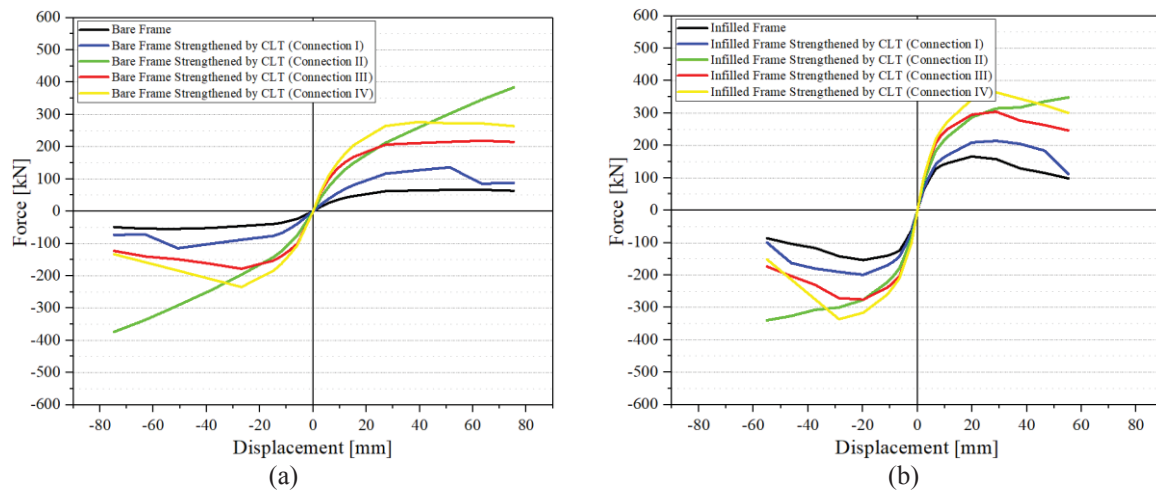

Figure 12: Pushover curves considering all connections, (a) Bare frame and bare frame strengthened by CLT; (b) Infilled frame and infilled frame strengthened by CLT

Figure 12 shows that connection II, which presents a higher strength capacity than the remaining ones, did not achieve its post-peak strength, while other connections underwent that region. Furthermore, connection III presented higher peak strength per rod strength in comparison with connection IV; maybe referring to that strength itself is not a priority in the seismic design of connections. It should be stated that the CLT strengthening using connection I (AE116), which has a small contribution to the frame, has about the same peak capacity as the infilled frame (~160 kN).

5.2 Structural ductility

Having extracted the Pushover curves from the cyclic curves, the structural ductility factor (R), according to FEMA 2004 [23], is computed for all cases as:

$$R = \Delta_m / \Delta_y \quad (1)$$

In which, Δ_y and Δ_m indicate the yield displacement and the displacement associated with the structure's maximum shear capacity, respectively. These amounts are achieved by calculating the equivalent bilinear curve, which has the same area as the envelope curve, as shown below.

Figure 13: Definition of yield and maximum displacement

Therefore, all envelope curves in Figure 12 are transformed to equivalent bilinear curves, and then the ductility factor is calculated for the bare frame, infilled frame, and infilled frame strengthened by adding a CLT panel, considering the four selected connections (Table 1).

Table 1: Structural Ductility Factor

Bare Frame	Bare Frame Strengthened by CLT			
	Connection I	Connection II	Connection III	Connection IV
14.29	18.87	11.63	15.63	10.00
Infilled Frame	Infilled Frame Strengthened by CLT			
	Connection I	Connection II	Connection III	Connection IV
7.04	15.63	9.17	9.09	9.01

As shown in the above table, the infilled frame and infilled frame strengthened by CLT have mostly a lower ductility factor than the bare frame and bare frame strengthened by CLT, respectively, owing to failures of masonry that usually happens before the frame or connections. In addition, adding CLT led to an enhanced ductility in the infilled frame strengthened by CLT compared to the infilled frame due to transferring a part of loading from the masonry infill to the CLT panel. However, regarding the bare frame, adding CLT panels might not result in ductility increment, as shown in the case of the bare frame strengthened by CLT with connection II and IV. Nevertheless, there are other definitions for ductility that may be accompanied by increasing these amounts.

5.3 Energy dissipation

In order to have better comparisons between all frames under cyclic loading, in terms of energy dissipation, the accumulated energy versus displacement was calculated from base shear versus top displacement (Figure 8-11) and presented in Figure 14. According to Figure 14 (a), energy dissipation of the bare frame strengthened by CLT with connections I-IV is 1.6, 4.4, 3.1, and 3.4 times higher than that of the bare frame, respectively. In addition, Figure 14 (b) shows that energy dissipation of infilled frame strengthened by CLT with connections I-IV is respectively 1.3, 2.2, 1.9, and 2 times of infilled frame. The direct result is the seismic efficacy of CLT panels as a renovation of infilled RC frames. On the other hand, for comparing the effect of masonry infill in dissipation, energy dissipation of infilled frame and infilled frame strengthened with CLT with connections I-IV (Figure 14 (b)) are, respectively, 95%, 57%, 0%, 18%, and 15% larger than those of bare frame in Figure 14 (a). As a matter of fact,

while masonry infills contribute to increasing energy dissipation of bare frames, there are not as efficient as adding CLT panels to bare frames.

6 CONCLUSIONS

In the present study, the seismic resistance of masonry-infilled RC frames retrofitted with CLT panels was evaluated. A collection of previous experimental tests on RC frame, masonry infills and connections was considered for calibrating finite element models that comprise four distinct connection techniques. The numerical simulations performed allowed to draw the following remarks:

- Adding a CLT panel increases the frame's load-carrying capacity, accompanied by an increment of the initial stiffness and post-yielding stiffness. However, in spite of the lessening pinching effect, stiffness and strength degradation, which is widely found in masonry-infilled frames, does not change considerably;
- Connections play a critical role in the post-yielding behavior of frames. An essential part of energy in cyclic loading is dissipated by these joints. The simulations showed a connection with lower load-carrying capacity and cheaper might result in better seismic behavior, mainly depending on joints' geometry;
- Regarding the ductility factor, defined by FEMA 2004, adding CLT panels does not always result in a ductility increment for bare frames, in opposition to what was expected. However, the ductility of infilled frames might be increased by adding CLT.
- Due to the first nonlinearity and failure observed in the structure by infill, along with the elastic behavior of CLT panels and high load-carrying capacity of connections in the post-elastic range, it can be concluded that CLT panels make much more contribution than masonry infills to energy dissipation under cyclic loadings.

Finally, it seems clear that CLT panels can be used as a strengthening measure that improves the seismic response of RC structures. However, it is crucial to develop connections able to ensure accurate performance, as the existing ones were not designed for this particular application.

Keywords: CLT shear walls, wall-to-wall connections, perpendicular walls interaction, mechanical models, parametric analyses

Abstract. *Cross-Laminated Timber (CLT) walls are used in CLT buildings to carry both vertical and horizontal loads. The mechanical behaviour of CLT shear walls for lateral loads is typically assumed to be governed from the base connections, which transfer the horizontal loads from the upper storeys to the foundations. However, in a CLT building, other connection typologies, such as the connection between shear walls and perpendicular walls, can contribute to the mechanical performances of the CLT shear walls. This paper presents a study on the effects of the perpendicular walls on the lateral stiffness of Cross-Laminated Timber shear walls. An analytical model for the calculation of the lateral stiffness of CLT shear walls connected at the base with typical hold-downs and angle brackets and to perpendicular walls by means of wall-to-wall connections is presented. The analytical model is compared with different models taken from the literature and validated against a numerical model developed in SAP2000. The analytical model is used to perform a parametric study in which the geometry and the connections are varied while different assumptions on the mechanical behaviour of the perpendicular walls are considered. Results of the parametric analyses showed that the perpendicular walls increase the lateral stiffness of CLT shear walls. The increase of lateral stiffness depends on the stiffness of the wall-to-wall connections, position and assumption on the behaviour of the perpendicular walls. Results of this study represent a basis for future studies in which the contribution of the perpendicular walls is investigated at building level.*

1. INTRODUCTION

1.1. Background

The wooden structures sector has been growing strongly in recent decades due to a combination of different factors, such as the sustainability of the material, the fact that the structures are made of prefabricated elements which permit a fast erection of buildings and their good mechanical performances in case of seismic actions. In this context, Cross-Laminated Timber (CLT) structures play an important role that strongly contributes to the growth of the sector.

CLT structures are realized by means of CLT panels, which are mutually connected with metal fasteners and mechanical anchors. The Lateral Load Resisting System (LLRS) of this structural typology is composed of the CLT shear walls, which are connected to foundations by steel brackets, such as hold-downs and angle brackets, using small diameter fasteners like screws and nails. The CLT panels have a stiff behaviour if compared to that of the mechanical connections, therefore in a CLT building most of the structural flexibility is provided from the connections, which consequently play the most important role in terms of stiffness, strength and ductility of the structure.

The seismic performance of CLT structures has been the central topic of several experimental research projects that were carried out on wall systems and full-scale buildings. In Europe several experimental campaigns were performed to investigate the seismic behaviour of CLT shear walls, see for instance [1-3]. The results of these studies showed that the layout of connections influence the cyclic behaviour of shear walls and that the CLT panels act as rigid bodies with low in-plane deformations. One of the largest experimental research activities on the seismic behaviour of low-and-medium-rise CLT buildings was carried out within the SOFIE Project [4], in which shake table tests on a three- and a seven-story CLT building were performed. The outcomes of tests on the buildings showed that the CLT panels remained undamaged and failures were observed only locally in joints and connections.

In CLT buildings, the lateral deformation mechanisms of the shear walls are considered when determining their lateral stiffness and resistance. CLT shear walls subjected to lateral loads typically deform with a combined mechanism of rocking and sliding. Regarding the lateral resistance, a global failure mechanism related to rocking behaviour is typically observed in CLT shear walls with a low width-to-height aspect ratios, while sliding failures occur in CLT shear walls with high width-to-height aspect ratios [3, 5]. Regarding the lateral stiffness, several analytical models are available in literature to calculate the shear wall lateral stiffness and some of these analytical studies are discussed in the next sections.

Knowing the lateral stiffness of CLT shear walls is important for determining the distribution of the lateral loads among the shear walls of CLT buildings. If a rigid behaviour can be assumed for the floor diaphragms, the distribution of the lateral loads among the shear walls can be assumed – in elastic analyses – proportional to their lateral stiffness. The load undertaken from each shear wall can be then used for designing the wall base connections, unless capacity design strategies are adopted. The overall lateral stiffness and capacity of the CLT building is therefore calculated as the sum of the capacities of the individual shear walls, which work as an in-parallel system.

However, the lateral stiffness of CLT shear walls can be influenced from other connections typologies that are present in CLT buildings, such as the connections between the shear walls and perpendicular walls, see Fig.1. Such connections can contribute to variate the lateral stiffness of CLT shear walls and contribute mostly to the so-called box-behaviour of the CLT buildings.

Fig.1: Representation of a typical CLT building with shear and perpendicular walls.

1.2. Effect of perpendicular walls

The behaviour of shear walls can be influenced from the three-dimensional behaviour of the building. In this respect, the perpendicular walls and the connections to the shear walls can play an important role. However, the research on the effects of perpendicular walls on seismic performance of CLT shear walls is limited.

The effects of perpendicular walls was found in several experimental campaigns on full-size Light Frame Timber (LFT) platform buildings [6, 7]. Such effects were found also from Popovski and Gavric [8], who investigated the three-dimensional performance of a two-story CLT building under lateral cyclic loads. In this experimental study, uplift of the perpendicular walls, which contributed to the overall building capacity, were detected. Such result highlighted that perpendicular walls may act as a hold-down system and have a significant effect on the lateral-load resistance and deformability of CLT structures. In a subsequent study [9] the same authors calculated the building lateral capacity and found an additional contribution to the lateral resistance given from the perpendicular walls. In the study, the authors concluded that the influence of perpendicular walls shall be included in the analytical design of CLT shear walls.

The influence of the perpendicular walls on the lateral stiffness and capacity of CLT buildings was found also in analytical and numerical studies.

Shahnewaz et al.[10], presented closed-form equations to estimate the deflection of single and coupled CLT shear walls under lateral loading considering the influence of wall-to-wall and floor-to-wall connections. Parametric analyses showed that the presence of perpendicular wall reduces the deflections as a function of the stiffness of the connections.

Hummel et al. [11] considered the influence of the perpendicular walls in seismic analyses of CLT buildings, to evaluate the q -factor. From this study, it is emerged that connecting shear walls to perpendicular walls provides an increase of the lateral resistance and of the deformation capacity of the building.

Tamagnone et al. [12], proposed a simplified non-linear procedure for seismic design of CLT wall systems that was validated against two- and three-dimensional numerical models. While acceptable accuracy was obtained in the comparison with two-dimensional numerical models, larger errors were detected in comparisons with three-dimensional models due to the box effect of the CLT building provided from the connection between perpendicular walls. In this study,

the authors concluded that the box behaviour has a stiffening influence on the response of shear walls, which decreases the sliding and rocking deformations of the shear walls.

Typically, in the practical design, the influence of the perpendicular walls on the mechanical behaviour of CLT buildings is not taken into account. Although this approach simplifies the seismic design procedure, from the other side it neglects the effects of the perpendicular walls and the box behaviour of the building, which was found in several studies to be significative.

With the aim to quantify these effects, this paper proposes an analytical model for the evaluation of the elastic horizontal stiffness of CLT shear walls connected to perpendicular walls through wall-to-wall connections.

2. HORIZONTAL STIFFNESS OF CLT SHEAR WALLS

2.1. Analytical models from the literature

Analytical models for the design of CLT shear walls are based on the different contributions of the shear wall deformations.

The evaluation of lateral stiffness of CLT shear walls is carried out with analytical models that consider the kinematic behaviour of the wall. Typically, three displacement contributions take place in CLT shear walls under lateral loads: rigid-body rotation (rocking), rigid-body translation (sliding), and panel deformation which has a shear and a bending contribution, see Fig.2.

Fig. 2: CLT shearwall deformation mechanisms: rocking (a), sliding (b), in plane shear deformation (c), in plane bending deformation (d).

The total displacement of CLT shear wall, δ_{wall} , subject to a horizontal force F , can be written as shown in equation Eq.(1):

$$\delta_{wall} = \delta_{rocking} + \delta_{sliding} + \delta_{GA} + \delta_{EI} \quad (1)$$

Eq.(1) is valid for a single CLT shear wall, while in the case of multi-storey shear wall assemblies the contribution of the cumulated rotation should be also taken into account.

Several models for calculating the horizontal displacement of a CLT shear wall, which are based on different assumptions regarding the deformation mechanisms, are available in literature, see for instance [3, 5, 13-15]. In the next, three of these models are discussed to report a short state-of-the-art. The models are reported by considering the effect of the lateral loads and neglecting the contribution of the vertical loads, as not of interest for the scope of this work.

2.1.1. Casagrande et al. [5]

Casagrande et al. [5] presented a simplified analytical method to evaluate the horizontal displacement of a CLT shear wall. Three deformation mechanisms are considered: rigid-body rotation, rigid-body translation and in plane shear panel deformation. In this model, the bending deformation of panel is neglected.

The contribution of rocking deformation depends on the stiffness of the hold-down and on the wall geometry, according to Eq.(2):

$$\delta_{rocking} = \left(\frac{Fh^2}{K_{HD}(\tau b)^2} \right) \quad (2)$$

In which:

F is the horizontal force,

h is height of the CLT shear wall,

(τb) is the distance of hold-down from the point of rotation of the CLT panel,

K_{HD} is the stiffness of the hold-down

The horizontal sliding contribution depends on the angle bracket's stiffness, see Eq.(3):

$$\delta_{sliding} = \frac{F}{n_{AB}k_{AB}} \quad (3)$$

In which:

n_{AB} is the number of angle brackets,

k_{AB} is the stiffness of one angle bracket.

The shear panel deformation depends on the geometry and the shear modulus of the CLT panel, see Eq.(4):

$$\delta_{GA} = \frac{Fh}{G_{CLT}A_{eff}} \quad (4)$$

In which:

G_{CLT} and A_{eff} are the shear modulus and the effective shear area of the CLT panel.

2.1.2. Hummel et al. [13]

Hummel et al. [13] proposed a method that takes into account the four deformation contributions shown in Fig.2.

Two cases are considered for the rocking deformation: a rigid foundation (for instance, concrete foundation) and an elastic foundation (for instance, CLT floor). While in case of rigid foundation, the rocking contribution is the same of Eq.(2), in case of elastic foundation, the rocking contribution is given in Eq.(5):

$$\delta_{rocking} = \frac{h^2}{l^* - \frac{l_c}{3}} \cdot \frac{2F}{K_D l_c^2} \quad (5)$$

In which K_D is the stiffness of elastic foundation and l^* is the distance between the centre of rotation of the wall and the furthest hold-down and l_c is the length of zone in compression. The stiffness of elastic foundation can be calculated as $K_D = \frac{E_s b_s}{t_s}$, where b_s and t_s define the wall width and thickness, respectively, and E_s is the modulus of elasticity of the elastic foundation.

The contributions due to sliding and shear deformation can be calculated with Eq.(3) and (4) respectively.

The contribution due to the bending deformation can be calculated with Eq.(6):

$$\delta_{EI} = \frac{Fh^3}{3E_{CLT}I_{eff}} \quad (6)$$

In which:

E_{CLT} and I_{eff} are the elastic modulus and the effective inertia of the CLT panel.

2.1.3. Gavric et al. [3]

The model proposed from Gavric et al. [3] takes into account the whole load-displacement curve of the connectors and it is able to predict the entire elasto-plastic behaviour of the shear wall, by means of a step-by-step analysis. In this paper, only the part related to elastic displacements is presented. The difference between the model proposed from Gavric et al. [3] and the previous two models regards the behaviour of angle brackets for tensile loads. The analytical model from Gavric et al. [3] assumes that all wall base connections react with vertical tensile loads.

This model considers the four shear wall deformation contributions given in Fig.2. The lateral displacement due to rigid-body rotation is given by the rotational equilibrium considering the tensile force in the generic connection. The contribution of rocking deformation can be calculated with Eq.(7)

$$\delta_{rocking} = \left(\frac{Fh^2}{\sum_{i=1}^n K_i x_i^2} \right) \quad (7)$$

In which:

K_i and x_i are the vertical stiffness and the distances from the point of rotation of the CLT panel of the i^{th} wall base connection.

The contributions due to sliding, shear and bending panel deformations can be calculated with Eq.(3), (4) and (6), respectively.

2.2. CLT shear walls connected to perpendicular walls

In the next, an analytical model of laterally loaded CLT that considers the contribution of the wall base connections and the contribution of the connection between the shear wall and the perpendicular wall is presented. The model is defined with the aim to quantify the additional contribution of the connection between the shear wall and the perpendicular wall on the lateral stiffness of the shear wall.

The model, shown in Fig.3, is based on the following assumptions: only the wall-base connections and the wall-to-wall connections between the shear wall and perpendicular wall are considered. The monodirectional behaviour of the wall base connection is considered, therefore hold-downs are modelled as vertical elastic springs whereas angle brackets as horizontal elastic springs. It is assumed that the CLT walls behave as rigid bodies, hence the deformations due to CLT panels are not taken into account.

Fig. 3: Mechanical system of CLT shear wall connected to a perpendicular wall.

Consider the kinematic variables of the mechanical system shown in Fig.3, v and ϑ , whose meaning is given in Fig.3 and the substitutions shown in Eq.8.

$$\delta_{rocking} = \vartheta h \quad (a)$$

$$\delta_{sliding} = v \quad (b)$$

$$\delta_{sys} = \vartheta h + v \quad (9)$$

The total potential energy principle is used for defining the equilibrium equations of the system shown in Fig.3, with the aim to define the horizontal displacement of the model as function of the stiffness of the connections. The total potential energy of the mechanical system can be evaluated as the difference between the elastic energy of the system and the energy associated to the external horizontal force, see Eq.(10).

$$E_{tot} = \frac{1}{2}K_{AB}v^2 + \frac{1}{2}K_{HD}(\vartheta b)^2 + \frac{1}{2} \sum_{i=1}^{n_{w-w}} K_x (v + \vartheta y_i)^2 + \frac{1}{2} n_{w-w} K_y (\vartheta a)^2 - F(v + \vartheta h) \quad (10)$$

In which K_{AB} represents the sum of the horizontal stiffness of the angle brackets, K_{HD} represents the vertical stiffness of the hold-down, K_x and K_y are the stiffness of the wall-to-wall connections in the horizontal and vertical direction, respectively, and n_{w-w} is the number of wall-to-wall connections.

According to the total potential energy principle, the equilibrium condition of the mechanical system shown in Fig.3 can be found by equating the first derivative of the total potential energy respect to the kinematic variables of the system to zero.

$$\frac{\partial E_{tot}}{\partial v} = K_{AB}v + n_{w-w}K_x v + K_x \sum_{i=1}^{n_{w-w}} y_i \vartheta + F = 0 \quad (11)$$

$$\frac{\partial E_{tot}}{\partial \vartheta} = K_{HD}b^2\vartheta + K_x \sum_{i=1}^{n_{w-w}} y_i^2 \vartheta + K_x \sum_{i=1}^{n_{w-w}} y_i v + n_{w-w}K_y a^2 \vartheta + Fh = 0 \quad (12)$$

Eq.(11) and Eq.(12) represent the system of two equations, one of translational equilibrium and one of rotational equilibrium, which describe the analytical model shown in Fig.3.

$$\begin{cases} F = (K_{AB} + n_{w-w}K_x)v + \left(K_x \sum_{i=1}^{n_{w-w}} y_i \right) \vartheta \\ Fh = \left(K_x \sum_{i=1}^{n_{w-w}} y_i \right) v + \left(K_{HD}b^2 + K_x \sum_{i=1}^{n_{w-w}} y_i^2 + n_{w-w}K_y a^2 \right) \vartheta \end{cases} \quad (13)$$

2.3. Comparison of elastic stiffness matrix

The different wall displacement contributions described in the previous sections represent equilibrium equations of different elastic systems. On this basis, the displacement contributions of the CLT wall system can be written in the form shown in Eq.(14).

$$\{F\} = [K] \cdot \{\delta\} \quad (14)$$

In which F is the vector of the forces, K is the elastic stiffness matrix of the system and δ is the vector of the displacements.

The analytical model of Casagrande et al. [5], described in section 2.1.1, can be written as shown in Eq.(15).

$$\begin{Bmatrix} F \\ Fh \end{Bmatrix} = \begin{bmatrix} n_{AB}k_{AB} & 0 \\ 0 & K_{HD}\tau^2b^2 \end{bmatrix} \begin{Bmatrix} v \\ \vartheta \end{Bmatrix} \quad (15)$$

The analytical model of Hummel et al. [13] can be written as in Eq.(15) in case of rigid foundation, whereas in case of elastic foundation can be written as shown in Eq.(16).

$$\begin{Bmatrix} F \\ Fh \end{Bmatrix} = \begin{bmatrix} n_{AB}k_{AB} & 0 \\ 0 & \frac{1}{2}K_Dl_c^2 \left(l^* - \frac{l_c}{3} \right) \end{bmatrix} \begin{Bmatrix} v \\ \vartheta \end{Bmatrix} \quad (16)$$

The analytical model of Gavric et al. [3], described in section 2.1.3, can be written as shown in Eq.(17).

$$\begin{Bmatrix} F \\ Fh \end{Bmatrix} = \begin{bmatrix} n_{AB}k_{AB} & 0 \\ 0 & \sum_{i=1}^n K_i x_i^2 \end{bmatrix} \begin{Bmatrix} v \\ \vartheta \end{Bmatrix} \quad (17)$$

The analytical model presented in this work, described at the Section 2.2, can be written as shown in Eq.(18).

$$\begin{Bmatrix} F \\ Fh \end{Bmatrix} = \begin{bmatrix} (K_{AB} + n_{w-w}K_x) & \left(K_x \sum_{i=1}^{n_{w-w}} y_i \right) \\ \left(K_x \sum_{i=1}^{n_{w-w}} y_i \right) & \left(K_{HD}b^2 + K_x \sum_{i=1}^{n_{w-w}} y_i^2 + n_{w-w}K_ya^2 \right) \end{bmatrix} \begin{Bmatrix} v \\ \vartheta \end{Bmatrix} \quad (18)$$

It is possible to observe that, the equations (15) to (17) describe diagonal matrices, in which sliding and rocking of a single shear wall are independent. In these cases, the stiffness of rocking ($K_{rocking}$) and the stiffness of sliding ($K_{sliding}$) depend on terms in the diagonal of the stiffness matrix.

The new model of shear wall with wall-to-wall connections given in Eq.(18) describes an elastic stiffness matrix in which sliding and rocking are mutually influenced. Shear wall connected to perpendicular wall model constitute a system, which is statically indeterminate, differently from the shear wall models without wall-to-wall connections between perpendicular walls.

From the resolution of the system described with Eq.(18), it is possible to obtain the horizontal contribution of deformation due to rocking ($\delta_{rocking}$), see Eq.8(a), and sliding ($\delta_{sliding}$), see Eq.8(b), which depend on the stiffness of hold-down, angle brackets and wall-to-wall connections. As consequence, the rocking stiffness ($K_{rocking}$) and the sliding stiffness ($K_{sliding}$) of the system depend on hold-down, angle brackets and wall-to-wall connections, and can be calculated with Eq.19(a) and (b).

$$K_{rocking} = \frac{F}{\delta_{rocking}} \quad (a)$$

$$K_{sliding} = \frac{F}{\delta_{sliding}} \quad (b) \quad (19)$$

Since the CLT walls deform under lateral load as an in-series system, the overall stiffness of the system can be calculated with Eq.(20). According to Casagrande et al. [5], Eq.(20) can

schematized as shown in Figure 4(a) in the case of shear wall without the wall-to-wall connections. Considering the effect of the wall-to-wall connections the system can be modified as shown in Figure 4(b), from which is possible to observe that the sliding and rocking stiffness continue to work as in-series system. However in this case, the mutual influence of the connections system contribute to increase their magnitude working as an internal in-parallel system.

$$K_{sys} = \left(\frac{1}{K_{rocking}} + \frac{1}{K_{sliding}} \right)^{-1} \quad (20)$$

Fig. 4: Scheme of two elastic in-series springs for single shear wall (a) and for shear wall connected to perpendicular wall (b).

The horizontal elastic displacement of the CLT shear wall can be calculated as function of the overall stiffness of the system as shown in Eq.(21):

$$\delta_{sys} = \frac{F}{K_{sys}} \quad (21)$$

3. NUMERICAL MODEL

To validate the correctness of the analytical model presented in the previous section, an analogous numerical model of CLT shear wall anchored with wall base and wall-to-wall connections is presented in this section. The numerical model, developed in the FE software SAP2000 [16], is a two-dimensional model composed of shell elements and elastic springs, see Fig.5.

To simulate the assumption of wall panel rigid behaviour, the CLT panel was modelled as isotropic shell element from SAP2000 library with a high elastic modulus equal to 200.000 MPa. Analogously to the analytical model, hold-downs and angle brackets were considered effective along their primary direction. Hold-downs were modelled as 1-joint vertical elastic springs connected to the tense side of the wall end. Angle brackets were modelled as a unique lumped 1-joint horizontal elastic springs connected to the wall end. The compressed corner of the CLT shear wall was modelled with a vertical support that allowed horizontal translation and rotation. The wall-to-wall connections were modelled with a series of 1-joint elastic springs acting in the vertical and horizontal direction, z and x according to Fig.5.

Fig. 5: FEM model of CLT shear wall and connections.

The values of stiffness of the elastic springs representing the different CLT connections were taken from experimental campaigns from the literature. Such values and the wall geometries are given in the next section, in which a parametric analysis is presented with the aim to check the correctness of the analytical model and to investigate the stiffening effect of the wall-to-wall connections in different geometrical and mechanical conditions.

4. PARAMETRIC ANALYSIS

The analytical model presented in section 2.2 and the numerical model presented in the previous sections are used in this chapter to perform a parametric analysis in which different geometrical and mechanical properties of CLT walls are considered.

Since the lateral behaviour of a CLT shear wall strongly depends on the wall aspect ratio three different wall aspect ratio equal to $b/h=0.5$, $b/h=1.0$ and $b/h=1.5$ were analysed in the parametric analysis, see Fig.6.

Fig. 6: Aspect ratio of the shear walls: $b/h=0.5$ (a), $b/h=1$ (b) and $b/h=1.5$ (c).

The parametric analysis was carried out by considering mechanical properties of wall base connections based on experimental results from Gavric et al. [3]. In this study, hold-downs with twelve 4×60 mm nails, and angle brackets with eleven 4×60 mm nails were tested under tension and shear loads, respectively. Based on these experimental results, the values of stiffness of hold-downs and one angle bracket used in the parametric analysis were set equal to 4.59 kN/mm and 1.96 kN/mm, respectively. As shown in Fig.6, one, two and three angle brackets were considered for the three different wall aspect ratios $b/h=0.5$, $b/h=1.0$ and $b/h=1.5$, respectively.

The stiffness of the wall-to-wall connections was assigned based on experimental results from [17], in which wall-to-wall connections between perpendicular walls with self-tapping screws 10×180 mm, installed with an inclination of 90° respect to the plane of the shear wall, were tested. A stiffness equal to 1.53 kN/mm was considered for the wall-to-wall connections in both vertical and horizontal direction. The spacing between each connection was set equal to 300 mm that for a wall height of 3 m led to a number of wall-to-wall connections equal to $n_w=10$.

As shown in Fig. 1, perpendicular walls can be connected to shear walls in different positions.

Such positions can differently influence the mechanical behaviour of the shear wall. To evaluate such aspect, three different position of the wall-to-wall connections were considered in this study, as shown in Fig. 7:

- i. Perpendicular wall on tense side of the shear wall,
- ii. Perpendicular wall on central side of the shear wall,
- iii. Perpendicular wall on compressed side of the shear wall.

Fig. 7: Position of perpendicular wall respect to shear wall: tense side (i), central side (ii) and compressed side (iii).

It should be mentioned that the stiffening contribution of the perpendicular walls on the lateral stiffness of the shear wall depends on the wall-to-wall connections as well as on the stiffness of the wall base connections of the perpendicular wall. From Fig. 8(a), it is possible to observe that the rocking mechanism of the shear wall is influenced from the vertical stiffness of the wall-to-wall connections and on the vertical stiffness of the hold-downs of the perpendicular wall. On the other hand, the sliding mechanism is differently influenced from the perpendicular walls, which cannot undertake the horizontal load of the wall-to-wall connections since their wall base connections mostly have a hinge behaviour in the direction out of the plane, which do not permit the transfer of such forces, see Fig. 8(b). To investigate such aspects, the parametric analysis was performed in three different conditions:

- iv. Both vertical and horizontal stiffness considered with $K_y=K_x=1.53$ kN/mm;
- v. Only the vertical stiffness considered with $K_y=1.53$ kN/mm and $K_x=0$;
- vi. Only the vertical stiffness considered with $K_y=0.35$ kN/mm and $K_x=0$;

While the condition iv is representative of the potential condition in which the lateral load can be transfer to the perpendicular wall by means of both rocking and sliding mechanism, the conditions v and vi represent the realistic conditions in which only the rocking mechanism contributes to transfer the lateral load to the perpendicular walls. The condition v represents the case of perpendicular wall connected at the base with highly rigid hold-downs whereas in the condition vi represents the case of perpendicular wall connected at the base with flexible hold-

downs. In the case vi the stiffness K_y is calculated assuming an in-series behaviour of wall-to-wall connections and hold-down of the perpendicular wall.

The parameters used for the parametric analyses are summarized in Table 1.

Fig. 8: Rocking (a) and sliding (b) mechanism of shear wall connected to perpendicular wall.

Perp. wall Position	h [m]	h/b [-]	K_{HD} [kN/mm]	K_{AB} [kN/mm]	K_y [kN/mm]	K_x [kN/mm]	n_{w-w} [-]
Tense side		0.5		1.96	$1.53^{(iv,v)}$	$1.53^{(iv)}$	
Central side	3	1.0	4.59	3.92	$0.35^{(vi)}$	$0^{(v,vi)}$	10
Compressed side		1.5		5.88			

Tab. 1: Parameters used for the parametric analyses.

5. RESULTS AND DISCUSSION

To evaluate the influence of the wall-to-wall connection on the lateral stiffness of the shear walls, the parametric analysis was carried out considering the conditions given in Table 1 and the benchmark condition in which the wall-to-wall connections are not considered. Such analyses were performed by using the equations of the analytical model given in Section 2.2 and the numerical model presented in Section 3. Results in terms of wall stiffness from the analytical and numerical models showed differences smaller than 1% for all the conditions analysed.

The results of parametric analysis are reported in Fig.9, Fig.10 and Fig.11, for the cases iv , v and vi described in the previous section, respectively. The figures show graphs organized in matrix form representing the different wall aspect ratios and perpendicular wall positions. Each graph reports the lateral stiffness and the rocking and sliding displacement contributions of the shear wall. The rocking and sliding displacement contributions were calculated as the ratio between the rocking and sliding displacement, calculated from Eq.8(a) and (b), and the total displacement, calculated from Eq.9.

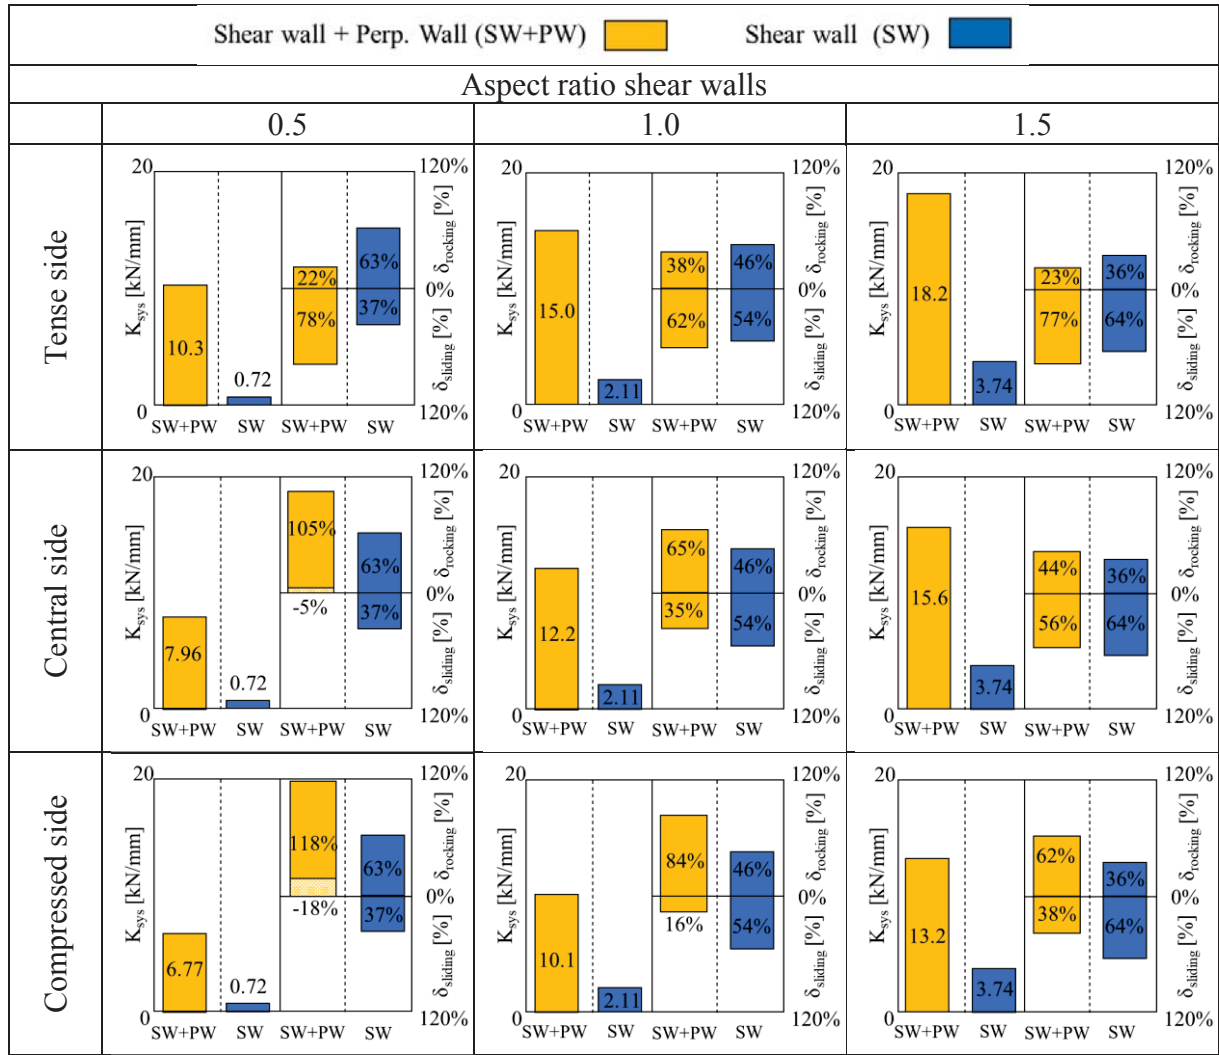

Fig. 9: Results of parametric analysis for the case *iv*.

It is possible to observe that there is an increase of the lateral stiffness in all cases analysed, due to the effect of the wall-to-wall connections. Such effect is always larger in the case of the perpendicular wall is anchored to the tense side of the shear wall and reduces as the perpendicular wall is moved toward the compressed side of the shear wall. The highest increases of stiffness are observed for wall aspect ratios equal to $b/h=0.5$ and such stiffening effect decreases as the wall aspect ratio b/h increases.

In the case *iv*, in which the shear walls can potentially transfer both uplift and lateral forces to the perpendicular walls, the highest increases of stiffness are observed. In this case, increases of the lateral stiffness up to 14 times respect to the case without the wall-to-wall connections can be observed. The results in terms of increase of lateral stiffness of the case *iv* show the potential effect of the wall-to-wall connections on the stiffness of the shear wall.

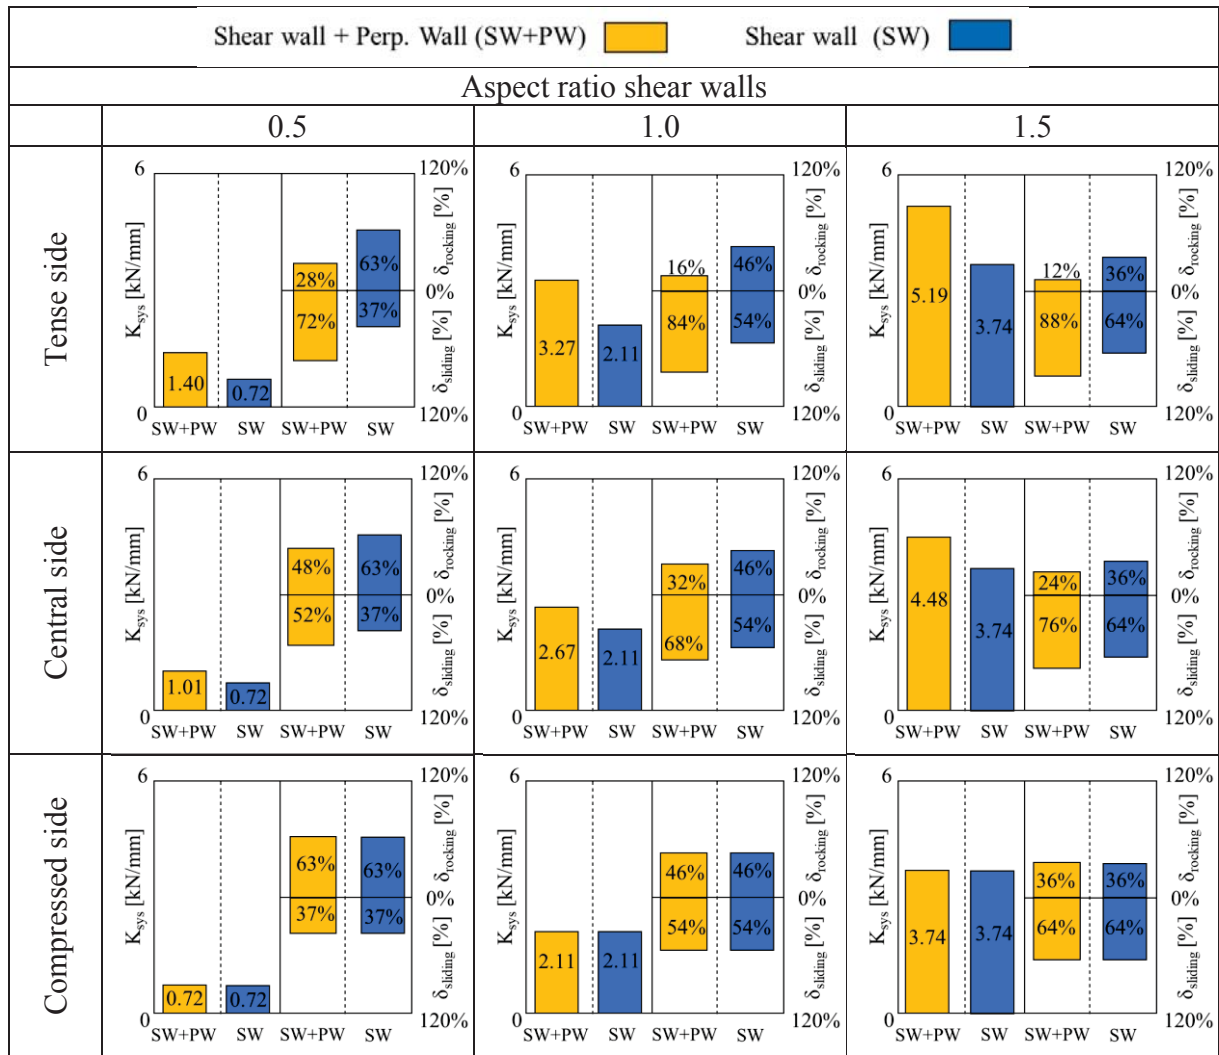

Fig. 10: Results of parametric analysis for the case *v*.

In the case *v*, in which the shear walls transfer only uplift forces to the perpendicular walls and the latter are anchored with stiff hold-downs, great reductions of the increase of lateral stiffness in comparison to the case *iv* are observed. In this case, increases of the lateral stiffness up to 2 times respect to the case without the wall-to-wall connections can be observed. Such result is due to the absence of the stiffening contribution for the sliding mechanism, which consequently become the predominant deformation mechanism. Such aspect can be observed also from the deformation mechanism contributions: in the cases where there are the highest increases of lateral stiffness there are also the greatest change in the deformation mechanisms of the shear wall.

In the case *vi*, in which the shear walls transfer only uplift forces to the perpendicular walls and the latter are anchored with flexible hold-downs, further reductions of the increase of lateral stiffness in comparison to the case *v* are observed. In this case, increases of the lateral stiffness up to 1.4 times respect to the case without the wall-to-wall connections can be observed.

In both cases *v* and *vi*, it is interesting to note the when the perpendicular wall is placed on the compressed side of the shear wall, none increase of stiffness is detected.

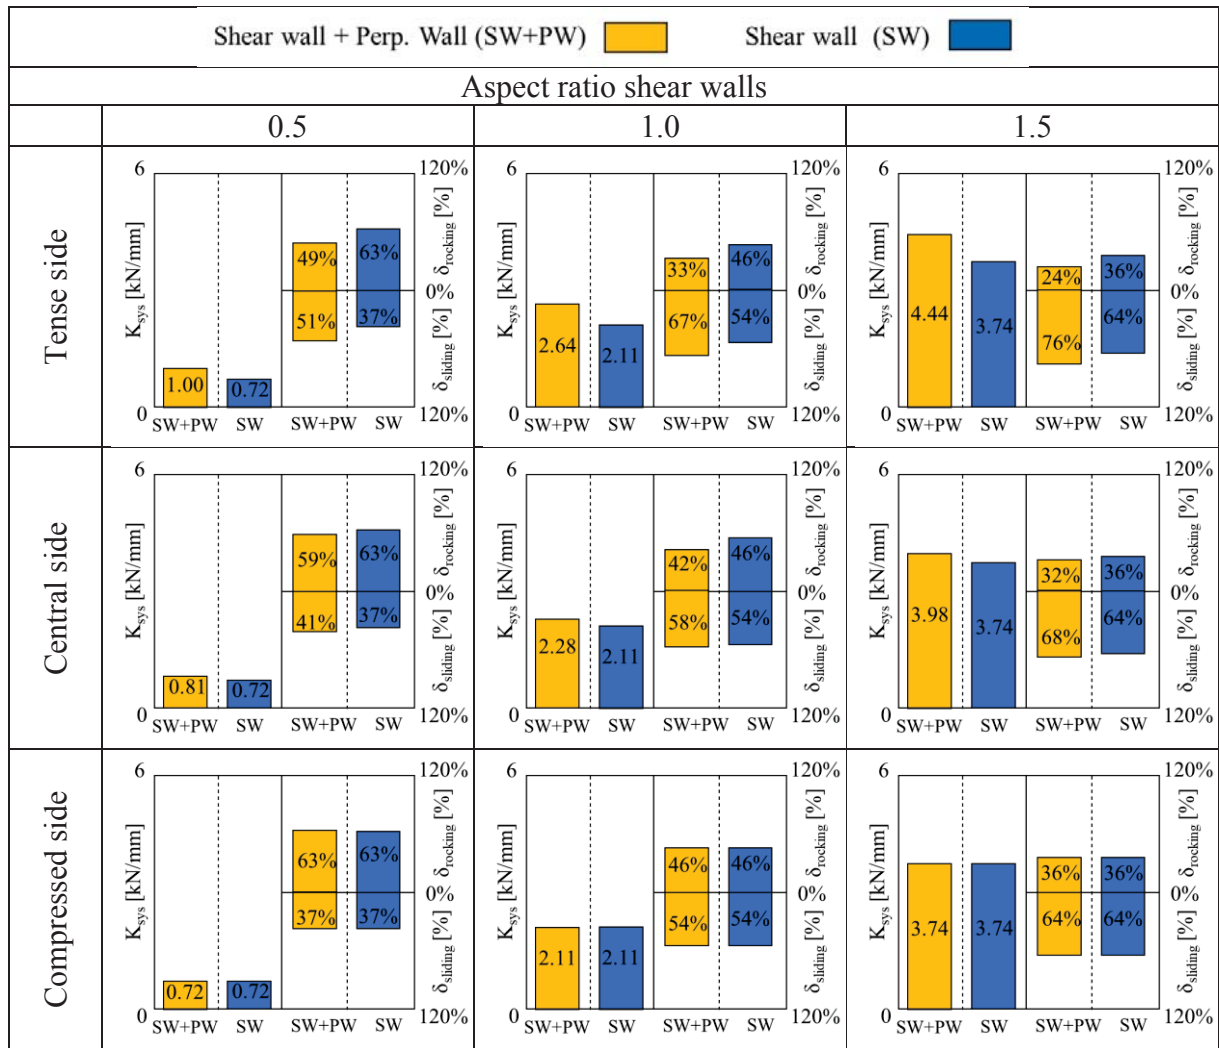

Fig. 11: Results of parametric analysis for the case vi.

CONCLUSIONS

In this paper, a study on the effect of the perpendicular walls on the lateral stiffness of CLT shear walls is presented. A new analytical model capable of calculating the stiffness of CLT shear walls connected to perpendicular walls through wall-to-wall connections is presented. The new analytical model is compared with several analytical models taken from the literature and the differences among the models are described through their stiffness matrices.

The analytical model was validated against numerical models developed in SAP2000 and used to perform a parametric analysis in which different wall geometries, anchoring configurations, position of the perpendicular walls and assumptions of the load transfer from the shear wall to the perpendicular walls were considered. The results of the parametric analysis showed that considering the effect of the perpendicular walls increase the lateral stiffness of the shear walls and modifies the contributions of rocking and sliding displacement of the shear walls in comparison to the cases in which the perpendicular walls are not taken into account. It was also shown that stiffening effect of the perpendicular walls strongly depends on the capability of their wall base connections to undertake the uplift and out-of-the-plane forces transferred from the shear walls. With current connection technologies available on the market, the perpendicular walls can contribute to increase up two times the lateral stiffness of shear walls.

Future studies of the authors will focus on the contribution of the perpendicular walls on the lateral capacity and ductility of the shear walls and on the effects of the box-behaviour at building level.

Abstract

This paper deals with the conception, the experimental and numerical characterization of an innovative post-tensioned CLT wall system equipped with external and replaceable hysteretic devices. The cyclic behavior of the post-tensioned walls was firstly investigated at the mechanical laboratory of CIRI-EC of University of Bologna by means of experimental tests on single component of the structural system and on the full-scale post-tensioned CLT walls prototypes. Results from experimental tests demonstrate the capability of the conceived post-tensioned wall systems to withstand significant drift without damage on the main timber and steel components. A good dissipative capacity of the wall configurations equipped with dissipaters was also observed. A nonlinear Finite Element model capable of reproducing the wall system hysteretic behavior was developed in the OpenSees framework. Implemented FE numerical model demonstrated a good capability of reproducing the experimental response.

Keywords: CLT walls, Experimental test, Hysteretic devices, Numerical Model, Post-tension

1 INTRODUCTION

The growing diffusion of timber buildings in seismic areas drawn the scientific community's attention to this kind of structures [1–4], leading to the conception of structural solutions able to preserve the buildings after a seismic event. To this aim, low damage post-tensioned technologies were introduced [5–8], which entrust the horizontal load to rocking dissipative timber walls. The rocking behavior is mainly controlled by PT (Post-Tensioned) bars positioned into cavities in the walls, fixed at the base and connected at the top of the wall, that control the re-centering of the system. The dissipative contribution is devoted to hysteretic dampers, simply replaceable after a seismic event, connecting the base wall to the foundation [9,10] or adjacent timber elements along elevation [10,11]. This paper deals with the experimental characterization, and numerical investigation of an innovative post-tensioned CLT wall system, equipped with external and replaceable hysteretic dampers. The investigated wall system was conceived referring to previous experience on GluLam and LVL post-tensioned technology available in literature [5,6,12] and then improved adapting the system to the use of CLT panel [7,8] and external replaceable hysteretic dampers [9].

The cyclic behaviour of the post-tensioned walls was investigated at the mechanical laboratory of CIRI-EC of University of Bologna by means of experimental tests on a single component of the structural system and on the full-scale post-tensioned CLT walls prototypes. Results from experimental tests demonstrated the capability of the conceived post-tensioned wall system to withstand significant drift without damage to the timber elements. A good dissipative capacity was also observed, mainly due to the entering into the plastic field of the dampers, which result severely damaged and easily replaceable.

A nonlinear Finite Element model capable of reproducing the wall system cyclic behaviour was developed in the OpenSees framework. The implemented FE numerical model demonstrated a good capability to reproduce the experimental response, resulting in an efficient tool for simulating the response of the entire building realized using the developed technology.

2 EXPERIMENTAL CAMPAIGN

The analyzed configuration is characterized by a single dissipative rocking wall connected to GluLam boundary columns. The GluLam columns are assumed to be part of a timber frame aiming to resist to vertical loads, while the CLT PT-wall system preserves the building against the horizontal action. The boundary columns were thought to be connected to the inter-floor beams, to avoid their direct connection with the rocking wall, that could lead to vertical displacements incompatible with the diaphragm system, as suggested by previous authors [12].

The rocking behavior is entrusted to the PT-bar and the dissipative contribution is devoted to hysteretic dampers. In particular, two pairs of dampers are placed along the base of the wall, working predominantly in the axial direction (axial dampers), and two pairs of dampers are positioned at the wall/column interfaces, working predominantly in the transversal direction (shear dampers). In addition, a post-tensioned only configuration (with no dampers) was considered, to highlight the dissipative and resistant contribution of the dampers. The PT-bars are also positioned in columns to simulate the presence of axial load.

The adopted hysteretic dampers are the so-called X-brackets [10,13], which was conceived to be employed both as axial and shear dampers. At the component level, tests were conducted to characterize the connection system developed for the fastening of the hysteretic dampers to the CLT panel adopting a superficial FRP reinforcement [14]. Results demonstrated the effectiveness of the fastening system, especially with regard to the replaceability of the hysteretic dampers. At the system level, the single wall configuration with boundary columns was considered with an initial post-tension load of 350 kN. Figure 1 reports the test setup, the sample's geometry,

and the cyclic protocol used to impose the top displacement to the wall, evaluated according to UNI EN 12512 [15], reaching 1.5% drift. The CLT panel was realized with C24 wood layers, while the initial PT (Post-Tensioned)- Force was conferred through a dywidag steel bar (“www.dywidag-systems.com/emea”) of 32 mm, characterized by a modulus of elasticity of 205 GPa and a yielding stress of 950 MPa. In addition, the X-Brackets are characterized by steel S275 and a thickness of 8 mm.

The horizontal cyclic displacement was applied to the system by means of an hydraulic actuator with a capacity of 1000 kN, positioned at 3.1 from the wall base, while the initial PT force was applied to the PT-bars by means of a hydraulic jack. Furthermore, the horizontal loads were measured during the test together with the PT forces. These records are essential for the reconstruction of the global response of the system. Moreover, in order to obtain information on the local response of the system, Linear Variable Displacement Transducers (LVDTs) were employed to measure displacements in crucial points of the system, as shown in Figure 1. In particular, one LVDT was positioned in correspondence of the actuator, to record the displacements imposed to the system; two LVDTs measured the slip between the wall and the steel foundation; eight LVDTs measured the base uplifts of the wall and columns, in order to derive the neutral axis depths; two LVDTs measured the vertical slip between column to wall interfaces.

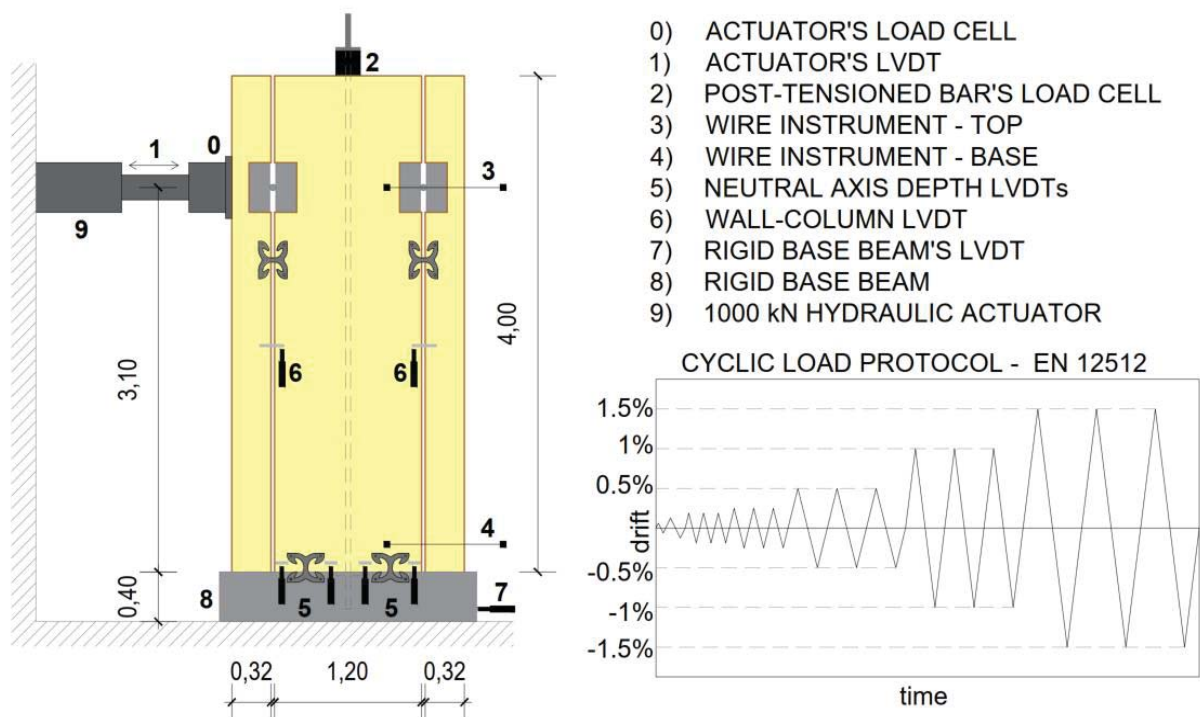

Figure 1: Column-wall-column test setup and adopted load protocol.

At tile of example, Figure 2 (a) show the view of the PT configuration equipped with both axial dampers (framed in red) and shear dampers (framed in blue). In Figure 2(b), global results in terms horizontal load/ drift curves are shows for the PT configuration (red) and for the PT configuration with dampers (blue). The two curves show an almost bilinear trend, more evident for the PT configuration, which transition point represents the drift at which the PT bar in the wall starts to deform. From the comparison between the two curves, it clearly emerges the contribution of dampers in terms of energy dissipation and strength, appreciable through the amplitude of the cycles and the horizontal load values reached with the same drift, respectively.

(a)

(b)

Figure 2: (a) View of the setup and (b) Experimental Horizontal load - Drift curves.

3 EXPERIMENTAL AND NUMERICAL RESULTS

In order to design, and then to simulate, the experimental campaign, a non-linear numerical model was developed in the OpesSees frame work[17]. The model took into account both geometrical and material non-linearities, the former due to the rocking behaviour of the system, and the latter due to the presence of axial and shear dampers. In particular, the behaviour of axial and shear dampers were calibrated on the base of experimental results obtained on the single components.

In this section, the main results of the experimental campaign are shown, compared with outputs of the numerical simulations. In particular, results obtained for the PT configuration (no dampers) and for the PT configuration equipped with axial and shear dampers are shown. Figure 3(a) and (b) report the horizontal load/ drift curves for the PT configuration and for the PT configuration equipped with dampers, respectively, highlighting their benefits in terms of energy dissipation and strength. The comparison between experimental and numerical results shows a good agreement in terms of initial stiffness, strength and cyclic behaviour. However, a slight underestimation of the cyclic behavior can be observed in the numerical simulations, mainly due to some frictional dissipation neglected in the numerical model.

The good agreement between experimental and numerical results is also confirmed by comparing the local behavior of the system, particularly on the wall uplifts measured along the base at the height of 20 cm shown in Figure 4. Furthermore, this plot helps to understand the behavior of the PT-bars, which, during the wall rocking, was subjected to elongation, and so to a PT-force increase, to accommodate the kinematic of the system. Figure 5 (a) shows the comparison between the experimental and numerical column to wall vertical slip versus drift, in which the left column, the wall and the right column are denoted as C1, W and C2, respectively. This comparison show a good agreement between results, even if the numerical model slightly overestimated vertical slips. These results are of particular interest, since the dissipative contribution of the shear dampers maily depends on the colum to wall vertical slip; it is therefore possible

to find information on the behavior of dampers even if it is not directly investigated from an experimental point of view. In this regard it is also useful to analyze some results carried out by the numerical model: as an example, the Figure 5 (b) shows numerical vertical slip/ shear force curves of the pair of shear dampers connecting the left column with the wall. In particular, it is evident that the shear dampers work in the plastic field ensuring a strong contribution in terms of energy dissipation; furthermore, it was predominantly exploited in one direction. In fact, due to the rocking behavior, when the system is pulled, the vertical slips between the left column and the wall is reduced, due to the limited width of the column, compared to that observed when it is pushed. The opposite is observed for the vertical slips between the wall and the right column.

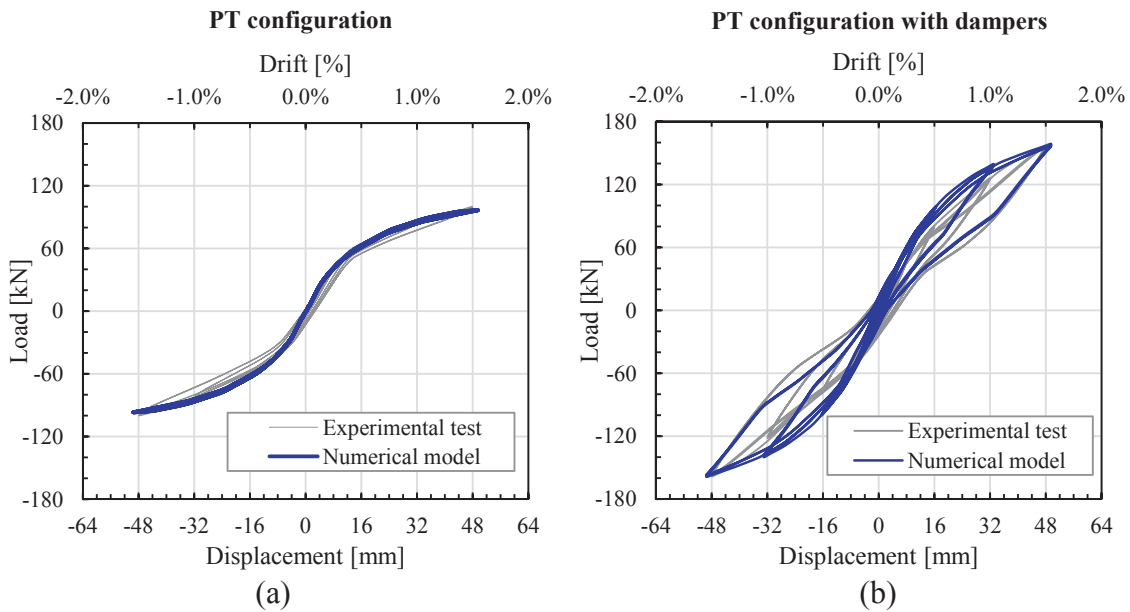

Figure 3: Horizontal Load-Drift curves: (a) PT configuration; (b) PT configuration with dampers.

Figure 4: Base vertical uplifts: PT configuration.

Figure 5: (a) Vertical slip/ Drift curves for the PT configuration with damper; (b) numerical vertical slip/ dampers' shear force.

CONCLUSIONS

Results of an experimental campaign on post-tensioned CLT wall system equipped with external and replaceable hysteretic devices were reported in this paper, demonstrating the capability of the developed system to withstand significant drift, until 1.5%, without damage in the structural timber elements and the principal connection systems. Moreover, a good dissipative capacity of the wall configuration equipped with both axial and shear dampers was observed, and the replaceability of the hysteretic dampers was also proved during the experimental campaign. Furthermore, a numerical model was specifically developed to predict the response of the proposed systems', considering the geometric and material non-linearities mainly due to the wall rocking behavior and to the hysteretic dampers. The proposed numerical model demonstrated a good capability of reproducing the experimental response both at global and local levels, and the ability to provide reliable prediction on behaviors not directly investigated during the experimental tests on the PT-wall system, such as the response of the hysteretic dampers. Therefore, it can be employed for the modelling of similar PT-wall systems supporting the design phase.

Abstract

For the design of dissipative heavy timber frame structures, in the context of modern seismic design approach based on the mechanical triad of strength, stiffness and ductility, brittle timber failure modes can be avoided by integrating hybrid timber-steel system into modern timber connection technology. Thus, the overall seismic performance of timber structures can be improved, entrusting the dissipation function to ad hoc conceived devices, like steel links. With reference to the structural type of Moment Resisting Frames (MRF), steel links located at the ends of the beams are able to provide a significant dissipative capacity, by means of cycles of plastic deformations, while timber members and steel connections, to be designed with an adequate overstrength as respect to the link, behave in elastic field. In this regards, the paper presents the capacity design and the mechanical characterization through monotonic numerical analyses of two different timber beam-to-column joint with steel link for MRF structures, consisting of a timber beam and a steel link connected each other by means of a stiffened end-plate and glued-in steel rods. The proposed design criteria of the joint are validated through the evaluation of performance, by means of nonlinear pushover analyses on the joint refined FEM models, in terms of key parameters, such as ultimate resistance, stiffness, rotation capacity and failure modes. The numerical results confirm the plastic deformation of the link, which large dissipative capacity of the joint corresponds to.

Keywords: Seismic resistant timber structures, beam-to-column joints for dissipative timber moment resisting frames, steel link, component method for timber joints, capacity design for timber structures, FEM analysis of beam-to column joints for timber MRFs.

1 INTRODUCTION

Toward the dissipative seismic resistant timber structures design, steps must be taken to overcome the seismic deficiencies related to the inherent fragility of wood. Since timber is a material with an elastic-fragile behavior, in the present anti-seismic regulations, such as in Europe the Eurocode 8 [1], it is indicated that the joints could dissipate through the plastic deformations of metallic connectors. However, joints are structural elements with an important role in bearing the design loads. In view of the development of heavy timber seismic resistant structures, in the context of modern seismic design approach based on the mechanical triad of strength, stiffness and ductility, the dissipative capabilities should be delegated to specific devices [2]. In fact, by integrating modern steel connection technology into timber system, brittle wood failure modes can be avoided and the overall seismic performance of timber structures can be improved. Some recent research has focused on the development of hybrid timber-steel, instead of relying on an all-timber structure, showing good potential for improving the behaviour of seismic resistant timber structures [2-4]. Very efficient solutions are steel links, to be located in timber members depending on the seismic resistant structural type, which are able to provide a significant dissipative capacity, by means of cycles of deformations in plastic field, if designed with adequate strength, stiffness and ductility.

It is therefore possible to take advantage of the knowhow on steel constructions related to the seismic design criteria, according to the approach based on the ductile and dissipation requirements (capacity design), adopting necessary adaptations corresponding to the peculiarities of timber, which should be based on the calibration of the fundamental parameters. With reference to the structural types of Moment Resisting Frames (MRF), steel links located at the ends of the beams [5-12] have the function of ductile fuses, where the plastic hinge in bending is concentrated, while the timber members should be designed with an adequate overstrength, to remain in elastic field. Recently Montuori and Sagarese [9] have applied the steel reduced beam sections, commonly proposed for steel MR frames [10, 11], to timber beams.

The crucial aspect is the design of joints. In timber structures engineering this issue is certainly innovative, it requiring a significant detailed study aimed at characterizing the mechanical behavior of connections in terms of stiffness, strength and ductility.

In this regards the paper focuses on the design of two beam to column timber joints, with the same configuration, equipped with different steel links, for dissipative heavy timber MRF. It illustrates a part of a wider study, including both numerical and experimental investigations on either joints or whole structural systems.

The joints are designed through the capacity design approach, by applying the component method, with the aim to allow the plastic hinge formation in the steel links, while the timber member and the connections are designed to remain elastic, with adequate overstrength.

The mechanical characterization of the joints is carried out through monotonic numerical analyses, on refined FE models, already calibrated upon past experimental tests [8], by means of the structural calculation program ABAQUS FEA (2019). As a result, the numerical F-u (vertical force-displacement) and M- θ (bending moment-rotation) curves obtained are compared to evaluate the capabilities of the joints and the adequacy of the proposed design criteria.

2 DISSIPATIVE JOINTS DESIGN

2.1 Design criteria of the joint

The detail of the configuration of the beam-to-column joint with steel link under study is shown in Figure 1a. In particular the steel link is connected to the timber members by means of bolted endplates stiffened by triangular plates. The capacity design is applied on two levels

[12]: for macro-components, they being timber beam and column, steel link, connection between link and timber members, so that timber members and connections have an over strength as respect to the steel link; for sub-components, they being timber members, steel link, connection elements, such as, end-plate, stiffeners and steel bars, imposing a collapse hierarchy of components for achieving an overall ductile failure of the joint (Fig. 1).

Figure 1: a) Identification of the joint components; b) the reference joint [mm; 12].

With regards to the capacity design for macro-components, the dissipative link should be designed in order to achieve a pure bending behavior, so that the full plastic bending resistance and the rotation capacity of the dissipative link should be not affected by axial and shear forces (Eurocode 3 (EC3) part 1-1[13]. At the same time, the link cross sections should have high ductility, according to EC8 [1]. For non-dissipative elements, such as timber beams and columns, the capacity design criterion should be satisfied, according to EC8 [1].

With regards to the capacity design for sub-components, according to the component method (EC3 part 1-8 [13]) the joint is assumed as an assembly of components, whose mechanical behavior is studied separately, taking into consideration the contribution of each one in terms of strength, stiffness and rotation. The link to column connection is assumed as rigid.

The design bending resistance of the joint is determined as it follows [12]:

$$M_{i,Rd} = F_{i,Rd} \cdot z \quad (1)$$

where z is the lever arm of the resistant bending moment (Fig. 2) and $F_{i,Rd}$ is the resistance of the weakest joint component, such as the smallest value among the following ones, where the stiffened endplate is studied as an equivalent T-stub (Fig. 2b, c; EC3 part 1-8 [13]).

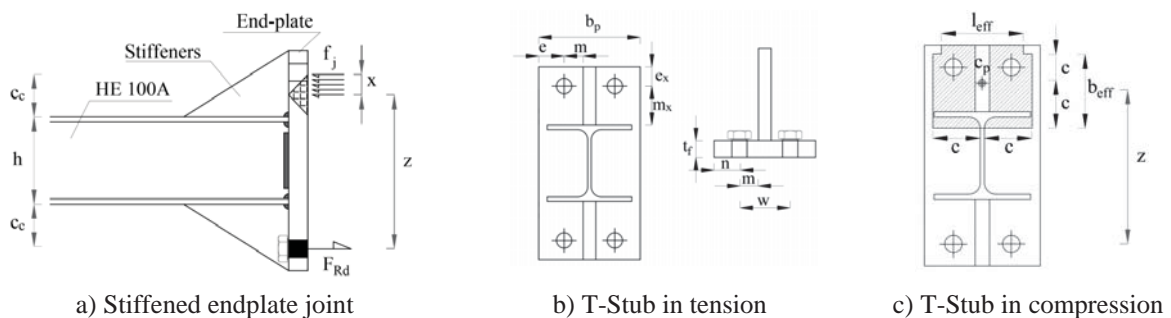

Figure 2: Joint models [13].

For the T-stub in tension (Fig. 2b), $F_{t,T-stub,Rd}$ is the minimum contribution provided by the following possible failure modes (EC3 part 1-8 [13]: 1) complete yielding of the flange; 2) bars failure with yielding of the flange in presence of prying forces; 3) bar failure in tension.

For the T-stub in compression (Fig. 2c; EC3 part 1-8 [13], $F_{c,T-stub,Rd}$ is evaluated with reference to an effective compression area, assuming the compression centre (c_p) approximately located at the centroid of the T section identified by the stiffener and the steel link flange.

For the steel stiffeners, $F_{s,Rd}$ is determined through the equivalent truss model [14], which defines the equivalent strut area of the stiffener, with a possible yielding failure mode.

For the glued-in steel bars in tension (pull-out; CNR-DT 206 R1/2018 [15]), $F_{ax,Rd}$ is evaluated with reference to the following possible failure modes: a) bar failure in tension; b) failure for debonding at the adhesive to timber interface; c) failure of timber in tension; d) failure of timber for splitting in the bar direction. The latter can be avoided by respecting the minimum distances from the edge and minimum spaces between the glued bars in tension [15].

2.2 The joints studied

The reference joint [12] is shown in Figure 1b. New link devices are here adopted, such as HE100A (Fig. 3a) and IPE100 (Fig. 3b) steel profiles. The hierarchy resistance criteria are applied to design the joints components (timber beam, end-plate, stiffeners, bars). Definitely the two study joints have the features shown in Figure 3, they also differ for the endplates thickness, they being 20 and 15 mm thick, respectively. Material grades are given in Figure 4.

In Table 3 the results of the joints design are presented. The outputs are provided for the joint components in terms of design resistance $F_{i,Rd}$, bending resistance $M_{i,Rd}$ (eq. 1) and over-strength (OS_i), evaluated as the ratio $M_{i,Rd}/M_{i,pl,Rd}$, where $M_{i,pl,Rd}$ is the bending design resistance of the link. It is apparent that the dissipative link is the first component to reach the elastic limit (yielding). Moreover the overstrength coefficient of the timber beam as respect to the link is larger for the IPE100 device and the collapse hierarchy changes for the two cases.

Figure 3: Geometrical features: a) HE100A and b) IPE100 joints.

HE100A				IPE100			
Collapse hierarchy	$F_{i,Rd}$ [kN]	$M_{i,Rd}$ [kNm]	OS_i [%]	Collapse hierarchy	$F_{i,Rd}$ [kN]	$M_{i,Rd}$ [kNm]	OS_i [%]

3 MECHANICAL CHARACTERIZATION OF THE JOINTS

3.1 Monotonic numerical analysis

The mechanical behavior of the HE100A and IPE100 joints is examined through a mono-

tonic nonlinear numerical analysis through the software ABAQUS FEA (2019). The implicit dynamic analysis is performed applying a load history in displacement control. The displacement is imposed at the end of the cantilever beam, with increment of 20mm up to collapse, corresponding to the test speed of 0,2 mm/s [16]. The F-u and M- θ curves are drawn to evaluate the global and local behavior of the joints. In particular, the bending moment at the joint (M) and the corresponding rotation (θ) are evaluated at the mid section of the link; the displacement (u) in z-direction is evaluated at the applied force (F) section (Fig. 4a).

Figure 4: a) Geometric model and performance parameters of the joint; b) Materials features: density (ρ), elastic modulus (E), elastic (σ_{el}) and ultimate resistance (σ_u) resistance, elastic (ϵ_{el}) and ultimate (ϵ_u) strains.

With regard to the material models, timber is assumed with an elastic fragile behavior, while for end-plate, bolts and link steels an isotropic hardening model is adopted, according to EC3 part 1-1 ([13] Fig. 4b), and true stress-true strain equations.

In Figure 5 the Force-displacement (F-u) and Moment-rotation (M- θ) curves of the HE100A and IPE100 joints are presented and compared. Specific performance points are evidenced, corresponding to the link yielding (P_Y), full plasticization (P_P) and ultimate strength (P_C), as collapse condition and the end of the numerical analysis, it corresponding to the buckling of the link web (HE100A) or flange (IPE100).

Figure 5: F-u and M- θ curves; performance points: Y-yielding, P- plasticization, C- collapse.

It is observed that the HE100A joint has greater stiffness, strength and ductility as respect to the IPE100 joint thanks to the link steel profile and the larger end-plate thickness. In both joints the plastic deformation of the link occurs, achieving the formation of the plastic hinge.

3.2 Analysis of results

The stress distribution in the joint and the AC yield (Actively Yielding) distribution that

identifies the attainment of yield stresses in the joint are shown in Table 5 at the collapse condition, where the maximum stress value (σ_{\max}) of each joint component is also given.

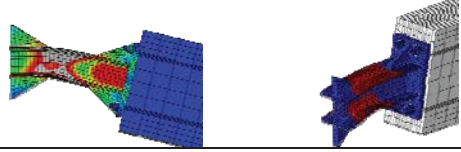

HE100A						IPE100				
										
	Link	End Plate	Threaded Bars	Timber beam	Stiffeners	Link	End Plate	Threaded Bars	Timber beam	Stiffeners
σ_{\max}	438	260	537	11,9	299	402	222	308	7,5	289

Table 5: Stress [MPa] distributions and maximum value in the joint components at collapse P_c .

For each i -th component (end-plate, stiffeners, threaded bars or timber beam) of the joints, the demand capacity ratio ($DCR_{i,j,el} = \sigma_{i,j} / \sigma_{i,el}$) between the maximum stress value evaluated at P_c point ($\sigma_{i,Pc}$) and the stress value at the elastic limit P_y point ($\sigma_{i,el}$) is provided in Table 6.

[%]	Link		End Plate		Thread Bars		Timber beam		Stiffeners	
	HE100A	IPE100	HE100A	IPE100	HE100A	IPE100	HE100A	IPE100	HE100A	IPE100
$DCR_{i,el}$	123	113	95	81	60	34	50	31	109	105

Table 6: DCR [%] at P_c for HE100A and IPE 100 joints.

The following collapse hierarchy of the joint components is evidenced: Link web (HE100A) or flange (IPE100) buckle, thus inducing the joint collapse, stiffeners undergoes plastic deformation, while end-plate, bars and timber beam are still in elastic field.

4 CONCLUSIVE REMARKS

The paper focuses on beam to column joints with dissipative steel link in the beam for seismic moment resistant heavy timber framed structures. In particular, the capacity design is applied through the component method, defining a collapse hierarchy on two levels, macro-components and sub-components. For both the joints, the numerical non linear pushover analysis has confirmed both the formation of the plastic hinge in the link which dissipates the energy through plastic deformation and the collapse hierarchy of the joint components, validating both the efficiency of the system and the proposed design method.

Future developments include the numerical evaluation of the cyclic behavior of the joints. Moreover, experimental tests will allow to check the accuracy of the proposed design criteria and the calibration of the design parameters.

The topic is noteworthy, as background for the development of the chapter on seismic-resistant timber structures of the technical standards for constructions.

Abstract

The paper focuses on a retrofit strategy applicable to existing reinforced concrete (RC) frame structures to reduce their seismic vulnerability. The intervention strategy, for the sake of brevity named RC-TP (Reinforced Concrete-Timber Panels), consists in the removal of the existing masonry infills and in their replacements with Cross Laminated Timber (CLT) panels fixed to the concrete elements by means of a timber subframe and a dissipative connection comprised of metal dowel-type fasteners. The analyses were performed via finite element modelling by adopting numerical strategies with different levels of refinement. In particular, refined 3-dimensional models (created using the software Abaqus) and simpler 2-dimensional models (created using the software SAP2000) were used. At first, the refined modelling approach was validated on experimental evidence on timber and concrete connectors available from the literature. Then, such 3-dimensional models were used to investigate the connection system of the proposed retrofit strategy paying particular attention to possible out-of-plane effects that cannot be directly observed with 2-dimensional models. The obtained results were used to calibrate the 2-dimensional models so that these “secondary” effects could be accounted for even in the simplified modelling. Subsequently, both modelling approaches were used to analyse an isolated one-storey one-bay frame via nonlinear static analyses that addressed the a) bare, b) original masonry infilled, and c) retrofitted configurations. The two alternative numerical strategies showed consistent results, both suggesting that the proposed intervention can significantly improve the seismic behaviour of existing RC frames.

1 INTRODUCTION

Reinforced concrete (RC) buildings represent a large percentage of the built heritage stock of many countries. Over the last decade, numerous studies have shown that, even in the case of minor earthquakes, past construction practices often led to vulnerabilities that resulted in extensive damage and collapse of the RC structure or portions of it [1], [2]. Examples of such vulnerabilities are the collapse of the masonry infills, the brittle shear failure of the RC elements or the activation of soft-storey mechanisms. Most of these buildings, indeed, were designed using codes that when they did not neglect the seismic action, accounted for it only partially. In addition, the presence of masonry infills was often disregarded in the modelling phase although nowadays it is well-known that their presence has a strong influence on the seismic behaviour of the structure [3], [4].

As a consequence, the interest of the scientific community towards such issues has grown over the years, with new solutions to improve the seismic behaviour of RC structures being proposed more and more frequently. Among these, the solutions that see the use of timber elements are gaining attention (e.g., [5]-[8]). In this regard, a retrofit intervention presented by Smioldo et al. [9], [10] is being developed at the University of Trento (Italy). Such intervention strategy aims at mitigating the seismic vulnerability of existing RC structures without modifying the original structural system. The intervention, named RC-TP (Reinforced Concrete-Timber Panels), consists in the removal of the existing masonry infills and in their replacement with Cross Laminated Timber (CLT) structural panels connected to the existing RC frame so as to redistribute the stresses due to the seismic action in order to avoid the development of brittle collapses and to favour the development of ductile mechanisms.

In this paper, the RC-TP retrofit strategy was studied via finite element modelling by adopting numerical strategies with two different levels of refinement: a 3-dimensional (3D), refined modelling approach was developed by using the finite element software Abaqus [11], while a 2-dimensional (2D), simpler approach was developed using the software SAP2000 [12]. In the first phase, the refined approach was calibrated on experimental evidence from the literature [13]-[15] concerning concrete-to-timber and timber-to-timber connections. Then, the 3D approach was used to reproduce the connection details implemented in the proposed intervention. Starting from the outcomes of the refined 3D models and focusing on the observed out-of-plane secondary effects that could have not been explicitly reproduced by 2-dimensional models, the 2D approach was tweaked to take implicitly into account such effects. Subsequently, the analyses were extended to more complex models of multiple-fastener connections and then to complete one-storey, one-bay RC frames retrofitted with the RC-TP intervention. The frame was analysed also considering the “bare frame” and “original masonry-infilled” configurations. Both in the refined and in the simplified approach, the masonry infills were simulated with modelling strategies adapted from the literature [16]-[18].

In all the configurations analysed, the alternative modelling approaches led to consistent results and confirmed the ability of the proposed intervention system to enhance the seismic behaviour of existing RC frames.

2 PRE-INTERVENTION RC FRAME

The intervention system presented in this paper is designed to be applied to existing structures. Consequently, the geometry, the detailing and the material properties of the case-study RC frame and masonry infill were selected so as to reflect the typical characteristics of buildings belonging to the existing stock. Table 1 reports the mechanical properties assumed for concrete (frame elements), steel (rebars and confinement reinforcement) and masonry (infills) in the numerical models.

Concrete		Steel		Masonry		
f_c	E_c	f_y	E_s	f_m	$f_{v,0}$	E_m
[MPa]	[MPa]	[MPa]	[MPa]	[MPa]	[MPa]	[MPa]
16,73	25673	440	21000	6,00	0,25	3000

Table 1: Mechanical properties of existing materials

Table 2 reports the geometrical and load characteristics of the RC frame used in the numerical analyses, where n is the number of longitudinal rebars, Φ is the diameter of rebars in millimetres and @ is the stirrup spacing in millimetres.

Pre-intervention characteristics		Value
Concrete frame	Length l [mm]	5000
	Height h [mm]	3000
	Column section (base \times height) [mm]	300 \times 300
	Beam section (base \times height) [mm]	300 \times 500
Reinforcements	Column longitudinal rebars	$n3+3 \Phi16$
	Column confinement reinforcement (2-legged stirrups)	$\Phi6 @150$
	Beam longitudinal rebars at ends (top – bottom side)	6 $\Phi14$ – 4 $\Phi14$
	Beam longitudinal rebars at mid-span (top – bottom side)	2 $\Phi14$ – 4 $\Phi14$
	Beam confinement reinforcement (2-legged stirrups)	$\Phi6 @200$
Masonry infill	Thickness [mm]	200
Loads	Vertical distributed (upper beam) [kN/m]	10
	Vertical concentrated (each column) [kN]	100

Table 2: Geometrical and load pre-intervention characteristics

3 INTERVENTION SYSTEM

Because the proposed intervention strategy has been fully illustrated in [9] and [10], in the present paper, only a brief description is reported. Starting from the masonry-infilled original configuration (Figure 1a), the first step is the removal of the masonry infill (Figure 1b).

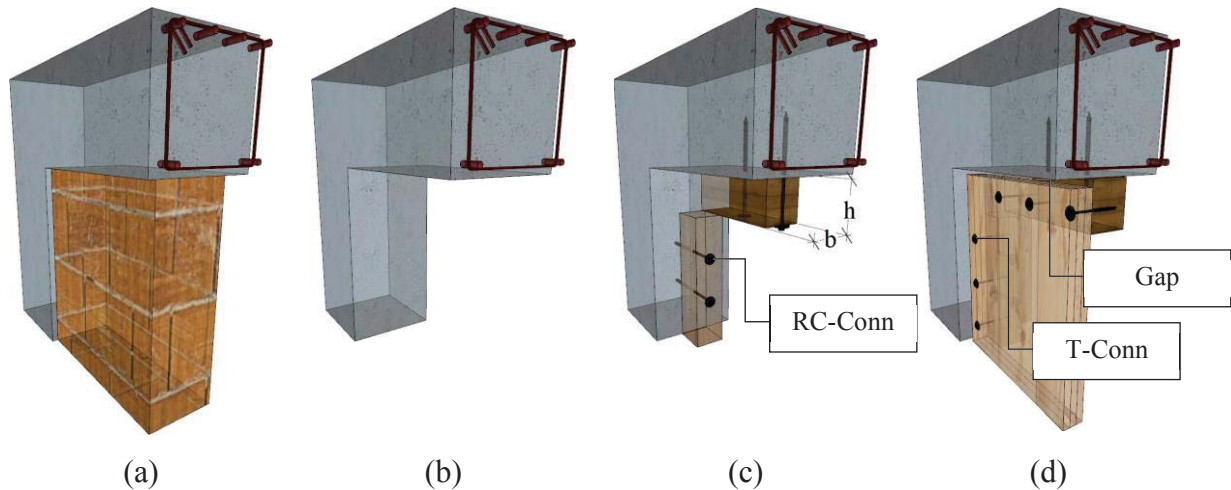

Figure 1: Intervention procedure

Subsequently, a timber subframe is connected to the RC elements through metal screw fasteners (Figure 1c). This connection is reported in Figure 2 and is named “RC-Conn” for the sake of brevity. It comprises partially-threaded concrete screws (named RC-F), inserted with washers (RC-W). The fasteners are regularly spaced at 15 cm and are designed not to exceed the elastic range when the structure is subjected to design-intensity earthquakes.

Figure 2: RC frame – timber subframe connection (RC-Conn)

In the last step of the implementation procedure (Figure 1d), a timber panel is inserted inside the RC frame and is connected to the timber subframe by using partially threaded timber screws (CLT-F) and washers (CLT-W) as those represented in Figure 3. This connection is named “T-Conn”. In the models described in the present paper, the screws were spaced at 10 cm. The role of the T-Conn is that of transferring the stresses from the timber subframe to the CLT panel and of dissipating seismic energy by engaging the post-elastic behaviour of the fasteners.

Figure 3: Timber subframe – CLT panel connection (T-Conn)

Table 3 and Table 4 give the geometrical characteristics of screws and washers, respectively.

	L [mm]	L_t [mm]	d_1 [mm]	d_2 [mm]
RC-F	200	80	12,0	8,8
CLT-F	120	60	10,0	6,4

Table 3: Geometrical properties for screws

	W_1 [mm]	W_2 [mm]	s [mm]
RC-W	44,0	13,5	4,0
CLT-W	30,0	10,8	6,4

Table 4: Geometrical properties for washers

At the perimeter of the CLT panel, between the panel edges and the internal faces of the RC frame there is a gap (visible in Figure 1d). This gap creates the necessary space for the insertion of the panel into the frame and, above all, ensures that the transfer of stress between the frame and the panel is governed by the T-Conn rather than by direct contact. In this way, it is possible to optimize the force-transfer mechanism so as to favour the development of ductile mechanisms (bending) instead of brittle failures (shear).

In the present study, the timber subframe is made of Glued Laminated Timber (grade class GL24h according to [19]) with $b \times h$ dimensions equal to 100×120 mm (Figure 1c), while the CLT panel (grade class C24 according to [20]) is 3-layered and 60 mm thick. The mechanical properties and the density of the timber elements are reported in Table 5 and were defined considering the relative Standard Codes [19], [20], and the studies of Bogensperger et al. (2011) [21], Harris et al. (2013) [22] and Gečys et al. (2015) [23].

	Bending f_m [MPa]	Tension $f_{t,0}$ [MPa]	$f_{t,90}$ [MPa]	Compression $f_{c,0}$ [MPa]	$f_{c,90}$ [MPa]	Shear f_v [MPa]	Density ρ [kg/m ³]
GL24h	24,0	19,2	0,5	24,0	2,5	3,5	420
C24	24,0	14,5	0,4	21,0	2,5	4,0	420

	Elastic modulus			Shear modulus			Poisson ratio		
	E_L [MPa]	E_R [MPa]	E_T [MPa]	G_{RL} [MPa]	G_{TL} [MPa]	G_{TR} [MPa]	ν_{RL}	ν_{TL}	ν_{RT}
GL24h	11500	300	300	650	650	65	0,00894	0,00894	0,538
C24	11000	370	370	690	690	69	0,0420	0,0270	0,602

Table 5: Mechanical properties and density for the timber elements

Additionally, in case of damage or collapse of the RC frame the use of structural CLT panel leads to a “bearing capacity reserve” for vertical actions. For this reason, the external layers of the CLT panel are oriented along the vertical axis.

4 NUMERICAL MODELS

In the present work, two different modelling approaches were used to investigate the RC-TP intervention system. The software Abaqus was used to develop 3-dimensional (3D) refined models (Figure 4a), while the software SAP2000 was used to develop 2-dimensional (2D) simplified models (Figure 4b). Specifically, the refined approach was calibrated based on experimental evidence available from the literature. Subsequently, it was used to investigate the connections implemented in the RC-TP intervention by reproducing them singularly. Furthermore, by using the 3D refined model it was possible to study possible secondary out-of-plane effects that could not have been directly observed with 2D models. The results obtained permitted to calibrate the simpler 2D models to account for the secondary effects with smaller computational effort than that required by the refined models.

Both the refined and the simpler models were used to analyse the above-mentioned RC frame under monotonic in-plane loading considering the bare, the masonry infilled and the retrofitted configurations.

Figure 4: Alternative numerical approaches: a) Refined 3D Abaqus model; b) Simplified 2D SAP2000 model

4.1 3D modelling

The present chapter focuses on the refined 3D modelling strategy used to reproduce the RC-TP intervention system previously described. This strategy was developed using the software Abaqus/Explicit and adopted to perform nonlinear dynamic quasi-static analyses under displacement-control.

In the definition of the analysis steps, the “target time increment” coefficient was calibrated through a sensitivity analysis so as to reduce the processing time to the minimum without affecting the quality of the numerical results.

With the purpose of verifying the absence of dynamic effects, and hence confirm the acceptability of the results, the ratio between internal and kinematics energy was checked a posteriori. As suggested by [24] and [25], this ratio should not exceed 10%. Thanks to the selection of an adequate “time step” and the application of a “smooth” displacement with a sufficiently small initial slope, it was possible to limit the dynamic effects within the predetermined range.

The refined 3D model is represented in Figure 5a. It was obtained by assembling the individual elements that compose the system (a few of these elements are visible in Figure 5b). The geometry of each element was carefully designed and then imported from a 3D CAD [26] environment.

Figure 5: Intervention system – refined 3D finite element model

Concrete frame, CLT panel, timber subframe, fasteners and washers were all modelled as three-dimensional solid elements (*3D solid part*) with a homogeneous solid section. Steel bars and stirrups, instead, were modelled as one-dimensional elements (*3D wire part*).

Regarding the definition of the materials, the steel elements (bars, stirrups, fasteners and washers) were simulated as isotropic elastic-plastic elements. The three layers that compose the CLT panel were obtained from the division of a single homogeneous solid element and are oriented alternately. Each layer was modelled as an elastic orthotropic material with Hill plasticity, as recommended by [27], where the failure surface was defined with reference to the $f_{c,0}$, $f_{c,90}$ and f_v strength values reported in Table 5. Because of the failure surface symmetry, the positive (tension) stress limit for each principal direction was assumed as identical to the related negative (compression) limit. It was therefore decided to refer to the values associated with the compression parallel and perpendicular to the grain. This choice is justified by the fact that the expected collapse mechanism sees the local bearing failure of the wood material in the proximity of the screw fasteners, which depends almost exclusively on the compressive strength parameters.

The timber subframe was modelled similarly to the layers of the CLT panel (i.e. elastic orthotropic material with Hill plasticity).

The concrete elements were simulated as homogeneous and isotropic, with a post-elastic behaviour based on the “Concrete Damage Plasticity” constitutive law available from the software library, which relies on the material fracture energy for governing the post-peak softening (for more details see [11]). The tension and compression curves for uniaxial loading are reported in Figure 6, where: $\sigma_t - \varepsilon_t$ and $\sigma_c - \varepsilon_c$ are the stress – strain values associated to tension and compression; E_0 is the initial elastic modulus; $\sigma_{t0} - \sigma_{c0}$ are the elastic stresses for tension – compression; σ_{cu} is the maximum compression stress.

Figure 6: “Concrete Damage Plasticity” behaviour

The interaction between steel reinforcements and frame elements was reproduced with an “Embedded region” constraint (Figure 7). This constraint implies a perfect adherence between the constrained elements.

Figure 7: Refined modelling approach – “Embedded region” constraint between concrete and the steel reinforcements

A general “Hard” contact was applied to all the solid elements of the model to avoid unrealistic material penetrations. Additional interaction properties were assigned to the surfaces between the elements (“Individual property assignments”) to reproduce the overall behaviour of the system. In particular, a “tangential behaviour” with penalty friction formulation was assigned to the contact surfaces (fasteners-washer, CLT panel-timber subframe, CLT panel-washer, timber subframe-washer, timber subframe-RC frame) using diversified frictional coefficients for the various surface types (e.g., Figure 8 shows the in-contact surfaces between metal fasteners and connected elements).

Figure 8: Refined modelling approach – Individual property assignments: fastener cylindrical contact-surfaces

The pull-out mechanisms associated with the threaded portion of the screw fasteners were modelled through a cohesive contact with an elastic uncoupled behaviour depending on K_n , K_s , K_t (stiffness associated respectively to the normal and the two shear-directions) for which, once the design strength is reached, a damage function reduces the tangential resistance (Figure 9).

Figure 9: Cohesive fracture energy – damage evolution

To obtain the above mentioned behaviour the "maximum nominal stress" (MAXS) option was selected [27]. As a consequence, the pull-out mechanism activates when Equation 1, which depends on the parameters t_n , t_s , t_t (normal and shear stresses) and t_n^0 , t_s^0 , t_t^0 (corresponding reference strength values), is satisfied.

$$\max \left\{ \frac{t_n}{t_n^0}; \frac{t_s}{t_s^0}; \frac{t_t}{t_t^0} \right\} = 1 \quad (1)$$

For the modelling of the contacts, the interacting surfaces were categorized into "master" and "slave" surfaces. The mesh characteristics played a fundamental role in the process of attributing the master/slave categories. For all solid components, prismatic "C3D8" elements were preferred to linear tetrahedral elements "C3D4" (which might lead to less reliable results) or quadratic tetrahedral elements "C3D10" (which imply longer analysis durations).

Because the solid models of the RC frame, CLT panel and timber subframe present numerous holes due to presence of the fasteners, it was necessary to partition the geometry to facilitate meshing. Sensitivity analyses were performed and meshes with diverse levels of refinement were adopted for different elements and for different areas in the same element. For example, in the CLT panel, the areas around the fastener holes required a more refined mesh with respect to the rest of the element (Figure 10).

Figure 10: RC-TP refined model – mesh

Once the main aspects of the model were defined, preliminary small-scale analyses were conducted with the aim of calibrating and validating the modelling parameters. The shear and pull-out behaviours of the fasteners were studied separately, considering both the connection with concrete and timber. The numerical results obtained were compared with experimental evidence available from the literature. As an example, Figure 11a and Figure 11b give the comparison between numerical results (red curves) and experimental results taken from [13] (for concrete pull-out) and from [15] (for timber shear) respectively.

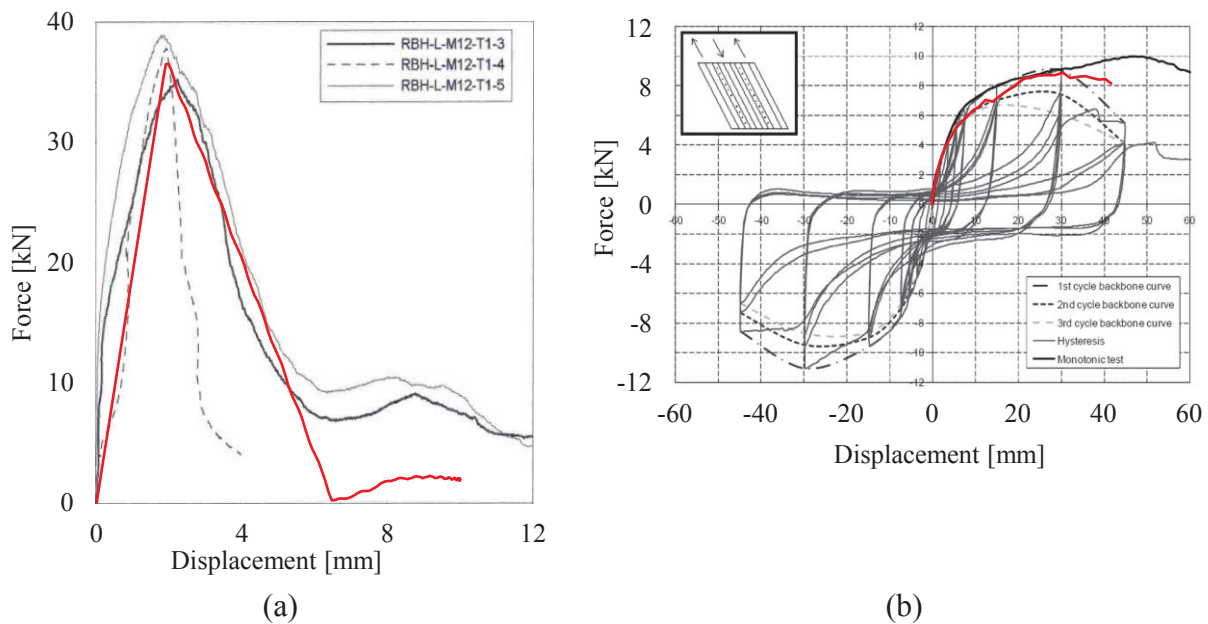

Figure 11: Numerical calibration and validation of the connection behaviour in the refined model (red curves) – comparison with experimental evidence: a) concrete pull-out, b) timber shear

For the original pre-intervention frame configuration, the masonry infill was treated similarly to the concrete elements. Specifically, the infill was modelled with a macro-modelling approach (Figure 12a) where mortar and bricks were represented by an equivalent homogeneous isotropic material (Figure 12b). The post-elastic behaviour was simulated by adopting the “Concrete Damage Plasticity” constitutive model (Figure 6) as suggested by [16]. With this

modelling strategy, it is possible to account for both rocking and diagonal shear failure mechanisms. The contact interaction between masonry and concrete is reproduced by a general “Hard” contact and a frictional “tangential behaviour”.

Figure 12: Refined modelling approach: a) masonry infilled frame; b) mortar and bricks represented as an equivalent homogeneous material

4.2 2D modelling

The present chapter focuses on the 2D modelling approaches adopted to simulate the bare frame, the original masonry-infilled frame and the retrofitted frame.

Regarding the retrofitted frame, the modelling strategy presented in this section Figure 13a) is an updated version of that exposed in detail in [9] and [10]. The main upgrades consist in an improved characterization of the non-linear properties of the elements and in an improved definition of the behaviour of the connections. By relying on the findings of the 3D refined models, the 2D approach was calibrated to account for possible out-of-plane secondary effects. The main characteristics of the 2D models are summarized in the following paragraphs.

The concrete frame was modelled by using *frame elements* capable of accounting for the nonlinear behaviour of concrete and steel. Deformation-controlled and force-controlled *hinge elements* were assigned at the extremities of columns and beams to consider respectively bending and shear collapse.

The nonlinear response of the beam-column joint was simulated by using two cross *nonlinear links* connected to the extremities of columns and beams. The joint model adopted herein has been proposed by Sung et al. (2013) [28] and it permits to account for the failure of the joints with small computational effort.

The CLT panel was modelled via *layered orthotropic nonlinear shell elements* where each of the three layers was assumed to be “inactive” along its weak direction.

The timber subframe was an *elastic frame element*. The validity of the elastic-behaviour assumption was confirmed a posteriori by investigating the subframe stress state.

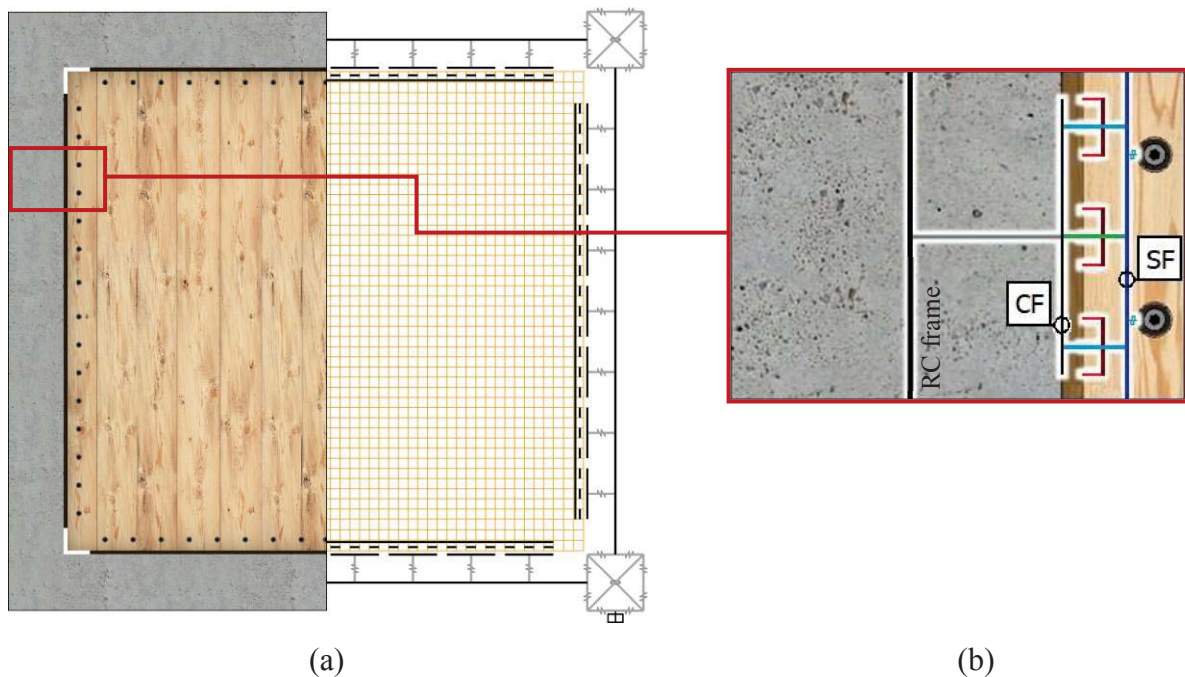

Figure 13: Simplified finite element model: a) Complete intervention system; b) Interaction system

As extensively described in [10], an “interaction system” reproduces the interaction between RC frame, timber subframe and CLT panel. In Figure 13b, it is possible to observe the frame elements that represent the middle line of the column “RC frame”, the internal face of the column “CF” and the middle line of the timber subframe “SF”.

The interaction system (Figure 13b and Figure 14a) is obtained from the overlap of a “connection system” and a “contact system”.

The connection system (Figure 14b) simulates the RC-Conn (represented by the *link elements* “CL”) and the T-Conn (represented by the *link elements* “TL”). In addition, this system simulates the contact-interaction between the timber subframe “SF” and the internal face of the concrete frame “CF”. This contact is governed by *gap link elements* “GL”.

