PREFACE

This volume contains the full-length papers presented in the 8th International Conference on Computational Methods in Structural Dynamics and Earthquake Engineering (COMPDYN 2021) that was streamed from Athens, Greece on June 28-30, 2021.

COMPDYN 2021 is one of the 32 Thematic Conferences of the European Community on Computational Methods in Applied Sciences (ECCOMAS) which were held in 2021 and is also a Special Interest Conference of the International Association for Computational Mechanics (IACM). The purpose of this Conference series is to bring together the scientific communities of Computational Mechanics, Structural Dynamics and Earthquake Engineering, to act as a forum for exchanging ideas in topics of mutual interests and to enhance the links between research groups with complementary activities. We believe that the communities of Structural Dynamics and Earthquake Engineering will benefit from their exposure to advanced computational methods and software tools which can highly assist in tackling complex problems in dynamic and seismic analysis and design of structures, while also giving the opportunity to the Computational Mechanics community to be exposed to very important engineering problems of great social interest.

The COMPDYN 2021 Conference is supported by the National Technical University of Athens (NTUA), the European Association for Structural Dynamics (EASD), the European Association for Earthquake Engineering (EAEE), the Greek Association for Computational Mechanics (GRACM).

The editors of this volume would like to thank all authors for their contributions. Special thanks go to the colleagues who contributed to the organization of the Minisymposia and to the reviewers who, with their work, contributed to the scientific quality of this e-book.

M. Papadrakakis

National Technical University of Athens, Greece

M. Fragiadakis

National Technical University of Athens, Greece

ACKNOWLEDGEMENTS

The conference organizers acknowledge the support towards the organization of the “8th International Conference on Computational Methods in Structural Dynamics and Earthquake Engineering”, to the following organizations:

- European Community on Computational Methods in Applied Sciences (ECCOMAS)
- International Association for Computational Mechanics (IACM)
- European Association for Structural Dynamics (EASD)
- European Association for Earthquake Engineering (EAEE)
- Greek Association for Computational Mechanics (GRACM)
- Hellenic Society for Earthquake Engineering (HSEE)
- School of Civil Engineering, National University of Athens (NTUA)

Plenary Speakers and Invited Session Organizers

We would also like to thank the Plenary and Semi-Plenary Speakers and the Minisymposia Organizers for their help in the setting up of a high standard Scientific Programme.

Plenary Speakers: Sondipon Adhikari, Peter Betsch, Hong Hao, Boris Jeremic, Geert Lombaert , Gabriele Milani , Shinobu Yoshimura

Semi-Plenary Speakers: Denis Duhamel, Fernando Fraternali, Muneo Hori, Alexander Idesman , Jean-Mathieu Mencik, Giuseppe Muscolino

MS Organizers: Christoph Adam, Hamid Ahmadi, Ada Amendola, Giulia Angelucci, António Arêde, Davide Arezzo, Nikolaos P. Bakas, Rui Carneiro Barros, Manuel Braz-César, Bruno Briseghella, Eleonora Bruschi, Bruno Calderoni, Guido Camata, Luca Caracoglia, Sandro Carbonari, Donatello Cardone, Claudia Casapulla, Serena Cattari, Nicola Cavallaghi, Liborio Cavaleri, Dimitrios Chronopoulos, Francesco Clementi, Marco Gaetani d’Aragona, Mario D’Aniello, Dario De Domenico, Maria Teresa De Risi, Matt DeJong, Carlo Del Gaudio, Ciro Del Vecchio, Pedro Delgado, Mariano Di Domenico, Raffaele Di Laora, Marco Di Ludovico, Luigi Di Sarno, Fabio Di Trapani, Beatrice Faggiano, Marco Filippo Ferrotto, Amedeo Flora, Antonio Formisano, Michalis Fragiadakis, Fernando Fraternali, Fabio Freddi, André Furtado, Stefano Galassi, Emanuele Gandelli, Linda Giresini, José A. González, Chiara Iacovino, Alper Ilki, Maria Iovino, Konstantinos Katakalo, Jin-Gyun Kim, Radek Kolman, Daniele Losanno, George C. Manos, Giuseppe Carlo Marano, George Markou, Angelo Masi, Konstantinos G. Megalooikonomou, Gabriele Milani, Lucia Minnucci, Fabrizio Mollaioli, Michele Morici, Lukas Moschen, Jiří Náprstek, Vanni Nicoletti, Ehsan Noroozinejad, Roger Ohayon, K. C. Park, Carlo Pettorruso, Vagelis Plevris, Maria Polese, Virginio Quaglini, Giuseppe Quaranta, Laura Ragni, Gian Andera Rassati, Paolo Ricci, Hugo Rodrigues, Emmanouil Rovithis, Juan Chiachío Ruano, Manuel Chiachío Ruano, Antonio Sandoli, Fabrizio Scozzese, Salvatore Sessa, Anastasios Sextos, P. Benson Shing, Castorina Silva Vieira, Aram Soroushian, Enrico Spacone, James Swanson, Francesca Taddei, Kumar Tamma, Marco Tanganelli, Roberto Tartaglia, Anton Tkachuk, Savvas Triantafyllou, Grigorios Tsinidis, Yiannis Tsompanakis, Enrico Tubaldi, Filippo Ubertini, Nicolò Vaiana, Humberto Varum, Michalis Vassiliou, Ilaria Venanzi, Gerardo M. Verderame, Stefania Viti, Marco Vona

VOLUME I

PLENARY	1
SEMI-PLENARY	28

Minisymposia

MS 1: INFLUENCE OF INFILL MASONRY WALLS IN THE RESPONSE AND SAFETY OF BUILDINGS	63
<i>Organized by Humberto Varum, Hugo Rodrigues, Enrico Spacone</i>	
MS 2: REPAIR AND RETROFIT OF STRUCTURES	111
<i>Organized by Ciro Del Vecchio, Marco Di Ludovico, Alper Ilki</i>	
MS 3: RECENT ADVANCES AND CHALLENGES IN GEOTECHNICAL EARTHQUAKE ENGINEERING	202
<i>Organized by Castorina Silva Vieira, Yiannis Tsompanakis</i>	
MS 4: ADVANCEMENTS IN NUMERICAL MODELLING AND SEISMIC INTERVENTION TECHNIQUES OF HISTORICAL MASONRY STRUCTURES	231
<i>Organized by Francesco Clementi, Nicola Cavalagli, Antonio Formisano, Gabriele Milani, Vagelis Plevris</i>	
MS 6: ADVANCES ON SEISMIC ASSESSMENT AND LOCAL COLLAPSE MECHANISMS OF RIGID BLOCKS IN STRUCTURES AND INFRASTRUCTURES	637
<i>Organized by Claudia Casapulla, Linda Giresini, Francesca Taddei, Ehsan Noroozinejad</i>	
MS 7: NEW ADVANCES IN COMPUTATIONAL MODELLING AND EXPERIMENTAL TESTING OF INFILLED FRAMES (2ND EDITION)	779
<i>Organized by Fabio Di Trapani, Liborio Cavaleri, Guido Camata, P. Benson Shing</i>	
MS 8: A MATTER OF SCALE: FROM REAL-TIME MONITORING TO AREA-WIDE SEISMIC RISK ASSESSMENT	987
<i>Organized by Konstantinos G. Megalooikonomou</i>	
MS 9: NONLINEAR MODELLING AND ASSESSMENT OF EXISTING REINFORCED CONCRETE ELEMENTS	1016
<i>Organized by Mariano Di Domenico, Paolo Ricci, Gerardo M. Verderame</i>	

MS 10: VULNERABILITY OF MUSEUM'S COLLECTIONS DYNAMIC RESPONSE, SAFETY ASSESSMENT AND DIGITAL INNOVATIONS	1125
<i>Organized by Stefania Viti, Marco Tanganelli, Stefano Galassi</i>	
MS 11: RECENT FINDINGS AND OPEN ISSUES IN SEISMIC PERFORMANCE ASSESSMENT OF AS-BUILT AND RETROFITTED EXISTING RC BUILDINGS	1188
<i>Organized by Maria Teresa De Risi, Carlo Del Gaudio, André Furtado, Gerardo M. Verderame, Humberto Varum</i>	
MS 12: ADVANCES IN COMPUTATIONAL MODELLING, EXPERIMENTAL TESTING AND OPTIMIZATION OF SEISMIC RETROFITTING.....	1322
<i>Organized by Liborio Cavaleri, Marco Filippo Ferrotto, Fabio Di Trapani, Giuseppe Carlo Marano</i>	
MS 13: MODELLING AND SOLUTION STRATEGIES FOR DYNAMIC PROBLEMS	1416
<i>Organized by Aram Soroushian, Kumar Tamma</i>	
MS 14: SEISMIC ASSESSMENT AND RETROFITTING OF EXISTING STEEL STRUCTURES	1492
<i>Organized by Luigi Di Sarno, Fabio Freddi, Mario D'Aniello</i>	
MS 16: DYNAMIC RESPONSE ASSESSMENT IN RAIL TRACK ENGINEERING	1550
<i>Organized by Lukas Moschen, Grigorios Tsinidis, Christoph Adam, Anastasios Sextos</i>	
MS 17: RECENT DEVELOPMENTS IN ROCKING STRUCTURES	1574
<i>Organized by Matt DeJong, Michalis Vassiliou</i>	
MS 19: ADVANCES IN THE OPTIMUM DESIGN AND CONTROL OF LARGE STRUCTURES UNDER DYNAMIC LOADS	1712
<i>Organized by Fabrizio Mollaioli, Giulia Angelucci, Bruno Briseghella, Giuseppe Carlo Marano, Giuseppe Quaranta</i>	
MS 20: COMPUTATIONAL DESIGN AND MODELING OF TENSEGRITY SYSTEMS FOR APPLICATIONS IN SCIENCE AND ENGINEERING	1825
<i>Organized by Fernando Fraternali, Ada Amendola</i>	
MS 22: CONDITION BASED MAINTENANCE AND POST-PROGNOSTICS OF COMPOSITE STRUCTURES: AN ENHANCED PLATFORM	1874
<i>Organized by Dimitrios Chronopoulos, Savvas Triantafyllou, Juan Chiachío Ruano, Manuel Chiachío Ruano</i>	
MS 23: ADVANCED MODELS AND NUMERICAL METHODS IN DYNAMICS, WAVE PROPAGATION AND COUPLED PROBLEMS	1892
<i>Organized by José A. González, Radek Kolman, Anton Tkachuk, Jiří Náprstek, K. C. Park</i>	
MS 24: LIFE-CYCLE RISK-BASED STRUCTURAL ASSESSMENT AND COST ANALYSIS	1941
<i>Organized by Ilaria Venanzi, Filippo Ubertini, Luca Caracoglia</i>	
MS 25: MONITORING, IDENTIFICATION AND VIBRATION CONTROL OF STRUCTURES	2014
<i>Organized by Rui Carneiro Barros, Manuel Braz-César</i>	
MS 26: SEISMIC SAFETY ASSESSMENT OF STRUCTURES	2157
<i>Organized by Pedro Delgado, António Arêde</i>	