The contact system (Figure 14c) replicates the direct contact between CLT panel and RC frame. This contact occurs when the gap between the CLT panel and the internal face of the RC frame (CF) goes to zero and it is reproduced by using *hook link elements* “HL”.

Figure 14: Interaction system between RC frame, timber subframe and CLT panel: (a) Complete interaction system; (b) connection system; (c) contact system

Table 6 reports a summary of the abbreviations used for the main elements and a brief description of the relative functions.

ID	Name	Functions
CF	Concrete Frame	<ul style="list-style-type: none"> - Massless rigid frame. - Represents the internal surface of the RC elements.
KF	Fake Frame	<ul style="list-style-type: none"> - Massless rigid frame. - Used as a support element in the contact system.
SF	Subframe Frame	<ul style="list-style-type: none"> - Elastic frame. - Geometrical characteristics of the timber subframe. - Positioned on the middle line of the timber subframe.
CL	Concrete fastener Link	<ul style="list-style-type: none"> - Nonlinear link. - Represents the RC-Conn.
FL	Frame-thickness Link	<ul style="list-style-type: none"> - Rigid link - Represents the in-plane semi-thickness of column and beams.

KL	Fake Link	<ul style="list-style-type: none"> - Rigid link. - Used as a support element in the contact system.

TL	Timber fastener Link	- Nonlinear link. - Represents the T-Conn..
----	-------------------------	--

Table 6: Interaction system – Abbreviations used and main functions

The nonlinear behaviour of CLs and TLs was defined based on the results obtained from the refined Abaqus 3D models because such models account for possible effects due to the out-of-plane eccentricity associated with the physical thickness of the various components. The details of the curves assigned to the CLs and TLs are given in the next section.

The response of the original masonry infilled system was simulated by using an equivalent diagonal struts model (Figure 15). This model was defined starting from the approaches proposed by Al-Chaar (2002) [17] and Liberatore et al. (2018) [18]. Specifically, the proposed masonry model consists of two eccentric diagonal rods, whose location in the RC frame is given by the provisions of [17], while the compression behaviour of the rods is defined according to [18]. The tensile strength of the diagonal elements reproduces the tensile strength of the masonry. Consequently, if a lateral force is applied as shown in Figure 15a, the two links work as strut and tie. The behaviour of each diagonal link is reported in Figure 15b, where the blue branch and the red branch represent the compression and the tension response respectively.

Figure 15: Original masonry-infilled system: a) Equivalent diagonal “strut and tie” model; b) Force-displacement response

According to [17], in order to consider the confinement produced by the masonry infill, the portions of beams and columns between the joints and the diagonal links are modelled as *rigid elements* (Figure 15a). Only the intermediate sections of columns and beams can therefore develop nonlinear responses.

5 NUMERICAL ANALYSES AND RESULTS

5.1 Preliminary analyses

The first step of the numerical study presented herein saw the simulation of isolated RC-Conn and T-Conn connections under pull-out and shear loading conditions. Several configurations were considered (e.g., pull-out tests carried out by pulling the screw directly or by pulling the subframe, or shear and pull-out tests performed “with and without” washers). Figure 16 shows the most relevant results: a) RC-Conn - push-out; b) RC-Conn - shear parallel to the subframe; c) T-Conn - shear perpendicular to the subframe; d) T-Conn - shear parallel to the subframe.

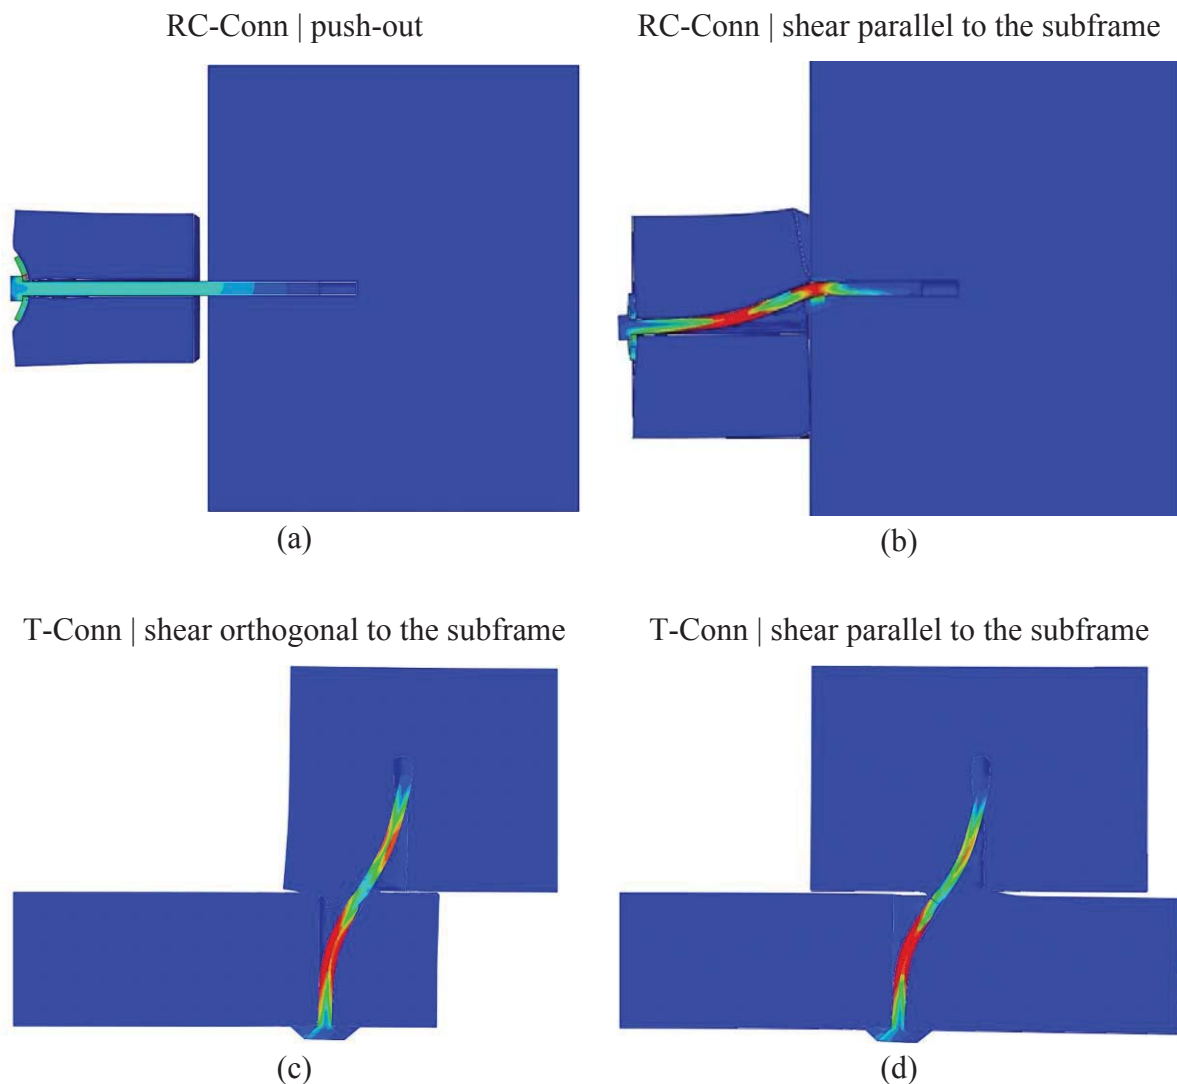

Figure 16: Tests on RC-Conn and T-Conn – stress contour

Subsequently, in order to account for possible out-of-plane displacements due to the eccentric interaction between RC frame – timber subframe – CLT panel, a test structure (referred to as "Test-Module") was defined (Figure 17). The size of the Test-Module was selected so as to replicate the “base-unit” of the retrofit system. Because the RC-Conns have a 15 cm spacing and the T-Conns have a 10 cm spacing, the Test-Module comprise two RC-Conn and three T-Conn fasteners.

Figure 17: “Test-Module”

The out-of-plane effects observed from the analysis of the Test-Module were included in the simplified 2D models through the response-curve attributed to the TL and the CL elements (for labelling details please see Table 6). In particular, such secondary effects were found to be non-negligible when the force was applied in the Z-direction (Figure 18a).

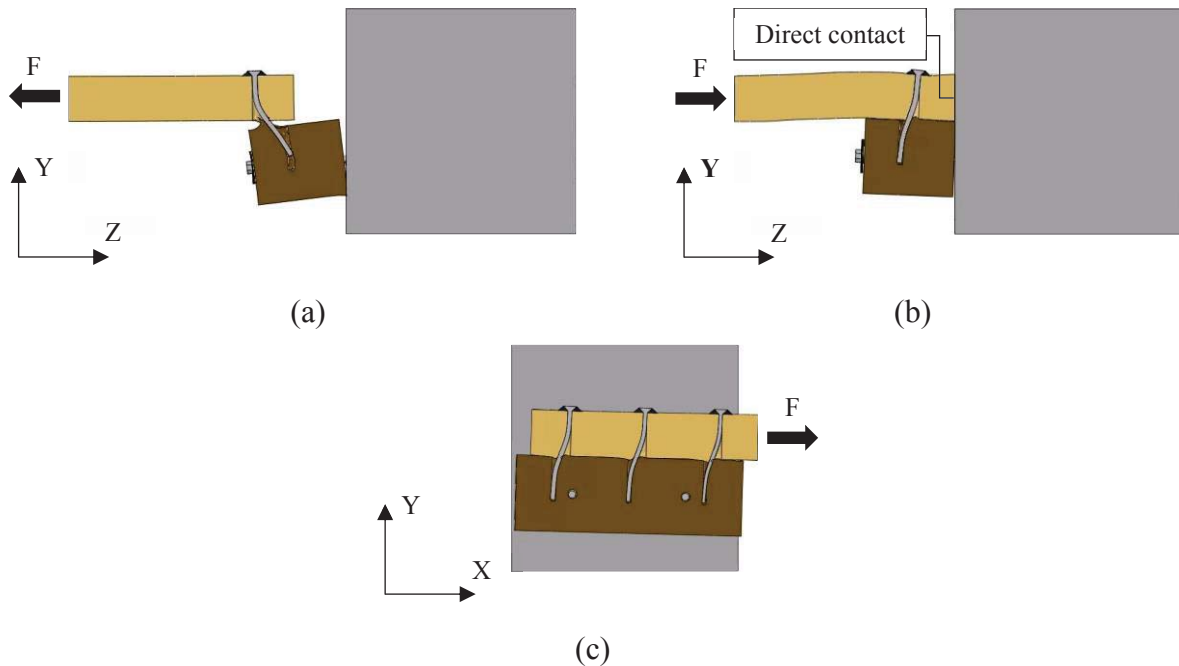

Figure 18: “Test-Module” – out-of-plane secondary effects

Figure 19 shows the backbone curves of the T-Conn shear tests (Figure 19a) and RC-Conn pull-out tests (Figure 19b). The green curves were obtained from the 3D model neglecting the secondary effects by restraining the out-of-plane movements. The blue curve obtained with the refined model considering the secondary effects. The red curves, which are the idealized versions of the blue curves, were subsequently implemented in the 2D model to account for the secondary effects.

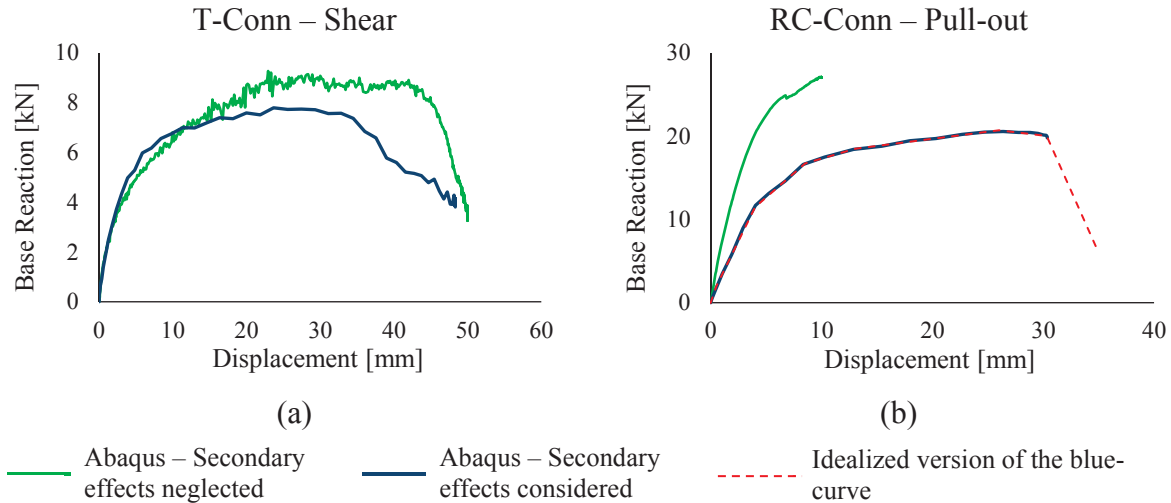

Figure 19: Backbone curves from single-connection tests: a) T-Conn shear; b) RC-Conn pull-out

Figure 20 shows the response of the Test-Module obtained by using the 3D refined modelling approach and the 2D modelling approach (with secondary effect accounted for). In particular, in Figure 20a, the force applied to the panel was parallel to the X-direction (Figure 18c), while in Figure 20b the panel was pulled and pushed in the Z-direction (see Figure 18a and Figure 18b).

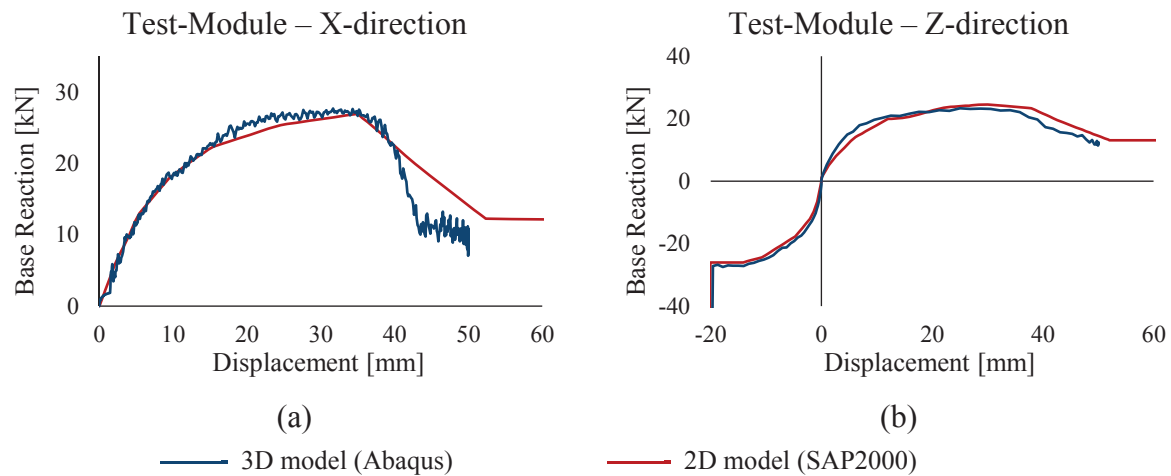

Figure 20: Behaviour of the Test-Module obtained with the 3D (blue) and the 2D (red) approach: a) X direction; b) Y direction

As it is possible to observe from the graphs, the outcomes of the two modelling approaches are consistent for both test configurations. When including the out-of-plane secondary effects in the 2D model, it was possible to match closely the curves from the 3D model at a much smaller computational effort. As visible from Figure 20b, it is interesting to notice that both the 3D and the 2D models experienced a sudden stiffness increase at a negative displacement close to -20 mm. This increase is due to the gap between the CLT panel and the RC frame (represented by the HL elements in the 2D model) that goes to zero involving a direct contact (observable from Figure 18b).

5.2 Full-scale one-storey one-bay frame

After having calibrated the 2D modelling approach on the results from the connection tests studied with the 3D approach, and having proof-checked the correspondence between the approaches through the analysis of the Test-Module, the case-study frame described in section 2 was modelled.

The one-storey, one-bay frame was analysed considering three alternative configurations: Bare frame (Figure 21a), Masonry infilled frame (Figure 21b) and RC-TP retrofitted frame (Figure 21c). Based on the findings reported in [9] and [10], the optimal RC-TP configuration for the case-study frame was assumed to be that having a GAP of 20 mm and T-Conns arranged only along the beams.

The three frame configurations were analysed with both modelling approaches via nonlinear static analysis. In the first step, the vertical loads (values reported in Table 2) were applied to the columns and the upper beam. Then, the in-plane horizontal force was introduced at the top joint level and was incremented until the collapse of any of the structural elements was reached.

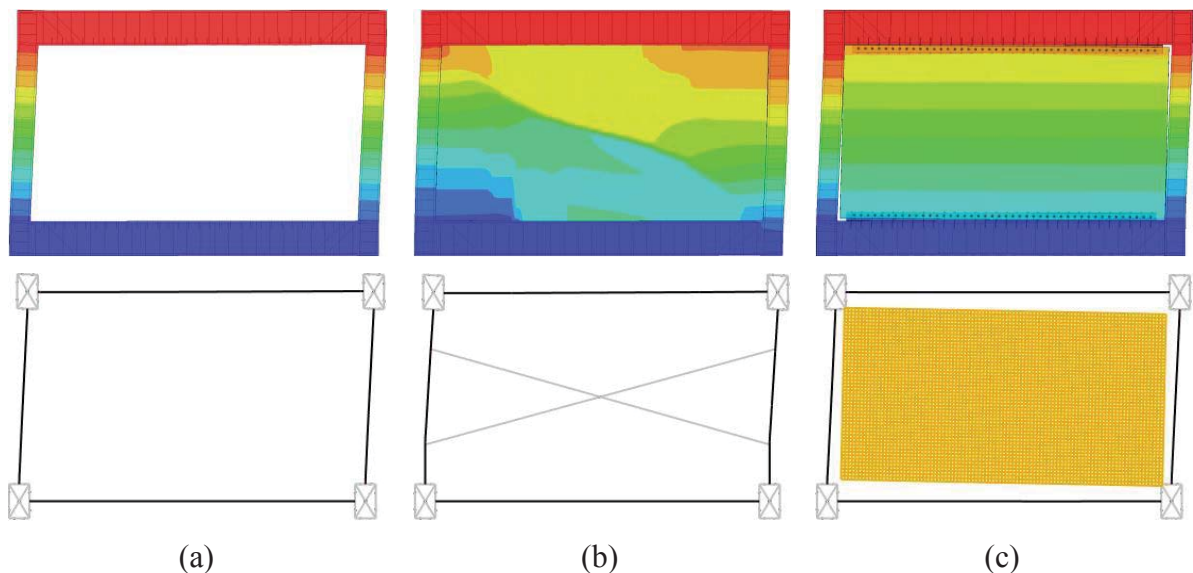

Figure 21: 3D and 2D models of the case-study frame configurations: a) Bare frame; b) Masonry infilled frame; RC-TP retrofitted frame

Figure 22: Isolated frame backbone curves – comparison between the 3D and the 2D modelling approach

Figure 22 reports the results obtained by performing the nonlinear static analyses of the isolated frame in the three configurations and using both modelling approaches. Both numerical strategies produced consistent results, showing similar behaviours for all the analysed configurations in terms of stiffness, strength and failure mechanism.

For all three configurations the frame collapsed due to the bending failure of the concrete column. However, for the masonry infilled frame, the column failure was preceded by the collapse of the infill which caused an evident reduction in the load bearing capacity at a displacement level close to 20 mm. The retrofitted frame, instead, showed a remarkable increase in the bearing capacity, with the peak capacity at a displacement of approximately 40 mm. The bending failure of the concrete columns in the retrofitted frame occurred at displacement values similar to those observed in the bare frame, attesting that the proposed intervention does not impede the full development of the column flexural ductility.

6 CONCLUSIONS

The present paper reports the results of a numerical study on a retrofit intervention for existing RC masonry infilled structures. The intervention, named RC-TP, is aimed at reducing the seismic vulnerability of this kind of structure by replacing the masonry infills with timber panels connected to the RC-frame with screw-fasteners. The present research focused on the modelling of the pre- and post- intervention system via two alternative numerical strategies with different levels of refinement. In particular, a 3D refined modelling approach and a 2D simpler modelling approach were investigated. Preliminary analyses on isolated connections permitted

both to validate the 3D modelling approach on experimental evidence available from the literature, and to calibrate the 2D models to account for secondary effects that cannot be directly observed by two-dimensional models. Consequently, an isolated one-storey one-bay concrete frame representative of the built stock of many Countries was modelled using both strategies and considering the “bare”, the “masonry infilled” and the “retrofitted” configurations. The RC frame was subjected to nonlinear static analyses until the collapse of any of the structural elements was reached. The analysis outcomes showed that the proposed retrofit system can effectively reduce the seismic vulnerability of existing masonry infilled RC frames, consistently with the findings of preliminary studies previously published. By virtue of the good correspondence between the refined 3D approach and the less refined but computationally far more efficient 2D approach, future steps of the research will be devoted to using the 2D models for extensive parametric studies on all the details affecting the performance of the timber-panel strengthening technique discussed herein.

7 ACKNOWLEDGEMENTS

The research work was carried out within the framework of the 2019-2021 ReLUIS-DPC network (Italian University Network of Seismic Engineering Laboratories and Italian Civil Protection Agency).

Abstract

In the aftermath of the 2014 South Napa Earthquake, several failures of fire-sprinkler systems were observed. The failures were related to excessive displacements of these systems leading to an uncontrolled interaction with the surrounding nonstructural components, e.g., suspended ceiling systems, light fixtures, and ventilation ducts. The large displacements of the fire-sprinkler system can be related to the support elements with under-designed flexibility and/or failures of the support elements in which demand exceeded capacity. In addition to the excessive interaction with the surrounding nonstructural components, the large displacements can result in failures of the joints that are designed to accommodate only a limited rotation. To investigate the seismic performance of a typical fire-sprinkler system, a building in Napa, California (USA) was selected. A fire-sprinkler system in this building was damaged by the 2014 South Napa Earthquake and the damages were captured in 3D with high accuracy by a laser scanner. A finite element model of this building was generated and studied earlier but was limited to elastic models of both the building and the fire-sprinkler system. Artificially large amplifications of the seismic excitation over the elevation of the building were observed. The building's model was evaluated based on the ambient vibration tests. Amplification of the seismic excitation over the elevation was estimated from an instrumented building with a similar design and resonant frequencies. The amplified seismic impact was imposed on the fire-sprinkler system, which was modelled as a system with nonlinear behavior.

Keywords: Fire-sprinkler System, Seismic Performance, Nonstructural Components, Ambient Vibration Study, Nonlinear Modelling.

1 INTRODUCTION

A fire-sprinkler system represents a complex piping system suspended from the ceiling that spreads out in space and consists of many joints. To investigate the seismic performance of a typical fire-sprinkler system, a building in Napa, California (USA) was selected. The fire-sprinkler system in this building was damaged by the 2014 South Napa Earthquake and the damages were captured in 3D with high accuracy by a laser scanner. A finite element model of this building was generated and studied earlier [1] but it was limited to elastic models of both the building and the fire-sprinkler system. In this study, artificially large amplifications of the seismic excitation over the elevation of the building were observed. To address this shortcoming, a new model of the building and the fire-sprinkler system was generated. The building's model was calibrated based on the ambient vibration tests. Amplification of the seismic excitation over the elevation was estimated from an instrumented building with a similar design and resonant frequencies.

2 AFTERMATH ANALYSIS BY LASER SCANNING

Immediately after the 2014 South Napa Earthquake, the parking structure with a failed fire-sprinkler system was laser scanned by means of a C10 ScanStation from Leica Geosystems [2]. A global view of the building taken from Google Earth is shown in Figure 1a. The overall view of the point cloud collected during this scanning project is presented in Figure 1b. The point cloud presented in Figure 1b is a registration of point clouds collected from more than 14 stations throughout the structure. The point cloud registration was conducted in Cyclone from Leica Geosystems [3].

Figure 1: Overall view of the parking structure.

As was discussed in the earlier paper [1], most failures of the fire-sprinkler system were observed on the 3rd floor of the structure, the structure's highest elevation, where the suspended fire-sprinkler system was located. In other words, this was the highest floor with a ceiling from which the system can be suspended. Therefore, this elevation was studied in more detail and 13 stations of the laser scanning project were conducted on this floor. As a result, all failures of the fire-sprinkler system were documented within a few millimeters of accuracy. In addition, the failures were captured from many points by the still imaging camera built into the scanner. A detailed discussion of the failures was provided in [1].

3 RESULTS OF AMBIENT VIBRATION STUDY

A solid element model of the parking structure was generated earlier. It was based on the geometry captured by the laser scanner and a few assumptions about the materials used in the structure's construction. To access the actual performance characteristics of the structure, an

ambient vibration study was conducted. It was conducted on the top floor of the parking structure from which the fire-sprinkler system was suspended as presented in Figure 2a.

A portable data acquisition system (PI-6008U from Pacific Instruments [4]) was used in this study. The system has a flexibility in its power supply and as one of the available options it can be powered by a car battery. This power supply option was used in this study. The acceleration of the ambient vibrations was recorded.

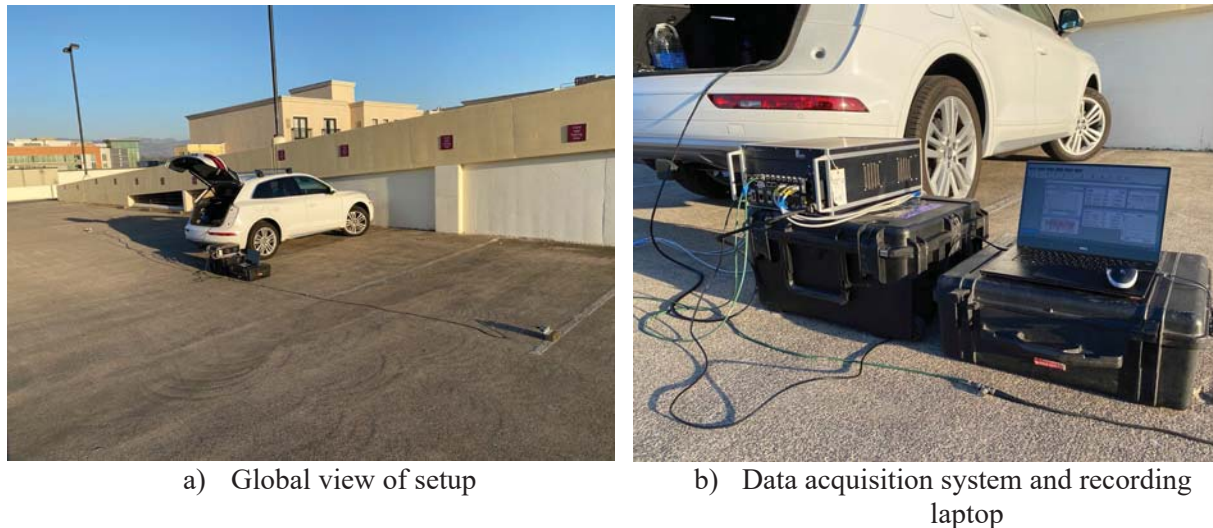

Figure 2: Setup of ambient vibration study.

Three different models of accelerometers were used. Two of them were of a piezoelectric type and the third one was a MEMS accelerometer. The results for one of the piezoelectric accelerometers discussed herein. The MEMS accelerometer was triaxial, therefore only the orientation of the piezoelectric accelerometers was changed to measure the structure's response in all three principal directions. The orientations of the piezoelectric accelerometer in Z and X are shown in Figure 3. The orientation of the accelerometer to measure the response in Y direction is presented in Figure 4a. The latter shows an example of another piezoelectric accelerometer. For comparative analysis of the MEMS and the piezoelectric accelerometer, both were installed on the same block as presented in Figure 4b.

Figure 3: Orientations of accelerometer to measure response in Z and X.

Figure 4: Orientation of accelerometer in Y and two accelerometers sharing at the same location for a comparative study.

Typical results of the ambient vibration study are presented in Figure 5. Both plots show Fast Fourier Transforms of the acceleration records. The plot on the left is obtained for the orientation in the transversal axis of the structure and the plot on the right corresponds to the records obtained for the longitudinal orientation of the accelerometer. Based on these plots, the lowest resonant frequencies of the structure are 4.8 Hz and 6.9 Hz in the transversal and longitudinal directions, respectively.

It is worth noting that both resonant frequencies of the structure are located within the frequency range of the AC156's spectral plateau [5].

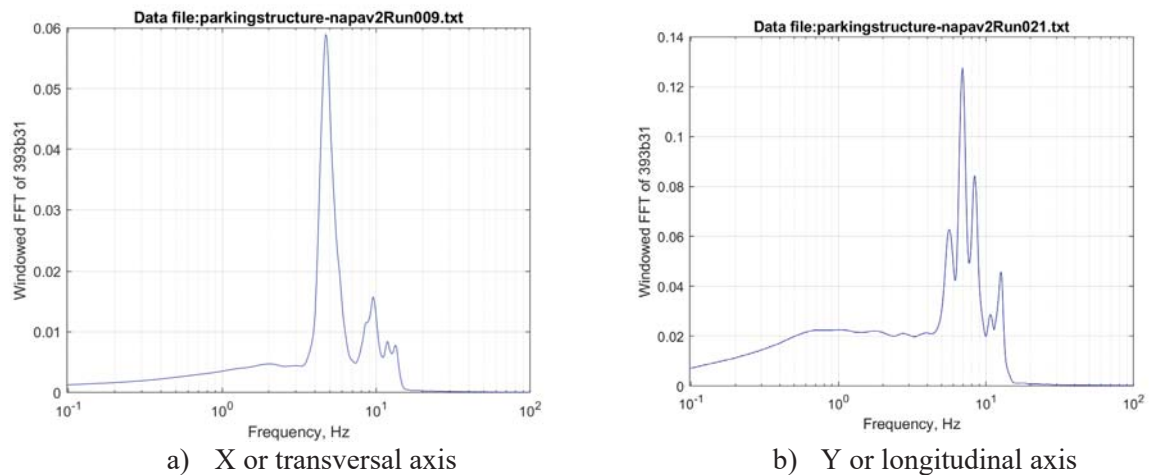

Figure 5: Results of ambient vibration study.

4 TIME HISTORY BASED ON AC156 SPECTRA

A selection of a time history for the finite element analysis was based on requirements of AC156. The hazard level at the site was taken from the USGS's maps [6]. The S_s values for California are presented in Figure 6a. In this figure the legend shows the correlation between the color and range of S_s expressed in percent of g. Figure 6b shows the close-up view of

these maps with the city of Napa shown in the magenta box. A tri-axial time history satisfying the requirements of AC156 was developed earlier [7] and had been utilized for the non-structural testing at the Pacific Earthquake Engineering Center (PEER) – UC Berkeley for quite some time. It was scaled accordingly, assuming a maximum value of S_S for Napa.

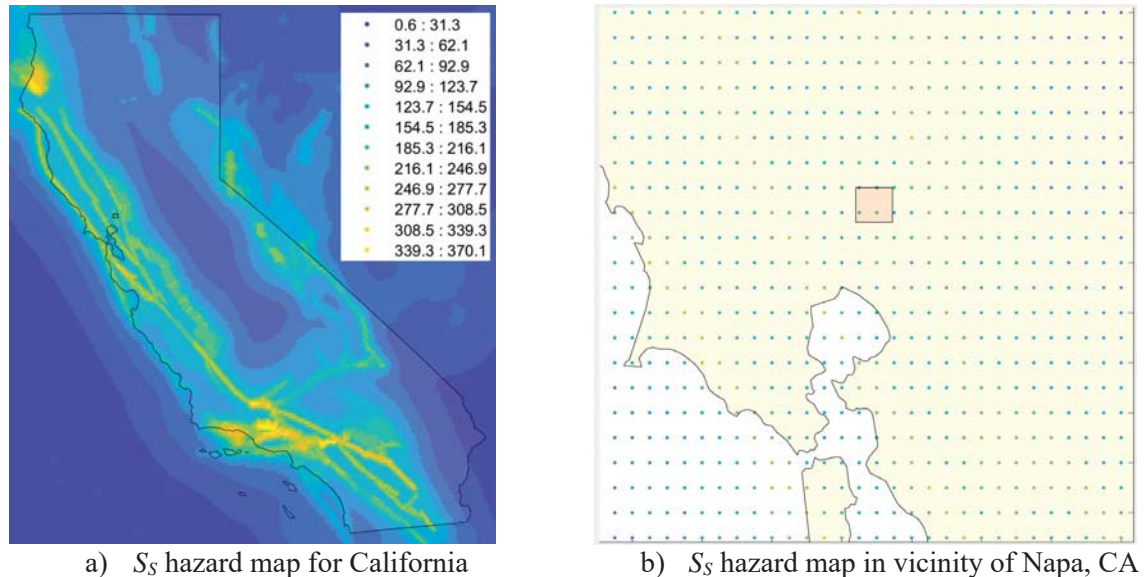

Figure 6: Hazard maps

5 FINITE ELEMENT MODEL

All modelling was conducted in SAP2000 [8]. The finite element model of the piping system is presented in Figure 7. It was generated based on the laser scans. It consists of the main supply constructed of a 114-mm pipe that branches out to a 50-mm pipe with sprinkler heads at the very end. The 114-mm pipeline consists of 3 major sections. Section 1 of the main supply runs along the length of the structure and is parallel to the horizontal ceiling or the third floor. Section 2 is shorter and runs across the width of the structure. Section 3 also runs along the structure's length, but it is inclined to accommodate the sloped ceiling of the ramped section of the floor as opposed to Section 1.

Figure 7: Finite element model of fire-sprinkler system.

All pipes were modelled as frames in SAP2000 terminology. The intersection points between the beams and the 114-mm pipelines were modelled as frictionless rollers allowing the

pipe to move along its longitudinal axis and restraining the pipe in both the vertical and transverse directions. The effective mass of the pipelines was increased to account for the weight of the water inside the pipes.

Typical installations of rods used for suspending the piping system from the ceiling are shown in Figure 8. The supporting rods were modelled as rods with rigid connections to the pipes and the ceiling. Since the actual installation used the threaded rods, the effective diameter of the rods was reduced accordingly, and they were also modelled as elastic frames in the first stage of analysis.

Figure 8: Typical installation of supporting rods.

Based on the results of the time history analysis of the elastic FE element model, it was concluded that the bending stress in a few supporting rods is below the yielding stress of mild steel. Nevertheless, failures of the supporting rods were observed as presented in Figure 9.

Figure 9: Typical failures of supporting rods [1].

The failure in the right image is related to the low-cycle fatigue capacity of the smaller rods in bending. As opposed to that, the left image shows a failure of the larger supporting rod that resulted from the failure of the anchoring part of the rod. The anchor's depth was not sufficient to avoid a failure of the concrete. These nonlinear effects will be modelled in the next stage of the finite element modelling. This part of the finite element modelling is ongoing. In this stage a number of component tests will be performed to generate a realistic model.

6 ACKNOWLEDGMENTS

The laser scans were collected during operations of nees@berkeley which was supported by the National Science Foundation (NSF). Special thanks are due to Smart Scanning Solutions, LLC (Tashkent, Uzbekistan) for the extensive work on converting the point cloud into solids. The authors would like to acknowledge Sensor Fusion and Monitoring Technologies, LLC (USA) for providing access to the portable data acquisition system. Special thanks are due to Holly Halligan of UC Berkeley for editing the paper.

7 CONCLUSIONS

- Based on the laser scans of a parking structure a finite element model of the fire-sprinkler piping system was generated.
- To estimate the dominant frequencies of the structure it was studied via ambient vibration tests.
- A few assumptions were made for the first stage of modelling. The resulting simplified model was studied in a linear time history analysis.
- The results of the first stage clearly show larger stresses as the locations of the observed failures, although they were below the yielding stress of mild steel.
- The first stage analysis shows a strong need for non-linear analysis based on component testing of typical connections. This part of the study is ongoing.

Keywords: Deformable rocking model, overturning, rocking maps, one-sine impulse, seismic excitation.

Abstract. *In this paper the possibility to improve the dynamic and seismic response of cabinets that can exhibit rocking dynamics is investigated. The generic cabinet is modelled as an assembly of rigid components and can undergo a change of configuration. The scope of the research is to verify if the allowed deformation could protect the cabinet by preventing the overturning or reducing the amplitude of rocking oscillations. The control of the deformation is obtained by using linear visco-elastic devices, whose mechanical characteristics are at the base of the parametric analysis performed in the paper. An extensive parametric analysis is carried out by numerically integrating the equations of motion. The effectiveness of this protection method is analyzed by comparing the behaviour of rigid and deformable cabinets under one-sine pulse and seismic excitations. For the one-sine pulse excitation, the comparison is made with overturning spectra that provide the amplitude of the excitation able to overturn the cabinets versus its circular frequency. For the seismic excitation, the comparison is performed by using different registered earthquakes and comparing the maximum rocking angle reached during the motion. The results show that the ability of cabinets to change their configuration improves the dynamical and seismic performances compared to those of the equivalent rigid cabinets.*

1 Introduction

The protection of rigid blocks from the overturning is a fascinating argument in the scientific literature. Most of the studies on the protection of rigid blocks from overturning are focused on the use of external devices such as base isolation [1, 2, 3, 4, 5] and base anchorages [6, 7]. Several authors used mass-dampers, that have been modeled either in the shape of a pendulum [8, 9, 10, 11] or as a single degree of freedom mass running on the top of the rigid body [12, 13, 14]. Some researchers studied the use of semi-active anchorages [15, 16] or base active control systems [17, 18, 19] to increase the amplitude of base excitation required to topple a rigid body.

This paper investigates the dynamic and seismic response of cabinets that are constituted by four external panels, hinged to each other in the four vertexes of the body. Four linear visco-elastic devices of equal characteristics are associated with these hinges. Due to this particular configuration, the body can deform as an articulated quadrilateral. Additionally, it is assumed that the body can undergo a rocking motion but cannot slide. The equations of motion are obtained by a Lagrangian approach. Two different impacts are considered in the paper: the classical impact of the base of the body with the support during the rocking motion and the impact on security stops, needed to limit the maximum angular deformation.

The model presented here is conceptually similar to the flexible rocking body models presented in [20, 21, 22] or [23], where the flexible rocking model was used to interpret the experimental response of tuff walls. However, the novelty of the paper is not in the description of a flexible rocking structure but in the investigation of the behaviour of a structure where specific devices are added to guide its deformation with the aim of reducing the amplitude of the rocking oscillation and preventing the overturning.

An extensive parametric analysis is performed by numerically integrating the equations of motion. The effectiveness of this protection method is analyzed by comparing the behaviour of rigid (i.e., with fixed connections) and deformable cabinets under one-sine pulse and seismic excitations. For the one-sine pulse excitation, the comparison is made with overturning spectra that provide the amplitude of the excitation able to overturn the cabinets versus its circular frequency. For the seismic excitation, the comparison is performed by building rocking maps that are contour plots of the maximum rocking angle in a specific parameter plane. Different recorded earthquakes have been used in the simulations.

2 Mechanical model of the cabinet

The mechanical system used to schematize the cabinet is shown in Fig. 1a. The perimeter panels are connected through hinges and four equal Kelvin-Voight devices in the vertexes of the cabinet (see Fig. 1a). With this particular structure, the mechanical system can deform as an articulated quadrilateral and its kinematics would be undetermined without the Kelvin-Voight devices. The vertical distance h between two consecutive shelves is constant so the total height of the cabinet is $4h$. The base of the cabinet has a dimension $2b$ and its depth (i.e., the dimension orthogonal to the plane of Fig. 1) is $d = 1.0\text{m}$.

All panels have a thickness $s = 0.02\text{m}$ and a bulk density $\rho = 650\text{kg/m}^3$ (i.e., chipboard wood). The cabinet may contain additional masses placed on the shelves. Such masses are quantified multiplying a bulk density $\rho_{fill} = 130\text{kg/m}^3$ for the volume between two consecutive horizontal panels and are added to the mass of the panel on which they are placed. Considering also the additional masses M , the masses of the seven panels m_j ($j = 1, \dots, 7$) are evaluated as

$$\begin{aligned} m_{1,3} &= \rho \cdot d \cdot s \cdot 4h \\ m_{2,4-7} &= \rho \cdot d \cdot s \cdot 2b + M \end{aligned} \quad (1)$$

It is assumed that the additional mass M is located in the same mass centre of the panel on which it is placed and that there is no inertia moment associated to these masses. Since the sliding of the cabinet is prevented, the motion of the body can be divided into two different phases: (i) the full-contact phase, where the body deforms as an articulated quadrilateral (Fig. 1b), and (ii) the rocking phase, where the body rotates alternatively around one of its base corners and deforms at the same time (Fig. 1c). The Lagrangian parameter $\theta(t)$ describes the deformation of the cabinet, whereas the parameter $\psi(t)$ describes the rocking motion.

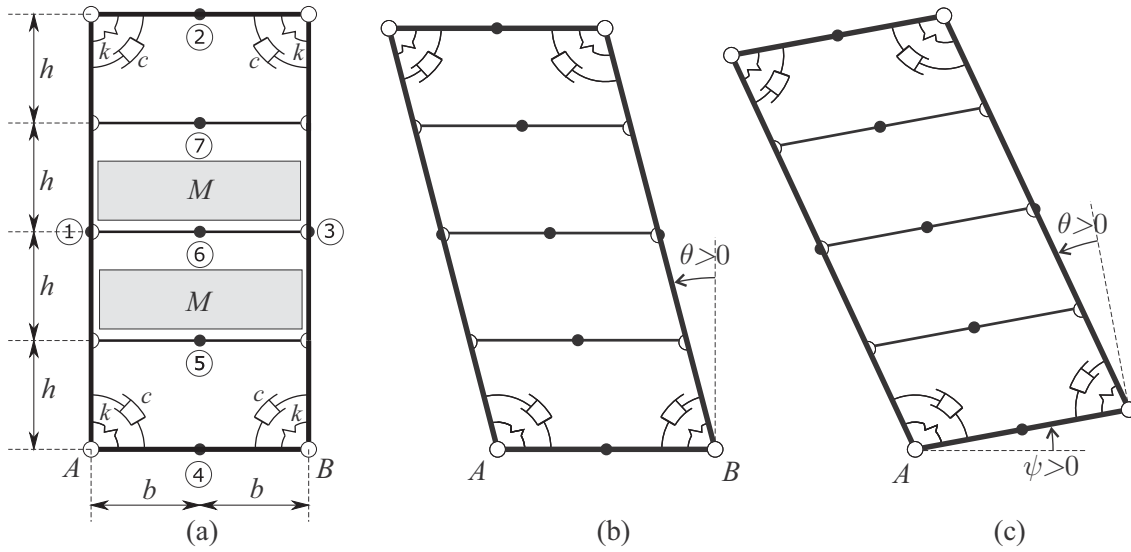

Figure 1: Model: (a) Geometrical characterization; (b) Full-contact deformed configuration; (c) Rocked and deformed configuration.

2.1 Equations of motion

The equations of motion are obtained through a Lagrangian approach. For brevity, only the equations of the rocking phase around the left corner A are presented in this section. The equations of the full-contact phase can be obtained by those of the rocking phase by neglecting the angle $\theta(t)$ and its time-derivatives ($\theta(t) = \dot{\theta}(t) = \ddot{\theta}(t) = 0$). The two equations of motion of the body that rocks around the left base corner read:

$$\begin{aligned} & h^2 (4m_1 + 16m_2 + 4m_3 + m_5 + 4m_6 + 9m_7) [\psi''(t) + \theta''(t)] - \\ & bh (4m_2 + 4m_3 + m_5 + 2m_6 + 3m_7) \{ \psi''(t) \sin[\theta(t)] - \psi'(t)^2 \cos[\theta(t)] \} - \\ & h (2m_1 + 4m_2 + 2m_3 + m_5 + 2m_6 + 3m_7) g \sin[\theta(t) + \psi(t)] - \\ & h (2m_1 + 4m_2 + 2m_3 + m_5 + 2m_6 + 3m_7) x_{gr}''(t) \cos[\theta(t) + \psi(t)] + \\ & (J_1 + J_3) \theta''(t) + 4c\theta'(t) + 4k\theta(t) = 0 \end{aligned} \quad (2)$$

$$\begin{aligned}
 & (J_1 + J_2 + J_3 + J_4 + J_5 + J_6 + J_7)\psi''(t) + \\
 & b^2 (m_2 + 4m_3 + m_4 + m_5 + m_6 + m_7) \psi''(t) - \\
 & 2bh (4m_2 + 4m_3 + m_5 + 2m_6 + 3m_7) \psi''(t) \sin [\theta(t)] - \\
 & 2bh (4m_2 + 4m_3 + m_5 + 2m_6 + 3m_7) \psi'(t) \theta'(t) \cos [\theta(t)] + \\
 & h^2 (4m_1 + 16m_2 + 4m_3 + m_5 + 4m_6 + 9m_7) [\psi''(t) + \theta''(t)] + \\
 & b (m_2 + 2m_3 + m_4 + m_5 + m_6 + m_7) \{g \cos [\psi(t)] - \sin [\psi(t)] x''_{gr}(t)\} - \\
 & bh (4m_2 + 4m_3 + m_5 + 2m_6 + 3m_7) \{\theta''(t) \sin [\theta(t)] + \theta'(t)^2 \cos [\theta(t)]\} - \\
 & h (2m_1 + 4m_2 + 2m_3 + m_5 + 2m_6 + 3m_7) g \sin [\theta(t) + \psi(t)] - \\
 & h (2m_1 + 4m_2 + 2m_3 + m_5 + 2m_6 + 3m_7) x''_{gr}(t) \cos [\theta(t) + \psi(t)] = 0
 \end{aligned} \tag{3}$$

Eq. 2 models the deformation of the body and Eq. 3 models the rocking motion. In the remaining of the paper, the dependence of θ , ψ , and x_{gr} on t is omitted.

2.2 Uplift conditions

The uplift acceleration a_{UP}^A , able to uplift the body around A coincides with the expression of x''_{gr} obtained from Eq. 3 when $\dot{\psi} = \ddot{\psi} = 0$

$$\begin{aligned}
 a_{UP}^A = & \{bg (m_2 + 2m_3 + m_4 + m_5 + m_6 + m_7) - \\
 & bh (4m_2 + 4m_3 + m_5 + 2m_6 + 3m_7) [\theta'' \sin (\theta) - \theta'^2 \cos (\theta)] - \\
 & gh (2m_1 + 4m_2 + 2m_3 + m_5 + 2m_6 + 3m_7) \sin (\theta) + \\
 & h^2 (4m_1 + 16m_2 + 4m_3 + m_5 + 4m_6 + 9m_7) \theta''\} / \\
 & [h(2m_1 + 4m_2 + 2m_3 + m_5 + 2m_6 + 3m_7) \cos (\theta)]
 \end{aligned} \tag{4}$$

The uplift acceleration a_{UP}^A depends on the geometry of the cabinet and on its deformation during the full-contact phase (i.e., depend on θ , $\dot{\theta}$ and $\ddot{\theta}$).

2.3 Impact conditions

The model presented in this paper considers two different kinds of impact: (i) the impact between the base of the cabinet and the support during the rocking motion and (ii) the impact on security stops that are used to limit the deformation of the cabinet.

The impact conditions referring to a cabinet that after an impact re-uplifts around the left corner A are obtained assuming that the cabinet position after the impact remains unchanged, the angular momentum of the whole cabinet around the re-uplifting corner A is preserved, and the horizontal momentum of the cabinet is also preserved. Under such assumptions, it is possible to evaluate the post-impact angular velocities $\dot{\theta}^+$ and $\dot{\psi}^+$ as functions of the pre-impact angular velocities $\dot{\theta}^-$ and $\dot{\psi}^-$

$$\dot{\theta}^+ = \dot{\theta}^- + r_{\theta}(\theta) \dot{\psi}^-; \quad \dot{\psi}^+ = s_{\theta}(\theta)(\dot{\theta}^- - \dot{\theta}^+) + s_{\psi}(\theta) \dot{\psi}^- \tag{5}$$

where

$$r_{\theta}(\theta) = \frac{\left[4b^2 (2m_1 + m_2 + m_4 + m_5 + m_6 + m_7) - 2bh (2m_1 + 4m_2 + 3m_3 + m_5 + 2m_6 + 2m_7) \theta \right]}{\left[b^2 (m_2 + 4m_3 + m_4 + m_5 + m_6 + m_7) - bh (8m_2 + 8m_3 + 2m_5 + 4m_6 + 6m_7) \theta + h^2 (4m_1 + 16m_2 + 4m_3 + m_5 + 4m_6 + 9m_7) \theta^2 + 4h^2 (m_1 + m_3) + J_2 + J_4 + J_5 + J_6 + J_7 \right]} \tag{6}$$

$$s_\theta(\theta) = \frac{h^2(16m_2 + m_5 + 4m_6 + 9m_7) + J_1 + J_3}{\left[\frac{J_A - bh(8m_1 + 8m_2 + 2m_5 + 4m_6 + 6m_7)\theta + h^2(4m_1 + 16m_2 + 4m_3 + m_5 + 4m_6 + 9m_7)\theta^2}{h^2(4m_1 + 16m_2 + 4m_3 + m_5 + 4m_6 + 9m_7)\theta^2} \right]} \quad (7)$$

$$s_\psi(\theta) = \frac{\left[\frac{J_A - 2bS_{yB} + bh(4m_1 - 4m_3)\theta + h^2(4m_1 + 16m_2 + 4m_3 + m_5 + 4m_6 + 9m_7)\theta^2}{J_A - bh(8m_1 + 8m_2 + 2m_5 + 4m_6 + 6m_7)\theta + h^2(4m_1 + 16m_2 + 4m_3 + m_5 + 4m_6 + 9m_7)\theta^2} \right]}{\left[\frac{J_A - bh(8m_1 + 8m_2 + 2m_5 + 4m_6 + 6m_7)\theta + h^2(4m_1 + 16m_2 + 4m_3 + m_5 + 4m_6 + 9m_7)\theta^2}{h^2(4m_1 + 16m_2 + 4m_3 + m_5 + 4m_6 + 9m_7)\theta^2} \right]} \quad (8)$$

The quantities $r_\theta(\theta)$, $s_\theta(\theta)$, and $s_\psi(\theta)$ play the role of restitution coefficients and depend on the deformed configuration of the system. Inside their expressions, J_A is the polar inertia of the whole cabinet with respect to A and S_{yA} is the static moment of the system with respect a vertical axis passing through A .

Security stops are introduced to limit the deformation (i.e., the maximum value of θ) during the motion. By referring to an impact on security stops during a rocking motion around the base corner A , it is possible to obtain the post-impact velocities $\dot{\theta}^+$ and $\dot{\psi}^+$ as functions of the pre-impact angular velocities $\dot{\theta}^-$ and $\dot{\psi}^-$ through the following relationships:

$$\dot{\theta}^+ = -\eta\dot{\theta}^-; \quad \dot{\psi}^+ = \dot{\psi}^- + p(\theta, \psi)\dot{\theta}^- \quad (9)$$

where

$$p(\theta, \psi) = \frac{(\eta + 1)h(2m_1 + 4m_2 + 2m_3 + m_5 + 2m_6 + 3m_7)}{\left[\frac{b(m_2 + 2m_3 + m_4 + m_5 + m_6 + m_7)\sin(\psi) - h(2m_1 + 4m_2 + 2m_3 + m_5 + 2m_6 + 3m_7)\theta\sin(\psi) + h(2m_1 + 4m_2 + 2m_3 + m_5 + 2m_6 + 3m_7)\cos(\psi)}{h(2m_1 + 4m_2 + 2m_3 + m_5 + 2m_6 + 3m_7)\cos(\psi)} \right]} \quad (10)$$

It is assumed that after an impact on security stops the value of $\dot{\theta}$ changes its sign and is reduced to a fraction of the value before the impact. The restitution coefficient η depends on the characteristics of the security stops and $\eta \leq 1$. The angular velocity $\dot{\psi}^+$ is obtained by assuring the conservation of the horizontal momentum of the cabinet.

3 Numerical simulations

An extensive parametric analysis is performed by numerically integrating the equations of motion. Such analyses are performed varying the oscillation period T of the cabinet in the full-contact phase and the dimensions (i.e., base $2b$ and slenderness $\lambda = 2h/b$) of the cabinet. All the other quantities are fixed: damping ratio of the cabinets $\xi = 0.05$, restitution coefficient of the security stops $\eta = 0.5$, maximum angle allowed by the security stops $\theta_{max} = 0.1\text{rad}$, and the cabinet is considered to be full (i.e., the additional mass M is added to the mass of the shelves from 4 to 7, see Fig. 1a).

3.1 One-sine impulsive excitation

In the analyses performed in this section, the cabinet is excited by a one-sine pulse excitation:

$$\ddot{x}_g(t) = \begin{cases} A_s \sin\left(\frac{2\pi}{T_s}t\right) & 0 \leq t \leq T_s \\ 0 & T_s < t \leq t_{max} \end{cases} \quad (11)$$

where T_s is the period of the one-sine cycle, $\Omega = 2\pi/T_s$ is the circular frequency of the excitation, A_s is its amplitude, and t_{\max} is the maximum time used in the numerical integrations ($t_{\max} = 10T_s$). The results are arranged in overturning spectra, that provide the amplitude of the excitation that generates the first overturning occurrence versus the circular frequency of the excitation.

An initial parametric analysis is performed to investigate the sensitivity of the dynamics of the cabinet to T . In such an analysis the geometrical characteristics of the cabinet are fixed, $2b = 0.6\text{m}$, $4h = 2.6\text{m}$. Figure 2a presents the results obtained with a model that does not include security stops, whereas Fig. 2b shows the corresponding results obtained by including the security stops. In the two figures, dashed lines refer to a rigid cabinet, whereas solid lines refer to a deformable cabinet. The spectra are labelled with the value of the period T used in the analysis. Such labels are surrounded by an ellipse if, during the motion, the cabinet impacts on security stops or by a rectangle otherwise. In Fig. 2a, since the security stops are not considered, the labels are all rectangular. Such a convention that shows the occurrence of impacts on security stops is used in all the figures of this section. In Figs. 2a and 2b, the overturning spectra of the deformable cabinets with periods $T \geq 1.0\text{s}$ are above the curves of the rigid cabinets in a wide range of the values of Ω . This means that the amplitude of the excitation A_s required to overturn a deformable cabinet is higher than amplitude needed to overturn the corresponding rigid cabinet. Moreover, the comparison between Fig. 2a and 2b shows that, when impacts on security stops occur (e.g., cabinet with $T = 1.5\text{s}$), the presence of the security stops significantly affects the dynamics of the cabinet. Nevertheless, the overturning spectrum obtained for $T = 1.5\text{s}$ in Fig. 2b is still above the curve of rigid cabinet in most of the considered range of Ω . In general all the overturning spectra in Fig. 2 present a jump. As it occurs in rigid blocks ([24, 25]), also in deformable rocking bodies such a jump is associated to a change of the overturning mode. Specifically, before the jump the body overturns hitting once the ground, whereas after the jump the body overturns without hitting the ground. The deformability of the cabinet shifts the jump on the left leading to a general improvement of the behaviour of the cabinet.

In the following analysis the dimensions of the cabinet, $2b$ and $4h$, are considered as variable parameters. In Fig. 3, the results of the analysis are arranged in matrix form. Each row refers to a different base dimension, whereas each column refers to a different height of the cabinet. As expected, the dimensions of the cabinet significantly affect the overturning spectra of the rigid body. In general, the deformable cabinets are less prone to overturn than the equivalent rigid cabinets, especially for more slender cabinets (i.e., those in the upper row). In Fig. 3, the left graph on the first row and the middle graph on the second row refer to cabinets with $\lambda = 3$ and different scale size. The comparison of the two graphs shows that the improvement in the dynamics of the deformable cabinets (solid lines) with respect to the correspondent rigid case (dashed lines) is smaller in the cabinet with larger scale.

3.2 Seismic excitation

A parametric analysis is performed to assess if the deformation of the cabinet can reduce the amplitude of the rocking oscillations and eventually avoid the overturning of the cabinet during a seismic event. For this analysis, seismic events with different characteristics are selected. Fig. 4 shows the time-histories of the seismic records that are listed in the following:

- Kobe, Takarazuka-000 station, ground motion recorded during the 1995 Japan earthquake;

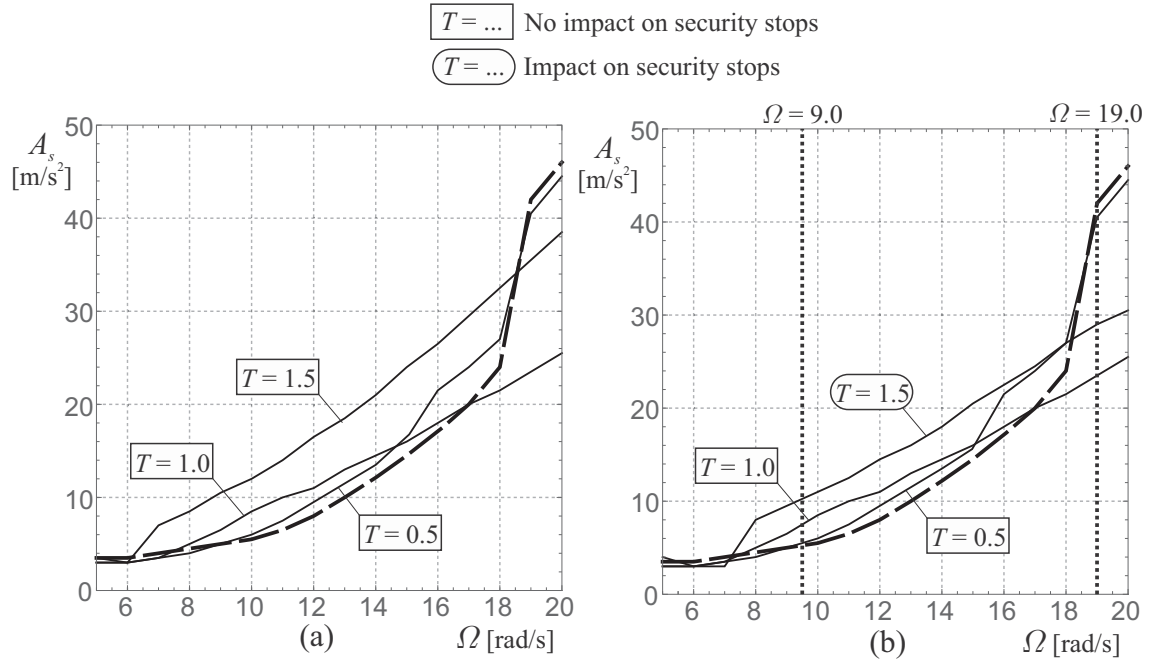

Figure 2: Overturning curves for different period T : (a) Overturning curves without security stops; (b) Overturning curves with security stops ($\xi = 0.05$, $\eta = 0.5$, $\theta_{max} = 0.1$, $2b = 0.6\text{m}$, $4h = 2.6\text{m}$, cabinet full).

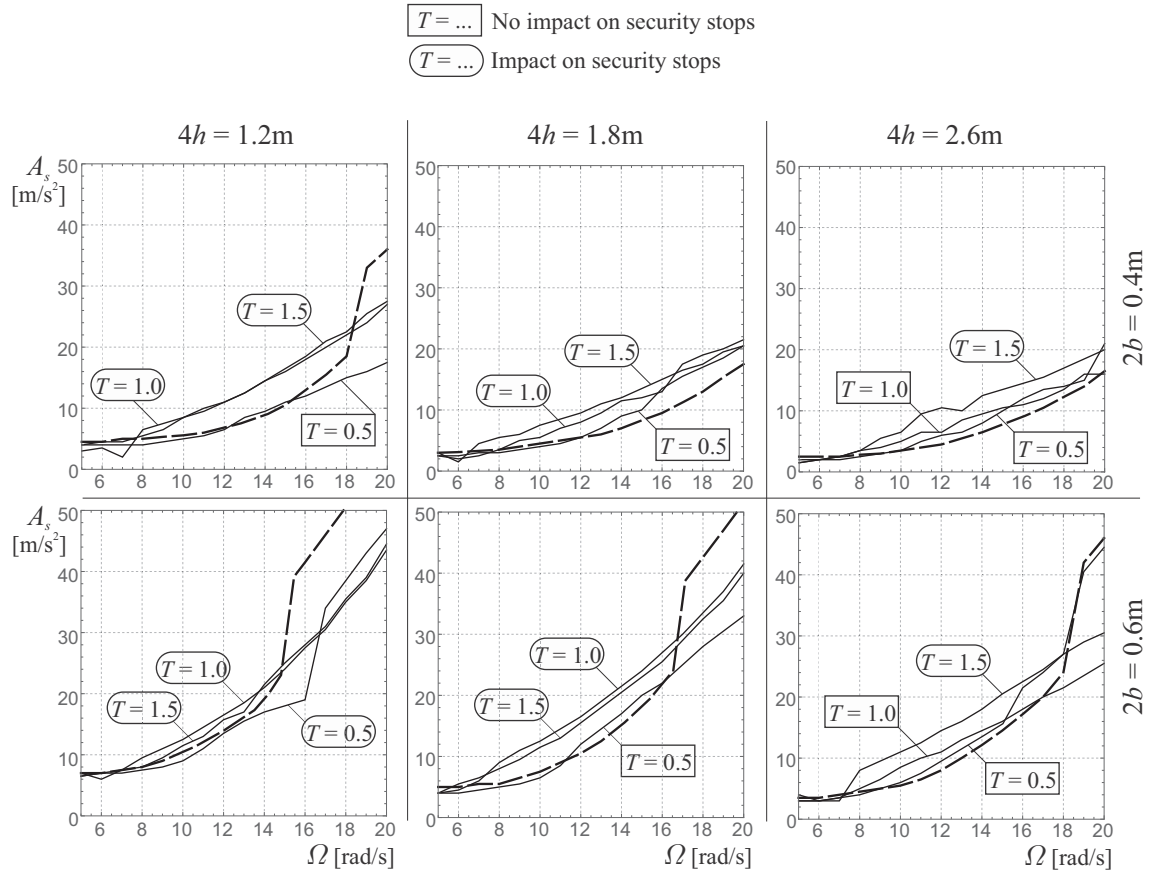

Figure 3: Overturning curve for different geometrical characteristics of the cabinet ($\xi = 0.05$, $\eta = 0.5$, $\theta_{max} = 0.1$, cabinet full).

- Newhall, Newhall-360 station, ground motion recorded during the 1994 Northridge, California earthquake;
- San José, Fremont Mission San Jose motion recorded during the October 17, 1989, Lorna Prieta earthquake.

Figure 4: Time-histories of the recorded earthquakes.

The results of the parametric analysis performed with seismic excitation are arranged in rocking maps. Such rocking maps are contour plots of the maximum rocking angle in the parameter plane $2b-\lambda$. The rocking maps obtained for rigid and deformable cabinets are compared to assess if the deformation improves the seismic behaviour of the cabinets.

In Fig. 5 the rocking maps are organized in matrix form where each column refers to a different earthquake (Kobe, Newhall, and San José). The first row shows the maps of the rigid cabinet, rows two and three refer to deformable cabinets with $T = 1.0$ s and $T = 1.5$ s, respectively. In the maps, the light grey regions (rocking regions) are those where the cabinet undergoes rocking motion. The contour levels inside these regions refer to the maximum rocking angle reached during the motion. The dark grey regions (overturning regions) are those where the cabinet overturns. The first row of Fig. 5 shows that the rigid cabinet overturns in almost all the parameter plane except that in the right lower part of the maps that correspond to combinations of larger values of the base and lower slenderness of the cabinet. Rows two and three of Fig. 5 show that deformable cabinets have smaller overturning regions that generally tend to shrink as T increases. As an exception, for the Newhall seismic event, the cabinet with $T = 1.0$ s does not overturn in the whole parameter plane, whereas the cabinet with $T = 1.5$ s overturns only in a small portion of the parameter space. Finally, the contour levels inside the light grey regions show a general reduction of the maximum rocking angle when the period T increases.

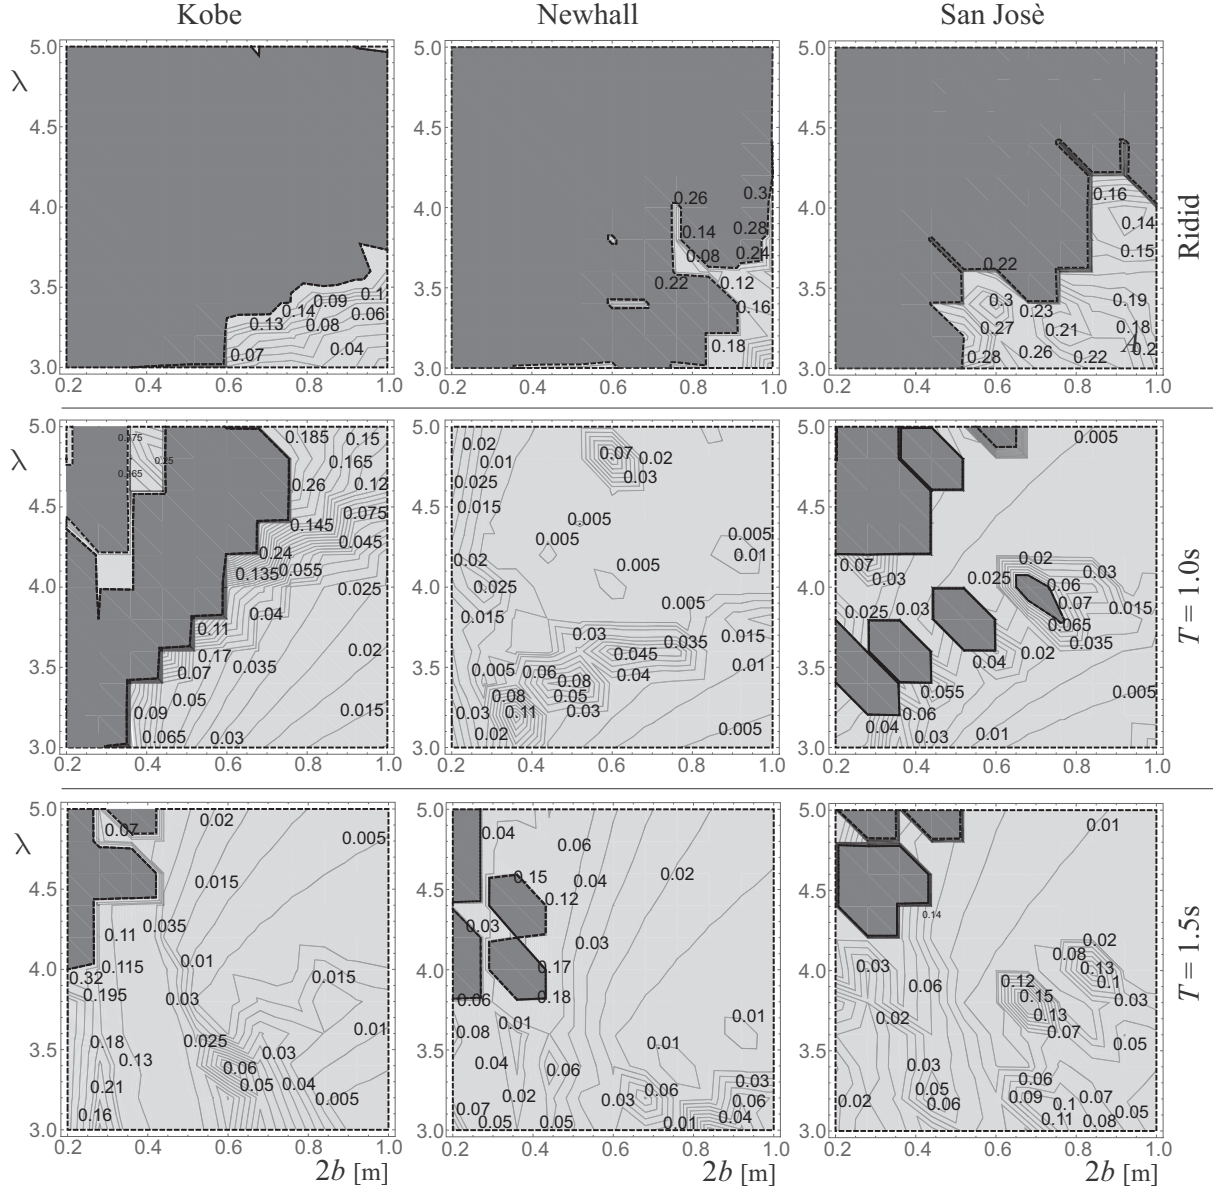

Figure 5: Rocking maps for three different earthquakes (Kobe, Newhall, San José) ($\xi = 0.25, \eta = 0.5, \theta_{max} = 0.1$, cabinet full).

4 Conclusions

This paper presents the model of a cabinet that can undergo a guided deformation. This model has been used to investigate the possibility to improve the dynamic and seismic behaviour of cabinets and racks by providing them of the ability to change their geometrical configuration during the rocking motion. The kinematic related to the change of geometrical configuration is specific to the model studied in this paper but can be easily generalized to other models representing cabinets and racks, both for civil and industrial use.

It has been assumed that the body can undergo only rocking motion, without sliding. The equations of motion have been obtained through a Lagrangian approach. The classical impact of the body base with the support during the rocking motion and the impact on security stops needed to limit the maximum angular deformation have been considered to describe the motion of the system.

An extensive parametric analysis has been performed by numerically integrating the equations of motion. The improvement in the dynamics has been analyzed by comparing the behaviour of rigid and deformable cabinets under one-sine pulse and seismic excitations. For the one-sine pulse excitation, the comparison has been made with overturning spectra that provide the amplitude of the excitation able to overturn the cabinets versus its circular frequency. For the seismic excitation, the maximum rocking angle reached during the motion under different recorded earthquakes have been arranged in rocking maps and compared.

The results shows that the ability of a cabinet to change its geometrical configuration before and after the start of the rocking motion significantly improves its dynamical and seismic performance compared to the performance of an equivalent rigid cabinet.

Abstract

This paper presents a finite element (FE) modeling approach for simulating the 3D response of a free-standing cylindrical column. The model is validated against experimental results, which involved testing of the cylindrical steel column under a set of 100 bidirectional ground motions. The specimen was free-standing and allowed to slide and rock in all directions. Both the tested specimen and the shake table platen were stiff enough to be modeled as rigid. The contact surface was modeled using Coulomb friction for the tangential behavior and stiff contact for the normal direction. Two energy dissipation mechanisms were modelled; friction and radiation damping. Since Rayleigh damping is not directly linked to the physical problem, it was set equal to zero.

It has been proven that the response of a single column to an individual ground motion is a chaotic and unpredictable problem. Therefore, a statistical approach was utilized to compare the numerical to the experimental results, using the cumulative distribution function (CDF) for the main response quantities (i.e., maximum displacement at the top of the column and residual displacement), demonstrating satisfying agreement.

The influence of the friction coefficient was assessed through an extensive sensitivity analysis using non-linear time-history analyses. Results proved that the statistics of the response only smoothly depend on the exact value of the friction coefficient even though the response to an individual ground motion seems chaotic.

1 INTRODUCTION

Rocking structures are the ones that are allowed to uplift. Under ground motion, uplifting occurs when:

$$\ddot{u}_g > g \tan \alpha \quad (1)$$

where \ddot{u}_g is the ground acceleration, g is the gravity acceleration, and α is the slenderness of the block (Figure 1). It is assumed that the sliding surface is sufficiently rough to prevent sliding. This uplifting effect acts as a fuse, limiting the inertial forces transmitted to the superstructure. After uplift, a rocking oscillator demonstrates negative stiffness, making the description of such systems significantly different to the conventional ones.

Figure 1. Geometric properties of a rocking block.

The first analytical study of this phenomenon is dated back to 1885 [1,2]. However, rocking structures have been systematically studied after 1963, when Housner published his seminal paper [3] where two main properties of the rocking structures were elucidated: i) out of two geometrically similar rocking blocks (same α) the larger one (larger R) can survive an excitation which will topple the smaller one ii) longer period ground motions have a higher overturning potential [3].

The rocking oscillator has been used to describe the dynamic behavior of free-standing equipment [4-16], masonry structures [17-26] and ancient temples [27-34]. Rocking is also a promising seismic response modification technique, both for bridges and buildings, with practical applications in the former USSR and New Zealand. Applications in buildings may comprise a soft-rocking-story mechanism [35-37], or a rocking wall [38, 39], whereas in bridges, rocking piers [40-56]. Several analytical studies investigated the response of rocking structures combined with external dampers or restraining tendons [57-60]. The influence of the flexibility of the rocking body was also studied, both analytically and experimentally [61-65].

The analytical model proposed by Housner describes the planar response of a rigid rocking body when subjected to one-directional excitation. However, under seismic excitation, rocking structures are subjected to bidirectional (or three-directional when the vertical acceleration is considered) excitation [66-69]. Under these conditions, an unanchored body may rock in 3D dimensions (wobble). When it is not restrained, it may also slide out of its initial position or completely detach from the support.

This study aims at developing a practical three-dimensional finite element model to predict the response of free-standing cylindrical rocking columns. The validity of the proposed model is assessed by statistically comparing numerical and experimental results. The experimental results comprise 100 shake table tests, using a cylindrical steel column with a slenderness (α) of 0.2. The number of tests performed is large enough to create an experimental benchmark

dataset, which could be used for a statistical comparison. The specimen was subjected to two-dimensional excitation, and it was free to slide, rock and wobble in all directions. As the column is free to slide and wobble out of its original position, it serves for validation of numerical models used for the description of the seismic behavior of unanchored equipment, rather than of structures that use rocking as a seismic isolation strategy, where the rocking members would not be allowed to slide.

2 STATISTICAL VALIDATION

Rocking is often characterized as “chaotic”, in the sense that the response of rocking objects is sensitive to the initial conditions [70], often making tests non-repeatable. Therefore, validating numerical models in a deterministic way does not even make sense.

Bachmann et al. [71] and Del Giudice et al. [72,73] claimed that validating a numerical model using a single ground motion is a sufficient but not necessary validation procedure. The seismic response is inherently stochastic since the excitation is stochastic. Therefore, a statistical (and not a deterministic) validation of the numerical model is proposed. During this statistical validation, the statistical distributions of the main response quantities of the model and the experiments are compared. This procedure requires an experimental benchmark dataset, where the same (or identical specimens) are excited by an ensemble of ground motions. Afterwards, a numerical model is used to create another dataset, using the same ensemble of excitations. The validity of the numerical model is assessed by comparing the Cumulative Distribution Function (CDF) of these two datasets for the same response quantities (i.e., maximum displacement at the top and residual displacement). This validation test is weaker (and easier to pass), yet sufficient for earthquake engineering applications.

3 NUMERICAL STUDIES OF ROCKING STRUCTURES: RESULTS OF A BLIND PREDICTION CONTEST

During the last decade, both FEM and DEM numerical models were developed to predict the rocking problem [74-79]. A recent blind prediction contest organized by ETH Zurich, the University of Bristol and the Pacific Earthquake Engineering Research (PEER) Center, shed light on the efficiency of numerical models used to describe the statistical response of a rocking podium structure [80,81]. Unlike the tests discussed in this paper, the tests of [80,81] concerned a rocking podium structure that was restrained not to slide or wobble out of its original position. Thirteen contestants participated, using FEM, DEM, and analytical rigid-body models [80,82-83]. One of the important outcomes of this contest is that there is no basis for recommending FEM or DEM to model the response of wobbling structures; the accuracy of these models depends on the modeling assumptions. Moreover, it was proven that even though the winning models precisely captured the Cumulative Distribution Function of the maxima of the responses to each set of excitations, they were unable to accurately predict the response to each individual ground motion.

4 EXPERIMENTAL PROCEDURE

This section briefly presents an experimental investigation designed at ETH Zurich and carried out at EQUALS Lab, University of Bristol [84]. This investigation includes 115 shake table tests of cylindrical free-standing rocking bodies, which were free to slide and rock in all directions. More details about the tests can be found in [84]. From the various free-standing columns which were experimentally tested (Figure 2), this paper utilizes the results of one cylindrical column to assess the efficiency of the proposed FE model (Figure 3, right). The ex-

perimental results from [84] served as an experimental (benchmark) dataset, to assess the proposed FE model.

The experimental results of [84] serve for model validation and were not chosen to represent specific free-standing rocking equipment. The specimens were designed to remain elastic after each test, so the same specimen could be excited with a large number of earthquake excitations to create a database suitable for a statistical validation. The specimens were made of round steel pipes, with different dimensions and slenderness.

The rocking response was induced by a di-directional dynamic excitation using a shake table. The applied ground motions were synthesized using a spectral version of the Rezaeian and Der Kiureghian stochastic ground motion model [85-86]. The 1989 Loma Prieta UCSC Lick Observatory ground motion record was used as a seed ground motion to generate an ensemble of 100 ground motions. The ground motions were scaled, with the frequency of ground motions increased by 2 without changing the amplitude. Therefore, in the prototype scale, the columns are 4 times larger.

5 NUMERICAL MODEL

The finite element software ABAQUS [87] was utilized to perform the analysis. The model comprised the cylindrical rocking body and a moving flat base-slab. The moving flat base emulates the top surface of the shake table. Both the rocking column and the flat base were modeled as rigid, since they were stiff enough and demonstrated no damage after testing. The flat base-slab was vertically supported by a spring-dashpot system to simulate the vertical stiffness of the shake-table platform and the radiation/impact damping mechanism (Figure 3, Left). Its rotation was constrained and set equal to zero. This approach was previously used in [88] in an effort to model radiation/impact damping, and it was shown that that in the planar case it leads to Housner's solution, as long as the stiffness of the spring is relatively high. Therefore, the spring constant was set to 10^9 N/m so that the pre-uplift vertical eigenperiod of the system is 0.001 sec. All rotations of the base were fixed. To apply the ground motion, the base moved parallel to x and y axis.

A uniform mesh with a size of 5 mm was utilized in all analyses. A 4-node 3D rigid quadrilateral finite element was used both for the rocking column and the flat base. The motion of the specimen was monitored with a reference point at the top of the column. The contact surface was simulated using Coulomb friction for the tangential behavior and ABAQUS stiff contact [87] for the normal direction. An explicit scheme with a fixed time increment of 10^{-6} sec was used in all cases.

The developed numerical model considers two main damping mechanisms; friction and radiation/impact damping. Inherent Rayleigh damping is set to zero since this energy dissipation mechanism is inconsistent with the physical problem. Energy dissipation through friction is considered through the friction coefficient, whereas radiation damping through the utilized dashpot. Neither the friction (μ) nor the dashpot (ζ) coefficient was known a priori; the influence of the friction coefficient was assessed through an extensive parametric analysis employing non-linear time history analysis.

Figure 2. Free-standing rocking column specimens on the shake table at EQUALS lab, University of Bristol.

Figure 3. Left: Schematic representation of the rocking column, the constraint of the flat base and the spring-dashpot system below the base; Right: Dimensions (in m) of the tested specimen.

In this parametric analysis, the coefficient of friction μ was varied from 0.3 to 2. Not all the above values are realistic, but the analysis explores the influence of extreme values of the modelling parameters on the rocking response. The damping ratio ζ corresponding to the vertical vibration mode (i.e. radiation damping) was set to $\zeta=1\%$. This damping should not be confused with Rayleigh, which was equal to zero in all tests.

6 RESULTS

6.1. Deterministic Comparison

Figure 4 presents scatter plots that compare the experimental to the numerical results for different values of the critical modeling parameter (i.e., friction coefficient). The investigated response parameters are the maximum displacement (u_{\max}) at the top of the rocking column,

and the residual displacement after the end of the excitation (u_{res}), both measured in meters. In the following plots, “OT” denotes overturning of the specimen. In all scatter plots, the horizontal axis corresponds to the experimental results, whereas the vertical to the numerical ones.

It is evident that the numerical results are moderately correlated to the experimental ones. Moreover, similarly to previous studies, the numerical model often fails to predict overturning. However, the relevant question in earthquake engineering is not whether the model is accurate but whether it is biased and whether it induces more uncertainty than the ground motion. Comparing the results of individual ground motions, it is not possible to identify clear patterns of the influence of the coefficient of friction on the maximum response of the body. Most importantly, minor changes in the coefficient of friction, lead to very large changes in the response.

6.2 Statistical Comparison

When the numerical results are statistically assessed, clear trends emerge (Figure 5), similarly to what was observed for the planar rocking model by Yim et al [89] as early as in 1980. An increase of the friction coefficient leads to an increase of the maximum displacement of the rocking column (Figure 5, left). The residual displacement does not seem to depend on the coefficient of friction, provided that there is no overturn. Hence, neglecting sliding (i.e. using a very high value for μ) is a conservative modelling approach, at least in terms of maximum displacement and prediction of overturning probability.

Figure 4. Deterministic comparison for experimental and numerical results of the columns. Sensitivity analysis for friction coefficient. Left: Maximum Displacement, Right: Residual Displacement

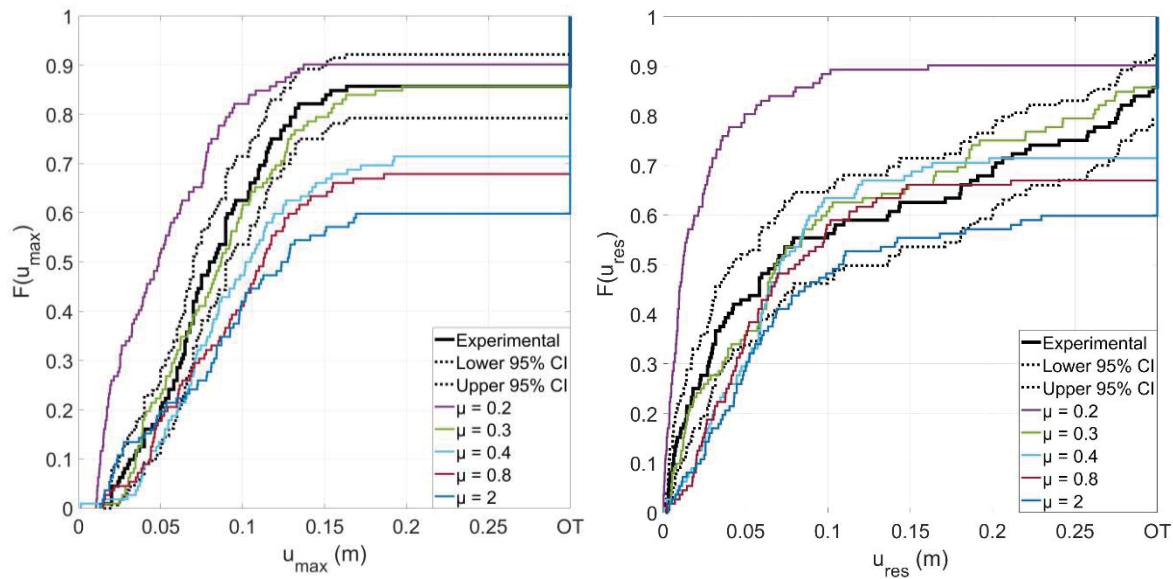

Figure 5. Statistical comparison for experimental and numerical results of the columns. Sensitivity analysis for friction coefficient. Left: Maximum Displacement, Right: Residual Displacement

7. CONCLUSIONS

The presented numerical model simulates the response of a free-standing cylindrical column. The column had a slenderness ratio of $\alpha = 0.2$, and, during testing, it was free to slide and rock in all directions. It is shown that the model performs poorly when it is deterministically assessed based on its ability to predict the maximum displacement at the top of the column. However, it can perform well, when it is evaluated based on its ability to predict the CDF of the maxima of the response to a set of ground motions.

The friction coefficient between the rocking block and the supporting surface was varied numerically and its influence was assessed with a large number of non-linear time-history analyses. Even though the exact value of the friction coefficient significantly influences the deterministic response, it affects the statistical response only moderately. The CDF curves show that an increase of the friction coefficient amplifies uplifting and leads to larger maximum rocking displacements, thus making the model more conservative. A friction coefficient equal to $\mu = 0.3$ and a radiation damping equal to $\zeta = 1\%$ leads to the optimal match between experimental and numerical results.

Keywords: building contents, Incremental Dynamic Analysis, fragility, nonstructural, rocking, freestanding.

Abstract. *The paper presents a fully performance-based seismic reliability and risk assessment framework for freestanding structural components and contents that can be modelled as rocking rigid blocks. It is shown that a drift-driven Incremental Dynamic Analysis approach can be adopted in order to obtain the floor timehistories which are then used as input for the response history analysis of the contents. Therefore, first the demand at the storey level is obtained and then the response of the contents is calculated using the storey acceleration response history. An alternative methodology where the fragility of the building and of the freestanding contents are derived separately is also examined and its limitations are discussed. The seismic response of building contents depends on several parameters such as the geometry of the object, the dynamic characteristics of the building and the storey that the object is located.*

1 INTRODUCTION

Earthquake losses may be due to structural damage, damage of non-structural components (e.g. infills, piping system) and also due to the damage of the structure's contents. Non-structural damage can be due to damage of components attached, or anchored, to the hosting building, or due to damage on the freestanding inventory of the building. In the latter case, there is a huge variability of systems and configurations hampering the systematic study of the problem and the recommendation of generally-applicable guidelines. The risk assessment of building contents is a complicated task since the response of the contents depends also on the behaviour of the hosting structure. As a result, there may be cases where a strong earthquake does not overturn an object but strongly damages the structure, while more benign ground motions may leave the structure intact however causing losses due to damage on the building's contents.

The paper focuses on the seismic performance, fragility and risk assessment of freestanding building contents. Freestanding building contents are treated as rocking rigid blocks and are modelled using Housner's theory [1]. A specifically tailored version of the Incremental Dynamic Analysis (IDA) method is proposed in order to assess the structure and its contents considering that the structural collapse implies also collapse/overturning of the contents [2]. A second point of interest is the derivation of fragility curves and the calculation of the Mean Annual Frequency (MAF) of building contents.

Despite the significance of the problem, there are relatively few past studies on the seismic response assessment of freestanding contents, especially compared to the case of anchored non-structural components and anchored building equipment. The paper presents a performance-based seismic fragility and risk assessment framework for freestanding building contents. Contrary to previous works on the seismic fragility assessment of rocking contents, the proposed methodology discusses how the response of the hosting building and that of the contents are coupled and also the effect of different stories and different block geometries. In order to consistently study the effect of increasing seismic intensity in a performance-based setting, a modified version of the well-known Incremental Dynamic Analysis (IDA) method is presented. It is shown that the EDP that should "drive" the IDA simulations is that of the building rather than that of the contents and also that the collapse of the building should not be neglected. Moreover, the calculation of fragility and risk are discussed. Existing fragility assessment methodologies are adopted showing that the IM of the building should be adopted (instead of that of the contents), while a procedure that uses the total probability theorem in order to calculate the MAFs combining fragilities that were separately generated for the structure and for the contents is investigated. Overall it is shown that the problem is not as simple, as it may initially seem, and that various tools should be appropriately combined in order to accurately and efficiently calculate the risk of freestanding contents.

2 Theory of the rocking block

In order to study the seismic response of freestanding bodies to an earthquake ground motion, it is assumed that the bodies are orthogonal blocks. Following the pioneering work of Housner [1], the problem of rocking and overturning of freestanding blocks to earthquakes has been the subject of intense analytical and experimental research. Despite its apparent simplicity, the rocking problem has been proven difficult, since the blocks behave nonlinearly and also due to the occurrence of many impacts between the rocking bodies and their base. The fundamentals of rocking theory are briefly summarized in order to allow studying the seismic behaviour of

freestanding rocking blocks. A rigid block of dimensions $2b \times 2h$ that oscillates about pivot point A (or A'). The block has weight W and moment of inertia I_0 about point A. Assuming that the block is homogeneous and thus the center of gravity is located at height h , the block's slenderness angle is equal to $\alpha = \text{atan}(b/h)$. The slenderness angle α together with the size parameter $R = \sqrt{b^2 + h^2}$ define fully the geometry of the block. Consequently, the equation of motion of the rocking block is [1]:

$$I_0 \ddot{\theta}(t) + mgR \sin[\alpha \text{sgn}(\theta(t) - \theta(t))] = -m\ddot{u}_g(t) R \cos[\alpha \text{sgn}(\theta(t) - \theta(t))] \quad (1)$$

where the angle of rotation θ is the only degree of freedom. The sign function is used to define the pivot point (A or A'), i.e. when A' is the pivot point, the angle θ is negative. The above Eq. 1 can be solved either with the aid of an Ordinary Differential Equation (ODE) solver or using simple Finite Element models (e.g. Diamantopoulos and Fragiadakis[3]).

3 Seismic response assessment of building contents

The procedure followed for the seismic response assessment of freestanding building contents is relatively easy. The building is subjected to an acceleration timehistory and the total acceleration response history of the storey of interest is stored. The stored storey acceleration response history is used as the input acceleration time history for the rigid block assessment. This conceptually simple cascading procedure requires two models, one for simulating the building and a second for simulating the freestanding contents. Moreover, after every building simulation the complete acceleration, or velocity, response history has to be stored for every storey. This workflow is used also for developing the fragility curves of the rocking objects of interest.

Seismic response assessment requires to define pertinent Intensity Measures (IM) and Engineering Demand Parameters (EDP) for both the structure and the contents. This step is also important for the fragility assessment. IMs represent seismic intensity, while the EDPs are used to measure the demand, or the "damage". In order to distinguish the quantities that refer to the "structure" and the "block", the superscripts "s" and "b" are used, respectively. Therefore, $EDP^{(s)}$ and $IM^{(s)}$ are the IM and the EDP of the structure, while $EDP^{(b)}$ and $IM^{(b)}$ refer to the rigid block. For a block at storey j , $IM^{(b)}$ will coincide with (or be derived from) the structure's $EDP_j^{(s)}$, or, simply, the peak floor acceleration of the storey is the peak ground acceleration for the rocking body. Therefore, the selection of $EDP_j^{(s)}$ and $IM^{(b)}$ should be consistent.

For moderate-period structures with no near-fault activity, an appropriate choice for the intensity measure of the building $IM^{(s)}$, is the 5%-damped, first-mode spectral acceleration, $S_a(T_1, 5\%)$. Moreover, the most common EDP for moment frames is the maximum interstorey drift. However, since our focus is on freestanding components, instead of the maximum interstorey drift, a consistent quantity should be chosen as the $EDP^{(s)}$, while the intensity measure $IM^{(s)}$ is always $S_a(T_1, 5\%)$, although other measures are also possible.

For a rocking block, the most intuitive IM choice is the peak ground acceleration (PGA), since it is the parameter that defines the maximum overturning moment, while according to $\ddot{u}_g \geq \tan \alpha$ and $\ddot{u}_g \geq \mu \tan \alpha$ the PGA defines whether rocking and sliding respectively or none of the two will occur. Although it is not necessary, the PGA is normalized with $g \tan \alpha$ and thus the block's IM is $IM^{(b)} = PGA / g \tan \alpha$, where $IM^{(b)} \leq 1$ implies that the block does not start rocking. Furthermore, past research[4, 5] has shown that the PGV is also an important response parameter that provides a good correlation between seismic demand and block overturning. For simplicity, we choose not to normalize the PGV , but researchers[?] have

also proposed the normalized quantity $pPGV/g\tan\alpha$ as an IM suitable for rocking blocks. Our results have shown that the PGV (or PFV) performs well as an IM and hence we have chosen the simplest IM possible. Therefore, the $IM^{(b)}$ for a rocking block at storey j considered, is either the normalized peak floor acceleration PFA_j , or the peak floor velocity PFV_j ; the parameter chosen will be also used as the demand parameter of the building $EDP_j^{(s)}$. The most suitable engineering demand parameter $EDP^{(b)}$ for the rocking block is the rotation angle θ normalized by slenderness angle α , i.e. $EDP^{(b)} = |\theta|/\alpha$.

In order to assess a system's capacity, meaningful performance objectives related with the system's modes of failure or damage have to be identified. For rocking systems, overturning is the primary limit-state of interest, while rocking initiation is also of interest but it can be easily identified from the PGA . Depending on the freestanding component, (e.g. its purpose, its material, etc), "limited" damage can be identified for normalized rotation values $\theta/\alpha \approx 0.1 \div 0.3$, "moderate" damage for $\theta/\alpha \approx 0.3 \div 0.5$ and "overturning" is assumed for $\theta/\alpha \geq 1$. Recommendations of limit-state thresholds for rocking bodies can be found in various publications, e.g. Dimitrakopoulos and Paraskeya[6], Psycharis *et al.*[7] and Kavvadias *et al.*[8]. In practice, these limits vary considerably and it is not possible to decide threshold values that are generally applicable. For example, for sensitive mechanical equipment a rotation $\theta/\alpha \geq 0.1$ may result to permanent damage and thus in terms of loss the outcome will be the same with overturning. Another important aspect is the geometry of the block. Slender blocks start rocking for smaller acceleration values, while stocky blocks require higher acceleration values to start rocking and are more stable.

4 Fragility and risk calculations

The seismic risk assessment of building contents requires the prior knowledge of their fragility. As fragility, or "fragility function", we refer to the cumulative distribution function of the capacity of an asset to resist an undesirable limit-state [9]. For building contents, the fragility provides the probability of overturning as a function of the seismic excitation. Although often in the literature the terms "fragility" and "vulnerability" are used interchangeably, in this work we assume that fragility refers to the overturning probability as function of seismic intensity, while vulnerability is used to measure loss. Past research on fragility assessment focuses on the risk assessment of the structure itself[10], while the contents are examined separately and, usually, neglecting the effect of the hosting structure. Independent, and often generic, fragility curves for various building contents can be found in guidelines (e.g. FEMA P-58[11]) and the literature. Such fragility curves are empirical and are targeted to specific component types (e.g. cladding panels, masonry parapets). The direct fragility calculation that is here proposed through simulations allows to consider additional sources of uncertainty (e.g. related to the shape of the object, its mass distribution) and hence is preferable.

The fragility function is the conditional limit-state exceedance probability, given by the expression:

$$F_R = P(EDP > edp|IM) \quad (2)$$

The structure is first examined. There will be simulations that the building collapses (denoted as "C") and simulations where no collapse occurs (denoted as "NC"). Making this separation and dropping the conditioning term in order to simplify the notation, i.e.: $P(EDP) = P(EDP > edp|IM)$, the probability of Eq. 2 is calculated using the total probability theorem (TPT) as follows:

$$F_R^{(s)} = P(EDP^{(s)}|NC)P_{NC} + P(EDP^{(s)}|C)P_C \Leftrightarrow$$

$$F_R^{(s)} = P(EDP^{(s)}|NC)(1 - P_C) + P_C \quad (3)$$

where $P(EDP > edp^{(s)}|C)$ is equal to 1 since the inequality is always satisfied and $P_{NC} = 1 - P_C$.

Focusing on the rocking body, when an object is subjected to a seismic ground motion there are three possible types of response: (i) the object may not rock and remain at rest, (ii) it may rock, or (iii) it may overturn. Using the total probability theorem for the block, the fragility function becomes:

$$F_R^{(b)} = P(EDP^{(b)}|NoRock)P_{NoRock} + P(EDP^{(b)}|Rocking)P_{Rocking} + P(EDP^{(b)}|Ovtn)P_{Ovtn} \quad (4)$$

where $P(EDP^{(b)}|NoRock)$, $P(EDP^{(b)}|Rocking)$ and $P(EDP^{(b)}|Ovtn)$ are the probabilities that $EDP^{(b)} = \theta/\alpha$ exceeds a threshold value $edp^{(b)}$ and P_{NoRock} , $P_{Rocking}$ and P_{Ovtn} are the corresponding probabilities of no rocking, rocking and overturning, respectively. Blocks that will not rock, will not exceed any $edp^{(b)}$ value and thus $P(EDP|NoRock) = 0$, while the overturning blocks always exceed the limit-state threshold and thus $P(EDP|Ovtn) = 1$. The conditional limit-state probability (fragility) is further simplified to:

$$F_R^{(b)} = P(EDP^{(b)} \geq edp|Rocking)(1 - P_{Ovtn} - P_{NoRock}) + P_{Ovtn} \quad (5)$$

The calculation of Eq. 5 is discussed in the sections that follow. A fundamental assumption of our derivation is that *the simulations that collapse the building also overturn/collapse the freestanding contents* [2].

The risk is expressed as the mean annual frequency (MAF) of a limit-state being exceeded. Adopting the PEER's formula, the limit-state MAF for the structure and for a rigid block are calculated with the aid of the following expressions: where $\lambda_{EDP}^{(s)}$, $\lambda_{EDP}^{(b)}$ is the mean annual frequency of the engineering demand parameter ($EDP^{(s)}$ or $EDP^{(b)}$) exceeding threshold level and $d\lambda_{IM}^{(s)}$, $d\lambda_{IM}^{(b)}$ is the slope of the seismic hazard curve. The limit-state MAFs are easily obtained convolving the site hazard curve, expressed as function of the IM, with the fragility curve obtained with respect to any of the EDPs of interest. For the structure, the IM of interest is always available, e.g. spectral acceleration $S_a(T_1, 5\%)$, but for the block this information is available only at the ground floor. For assets located at a storey, the calculation of $d\lambda_{IM}^{(b)}$ has no meaning and thus their fragility should be calculated as function of $IM^{(s)}$ instead of $IM^{(b)}$:

$$\lambda_{EDP}^{(b)} = \int_{IM^{(s)}} P(EDP^{(b)}|IM^{(s)}) |d\lambda_{IM}| \quad (6)$$

Conditioning the block's fragility to $IM^{(s)}$, i.e. using Eq. 6 is also conceptually preferable since the MAF is directly calculated from the site's hazard. Note that we have dropped the superscript "s" from $d\lambda_{IM^{(s)}}$, since $d\lambda_{IM}$ always refers to the site and thus the structure.

A simplified and more generic methodology for the seismic risk of structure's contents is possible if we apply the total probability theorem (TPT), using the block's intensity measure $IM^{(b)}$ as an intermediate variable. This allows to expand Eq. 6 and obtain the MAF using the expression:

$$\lambda_{EDP}^{(b)} = \int_{IM^{(s)}} \int_{IM^{(b)}} P(EDP^{(b)}|IM^{(b)}) dP(IM^{(b)}|IM^{(s)}) |d\lambda_{IM}| \quad (7)$$

where $P(IM^{(b)}|IM^{(s)}) = P(EDP^{(s)}|IM^{(s)})$ is the building's fragility curve. Eq. 7 can be used in order to calculate separately the fragilities thus bypassing the need for performing building simulations and storing the response acceleration histories for the stories of interest.

5 Incremental Dynamic Analysis for freestanding components

The Incremental Dynamic Analysis (IDA) method is used for calculating the limit-state fragilities for both the structure and its contents. IDA involves subjecting the structure, or the block, to a suite of ground motion records, each scaled to multiple levels of intensity. After incrementally scaling every ground motion, single record capacity curves are produced in terms of demand versus seismic intensity. IDA has conceptual similarities to the Multiple Stripe Analysis (MSA) method [12, 13], where instead of scaling separately all ground motions, every record is scaled to the same IM level. Since for every scaling level the ground motions have the same IM value, the EDP values form a “stripe” which allows to directly calculate the median (50% percentile) and the 16% and 84% percentile capacity curves conditional on the IM. Strictly speaking, in IDA the scaling factors will be different, but stripped data can be easily obtained with interpolation. For the sake of simplicity, in this work MSA was performed (i.e. scaling the records to a common IM level), but loosely speaking the “term” IDA is used since it is more widespread and difference is merely a matter of implementation. Below we first discuss how the IDA method is applied for the cascading problem at hand. We first examine the structure since the ground motions are applied at the base of the building and in the subsection that follows we discuss how the fragilities of the freestanding contents are obtained from the floor response histories.

5.1 Hosting structure

For the four-storey RC building considered [2], every IDA curve is plotted in the EDP-IM plane as shown in Figure 1. The median curve (50% percentile) provides an estimate of the expected value and the fractile curves can be used to measure the dispersion [14]. The IDA capacity curve of Figure 1 is not the most common form of IDA where $EDP^{(s)}$ is the maximum interstorey drift ratio. A different EDP has to be adopted for studying building contents which leads to the representation of Figure 1, where the $EDP^{(s)}$ is either the normalised peak floor acceleration (PFA), or the peak floor velocity (PFV). The summarized EDP-IM plots (Fig. 1a or b) allow to directly calculate $P(EDP_j^{(s)}|NC)$ and P_C (Eq. 3) for every IM stripe. If the $EDP_j^{(s)}$ values are lognormally distributed, the buildings fragility for the j^{th} storey is calculated as follows:

$$P(EDP^{(s)} \geq edp^{(s)}) = 1 - P(EDP^{(s)} < edp^{(s)}) = \Phi \left(\frac{\mu_{\log EDP} - edp^{(s)}}{\sigma_{\log EDP}} \right) \quad (8)$$

where $\mu_{\log EDP}$ and $\sigma_{\log EDP}$ are the mean and the standard deviation of the logarithm of the demand, always conditional on the $IM^{(s)}$. Regardless the IM, the fragility of the building should be obtained combining Eq. 8 with Eq. 3:

$$F_R^{(s)} = \Phi \left(\frac{\mu_{\log EDP} - edp^{(s)}}{\sigma_{\log EDP}} \right) (1 - P_C) + P_C \quad (9)$$

where P_C is the percentage of collapsed simulations. Obviously different fragilities will be obtained depending on the EDP of interest.