MS 27: TIMBER-BASED ELEMENTS: RECENT ADVANCEMENTS FOR NEW AND EXISTING SEISMIC-RESISTANT STRUCTURES	2195
<i>Organized by Antonio Sandoli, Bruno Calderoni, Beatrice Faggiano</i>	
MS 29: SEISMIC PROTECTION OF NON-STRUCTURAL COMPONENTS: RECENT DEVELOPMENTS AND FUTURE CHALLENGES	2388
<i>Organized by Luigi Di Sarno, Michalis Fragiadakis</i>	
MS 30: DYNAMIC PROTECTION SYSTEMS AND DEVICES: EXPERIMENTAL TESTS, MATHEMATICAL MODELING AND DESIGN METHODS	2435
<i>Organized by Nicolò Vaiana, Daniele Losanno, Salvatore Sessa</i>	
MS 32: SIMPLIFIED METHODOLOGIES FOR PERFORMANCE AND LOSS ASSESSMENT AT BUILDING OR TERRITORIAL SCALE	2557
<i>Organized by Maria Polese, Marco Gaetani d'Aragona</i>	

VOLUME II

Minisymposia

MS 33: EXPERIMENTAL MEASUREMENTS AND NUMERICAL SIMULATION ON PROBLEMS IN THE FIELD OF EARTHQUAKE ENGINEERING AND STRUCTURAL DYNAMICS	2718
<i>Organized by George C. Manos, Konstantinos Katakalos</i>	
MS 34: FRAGILITY CURVES FOR EXISTING BUILDINGS: OPEN CHALLENGES IN THEIR DEFINITION AND USE FOR SEISMIC RISK ANALYSES	3059
<i>Organized by Serena Cattari, Angelo Masi</i>	
MS 35: RECENT ADVANCES IN SEISMIC ISOLATION AND SUPPLEMENTAL DAMPING SYSTEMS FOR VIBRATION CONTROL	3187
<i>Organized by Virginio Quaglini, Eleonora Bruschi, Emanuele Gandelli, Carlo Pettoruso</i>	
MS 36: METHODOLOGIES AND ADVANCED TOOLS FOR SEISMIC RISK ASSESSMENT, MANAGEMENT, AND MITIGATION: ADVANCES AND OPEN CHALLENGES	3305
<i>Organized by Marco Vona, Donatello Cardone, Amedeo Flora, Chiara Iacovino</i>	
MS 37: RISK ASSESSMENT OF BRIDGES AND ROAD NETWORKS SUBJECTED TO NATURAL HAZARDS	3377
<i>Organized by Michele Morici, Fabrizio Scozzese, Lucia Minnucci</i>	
MS 38: DYNAMIC SOIL-FOUNDATION-STRUCTURE INTERACTION: DEVELOPMENTS AND EMERGING ISSUES	3577
<i>Organized by Emmanouil Rovithis, Raffaele Di Laora, Maria Iovino</i>	
MS 39: THE CONTRIBUTION OF DYNAMIC TESTS AND STRUCTURAL MONITORING ON THE SEISMIC RISK ASSESSMENT AND MITIGATION	3697
<i>Organized by Davide Arezzo, Sandro Carbonari, Vanni Nicoletti</i>	

MS 40: ARTIFICIAL INTELLIGENCE & MACHINE LEARNING IN DESIGN AND ASSESSMENT OF STRUCTURES	3795
<i>Organized by George Markou, Nikolaos P. Bakas</i>	

MS 41: SEISMIC PERFORMANCE OF STRUCTURES WITH ISOLATION AND/OR ENERGY DISSIPATION DEVICES	3912
<i>Organized by Enrico Tubaldi, Laura Ragni, Dario De Domenico, Hamid Ahmadi</i>	

MS 42: ADVANCES IN MODEL REDUCTION TECHNIQUES OF COMPUTATIONAL AND STRUCTURAL DYNAMICS	4111
<i>Organized by Jin-Gyun Kim, K. C. Park, Roger Ohayon</i>	

MS 43: ANALYSES AND DESIGN OF STEEL JOINTS UNDER CYCLIC ACTION	4134
<i>Organized by Roberto Tartaglia, Mario D'Aniello, Gian Andera Rassati, James Swanson</i>	

Thematic Sessions

TS 5: DYNAMICS OF CONCRETE AND MASONRY STRUCTURES	4226

CONTENTS

VOLUME I

PLENARY

SEISMIC VULNERABILITY OF MASONRY HISTORICAL STRUCTURES: A SIMPLE ADAPTIVE NURBS FE APPROACH FOR THE LIMIT AND THE SUBSEQUENT NON-LINEAR STATIC ANALYSIS WITH FEW DOFS	1
<i>Nicola Grillanda, Gabriele Milani</i>	

SEMI-PLENARY

SOME RECENT ADVANCES IN THE WAVE FINITE ELEMENT METHOD	28
<i>Denis Duhamel, B. Claudet, T. Hoang, G. Foret, Jean-Mathieu Mencik</i>	
DYNAMIC ANALYSIS OF PERIODIC STRUCTURES AND METAMATERIALS VIA WAVE APPROACHES AND FINITE ELEMENT PROCEDURES	42
<i>Jean-Mathieu Mencik, Denis Duhamel</i>	

Minisymposia

MS 1: INFLUENCE OF INFILL MASONRY WALLS IN THE RESPONSE AND SAFETY OF BUILDINGS

IMPACT OF MASONRY INFILL VARIABILITY ON THE ESTIMATION OF FLOOR RESPONSE SPECTRA IN RC BUILDINGS	63
<i>Gianrocco Mucedero, Daniele Perrone, Emanuele Brunesi, Ricardo Monteiro</i>	
EFFECT OF IN-PLANE/OUT-OF-PLANE INTERACTION IN INFILL WALLS ON THE FLOOR SPECTRA OF REINFORCED CONCRETE BUILDINGS	84
<i>Mariano Di Domenico, Paolo Ricci, Gerardo M. Verderame</i>	
SEISMIC LOSS ANALYSIS OF A CODE-DESIGNED INFILLED RC BUILDING ACCOUNTING FOR INFILL MODEL CLASS UNCERTAINTY	102
<i>Fabio Romano, Mohammad S. Alam, Maria Zucconi, Marco Faggella, Andre R. Barbosa, Barbara Ferracuti</i>	

MS 2: REPAIR AND RETROFIT OF STRUCTURES

SEISMIC BEHAVIOR OF SUBSTANDARD EXTENDED RECTANGULAR RC COLUMNS JACKETED WITH SPRAYED GFRM	111
<i>Muhsin Can Lülecı, Bilal Sari, Ugur Demir, Muhammed Maraslı, Alper İlki</i>	
DAMAGE EVOLUTION FOR REPAIRABILITY OF SUBSTANDARD BEAM-COLUMN JOINTS	120
<i>Özgür Yurdakul, Ciro Del Vecchio, Marco Di Ludovico, Ladislav Řoutil, Özgür Avşar</i>	