Based on Figure 1 and Eq. 8 it is understood that the calculation of Eq. 8 is not efficient when the drift is used as the EDP. This is understood looking at Figure 1 where it is evident that the median (or the 16, 84% fractile) curves, conditional on the IM, cannot be calculated above the IM level where more than 50% (or the 16, 84% fractile, respectively) of the single-record

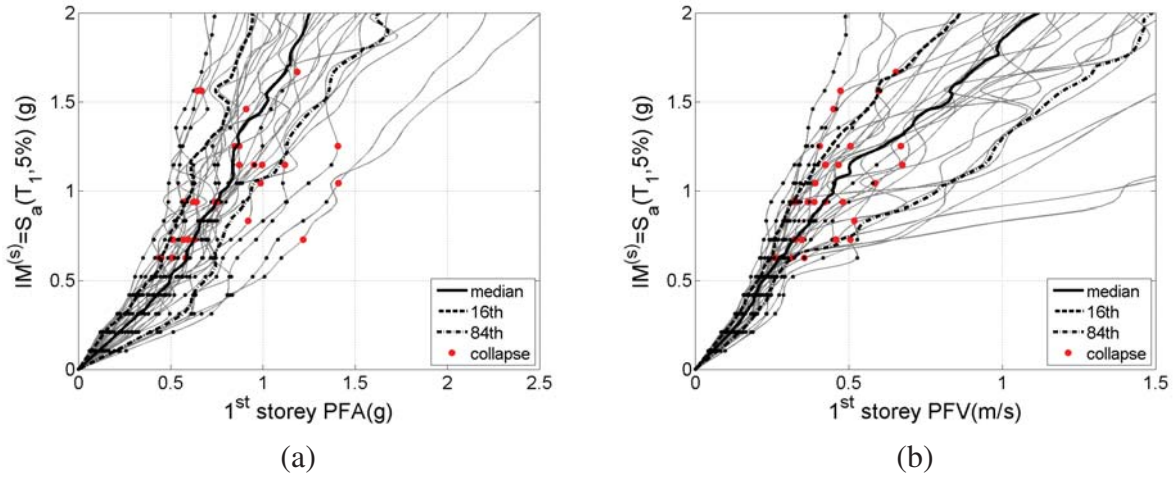

Figure 1: Storey capacity curves for the four-storey RC building considered, using as EDP: (a) the Peak Floor Acceleration (PFA), and (b) the Peak Floor Velocity (PFV).

IDAs become horizontal. On the contrary, when the PFA , or the PFV , is adopted, the median and the 16, 84% fractiles can be easily calculated due to the practically monotonic increase of the IDA curves.

Moreover, although the drift is not the primary EDP of interest, the IDAs should be driven by the drift, or any other EDP that is related with the structural damage. This is because when structural collapse occurs, the freestanding contents are also considered collapsed (overturned). In the single-record capacity curves of Figure 1, the solid dots indicate when the building collapses, i.e. either when the analysis structurally fails, or when the maximum drift threshold is exceeded. The dots are transferred in Figure 1 indicating the occurrence of structural failure. This is done merely for visualization purposes since all simulations after the dots are assumed collapsed. This visualization shows that even for relatively low PFA , or PFV values, structural damage may have already occurred.

5.2 Rocking contents

Figure 2 shows the EDP-IM plots of a freestanding block with $R = 1.0m$ and $\alpha = 0.2$. The hosting structure was subjected to the IDA simulations of Figures 1 and 3 and then the simulations (shown as black dots in Fig. 1) are transferred to the $EDP^{(b)} - IM^{(b)}$ (Fig. 2a), or the $EDP^{(b)} - IM^{(s)}$ plane (Fig. 2b). In both plots the collapsed simulations appear as dots just right to the vertical line at $EDP^{(b)} = 1$. The dots below the horizontal line at $IM^{(b)} = 1$ (Fig. 2a) correspond to the no rocking simulations. As already discussed in a previous section, the $EDP^{(b)} - IM^{(b)}$ representation is the natural EDP-IM choice, but is not the easiest choice when it comes to the calculation of MAF $\lambda_{EDP}^{(b)}$. Moreover, as shown in Figure 2a, the data in the $EDP^{(b)} - IM^{(b)}$ form a cloud, while if they are plotted in the $EDP^{(b)} - IM^{(s)}$ place they are already conditional on the $IM^{(s)}$.

Both EDP-IM representations allow to calculate the fragility of the blocks, but with respect to a different IM. Defining the fragility conditional on the IM of the structure, i.e. $F_R^{(b)} = P(EDP^{(b)}|IM^{(s)})$ can be used for directly calculating the MAF using Eq. 6. On the other hand, the intuitive definition $F_R^{(b)} = P(EDP^{(b)}|IM^{(b)})$ provides the storey fragilities with respect to the block's IM and always for the storey of interest. Another major difference is that when $IM^{(b)}$ is adopted, the EDP-IM data appear as a “cloud” (Fig. 2a), while when $IM^{(s)}$

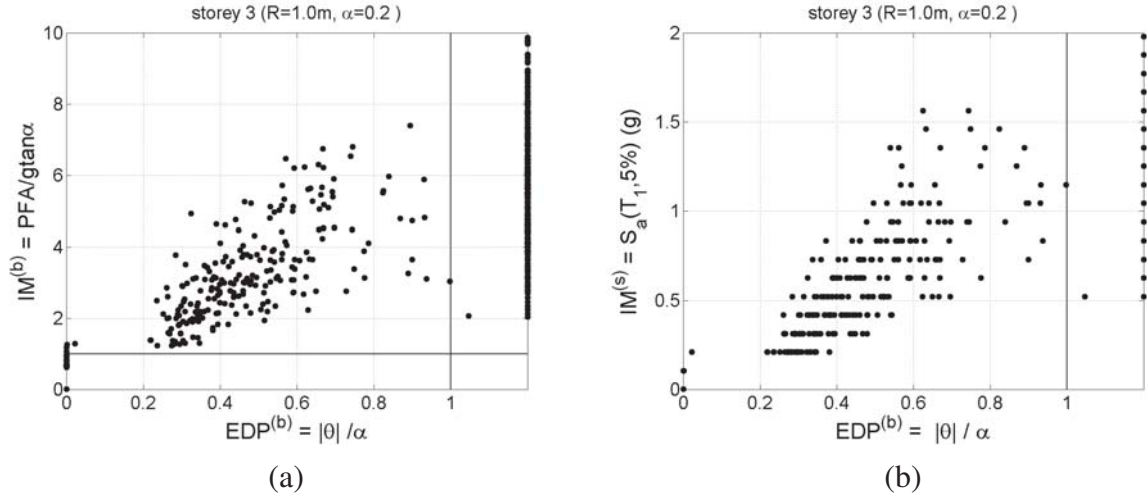

Figure 2: Seismic response of a freestanding building object with $R = 1.0m$ and $\alpha = 0.2$: (a) plotting $EDP^{(b)} - IM^{(b)}$ results to cloud data, (b) plotting $EDP^{(b)} - IM^{(s)}$ results to data in stripes.

is adopted instead, they appear in stripes (Fig. 2b). The IDA method can be directly applied to the striped data, while the cloud data require a different post-processing in order to derive the fragility curve. In the case of Figure 2b, the data form stripes and hence they can be post processed as was already shown in Section 5.1 for the building:

$$F_R^{(b)} = \Phi \left(\frac{\mu_{\log EDPb} - edp^{(b)}}{\sigma_{\log EDPb}} \right) (1 - P_{Ovtn} - P_{NoRock}) + P_{Ovtn} \quad (10)$$

Since the $F_R^{(b)}$ is calculated at every stripe P_{NoRock} , P_{Ovtn} are simply obtained as the percentage of simulations where no-rocking and overturning was observed, respectively. An alternative efficient way is to fit the cumulative distribution function (CDF) of a lognormal distribution on the striped EDP-IM data as discussed by Baker [15]. If the data are not stripped, as in Figure 2a, the cloud analysis method should be used instead.

6 Numerical Results

The acceleration and the velocity response spectra [2] allow to understand how the structure filters the record, i.e. they show the modes that are amplified and those that are filtered out. However, rocking structures do not have modes of vibration in the classical sense, i.e. like an elastically deforming body. For this reason, Figure 3 shows the mean rotation demand for two rigid blocks with the same size parameter $R = 1m$ and varying slenderness angle α . A smaller slenderness α value implies a more slender block, hence the block is more sensitive to overturning and keen to larger rotations. Having set overturning simulations to $\theta/\alpha = 1$, very interesting findings are offered by Figure 3. At $S_a(T_1, 5\%) = 0.4g$ (Fig. 3), the mean rotations of the scaled ground motions are very close to that of the top storey, while the demand is considerably smaller at lower stories. When the building is inelastic ($S_a(T_1, 5\%) = 1.0g$, Fig. 3b), the blocks that are subjected to the storey response histories have smaller rotation demand compared to the “ground” records. Therefore, regardless of the $S_a(T_1, 5\%)$ level, the building alters the frequency content of the ground motions reducing the fragility of the block for any slenderness angle α .

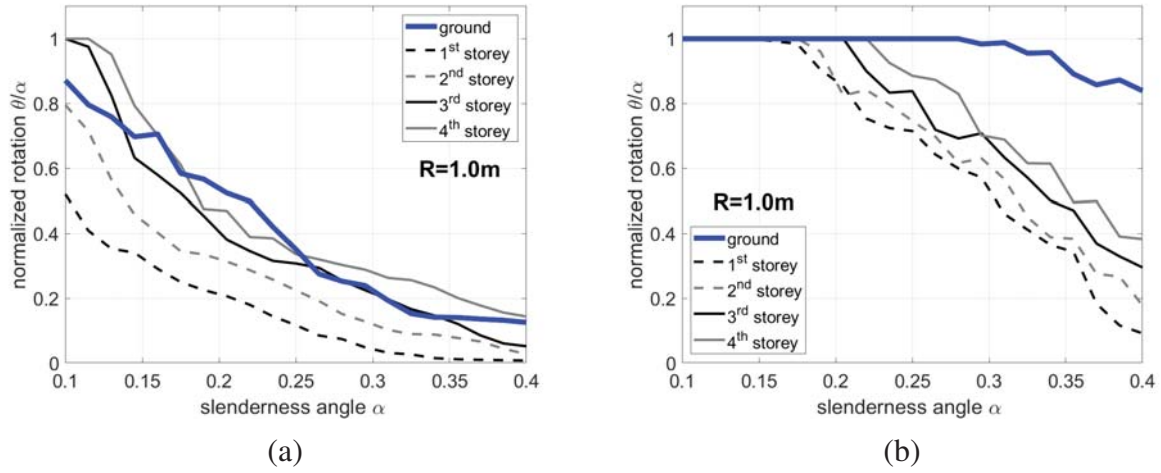

Figure 3: Mean rotation demands for rigid blocks with $R = 1m$ as function of the slenderness angle. The spectra were produced for building response histories scaled at: (a) $IM^{(s)} = 0.4g$ (elastic structure), and (b) $IM^{(s)} = 1.0g$ (inelastic structure).

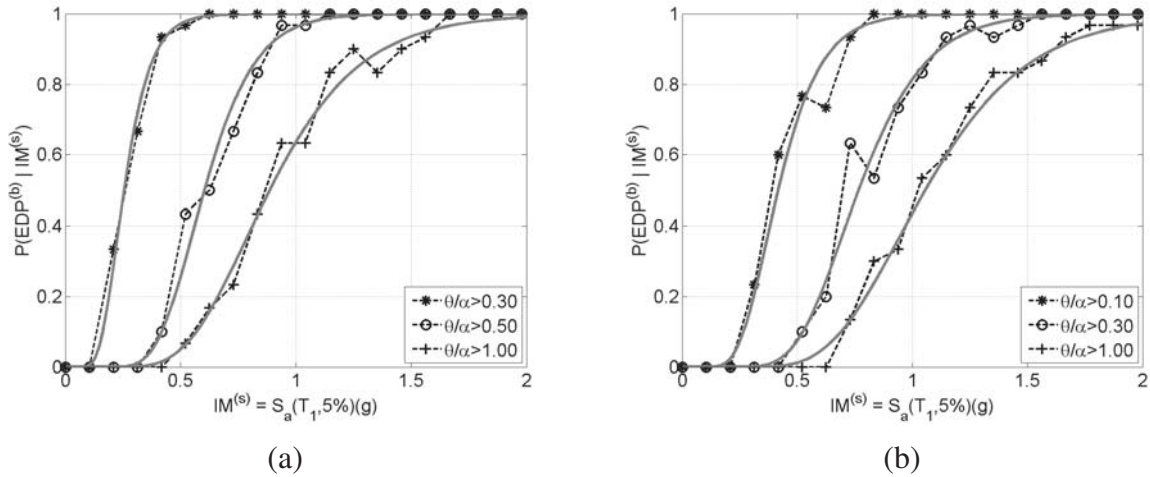

Figure 4: Fragility curves for a block located at the 3rd storey of the building: (a) slender block ($R = 1.0m$, $\alpha = 0.2$), (b) stocky block ($R = 1.0m$, $\alpha = 0.35$).

The remaining of the paper is focused on the seismic fragility assessment of the freestanding contents. We isolate two freestanding rocking blocks with $R = 1m$. The first has a slenderness angle $\alpha = 0.20$ and is considered as “slender”, while the second has $\alpha = 0.35$ and is referred as “stocky”. Three limit-states are identified for each block. For the slender block, the corresponding $EDP^{(b)} = \theta/\alpha$ threshold values are assumed as 0.3, 0.5 and 1, respectively, while for the stocky block the values are 0.1, 0.3 and 1. Different threshold values are used for each block due to their very different dynamic behaviour (e.g. see Fig 3). For example, $\theta/\alpha = 0.1$ is easily exceeded for the slender block and thus it is not a reasonable threshold, while for a stocky block the limit-state fragility of $\theta/\alpha = 0.5$ will, practically, coincide with that of overturning ($\theta/\alpha \geq 1$).

Figure 5 shows the block overturning fragilities using PFA as the intensity measure $IM^{(b)}$ of the block. The solid lines refer to the block subjected to the original ground motions, while the dashed lines were obtained using the response history of the fourth storey. Also, the dark

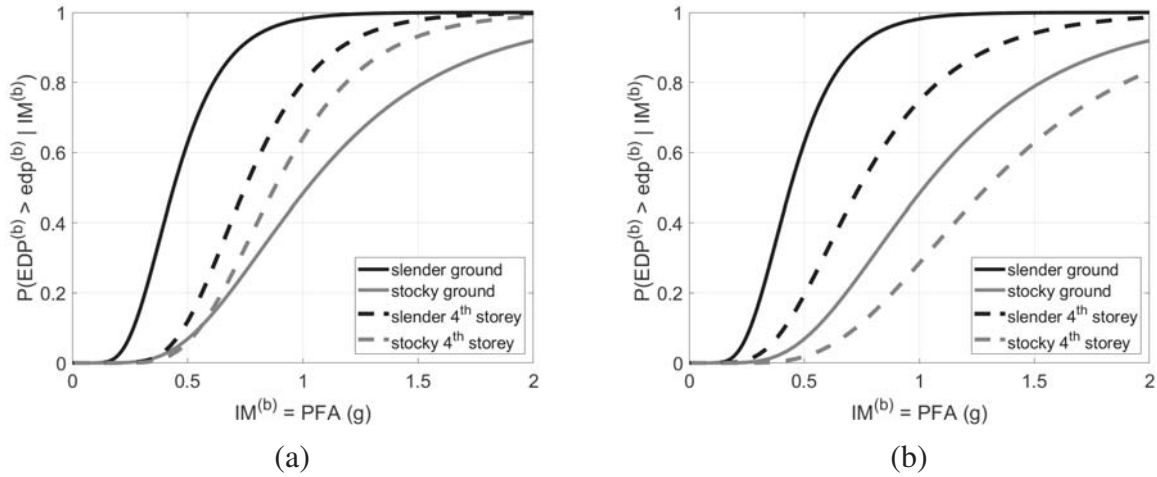

Figure 5: Overturning fragility curves of a slender ($R = 1.0m$, $\alpha = 0.2$) and a stocky block ($R = 1.0m$, $\alpha = 0.35$) assuming $IM^{(b)} = PFA$: (a) the block is considered overturned when the structure collapses, (b) the collapse of the structure is omitted.

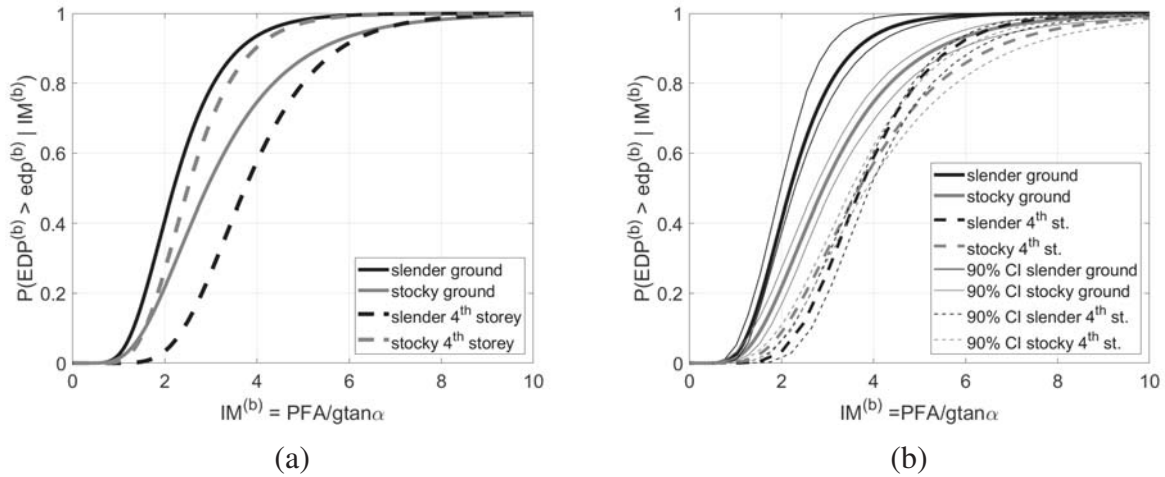

Figure 6: Overturning fragility curves of a slender ($R = 1.0m$, $\alpha = 0.2$) and a stocky block ($R = 1.0m$, $\alpha = 0.35$) assuming $IM^{(b)} = PFA/g \tan \alpha$: (a) the block is considered overturned when the structure collapses, (b) the collapse of the structure is omitted.

lines correspond to the slender block and the grey to the stocky. As expected, the slender block is always more vulnerable, while the building reduces its fragility (Fig. 5a). On the contrary, the building fragility overall increases for the stocky block. This is in agreement with the rocking spectra of Figure 3. In order to better understand the importance of considering the collapse of the structure, Figure 5b, repeats the fragility curves of Figure 5a, but this time ignoring the coupling between the structure and the block. In other words, in Figure 5b, we do not assume that the block overturns when structural collapse occurs. As before, for the slender block the fragilities are only slightly affected, but for the stocky block the fragility is very different. According to Figure 5a and b, when the coupling is neglected, the building is beneficial also for the stocky block.

The results of Figure 5 are repeated in Figure 6 but with $IM^{(b)} = PFA/g \tan \alpha$, instead of PFA . Since the blocks have a different slenderness angle α , the normalized $IM^{(b)}$ affects the

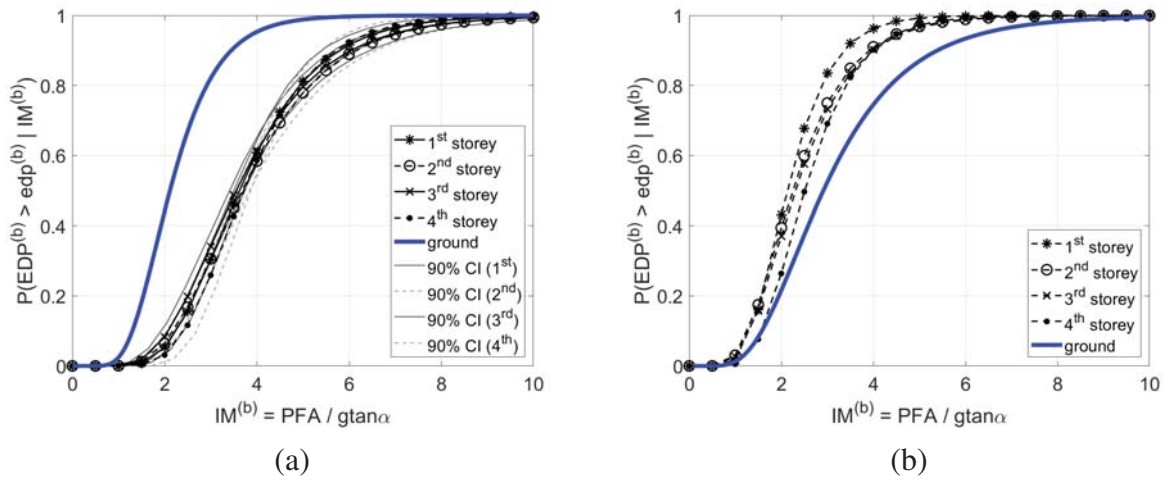

Figure 7: Storey overturning fragility curves: (a) slender block ($R = 1.0m$, $\alpha = 0.2$), (b) stocky block ($R = 1.0m$, $\alpha = 0.35$).

fragilities obtained. Qualitatively the results are the same compared to those of Figure 5a and b, but the fragilities curves are less dispersed, bringing closer the slender and the stocky block fragilities. Figure 6b also shows the 90% bootstrap confidence intervals around each fragility curve. The narrow confidence intervals obtained, verify that the comparison is statistically significant.

Figure 7 presents for all stories of the structure the block overturning fragilities assuming $IM^{(b)} = PGA/g \tan \alpha$. For both blocks, the storey fragilities practically coincide, while the “ground” fragilities differ considerably from those of the four stories. In principle, the fragility curves should coincide since they provide a property of the system that should not be sensitive to the ground motion set. However, due to the substantially different frequency content of the ground motions this is not the case here. Of interest is also to show the fragilities obtained using as $IM^{(b)}$ the PGV (or PFV) instead of the PGA (Fig. 8). Adopting the PGV , the storey fragilities appear more dispersed compared to the $PFA/g \tan \alpha$, which is more profound for the stocky block. Quantitatively, as before, the stocky block is more vulnerable on the ground, while the slender block is less affected by the structure compared Figure 5a. As a general conclusion, although qualitatively our conclusions are not affected by the $IM^{(b)}$, the fragility curves will differ and their interpretation requires attention. Furthermore, Figures 7a and 8a show the 90% confidence intervals which again verify the statistical significance of the fragilities obtained.

In order to calculate the limit-state mean annual frequencies (MAF) of the block, we adopt the hazard curve that corresponds to a site in the island of Crete, Greece. As discussed in a previous section, the limit-state MAFs are “exactly” calculated with Eq. 6. Alternatively, the MAFs can be calculated with Eq. 7 finding separately the fragility of the block and of the structure. The calculation of Eq. 7 requires the derivative of the block’s fragility, which essentially is the probability density function (PDF) for a number of discrete limit-states. For the example considered, the MAFs of Eq. 6 and Eq. 7 are shown in Table 1 for the first and the fourth storey of the RC building considered. In Eq. 7 two $IM^{(b)}$ were considered, $PGA/g \tan \alpha$ and PFV . Sufficient accuracy between the MAFs of the two approaches is achieved when the PFV is used as the intermediate variable in Eq. 7, while significant errors are observed for $IM^{(b)} = PFA/g \tan \alpha$. Although not shown, poor results were observed when the PFA was

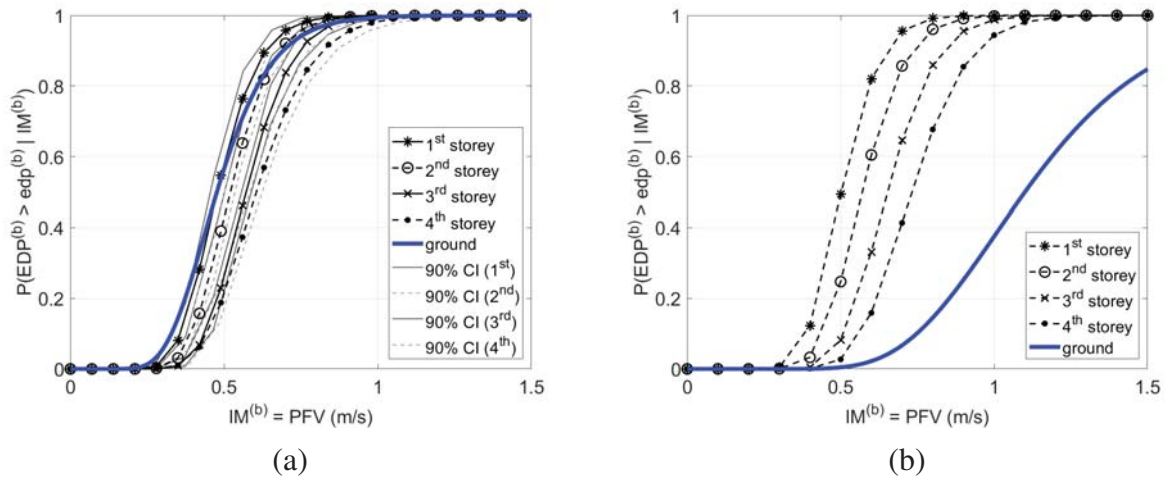

Figure 8: Storey overturning fragility curves using PFV as the IM of the block: (a) slender block ($R = 1.0m, \alpha = 0.2$), (b) stocky block ($R = 1.0m, \alpha = 0.35$).

used as $IM^{(b)}$. Moreover, the simplified method of Eq. 7 produces slightly better estimates for the slender block. The cloud data should be handled carefully, since the associated dispersion is naturally large. The main reason for the large variation of the MAFs in Table 1 is the biased fragilities of the blocks when the IM considered is the PFA. However, we have observed that using the PFV as IM, the approximate evaluation tends to produce smaller errors.

Table 1: Limit-state MAFs obtained for a rocking block using the exact (Eq. 6) and the simplified approach (Eq. 7) with either $PFA/gtan\alpha$ or PFV as the intermediate variables.

The comparison of the MAF estimates is better understood looking at the fragilities of Figure 9. The fragility $P(EDP^{(b)} | IM^{(s)})$ is compared with the direct calculation and is calculated as $P(EDP^{(b)} | IM^{(s)}) = \int_{IM^{(b)}} P(EDP^{(b)} | IM^{(b)}) dP(IM^{(b)} | IM^{(s)})$. Essentially the calculation

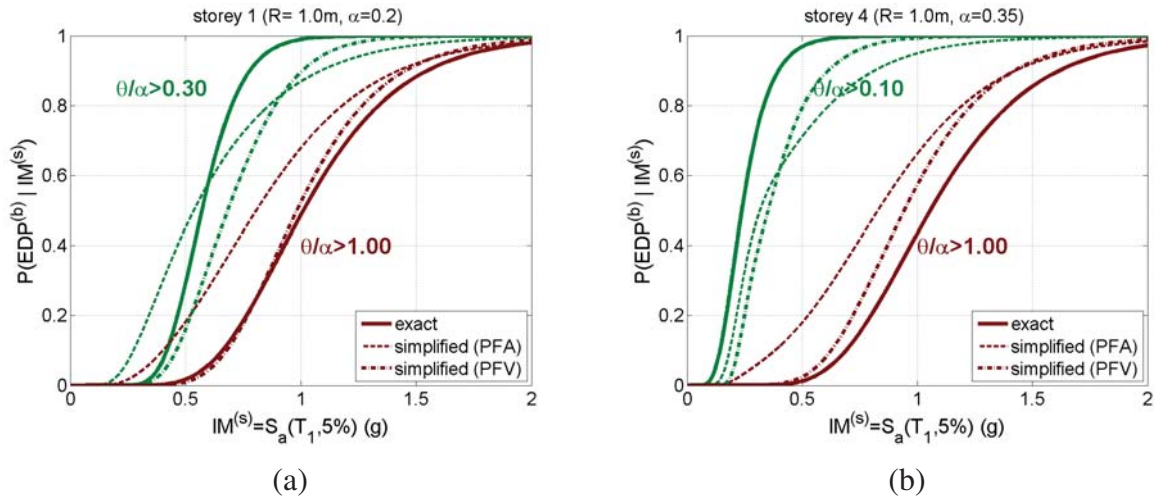

Figure 9: Fragility curves using the exact (Eq. 6) and the simplified approach (Eq. 7) for the slender block ($R = 1.0m, \alpha = 0.2$) and the stocky block ($R = 1.0m, \alpha = 0.35$): (a) first storey, (b) forth storey, respectively.

of Eq. 7 is repeated leaving out the slope of the hazard curve $d\lambda_{IM^{(s)}}$, which is common for both MAF equations. Figure 9 shows the good performance of *PFV* as opposed to *PFA*/ $gtan\alpha$, while better agreement is shown for the overturning limit-state and for the slender block.

Accepting that the choice of the $IM^{(b)}$ is important, it is necessary to investigate where do the errors shown in Figure 9 come from. This is understood comparing Figure 7 and Figure 9. Figure 7 shows that the fragility curves of the block at the building and at the ground will differ for the stocky block but not for the slender block. Since the collapse of the building does not affect the overturning fragility of the slender block (Fig. 7a), the overturning fragility of the slender block is almost the same regardless, if the structure's collapse is neglected or not, hence the overturning MAF of Figure 9 is closely estimated. On the other hand, for the slender block, the building and the ground fragilities differ and this is transferred to Figure 9b. However, even for the stocky block, the solution provided is acceptable given the many sources of uncertainty on the problem at hand. Another important remark is that the block used in this example were obtained including the building's collapse. Therefore, when the building's collapse does affect the fragilities, as in the case of the slender block, Eq. 7 is accurate. This hampers the use of Eq. 7 when generic fragility curves are to be adopted.

7 CONCLUSIONS

The fragility assessment of freestanding building contents has been discussed. The building contents were modelled as rigid blocks and it was assumed that they are hosted in a four-storey RC building. It has been shown that the problem addressed is complicated since the response of the structure and the contents are coupled. The findings of the study have been obtained using a single two-dimensional, four-storey building and hence cannot be always generalized. For this reason, further research is required in order to fully understand the effect of the structure on the fragility of freestanding contents. Nevertheless, the work presented should be considered as an attempt to offer some first guidelines on how the rocking problem can be handled for freestanding objects that are hosted in a building.

Keywords: Energy Dissipation Device, Hysteretic Behavior, Nonlinear Dynamic Analysis, Phenomenological Model, Shear Link.

Abstract. *Structures with passive energy dissipation systems are characterized by a complex dynamic behavior due to the hysteretic nature governing the response of the adopted devices. Mathematically speaking, the hysteretic models currently available to simulate the behavior of rate-independent devices, such as metallic and friction dampers, are much more complicated than those developed for rate-dependent devices, such as viscous fluid and viscoelastic solid dampers. To allow for a straightforward, accurate and efficient modeling of rate-independent energy dissipation devices in practice, we introduce a novel phenomenological model suitable for both metallic and friction dampers. Such a model offers the advantage of requiring an easy calibration procedure since it is based on a set of only four parameters having a clear mechanical significance. The proposed model is employed to simulate the actual behavior of some metallic dampers, denominated Shear Links, that have been experimentally tested at the University of Naples Federico II. In addition, numerical simulations are performed to show the capability of such devices in protecting structures from earthquake excitations.*

1 INTRODUCTION

Passive energy dissipation represents one of the most effective techniques for the seismic protection of buildings and bridges [1, 2, 3, 4]. This technique requires the use of special devices, called *dampers*, that are characterized by a high energy dissipation capacity and are generally incorporated in the external frames of a structure thus dissipating energy throughout its entire height [5].

Dampers typically exhibit a complex hysteretic behavior. In particular, such a behavior is referred to as *rate-independent* if the device restoring force depends on the device displacement, whereas it is defined *rate-dependent* when the device restoring force is a function of the device velocity. Clearly, there may exist some dampers showing both types of behavior at the same time [6].

Examples of rate-independent passive energy dissipation devices, commonly used for seismic protection of structures, are *metallic dampers* and *friction dampers*, whereas examples of rate-dependent devices are *viscous fluid dampers* and *viscoelastic solid dampers*.

Several hysteretic models have been proposed in the literature for simulating the complex behavior occurring in dampers [7]. Typically, rate-independent hysteretic models are much more complex than the rate-dependent ones from a mathematical point of view [8].

Among existing rate-independent models, the Bouc-Wen model [9, 10] and its modified versions [7] seem to be the most suitable ones since they allow for an accurate prediction of the hysteretic response of both metallic and friction dampers by using a relatively small number of parameters. Unfortunately, these models require parameters with no clear mechanical meaning thus involving the use of complex and time-consuming identification procedures. In addition, due to their differential nature, they are not computationally efficient since they require the numerical solution of a first-order nonlinear ordinary differential equation for the evaluation of the hysteretic variable at each time step of a nonlinear dynamic analysis.

To foster the use of accurate and efficient rate-independent models in practice, this paper proposes a novel phenomenological model able to predict the hysteretic behavior generally displayed by metallic and friction dampers. Compared to the celebrated Bouc-Wen model or its modified versions, the proposed model, belonging to a more general class formulated in [11, 12, 13], is based on a set of only four parameters having a clear mechanical significance. For such a reason, it needs a straightforward calibration procedure and, consequently, it may be easily adopted in practice.

The paper is organized into three parts. In the first part (Sections 2 and 3), we first derive the nonlinear equilibrium equations of a typical building frame equipped with energy dissipation devices and subjected to earthquake excitation. Subsequently, we briefly describe, for the reader's convenience, the three main categories of dampers with particular emphasis on the description of their hysteretic behavior.

In the second part (Section 4), we present a preliminary formulation of the proposed hysteretic model suitable for rate-independent dampers, such as metallic and friction devices, and then we illustrate the influence of the four parameters on the hysteresis loop size and/or shape.

Finally, in the third part (Section 5), we adopt the proposed hysteretic model to simulate the experimental behavior of a particular class of metallic dampers, denominated Shear Links, and we perform several nonlinear dynamic analyses on a building frame equipped with such devices to show their capability in reducing both floor relative displacements and absolute accelerations.

2 NONLINEAR EQUILIBRIUM EQUATIONS

The response of a Multi-Degree-Of-Freedom (MDOF) system is generally governed by the following system of coupled second-order nonlinear Ordinary Differential Equations (ODEs):

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) + \mathbf{f}_n(t) = \mathbf{p}(t), \quad (1)$$

in which $\mathbf{u}(t)$, $\dot{\mathbf{u}}(t)$, and $\ddot{\mathbf{u}}(t)$ are the generalized displacement, velocity, and acceleration vectors, respectively, whereas \mathbf{M} , \mathbf{C} , and \mathbf{K} represent the generalized constant mass, damping, and elastic stiffness matrices, respectively; in addition, $\mathbf{f}_n(t)$ is the generalized nonlinear force vector, which may have rate-independent and/or rate-dependent hysteretic nature, whereas $\mathbf{p}(t)$ represents the generalized external force vector depending on time t .

In this work, we specialize such nonlinear equilibrium equations to the structural model of a typical building frame equipped with energy dissipation devices, each mounted in combination with two diagonal braces. In particular, we introduce a 3-story two-dimensional (2D) structural model whose geometry is defined in a global, right-handed Cartesian coordinate system (O , Y , Z), as shown in Figure 1.

For simplicity, we assume that: a) frame elements, such as beams, columns, and braces, deform within their linear elastic range during the earthquake excitation, whereas the hysteretic devices exhibit nonlinear behavior; b) columns are axially inextensible; c) beams and braces are axially inextensible and flexurally rigid. We observe that these assumptions, typically introduced in the literature [14], can be removed without any influence on the proposed results.

Figure 1: 2D structural model of a typical building frame with added dampers.

The above-described structural idealization allows us to write the displacement, velocity, and acceleration vectors of the 2D structural model, relative to the ground, as follows:

$$\mathbf{u} = \begin{Bmatrix} u^{(1)} \\ u^{(2)} \\ u^{(3)} \end{Bmatrix}, \quad \dot{\mathbf{u}} = \begin{Bmatrix} \dot{u}^{(1)} \\ \dot{u}^{(2)} \\ \dot{u}^{(3)} \end{Bmatrix}, \quad \ddot{\mathbf{u}} = \begin{Bmatrix} \ddot{u}^{(1)} \\ \ddot{u}^{(2)} \\ \ddot{u}^{(3)} \end{Bmatrix}, \quad (2)$$

where $u^{(i)}$, $\dot{u}^{(i)}$, $\ddot{u}^{(i)}$ represent, respectively, the displacement, velocity, and acceleration along the Y -axis of the i -th floor.

On account of that, the constant mass, damping, and elastic stiffness matrices become:

$$\mathbf{M} = \begin{bmatrix} M^{(1)} & 0 & 0 \\ 0 & M^{(2)} & 0 \\ 0 & 0 & M^{(3)} \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} C^{(1)} + C^{(2)} & -C^{(2)} & 0 \\ -C^{(2)} & C^{(2)} + C^{(3)} & -C^{(3)} \\ 0 & -C^{(3)} & C^{(3)} \end{bmatrix}, \quad (3)$$

$$\mathbf{K} = \begin{bmatrix} K^{(1)} + K^{(2)} & -K^{(2)} & 0 \\ -K^{(2)} & K^{(2)} + K^{(3)} & -K^{(3)} \\ 0 & -K^{(3)} & K^{(3)} \end{bmatrix},$$

where $M^{(i)}$ is the i -th floor mass, $C^{(i)}$ is the i -th floor damping coefficient, whereas $K^{(i)}$ is the i -th floor elastic stiffness, obtained by summing the elastic stiffnesses of the i -th floor columns.

Finally, the nonlinear force vector and the external force vector are given by:

$$\mathbf{f}_n = \begin{Bmatrix} f_n^{(1)} \\ f_n^{(2)} \\ f_n^{(3)} \end{Bmatrix}, \quad \mathbf{p} = - \begin{bmatrix} M^{(1)} & 0 & 0 \\ 0 & M^{(2)} & 0 \\ 0 & 0 & M^{(3)} \end{bmatrix} \begin{Bmatrix} 1 \\ 1 \\ 1 \end{Bmatrix} \ddot{u}_g, \quad (4)$$

where $f_n^{(i)}$ represents the nonlinear force of the i -th floor, whereas \ddot{u}_g is the ground acceleration applied along the Y -axis. In particular, if the vector \mathbf{f}_n is a function of the displacement vector \mathbf{u} , its three components are computed as:

$$\begin{aligned} f_n^{(1)} &= \sum_{j=1}^3 f_j^{(1)}(u^{(1)}) - \sum_{j=1}^2 f_j^{(2)}(u^{(2)} - u^{(1)}), \\ f_n^{(2)} &= \sum_{j=1}^2 f_j^{(2)}(u^{(2)} - u^{(1)}) - \sum_{j=1}^2 f_j^{(3)}(u^{(3)} - u^{(2)}), \\ f_n^{(3)} &= \sum_{j=1}^2 f_j^{(3)}(u^{(3)} - u^{(2)}), \end{aligned} \quad (5)$$

where $f_j^{(i)}$ is the *rate-independent hysteretic force* exhibited by the j -th damper of the i -th floor.

Conversely, if the vector \mathbf{f}_n is a function of the velocity vector $\dot{\mathbf{u}}$, the displacement $u^{(i)}$, appearing in Equation 5, has to be substituted with the velocity $\dot{u}^{(i)}$; in such a case, $f_j^{(i)}$ would represent the *rate-dependent hysteretic force* displayed by the j -th damper of the i -th floor.

3 ENERGY DISSIPATION DEVICES

Several types of passive energy dissipation devices have been adopted worldwide to protect structures from earthquake excitations. According to the nature of their hysteretic behavior, such devices may be classified into three categories [7]:

1. *rate-independent hysteretic devices*: dampers whose restoring force does not depend on the rate of variation of the displacement (i.e., velocity) but only upon the displacement amplitude and the sign of the velocity (i.e., direction of the motion). Some examples are represented by *metallic dampers* and *friction dampers*.
2. *rate-dependent hysteretic devices*: dampers whose restoring force depends, partially or totally, on the rate of variation of the displacement (i.e., velocity). Examples of such devices are *viscous fluid dampers* and *viscoelastic solid dampers*.

Figure 2: Typical hysteresis loop of (a) metallic and (b) friction dampers.

Figure 3: Typical hysteresis loop of (a) viscous fluid and (b) viscoelastic solid dampers.

3. *further devices*: dampers which cannot be classified by one of the above-described basic types. Some examples are friction-spring devices with re-centering capability and fluid restoring force-damping devices.

Figure 2a (b) illustrates the typical force-displacement hysteresis loop of a metallic (friction) damper, whereas Figure 3a (b) shows the hysteresis loop which generally characterizes a viscous fluid (viscoelastic solid) damper.

Clearly, the hysteresis phenomena observed in these devices are induced by different types of mechanisms. As a matter of fact, in metallic dampers such a nonlinear behavior is associated with yielding of mild steel, whereas in friction dampers it is due to the sliding friction across the interface between two solid bodies.

Furthermore, in viscous fluid dampers the energy dissipation is due to the friction between fluid particles and the piston head, whereas in viscoelastic solid dampers it is related to the deformation of solid elastomeric pads.

4 PROPOSED HYSTERETIC MODEL

In this Section, we focus on the modeling of rate-independent hysteretic devices which, differently from the rate-dependent ones, require much more complex hysteretic models.

In particular, we first summarize the formulation of a novel uniaxial phenomenological

model belonging to a more general class introduced by Vaiana et al. [11, 12, 13, 15]; subsequently, we illustrate the influence of the four model parameters on the size and/or shape of the restoring force-displacement hysteresis loops.

4.1 Model Formulation

In the Proposed Hysteretic Model (PHM), u (f) represents the damper axial/transverse displacement (restoring force), whereas \dot{u} is the damper axial/transverse velocity.

The restoring force, during the generic loading case ($\dot{u} > 0$), is evaluated as:

$$f(u, u_j^+) = \begin{cases} c^+(u, u_j^+) & u \in [u_j^+ - 2u_0, u_j^+] \\ c_u(u) & u \in [u_j^+, \infty) \end{cases} \quad (6a)$$

$$(6b)$$

whereas, during the generic unloading case ($\dot{u} < 0$), it is computed as:

$$f(u, u_j^-) = \begin{cases} c^-(u, u_j^-) & u \in [u_j^-, u_j^- + 2u_0] \\ c_l(u) & u \in (-\infty, u_j^-] \end{cases} \quad (7a)$$

$$(7b)$$

In Equations 6 and 7, c^+ and c^- represent, respectively, the generic loading and unloading curves:

$$c^+(u, u_j^+) = k_b u + f_0 + \frac{k_a - k_b}{c_1} \left[+u - u_j^+ - \alpha_1 \log \left(c_1 + e^{\frac{+u - u_j^+ + 2u_0 - \alpha_2}{\alpha_1}} \right) + c_2 \right], \quad (8)$$

$$c^-(u, u_j^-) = k_b u - f_0 - \frac{k_a - k_b}{c_1} \left[-u + u_j^- - \alpha_1 \log \left(c_1 + e^{\frac{-u + u_j^- + 2u_0 - \alpha_2}{\alpha_1}} \right) + c_2 \right], \quad (9)$$

whereas c_u and c_l are, respectively, the upper and lower limiting curves:

$$c_u(u) = k_b u + f_0, \quad (10)$$

$$c_l(u) = k_b u - f_0. \quad (11)$$

The internal variable u_j^+ (u_j^-), that represents the displacement value where the generic loading (unloading) curve intersects the upper (lower) limiting curve, is given by:

$$u_j^+ = +\alpha_1 \log \left\{ c_1^{-1} \left[e^{+\frac{u_P + c_2 - c_1(k_a - k_b)^{-1}(f_P - k_b u_P - f_0)}{\alpha_1}} - e^{\frac{+u_P + 2u_0 - \alpha_2}{\alpha_1}} \right] \right\}, \quad (12)$$

$$u_j^- = -\alpha_1 \log \left\{ c_1^{-1} \left[e^{-\frac{u_P - c_2 - c_1(k_a - k_b)^{-1}(f_P - k_b u_P + f_0)}{\alpha_1}} - e^{\frac{-u_P + 2u_0 - \alpha_2}{\alpha_1}} \right] \right\}, \quad (13)$$

in which u_P and f_P are the coordinates of a generic point P belonging to c^+ or c^- .

As regards the internal parameters f_0 and u_0 , they are evaluated as:

$$f_0 = \frac{k_a - k_b}{2c_1} (2u_0 - c_2), \quad (14)$$

$$u_0 = \frac{1}{2} \left[\alpha_2 + \alpha_1 \log \left(\frac{k_a - k_b}{\delta_k} - c_1 \right) \right], \quad (15)$$

where δ_k is a numerical parameter set equal to 10^{-20} , whereas k_a , k_b , α_1 and α_2 represent the four model parameters to be calibrated from experimental or numerical data, with $k_a > k_b$, $k_a > 0$, $\alpha_1 > 0$, $\alpha_2 > 0$. Finally, c_1 and c_2 are two constants whose expressions, depending on the four model parameters and omitted for brevity, will be illustrated in detail in a future work.

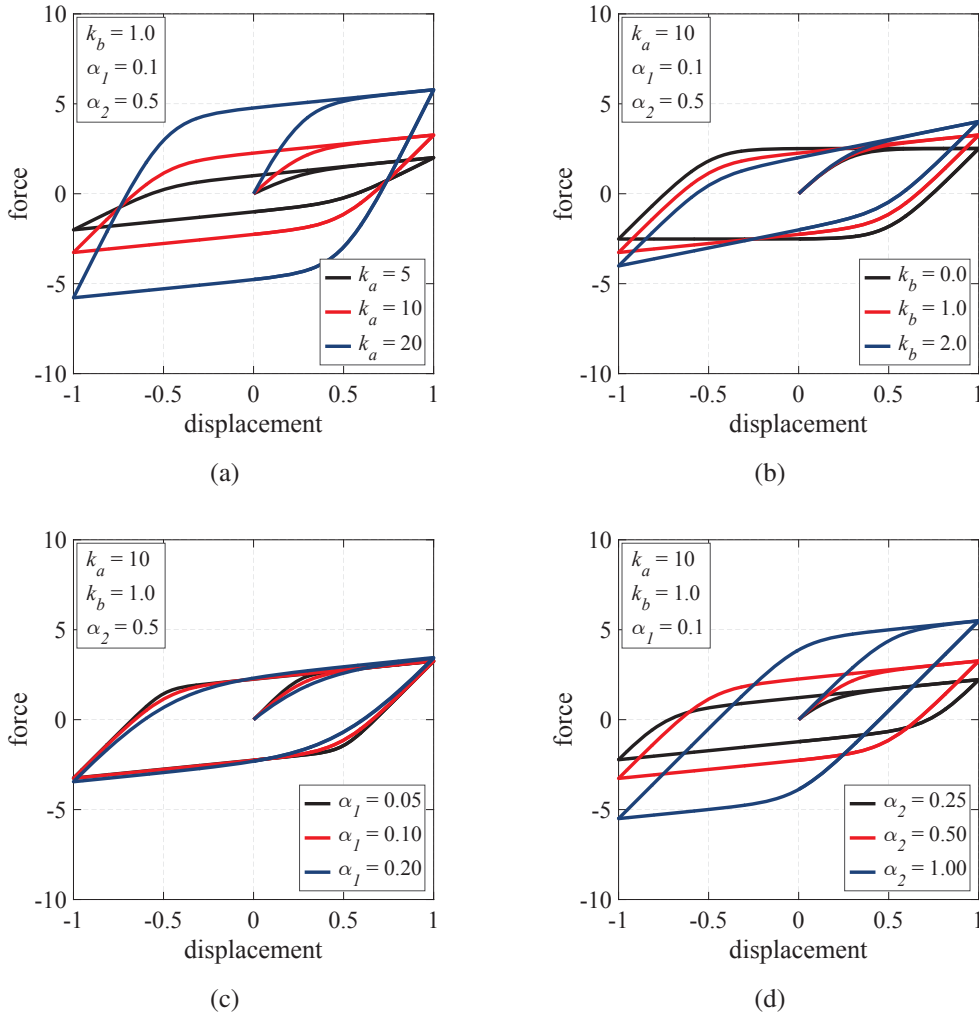

Figure 4: Influence of the PHM parameters variation on the hysteresis loop size and/or shape: (a) k_a , (b) k_b , (c) α_1 , and (d) α_2 .

4.2 Parameter Sensitivity Analysis

Figure 4 shows how the size and (or) the shape of hysteresis loops, obtained by imposing a full sinusoidal cycle of displacement having unit amplitude and frequency, change(s) due to the variation of each PHM parameter, namely k_a , k_b , α_1 and α_2 .

5 NUMERICAL EXPERIMENTS

This Section illustrates the results of several nonlinear time history analyses performed on a building frame equipped with energy dissipation devices and subjected to earthquake excitation. In order to demonstrate the effectiveness of the adopted passive control system and its capability to significantly decrease both floor relative displacements and absolute accelerations, the numerical results are compared with those obtained by analyzing the same building frame, having linear elastic behavior, without using the hysteretic devices.

To carry out the nonlinear dynamic analyses, the proposed hysteretic model, described in Section 4, is employed to simulate the behavior of each damper adopted in the passive control system. Furthermore, an accurate and computationally efficient explicit time integration method, described in [8], is adopted to numerically integrate the system of nonlinear equilib-

Figure 5: Shear Link: (a) typical lateral view and (b) comparison between experimental and analytical hysteresis loops of device *SL_30_3*.

rium equations. Due to its explicit nature, such a method offers the advantage of performing nonlinear dynamic analyses without adopting iterative procedures.

Both the hysteretic model and the numerical method have been implemented in the computer program MATLAB.

5.1 Structure Properties

Figure 1 shows the 2D structural model of the building frame selected to perform the numerical experiments. In particular, it is a three-story, three-bay reinforced concrete structure whose beams (columns) have a length of 6.0 m (3.2 m) and are characterized by a rectangular section with size 0.3 m x 0.4 m (0.5 m x 0.5 m).

The masses of the first, second, and third floor are equal to $85200 \text{ N s}^2 \text{ m}^{-1}$, $57400 \text{ N s}^2 \text{ m}^{-1}$, and $42600 \text{ N s}^2 \text{ m}^{-1}$, respectively, and are assumed to be lumped in the respective floor mass center, namely MC_1 , MC_2 , and MC_3 .

As a result of the assumptions made in Section 2, the total number of Degrees-Of-Freedom (DOFs) is equal to 3, whereas the three natural periods, evaluated without taking into account dampers and steel braces, are $T_1 = 0.2220 \text{ s}$, $T_2 = 0.0916 \text{ s}$, and $T_3 = 0.0630 \text{ s}$. As typically done with reinforced concrete structures, it is assumed that each mode has a damping ratio of 5% [14].

The passive control system consists of 7 dampers which are mounted between the steel braces and the upper beam, as illustrated in Figure 1. The adopted devices, denominated *Shear Links*, are metallic dampers, having rate-independent hysteretic behavior, that are manufactured from a I-shaped laminated steel plate [16, 17]. As shown in Figure 5(a), this type of device is typically made up of a) vertical stiffeners, that ensure the device stability, b) external flanges, that allow for the device connection to structural elements, and c) dissipative windows, that are capable of dissipating energy. Bolted connections are employed to facilitate the installation process; in particular, slotted holes are used for the upper connection in order to avoid axial forces on the device.

The Shear Links employed in this paper have been experimentally tested by Nuzzo et al. [18]

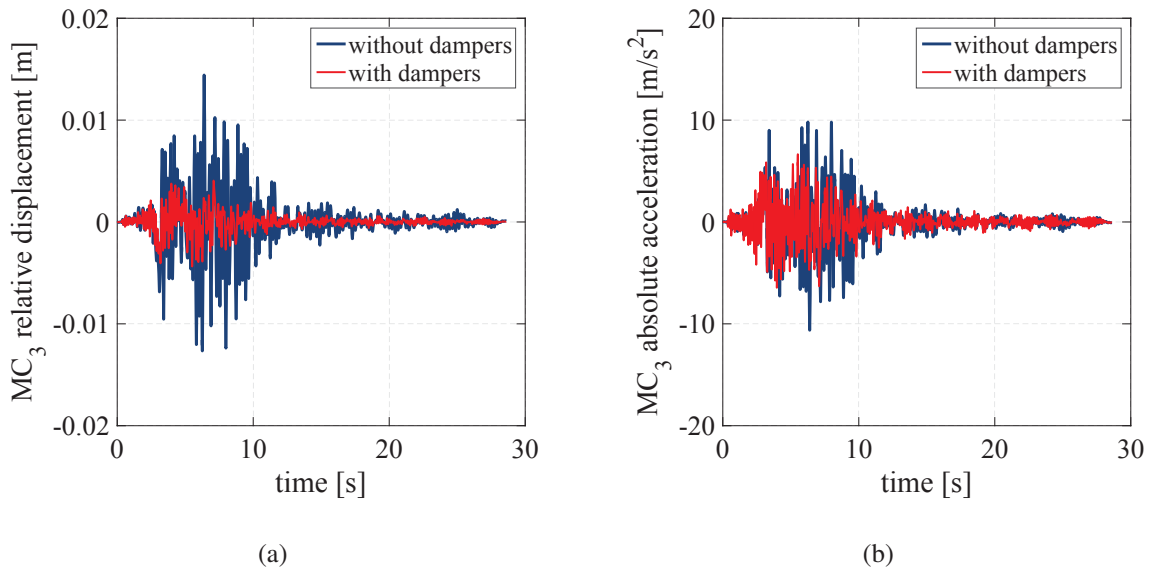

Figure 6: Time histories of the MC_3 (a) relative displacement and (b) absolute acceleration obtained with (red line) and without (blue line) metallic dampers.

at the laboratory of Department of Structures for Engineering and Architecture of the University of Naples Federico II (Italy). In particular, the device adopted in the numerical simulation, denominated SL_{30_3} , exhibits the restoring force-displacement hysteresis loops of Figure 5(b) when subjected to a displacement time history having increasing amplitude [18].

5.2 Applied earthquake excitation

The analyses are performed by imposing, along the Y -axis, the component SN of the 1994 Northridge motion, and by adopting a ground acceleration record time step of 0.005 s.

5.3 Hysteretic model parameters

The complex behavior of each Shear Link is simulated with the novel phenomenological model, presented in Section 4, whose 4 parameters have been calibrated on the basis of the experimental hysteresis loops obtained by Nuzzo et al. [18]. In particular, the values identified for such parameters are: $k_a = 2 \times 10^8$ N/m, $k_b = 6 \times 10^6$ N/m, and $\alpha_1 = \alpha_2 = 0.002$ m.

Figure 5(b) compares the experimental hysteresis loops of the device SL_{30_3} with those predicted by means of the proposed hysteretic model thus demonstrating a satisfactory agreement between them.

5.4 Numerical results

Figure 6(a) illustrates the time histories of the MC_3 displacement, relative to the ground, obtained with (red line) and without (blue line) metallic dampers; similarly, Figure 6(b) shows the time histories of the MC_3 absolute acceleration obtained with (red line) and without (blue line) Shear Links. Looking at such comparisons, it is evident that the adopted passive protection system is capable of limiting potential damages induced by seismic events since it allows for the reduction of both floor relative displacements and absolute accelerations.

6 CONCLUSIONS

We have presented a preliminary formulation of a novel uniaxial phenomenological model that is capable of simulating the complex behavior of both metallic and friction dampers by employing four parameters having a clear mechanical significance.

The proposed model has been calibrated on the basis of some experimental hysteresis loops obtained by Nuzzo et al. [18] during an experimental campaign performed on Shear Link devices. In particular, the accuracy of the model has been verified by comparing the simulated restoring force-displacement hysteresis loops with those obtained from the experimental tests.

In addition, the proposed model has been employed to analyze a building frame equipped with Shear Links. The numerical results obtained by applying an earthquake ground acceleration have demonstrated the capability of the adopted dampers in controlling excessive floor displacements and accelerations.

Keywords: Seismic Protection; Art Objects; Elastomeric Isolators; Lead Rubber Bearings; Hysteretic Model.

Abstract. *We investigate the rocking response of a Caryatid from the Erechtheion, modelled as a rigid body freestanding on an isolation system made of Lead Rubber Bearings. An efficient uniaxial phenomenological model belonging to a recently developed class is used to simulate the strongly nonlinear response typically exhibited by elastomeric devices. The algebraic nature of the proposed hysteretic model allows one to obtain the device restoring force by solving an algebraic equation, thus reducing the computational effort of the nonlinear dynamic analyses that have been carried out on the above-mentioned Caryatid statue. In order to establish the effective performances of the proposed isolation system the isolated and non-isolated rocking responses of the statue are derived and compared.*

1 INTRODUCTION

Nowadays the large majority of statues contained in museums are not equipped to resist oscillations induced by earthquakes. For this reason, seismic protection of artefacts belonging to the cultural heritage is a topic that has received significant interest over the last years [1, 2, 3, 4, 5, 6, 7, 8]. In particular, researchers focused on the study of the rocking behaviour of rigid bodies since the statues, which are simply supported on the floor or a pedestal, could overturn under seismic excitation. Moreover, their overturning and damage is potentially associated with significant human and economic losses [9, 10].

Base isolation represents one of the most adopted strategies for the seismic protection of artefacts belonging to the cultural heritage. In fact, such a technique has been used for the protection of some statues in Italy, such as the Riace bronzes exhibited in the Archaeological Museum in Reggio Calabria [11], the Dancing Satyr at the Dancing Satyr Museum in Mazara del Vallo, and the Imperatore Germanico at the Edilberto Rosa Museum in Amelia [12].

The most used isolation device - mostly for the seismic protection of buildings and bridges - are the Elastomeric and Sliding isolators. The formers provide energy dissipation by using an elastomeric material, whereas the latter display an energy dissipation capacity due to the friction damping occurring at the sliding interface. Both seismic isolation bearings display a force-transverse displacement relationship of hysteretic nature.

The dynamics of a base-isolated rigid body strictly depends on the interaction between the complex nonlinear behaviour of the isolation devices and the rocking behaviour of the rigid body. Consequently, it is very important to adopt a hysteretic model able to accurately predict the seismic isolators response.

In this paper, we investigate the rocking response of a Caryatid from the Erechtheion, modelled as a rigid body freestanding on an isolation system made of Lead Rubber Bearings, i.e. one of the most popular elastomeric isolators used in Civil Engineering applications.

The behaviour of the elastomeric devices is predicted by using an efficient uniaxial phenomenological model belonging to a recently developed class [13, 14, 15]. Since the model has an algebraic nature, the device restoring force is computed by solving an algebraic equation so that the numerical solution of a first-order nonlinear ordinary differential equation at each time step of the analysis is not required. Moreover, the model is based on a small set of parameters having a clear mechanical significance.

Nonlinear dynamic analyses are carried out on the above-mentioned Caryatid statue, with and without isolation, in order to establish the performance of the latter in protecting the analysed art object from seismic excitations.

2 SEISMICALLY ISOLATED RIGID BODY MODEL

The Caryatid from the Erechtheion under investigation has been modelled as a symmetric rigid body freestanding on an isolation system made of elastomeric bearings. We supposed that the friction between the statue and the isolated base is high enough to avoid the sliding.

The geometrical parameters of the model are shown in Fig. 1(a), namely the distance R between the centre of gravity and the centre of rotation, and the slenderness γ measured as the tilt angle relative to the vertical axis when the body is at rest. Their values are taken from a paper by Constantinides et al. [16] who studied the seismic response of six statues belonging to a collection shown at the University of California, Berkeley.

The Caryatid's mass m , equal to 3 172.05 kg, has been obtained supposing that the density of Caryatid's material is equal to 2 650 kg m⁻³. Hence, the Caryatid's fundamental angular

Figure 1: The Caryatid from the Erechtheion.

rocking frequency is given by

$$\omega_r = \sqrt{\frac{m g R}{J_O}} \approx 2.60 \text{ rad s}^{-1}, \quad (1)$$

where g is the gravity acceleration and J_O is the polar inertia around one of the two Caryatid's centre of rotation.

Finally, the mass of the isolated base m_b is supposed to equal to 212 kg.

2.1 Kinematic phases

There are two phases of motion that can occur, namely the full-contact and the rocking motion. The former is described by one degree of freedom, i.e. the horizontal movement of the base $x(t)$, whereas in the latter there are two degrees of freedom activated: one is the horizontal movement and the other measures the tilt angle of the body $\varphi(t)$.

The equations of motion change depending on the phase of motion that the rigid body undergoes.

2.2 The full-contact motion

In the full-contact phase, the Caryatid does not rock while the isolated base moves as shown in Fig. 1(b).

The equation of motion that describes this phase is

$$(m + m_b) (\ddot{x}_g + \ddot{x}) + n_d f = 0, \quad (2)$$

where \ddot{x}_g is the ground acceleration, n_d is the number of devices that support the isolated base and the statue, and f is the generalised restoring force of the elastomeric isolator.

2.3 The rocking motion

Fig. 1(c) illustrates the rocking motion. In this phase, the Caryatid rocks while the isolated base moves; thus there are two degrees of freedom activated.

By using the signum function $\text{sgn}(\cdot)$, as shown in [3], this phase can be described by just one set of two equations, regardless of the centre of rotation around which the Caryatid rocks. Hence, we have

$$m(\ddot{x}_g + \ddot{x} + \ddot{x}_\varphi) + m_b(\ddot{x}_g + \ddot{x}) + n_d f = 0, \quad (3)$$

$$J_O \ddot{\varphi} + m(\ddot{x}_g + \ddot{x}) R \cos(\text{sgn}(\varphi) \gamma - \varphi) = -m g R \sin(\text{sgn}(\varphi) \gamma - \varphi), \quad (4)$$

in which \ddot{x}_φ is the acceleration of the centre of mass relative to the ground. This acceleration depends on the rocking angle φ , since

$$x_\varphi = \text{sgn}(\varphi) R \sin(\gamma) - R \sin(\text{sgn}(\varphi) \gamma - \varphi). \quad (5)$$

Consequently, the second derivative with respect to the time of (5) is:

$$\ddot{x}_\varphi = R \sin(\text{sgn}(\varphi) \gamma - \varphi) \dot{\varphi}^2 + R \cos(\text{sgn}(\varphi) \gamma - \varphi) \ddot{\varphi}. \quad (6)$$

2.4 Collisions

As usual in the specialised literature, we assume that when the Caryatid collides with the isolated base, the linear (angular) momentum remains unchanged whereas the linear (angular) kinetic energy decreases. Accordingly, the angular and the linear coefficients of restitution obtained by the law of momentum conservation are [2]:

$$e_\varphi = 1 + \frac{2 R^2 \sin^2(\gamma) m}{R^2 \cos^2(\gamma) m \tilde{m} - J_O}, \quad (7)$$

and

$$e_x = \frac{2 R^4 \sin^2(\gamma) \cos^2(\gamma) m \tilde{m}}{R^2 \cos^2(\gamma) m \tilde{m} - J_O}, \quad (8)$$

where $\tilde{m} = m/(m + m_b)$.

3 LEAD RUBBER BEARINGS AND THEIR MATHEMATICAL MODEL

Elastomeric isolators are one of the most popular devices used for the protection of mechanical and civil systems from seismic events. They are characterised by layers of elastomeric materials and thin reinforcing elements. Elastomers provide energy dissipation and flexibility, whereas the reinforcing elements avoid the lateral expansion of the elastomer due to the axial compressive load.

In this Section, the main characteristics of Lead Rubber Bearings (LRBs) - one of the most used types of elastomeric isolators - are illustrated. In addition, the proposed hysteretic model, able to predict the complex hysteretic behaviour of such isolators, is described.

3.1 Lead Rubber Bearings

Lead Rubber Bearings have a circular or square transverse cross-section and are connected with the superstructure and the substructure by means of two steel plates bounded to the top and the bottom surfaces of the devices, see Fig. 2(a). Additionally, they are characterised by one or more lead cores that provide high values of horizontal stiffness and energy dissipation. In particular, the damping factor of such devices can reach a value up to $\xi \approx 15 \div 35\%$. Fig. 2(b) shows the typical hysteresis loop shape displayed by LRBs.

Figure 2: Lead Rubber Bearing.

3.2 Proposed hysteretic model

In this Section, we present the proposed hysteretic model able to predict the complex behaviour of the LRBs isolators. The accuracy and the computational efficiency of such a model have been demonstrated in previous papers [13, 17], by comparison with the celebrated Bouc-Wen model [18, 19]. In fact, the latter model requires the numerical solution of a differential equation to compute the restoring force of the device, what increases the overall computational effort. On the contrary, the proposed hysteretic model is of algebraic nature, i.e. the restoring force can be computed by means of algebraic equations; moreover, the model is based on just three constitutive parameters that can be calibrated from experimental tests [20] or by means of a design procedure described in [21].

Making reference to [22] for further details, the generic hysteresis loop is modelled by four types of curves, namely the upper (lower) limiting curve c_u (c_l) and the generic loading (unloading) curve c^+ (c^-), as shown in Fig. 3. The point of intersection between the upper (lower) limiting curve and the axis of ordinate is denoted as f_0 ($-f_0$). In addition, the starting and the ending points of the generic loading (unloading) limiting curve have abscissa x_i^+ and x_j^+ (x_i^- and x_j^-), respectively. The model assumes that the horizontal distance between the starting and the ending points for both loading and unloading curves is constant and equal to $2x_0$, where x_0 is an internal model parameter.

The restoring force in the generic loading case is equal to $f = c^+$ when $x_i^+ < x < x_j^+$ and $f = c_u$ when $x > x_j^+$; whereas $f = c^-$ when $x_j^- < x < x_i^-$ and $f = c_l$ when $x < x_j^-$.

The expressions of the upper (lower) and the loading (unloading) limiting curves used for predicting the hysteretic behaviour of LRBs are

$$c_u = k_b x + f_0, \quad (9)$$

$$c_l = k_b x - f_0, \quad (10)$$

and

$$c^+ = k_b x + (k_a - k_b) \left[\frac{(1 + x - x_j^+ + 2x_0)^{(1-\alpha)}}{1-\alpha} - \frac{(1 + 2x_0)^{(1-\alpha)}}{1-\alpha} \right] + f_0, \quad (11)$$

$$c^- = k_b x + (k_a - k_b) \left[\frac{(1 + x - x_j^- + 2x_0)^{(1-\alpha)}}{\alpha - 1} - \frac{(1 + 2x_0)^{(1-\alpha)}}{\alpha - 1} \right] - f_0, \quad (12)$$

Figure 3: Proposed hysteretic model.

where k_a , k_b and α are the model's constitutive parameters. The mechanical significance of these parameters is illustrated in [22].

Finally, the internal model parameters x_0 and f_0 are computed as follows:

$$x_0 = \frac{1}{2} \left[\left(\frac{k_a - k_b}{\delta_k} \right)^{\frac{1}{\alpha}} - 1 \right], \quad (13)$$

$$f_0 = \frac{k_a - k_b}{2} \left[\frac{(1 + 2x_0)^{(1-\alpha)} - 1}{1 - \alpha} \right], \quad (14)$$

in which δ_k may be set equal to 10^{-20} , as shown in [13].

4 APPLICATION TO A CARYATID FROM THE ERECHTHEION

In this Section, we show the results obtained from some nonlinear time history analyses on the Caryatid from the Erechtheion described in Sec. 2. The East-West component of ground acceleration recorded at the AL011_DZC station during the Düzce earthquake (Turkey), that occurred on the 12th of November 1999, is used as seismic input. Such an acceleration, displayed in Fig. 4(a), has been taken from the Engineering Strong Motion (ESM) database [23]. The rocking response of the non-isolated Caryatid subjected to the above-mentioned acceleration is shown in Fig. 4(b). As a result, the Caryatid needs to be protected since, due to the assumed excitation, it overturns after approximately thirty-five seconds.

Firstly, we built the Caryatid's rocking spectrum when it is subjected to the Düzce earthquake acceleration, see Fig. 5(a), where T_r refers to the rocking period. We observe that the Caryatid is vulnerable to such an excitation when its rocking period is less than four seconds. Hence, the base isolation will be efficient if it increases the Caryatid rocking period above four seconds.

Fig. 5(b) shows the horizontal displacement spectrum referred to the isolated Caryatid with LRBs devices by increasing the viscous damping factor, where T_{bi} is the isolation period. This spectrum allows one to infer the isolation period and the equivalent viscous damping factor providing a displacement less than the device's maximum allowed displacement, x_{\max} .

Fig. 6 illustrates the time histories of the rocking angle (a) and displacement (b) of the base-isolated Caryatid characterised by the properties shown in Tab. 1(a). The adopted constitutive parameters of the model are shown in Tab. 1(b). Such parameters have been obtained from the design procedure described in [21].

Figure 4: The East-West component of the Düzce earthquake acceleration recorded on the 12th of November 1999 (a); Non-isolated Caryatid's rocking response (b).

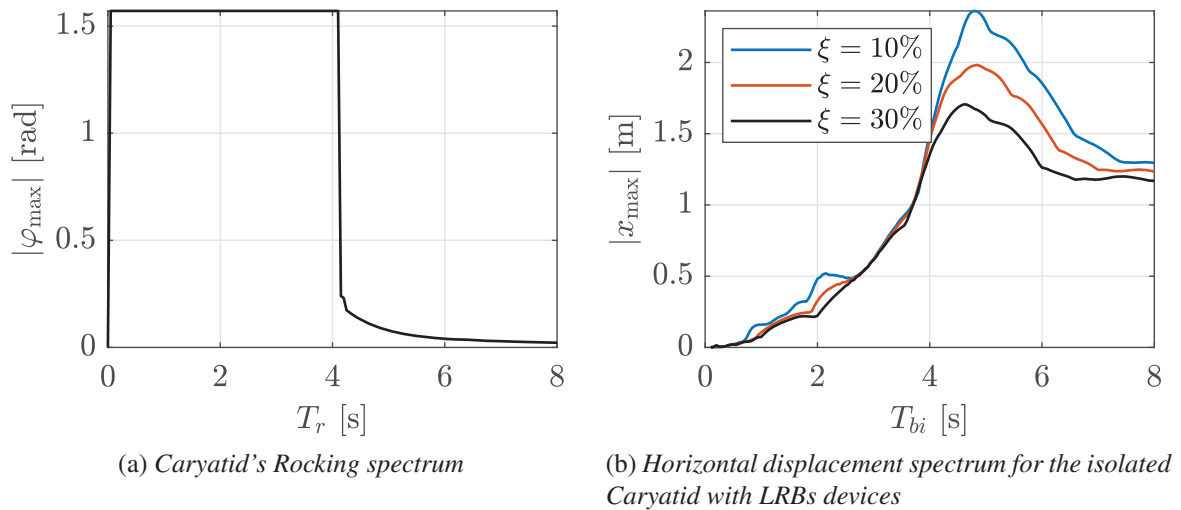

Figure 5: Response spectra obtained from the Düzce earthquake acceleration.

The results are very satisfactory, given that the base-isolated Caryatid does not rock, removing the possibility of damage due to collisions. Moreover, the attained displacements are much smaller than the device's maximum assumed displacement whose value is shown in Tab. 1(a).

Table 1: LRBs' properties (a); The model constitutive parameters of the model (b).

n_d [-]	T_{bi} [s]	x_{\max} [m]	ξ [%]	k_a [N m ⁻¹]	k_b [N m ⁻¹]	α [-]
4	2	0.30	30	6.22×10^4	6.22×10^3	44.69

5 CONCLUSIONS

The rocking behaviour of a Caryatid from the Erechtheion subjected to the 1999 Düzce earthquake (Turkey) has been investigated. After approximately thirty-five seconds the statue overturns. Consequently, a base isolation supported on four Lead Rubber Bearings as seismic protection system has been considered. We modelled the Caryatid object under study as a symmetric rigid body able to rock about one of the two bottom corners and assuming that sliding was prevented. Regarding the collisions, we applied the laws of conservation of linear and angular momentum in order to evaluate the angular and linear coefficients of restitution.

The complex hysteretic behaviour of the assumed elastomeric devices has been predicted by an innovative uniaxial phenomenological model of algebraic nature. As a consequence, the computational effort is drastically reduced, since there is no need to solve any differential equation to evaluate the device's restoring force as in the well-known Bouc-Wen model. In addition, the algebraic nature makes the model suitable for a design procedure able to provide the required constitutive parameters. The related procedure will be illustrated in a forthcoming paper [21].

Numerical assessments have been carried out on the Caryatid statue, with and without isolation. Firstly, we computed the rocking and horizontal displacement response spectra of the statue subjected to seismic excitation, in order to establish the isolation period and the device's maximum displacement to utilise. The results have shown that the Lead Rubber Bearings isolation system not only avoids overturning of the Caryatid, but it completely removes the rocking motion; hence, any kind of damage due to collision is avoided. Moreover, the horizontal displacements attained by the base-isolated are less than the maximum displacement allowed for the adopted device.

In future papers, further types of rate-independent hysteretic devices [24, 25, 26, 27, 28] will be employed to evaluate their capability in protecting rigid bodies from earthquake excitations.

Abstract

Fiber-reinforced elastomeric isolators (FREIs) are elastomeric devices which have been introduced as a low-cost alternative to the well-known steel-reinforced elastomeric isolators (SREIs). As common in rubber-based devices, the application of FREIs to lightweight structures is challenging: when the mass is limited, the resulting slender bearings tend to become unstable under large horizontal displacements. On the basis of numerical and experimental findings, this research work aims to demonstrate a simple to implement and low-cost approach to extend the application of FREIs to lightweight structures. The technique here discussed allows (i) to reduce the horizontal stiffness of FREIs, (ii) to increase the stability range of the bearings, and (iii) to obtain a desired hardening response for large lateral deformations, with no instability.

Keywords: seismic isolation, elastomeric isolators, fiber-reinforced elastomeric isolators, low-cost seismic isolation, finite element analysis.

1. INTRODUCTION

Fiber-reinforced elastomeric isolators (FREIs) are made by bonding together layers of elastomer and layers of carbon or glass fibers. These bearings were introduced as a low-cost alternative to common steel-reinforced elastomeric isolators (SREIs) [1]. Several studies have shown the advantages of using FREIs in common base isolation applications. In particular, it has been proved that FREIs can be made using a cold vulcanization process, which is less expensive than the vulcanization process used for SREIs [2]. With the same process it is possible to manufacture eco-friendly and low-cost devices using elastomeric layers of recycled rubber and readily available fiber fabrics [3, 4].

FREIs are generally used in unbonded applications (U-FREIs). In this configuration, the imposed shear load is transferred through friction [5]. U-FREIs show a unique rollover deformation when they are displaced under lateral loads ([1], [6]): the top and bottom sides of the bearings detach from the horizontal subgrades, while the lateral surfaces of the bearings rotate until they touch the horizontal plates [7]. Depending on the aspect ratio of the bearing and the applied axial load, the lateral response of a FREI can become unstable for a lateral displacement larger than half of its base ([8], [9]). Analytical models for the static and dynamic response of rubber bearings have been

proposed ([10, 11, 12, 13, 14]). But the challenging lateral response of the bearings has prompted several experimental ([15], [16], [17], [18], [19], [20]) and numerical studies ([21, 22]).

For elastomeric base isolation systems, the period of isolation is function of the applied vertical load ([23], [24]). Ideally, a rubber-based device should be flexible, stable under large lateral deformations, and should show hardening for very large displacements to contain the deformation of the bearing and to prevent damage. With this aim in mind, different geometric configurations have been tested, most of which have been obtained by creating vertical holes in FREIs to reduce their horizontal stiffness, with a minimal impact on the stability of the bearing under lateral loads ([25], [26], [27], [28]). A different concept for the modification of the response of U-FREIs is discussed in the present work. In particular, the effects of horizontal holes on the lateral response of rubber-based devices, introduced by the authors earlier [29], are discussed. Results of experimental and numerical analyses are presented to show that by changing the geometry of a FREI, it is possible to obtain:

- a controlled reduction of the horizontal stiffness.
- hardening under large lateral deformations.
- a wide range of stable response.

2. EXPERIMENTAL TESTS

2.1. Description of the tested samples

The bearings tested in this study were manufactured by Kirkhill Manufacturing Company, Downey, CA following Caltrans specifications [30]. As per specifications, laminated pads were made by bonding together elastomeric layers and fabric reinforcements. Each of the tested bearings was cut from a pad of bigger dimensions. Each sample was made by bonding 9 layers of neoprene to 8 layers of bidirectional glass fiber reinforcements.

A total of 4 bearings were tested; Table 1 gives an overview of the main geometric characteristics of the bearings. In Table 1: $2b$ is the side of the bearing perpendicular to the holes, $2a$ is the side parallel to the holes; $A = 4ab$ is the plan area of the bearing; H is its total height; $V = A \cdot H$ is the volume of the bearing; \emptyset is the diameter of the single hole; V_{holes} is the total volume of the holes.

Figure 1 is a schematic of the tested samples, with dimensions. The four samples have the same geometry (130(2a)x60(2b)x52(H) mm) and an increasing number of holes (0, 4, 12, 20).

Table 1: Description of the tested bearings.

1	Neoprene	Glass	Unmodified	130	60	7800	52	40560	0	6	0.0	0.00%	130x60 U
2	Neoprene	Glass	4 holes Ø6	130	60	7800	52	40560	4	6	67856	1.67%	130x60 4H
3	Neoprene	Glass	12 holes Ø6	130	60	7800	52	40560	12	6	20357	5.02%	130x60 12H
4	Neoprene	Glass	20 holes Ø6	130	60	7800	52	40560	20	6	33929	8.37%	130x60 20H

Figure 1: Bearing: a) 130x60 U, b) 130x60 4H, c) 130x60 12H, d) 130x60 20H. All the bearings have 52 mm height.

The holes are made using a drill press (Figure 2), while clamping the sample between two steel plates for alignment. As clear from Table 1, the percentage of removed volume is rather low, being always less than 10% of the total volume of the bearing.

Figure 2: Creation of the pattern of holes in a FREI.

2.2. Description of the tests

The shear tests were performed using the test frame shown in Figure 3a. and applying the quasi-static lateral displacement of Figure 3b (strain rate of 1%/s). During testing, a vertical load of 18.8 kN was imposed on the bearings. Additional information on the testing apparatus are available in literature [31].

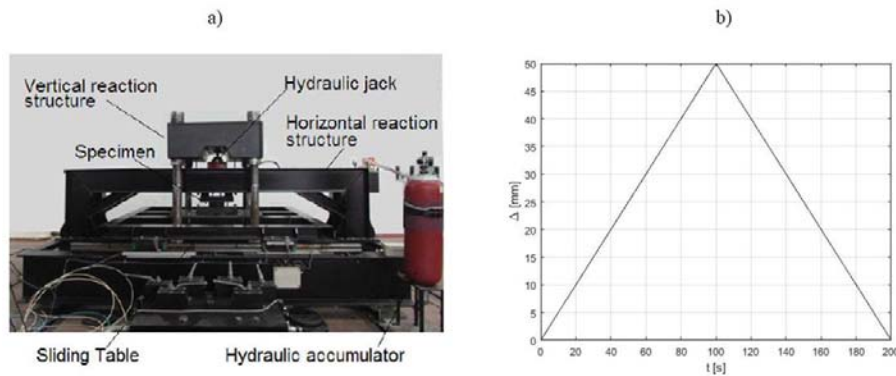

Figure 3: a) Testing frame, b) Time-history of the imposed lateral displacement.

2.3. Experimental test results

Figure 4 shows the deformed shape of the bearing during testing. Each column shows three different steps:

- Column 1 - full vertical load and zero lateral displacement.
- Column 2 - full vertical load at a shear deformation of 50%.
- Column 3 - full vertical load at a shear deformation of 100%.

The four rows of the Figure show the four test pieces described in Table 1: Description of the tested bearings. Table 1 (first row: no modification; last row: 20 holes). As intuition suggests, a greater vertical

deformation corresponds to a larger number of holes. Nevertheless, this variation is minor because of the very low volume of the rubber removed during drilling. All the samples show the onset of a stable roll-over deformation well before $\gamma_H = 50\%$.

Figure 4: Tested samples at $\gamma_H = 0\%$ with full compression, $\gamma_H = 50\%$ and $\gamma_H = 100\%$: a) 130x60 U, b) 130x60 4H, c) 130x60 12H, d) 130x60 20H

Figure 5 shows the horizontal force-displacement curves obtained from the experimental tests and the comparison between specimens with the same geometry (130x60x52 mm) and variable number of holes. As clear from this plot, while the peak horizontal load is substantially reduced by the holes, the curve of the bearing with 20 holes shows a positive tangent stiffness, with no instability of the rubber device. Table 2 reports the numerical value of the secant stiffness for each of the samples.

Figure 5: Lateral force displacement response of the tested bearings.

As clear from Figure 5, the sample 130x60 U (top line with + markers) shows a large initial stiffness, with an initial linear response. As the displacement increases past the initial deformation, the bearing shows softening and a peak of the response for a lateral deformation of 45 mm ($\gamma_H = 86\%$). A similar result is obtained for the sample with one column of holes (130x60 4H, second curve from the top). The curve differs very little from the one of the unmodified 130x60 U, which is not surprising considering the low percentage of removed volume (1.67%, see Table 1). The lateral secant stiffness differs no more than 7% from that of the unmodified sample (Table 2). Again, the response shows negative horizontal stiffness starting from a lateral displacement value of 48 mm ($\gamma_H = 96\%$) that is the peak of the lateral force. Compared to the bearing with no holes, an improvement in the lateral response of the sample with 4 holes is evident, as this device has a large range of stable deformations. Because the peak of the response was reached during testing, by increasing the lateral displacement, the bearing 130x60 4H would show instability. By increasing the number of holes, the lateral response of the sample changes significantly. For the bearing with 20 holes, the lateral stiffness is largely reduced. In general, the reduction of stiffness is proportional to the percentage of volume removed from the sample (Table 2).

Table 2: Lateral secant stiffness at different imposed deformations, for the tested bearings.

Δ [mm]	130x60 U		130x60 4H		130x60 12H		130x60 20H	
	K_H		K_H	$1 - \%K_H^U$	K_H	$1 - \%K_H^U$	K_H	$1 - \%K_H^U$
	[N/mm]		[N/mm]	[N/mm]	[N/mm]	[N/mm]	[N/mm]	[N/mm]
5	200		188	6.20%	159	20.5%	124	37.9%
10	156		150	3.52%	118	23.9%	91	41.5%
15	136		128	5.44%	104	23.6%	77	43.0%
20	122		114	6.51%	87	29.0%	67	45.1%
25	111		103	7.30%	79	29.1%	58	47.9%
30	102		97	5.03%	73	27.8%	54	46.9%
35	93		87	6.50%	66	29.7%	51	45.3%
40	87		83	4.22%	63	27.7%	48	44.5%
45	81		77	4.27%	60	25.8%	47	41.7%
50	72		71	1.37%	55	23.2%	43	40.1%

For the bearing with 20 holes, the most significant improvement concerns the overall response of the sample: as can be seen in Figure 5, when the lateral displacement increases, the response remains stable. The bearing shows no softening and the lateral stiffness is always positive: by creating holes in a bearing, it is possible to modify an unstable device to obtain a stable response. This modification of the response is only possible when a larger volume of rubber is removed. If the volume of removed rubber is less than 5%, the modification of the response is not appreciable. Figure 6 is a plot of the tangent stiffness of each bearing as function of the imposed deformation. As clear from the figure, the first two samples show a softening response with a stable peak around 25 mm of lateral displacement ($\gamma_H = 50\%$); for the unmodified sample, the tangent stiffness then becomes negative around 45 mm as mentioned above, while the sample with 4 holes shows a negative tangent stiffness for large deformation. The samples with 12 and 20 holes, show a decreasing stiffness up to $\gamma_H \approx 65\%$, with hardening past this level of deformation.

Figure 6: Tangent stiffness vs imposed displacement for the tested devices.

3. FINITE ELEMENT ANALYSIS

3.1. Analysis setting

The numerical analysis were performed using MSC Marc [32], a general-purpose finite element analysis software. Marc is designed to perform complex non-linear analyses in one, two or three dimensions. This characteristic, combined with the ability to perform complex contact analyses at large strains and the wide choice of hyperelastic material models suitable for elastomers, makes MARC a good choice for numerical analysis of rubber-based devices such as FREIs. Two-dimensional plain strain analyses were used for this study. In all the FEAs, the elastomer was modeled using a Neo-Hookean hyperelastic material fully defined by two constants C_1 and C_2 , where [33]:

$$C_1 = \frac{G}{2} \quad (3.1)$$

$$C_2 = \frac{\lambda}{2} = \frac{K}{2} - \frac{G}{3} = \frac{K}{2} - \frac{2C_1}{3}$$

with K being the bulk modulus of the rubber. The fiber reinforcement layers were modeled using a linear elastic material. The layers are fully defined by three parameters: the elastic modulus E_f , the Poisson's ratio ν_f and the equivalent thickness of the fiber layer t_f . All the parameters used for FEAs are detailed in Table 3.

Table 3: Parameters of the numerical model defined in MARC.

C_1	C_2	E_f	ν_f	t_f
[MPa]	[MPa]	[MPa]	[-]	[mm]
0.55	1000	70000	0.1	0.1

The elastomeric layers were modeled using a four-node, isoparametric, quadrilateral element, written for plane strain incompressible applications [34]. The reinforcement layers were modeled using an isoparametric, plane strain, 2-node element [34]. The top and bottom supports were modeled using rigid contact lines. The interface between the bearing and the rigid supports has been set as "contact" in MARC with a friction coefficient of 1 ([5], [6]).

3.2.FEA results: lateral load-displacement curves

Figure 7a shows the horizontal force-displacement curves obtained from FEAs. As clear from Table 4, the variations of horizontal stiffness when holes are made in the bearings are the same as those obtained from the experimental tests (see Table 2). The FEAs results are consistent with the experimental findings. Starting from the basic 130x60 geometry, the horizontal stiffness is reduced on by 6%, 27% and 45%, by drilling 4 holes on one column, 12 holes on three columns and 20 holes on 4 columns respectively.

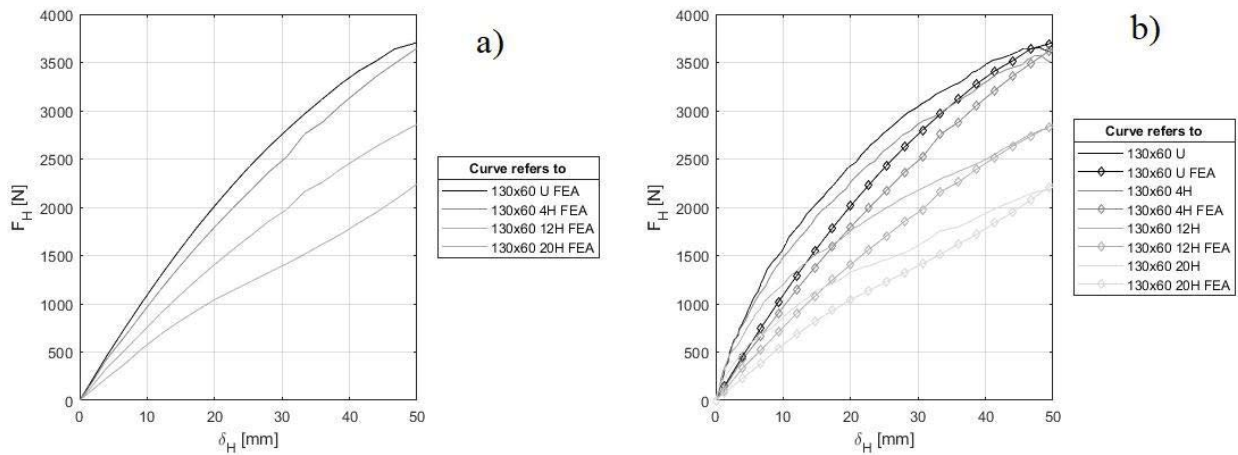

Figure 7: Lateral load-displacement curves: a) 130x60 FEA with variable number of holes, b) comparison of experimental vs FEAs results.

Figure 7a, shows a FEAs response of the bearing similar to that determined with experimental tests.

From the lateral response, it is clear that the stable range for bearing 130x60 12H is larger than that of bearing 130x60 U, as the latter reaches a peak of the response for a displacement of only 50mm. Moreover, the bearing with 20 holes shows hardening, with no softening.

Table 4: Lateral secant stiffness at different imposed displacements from FEAs.

35	85	78.81	7.0%	61.79	27.1%	43.25	49.0%
40	82	76.35	6.8%	59.86	26.9%	42.96	47.6%
45	78	74.60	4.6%	58.49	25.2%	43.27	44.6%
50	74	72.31	2.1%	56.69	23.2%	44.14	40.2%

3.3.FEA results: stress distribution in the bearings

Figure 8 shows the Von Mises stress contours at three levels of lateral deformation for each of the tested bearings. From left to right, a snapshot is given for $\gamma_H = 0$, $\gamma_H = 50\%$ and $\gamma_H = 100\%$ under the same axial load of 18 kN. As clear from Figure 8, the holes change the stress distribution in the device, with the bearing becoming mostly unloaded in the central area, with a large increase of stress in the confined regions of the elastomer. Compared to the unmodified bearing, under pure compression and zero lateral displacement, there is an increase in peak stress in the bearings with 12 holes and 20 holes. These devices show an increase of stress of 27% and 42% respectively.

Under large lateral displacements, as the holes in the bearings tend to collapse under the imposed deformation, a stress redistribution happens. For the bearing with one column of holes, at $\gamma_H = 100\%$, the stress level is very similar to that of the unmodified device (Figure 8c, Figure 8f), with a difference of only 3%. The percentage of removed volume with a single column of holes is too low to induce significant changes in the lateral response of the device. By removing at least 5% of the initial volume, a controlled reduction of the initial stiffness at low deformations can be obtained. Due to the presence of the holes, a redistribution of the stresses at the edge of the bearing is induced. Under large imposed deformations, the small holes created in the samples collapse on themselves, with the bearing showing hardening.

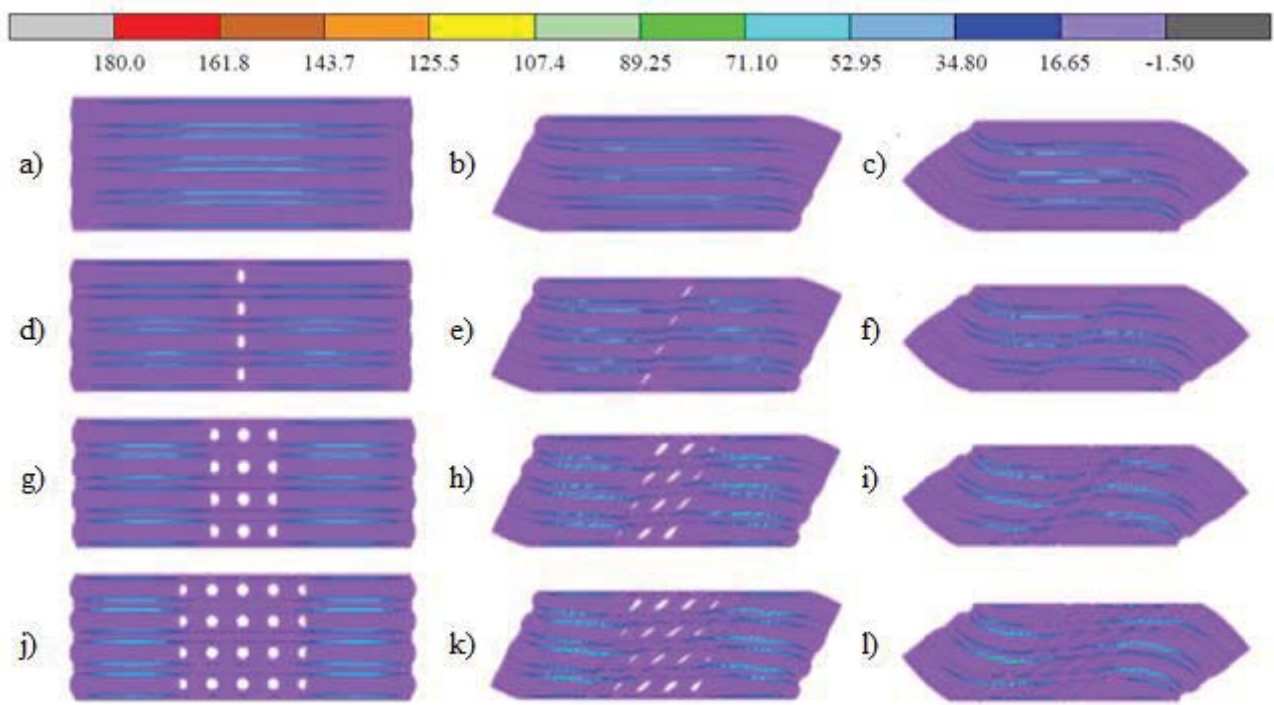

Figure 8: Equivalent Von Mises stresses: a) compression and zero lateral displacement, 130x60 U; b) 50% γ 130x60 U; c) 100% γ 130x60 U; d) compression and zero lateral displacement, 130x60 4H; e) 50% γ 130x60 4H; f) 100% γ 130x60 4H; g) compression and zero lateral displacement, 130x60 12H; h) 50% γ 130x60 12H; i) 100% γ 130x60 12H; j) compression and zero lateral displacement, 130x60 20H; k) 50% γ 130x60 20H; l) 100% γ 130x60 20H.

4. CONCLUSIONS

This study aims to introduce a new rubber-based technology for base isolation of lightweight structures. Experimental and FEAs show that it is possible to obtain an improvement in the response of FREIs by creating simple patterns of holes in the elastomer. It was found that by removing at least 5% of the initial volume of rubber an improvement in the lateral response of the device can be obtained, to get:

- i. a controlled reduction of the horizontal stiffness (6%, 27% and 45% reduction with 4, 12 and 20 holes respectively),
- ii. an extension of the stable range of deformation of the bearing. With imposed deformations up to $\gamma_H = 100\%$, the bearing always showed a positive horizontal stiffness. Devices which are unstable beyond a deformation of $\gamma_H \approx 90\%$ show a larger stable range when modified with lateral holes.

FEAs confirmed the experimental results. The stress analysis of the bearing helps understanding the behavior of the modified FREIs under combined axial and shear loads. As the number of holes (columns of holes) increases, the area close to the holes becomes stress free. Under large imposed deformations, the small holes created in the bearing collapse, and a redistribution of stresses occurs in the device. Additional studies are needed to investigate the effect of the aspect ratio of the bearing, of different materials and geometries on the lateral and vertical response of the devices when pattern of holes of different sizes and shapes are created.

Abstract

The vertical behavior of Fiber Reinforced Elastomeric Isolators (FREIs) is controlled by geometric and mechanical parameters, such as primary and secondary shape factors, shear modulus of the rubber and effective compressive modulus of the rubber-reinforcements compound. Several studies dealt with the vertical properties of the bearings, deriving analytical formulations in function of the bearing geometry and materials' properties. These relations have been derived under pure compression, considering the interaction between single rubber layers and flexible reinforcements. As of today, few works have been proposed on the influence of the horizontal displacement imposed on the bearing, i.e. no interaction between vertical pressure and horizontal displacement on the vertical stiffness and the compressive modulus has been accounted for. In this paper, a numerical study on the influence of the primary and secondary shape factor, the shear modulus of the rubber and the vertical pressure on the vertical properties of the FREIs is presented. In a first stage the behavior of square shaped FREIs under pure compression is examined and relative outcomes are presented. Then the influence of the horizontal displacement on the vertical response of the bearings is considered. Interesting results on the trend of the vertical stiffness and compressive modulus are obtained and useful considerations on the stability of FREIs are provided.

Keywords: Fiber-Reinforced Elastomeric Isolators, Vertical Properties, Elastomeric Seismic Isolators, Rubber bearings, Seismic Isolation.

1. INTRODUCTION

Fiber-reinforced elastomeric isolators (FREIs) were introduced as alternative seismic isolation devices to steel-reinforced elastomeric isolators (SREIs). Several advantages in cost and manufacturing result replacing steel reinforcements with fiber fabrics such as:

- Fiber fabrics are much lighter than steel, despite having similar elastic mechanical properties. With the same volume of reinforcement, fiber-reinforced bearings are therefore lighter than steel-reinforced ones [1].
- Fiber-reinforced bearings can be produced in a cheaper and faster manufacturing process, i.e. cold vulcanization process [2].

- From larger sized pads, it would be possible to cut bearings of the required size and different shapes (i.e. strip-shaped) [1, 3, 4].

Using fiber-reinforced bearings in unbonded configuration, i.e. allowing the marginal areas of the bearing to detach from the supports during horizontal displacement resulting in the rollover deformation, further advantages can be achieved.

- As the marginal portions of the bearing gradually detach from the supports during horizontal displacement, the contact area reduces and consequently the lateral stiffness of the bearing, increasing the efficiency of the isolation system [5].
- The tensile stresses that would develop in the marginal area of the bearing in bonded configuration are greatly reduced when these marginal portions can detach from the supports [6].
- The rollover deformation proceeds until the initial vertical faces of the bearing fully touch the supports becoming horizontal and increasing the lateral stiffness of the bearing. As this occurs at large deformations, the isolation system acquires greater stability at large displacements [5, 6].

The response of fiber reinforced elastomeric isolators has been studied in several works. Analytical formulations for vertical ([1, 7, 8, 9]) and horizontal stiffness ([10, 11, 12, 13]) have been proposed, and a number of other studies have investigated the mechanical properties of bearings through experimental tests ([4, 3, 14, 15, 16, 17, 18, 19, 20, 21]) and finite element analysis ([22, 23, 24, 25]). Furthermore, analytical models for static and dynamic response have been proposed ([26, 27, 28, 29, 30]).

The vertical stiffness of an elastomeric bearing is primarily controlled by two parameters [31]: primary shape factor S_1 (defined as the ratio between the loaded area and the area free to bulge) and effective compressive modulus E_c (defined as the instantaneous elastic modulus of the rubber-reinforcements compound). The lateral response of an unbonded FREIs can be stable or unstable (Figure 1). In the first case, the bearing shows a positive tangent lateral stiffness throughout the lateral deformation; in the second case the horizontal tangent stiffness of the bearing could decrease until becoming equal or less than zero. The horizontal response is mainly controlled by the secondary shape factor [32], that is the ratio between the base side in the horizontal displacement direction and the total height of the bearing ($S_2 = B / H$). Current codes require stable behavior to bearings [33, 34, 35], i.e. a sufficiently high secondary shape factor. Several experimental and numerical studies have shown that a stable behavior is ensured if S_2 is at least equal to 2.5 [36, 37, 36, 38].

Figure 1: Stable vs unstable lateral behavior of U-FREIs under combined axial and shear load.

Elastomeric bearings require larger vertical stiffness than horizontal one (e.g. at least two order of magnitude) to support the weight of the superstructure and avoid potential rocking motions [39, 31]. Comparing the vertical stiffness under pure compression and the secant horizontal stiffness of a generic bearing with a sufficiently large primary shape factor, this requirement is easily met. However, during the rollover of the lateral displacement, the contact area between the bearing and the supports is reduced, which also reduces the vertical stiffness of the bearing. It is therefore necessary to take this reduction into account when comparing vertical and horizontal stiffness. In a safety evaluation, the vertical and horizontal stiffnesses could be compared at a given level of horizontal displacement.

However, few studies have considered the reduction of vertical stiffness with increasing horizontal displacement [40] and there is a lack of knowledge on the influence of the main geometric and mechanical parameters on the interaction between vertical and horizontal response. This work proposes a large number of finite element analysis on square shaped FREIs, varying different mechanical and numerical parameters. The influence of the primary and secondary shape factor on the combined vertical and horizontal response is taken into account.

2. FINITE ELEMENT ANALYSIS: OVERVIEW

Several different values for two combinations of geometric and mechanical parameters were considered:

- Geometric: base dimensions $B = 2a = 2b$ and thickness of the elastomeric layers t_e ;
- Mechanical: shear modulus G of the elastomer and vertical applied pressure σ_v .

In addition, four parameters were also kept constant: the total height of the bearing $H = nt_e + (n-1)t_f$, the equivalent thickness of the fiber reinforcement t_f , Young's modulus E_f of the fiber fabric and its Poisson's ratio ν_f . All the considered parameters are listed in Table 1. By permuting the parameters shown in Table 1, a total of 240 numerical models were obtained, with 9 different secondary shape factors, ranging from 1 to 5, and 16 primary shape factors, from 5 to 62.5.

Table 1: Variable parameters considered in the finite element analysis.

$2a = 2b = B$	H	t_e	G	σ_v	E_f	t_f	ν_f
[mm]	[mm]	[mm]	[MPa]	[MPa]	[MPa]	[mm]	[-]
100	100	2	0.4	2	70000	0.1	0.1
150		5	0.8	4			
200			1.2	6			
250				8			
300							
350							
400							
450							
500							

All the finite element analyses were carried out using MSC Marc [41], a general purpose FEA software optimized for non-linear analyses. This software allows careful modeling of nonlinear behavior, with a wide choice of hyperelastic material models for elastomers.

The elastomer was modeled using a Neo-Hookean hyperelastic material. When the compressibility of the elastomer is taken into account, the strain energy density function can be obtained as [42]:

$$W = C_1(I_1 - 3 - 2 \ln J) + C_2(J - 1)^2 \quad (2.1)$$

where C_1 and C_2 are material constants, $I_1 = \lambda_1^2 + \lambda_2^2 + \lambda_3^2$ the first invariant of the right Cauchy-Green deformation tensor and $J = \lambda_1 \lambda_2 \lambda_3$ the determinant of the deformation gradient.

The strain energy density function for an incompressible Neo-Hookean material is given by:

$$W = C_1(I_1 - 3) \quad (2.2)$$

obtained from (2.1) when $J = 1$. The two constants C_1 and C_2 can be correlated to the Lamè constants:

$$\begin{aligned} C_1 &= \frac{G}{2} \\ C_2 &= \frac{\lambda}{2} = \frac{K}{2} - \frac{G}{3} = \frac{K}{2} - \frac{2C_1}{3} \end{aligned} \quad (2.3)$$

The fiber reinforcement layers were modeled using a linear elastic model, with each layer is fully defined by the three parameters shown in Table 1 (E_f , ν_f and t_f). The elastomeric layers were modeled using a four-node, isoparametric, quadrilateral elements, implemented for plane-strain incompressible applications [43]. The reinforcement layers were modeled using an isoparametric, plane-strain, 2-node rods or cords (*i.e.* rebars), in conjunction with the 4-node plane strain continuum elements used for the rubber layers [43]. Top and bottom supports were modeled using rigid contact curves. A “touch” type of contact between the bearing and the rigid supports has been set, with a friction coefficient of 1, a reasonable value to describe the friction at the rubber-steel interface [44].

2D models were used for this study, taking into account the out of plane dimension of the bearing, resulting in equivalent 3D models (Figure 2).

Figure 2: Full 3D numerical model vs equivalent 3D FEA model.

3. FINITE ELEMENT ANALYSIS RESULTS: VERTICAL STIFFNESS

3.1 – Pure compression

The trend of vertical stiffness under four different values of vertical pressure (from 2 to 8 MPa) and for different values of the shear modulus is shown in Figure 3 and Figure 4 for $t_e = 2$ mm and $t_e = 5$. In each graph, the vertical stiffness is plotted with respect to the vertical displacement (primary axes, black curves) and to the primary shape factor (secondary axes, gray curves); for each curve, each marker stands for a different secondary shape factor, i.e. one of the bases listed in Table 1 being the total height constant. This representation allows to simultaneously monitor the interaction between mechanical and geometric parameters on the vertical stiffness of the bearings.

The significant role of the primary shape factor S_1 is confirmed, i.e. an approximately quadratic relationship with the vertical stiffness is found. The vertical stiffness does not vary appreciably with the vertical pressure applied as S_1 varies. With the same S_1 , even if the vertical pressure is four times higher, the vertical stiffness is almost constant. A clear change of response is appreciable in vertical displacements. The vertical response may be split into two ranges of S_2 ; for a generic G modulus and a generic vertical pressure σ_v :

- If $S_2 > 2.5$: the vertical displacement varies slightly between one bearing and another, varying less and less and tending to a vertical asymptote as S_2 increases, regardless of mechanical parameters (pressure and shear modulus).
- If $S_2 \leq 2.5$: displacements under vertical load vary more and more as S_2 decreases..

The transition value $S_2 = 2.5$ agrees with previous findings from literature regarding the stability of bearings subjected to simultaneous vertical and horizontal load: bearings with a larger value of S_2 have a more stable behavior and are less dependent on mechanical parameters ([37, 38]).

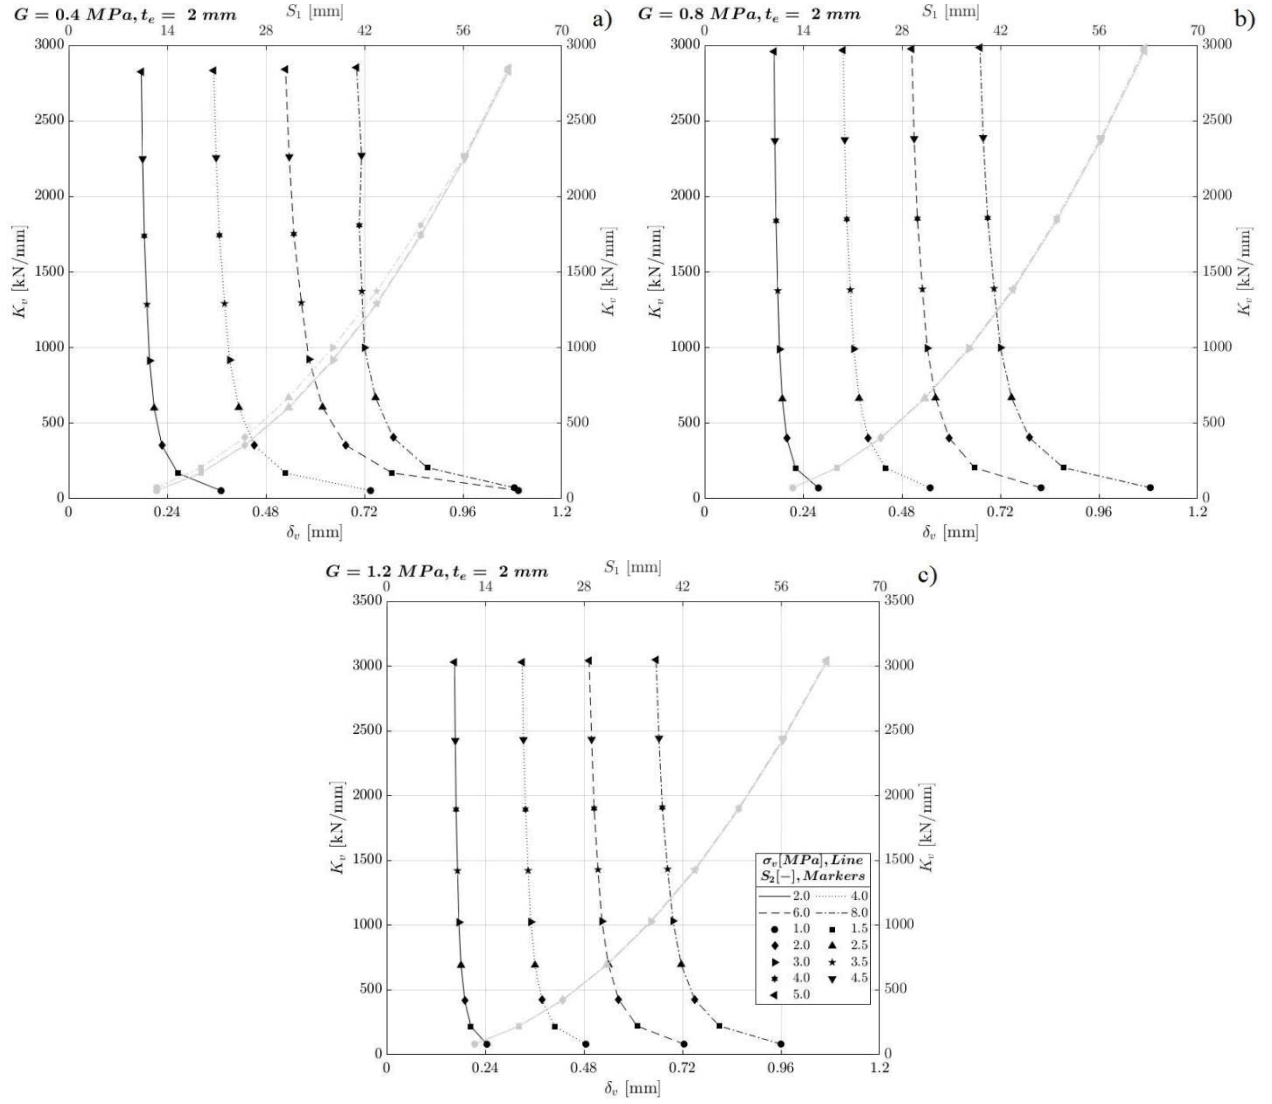

Figure 3: Vertical stiffness under pure compression for different vertical pressure, primary and secondary shape factor, $t_e = 2$ mm: a) $G = 0.4$ MPa, b) $G = 0.8$ MPa, c) $G = 1.2$ MPa

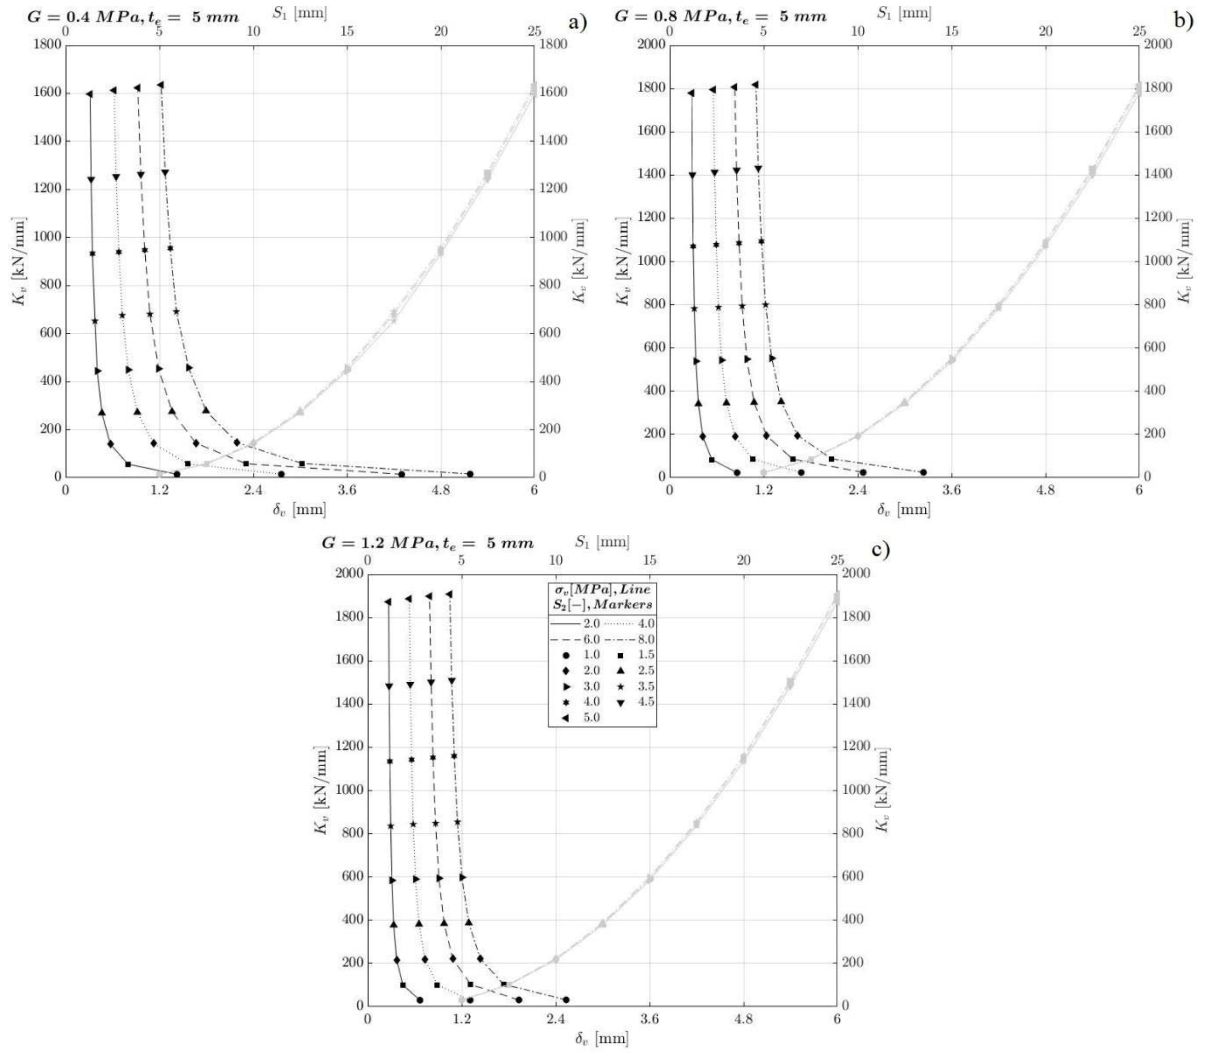

Figure 4: Vertical stiffness under pure compression for different vertical pressure and secondary shape factor, $t_e = 5$ mm: a) $G = 0.4$ MPa, b) $G = 0.8$ MPa, c) $G = 1.2$ MPa

3.2 – Combined vertical and horizontal load

The vertical stiffness of bearings under combined vertical and horizontal load is reduced due to the rollover: the marginal areas of the bearing detach from the supports, the contact area is reduced and consequently the vertical stiffness. The reduction of vertical stiffness involves an increase in the axial compressibility of the bearing. Figure 5 and Figure 6 show the trends of vertical stiffness with vertical and horizontal displacement, for $t_e = 2$ mm and $t_e = 5$ mm. The left columns of the figures show the $K_v - \delta_v$ trends, while those on the right show the $K_v - \delta_H$ trends; each row refers to a different value of the shear modulus G .

As from Figure 3 and from Figure 4 it can be deduced that the trend of the vertical stiffness does not depend on the applied pressure (its effect is to increase the compression and, therefore, the vertical displacements), e.g. $\sigma_v = 8$ MPa was considered in Figure 5 and Figure 6.

Compared to the vertical displacement, the stiffness is constant in a first part, where the horizontal displacement is zero. The horizontal extension of the constant stiffness section is smaller as S_2 increases, because the vertical stiffness increases.

Vertical stiffness is always decreasing as the horizontal displacement increases with an almost linear trend; this decrease is smaller for the higher values of S_2 . Table 2 shows the average on the pressures and on the G modulus of the ratios between the vertical stiffness at the generic level of horizontal displacement (K_v) and that under pure compression ($K_v^{(0)}$). Again, there is a difference in vertical response between bearings with S_2 lower and higher than 2.5:

- If $S_2 > 2.5$: the vertical stiffness, even at large displacements, still anyway around the 50% of that under pure compression. This reduction tends to zero as S_2 increases, with a vertical stiffness at $\gamma_H = 2.00$ for $S_2 = 5.00$ on average 17% lower than the stiffness under pure vertical load.
- If $S_2 \leq 2.5$: as S_2 decreases, the bearings is unstable before one of the selected thresholds of horizontal displacement and the computation of the vertical stiffness is meaningless. For bearings that reach full rollover, the vertical stiffness almost drops to zero.

As mentioned, the vertical stiffness must be sufficiently higher than the horizontal stiffness. Their ratio must have at least two orders of magnitude of difference. Considering a ratio between vertical stiffness under pure compression and horizontal stiffness equal to 500, this ratio is reduced under combined vertical and horizontal action according to Table 2. The numerical values are shown in Table 3. As can be seen, only where S_2 is at least equal to 2.5 this ratio remains greater than 100 up to full rollover.

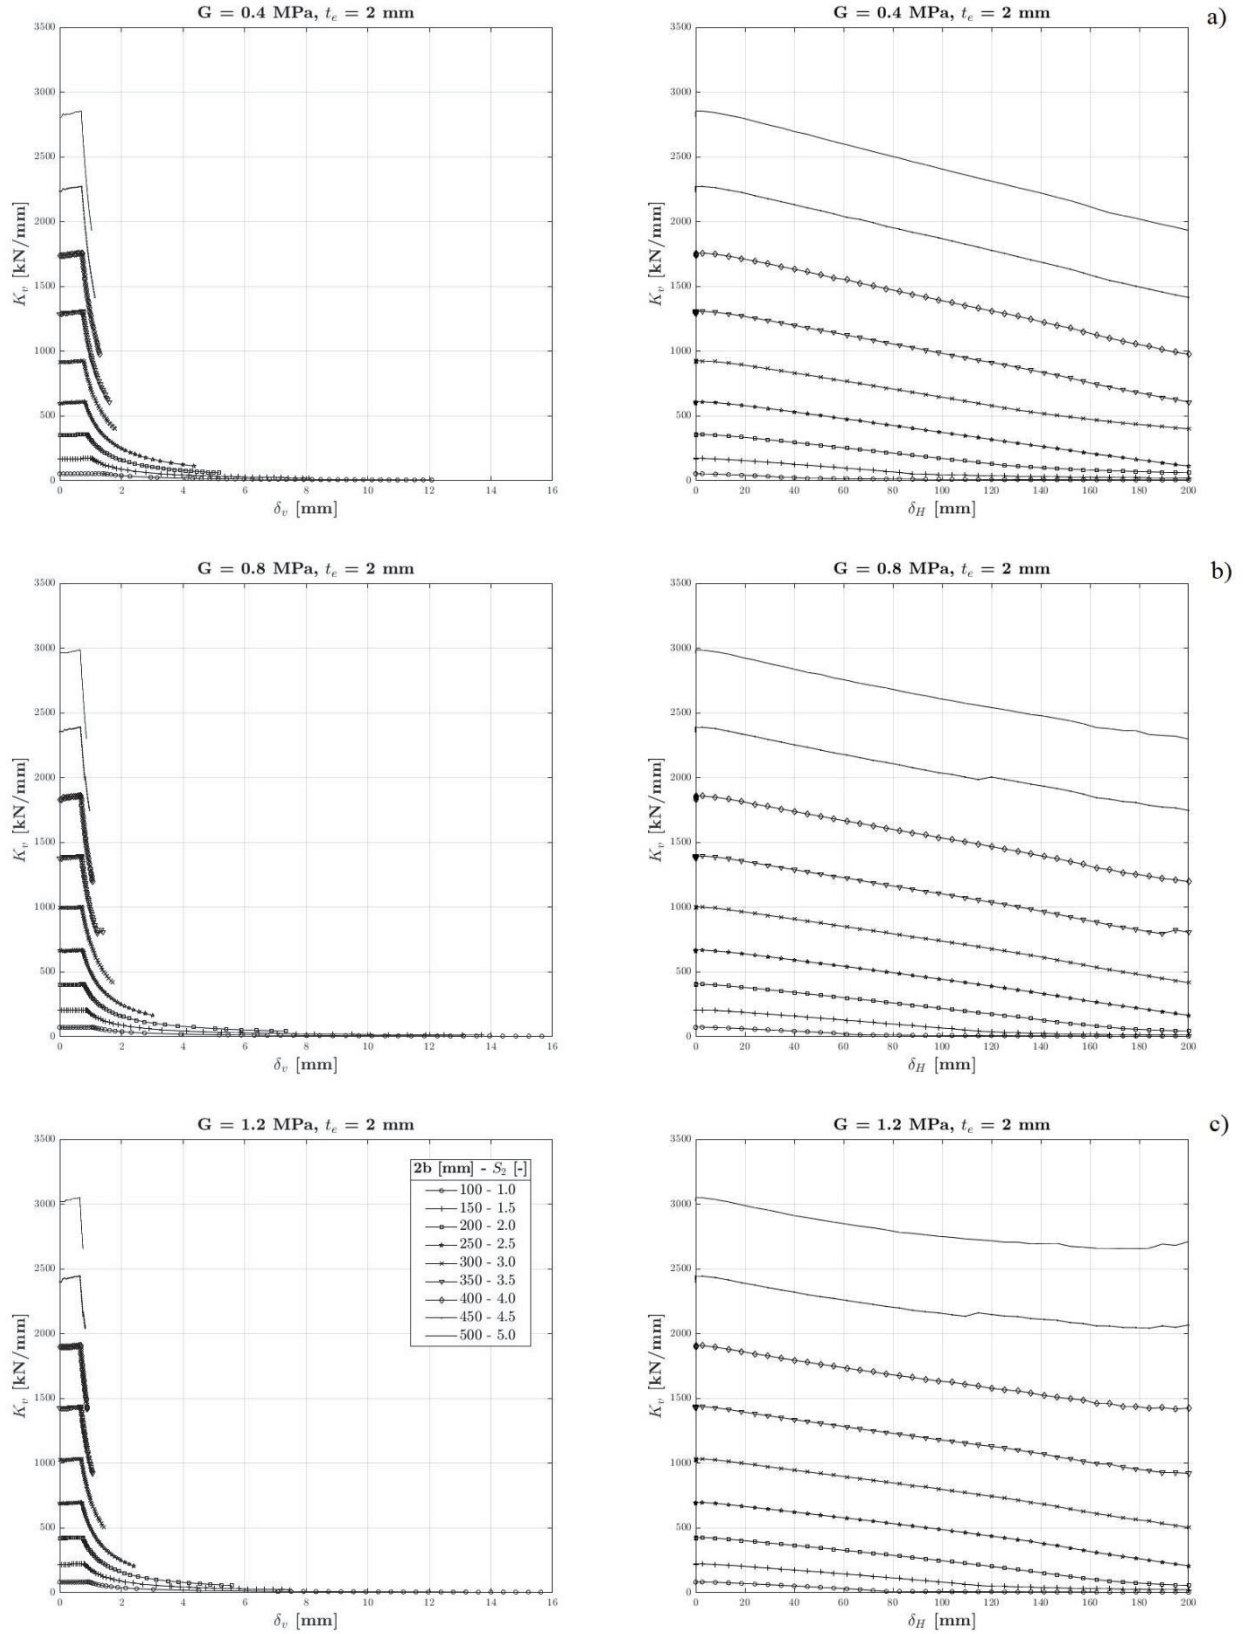

Figure 5: Vertical stiffness variable with vertical and horizontal displacement, $t_e = 2$ mm: a) $G = 0.4$ MPa, b) $G = 0.8$ MPa, c) $G = 1.2$ MPa.

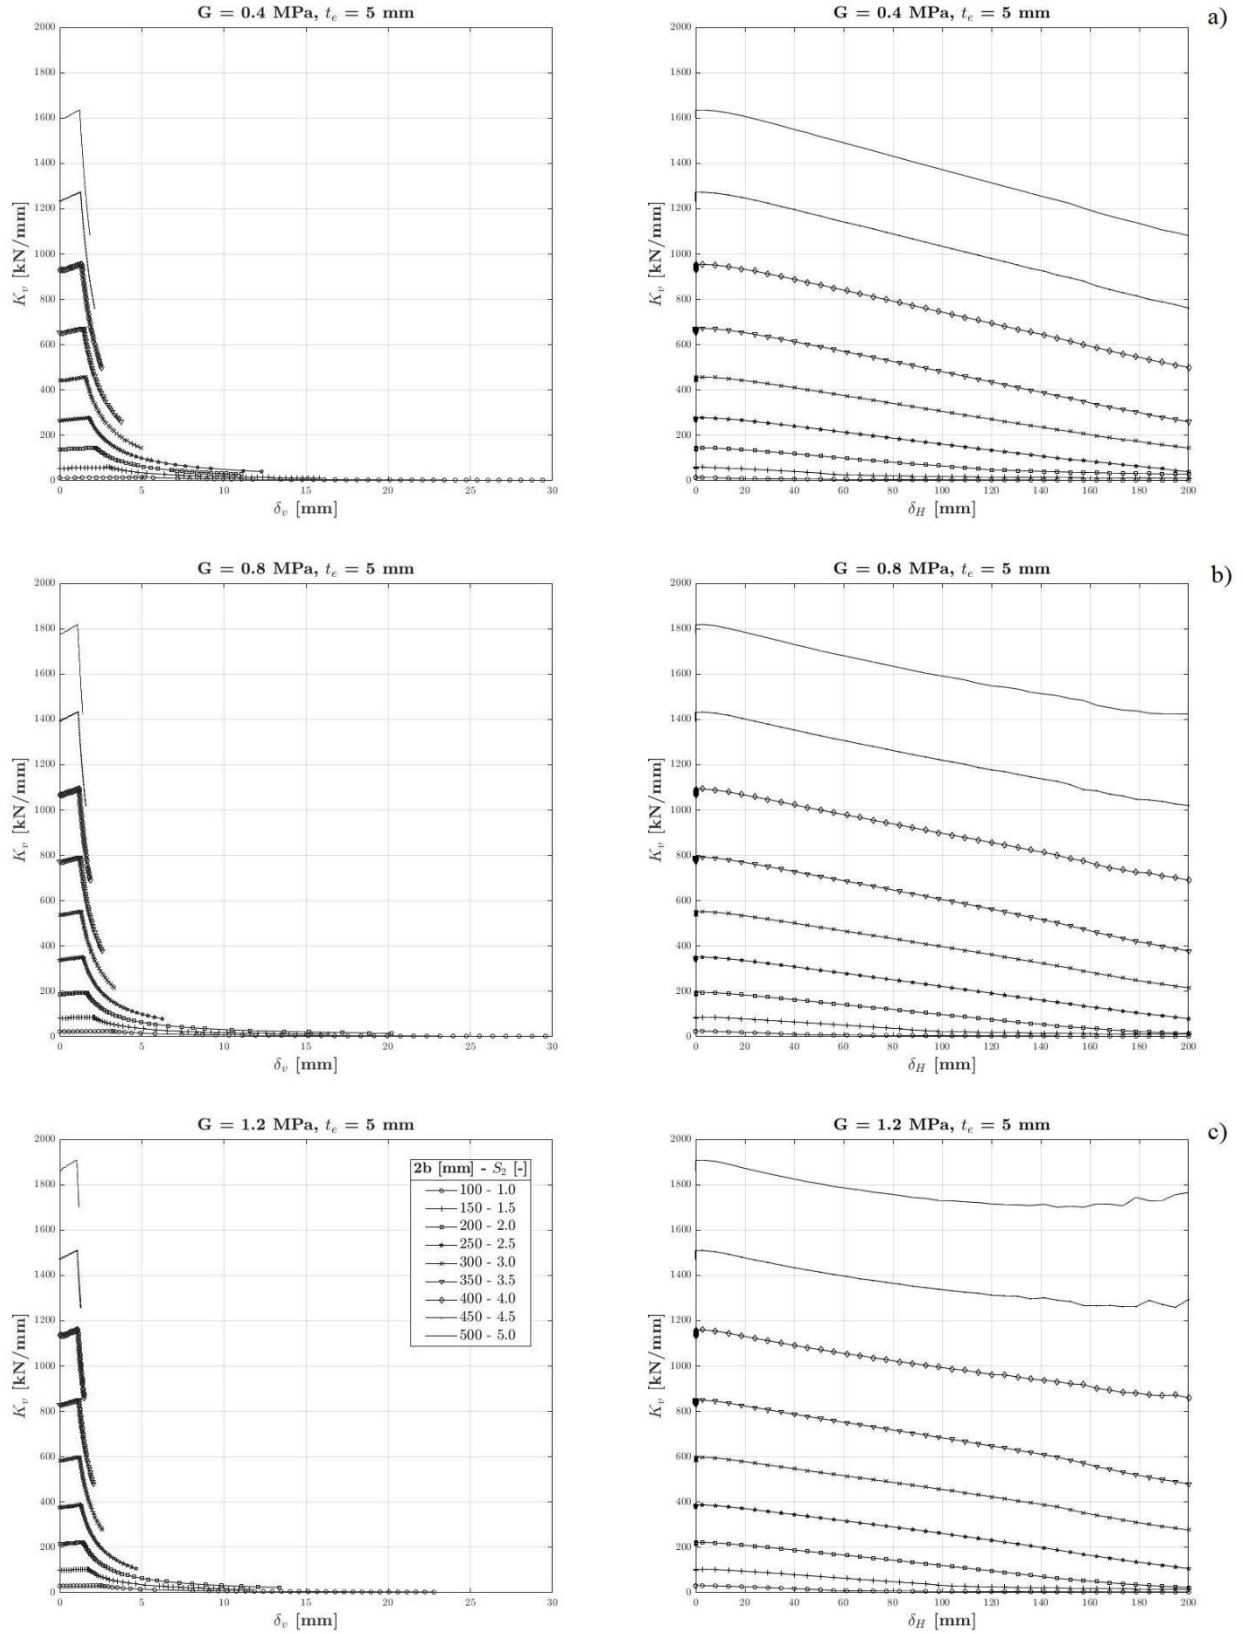

Figure 6: Vertical stiffness variable with vertical and horizontal displacement, $t_e = 5$ mm: a) $G=0.4$ MPa , b) $G=0.8$ MPa . c) $G=1.2$ MPa .

Table 2: Average $K_v / K_v^{(0)}$ ratios for different horizontal displacement levels.

4. FINITE ELEMENT ANALYSIS RESULTS: COMPRESSIVE MODULUS

4.1 – Pure compression

The compressive modulus E_c under pure compression depends solely on the mechanical and geometric properties of the bearing. Starting from the vertical stiffness obtained in §3.1, it is therefore possible to obtain the E_c modulus under pure compression by varying both the geometry (S_1 , S_2) and the mechanical parameters (G , σ_v), as follows:

$$E_c(\delta_H = 0) = \frac{K_v \cdot t_r}{A_c} \quad (4.1)$$

where t_r is the total rubber height and A_c the contact area between bearing and support. Figure 7 and Figure 8, as done for vertical stiffness, show the trends of the compressive modulus under pure compression as the vertical pressure, secondary shape factor (primary axes, black curves) and primary shape factor vary (secondary axes, gray curves). Again, the vertical pressure does not affect the shape of the curves, making these translate horizontally (black curves) or vertically (gray curves). The secondary shape factor affects the response under pure compression only for low values ($S_2 < 2.5$), while for high values the compressive modulus seems to converge to a common value for a fixed G and σ_v . Finally, the G modulus clearly affects the compressibility of the bearing, more significantly when the thickness of the elastomeric layer is greater.

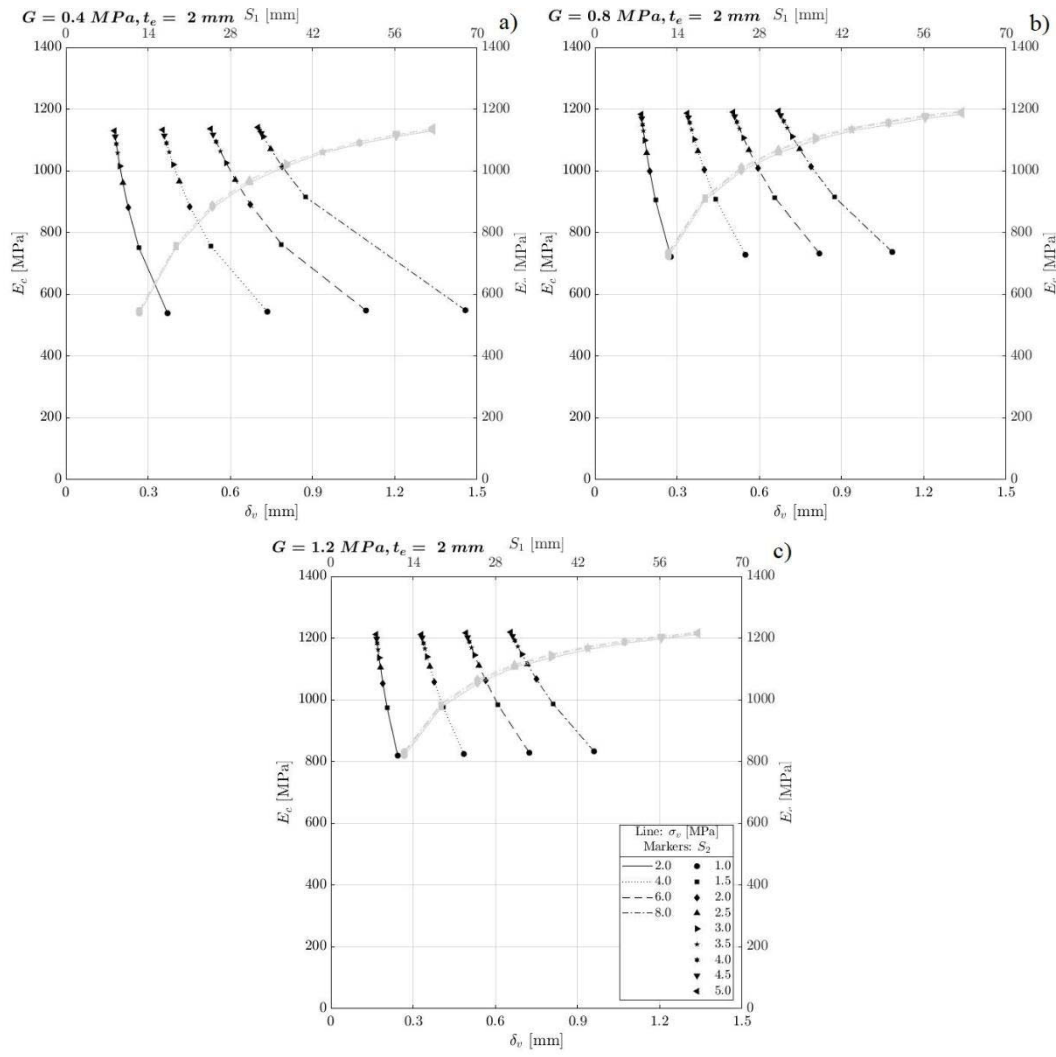

Figure 7: Effective compressive modulus under pure compression for different vertical pressure, primary and secondary shape factor, $t_e = 2$ mm: a) $G = 0.4$ MPa, b) $G = 0.8$ MPa, c) $G = 1.2$ MPa

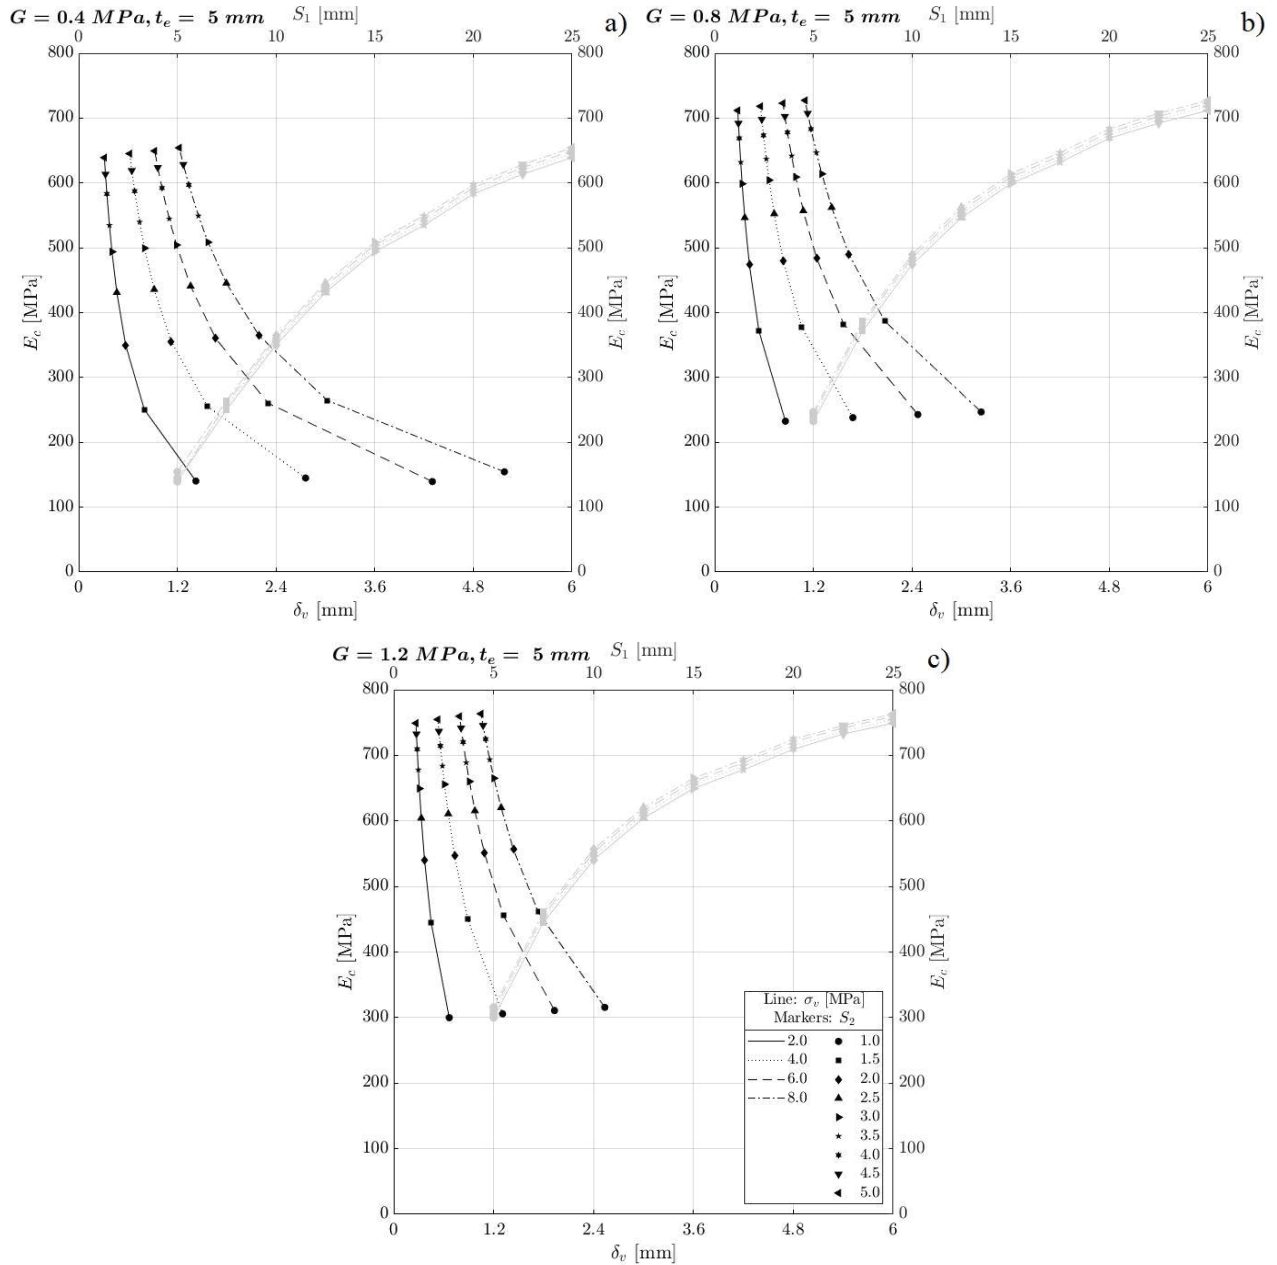

Figure 8: Effective compressive modulus under pure compression for different vertical pressure, primary and secondary shape factor, $t_e = 5$ mm: a) $G = 0.4$ MPa, b) $G = 0.8$ MPa, c) $G = 1.2$ MPa

4.2 – Combined vertical and horizontal load

The effective compressive modulus E_c of the bearings under combined axial and shear load was determined as follow:

$$E_c(\delta_H) = \frac{K_v \cdot t_r}{A_c(\delta_H)} = \frac{F_v \cdot t_r}{\delta_v(\delta_H) \cdot A_c(\delta_H)} \quad (4.2)$$

being $F_v = \sigma_v \cdot A$ the vertical applied force and δ_v the total vertical displacement at the top of the bearing. During horizontal displacement, the total vertical displacement and the contact area vary, increasing and decreasing respectively, resulting functions of the horizontal displacement. Since the

vertical displacement increases as the horizontal displacement increases while the contact area decreases, the E_c modulus can either decrease or increase.

Figure 9 and Figure 10 show the trends of the E_c modulus with the horizontal displacement. Again, a dual range can be defined by the secondary shape factor:

- If $S_2 \leq 2.5$: the modulus has a strictly decreasing trend with the horizontal displacement, the more marked the lower is S_2 . This is because the vertical displacement in formula (4.2) increases faster than the contact area decreases.
- If $S_2 > 2.5$: the E_c modulus is constant in a first section up to a horizontal displacement around 150 mm, then E_c rapidly decreases. In the first section, the variations in vertical displacement and contact area are almost equivalent, so the modulus varies little noticeably. In the second section, due to the full rollover, the contact area increases and the E_c modulus can only decrease.

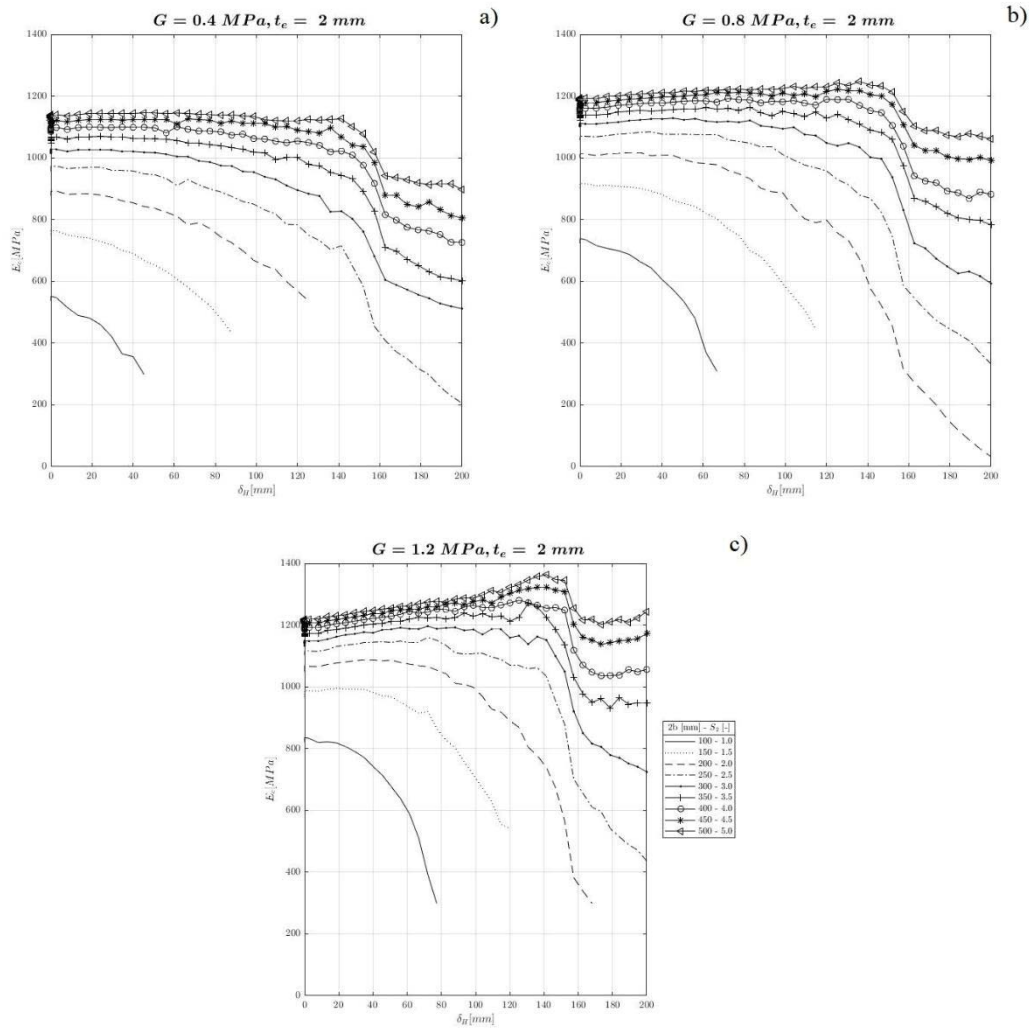

Figure 9: Effective compressive modulus vs horizontal displacement, $t_e = 2$ mm: a) $G = 0.4$ MPa, b) $G = 0.8$ MPa . c) $G = 1.2$ MPa .

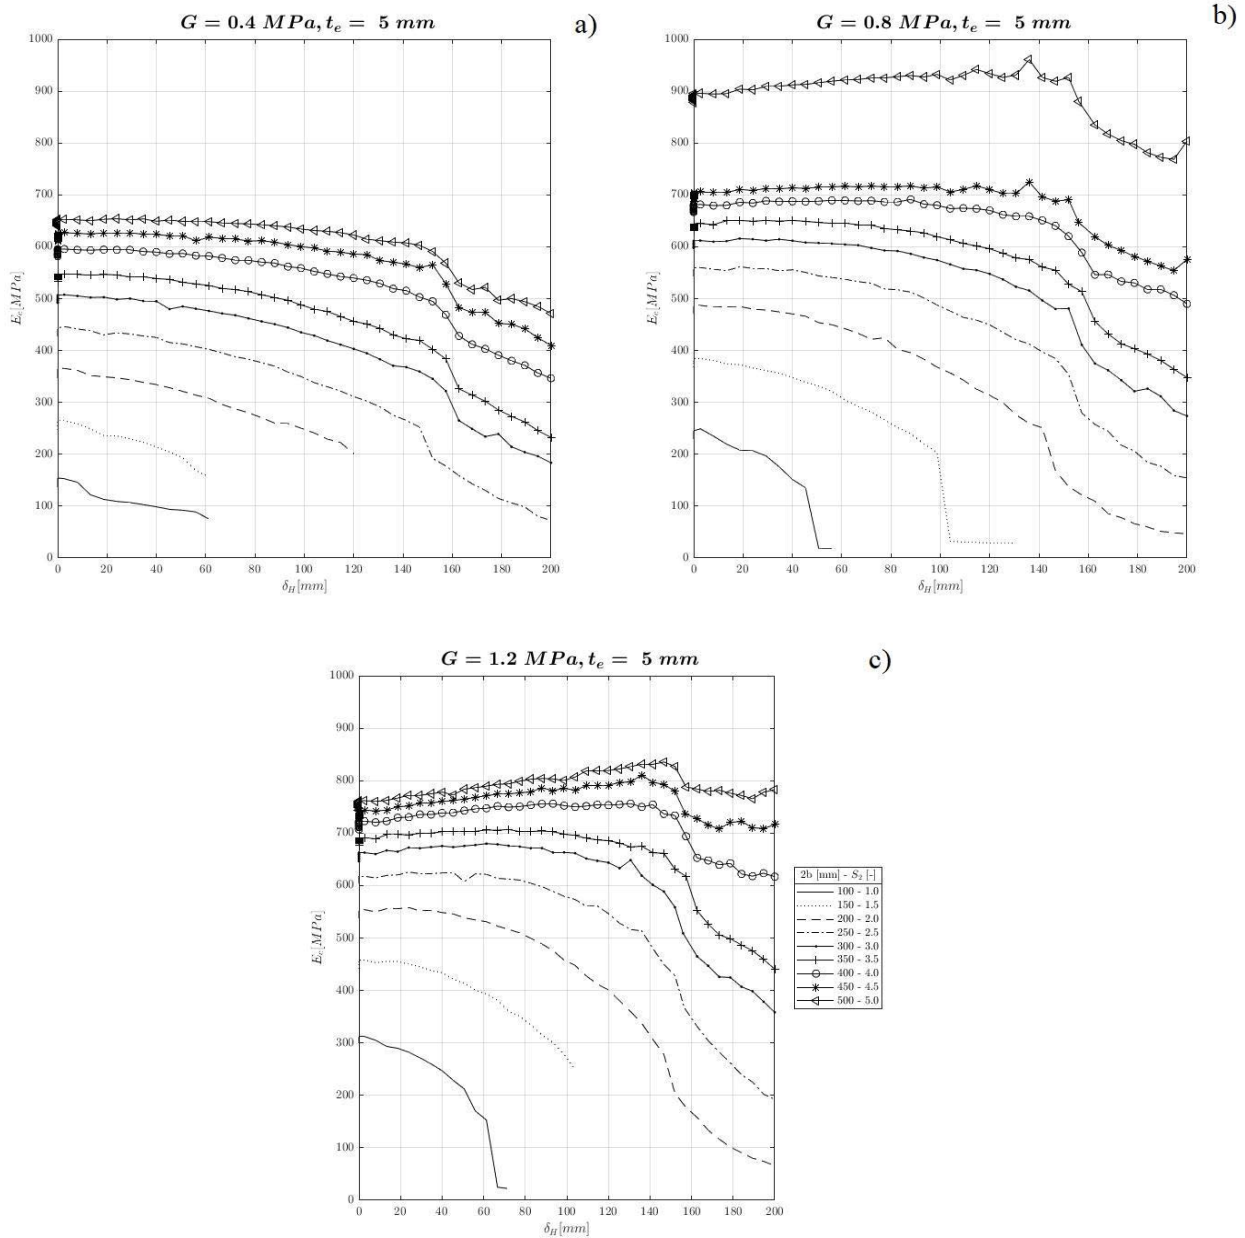

Figure 10: Effective compressive modulus vs horizontal displacement, $t_e = 5$ mm: a) $G = 0.4$ MPa, b) $G = 0.8$ MPa. c) $G = 1.2$ MPa.

5. CONCLUSIONS

The vertical response of a large number of fiber-reinforced elastomeric isolators was analyzed in this paper, i.e. vertical stiffness and effective compressive modulus have been studied into details. Two conditions of variation of the vertical properties were considered: vertical properties both under pure compression and combined vertical and horizontal load. The geometric and mechanical factors considered allowed to draw general conclusions on the variability of the vertical response. The bearings exhibit a response mainly dependent on geometry rather than on applied pressure; the mechanical parameters influence the magnitude of the response but not the shape, which is preserved. The main role of the primary shape factor S_1 on the vertical response of a single bearings under pure compression is confirmed. When the bearing is subjected to simultaneous

vertical and horizontal action, the secondary shape factor S_2 plays a key role, particularly affecting the stability of the bearing. A transition value approximately equal to 2.5 can be found, which separates the response of stable from unstable bearings. Unstable bearings show a rapid decrease in vertical stiffness and effective compressive modulus; in stable bearings the vertical response parameters decrease less noticeably as the lateral stiffness increases. It is essential that the vertical stiffness tends to be higher than horizontal stiffness even under lateral deformation: this requirement tends to be met by bearings with a secondary shape factor greater than 2.5.

Abstract

The work presents some preliminary results of experimental tests performed on a Helical Wire Rope Isolator (HWRI), to the aim of describing the dynamic behavior of the metal isolation device, without pre-load and under the effect of a vertical pre-load, for different displacement amplitudes. During the dynamic tests, the testing machine allows to apply a vertical displacement or load history to the tested device, subjected to a constant vertical pre-load. The dynamic behavior of the tested device depends on the applied displacement amplitude: the HWRI displays an asymmetric behaviour, i.e. a different response when it is subjected to compression or tension; in the latter case, it shows an hardening effect for larger displacements. Moreover, the experimental tests make clear that the application of a vertical pre-load determines a different behaviour in Compression vs. Tension, with slightly variable damping properties. In order to simulate the dynamic behavior of the HWRI in Compression-Tension direction, a nonlinear model is proposed, that is validated by comparing the experimental hysteresis loops obtained during cyclic tests with those predicted analytically.

Keywords: Base Isolation, Experimental Dynamic Characterization, Wire-Rope Isolators.

1 INTRODUCTION

Helical Wire Rope Isolators (HWRI) are metal devices which are effective in protecting sensitive equipment from shock and vibration [1], so that they are frequently used as devices for the earthquake protection of that equipment installed in buildings [2] and for the reduction of seismic vibration induced on high voltage ceramic circuit breakers [3-6]. But, they have been also adopted as vertical isolators under the basement of the two statues known as “Bronzes of Riace” [7].

HWRI are made of a stainless steel cable embedded into two aluminum alloy or steel retainer bars. They can deform in both vertical and horizontal directions and they have a significant dissipation capacity caused by the inner sliding friction and rubbing among the various strand's wires and among the intertwined strands [1]. The mechanical behavior of HWRI depends on their geometrical characteristics: the height to width ratio, the device's diameter, the number of strands, the cable length and twist, the number of cables per section and the number of loops [2].

A HWR Isolator, manufactured by Powerflex s.r.l (Limatola, Italy), has been experimentally investigated in its vertical direction, named Compression/Tension. The aim of the experimental tests was to study the dynamic behaviour of the considered device in a quite large displacements range, by assigning four different values to the vertical pre-load. Literature shows the results of experimental tests performed within a relatively small displacements range [2, 6, 8].

The experimental investigation of the tested HWRI has been carried out by operating a testing machine available at the Laboratory of Department of Structures for Engineering and Architecture of the University of Naples Federico II. Its dynamic behavior has been studied by analyzing the values assumed by two parameters computed from the experimental hysteresis loops: the average effective (or secant) stiffness in both Compression and Tension, and the average equivalent viscous damping ratio.

2 HELICAL WIRE ROPE ISOLATOR UNDER TESTING

HWRI are metal devices that are obtained by wounding a wire rope in the form of a helix and embedding into two drilled metal retainer bars. The rope is given by the layering of several strands around a central one. The HWRI manufactured by Powerflex S.r.l (Limatola, Italy), have a rope that is composed by six strands, each consisting in 25 wires, and a central strand with 49 wires. The cable is made of stainless steel type 316, whereas the material of the retainer bars is an aluminum alloy.

Figure 1 shows the geometrical characteristics of the tested HWRI and the indication of the tested vertical direction: Compression/Tension.

Table 1 lists the geometrical characteristics (cable's diameter, length, width and height of the device) of the tested devices: HWRI PWHS16010 and HWRI PWHS16040.

Figure 1: Mount of a wire rope (a); helical configuration of the cable (b); stranded cable's cross section (c).

HWRI	l [mm]	h [mm]	v [mm]	h/v	d_r [mm]
PWHS 16010	267	100	110	0.90	16
PWHS 16040	267	125	150	0.83	16

Table 1: Geometrical characteristics of the HWRIs selected for experimental tests.

3 TESTING MACHINE FOR COMPRESSION/TENSION TESTS

The dynamic experimental tests on the selected HWRIs in Compression/Tension direction have been carried out through a testing machine (Figure 2) available at the Department of Structures for Engineering and Architecture of the University of Naples Federico II (Italy): an MTS Series 370 Servohydraulic Load Frame. The load frame is suitable to perform tests in compression and tension. It includes an axial hydraulic actuator with a maximum capacity of 250 kN and a stroke of 150 mm. Both displacement and force controlled procedures can be followed. In the configuration shown in Figure 2, the dynamic actuator is mounted on the upper crosshead, while a load cell is mounted below the lower hydraulic wedge. The data acquisition system along with the control of the hydraulic actuator are performed with a software running on a personal computer. For Compression/Tension tests, the steel retainer bars of the isolator are gripped by the upper and lower rigid steel parts of the machine. All tests were conducted by imposing vertical displacements at room temperature and the data were sampled at 102.4 Hz. The relative vertical displacement and vertical load time histories have been measured.

Figure 2: Testing machine and the HWRI mounted in vertical direction.

4 EXPERIMENTAL CHARACTERIZATION TESTS

Cyclic tests have been carried out in order to understand the influence of displacement amplitude and vertical pre-load on the dynamic behavior of the selected HWRIs in vertical (Compression/Tension) direction. Nine different displacement amplitudes, four vertical pre-

load values and a testing frequency of 0.1 Hz have been assumed, where the maximum amplitude has been chosen to prevent damage to the aluminum alloy retainer bars. The testing protocol consisted in applying ten fully reversed sinusoidal cycles of vertical displacement, having specified amplitude A and frequency f , while a constant vertical pre-load was applied to the device. The dynamic displacement-controlled tests are listed in Table 2.

No. of Tests	Frequency [Hz]	Amplitude [mm]	Vertical Load [kN]
HWRI PWHS 16010			
6	0.1	2.5, 5, 7.5, 10, 12.5, 15	0
6	0.1	2.5, 5, 7.5, 10, 12.5, 15	2
HWRI PWHS 16040			
6	0.1	5, 10, 15, 20, 25, 30	0
6	0.1	5, 10, 15, 20, 25, 30	1.2
6	0.1	5, 10, 15, 20, 25, 30	2
6	0.1	5, 10, 15, 20, 25, 30	3

Table 2: Dynamic tests in vertical direction.

5 EXPERIMENTAL TESTS OUTCOMES

The results of the dynamic experimental tests performed on the investigated HWRI PWHS 16040 are presented in this paragraph. The dynamic parameters evaluated from the asymmetric experimental force-displacement hysteresis loops are the average effective (or secant) stiffness values in Compression and Tension, and the average equivalent viscous damping ratio. The effective stiffnesses in Compression and in Tension, corresponding to each load cycle of a dynamic test, have been evaluated based on the peak vertical load and displacement [10], both on Compression side and on Tension side:

$$k_{eff,T} = \frac{f_{max}}{u_{max}} \quad k_{eff,C} = \frac{f_{min}}{u_{min}} \quad (1)$$

where f_{max} , f_{min} , u_{max} , and u_{min} are the peak values of vertical load and displacement, respectively, at the extremes of the cyclic displacement range. The average effective stiffnesses $k_{eff,T,a}$ and $k_{eff,C,a}$ have been calculated as mean values of those obtained from seven of the ten experimental loading cycles. The equivalent viscous damping ratio of the device at each cycle has been evaluated as [11, 12]:

$$\xi_{eq} = \frac{1}{\pi} \frac{E_d}{(A_{sT} + A_{sC} + A_{rect})} \quad (2)$$

where E_d represents the dissipated energy, that is, the area within the asymmetric hysteresis loop, and A_{sT} , A_{sC} and A_{rect} are the following areas:

$$A_{sT} = \frac{1}{2} k_{eff,T} u_{max}^2, \quad A_{sC} = \frac{1}{2} k_{eff,C} u_{min}^2, \quad A_{rect} = u_{max} \cdot f_{min} \quad (3)$$

with $u_{max} = u_{min}$ the positive and negative maximum displacements, and f_{min} the negative peak value of vertical load. The average equivalent viscous damping ratio $\xi_{eq,a}$ has been calculated as mean value of those obtained from seven of the ten loading cycles applied to the device.

Regarding the influence of the displacement amplitude on the dynamic behavior of the tested HWRI, Table 3 presents the values of the average effective stiffnesses and the equivalent viscous damping ratio obtained for six different amplitudes without the effect of the vertical pre-load. It can be observed that the tested metal device displays higher effective

stiffnesses and equivalent damping ratio at smaller displacements. The effective stiffness in Compression and the equivalent damping ratio decrease with increasing displacement amplitude, whereas the effective stiffness in Tension increases dramatically at the largest amplitudes. Figure 3 shows the asymmetric force-displacement hysteresis loops obtained in Compression/Tension direction (compression and tension are assumed, respectively, negative and positive) for all six different values of amplitude, for $f = 0.1$ Hz and without the effect of the vertical pre-load. It is worth to note that the shape of the hysteresis loops changes according to the displacement amplitude: at the smallest amplitude the hysteresis loops display a softening stiffness in Compression and a slightly hardening stiffness in Tension, whereas at the highest amplitude the experimental cycles exhibit a stronger nonlinear stiffening behavior only on Tension side.

$P_v = 0$ kN, $f = 0.1$ Hz	Amplitude [mm]	k_{eff,C_a} [N/m]	k_{eff,T_a} [N/m]	$\xi_{eq,a}$ [%]
Compression/Tension	5	859659	1238110	22.7
Compression/Tension	10	576639	1038541	17.5
Compression/Tension	15	454733	999633	15.0
Compression/Tension	20	386610	1023578	13.5
Compression/Tension	25	341244	1114642	12.4
Compression/Tension	30	305053	1343628	11.4

Table 3: Influence of displacement amplitude.

As regards to the effect of the vertical pre-load on the dynamic behavior of the tested metal device, Tables 4 and 5 show the results obtained in Compression/Tension direction for four different values of vertical pre-load, by applying a sinusoidal harmonic motion having frequency of 0.1 Hz and amplitude equal to 15 mm and 30 mm, respectively. From the examination of the outcomes, it can be deduced that, in the case of an intermediate displacement amplitude (15 mm), an increase in the pre-load produces a reduction in the average effective stiffnesses and an approximately constant equivalent viscous damping ratio (Table 4).

$A = 15$ mm, $f = 0.1$ Hz	Vertical Load [kN]	k_{eff,C_a} [N/m]	k_{eff,T_a} [N/m]	$\xi_{eq,a}$ [%]
Compression/Tension	0.0	454733	999633	15.0
Compression/Tension	1.2	406447	864757	14.6
Compression/Tension	2.0	410924	878796	15.0
Compression/Tension	3.0	413397	894691	14.7

Table 4: Influence of vertical load for $A = 15$ mm.

On the other hand, in the case of a larger displacement amplitude (30 mm), an increase in the vertical pre-load produces a strong increase of the average effective stiffness in Tension while the variation of the stiffness in Compression is negligible, and determines a slight decrease of the equivalent viscous damping ratio (Table 5).

$A = 30$ mm, $f = 0.1$ Hz	Vertical Load [kN]	k_{eff,C_a} [N/m]	k_{eff,T_a} [N/m]	$\xi_{eq,a}$ [%]
Compression/Tension	0.0	305453	1343628	11.4
Compression/Tension	1.2	304997	1693672	10.6
Compression/Tension	2.0	305366	1736038	10.0
Compression/Tension	3.0	307147	1943828	9.5

Table 5: Influence of vertical load for $A = 30$ mm.

Figure 3: Force-displacement hysteresis loops of HWRI PWHS 16040 at different displacement amplitudes in C/T direction, for $P_v = 0$ kN and $f = 0.1$ Hz: (a) ± 5 , (b) ± 10 , (c) ± 15 , (d) ± 20 , (e) ± 25 , (f) ± 30 .

Figure 4: HWRI PWHS 16040: Influence of vertical pre-load at $A = 15$ mm in Compression/Tension direction.

Figure 5: HWRI PWHS 16040: Influence of vertical pre-load at $A = 30$ mm in Compression/Tension direction.

Figures 4 and 5 show the asymmetric force-displacement hysteresis loops obtained in Compression/Tension direction, under the effect of different values of vertical pre-load, at the displacement amplitudes $A = 15$ mm (Figure 4) and $A = 30$ mm (Figure 5). It can be observed that at the largest displacements, the applied vertical pre-load affects much less the dynamic response of the metal device only on Compression side.

6 NUMERICAL SIMULATION OF THE EXPERIMENTAL BEHAVIOUR

As far as the modeling of the dynamic behavior of HWRI in the vertical direction is concerned, a Modified Bouc-Wen Model (MBWM) is proposed to predict their response. This analytical model is obtained by modifying the expression of the generalized force (Eq. (4)) of the Bouc-Wen Model (depending on five parameters k_2 , k_d , β , γ , ϵ):

$$f_u = k_2 u + z(u) \quad (4)$$

where u is the generalized relative displacement, and $z(u)$ is the hysteretic variable given by solving the following first order differential equation:

$$\dot{z} = \left\{ k_d - [\gamma + \beta \cdot \text{sgn}(z \cdot \dot{u})] |z|^n \right\} \dot{u} \quad (5)$$

The proposed modification of the generalized force:

$$f = -(\lambda_1 + \lambda_2)u + e^{(\lambda_1 u)} - e^{(-\lambda_2 u)} + e^{(\eta u)} (k_2 u + z) \quad (6)$$

allows to simulate the asymmetric behaviour in Compression/Tension direction. The proposed model depends by eight parameters k_2 , k_d , n , β , γ , λ_1 , λ_2 and η , where the latter λ_1 , λ_2 and η are those determining the asymmetry of the loops.

The experimental hysteresis loops, obtained by the dynamic tests performed on the different HWRI, are compared to those derived by the application of the proposed numerical model: the values of the above eight parameters are calibrated in order to simulate the experimental response for a certain vertical pre-load and all the different displacement amplitudes. In particular, such values are: $k_2 = 1100000$, $k_d = 8500000$, $n = 1$, $\beta = 3000$, $\gamma = 0$, $\lambda_1 = 775$, $\lambda_2 = 630$ and $\eta = 55$.

Figure 6 shows the analytical versus experimental comparison for the HWRI PWHS 16010, subjected to a pre-load of 2 kN, with varying the displacement amplitude as described in Table 2. It demonstrates that the proposed mathematical model can satisfactorily predict the dynamic response in a wide displacement range. This satisfying agreement is achieved by all the tested devices, under the different vertical pre-loads.

Figure 6: HWRI PWHS 16010: experimental versus numerical hysteresis loops, under a pre-load of 2 kN.

7 CONCLUSIONS

The experimental investigation of the dynamic response of HWRI, manufactured by Powerflex S.r.l (Limatola, Italy), has been carried out by adopting a testing machine available at the Department of Structures for Engineering and Architecture of the University of Naples Federico II, which allows to impose vertical displacement or load histories to the tested device with a constant vertical pre-load.

Each test consisted in imposing ten cycles of sinusoidal displacement having specified amplitude and frequency, under four different values of vertical pre-load. Six amplitude values have been chosen with the maximum one selected in order to avoid damages to the two alu-

minum alloy retainer bars of the device during the experimental tests. The most investigated loading frequency was assumed equal to 0.1 Hz.

According to the experimental tests results, the tested device is characterized by high effective stiffnesses and equivalent damping ratio in the case of very small imposed displacement amplitudes. These parameters decrease with increasing displacement amplitude, except for the effective stiffness in Tension that dramatically increase towards the largest amplitudes. The shape of the hysteresis loops changes according to the displacements amplitude: at the smallest imposed displacements, the hysteresis loops display a softening stiffness in Compression and a slight hardening in Tension, whereas, at the largest imposed displacements, the device exhibits a hardening stiffness in Tension.

Regarding the effect of the vertical pre-load on the dynamic behavior of the tested HWRI, the experimental outcomes reveal a reduction in the effective stiffness in Compression and an approximately constant equivalent viscous damping ratio due to the increase of the vertical load, while the effective stiffness in Tension increases for the largest amplitudes.

In order to simulate the dynamic behavior of the HWRI in Compression-Tension direction, a nonlinear model has been proposed, accurately calibrated, and validated by comparing the experimental hysteresis loops provided by cyclic tests with those predicted mathematically. In future papers, it will be necessary to identify a more suitable hysteretic model among those already available in the literature [13-20].

Abstract

More than 87% of the Colombian population lives in zones of intermediate and high seismic hazard, which has generated an increasing interest toward base isolated structures. Nowadays, this technique has been mainly applied to hospitals and bridges. However, it is necessary to expand the action field of isolators to diverse kind of structures in countries with high seismic hazard. In this direction, the performance of circular unbounded fiber reinforced elastomeric isolators (U-FREI) was studied in a two degrees-of-freedom (DoF), medium scale structure, under seismic excitation. This evaluation was achieved employing a Real-Time Hybrid Simulation (RTHS), which is defined as a modern cyber-physical technique used for the experimental evaluation of complex systems, that treats the system components with predictable behavior as a numerical substructure, and the components that are difficult to model as an experimental substructure. In this case, the main structure was considered as the numerical substructure and a couple of U-FREI was treated as the experimental substructure. The RTHS was evaluated using a set of Current Assessment Measurements, where an accurate tracking of the transfer system was determined. Furthermore, the experimental results were compared with Shaking Table Tests (STT) developed at University of Naples Federico II. Particularly, peak and RMS comparison of force and acceleration signals showed a similar behavior of the RTHS according to the STT results. Overall, both approaches demonstrated that the U-FREI were able to reduce more than the 70% of the structural drift with respect to the fixed structure, and the applied RTHS methodology was verified.

Keywords: structural control, real-time hybrid simulation, unbounded circular fiber reinforced elastomeric isolator, current assessment measurements.

1 INTRODUCTION

Earthquakes are one of the main natural hazards in countries of the Pacific zone such as Colombia, Mexico, Ecuador, Chile and Japan. To counteract the effect of the earthquake, there are two widely accepted and implemented alternatives. The first consists in isolating the structure at the base, thus reducing the energy input of the earthquake to the building [1–3]. While the second one concentrates in mitigating, through auxiliary devices, the energy that has been transmitted by the earthquake to the structure [4–6]. In a conventional design, the building will dissipate this energy through vibrations that can lead to the generation of damage in its structural and non-structural elements.

In response to this issue, one of the alternatives for structural control that became popular in Japan was the seismic isolation, due to its great performance during the Kobe earthquake of 1995 [7]. De la Llera et al. in [8] has shown the positive experience of the base isolation application with budget limitation and other technological constraints. A cost reduction alternative consists of simplifying the isolator installation process, due to it can be located between the foundation and the structure without bonding at the contact surfaces. This simplified installation method is named ‘unbonded application’ which has been recently investigated on Fiber Reinforced Elastomeric Isolators (FREI) [9].

Unfortunately, to validate the performance of such systems in civil structures would be necessary to implement full-scale experimental tests. These tests require enormous resources that can be prohibitive for some projects. In contrast, the evaluation of non-conventional and earthquake-prone structures is currently being promoted using Real-Time Hybrid Simulation (RTHS). These simulations allow the study of complex systems by classifying components that are easy to model as numerical substructure and components whose behavior is difficult to predict as experimental substructure [10–12]. Thus, the numerical substructure is represented computationally, while the experimental substructure is constructed and tested physically [13–15]. Therefore, RTHS technique involves advantages as low cost, small space, low loading capacity requirements [12, 16].

This study addressed this issue developing a RTHS for a structure with unbounded seismic isolators U-FREI (Unbounded Fiber Reinforced Elastomeric Isolators).

2 SHAKING TABLE TEST (STT)

2.1 Main structure

Losanno et al. [17] conducted a series of Shaking Table Tests (STT) with an experimental two degrees-of-freedom (DoF) base isolated system. This structure was installed at the Department of Structures for Engineering and Architecture (DiST) of the University of Naples Federico II in Italy. A cylindrical U-FREI was used below each column. Also, previously in the research [18] both polyester and carbon reinforcement were considered, where their characterization was developed through uniaxial shear and compression tests. In this case, the results obtained by Losanno et al. in [17] are used as the reference data, with the aim of validating the RTHS results achieved in this application. The reference structure consists of a steel frame, with a total height of 2.9 m and plan dimensions of 2.65x2.15 m², as shown in Figure 1. The total weight of the structure is 77 kN, with a base load of 36 kN and a top load of 41 kN. Additionally, the structural response was measured through 3-axis accelerometers (PCB356A17) and displacement sensors (Micro-epsilon ILD1402-600, Wenglor CP35MHT80) in each level.

Figure 1: Scheme of the reference structure.

The dynamic characteristics of the main structure in fixed-based configuration were identified through shaking table tests in [19], and masses, natural frequency and damping ratio are presented in Table 1.

$m_{bottom}(kg)$	$m_{top}(kg)$	$f_n(Hz)$	$\zeta(\%)$
3675	4180	3.81	1.00

Table 1: Dynamic properties of the main structure.

2.2 Circular unbounded fiber reinforced elastomeric isolators

The main structure was supported by four cylindrical U-FREI, as shown in Figure 2. These isolators have a diameter of 80 mm and total height of 44 mm. Particularly, these U-FREIs are composed of 15 rubber layers with a thick of 2 mm, which were reinforced by 14 polyester fiber layers with a thick of 1 mm. The total height of rubber is $H_r = 30$ mm. The same manufacturing process is also described in Madera Sierra et al. [20].

Figure 2: U-FREI.

The U-FREIs employed in the STT were characterized using a cyclic test with a maximum displacement of 9 cm, i.e. 300% shear strain. The hysteretic behavior of two set of these isolators is shown in Figure 3, as references T1a and T1b. In this study, two set of isolators, with the same geometry of those used at University of Naples, were analyzed in the LINSE Laboratory at Universidad del Valle, Cali, Colombia. These isolators were characterized with an equivalent cyclic test that presents a maximum displacement of 5 cm, whose results are

indicated in Figure 3 as LINSE (Sp1) and LINSE (Sp2). A challenging non-linear behavior is exhibited by U-FREIs as recently confirmed by several attempts to develop accurate hysteretic models [21–23].

The effective lateral stiffness $K_{h,i}$ of the devices was calculated based on the peak-to-peak lateral response for each deformation cycle, as shown in Eq. (1), where $F_{max,i}$ and $F_{min,i}$ are the maximum and minimum values of the force during the i -th cycle, and $D_{max,i}$ and $D_{min,i}$ are the corresponding for the displacement. The equivalent damping ratio β_i was estimated as a function of the dissipated area, $E_{d,i}$, during each deformation cycle, as shown in Eq. (2). Both parameters are shown in Figure 4.

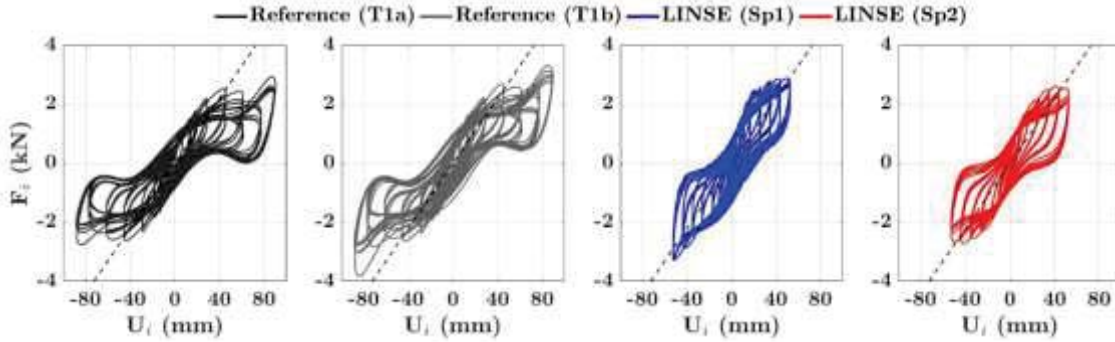

Figure 3: Hysteresis loops from cyclic tests for (a) Reference specimen T1a; (b) Reference specimen T1b; (c) LINSE specimen 1; (d) LINSE specimen 2.

$$K_{h,i} = \frac{F_{max,i} - F_{min,i}}{D_{max,i} - D_{min,i}} \quad (1)$$

$$\beta_i = \frac{E_{d,i}}{2 \cdot \pi \cdot K_{h,i} \cdot (D_{max,i})^2} \quad (2)$$

Figure 4: Comparison for the LINSE's and Federico II specimens of the (a) Secant stiffnesses and (b) Damping coefficients.

Even if secant stiffness of LINSE prototypes lightly exceeds the values from previous ones, it can be noted that a significantly lower damping is obtained especially at low deformation levels. This is probably due to a different rubber compound assumed in the manufacturing.

3 REAL-TIME HYBRID SIMULATION

Real-time hybrid simulation (RTHS) is a modern cyber-physical technique used for the experimental evaluation of complex systems, which treats the components with predictable behavior of the system as numerical substructure and the components that are difficult to model as experimental substructure. In this implementation, the structural system (without isolators) is considered as the numerical substructure since it can be modeled with a high level of accuracy, whilst the isolators are considered as the experimental substructure.

One of the main challenges of the RTHS is the generation of the boundary conditions in the experimental substructure. This process demands a detailed knowledge of the actuators that apply the information obtained from the numerical integration. These actuators are known as transfer systems. In this implementation two decentralized transfer systems are included. One of them is focused on the normal force, which is directly applied to the isolator specimens, and the other reproduces the horizontal displacement at the base of the numerical substructure through a shear force.

The input of the RTHS is the base acceleration caused by the Campano-Lucano (CAM 50%) earthquake scaled to the 50%, $a_g(t)$, which corresponds to the first input of the numerical substructure model (see, Figure 6). The horizontal displacement of the numerical substructure at the isolator location was taken as the reference signal of the horizontal transfer system, $x_{i,d}(t)$. This process generates physically a displacement in the experimental substructure that corresponds to the measured displacement, $x_{i,m}(t)$, as shown in Figure 5. Furthermore, the vertical transfer system induces a normal force, $F_v(t)$, with a reference value of 19 kN, being this value, the structural weight supported by each isolator during the STT. In this direction, the shear force produced by the experimental substructure is the feedback force, $F_{i,fb}(t)$, and this signal is assigned as the second input of the numerical substructure.

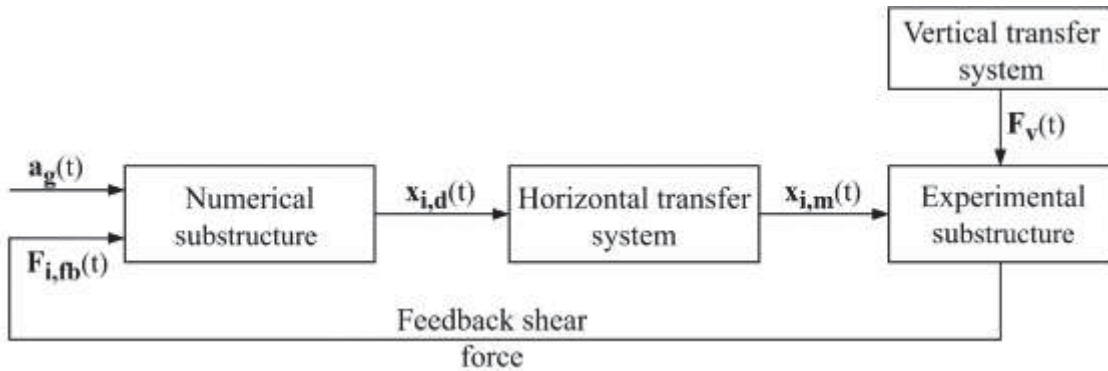

Figure 5: RTHS scheme.

Figure 6: Ground acceleration of the CAM50% earthquake.

3.1 Numerical substructure

The main structure was modeled as a two DoF system, as shown in Eq. (3). In this state space representation m_1 and m_2 are the bottom and top structural masses, as indicates in Figure 7. k_s and c_s are the stiffness and damping of the main structure, respectively. Moreover, $u_i(t)$ and $u_s(t)$ are the displacement of the isolators and the structural displacement. The four system states correspond to the isolator displacement, x_1 , the structural displacement, x_2 , the isolator velocity, x_3 , and the structural velocity, x_4 . As mentioned above, the system inputs are the ground acceleration, $a_g(t)$, and the isolator shear force, $F_{i,fb}$, which is measured during the RTHS. It is important to mention that the system output is the first state of the numerical model.

Figure 7: Main structure scheme.

3.2 Experimental substructure

The behavior of the isolators in unbounded configuration is highly complex: because of the variation of the contact area [14, 18], it tends to decrease the horizontal stiffness and increase the energy dissipation. Also, U-FREI performs a phenomenon denominated roll-over as mentioned previously. A complete roll-over takes place when the original vertical face of the isolator is approaching the horizontal support [9, 18, 24, 25]. It is shown that after the initial point of roll-over, a gradual softening of the isolators is produced, and after the end point of full roll-over, it can be observed an effect of stiffness hardening. Thus, in this study the U-FREIs are considered as the experimental substructure. For this purpose, an experimental setup was developed to couple the experimental substructure with the cybernetic component of the RTHS.

The experimental setup involves a moving plate, which is released in the vertical direction to allow the movement associated with the compression of the isolators. In addition, this plate is supported on linear bearings, which are oriented in the horizontal direction. In this configuration, two isolators are disposed in the experimental setup as shown in Figure 8. Thus, the opposition force of the isolators was measured by a load cell Optima OP-312-3. The normal force was set to 19 kN during the simulation, which is applied by a vertical hydraulic actuator. The compression load cell Omega LPCH-5-M12 was used to control the vertical compression.

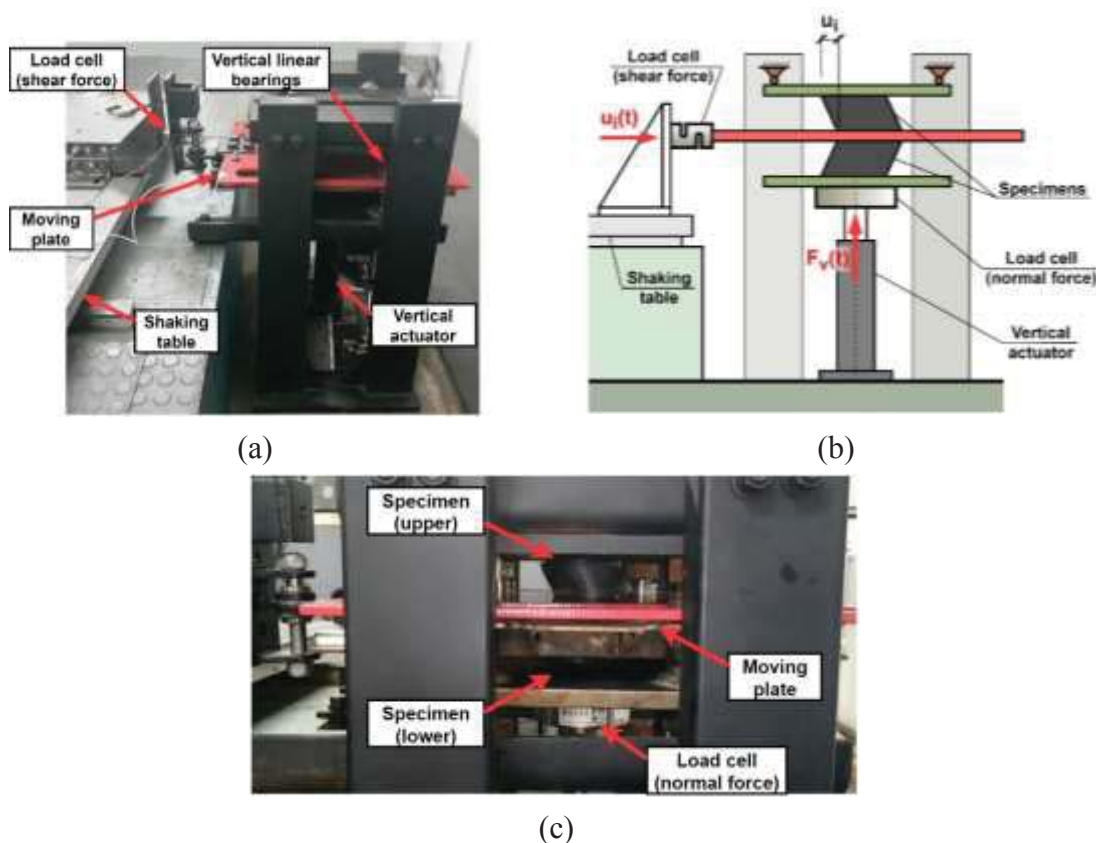

Figure 8: (a) Experimental setup, (b) Experimental setup scheme, and (c) Deformed U-FREI.

3.3 Transfer systems

The RTHS control scheme is shown in Figure 9, where the horizontal control displacement is achieved through an actuator Shore Wester 911D, which has a linear variable differential transformer (LVDT). This LVDT allows to measure the displacement of the actuator piston with higher precision. This actuator is activated by a hydraulic pump that presents a maximum flow of 13.2 liters per minute. Particularly, the system pump-actuator or plant was modeled as a continuous system with one pole at the origin, without zeros, a nominal gain of 14, and a delay of 33 milliseconds. Due to the considerable noise in the LVDT measure, a Kalman filter was designed to obtain an adequate signal, according to the RTHS scope. As shown in Figure 9, the plant was feed-back using the filtered actuator displacement, $x_{m,f}[kT]$, and a unit delay. This close loop generates a stable system, in contrast to the marginal stability of the plant in open loop. Moreover, the internal loop can filter the high frequency components of the controller output, $v[kT]$. Nevertheless, the adequate tracking characteristics (amplitude and angle phase) of the horizontal transfer system were achieved using an optimal control technique in the external loop. In this case, a H_∞ controller was employed, which Riascos et al. in [26–28] designed using the hinfstruc Matlab function, where the optimization was developed for minimizing the error signal, $e[kT]$, and the operational voltage signal, $u[kT]$.

On the other hand, the vertical control force consists of three components. The first component is a linear function expressed as $a F_{v,d} + b$, which determines the nominal voltage required by a Power Unity to apply a force, $F_{v,d}$, in the actuator. The second component is a term based on a hysteretic loop between the actuator force and the power unity voltage. This term depends on the error sign, as described in Figure 9. The third component consists of a proportional-integral (PI) controller, which fits the voltage to achieve a measured force close to the reference despite of the isolator deformation.

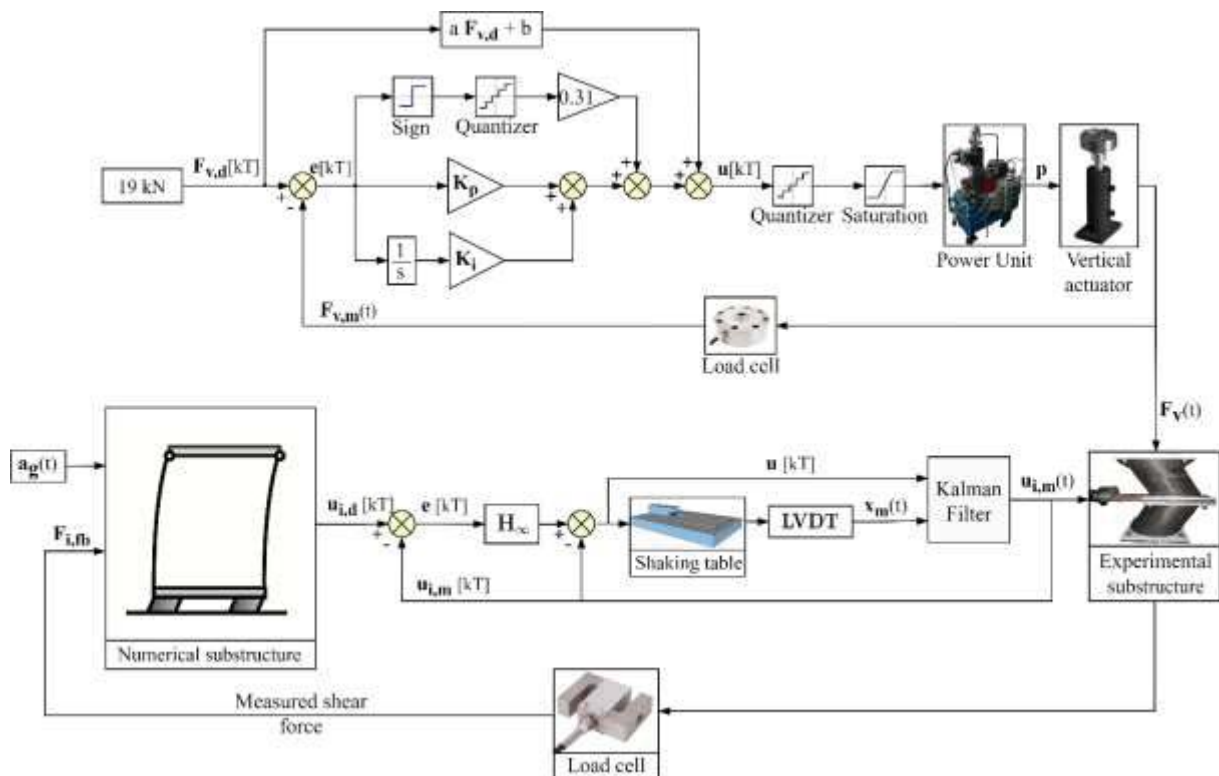

Figure 9: RTHS scheme.

4 RTHS IMPLEMENTATION

This RTHS was implemented with a high-speed executing computer (SpeedGoat target machine). For this task, a host computer with Matlab's Xpc protocol and a sampling frequency of 1024 Hz was used. The SpeedGoat has high processing capacity to guarantee real-time evaluation of the hybrid simulation. For the CAM 50% earthquake, a comparison between STT and RTHS approaches is presented in Figure 10.

Figure 10: RTHS implementation.

4.1 RTHS performance

Assessment measures are adopted to determine the accuracy of the RTHS. The parameters selected in this study focused especially on the tracking accuracy of the main transfer system. These parameters involve time or frequency domains. For example, the difference of maximum error and the maximum difference errors are calculated in time domain, as given in Eqs. (4) and (5). The frequency evaluation index (FEI) compares the target and measured signals in the frequency domain using the fast Fourier transform (FFT), and the equivalent frequency (f^{eq}) identifies the cycle frequency where there is the most energy of the signal, as given in Eqs. (6) and (7), respectively. The generalized amplitude, A_0 , and generalized angle, ϕ , depend on the FEI as expressed in Eqs. (8)-(9). Further, the delay, δ , between the target and measured signals is determined in function of FEI, which is the opposite value of the FEI argument over the equivalent angular frequency, as given by Eq. (10).

$$e_{DM} = \frac{||x_t|^{max} - |x_m|^{max}|}{|x_m|^{max}} \quad (4)$$

$$e_{MD} = \frac{|x_t - x_m|^{max}}{|x_m|^{max}} \quad (5)$$

$$FEI = \sum_{j=1}^N \left\{ \frac{y_m(j)}{y_c(j)} \cdot \frac{\|y_c(j)\|^l}{\sum_{i=1}^p \|y_c(j)\|^l} \right\} \quad (6)$$

$$f^{eq} = \frac{\sum_{j=1}^N \{\|y_c(j)\|^l \cdot f_j\}}{\sum_{j=1}^N \|y_c(j)\|^l} \quad (7)$$

$$A_0 = \|FEI\| \quad (8)$$

$$\emptyset = \arctan[Im(FEI)/Re(FEI)] \quad (9)$$

$$\delta = -\frac{\emptyset}{2\pi f^{eq}} \quad (10)$$

FEI	$f^{eq}(Hz)$	A_0	$e_{DM}(\%)$	$e_{MD}(\%)$	δ (ms)
1.000 – 0.009 i	0.52	1.00	0.27	2.25	2.87

Table 2: Assessment measures.

4.2 RTHS Comparison

To validate the RTHS results some comparison indexes were proposed. These indexes allow to determine the peak and Root Mean Square (RMS) coherence between the force, acceleration, or displacement, of the RTHS (y_{RTHS}), with respect to those obtained with the STT (y_{STT}). Both indexes are defined in Eqs. (11)-(12). The comparison index results are listed in Table 3, where can be observed the adequate correspondence between the force and acceleration signals obtained with the RTHS in comparison with those of the STT. However, the displacement signal between both approaches presented considerable differences. These differences indicate that the isolator displacement in the RTHS technique was approximately only 66% of the STT response. This was caused by the higher stiffness of the specimens used in this study, which also present lower damping for small deformations. In addition, the upper structure presented a maximum inter-story drift of 0.109% through the STT, whilst a drift of 0.179% was achieved with the RTHS approach. This drift difference was caused by the high stiffness of the U-FREIs employed during the RTHS, since these isolators transmit more seismic energy to the upper structure in comparison with those implemented in the STT.

$$J_{peak} (\%) = 100 \frac{\max(y_{RTHS})}{\max(y_{STT})} \quad (11)$$

$$J_{RMS} (\%) = 100 \frac{RMS(y_{RTHS})}{RMS(y_{STT})} \quad (12)$$

Signal	J_{peak} (%)	J_{RMS} (%)
Force	104	105
Acceleration	91	95
Displacement	67	66

Table 3: Indexes of comparison between responses for RTHS and STT.

5 CONCLUSIONS

The main findings of this study can be listed as follows:

- Experimental results show that the horizontal transfer system was able to generate the isolator displacement obtained from the numerical integration with good accuracy.
- The equivalent frequency of the RTHS reported an operational frequency at 0.52 Hz, which allowed to the transfer system achieving an excellent tracking with respect to the desired displacement, where generalized amplitude of 1.00 and delay lower than 3 milliseconds were obtained.
- The RTHS achieved an adequate prediction of the peak and RMS force and acceleration of the isolated structure, despite of using a simplified model of the main structure and an experimental substructure with different mechanical characteristics in terms of stiffness and damping, with respect to that presented during the STT.
- In the RTHS technique, the isolator displacement was approximately a fraction, i.e. 66% of the STT response. This was caused by the higher stiffness that presents the specimens used in this study, which present poor damping for small deformations.
- Overall, both approaches demonstrated that the U-FREIs were able to reduce considerably the structural drift with respect to the fixed structure, and the applied RTHS methodology was verified.
- As a further development the authors will improve the numerical models of the structure in order to improve the accuracy of the RTHS.

Abstract

In common practice, uncoupled hysteretic models, that is, models that do not consider the biaxial interaction between the restoring forces along two generic orthogonal transverse directions, are typically employed to perform nonlinear time history analyses of base isolated structures. However, such models do not suitably reproduce the exact response of the structure when the system is subjected to external excitation in two orthogonal directions. Thus, the selection of suitable phenomenological model and the time integration method is important while carrying out nonlinear time history analysis (NLTHA) of base isolated structures. In the present study, a detailed investigation is carried out to assess the effectiveness of two hysteretic models to reproduce the hysteretic behaviour of the elastomeric bearings. A three-dimensional base-isolated reinforced concrete building is analysed under earthquake excitations, by employing a novel biaxial phenomenological model denominated Multiple Springs Exponential Model (MSEM) and Biaxial Bouc-Wen model (BBWM). Numerical accuracy and the computational efficiency of these methods are assessed through NLTHA. The results show that the novel method is advantageous and computationally efficient in comparison with BBWM.

Keywords: Hysteresis model, base isolated structure, phenomenological model, multiple springs, nonlinear time history analysis.

1 INTRODUCTION

Base isolation is one of the effective response control technologies that helps in reducing the seismic response of structures by introducing isolation bearings between the foundation and superstructure of the building [1,2,3,4]. The continuous development in the base isolation technology and innovative isolation devices [5,6,7,8] lead to a significant increase in the base isolated structures in the recent years. The behaviour of base isolated structures is highly influenced by the base isolation system, which need to be carefully investigated [9,10,11]. Due to the difficulties associated with the development of detailed finite element models of isolation bearings, several studies were carried out to identify a hysteresis model to reproduce the most realistic behaviour of the bearings [12].

In addition, the isolation bearings display a coupled behaviour when subjected to external excitation in two orthogonal directions [13]. Several phenomenological models are widely used to reproduce the biaxial rate-independent behaviour of seismic isolation bearings obtained from cyclic experimental tests. Biaxial differential models are mostly employed to reproduce the hysteresis phenomena, due to its accuracy and requirement of a smaller number of model parameters [14]. However, the computational efficiency of such models are affected due to the physical insignificance of the model parameters. Also, they demand a numerical solution of a differential vector equation to obtain the response of the building at each time step of a Nonlinear Time History Analysis (NLTHA).

One of the most commonly used models is the Bouc-Wen model (BWM), but the nonlinear time history analysis of a structural model using BWM demands increased computational effort. Further, the interpretation of BWM parameters is not straightforward due to its peculiar formulation [15]. The recently formulated Biaxial Bouc-Wen model (BBWM) is capable of reproducing the biaxial behaviour of the isolation bearings. Despite its reported accuracy, the physical interpretation of model parameters and the computational time remains as a major difficulty during the response analyses of base isolated buildings.

Considering the assessment of base-isolated building response, the accuracy of the nonlinear analyses depends on the selection of suitable phenomenological model and the time integration method to solve the nonlinear equilibrium equations. In this context, the present study aims at investigating the novel coupled phenomenological model developed by Vaiana et al. [14] to simulate the rate-independent hysteretic behaviour of isolation bearings of a base isolated structure. Multiple Springs Exponential Model (MSEM), formulated from the general class of novel phenomenological model, is considered for the study. The obtained results are compared with the BBWM results in order to check the accuracy and computational efficiency of the MSEM. Further, Nonlinear Time History Analyses (NLTHAs) of a two-story base-isolated reinforced concrete building is also carried out using MSEM and BBWM to model the behaviour of isolation bearings. Considering the importance of time integration method in the NLTHA of base-isolated buildings, the widely used Newmark's constant acceleration method is used along with the BBWM model. In case of base isolated building with MSEM mode, Chang's explicit method is used for NLTHA due to reduced computational effort and the results obtained from this novel methodology is compared with the conventional procedure.

2 HYSTERESIS MODELS

The response of a base-isolated structure is highly influenced by the dynamic properties of the isolation devices. Hence, the selection of a suitable hysteresis model plays a major role in the nonlinear analysis of such structures. Hysteresis models, ranging from simple bilinear models to complex models and developed for particular applications, are available in the liter-

ature [16,17]. In the present study, a novel biaxial phenomenological model, denominated Multiple Springs Exponential Model (MSEM) and formulated by Vaiana et al. [14], is considered along with the celebrated BBWM. The hysteresis models used to represent the behaviour of isolation bearings are presented in the following subsections.

2.1 Bouc-Wen model

BWM is governed by a first-order nonlinear Ordinary Differential Equation (ODE) characterized by six parameters that govern the shape and size of the hysteresis loops. The model is based in the Duhem hysteresis operator and simulates a smooth transition between elastic and post-elastic states [18,19]. Park et al. [20] extended the uniaxial model to simulate the biaxial rate-independent hysteretic behaviour of systems and materials. Finally, the generalized biaxial formulation of the model is proposed by Harvey and Gavin [21], and the components of the generalized force vector are given by:

$$\begin{Bmatrix} f_x(u_x) \\ f_y(u_y) \end{Bmatrix} = a k \begin{Bmatrix} u_x \\ u_y \end{Bmatrix} + (1 - a) k d \begin{Bmatrix} z_x \\ z_y \end{Bmatrix} \quad (1)$$

where k and d are parameters with dimensions of stiffness and displacement, respectively, u_x and u_y are the generalized displacements along X-axis and Y-axis, respectively, a is a dimensionless parameter, and z_x and z_y are dimensionless variables which can be obtained from the following system of two coupled first-order nonlinear ODEs:

$$\dot{z}_x = d^{-1} \left[A \dot{u}_x - z_x (b |\dot{u}_x z_x| + c \dot{u}_x z_x + b |\dot{u}_y z_y| + c \dot{u}_y z_y) (z_x^2 + z_y^2)^{\frac{e-2}{2}} \right] \quad (2)$$

$$\dot{z}_y = d^{-1} \left[A \dot{u}_y - z_y (b |\dot{u}_x z_x| + c \dot{u}_x z_x + b |\dot{u}_y z_y| + c \dot{u}_y z_y) (z_x^2 + z_y^2)^{\frac{e-2}{2}} \right] \quad (3)$$

where A , b , and c are dimensionless parameters that control the shape of the hysteresis loops. Thus, BBWM requires the calibration of seven parameters to simulate the exact hysteresis behaviour of isolation bearings through experiments. BWM is used along with Newmark's constant average acceleration method to solve the nonlinear equilibrium equations. This method is unconditionally stable and also allows the use of large time steps while fulfilling the requirement for accuracy [22,23]. However, the computational efficiency of the method is highly affected by the convergence issues due to the conjunction of the method along with the iterative procedure [24].

2.2 Multiple Springs Exponential Model

The novel family of biaxial models proposed by Vaiana et al. [14] is capable of simulating the typical bidirectional kinematic rate-independent hysteretic behaviour displayed by mechanical systems and materials. The biaxial model is formulated by employing the multiple springs model [25] in conjunction with the uniaxial phenomenological models developed by Vaiana et al. [26,27]. The model was developed by introducing n evenly spaced springs in a circular configuration around the origin of the adopted coordinate system as shown in Figure 1(a). Each spring is made up of two different springs in parallel such as the elastic spring with generalized tangent stiffness k_e , and a rate-independent hysteretic spring with generalized tangent stiffness k_b , as shown in Figure 1(b). The generalized tangent stiffness k_t is obtained by summing k_e and k_b .

Figure 1: (a) Plan view of the multiple springs model, and (b) i-th spring [14].

The generalized force-displacement hysteresis loops characterizing the i-th spring of the proposed model may be limited to two parallel straight lines (curves), as shown in Figure 2. The integration of the general expression of the generalized tangent stiffness functions yields the expressions for the generic loading (unloading) curve and for the upper (lower) limiting curve. The integration constants are obtained by considering the intersection of generic loading (unloading) curve and upper (lower) limiting curve. The abscissa of the intersection point is represented as the generalized history variable.

Figure 2: Hysteresis loop limited by two parallel (a) straight lines, and (b) curves [14].

Multiple Springs Exponential Model (MSEM) considered in the present study belongs to this family of biaxial models, which is obtained by selecting a suitable generalized tangent stiffness functions and then by deriving the particularized expression of the generalized force, history variable, and internal constant parameters. For simplicity, same properties are assigned for all the springs in the model, thus obtaining an isotropic model. MSEM is a more sophisticated model where the typical generalized force-displacement hysteresis loop of the i-th spring is limited by two parallel straight lines or curves. This model requires four parameters to simulate the complex biaxial hysteresis phenomena. The general expression of the generalized tangent stiffness functions can be obtained from the sum of following expressions of k_e and k_h :

$$k_e(u) = -2\beta + \beta(e^{\beta u} + e^{-\beta u}) \quad \text{on } (-\infty, \infty) \quad (4)$$

$$k_h(u, u_j^+) = \begin{cases} k_b + (k_a - k_b)e^{-\alpha(u - u_j^+ + 2u_0)} & \text{on } [u_j^+ - 2u_0, u_j^+ [\\ k_b & \text{on }]u_j^+, \infty), \end{cases} \quad (5)$$

$$k_h(u, u_j^-) = \begin{cases} k_b + (k_a - k_b)e^{-\alpha(-u + u_j^- + 2u_0)} & \text{on }]u_j^-, u_j^- + 2u_0] \\ k_b & \text{on } (-\infty, u_j^- [\end{cases} \quad (6)$$

where k_a , k_b , α , and β are the four model parameters that fulfill the following conditions: $k_a > k_b$, $k_a > 0$, $\alpha > 0$, whereas β is real.

The general expression of the i -th spring generic loading and unloading curves can be written as follows:

$$c^+(u, u_j^+) = -2\beta u + e^{\beta u} - e^{-\beta u} + k_b u - \frac{(k_a - k_b)}{\alpha} \left[e^{-\alpha(u - u_j^+ + 2u_0)} - e^{-2\alpha u_0} \right] + f_0 \quad (7)$$

$$c^-(u, u_j^-) = -2\beta u + e^{\beta u} - e^{-\beta u} + k_b u + \frac{(k_a - k_b)}{\alpha} \left[e^{-\alpha(-u + u_j^- + 2u_0)} - e^{-2\alpha u_0} \right] - f_0 \quad (8)$$

Further, the expressions of the upper and lower limiting curves are given by:

$$c_u(u) = -2\beta u + e^{\beta u} + e^{-\beta u} + k_b u + f_0 \quad (9)$$

$$c_l(u) = -2\beta u + e^{\beta u} - e^{-\beta u} + k_b u - f_0 \quad (10)$$

The general equations used to evaluate the generalized history variable for the generic loading and unloading cases are as follows:

$$u_j^+ = u_p + 2u_0 + \frac{1}{\alpha} \ln \left[+ \frac{\alpha}{k_a - k_b} \left(-2\beta u_p + e^{\beta u_p} - e^{-\beta u_p} + k_b u_p + \frac{(k_a - k_b)}{\alpha} e^{-2\alpha u_0} + f_0 - f_p \right) \right] \quad (11)$$

$$u_j^- = u_p - 2u_0 - \frac{1}{\alpha} \ln \left[- \frac{\alpha}{k_a - k_b} \left(-2\beta u_p + e^{\beta u_p} - e^{-\beta u_p} + k_b u_p - \frac{(k_a - k_b)}{\alpha} e^{-2\alpha u_0} - f_0 - f_p \right) \right] \quad (12)$$

The expression of the constant parameter u_0 can be derived by assuming that the upper (lower) limiting curves and generic loading (unloading) curves have the same generalized tangent stiffness functions at their intersection point. It can be given by:

$$u_0 = -\frac{1}{2\alpha} \ln \left(\frac{\delta_k}{k_a - k_b} \right) \quad (13)$$

Further, the expression for the constant parameter f_0 is obtained as follows:

$$f_0 = \frac{k_a - k_b}{2\alpha} (1 - e^{-2\alpha u_0}) \quad (14)$$

In the present study, this novel coupled phenomenological model is used along with an explicit unconditionally stable time integration method. This strategy avoids the use of iterative procedures for solving nonlinear equilibrium equations and it is useful when complex prob-

lems need to be addressed [28,29]. The explicit time integration method considered in the study represents a specific algorithm developed by Chang [30] and adopted by Vaiana et al. [31] for base-isolated structures. In case of non-stiffening systems, this method tends to be unconditionally stable and has a second-order accuracy. Further, the method does not suffer from numerical damping and displays only a small relative period error.

3 NUMERICAL MODEL

A three dimensional (3D) structural model with two substructures such as the n -story superstructure and a base isolation system is considered to assess the accuracy and computational efficiency of the proposed model. The 3D model defined in global, right-handed cartesian coordinate system attached to the mass centre of the base isolation system is shown in Figure 3. The nonlinear analysis of the base isolated structure is carried out considering the following assumptions: (a) the deformation of the superstructure is within the linear elastic range during the earthquake excitation, (b) the floor diaphragm is infinitely rigid in its own plane, (c) the columns are axially inextensible, (d) the beams are flexurally rigid and axially inextensible, (e) the base isolation bearings are axially inextensible.

Figure 3: Three-dimensional model of base isolated structure.

The superstructure of the base isolated structure is a two-story reinforced concrete structure with vertical geometrical irregularity. The plan dimension of the building is 10.0 m x 8.0 m with a story height of 3.50 m. The weight of the superstructure is 1802.90 kN. The first three natural periods of the superstructure are 0.15 s, 0.14 s and 0.10 s. The total weight of base isolation system with 9 elastomeric bearings is 914.90 kN. The bearings are placed between the superstructure columns full diaphragm. The base isolation system is designed to provide an effective isolation period of 2.25 s and an effective viscous damping of 15% at the design displacement 0.50 m. As per the assumptions considered for the nonlinear analysis of the structure, the number of degrees-of-freedom of the super structure and the isolation system are equal to 6 and 3, respectively.