EXPERIMENTAL RESPONSE AND NUMERICAL MODELLING OF TWO-STOREY INFILLED RC FRAME	131
<i>Ciro Del Vecchio, C. Moliterno, Marco Di Ludovico, Gerardo Mario Verderame, Andrea Prota, Gaetano Manfredi</i>	
DEFENCE OF ARCHITECTURAL HERITAGE: EXPERIMENTAL CAMPAIGN ON MASONRIES REINFORCED WITH NATURAL FRCM COMPOSITE MATERIALS	141
<i>Riccardo Liberotti, Nicola Cavalagli, Federico Cluni, Massimiliano Gioffrè, Chiara Pepi, Vittorio Gusella</i>	
NUMERICAL MODELLING AND ANALYSIS OF ECCENTRIC BRACING WITH VERTICAL SHEAR LINKS	151
<i>Gaetano Cantisani, Emilio Rodontini, Gaetano Della Corte</i>	
PERFORMANCE OF EXISTING REINFORCED CONCRETE ARCH BRIDGES UNDER CURRENT NON SEISMIC LOADS	164
<i>Giovanni Crisci, Francesca Ceroni, Gian Piero Lignola, Andrea Prota</i>	
A SUSTAINABLE SOLUTION FOR THE SEISMIC STRENGTHENING OF RC EXISTING BUILDINGS THROUGH THE HPDF SYSTEM (HPDF): A CASE STUDY	180
<i>Giuseppe Ventura, Vincenzo Manfredi, Angelo Masi, Giuseppe Santarsiero, Andrea Digrisolo</i>	
APPLICATION OF C-FRP SHEETS FOR STRUCTURAL REPAIRING OF RC BEAM-COLUMN CONNECTIONS DAMAGED UNDER CYCLIC LOADING – EXPERIMENTAL STUDY	191
<i>Emmanouil Golias, Stavroula Katsimante, Eirini Ziavra, Konstantinos Kirtsonis, Constantin E. Chaliotis, Chris C. Karayannis</i>	
 MS 3: RECENT ADVANCES AND CHALLENGES IN GEOTECHNICAL EARTHQUAKE ENGINEERING	
SEISMIC VULNERABILITY OF SHALLOW UNDERGROUND CAVITIES IN SOFT ROCK	202
<i>Stefania Fabozzi, Filomena De Silva, Marco Nocentini, Edoardo Peronace, Emilio Bilotta, Massimiliano Moscatelli</i>	
EFFICIENCY OF SEISMIC LIQUEFACTION MITIGATION METHODS FOR EXISTING STRUCTURES	212
<i>Alexandros Valsamis, Taxiarchoula Limnaiou, Achilleas Papadimitriou</i>	
PREDICTING RAILWAY TRACK DISPLACEMENTS WITH THE HARDENING SOIL SMALL STRAIN MODEL NEAR CRITICAL SPEED	222
<i>Jesús Fernández-Ruiz, Pedro Alves Costa</i>	
 MS 4: ADVANCEMENTS IN NUMERICAL MODELLING AND SEISMIC INTERVENTION TECHNIQUES OF HISTORICAL MASONRY STRUCTURES	
NON-DESTRUCTIVE AND DESTRUCTIVE TESTS ON OPUS INCERTUM MASONRY PANELS	231
<i>Francesca Autiero, Giuseppina De Martino, Marco Di Ludovico, Andrea Prota</i>	
PRELIMINARY NONLINEAR STATIC AND DYNAMIC ANALYSIS OF THE MAIN PYRAMID OF HUACA DE LA LUNA, PERU	244
<i>Selman Tezcan, Miguel a. Pando, Rafael Aguilar, Benjamin Castañeda, Carol Rojas, Renato Perucchio</i>	

MODELING STRATEGIES FOR NON-LINEAR SEISMIC ANALYSES: COMPARISON AMONG EFM AND FEM RESULTS ON AN EXISTING URM CASE STUDY	258
<i>Marco Pegoraro, Elisa Saler, Matteo Salvalaggio, Maria Rosa Valluzzi</i>	
ANALYSIS OF THE DAMAGE STATE OF A MONUMENTAL BUILDING BY CONSIDERING THE VARIATIONS IN SOIL CONDITIONS	268
<i>Erica Lenticchia, Gaetano Miraglia, Stefania Coccimiglio, Rosario Ceravolo</i>	
ADVANCED NUMERICAL PREDICTION OF UNREINFORCED U-SHAPED MASONRY WALLS LOADED OUT-OF-PLANE	278
<i>Jacopo Scacco, Luís C. Silva, Graça Vasconcelos, Gabriele Milani, Paulo B. Lourenço</i>	
LOW-COST BASE ISOLATION SYSTEMS FOR UNREINFORCED MASONRY BUILDINGS IN DEVELOPING COUNTRIES	286
<i>Nagavinothini Ravichandran, Daniele Losanno, Fulvio Parisi</i>	
NONLINEAR STATIC ANALYSIS OF MASONRY BUILDINGS THROUGH FIBRE-BASED CAPACITY MODELLING	298
<i>Elia Acconcia, Valentina Buonocunto, Fulvio Parisi</i>	
A DISCRETE-MACRO-ELEMENT-MODEL FOR THE IN-PLANE ANALYSIS OF MASONRY STRUCTURES STRENGTHENED BY FRCMS	309
<i>Paolo Zampieri, Riccardo Piazzon, Bartolomeo Pantò, Carlo Pellegrino</i>	
NUMERICAL MODELLING OF DIAGONAL COMPRESSION TESTS ON MASONRY PANELS STRENGTHENED BY FRCM	318
<i>Francesca Ferretti, Francesco Saverio Murgo, Claudio Mazzotti</i>	
EMPIRICAL AND MECHANICAL ANALYSIS METHODS FOR SEISMIC VULNERABILITY ASSESSMENT OF CLUSTERED BUILDINGS OF HISTORICAL CENTRES: A CASE STUDY	331
<i>Antonio Formisano, Giovanni Mochi, Nicola Chieffo</i>	
SETTLEMENT-INDUCED DAMAGE ASSESSMENT IN UNILATERAL MASONRY-LIKE STRUCTURES: A PIECEWISE RIGID DISPLACEMENT APPROACH	338
<i>Ida Mascolo, Antonio Fortunato</i>	
ON THE USE OF DIGITAL TWINS FOR SEISMIC STRUCTURAL HEALTH MONITORING OF A MONUMENTAL MASONRY TOWER	346
<i>Alban Kita, Nicola Cavalagli, Ilaria Venanzi, Filippo Ubertini</i>	
MICROMECHANICAL ANALYSIS OF UNREINFORCED AND REINFORCED MASONRY ARCHES	354
<i>Daniela Addressi, Cristina Gatta, Mariacarla Nocera, Domenico Liberatore</i>	
ANALYTICAL AND NUMERICAL ANALYSIS OF S. MARTINO'S DEI GUALDESI CHURCH DAMAGED DURING THE 2016 CENTRAL ITALY SEISMIC SEQUENCE	367
<i>Ivis Cescatti, Michol Rampado, Veronica Follador, Francesca da Porto, Claudio Modena</i>	
A NURBS-BASED NUMERICAL APPROACH FOR THE ASSESSMENT OF MASONRY VAULTS UNDERGOING DIFFERENTIAL SETTLEMENTS	380
<i>Andrea Chiozzi, Nicola Grillanda, Gabriele Milani, Antonio Tralli</i>	

NUMERICAL MODELLING OF BONDED BRICKWORK UNDER CYCLIC COMPRESSION LOADING	387
<i>Mohammad Asad, Tatheer Zahra, Julian Thamboo</i>	
FULL 3D CAD PROCEDURE FOR THE LIMIT ANALYSIS OF LONGHU PAGODA IN CHINA	398
<i>Peixuan Wang, Alessandro De lasio, Jacopo Scacco, Gabriele Milani, Shengcai Li</i>	
ROLE OF REPEATED SEISMIC EVENTS ON THE COLLAPSE OF TWO CALIDARIA IN ROME DATING BACK TO THE IMPERIAL AGE	406
<i>Francesca Faleri, Nicola Grillanda, Selman Tezcan, Renato Perucchio, Gabriele Milani</i>	
3D ADVANCED NUMERICAL MODELLING OF A CATALAN-LAYERED MASONRY VAULT UNREINFORCED AND REINFORCED WITH GLASS-TRM MATERIALS AND SUBJECTED TO VERTICAL SUPPORT MOVEMENTS	415
<i>Elisa Bertolesi, Gabriele Milani, José M. Adam, Pedro A. Calderón</i>	
DYNAMIC ANALYSIS OF MASONRY CHIMNEYS BY MEANS OF A SIMPLE RIGID BEAM MODEL	423
<i>Daniele Baraldi, Gabriele Milani, Vasilis Sarhosis</i>	
COMPARATIVE ANALYSIS AMONG DIFFERENT ANALYSIS PROGRAMS FOR SEISMIC VULNERABILITY EVALUATION OF A MASONRY BUILDING COMPOUND IN THE DISTRICT OF NAPLES	433
<i>Generoso Vaiano, Antonio Formisano</i>	
TERRITORIAL ANALYSIS OF SEISMIC PERFORMANCE OF ANCIENT CHURCHES: METHODS AND APPLICATION TO CASE STUDIES	447

EARTHQUAKE EARLY WARNING AND RAPID RESPONSE SYSTEM BASED ON SMART SEISMIC AND MONITORING SENSORS EMBEDDED IN A COMMUNICATION PLATFORM AND COUPLED WITH BIM MODELS	987
<i>Georgios Balaskas, Benno Hoffmeister, Christoph Butenweg, Marco Pilz, Anna Bauer</i>	
MONITORING OF A PRESTRESSED BRIDGE MODEL BY ULTRASONIC MEASUREMENT AND VIBRATION RECORDINGS	999
<i>Chun-Man Liao, Falk Hille, Daniel Fontoura Barroso, Ernst Niederleithinger</i>	

COMPARATIVE NON-STRUCTURAL VULNERABILITY ASSESSMENT METHODS FOR HISTORICAL RESIDENTIAL MASONRY BUILDINGS	1008
<i>Filippos Alogdianakis, Konstantinos G. Megalooikonomou, Georgios S. Papavasileiou</i>	

MS 9: NONLINEAR MODELLING AND ASSESSMENT OF EXISTING REINFORCED CONCRETE ELEMENTS

STUDY OF BIAXIAL SHEAR FAILURE ENVELOPE OF REINFORCED CONCRETE COLUMNS	1016
<i>Beatrice Belletti, Simone Ravasini, Andrea Alberici</i>	