The nonlinear equilibrium equation considered for the analysis of the Multi-Degree-Of-Freedom (MDOF) base isolated structure is given by:

$$M\ddot{u}(t) + C\dot{u}(t) + Ku(t) + f_n(t) = p(t) \quad (15)$$

where, $u(t)$, $\dot{u}(t)$, and $\ddot{u}(t)$ are the generalized displacement, velocity, acceleration vectors, respectively, M , C , and K are the generalized constant mass, damping and elastic stiffness matrices, respectively, $f_n(t)$ is the generalized nonlinear force vector, and $p(t)$ is the generalized external force vector at time t .

For the adopted base isolated structure idealization, the motion vectors of the model relative to the ground can be written as follows:

$$u = \begin{Bmatrix} u_b \\ u_s \end{Bmatrix}, \quad \dot{u} = \begin{Bmatrix} \dot{u}_b \\ \dot{u}_s \end{Bmatrix}, \quad \ddot{u} = \begin{Bmatrix} \ddot{u}_b \\ \ddot{u}_s \end{Bmatrix} \quad (16)$$

where, $u_b, \dot{u}_b, \ddot{u}_b$ ($u_s, \dot{u}_s, \ddot{u}_s$) are the displacement, velocity and acceleration vectors of base isolation device (superstructure) of size 3×1 ($3n \times 1$), respectively.

The force vectors are given by:

$$f_n = \begin{Bmatrix} f_{nb} \\ 0 \end{Bmatrix}, \quad p = - \begin{bmatrix} M_b & 0^T \\ 0 & M_s \end{bmatrix} \begin{Bmatrix} R_b \\ R_s \end{Bmatrix} \ddot{u}_g \quad (17)$$

where, f_{nb} is the nonlinear force vector of the base isolation system with dimension 3×1 , $R_b(R_s)$ is the influence matrix of base isolation system (superstructure), and \ddot{u}_g is the ground acceleration vector of dimension 3×1 .

4 HYSTERESIS MODEL PARAMETERS

The parameters of the biaxial Bouc-Wen model adopted to simulate the behaviour of the elastomeric bearings are shown in Table 1. MSEM requires calibration of four parameters (k_a, k_b, α, β) and 'n' number of springs. MSEM model parameters are identified using Particle Swarm Optimization (PSO) algorithm [32] which is a computational technique with easy implementation and convergence properties. In the algorithm, a set of random parameters are first initialized, and the value of each parameter is iteratively modified. The optimization is performed by considering the interaction among the parameters and the objective function is minimized. MSEM parameters are calibrated in the present study by minimizing the following objective function:

$$\Theta = \sum_j \sqrt{(f_j^{MSEM} - f_j)^2} \quad \text{with } j = x, y \quad (18)$$

where, f_j^{MSEM} is the j-th component of the generalized force vector computed using MSEM and f_j is the j-th component of the generalized force vector describing the behaviour of the isolation bearings using BWM. The following PSO parameters are used to avoid premature convergence of the solution in the local optimum points:

- population size: 100,
- number of iterations: 200,
- acceleration factors: $c_1 = c_2 = 2$,
- maximum and minimum inertia weights: $w_{\max} = 0.9$ and $w_{\min} = 0.4$.

The adopted MSEM parameters are listed in Table 2. The comparison of hysteresis loops of BWM and MSEM model with the calibrated parameters are shown in Figure 4. The plots are obtained by imposing eight-shaped displacement orbit given by $u_x = a_o \sin \omega t$ and $u_y = a_o \sin 2\omega t$, with $a_o = 0.5$ m and $\omega = 2\pi$ rad/s. It can be clearly seen that the MSEM model is capable of representing the hysteresis behaviour of the isolation bearing with reduced number of parameters, in comparison with BWM.

K [N/m]	A	a	b	c	d [m]	e
1.83e6	1	0.10	1.00	0.00	0.017	1.00

Table 1: BWM parameters used in the NLTHAs.

n	k_a [N/m]	k_b [N/m]	α [m ⁻¹]	β [N/m]
16.00	5.78e8	1.83e5	1.04e4	0

Table 2: MSEM parameters used in the NLTHAs.

Figure 4: Comparison between BBWM and MSEM hysteresis loops along (a) X-axis, (b) Y-axis, and (c) generalized force paths by applying eight-shaped generalized displacement orbit.

The numerical model has been programmed in MATLAB and run on a computer with Intel® Core™ i5-5200U processor and a CPU at 2.20GHz with 8.00 GB RAM. The computational time of BBWM is 20.97 s, whereas the MSEM model required only 0.53s, which is about 2.50% of the BBWM computational time. Along with the computational time, the model also exhibits acceptable accuracy with reduced number of model parameters, making the calibration process easier.

5 NUMERICAL ANALYSES OF A BASE-ISOLATED STRUCTURE

The response of the base isolated structure under bidirectional earthquake excitation is presented in this section. In the analyses, the BBWM and MSEM are used to reproduce the dynamic behaviour of the isolation bearings of the base isolated structure. Further, conventional time integration method is used along with BBWM to numerically integrate the nonlinear equilibrium equations, whereas Chang's explicit method is used along with the novel MSEM. The NLTHA of the base isolated structure is performed by imposing Northridge earthquake acceleration time history along X-axis and Y-axis as shown in Figure 5.

Figure 5: Ground acceleration time histories of Northridge earthquake along (a) X-axis and (b) Y-axis.

The numerical results and computational time are compared to assess the accuracy and computational efficiency of the solution strategies. The first order nonlinear ODE in the BWM is solved using the unconditionally stable semi-implicit Range-Kutta method with 50 number of steps [33]. The results of the NLTHAs are listed in Table 3. It can be clearly seen that the maximum and minimum values of the base isolation system mass centre displacements (\mathbf{u}), velocities ($\dot{\mathbf{u}}$) and accelerations ($\ddot{\mathbf{u}}$) obtained using BBWM and MSEM are almost equal. In addition to the seismic response of the base isolated structure, the total computational time tct required to perform NLTHAs by BBWM and MSEM are also given in Table 3. It can be clearly seen that the MSEM reduces the computational time drastically. Since, the obtained computational time highly depends on the CPU speed, relevant memory and background process running on the computer, an additional parameter $tctp$ which is the total computational time percentage is also evaluated as follows:

$$\text{MSEM } tctp [\%] = \frac{\text{MSEM } tct}{\text{BBWM } tct} \cdot 100 \quad (19)$$

This parameter provides a more meaningful measure of the computational benefits associated with MSEM, in comparison with BBWM. The value of the $tctp$ in the order of 0.87% highlights the advantages of implementing this model in structural analysis tools and commercial computer programs.

Further, the comparison of displacement, velocity and acceleration response measured at the base isolation system mass centre obtained using BBWM and MSEM models are shown in Figure 6(a) to 6(f). The results clearly highlight the accuracy of the novel biaxial phenomenological model in comparison with the BBWM. A minor difference arises in terms of hysteresis

etic response of the isolation bearings in Figure 6(g) and 6(h) due to different formulations of the models to be properly calibrated on experimental tests.

		BBWM	MSEM	ϵ [%]
t_{ct} [s]		12104	105	
t_{ctp} [%]		-	0.87	
u_x [m]	Max	0.33	0.33	0.00
	Min	-0.33	-0.33	0.00
u_y [m]	Max	0.23	0.25	8.00
	min	-0.18	-0.21	14.29
\dot{u}_x [ms ⁻¹]	Max	0.89	0.90	1.11
	min	-0.83	-0.82	-1.20
\dot{u}_y [ms ⁻¹]	Max	0.98	1.08	9.26
	min	-0.85	-0.89	1.12
\ddot{u}_x [ms ⁻²]	Max	5.16	4.90	-5.04
	min	-3.93	-3.83	-2.54
\ddot{u}_y [ms ⁻²]	Max	10.37	10.47	0.96
	min	-10.55	-10.30	-2.37

6 CONCLUSIONS

In the present study, the accuracy and computational efficiency of the two biaxial hysteretic models to reproduce the behaviour of elastomeric bearings is assessed. A novel biaxial phenomenological model denominated Multiple Springs Exponential Model is compared with the commonly used Biaxial Bouc-Wen Model. The novel model is found to be advantageous in comparison with BBWM due its reduced number of model parameters, physical interpretation of parameters, easier calibration, and reduced computational time.

Further, NLTHA of a three-dimensional base isolated reinforced concrete building is also carried out. Considering the importance of time integration methods employed in NLTHA of base isolated structures, Newmark's constant average acceleration method and Chang's explicit method are used along with BBWM and MSEM, respectively. The dynamic response of the base isolated structure obtained using the MSEM model and Chang's explicit method closely matches with the results from the conventional procedure using BBWM and Newmark's method. Further, the total computational time percentage of the novel method is only around 0.87% which highlights the computational efficiency and suitability of this model for implementation in structural analysis tools.

Abstract

Although seismic isolation devices are effective in protecting structures during an earthquake, they are generally large, heavy, and expensive, making their application prohibitive for housing buildings. In the last few years, different strategies have been investigated to make seismic isolators cheaper and lighter for housing buildings in developing countries. Lower costs can be obtained at different scales: simplifying the installation process of devices, reducing energy consumption during manufacturing, and using recycled materials. Both weight and cost of isolators could be reduced by adopting flexible reinforcements in place of steel reinforcing plates, also allowing easier installation without bolted connections in unbounded configuration. Costs can be further reduced by replacing natural rubber with a recycled elastomer. It has been demonstrated that trying to give a second life to rubber is challenging, since devulcanization process, capable of breaking chemical bonds between rubber and sulphur, is highly polluting and requires high consumption of energy. In the present work, a recycled compound has been preliminary developed with mechanical properties not significantly lower than virgin rubber. Obtained parameters are satisfactory for use in unbounded isolators with flexible internal reinforcement where internal stresses are significantly reduced. In particular, a novel compound has been properly formulated in order to be lower cost in comparison to traditional one. Mechanical characterization of the material showed excellent properties including shear modulus and hardness similar to those of a soft rubber, even if a reduced ultimate deformation capacity is achieved. Furthermore, rubber adhesion with different fabrics has been investigated. Preliminary results are very promising and pave the way for the development of high-performance and low-cost rubber isolators.

Keywords: Base isolation, fibre reinforced elastomeric rubber isolators, recycled rubber

1 INTRODUCTION

Base isolation is one of the most effective technologies in seismic protection of structures [1]. Its objectives are the protection of human life and the reduction of damage caused to buildings during earthquakes. Despite all, the system is rarely used in emerging countries due to its relatively high cost and features of the design codes. In fact, classical steel-reinforced elastomeric isolators (SREIs) are generally large, heavy, and expensive due to the highly labor-intensive manufacturing process, making their application prohibitive in the case of housing buildings. In the last years, many efforts have been done trying to develop novel low-cost seismic devices, in order to expand the market of seismic protection systems also to ordinary housing buildings, particularly in high seismicity areas of developing countries [2,3]. Lower costs can be obtained by: (i) simplifying the installation process of the devices, (ii) reducing energy consumption during manufacturing process and (iii) using waste and recycled materials. The first approach was aimed to replace steel plates with fibre sheets [4]. In comparison with rigid reinforcements, flexible reinforcements are lighter and can be easily introduced in the manufacturing process of elastomeric rubber bearing to be installed under the structure in an unbonded configuration [5,6]. In fact, in masonry buildings, these devices are placed directly under the foundations of the structure, with no need for additional transfer elements, leading to a significant reduction of the construction costs [3]. These new devices are known as fiber reinforced elastomeric isolators (FREIs) [7]. Costs can be further reduced by replacing virgin rubber with a recycled low-cost elastomer, mitigating, at the same time, the threat of rubber scraps increasing all over the world. However, recycling rubber is challenging, due to its chemical structure and composition, which make it an insoluble and infusible material that cannot be easily reprocessed. One of the major methods of sustainable management of used tyres is grinding them and use the rubber particles to produce a new environmental-friendly polymer. The fabrication process of these material consists in grinding rubber into particles of different shape and dimensions, mixing them with a low amount of polyurethane and then hot pressing or cold forging the material in order to obtain recycled rubber pads. This material is characterized by density low and low mechanical properties [8]. Another method to obtain a 100% recycled rubber material consists in compression moulding of rubber granules at elevated temperature and pressure, necessary to break the crosslink bond, without the addition of any binder [9–11]. This material exhibits good mechanical properties and high density [12]. Some studies have shown the possibility of using rubber pads to produce recycled rubber isolators reinforced with carbon fibres (RU-FREI) avoiding the vulcanization process [13]. In fact, manufacturing cost of one RU-FREI is of a few Euros and about 1/10 of the cost of a traditional SREI. Shaking table tests, performed by Losanno et al. [14,15] confirmed the effectiveness of the RU-FREI isolation systems in reducing the accelerations and inter-story drifts along the height of the building. However, RU-FREI could be employed as seismic isolation system for heavy structures, such as masonry buildings, because when designed for a lightweight frame, these bearings end up having a low aspect ratio, becoming unstable under large lateral deformations [7]. In the present work, the authors introduce a new compound whose characteristics are in between virgin natural rubber and recycled rubber. For this purpose, a novel compound has been formulated and the physical and mechanical properties have been investigated. The material has shown excellent mechanical properties compared to that of natural rubber, in terms of both shear modulus and hardness, even if a reduced ultimate deformation capacity is achieved. Most importantly, the material exhibited excellent adhesion both with metal and synthetic fabric, preventing debonding which characterized RU-FREI. Thus, the cost savings for raw materials combined with satisfactory mechanical performance could pave the way to a novel low-cost isolation system. Finally, the preliminary design of

seismic isolator reinforced with nylon and polyester fabric is presented as prototypes to be tested in the near future.

2 DEVELOPMENT OF THE COMPOUND

Both physical and mechanical properties of the compound are investigated to assess hardness, stiffness, equivalent viscous damping, deformation, and durability properties of the compound.

The rheometric behaviour of the material has been investigated according to ISO 3417 [16]. Two moulding temperatures, 140°C and 177°C, are considered in order to find the optimal combination of curing temperature and time. This test describes precisely and quickly curing and processing characteristics of vulcanizable rubber compounds. A test piece of rubber compound is contained in a sealed test cavity under positive pressure and maintained at a specified elevated temperature. A rotor biconical disc is embedded in the test piece and is oscillated through small specified rotary amplitude. A complete cure in terms of applied torque versus cure time is obtained.

Shore Durometer A (UNI EN ISO 868 [17]) and international rubber hardness degrees (IRHD) (ISO 48 Method N [18]) were evaluated. The hardness is evaluated by inducing reversible, elastic deformation by means of a specially shaped indenter. Five samples of 35 mm diameter and 6 mm thick, with smooth, flat surface are tested for 3 sec in case of Shore A and 30 sec for IRHD, and the average values of hardness are computed. Tests are conducted both on samples cured at 140°C for 25 minutes and 170°C for 9 minutes.

Tensile tests are conducted on dumb-bells specimens, according to ISO 37 [19], using tensile tester, equipped with 10 kN loadcell. Six samples of thickness 2 mm, width 4 mm and length 20 mm were tested and the average value was computed for the only rubber compound moulded at 140°C for 25 minutes. Test are conducted with a strain rate of 500 mm/min up to failure.

Tear tests are conducted following ISO 34-1 [20], using the trouser test pieces. It is preferred to other methods since providing information about the fundamental tear properties of the material and less sensitive to the length of the cut. The tearing force is applied by means of a tensile testing machine, which operates continuously at 100 mm/min until the test piece breaks. Five samples of thickness 2 mm, width 15 mm and length 100 mm were considered and a cut of length 40 mm was applied in the longitudinal direction.

Shear tests are conducted with a quadrupole setup. The test pieces consist of four rectangular rubber pads 4 mm thick, 25 mm long and 20 mm wide, bonded on four rigid plates of the same width. This system is connected to an actuator, which applies shear deflection with a strain rate of 5mm/min. Samples are subjected to four static half-cycles of shear amplitude 20%, 40%, 60%, 80% and then 100%. Also dynamic properties are estimated considering a frequency of 0,5 Hz.

Rubber aging behaviour is also investigated by performing accelerated aging, according to ISO 188 [21]. Samples are conditioned at 70°C for 168h (7 days).

Finally, the adhesion of rubber with different supports (steel, nylon, polyester) is investigated performing peeling tests, according to ISO 813 [22]. A strip of rubber is bonded to a single plate of rigid material and peeled with an angle of 90° with a strain rate of 50 mm/min. The applied force required to tear the rubber from the support is measured. The standard test piece consists of a strip 6 mm thick, 25 mm wide and 125 mm long, bonded to a square area of size 25 mm on the surface of a metal plate and of the fiber textiles bonded on a rigid support.

3 CHARACTERIZATION TESTS

3.1 Tyre rubber crumb

Use of tyre rubber crumb provides advantages during the moulding process due to the bonds that are activated during the grinding. In particular, styrene butadiene rubber (SBR) and natural rubber (NR), unlike butyl rubber, ensure good compatibility not only with the virgin rubber compound, but also with the fabric providing good adhesion. For this purpose, a rubber crumb composed by SBR and NR was chosen.

TGA analysis are performed by considering the temperature ramp of Figure 1a and the weight loss percentages are reported in Figure 1b and summarized in Table 1. A first weight loss of 14 wt% is observed at around 350°C due to the plasticizers, followed by significant weight loss of 54 wt% at around 545°C, which corresponds to SBR and NR. Residuals are attributed to other fillers, such as silica, typical of tyre compounds, or other additives.

Table 1. Reclaimed rubber composition

<i>Components</i>	<i>T [°C]</i>	<i>wt %</i>
Absorbed water	70	0.47
Plasticizer (oil, volatile components)	350	13.63
Polymers (NR and SBR)	545	54.96
Carbon black	700	25.13
Ash, inorganic components (ZnO, SiO ₂ ,...)	>700	5.85

Figure 1. TGA analysis of tyre reclaimed rubber: (a) Temperature-Time procedure; (b) Weight loss

3.2 Novel rubber compound investigation

The vulcanization process of the compound at different temperature was investigated. Rheometric curves at 140°C and 177°C are reported in Figure 2. Curing is governed by activators, catalysts, cross-linking agents, hardeners, and accelerators. The time required to obtain the curing curve is a function of the test temperature and the vulcanization characteristics of the rubber compound [23]. By increasing the testing temperature from 140°C to 177°C, the time to achieve the 90% of cure decreases of about 8 times. The material also shows a stable behaviour at 140°C, since the curve reaches a plateau, without experiencing a reversion of torque [24].

Figure 2. Rheometric curves of the novel rubber compound at 140°C and 177°C

Average values of hardness are reported in Table 2, for samples cured at both 140°C and 170°C. Durometer values are typical of a soft vulcanized rubber [17]. These results indicate that hardness is sensitive to the vulcanization process. In particular, the curing cycle of sample moulded at 140°C is longer than that of samples moulded at 170°C. In fact, slower vulcanization processes at lower temperature allow the formation of stronger networks, which results in higher hardness of the material.

Table 2. Hardness values

	Shore A		IRHD	
<i>Test temperature</i>	140°C	170°C	140°C	170°C
<i>Average value</i>	47.4	45.1	41.32	34.65

Tensile and tear tests on rubber specimens cured at 140°C for 25 min, revealed an excellent behaviour of rubber compound (Figure 3a-b). The maximum average stress and strains are 2.6 MPa and 330%, respectively. Even if these values are lower than virgin rubber compounds, they are significantly higher than previously adopted reclaimed compounds for RU-FREIs [8,12]. A tear resistance of 6.94 N/mm was measured, which is lightly lower than the minimum requirements, i.e. 8 N/mm [20]. However, these results are highly promising for applicability to elastomeric seismic isolators in unbonded configuration. Unlike isolators in bolted configuration, in unbonded application rubber ends are not constrained by steel plates and are free to strain with very limited internal stress. With increasing shear deformations, the ends at contact with the supports tend to roll-off and vertical faces rotate in a roll-over mechanism [25]. This also results in a significantly lower internal peeling stress at rubber-fibre interface.

Hardness and mechanical properties of the material are also investigated after accelerated aging. In particular, after conditioning rubber at 70°C for 7 days a hardness and tensile strength increase of 9% and 36% were measured, while elongation at break decreased of 8.5%.

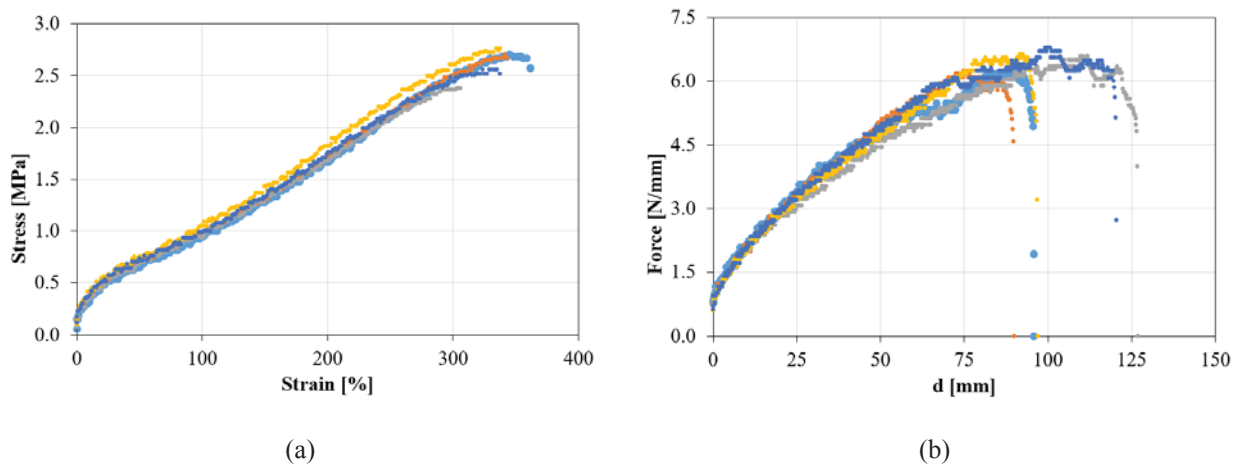

Figure 3. (a) Tensile test and (b) tear test

Figure 4. Shear test on rubber: (a) Setup of quadrupole test; (b) Results

Shear modulus and damping were evaluated for a shear strain $\gamma=100\%$ being 0.39 MPa and 4.9% respectively, while dynamic properties were estimated around 0.52 MPa and 10.4 %, respectively. A low shear modulus of the compound, combined with a higher shear strain capacity, can lead to design of seismic isolators with higher shape factors, thus preventing lateral instability which strongly limited previous investigations on RU-FREIs.

In FREIs, the bonding between layers is of paramount importance since it may govern the failure of the bearing. Tests showed an excellent adhesion of rubber with metal. For all samples rubber tearing occurred before any debonding from the support (Figure 5), providing optimal adhesion between the two materials. For nylon and polyester fabric, a proper adhesive was introduced to impregnate the textiles in order to promote the adhesion. Also in this case, tests showed an excellent behaviour with the tearing of the rubber from the support both for nylon and polyester (Table 3).

4. PRELIMINARY DESIGN OF ISOLATORS

On the basis of the preliminary characterization of the novel rubber compound whose main properties are summarised in Table 4, prototype isolators reinforced with polyester and nylon fabric have been designed. Nylon fabric and Polyester fabric coated with graphene were adopted as reinforcement. These are balanced fabrics with a very low cost with respect to conventional steel shims. The geometry of the devices is summarized in Table 5 and sketched in Figure 6.

Table 5. Geometry of rubber isolator reinforced with polyester/nylon fabrics

Device	n° of rubber layers	D [mm]	H [mm]	t _r [mm]	t _f [mm]	S [-]
<i>RR - Nylon</i>	8	200	49.5	5.17	1.16	9.7
<i>RR - Polyester</i>	9	200	49.5	5.02	0.54	10.0

Compared to RU-FREIs from literature [13–15], these prototypes are characterized by a higher shape factor roughly equal to 10. These values are consistent with those of FREI devices fabricated with virgin rubber. Differently, in case of RU-FREIs, the relatively large shear modulus of the rubber and the limited shear strain ($\gamma=50\%$), resulted in a slender geometry with an aspect ratio close to 1. Consequently, the use of softer compound with higher deformation capacity allows to design more squat geometry thus preventing instability issues [26]. Lateral stability will be investigated up to complete roll-over of the vertical faces under shear tests. In addition to this, vertical behavior will be tested in order to assess the compressibility of the bearing and the influence of limited elastic modulus of the reinforcement in comparison to conventional steel plates and carbon fibers.

Finally, it will be necessary to select the most suitable hysteretic model, among those introduced in the literature [27–31], to allow for an accurate simulation of their nonlinear response.

Figure 6. Elastomeric rubber isolator reinforced with polyester/nylon fabrics

4 5 CONCLUSIONS

A new recycled compound with promising mechanical properties has been developed. The material has been extensively characterized and its physical and mechanical properties have been investigated and properly calibrated.

The shear properties of the material are in between natural rubber and totally-recycled rubber pads, exhibiting shear strain up to 100%, i.e. around two times higher than the latters. Also, tensile strength is satisfactory for use in unbounded configuration with flexible internal reinforcement where internal stresses are significantly released.

In addition to this, the novel compound has shown excellent adhesion not only with steel but also with different fabrics such as nylon and polyester. These are very common, cheap textiles commonly used for industrial application such as conveyor belt or work clothes. They can be easily purchased and inserted in the manufacturing process. Devices can be produced

by direct molding, overlaying rubber layers and flexible reinforcements. Consequently, not only the weight of the devices is significantly reduced, but also the efforts associated to their fabrication.

The lower shear modulus and the higher shear strain of the compound compared to that of recycled rubber pads allow the fabrication of devices with higher shape factors. This can significantly increase the stability limits that were poorly investigated in previous investigations.

The next step of the study is aimed to develop prototype of isolators to be experimentally tested. The proposed technology is very promising and could pave the way for the development of high-performance and low-cost rubber isolators.

Abstract

The most important demand parameter for a seismically isolated structure is the maximum displacement at the isolation level. Currently, the most accurate way to estimate both the maximum isolator displacement and the isolator shear force is to perform bounding analyses. Accordingly, in bounding analyses, the lower and upper bound characteristics of isolator units are used in order to consider the change in isolator properties due variation in loading history, aging and environmental factors such as climatic conditions that the isolator is exposed during its lifetime. The objective of this study is to experimentally investigate the change in mechanical properties of a lead rubber bearing under very low ambient temperature. For this purpose, a lead rubber bearing with a total height of 361 mm, a diameter of 1020 mm and a lead core diameter of 190 mm is subjected to displacement-controlled loading at different ambient temperatures. The seismic isolator unit was first kept in room condition (20°C) for 24 hours in ESQUAKE Seismic Isolator Test Laboratory established in Eskisehir Technical University and then tested under cyclic motion. Then, the isolator unit which was conditioned at -30°C for 24 hours, was subjected to the same cyclic loading. Recorded force-displacement curves for both ambient temperatures are compared. In the loading protocol, the amount of axial load was 4500 kN (6 MPa normal stress), the amplitude of the horizontal motion was 280 mm (100% shear strain), the number of cycles was 3 and the frequency of motion was 0.1 Hz. Based on the test results conducted for both ambient temperatures, post-yield stiffness, effective stiffness, energy dissipated per cycle and equivalent damping ratios of the isolator were calculated for each cycle and compared with each other. Results showed that mechanical properties of lead rubber bearing significantly changed under low ambient temperature when compared to those obtained at laboratory conditions. When the ambient temperature drops down to -30°C from 20°C, the amplifications in post yield stiffness and characteristic strength are 10% and 50%, respectively.

Keywords: Seismic Isolation, Ambient Temperature, Cyclic Loading, Lead Rubber Bearing.

1 INTRODUCTION

Seismic isolation is an earthquake resistant design strategy which is adopted to protect structures against adverse effects of ground motions. It relies on lengthening of natural period of structure by introducing systems, that possess low horizontal stiffness, between the superstructure and substructure. Accordingly, in case of a seismic excitation, rather than the seismically isolated structure, seismic isolators will undergo large deformations and dissipate energy. Among various seismic isolation systems, lead rubber bearing (LRB) is one of the most widely used seismic isolators. They are composed of alternate layers of rubber and steel plates with a lead core at the center that passes through the height of the bearing. Rubber layers are responsible for the lateral stiffness of the bearing whereas lead core provides the required lateral strength. Since it was invented by Robinson in the 1970s, LRBs have been used in several structures (bridges, hospitals, data centers etc.) around the world [1-3]. In parallel, several research has been conducted to determine performance of LRBs under the effect of different parameters [4-10]. One of these parameters is the change in ambient temperature.

Mechanical properties of LRBs, mainly post yield stiffness and characteristic strength, are related to properties of rubber and lead, respectively. Although there are numerous studies that focused on the change in rigidity of rubber at low temperatures [11-17], very few experimental data are available for modification of LRB properties at low temperatures [18-20]. The LRB tested by Hasegawa et al. [18] was 250 mm in diameter with a lead core diameter of 38 mm. Displacement controlled LRB tests were conducted at temperatures of 40, 20, 0 and -20°C for a shear strain of 100% at 0.3 Hz. It was reported that the exposure time of the bearing to these temperatures is 5hrs. Similarly, Constantinou et al. [7] conducted tests with an LRB having rubber and lead core diameters of 381 mm and 70 mm, respectively. Isolator tests were carried out at a shear strain of 58% and loading frequency was 0.35 Hz. Constantinou et al. [7] stated that LRB was conditioned at -26°C and 20°C for 48 hrs prior to tests. Compared to LRBs used in experimental studies of Hasegawa et al. [18] and Constantinou et al. [7], LRB tested by Cho et al. [19] was a large size bearing with rubber and lead core diameters of 860 mm and 170 mm, respectively. The total rubber thickness was 288 mm and tested at a shear strain of 15%. Temperatures considered by Cho et al. [19] were -20, -10, 0 and 23°C. It is to be mentioned that 15% shear strain is very low to be representative of seismic behavior of an LRB designed to undergo large deformations. Accordingly, variation in mechanical properties of a large size LRB exposed to low temperature was revisited by Park et al. [20]. Rubber and lead core diameters of the LRB were 800 mm and 180 mm, respectively and tested at a shear strain of 100%.

The objective of this study is to determine the effect of low ambient temperature on mechanical properties of a lead rubber bearing. Accordingly, first, a large-size LRB was tested at both room (20°C) and low (-30°C) temperatures under dynamic conditions. The tested seismic isolator is subjected to displacement-controlled loading cycles that corresponds to 100% shear strain. Test results obtained for two distinct ambient temperatures are used to construct force-displacement curves for both conditions. Variation in characteristic strength (Q), post yield stiffness (K_d), effective stiffness (K_{eff}), dissipated energy per cycle (EDC) and equivalent damping ratio (ξ_{eff}) computed for both conditions are compared with each other.

2 TESTED LEAD RUBBER BEARING

The bearing tested in this study is a large-size LRB with rubber and lead core diameters of 1020 mm and 190 mm, respectively. Height of the bearing is 436 mm including the top and bottom plates together with the end shim at the top. It is composed of 28 layers of rubber each of which has 10 mm thickness with a total rubber height of 280 mm. Geometrical properties of the tested LRB is presented in Figure 1.

Figure 1: Section cut of test specimen.

3 ISOLATOR TESTS AT ROOM AND LOW AIR TEMPERATURE

In order to determine the mechanical properties of the specimen, its hysteretic response in shear was recorded under a constant compressive load. Accordingly, the LRB was subjected to three cycles of sinusoidal motion with amplitude equals to 280 mm that corresponds to 100% shear strain. Frequency of the motion was 0.1 Hz where the maximum velocity is 176 mm/s. The axial force acting on the bearing was 4500 kN which result in 6 MPa normal stress. The LRB was first tested at a temperature of 20°C after conditioning for 24 hours inside the laboratory and tested again at a temperature of -30°C after conditioning for 24 hours inside the air-conditioned room (Figure 2.a). Tests were conducted at ESQUAKE Seismic Isolator Test Laboratory of Eskisehir Technical University. The test setup of ESQUAKE shown in Figure 2.b is capable of applying dynamic motions in both horizontal and vertical directions. Table 1 presents the loading capacities of ESQUAKE test setup. Horizontal force-displacement curves obtained from tests for 20°C and -30°C are given in Figure 3.

4 MECHANICAL PROPERTIES OF LRB

Mechanical properties of the tested LRB such as post-yield stiffness (K_d), characteristic strength (Q_d), effective stiffness (K_{eff}), energy dissipation capacity (EDC) and effective damping ratio (ζ_{eff}) for temperatures of 20°C and -30°C are presented in Table 2. Data given in Table 2 are computed by means of Equations (1)-(4) and Figure 4. In Equations (1) and (2), Q_1' , Q_1'' , Q_2' and Q_2'' are the isolator forces at 50% of the maximum positive and negative horizontal displacements d_{max} and d_{min} as per ISO 22762-1 [21]. Q_1 and Q_2 of Equation (3) are the isolator forces at d_{max} and d_{min} , respectively (see Figure 4).

Temperature	Cycle	Q_d (kN)	K_d (kN/m)	K_{eff} (kN/m)	EDC (kN·m)	ζ_{eff} (%)
-30°C	1	489	2020	3441	504	0.29
	2	414	1919	3100	433	0.28
	3	372	1864	2913	382	0.26
20°C	1	324	1833	2706	335	0.25
	2	286	1796	2510	297	0.24
	3	260	1766	2392	264	0.22

Table 2: Mechanical properties of LRB at 20°C and -30°C

In order to better understanding of change in mechanical properties of LRB isolator at low temperature, Figure 5 is depicted. In this figure amount of variation in isolator properties with respect to the room temperature is presented for all considered features. Accordingly, comparison of test results obtained for temperatures of 20°C and -30°C reveals the following conclusions. Characteristic strength (force intercept at zero displacement) Q_d of the tested LRB increases when the temperature drops down to -30°C. The amount of amplification in Q_d is 50% for the first cycle whereas it is 45% and 43% for the second and third cycles,

respectively. Similarly, post-yield stiffness K_d of the LRB increases as the temperature decreases. However, the amount of variations in K_d , which are 10%, 7% and 6% for first, second and third cycles, are relatively small compared to those computed for Q_d . Based on the data presented in Table 2, the amount of change in effective stiffness K_{eff} due to temperature decrease is 27% for the first cycle and reduced to 24% and 22% for the second and third cycles, respectively. According to Table 2, energy dissipation capacity EDC , defined as the area under force-displacement curve at each cycle, increases as the temperature decreases. Amplification in EDC at first, second and third cycles are computed as 50%, 46% and 44% in the same order. In parallel, reducing the temperature from 20°C to -30°C contributes to an increase in effective damping ratio ξ_{eff} equal to 17% for the first cycle. The amplifications are 19% and 18% for the second and third cycles, respectively. Considering the test results, it is evident that amount of variation in mechanical properties of LRB is not constant at all loading cycles and the trend is to decrease with increasing number of cycles.

Figure 4 - Force-displacement definitions for LRBs.

$$Q_d = \left[\frac{Q_1'' d_{\max}/2 - Q_1' d_{\min}/2}{(d_{\max} - d_{\min})/2} - \frac{Q_2' d_{\max}/2 - Q_2'' d_{\min}/2}{(d_{\max} - d_{\min})/2} \right] / 2 \quad (1)$$

$$K_d = \left[\frac{Q_1' - Q_1''}{(d_{\max} - d_{\min})/2} + \frac{Q_2'' - Q_2'}{(d_{\max} - d_{\min})/2} \right] / 2 \quad (2)$$

$$K_{eff} = \left[\frac{Q_1 - Q_2}{d_{\max} - d_{\min}} \right] \quad (3)$$

$$\xi = \left[\frac{EDC}{\pi(F_{\max} D_{\max} + F_{\min} D_{\min})} \right] \quad (4)$$

Figure 5: Amount of variation in mechanical properties of LRB isolator per cycle with respect to room temperature.

5 CONCLUSIONS

This study quantifies the variation in mechanical properties of an LRB isolator under the effect of very low ambient temperatures. For this purpose, an experimental investigation was performed at 20°C to -30°C. Recorded force-displacement curves for both considered temperatures are compared. Results showed that characteristic strength and post-yield stiffness of bilinear force-displacement curve of the tested LRB increases when the temperature drops from 20°C to -30°C. The amplifications in strength and stiffness are observed to be in the order of 50% and 10%, respectively. As the number of cycles increases, these values decrease gradually.

Abstract

The majority of the existing seismic protection systems and techniques are related to horizontal ground motions, while there are only a few vertical seismic protection systems. The main reason is due to the conflict concerning the demand for isolation stiffness. More specifically, a vertical isolated system must have sufficient vertical rigidity to sustain the weight of the isolated object/system and retain the static vertical deflection in reasonable limits. On the other hand, the isolated system must also have enough flexibility to isolate the accelerations. In order to overcome this difficulty, a novel vertical seismic absorber system is proposed, that combines a Quasi-Zero Stiffness (QZS) design including negative stiffness elements, an enhanced Tuned Mass Damper (TMD) and an inerter. The QZS oscillator manages to maintain the vertical rigidity of the structure, the inerter manages to reduce the frequency of the system, without weakening the structure or increase the seismic load and the TMD is responsible for absorbing the external excitations, significantly increasing the effective damping. This way, the dynamic behavior of the system is improved, in terms of absolute accelerations, and simultaneously, the static settlements are retained at any desired level. The design is based on engineering criteria, and the excitation input is selected according to the seismic design codes.

Keywords: Vertical Seismic Protection, Negative Stiffness, KDamper, Damping, Vibration Absorption.

1. INTRODUCTION

Earthquakes consist one of the major environmental hazards. During 2011 e.g., over 20,000 people died and about a million people lost their homes globally, due to earthquakes and their effects. Moreover, a wide class of ground vibrations generated by heavy and high-speed vehicles such as trains and trucks, construction activities (i.e., dynamic compaction, roadbed compaction, pile driving, blasting) or blasts, present a frequency spectrum in the order of a few Hz. Together with other sources inside the building, (e.g., impact noise between floors), noise pollution is their major effect.

The conventional design approach to address such loads consists of stiff and highly damped structures. Apart from technical (and financial) constraints in their realization, (e.g., current unavailability of large sized dampers, cases of heavy structures, etc.), such designs may result to reverse effects concerning certain aspects of their desired dynamic behavior. For example, stiff and highly damped structures can enhance the transfer of base acceleration excitations to the main structure. This may result to damaging effects in the interior of the structure relating e.g., to the secondary loads (machines, sensitive equipment, etc.) in the case of earthquakes.

Isolation appears to be a promising alternative, as it is based on the concept of altering the dynamics of the system and to reduce the vibration, rather than increasing the resistance capacity of the structure. The concept of isolation relies on a flexible layer between the structure and its base. This way, the fundamental natural period of the base isolated system is significantly longer, and thus, the structure can absorb less energy from the broad base excitation frequency spectrum. However, in order to isolate the building from its base, large displacements are required due to the fundamental dynamic behavior of the system, which can be even in the range of tenths of centimeters for certain earthquakes. These displacements can be hardly acceptable for numerous reasons, such as structural pounding, sensitivity in horizontal loads, proper connection for utilities, and more, rendering this concept inadequate for retrofitting.

The above comments have motivated the development of alternative vibration control strategies, which among others, include: (i) Tuned Mass Dampers (TMDs), (ii) Inerters, (iii) Negative Stiffness Devices (NSD) and “Quazi Zero Stiffness” (QZS) oscillators, and (iv) Negative Stiffness driven Absorbers/KDampers. (Figure 1)

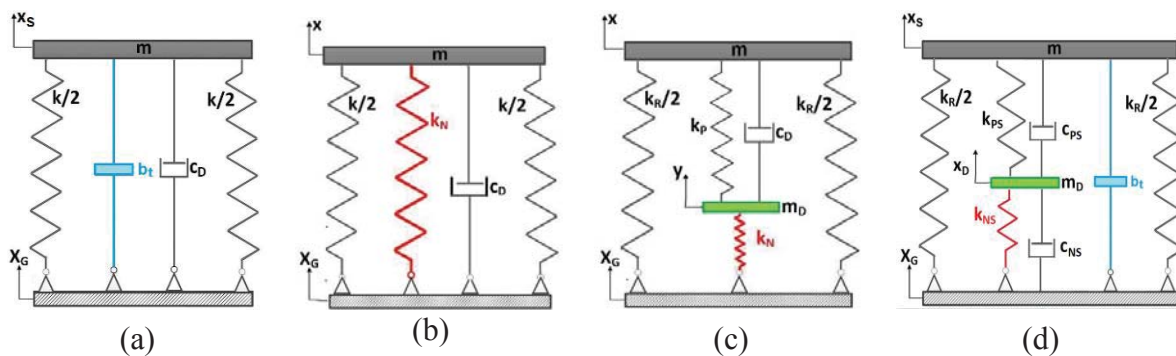

Figure 1 (a) Inerters; (b) Negative Stiffness Absorbers/QZS oscillators; (c) KDamper concept; (d) Proposed Stiff Dynamic Absorbers

The Tuned Mass Damper (TMD) has a long history, with applications in several types of engineering structures, such as high-rise buildings and skyscrapers [1,2,3], bridges [4], wind and wave excitation in wind turbines [5], etc. In addition, the TMD can be used as a possible supplement to the conventional base isolation approaches, implemented within the bases of structures, aiming to reduce the displacement demand [6–8]. The main disadvantages of

vibration absorption techniques that use a TMD-related approach are associated with the requirement for large additional masses in order for the TMD to be effective, and with the fact that a slight alteration of its parameters can alter the TMD tuning and consequently reduce the system's performance significantly [9].

In an attempt to reduce the requirements for heavy oscillating masses under the TMD concept, the inerter has been introduced in the early 2000s [10,11]. The inerter is a two-terminal element (Figure 1.a), which has the property of generating at its ends a force that is proportional to the relative acceleration of its terminals. The main advantage of the inerter lies in the fact that it does not need to have large mass in order to achieve the same inertia effect as the additional mass required under the TMD approach. The essential limitation of the inerter is the complex and elaborate mechanical design configurations needed for its implementation, and the reduction of the effective damping of the system due to the increase of the effective mass. Moreover, the major disadvantage of the TMD in base isolation applications, is that enhances the transfer of base acceleration excitations to the main structure, even more significantly than a damper of a high value. As mentioned, this can result to damaging effects in the interior of the structure.

A parallel direction to the various TMD approaches is the concept of introducing negative stiffness (NS) elements for vibration absorption (Figure 1.b). The use of negative stiffness elements (or “anti-springs”) for vibration isolation was first introduced in the pioneering works of Molyneaux [12], and of Platus [13]. The central concept of these approaches is the significant reduction of the isolator's stiffness, which, consequently, leads to the decrease of the natural frequency of the system even at almost zero levels. Towards this direction, the so called “Quasi-Zero Stiffness” (QZS) oscillators have been proposed [14]. An initial comprehensive review of such designs can be found in [15]. Nagarajaiah et. al [16] introduced a new structural modification approach for the seismic protection of structures using an adaptive negative stiffness device that resulted to the decrease of the dynamic forces imposed on the structure. The QZS oscillators are designs of an essentially non-linear stiffness, combining a positive spring in parallel with a non-linear spring, which exhibits a negative stiffness region under nominal load. In this way, QZS oscillators combine a high static stiffness, capable of maintaining the structural load, with a low dynamic stiffness, enabling a low isolation frequency. However, QZS oscillators offer a low damping capacity. In addition, even small load disturbances around the static equilibrium point of the QZS designs can significantly affect their response.

Extending the concept of the traditional Tuned Mass Dampers, a novel passive vibration absorption and damping concept (the KDamper) is introduced [17]. Compared to the TMD, the KDamper uses an additional negative stiffness spring (Figure 1.c). connecting the additional mass to the ground. This negative stiffness spring generates a force in phase with the acceleration response, acting essentially as an inertial force of the additional mass. In this way, the performance of the KDamper can be drastically increased, just by increasing the value of the negative stiffness spring and without the need to increase the value of the additional mass. Thus, the KDamper has been shown to present extraordinary damping/absorption properties, with relatively small (even minimal) values of the additional mass.

Although the KDamper incorporates a negative stiffness element, it is designed to be both statically and dynamically stable. Thus, the KDamper can be designed to present the same overall (static) stiffness as a traditional reference original oscillator, while simultaneously offering drastically increased damping properties. Since the presence of a negative stiffness spring in series with a positive stiffness spring can result to a negative stiffness value, the static behavior of the KDamper can be controlled to be similar to that of a QZS oscillator, ensuring both high static stiffness and low dynamic stiffness.

A number of KDamper designs [18] and extensions [19] have been applied as seismic absorbers in the bases of structures. Their overall static stiffness is allowed to vary, ranging from low values that are similar to that of seismic isolation systems, up to values corresponding to a significantly higher stiffness. In the former case, the KDamper presents a behavior similar to that of a base isolated system, combined however with a drastically increased damping. In the latter case, the KDamper has shown the ability to drastically reduce the structure base displacements relative to the ground in the range of few centimeters, while maintaining the absolute structure accelerations within reasonable limits. This aforementioned result implies that the KDamper can be used as an alternative method to conventional base isolation systems, enabling its implementation (under certain conditions) even for retrofitting existing structures.

Quite recently, the extended KDamper has been used in parallel to an inerter (Figure 1.d). [20] for vertical seismic protection. Under a proper optimization procedure, this combination has shown to result to configurations offering a stiff vertical static stiffness (and thus an acceptable vertical static displacement of the structure) with an acceptable level of reduction of the vertical accelerations induced to the structure. This concept is the underlying notion and configuration of the Stiff Dynamic Absorbers.

The first key difference between the proposed design and the one proposed in [20], is that the static loading is now borne only by the external k_R (Figure 1.d) spring element of the SDA, and not by the overall static stiffness of the assembly. The rest of the spring elements k_N , k_P (Figure 1.d) need to participate only in the dynamic response of the excited system, similarly to the concept of the QZSs.

The second key difference is the fact that a new more general objective function is introduced for the optimization procedure. It is thus shown that a unique optimal SDA design can be used, not only for the vertical seismic protection of the structures, but also for a range of important vertical dynamic absorption applications, including low frequency machine mounts and impact noise insulation.

2. STIFF BASE ABSORBER WITH EXTENDED KDAMPER AND INERTER

2.1. Conventional SDoF damping system

The fundamental aim of seismic isolation is to decrease the natural frequency of the system, f , below the dominant energy-containing frequencies of ground motion excitation, thus allowing reduced peak accelerations of the structure. A major constraint with this approach lies in the weakened static loading capacity of the structure as a result decreasing its overall stiffness, k , leading to large static displacements. Denoting with the X_{VSD} vertical static deflection of the conventional spring-mass system in Figure 2:

Figure 2. Conventional vibration damper

$$X_{VSD} = \frac{mg}{k} = \frac{g}{(2\pi f)^2} \quad (1)$$

The equation of motion of this system is:

$$m\ddot{u}_S + c\dot{u}_S + ku_S = -m_S\ddot{X}_G, \quad (2)$$

where $u_S = X_S - X_G$. Assuming a harmonic base excitation in the form of $\ddot{X}_G(t) = A_G e^{j\omega t}$, the steady-state response will be:

$$u_S(t) = \tilde{U}_S e^{j\omega t} \quad (3)$$

where \tilde{U}_S denotes the complex amplitude. The equation of motion of the SDoF system can be written in the following form:

$$-\omega^2 m \tilde{U}_S + j\omega c \tilde{U}_S + k \tilde{U}_S = -m A_G \quad (4)$$

The Transfer Functions of the system are calculated as:

$$\tilde{H}_{US} = \tilde{U}_S / A_G = -\tilde{H}^{-1} m \quad (5)$$

where:

$$\tilde{H} = [-\omega^2 m + j\omega c + k] \quad (6)$$

$$\tilde{H}_{AS} = A_S / A_G = -\omega^2 \tilde{X}_S / A_G = 1 - \omega^2 \tilde{H}_{US} \quad (7)$$

The natural frequency and the damping ratio of the SDoF isolated system are:

$$f = \frac{1}{2\pi} \sqrt{\frac{k}{m}} \quad (8)$$

$$\zeta = c / (2\sqrt{mk}) \quad (9)$$

2.2. Proposed extension of KDamper equipped with inerter

This paper proposes a seismic protection system based on the combination of a Tuned Mass Damper (TMD) and a Quasi-Zero Stiffness (QZS) design introducing negative stiffness elements, accompanied by an inerter (Figure 1.d). The first component of the proposed system (combination of a TMD with a QZS design) is essentially based on the KDamper concept [17], whereby the introduction of the negative stiffness element reduces transmissibility of the system by lowering the natural frequency while increasing the effective damping of a conventional TMD. The introduction of an inerter between the structure and the ground results to an increased effective mass of the system without the need for additional weight, further improving its dynamic behavior. The proposed design is based on the one proposed by [20], with several differentiations. The positive stiffness element k_P connects the structure to the additional mass m_D , which in turn is connected to the ground through the NS element k_N , as per the initial KDamper design [17]. The k_R spring element connects the structure directly to the ground, accompanied by the inerter (b_R).

The overall stiffness of the system can be calculated as:

$$k_{tot} = k_R + \frac{k_P k_N}{k_P + k_N} \quad (10)$$

A key difference between the proposed design and the one proposed by [20], 2020 is that the static loading is now borne by the k_R element only (which is equal to the stiffness of the initial structure, k_S) and not the overall k_{tot} , while the k_N , k_P elements participate only in the dynamic response of the excited system. As the static capacity of the system is fully maintained, the system can be designed for larger absolute magnitudes of the NS element k_N , while the static deflection X_{VSD} remains at acceptable levels. This enables better seismic isolation and reduced transmissibility of the system, while maintaining its static rigidity.

Denoting the relative displacement between the structure and the ground as $u_s = X_S - X_G$, the equations of motion for the two masses are:

$$(m_S + b_R)\ddot{u}_S + c_P(\dot{u}_S - \dot{u}_D) + k_R u_S + k_P(u_S - u_D) = -m_S \ddot{X}_G \quad (11)$$

$$m_D \ddot{u}_D + c_P(\dot{u}_D - \dot{u}_S) + c_N \dot{u}_D + k_N u_D + k_P(u_D - u_S) = -m_D \ddot{X}_G \quad (12)$$

The steady state responses of the system are:

$$u_S(t) = \tilde{U}_S e^{j\omega t} \quad (13)$$

$$u_D(t) = \tilde{U}_D e^{j\omega t} \quad (14)$$

where \tilde{U}_S, \tilde{U}_D , denote the response complex amplitudes. The abovementioned equations of motion of the system hence become:

$$-\omega^2(m_S + b_R)\tilde{U}_S + j\omega c_P(\tilde{U}_S - \tilde{U}_D) + k_R \tilde{U}_S + k_P(\tilde{U}_S - \tilde{U}_D) = -m_S A_G \quad (15)$$

$$-\omega^2 m_D \tilde{U}_D + j\omega c_P(\tilde{U}_D - \tilde{U}_S) + j\omega c_N \tilde{U}_D + k_N \tilde{U}_D + k_P(\tilde{U}_D - \tilde{U}_S) = -m_D A_G \quad (16)$$

The resulting transfer functions (TFs) can be derived:

$$\begin{bmatrix} \tilde{H}_{US} \\ \tilde{H}_{UD} \end{bmatrix} = \begin{bmatrix} \tilde{U}_S/A_G \\ \tilde{U}_D/A_G \end{bmatrix} = H^{-1} \begin{bmatrix} m_S \\ m_D \end{bmatrix} \quad (17)$$

where:

$\tilde{H} =$

$$\begin{bmatrix} -\omega^2(m_S + b_R) + j\omega c_P + (k_R + k_P) & -(j\omega c_P + k_P) \\ -(j\omega c_P + k_P) & -\omega^2 m_D + j\omega(c_P + c_N) + (k_N + k_P) \end{bmatrix} \quad (18)$$

$$\tilde{H}_{AS} = A_S/A_G = 1 - \omega^2 \tilde{H}_{US} \quad (19)$$

$$\tilde{H}_{AD} = A_D/A_G = 1 - \omega^2 \tilde{H}_{UD} \quad (20)$$

The following quantities represent the area under the transfer functions of the system (scaled by the factor $d\omega$) and are indicators of the transmissibility of the system within the frequency range of interest (ω_1 to ω_2).

$$Q_{US} = \frac{1}{d\omega} \int_{\omega_1}^{\omega_2} |H(\omega)_{US}|^2 \quad (21)$$

$$Q_{UD} = \frac{1}{d\omega} \int_{\omega_1}^{\omega_2} |H(\omega)_{UD}|^2 \quad (22)$$

$$Q_{AS} = \frac{1}{d\omega} \int_{\omega_1}^{\omega_2} |H(\omega)_{AS}|^2 \quad (23)$$

Denoting by S_A the PSD of the ground motion acceleration, the response power spectral densities can be calculated:

$$S_{US}=|H_{US}|^2 S_A \quad (24)$$

$$S_{UD}=|H_{UD}|^2 S_A \quad (25)$$

$$S_{AS}=|H_{AS}|^2 S_A \quad (26)$$

The root mean square (RMS) values of the responses are finally defined as the root under the area of the PSD curve, which can be used as indicators of the actual energy content of the response:

$$R_{US}=\sqrt{\int_{-\infty}^{+\infty} S_{US}(\omega)d\omega} \quad (27)$$

$$R_{UD}=\sqrt{\int_{-\infty}^{+\infty} S_{UD}(\omega)d\omega} \quad (28)$$

$$R_{AS}=\sqrt{\int_{-\infty}^{+\infty} S_{AS}(\omega)d\omega} \quad (29)$$

Next, the following quantities concerning the system configuration are introduced:

$$m_D=\mu_D m_S \quad (30)$$

$$b_R=\mu_R m_S \quad (31)$$

$$\zeta_N= c_N/(2\sqrt{m_S k_R}) \quad (32)$$

$$\zeta_P= c_P/(2\sqrt{m_S k_R}) \quad (33)$$

3. OPTIMISATION METHOD FOR THE CONFIGURATION OF THE VERTICAL EXTENDED KDAMPER & INERTER SYSTEM

3.1. Objective function

The quantity Q_{AS} as defined in equation (23) is selected as the primary objective function for the reference optimization of the structure under the proposed approach. Q_{AS} represents the area under the acceleration transfer function of the system and is a measure of the transmissibility of the system. Hence, this quantity can be a good indicator of the portion of energy that is transferred to the structure as absolute acceleration, and consequently for the magnitude of the expected force reactions borne by the structure during the earthquake. It is noted that this approach does not require the use of a specific excitation power spectrum or time history excitation, leading to an optimized design that depends solely on the characteristics of the structure and can be used across a range of low-frequency excitations.

As a secondary approach, and for the purposes of comparison and verification of the proposed method, the quantity R_{AS} as defined in equation (29) is used as an alternative objective function. R_{AS} is an indicator of the actual energy content of the response to a specific excitation PSD. Section 4.2 explores the extent to which the response results derived from solving the problem with either of the two objective functions are equivalent.

3.2. Fixed parameters

The following are considered as fixed parameters of the system with regards of the optimization problem:

- X_{VSD} : The static deflection of the structure depends on the initial stiffness of the structure and its mass, or, in other words, its natural frequency, f_0 :

$$X_{VSD} = \frac{m_S g}{k_S} \quad (34)$$

As mentioned in section 2.2, a highlight in the proposed system is the fact that the static vertical deflections are determined by the initial vertical stiffness elements of the structure, hence:

$$k_R = k_S \quad (35)$$

This way, the static vertical deflections of the system are maintained at the desired level, while the negative stiffness element participates only in the dynamic response of the system. The static settlement of the rigid mass X_{VSD} (or, alternatively the initial stiffness of the structure (k_S) or its initial natural frequency (f_0)) is therefore the first fixed design variable of the system. X_{VSD} is taken equal to 2cm in the reference problem. The impact of X_{VSD} is also explored in section 4.2 where results of the optimization are shown for the range 1-3cm.

- m_S, m_D : The reference structure mass m_S is taken 1000kg. The small oscillating mass m_D is determined through (30) where μ_D is taken equal to 5%.
- $\varepsilon_N, \varepsilon_P$ and ε_R : Variations from the design values of the various stiffness can occur due to many factors such as temperature variations, manufacturing tolerances, or nonlinear behavior. The values of $\varepsilon_N, \varepsilon_P$ and ε_R are taken equal to 10%, 5% and 5% respectively.

3.3. Optimized parameters

The four parameters that are optimized under the proposed method are:

- k_N : The value of the NS element. The NS element maximum (absolute) value is equal to -100 N/m per kg of structure mass, as presented in [17]; the minimum value is equal to -800 N/m per kg
- c_N and c_P : The damping factors related to the stiffness elements k_P, k_N . In the reference problem, the upper limit of the damping ratios ζ_N, ζ_P is set 1.0%.
- μ_R : The inertance ratio of the main structure inerter, b_R . The upper limit of μ_R is set to 2.0.

3.4. Dependent variables

Positive stiffness element K_p derived from the static stability limit case:

To ensure that potential loss of the static stability is prevented, the possible variations of k_N, k_P, k_R should be taken into consideration in the design and optimization of the system. The stiffness parameters of the system may present significant fluctuations since almost all NS designs result from unstable non-linear configurations [21]. Consequently, an increase of the absolute value of k_N and/or a decrease of the values of k_P and k_R by a factor $\varepsilon_N, \varepsilon_P$ and

ε_R respectively, may result in the system being unstable. In the limit case that the total overall stiffness k_{tot} as calculated by equation (10) is equal to zero, the system is unstable:

$$k_{tot}=0 \Leftrightarrow (1 - \varepsilon_R)k_R + \frac{(1 - \varepsilon_P)k_P(1 + \varepsilon_N)k_N}{(1 - \varepsilon_P)k_P + (1 + \varepsilon_N)k_N} = 0 \quad (36)$$

$$\Rightarrow k_P = - \frac{(1 - \varepsilon_R)(1 + \varepsilon_N)}{(1 - \varepsilon_P) [(1 - \varepsilon_R) + (1 + \varepsilon_N)(k_N/k_R)]} k_N \quad (37)$$

Equation (36) shows the dependance of k_P on k_N , ε_N , ε_P and ε_R . The values of ε_N , ε_P and ε_R are fixed design parameters (paragraph 3.2), and k_N is obtained through the optimization (paragraph 3.3); hence the value of k_P can be derived from the above.

4. OPTIMIZATION RESULTS AND ANALYSIS

4.1. Reference optimization problem and results

The extended KDamper & inerter system is configured to control vibrations of a rigid mass of $m_s=1000$ kg. The optimal parameters are selected according to the optimization procedure described in section 3, using the interior-point optimization method. The results are presented for different values of the fixed parameter X_{VSD} within the allowable range of [1 3] (cm). The full set of parameters is presented in Table 1. The transfer functions H_{AS} , H_{US} , and the response PSDs S_{AS} , S_{US} are presented in Figure 3 and Figure 4 for different values of the design parameter X_{VSD} in order to evaluate the sensitivity of the TFs and response PSDs to the parameter X_{VSD} . The acceleration response spectrum utilized in this paper is the one used in [20] and it is based on a database of 50 artificial accelerograms, generated to match the EC8 spectrum with characteristics: Type 1 with spectral acceleration $\text{avg}(g)=0.9*0.36$.

It can be observed from Figure 3 that the maximum values of acceleration H_{AS} and S_{AS} are not substantially affected by the X_{VSD} . The relative displacement H_{US} is affected in the low-frequency range, while the S_{US} is less affected.

	μ_D	μ_b	k_N (kN/m)	k_R (kN/m)	k_P (kN/m)	ζ_N (%)	c_N (kNs/m)	ζ_P (%)	c_P (kNs/m)
$X_{VSD}=1\text{cm}$	0.05	0.60	-164.31	981.00	236.03	1.00	0.626	1.00	0.626
$X_{VSD}=2\text{cm}$	0.05	0.43	-86.45	490.50	125.76	1.00	0.442	1.00	0.442
$X_{VSD}=3\text{cm}$	0.05	0.36	-59.10	327.00	86.55	1.00	0.362	1.00	0.362

Table 1: Full set of the system parameters in the range of the design parameter $X_{VSD}=[1\ 3]$ (cm).

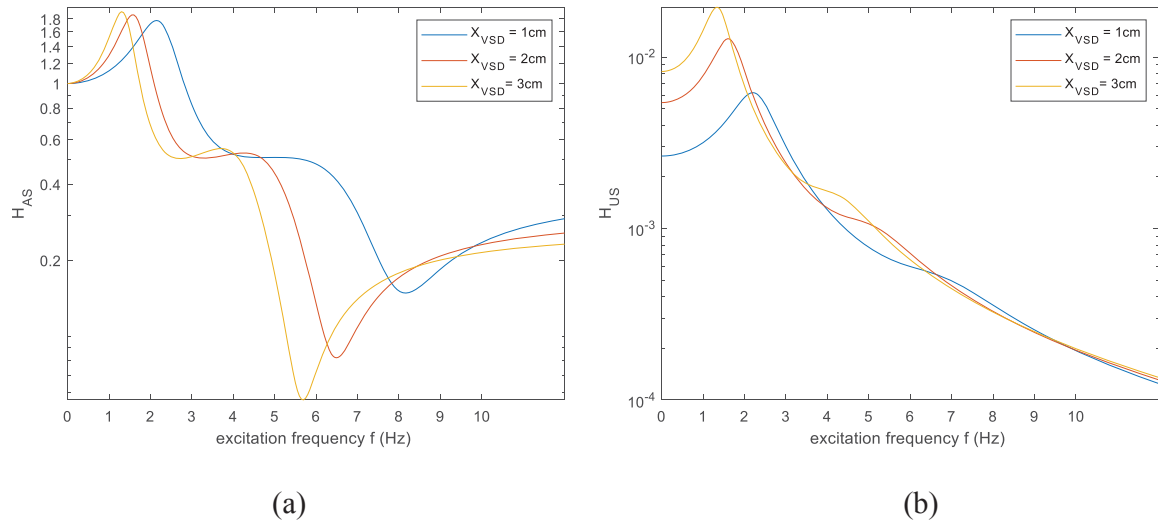

Figure 3. Transfer Functions of the optimized system with X_{VSD} varying in the range [1 3] (cm). (a) Structure absolute acceleration H_{AS} ; (b) structure relative displacement H_{US} .

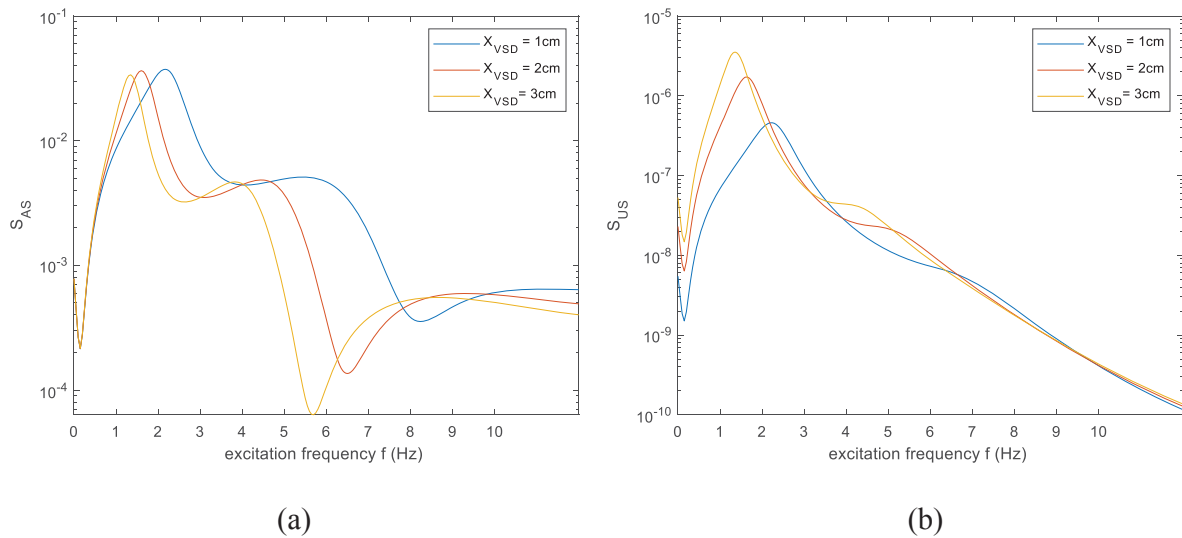

Figure 4. Response PSDs considering the ground motion acceleration excitation PSD, S_A , (a) Structure absolute acceleration S_{AS} ; and (b) relative displacement S_{US} .

The following section explores the impact of the selection of objective function to the optimization problem. This is evaluated in terms of response to excitation PSD and time history response to the sample of 50 artificial accelerograms. In order to better observe the effectiveness of the proposed configuration, in the next sections the responses are compared with a highly damped ($\zeta=15\%$) conventional damper (CD) as described in paragraph 2.1.

4.2. Effect of objective function (Q_{AS} , R_{AS})

As discussed in paragraph 3, the optimization approach considers the area under the acceleration transfer function of the system (scaled by a factor $d\omega$) as the primary objective function for this problem, Q_{AS} as defined in equation (23). One of the motivations of this paper is to explore its equivalency vs. the more conventional approach of using a measure of the actual content of the response (such as R_{AS} defined in equation (29)) as the objective function.

The results are shown for a ground motion acceleration excitation PSD and subsequently verified through time history analyses. An acceleration response indicator r_{AS} is defined as:

$$r_{AS,CD} = \frac{R_{AS,CD}}{\sqrt{\int_{-\infty}^{+\infty} S_{AS}(\omega) d\omega (= PGA)}} \quad (38)$$

$$r_{AS,KD,Opt} = \frac{R_{AS,KD,Opt}}{\sqrt{\int_{-\infty}^{+\infty} S_{AS}(\omega) d\omega (= PGA)}} \quad (39)$$

Figure 5. Variation of the acceleration response indicator r_{AS} over the X_{VSD} , of the conventional damping system and proposed configuration, for the two objective functions examined.

Figure 5 above presents the response indicators with respect to varying X_{VSD} in the cases of: (i) the Ext. KDamper & inerter system optimized via Q_{AS} as the objective function (blue line), (ii) the Ext. KDamper & inerter system optimized via R_{AS} as the objective function (red circles), (iii) the conventional damper (yellow line). It is evident that the two optimization methods coincide.

The PSD response results are subsequently verified with time history analyses from the 50 accelerograms. Below are the cumulative results showing the peak values of the quantities of interest (structure absolute acceleration a_S , structure relative displacement u_S , and oscillating mass relative displacement u_D) for X_{VSD} in the range of [1 3] (cm). Blue color corresponds to the reference optimization of the extended KDamper & inerter system, as described in Table 1. Red color shows the optimization using the same fixed parameters and constraints, but using R_{AS} as the objective function (instead of Q_{AS}). Finally, the orange bar represents the conventional damping system. Figure 6(a) shows the peak a_S averaged over the 50 accelerograms, while Figure 6(b)-(d) show the overall maxima of the peak quantities. It can be verified that the two objective functions yield very similar results across all quantities of interest. Moreover, it is observed that the proposed optimized system can reduce the structure peak acceleration up to more than 50% when compared to a conventional damping system, while maintaining the displacement within a satisfactory range.

Figure 6. Results from the time history responses over 50 artificial accelerograms with the system optimized for the two different objective functions, and for the conventional damper. (a) Peak absolute acceleration averaged over the 50 accelerograms; (b) Overall maximum of the peak absolute acceleration; (c) Overall maximum of the peak relative structure displacement absolute accelerations; (d) Overall maximum of the peak relative oscillating mass displacement.

5. CONCLUSIONS

This paper proposes a stiff dynamic absorber, combining a negative stiffness element, a tuned-mass damper and an inerter. The system is configured under a proper optimization procedure, and the results are subsequently verified with an excitation PSD, generated from a database of artificial accelerograms designed to match the EC8 vertical spectrum as well as with time history results from the individual accelerograms.

Results indicate that the proposed system can drastically reduce structure accelerations (>50% reduction compared to a conventional damping system), while the vertical displacement remains at satisfactory levels. The proposed system thus demonstrates an enhanced dynamic behavior while maintaining suitable vertical stiffness. A key highlight of the proposed system in relation to previous works is the fact that the initial static stiffness is retained, since the negative stiffness elements participate only in the dynamic response.

Moreover, a new optimization approach is utilized through the introduction of a more general objective function which depends solely on the characteristics of the structure and not the excitation parameters. The suitability of this method is tested using response spectra and time history analyses for the abovementioned excitations, and verified through a comparison with previous optimization strategies that depend on a specific spectral excitation. The comparison

results confirm that a unique optimal stiff dynamic absorber design can be used across a wide range of important vertical dynamic absorption applications, as well as structure seismic protection.

Abstract

The seismic assessment of reinforced concrete (RC) structures with masonry infills is an important issue in modern earthquake engineering. This typology is prevalent in the southern-Mediterranean region and represents a large percentage of the Italian building stock. A pertinent aspect in their seismic assessment entails the quantification of structural performance up to global collapse. Collapse capacity can be quantified through a fragility function, which relates the probability of collapse to seismic intensity and is typically generated through computationally expensive non-linear dynamic analyses. However, simplified methodologies exist, offering a trade-off between accuracy and extensive analyses through empirical relationships derived from large analyses databases, and are typically referred to as $R-\mu-T$ relationships. To this end, this paper explores a simplified methodology for collapse assessment of infilled RC frames using such $R-\mu-T$ relationships, incorporating the general response of the structural typology and employing average spectral acceleration AvgSa as a more accurate and appropriate intensity measure (IM). Such an approach can be of great assistance to practitioners, stakeholders and decision-makers in quantifying the collapse capacity of structures, as it removes the need for large computational analysis whilst still maintaining a high level of accuracy. This paper illustrates the robustness of the developed $R-\mu-T$ relationships for infilled RC frames in quantifying median collapse intensities and dispersions and compares the outcome with traditional non-linear dynamic analyses for several archetypical 3D buildings, representative of the aforementioned typology found in Italy.

Keywords: infilled; assessment; collapse quantification; average spectral acceleration; performance-based.

1 INTRODUCTION

Italian and European reinforced concrete (RC) frame buildings with masonry infill panels comprise a significant portion of the Mediterranean building stock (Figure 1). Before the 1970s (i.e. before the introduction of suitable seismic provisions), buildings in Italy in specific, and also across Southern Europe, were generally designed and constructed to resist gravity loads only [1,2]. In Italy, these were designed according to Regio Decreto (RD2229/1939) [3]. This design approach entails the use of the allowable stress method for the detailing of structural sections. Structural elements designed this way were typically characterised with inadequate seismic detailing. For example, the use of smooth rebars, low compressive strengths for concrete, and no consideration for a ductile failure mechanism (i.e. capacity design, strong column-weak beam formulation). Furthermore, unreinforced clay brick masonry infills were typically used as partitioning and façade elements based on their thermal and acoustic insulation, fire retarding and moisture control behaviour. These elements, however, were not considered in the structural design and therefore their effects on the structural response were neglected. Experimental and analytical studies, however, have outlined the effects of masonry infills on the global lateral response of the structural system [4–11]. These effects are characterised by a significant addition in lateral stiffness and a sudden drop in lateral strength with the rupture of infills on one or several storeys.

Figure 1: Typical Italian residential housing using infilled frame structures

Moreover, assessing the structural performance of structures requires accurate quantification of the exceedance of any structural demand-based performance level. The latter is typically quantified using fragility curves, which link the probability of exceeding predefined thresholds of demand for a given intensity level of ground-shaking. These are usually the end-result of extensive numerical analysis (i.e. numerical modelling, ground-motion selection, nonlinear dynamic analyses). To reduce the computational effort and time required by such analyses, simplified tools and methodologies for the assessment of RC frame structures have emerged, with the introduction of the SPO2IDA [12], SPO2FRAG [13] and other simplified methodologies [14–16]. These simplified approaches utilise $R-\mu-T$ for a direct estimation of the seismic demand and capacity. The aim of these tools is to supply users with aid in the quantification and mitigation of seismic risk compatible with different guidelines [17,18]. For example, the inclusion of SPO2IDA within the FEMA P-58 guidelines [19] can be considered a testimony to the added value of simplified tools in performance-based earthquake engineering (PBE) [20]. To this end, the aim of the study is to present and further develop a simplified methodology previously introduced as ExtendedSPO2IDA [21], which had been tailored specifically for infilled RC frame structures. Previously, the $R-\mu-T$ relationships used in this tool were fitted considering the 5% damped spectral acceleration at the fundamental period,

$Sa(T_1)$. Therefore, subsequent sections will revisit the issue of a suitable IM choice for the characterisation of seismic demand in infilled RC frames. Subsequently, a refitting of the aforementioned tool is then conducted with reference to the selected IM. Two case study buildings are then presented to verify and evaluate the refitted tool in terms of median collapse intensities in comparison with results obtained from a non-linear dynamic analysis with a rigorous ground-motion selection and fully detailed numerical models.

2 SUITABLE CHOICE OF INTENSITY MEASURE

Average spectral acceleration ($AvgSa$) has been observed in several studies [22–24] to be a more advantageous intensity measure (IM) when compared to spectral acceleration at the fundamental period ($Sa(T_1)$) and particularly for the quantification of the collapse intensity for RC frames [25–27]. Efficiency and sufficiency are often the metrics used when comparing IMs. The former represents the capability of a selected IM to accurately predict a designated EDP, while the latter examines the level of independence of the structural response value from seismological properties (e.g. magnitude, rupture distance).

The definition of $AvgSa$ thus incorporates spectral acceleration intensities at periods around T_1 , which can consider the elongation effects of a structural system up to collapse and also the higher mode contributions at periods shorter than T_1 . This definition has rendered it a better predictor in terms of reduced dispersion (i.e. increased efficiency) when large deformations and non-linearities start occurring in the structural model. This comparison is highlighted in Figure 2, in terms of incremental dynamic analysis (IDA) results on two single-degree-of-freedom (SDOF) systems studied previously in Nafeh et al. [21]. IDA is conducted using the FEMA P695 [28] far-field record set and is presented in terms of the median, 16th and 84th percentiles with $Sa(T_1)$ and $AvgSa$ as IMs. From these IDA results, one can notice a noticeable change in the dispersion of the results reflected in the quantiles at each intensity measure level. IDA curves for two SDOF systems are presented herein in Figure 2. It can be observed that for both cases, when employing $AvgSa$, the dispersion at collapse decreased by 46.9% ($\beta_{IM=Sa(T_1)} = 0.35$, $\beta_{IM=AvgSa} = 0.18$) and 41.5% ($\beta_{IM=Sa(T_1)} = 0.34$, $\beta_{IM=AvgSa} = 0.20$) as opposed to using $Sa(T_1)$ for the two respective cases.

Eads et al. [25] noted relatively stable collapse risk estimates across various ground motions sets for steel MRFs and shear wall structures when employing $AvgSa$. O'Reilly [29] infers similar conclusions on the beneficial use of $AvgSa$ and the limitations of $Sa(T_1)$ in the collapse assessment of non-ductile infilled RC frames, of interest to this study. Following the above remarks, $AvgSa$ has been seen to be an advantageous IM for assessing the collapse capacity of infilled RC frames and will be explored herein for the development of simplified collapse assessment tools.

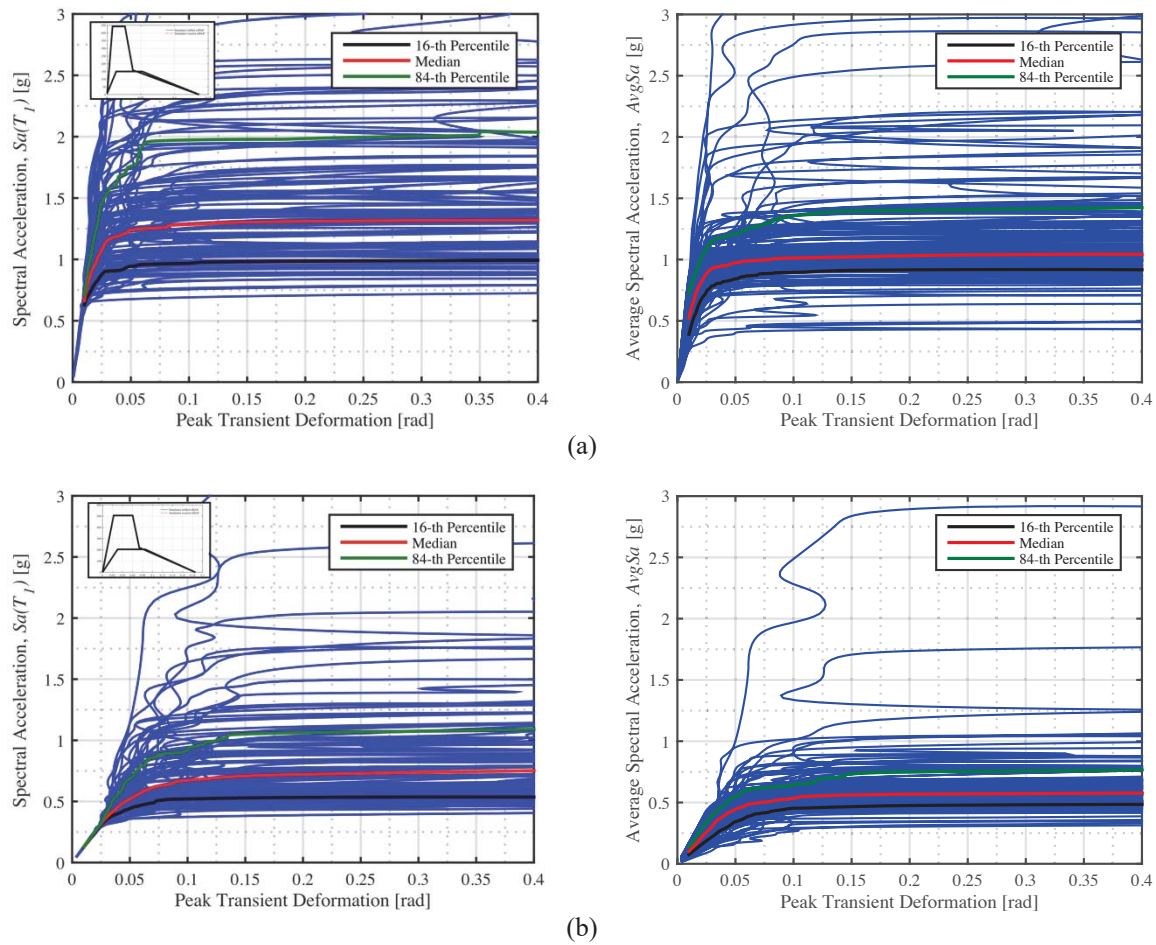

Figure 2. Comparison of IDA quantiles (16th, 50th and 84th) for two SDOF systems (a-b) considering $AvgSa$ (left) and $Sa(T_1)$ (right) as IMs using FEMA P695 Far-Field record set

3 DEVELOPMENT OF A SIMPLIFIED TOOL FOR COLLAPSE ASSESSMENT

The fundamental concept behind the development [12] and extension [21] of the SPO2IDA tool is to relate the force-deformation capacity of a given frame structure (obtained through non-linear static, or static pushover (SPO), analysis) to its dynamic counterpart, typically illustrated using IDA [30]. The extension of SPO2IDA was developed to incorporate the behaviour of infilled RC frames whose behaviour was not properly represented in the original version. This behaviour is characterised by a significant addition in lateral stiffness followed by a sudden loss of lateral strength capacity due to the localisation of damage on one or several storeys (i.e. formation of a soft-storey mechanism due to the sudden rupture of infill panels) shown in Figure 3.

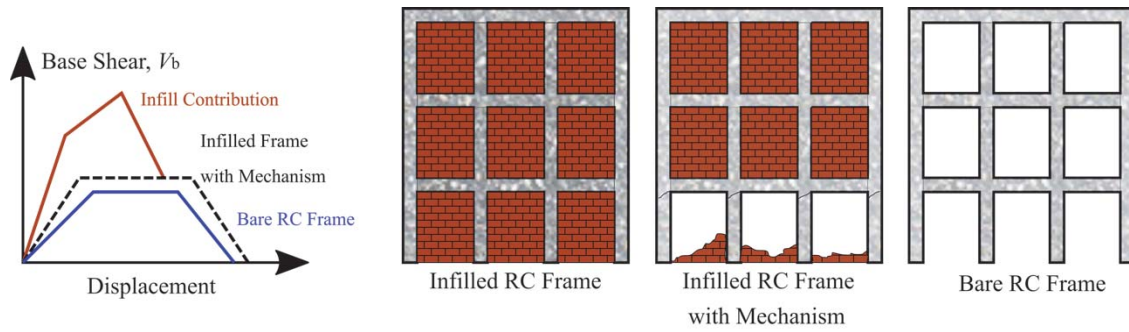

Figure 3: Illustration of the contribution of infill panels on the stiffness and strength of the global system before period elongation due to the formation of a non-ductile mechanism.

For the development of the tool, a large dataset of SDOF systems with varying backbone parameters is required. IDA then subjects the set of SDOF systems to increasing levels of intensity until numerical collapse is achieved. This forms a library of seismic demand-capacity models for various SDOF with distinct features. The library can then be utilised for a direct estimation of the seismic demand and capacity through interpolation and fitted closed-form expressions. This is done using results from SPO and eigenvalue (modal) analyses to relate a multi-degree-of-freedom (MDOF) system to an SDOF oscillator (presented in Figure 4). Then, the median collapse intensity and dispersion associated with the collapsing intensity are estimated using the results of the extensive numerical analysis (i.e. IDAs) and a set of R - μ - T relationships relating the SPO backbone characteristics with the medians and dispersions obtained.

The two ground motion record sets from INNOSIS [31] that are representative of European seismicity (i.e. medium and high seismicity) were utilised for the IDA related to this study. Subsequent sections will highlight the methodology proposed in this study, which incorporates the use of SDOF systems representative of the response of infilled RC typology, quantifying the dynamic response through IDA and fitting closed-form expression at each response branch up to global collapse.

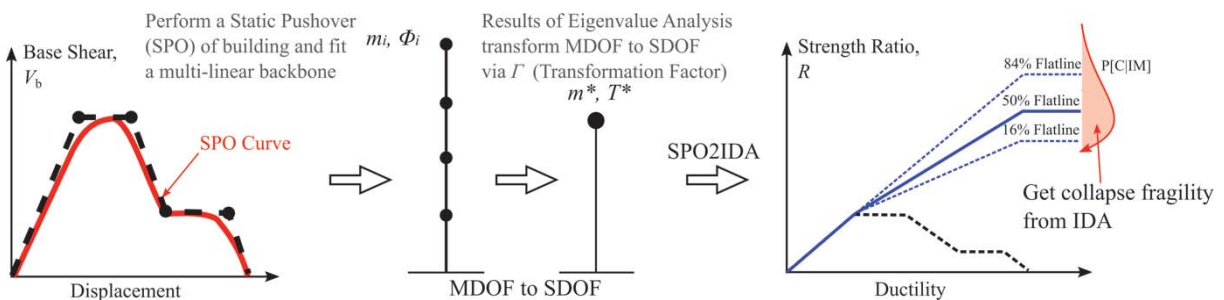

Figure 4: Direct estimation of seismic demand-capacity of a multi-degree-of-freedom system using single-degree-of-freedom systems through extendedSPO2IDA via results of pushover and eigenvalue analysis.

3.1. Methodology

This section introduces the methodology employed for analysing a set of equivalent SDOF oscillators to analyse the dynamic capacity properties of infilled RC frames. The methodology is as follows:

- 1) Perform IDAs on SDOFs whose capacity curve parameters are known *a priori* (from a previously generated set accounting for the variability in the backbone parameters) to relate the IM (i.e. $AvgSa$) to the engineering demand parameter (EDP) of the system.

- 2) Find the static response parameters corresponding to each SDOF analysis ($R_{st,i}$, $\mu_{st,i}$) defined in Equations 1.1 and 1.2, where i corresponds to the response branch (i.e. elastic, post-capping, softening, residual strength (plateau) and strength degradation), $V_{b,st,i}$ and $V_{b,y}$ are respectively the base shear values at the response branch and the nominal yield force, $\Delta_{r,st,i}$ and $\Delta_{r,y}$ are respectively the roof displacement values at the response branch and displacement corresponding to the nominal yield force.

$$R_{st,i} = V_{b,st,i}/V_{b,y} \quad \text{Equation 1.1}$$

$$\mu_{st,i} = \Delta_{r,st,i}/\Delta_{r,y} \quad \text{Equation 1.2}$$

- 3) Process the IDA results and convert the median and fractile quantities (i.e. 16th and 84th percentiles) IM-EDP IDA curves to the corresponding dynamic response parameters ($R_{dyn,i}$, $\mu_{dyn,i}$) defined in Equations 2.1 and 2.2. Sa_y is the yield spectral acceleration, Γ is the transformation factor obtained from eigenvalue analysis. T^* , m^* , Δ_y^* and V_y^* are respectively the period, effective mass, deformation capacity at yield and the nominal yielding force of the SDOF system. Sa_{ratio} is the ratio of the spectral shape introduced by Eads et al. [26]. The steps presented herein were only performed during the processing of the IDAs and will not be later required by the user as input.

$$R_{dyn,i} = \frac{Sa(T^*)_i}{Sa_y} \quad \text{Equation 2.1}$$

$$\mu_{dyn,i} = \frac{\Delta_{dyn,i}}{\Delta_{dyn,y}} \quad \text{Equation 2.2}$$

$$Sa_{ratio} = \frac{Sa(T^*)}{AvgSa(T^*[a, b])} \quad \text{Equation 2.3}$$

From Equations 2.1 and 2.3:

$$Sa_{ratio} AvgSa(T^*[a, b]) = Sa(T^*) = R_{dyn,i} Sa_y \quad \text{Equation 2.4}$$

$$\frac{AvgSa(T^*[a, b])}{Sa_y} = \frac{R_{dyn,i}}{Sa_{ratio}} = \rho \quad \text{Equation 2.5}$$

$$\widehat{AvgSa} = \rho Sa_y \Gamma \quad \text{Equation 2.6}$$

where the transformation factor is introduced in Equation 2.6 to estimate the AvgSa for the MDOF system. It is also noted that:

$$Sa_y = \frac{4\pi^2 * \Delta_y^*}{T^{*2}} = \frac{V_y}{m^*} \quad \text{Equation 2.7}$$

$$T^* = 2\pi \sqrt{\frac{m^* * \Delta_y^*}{V_y^*}} \quad \text{Equation 2.8}$$

- 4) Interpolate the dynamic response parameters ($R_{dyn,i}$, $\mu_{dyn,i}$) corresponding to the former (as highlighted in Figure 5) for each static response branch of every SDOF system. The step herein populates a database of static vs dynamic response parameters which will be further utilised to fit the expressions in Table 1 via two-step regression analysis.

- a) 1st step: obtain a functional form expressing the median and fractile quantities (i.e. $R_{dyn,i}$, $\mu_{dyn,i}$) of the IDA in function of the static parameters ($R_{st,i}$, $\mu_{st,i}$) obtained from static pushover analyses.
- b) 2nd step: relate the functional form coefficients in step (a) to the fundamental period and other relevant capacity parameters.

3.2. Fitting of Functions

For the two-step regression analysis conducted herein, the Least Absolute Residuals (LAR) and the Bisquare weights methods were employed to increase the robustness of the fitting routine. The LAR method finds a curve that minimises the absolute difference of the residuals, rather than the squared differences. Therefore, extreme values have a lesser influence on the fit. The Bisquare weights method minimises a weighted sum of squares, where the weight given to each data point depends on how far the point is from the fitted line. Points near the line get full weight and points farther from the line get reduced weight. The LAR method has been used herein.

The resulting R - μ - T relationships from two-step regression analysis are presented in Table 1, whereas Figure 5 illustrates the strength and ductility factors figuring in the Equations for each response branch. A simple linear functional form is attributed to the relationship between the dynamic strength factors and the ductilities at each response branch threshold. A more complex functional form is used for the introduction of the fundamental period, reduction in strength due to the rupture of infills, and the corresponding residual strength capacity of the structure (i.e. as seen in the 2nd step regression). Previous work in Nafeh et al. [21] opted for the use of more complex functional forms to characterise the relationship between the static and dynamic response parameters presented in the previous section. Moreover, the reduction in strength and residual capacity of the global system was not incorporated in past work.

Figure 5: Illustration of the normalized static pushover curve and the response branch parameters noted in the Equations in Table 1

	Where $\mu_{SD} \in (\mu_{RP}; \mu_{ult}]$	

3.3. Verification of extendedSPO2IDA using SDOF validation set

An additional set of 40 equivalent SDOFs was employed as a test set for the functions previously fitted. IDA was again carried out using the INNOSIS record set. Subsequently, the median collapse intensity of the SDOF systems and their corresponding dispersions were extracted. Consequently, the verification of the developed tool refers to the comparison of the extracted values, obtained via traditional IDA and the values obtained from applying extendedSPO2IDA. The median intensity and associated dispersion for the collapsing cases are illustrated in Figure 6. The observations show a relatively good agreement when comparing the two analysis methods (i.e. extensive IDA and simplified SPO2IDA). Additionally, Figure 6 reports the comparison of the median collapse intensities and dispersions obtained using the original version of the extendedSPO2IDA tool (i.e. calibrated on the spectral acceleration at the fundamental period $Sa(T_1)$). The comparison shows the capability of the original version in predicting the response of the system. However, the main difference and benefit of the $AvgSa$ -based tool are noted in the dispersion at collapse, where higher values for $IM = Sa(T_1)$ can be

clearly seen when compared to *AvgSa*, indicating a reduction in uncertainty and increased efficiency and accuracy of the tool.

Further validation of the $R-\mu-T$ relationships is conducted on two case study structures by considering two distinct locations, where records differing from the INNOSEIS record set will be selected based on the seismicity of the said locations.

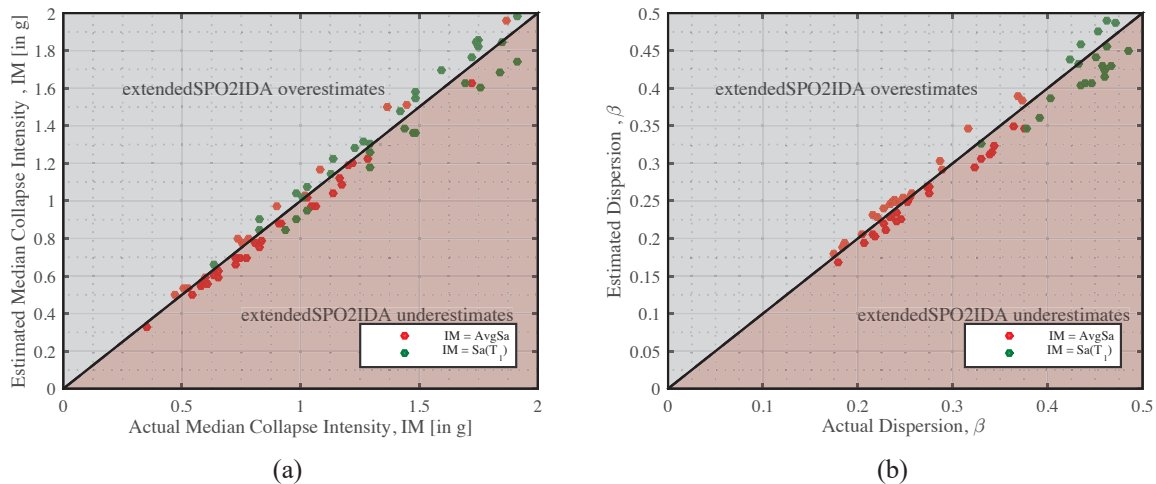

Figure 6. Comparison of the estimated (using extendedSPO2IDA) vs actual (using IDA) (a) median collapse intensity given in terms of *AvgSa* and *Sa(T₁)* [in g] and (b) dispersion at collapsing runs considering an SDOF validation set.

4 CHARACTERISATION AND NUMERICAL MODELLING OF CASE STUDY BUILDINGS

The development of archetype numerical models characterising a particular building class forms the basis of structural performance quantification. To this end, population and housing statistics provide important information related to the prevalence of a structural typology as part of the regional building stock. Additional information concerning the architectural features of the built environment can be extracted from databases like ISTAT [32] to further characterise the building class.

Moreover, geographical specifications and conditions (i.e. building material, design methodology specific for a region, etc.) need to be accounted for. Generally, before the introduction of seismic provisions (i.e. before the 1970s), southern European RC residential buildings with masonry infills were designed to resist gravity loads only (termed GLD herein) with no consideration to ductile detailing. For the specific case of Italian structures, said buildings were designed to Regio Decreto 39 (RD2229/39) [3] with complementary references [33,34]. Design features include: frames span in one direction only, the use of smooth plain rebars and concrete with respectively low yield and compressive strengths; poor transverse detailing and shear reinforcement; inadequate detailing of the beam-column joints.

The two archetypes described herein form a subset of a larger database of RC buildings with masonry infill panels. They comprise two and six-storey structures with dimensioning of the span widths and space designations presented in Figure 7. The latter elements are representative of the Italian architectural definition at the construction period of interest. Applied permanent loads were defined as 500 and 450 kg/m² for typical floors and roofs respectively, whereas accidental loads of 200 and 150 kg/m² were applied. Allowable stresses equal to 5 N/mm² for concrete and 140 N/mm² for reinforcing steel were considered, as per RD2229/39. These values correspond to 29.2% and 33.3% of the maximum stresses for concrete and steel respectively.

The corresponding sections and detailing found when conducting a simulated design for the two GLD archetype buildings are presented in Table 2.

The numerical modelling of the case study buildings was performed in OpenSees [35] using a 3D lumped-plasticity model. “*forceBeamColumn*” elements with a finite plastic hinge length were used to describe the structural response of beam-column elements. The latter elements are then coupled with *zero-length* elements at the plastic hinge locations utilising a “*Pinching4*” hysteretic material model based on the force-deformation relationships for non-conforming structures [4,36]. Interior and exterior beam-column joints with poor detailing and smooth bars with end-hooks were modelled using *zero-length* elements using a “*Hysteretic*” model elements to capture both flexural and axial behaviour accordingly with the recommendations of O'Reilly and Sullivan and De Risi et al. [4,37]. Rigid offsets were accounted for in the element transformation. Furthermore, the in-plane behaviour of masonry infill panels was modelled using the equivalent strut approach following the recommendations of Verderame et al. [36]. The difference in infill strength (weak, medium and strong) parameters used herein depends on the characterisation performed in Hak et al. [38]. Staircase elements were modelled similarly to the beam-column elements, accounting for the inclination through assigning adequate geometric transformations in both directions. Additionally, shear hinges were also implemented to account for the shear behaviour caused due to the short column effect typically observed in stairs elements. The architectural plan layouts and the corresponding numerical model of the case study buildings are presented in Figure 7.

Table 2. Structural detailing and material properties for the gravity-load designed archetypes #1 and #2.

ID	Number of Frames	Column Sections (mm)	Beam Sections (mm)	Longitudinal Reinforcement Ratios (%)	Transverse Reinforcement (diameter/spacing)	Material Characteristics
GLD#1	Exterior	2	500x300mm	C: 0.89% - 0.98% ($\phi 14 - \phi 16$) B: 0.21% - 0.31% ($\phi 14$)	C: $\phi 6 @ 150\text{mm}$ B: $\phi 6 @ 200\text{mm}$	Smooth Rebars (Aq42, $\sigma=140$ MPa); Concrete ($\sigma=5$ MPa);
	Dir-X	2				
	Interior	2				
	Exterior	2				
GLD#2	Interior	0	500x300mm	C: 0.89% - 0.98% ($\phi 14 - \phi 16$) B: 0.40% - 0.67% ($\phi 16$)	C: $\phi 6 @ 150\text{mm}$ B: $\phi 6 @ 200\text{mm}$

5 APPLICATION OF EXTENDED SPO2IDA

Considering the application of extendedSPO2IDA, Monteleone di Spoleto and San Severo located in Central Italy were selected as case study locations for the archetypes GLD#1 and GLD#2, respectively, and correspond to high and medium seismicity. Subsequently, hazard analysis for record selection (as shown in Figure 8) was conducted using the OpenQuake engine [39] considering *AvgSa* as the IM and the site characteristics presented in Mori et al. [40]. The period range $[T_{lower}, T_{upper}]$ was defined as outlined for non-ductile infilled RC frames in O'Reilly [29] with a spacing of 0.1s and are shown in Table 3. Records were then selected from the NGA database using the conditional mean spectrum method [41] with the modifications suggested by Kohrangi et al. [23] for *AvgSa*. The correlation model by Baker and Jayaram [42] was used in all cases and the geometric mean of the two components was used in the selection. Six intensity measure levels (IMLs) were investigated for the characterization of the structural response covering initial damage of the masonry infill panels up to global structural collapse.

Figure 8: Hazard curves of Monteleone di Spoleto and San Severa highlighting the annual probability of exceedance of increasing intensity measure levels corresponding to *AvgSa*

Table 3: Modal properties of the case study buildings

ID	Direction	Period, T	Modal Mass, M	$AvgSa$	
				T_{lower}	T_{upper}
1	X ₁	0.19s	81.6%	0.09s	0.60s
	Y ₁	0.21s	84.3%		
	X ₂	0.07s	11.5%		
	Y ₂	0.08s	10.6%		
2	X ₁	0.48s	82.0%	0.30s	1.50s
	Y ₁	0.52s	83.4%		
	X ₂	0.16s	11.0%		
	Y ₂	0.35s	10.4%		

First, a static pushover (SPO) analysis was conducted, where an inverse triangular load was applied laterally to the two principal directions of the case study structures. The results are presented in Figure 9(a), which when combined with the modal analysis output (i.e. the modal masses at each floor and the modal shape corresponding to the first-mode), can be used as input

for the extendedSPO2IDA tool by considering the SPO analysis results in both directions and then linearizing the curves as suggested in Nafeh et al. [21] for the earlier versions of the tool. The median collapse intensity and dispersions are then directly extracted from the tool.

Second, a multiple stripe analysis (MSA) was conducted in OpenSees at increasing levels of intensity. The ground-motion pairs were applied simultaneously in both principal directions of the three-dimensional case study buildings. The results of the analysis in terms of $AvgSa$ and maximum peak storey drift θ_{max} are illustrated in Figure 9(b). The median collapse intensity and dispersion due to the record-to-record variability were obtained using the maximum likelihood method. The collapse fragility curves obtained from MSA and extendedSPO2IDA are illustrated and compared in Figure 10.

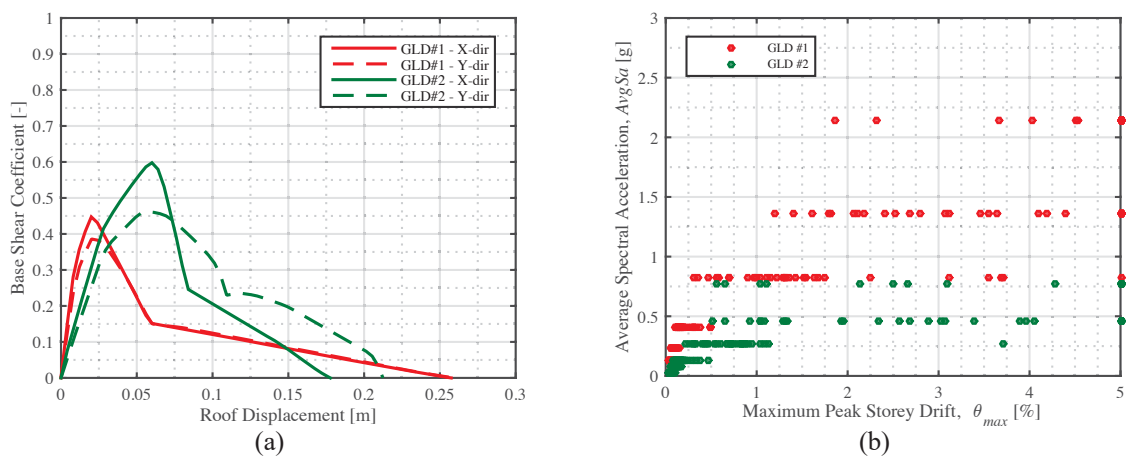

Figure 9: (a) Static pushover analysis curves for GLD#1 and #2 in both principal directions (b) Multiple stripe analysis results of GLD#1 and #2

Subsequently, the collapse fragility functions were obtained considering a lognormal distribution with median collapse intensities and dispersions obtained from the MSA analysis and the simplified relationships developed herein. The comparison is illustrated in Figure 9, where the collapse fragilities for both case study buildings were plotted. Comparing the fragility functions, an excellent match is observed between the two sets in both locations and in the two principal directions of the numerical models. This is true both in terms of the median intensity required to exceed each of these performance limit states and also the level of dispersion. The median collapse intensities reported from the MSA and the associate dispersions pair were respectively 1.58g and 0.36 for GLD#1 and 0.61g and 0.39 for GLD#2. Considering extendedSPO2IDA, the values reported for GLD#1 in the X-direction are 1.53g and 0.29, whereas for the Y-direction, a median collapse intensity of 1.64g and an associated dispersion of 0.31 were estimated. Similarly for GLD#2, collapse intensities of 0.63g and 0.53g with dispersion values of 0.20 and 0.23 were predicted for the X and Y directions, respectively.

This comparison illustrates the accuracy of the proposed tool to be generally employed for such typologies of different building height and period range across different seismicity types. Moreover, other aspects of the tool not discussed herein but worth mentioning are: (1) the inclusion of the period elongation effect by considering an SDOF system aggregating the backbones of the infill contribution and the frame with the critical storey mechanism formed [21]; (2) the consideration of the sudden rupture of infills on the dynamic stability of the global system.

Figure 10: Collapse fragility functions of GLD#1 and #2 considering the median collapse intensities and dispersion obtained from MSA and extendedSPO2IDA.

6 CONCLUSIONS

The seismic assessment of RC structures with masonry infills is an important issue in modern earthquake engineering considering the prevalence of such typology in the southern European building stock. The characterisation of their behaviour up to global collapse is essential when performing risk-based analyses associated with performance-based earthquake engineering. Non-linear dynamic analyses such as IDA or MSA are computationally expensive in terms of time and effort. To this end, R - μ - T relationships, incorporating the general response of the structural typology were developed herein. The latter was developed here in terms of $AvgSa$, which demonstrated itself as a more accurate and appropriate IM. From the results of the study developed herein, the following can be noted considering the benefits of the developed tool:

- The consideration of $AvgSa$ as an intensity measure for infilled RC frames is characterised with low dispersions, rendering it a good predictor for collapse estimation.
- The ease of applicability of the tool by simplifies the estimation of collapse capacity and reduces the need for non-linear dynamic analyses by employing eigenvalue and non-linear static procedures as inputs.
- The accuracy of the tool in terms of its ability to predict the median collapse intensity and dispersion for two case study buildings and two different site hazards has been illustrated.