EVALUATION OF THE SEISMIC VULNERABILITY OF EXISTING PRE-CODE RC CORE STRUCTURAL SYSTEMS THROUGH NON-LINEAR PUSHOVER ANALYSES	1027
<i>Beatrice Belletti, Enzo Martinelli, Elena Michelin, Francesca Vecchi</i>	

CALIBRATION AND VALIDATION OF AN OVERDAMPED DISPLACEMENT ADAPTIVE PROCEDURE FOR SEISMIC ASSESSMENT OF INFILLED RC FRAMES	1039
<i>Francesca Barbagallo, Melina Bosco, Aurelio Gherzi, Edoardo Michele Marino, Pier Paolo Rossi</i>	

CYCLIC TESTING OF 1:40 SCALE CANTILEVER RC ELEMENTS WITH DIGITALLY MANUFACTURED REINFORCEMENT	1053
<i>Lorenzo Del Giudice, Rafal Wrobel, Antonios Katsamakas, Christian Leinenbach, Michalis Vassiliou</i>	

R/C COLUMN MODELLING USING ANSYS AND LOADING RATE AND MESH METHOD INFLUENCE STUDIES	1063
<i>Theodora Mitkou, Theodoros Chrysanidis</i>	

CALIBRATION AND NUMERICAL MODELING OF RC BEAM-COLUMN JOINTS DESIGNED FOR GRAVITY LOADS	1085
<i>Marcello Sabene, Maria Zucconi, Stefano Pampanin, Barbara Ferracuti</i>	

ASSESSMENT OF THE RESPONSE ENVELOPE OF REINFORCED CONCRETE MEMBERS WITH DIFFERENT FAILURE MODES	1097
<i>Mariano Di Domenico, Paolo Ricci, Gerardo M. Verderame</i>	

SEISMIC ASSESSMENT OF AN EXISTING RC BUILDING AFFECTED BY SLOW-MOVING LANDSLIDES INDUCED DISPLACEMENTS MONITORED BY REMOTE SENSING TECHNIQUE	1112
<i>Annalisa Mele, Andrea Miano, Diego Di Martire, Donato Infante, Andrea Prota, Massimo Ramondini</i>	

MS 10: VULNERABILITY OF MUSEUM'S COLLECTIONS DYNAMIC RESPONSE, SAFETY ASSESSMENT AND DIGITAL INNOVATIONS

VULNERABILITY OF ART WORKS TO BLAST HAZARD: THE FOUNTAIN OF NEPTUNE IN FLORENCE	1125
<i>Marco Domaneschi, Marco Tanganelli, Stefania Viti, Gian Paolo Cimellaro</i>	

SIMPLIFIED ANALYSES FOR THE MODEL SETTING OF SCULPTURES: THE "OCEANO" BY GIAMBOLOGNA	1135
<i>Marco Tanganelli, Stefano Galassi, Stefania Viti</i>	

VULNERABILITY ASSESSMENT OF MONUMENTAL ARTWORKS USING CONTACT TIME-HISTORY ANALYSIS	1145
<i>Raffaele Gagliardo, Michele Godio, Lucrezia Cascini, Francesco Portioli, Raffaele Landolfo</i>	

THE TARANTOLA ETRUSCAN PEDIMENT: NDT AND 3D MODEL CONTENT	1153
<i>Anna Livia Ciuffreda, Massimo Coli, Tessa Donigaglia, Paola Ilaria Mariotti, Teresa Salvatici, Gabriela Simoni</i>	
CORRELATION OF VULNERABILITY AND CONSERVATION BETWEEN ARTISTIC ASSETS AND STRUCTURAL ELEMENTS: CAMPAIGN OF THERMOGRAPHIC SURVEYS ON THE FRESCOS OF THE TEMPLAR CHURCH OF SAN BEVIGNATE	1170
<i>Riccardo Liberotti, Federico Cluni, F. Faralli, Vittorio Gusella</i>	
 MS 11: RECENT FINDINGS AND OPEN ISSUES IN SEISMIC PERFORMANCE ASSESSMENT OF AS-BUILT AND RETROFITTED EXISTING RC BUILDINGS	
EVALUATION OF A NUMERICAL MODELLING APPROACH FOR THE SIMULATION OF RETROFITTED RC ELEMENTS	1188
<i>Ines Sousa, Rita Couto, Rita Peres, José Miguel Castro, Rita Bento</i>	
EXPERIMENTAL INVESTIGATION ON ANCHORAGE PERFORMANCE OF EMBEDDED SMOOTH REBARS SUBJECTED TO CYCLICNG LOADING	1201
<i>Anthony Paderno, Simone Pelucco, Marco Preti</i>	
OUT-OF-PLANE TESTING OF MASONRY INFILL WALLS MADE WITH LIGHTWEIGHT CONCRETE BLOCKS	1212
<i>M. Agante, André Furtado, Hugo Rodrigues, António Arêde, P. Fernandes, Humberto Varum</i>	
SELECTION OF OPTIMAL SEISMIC RETROFITTING FOR EXISTING SCHOOL BUILDINGS THROUGH MULTI- CRITERIA DECISION MAKING	1223
<i>Wilson Carofilis, Nicholas Clemett, Giammaria Gabbianelli, Gerard O'Reilly, Ricardo Monteiro</i>	
NUMERICAL INVESTIGATIONS ON THE RESIDUAL CAPACITY AND ECONOMIC LOSSES OF EARTHQUAKE- DAMAGED REINFORCED CONCRETE WALL STRUCTURES	1242
<i>Cristiana Ceccarelli, Simona Bianchi, Livio Pedone, Stefano Pampanin</i>	
SIMPLIFIED LOSS ESTIMATION IN INFILLED RC BUILDINGS: MECHANICAL METHOD AND VALIDATION	1261
<i>Carlo Del Gaudio, Maria Teresa De Risi, Gerardo Mario Verderame</i>	
SEISMIC PERFORMANCE ASSESSMENT OF AS-BUILT AND RETROFITTED RC BUILDINGS CONSIDERING THE INFLUENCE OF INFILLS: PRE-'70 LOW-MIDE RISE CASE-STUDIES	1275
<i>Maria Teresa De Risi, Santa Anna Scala, Carlo Del Gaudio, Gerardo Mario Verderame</i>	
MAPPING PERFORMANCE-TARGETED RETROFITTING TO SEISMIC FRAGILITY REDUCTION	1301
<i>Karim Aljawhari, Roberto Gentile, Carmine Galasso</i>	

MS 12: ADVANCES IN COMPUTATIONAL MODELLING, EXPERIMENTAL TESTING AND OPTIMIZATION OF SEISMIC RETROFITTING

EXPERIMENTAL STUDY ON THE IN-PLANE RESPONSE OF ADOBE MASONRY WALLS STRENGTHENED WITH TEXTILE REINFORCED MATRIX SYSTEMS	1322
<i>Paolino Cassese, Luigi Fenu, Domenico Asprone, Antonio Occhiuzzi, Fulvio Parisi</i>	
GENETIC OPTIMIZATION FOR THE DESIGN OF SEISMIC RETROFITTING OF PLANE RC FRAMES WITH BUCKLING RESTRAINED BRACES (BRBS)	1333
<i>Giovanni Minafò, Gaetano Camarda</i>	
INFLUENCE OF THE EFFECTIVENESS FACTORS IN ASSESSING THE SHEAR CAPACITY OF RC BEAMS STRENGTHENED WITH FRP	1345
<i>Piero Colajanni, Salvatore Pagnotta</i>	
OPTIMIZATION OF STEEL-JACKETING RETROFITTING OF SHEAR-CRITICAL AND DUCTILITY CRITICAL RC FRAME STRUCTURES BY A NOVEL GENETIC ALGORITHM FRAMEWORK	1368
<i>Antonio Pio Sberna, Fabio Di Trapani, Giuseppe Carlo Marano</i>	
EXPECTED ANNUAL LOSS ORIENTED SEISMIC RETROFITTING OPTIMIZATION OF RC FRAME STRUCTURES USING A NEW AI-BASED FRAMEWORK	1383
<i>Fabio Di Trapani, Antonio Pio Sberna, Giuseppe Carlo Marano</i>	
THE ROLE OF THE SUSTAINED LOADS ON THE BEARING CAPACITY OF REINFORCED CONCRETE COLUMNS RETROFITTED BY STEEL JACKETS	1401
<i>Marco Filippo Ferrotto, Bharat Pradhan, Liborio Cavaleri</i>	

MS 13: MODELLING AND SOLUTION STRATEGIES FOR DYNAMIC PROBLEMS

CASE STUDY OF CONNECTIVITY OF DIGITAL TWINS AND EXPERIMENTAL SYSTEMS	1416
<i>Matthew Bonney, Paul Gardner, David Wagg, Robin Mills</i>	
AN ADAPTIVE FAST NONLINEAR ANALYSIS (AFNA) ALGORITHM FOR RAPID TIME HISTORY ANALYSIS	1426
<i>Bowei Li, Wei-Chu Chuang, Seymour M.J. Spence</i>	
A NOVEL METHOD FOR THE GENERATION OF FULLY NON-STATIONARY SPECTRUM COMPATIBLE ARTIFICIAL ACCELEROGRAMS	1437
<i>Federica Genovese, Giuseppe Muscolino, G. Biondi, E. Cascone</i>	
AN APPLICATION OF THE PROPER ORTHOGONAL DECOMPOSITION METHOD FOR NONLINEAR DYNAMIC ANALYSIS OF REINFORCED CONCRETE STRUCTURES SUBJECTED TO EARTHQUAKES	1445
<i>Naim Ayoub, Walid Labri, Joseph Pais, Lucie Rouleau, Jean-François Deu</i>	
MULTI-RESOLUTION FINITE WAVELET DOMAIN METHOD FOR FAST TRANSIENT DYNAMIC ANALYSIS IN HOMOGENEOUS AND HETEROGENEOUS RODS AND BEAMS	1458
<i>Dimitris K. Dimitriou, Christos V. Nastos, Dimitris A. Saravanos</i>	