7 ACKNOWLEDGEMENTS

The work presented in this paper has been developed within the framework of the project “Dipartimenti di Eccellenza”, funded by the Italian Ministry of Education, University and Research at IUSS Pavia. The authors would like to acknowledge the contribution of Arch. Ing. Tereza Nádeníková and Arch. Ing. Barbara Ferma during the conception of the case study buildings presented in this study.

Abstract

With the development of performance-based earthquake engineering (PBEE) for mitigating seismic risk, significant work has been carried out to implement risk-based design and assessment frameworks. However, the probabilistic nature and computationally heavy implementation of the PBEE framework when using a component-based loss assessment approach, made it less desirable for practitioners. As a consequence, methods employing storey loss functions (SLFs), which ease the computational cost of the component-based approach, have emerged. The use of predefined SLFs, especially at a design stage, is desirable where component information is likely missing. This article describes an object-oriented toolbox, recently developed in Python, for the estimation of SLFs. The step-by-step implementation is described along with a comparative demonstration of its application to a case study existing building versus the more rigorous component-based approach described in FEMA P-58. The attained loss metrics demonstrate the quality and prove that the SLF-based approach, while being more simplistic in nature, achieves accurate results with relative ease across all levels of seismic response.

Keywords: PBEE, seismic assessment, loss estimation, storey loss function.

1 INTRODUCTION

Over the years, it has become paramount to characterize seismic risk using terms more meaningful to stakeholders and practitioners. These performance measures can be characterised by losses, downtime and casualties/fatalities. To avoid describing performance at discrete hazard levels, as typically prescribed in design codes (e.g. [1]–[3]), probabilistic frameworks have been developed to include uncertainties for hazard, structural response, damage and monetary loss. One of these frameworks is the performance-based earthquake engineering (PBEE) proposed by the Pacific Earthquake Engineering Research (PEER) Center [4]. However, due to its probabilistic nature and computationally expensive implementation, it has become popular primarily within academic research or specialized reports, such as FEMA P-58 [5], rather than a widespread code-based implementation for practitioners. While existing structures might offer easily-accessible information regarding their component inventory, the opposite is the case for newly designed structures and practitioners may be hesitant to carry out a full loss-driven design consisting of many trials and iterations. Over the years, many risk-targeted design methods have been developed, where many of them ([6]–[13]) are risk-targeted approaches using collapse risk as their primary design objective, while others ([9], [11], [14]) explore the possibility of using economic loss as well. To simplify the codification of these approaches, alternatives to component-based probabilistic loss estimation are sought.

Ramirez and Miranda [15] looked into simplifying the PEER's building-specific loss estimation methodology by creating so-called engineering demand parameters versus decision variable (EDP-DV) functions, where the structural response parameters, or EDPs, are directly related to economic losses, or DVs. These functions typically define monetary loss at a storey level hence are termed storey loss functions (SLF). They provide readymade loss functions describing the repair costs over a predefined building inventory of damageable components in a simplified manner, thus reducing the amount of data required to be handled for the building's inventory during loss assessment. As mentioned earlier, during the design phase of new buildings, the complete component inventory of the building might not be fully known, therefore generic SLFs will potentially help avoid the issue of having excessive computations required in component-based driven approaches. These SLFs have been recently implemented in Silva *et al.* [16] for steel buildings in a European context, for example, although options for reinforced concrete (RC) buildings are generally lacking.

Based on the storey loss estimation framework by Ramirez and Miranda [15], a toolbox for creating generic user-based SLFs has been developed. Component quantities, fragility and consequence functions are used as input elements to generate FEMA P-58 compatible SLFs [5]. While the framework by Ramirez and Miranda [15] uses cost distributions for different RC building occupancies in California, Papadopoulos *et al.* [17] developed SLFs for steel buildings in Greece. Similarly, SLFs were developed for URM buildings by Ottonelli *et al.* [18] and masonry infill walls by other researchers [19]–[21]. Additionally, recent studies on loss estimation ([22], [23]) highlighted the need for developing SLFs to cover a wide range of building characteristics, such as its storey-wise functionality, typology of structure, and occupancy. Sullivan [23] presented a simplified loss assessment approach to calculate expected annual loss, EAL, however, a limitation was mentioned, whereby the knowledge of quantity, distribution, and characteristics of all damageable components within the building inventory might not always necessarily be readily available and, to address it, SLFs may be used. On the contrary, Perrone *et al.* [22] proposed a method for estimating the EAL of Italian RC buildings using suitable SLFs, further highlighting the need for developing simplified alternatives.

This paper describes the development of a toolbox that allows the automated production of SLFs through regression analysis using the results of random sampling of component damage

states and costs, including damage correlation among components. Contrary to past research, the aim is not to create generic readymade loss functions for a specific building category, but to develop a tool for any user to create their own functions, based on an existing database of components, such as FEMA P-58 or expert opinion, without being limited to existing SLF libraries. The framework implemented within the toolbox is described herein. The main decisions encompassing the use of the toolbox include: the building characterisation through the definition of component inventory, defined by component quantities, fragility and consequence functions; performance grouping of components based on EDP sensitivity; identification of possible interactions among different components; choosing the number of simulations for the sampling of damage states; and selecting a regression fitting type. The latter may be extended by adding more regression options. Finally, the framework is validated with a case-study application to a generic RC building, and the results are compared with a component-based loss assessment of the same building (Figure 1) following FEMA P-58.

2 STOREY LOSS FUNCTION ESTIMATION TOOLBOX

As previously mentioned, the framework implemented within the SLF estimation toolbox consists of the following steps:

1. Building characterisation;
2. Component inventory definition;
3. Component grouping;
4. Consideration of correlations between components;
5. Monte Carlo Simulation of damage states;
6. Repair cost computation;
7. Storey loss function fitting.

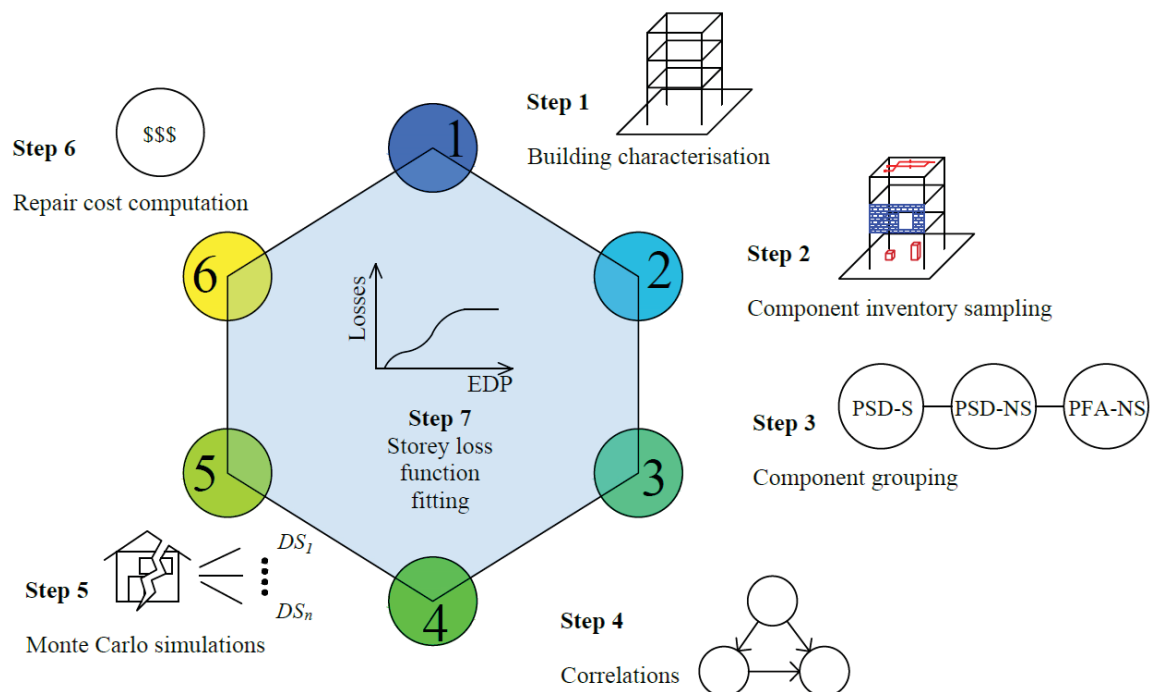

Figure 1: Flowchart of storey loss function generation framework.

The first step of the framework is the identification of the building's characteristics including the number of storeys, global dimensions, occupancy type and usage. However, if those are yet

to be identified, SLFs may still be identified for a desired reference area and extrapolated to a specific building configuration through the actual building area. Once the building characteristics have been identified, or the reference area selected, a damageable component inventory may be created. Building occupancy type and structural typology will play a key role in gaining insight into possible distributions of components if they are not preliminary known, as is common for new designs. The distributions (mean and uncertainty) of those components may be obtained from empirical and statistical data, collected from existing buildings and surveys, or based on expert opinion or personal judgment. The inventory consists of structural, non-structural components, and building contents likely to be damaged, all of which contribute to the economic losses deriving from required repair costs following seismic damage.

Typically, the component inventory has information on item types, component quantities, EDP sensitivity and typology (structural or non-structural) of each component. Three performance groups are identified unless otherwise specified, and fragility and consequence functions for the components should be provided. To compile the component database, damage states and associated fragility and consequence functions may be adapted from the FEMA P-58 database or other similar sources. Additionally, it needs to be specified whether the component will be affected by the EDP of the floor slab above the current storey or by the supporting floor slab at the current storey. For example, water distribution piping systems connected to the ceiling in a storey will be sensitive to the peak floor acceleration (PFA) of the above floor, while contents, such as electronic equipment will usually be sensitive to the PFA of the supporting floor. To account for this, a simplifying assumption is made within the toolbox, whereby the component losses in storey i , but affected by the upper floor, are computed as part of, or moved to, storey $i+1$. Even though the physical location of costs with respect to which storey the loss will be assigned is not quite correct, it will still lead to a correct total cost in the building.

In order to utilize the framework for 3D buildings, it needs to be applied to both directions of the building separately. Additionally, each direction will include components oriented along that direction. Essentially, the analyst would need to identify, for each damageable component at each storey level, in which principal direction of the building it is sensitive to damage. This way, the components can be grouped and analysed separately using the structural demands in the two orthogonal directions. To what pertains non-directional components, the framework is applied only once. In this case, both directions of seismic action are of importance, and the maximum value of two demand parameters in both directions may be multiplied by a non-directional conversion factor, as suggested in FEMA P-58, and used for a single SLF in the analysis. However, interactions of seismic effects in two orthogonal directions on a given component are not accounted for in cases where such interaction is expected to be significant, more advanced methods of loss assessment should be adopted.

Once the component inventory is identified, components may be classified into groups depending on the type of the component (i.e. structural or non-structural) and their EDP (e.g. peak storey drift (PSD) or PFA). Components within a performance group will be assessed together for a mutual demand and subsequent losses will be summed up to estimate the group's SLF. In other words, losses from all components within a performance group will be tied to the same EDP.

Similar to past studies ([15], [17]), the effects of such EDPs, such as vertical acceleration or building torsion, are not accounted for within the framework. Additionally, as discussed in O'Reilly *et al.* [24], torsion could be better dealt with by adopting a component-based approach. However, if one is to provide the toolbox with fragility and consequence functions associated with components other than PSD- or PFA-sensitive (e.g. peak floor velocity), the toolbox will still be capable of producing the appropriate SLFs. This classification of components into

different performance groups allows the disaggregation of losses at later stages to identify the main contributors to the economic losses, which can be useful in deciding which type of retrofitting strategies should be adopted as demonstrated by Carofilis *et al.* [25].

Similar to the studies of Ramirez and Miranda [15], structural and non-structural components sensitive to the same EDP may be grouped to allow for the consideration of possible correlations between the damage states. For example, a specific intensity level may not result in damage to a specific non-structural component, but it may affect a different component connected to it that does suffer a degree of damage. To repair this damaged component, access should be first granted, which foresees the removal of the portion or the entirety of the undamaged non-structural component. Essentially, for any independent component i , all damage states (DSs) are assumed to have an independent sequential occurrence unless otherwise specified and each DS is assumed to be mutually exclusive. A probability of occurrence is assigned to mutually exclusive DSs, which sum up to 100%. In contrast, if DS j of component i is dependent on the occurrence of a DS d of a component m , then the DS of component i is assumed independent of component m unless component m is in DS d or higher (i.e. DS d in component m triggers DS j in component i). As illustrated in Figure 2, for an EDP of edp , if component m is in DS3, then even if there is no indication of damage for component i , the latter component is assumed to be in DS2.

Figure 2: Relationship between causation and dependent components.

With a component inventory identified along with possible correlations among the damage states of different components, Monte Carlo simulations are performed. For each simulation, damage and repair costs are sampled for each component within the performance group, where all costs are added to obtain the performance group's total loss for a given EDP. Essentially, the algorithm samples damage states for each component at a given EDP level and for a specified number of simulations. A random value is generated within 0 and 1 and a DS is assigned to a component based on its fragility functions. An example describing the relationship between causation and dependent components is illustrated in Figure 3. At an EDP level of 0.02 (point 1 in Figure 3), if the sampled probability for the causation component is 0.3, then DS3 is assigned to the component. At the same EDP level, a sampled probability of 0.8 is assigned to the dependent component, which sets it in DS1. Following the relationship of the components described in Figure 2, the DS of the dependent component is modified to DS2.

Figure 3: Damage states and fragility functions of a sample: (left) causation component and (right) dependent component.

Once damage states for all components have been sampled, repair costs may be evaluated. For each component, at each sampled DS, the repair cost is assigned based on the provided consequence function. If the consequence function is represented only by the mean value, then the mean value is assigned, while if a distribution is provided, then a value as the repair cost is sampled from the repair cost distribution.

Finally, SLFs for component groups may be identified through regression analysis on sampled repair costs. More than one analytical expression may be used within the toolbox at <https://github.com/davitshahnazaryan3/SLFGenerator> (Figure 4), while possible addition of new functions may be considered, as future research identifies better alternatives. The Weibull cumulative distribution function may be used to perform the regression, described in Equation 1:

$$y = \alpha \left(1 - \exp \left(- \left(\frac{x}{\beta} \right)^\gamma \right) \right) \quad (1)$$

where, α , β and γ are the fitting coefficients, x is the EDP value and y is the fitted loss value. Alternatively, the regression model proposed by Papadopoulos *et al.* [17], defined in Equation 2, may be used:

$$y = \varepsilon \frac{x^\alpha}{\beta^\alpha + x^\alpha} + (1 - \varepsilon) \frac{x^\gamma}{\beta^\gamma + x^\gamma} \quad (2)$$

where, α , β , γ , δ and ε are the fitting coefficients, x is the EDP value and y is the fitted loss value.

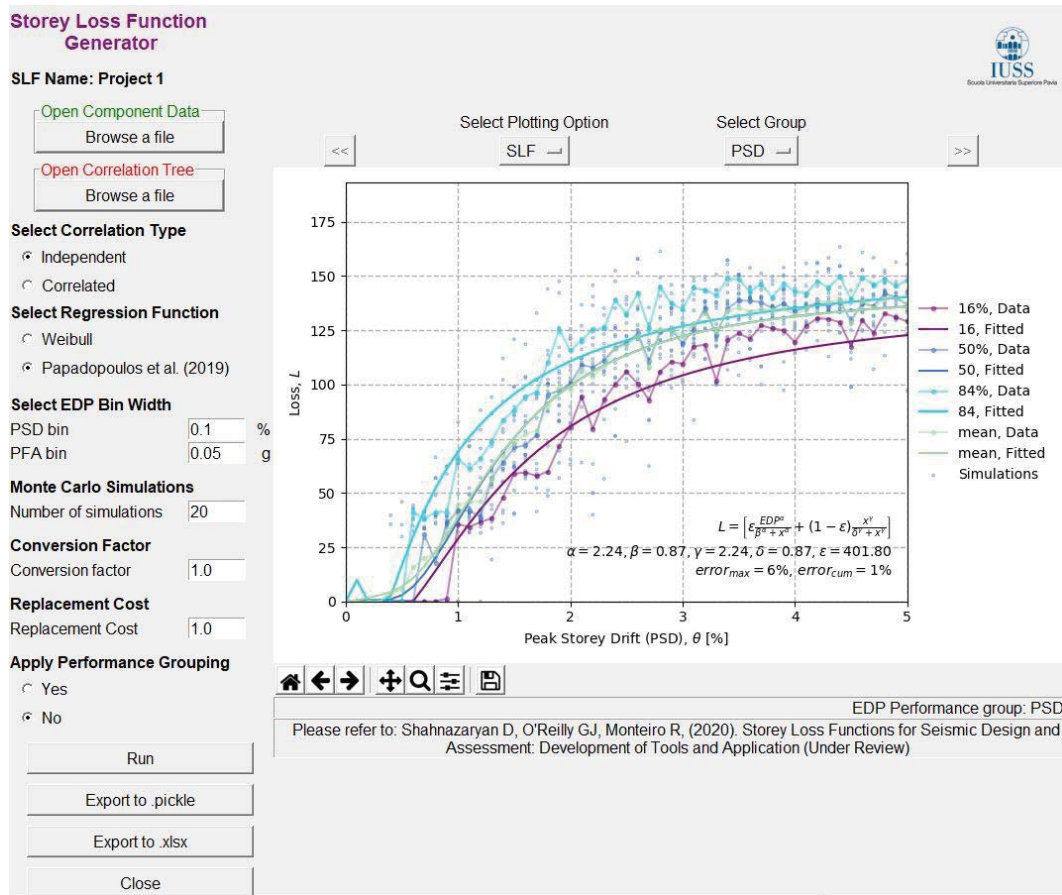

Figure 4: Overview of the storey loss function generator interface.

3 EXAMPLE APPLICATION

To demonstrate the capabilities of the toolbox for generating SLFs, a generic case-study RC building of 3 storeys and a reference area of 432 m² (Figure 5) is designed according to Eurocode 2 [26] and Eurocode 8, EC8, [27] provisions. Based on the design, a three-dimensional non-linear numerical model was created using OpenSees [28] and incremental dynamic analysis [29] was carried out. Finally, using the generated SLFs, loss assessment was carried out and compared with the component-based assessment following the FEMA P-58 guidelines. It is important to note that the results are not meant to be indicative of typical RC building performance, but more as a comparative exercise between the two approaches. The building is assumed to be located in the city of L'Aquila, Italy on a stiff clay site according to EC8's site classification. The gravity loads, including imposed and dead loads, were assumed as 8.06 kN/m² and 6.56 kN/m² at the general floor and roof level, respectively. The building has two seismic frames along its perimeter in each of the principal directions. The material properties used in the design and detailing were 25 MPa for the concrete compressive strength and 415 MPa for the steel yield strength. No plan or elevation irregularities are present. The replacement cost of the building was assumed as 1572000€.

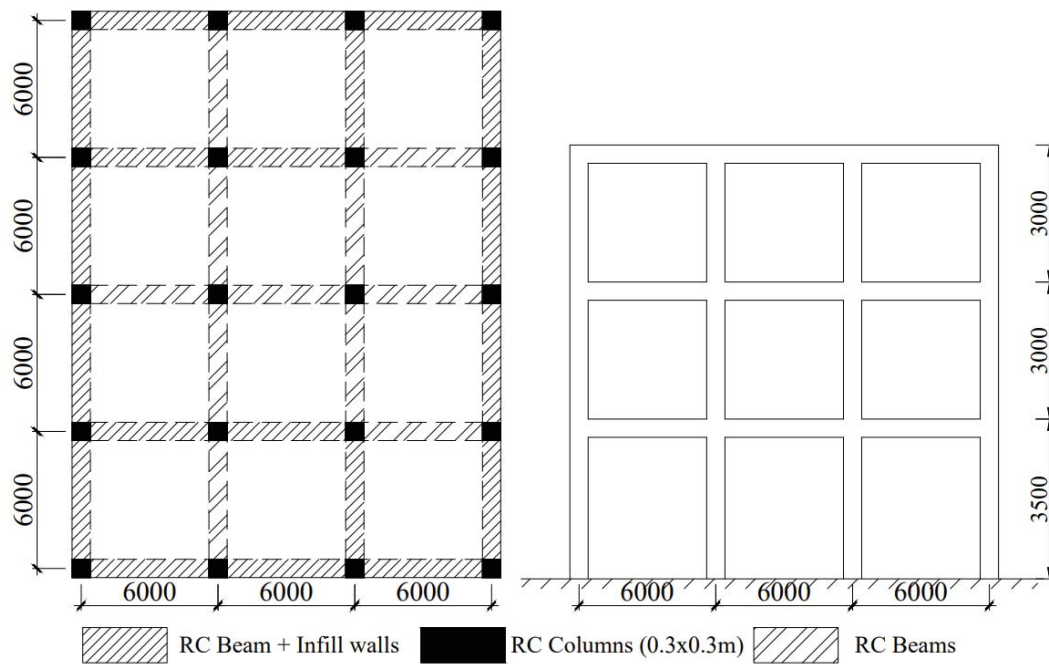

Figure 5: Plan and elevation view of the structural configuration of the case study building.

PFA and PSD sensitive components were considered within the component inventory of the case study building. Components with sensitivity towards one direction of seismic action and having the same EDP sensitivity were grouped, while non-directional components were classified into a different performance group. Moreover, PFA-sensitive components were grouped depending on the location within a storey and to which EDP they were sensitive. For example, components such as piping systems located in a storey j but sensitive to the EDP of the above storey were tied to the PFA of storey $j+1$, while electronic devices in storey j were tied to the PFA of storey j , as described previously. Table 1 to Table 3 summarise the mean structural, PSD-sensitive and PFA-sensitive non-structural component quantities.

Table 1: Mean quantities for the damageable PSD-sensitive non-structural components of the case-study RC building in X (Y) direction.

ID	Component	Unit	Quantity per storey		
			Storey 1	Storey 2	Storey 3
B101	Exterior masonry infill with windows	per m ²	84(63)	72(54)	72(54)
B102	Internal masonry partition		67.75 (32.3)	59.8 (24.2)	59.8 (24.2)
B103	Internal gypsum partition		105(75)	95(62)	95(62)
B104	Non-monolithic precast concrete stairs		1(-)	1(-)	1(-)

Knowing the quantities at each storey, creating SLFs necessitates the definition of fragility and consequence functions for all components within the inventory. Table 4 to Table 6 summarise the damage descriptions, the sources for the function definitions and the fragility parameters for structural, PSD-sensitive and PFA-sensitive non-structural components, respectively. For the majority of the components, fragility and consequence functions were adopted from the available literature ([19], [30], [31]), while for the remaining components, mean repair costs were based on typical costs expected in Italy. To what pertains the fragility functions of the latter components, they were primarily tied to fragilities of other components. This is a correlation assumption between two components, even though it was not directly implemented. In the absence of fragility functions for some non-structural components, some assumptions were made using engineering judgment. While many components (e.g. doors, chairs, fridges, washing machines) were assumed damaged when the interior masonry partitions have reached collapse DS, others (e.g. windows) were assumed damaged when the exterior masonry walls have reached collapse DS, considering that collapse of walls or partitions would damage the adjacent chairs, doors and windows. Similarly, TV and computers were considered damaged once there was 30% damage and falling of ceiling tiles and many other components (e.g. bookshelves, wardrobes, sofas, tables, shelves, beds and kitchen equipment) were damaged once there was large leakage of piping systems.

Table 4: Fragility function parameters and repair costs for PSD-sensitive non-structural components.

ID	Damage states	Source	Fragility function parameters		Mean repair cost €

Consideration was already given here for correlations among damage states of different components in the case study building. Components like doors, windows, chairs were tied to the DS of causation component due to the absence of fragility functions in the literature. However, additional logical correlations based on engineering judgment were assigned among other components within the same EDP-sensitivity group. Table 7 describes the damage of the causation component, as well as its effect on the correlated component. It is important to note that this set of correlations will not be considered within the component-based loss assessment framework hence some difference in results should be expected a priori should this aspect have

a notable impact. However, a demonstration of variation of including such correlations with respect to ignoring them in an SLF-based approach will be commented on later.

Table 6: Fragility function parameters and repair costs for structural components.

ID	Damage states	Source	Fragility function parameters		Mean repair cost €
			Median (% for PSD, g for PFA)	Dispersion

		C103	Disassembly of rod system at connections	DS1

4 RESULTS

The toolbox was applied at each storey of the building and SLFs were derived based on the component data provided previously. Correlations among dependent component DSs were considered as described in Table 7. For PSD-sensitive components, a set of three SLFs were derived for both principal directions and the non-directional components, corresponding to each of the three storeys of the building. For PFA-sensitive components, loss functions for four floors were derived, based on whether the component was sensitive to the PFA of the above floor or the floor upon which it is placed. The PACT software [32] provided with FEMA P-58 was used to conduct the component-based loss estimation, where a non-directional conversion factor was assumed to be 1.2. Apart from record-to-record variability, no epistemic uncertainty was considered for simplicity, as this study acts as a comparative study between two methodologies.

To attain the SLFs, performance grouping was applied and Equation 2 was used to carry out regression and identify mean curves. Sample SLFs for the 2nd storey and 2nd floor of the building are provided in Figure 6 and regression parameters are provided in Table 8. Losses of non-structural (NS) components start accumulating at low values of PSD, which is particularly due to low capacities of interior and exterior infills (Table 4). In contrast, losses of structural (S) components start accumulating once a certain threshold of PSD value is reached, which could be attributed to the high capacities of well-designed ductile columns. The toolbox was also applied assuming component correlations. Figure 6(b) demonstrates the SLFs of PFA-sensitive components on the 2nd floor of the case study building. The consideration of correlation among some of the components as detailed in Table 7, has an impact on the losses within PFA values of 0.5 to 2.5g. The inclusion of correlations results in an increase in vulnerability through the curves shifting to the left in Figure 6(b).

Figure 6: SLFs for the case-study building intermediate (2nd) storey level and 2nd floor (Equation 2). (a) PSD-sensitive components, (b) PFA-sensitive non-structural components.

Table 8: Regression parameters for the fitted SLFs at the 2nd storey of the case study building using Equation 2.

Performance group	Direction 1					Direction 2				
	α	β	γ	δ	ε	α	β	γ	δ	ε
PSD S	2.435	2.285	5.300	0.970	1.333	2.020	1.676	2.936	0.978	2.168
PSD NS	1.348	1.892	1.351	1.908	138.3	1.402	1.563	1.406	1.574	174.7
PFA NS, correlated	2.003	0.271	2.010	0.270	176.7	-	-	-	-	-
PFA NS, uncorrelated	2.112	0.410	2.115	0.408	259.7	-	-	-	-	-

Probabilistic seismic hazard analysis (PSHA) was performed using OpenQuake [34] with the SHARE hazard model [35]. A set of 30 ground motion record pairs were selected from the NGA West-2 database [36] with each record's soil type being consistent with that of the site. Hazard curves obtained from PSHA were used to carry out the loss assessment. Figure 7 illustrates the hazard curve for the selected case study location. The intensity measure (IM) selected was the spectral acceleration, $Sa(T^*)$, at a conditioning period, T^* . Since the building has two principal modes of vibration in two orthogonal directions, following the suggestion of FEMA P58 [5], a T^* of 1.1s corresponding to the arithmetic mean of two orthogonal modal periods was selected. Non-linear response-history analyses were conducted and the results were used to carry out loss assessment using the PACT software for a component-based approach and using the SLFs generated via the proposed toolbox for the SLF-based approach.

Figure 7: Hazard curve for the site considered in L'Aquila, Italy at a period of 1.1s.

The approach proposed by Ramirez and Miranda [37] was used to perform an SLF-based loss assessment. Residual deformations are accounted for to compute the probability of the building being demolished after an earthquake. The economic loss computed consists of the following terms: losses due to building collapsing; repair costs due to the building's structural and non-structural components being damaged; and losses resulting from the demolition of the building if excessive residual drifts were recorded. For the case-study building, probability of the building being demolished due to excessive residual drifts is assumed to be lognormally distributed with a median of 0.015 and a logarithmic standard deviation of 0.3 [37].

Based on the loss assessment results, the expected annual loss (EAL) was computed for the case study building by integrating the vulnerability curve, expressed in terms of expected direct economic loss as a function of IM, with the site hazard curve defined according to Equation 3.

$$EAL = \int E[L_r | IM] \left| \frac{dH}{dIM} \right| dIM \quad (3)$$

where dH/dIM is the mean annual frequency of the ground motion IM. EAL disaggregated by cost type and vulnerability curves are presented in Figure 8. The EAL computed using SLFs was 0.63%, which is slightly lower when compared to the one computed via the FEMA P-58 component-based approach, which amounted to 0.66%. As observed, the main contribution to the EAL comes from non-structural components, while structural components represent the lowest proportion. This demonstrates how structural components designed following seismic code provisions have larger capacities against damage. The similarity of vulnerability curves, as well as the proportions of contributions towards EAL, enforce the quality of a more simplistic SLF-based approach in ensuring proper assessment of losses when compared to the more rigorous component-based approach.

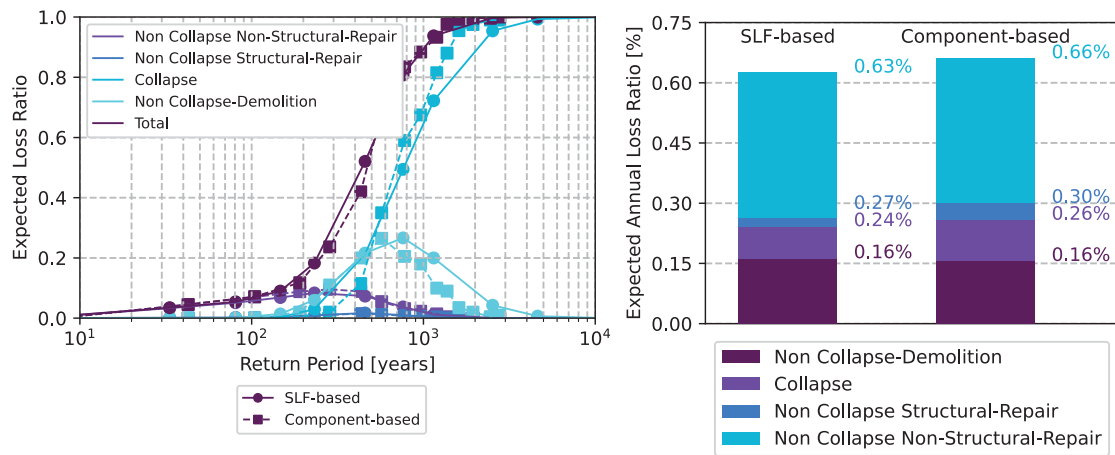

Figure 8: (left) Vulnerability curves and (right) expected annual loss showing the breakdown of different contributors in a comparative assessment between an SLF-based and component-based loss assessment approach.

Finally, Figure 9 provides the relative contributions to the vulnerability curves as a function of the return period. As observed, the main contributors at low hazard levels are the non-structural repair costs. With increasing return period, the costs from collapse and demolition start increasing, with collapse taking a significant portion of the costs at higher return periods. Cost contributions from demolition losses are quite high at high return periods, where in the absence of collapse the building needs to be demolished. Essentially, even though one might expect for structural component repair costs to increase with increasing return period, as they undergo damage, it precedes by the building needing demolition or collapse, therefore loss contributions from structural repair costs are inexistent at higher return periods as well.

Figure 9: Relative contribution to expected loss with respect to increasing return period for a (left) SLF-based approach and (right) component-based approach. As reference points, the 100, 475 and 2475-year return periods have been annotated on each plot.

5 SUMMARY AND CONCLUSIONS

With the lack of available tools to develop storey loss functions (SLFs) to fit specific needs, this article aims to fill the gap by introducing an SLF generation toolbox for seismic design and assessment of buildings. A description of the toolbox is presented, and it was validated through an application to a case study building in a comparative study with the more rigorous component-based loss assessment described in FEMA P-58. Additionally, the toolbox was

applied to compare the effects of assumptions where component damage states were considered independent and where the dependency of damage states of different components was assumed. The main observations from the study are as follows:

- The toolbox can consider component correlations. An example at the 2nd floor of the building considering peak floor acceleration sensitive components demonstrated that inclusion of dependencies and interactions of various components may impact the vulnerabilities avoiding potential underestimations in costs;
- SLFs were developed for the entire case study reinforced concrete building accounting for the response in both directions and a subsequent loss assessment was carried out. Results were compared to a component-based loss assessment approach with a good match in EAL between the two approaches;
- A close match of SLF-based loss estimates to the detailed component-based loss assessment was observed in the distribution of losses among performance groups per intensity highlighting the validity of the developed tool and its accurate applicability for the intended scopes initially outlined;
- While important for loss assessment on existing buildings, the SLF generation toolbox may be even more of an important tool for new designs within new risk-based design approaches.

ACKNOWLEDGEMENTS

The work presented in this paper has been developed within the framework of the project “Dipartimenti di Eccellenza”, funded by the Italian Ministry of Education, University and Research at IUSS Pavia.

Abstract

The Italian peninsula has been subjected to several destructive earthquakes over the last 50 years which denoted the high vulnerability of the existing building stock. In this context, the analysis of post-earthquake damages is of paramount importance for manifold reasons, such as the management of the emergency phase for establishing the usability of buildings and the identification of the main sources of vulnerability for future risk mitigation plans. Since about 50 years, the post-earthquake usability of buildings is assessed through simplified forms filled by experts and practitioners during extensive in-situ inspections. The data collected during the post-earthquake inspections have been recently catalogued in the Observed Damage Database (DA.D.O), which is a freely available platform for the scientific community. Starting from the data available in the DA.D.O platform, the damage reported by Italian school buildings have been analyzed in order to elaborate a proper school buildings database. The results of this statistical investigation are used for identifying the main sources of vulnerability characterizing the Italian school buildings and assuming a key role for the empirical calibration of reliable procedures of large-scale seismic risk assessment, mapping and reduction.

Keywords: Risk Assessment, School Buildings, Post-Earthquake Damages, DA.D.O platform.

1 INTRODUCTION

The post-earthquake inspections made after major earthquakes in the Mediterranean area highlighted the high vulnerability of building portfolios, especially with regard to existing structures built before the introduction of seismic provisions in national and international building codes. In Italy, the damages observed after the major seismic events occurred over the last 50 years raised the awareness of public institutions, researchers and practitioners about the vulnerability of existing buildings and the need for a large-scale seismic risk assessment to promote seismic risk mitigation programs [1-6]. Within this framework, the scientific community has developed several empirical and analytical procedures to define vulnerability curves for different building typologies, e.g. reinforced concrete (RC) buildings [7-11], masonry buildings [12-13], precast buildings [14], based on post-earthquake damage observations. Specific studies dealing with the seismic vulnerability assessment of relevant building typologies, such as schools [15-17], hospitals [18] and ecclesiastic heritage [19-22] are also available. Among the most common approaches adopted to assess and mitigate seismic risk, it is worthwhile mentioning also mechanical-based approaches [23-25], rapid visual screening (RVS) methodologies [26-27] and hybrid methods.

Empirical methods consist in the statistical processing of data about damages observed after past earthquakes. The data analysis allows to estimate the probability of occurrence of a certain damage state for increasing seismic intensities. The final output is represented by fragility curves, which can be considered vulnerability curves if a certain quantification of the expected losses is taken into account in the adopted intensity measure (IM). Over the years, several empirical-based vulnerability functions have been developed by referring to different building typologies. Qualitative and quantitative measures have been adopted to define the IM used in the vulnerability curves. In particular, the most widely adopted quantitative measure is the peak ground acceleration (PGA), while for the qualitative measures, some macro-seismic scales are defined, such as the Modified Mercalli Intensity (MMI), Medvedev–Sponheuer–Karnik (MSK) and Mercalli–Cancani–Sieberg (MCS). Qualitative and quantitative measures are often freely available online for different seismic events [28-29].

The damage probability matrix (DPM) proposed by Braga et al. [30] was one of the first empirical methods to be developed. It consists in the definition of the discrete probability that a certain damage - measured according to a macro-seismic scale - occurs in the total sample of investigated buildings. Braga et al. adopted the MSK scale to apply the DPM method to RC buildings damaged by the Irpinia earthquake (1980). Rossetto and Elnashai [31] proposed empirical fragility curves for RC buildings using a database of about 350.000 units. Di Pasquale et al. [32] developed a loss model based on the damage observed during past earthquakes in Italy. Lagomarsino and Giovinazzi [33] proposed, for several building typologies in the Mediterranean area, a methodology for relating macro-seismic and mechanical models for vulnerability assessment, basing on post-earthquake observations. Recent works [6-22] have refined the empirical methodologies and the related vulnerability and fragility curves by using large samples of buildings damaged by recent earthquakes. A useful tool for analyzing the damage occurred after Italian earthquakes has been recently developed by the Italian Department of Civil Protection: the Observed Damage Database (DA.D.O) web-gis platform, which collects the results of post-earthquake inspections made after the major Italian earthquakes.

Using the data available in DA.D.O. platform, the present study focuses on the assessment of damages occurred in Italian school buildings after the main Italian seismic events over the last 50 years. All data have been firstly extracted from DA.D.O. platform and then processed by taking into account some typological parameters, such as construction typology, year of construction, number of storeys, area and structural regularity. Once all data have been orga-

nized in a specific database, they have been processed for a twofold scope: (a) providing a statistical quantification of the damaged school buildings and their main typological features; (b) providing vulnerability curves, according to the defined building classification.

2 DA.D.O. PLATFORM: A DATA COLLECTION OF EARTHQUAKE RELATED DAMAGE OVER THE LAST 50 YEARS IN ITALY

The Da.D.O. web-gis platform has been conceived with the specific purpose to collect, catalogue and compare data related to damage and structural characteristics of buildings inspected after earthquakes occurred in Italy over the last 50 years. Data from ten seismic events characterized by a high seismic intensity are provided [34]: Friuli 1976; Irpinia 1980; Abruzzi 1984; Umbria-Marche 1997; Pollino 1998; Molise 2002; Emilia 2003; L'Aquila 2009; Emilia 2012, Garfagnana 2013. A summary of the general information present in the database is provided in Del Gaudio et al. [8], which reports that the total number of inspected buildings amounts to 320.000, subdivided among 78% of masonry buildings, 8% of RC buildings and 14% for other construction typologies. Since the survey forms have been modified over the years, the information available for each seismic event can vary. Presently, post-earthquake inspections are carried out by using the AeDES form [36], which was firstly introduced following the Umbria-Marche 1997 event. Previously, different survey forms were adopted (former versions of the AeDES form). For each seismic event collected in the Da.D.O. platform, Table 1 reports the key information accessible for each building. In particular, the information available in each survey form can be summarized in five macro-sections:

1. Building registry: general information and location of the buildings (e.g. year of construction, latitude and longitude, municipality, census code);
2. Geometry: main typological and geometrical features (e.g. number of storeys, qualitative estimate of area, inter-storey height);
3. Use destination: information about the use of the building from stakeholders (e.g. building use, number of occupants, strategic destination);
4. Position in urban context: information about the position of the building (e.g. reference with the position of near buildings, soil and topography);
5. Construction typology: main structural features (e.g. construction material, presence of retrofit devices, regularity).

The level of completeness and the quality of the data depends on the seismic events, more detailed information being available for more recent earthquakes. Table 1 reports a general indication about the level of detail of the recorded information distinguishing between: complete (C), incomplete (I) and absent (A) information. Regarding the building registry, all survey forms contain some details, however, for the first three considered events (Friuli 1976, Irpinia 1980 and Abruzzi 1984), the latitude and longitude are referred to the municipality in which the buildings are located and not to the specific location of the analyzed building. Concerning the geometry, the survey forms used after the first three events only report the plan dimension, while from the Irpinia 1980 earthquake the number of storeys and inter-storey height are also available. Only the data about the Abruzzi 1984 earthquake do not report the inter-storey height. The forms used in the first three events did not provide details about the use of the buildings, while for the Umbria-Marche 1997 and the Pollino 1998 earthquakes this information is reported, allowing to classify the buildings also based on their strategic importance. With regard to the position in the urban context, the form used in the Friuli 1976 earthquake reports if the building is isolated, outer-edge or in the corner of other building complexes. Only in the case of the Irpinia 1980 and the Abruzzi 1984 earthquakes, this data is

not reported. Lastly, with reference to the construction typology, complete information is provided for all seismic events but for the first three events only the construction material is reported.

Seismic event	Building registry	Geometry	Use destination	Position in urban context	Construction typology
Friuli 1976	I	I	A	I	I
Irpinia 1980	I	C	A	A	I
Abruzzi 1984	I	I	A	A	I
Umbria-Marche 1997	C	C	I	C	C
Pollino 1998	C	C	I	C	C
Molise 2002	C	C	C	C	C
Emilia 2003	C	C	C	C	C
L'Aquila 2009	C	C	C	C	C
Emilia 2012	C	C	C	C	C
Garfagnana 2013	C	C	C	C	C

Table 1: Summary of the key information reported in the survey forms adopted after the Italian seismic events occurred over the last 50 years (information about damage data are herein excluded)

As for the details related to the identification of the building's features, also the damage classification is related to the survey form adopted for the post-earthquake inspections. The forms used for the first three considered seismic events (Friuli 1976, Irpinia 1980 and Abruzzi 1984) do not allow to identify the damage extension [8]. The form adopted following the Friuli 1976 earthquake only allowed to classify buildings based on their global damage state, while more detailed information was introduced in the forms adopted during the following earthquakes. In particular, starting from the Pollino 1998 earthquake, it was possible to collect details about the damage state of five building components (vertical structures, horizontal structures, stairs, roofs and infill panels or non-structural elements). Table 2 reports the damage levels adopted in each survey form by grouping the different damage states in four main sub-categories. More in detail, the survey form adopted after the Friuli 1976 earthquake provides a synthetic judgement about observed damages (from destroyed to undamaged) subdivided in five damage levels (L0-L4). The survey form adopted after the Irpinia 1980 earthquake presents eight damage levels (L0-L7), while in the case of Abruzzi 1984 earthquake, the damage state was classified distinguishing between five damage levels (L1-L5) defined according to the EMS98 scale. From the Umbria-Marche 1997 earthquake, the AEDS survey form was introduced and the damage levels were classified according to damage states (D) defined according to the EMS98 scale.

It is worth mentioning that in the DA.D.O platform the details provided by the Institute of Geophysics and Vulcanology (INGV) for the characterization of the seismic events are also reported. This data includes: shake maps [37], date, magnitude, distance, geographic position (epicentre and hypocentre) and macro-seismic intensities in terms of Mercalli-Cancani-Sieberg scale (IMCS) [38].

Seismic event	Damage levels	Heavy damages	Medium damages	Light damages	Null damage
Friuli 1976	5	L3-L4	L2	L1	L0
Irpinia 1980	8	L5-L6-L7	L3-L4	L1-L2	L0
Abruzzi 1984	5	L4-L5	L2-L3	L1	/
Umbria-Marche 1997	3	D4-D5	D2-D3	D0-D1	/

Pollino 1998	4	D4-D5	D2-D3	D1	D0
Molise 2002	4	D4-D5	D2-D3	D1	D0
Emilia 2003	4	D4-D5	D2-D3	D1	D0
L'Aquila 2009	4	D4-D5	D2-D3	D1	D0
Emilia 2012	4	D4-D5	D2-D3	D1	D0
Garfagnana 2013	4	D4-D5	D2-D3	D1	D0

Table 2: Summary of the damage classification in the survey forms used after the main Italian seismic events, considering 4 macro-sections of damage: heavy, medium, light and null.

3 SCHOOL BUILDINGS DAMAGED BY ITALIAN EARTHQUAKES: STATISTICAL ANALYSIS ON THE SPECIFIC-CLASS PARAMETERS

Using the data available in the DA.D.O platform, all the school buildings damaged following the selected seismic events have been classified and statistically analysed. As reported in Table 1, the usage of the buildings was not available for seismic events occurred before 2002. In order to identify the school buildings for all considered seismic events, the information provided by DA.D.O platform has been compared with the Open Data about Italian schools provided by Italian Ministry of University and Research (MIUR) [39]. For each damaged building, DA.D.O provides the latitude and the longitude, while the MIUR database provides the address and the municipality of all Italian school buildings. Using reverse geocoding algorithm [40], latitude and longitude of all Italian school buildings have been found and matched with latitude and longitude of the damaged buildings, by imposing a tolerance -in absolute value- to the fourth decimal place. The summary of the identified school buildings, subdivided for construction typology, is provided in Table 3.

Seismic event	Number of school buildings extracted by DA.D.O.	RC [%]	Masonry [%]	Other typologies [%]
Friuli 1976	/	/	/	/
Irpinia 1980	/	/	/	/
Abruzzi 1984	3	0.0	100.0	0
Umbria-Marche 1997	153	15.0	79.5	5.5
Pollino 1998	25	12.0	64.0	24.0
Molise 2002	248	48.8	35.1	16.1
Emilia 2003	17	0.0	88.2	11.8
L'Aquila 2009	616	54.7	27.8	17.5
Emilia 2012	577	34.9	44.7	20.4
Garfagnana 2013	/	/	/	/

Table 3: Number of school buildings damaged by Italian seismic events over the last 50 years, accounting for the construction typology.

For Friuli 1976 earthquake, for the fixed tolerance, the matching procedure has not provided any useful results. The Irpinia 1980 earthquake, although several data are available, has been discarded because for this event the coordinates available are referred to the municipality and not to the specific location of the building. For Abruzzi 1984, Umbria-Marche 1997 and Pollino 1998 earthquakes, several units have been identified, as reported in Table 3. Although the adopted identification procedure can be affected by uncertainty, some random checks have been performed, observing a good level of accuracy. The distribution of the selected school buildings along the entire territory can be displayed using the extracted data. Figures 1 and 2

report the identified school buildings for Pollino 1998 and Emilia 2013 earthquakes and, additionally, the I_{MCS} for each municipality.

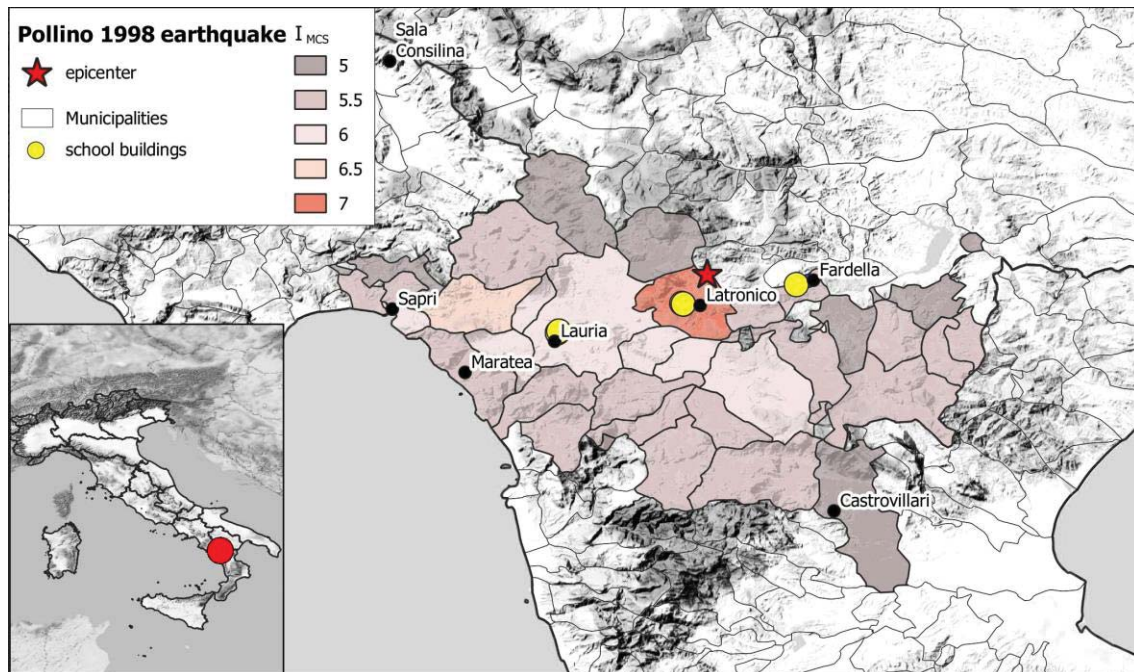

Figure 1: Distribution of school buildings damaged by Umbria-Marche 1997 earthquakes, with indication of I_{MCS} for each municipality.

Based on the defined school building database, several observations can be made on damaged masonry and RC school buildings, with the aim to evaluate the entire school building portfolio damaged by recent Italian earthquakes. Firstly, the year of construction for masonry and RC school buildings has been analyzed (Figure 3) NC indicates the school for which this information was not available. As expected, about 75% of masonry units were built before 1961 and about 90% before 1980. A different situation is observed for RC school buildings, where about 60% of the units were built before 1980. In 1980, the first seismic building code was released in Italy. This aspect suggests that the greater part of masonry and RC school buildings was not designed according to seismic details, which highlight a high seismic vulnerability of the building portfolio.

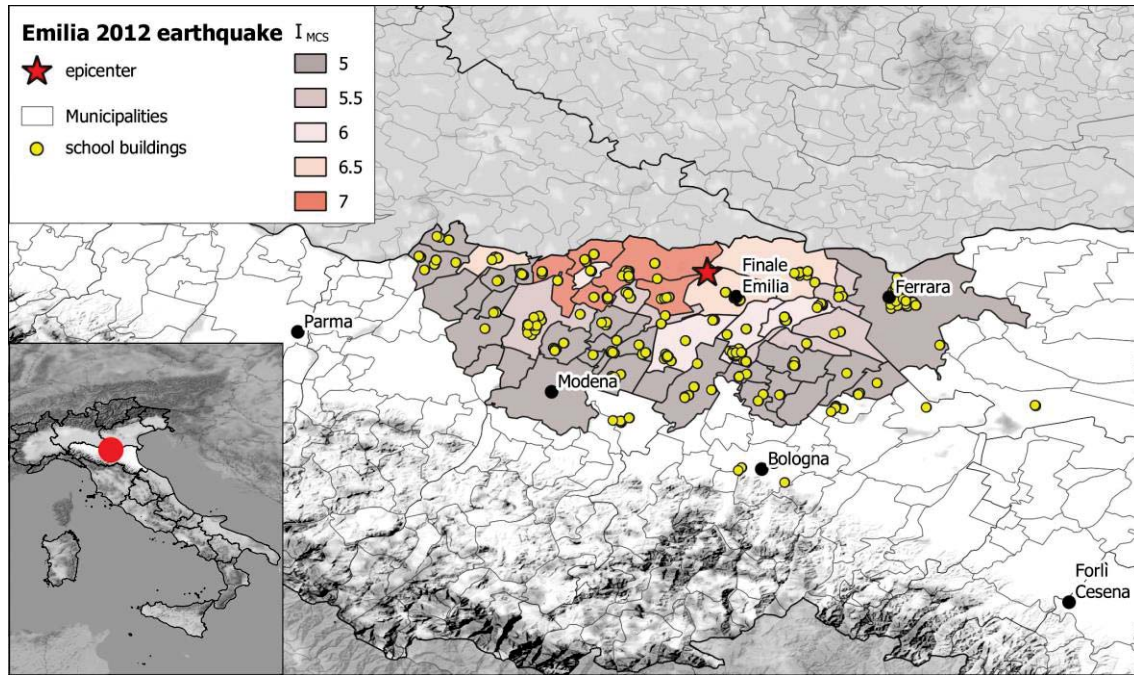

Figure 2: Distribution of school buildings damaged by Emilia 2013 earthquakes, with indication of I_{MCS} for each municipality.

Figure 3: Percentage of masonry and RC school buildings, subdivided for year of construction parameter.

Figure 4 reports the number of storeys by distinguishing between masonry and RC buildings. Approximately 75% of the masonry and RC school buildings have three or fewer storeys. This observation implies that most of the damaged Italian school buildings can be classified as low-rise buildings (this evidence is also reported in several scientific works, e.g. [25, 27]). No particular evidence can be extracted from the inter-storey height parameter: about 85% of the RC school buildings presents values that range from 2.50 m and 3.50 m, while the remaining 15% presents higher values. The inter-storey height is more discretized for masonry buildings; higher inter-storey heights are observed in the schools built before 1920 (> 5.00 m), while inter-storey heights ranging from 3.50 m to 5.00 m have been observed for more recent buildings.

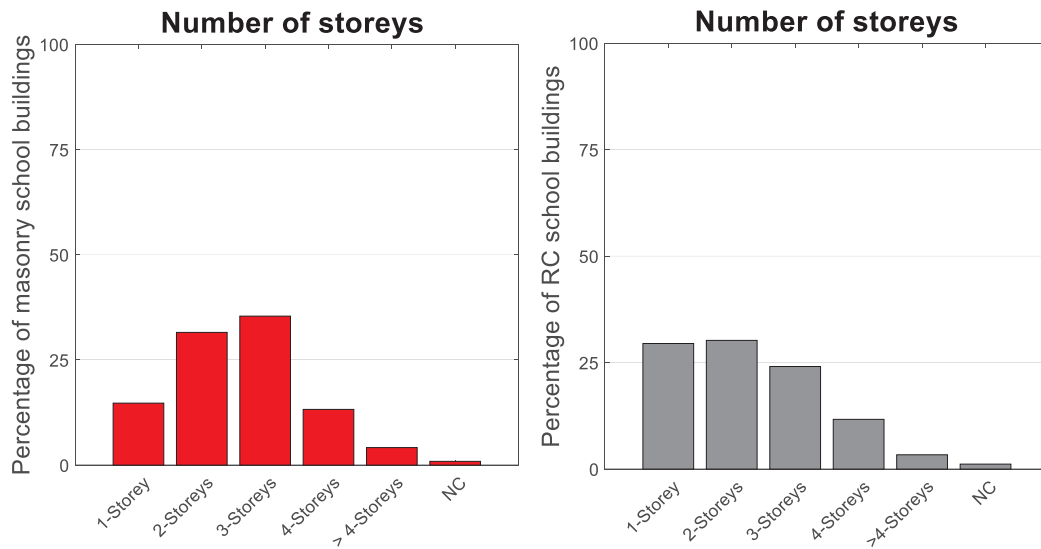

Figure 4: Percentage of masonry and RC school buildings, subdivided for number of storeys parameter.

Less homogenous is the distribution of the area parameter. As shown in Figure 5, about 40% of masonry school buildings and 25% of RC school buildings have an area ranging from 50 m² to 300 m², while about 50% of masonry and RC school buildings presents an area comprised from 300 m² to 1200 m². The high percentage of buildings characterized by large plan dimensions might suggests that this parameter can influence the seismic behavior.

As for the area parameter, also the structural regularity is an important parameter for defining the seismic vulnerability. This information is not available for all the units. In particular, the data available for school buildings damaged by Abruzzi 1984 and Umbria-Marche 1997 earthquakes do not report information on regularity and then they have been classified as NC. Looking at the percentage of regular and irregular school buildings, Figure 5 reports a summary for all the units. It is evident that about 50% of masonry and RC buildings presents structural irregularities. This aspect needs to be taken into account, considering that the structural irregularity assumes a key role in the seismic response of buildings.

Figure 5: Percentage of masonry and RC school buildings, subdivided for area parameter.

Figure 6: Percentage of masonry and RC school buildings, subdivided for structural regularity parameter.

4 EMPIRICAL ESTIMATION OF THE SEISMIC BEHAVIOUR OF ITALIAN SCHOOL BUILDINGS: DAMAGE DISTRIBUTION AND VULNERABILITY CURVES

The data collected in the DA.D.O. platform reports the results of the inspections made by practitioners and researchers rushed to the scene in the days after the earthquakes. As for rapid visual screening procedures, the definition of the damage state is based on the surveyors' experience, although some guidelines describing the different damage states are available. As previously discussed, it is worth mentioning that the survey forms adopted over the years can differ both in terms of investigated structural elements and damage classification. The survey form adopted in the Abruzzi 1984 earthquake contains judgments only about vertical and horizontal structures, while the one employed in the Umbria-Marche 1997 earthquake also considers damage to stairs. A complete information is provided for the Irpinia 1980 earthquake and for earthquakes after the Pollino 1998 and the Molise 2002 earthquake (AeDES form), in which damage data about vertical and horizontal structures, stairs, roofs and non-structural elements (such as infill panels for RC buildings) are present.

Basing on the developed school buildings database, it is possible to provide a critical discussion on the damages reported by school buildings after the selected earthquakes, by means of DPMs. Since the damages in AeDES form are classified according to the EMS98 scale, it is necessary to convert the damage levels reported for those earthquakes in which the AeDES form was not adopted (see Table 2) into the EMS98 measure scale. The methodology proposed by Del Gaudio et al. [8] has been adopted for the conversion into the EMS98 measure scale. Then, DPMs can be elaborated, as shown in Figures 7 and 8, accounting for horizontal structures, stairs, roofs and non-structural elements and by separating the RC and masonry school building samples.

Figure 7: DPM for masonry and RC school buildings, accounting for damages on horizontal structures and stairs.

The results of the statistical analysis show that about 85-90% of the RC buildings have a damage level D0 and 10% have a damage level D1, with regard to horizontal structures, stairs and roofs. Despite the sample was not sorted for year of construction, few damages were detected. Different evidence is shown for non-structural elements (e.g. masonry infill panels and partitions), which show about 40% of units having damage level D1 and about 20% having damage levels ranging from D2 to D5. For non-structural elements, similar percentages are reported for masonry school buildings, for which non-structural elements present damage levels greater than D0 for about 55% of the units. Again for masonry buildings, DPMs show several damages on horizontal structures (about 45% of buildings have a damage level greater than D0), whereas few units present damages to stairs and roofs.

Figure 8: DPM for masonry and RC school buildings, accounting for damages on roofs and non-structural elements.

With regard to vertical structural elements, data can be processed by means of vulnerability curves. In particular, the entire set of school buildings has been subdivided into three samples: (a) Masonry school buildings, (b) RC school buildings designed before 1980 (pre 1980), (c) RC school buildings designed after 1980 (post 1980), by assuming 1980 as the threshold year that separate the buildings with and without seismic details. To this scope, for each unit of the three samples (N_{units}), damage data are reported in Figure 9, in which the abscissa reports the I_{MCS} identified for each municipality and the ordinate reports the mean damage (μ_D), evaluated as the weighted average of the buildings having a certain damage “DS” equal to an assigned value of damage “ds”. This formulation, as proposed in [8], is reported in the following:

$$\mu_{D,j} = \frac{1}{5} \frac{\sum_{ds=0}^5 N_{units}(DS=ds) * ds}{\sum N_{units}} \quad (1)$$

Figure 9: Vulnerability curves of RC and masonry school buildings damaged by Italian earthquakes.

Three points have been obtained for each value of I_{MCS} and all points have been fitted by lognormal cumulative functions and by optimizing the problem, assuming the minimum of the sum of squared errors between the set of points and the proposed curve. The result shows that RC buildings designed after 1980 present lower damages also for the highest values of the IM assumed, while the trend increases for RC buildings designed before 1980. Masonry buildings present substantial damages for high values of I_{MCS} , also arriving at values of μ_D equal to 0.4. Overall, the obtained vulnerability curves present a safer scenario for RC buildings than masonry ones. The observed low values of μ_D , also for higher values of IM, requires to better investigate the vulnerability of this typology of buildings, also considering other damage sources. As a matter of fact, it seems that the RC school buildings did not suffer damages.

5 CONCLUSIONS AND FUTURE DEVELOPMENTS

This study has analyzed the effects of earthquakes occurred over the last 50 years on the Italian school building portfolio. The data collected in the DA.D.O. platform have been used to perform this investigation. A database including information about masonry and RC school buildings surveyed after Italian earthquakes has been created. A critical discussion of the key features of Italian school buildings, accounting for construction typology, year of construction, number of storeys, area and structural regularity is provided. In addition, a post-processing of the damages suffered after the selected seismic events has been carried out, by providing damage probability matrices for damages on horizontal structures, stairs, roofs and non-structural elements and vulnerability curves accounting for damages on vertical structural elements.

The results of the statistical investigations have provided a basic idea about the seismic performance of Italian school buildings. The database will be used for future investigations aimed at defining a taxonomy of Italian school building and identifying the main vulnerability sources, basing on the damages suffered during past seismic events. The elaboration of the information collected in the database can assume a key role for future empirical procedures, aimed at investigating the seismic risk at regional scale for school buildings and at providing strategies of seismic risk mapping and reduction.

Abstract

Italy is one of the countries most subject to seismic risk, not only because of high seismicity, but also because of its significant exposure and vulnerability. These aspects can determine very high social and economic costs for the country. In order to have a good estimate of risk indicators such as economic losses, casualties and usability of buildings in the aftermath of an earthquake, some computation tools that perform damage and risk assessments can be utilized. Particularly, this work uses the Italian Risk MAPs (IRMA) platform developed by Eucentre, which can produce maps of conditional damage (with a selected return period) or unconditional damage (with an observation time window) to evaluate seismic risk in Italy. IRMA allows the combination of hazard and exposure data included in the platform with vulnerability models. In this case, a vulnerability model for residential masonry is implemented within the platform to obtain the as-built risk evaluation. Moreover, a retrofitted vulnerability model is also derived, obtaining fragility curves that consider the main seismic retrofit interventions that can be performed on masonry buildings. By comparing the as-built risk evaluations with the mitigated ones, it is possible to highlight the entity of the benefit after a retrofit and compare it to its cost, at territorial scale. This analysis allows the assessment of the economic effectiveness of different seismic mitigation strategies.

Keywords: Residential Masonry Buildings, Seismic Risk Assessment, Cost-benefit analysis, Retrofit Interventions, Mitigation strategies

1 INTRODUCTION

Seismic risk assessment is an essential task for countries with intense seismic activity, such as Italy. To carry out seismic risk analyses, it is necessary to deepen the knowledge about the various components of this risk at national scale, starting from the vulnerability assessment of the built heritage. Particular attention should be paid to historical buildings, as they usually represent the most vulnerable component of the built stock.

Not only is it important to correctly assess the seismic vulnerability of the buildings as they currently are (i.e., as-built configuration), but it is also essential to plan possible retrofit intervention strategies, in order to mitigate seismic vulnerability and reduce the losses due to seismic events. In order to do so, simulations of intervention strategies should be performed, and the mitigated vulnerability should be compared with the “as-built” one.

Seismic vulnerability is often expressed by fragility curves. In literature, several methods to derive fragility curves are available [1]: empirical methods, that calibrate fragility curves from damage data collected after seismic events [2, 3]; mechanical methods, based on numerical or simplified models that simulate the seismic behavior of buildings [4, 5]; and hybrid methods, characterized by features of both empirical and analytical methods [6].

In this study, the simplified mechanical method proposed by Donà et al. [7-9] was followed. Specifically, a database of 205 buildings dating from before 1919 was considered, and the seismic vulnerability for this typology was evaluated with the software *Vulnus vb 4.0* [10, 11], described at §2.1. Different vulnerability models were thus obtained, for the as built configuration and for eight retrofit solutions, considered suitable for the construction period under consideration.

As a final elaboration, the vulnerability models were used to produce seismic risk maps of Italy through the IRMA platform [12, 13], highlighting the differences in terms of benefit that each intervention can bring in different parts of the country.

The maps presented in this paper may reach very practical outcomes, and they can be used by risk management institutions (such as the Department of Civil Protection) as guidelines to prioritize anti-seismic actions. The results may suggest where to take action and with which strategies, in order to move towards a targeted risk mitigation at a national level.

2 FRAGILITY CURVES FOR ITALIAN MASONRY BUILDINGS

2.1 Elaboration of fragility sets: tools and methodology

In this work, the elaboration of fragility curves is carried out with *Vulnus vb 4.0*. *Vulnus* is a software developed by the University of Padova, which analyzes load-bearing masonry structures in a simplified way. It uses few geometrical, structural, and qualitative information to calculate three fragility curves representative of the overall response of buildings to horizontal actions. The three fragility curves represent the mean (White curve) and the extreme (Lower-Bounds and Upper-Bounds curves) probabilities of reaching or exceeding the acceleration value that triggers in-plane or out-of-plane mechanisms. For this reason, they are associated to a medium-severe damage state (DS2-3, intermediate between DS2 and DS3 of the EMS98 scale [14]).

The aim of the procedure presented in Donà et al. [8] is to define a fragility curve describing the behavior of an entire building macro-typology (i.e., of a category of masonry buildings belonging to the same construction period). For this reason, when applying the *Vulnus* procedure to a database of buildings, the curves obtained for every building have to be eventually combined. The first step of the procedure consists of averaging the single curves by municipality and by number of floors. Then, weighted means between the curves belonging to

buildings of 1 and 2 stories and between the curves of 3, 4 and 5 stories are calculated. The weights are selected following the real distribution of the different typologies in Italy, using ISTAT 2001 census data [15]. The results are two sets of DS2-3 fragility curves representative of Low Rise (1 and 2 stories) and Mid Rise (3, 4 and 5 stories) buildings.

In order to represent seismic fragility over the five damage states (from DS1 to DS5), the fragility model of Lagomarsino and Cattari [16] is calibrated on the DS2-3 mechanical fragility curves previously obtained.

Lastly, the White, Upper- and Lower-Bounds sets are combined. The average fragility defined by the White curves is maintained (mean value of the lognormal fragility curve), whereas the dispersion parameter is adapted to the extreme probabilities range. In this way, the single fragility set derived for each building typology is more suitable to represent large-scale vulnerability.

For more detailed explanations on how the procedure is implemented, please refer to Donà et al. [8].

2.2 Retrofit interventions for Pre-1919 buildings

The first goal of this study is to compare different retrofit strategies and their ability to reduce seismic risk. To do so, the most adequate retrofit interventions for the building typology under investigation were studied.

As said before, this work focuses on Pre-1919 buildings. This typology of buildings is usually characterized by stone (mainly random) and solid brick masonry, timber floors and roofs, and absence of retaining elements. The consequence is usually an inadequate response to the seismic actions, making strengthening interventions necessary.

A considerable number of studies has been published on retrofit interventions for seismic vulnerability reduction. In particular, the most effective interventions for historical ordinary buildings are the following: interventions that increase strength and compactness of walls [17-20], interventions that improve connections [21-23], and interventions of stiffening of floors and roofs [24-27].

For the construction period Pre-1919, four individual retrofit interventions and four combined ones were selected on the basis of field experiences in past works [28-30]. The final eight interventions are shown in Table 1.

<i>individual interventions</i>			<i>combined interventions</i>	
<i>MSN1</i>	1 st stage of masonry strengthening	→	<i>MSN1+TR</i>	1 st stage of masonry strengthening + addition of tie-rods
<i>MSN2</i>	2 nd stage of masonry strengthening		<i>MSN1+FLR</i>	1 st stage of masonry strengthening + stiffening of floors
<i>TR</i>	addition of tie-rods		<i>MSN2+TR</i>	2 nd stage of masonry strengthening + addition of tie-rods
<i>FLR</i>	stiffening of floors (light interventions)		<i>MSN2+FLR</i>	2 nd stage of masonry strengthening + stiffening of floors

Table 1: Individual and combined retrofit interventions considered significant for Pre-1919 buildings

Specifically, masonry strengthening consists in the application of light or single interventions for the 1st stage (MSN1), while more phases of interventions or a single overall heavy intervention are associated to the 2nd stage (MSN2). Usually, masonry interventions for Pre-1919 buildings depend on type and quality of masonry. When the masonry is inconsistent

(i.e., random rubble and multi-leaf masonry), injections of mortar are often considered, whereas FRCM-TRM reinforced plaster (Fiber/Fabric Reinforced Cementitious Matrix/Mortar – Textile Reinforced Mortars) is taken into account in presence of stone ashlar or brick masonry.

The insertion of tie-rods (TR) is another typical intervention for masonry buildings. It improves (or even creates) the connections between structural elements (wall-to-wall and wall-to-floor) and prevents the activation of out-of-plane mechanisms.

As regards to floor interventions (FLR), the most efficient solutions for historical buildings are the insertion of bracing systems or the installation of double timber planks, in order to increase the stiffness without excessively affecting the loads. In addition, connection elements anchored to the masonry and to the bearing elements of the floor must be placed to ensure the effectiveness of the intervention.

Lastly, the combined application of different interventions can improve even more the seismic response of the building.

Since Vulnus performs simplified vulnerability analyses of masonry buildings, even the interventions were implemented in a simplified way [31]. In fact, it is possible to implement some interventions directly through the options allowed by the software (insertion of tie-rods), whereas others have to be implemented indirectly, using corrective coefficients (masonry strengthening) or reproducing the effect of the intervention on the overall behavior of the building (stiffening of floors).

2.3 Fragility curves for the as-built configuration and the intervention strategies

The Donà et al. [8] methodology was implemented for Pre-19 buildings, firstly for the as-built configuration and then for each intervention presented in §2.2. Therefore, the fragility sets related to the two building sub-typologies analyzed (Pre-1919 Low-Rise - 1, 2 stories, and Pre-1919 Mid-Rise - 3, 4, 5 stories) were obtained. In Table 2 the means (μ) and standard deviations (β) of the resulting model are reported, and in Figure 1 the values of μ for each DS are compared for Low-Rise and Mid-Rise buildings.

As expected, the results show that the interventions of masonry strengthening are overall more effective than the insertion of tie-rods or the intervention on floors. In addition, combined interventions are more effective than single ones. Moreover, it should be noticed that the reduction of vulnerability deriving from a combination of two interventions is not simply the sum of the reductions of vulnerability deriving from the two interventions performed individually.

3 RISK MAPS

Once the fragility curves for the as-built configuration and the intervention strategies are defined, they can be implemented in the IRMA platform. IRMA is a tool developed by Eucentre (*European centre for training and research in earthquake engineering*) for the Italian Department of Civil Protection: it elaborates seismic hazard, vulnerability and exposure data in Italy, in order to produce damage and risk maps. The hazard used in the platform is the MPS04 hazard model, developed by the National Institute of Geophysics and Volcanology [32]. The exposure for residential buildings derives from the Italian census data (ISTAT) and is presented in terms of number of buildings, dwellings or their total floor area at municipality level. Lastly, vulnerability can be customized and has to be given as an input by the user. In this work, the fragility models defined in §2.3 were used.

Combining these three components, IRMA can elaborate maps of conditional damage and risk (i.e., the return period is selected), as well as maps of unconditional damage and risks (i.e., an observation time window is selected).

In this work, mainly the direct economic losses caused by earthquakes were taken into account. Table 3 shows the percentages of the repair (or replacement) cost as a function of building damage. In IRMA, the default reconstruction cost is 1350 €/m², and this value was kept throughout all the simulations. The parameters proposed in IRMA were calibrated on the actual repair costs incurred after the Italian earthquake of L'Aquila 2009 [33, 34].

The analyses carried out in the following §3.1 and §3.2 refer to an unconditional time window of 50 years, and are related to a type A soil (rocks or very rigid soils). Also, since the vulnerability models described in §2.3 only refer to buildings belonging to Pre-1919, all the

maps and results shown in this paper are related only to the Italian built stock from that construction period.

For further explanations about how the platform works, please refer to [13].

	<i>DS1</i>	<i>DS2</i>	<i>DS3</i>	<i>DS4</i>	<i>DS5</i>
% of total cost (1350 €/m ²)	2%	10%	30%	60%	100%

Table 3: Percentages used by the IRMA platform for computation of economic losses

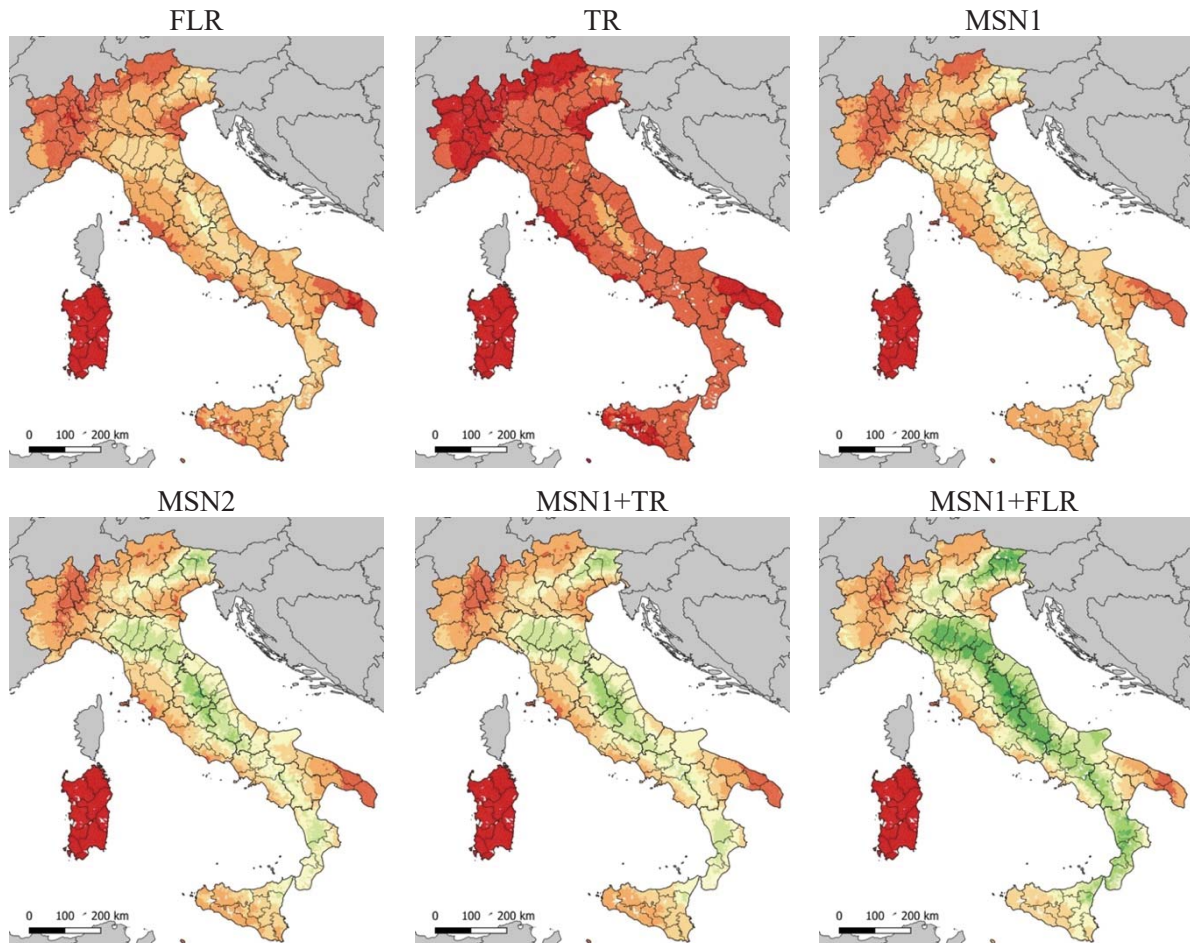

3.1 Benefit and normalized benefit

As a first step, it is useful to compute the benefit (B) expected in a time window of 50 year. B is defined as the difference between economic losses for a scenario where all the buildings are in the as-built configuration ($EL_{as-built}$) and the economic losses in case an intervention strategy is extensively implemented at national level (EL_{int}), according to equation (1):

$$B = EL_{as\ built} - EL_{int} \quad (1)$$

Of course, benefit is deeply influenced by exposure, as higher losses are expected in bigger towns with higher exposure. For this reason, it can be useful to visualize the results in terms of normalized benefit (NB): to obtain this variable, the benefit in each municipality is divided by its Pre-1919 exposure.

Figure 2 shows the maps with the NB results for all Italian municipalities, and for each possibility of intervention presented in §2.2 (both individual and combined interventions).

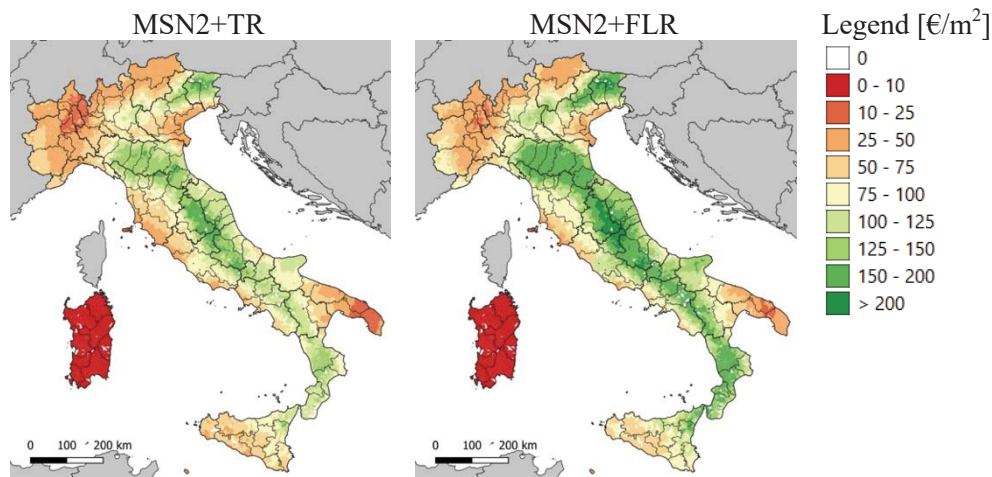

Figure 2: Normalized benefit (NB) maps of Italy for the retrofit interventions considered

It should be notice how some combined strategies lead to the same overall results as some individual ones (for example, the map for $MSN1+TR$ is very similar to the one for $MSN2$). This consideration could be significant when planning mitigation actions at territorial scale.

3.2 Cost-benefit analysis

In order to assess the real economic effectiveness of the interventions analyzed, the benefit B has to be compared with the cost C of these interventions. In particular, B is divided by C , thus obtaining an index I .

When I is equal to or greater than 1, this means that the benefit exceeds the cost, making the initial investment economically reasonable. The lower the value of I , the less economically justified the intervention will be. Table 4 shows the costs per square meter that were estimated for each intervention [35].

INTERVENTIONS	COST [€/m²]
FLR	185
TR	
<i>Low-Rise buildings (1-2 stories)</i>	110
<i>Mid-Rise buildings (3-4-5 stories)</i>	45
MSN1	140
MSN1 + FLR	330
MSN1 + TR	
<i>Low-Rise buildings (1-2 stories)</i>	250
<i>Mid-Rise buildings (3-4-5 stories)</i>	190
MSN2	210
MSN2 + FLR	395
MSN2 + TR	
<i>Low-Rise buildings (1-2 stories)</i>	320
<i>Mid-Rise buildings (3-4-5 stories)</i>	255

Table 4: Costs in €/m² for each intervention considered

In this work, the aim of the cost-benefit analysis is to identify the most convenient retrofit strategy in different Italian locations.

In this procedure, each Italian municipality will have eight indices I (one for each intervention proposed). The group of eight indices I for each municipality will match one of the following cases:

1. if some or all of them are greater than 0.5 (i.e., more than 50% of the initial cost will be totally recovered in 50 years): among the ones that meet this condition, the most performing intervention is chosen (i.e., the one that gives the greatest benefit B);
2. if some or all of them are lower than 0.5 but greater than 0.3 (i.e., between 30 and 50% of the initial cost will be totally recovered in 50 years): among the ones that meet this condition, the cheapest intervention is chosen (i.e., the ones with the lowest cost C);
3. if all the indices are less than 0.3 (i.e., less than 30% of the initial cost will be totally recovered in 50 years): no intervention strategy is considered effective enough.

As can be noticed, the value $I=0.5$ sets a decision boundary: in case interventions have $I>0.5$, their performance is taken into account, while when $I<0.5$ their affordability will be considered first. This choice can be explained remembering that the values here calculated only take into consideration the direct losses; if all the other costs were included, the values of I would approximately double [36].

Figure 3 shows the results of this calculation for each Italian municipality.

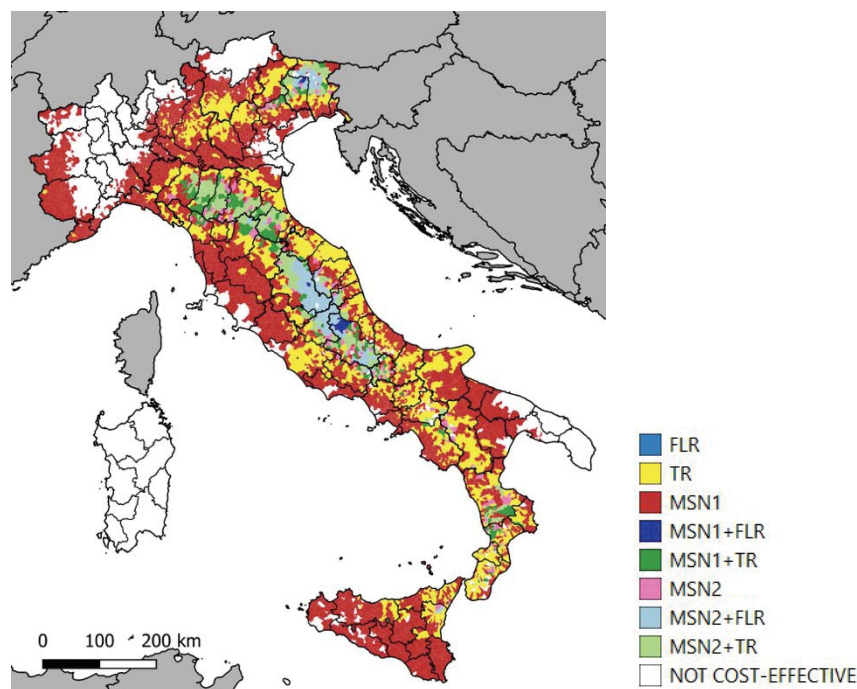

Figure 3: Cost-effectiveness map, derived from the cost-benefit analysis

Firstly, the map shows how more invasive interventions (as, for example, combined ones) are economically effective in areas with a higher seismic hazard (Central Italy, North-East Italy). The choice of which specific intervention should be implemented often derives from the exposure in the specific analyzed municipality. In zones with a medium-low seismic hazard, usually individual interventions are considered sufficient. Where seismic hazard is very low, no retrofit intervention seems economically effective in a time window of 50 years.

3.3 Recovery time of the initial cost of interventions

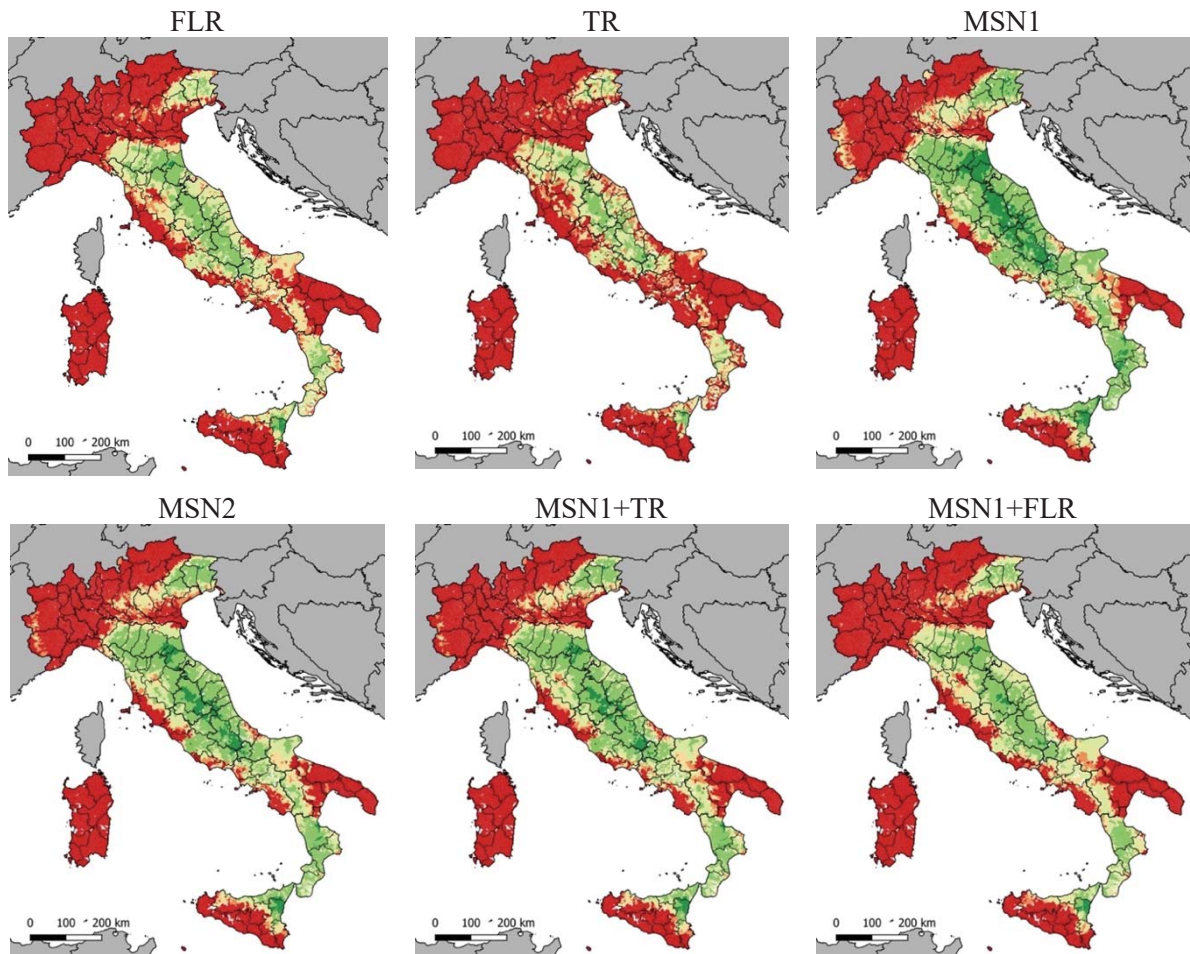

Other than the choice of the most effective intervention strategy, it is interesting to evaluate in how many years the cost of interventions can be recovered, i.e., in what year t , from the date on which the intervention was implemented, the benefit B fully recovers the initial cost C . In order to do so, the benefit is initially calculated for a time window of 1 year, and then updated year by year to obtain a gross present value (GPV), according to equation (2):

$$GPV(t) = B_{1\text{ year}} \cdot \sum_{t=1}^T \frac{(1+f)^t}{(1+r)^t} \quad (2)$$

where f is the inflation rate, and r is the discount rate. For this work, $f=0.01$ and $r=0.02$ were assumed [37].

By updating the benefit B , there will be a year t when the benefit B reaches or overcomes the initial cost C . This represents indeed the recovery time of an intervention. The maps in Figure 4 show the recovery time of the interventions considered.

The single light intervention on masonry (MSN1) results to have the shortest recovery time in large part of the national area, due to its well-balanced benefits and costs of intervention. Other types of light retrofit strategies instead, such as tie-rods, are surely less expensive, but the provided benefit appears to be insufficient to effectively recover the cost (albeit limited) of intervention.

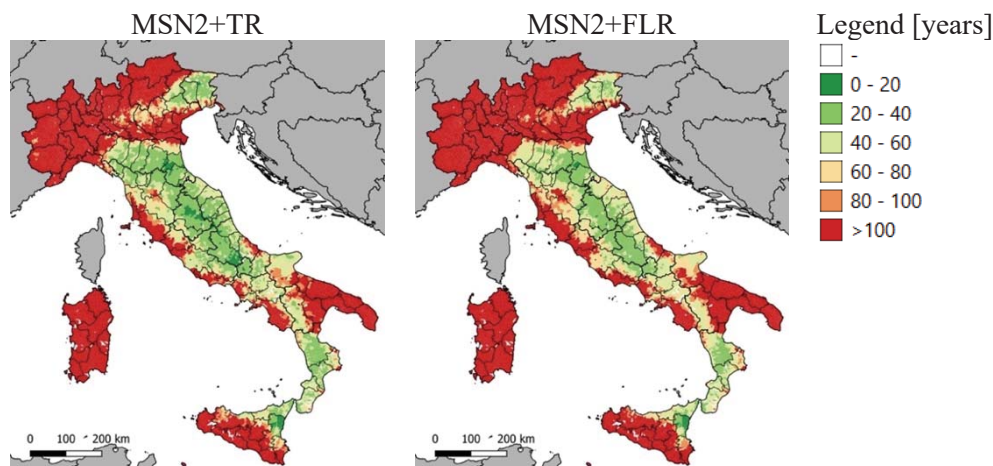

Figure 4: Recovery time of the initial cost of each intervention strategy

4 CONCLUSIONS

- A simplified mechanical method was used to create fragility curves for Pre-1919 buildings, both in their as-built configuration and with simulated retrofit interventions.
- Some applications of these fragility curves have been shown in terms of risk maps. Mitigated risk maps were created, showing the difference between the as-built configuration and the retrofitted one. Through a cost-benefit analysis, the cost-effectiveness of the retrofit interventions was evaluated. For each Italian municipality, a specific intervention strategy was considered more convenient, depending on seismic hazard and exposure. A calculation for estimating the recovery time of the interventions was also proposed.
- The maps presented in this paper can be essential tools for authorities and decision-makers, when planning risk mitigation strategies at territorial or even national scale.
- The results provided in this paper only take into account the masonry historical built stock in Italy (i.e., built before 1919). The final aim of this work is to obtain a vulnerability model (both as-built and retrofitted) also for more recent building typologies. In this way, the seismic risk analyses and the mitigation assessments will consider the whole exposure in Italy. Then, a natural progression of the present work is to carry out more detailed risk analyses in terms of economic losses (including the estimation of indirect losses), which would lead to the selection of intervention strategies in a more sophisticated way. In addition, possible casualties (in terms of injuries and victims) will have to be taken into account in order to make these estimations more valid.

ACKNOWLEDGEMENTS

Special thanks are due to the Italian Department of Civil Protection (DPC), which funded this study in the framework of the *ReLUIS-DPC Project 2019-2021 – Work Package 4: MARS (Maps of Risk and Scenarios of seismic damage) – Task 6: Preventive strategies: comparative analysis in terms of risk at national scale (Strategie preventive: analisi comparata in termini di rischio a scala nazionale)*.

We would also like to thank Eucentre (*European centre for training and research in earthquake engineering*) for creating the IRMA platform and giving access to our research unit.

THE USE OF STICK-IT MODEL FOR EDP ASSESSMENT IN EXISTING RC INFILLED TYPOLOGIES

Abstract

The estimation of expected seismic losses at regional scale represents a critical issue for the assessment of the seismic risk and for the evaluation of the seismic resilience of large communities. As a basic step, the assessment of economic losses requires the computation of the building performances in terms of engineering demand parameters such as interstorey drift ratios and peak floor accelerations in order to assess the distribution and the extent of the damage experienced by various building components. The Stick-IT model (Stick for Infilled frames Typologies) was recently proposed to predict the response, in terms of engineering demand parameters, for infilled RC building typologies. Stick-IT is a MDOF system consisting of a series of lumped masses connected by nonlinear shear link elements. The model parameters can be defined for building typologies starting from low level information that can be easily retrievable at the large scale via image-based processing techniques integrated with generic information about typical construction features, such as in plan dimensions, the number of stories or the percentage of infills openings and considering the infills consistency. This paper adopts the Stick-IT model to predict damage and expected losses for a set of RC infilled buildings located in L'Aquila town. The application shows the advantages and the potentiality of the proposed model when adopted for large scale loss assessments.

Keywords: nonlinear response history analysis; IDR; PFA; Stick model.

1 INTRODUCTION

The PEER framework [1] allows estimating the expected losses in the aftermath of damaging earthquakes involving a four-step procedure: hazard analysis, structural analysis, damage, and loss analysis. In this context, the structural analysis is required to calculate the building performances expressed in terms of engineering demand parameters (EDPs) such as inter-story drift ratios (IDRs) and peak floor accelerations (PFAs). The EDPs may be used to predict the distribution and the extent of the damage in structural, non-structural components and building contents and then, relying on suitable cost functions, are often adopted to quantify the economic losses.

At the building level, the most complete procedure to assess building structural performances consists of performing Nonlinear Response History Analyses (NRHA) on refined finite element models (e.g., [2]). However, the structural modeling and computational effort required for the analysis at the single building level are not suitable also for large-scale analyses. To overcome this issue, faster and simpler approaches are required. In this sense, different approaches were proposed in the last years relying on static analysis performed on refined [3] or simplified models [4]-[6], or on NRHAs performed on simplified models (e.g., shear models [7]). The latter models have been demonstrated to describe the non-linear characteristics and failure modes of multi-story buildings with sufficient accuracy both at the building scale and at the regional scale, enabling to capture the story-level damage concentration due to seismic loads [8]-[10]. Further, appropriate calibration of the simplified MDOF model, depending on specific features of the building typologies to be assessed, improves the accuracy of response prediction [7]. Recently, in Gaetani d'Aragona et al. [11] a simplified multi-degree of freedom (MDOF) model, named Stick-IT, was proposed to evaluate the response of building typologies representative of RC infilled moment resisting frames. The model was calibrated to represent the behavior of infilled Italian typologies and has been demonstrated to reliably predict the building response and direct economic losses when compared to more refined finite element models [12].

In Gaetani d'Aragona et al. [11] simplified formulas based on few geometrical and structural parameters are proposed to define the structural model. The formulations require assumptions in defining the infill consistency which may affect structural behavior and the assessment of repair costs [7]. The definition of these properties can be of difficult when dealing with the assessment of the behavior of a large building portfolio and need to be hypothesized on the basis of specific considerations based on construction techniques in force in the analyzed region also depending on the construction time. For this reason, in this paper, the impact of these assumptions on the assessment of repair costs is analyzed.

Following, the Stick-IT model is first briefly introduced. Next, the adopted methodology to evaluate expected seismic losses is described and an application of the model for L'Aquila town is presented.

2 STICK-IT FOR RAPID EDP ASSESSMENT

In Gaetani d'Aragona et al. [7], building typologies representative of RC infilled moment resisting frames are modeled with simplified Stick model (Stick-I), which is a MDOF Non-Linear Shear Model consisting of a series of masses lumped at the story level and connected in series by means of nonlinear shear springs; the Stick-I model is developed for each direction of the building (see Figure 1).

Figure 1: Simplified Stick model for infilled RC frames.

The story-level backbone of such spring is approximated by a four-linear backbone curve which can be defined based on 7 parameters (Figure 2). To simulate the hysteretic behavior, and in particular the pinched response and the strength and stiffness cyclic degradation of the story-level spring link element, the Pinching4 material available in OpenSees [13] is adopted. In general, such material requires the definition of 21 parameters governing the pinching response as well as stiffness and strength deterioration.

Figure 2: Definition of Stick-IT parameters for envelope curves.

In Gaetani d'Aragona et al. [11] an evolution of the stick model to predict the response of existing infilled RC typologies was introduced. The latter, denominated Stick-IT (i.e. Stick-I referred to a building Typology), is characterized by suitable parameters enabling to describe the backbone and hysteretic behavior at the generic story of the typology. In order to derive the story-level backbone and hysteretic parameters of Stick-IT, in [11] a regression study was performed on a large database, comprising 5632 Stick-I models. The database of Stick-I models was obtained with the following procedure: (a) assemble a large portfolio of building FE models with simulated design procedure; (b) determine the backbone (depending on 7 model parameters) for stick-I referring to longitudinal and transversal directions for all the building models in the generated portfolio; (c) perform calibration of the hysteretic behavior for stick-I model adopting a generic algorithm GA procedure and determine hysteretic model parameters (7 model parameters for the pinching4 material).

The regression study was finalized to describe the Stick-IT model as a function of few variables, mainly those ones that could be easily retrieved for large scale studies, e.g. from rapid on-site surveys or remote sensing procedures. As a result of the regression study performed in [11], given the building storey class n_s , the Stick-IT backbone curve at each story can be derived by the following parameters: dimension of the building in the analyzed direction ($L=L_x$ or L_y depending if longitudinal or transversal direction is considered), the normal-

ized storey number for the generic i^{th} level $n_{\text{nsi}} (=i/n_s)$ and the opening percentage α_{op} , representing the area of openings for the infills with respect to of the infill area for each panel. In addition, the infill elastic shear modulus G_w is considered to represent the infills consistency.

The model parameters for envelope curves are expressed with an exponential type formulation as in Eq. (1), that expresses the generic parameter $P_{b,i}$ of the backbone curve at the i^{th} storey:

$$P_{b,i} = a_1 + a_2 \cdot L^{a_3} \cdot G_w^{a_4} \cdot (1 - \alpha_{\text{op}})^{a_5} \cdot n_{\text{nsi}}^{a_6} \quad (1)$$

In Eq. (1) L is the dimension of the building in the analyzed direction ($L=L_x$ or L_y depending if longitudinal or transversal direction is considered), while other parameters are explained above.

Concerning the parameters defining the hysteretic behavior, a simplified approach was adopted in Gaetani d'Aragona et al. [11], assuming that the pinched behavior is symmetric in both the positive and the negative direction and neglecting the strength deterioration mode. This way the number of parameters defining the hysteretic behavior of the spring is limited to 3 pinching parameters and 4 degradation parameters depending on energy. Eq. (2) expresses the stiffness deterioration index (δk_i) as a function of n_{cyc} depending on two parameters g_{K2} and g_{K4} :

$$\delta k_i = g_{K2} (n_{\text{cyc}})^{g_{K4}} \leq g_{K_{\text{lim}}} \quad (2)$$

Similar expression can be adopted for deterioration of reloading stiffness. For further details, please refer to Gaetani d'Aragona et al. [11].

3 APPLICATION TO L'AQUILA TOWN

3.1 Building inventory

In the aftermath of L'Aquila earthquake, the Italian government fully funded the reconstruction process of damaged buildings. In Del Vecchio et al. [14] the repair costs for a database composed of 120 residential buildings damaged and repaired after L'Aquila earthquake is analyzed. The repair costs were defined and calculated, after suitable design, by practitioners during the reconstruction process. In this paper, the repair costs by Del Vecchio et al. [14] are adopted as a reference for comparison of repair cost predictions.

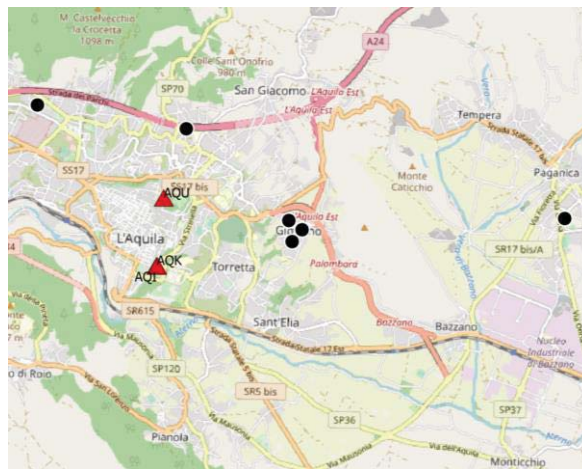

Figure 3: Location of selected buildings (black dot) and accelerometric stations (AQU, AQK).

Generally, damage and loss assessment of large building portfolios is carried by grouping buildings with similar characteristics (e.g., [15]). However, the method analyzed in this paper lend itself to be applied considering more specific building features as explained above.

For this application, a subset of 6 buildings from the database analyzed in Del Vecchio [14] was selected (see Figure 3). The buildings were selected to be close to the accelerometric station and to have approximately a rectangular shape in plan, to be representative typical height distributions in the town (3,4, and 5 stories). In Table 1, the main geometrical features for the analyzed buildings are reported, including the angle of orientation with respect to North, the number of stories (n_s), the Surface Area (SA), and the longitudinal and transverse building dimensions (L_x , L_y).

id	Angle to N(°)	n_s	SA (m ²)	L_x (m)	L_y (m)
1	5	5	274	23.60	11.60
2	30	5	256	18.00	14.20
3	45	4	90	12.70	7.10
4	45	4	170	17.00	10.00
5	30	3	210	20.40	10.30
6	35	3	193	16.60	11.65

Table 1: Geometry of the selected buildings.

3.2 Seismic hazard

The 2009 L'Aquila earthquake was characterized by a magnitude $M_w=6.3$ and a fault-normal mechanism at about 9 km depth and an epicentral distance from L'Aquila city of about 6 km. For the analysis, the acceleration time-histories recorded for the L'Aquila earthquake by two different accelerometric stations (AQU, AQK) located in proximity with the analyzed buildings were analyzed. Both ground motion records were recorded on soil class B, with a PGA ranging between 0.25-0.35g, and were extracted from the Italian Accelerometric Archive (ITACA 3.1, <http://itaca.mi.ingv.it/>). Figure 4 represents the 5%-damped Pseudo-acceleration spectrum for both records in the N-S and E-W directions.

Figure 4: 5%-damped Pseudo-acceleration spectrum for AQU and AQK ground motion records.

The horizontal components of the selected records were suitably scaled in order to account for the local amplification at the building site, and rotated according to the orientation of the principal directions of the structure [16].

3.3 Model and Structural Analysis

The structural analysis is performed via NTHA for each selected building, considering the simplified Stick-IT model generated according to the procedure described in §2 and by adopting median parameters for regression parameters. The building geometry (i.e., approximate longitudinal and transversal dimensions as well as number of stories) necessary to retrieve model features can be obtained with rapid image-based processing techniques (e.g., [17]-[18]). However, in this study, such features were derived from the original building database [14]. The analyzed buildings are assumed approximately regular both in plan and in elevation. Finally, the storey mass is obtained multiplying the surface area $SA(=L_x \cdot L_y)$ by unit load of 1.1 tons/m². For the upper story the unit load is assumed equal to 0.9 tons/m².

The infill panel consistency, represented by the infill thickness, shear modulus, and opening percentage are considered as a variable parameter to quantify its influence on the building response and assessment of repair costs. To this end, three different thicknesses for the infill panels are considered, 20cm-24cm-30cm, corresponding to weak, medium and strong infill, respectively, according to Hak et al. [19]. To simulate different infill thicknesses, the procedure proposed in [12] is adopted. The opening percentage is considered constant and equal to 20% of the area of the infill panel. The adoption of different opening percentages along the height also significantly influences the building response and the distribution of lateral deformations (e.g., [21]-[22]). However, this effect is not investigated in this study.

For each one of the two ground motion records in §3.2, each model was analyzed by rotating and scaling the ground motion components in the two separate directions (longitudinal and transverse).

The Stick-IT model is able to predict the intensity and distribution of Engineering Demand Parameters such as Interstory Drift Ratios (IDRs) and Peak Floor Accelerations (PFAs). However, in this study only IDRs are evaluated, since only damage experienced by drift-sensitive components is considered.

As an example, Figure 5 depicts the maximum IDR profiles obtained for the Stick-IT model of the building with 'id 1' (see Table 1) subjected to the two records AQU and AQR and analyzed in the two orthogonal directions. As an assumption, the longitudinal direction is the direction of maximum extension of the building in plan. For this reason, due to the largest amount of infill panels, it represents the direction characterized by higher capacity to withstand to lateral loads, and with lower deformability. In particular, due to the lower excursion in the nonlinear range for the longitudinal direction, the IDRs for AQU and AQR are much closer than those obtained in the transverse direction, where the two records may lead to significantly different IDR (due to concentration of damage) and the maximum IDR may be localized in a different story.

In particular, the Figure 5(a)-(c) depicts the shape of IDR for varying infill thicknesses. Obviously, the higher the infill panel thickness, the lower the maximum experienced IDR. However, while for the transverse direction this effect is evident, in the longitudinal direction this effect is negligible. Further, by keeping as a reference the panels with $t_w=24\text{cm}$, the maximum scatter between different thicknesses is obtained for the AQR record in the transverse direction, at the third story, where a scatter of 76% in IDR value is achieved. The effect of infill thickness produces a significant variation of IDR [22], and thus of the potential damage experienced by drift-sensitive components.

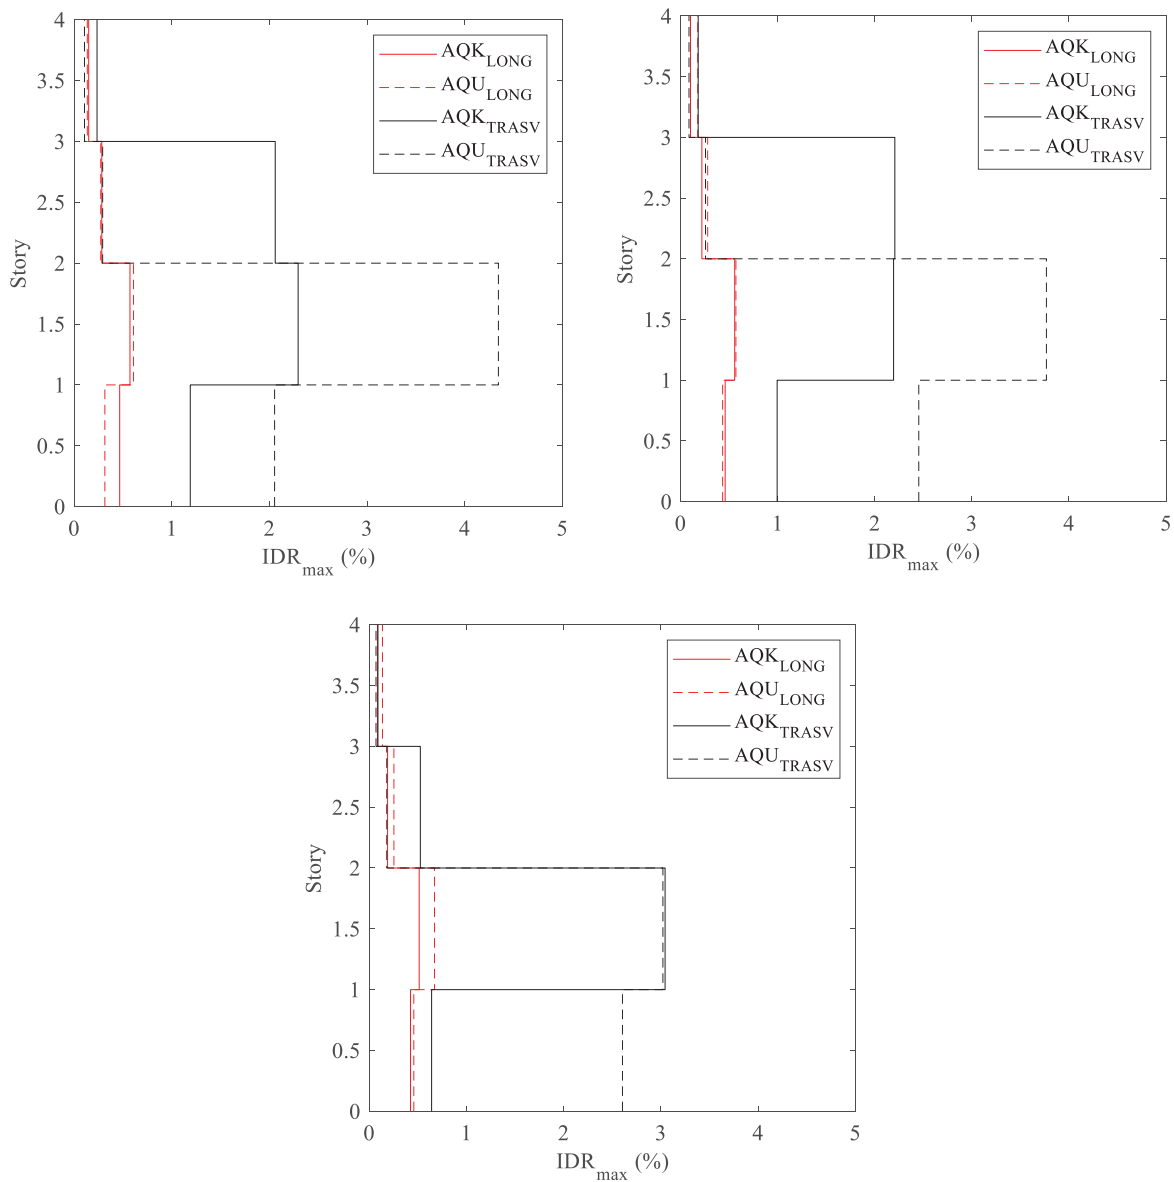

Figure 5: Distribution of maximum IDRs for (a) $t_w=20\text{cm}$, (b) $t_w=24\text{cm}$ and (c) $t_w=30\text{cm}$ for building 'id 1'.

3.4 Damage and Loss assessment

In this section the damage and loss assessment is performed adopting global indicators (i.e., EDPs) as a proxy for damage prediction. To this end, suitable EDP-dependent damage functions for both structural and nonstructural components specifically calibrated for typical Italian standard components need to be adopted. For residential buildings the largest amount of repair costs mainly depends on damage to infills and partitions [14]. For this reason, this paper limits the assessment of repair costs only referring to the costs related to repair of infill, partitions and integrated components (i.e., plumbing and electrical system, doors and windows).

With reference to the infill walls and interior partitions, Del Gaudio et al. [23] recently proposed damage fragility functions for typical Italian hollow clay infills, with and without

openings, based on the analysis of a large experimental dataset. The proposed values were adopted to capture the observed damage experienced by exterior and interior infills at different stories.

Direct losses associated to infills, partitions and integrated components are calculated by adopting the cost function developed in Del Vecchio et al. [14] for Italian standards. The functions include the cost of all the repair actions needed to restore the building to its pre-event conditions depending on the presence/absence of openings, the damage state experienced, and the extension of the damaged components.

The extent of damageable components need to be quantified based on a simulated architectural layout that can be obtained based on the procedure reported in [12]. In particular, the procedure assumes that infill wall panels extend along the whole exterior perimeter of the building, while partitions are located along each bay in each building direction. Further, it is considered that the 50% of exterior infill panels has openings while the 50% has no openings, and interior partitions are always classified as elements with openings. The simulation of the architectural layout, significantly influences the prediction of repair costs, while it has no influence on the building structural response. Thus, in this section the extent of partitions will be also varied in order to quantify the influence of this assumption. In particular, it will be considered the 100% of the extension of the simulated layout and then, the 50% and the 150% of the extension obtained for interior partitions. For instance 50% means that only the one half the bays in the longitudinal and transverse direction of the building, the number and extension of which depends on the simulated design, are filled with partitions. Finally 150% of the extension of the simulated layout means that there is the 50% more of partitions with respect to those simulated. Instead, the extension of perimeter infills is considered invariant.

Figure 6: Actual vs Predicted repair costs to infill panels, partitions and integrated components for $t_w=20\text{cm}$ - 24cm - 30cm .

The damage level was calculated by adopting as input parameters the IDR for each story and direction obtained in §3.3. The maximum repair cost between those obtained considering the records AQU and AQK is assumed as a reference. By summing up the repair cost between each story and direction, the total repair cost for infills, partitions and integrated components is calculated. For each story, it is assumed that the level of damage for the generic type of

component (i.e., infill/partition with openings or without openings) is the same throughout the story, but may be different between orthogonal directions. Figure 6 depicts the comparison between the actual and the predicted repair cost obtained by adopting different infill wall thicknesses (and 100% of the extension of infill/partitions obtained via simulated architectural layout). It can be noted that the prediction is in general acceptable, and it is most approximated when adopting $t_w=24\text{cm}$.

In particular, for $t_w=20\text{cm}$ the mean (median) ratio between the predicted and the actual repair cost for infills, partitions and integrated components is 1.39 (1.15). For $t_w=24\text{cm}$ these ratios reduces to 1.00 (1.04), and for $t_w=30\text{cm}$ to 0.93 (0.81). The maximum scatter between predicted and actual repair cost is achieved for $t_w=20\text{cm}$ and is of 134%. Thus, the mean consistency for infill panel seems to lead to more reliable predictions for repair costs. However, this assumption should be validated on a larger building database.

Another assumption regards the extension of damageable components. This is expected to be an influential parameter in terms of estimation of repair cost, characterized by a larger dispersion due to extreme variability of the possible configurations of the interior architectural layout. Obviously, the incidence on the total repair cost due to the different architectural layout of interior partitions mainly depends on the surface area of the building.

Figure 7: Actual vs Predicted repair costs to infill panels, partitions and integrated components for $t_w=24\text{cm}$ and considering 50% and 150% of simulated architectural layout for interior partitions.

As evidenced in Figure 7, which depicts the comparison between the actual and predicted repair cost considering different extensions for interior partitions (architectural layout), accounting for lower extension leads to underprediction or repair costs, while larger extension to overprediction of repair costs. In this case, by adopting the IDRs obtained considering the mean infill consistency for the model, the adoption of 50% of initial simulation of partition layout leads to a median (and median) underestimation of repair costs with respect to the actual ones of 15% and to an overestimation of 23% if a 150% of the initial layout is adopted, suggesting that the original simulated layout leads to the best prediction of repair costs. Finally, the maximum scatter between predicted and actual repair cost of $\pm 30\%$ is obtained for the single building.

4 CONCLUSIONS

This study presents the first comparisons of a simplified loss assessment procedure to evaluate expected seismic losses at the large scale.

The procedure is based on the adoption of a simplified multi degree of freedom MDOF Stick-IT model introduced in [11], which allows to rapidly calculate the performance of infilled RC buildings in terms of engineering demand parameters EDP such as interstory drift ratios, IDRs, and peak floor accelerations, PFAs, using Nonlinear Response History Analyses.

The loss assessment procedure was tested on a set of 6 buildings damaged and repaired after the 2009 L'Aquila earthquake. Firstly, main building features such as in plan dimensions and story number were retrieved, and a building inventory defined. Then, the Stick-IT model were defined for each one of the considered building. Next, after rotating and scaling two ground motion records for the L'Aquila earthquake, NRHA were performed by adopting the Stick-IT models. The response for each typology was expressed in terms of maximum IDR along building height. Finally, by adopting suitable cost functions, the repair costs for infills, partitions and integrated components are calculated and compared to the actual repair costs for these components.

In this study the validity of some assumptions to be adopted for large scale assessment purposes were tested. Firstly, the model requires the definition of the consistency of infill panels that contribute to the resistance and deformability against lateral loads. While this parameter is easy to define at the building level, it is of difficult definition for a large building portfolio for which only low-level information are available. By considering three possible consistencies according to the technical literature (weak, medium and strong), it has been found that the 'mean' consistency for infill panels generally leads to the best prediction for repair costs of infill, partitions and integrated components, while the other generally leads to an overestimation or underestimation of repair costs due to a different prediction of lateral deformations that is about 40% in terms of mean error for the considered building set, while a maximum scatter of 135% may be achieved for the single building.

Further, also the simulated design procedure adopted to quantify of the extension of damageable components was tested. This is characterized by a large dispersion due to extreme variability of the possible configurations of the interior architectural layout. The influence of this quantification alter the prediction of repair cost of about 20% in mean terms for the considered building set, while it led to a maximum scatter of about 30% for the single building. However, it is expected that the influence of this parameter is conditioned on the in plane shape ratio and the surface area of the building, and further studies are required to quantify the effect of these hypotheses.

In this proposed study, median values for definition of Stick-IT model parameters as proposed in [11] were employed. However, due to the large amount of uncertainties in the Stick-IT model definition, a fully probabilistic framework application would allow a more realistic assessment of repair costs. Moreover, time-based assessment of expected seismic losses could be performed by repeating the evaluation at various level of earthquake intensity according to the seismic hazard of the area. Future studies will address these issues.

Despite this application is limited to the assessment of infills, it shows the possibility to easily implement the proposed methodology for rapid estimation of expected losses at the large scale. Other cost-functions could be adopted, suitably accounting, e.g. for costs of acceleration sensitive components.

Abstract

Strong seismic events are the main cause of serious damage to cultural heritage, especially to historical churches characterized by a lack of efficient resisting mechanisms and by high vulnerability due to their structural systems peculiarities. Their poor seismic performance is demonstrated by the recurrence of specific seismic damage mechanisms. In this paper, an empirical probabilistic damage predictive model recently presented in the literature is used to provide a scenario dependent risk assessment in a seismic prone area in Italy. In this response model, the damage is expressed by a continuous index and the seismic action is described by a scalar intensity measure. For the illustrative case study, a sample of churches falling into a limited area of Marche Region, hit by the Central Italy 2016 seismic sequence, has been chosen. The sample includes all the historical churches belonging to the Archdiocese of Camerino-San Severino. The damage scenario following a seismic event of magnitude 5.8, generated by the Camerino fault, has been evaluated to illustrate the capability of this model in the prediction of post-earthquake situation. Risk maps obtained by means of the method presented in the paper, can provide a notable support to the organization of post-event emergency actions and to the planning of preventive actions for the risk mitigation.

Keywords: Historical churches; Seismic damage; Predictive empirical model; Shear-wave velocity.

1 INTRODUCTION

The Italian territory is popular for its high number of historical churches constituting a very dominant part of the cultural heritage for the country. Unfortunately, most of the Italian territory is characterized by high seismicity and the effects of seismic events on the cultural heritage may be destructive, as demonstrated over the last years by seismic sequences, such as Irpinia earthquake (1980), Umbria Marche earthquake (1997), Molise earthquake (2002), L'Aquila earthquake (2009), Emilia Romagna earthquake (2012), Central Italy seismic sequence (2016).

Churches are characterized by structural and typological vulnerabilities higher than vulnerabilities of ordinary masonry buildings [1]. This bad seismic performance is caused by specific architectural configurations, such as large halls, absence of internal diaphragms, and presence of vaults and arches.

Studies carried out after seismic events, highlighted that the seismic response of churches is featured by a set of macro-elements, such as façade, transept, nave, apse, characterized by independent dynamic behaviors [2]; this is also confirmed by different analytical studies on the vulnerability assessment of single churches (e.g. [3-5]) and of groups of churches (e.g. [6-8]). In addition, the analysis of the observed damage after past seismic events, such as the Umbria-Marche 1997 earthquake [9-11], the Molise 2002 earthquake [12], L'Aquila 2009 earthquake [13-15], the Emilia 2012 earthquake [16,17], and Central Italy 2016 seismic sequence [18-23] demonstrated that damage mechanisms have constant characteristics, in spite of the uniqueness of each structure.

Starting from the damage observed after the seismic events, it is possible to define empirical predictive models relating damage with intensity measure. In literature, studies on this topic provided statistical analyses of the damages and models based on a discrete description of damage (damage limit states) [10, 13, 15, 18, 21, 23, 24, 25, 26].

Moreover, thanks to the enhancement of the seismographic network in recent years, recorded ground motions allow to develop more accurate relationships between ground motion intensity measure and observed damage. Indeed, recent works avoided the approximate description provided by macro-seismic scales and preferred a description based on objective measures of the ground motion, such as the Peak Ground Acceleration (PGA) [18, 21, 23, 26].

A probabilistic response model based on the analysis of data coming from post-earthquake surveys of historical churches has been defined in [27]. This empirical probabilistic damage model relates the measure of the ground motion intensity to the overall damage index, defined in a continuous range.

In this paper, an application of this predictive probabilistic damage model has been developed, considering a strong event generated by the main local seismogenetic source that struck 514 historical churches (Archdiocese of Camerino-San Severino) located in this seismic prone area. A damage scenario following an event of magnitude 5.8 generated by the Camerino fault has been considered and the intensity measure at the site of each church has been evaluated using the Ground Motion Prediction Equations of Sabetta and Pugliese [28]. In addition, the effects of local site amplification due to soil type is taken into account by means of the specific values of the time-averaged shear-wave velocity $V_{s,30}$. The application depicts the potentialities of the model in the prediction of post-earthquake damage scenarios model, and the potential use of this risk assessment in the decision-making process by simulating a problem often arising in the post-event emergency phase, regarding the selection of those historical churches that may have suffered the highest damage levels.

2 EMPIRICAL DAMAGE PROBABILISTIC MODEL

In this section, a brief introduction of the damage probabilistic model proposed by Morici et al. [27] and used in the following, is reported.

The model assumes that the damage index is a continuous random variable D , and the values d are in the domain $[0,1]$ while the seismic intensity is described by a positive scalar random variable I , in the domain $i \in (0, \infty)$. The boundary value $d = 0$ represents the case of marginal damage while $d = 1$ represents the case of collapsed church.

The probability to observe a damage level lower than an assigned value d , given the seismic intensity, defines the system response, described by the following Cumulative Density Function (CDF)

$$F_{D|I}(d|i) = P[D < d|i] \quad (1)$$

where $d \in [0,1]$. The conditional CDF of damage, given i , can be expressed in the form:

$$F_{D|I}(d|i) = F_0(i)H(d) + (1 - F_0(i) - F_1(i))F_{D|I}^*(d|i) + F_1(i)H(d-1) \quad (2)$$

since the expected conditional Probability Density Function (PDF) is expressed by a continuous function in the open interval $(0,1)$, and discontinuities are awaited at the boundaries $d = 0$ (no damage) and $d = 1$ (collapse).

In Equation 2, $F_0(i)$ provides the probability of observing $d = 0$, $F_1(i)$ the probability of observing a damage $d = 1$, and the function $F_{D|I}^*(d|i; \Theta_d)$ is a conditional CDF describing the distribution of damage probability for the range $0 < d < 1$. $H(x)$ is the Heaviside step function, such that $H(x) = 1$ for $x \geq 0$ and it is 0 elsewhere.

The associated conditional PDF has the form

$$f_{D|I}(d|i) = F_0(i)\delta(d) + (1 - F_0(i) - F_1(i))f_{D|I}^*(d|i) + F_1(i)\delta(d-1) \quad (3)$$

where δ is the delta Dirac function that expresses the derivative of the Heaviside function, while $f_{D|I}^*(d|i)$ is the derivative of $F_{D|I}^*(d|i)$ with respect to d . Figure 1 shows the conditional CDF $F_{D|I}(d|i)$ and PDF $f_{D|I}(d|i)$ adopted in the model.

The functions $F_0(i; \Theta_0)$ and $F_1(i; \Theta_1)$ are selected from the exponential family according with the available data and model discussed in [27]. In particular, the functions assume the forms $F_0(i) = e^{-6.32i}$ and $F_1(i) = 1 - e^{-0.076i}$. The conditional PDF $f_{D|I}^*(d|i; \Theta_d)$ consists of a combination of two Exponential Distribution Functions (EDF), $f_{D|I}^*(d|i) = \frac{1}{A(i)} \left(e^{-(4.9111-9.2474i)d} - e^{-(4.9111-9.2474i)} \right) \left(e^{-(4.5176+12.4867i)(1-d)} - e^{-(4.5176+12.4867i)} \right)$ where the

term $A(i)$ is a normalization coefficient $A(i) = \int_0^1 f_{D|I}^*(d|i) dd$. Finally, in the model, the measurement of the seismic intensity is described by means of the Peak Ground Acceleration (PGA).

Figure 1: (a) Conditional CDF and (b) conditional PDF assumed in the [27] model.

3 APPLICATION OF THE PROBABILISTIC DAMAGE MODEL

3.1 Seismic scenario

In this paragraph, the evaluation of a damage scenario is presented, the Camerino fault has been considered as the seismic source and the damage expected in the set of historical churches belonging to Archdiocese of Camerino-San Severino, has been evaluated.

The Fault is located to a depth of 9-15 km (Figure 2b) and it is characterized by a potential magnitude $M_w=5.8$, testified by the seismic event of 1799 that had a complex, and probably multiple, source that produced two separate areas of maximum damage [29]. The fault belongs to the Central Apennines fault system, where the active faults consist of arrays of distinct overlapping segments which may be unconnected or linked into a single continuous fault surface [30] as illustrated in Figure 2c. In addition, unconnected adjacent faults may interact each other through their stress fields, activating different earthquake sequences [30]. However, according with [31], it is possible to assume that the surface faults, belonging to each seismogenic zone responsible for generating single seismic events with multiple ruptures, are the surface manifestations of earthquake-related deformation.

Figure 2a reports the geographic location of Camerino fault, and Figure 2b shows the distribution of the historical and recent seismic activity of the region and the areas mainly damaged after the event of 1799, identified with light blue rectangles [29]. Finally, Figure 2c displays the Central Apennines Fault System where measured active surface faults and related deep seismogenic structures are also shown [30].

The distribution of intensity measure $f_I(i)$ in terms of PGA, given the epicentral distance r and the magnitude M , is evaluated by using Ambraseys et al. Ground Motion Prediction Equation (GMPE) [28] that assumes the form

$$\log_{10}(I) = C_1 + C_2 M_S + C_4 \log_{10} \rho + C_A S_A + C_S S_S + \varepsilon(\sigma) \quad (4)$$

where $\varepsilon(\sigma)$ is a 0-mean Gaussian random variable with standard deviation σ that represent the inter-event residual, S_A and S_S are dummy variables depending on superficial soil category (rock, stiff, soft and very soft soil), $\rho = \sqrt{r^2 + h_0^2}$ contains the epicentral distance r and the fictitious depth h , and C_1, C_2, C_4, C_A, C_S are the model constants.

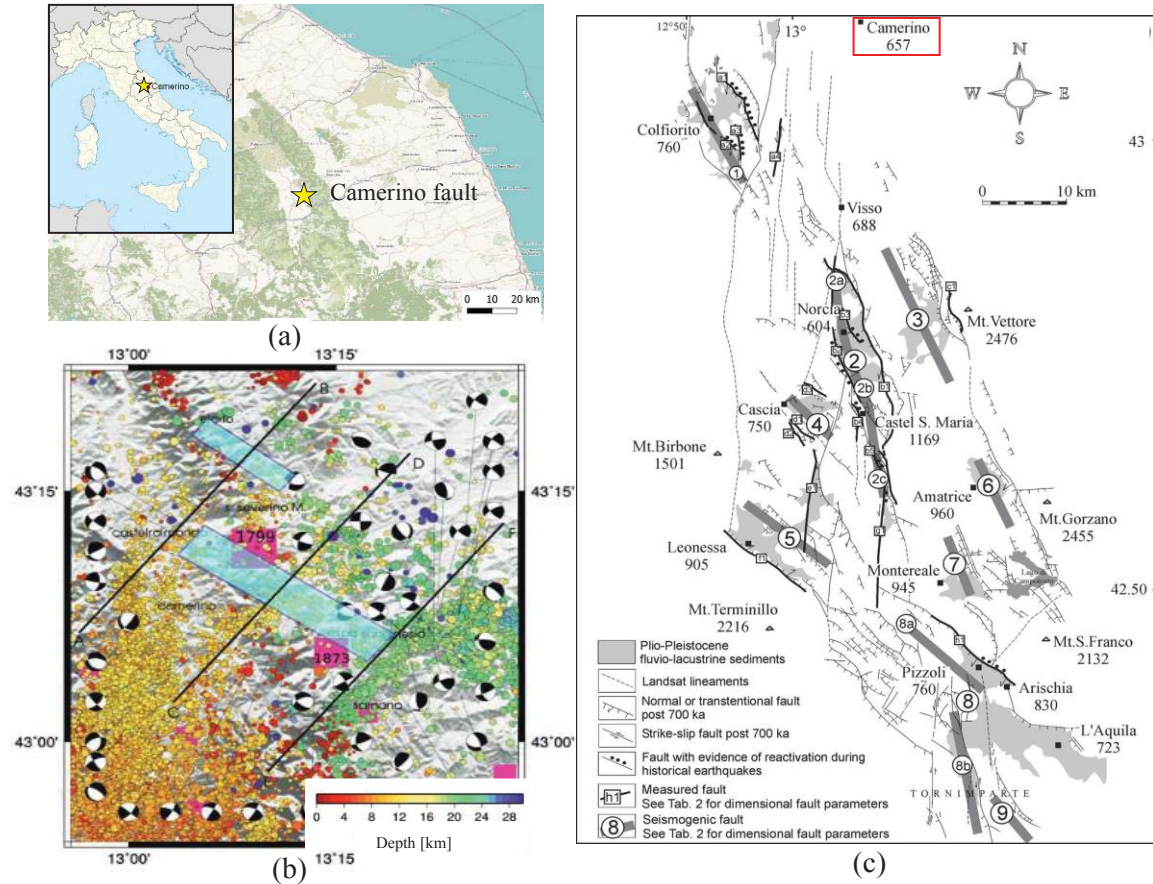

Figure 2: (a) Geographic location of Camerino fault; (b) Distribution of the historical and recent seismicity of the area with the areas mainly damaged after the 1799 earthquake [29]; (c) the Central Apennines Fault System [30].

In this study, parameters of the Eq. (4) are evaluated from the work [28] and the following values are assumed: $C_1 = -1.48$, $C_2 = 0.266$, $C_4 = -0.922$, $C_A = 0.117$, $C_S = 0.124$ and $h_0 = 3.5$, while the standard deviation of ε is equal to 0.25. The dummy variables S_A and S_S refer to the site classification: for $V_{s,30} < 180 \text{ m/s}$, $S_A = 0$ and $S_S = 1$ (very soft soil), for $180 \text{ m/s} \leq V_{s,30} < 360 \text{ m/s}$, $S_A = 0$ and $S_S = 1$ (soft soil), for $360 \text{ m/s} \leq V_{s,30} < 750 \text{ m/s}$, $S_A = 1$ and $S_S = 0$ (stiff soil), and for $V_{s,30} > 750 \text{ m/s}$, $S_A = 0$ and $S_S = 0$ (rock).

The possible effects of local amplification caused by the local geology of the site and identified by the category of soil, are evaluated by means of the $V_{s,30}$ parameter. The $V_{s,30}$ value represents the time-averaged shear-wave velocity to 30 m depth, and it is representative of the soil deformability. The specific $V_{s,30}$ of each church site has been selected on the basis of the studies of USGS [32-33].

Figure 3 shows the distribution of the $V_{s,30}$ at each church site derived from the USGS $V_{s,30}$ Map Viewer. The table reports the number of historical churches placed in sites with different range of $V_{s,30}$. Figure 4a shows the distribution of the mean value of intensity measure for each k^{th} church ($k = 1, \dots, 514$) where the index has been assigned after the churches have been ordered according to the expected intensity measure. Figure 4b reports the PDF of the intensity $f_i^k(i)$ expected at each k^{th} church, considering their epicentral distance and the relevant $V_{s,30}$.

It can be observed that the seismic intensity is mainly related to the epicentral distance while the local amplification related to $V_{s,30}$ plays a secondary role.

The distribution of damage can be evaluated by combining the damage model with the distribution of seismic intensity:

$$F_D^k(d) = \int_{\mathbb{R}^+} F_D(d) f_I^k(i) di \quad (5)$$

where $F_D^k(d)$ is the CDF of the damage relative to the k^{th} church.

Figure 5 reports the CDF $F_D^k(d)$ and the related PDF $f_D^k(d)$ of damage for each church. It can be noticed that the probability of observing undamaged churches ($d = 0$) increases with the reduction of the seismic intensity.

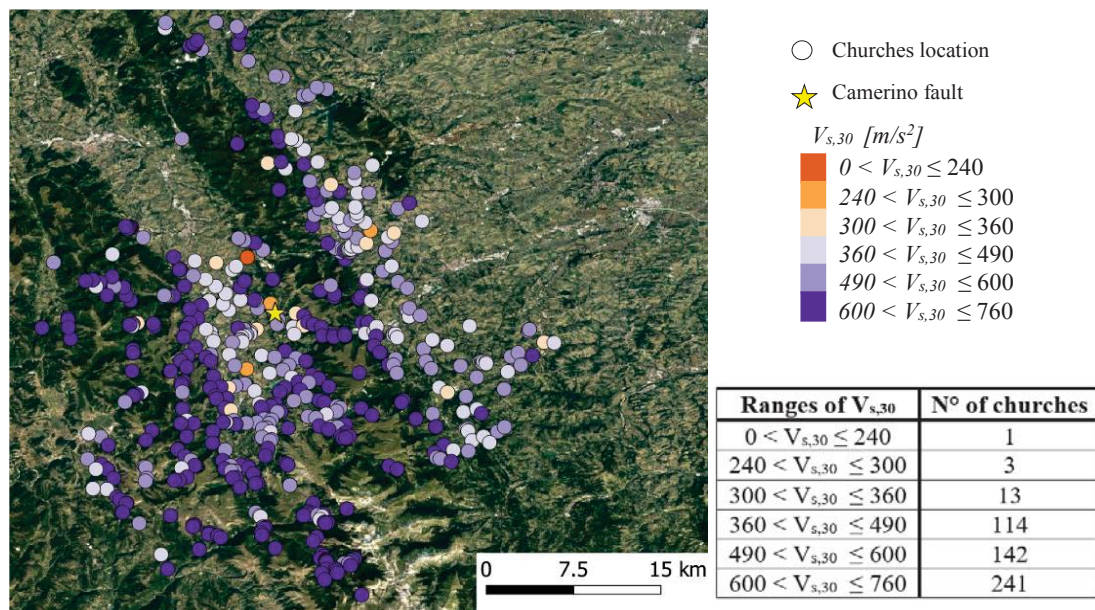

Figure 3: $V_{s,30}$ distribution over the territory for the churches of the Archdiocese of Camerino San-Severino.

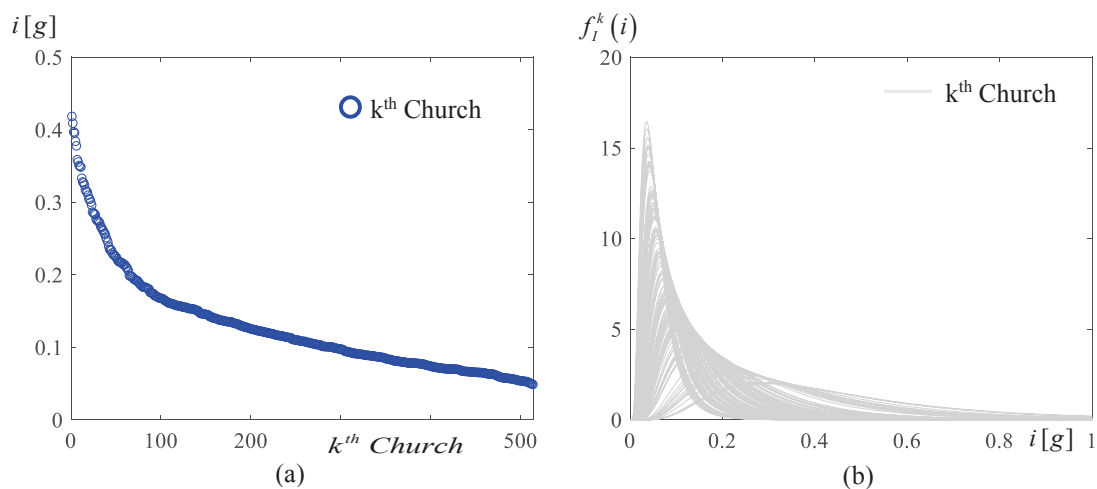

Figure 4: (a) mean expected intensity measure of seismic hazard; (b) distribution of intensity given epicentral distance

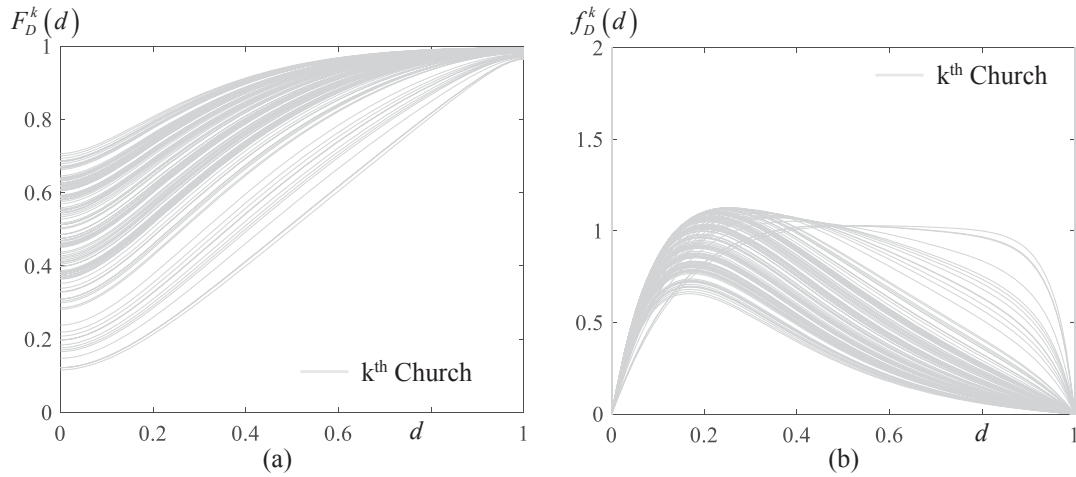

Figure 5: Damage distribution given epicentral distance and $V_{S,30}$: (a) CDF $F_D^k(d)$ and (b) PDF $f_D^k(d)$.

Figure 6a shows the distribution of the mean damage μ_D^k and $\mu_D^k \pm \sigma_D^k$ where σ_D^k is the standard deviation of each church, over the seismic intensity. Figure 6b reports the 25th percentile, the median, and the 75th percentile for the damage of each church. Moreover, also the extreme values corresponding to the 5 and 95 percentiles are reported.

Finally, Figure 7 describes the overall damage scenario expected for the churches of the Archdiocese of Camerino- San Severino, by combining results obtained from the damage models with the location of the historical churches. In details, the expected mean value of d of each church is illustrated by a red color scale and the table reports the number of historical churches suffering of different levels of damage.

Figure 6: Damage distribution given seismic intensity (a) mean damage and (b) percentiles of damage.

3.2 Decision making

The damage scenario, that represents the combination between the response model and the seismic hazard, may be used to take decisions concerning specific actions oriented to mitigate the seismic risk or to improve the emergency management.

In particular, the following decision problem concerning the emergency management is considered to illustrate the potentialities of the methodology presented for the risk assessment.

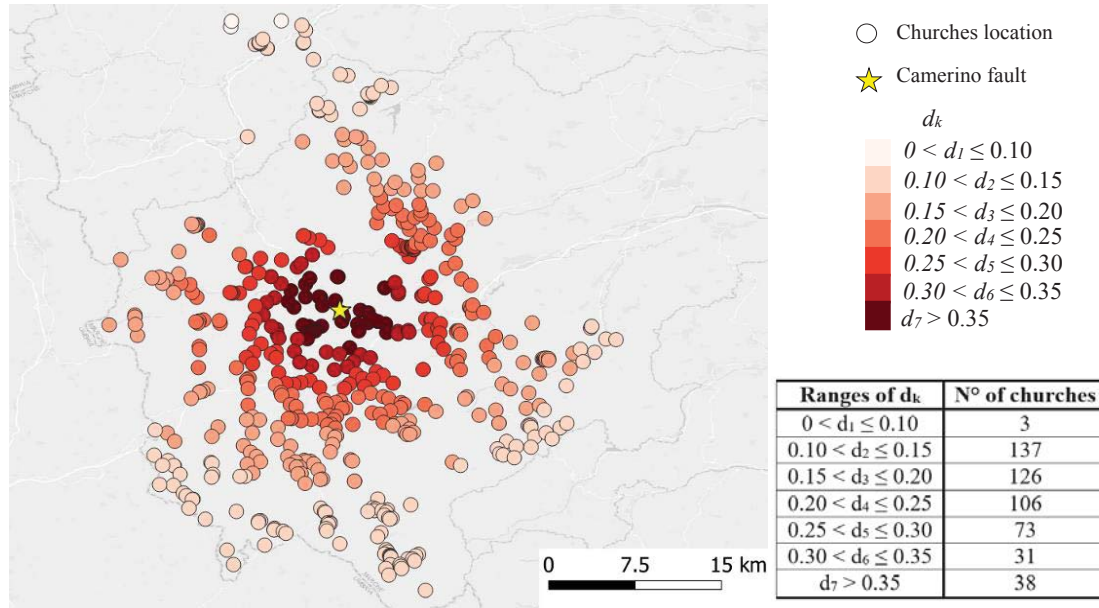

Figure 7: Damage distribution over the territory for the churches of the Archdiocese of Camerino San-Severino.

After a seismic event, the total set of churches must be divided into two subsets where, in one case, a damage larger than an assigned threshold is expected while, in the other case a damage lower than this threshold is expected. The sub-division is based on the location of the churches. A percentage of misclassification is expected in both the subsets, and the study wants to divide the total set in such a way that the misclassification is minimized.

The churches have been classified considering the median value of the seismic intensity at their site. This is an information usually available after the seismic event and it depends on the church location only, so that a classification based on the geographical position is possible. The median value of the intensity can be evaluated by Eq. 4, neglecting the last term related to the uncertainties. A threshold i_0 is chosen to divide the total set into two subsets where the median value of the expected intensity is lower or higher than i_0 .

The number of churches falling in the set where the median value of the intensity is lower than i_0 is denoted by $n_0(i_0)$. It can be concluded that the total probability to observe the event E_0 in this subset can be obtained by combining the probability to observe a damage lower than the threshold \bar{d} with the probability of selecting a church in this subset

$$P_E[E_0|i_0] = \frac{1}{n_0(i_0)} \sum_0^{n_0(i_0)} \int_0^{\bar{d}} f_D^k(d) dd \quad (6)$$

while $P_E[E_1|i_0] = 1 - P_E[E_0|i_0]$ provides the probability to observe the event E_1 within the same subset.

In this analysis, two threshold damage values $\bar{d} = 0.1$ and $\bar{d} = 0.2$ have been considered. Figure 8 shows the trends of $P_E[E_0|i_0]$ and $P_E[E_1|i_0]$, the value of seismic intensity i_0 that minimizes the probability of misprediction is highlighted by the dashed line. The optimal values of the seismic intensities i_0 are 0.1240g for $\bar{d} = 0.1$, and 0.1708g for $\bar{d} = 0.2$, respectively.

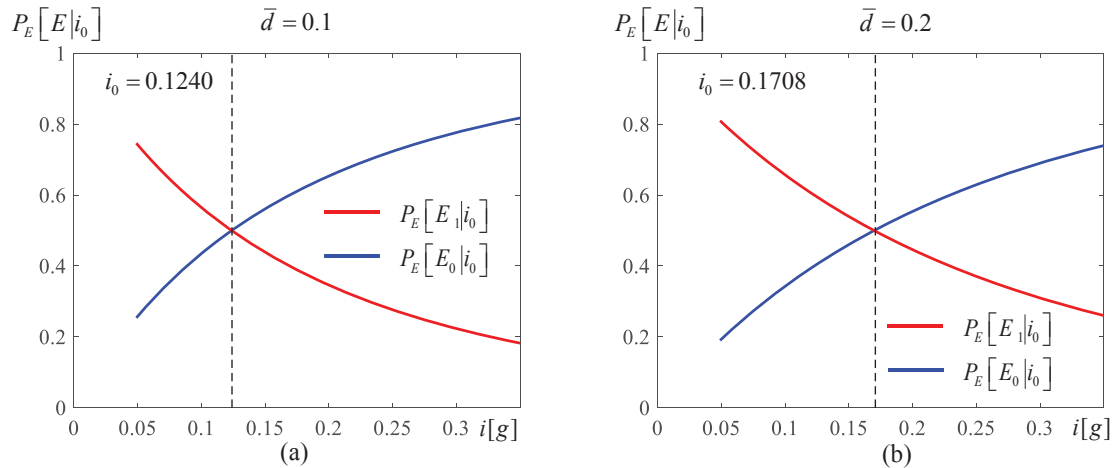

Figure 8: Probability of the two events E_0 and E_1 for different threshold of the intensity, for $\bar{d} = 0.1$ and $\bar{d} = 0.2$.

4 CONCLUSIONS

An illustrative application, starting from the empirical predictive model for the seismic damage of historical churches recently presented in the technical literature, has been proposed in this paper. In this empirical probabilistic model, the damage is expressed by a continuous index and the seismic action is described by a scalar intensity measure. A sample of churches falling into a limited area of Marche Region hit by the Central Italy 2016 seismic sequence has been chosen for the illustrative case study.

A specific scenario has been considered, assuming a seismic event of magnitude 5.8 generated by the Camerino fault. The probability distribution of damage has been evaluated for 514 historical churches, according to their locations and the mechanical properties of the soil. Results have been discussed and risk maps have been presented.

Potential use of this risk assessment methodology in the decision-making process has been illustrated by simulating a problem often arising in the post-event emergency phase: the selection of those historical churches that may have suffered the highest damage levels.

Abstract

In this paper, a framework developed for the seismic risk assessment and loss estimate of the Health-Care sector is described. The methodology herein presented derived from a wider study that refers to a multi-hazard (earthquake, hurricane, flood, landslide, rockfall, avalanche) and multi-asset (healthcare and energy infrastructure).

The loss estimate is based on the probabilistic modelling of hazards and asset vulnerability and an overall assessment of the impact generated from the suffered damage treated as a deterministic consequence of it.

Specifically, the total impact computation is based on the combined analysis of different aspects, such as physical damages, service reduction, and social impact. For the sake of completeness also the impact is evaluated per each aftermath level. It must be pointed out that in so doing the loss computed per each impact can be ensured as hazard independent.

An important role in the impact evaluation is also played by resilience. A simplified evaluation of preparedness and resourcefulness at asset and local level is performed to originate a set of resilience-based coefficients which, in turn, are used to influence the evaluation of the loss per each impact component and level of damage.

Finally, the Expected Annual Loss (EAL) is provided as the exponential relation between the probability of damage occurrence expressed as mean annual frequency, and the loss, expressed in economic terms. So, this relation can define the properties of damage occurrence and loss of each possible event. Thanks to the quantitative approach of the framework it can be seen how each risk aspect influence the curve properties, such as the horizontal stretch due to resilience influence on the loss degree and the vertical stretch due to vulnerability effect on the damage occurrence.

Keywords: Asset Integrity Management, Loss assessment, Probabilistic assessment, Expected Annual Loss, Territorial scale, Decision Support System

1 INTRODUCTION

When assessing the risk posed by a certain hazard the first parameter to be qualified is its frequency of occurrence. The definition is deeply related to the relevant historical data for a given geographic reference. The determination of the hazard alone cannot be directly used if not correctly correlated in space and time.

The determination of the hazard starts from the qualitative depiction of a plausible threat scenario for which the occurring frequency is determined. The definition of exposure calls into play the time and spatial correlation as some areas might be more prone to a certain hazard rather than others (e.g. the threat of an earthquake is deeply correlated to the geographic location of an asset and the surrounding context).

Along with the determination of possible threats and relevant frequencies, the vulnerability of the asset shall be determined as well using a structural and logistics assessment. The impact could be evaluated for different kind of assets as well as for different kind of targets. The weighted average of all the estimated impacts (damages) arising from the execution of a threat is called Impact.

Figure 1: Key elements of Risk Assessment

2 HAZARD ASSESSMENT

In the proposed methodologies the Hazard is considered through the definition of the Hazard curves (Figure 2). They describe the frequency of occurrence of the Intensity Measure (IM) of a certain hazard (e.g. PGA for earthquake), allowing in this way extended and detailed analyses. For the Hazard data collection, it will be possible to consider the following sources:

- Literature Databases;
- National Codes (it provides the procedure to obtain the hazard curve, if available);
- Websites Databases;
- Thematic maps on hazard distribution produced at the national level.

In the case of Literature databases and National Codes, besides having the entire hazard curve, we can obtain a limited number of IMs with the associated frequency/probability of occurrence. In this case, the few data available (IMs) can be used to build up the hazard curve through a fitting process through power or exponential laws, following the procedure presented hereafter.

2.1 Hazard curve definition

The Peak Ground Acceleration (PGA), expressed in g, are commonly given for 4 different percentage of exceedance in 50 years, which are commonly 2%, 10%, 50%, and 68%.

The hazard is often expressed in terms of exceedance probability, rather than in terms of exceedance rate (number of events per unit time). The exceedance probability is the probability that a certain intensity will occur at least once in a given period.

The two can be related using a concept called a Poisson process, which is a stochastic process that counts the number of events and the number of times in which they occur in a given interval. The relationship is explained in the following formula:

$$G = -\ln(1 - P)/t \quad (1)$$

In which G is the occurrence rate (i.e. events per unit time) that is expressed as the inverse of the return period Tr , while P is the probability of occurrence of at least one event in the considered period t .

Based on this formulation the occurrence rate, Mean Annual Frequency (MAF), and the return periods (Tr) can be calculated considering a reference period $t=50$ years:

$$\begin{aligned} MAF &= -\ln(1 - P) / 50 \\ Tr &= 50 / \ln(1 - P) \end{aligned} \quad (2)$$

Therefore, The Mean Annual Frequency (MAF) and the return period (Tr) can be computed by the 4-given percentage of exceedance in 50 years (Table 1).

Probability in 50 years	Tr	MAF
%	y	1/y
2	2475	0.0004
10	475	0.0021
50	72	0.0138
68	40	0.0228

Table 1: Mean Annual Frequency values (MAF) – Earthquake case

For each site is possible, by using the IMs (e.g. PGA for the earthquake) of the different return periods and the MAF, to define the hazard curve (Figure 2) by fitting the 4 points.

Figure 2: Typical Hazard curves for Earthquake

3 VULNERABILITY DEFINITION

Vulnerability is a measure of asset damage/failure due to a hazardous event. As an alternative, it could be also defined as the target's inability to deter and withstand the specific disaster. The assessment can be defined considering three different factors: Geographical location; Hazard response; Target hardness.

The vulnerability assessment is made by an exhaustive Database generated through the knowledge from literature, internal resources or by directly inputting the fragility curves parameters, in case of ad hoc developed fragility curves.

For each asset category, 4 damage states are selected (DS1, DS2, DS3, DS4), defined to represent the most important probability of exceedance, following the *Hazus* [5] subdivision of damage levels.

DS1 (Slight)	Flexural or shear type hairline cracks in some beams and columns near joints or within joints
DS2 (Moderate)	Most beams and columns exhibit hairline cracks. In ductile frames, some of the elements have reached yield capacity, showing larger flexural cracks and spalling. Nonductile frames may exhibit larger shear cracks and spalling
DS3 (Extensive)	Some of the elements have reached the ultimate capacity. In ductile frames large flexural cracks, spalled concrete and buckled reinforcement occur. The nonductile elements may experience shear or bond failures at reinforcement splices, or broken ties or buckled reinforcement in columns, leading to a partial collapse
DS4 (Complete)	The structure is collapsed or in imminent danger of collapse due to brittle failure of nonductile elements or loss of frame stability. Approximately 13%(low-rise), 10%(mid-rise) or 5%(high-rise), respectively for low/mid/high-rise, of the area of buildings, is expected to be collapsed

Table 2: Limit states description [5]

As can be seen in Figure 3 and Table 3, for each asset category is set 4 levels of damage, which represent 4 levels of criticality. For each damage state is defined:

- Percentage of damage, per each level and asset, which are stored in an internal database;
- The description of the visible effect on the facility per each damage level (Table 2).

This subdivision in 4 levels is useful to check out the probability of damaging and to know also the damage level that can be reached with this value of probability. The 4 levels are used in this analysis to reach a desirable level of simplicity, without losing the minimum level of accuracy required. Therefore, this kind of subdivision gives the possibility to set, among the different subsectors, different criticality levels depending on the specific asset considered.

In the following tables, characteristics (structural and temporal) and parameters (mean values and standard deviation) used respectively to select and define the fragility curves are listed.

Asset	Parameter 1	Parameter 2	Mean values [g]				Standard deviation			
			DS1	DS2	DS3	DS4	DS1	DS2	DS3	DS4
Hospital	1-3 storeys	pre-1950	0.09	0.18	0.30	0.42	0.78	0.74	0.73	0.73
	4-7 storeys	pre-1950	0.02	0.15	0.24	0.29	0.97	0.69	0.67	0.67
	8+ storeys	pre-1950	0.07	0.19	0.37	1.24	0.74	0.66	0.64	0.64
	1-3 storeys	post-1950	0.12	0.29	1.67	2.17	0.75	0.71	0.70	0.70
	4-7 storeys	post-1950	0.10	0.21	0.86	1.70	0.66	0.64	0.64	0.62
	8+ storeys	post-1950	0.10	0.27	1.58	4.26	0.63	0.60	0.59	0.53

Table 3: Limit states description [7]

For the selection of the appropriate Fragility curve (Figure 3) many parameters are considered, such as the principal construction material, construction typology, year of construction, the presence or not of codes during the design phase of the asset, dimensions of the asset (e.g. footprint, ground floors, n° of stories etc.).

A specific database is built with standardized unitary value to overcome the potential lack of information. So, starting from the main characteristics of the asset, the fragility function can be selected. In Figure 3 an example is shown.

Figure 3: Example of fragility curves

4 IMPACT ANALYSIS

The Impact is defined as the presence of people, livelihoods, species or ecosystems, environmental functions, services, and resources, infrastructure, or economic, social, or cultural assets in places and settings that could be adversely affected by a hazard. Therefore, it can be seen as the scale of the consequences of a hazard.

The impact is normally quantified in the determination of damages and losses caused to stakeholders, environment and human life. In this particular study case, the analysis of the impact is based on the analysis of three different categories:

- Impacts on People (fatalities/injuries);
- impacts on the Physical System/Infrastructure (damages on the structures);
- impacts on Service continuity (interruptions/downtime).

The evaluation of each component is also provided in economic terms; in such a way the combination of the three is possible, providing a unique impact value.

4.1 Impacts on People

The analysis of the impact on the people (IP_{DSi}) is based on the evaluation of the number of fatalities and injuries [6] due to the occurrence of a certain hazard. The methodology used is based on the definition of three categories: Death, Slightly injured, and Severe injured.

The evaluation is provided according to the relation carried out by *Cimellaro et al.* [1], in the paper the percentage of death and injured people is related to the damage state that occurred after the hazardous event.

	U.M.	DS1	DS2	DS3	DS4
Death _{DSi}	%	0.000	0.000	0.0015	12.500
Injury _{DSi}	%	0.000	0.030	0.1005	22.500

Table 4: Normalized human losses ratios for different damage state [1]

The number of deaths can be obtained by multiplying the death loss ratio shown above (Table 4) with the number of people inside the hospital:

$$Death_{DSi} = Death_{DSi}(\%) \cdot \delta_t \cdot People_in_hospital \quad (3)$$

In which $Death_{DSi}(\%)$ is the percentage derived from Table 4, $People_in_hospital$ is the number of people in the hospital, and δ_t is the coefficient of reduction that consider the effect of the asset preparedness on the people evacuation (section 5.1).

Furthermore, thanks to the *Syner-G* [2] a further distinction could be made on the injury. They are divided into slightly and severely injured through the severity injured ratio ζ that typically varies between 1/3 and 1/2 (in the evaluation 1/3 is used).

It must be pointed out that some further consideration must be performed on the analysis of the severely injured. They are assumed to be the people which need surgical treatment, thus they are considered as the Hospital Treatment Demand, HTD, which must be compared with the Hospital Treatment Capacity per hours, HTC [2].

$$HTD_{DSi} = People \cdot (1 - \delta_p) \cdot Severe_injured_{DSi}(\%) \quad (4)$$

In which δ_p is the percentage of people evacuated within the due time (section 5.2).

The people affected are obtained by the district density and the analyzed area:

$$People = density_{distric} \cdot Area \quad (5)$$

The area used for this evaluation should be selected as the minor between the influence area of the hospital and the hazard area:

- Influence Area: A rough area of influence per each hospital is evaluated simply implementing the Voronoi Diagram using the hospitals as discrete points;
- The hazard area rather is defined as the one on which the considered hazard produces the selected damage. It can be defined considering the attenuation function of the hazard intensity, starting from the studied point. In literature several examples can be found, e.g. for the earthquake, this area is defined according to the empirical attenuation formula for the PGA [8]:

$$\log(a) = \alpha + \beta \cdot M - \log(r) + b \cdot r \quad (6)$$

$$r = \sqrt{d^2 + h^2}$$

Where d is the distance from the source which can be computed per each damage state through a solver algorithm. The other parameters are: a is in g, α is -1.09, β is 0.238, b is -0.0005, and h is 6.0 for horizontal PGA [8].

	U.M.	DS1	DS2	DS3	DS4
Severe injured	%	0.00	$\zeta \cdot 0.03$	$\zeta \cdot 0.1005$	$\zeta \cdot 22.50$
Hazard area	km ²	Empirical evaluation of affect area			
Hospital influence area	km ²	Voronoi Diagram			

Table 5: Hospital Treatment Demand evaluation

The hospital Capacity per one day is computed considering the operative functionalities decay after the hazardous event [2].

$$HTC_{DSi} = \frac{1}{\delta_{int}} \cdot \frac{\gamma_{1,DSi} \gamma_2}{t_m} \cdot 24h \quad (7)$$

Where $\gamma_{1,DSi}$ is the number of operating theatres which remain operative after the hazardous event, γ_2 is a Boolean function (equal to 1 if the system “survives” and to 0 otherwise), t_m is the mean duration of a surgical operation, measured in hours (in this study this value is assumed equal to 2h according to [2]), and δ_{int} is the coefficient that considers goodness of the internal coordination among facilities and department (section 5.4).

The number of operating theatres (γ_1) is evaluated by considering the decay of the capacity of the hospital:

$$\gamma_{1,DSi} = OT \cdot (1 - Service_{DSi}) \quad (8)$$

In which OT is the number of operating theatres and $Service_{DSi}$ represent the percentage decrease of the hospital service, which can be derived from literature per each damage state.

The economic loss due to the impact on the people (IPDSi) can be evaluated by considering two different aspect:

- The “direct” death due to the event (computed by people inside the hospital).
- If $HTD > HTC$, the “indirect” death is determined as the severely injured people that cannot have access to the surgical treatment (computed using the people inside the so-called influence area) [2].

Therefore, the number of human life losses can be multiplied by the mean value of human life.

$$IP_{DSi} = \{Death_{DSi} + [(HTD_{DSi} - \delta_{E2} \cdot Share_P \cdot N_Hospital) - HTC_{DSi}]\} \cdot Life\ Value \quad (9)$$

In which *Life value* is expressed in k\$/person and δ_{E2} represents the coefficient related to hospital redistribution capacity during an emergency (section 5.6).

Share_P represent the sharing capacity between two hospitals, calibrated considering the average number of patients that can be relocated during an emergency. It sets equal to 35, based on the experience derived from the Italian 2020 healthcare crisis due to Covid-19 [13].

$N_Hospital$ is the number of hospitals within the sharing distance, which in first approximation is set to 30km. Such value is computed by the hospital influence area, according to the following formulation:

$$N_Hospital = 2 \left[\left(\frac{30km}{2\sqrt{A_{inf}/\pi}} \right) + 2 \right] \quad (10)$$

To have a better understanding of the approach a simplified scheme is listed below.

Figure 4: Hypothetic sharing scheme

- The points in this scheme represent the hospitals.
- A_{inf} , which is drawn in green is the area of influence of each hospital. It can be computed as the mean of the district/province.
- r_{inf} is consequently the radius of influence.
- 30km, as said before, represents the distance over which the sharing is no more feasible.

Therefore, the value inside the round bracket should be rounded down. Since inside the square bracket, an integer number must be used, because it represents the number of rings of hospitals inside the sharing distance.

4.2 Impacts on Physical system

The impact on the physical system (ID_{DSi}) can be defined as the impact cost due to the direct damage experienced by the facility [6]. The economic loss can be ease defined as follow:

$$ID_{DSi} = Damage_{DSi}(\%) \cdot Reconstruction_Cost \quad (11)$$

In which $Damage_{DSi}(\%)$ is the damage value associated with each damage state, that can be derived from literature per each damage state [3], while $Reconstruction_Cost$ is the expected cost to take back the asset to full operation, comprehensive of both structural and equipment cost. It can be calculated in two different way: directly calculated from the construction cost or indirectly derived from dimension and the unitary cost, taken from the literature [4].

4.3 Impacts on Service continuity

The impact on service continuity (IR_{DSi}) can be related to the effects on the population, of the reduction of the service due to damage [6]. The evaluation is based on the information on the mean recovery time and service reduction per each damage state, according to the relation carried out by *Cimellaro et al.* [1].

The additional time that the people need to get access to the health care facilities is the base of the economic loss evaluation. As can be seen in the following formula the recovery is considered as a linear function:

$$IR_{DSi} = \delta_{rec} \cdot t_{r,DSi} [Service_{DSi}(\%) \cdot (Size - \delta_{E1} \cdot Mobile_P \cdot Gr)] (2t_{dist} \cdot Value_{time}) \quad (12)$$

Where $Service_{DSi}(\%)$ is the percentage of service reduction per each damage state, that can be derived from literature per each damage state, $t_{r,DSi}$ is the recovery time, that can be derived from literature per each damage state, t_{dist} is the time needed to reach the nearest facility per each damage state, $Size$, it must be expressed by the characteristic unit of measure (number of people), $Value_{time}$, it is the value of the people time, δ_{E1} represents the coefficient related to the accessibility to the eventual mobile health care post (section 5.5), δ_{rec} is the coefficient that considers how the recovery is carried out (section 5.3), $Mobile_P$ represent the number of patients that can be endorsed by this mobile healthcare post, that usually has a capacity of 25 beds [14], and Gr represents the ratio among bed capacity and the average people inside the hospital.

Total impact

The total impact ($I_{TOT,DSi}$) is evaluated by summing the different economic losses categories per each damage state, as shown in the following formula:

$$I_{TOT,DSi} = IP_{DSi} + ID_{DSi} + IR_{DSi} \quad (13)$$

In which IP_{DSi} is the Impact on People economic loss, ID_{DSi} is the Impact on Physical System economic loss, and IR_{DSi} is the Impact on Service Continuity economic loss.

5 RESILIENCE

The term resilience means the ability to prepare for and adapt to changing conditions and withstand and recover rapidly from disruptions, it includes the ability to withstand and recover from occurring threats or incidents.

The resilience is evaluated using a score index (from 0 to 3). Three main categories are considered for its definition:

- Preparation (planning in advance), which consider the existence/status of emergency plans (P1) and the frequency of training courses/exercise (P2), the existence of insurance cover (P3), the existence of backup systems (P4), the community experience on the hazardous event (P5), and the warning time before the hazardous event (P6).
- Internal resourcefulness considers the effectiveness and availability of resources, such as early warning system and/or specific countermeasure (Int1), materials to offset the loss (Int2), and coordination with facilities/department of Hospitals (Int3).
- External resourcefulness in which are considered the existence of the external agreement and coordination plants with other subjects: institution and/or organizations (Ext1), public units and/or local government institutions (Ext2), provincial health directorate institutions (Ext3), and special treatment units of hospitals (Ext4).

Resilience is considered in the risk assessment through the evaluation of resilience (I_{Res}). The score of each asset is therefore evaluated developing a resilience matrix (Table 6), in which the score can be obtained for every single hazard or as the total one. The final value of the resilience index is computed by a weighted average [9]:

$$I_{Res} = \sum_{i=1}^3 RC_i \cdot W_i \quad (14)$$

Where RC_i is the resilience component score and W_i is the weight of each component.

Earthquake	Preparation	Internal Resourcefulness	External Resourcefulness	I_{Res}
Score [0 to 3]	1.76	3.00	3.00	84%
Weight	0.38	0.316	0.304	1

Table 6: Resilience analysis matrix (example of compilation)

It is important to note that the Resilience Index is a way to compare the levels of resilience of critical infrastructures and to help the prioritization of investment [9] together with the just explained Expected Annual Loss.

This resilience, beyond the assignment of the so-called resilience indicator, are also used to affect the impact analysis. Some resilience coefficients are defined to consider these resilience factors also into the impact analysis, as can be seen in the following table.

Resilience Indicators	Preparation						Resourcefulness							
							Internal				External			
	P1	P2	P3	P4	P5	P6	Int1	Int2	Int3	Int4	Ext1	Ext2	Ext3	Ext4
IP	δ_t	δ_t			δ_p	δ_p			δ_{int}				δ_{E2}	δ_{E2}
ID														
IS				δ_{rec}			δ_{rec}	δ_{rec}			δ_{E1}	δ_{E1}		

Table 7: Resilience indicators dependency on the resilience aspects and their influence on the impact on people (IP), on the physical system (ID), and service continuity (IS)

5.1 δ_t : Preparedness - Evacuation efficiency inside the asset

The evaluation of the casualties should consider the capacity of the people inside the asset to evacuate in the best way. Usually, this capacity can be related to the existence or not of the emergency plan and also its quality. The second aspect is the training. Also, in this case, this can be asses analyzing not only its occurrence or not, but also the frequency at which it is set.

In the work done by *Li et al.* [10] the evacuation efficiency is assessed through two factors:

- k_s is defined as the attraction capacity of the exit to the people inside the asset;
- k_D is related to the people evacuation behaviour and its coordination.

In so doing the planning and training can be used to build a matrix that describes the preparedness effect on the number of deaths.

		Training (k_D)		
		Yearly	Yes	No
Plan (k_s)	No	0.35	0.73	1.00
	Yes	0.15	0.15	0.15
	Detailed	0.15	0.15	0.15

Table 8: δ_t evaluation

5.2 δ_p : Preparedness - Evacuation efficiency around the asset

The second aspect of preparedness that is considered is related to the around community preparedness. This resilience coefficient is very important to fit the real number of people heated by a hazardous event. It is known from the literature that exists a relation between the warning time and the percentage of people evacuated from a certain area.

Figure 5: Example of evacuation curves

This quite wide range can be attributed to the community capacity to react to a determined hazardous event. This aspect can be related to the so-called community experience. A community that has already experienced a certain event should have a better reaction capacity.

Therefore, the two boundaries find in literature [11] can be associated with ones of the community experience, namely less than 10 years and more the 100 years. Successively the other values can be included in the just mentioned two boundaries.

	δ_p	Community experience			
		> 100 years	< 100 years	< 50 years	< 10 years
Warning time	< 1 hour	0.003	0.007	0.010	0.007
	< 12 hours	0.615	0.680	0.746	0.824
	< 1 day	0.885	0.891	0.897	0.900
	> 1 day	0.900	0.900	0.900	0.900

Table 9: δ_p evaluationFigure 6: δ_p evaluation

5.3 δ_{rec} : Recovery efficiency

During the aftermath of the event impact, an important role is played by the recovery efficiency. This efficiency has an important role in the way in which the recovery is carried out.

The recovery coefficient is set to consider the changing recovery performance during the aftermath period. This variation is related to the internal resourcefulness and preparedness of the assets according to *Cimellaro et al.*[1].

Since the recovery economic loss is related to the unserved characteristic in a certain period. Therefore, the coefficient is simply evaluated as the reciprocal of the area under the recovery function.

$$\delta_{rec,i} = \int 1 - f_{rec}(t) dt \quad (15)$$

Figure 7: δ_{rec} evaluation

Two different values of $\delta_{rec,i}$ are defined, which are the lower 0.19 (well) and upper 0.5 (average and not-well) bound. The coefficient varies linearly between these two limits. To obtain the exact value, the average score of the above-mentioned question should be computed, the scoring value varies from 0 to 3.

$$\delta_{rec} = \delta_{rec,up} - \frac{Avg.Score}{3} \cdot (\delta_{rec,up} - \delta_{rec,down}) \quad (16)$$

As shown in the following table an average scoring can be computed.

Internal resourcefulness & preparedness	Material to offset the loss	Backup system	Warning System / Measures
No	0	0	0
Yes Partly	1	3	3
Yes Full	3	3	3

Table 10: δ_{rec} evaluation

5.4 δ_{int} : Internal resourcefulness

In the specific case of the analysis on the event impact on the hospital another coefficient should be considered. More precisely the internal resourcefulness should be considered.

This coefficient is called δ_{int} and it considers the goodness of the internal coordination among facilities and department. This coefficient is the merge of two different factors α and β that describe the organizational and the human component during emergencies, according to *Syner-G* [2]. The coefficient represents the capacity of the hospital system to increase its treatment capacity during the emergency.

Since in the treatment capacity formula is inserted as $1/\delta_{int}$, the lowest in the value, the highest is the capacity. Therefore, if the increased capacity is not ensured then the coefficient is set equal to 1, while it is equal to 0.57. This value is carried out according to Italian increase capacity in terms of treatment capacity during the Italian 2020 healthcare crisis, according to the data given by the *Italian Ministry of Health* [12]. Such a document underlined the increasing treatment capacity of 75% in the most affected regions. The value can be defined as follow:

- Existence of coordination with facilities/departments of the hospital - $\delta_{int} = 0.57$.
- Not existence of coordination with facilities/departments of the hospital - $\delta_{int} = 1$.

5.5 δ_{E1} : External resourcefulness – Institution efficiency

An important aspect that should be considered is the external resourcefulness, especially related to the institution efficiency. The coefficient, in this case, can be related to the accessibility to the eventual mobile healthcare post, which can ensure a certain level of treatment capacity despite the service reduction due to the damage experienced. Therefore, δ_{E1} can be set according to the scheme shown in the following table.

δ_{E1}		Agreements with organization/institutions	
		Yes	No
Local government coordination	Yes	1	0.5
	No	0.5	0

Table 11: δ_{E1} evaluation

The value of this parameter is defined initially as a Boolean function if both the question leads to a positive effect leads is equal to 1, or 0 otherwise. If the two questions have opposite answered the half is taken.

5.6 δ_{E2} : External resourcefulness – Care system efficiency

An important aspect that should be considered is the external resourcefulness, especially related to the health care system efficiency, at the interhospital level. The coefficient, in this case, can be related to hospital redistribution capacity during an emergency. Therefore, δ_{E2} can be set according to the scheme shown in the following table.

δ_{E2}		Health directorate coordination	
		Yes	No
Coordination among hospitals	Yes	1	0.5
	No	0.5	0

Table 12: δ_{E2} evaluation

The value of this parameter is defined initially as a Boolean function if both the question leads to a positive effect leads is equal to 1, or 0 otherwise. If the two questions have opposite answered the half is taken.

6 PROBABILITY OF DAMAGE OCCURRENCE

In this paragraph, the hazard and vulnerability properties are combined to obtain the value of the probability of occurrence of a certain damage state. The results of this combination are representing the probability of occurrence of the impact.

The Damage probability per each damage state (P_D) can be computed as the convolution integral between the Hazard curve, if available, and the fragility curves of the limit state DS.

$$P_{D,DSi} = \int_0^{+\infty} F_{R,DSi}(IM) * H_S(IM) d(IM) \quad (17)$$

Where F_R represents the fragility curve and H_S the hazard curve, both expressed as a function of IM (PGA [g] for earthquake).

Figure 8: Damage probability per each DS

If the hazard curve is not available, which means that is unknown the occurrence probability of all the intensity measures but only of some of them, the approach is the one shown below.

$$P_D = \sum_{i=1}^n F_{i-1} MAF_{i-1} (1 - \exp(m_i \Delta IM_i)) - \frac{\Delta F_i}{\Delta IM_i} MAF_{i-1} (\exp(m_i \Delta IM_i) \left(\Delta IM_i - \frac{1}{m_i} \right) + \frac{1}{m_i}) \quad (18)$$

In which:

- $\Delta IM_i = IM_i - IM_{i-1}$;
- $F_i = F_i - F_{i-1}$, in which $F(s)$ is the fragility cumulative lognormal distribution function;
- $m_i = \frac{\ln\left(\frac{MAF_i}{MAF_{i-1}}\right)}{\Delta IM_i}$, that is the angular coefficient of the MAF curve;
- $a_i = MAF_{i-1} (1 - \exp(m_i \Delta IM_i))$;
- $b_i = \frac{MAF_{i-1}}{\Delta IM_i} \left(\exp(m_i \Delta IM_i) \left(\Delta IM_i - \frac{1}{m_i} \right) + \frac{1}{m_i} \right)$.

7 EXPECTED ANNUAL LOSS

The last step of this study consists of the definition of the Expected Annual Loss (EAL). EAL is used in this methodology as the quantification of the risk level. This final value considers all the different component of the risk assessment theory, such as the probability of damage occurrence (Hazard and Vulnerability) and the total impact (Impact and Resilience).

The EAL, which can be built using the total impact and the damage (Figure 9).

Figure 9: EAL evaluation

Finally, the area under the EAL curve is computed. This kind of results gives a unique value representing the loss of the assets per year for the considered hazard.

$$EAL = \sum_{i=1}^n \frac{(I_{TOT,DS(i+1)} - I_{TOT,DSi})(P_{D,DS(i+1)} + P_{D,DSi})}{2} \quad (19)$$

In which P_D is the Mean Annual Frequency (MAF) and I_{TOT} is the impact loss. Therefore, the EAL is the final measure of the risk per a certain asset, subjected to an earthquake.

8 CONCLUSIONS

A procedure for the seismic risk assessment of hospital buildings has been presented. The following advantages are worth to be highlighted:

- The framework can be extended to the assessment of different hazards. This is mainly related to the fact that the approach used in the hazard evaluation can be used for whichever kind of natural hazard that can be expressed as an intensity measure (i.e. acceleration for earthquake, wind speed for a hurricane, water height for flood etc...) as a function of a probability of occurrence.
- This procedure is capable to compare different assets, thanks to the computation of the economic value of the risk, known as the expected annual loss (EAL) which is derived from the calculated total impact and the probability of damage occurrence (hazard + vulnerability). The result is a scalar value, computed as the area under the loss curve (Figure 9), that should be used to compare the risk among the different assets.
- The Impact is defined by considering the presence of people, livelihoods, species or ecosystems, environmental functions, services, and resources, infrastructure, or economic, social, or cultural assets in places and settings that could be adversely affected by a seismic hazard. Thus impact is normally quantified as the consequence of damages and losses caused to stakeholders, to the environment and human life. The analysis of the impact is consequently based on the definition of 3 loss categories: Impacts on People, impacts on the Physical System/Infrastructure, and Impacts on Service continuity. The consideration of all these different aspects of the impact leads to a real representation of the current value of the critical infrastructure sectors.
- The already mentioned criticality level should be defined uniquely. In so doing each level, labelled DS1, DS2, DS3, and DS4, represent always the same damage state, per each asset analysed.
- The losses are evaluated as a function of time as can be appreciated in the impact analysis. This is mainly related to the concept of damage and service which can be recovered in a certain time, called recovery time. How the impact is assessed permit also to take into account the resilience as a coefficient able to affect the recovery function.

Abstract

Italy is a country with high seismic risk; however, a broad seismic classification of the national territory has been introduced only in the last twenty years. Therefore, most of the existing buildings stock do not comply with the current anti-seismic codes. In recent years, the seismic events that occurred in Italy have highlighted the complexity of emergency management and the great challenge for public authorities called to answer to the post-event reconstruction and the planning of effective risk prevention and mitigation measures implemented in "peacetime".

In this perspective, the CAESAR II project (Controlling, Mitigating and Managing Earthquake Emergency: Cost-Benefit and Multi-criteria Analysis of Impact Scenarios for Risk Reduction and Increased Resilience) has been developed as a decision support system for public authorities engaged in the development of seismic disaster risk reduction plans. CAESAR II includes a module for the simulation of retrofitting measures applied at the municipal scale, integrating different categories of anti-seismic and energy improvement measures based on the vulnerability analysis of the existing buildings stock. The CAESAR II tool's core is the module for evaluating "seismic impact scenarios" based on the end-users' hazard. The output of the model includes information on expected damage levels for buildings (from D0-no damage to D5- total collapse) and population (dead, injured and homeless). Impact scenarios can be customised according to the minimum unit of analysis assumed (municipality or 250x250m square mesh grid) and the availability of exposure data (from national census data or survey on the spot building by building according to the PLINIVS form). Scenarios include geo-referenced data managed by geo-servers to exchange data in a format compliant with OGC (Open Gis Consortium) standards and the European INSPIRE Directive. Simulation results can be further processed through the Multi-Criteria and Cost-Benefit Analysis modules to support the comparative assessment of alternative seismic and energy measurements.

In this work, the procedures included in CAESAR II are described and a case study is reported. It concerns the analysis of the expected damage assessment on buildings and population for three municipalities in northern Italy, Torre Pellice, Villar Pellice and Pinerolo (Piedmont Region).

1. INTRODUCTION

Effective planning and programming in seismic emergencies require preliminary assessments of the effects on the territory. Due to the different objectives, it is possible to distinguish two types of assessments based on risk analysis and scenario analysis.

Risk is the probability that a prefixed level of damage (on people, buildings, infrastructures, economy, etc.) caused by seismic events will occur within a given period in a specific geographical area. Therefore, the risk should be intended as a cumulative assessment, which considers the total potential damage in the same area generated by different events in a fixed time frame. Scenario, instead, represents the probabilistic distribution, in a particular geographical area, of the damage induced by a single seismic event with an assigned probability of occurrence (assumed as the reference scenario).

In both types of analyses, three random variables come into question: hazard, exposure, and vulnerability. The “hazard” is the probability of occurrence, in a specific area and a specific period, of all possible seismic events, for risk analysis, or of a single event, in the case of scenario analysis. The “exposure” is the geographic distribution in quantitative and qualitative terms of the different elements at risk that characterise the area under consideration (people, buildings, infrastructure, activities and movable property). The conditions and/or operation may be damaged, altered or destroyed due to the occurrence of the natural event. The “vulnerability” is the sensitivity of an exposed element to a natural event. It can be evaluated as the probability that the exposed element will suffer a certain level of damage or change of state, concerning an appropriate scale, because of a seismic event of assigned intensity.

In emergency planning, both risk and scenario analyses can be used in response to the different goals that are to be pursued. Risk analyses allow comparative evaluations of areas subject to planning both for decisions on intervention strategies (e.g. evacuation priorities, etc.) and the definition of damage mitigation interventions. Scenario analyses, through the identification of the extension of the area of interest and the evaluation of the territorial impact, help quantify the resources necessary for the emergency planning and the organisation of the operative intervention.

In the literature, there are many works related to risk analysis in a broad sense or to some specific factor. Some specific studies on the vulnerability can be found in [1], [2], [3] and [4], and the exposure in [5], [6] and [7]. About the costs analyses some works are reported in [8] and [9] and on the multi-criteria there are [10] and [11].

In recent years, research has focused on creating comprehensive tools for every aspect of the process. One of the newcomers is the IRMA (Italian Risk MAPs) platform [12], developed by the Department of Italian Civil Protection (DPC). It integrates tools for calculating damage scenarios and risk maps for the Italian territory. The IRMA platform is designed for the scientific community and allows to create and load different exposure/vulnerability databases and different sets of fragility curves. The hazard for calculating risk maps is instead preloaded and is the hazard model developed by INGV (National Institute of Geophysics and Volcanology) and adopted at the national level.

In this framework, the CAESAR II project (Controlling, Mitigating and Managing Seismic Emergencies: Cost-Benefit and Multi-Criteria Analysis of Impact Scenarios for Risk Reduction and Increased Resilience) is born. It is a web-service procedure conceived as a decision support system for public authorities engaged in the development of disaster risk reduction plans, with the possibility to plan medium and long-term investments, as well as to define customised financial support mechanisms and fiscal incentives.

The project, developed as a follow-up to the CRISMA EU-FP7 (http://www.protezionecivile.gov.it/resources/cms/documents/CRISMA_locandina.pdf) and CAESAR I projects (a seismic impact model developed for the Campania region operations room in 2005), is funded by the Agenzia per la Coesione Territoriale (National Territorial Cohesion Agency), within the framework of the PON (National Operative Project) Governance and Institutional Capacities 2014-2020, as an intervention aimed at the transfer, evolution and dissemination of best practices among Public Administrations. CAESAR II includes a module for the simulation of

retrofitting measures applied at the municipal scale, integrating different categories of anti-seismic and energy improvement measures based on analysing the existing building stock's vulnerability.

The CAESAR II tool's core is the 'seismic impact scenarios' evaluation module, based on the hazard assumed by the end-users. The output of the model includes information on the expected damage levels for buildings (from D0- no damage to D5- total collapse) and population (deaths, injuries and homelessness). Impact scenarios can be customised according to the minimum unit of analysis assumed (municipality or 250x250m square mesh grid) and the availability of exposure data. The exposure is estimated by exploiting the ISTAT (National Institute of Statistics) Census 2011 [13], an Italian database that provides, for census zones, aggregated information on the buildings and the number of residents.

The scenarios include geo-referenced data managed by geo-servers capable of exchanging data in a format compliant with OGC standards and the European INSPIRE Directive. Simulation results can be further processed through the Multi-Criteria and Cost-Benefit Analysis modules to support the comparative evaluation of alternative seismic and energy measures. One of the CAESAR II tool's main strengths is that it does not require specific technical or engineering skills from the user, as it is offered as a complete package that needs some input data.

The paper has been structured in two main sections: the former one describes the calculation models and assumptions on which the CAESAR II procedure is based and the format of the information that is requested from the user; the latter one shows an application example on three Piedmontese municipalities (Pinerolo, Torre Pellice and Villar Pellice) made possible thanks to the data provided by the RISVAL project (<https://www.interreg-alcotra.eu/it/decouvrir-alcotra/les-projets-finances/risvalrischio-sismico-e-vulnerabilita-alpina>).

2. THE CAESAR II MODEL

Caesar II is a web-service procedure developed for the Territorial Cohesion Agency, producing scenario and seismic risk analyses in terms of economic, building and human life losses and evaluating their possible reduction through cost-benefit and multi-criteria analyses to support decisions. The application works on municipalities on a grid of 250x250m for which hazard and exposure factors are defined. CAESAR II is based on three models of analysis, described below:

1. Seismic Impact Risk and Scenario Analysis Model;
2. Post-seismic economic loss forecasting Model;
3. Multi-Criteria Analysis Model.

The three models have been synergistically implemented in as many modules within the so-called reuse kit.

2.1. Seismic Impact Risk and Scenario Analysis Model

Hazard

The seismic hazard adopted in CAESAR II is a function of the type of analysis to be developed. In the case of "risk" analysis, the primary seismic hazard is adopted, i.e. the maximum value of horizontal ground acceleration (PGA, peak ground acceleration), calculated by the INGV. The PGA values are given in correspondence of a grid of 10.751 points, defined by latitude and longitude coordinates, covering the whole national territory (**Figure 1**).

For each node in the geographic grid, parameters are provided at specified return periods, TR (30, 50, 72, 101, 140, 201, 475, 975, and 2,475 years). PGA maps are calculated for different exceedance probabilities over 50 years (9 in total, ranging from 2% to 81%). For each estimation, the 50th percentile distribution (median map, which is the reference map for each exceedance probability) and the 16th and 84th percentile distributions are available, indicating the variability of the estimates.

In the case of "scenario" analysis, the seismic event taken as a reference can be assumed through: 1) an attenuation law as a function of some seismic parameters, such as the coordinates of the hypocenter and the magnitude value, or 2) a shaking map (ShakeMap). The distribution over the territory of the parameters that define the extent of a seismic event (e.g., the PGA) can be derived

through the adoption of an attenuation law, as a function of other seismic parameters (usually the magnitude) and epicentral (or hypocentral) coordinates. CAESAR II adopts, as attenuation law, the relation of Blake [14], which assumes a decimal logarithmic decay, and the conversion law determined by Faenza and Michelini [15], [16] between the observed shaking parameters and the MCS intensity scale. In Italy, shaking maps are provided by INGV for all earthquakes with magnitude $M \geq 3.0$ occurring in the national territory and surrounding areas. They are published on the website <http://shakemap.rm.ingv.it>. When new information or additional earthquake data become available (e.g., the size of the earthquake fault -extended fault-, new data from networks operated by other agencies), the maps are updated to improve the definition of ground shaking, particularly in epicentral areas. They provide an immediate visualisation of the level of shaking of an area affected or interested by an earthquake, reporting the peak values recorded by accelerometers and seismometers, mainly provided by the National Accelerometric Network (RAN) of the Department of Civil Protection and the National Seismic Network (RSN) of INGV, present in the area of the earthquake. If there are no observed values, an ad hoc software interpolates the data using, for example, the attenuation laws of the shaking with the distance available for the centre of each cell of the grid belonging to the area under examination.

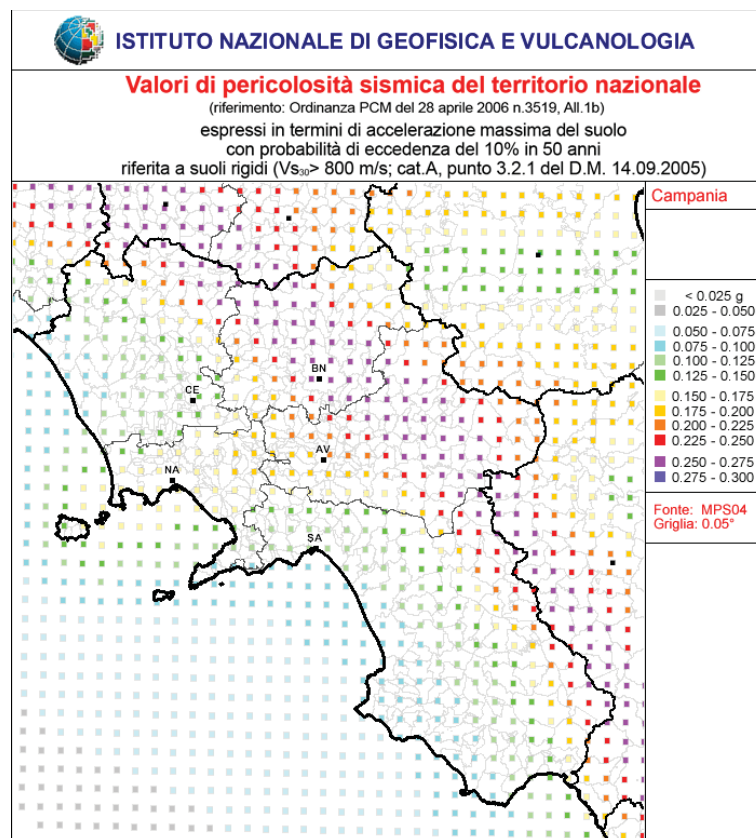

Figure 1. Seismic hazard values of the national territory expressed in terms of maximum ground acceleration with a probability of exceeding 10% in 50 years, referred to rigid soils.

Exposure

Exposure and vulnerability are closely related factors. For each category of elements at risk, the estimate of vulnerability to the seismic event must be accompanied by "a qualitative and quantitative analysis of the exposed property" (exposure), in order to identify the spatial distribution, and possibly temporal, of typological classes of elements at risk, called classes of vulnerability, each of which is a set of elements that for characteristics present similar behaviour (Vulnerability) concerning the earthquake. In other words, it is necessary to identify the salient characteristics of the element at risk (vulnerability factors), to which a specific capacity to respond to the natural phenomenon is attributed.

CAESAR II refers to two types of elements at risk: ordinary buildings and their occupants. The estimation of the buildings in the area under examination can be based on a statistical analysis, which

evaluates the percentage distribution of the different classes of vulnerability of the buildings (A, B, C, D for decreasing vulnerability) based on their different behaviour towards the natural event. A similar procedure is adopted to estimate the population and the distribution of occupants for buildings divided by class of vulnerability.

The exposure model uses a procedure that can take into account both the ISTAT data only and the ISTAT data combined with information coming from a data collection activity on the investigated area. These input data are processed by the tools S.A.V.E. [17] and B.I.N.C. [7], two procedures developed by the PLINIVS Study Centre which aim to characterise the seismic vulnerability of specific building typologies (S.A.V.E.) and to evaluate a probable geographical distribution of these building typologies according to their recurrence in the ISTAT census data (B.I.N.C.).

In particular, the S.A.V.E. model is used to assign vulnerability classes to single buildings, detected in the data collection campaigns on the territory, according to their typological and structural characteristics. The B.I.N.C. model exploits the S.A.V.E. method and defines a probable distribution of the ISTAT buildings on the vulnerability classes, starting from the population density of the considered municipality and from the ages of construction of the buildings identified on each census section.

The distribution of vulnerability classes (exposure) is defined for each minimum reference unit of the model (250x250m cell of a regular square-mesh grid). However, ISTAT data on buildings refer to individual census sections, which may also contain a large number of cells, so a criterion for assigning census data to each cell was adopted, following relations (1) and (2), having defined "zones" as the areas of intersection between census sections and the grid (**Figure 2**):

Figure 2. Illustrative representation of the "zones" (green), defined as the areas of intersection between the ISTAT census sections (yellow) and the 250x250m cells (red) of the model's reference grid (blue).

The number of buildings in zone i of census section j of vulnerability class k are estimated as in the equation (1); the number of buildings in cell c of vulnerability class k are obtained by the relation (2):

$$E_{i,j}^k = \begin{cases} E_{i,j}^{k,R} & \text{se: } E_j^{ISTAT} / E_j^R \leq 1 \\ E_{i,j}^{k,R} + E_{i,j}^{k,R} = E_{i,j}^{k,R} + E_j^k / E_j^{ISTAT} \cdot (E_{i,j} - E_{i,j}^R) & \text{se: } E_j^{ISTAT} / E_j^R > 1 \end{cases} \quad (1)$$

$$E_c^k = \sum_{i=1}^n E_{i,j}^k \quad (2)$$

Where:

c is the cell

j is the census section

i is the zone, intersection of the reference grid and census section

k is the vulnerability class ($k = A, B, C, D$)

n is the number of zones constituting cell i

E_j^{ISTAT} is the number of buildings in census section j

E_j^k is the number of buildings of census section j of vulnerability class k (BINC)

E_j^R is the number of buildings of census section j surveyed

$E_{i,j}^k$ is the number of buildings in zone i of census section j of vulnerability class k

$E_{i,j}^{k,R}$ is the number of buildings detected of zone i of census section j of vulnerability class k

(S.A.V.E.)

$E_{i,j}^{k,R}$ is the number of undetected buildings of zone i of census section j of vulnerability class k

E_c^k is the number of buildings in cell c of vulnerability class k .

Regarding the occupants' exposure, the CAESAR II model considers the assumption that the population is uniformly distributed over the homes. The data collected by the PLINIVS Study Centre and processed with the SAVE method have allowed to define a correlation between the number of houses present in a building and the vulnerability class to which the building belongs (**Table 1**).

average of dwellings	Vulnerability class of the building			
	A	B	C	D
M_{Ab}	2.0	2.7	3.45	6.90

Table 1. average of dwellings for buildings related to the vulnerability class

Therefore, the population distribution over the vulnerability classes is calculated as in equation (3).

$$N_{P_k} = \frac{E_k \cdot M_{Ab_k}}{\sum_{t=A, \dots, D} E_t \cdot M_{Ab_t}} P^{ISTAT} \quad (3)$$

Where

E_k is the number of buildings of vulnerability class k ,

M_{Ab_k} is the average of dwellings for the buildings of vulnerability class k ,

E_t is the number of buildings of vulnerability class t ,

M_{Ab_t} is the average of dwellings for the buildings of vulnerability class t ,

P^{ISTAT} is the population indicated in the ISTAT data

Finally, the average number of occupants as the seismic class k (N_{O_k}) of each cell in the reference grid varied was evaluated using relation (4).

$$N_{O_k} = N_{P_k} \cdot Q_{m,o} \quad (4)$$

Where:

N_{P_k} is the number of people per seismic class k estimated, cell by cell, based on ISTAT data;

$Q_{m,o}$ is the average percentage of occupants, assumed to be 65%, of the total population.

Vulnerability

A building's vulnerability is the probability that the system (entire building), subsystems (walls, framing, roofs, etc.), or components of the system (beams, columns, infill panels, windows, doors, etc.) will be damaged as a result of an assigned action to which they are subjected. The concept of vulnerability requires to define unambiguously the level of "damageability" of the exposed asset due to the natural event. The damage scale adopted in CAESAR II refers to the six levels of damage of the: D0: no damage; D1: not structural damage; D2: light structural damage; D3: structural damage; D4: partial collapse; D5: total collapse.

The propensity of a building to sustain damage is a function of its constituent elements. The strength and technological aspects of structural (walls, beams, columns, floors, roofs, etc.) and non-structural (infill panels, openings, protective panels, etc.) elements strongly influence the vulnerability of the building itself [18].

The vulnerability of a building to an earthquake can be assessed through the so-called vulnerability curves. For an assigned class of vulnerability, they express the probability of exceeding a certain level of damage as the hazard measurement parameter varies, which may be the peak seismic acceleration, spectral intensity, macroseismic intensity, etc..

CAESAR II uses the model of vulnerability curves for ordinary buildings. These curves were calibrated on data from damage probability matrices produced through a statistical analysis of observed damage following earthquakes that have occurred in Italy since 1980, and converted to PGAs via Margottini's law [19]. The mean and standard deviation parameters of the vulnerability curves are shown in **Table 2**.

The vulnerability of the population to the earthquake is determined with reference to the damage suffered by the buildings occupied by the people. In **Table 3**, the percentages of dead QD and injured QI are reported as a function of the building's level of damage. The values shown were calibrated based on data collected from past earthquake events [20].

CLASS	PERCENTILE	D1		D2		D3		D4		D5	
		μ	σ	μ	σ	μ	σ	μ	σ	μ	σ
A	16%	-3,50	0,80	-2,70	0,80	-1,95	0,70	-1,35	0,60	-0,75	0,60
A	50%	-3,35	0,80	-2,60	0,80	-1,74	0,80	-0,95	0,75	-0,40	0,75

Table 2. logarithmic mean and logarithmic standard deviation of the vulnerability curves

Percentage of death (Q _D) and injured (Q _I)	Level of damage						Vulnerability Class
	D0	D1	D2	D3	D4	D5	
Q _D	0	0	0	0	0.03	0.14	A, B, C
Q _D	0	0	0	0	0.06	0.28	D
Q _I	0	0	0	0	0.10	0.56	A, B, C
Q _I	0	0	0	0	0.12	0.42	D

Table 3. Percentage of death and injured regarding the levels of damage and vulnerability class

Finally, The EASE model (Zuccaro et al., 2008; Zuccaro and Cacace, 2010), developed and engineered by the PLINIVS centre for DPC, was adopted to estimate the effects of risk related to the chosen reference period. The model discretises the territory through a square-mesh grid of size 250x250m. To each cell is assigned: hazard data, in terms of PGA; and exposure data, in terms of the number of buildings for each structural vulnerability class and the number of occupants. Combining these data with seismic vulnerability (percentiles 16, 50, and 84%), the model yields the following products on a cell-by-cell basis:

- Number of collapsed buildings, as the sum of buildings with D4 and D5 damage.
- Number of uninhabitable buildings, as the sum of buildings with D4 and D5 damage and 60% of buildings with D3 damage.
- Number of deaths N_D and injuries N_I , as assessed through the equations (5) and (6):

$$N_D = (1 + TI_c) \cdot \sum_{t=1}^4 \sum_{j=1}^5 N_{t,j} \cdot NO_t \cdot Q_{Dt,j} \quad (5)$$

$$N_I = (1 + TI_c) \cdot \sum_{t=1}^4 \sum_{j=1}^5 N_{t,j} \cdot NO_t \cdot Q_{It,j} \quad (6)$$

Where:

- t is the seismic class of the building (A, B, C, D);
- j is the damage level of the building (D1, D2, D3, D4, D5);
- $N_{t,j}$ is the number of buildings, per cell, of seismic class t having damage level j ;
- NO_t is the average number of occupants per building of seismic class t ;
- TI_c is the tourism index of the city [0-100%];
- $Q_{Dt,j}$ is the percentage of deaths per seismic class t and damage level j ;
- $Q_{It,j}$ is the percent injured per seismic class t and damage level j .
- Number of homeless assessed through the relationship (7):

$$N_H = \sum_{t=1}^4 [(0.5 \cdot N_{t,D3} + N_{t,D4} + N_{t,D5}) - N_D] \quad (7)$$

Where:

- $N_{t,D3}$ is the number of buildings, per cell, of seismic class t having damage level D3;
- $N_{t,D4}$ is the number of buildings, per cell, of seismic class t having damage level D4;
- $N_{t,D5}$ is the number of buildings, per cell, of seismic class t having damage level D5.

2.2. A post-seismic economic loss forecasting model

Seismic emergency management requires specific programs for identifying the objectives to organise an adequate and quick response. They manage a complex workforce, equipment and resources arranged and coordinated by local administrations both in space and time.

The introductory knowledge basis, necessary to allocate resources, is represented by damage scenarios, useful to predict possible damages due to an earthquake impact and following population involvement in the affected area [21]. Such scenarios contain data like territorial seismic vulnerability with particular attention to the built environment. Moreover, they can provide valuable information about the extension of the most seriously affected area, working of transport infrastructures, roads and service networks, damage on buildings and the expected casualties, as well as the corresponding financial burden.

Within this dense framework, an earthquake can be described as a phenomenon characterised by a two-phases temporal sequence, each of which has direct and indirect economic consequences. For what that concerns the directly related ones, it is possible to find all those connected to protection, improvement, and structural seismic adaptation to reduce the general vulnerability of ordinary buildings. Equation (8) can assess these mitigation costs (MTC). In **Table 4** the Average cost of mitigation interventions from a vulnerability class to another (€/m²) are summarized.

$$MTC = \sum_{j=A}^D emc_j \cdot sm_{emc_j} \cdot cm_{emc_j} + \sum_{j=A}^D emc_j \cdot cman_{emc_j} \quad (8)$$

Where:

- emc_j is the number of j -th vulnerability class buildings to be mitigated;

sm_{emc_j} is the average area of the j -th vulnerability class building to be mitigated;
 cm_{emc_j} is the average mitigation cost for the j -th vulnerability class building (Table 4);
 $cman_{emc_j}$ is the average maintenance cost for the j -th vulnerability class building ($cman_{emc_A} = 1.500$ €/year; $cman_{emc_B} = 1.800$ €/year; $cman_{emc_C} = 2.000$ €/year; $cman_{emc_D} = 2.600$ €/year).

Class	B	C	D
A	360	510	624
B	-	390	540
C	-	-	378

Table 4. Average cost of mitigation interventions from a vulnerability class to another (€/m²)

Inside the area hit by an earthquake of a given magnitude, all post-event operations can be immediately translated into costs directly linked to the buildings' damage and affected population. As part of the post-event costs, those related to reconstruction, on-site or in a new different location, involve buildings irreversibly damaged by the earthquake (damage level D4-D5 under the EMS'98 classification). The relation (9) can assess these reconstruction costs (RC).

$$RC = \sum_{i=4}^5 edl_i \cdot sm_{edl_i} \cdot crl + \sum_{i=4}^5 edd_i \cdot sm_{edd_i} \cdot crd \quad (9)$$

Where:

sm_{edl_i} is the average area of the i -th damage level building to be rebuilt on-site;
 crl is the reconstruction cost for a residential building on-site (1.235,94 €/m²);
 edd_i is the number of i -th damage level buildings to be rebuilt delocalised;
 sm_{edd_i} is the average area of the i -th damage level building to be rebuilt delocalised;
 crd is the reconstruction cost for a residential building delocalised (1.250 €/m²).

The Restoration costs (RT) are, instead, connected to the activities planned for recovery buildings and infrastructures damaged in a non-irreversible way by the earthquake (damage level D1-D2-D3 under the EMS'98 classification) and can be calculated as in the formula (10).

$$RT = \sum_{i=1}^3 ed_i \cdot sm_{ed_i} \cdot cr_{ed_i} \quad (10)$$

Where:

ed_i : number of i -th damage level buildings to be restored;
 sm_{ed_i} : average area of the i -th damage level building to be restored;
 cr_{ed_i} : restoration cost for a residential building as a function of damage level ($cr_{ed1}=360$ €/m²; $cr_{ed2}=458$ €/m²; $cr_{ed3}=545$ €/m²).

At this stage, all those costs related to the *demolition and rubble removal (DR)* of lost buildings are certainly not negligible, as well as the management cost for specialised landfills. The formula (11) can assess these efforts:

$$DR = \sum_{i=4}^5 ed_i \cdot vm_{ed_i} \cdot cd + \sum_{i=4}^5 ed_i \cdot vm_{ed_i} \cdot ct \cdot dm + \sum_{i=4}^5 ed_i \cdot vm_{ed_i} \cdot cg \quad (11)$$

where:

ed_i is the number of i -th damage level buildings to be demolished;
 vm_{ed_i} is the average volume of the i -th damage level building to be demolished;
 cd is the demolition cost for a lost building as a function of vulnerability class ($cd_{A-B}=12$ €/m³; $cd_C=14$ €/m³; $cd_D=16$ €/m³);
 ct is the cost of rubble transportation to the landfill (0,6 €/m);

dm is the average site distance from the landfill (300 m);

cg is the average landfill management cost (1,4682 €/m²).

As part of the costs associated with safeguarding the population affected by the earthquake, it is possible to include *health care* costs (HT) for establishing medical equipment, strengthening existing local public facilities, as well as physical and psychological support. These costs can be calculated as in the equation (12).

$$HT = f \cdot cm \cdot tm \quad (12)$$

where:

f is the number of people in need of medical care;

cm is the unit cost of medical care operations (200 €);

tm is the average time for medical care (10 days).

The formula (13) calculates the *evacuation* costs (EV) of the population, split up according to the destination and the means of transport employed:

$$EV = s_{nm} \cdot cm_t + cm_c \cdot \frac{s_t}{s_c} + cm_{pc} \cdot tu_c + cm_{kp} \cdot s_t + cg_{at} \cdot \frac{st_t}{sm_t} \cdot tu_c + cg_t \cdot s_{te} + cg_h \cdot s_h \quad (13)$$

Where:

s_{nm} is the number of homeless people with no vehicle;

cm_t is the total cost of public transport (15.599 €);

cm_c is the cost of checkpoints set-up (7.050 €);

s_t is the total number of homeless people;

s_c is the number of homeless people evacuated at checkpoints;

cm_{pc} is the daily cost of checkpoints staff (5.930 €);

tu_c is the checkpoints' time usage;

cm_{kp} is the unit cost of the emergency kit (10 €);

cg_{at} is the daily depreciation cost per tent set up (20,55 €);

st_t is the number of homeless people evacuated in tents;

sm_t is the average number of people for each tent set up;

cg_h is the daily cost for the stay in the hotel (45 €);

s_h is the number of homeless people accommodated in hotels;

cg_t is the daily cost for accommodation in the tent;

s_{te} is the number of homeless people placed in tents.

The last cost item estimated is related to *emergency management* (EM) activities following an earthquake, which includes the construction of operational structures and the deployment of vehicles and employees to prepare equipped areas. The formula (14) is used to this purpose.

$$EM = pg_{pc} \cdot cm_{cc} + c_r + cp_{gpc} \cdot tp_{pc} + cp_{gpo} \cdot tp_{po} + cp_{gmo} \cdot tp_{mo} + cm_{pv} \cdot tp_{pv} \quad (14)$$

Where:

pg_{pc} is the average daily presence of Department of Italian Civil Protection staff;

cm_{cc} is the unit cost for coordination centre set-up (3.000 €);

c_r is the cost of communication networks and IT services (5.000.000 €);

cp_{gpc} is the cost for daily presence of Department of Italian Civil Protection staff (126.18 €/day);

tp_{pc} is the presence of the Department of Italian Civil Protection staff;

cp_{gpo} is the cost for daily presence of operating structures staff (130 €/day);

tp_{po} is the presence of operating structures staff;

cp_{gmo} is the cost for daily presence of operating structures means of transport (20 €/day);

tp_{mo} is the presence of operating structures means of transport;

cm_{pv} is the cost for daily presence of volunteer staff (100 €/day);

tp_{pv} is the presence of volunteer staff.

All the parametric costs showed are from the Department of Italian Civil Protection's elaborations about the L'Aquila 2009's earthquake.

2.3. The multi-criteria analysis model

The amount of damage caused by earthquakes can be minimised by adopting systematic measures of emergency management. Within this context, it is crucial to intervene immediately by making decisions that result as accurate and objective as possible, by recognising all the viable alternatives and analysing their consequences. Decision-making problems framed into this background involve a multiplicity of relevant aspects and the presence of various goals and constraints, often not explicit or even contrasting. These items can be inserted in a so-called *decision tree* with a general objective at the top and at least a decision-maker. Such models can keep account of the conflicting nature of uncommonly complex situations and explain the criteria for selecting the alternatives in terms of specific targets to reach.

The multi-criteria analysis' main point is not a pursuit for objectively optimal solutions but the support to rationalise the decision-making process and optimise a set of criteria weighted according to the decision-makers' preferences. This new kind of evaluation scheme identifies alternatives that satisfy a certain number of explicitly defined standards. It is possible to sort the elements of a decision tree as:

- Objectives: statements regarding the condition to achieve, made operational by allocating one or more qualitative and quantitative attributes;
- Criteria: standards of judgment or rules useful to test the worth of decision alternatives, including both the concept of goal and attribute;
- Alternatives: elements of evaluation and choice that must be ordered based on dominance scores representing the entries of the decision matrix.

One of multi-criteria's most powerful tool is undoubtedly the *Analytic Hierarchy Process* [22]. Such a complex algorithm makes it possible to evaluate the priority of actions, programs, intervention strategies, plans and projects by applying mathematical concepts to decision-making, as well as quantitative methodologies to evaluate mostly intangible and subjective judgments. They oppose the classic single-criterion linear analysis models suitable only to straightforward cases and under enough simplified hypotheses. The main advantage is now the flexibility in solving difficult problems by adopting a typical human mind's cognitive model.

It is possible to obtain reliable scales by only using personal judgments, identifying all the single elements of a problem, placing them inside homogeneous sets and sorting each set at a different level. In hierarchies, intricate schemes are top-down analysed in their basics, simulating how the human brain analyses complexity and breaks down the objects perceived by the senses into categories and sub-categories, building a so-called dominance hierarchy (**Figure 3**).