A TECHNIQUE FOR TIME INTEGRATION WITH STEPS LARGER THAN THE EXCITATION STEPS: REVIEW OF THE PAST AND ADDRESSING THE EXISTING CHALLENGES AND A PERSPECTIVE OF THE FUTURE	1476
<i>Aram Soroushian</i>	

MS 14: SEISMIC ASSESSMENT AND RETROFITTING OF EXISTING STEEL STRUCTURES

A SIMPLIFIED APPROACH FOR THE ESTIMATION OF SEISMIC VULNERABILITY OF STEEL MOMENT RESISTING FRAMES	1492
<i>Rosario Montuori, Elide Nastri, Vincenzo Piluso, Paolo Todisco</i>	

PRELIMINARY NUMERICAL ANALYSIS OF THE SEISMIC RESPONSE OF STEEL FRAMES WITH MASONRY INFILLS RETROFITTED BY BUCKLING RESTRAINED BRACES	1506
<i>Fernando Gutiérrez-Urzúa, Fabio Freddi, Luigi Di Sarno, Jing-Ren Wu, Mario D'Aniello, Raffaele Landolfo, Stathis Bousias</i>	

NUMERICAL MODELLING OF MASONRY INFILL WALLS IN EXISTING STEEL FRAMES	1519
<i>Luigi Di Sarno, Jing-Ren Wu, Fabio Freddi, Mario D'Aniello, Stathis Bousias, Fernando Gutiérrez-Urzúa, Raffaele Landolfo, Nikolaos Stathas</i>	

HYBRID COLD-FORMED/TUBULAR MODULAR STRUCTURAL SYSTEM WITH INNOVATIVE JOINTS	1532
<i>Luís Carlos Silva, Hélder David Craviero, Trayana Tankova, Rui Simões, Ricardo Costa, Mario D'Aniello, Raffaele Landolfo, Luís Simões da Silva</i>	

SEISMIC ASSESSMENT OF BEAM-TO-COLUMN JOINTS FOR A NON-CONFORMING MRF EXISTING STRUCTURE	1542
<i>Roberto Tartaglia, Mario D'Aniello, Aldo Milone, Raffaele Landolfo</i>	

MS 16: DYNAMIC RESPONSE ASSESSMENT IN RAIL TRACK ENGINEERING

APPLICATION AND ASSESSMENT OF A DYNAMIC SOIL-BRIDGE-TRAIN INTERACTION MODEL	1550
<i>Benjamin Hirzinger, Christoph Adam</i>	

SEISMIC FRAGILITY ANALYSIS OF RAILWAY RC BRIDGES. ACCOUNTING FOR BRIDGE-TRAIN INTERACTION BASED ON A NOVEL FORMULATION FOR CONSTRAINED DYNAMICAL SYSTEMS AND A CO-SIMULATION TECHNIQUE	1562
<i>Sotiria Stefanidou, Elias Paraskevopoulos</i>	

MS 17: RECENT DEVELOPMENTS IN ROCKING STRUCTURES

REDUCTION OF LOCAL DAMAGES IN PRECAST POST-TENSIONED SEGMENTAL BRIDGE PIERS	1574
<i>Parya Ahmadi, Ehsan Ahmadi, Mohammad M. Kashani</i>	

BASE VERSUS TOP ACTIVE CONTROL TO IMPROVE DYNAMIC AND SEISMIC PERFORMANCES OF RIGID BLOCKS .	1583
<i>Angelo Di Egidio, Alessandro Contento, Stefano Pagliaro</i>	

UNIFORM RISK SPECTRA FOR NEGATIVE STIFFNESS SYSTEMS	1596
<i>Natalia Reggiani Manzo, Christos Lachanas, Michalis Vassiliou, Dimitrios Vamvatsikos</i>	
SEISMIC BEHAVIOR OF ARCHAEOLOGICAL MULTIDRUM COLUMNS AT THE POMPEII SITE	1607
<i>Francesca Autiero, Giuseppina De Martino, Marco Di Ludovico, Andrea Prota</i>	
THE INFLUENCE OF IMPACT MODELLING ASSUMPTIONS ON THE DYNAMIC BEHAVIOUR OF FLEXIBLE ROCKING OSCILLATORS	1618
<i>Huanian Zhu, Manolis Chatzis, Sinan Acikgoz</i>	
QUANTIFYING SEISMIC RESILIENCE OF SINGLE-COLUMN ROCKING BRIDGES – A COMPARATIVE STUDY	1626
<i>Anastasios Giouvanidis, You Dong</i>	
DYNAMIC RESPONSE OF MULTI-STOREY STRUCTURES SEISMICALLY ISOLATED USING KINEMATIC BEARINGS	1641
<i>Kosmas E. Bantilas, Ioannis E. Kavvadias, Lazaros Vasiliadis, Anaxagoras Elenas</i>	
THE EFFECT OF IMPACT MODELING ON THE SEISMIC RESPONSE OF MULTI-STOREY PODIUM STRUCTURES	1657
<i>Ioannis E. Kavvadias, Kosmas E. Bantilas, Lazaros Vasiliadis, Anaxagoras Elenas</i>	
3D ROCKING MOTION: BLIND PREDICTION CONTEST RESULTS AND INFLUENCE OF EVALUATION METRIC ON THE RANKINGS	1672
<i>Michalis F. Vassiliou, Marco Broccardo, Cihan Cengiz, Matt Dietz, Luiza Dihoru, Selim Gunay, Khalid M. Mosalam, George Mylonakis, Anastasios Sextos, Bozidar Stojadinovic</i>	
FINITE ELEMENT MODELLING OF A RC ROCKING WALL WITH ADDITIONAL STEEL REBARS	1688
<i>Michele Egidio Bressanelli, Andrea Belleri, Jose Ignacio Restrepo</i>	
CYCLIC TEST OF A PRECAST BRIDGE COLUMN FOR SUSTAINABLE BRIDGE DESIGN	1700
<i>Natalia Reggiani Manzo, Michalis Vassiliou</i>	
 MS 19: ADVANCES IN THE OPTIMUM DESIGN AND CONTROL OF LARGE STRUCTURES UNDER DYNAMIC LOADS	
STUDY OF THE INFLUENCE OF SEISMIC ACTION ON THE CONSTRUCTION COST OF THE LOAD-BEARING STRUCTURE OF A TEN-STOREY R/C BUILDING	1712
<i>Panagiotis Sioulas, Theodoros Chrysanidis, Nikolaos Alamanis, Grigorios Papageorgiou</i>	
ASSESSMENT AND RETROFITTING OF A RC BUILDING THROUGH A MULTI-HAZARD APPROACH: SEISMIC RESISTANCE AND ROBUSTNESS	1725
<i>Martina Scalvenzi, Fabio Freddi, Fulvio Parisi</i>	
OPTIMAL LATERAL RESISTING SYSTEMS FOR HIGH-RISE BUILDINGS UNDER SEISMIC EXCITATIONS	1737
<i>Giulia Angelucci, Giuseppe Quaranta, Fabrizio Mollaioli</i>	
NON-INVASIVE VIBRATING CONTROL OF THE ZOSER PYRAMID	1751
<i>Masoud Shadlou, Pierfrancesco Cacciola, Ashraf Ayoub, Youssef Rashed, Alessandro Tombari</i>	

OPTIMUM DESIGN OF A HYBRID ISOLATION DEVICE FOR SERVER RACKS USING CONSTRAINED DIFFERENTIAL EVOLUTION ALGORITHM	1767
<i>Luca Aceto, Giuseppe Quaranta, Guido Camata, Bruno Briseghella, Enrico Spacone</i>	
INNOVATIVE MASS-DAMPING-BASED APPROACHES FOR SEISMIC DESIGN OF TALL BUILDINGS	1778
<i>Elena Mele, Diana Faiella, Mario Argenziano</i>	
DIAGRID SYSTEM COUPLED WITH SHEAR WALLS: ANALYTICAL INVESTIGATION ON THE DYNAMICAL RESPONSE IN TALL BUILDINGS	1793
<i>Giuseppe Lacidogna, Giuseppe Nitti, Domenico Scaramozzino, Alberto Carpinteri</i>	
OPTIMUM DAMPING OF SLENDER MONOPOLE TOWERS BY GYROSCOPIC STABILIZER	1803
<i>Gian Felice Giaccu, Luigi Fenu, Bruno Briseghella, Camillo Nuti</i>	
VIBRATION CONTROL OF WIND TURBINE TOWERS WITH KDAMPER-BASED DESIGNS	1812
<i>Konstantinos Kapasakalis, Ioannis Antoniadis, Evangelos Sapountzakis</i>	
 MS 20: COMPUTATIONAL DESIGN AND MODELING OF TENSEGRITY SYSTEMS FOR APPLICATIONS IN SCIENCE AND ENGINEERING	
ADAPTIVE BENDING-ACTIVE MODULES FOR A TENSILE SOLAR SHADING SYSTEM	1825
<i>Alessandro D'Ambrosio, Maria Matheou, Rosario Montuori, Elide Nastri</i>	
A MESOSCALE TENSEGRITY MODEL OF SPIDER DRAGLINE SILK FIBER	1834
<i>Ada Amendola, Narinder Singh, Cornelia Rodenburg, Chris Holland, Fernando Fraternali</i>	
GEOMETRIC PATTERNS AND DYNAMICS OF FOLDABLE MODULI FOR ADAPTIVE FAÇADES	1840
<i>Veronica Abbate, Enrico Babilio, Filipe Amarante dos Santos, Narinder Singh, Fernando Fraternali</i>	
MODELING AND DESIGN OF PERIODIC LATTICES WITH TENSEGRITY ARCHITECTURE AND HIGHLY NONLINEAR RESPONSE	1848
<i>Andrea Micheletti, Claudio Intrigila, Nicola Nodargi, Edoardo Artioli, Fernando Fraternali, Paolo Bisegna</i>	
A DYNAMIC-STIFFNESS APPROACH FOR DAMPED LOCALLY-RESONANT TIMOSHENKO BEAMS	1856
<i>Andrea Francesco Russillo, Giuseppe Failla, Antonina Pirrotta, Fernando Fraternali</i>	
SEISMIC METAMATERIALS WITH TENSEGRITY ARCHITECTURE	1867
<i>Filipe Santos, Narinder Singh, Ada Amendola, Fernando Fraternali, Andrea Micheletti</i>	
 MS 22: CONDITION BASED MAINTENANCE AND POST-PROGNOSTICS OF COMPOSITE STRUCTURES: AN ENHANCED PLATFORM	
RECONSTRUCTION OF MATERIAL STIFFNESS PROPERTIES FROM DISPERSION RELATIONS USING GENETIC ALGORITHMS	1874
<i>Victor Thierry, Wen Wu, Dimitrios Chronopoulos, Sergio Cantero-Chinchilla</i>	

PARTICLE FILTER-BASED HYBRID DAMAGE PROGNOSIS CONSIDERING BIAS	1881
<i>Tianzhi Li, Francesco Cadini, Claudio Sbarufatti</i>	

MS 23: ADVANCED MODELS AND NUMERICAL METHODS IN DYNAMICS, WAVE PROPAGATION AND COUPLED PROBLEMS

DISPERSION ANALYSIS OF BULK ACOUSTIC WAVES IN PIEZOELECTRIC MEDIA DISCRETIZED BY ENERGY-ORTHOGONAL FINITE ELEMENTS	1892
<i>Francisco J. Brito Castro</i>	

DISPERSION DESIGN OF 1D PERIODIC DISCRETE SYSTEMS USING LOG-DET HEURISTICS	1922
<i>Anton Tkachuk, Mykola Tkachuk</i>	

AN EFFICIENT PRECONDITIONER FOR MODAL FREQUENCY RESPONSE	1934
<i>Tobias Willerding</i>	

MS 24: LIFE-CYCLE RISK-BASED STRUCTURAL ASSESSMENT AND COST ANALYSIS

FRAGILITY ASSESSMENT OF WIND-EXCITED VIDEO SCREEN ROOMS IN HIGH-RISE BUILDINGS	1941
<i>Fabio Rizzo, Laura Ierimonti, Stefano Sacconi, Ilaria Venanzi</i>	

FRAGILITY OF EXISTING ITALIAN BRIDGES TO TRAFFIC LOADS	1950
<i>Giacomo Miluccio, Daniele Losanno, Fulvio Parisi, Edoardo Cosenza</i>	

TOWARDS THE DEVELOPMENT OF A COMPREHENSIVE FRAMEWORK FOR LIFE CYCLE COST ANALYSIS OF BRIDGES SUBJECTED TO MULTIPLE HAZARDS	1961
<i>Stefano Sacconi, Laura Ierimonti, Ilaria Venanzi, Filippo Ubertini</i>	

LIFE-CYCLE COST ANALYSIS OF TALL BUILDINGS IN SYNOPTIC, MIXED WIND LOAD CLIMATES BY LAYERED STOCHASTIC APPROXIMATION MONTE-CARLO METHOD	1973
<i>Lei Zhang, Luca Caracoglia</i>	

APPLICATION OF BAYESIAN FE MODEL SELECTION FOR SHM OF A MONUMENTAL MASONRY PALACE THROUGH SEMI-SUPERVISED LEARNING	1988
<i>Laura Ierimonti, Nicola Cavalagli, Enrique García-Macías, Ilaria Venanzi, Filippo Ubertini</i>	

A NEURAL NETWORK-BASED APPROACH FOR SEISMIC-INDUCED DAMAGE ASSESSMENT OF STEEL LIQUID STORAGE TANKS	2003
<i>Laura Micheli, Mahmoud Faytarouni</i>	

MS 25: MONITORING, IDENTIFICATION AND VIBRATION CONTROL OF STRUCTURES

APPLICATION OF WAVELET TRANSFORMS ON ACCELERATION RECORDS: PRACTICAL APPROACH	2014
<i>Vladimir Vukobratović, Trevor Yeow, Koichi Kusunoki</i>	

NUMERICAL INVESTIGATION ON THE PRINCIPAL STRESS ROTATION EFFECT UNDER EARTHQUAKE LOADINGS ..	2022
<i>Zhe Wang, Yunming Yang</i>	
ENRICHED BEAM FINITE ELEMENT MODELS WITH TORSION AND SHEAR WARPING FOR DYNAMIC ANALYSIS OF FRAME STRUCTURES	2033
<i>Daniela Addessi, Paolo Di Re, Cristina Gatta</i>	
EARTHQUAKE-INDUCED STRUCTURAL POUNDING BETWEEN TWO INELASTIC SDOF STRUCTURAL SYSTEMS	2058
<i>Pedro Folhento, Rui Barros, Manuel Braz-César</i>	
INFLUENCE OF STRUCTURAL INELASTIC BEHAVIOR IN THE STUDY OF COLLIDING SDOF STRUCTURES	2085
<i>Pedro Folhento, Rui Barros, Manuel Braz-César</i>	
VIRTUAL SENSING AND STRAIN ESTIMATION ON AN OFFSHORE WIND TURBINE USING SUPERVISED LEARNING	2112
<i>Marius Tarpø, Sandro Amador, Evangelos Katsanos, Mattias Skog, Johan Gjødvad, Rune Brincker</i>	
SIMPLIFIED METHODS FOR FREQUENCY ESTIMATION OF SMALL WIND TURBINE TOWER	2121
<i>Anelise Dick, Rui Carneiro-Barros, Manuel Braz-César</i>	
FINITE ELEMENT MODEL CALIBRATION EFFECTS ON THE STATIC AND DYNAMIC RESPONSE OF A METALLIC HOLLOW TOWER	2132
<i>Anelise Dick, Rui Carneiro-Barros, Manuel Braz-César</i>	
PARAMETRIC STUDY OF LATTICE TOWERS ON THE INFLUENCE OF WIND ACTION FOR DIFFERENT TYPOLOGIES OF BRACING	2143
<i>Rui Carneiro-Barros, Luís Barros</i>	
 MS 26: SEISMIC SAFETY ASSESSMENT OF STRUCTURES	
EXPERIMENTAL IN-PLANE LATERAL RESPONSE OF A FULL-SCALE ADOBE MASONRY WALL WITH OPENING	2157
<i>Paolino Cassese, Luigi Fenu, Domenico Asprone, Antonio Occhiuzzi, Fulvio Parisi</i>	
INFLUENCE OF BEAM-TO-COLUMN CONNECTIONS IN SEISMIC VULNERABILITY ASSESSMENT OF STEEL STRUCTURES	2170
<i>Giammaria Gabbianelli, Daniele Perrone, Emanuele Brunesi</i>	
ASSESSMENT OF RC HOLLOW-PIERS FOR SEISMIC LIMIT STATE OF DAMAGE - DIRECT REPAIR COSTS	2185
<i>Pedro Delgado, Naiara Silva, Mário Marques, António Arêde</i>	
 MS 27: TIMBER-BASED ELEMENTS: RECENT ADVANCEMENTS FOR NEW AND EXISTING SEISMIC-RESISTANT STRUCTURES	
OPTIMIZATION OF THE SLIP FORCE IN A NOVEL FRICTION-BASED CONNECTION FOR THE E-CLT TECHNOLOGY ..	2195
<i>Angelo Aloisio, Francesco Boggian, Roberto Tomasi</i>	