The first level contains the general objective, while the second level contains its further specifications. A possible third level can add more details to the upper level and so on. Finally, alternatives are placed at the base of the dominance hierarchy. Once completed this initial phase, pairwise comparisons are performed for each element of a certain level, with reference to the element placed at that immediately higher. According to the hierarchy shown in Figure 1, second-level criteria are pairwise compared with reference to the overall objective. Third-level sub-criteria are pairwise compared with reference to each second-level criterion until the alternatives are compared according to each third-level sub-criterion, each second-level criterion and, finally, the overall objective.

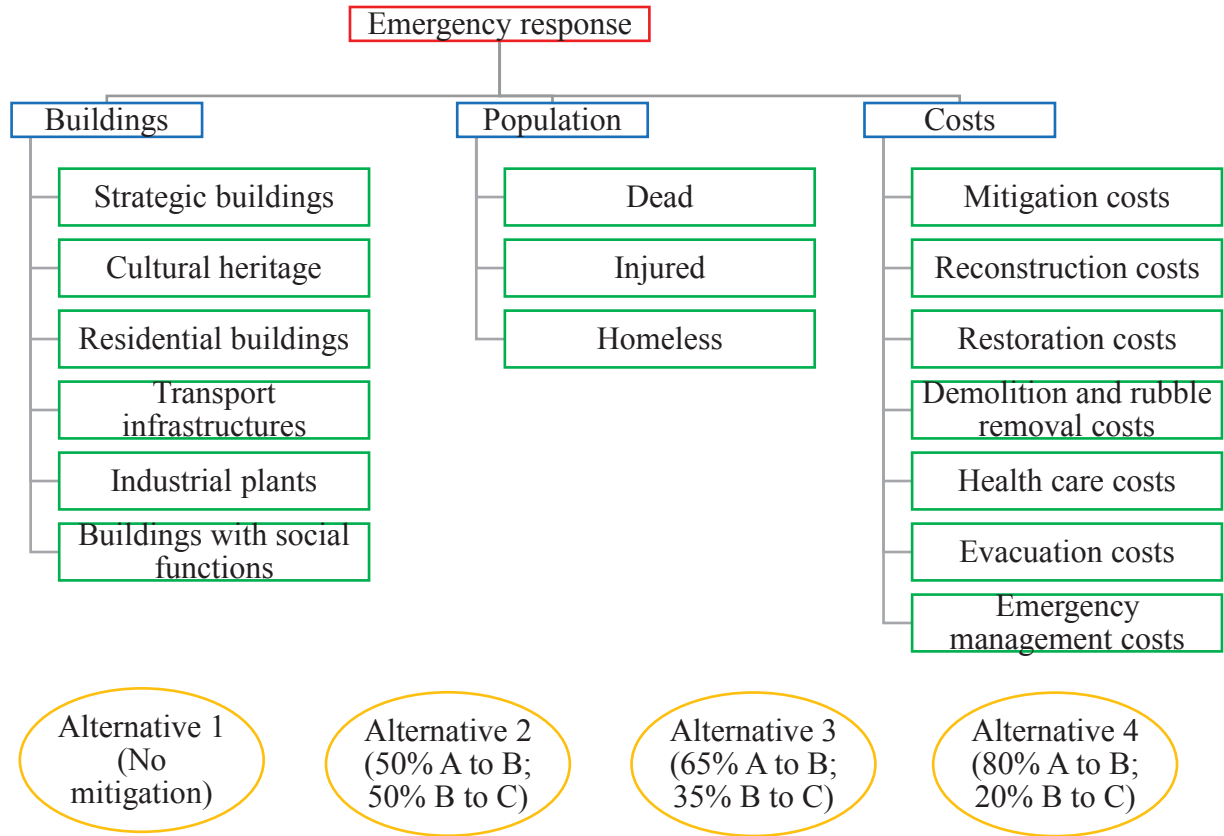

Figure 3. The dominance hierarchy

These operations provide a series of comparison coefficients placed into a so-called dominance matrix and a priority vector that measures all the alternatives' relative reasonability. When the use of judgments is necessary, these can be expressed via the semantic scale of Saaty (Table 5). Such a scheme links natural numbers to qualitative linguistic variables making it possible to answer the crucial question behind all pairwise comparisons: "How much does an element dominate another with reference to a specific criterion or attribute? ".

Intensity of dominance (a_{ij})	Judgement
1	Equal importance
3	Weak predominance
5	Moderate predominance
7	Strong predominance
9	Absolute predominance
2 4 6 8	Values of compromise

Table 5. The semantic scale of Saaty

Denoting by n the number of criteria to be considered, the dominance matrix A^k , built by an individual decision-maker, will be square and symmetrical (Equation (15):

$$A^k = \begin{bmatrix} a_{11}^k & a_{12}^k & \dots & a_{1n}^k \\ a_{21}^k & a_{22}^k & \dots & a_{2n}^k \\ \dots & \dots & \dots & \dots \\ a_{n1}^k & a_{n2}^k & \dots & a_{nn}^k \end{bmatrix} \quad (15)$$

where a_{ij}^k denotes the k -th preference of the generic decision-maker, referred to the i -th criterion concerning the j -th one. If there are more than one decision-makers, individual preferences are averaged and inserted into a new dominance matrix A (Equation (16))

$$A = \begin{bmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & a_{22} & \dots & a_{2n} \\ \dots & \dots & \dots & \dots \\ a_{n1} & a_{n2} & \dots & a_{nn} \end{bmatrix} \quad (16)$$

Following the Analytic Hierarchy Process, every criterion's normalised weight w_{Ni} is calculated as in the (17).

$$w_{Ni} = \frac{(\prod_{j=1}^n a_{ij})^{\frac{1}{n}}}{\sum_{i=1}^n w_i} \quad i = 1, \dots, n \quad (17)$$

The eigenvalue for each row of the dominance matrix A is computed as in the (18).

$$\lambda_i = w_i \left(\frac{\sum_{j=1}^n a_{ij}}{\sum_{i=1}^n w_i} \right) \quad i, j = 1, \dots, n \quad (18)$$

and so the maximum eigenvalue is calculated as in (19), that represents the limit value that n must take in order for the (20).

$$\lambda_{max} = \sum_{i=1}^n \lambda_i \quad (19)$$

$$w_i = \frac{\sum_{j=1}^n a_{ij} w_j}{(\lambda_{max} = n)} \rightarrow \sum_{j=1}^n a_{ij} w_j = \lambda_{max} w_i \quad (20)$$

The following *consistency index* CI measures the deviation of A from the coherence and allows to measure the overall difference between the two sets of values, as in the (21).

$$CI = \frac{\lambda_{max} - n}{n - 1} \quad (21)$$

Impossibility to make reliable judgments, lack of data and inexperience can drive inconsistency. However, it is crucial to establish its maximum admissible value to avoid having completely erroneous data, so the consistency index is compared with arbitrary *random index* RI . The ratio between CI and RI provides the *consistency ratio* CR expressed in the (22).

$$CR = \frac{CI}{RI} \leq 0.10 \quad (22)$$

3. A CASE STUDY: PINEROLO, TORRE PELLICE AND VILLAR PELLICE MUNICIPALITIES

This section shows the application of CAESAR II system on three municipalities in the Piedmont Region: Pinerolo, Torre Pellice and Villar Pellice.

First of all, the impact model requires the choice of the kind of analysis (risk or scenario). In case of risk, the return period must be defined, while in case of scenario a shakemap has to be uploaded or coordinates and depth of the epicentre have to be provided

The analyses proposed for the Piedmontese municipalities have been done considering the area's risk, with reference to a seismic hazard expressed in acceleration (ag) and a probability of exceedance in 50 years of 10% (return period of 475 years). The hazard value is almost homogeneous on the three municipalities.

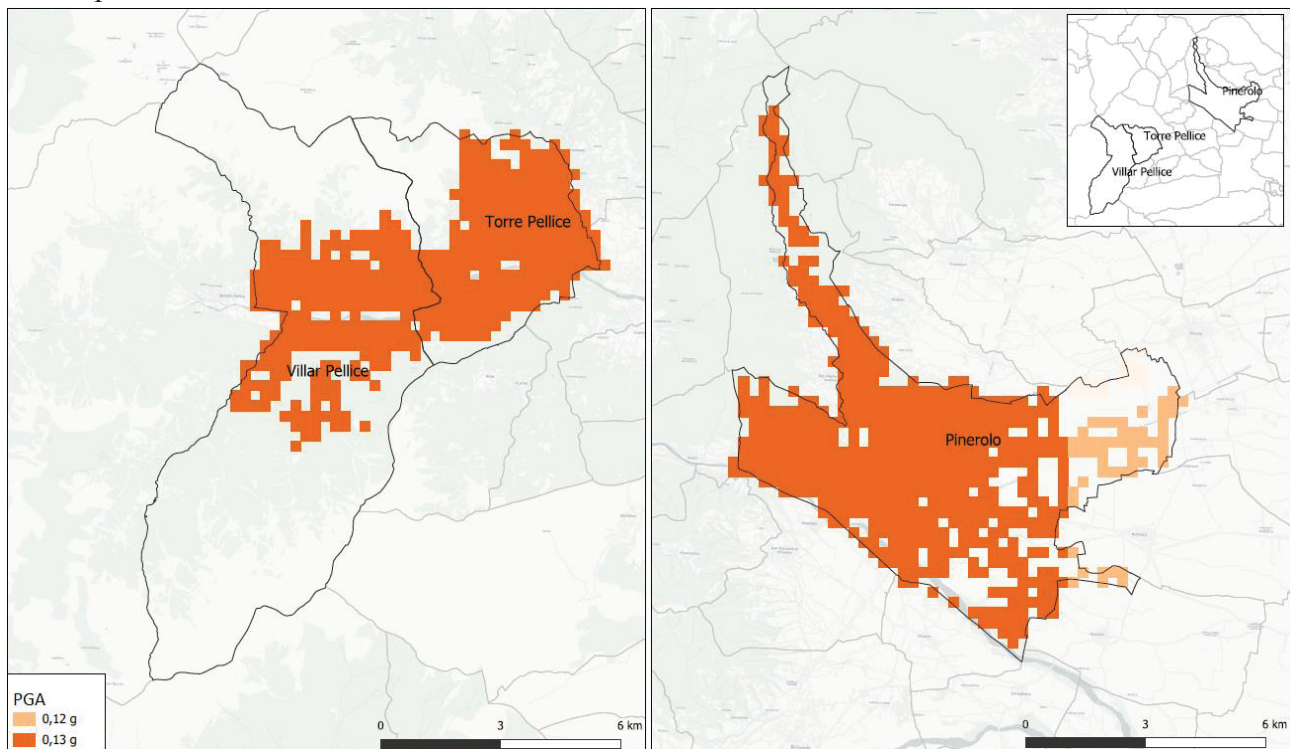

Figure 4. Hazard distribution on the cells of the investigated municipalities

Also, a dataset of 1,642 detected buildings has been provided by the Piedmont Region. With reference to the exposure model, estimated based on equations (1) and (2), the buildings distribution on the vulnerability classes summarised in the **Table 6** has been obtained. It is shown that all the investigated municipalities have a high percentage of buildings in class A (Villar Pellice 66%, Torre Pellice 52 % and Pinerolo 41%). With reference to class D, the high percentage is found in Pinerolo (28%), followed by Torre Pellice (21%) and, at the end, Villar Pellice (11%). The intermediated classes have similar values: class B occurs with a frequency of 18% in Pinerolo and Torre Pellice, and 17% in Villar Pellice; instead class C is manifested by a percentage of 13% in Pinerolo, 10% in Torre Pellice and 6% in Villar Pellice.

Table 8. Impact on the population

The impact estimated by the CAESAR II model with reference to the buildings and the population have been summarised in the Table 7 and Table 8 respectively, on the basis of the vulnerability model in the Table 2. The minimum values has been obtained with the vulnerability parameters related to the 16%, the medium values with the ones related to the 50% and the maximum values with the ones related to the 84%.

Although Pinerolo is the municipality with a high impact on the buildings and the population in total terms, it has a low percentage term. Contrary, Villar Pellice shows the low impact in full terms and the high impact in percentage terms. These results are perfectly consistent with the input data. The three municipalities are affected by an almost homogeneous hazard, so the exposure model dictates the differences. As shown, Villar Pellice is the most fragile municipality (high percentage of class A buildings), while Pinerolo has higher percentages of class C and D buildings. However, the buildings and inhabitants in Villar Pellice are 19% and 3% respectively of those in Pinerolo, so in total terms, the incidence is much lower.

The cost analysis model does not require information; the input data are the impact model's casualties and losses. In **Table 9** the costs analyses for each municipality, with reference to minimum, medium and maximum values, have been summarised. Since there are no hypotheses of mitigations in this phase, in all the cases, this value is equal to zero. The higher costs are always related to the restoration that in each case represent more than the 50% of the total costs.

The multi-criteria analysis's input data are provided by the casualties and economic losses resulting from some possible scenarios. In the case study four scenarios have been considered: the first one (SCENARIO 0) is related to the actual state while the remaining three are obtained by assuming forms of mitigation on existing buildings (SCENARIO 1: 50% of class A buildings are transformed into class B buildings and 50% of class B buildings are transformed into class C buildings; SCENARIO 2: 65% of class A buildings are transformed into class B buildings and 35% of class B buildings are transformed into class C buildings; SCENARIO 3: 80% of class A buildings are transformed into class B buildings and 20% of class B buildings are transformed into class C buildings). For each scenario have been considered the data estimated with the vulnerability model at 50%.

Table 10. Impact (on the buildings and the population) and costs of each scenario and percentage of the impact aspects of each hypothesised scenario with reference to the actual case (SCENARIO 0)

The objective of this case study is to draw up an adequate response to a seismic emergency. Such a program represents a dynamic tool open to updates and revisions, subject to the identification and definition of multiple criteria articulated on different levels and configured to anticipate, prevent or deal with an earthquake that hits territory and social community

The dominance hierarchy proposed for this case identifies an objective O represented by the *emergency response* and three criteria C_i that specify the contents and meanings of the objective. *Buildings*, *population* and *costs* represent these first-level criteria. Sixteen second-level sub-criteria S_i further characterising the criteria in the higher level are expressed by *strategic buildings*, *cultural heritage*, *residential buildings*, *transport infrastructures*, *industrial plants*, *buildings with social functions*, *dead*, *injured*, *homeless*, *mitigation costs*, *reconstruction costs*, *restoration costs*, *demolition and rubble removal costs*, *health care costs*, *evacuation costs* and *emergency management costs*. The four decision alternatives A_i are described by the four scenarios derived from the two impact models already mentioned.

The first phase of the decision-making process is the composition of a team in which each member involved has specific skills within disciplines related to the strategic resolution of the problem. Based on the semantic scale of Saaty, every opinion expressed by the single decision-maker on an explanatory and simplified questionnaire represents the intensity of dominance to each pairwise comparison between elements belonging to the same hierarchical level. Results are averaged to take account of the multidisciplinary nature of the problem and transferred into the Analytic Hierarchy Process in the form of matrices of pairwise comparisons.

The first matrix of pairwise comparisons contains the criteria *buildings* C_1 , *population* C_2 and *costs* C_3 that are compared with each other regarding the objective *emergency response* O . Consequently, the normalised weight of each criterion is calculated.

O	C_1	C_2	C_3
C_1	1	1/5	3
C_2	5	1	6
C_3	1/3	1/6	1

Table 11. Matrix of pairwise comparison of criteria regarding the objective O

The second matrix of pairwise comparisons contains the sub-criteria *strategic buildings* S_1 , *cultural heritage* S_2 , *residential buildings* S_3 , *transport infrastructure* S_4 , *industrial plants* S_5 and *buildings with social functions* S_6 that are mutually compared regarding the criterion *buildings* C_1 . The third matrix of pairwise comparisons contains the sub-criteria *dead* S_7 , *injured* S_8 and *homeless* S_9 that are mutually compared regarding the criterion *population* C_2 . The fourth matrix of pairwise comparisons contains the sub-criteria *mitigation costs* S_{10} , *reconstruction costs* S_{11} , *restoration costs* S_{12} , *demolition and rubble removal costs* S_{13} , *health care* S_{14} , *evacuation costs* S_{15} and *emergency management costs* S_{16} that are mutually compared regarding the criterion *costs* C_3 . Therefore, all the weights are calculated and inserted into specific vectors.

Finally, sixteen matrices of pairwise comparisons are assembled: the alternatives *seismic vulnerability condition 1* A_1 , *seismic vulnerability condition 2* A_2 , *seismic vulnerability condition 3* A_3 and *seismic vulnerability condition 4* A_4 are compared with each other concerning the various sub-criteria S_i by an automatic algorithm able to assign a value from the semantic scale of Saaty to every ratio. All the matrices so calculated can provide the weight of each alternative with reference to each sub-criterion.

These decision alternatives are subsequently weighted in relation to the criteria *buildings* C_1 , *population* C_2 , *costs* C_3 and, ultimately, with reference to the objective *emergency response* O . The decision alternative *seismic vulnerability condition 4* A_4 turns out to be the best compromise between expected losses and economic burden for the community.

O	C_1	C_2	C_3	w_{Ai}
w_{Si}	0,195	0,717	0,088	
A_i				
w_{A1}	0,230	0,045	0,419	0,114
w_{A2}	0,238	0,143	0,126	0,160
w_{A3}	0,252	0,248	0,164	0,242
w_{A4}	0,280	0,563	0,291	0,484

Table 12. Calculation of the weights of the alternatives regarding the objective O

4. CONCLUSIONS

CAESAR II is a web-service procedure conceived as a decision support system for public authorities engaged in disaster risk reduction plans. The platform gives the possibility to plan medium and long-term investments and define customised financial support mechanisms and fiscal incentives. The 'seismic impact scenarios' evaluation module estimates the impact on the buildings and the population based on the user's few values on the hazard and, eventually, on the exposure. Simulation results can be further processed through the Multi-Criteria Cost-Benefit Analysis modules to support the comparative evaluation of alternative seismic and energy measures.

This paper described the procedure and the parameters included in each module of the tool and shows an application on three municipalities of the Pedimont region: Pinerolo, Villar Pellice and Torre Pellice. It is shown that CAESAR II requires few and easy data to the user, although it is able to provides a complete package of outcomes useful to support the emergency management and the mitigation decisions.

Abstract

Reproducibility and transparency have become standard practice in earthquake loss modelling following a growing demand from both the public and private sectors for understandable and accessible risk model input data, software and results. Since the 1990's the European scientific community has worked together on many aspects of seismic hazard and risk modelling. These advances have led to the 2020 European Seismic Risk Model (ESRM20), which has been computed with open source software and is now being openly released to the wider scientific community. This paper presents the recently released input models and software to assess the vulnerability of the European building stock within ESRM20.

Keywords: Vulnerability, Fragility, European Exposure, Open-Source, Open Data.

1 INTRODUCTION

Reproducibility and transparency have become standard practice in earthquake loss modelling following a growing demand from both the public and private sectors for understandable and accessible risk model input data, software and results. Since the 1990's the European scientific community has worked together on many aspects of seismic hazard and risk modelling. These advances have led to the 2020 European Seismic Risk Model (ESRM20), which has been computed with open source software and is now being openly released to the wider scientific community (Crowley et al., 2019 [1]). This paper summarises the recently released input models and software to assess the vulnerability of the European building stock within ESRM20.

2 CAPACITY CURVES FOR EUROPEAN BUILDING STOCK

Capacity curves provide a description of the lateral strength and deformation capacity of buildings or building classes, and are often transformed to the ADRS (acceleration displacement response spectrum) format for the purposes of developing fragility functions.

For ESRM20, capacity curves for a large range of building classes are needed to cover the varying construction types in Europe (as included within the European exposure model: Crowley et al., 2020a [2]; Crowley et al., 2020b [3]). The GED4ALL Building Taxonomy has been used to classify the vulnerability of European buildings (Brzev et al., 2021 [4]) with the attributes summarised below:

- **Materials.** CR: reinforced concrete, MR: reinforced masonry, MCF: confined masonry, MUR: unreinforced masonry, MUR-ADO: adobe, MUR-CB99: concrete block masonry, MUR-CL99: clay brick masonry, MUR-STDRE: dressed stone masonry, MUR-STRUB: rubble stone masonry, S: steel, W: wood/timber.
- **Lateral load resisting systems.** LDUAL: dual frame-wall system, LFINF: infilled frame, LWAL: load bearing wall, LFM: moment frame, LFBR: braced frame.
- **Code Level or Ductility.** CDN: absence of seismic design, CDL: low code level (designed for lateral resistance using allowable stress design), CDM: moderate code level (designed for lateral resistance with modern limit state design), CDH: high code level (designed for lateral resistance coupled with target ductility requirements and capacity design), DNO: non-ductile, DUL: low ductility, DUM: moderate ductility, DUH: high ductility.
- **Height.** H: number of storeys.
- **Lateral Force Coefficient.** The value of the lateral force coefficient, i.e. the fraction of the weight that was specified as the design lateral force in the seismic design code (see Code Level), expressed in % (applied to reinforced concrete moment and infilled frames only).

Following their use in the calculation of their Global Seismic Risk Map (GEM, 2018), the GEM Foundation has released a global database of capacity curves (Martins and Silva, 2020 [5]) which have been derived through the compilation of data coming from research studies and experimental campaigns. These capacity curves have been used to represent the European CR_LDUAL, CR_LWAL, MCF, MR, MUR, S and W typologies with different heights and ductility, for a total of 217 building classes.

As part of the European SERA project (www.sera-eu.org), a detailed set of capacity curves for European reinforced concrete infilled frames (CR_LFINF) and moment frames (CR_LFM) has been recently developed (Romão et al., 2019 [6]). A total of 264 reinforced concrete classes have been identified by combining different numbers of storeys (1 to 6), seismic design code levels (no code: CDN, low code: CDL, moderate code: CDM, high code: CDH) and lateral force coefficient levels (0, 5, 10, 15, 20, 25, 30 % of the weight of the structure). Buildings of

design class CDN were typically designed to older codes (from before the 1960's) that used allowable stresses and very low material strength values and considered predominantly the gravity loads. Buildings of design class CDL were designed considering the seismic action by enforcing values of the seismic coefficient, β (referred to herein as lateral force coefficient). Structural design for these codes was typically based on material-specific standards that used allowable stress design or a stress-block approach. Seismic design including modern concepts of ultimate capacity and partial safety factors (limit state design) was the basis of the CDM category of codes. The seismic action was also accounted for in the design by enforcing values for the lateral force coefficient, β . Finally, the CDH class refers to modern seismic design principles that account for capacity design and local ductility measures, similar to those available in Eurocode 8 (CEN, 2004 [7]). Seismic zonation maps associated with the seismic design codes employed in Europe over the last century can be used to identify the lateral force coefficient (i.e. the fraction of the weight that was specified as the design lateral force in the seismic design code, expressed in %) (see Crowley et al., 2021 [2] and Crowley et al., 2020c [9]).

The capacity curves for the 264 building classes were developed through simulated design of prototype frames (see e.g. Borzi et al., 2008 [10]; Verderame et al., 2010 [11]) and then nonlinear analysis has been undertaken to obtain the backbone capacity curves of these frames. Up to 300 capacity curves have been simulated per class by modifying the geometrical and material properties of the prototype frames, and thus accounting for the building-to-building variability in the simulated design. Figure 1 shows the median capacity curves for reinforced concrete frames with masonry infills not designed with seismic loads (CDN).

Figure 1: Median capacity curves from Romão et al. (2020) [12] for reinforced concrete frames with masonry infills (CR/LFINF) not designed with seismic loads (CDN)

All of the median capacity curves for the 481 building classes are publicly available on a GitLab repository (Romão et al. 2020 [12]).

3 VULNERABILITY MODELLING

3.1 Vulnerability Modellers' Toolkit (VMTK)

The fragility functions of these European building classes have been computed using the Vulnerability Modeller's Toolkit, a resource that has been developed and released by the GEM Foundation in collaboration with members of the European risk community (Martins et al., 2021 [13]). This toolkit is a set of Python scripts that read the capacity curves, produce SDOF

hysteretic models, launch OpenSeesPy¹ to run nonlinear dynamic analysis, apply linear censored regression to the cloud of nonlinear responses, and compute fragility functions for different damage states, based on the user-defined damage state thresholds. A graphical user interface is included with the toolkit and includes a set of default assumptions, allowing less experienced users to interact with the VMTK (Figure 2). Experienced users are instead encouraged to make use of Python's scripting capabilities to explore all the features of the VMTK source code and to contribute to future releases of the toolkit. The complete toolkit, including source code and GUI, is currently hosted in a publicly available GitHub repository².

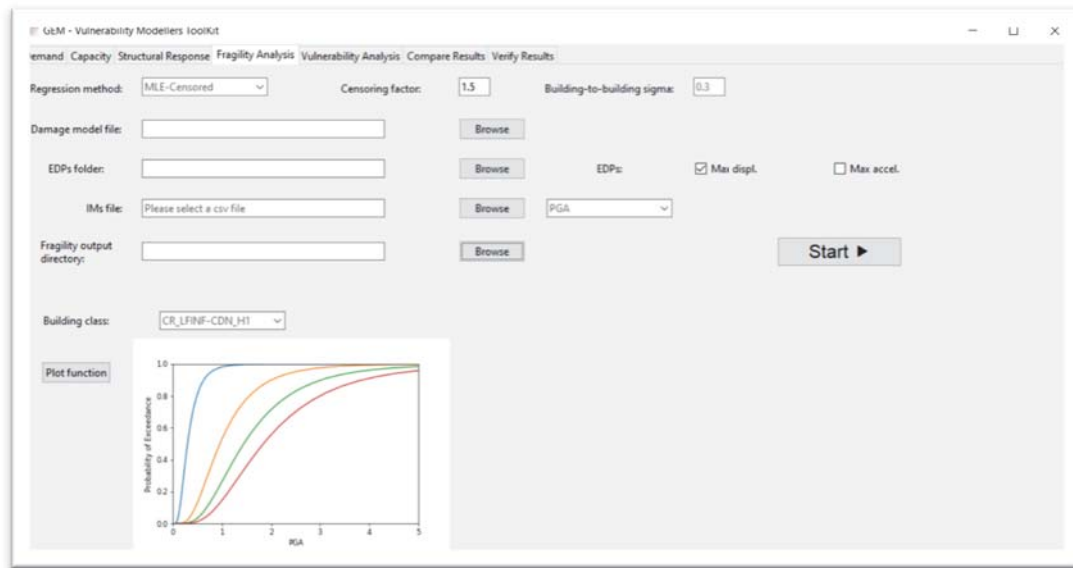

Figure 2: Graphical user interface of the fragility module of the VMTK (Martins et al., 2021 [13])

3.2 Fragility Functions

The median capacity curves in Romão et al. 2020 [12] have been read by the VMTK's 'nlth_on_s dof.py' script which has been used to produce SDOF models using the Pinching4 hyseresis curve of OpenSeesPy. Pinching4 is a uniaxial material that represents a 'pinched' load-deformation response and exhibits degradation under cyclic loading. In addition to the response envelope (taken from the capacity curves), the hysteretic properties given in Table 1 have been assumed for the SDOF models for the different material types. Cyclic degradation of the strength and stiffness is modelled for the CR, MUR, MCF and MR typologies through unloading stiffness degradation, reloading stiffness degradation, and strength degradation. Mass proportional damping is used with different damping ratios for each typology. Typically, masonry is assigned 10% damping, reinforced concrete and wood is 5%, and steel is 3%. The 'nlth_on_s dof.py' script runs nonlinear dynamic analysis using each SDOF and a set of records. A database of recordings has been compiled for the nonlinear dynamic analyses using records with PGA above 0.05g in the Engineering Strong Motion (ESM, Luzi *et al* 2016 [14]; Luzi *et al.* 2020 [15]) and NGA (Chiou et al. 2008 [16]) databases. Records have then been selected from this database to match a range of intensity measure bins with a maximum scaling factor of 2.

² <https://github.com/GEMScienceTools/VMTK-Vulnerability-Modellers-ToolKit>

The SDOF properties reported above are currently being further tested and modifications might still be incorporated in the final European fragility models. The final scripts used to develop the models will be made available on the aforementioned GitLab repository (Romão et al. 2020 [12]) so that are final assumptions are transparent and it will be possible to easily reproduce the models.

Table 1: Adopted parameters of the Pinching4 hysteresis model

Parameters of Pinching4*	CR, MUR, MCF, MR	W, S
rdispP/N, fForceP/N, uForceP/N	0.5, 0.25, 0.05	0.5, 0.25, 0.5
gK1 gK2 gK3 gK4 gKLim	0, 0.1, 0, 0, 0.2	0,0,0,0,0
gD1 gD2 gD3 gD4 gDLim	0, 0.1, 0, 0, 0.2	0,0,0,0,0
gF1 gF2 gF3 gF4 gFLim	0, 0.4, 0, 0.4, 0.9	0,0,0,0,0
gE	10	10
dmgType	energy	energy

* See <https://openseespydoc.readthedocs.io/en/latest/src/Pinching4.html?highlight=pinching4> for definition of the parameters

The ‘fragility_censored_cloud_analysis.py’ script in the VMTK uses the nonlinear response outputs from each dynamic analysis together with damage thresholds to apply linear censored regression, and this is then used to compute fragility functions (lognormal distributions) for different damage states, based on the user-defined damage state thresholds. For the European fragility functions, the damage thresholds presented in Figure 3 have been assumed.

Figure 3: Damage thresholds assumed in the development of the fragility functions (Martins and Silva, 2020 [8])

Four different intensity measure types have been used in the censored regression: PGA, Sa(0.3), Sa(0.6) and Sa(1.0). An average spectral acceleration (see e.g. Baker and Cornell (2006) [17]; Eads et al., 2015 [18]) with 20 intervals between 0.05 and 3 seconds is also currently being investigated. The final intensity measure for each building typology is taken as that with the lowest lognormal dispersion in the fragility function given that this is related to efficiency (i.e. low dispersion in the nonlinear response, given the intensity measure), and it has been found by checking the sufficiency (i.e. conditional independence of the distribution of nonlinear response, given IM, on other parameters of the ground motion) of the different intensity measures that the most efficient is typically also sufficient. Some recent studies have shown that the higher the efficiency, the higher the sufficiency of the intensity measure (e.g. Bradley et al. 2010 [19]). Others have cautioned that the typical checks for sufficiency (e.g. Luco and Cornell, 2007 [20]) only provide evidence rather than proof of sufficiency and that it should be ensured

that the intensity measure is also efficient to ensure that the additional parameters really are having a significant influence on the response (Kazantzi and Vamvatsikos, 2015 [21]). For illustration purposes, Figure 4 shows the fragility functions in terms of $S_a(0.3s)$ that have been obtained with the capacity curves presented in Figure 1.

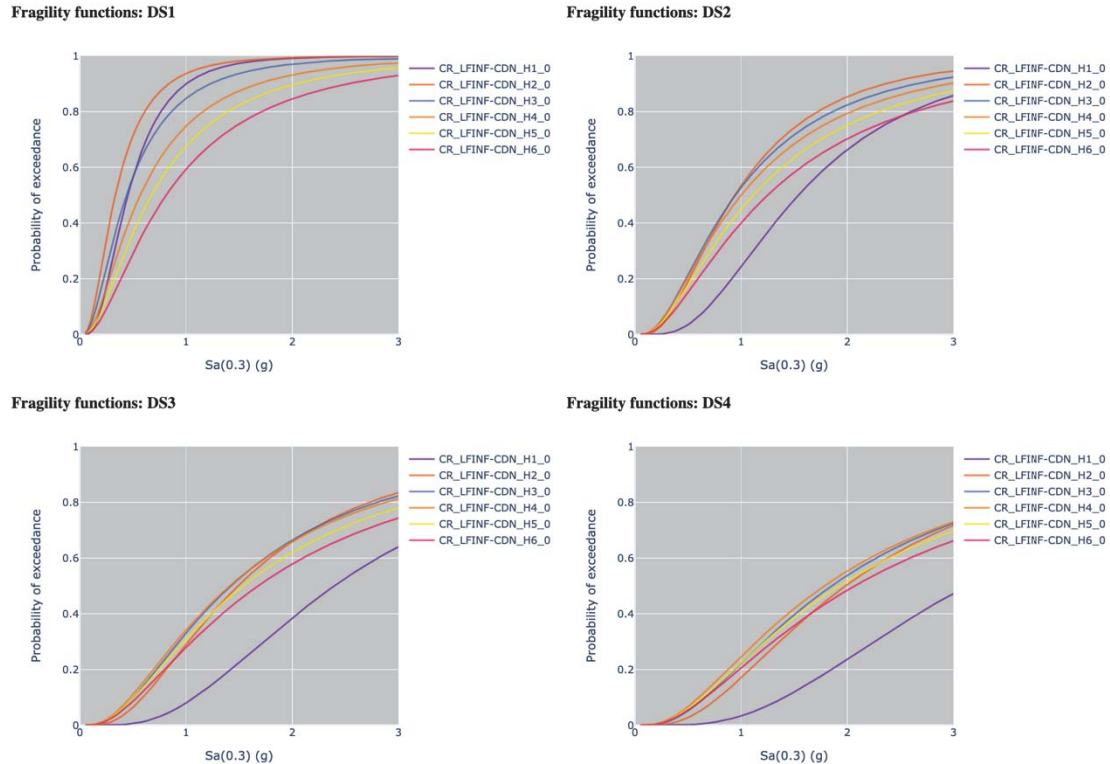

Figure 4: Fragility functions calculated using the capacity curves presented in Figure 1, where DS1 = slight damage, DS2 = moderate damage, DS3 = extensive damage and DS4 = complete damage

3.3 Vulnerability functions for cost of repair/replacement

The fragility functions are converted into vulnerability models using damage-loss models which provide damage ratios for each damage state (slight, moderate, extensive and complete). For losses due to the repair of damage, the damage ratios (which represent the ratio of cost of repair to cost of replacement) from HAZUS (FEMA, 2004 [22]) are being adopted, i.e. 0.02 (slight damage), 0.1 (moderate damage), 0.5 (extensive damage), 1.0 (complete damage). These values are being further tested and calibrated using the results of the tests described in Section 4 and may be adapted before the final release of ESRM20. For a range of intensity measure levels, the probability of occurrence of each damage state is obtained from the fragility functions, multiplied by the damage ratios and summed leading to a mean loss ratio. A lognormal cumulative distribution function has then been fit to the vulnerability data to obtain the median and lognormal standard deviation (dispersion).

In order to account for the building-to-building variability, which is not accounted for given the use of the median capacity curves, a separate study to produce vulnerability functions using all available capacity curves for the CR/LFINF and CR/LFM typologies has been undertaken. This study showed that the mean vulnerability function based on all of the capacity curves of a given typology had a very similar median to the vulnerability function based on the median capacity curves. However, the dispersion was, as expected, slightly higher. It was found that the additional dispersion required to account for building-to-building variability was around 0.3,

and this is therefore combined with the dispersion obtained with the median capacity curves through the square-root-sum-of-squares to produce the final vulnerability functions.

3.4 Vulnerability functions for loss of life

For loss of life, the model uses a number of factors obtained from both past observations and expert judgment, including the likelihood that a completely damaged building will collapse to the extent that it could cause loss of life (currently taken as 1.5% based on the data from recent earthquakes: Antonios Pomonis, personal communication), the probability of entrapment given collapse (Reinoso et al. 2017 [23]), and the probability of loss of life given entrapment (Reinoso et al. 2017 [23]). Different entrapment ratio for day and night are assumed, with higher values for the latter given the increased time required for people to wake up and escape from the collapsing building. Also, an increase in the entrapment ratio with number of storeys has been implemented for the day-time entrapment rates. The loss of life given entrapment has been obtained from the data in Table 2 of Reinoso et al. (2017 [23]) with a clear distinction between buildings with less than and more than 5 storeys being observed and thus applied. Table 2 presents all of the assumed values.

Table 2: Adopted fatality model input parameters

Number of storeys	P-entrapment (day)	P-entrapment (night)	P-loss-life entrapment
1	0.25	0.95	0.4
2	0.5	0.95	0.4
3-4	0.75	0.95	0.4
>5	0.95	0.95	0.7

The fatality vulnerability models are obtained by multiplying the complete damage fragility functions by 1.5% and the factors presented in Table 2. A lognormal function is then fit to the data and the dispersion is increased to account for building-to-building variability (as presented in the previous section).

3.5 Vulnerability Viewer

A Dash App is currently under development to allow users to view and compare the fragility and vulnerability functions for all of building classes and for all the available intensity measure types. A prototype that presents the vulnerability functions in terms of $S_a(0.3)$ is currently available at <http://vulncurves.eu-risk.eucentre.it/> (see Figure 5).

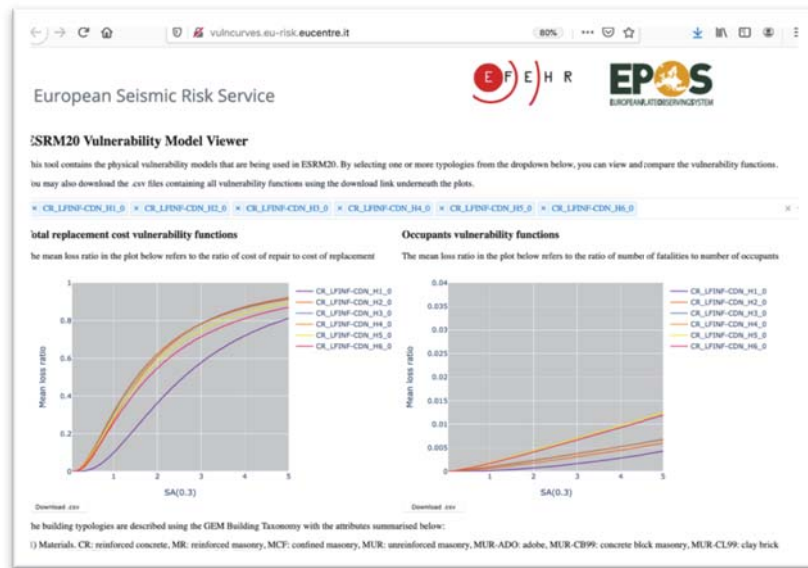

Figure 5: Screenshot of the vulnerability viewer currently under development

4 VULNERABILITY TESTING

Extensive testing of the resulting fragility and vulnerability models has been undertaken by comparing the modelled damage/losses with empirical models as well as with observations from a large number of past European earthquake scenarios (Crowley et al. 2020d [24]).

Simple sanity checks, so-called ‘unit tests’ are undertaken to ensure the median and dispersion values are within sensible ranges, and to compare with existing functions from the literature. The VMTK includes a module that allows users to test their model’s against GEM’s global vulnerability models, which have been calibrated or tested using past earthquake damage and loss data. Useful, and openly available, data for this purpose includes the empirical vulnerability models developed by PAGER (Jaiswal et al., 2009 [25]; Jaiswal and Wald, 2013 [26]), as well as fatality, economic loss and damage data from various databases including the Centre for Research on the Epidemiology of Disasters (CRED)’s EMDAT data-base (EMDAT, 2019 [27]), the Italian Department of Civil Protection’s Da.D.O. data-base (Dolce et al., 2019 [28]), NOAA’s Significant Earthquake Database (NGDC/WGS), and the Cambridge Earthquake Impact Database (www.ceqid.org).

Figure 6 shows two examples of tests that have been undertaken with the European vulnerability model. In the first example, a mean vulnerability function calculated through an exposure-weighted combination of all the building classes in the country has been produced and compared with the empirical models developed by PAGER, following conversion of the spectral ordinates to macroseismic intensity (with the associated uncertainty in the conversion shown by the mean and ± 1 standard deviation vulnerability curves). In the second example, ground motion fields (modelled using scenario rupture models and the latest European ground motion and site amplification models) have been developed for over 30 damaging historical events above magnitude 5 in Europe since the 1980’s. These ground motions are then combined with the current exposure and vulnerability models to estimate direct economic losses. These are then compared in a statistical sense with the reports on economic losses (that are corrected to today’s value). Similar tests can also be undertaken for fatalities. These tests provide a check to ensure that probabilistic losses predicted by the risk model are not biased.

Figure 6: Example tests of the European vulnerability model: (left) comparison with the PAGER vulnerability model, where the three blue dashed lines represent the mean and \pm sigma, (right) comparison of estimated and observed losses for damaging European events since 1980

These tests will continue to be undertaken until the finalization and release of ESRM20 which is expected in October 2021. As mentioned previously, all of the scripts and input data described herein will then be released on the dedicated vulnerability GitLab repository (Romão et al. 2020 [12]).

Abstract

PELL, Public Energy Living Lab, is a platform conceived to support the Public Administration in Italy towards the definition and implementation of interventions on public buildings, aiming to jointly pursue their seismic safety, energy efficiency and environmental certification. This paper presents the on-going activities for the development of the platform PELL-Schools, focusing, in particular, on the “Seismic-Response” module that aims to become a standardized and interoperable database for the collection and collation of relevant data for the seismic vulnerability assessment and for the seismic monitoring of Italian schools. In order to test, tune and modify, if necessary, the proposed PELL-School Seismic-Response module and to contribute to its implementation on Italian school buildings a Working Group has been set up involving several Italian municipalities and stakeholders. The paper concludes with a call to action inviting researchers working on the seismic vulnerability assessment and monitoring of strategic buildings to join the Working Group to contribute their knowledge towards the common goal of guarantying the seismic safety of schools and other strategic buildings in Italy.

Keywords: School Buildings; Geodatabase; Standardization; Interoperability, Seismic Vulnerability Assessment; Seismic Risk; Public Administration; Energy Efficiency

1 INTRODUCTION

The Italian Ministry of Education and Research (MIUR) permanently guarantees the access and reusability of the data of the national education and training system, making accessible in open format, among others, the data from the National School Building Registry System (SNAES). According to SNAES data, the portfolio of Italian schools includes 40.151 actively operating buildings belonging to local authorities, out of which: about 50% were built before 1970; 46.8% do not hold a static safety certificate; 59.5% do not hold the fire prevention certificate; and 53.8% do not hold the certificate of viability/habitability. The situation is indeed critical. As far as the seismic vulnerability of school is concerned, the situation is possibly even worse despite the several initiatives undertaken by the Italian Government. After the 2002 earthquake in Puglia and Molise, the directive of the President of the Council of Ministers (PCM) n. 3274 of 20 March 2003, referred hereafter as OPCM 3274 [1], reclassified the entire national territory into four areas with different level of hazards (removing the non-seismic areas) and introduced the obligation for the owners to proceed with the seismic verification of strategic buildings and of buildings relevant for civil protection purposes, including school buildings. Specific funds for extraordinary interventions, including seismic checks and first urgent interventions, were made available¹, and were allocated by the Civil Protection Department - through the Regions – for financing the seismic checks of about 2.300 school buildings (out of the 40.151 building patrimony). Furthermore, the Regions and Municipalities carried out further seismic checks of school buildings with their own funds. At the moment the Italian Civil Protection Department is digitizing the summary data of the checks carried out in order to establish a centralized database associated with ARES, the *Regional Registry of School Building* (in Italian, “*Anagrafe Regionale Edilizia Scolastica*”)².

To support this process, ENEA intends to make available all the technologies and experience gained, thanks to the PELL experience, to contribute to build an interoperable database of Italian school buildings throughout the national territory. PELL, Public Energy Living Lab, is a platform conceived to: a) achieve a minimum standard of building knowledge; b) monitor and evaluate the state of art of buildings and performances; and c) support the Public Administration (PA) in Italy towards the definition and implementation of interventions on public buildings, aiming to jointly pursue their seismic safety, energy management efficiency [2]. PELL-IP, the platform for the census and monitoring of Public Lighting at national scale, is already a successful reality in Italy (since 2019).

This paper presents the on-going activities for the development of the *PELL-School* platform, focusing, in particular, on the “Seismic-Response” module, referred hereafter as *PELL-School-RS* that aims to become a standardized and interoperable database for the collection and collation of relevant data for the seismic vulnerability assessment and for the seismic monitoring of Italian schools. As far as the seismic vulnerability assessment is concerned, *PELL-Schools-RS* will faithfully replicate and build on the data structure of the official form [3] defined by the Italian Presidency of the Council of Ministers (PdCM), Department of Civil Protection, for the seismic vulnerability assessment of strategic buildings. The inclusion in *PELL-Schools* of additional input data, aimed at identifying critical vulnerabilities and at estimating a risk class and the expected average annual loss (EAL), before and after seismic retrofitting interventions, is proposed in line with the approach officially adopted in Italy for the classification of the seismic risk of residential buildings [4].

¹ The Fund of 200 million euros was implemented through the opcm n. 3362 of 8 July 2004 and no. 3505 of 9 March 2006

² Quoting from - <http://www.protezionecivile.gov.it/attivita-rischi/rischio-sismico/attivita/sicurezza-scuole>

The paper also presents the Key Performance Indicators (KPIs) indicators included in *PELL-School-RS*, namely: *Static KPIs*, providing a measure of the building seismic vulnerability and expected “nominal” risk (Section 4.1), and *dynamically computed KPIs* (Section 4.2) that aim to provide a quasi-real time estimation of the extent of earthquake-induced damage. The KPI assessment is performed in *PELL-School-RS*, at different level of reliability, Tiered approaches, based on the state-of-the-art methodologies and via a simplified analytical-mechanical approach referred to as SLAMA method [5], [6] depending on the level of knowledge achievable and on the information available for each school.

In summary, as showcased in the paper *PELL-School* aims to become a national database/cadaster of school buildings, working as:

1. a standardized and homogeneous geospatial repository of identity, consumption and seismic vulnerability data of Italian school buildings, where data are structured according to ad-hoc technical specifications from AgID³ the Agency for Digital Italy, a technical agency of the *PdCM*;
2. an interoperable platform that, thanks to the development of appropriate communication protocols and webservices, allows for a two way data exchange and update with other existing DBs;
3. a tool for monitoring the service performance and the residual functionality of schools for both business-as-usual and post-disaster times.

2 PELL PUBLIC BUILDINGS – ENERGY AND SEISMIC RESPONSE LIVING LAB

Since several years ENEA has been promoting and boosting the digitization of data and information related to the public administration assets. Particular focus has been given to energy-intensive infrastructures (such as street Public Lighting) and to the strategic infrastructures (e.g. school buildings, hospital systems among others) and/or critical for the smart management of cities and territories.

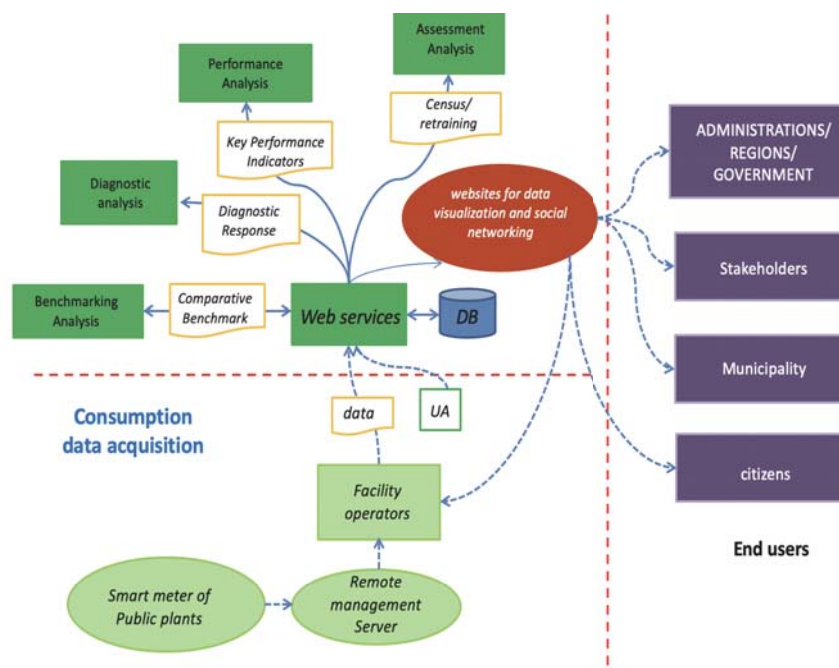

Figure 1. PELL Platform, ICT layout.

³ Agenzia per l'Italia Digitale (<https://www.agid.gov.it/>)

The goal is to promote a more efficient and effective management of these infrastructures and associated services, through the development and adoption of new methodological and technological solutions, allowing to provide to the stakeholders a set of management tools, embedded in the PELL platform, that can support and inform their decision-making processes about the adoption of targeted development goals.

Towards that the idea is to automatically and constantly assess, in a uniform and standardized way, at both national and local level, both the physical conditions of the structure or infrastructure under analysis as well as the functional ones, the latter by monitoring the quality level of the service provided.

The PELL platform, developed thanks to the System Research Program Agreement under the Italian Minister of Economic Development, MISE, is made available free of charge by ENEA. The vertical PELL platform is a smart city as-a-service platform, whose general architecture defines the retrieval of data from different infrastructures and managers and the creation of a series of services for end users (Figure 1). The PELL platform is structured to operate both a static mode, to support the census of the identity data of the infrastructure, and in a dynamic mode, to support the continuous monitoring of the structure/infrastructure functioning.

3 PELL-School-RS DATA STRUCTURE

Figure 2 presents the data structure proposed for the *PELL-School-RS* module.

<ul style="list-style-type: none"> ✓ Seismic and hydrogeological hazard (ES) ✓ Year of construction; original and current use (ES) ✓ Interventions and their compliance with standards (ES) ✓ Dimensional characteristics (ES) ✓ State of conservation (ES)
<ol style="list-style-type: none"> 1. Identification of Structural Unit (US) 2. Dimensional data, Age of construction/renovation, Description of any structural intervention performed. Figure 2. Main group of data included in the *PELL-School-RS* module.

In line with the structure of the ARES DB, some group of data (i.e. those included in the grey box in Figure 2) are acquired at building level, while all the others (fields from 1 to 18 in the blue box in Figure 2) refer to the Structural Unit (US, i.e. *Unità Strutturale* in Italian) and therefore need to be collected and collated for each one of the US identified within the school building.

A *Structural Unit*, *US* (Figure 3b), is identifiable by the homogeneity of the structural characteristics and therefore distinguishable from the adjacent buildings by these characteristics and also by the difference in height and/or age of construction and/or staggered floors, etc. The US is also the reference survey unit for *PdCM Level 1 and Level 2 forms* [3].

A full presentation of the data included in *PELL-School-RS* is out of the scope of the paper.

In the following a brief overview is provided on:

- 1) ARES DB, *PdCM Level 0* and *PdCM Level 1-2 forms* [3], and other “institutional” forms such as [4] and [7], that have been taken as a reference to build the data structure of *PELL-School-RS* module;
- 2) the proposal of additional data to be collected in order to identify the constructive, material and geometric criticalities and peculiarities that might significantly affect the seismic response of a building.

3.1 Data sourced from existing institutional forms

As mentioned *PELL-School* is interoperable with ARES Database (*Anagrafe Regionale Edilizia Scolastica*) that is part of the National School Building Registry System, SNAES. ARES is managed by the Italian Regions and is continuously updated by Municipalities, Provinces and Metropolitan Cities through a user-friendly graphical user interface (Figure 3).

ARES includes two different data structure, namely: a *Building* and *US* (Structural Unit) *Form* dedicated to the survey of data related to the conditions of the school building; and a *PES Form* (i.e. *Punto di Erogazione del Servizio Scolastico*, in Italian) dedicated to the collection of data relevant to the school consistency and functionality (one school building might have multiple PES, e.g. Figure 3a).

The *ARES Building Form* and *US Form* have to be filled in by the local authority owning/responsible for the school. The *ARES PES Form* has to be filled in by the headmaster. Figure 3 shows an overview of the ARES Platform dashboard and of some images extracted from an ARES manual.

ARES Building and *US Form* includes 8 sections. *PELL-School-RS* sources data from the first three of them, namely:

- *Section A*, including: identifier data of the school building, comprising a unique ID;
- *Section B*, including: identifier data of each Structural Unit, US; structural information of the US, i.e. material and typology of the main vertical and horizontal structural systems and their peculiar constructive techniques; design code; any strengthening and seismic retrofit interventions, and related risk indicator assessed according to the legislation in force at the time of the design and execution of the work;
- *Section C*, including: data on the use of the US; some geometrical and dimensional features (number of storeys, area floor, etc.); constructive techniques of non-structural elements, such as infills, facade/claddings; information on maintenance/retrofitting interventions if any, for both structural and non-structural element, (e.g. beams, columns, floors, infills, facade/cladding; hydraulic and electrical systems).

Not all the *ARES DB* is included in the *PELL-School* platform, as the aims of the two platforms are indeed different. *PELL-School* will acquire only ARES data relevant for the identification of the school building and of its structural units, and for performing their seismic

vulnerability assessment as well as their energy efficiency assessment. Any data included in ARES that is judged to be relevant for the aforementioned aims is directly acquired in PELL-School automatically sourcing it from ARES, thus avoiding any replication of data request to the Public Administrations, PAs.

This is possible thanks to the interoperability between *ARES DB* and *PELL-School-RS*, meaning that all the relevant data collected and collated in ARES will be available in PELL-School; after an initial acquisition of the data already included in ARES and relevant to PELL a webservice will be established between ARES and PELL-Schools allowing to periodically check for and to periodically acquire newly uploaded data and/or updated data.

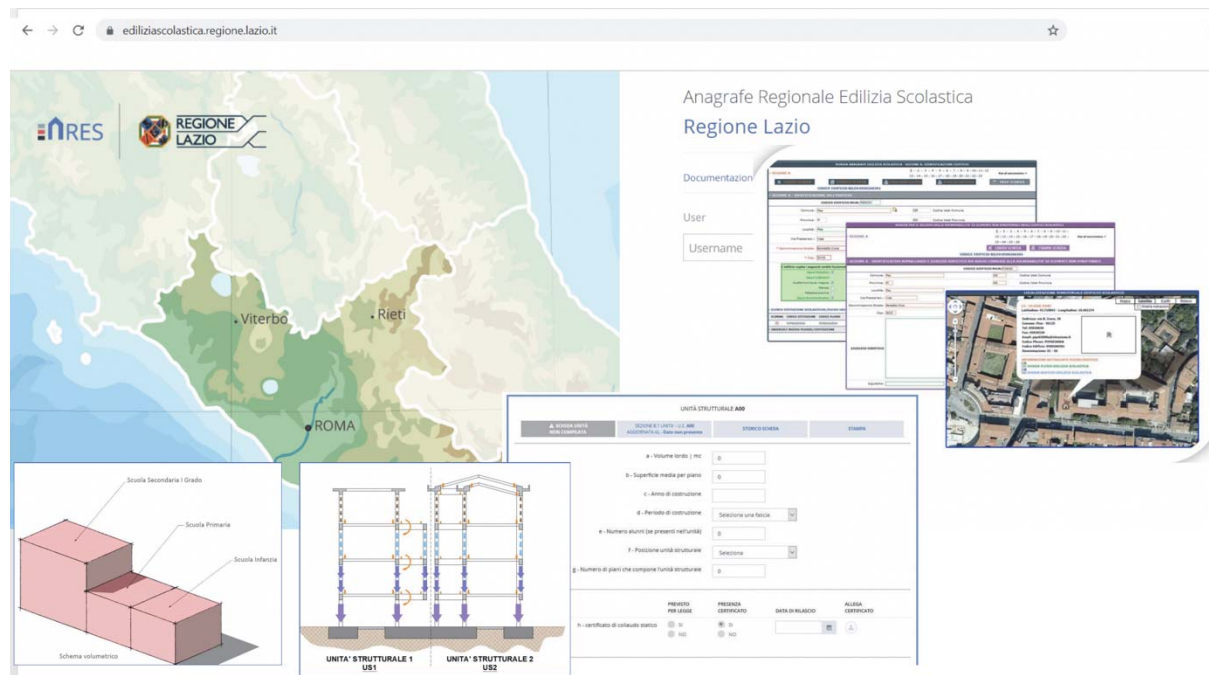

Figure 3. ARES Platform: Layout of the dashboard and GUI interfaces and pictures from ARES manual that clarifies the concept of PES and of US, Structural Unit.

PELL-School replicates in its data structure (Figure 2) the two seismic vulnerability assessment forms established by OPCM n. 3274 2003 [1], namely: *PdCM Level 0 Form*, and *PdCM Level 1-2 Form*. *PdCM Level 0 Form* aimed to support a first-step screening of the structures whose seismic vulnerability should have been assessed according to OPCM n. 3274 and to support a prioritization for their thorough seismic vulnerability assessment and identification of any required seismic retrofit intervention. Several data requested by *PdCM Level 0 Form* are already included in the ARES DB, namely: identifying data, geometrical data, construction period, material of the main vertical structural system, use of the building and presence of retrofitting interventions.

PdCM Level 1-2 Form, collect the necessary information to perform an engineering assessment of the seismic vulnerability, according to the codified methodology in the current Italian seismic code, NTC 2018 [8], to assess the a Risk Indicators (α), defined as US Capacity vs. Demand ratios; a brief summary on the concept underpinning the assessment of the seismic Capacity for US in terms of its performance at the various Limit States, according to [8], is provided in section 4.1. *PdCM Level 1-2 Form* includes 30 different sections where data are collected either as unique or multiple choice questions or by fill-in boxes where written or numerical information have to be provided, as appropriate. Data included in *PdCM Level 1-2 Form* have been replicated in the *PELL-School RS* module, as follow: sections from 1 to 20 and

section from 29 to 30 have been replicated and expanded (as briefly mentioned in the following); sections from 21 to 28 included have been grouped in the field 11 of the *PELL-School RS* module (see Figure 2) and faithfully replicated with no proposed addition.

For both *PdCM Level 0* and *Level 1-2 Forms*, that were originally conceived in paper format, data digitization is allowed through an ad-hoc software that the Department of Civil Protection, DPC, has prepared and made available to the Italian Regions⁴. Provided DPC approval already digitalized data, available as *.mdb files will be acquired by the *PELL-School RS* module and interoperability between the DPC repository and *PELL-School* will be established.

Further institutional forms/approaches, that have been taken as a reference and from where some data were sourced for inclusion in the *PELL-School RS* module include: “*Guidelines for the Seismic Risk Classification of Buildings*” so-called “*SismaBonus*” [4] and “*CLE, Limit Condition in Emergency*”⁵ form [6].

“*SismaBonus*” approach (Figure 4), that is briefly described in section 4.1, uses EMS-98 [8] typological classification to attribute a typological seismic vulnerability class to a building (Figure 4, step 1) and provides a list of constructive and geometric criticalities/peculiarities (Figure 4, step 2) to be surveyed and accounted for towards refining the assessment. Retracing the macroseismic approach proposed by [7], “*SismaBonus*” approach [4] establishes that a building can be judged to belong to a worse or better seismic vulnerability class, on respect to the one attributed simply by a typological identification, once considered respectively any anti-seismic peculiarities or criticalities that can be recognised in the building.

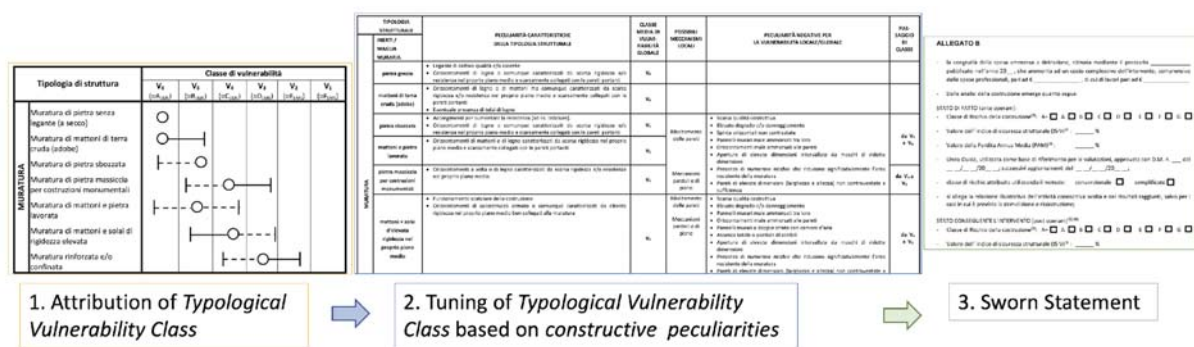

Figure 4. Schematic representation of the simplified “*SismaBonus*” approach for masonry building typologies.

As an example, for the definition of field 5 of the *PELL-School RS* module, namely “*Main structural material of vertical structures*”, as far as masonry buildings are concerned, the masonry typologies recognized by “*SismaBonus*” (indeed the same recognized by EMS-98) were integrated in *PELL-School RS* module with the ones considered by the *PdCM Level 1-2* form and with the ones included in the *ARES DB* (Figure 5); as a matter of fact the three aforementioned forms/approaches refer to a different classification system for masonry buildings and *PELL-School* aims to be inclusive and interoperable with them all and avoid data replication as said (Section 1). Furthermore several geometric criticalities/peculiarities (Figure 4, step 2) included in “*SismaBonus*” have been included in the fields from 16 to 18 of the *PELL-School-RS* module (Figure 5).

⁴ DPC circular /SISM/0092847 of 09/12/2010 rules the digitization *PdCM Level 0* and *Level 1-2 Forms* through the software “DPC Liv1-2.msi” prepared by DPC and available at <http://www.fileserve.com/file/CUkc9mM>

Figure 5. Screenshot of some of the data included in *PELL-School RS* for masonry building typologies where in (last column of the table) is clarified the origin of the data field: ARES (green rows); newly proposed (white); Sismabonus (yellow); PdCM (light blue).

As far as the “*CLE, Limit Condition in Emergency*” approach⁶ is concerned that included 5 forms (namely: Strategic Building, ES; Emergency Area, AE; Infrastructure Accessibility/Connection, AC; Structural Aggregate, AS; Structural Unit, US), *PELL-School RS* is including in fields from 16 to 18 the *CLE AS Form* data structure that collect relevant data on the possible negative interaction between adjacent US due to, for instance: the misalignment between roofs, slabs or façade walls; the misalignment in interior spaces; juxtaposition or structurally poorly connected elements (such as stairwells, canopies, balconies); incongruous punching system; isolated pillars, arcades, piloty floors; the presence of terraces, towers, chimneys. Data-structure of the further *CLS Forms* will be included in the near future development of *PELL-School-RS* as the aim would be to assess *PELL-School KPI*, not only for the school in itself but also for all the essential structures and services whose functionality are strongly influential, if not vital, for the functioning of the school.

As a matter of fact the final goal of the *PELL-School* should be to collect data and assess KPI towards a continuous monitoring of the school resilience both in business as usual time and in consideration of possible crises event. For the latter point, as far as seismic events are concerned, the idea is to include in *PELL-School* data relevant to all the Disaster Risk Management, DRM, cycle. In Figure 6 are showcased, as an example, forms currently used by the National and Regional Civil Departments and relevant to school buildings as well as to other strategic buildings for the three phases of DRM, namely before, during and after disaster:

a) Before disaster: *PCdM Level 0* and *Level 1-2* forms (already fully included in *PELL-School-RS*) and *CLE Forms* (partially included in *PELL*, only *CLE AS* data at the time being);

⁶ The analysis of the CLE of the urban settlement is carried out using standards of storage and cartographic representation of data, collected through a special form prepared by the Technical Commission for the studies of MS, established by OPCM 3907/2010 (art. 5 paragraphs 7 and 8), and issued by a special decree of the Head of the Department of Civil Protection.

b) During disaster: *FAST Form* for the synthetic assessment of post-earthquake usability (all the structural, geometrical and typological data of the *FAST form* are already included in *PELL-School-RS*; to be included data on the FAST 4 levels usability scale, i.e.: usable; non usable; non usable because of external risks; inspection non performed for causes to be specified.

c) After disaster: *AeDES Form*⁷ for post-earthquake damage and safety assessment and short term countermeasures identification; and form used by Region for post-disaster reconstruction reconnaissance as the ones used after 2009 L'Aquila (Italy) earthquake and stored in an ad-hoc created repository, i.e. *School Building Information System (in Italian Sistema Informatico Edilizia Scolastico, SIES)* with whom, needless to say *PELL-School-RS* will try to establish interoperability and data exchange.

AeDES form include 8 sections plus a note section. *PELL-School-RS* includes already data of 4 of those sections related to building identification, description, typology, soil and foundation. Still to be included in *PELL-School-RS* is the *AeDES* data structure related to damage assessment (i.e., damage to main structural components; damage to non-structural elements; external risk and existing short term countermeasures) and usability assessment.

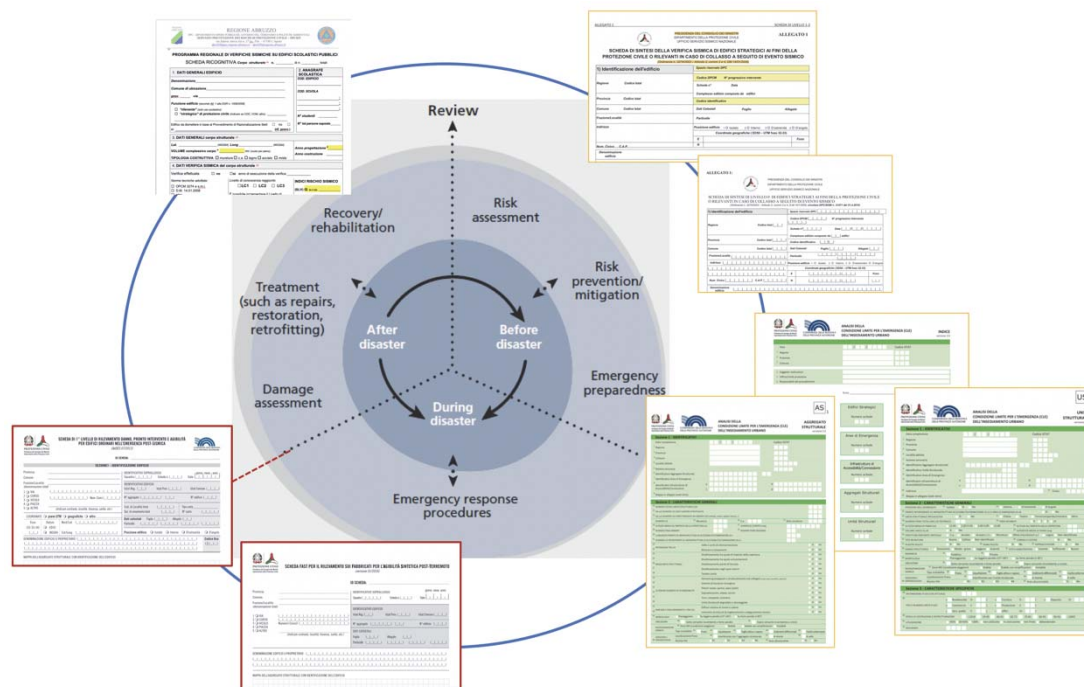

Figure 6. Some of the institutional forms used in Italy in the different phases of the Disaster Risk Management cycle, namely: before disaster PdCM and CLE forms; during disaster FAST form; post disaster AeDES and

It is worth highlighting that:

- more than 50% of the information that are usually collected and collated in post-disaster circumstances with the *FAST Form* and the *AeDES Form* would be already available in *PELL-School-RS*; this will significantly speed up the post-disaster operations of damage and usability assessment;
- *PELL-School-RS* dynamically assessed KPI can support and inform post-disaster operations of damage and usability assessment;
- It is also worth highlighting that on the other hand it will be important to include in *PELL-School-RS* the additional fields comprised in the *FAST Form* and *AeDES Form*, as those

⁷ <https://core.ac.uk/download/pdf/38619561.pdf>

data will be a vital source of information to validate and tune, if necessary, dynamically calculated KPIs.

3.2 Newly proposed data

When assessing the earthquake prone status of buildings, initial screenings are needed to identify any weakness in the structure that could potentially influence its capacity, consequently reducing the building seismic performance thereby increasing the life safety risks to occupants and/or having a negative effect on neighbouring buildings. In order to collect key vulnerabilities without going through the length of an extensive analysis, new defined data/information have been proposed and included in *PELL-School-RS*. These data can be easily collected from available architectural and structural drawings (digital files and/or original paper documents), photographic records and technical reports on the building seismic vulnerability.

Focusing on Reinforced Concrete (RC) buildings, general information on the building position (isolated, internal, edge), type of structural system resisting to lateral loads (frame, wall, combination of both) as well as warping and typology of flooring system (e.g. heavy/light) are added to the existing data, as crucial aspects to determine the structural capacity in earthquakes and potential impacts on adjacent buildings. As an example, a brief explanation is provided for the newly proposed data included in the data groups from 16 to 18 (Figure 2), in particular:

16. Geometric Criticalities: Data collected here are related to the possible presence of: both plan and vertical irregularities. Plan irregularities might include non-symmetrical plan shapes, e.g. L-, T-, E- (Figure 7a) and non-symmetrical structural systems; large spacing of lateral systems in case of long-narrow buildings; non-uniform and eccentric distribution of weights (as well as ramps, stairs, walls, stiff partitions); the presence of torsional effects in case of corner buildings. Vertical irregularities concern the possible presence of soft stories, mass variation, vertical discontinuity of structural systems (Figure 7b). Moreover, geometrical weaknesses might also include the presence and dimensions of structural gaps (building separation), that can lead to pounding effects.

Figure 7. Schematic illustration of: a) plan irregularities; b) vertical irregularities.

17. Constructive and Material-related Criticalities: Constructive criticalities for RC building mainly relate to the peculiar plan and vertical distribution of infill walls (that severely interact with the primary structure system during earthquakes, possibly contributing to the increase of both stiffness and strength or to brittle global collapse mechanisms such as soft story mechanisms), the presence of short columns, the absence of measures able to mitigate brittle collapse mechanisms and out-of-plane expulsions. Material-related criticalities for RC buildings refers to: low quality concrete and/or degraded concrete; low quality steel bars, or presence of plain round bars, corrosion. Poor materials and deterioration might lower even considerably the capacity of structural members.

18 Structural Details critical to the seismic response: These comprise indications on the detailing of beam-column joints, the steel reinforcement ratios, longitudinal and transverse steel spacing and detailing of structural members, the location of lap splices and anchorage of longitudinal bars, the detailing in the critical dissipative zones, as well as the absence of hierarchy of strengths (capacity design) principles. Structural deficiencies are in fact a consequence of incorrect design methods adopted in the past, based on gravity loading only and not accounting for seismic forces. Therefore, structural details are required as additional data in order to identify possible failure modes of the building structural elements.

In addition to the judgment on each structural weakness, the provision on numerical dimensional data is requested, specifically: the length and number of spans in both structural directions; the section geometry (width, height) and reinforcement quantities (longitudinal, transverse) for beams, columns, walls, the beam-column joint details (w/ or w/o stirrups, type of bar anchorage in the joints); the thickness of the floor slab and its reinforcement details. These quantities allow to estimate the local and global capacity of the building by simple analytical calculations, as briefly explained in the following section.

4 PELL-SCHOOL-RS KEY PERFORMANCE INDICATORS, KPI

PELL platform assess both static KPI, providing a measure of the building seismic vulnerability and expected “nominal” risk index through the estimation or evaluation of capacity/demand ratio with reference to a nominal/code design earthquake intensity (Section 4.1), and dynamically computed KPI (Section 4.2) that in the occurrence of a seismic event aim to provide a quasi-real time estimation of the extent of damage occurred and of the expected level of safety and functionality of the school building. This is done through comparison with the engineering demand parameter thresholds associated to various limit states: i.e. Operational (SLO), Damage Control (SLD), Life Safety (SLV) and Collapse Prevention (SLC).

As far as the monitoring of the seismic response is concerned, *PELL-School-RS* conveys continuous Key Performance Indicators, as a ratio between the recorded engineering demand parameters, EDP, (actual demand) and the estimated/calculated EDP capacity thresholds associated to the various Limit/Damage States, calculated after the automatic processing of data

recorded from MEMS- based accelerometers. The final aim is to derive an objective, prompt and quantitative indication of the damage state and level of safety and functionality of the school building in the aftermath of a seismic event.

4.1 Static KPI

As discussed in the previous section, the collection of additional input data in the *PELL-School-RS* aims at identifying the critical weaknesses/vulnerabilities of buildings. Moreover, these data allow to assess the Seismic Risk Class, including both the Safety Index (IS-V, ζ_E) and Expected Annual Losses (EAL) before and after seismic retrofitting interventions. The estimation of these safety and (economic) performance indicators is proposed in the *PELL-School-RS* by adopting the methodology currently adopted in Italy for the classification of the seismic risk of residential buildings [4].

Referring to the official forms provided by the Italian Presidency of the Council of Ministers (PCM), according to the OPCM n. 3274, 2003, namely *Levels 1-2* assessment for strategic structures, Risk Indicators (α) are defined as Capacity vs. Demand ratios in terms of both Peak Ground Acceleration (PGA) - PGA_C/PGA_D - and Return Period (T_R) - TR_C/TR_D -. The α values are computed at the four different seismic intensity levels or Limit States, namely: Operational (SLO), Damage Control (SLD), Life Safety (SLV) and Collapse Prevention (SLC). The seismic Demand (PGA_D , TR_D) represents the design demand in acceleration/period for a new building located in the same site. The seismic Capacity in terms of acceleration (PGA_C) depends on the building performance at the various Limit States and is evaluated according to the codified methodology in the current Italian seismic code, NTC 2018 [9], considering both brittle and ductile failure modes. On the other hand, the Capacity in terms of Return Period (TR_C) can be computed from the PGA_C by using the seismic hazard maps provided by the Italian seismic code. It is worth noting that, typically, the seismic hazard curves have a concave shape. Therefore, in order to provide a T_R -based risk scale similar to the PGA-based scale and according to the PCM approach, the Return Period ratio (TR_C/TR_D) is raised to the power of 0.41 (value obtained from statistics on hazard curves at national level). Referring to these Risk Indicators (T_R , PGA ratios), low α values clearly mean high seismic risk, while values of around 1 indicate a safety level comparable to new buildings.

Similarly, in the “*Guidelines for the Seismic Risk Classification of Buildings*”, DM 65 2017 [4], a Safety Index (IS-V) of the building is proposed and defined as the Capacity vs Demand ratio in terms of PGA at SLV intensity level (same as the Risk Indicator defined in the PCM).

Figure 7. a) Evaluation grid based on the European Macroseismic Scale EMS-98 [8] for masonry buildings (adopted in the simplified method); b) PAM curve as defined in the SismaBonus guidelines [4].

These guidelines, so-called “*Sisma Bonus*”, define a general framework to identify the Seismic Risk Class of buildings as well as the rules to access significant financial incentives (from 75% to 110% in the form of tax deductions in 5 years) when implementing seismic retrofitting interventions. The Risk Class can be assessed by two alternative approaches: 1) the so-called “*simplified*” approach, applicable to masonry structures only and based on the qualitative and archetype-based classification provided by the European Macroseismic Scale (EMS-98 [8], Figure 7a); 2) the “*conventional*” approach, based on the quantification of the capacity and demand, through the implementation of the current code provisions, NTC2018 for the estimation of both the Safety Index (IS-V or ζ_E) and the Expected Annual Losses index (EAL, or PAM in the Italian guidelines). In the latter approach, the Seismic Risk Class of the building is defined as the minimum between the two classes associated with the two mentioned indicators (from A+ to F for IS-V, from A+ to G for PAM, where A+ indicates higher performance).

The EAL (or PAM) index is evaluated by assessing the seismic performance in terms of Mean Annual Frequency of exceedance (MAF or $\lambda = 1/T_R$) at different Limit States (SLO, SLD, SLV, SLC, plus SLDI, SLR, i.e. Non-structural Damage, Demolition and Reconstruction, respectively). Then, a direct economic loss, expressed as a percentage of the Reconstruction Cost of the building (%RC), is associated with each Limit State. Hence, the EAL index is defined as the area under the curve obtained by connecting the λ -RC points, as shown in Figure 7b.

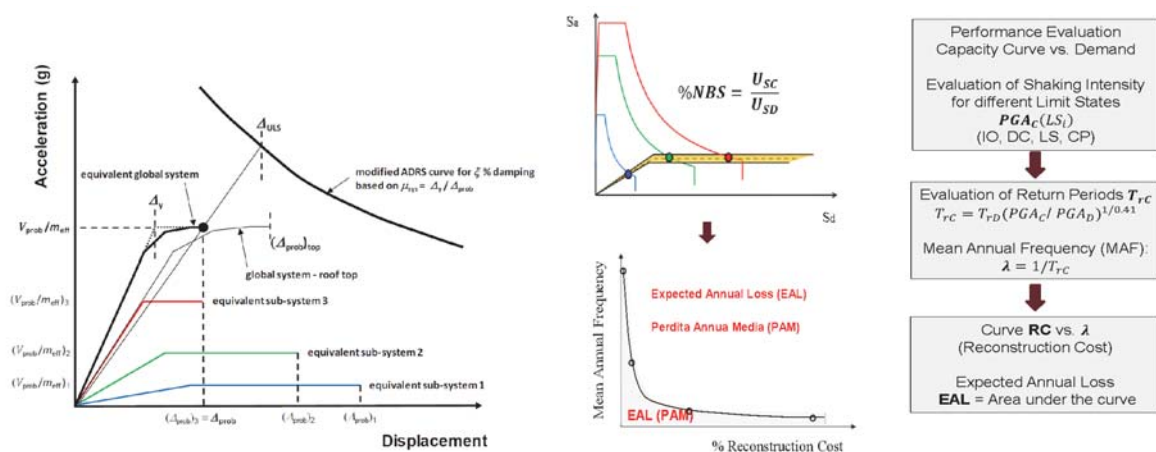

Figure 8. Evaluation of the Safety Index α /IS-V (left) and EAL (right) through the SLaMa Method

The data included in the PELL form allow to compute these key performance indicators (α /IS-V/ ζ_E and EAL/PAM). More specifically, as a further step of this research, the building data can be used to implement a simplified analytical-mechanical seismic assessment of the structure, referred to as SLaMA method (Simple Lateral Analysis Mechanism), developed and introduced in the NZSEE2017 Seismic Assessment Guidelines and fully compatible with, and applicable within, the framework of the Italian NTC2018 code provisions. Following this method, a rapid estimation of the safety level of existing buildings as well as of the expected annual losses can be analytically computed, without any need for a computer/numerical model. In fact, SLaMA allows to determine the force-displacement (pushover) capacity curve and the sequence of local and global mechanisms of a structure by simple analytical (by “hand”) calculations. Therefore, SLaMA results can be used to determine the α /IS-V and EAL classes

(Figure 8) according to the state-of-the-art methodologies available for non-linear static analysis (pushover curve, Capacity) in combination with the Demand within a ADRS, Acceleration-Displacement Response Spectrum (i.e., Capacity Spectrum Method, ATC 1996 [10], or N2 method, Fajfar 2000 [11]).

Overall, four levels of vulnerability assessment evaluation are envisaged (Table 1) for the assessment of static KPI, (Tiers Sn, n from 1 to 4) including a vulnerability-index based analysis as a Tier 0S, plus three Tier level based on either static and dynamic analyses, and on either analytical or numerical models, namely:

- *Tier S0*, vulnerability-index based analysis that envisages the attribution of a vulnerability class and vulnerability index, V, according to [4] and [7] respectively to be adopted for screening and prioritization purposes;
- *Tier S1*, dynamic elastic (modal, response spectrum) analysis - numerical model;
- *Tier S2*, a) non-linear static (pushover) analysis - analytical model (SLaMa method), b) non-linear static (pushover) analysis - numerical model (SLaMa method);
- *Tier S3*, non-linear dynamic (time-history) analysis – numerical model.

Table 1. *PELL-School-RS* Tiered approach for static KPI assessment.

Each approach allows to evaluate, with difference level of trade-off between complexity of the analysis, accuracy, effort/cost and engineering judgement (Figure 9), the expected performance of the school building both in terms of Safety Index and Expected Annual Losses, under various levels of earthquake intensities, i.e. represented by design spectra or spectrum compatible input ground motions (accelerograms).

Figure 9. Trade-off and relationship between complexity of the analysis and accuracy, effort/cost, engineering judgement (Kam and Jury, 2015, NZSEE2017)

4.2 Dynamically assessed KPIs

The seismic monitoring is of fundamental importance to assess the post-event response, performance and actual EDPs and expected damage and validate/integrate the model prediction with the observed damage and actual response of the instrumented buildings.

Similarly to what proposed for the static KPI, *PELL-School-RS* will follow a tiered approach for dynamically assessing KPIs post-event including two Tiers (Table 2), namely:

- *Tier D1*, Dynamic Simplified analysis - analytical model;
- *Tier D2*, Dynamic Simplified analysis - numerical model.

	Required information	Demand Parameter	Approach	Risk or damage KPI
Tier D1 Dynamic Simplified	PELL-Building RS Static Data (mandatory only)* Dynamically collected data from SHM	T_R , PGA for SLO, SLD, SLV and SLC Limit States using response Spectra from recorded event accelerogram	SLaMA method +SHM	Limit States KPIs
Tier D2 Dynamic	PELL-Building RS <ul style="list-style-type: none"> • Static Data (ALL) • Dynamically collected data from SHM 	Recorded accelerogram and actual EDP from SHM monitoring	Numerical Model +SHM	Limit States KPIs

Table 2: *PELL-School-RS* Post-event Tiered approach for dynamically assessed KPI assessment.

As far as the Tier D2 approach is concerned, the idea is to adopt the procedure set-up by Mori et al. [12] that includes four steps, namely: i) collecting basic data on the foundation soil and on the building; ii) in situ experimental measurements on the foundation soil and on the building; iii) Operational Modal Analysis (OMA) analysis and modeling through the SMAV software; iv) evaluation of the structural and operational performance of the building.

With reference to the data collection (i), the required basic data include the structural and architectural plans, the floor heights, the type of structural elements and the volume mass of materials; all these data are already collected as part of the *PELL-School-RS* module (Figure 2).

As for the experimental measures (ii), polygons with rigid behavior are identified within each floor of the building, and sensors are deployed at all the building floors and at least at two locations within each polygon using, if possible, the same configuration for all the floors.

As for the OMA (iii) the SMAV software is used: the translational and rotational mass of each identified polygon is considered concentrated in its center of gravity), the participation coefficients and the modal masses are calculated starting from the mass matrix and the experimental deformations defined in terms of translations and rotations of the polygons. From the identified frequencies and modal shapes for each configuration, and after a suitable check for their independency, the global modal shapes of the entire building are obtained.

As for the evaluation of the structural and operational performance of the building (iv) the SMAV software implements the "frequency drop-drift" literature curves and updates the natural frequencies identified with the OMA by means of an iterative algorithm, which recalculates accelerations, displacements and inter-story drift up to convergence. This equivalent linear dynamic analysis allows to follow the variation of natural frequencies up to the drift thresholds which represent the beginning of the structural damage, including in this damage also the non-structural elements interacting with the structure.

5 CONCLUSIONS

This paper presents the on-going activities for the development of the *PELL-School* platform. With the *PELL-School* platform ENEA aims to introduce a shared minimum standard of building knowledge among stakeholders, governance, municipalities and all the involved operators in order to reach a national knowledge and updated evaluation of a very important strategic infrastructure and patrimony, which includes approximately 45.000 public schools in Italy.

In order to test, tune and modify, if necessary, the proposed *PELL-School Seismic-Response* module and to contribute to its implementation on Italian school buildings a Working Group has been set up. The *PELL-School Seismic-Response* Working Group led by ENEA is involving several Municipalities and stakeholders to share and promote the test of the *PELL-School-RS* form (Figure 5) and to contribute to its implementation. The process is also engaging Italian Regions who are in charge of the ARES platform.

Thanks to Municipalities and stakeholders who first joined the Working Group, it has been possible to discuss and test the proposed form on different public schools and so doing, to customize it to the different building peculiarities and to the application capability of the operators. Following the test phase, the *PELL-School-RS* form will be digitized following AgID specifications for data models and will be embedded in the PELL platform, which should be ready by the end of 2022.

Although significant effort have been dedicated by the authors to ensure that the data and KPIs proposed for inclusion in the *PELL-School Seismic-Response* module are aligned and best

represent the scientific and professional advancements in the fields of seismic engineering, seismic vulnerability assessment and seismic monitoring of buildings in Italy, that Italy can boast thanks to the work of professional associations, universities, networks of laboratories, research institutions and research foundations, the collaboration of such experts in the Working Group would be welcome and much appreciated.

All the interest experts are therefore warmly invited to take part in the activities of the *PELL-School Seismic-Response Working Group* towards the common goal of guarantying in the short run the seismic safety of schools and other strategic buildings in Italy.

PELL Schools, is a further step towards the digitization and automation of the information, management and evaluation processes of the strategic infrastructure aiming to renovate streets, districts, towns and territories in order to make them more sustainable, resilient and sharply managed.

ENEA's goal is to make available the *PELL-School* by 2023 for operational use by municipalities and stakeholders.

ACKNOWLEDGEMENTS

The activities of the *PELL Public Energy Living Lab*, research are funded under the Project 1.7 “*Technologies for the efficient penetration of the electric vector in the final uses*” within the “*Electrical System Research*” Programme Agreements 19-21 between ENEA and the Ministry of Economic Development

Abstract

A reliable estimate of the seismic vulnerability of building typological classes is a crucial issue to understand how to manage the limited funds available for the reduction of the social and economic losses caused by seismic events. In this context, the goal of this paper is to develop typological empirical fragility curves for reinforced concrete building classes at different damage states. The vulnerability probabilistic assessment is deduced starting from the damage scenario observed after the 2012 Emilia earthquake, available from the Da.D.O. platform. The element-level damage information for the different structural elements is used to define a global building damage state according to a damage index available in the literature. A single value of seismic demand is estimated for each locality and is associated with each building in that locality. Census data have been added to the detected typological building sample with the aim to account for uninspected buildings, and the effect on fragility curves due to the increased dataset is evaluated. Moreover, a completeness ratio is defined for each locality, and lower bounds on the locality seismic demand and completeness ratio are introduced to discard irrelevant damage data and evaluate the consequent effect on the damage state fragility curves.

Keywords: Vulnerability assessment; post-earthquake damage data; Emilia earthquake; Census data; completeness ratio.

1 INTRODUCTION

The increasing interest of national governments in social and economic losses caused by seismic events over the years is demonstrated by the large number of research projects and guidelines that are developing worldwide, dealing with risk or vulnerability predictive models [1, 2]. Predicting losses from future earthquakes at territorial scale requires the development of robust frameworks and procedures [3–7]. Empirical methods have been the first methods developed for the seismic vulnerability assessment starting from the early 70's, because based on the statistical analysis of the observed damage collected after a seismic event. The results are represented in terms of Damage Probability Matrix (DPM), which expresses in a discrete form the conditional probability of reaching a damage level for a given IM value, or in terms of vulnerability or fragility curves. In particular, fragility curves are one of the most effective representations of the buildings seismic vulnerability at territorial scale for specific typological building classes, expressing the probability of exceeding discrete building damage states [8–10]. In general, the results of empirical vulnerability methods have always been affected by a great variety of features [11–13], because directly based on the damage scenarios observed during post-earthquake surveys. The selection of a statistically relevant building sample is a critical issue in the development of fragility curves, because in general only municipalities closer to the earthquake epicenter are completely surveyed, whereas buildings with no damage or very low damage far away from the epicentral area are often not surveyed [14–18]. Such incompleteness of damage dataset could introduce a certain level of bias in the estimation of damage state relative frequencies, consequently in the shape of the fitted damage state fragility curves.

This paper first reports a brief review on main features concerning the seismic vulnerability assessment methods, then the work focuses on the development of sets of empirical fragility curves for RC frame buildings class. The goal is to evaluate the influence on the fragility curve parameters of the building sample selection and the addition of Census data. Fragility curves are calibrated on the damage scenario data observed after the 2012 Emilia earthquake, surveyed via the AeDES post-earthquake damage assessment form [19]. The damage scenarios are obtained from the database Da.D.O. (Observed Damage Database) [20]. The IM is expressed in terms of PGA and estimated at locality-level. Moreover, a completeness ratio is computed for each hit locality, to assess the completeness rate of surveys in post-earthquake emergency.

2 DAMAGE SCALE, DAMAGE FORMS AND BUILDING CLASSIFICATION

2.1 Damage state scales

The definition of a qualitative damage scale is fundamental to obtain a meaningful estimate of the seismic vulnerability. Damage onset and evolution is a continuous process but describing the actual damage condition of a single element or the entire building requires the detection of discrete damage states, incorporated in a damage scale. They can be related to the damage condition of the entire building or of structural and nonstructural elements. In the description of RC buildings global damage, both the damage to RC frames and infill walls is considered, as reported in the damage scales provided by the European Macroseismic Scale (EMS-98) [21] and ASCE/SEI 41-06 [22], underlying the relevant role of infill panels on the RC buildings seismic response.

Different damage indices have been proposed in the literature to trace back the element damage level to one of the five damage states of the EMS-98 damage scale [23–25]. In the present work the damage index proposed by De Martino et al. [26] has been adopted.

2.2 Damage assessment forms

Both at global and element level, the damage described in damage scales is fundamental to properly detect the damage observed in post-earthquake surveys. The damage datasets thereby collected constitutes the statistical basis to develop empirical vulnerability predictive models. Rapid damage assessment forms are very useful instruments to gather standardized and organized information on the damage at building level or at element level, together with the essential geometrical and mechanical features of the building [19, 27, 28]. To be employed in the vulnerability assessment of different building types, the data required in a damage assessment form should be sufficiently detailed and at the same time easily identifiable during a rapid visual inspection. Moreover, they should be reported in a standardized manner, in this way understandable and usable by all researchers worldwide. In fact, the quality and reliability of vulnerability assessment results increase at the increasing of the damage statistical dataset. Unfortunately, damage data collected after different earthquakes are not directly comparable to each other, due to the different forms used in post-earthquake surveys, varying over the years and from country to country, and preliminary activities are necessary to homogenize the different datasets [20, 29]. Moreover, observational data can be affected by errors due to the inspector judgment, hence further effort is necessary to avoid a different interpretation of similar damage conditions by inspector operating in post-earthquake surveys. Much progress has been made over the years trying to reduce the uncertainties in the collection of data from post-earthquake surveys and to homogenize their interpretation, such as the updating of the damage forms or creating training programs for the inspectors. In the present paper, the data collected using the updated Italian form is analyzed.

2.3 Typological building classification

The results of seismic vulnerability assessment methods should represent in a realistic way the actual building damage under a specific seismic action. The building vulnerability however depends on a great number of specific characteristics, such as the quality of materials, the correct application of construction technologies, or the level of in-plan and elevation regularity. The presence of pre-existing damage or strengthening interventions can also influence the structural seismic response. However, the development of specific fragility curve sets for each single building would be unpractical, requiring a great number of information, and a so elevate level of accuracy probably would not even be necessary in a context of vulnerability assessment at territorial scale. In order to regroup together facilities with a similar expected seismic behavior, a suitable classification of building typologies is hence required, based on a limited number of relevant information easily accessible.

Among the various constructive features that affect the building response and performance under seismic action, those generally adopted are the earthquake-resistant structural system, the number of stories, N , and the level of seismic design, the latter strictly related to the age of construction and the site seismicity. Within the European context, different guidelines and research groups proposed a typological building classification based on the number of stories and the seismic design level. For what concern the number of stories classification, i) two building classes or ii) three building classes are generally detected: i) Low-rise and Mid-High-rise buildings, [9, 30] or ii) Low-rise, Mid-rise, and High-rise buildings [31–33]. Low-rise buildings are mostly up to 3-story buildings ($N \leq 3$) while the threshold separating Mid-rise and High-rise buildings is generally 7 stories.

Regarding the seismic design level typological classification, EMS-98 guidelines [21] considered three building classes based on the site seismicity defined at the building time of construction, while Lagomarsino and Giovinazzi [32] defined four classes based on the level of ductility prescriptions and the site seismicity level. More recently, and specifically to the Italian context, the seismic design level has been related to the age of construction, in general distinguishing two building classes composed of non-compliant or compliant buildings to modern design seismic codes [30, 33, 34]. The year threshold adopted to separate the two classes depends on the building stock employed for the vulnerability assessment, influenced by the introduction of regional or national seismic codes and the changes in site seismicity over the years. It is worth noting that, within each abovementioned proposal, the earthquake-resistant structural system does not affect the thresholds selected to distinguish the different story-based or seismic-design-level-based building classes.

3 BUILDING SAMPLE SELECTION AND COMPLETENESS RATIO

In this paper, the damage scenario surveyed after the 2012 Emilia earthquake is employed to assess the probabilistic vulnerability of the regional RC frames building stock. Two main shocks stroke the Emilia territory over late May 2012, May 20th event, with momentum magnitude $M_w = 5.9$, and the May 29th event, $M_w = 5.6$. Starting from the whole dataset of surveyed buildings available from the web platform Da.D.O. (Observed Damage Database) [20], the RC frame subsets of 1,993 is first extracted. Then, the subset of precast RC buildings is discarded from the RC frame subset, in order to restrict the probabilistic vulnerability assessment to sample of RC moment-resisting frames. In order to remove such constructions typology from the dataset, the one-story buildings with interstory height $H \geq 5.0$ m and floor area $A_{floor} \geq 130$ m² are discarded. According to these criteria, a total amount of 362 buildings is discarded, reducing the subset to 1,631 RC moment-resisting frames.

The characteristics of the RC frames subset are presented in Figure 1. Figure 1(a) shows a strong increase of new RC frames starting from the 1960s of the last century, with the timespans 1972 – 1981 and 1982 – 1991 be the most populated, whereas Figure 1(b) underlines a prevalence of buildings having less than 4 stories.

Figure 1: Relative frequency distribution of the RC frames: (a) construction timespan; (b) number of stories. Total number of the buildings: 1,631

In order to obtain fragility curve sets representative of a homogeneous buildings vulnerability to the seismic action, the building sample was separated into two typological classes based on the number of stories: Low-rise = 1 – 3 stories; Mid-High-rise ≥ 4 stories. Because of the selected typological classification, the surveyed buildings for which the information on the number of stories is missing have been discarded, hence the final building sample is composed of 1,616 RC frames.

In general, only the most damaged areas close to the earthquake epicenter are completely surveyed after a seismic event. Such lack of information, mainly related to the undamaged buildings, produce errors in the estimation of a given damage state probability of exceedance. Because of this reason, in the present work a completeness ratio, r , is defined for each locality hit by the Emilia earthquake as the number of buildings surveyed after the seismic event and the total number of buildings in that locality from Census database. It is assumed that buildings added from Census were not surveyed because not exhibiting damage, hence they are assumed to be undamaged. Table 1 summarizes the population of the surveyed RC frames sample and the number of added Census buildings, both separated into the two building classes; the results reveal for the Emilia earthquake a very low average completeness ratio of only 7.3%, probably because the surveys for the Emilia earthquake were performed only on owners' request.

Building samples	$N \leq 3$	$N \geq 4$	Total
Buildings from surveys (Da.D.O.)	965	651	1,616
Added Census buildings (ISTAT)	14,504	5,897	20,401
Total category RC frames	15,469	6,548	22,017

Table 1: Number of RC frames for the selected sample and number of added Census buildings

4 SEISMIC DEMAND AND DAMAGE SCENARIO

In this work, the earthquake IM is expressed in terms of peak ground acceleration (PGA). In particular, a specific value of PGA is estimated in correspondence of the urban center of each locality involved during the seismic events, starting from the PGA values provided by the INGV for the spatial square grid with nodes every 1 km. Since the Emilia earthquake is characterized by two mainshocks, the PGA value is estimated as the maximum between the two mainshocks. Then, the surveyed RC buildings and those added from Census for each locality are regrouped into 0.05 g PGA bins.

For what concern the damage scenario collected from the post-earthquake surveys, the damage was obtained through the Italian AeDES form [19] that defines three damage levels (D1: Light, D2-D3: Medium-Severe, and D4-D5: Very Heavy) to estimate the damage of structural components. Table 2 reports the normalized damage distribution for the different structural elements. The comparison shows that masonry infill walls are the most damaged components (around 70% of buildings), while only 30% of RC frames presents damage; such percentage is approximately 15% for the remaining structural elements. In all the cases, the damaged elements mainly present a slight damage level.

Structural element	AeDES damage state			
	Null	D1: Slight	D2-D3: Medium-heavy	D4-D5: Very heavy
RC frames	72%	14%	8%	6%
Masonry infill walls	32%	43%	17%	8%
Floors	86%	10%	2%	1%
Stairs	86%	10%	2%	2%
Roof	87%	8%	3%	3%

Table 2: Percentage distribution of buildings according to AeDES form damage scale and type of damageable structural element. Total number of RC frames: 1,616.

In order to develop fragility curves, the damage at element level is summarized as a unique damage state for each RC building in the sample via a damage index. The damage index proposed by De Martino et al. [26] estimates the global building damage, as defined according to the EMS-98 scale [21], considering the damage contribution from all the structural elements considered by the AeDES damage form.

5 FRAGILITY CURVES

The effect of adding Census data, treated as undamaged buildings, to the sample of surveyed buildings is here reported in terms of fragility curves. The Maximum Likelihood Estimation (MLE) method is used for the calibration of the typological damage states fragility curves

$$\text{Likelihood} = \prod_{j=1}^m \binom{n_j}{z_j} P(DS \geq DS_i | PGA_j)^{z_j} \left(1 - P(DS \geq DS_i | PGA_j)\right)^{n_j - z_j} \quad (1)$$

where the damage data in each j -th PGA interval are binomially distributed and $P(DS \geq DS_i | PGA_j)$ is the probability of exceeding a the i -th damage state for a given j -th PGA interval. The lognormal distribution is the model assumed for the damage state fragility curves, the most used in the recent literature [35, 36].

Figure 2 shows the sets of fragility curves obtained considering only the surveyed buildings and those obtained adding undamaged buildings from Census; the low-rise building class is selected for the comparison because is the most populated class. Figure 2(a) shows that the set of fragility curves obtained using only the surveyed buildings presents a very flat trend, probably due to the high incompleteness level of the surveys at lowest PGA intervals. The comparison between Figure 2(a) and Figure 2(b) shows a strong reduction of the probability of exceeding the different EMS-98 damage states when undamaged buildings from Census data are introduced, especially at lower PGA bins. It is worth noting that a great number of undamaged buildings is added also in the areas at highest PGA values, hence for the Emilia earthquake the surveys completeness ratio is low also for municipalities close to the epicenter.

Figure 2. Influence of including Census data (undamaged buildings) on damage state fragility curves for low-rise buildings.

In this work, a completeness ratio, r , is computed for each locality and a unique PGA value is assigned to the selected buildings within each locality. It is comprehensible to recognize that the localities very distant from the epicenter or scarcely surveyed can introduce a bias in the fragility curve shape, hence a $0.05g$ minimum threshold is applied to the PGA range and a 5% minimum threshold on the locality completeness ratio, in order to discard the localities presenting values lower than such thresholds. Figure 3 shows neglectable changes in the set of fragility curves both for low-rise buildings and mid-high-rise buildings, only an increases of the probability of exceeding $DS1$ is appreciable, probably because the influence of the Census undamaged buildings is prevalent for the fragility curves shape. It is worth noting that the curves shown in Figure 3(a) are the same of Figure 2(b).

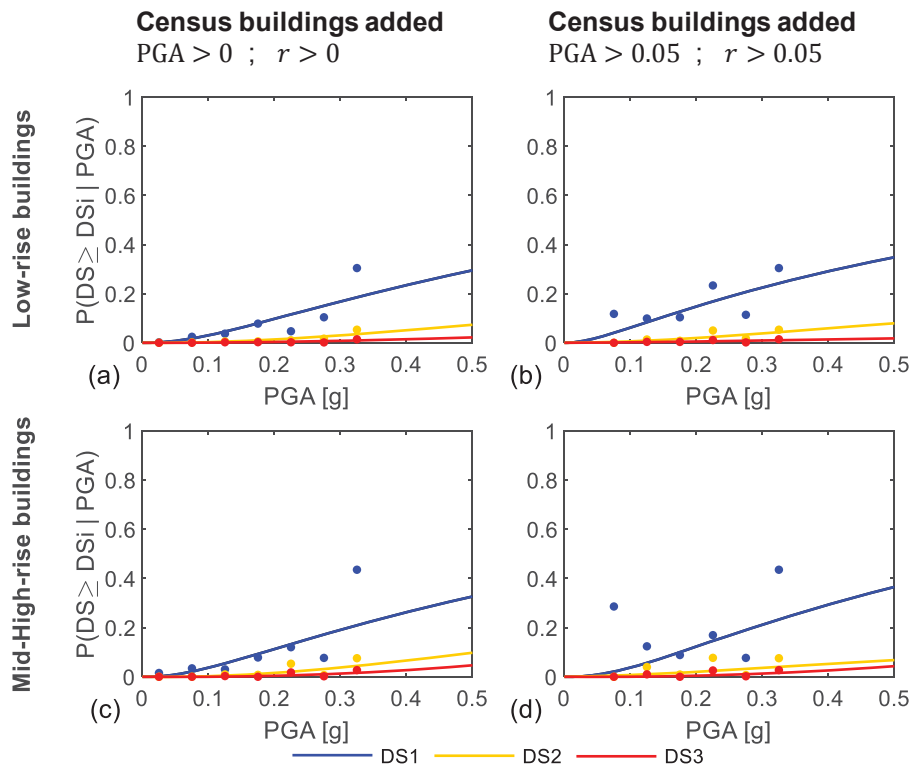

Figure 3. Influence of different criteria for buildings sample selection on damage state fragility curves developed for low-rise buildings.

6 CONCLUSIONS

In the present paper, fragility curves are calibrated for RC frame buildings, based on the observational damage data collected after the 2012 Emilia earthquake and available from the damage database Da.D.O. In particular, the influence of uninspected buildings added to the starting damage datasets have been evaluated. A statistical sample composed of 1,616 RC frames is selected, divided into two typological building classes. The surveyed buildings sample is hence increased by RC frames from Census database, the latter assumed undamaged, and new sets of fragility curves are calibrated. A unique PGA value is estimated for all the RC frames in a specific locality, and a completeness ratio of post-earthquake surveys is computed for each locality.

The vulnerability assessment results show the great influence of added Census data on the fragility curves shape, especially for the first damage state at lower PGA bins. Moreover, the comparison reveals that the survey completeness ratio is low also for municipalities close to the epicenter. On the contrary, neglectable differences are observed between the seismic vulnerability of low-rise and mid-high-rise building classes, and the fragility curve parameters are scarcely affected by the lower bounds on the seismic demand and the completeness ratio parameter.