EXPERIMENTAL AND NUMERICAL INVESTIGATION OF INNOVATIVE DUCTILE AND REPLACEABLE ANCHORING SYSTEMS FOR WOOD SHEAR WALLS UNDER SEISMIC LOADS	2211
<i>Georgios Balaskas, Vera Wilden, Benno Hoffmeister</i>	
ANALYTICAL AND NUMERICAL MODELLING OF THE IN-PLANE RESPONSE OF TIMBER DIAPHRAGMS RETROFITTED WITH PLYWOOD PANELS	2227
<i>Michele Mirra, Marianthi Sousamli, Michele Longo, Geert Ravenshorst</i>	
MOMENT-CURVATURE DIAGRAMS FOR CLT PANELS ACCOUNTING FOR ORTOGONAL TO GRAIN COMPRESSION TIMBER PROPERTIES	2254
<i>Antonio Sandoli, Claudio D'Ambra, Maria Lippiello, Carla Ceraldi, Bruno Calderoni, Andrea Prota</i>	
REINFORCING STOP-SPLAYED SCARF JOINTS WITH TIMBER PEG: ROLE OF SLENDERNESS	2272
<i>Carla Ceraldi, Claudio D'Ambra, Maria Lippiello, Antonio Sandoli, Andrea Prota</i>	
IMPACT OF RETROFIT OF RC FRAMES BY CLT PANELS AND FRICTION DAMPERS	2287
<i>Francesca Barbagallo, Giuseppe Margani, Edoardo M. Marino, A. Moretti, Carola Tardo</i>	
SEISMIC STRENGTHENING OF EXISTING URM STRUCTURES THROUGH CLT ELEMENTS: NUMERICAL ANALYSIS OF THE APPLICATION OF A NOVEL INTERVENTION TECHNIQUE	2300
<i>Matteo Salvalaggio, Marco Pegoraro, Elisa Saler, Umberto Turrini, Maria Rosa Valluzzi</i>	
POST-TENSIONED LOW DAMAGE TIMBER WALLS WITH DISSIPATIVE DEVICES BEHAVIOUR: NUMERICAL PREDICTION	2314
<i>Valentina Tomei, Maria Zucconi, Barbara Ferracuti</i>	
MANSORY-INFILLED RC FRAMES STRENGTHENED WITH CROSS-LAMINATED TIMBER PANELS	2323
<i>Zabih Mehdipour, Jorge Branco, Iztok Sustersic, Leonardo Filipe Rodrigues, Paulo Lourenço</i>	
INFLUENCE OF PERPENDICULAR WALLS ON THE LATERAL STIFFNESS OF CLT SHEAR WALLS	2336
<i>Elisabetta Maria Ruggeri, Giuseppe D'Arenzo, Marinella Fossetti, Werner Seim</i>	
POST-TENSIONED LOW DAMAGE CLT WALLS WITH REPLACEABLE HYSTERETIC DEVICES – CONCEPT, EXPERIMENTAL AND NUMERICAL CHARACTERIZATION	2352
<i>Luca Pozza, Luca Benedetti, Valentina Tomei, Barbara Ferracuti, Maria Zucconi, Claudio Mazzotti</i>	
TIMBER BEAM-TO-COLUMN JOINT WITH STEEL LINK: DESIGN AND MECHANICAL CHARACTERIZATION THROUGH NUMERICAL INVESTIGATION	2359
<i>Giacomo Iovane, Beatrice Faggiano</i>	
A NUMERICAL STUDY ON A TIMBER-BASED SEISMIC RETROFIT INTERVENTION FOR MASONRY INFILLED CONCRETE FRAMES	2366
<i>Francesco Smirolto, Davide Viel, Ivan Giongo, Maurizio Piazza</i>	

MS 29: SEISMIC PROTECTION OF NON-STRUCTURAL COMPONENTS: RECENT DEVELOPMENTS AND FUTURE CHALLENGES

COMPREHENSIVE NONLINEAR ANALYSIS OF FAILURES OF FIRE-SPRINKLER SYSTEM BASED ON FINITE ELEMENT MODELLING AND AMBIENT VIBRATION TESTS	2388
<i>Shakhzod Takhirov, Amir Gilani</i>	
IMPROVEMENT OF DYNAMIC AND SEISMIC BEHAVIOUR OF CABINETS THROUGH CONTROLLED DEFORMATION	2396
<i>Stefano Pagliaro, Angelo Di Egidio, Alessandro Contento</i>	
NUMERICAL MODELING OF ROCKING AND SLIDING CYLINDRICAL COLUMNS UNDER SEISMIC EXCITATION	2408
<i>Antonios Katsamakas, Michalis Vassiliou</i>	
SEISMIC RISK ASSESSMENT OF ROCKING BUILDING CONTENTS	2421
<i>Michalis Fragiadakis, Spyridon Diamantopoulos</i>	

MS 30: DYNAMIC PROTECTION SYSTEMS AND DEVICES: EXPERIMENTAL TESTS, MATHEMATICAL MODELING AND DESIGN METHODS

SOME RECENT ADVANCES ON THE MODELING OF THE HYSTERETIC BEHAVIOR OF RATE-INDEPENDENT PASSIVE ENERGY DISSIPATION DEVICES	2435
<i>Nicolò Vaiana, Ciro Napolitano, Luciano Rosati</i>	
SEISMIC PROTECTION OF CULTURAL HERITAGE ARTEFACTS BY MEANS OF ELASTOMERIC ISOLATORS: A CASE STUDY	2446
<i>Davide Pellecchia, Stefania Lo Feudo, Nicolo Vaiana, Jean-Luc Dion, Luciano Rosati</i>	
TUNING THE LATERAL RESPONSE OF UNBONDED FIBER REINFORCED ELASTOMERIC ISOLATORS (U-FREIS): EXPERIMENTAL-NUMERICAL FINDINGS	2456
<i>Simone Galano, Andrea Calabrese, Daniele Losanno</i>	
ON THE VERTICAL RESPONSE OF FIBER REINFORCED ELASTOMERIC ISOLATORS (FREIS) UNDER COMBINED VERTICAL AND LATERAL LOADING	2468
<i>Simone Galano</i>	
SEISMIC ISOLATION OF LIGHTWEIGHT STRUCTURES THROUGH WIRE ROPE DEVICES: PRELIMINARY EXPERIMENTAL RESULTS AND SIMULATION	2488
<i>Mariacristina Spizzuoco, Giorgio Serino</i>	
REAL-TIME HYBRID SIMULATION OF A STRUCTURE WITH CIRCULAR FIBER REINFORCED ISOLATORS	2498
<i>Carlos Riascos, Semion Klopov, Johannio Marulanda, Peter Thomson, Giorgio Serino</i>	
A COMPARATIVE STUDY ON THE ACCURACY AND EFFICIENCY OF TWO BIAXIAL HYSTERETIC MODELS SUITABLE FOR ELASTOMERIC BEARINGS	2511
<i>Nagavinothini Ravichandran</i>	

LABORATORY CHARACTERIZATION OF A RECLAIMED RUBBER COMPOUND FOR LOW-COST ELASTOMERIC ISOLATORS	2525
<i>Fabrizia Cilento, Daniele Losanno, Luigi Piga</i>	
EFFECT OF EXTREMELY LOW TEMPERATURE ON MECHANICAL PROPERTIES OF A LARGE SIZE LRB	2536
<i>Gokhan Ozdemir, Esengul Cavdar, Volkan Karuk</i>	
STIFF DYNAMIC ABSORBERS FOR THE VERTICAL SEISMIC PROTECTION OF STRUCTURES	2543
<i>Marina Kalogerakou, Konstantinos Kapasakalis, Ioannis Antoniadis, Evangelos Sapountzakis</i>	
 MS 32: SIMPLIFIED METHODOLOGIES FOR PERFORMANCE AND LOSS ASSESSMENT AT BUILDING OR TERRITORIAL SCALE	
ACCURATE COLLAPSE CAPACITY QUANTIFICATION FOR INFILLED RC FRAME BUILDINGS	2557
<i>Al Mouayed Bellah Nafeh, Gerard O'Reilly</i>	
DEVELOPMENT OF A PYTHON-BASED STOREY LOSS FUNCTION GENERATOR	2573
<i>Davit Shahnazaryan, Gerard O'Reilly, Ricardo Monteiro</i>	
ASSESSMENT OF POST-EARTHQUAKE DAMAGES ON ITALIAN SCHOOL BUILDINGS PORTFOLIO OVER THE LAST 50 YEARS	2591
<i>Sergio Ruggieri, Chiara Tosto, Daniele Perrone, Giuseppina Uva, Maria Antonietta Aiello</i>	
SEISMIC RISK ASSESSMENT FOR THE ITALIAN RESIDENTIAL MASONRY BUILT STOCK AND EFFECTIVENESS OF DIFFERENT MITIGATION STRATEGIES	2606
<i>Pietro Carpanese, Veronica Follador, Elisa Saler, Francesca da Porto</i>	
THE USE OF STICK-IT MODEL FOR EDP ASSESSMENT IN EXISTING RC INFILLED TYPOLOGIES	2619
<i>Marco Gaetani d'Aragona, Maria Polese, Marco Di Ludovico, Andrea Prota</i>	
APPLICATION OF THE EMPIRICAL PREDICTIVE DAMAGE MODEL OF HISTORICAL CHURCHES	2631
<i>Claudia Canuti, Michele Morici, Andrea Dall'Asta, Graziano Leoni</i>	
A SEISMIC RISK ASSESSMENT FRAMEWORK FOR LOSS ESTIMATION OF CRITICAL INFRASTRUCTURE – HOSPITALS CASE	2643
<i>Paolo Basso, Saimir Osmani, Matteo Scolari, Ruben Valsecchi</i>	
CAESAR II: AN ITALIAN DECISION SUPPORT TOOL FOR THE SEISMIC RISK. THE CASE STUDY OF TORRE PELLICE, VILLAR PELLICE AND PINEROLO MUNICIPALITIES	2659
<i>Giulio Zuccaro, Francesca Linda Perelli, Daniela De Gregorio, Daniele Masi</i>	
OPEN MODELS AND SOFTWARE FOR ASSESSING THE VULNERABILITY OF THE EUROPEAN BUILDING STOCK	2678
<i>Helen Crowley, Vitor Silva, Luis Martins, Xavier Romão, Nuno Pereira</i>	

PELL-SCHOOLS A STANDARDIZED AND INTEROPERABLE PLATFORM FOR THE SEISMIC VULNERABILITY AND ENERGY EFFICIENCY DATA MANAGEMENT OF ITALIAN SCHOOLS	2689
<i>Laura Blaso, Sonia Giovinazzi, Simona Bianchi, Livio Pedone, Chiara Ormando, Paolo Clemente, Stefano Pampanin, Nicoletta Gozo, Giuseppina Giuliani, Maurizio Pollino</i>	

EFFECT OF BUILDING SAMPLE SELECTION ON SEISMIC FRAGILITY CURVES FOR RC BUILDINGS AT TERRITORIAL SCALE	2707
<i>Maria Zucconi, Fabio Romano, Barbara Ferracuti</i>	

VOLUME II

Minisymposia

MS 33: EXPERIMENTAL MEASUREMENTS AND NUMERICAL SIMULATION ON PROBLEMS IN THE FIELD OF EARTHQUAKE ENGINEERING AND STRUCTURAL DYNAMICS

ANALYTICAL INVESTIGATION OF THE TENSILE EXPERIMENTS MODELING THE ELONGATION DEGREE OF R/C WALLS FOR STUDYING THE LATERAL BUCKLING PHENOMENON	2718
<i>Theodoros Chrysanidis, Vassilis Panoskaltsis</i>	

ANALYTICAL INVESTIGATION OF THE TENSILE EXPERIMENTS TO PRISMS WITH VARYING LONGITUDINAL RATIO FOR STUDYING THE LATERAL BUCKLING OF R/C WALLS	2730
<i>Theodoros Chrysanidis, Vassilis Panoskaltsis</i>	

PRELIMINARY CONSIDERATIONS ON THE LOSS OF SUPPORT FOR PRECAST BEAM ELEMENTS	2744
<i>Marius Eteme Minkada, Simone Labò, Alessandra Marini, Andrea Belleri</i>	

SEISMIC PERFORMANCE OF BELL TOWERS	2754

MS 38: DYNAMIC SOIL-FOUNDATION-STRUCTURE INTERACTION: DEVELOPMENTS AND EMERGING ISSUES	
DYNAMIC CROSS-INTERACTION BETWEEN TWO CLOSELY-SPACED SHALLOW FOUNDATIONS	3577
<i>Enza Zeolla, Filomena de Silva, Stefania Sica</i>	
ON THE SITE-AMPLIFICATION AND SOIL-STRUCTURE INTERACTION IN URM STRUCTURES: USE OF FRAGILITY CURVES TO ASSESS THE SIMPLIFIED CODE-APPROACH	3589
<i>Andrea Brunelli, Filomena de Silva, Serena Cattari</i>	
ELASTODYNAMIC ANALYSIS OF LATERALLY LOADED PILES: MODIFICATIONS TO A SIMPLIFIED ENERGY APPROACH	3605
<i>Jamie J. Crispin, George Mylonakis</i>	
ON THE EFFECTIVENESS OF EXPERIMENTALLY-DERIVED FOUNDATION IMPEDANCE FUNCTIONS	3617
<i>Chiara Amendola, Filomena de Silva, Dimitrios Pitilakis, Francesco Silvestri</i>	
NUMERICAL ANALYSIS ON THE INFLUENCE OF DYNAMIC SOIL-STRUCTURE INTERACTION IN SORIA ARCH DAM: A CASE STUDY	3633
<i>J.C. Galván, L.A. Padrón, J.J. Aznárez, O. Maeso</i>	
SOIL-CAISSON-BRIDGE PIER-DECK DYNAMIC INTERACTION UNDER STRONG EARTHQUAKES: THE INFLUENCE OF PRIMARY AND SECONDARY SOIL NONLINEARITIES	3645
<i>Domenico Gaudio, Sebastiano Rampello</i>	

INFLUENCE OF SCOUR ON DYNAMIC IMPEDANCES OF BRIDGE SHALLOW FOUNDATIONS	3658
<i>Christos Antonopoulos, Enrico Tubaldi, Sandro Carbonari, Fabrizio Gara, Francesca Dezi</i>	

KINEMATIC PILE-HEAD BENDING UNDER LARGE EARTHQUAKE-INDUCED SHEAR STRAINS	3671
<i>Stefano Stacul, Emmanouil Rovithis, Raffaele Di Laora</i>	

ASPECTS OF SEISMIC SOIL-PILE-STRUCTURE INTERACTION IN SOFT CLAY BY CENTRIFUGE TESTING	3685
<i>Maria Iovino, Emmanouil Rovithis, Raffaele Di Laora, Cristiano D'Alterio, Luca de Sanctis, Thejesh K. Garala, Stuart Haigh, Gopal S. Madabhushi</i>	

MS 39: THE CONTRIBUTION OF DYNAMIC TESTS AND STRUCTURAL MONITORING ON THE SEISMIC RISK ASSESSMENT AND MITIGATION

LONG TERM MONITORING OF THE SANTA MARIA DI COLLEMAGGIO BASILICA	3697
<i>Angelo Aloisio, Riccardo Cirella, Antonacci Elena, Rocco Alaggio</i>	

AMBIENT VIBRATION TEST ON AN EXISTING PRESTRESSED CONCRETE BRIDGE	3720
<i>Alessandra De Angelis, Giacomo Esposito, Giuseppe Maddaloni, Edoardo Cosenza, Maria Rosaria Pecce</i>	

MODAL ANALYSIS OF THE HISTORICAL SS FILIPPO E GIACOMO MASONRY ARCH BRIDGE IN ASCOLI PICENO (ITALY)	3731
<i>Fabrizio Gara, Graziano Leoni, Michele Morici</i>	

THE TRACKING OF MODAL PARAMETERS FOR A REINFORCED CONCRETE BUILDING DURING LOW-MEDIUM INTENSITY EARTHQUAKES	3743
<i>Davide Arezzo, Vanni Nicoletti, Sandro Carbonari, Fabrizio Gara</i>	

FIRST RESULTS OF LONG-TERM MONITORING OF PORTICO VARANO IN THE CAMERINO DUCAL PALACE (ITALY)	3752
<i>Leonardo Cipriani, Andrea Dall'Asta, Graziano Leoni, Michele Morici, Alessandro Zona</i>	

DEVELOPMENT OF LOW COST SENSORS FOR MONITORING OF STRUCTURES	3762
<i>Giuseppe Maddaloni, Alessandra De Angelis, Francesco Minicozzi, Claudio Martino, Maria Rosaria Pecce</i>	

CALIBRATION OF NUMERICAL MODELS TO SUPPORT SHM: THE CONSOLI PALACE OF GUBBIO, ITALY	3778
<i>Serena Cattari, Daniele Sivori, Sara Alfano, Laura Ierimonti, Nicola Cavalagli, Ilaria Venanzi, Filippo Ubertini</i>	

MS 40: ARTIFICIAL INTELLIGENCE & MACHINE LEARNING IN DESIGN AND ASSESSMENT OF STRUCTURES

RAPID DESIGN OF R/C COLUMNS USING MACHINE LEARNING TECHNIQUES	3795
<i>Vassilis Papanikolaou, Aristotelis Charalampakis</i>	

DEVELOPMENT OF A NEW FUNDAMENTAL PERIOD FORMULA BY CONSIDERING SOIL-STRUCTURE INTERACTION WITH THE USE OF MACHINE LEARNING ALGORITHMS	3801
<i>Vicky-Lee Taljaard, Dewald Z. Gravett, Christos Mourtas, George Markou, Nikolaos Bakas, Manolis Papadrakakis</i>	
PREDICTING THE SHEAR CAPACITY OF REINFORCED CONCRETE SLENDER BEAMS WITHOUT STIRRUPS BY APPLYING ARTIFICIAL INTELLIGENCE ALGORITHMS	3810
<i>Zelda Spijkerman, Nikolaos Bakas, George Markou, Manolis Papadrakakis</i>	
STRUCTURAL DAMAGE PREDICTION UNDER SEISMIC SEQUENCE USING NEURAL NETWORKS	3820
<i>Petros C. Lazaridis, Ioannis E. Kavvadias, Konstantinos Demertzis, Lazaros Iliadis, Antonios Papaleonidas, Lazaros K. Vasiliadis, Anaxagoras Elenas</i>	
AUTOMATED ESTIMATION OF BUILDING HEIGHT THROUGH IMAGE PROCESSING	3837
<i>Pietro Carpanese, Marco Donà, Francesca da Porto</i>	
MACHINE LEARNING TECHNIQUES FOR THE ESTIMATION OF LIMIT STATE THRESHOLDS AND BRIDGE-SPECIFIC FRAGILITY ANALYSIS OF R/C BRIDGES	3848
<i>Sotiria Stefanidou, Vassilis Papanikolaou, Elias Paraskevopoulos, Andreas Kappos</i>	
LINKS OF AESTHETIC VALUE OF MULTI-CURVATURE ARTIFACTS, WITH THEIR STRUCTURAL BEHAVIOR, UTILIZING MACHINE LEARNING ALGORITHMS	3857
<i>Nikolaos Bakas, Neofytos Christofi, John Bellos, Dimitrios Antoniou, George Markou</i>	
PERFORMANCE AND SCALABILITY OF DEEP LEARNING MODELS TRAINED ON A HYBRID SUPERCOMPUTER: APPLICATION IN THE PREDICTION OF THE SHEAR STRENGTH OF SLENDER RC BEAMS	3878
<i>Nikolaos Bakas, George Markou, Dimos Charmpis, Kyriakos Hadjiyiannakou</i>	
PREDICTION OF THE EIGENPERIODS OF MDOF SHEAR BUILDINGS USING NEURAL NETWORKS	3894
<i>Vagelis Plevris, German Solorzano</i>	
 MS 41: SEISMIC PERFORMANCE OF STRUCTURES WITH ISOLATION AND/OR ENERGY DISSIPATION DEVICES	
SEISMIC PERFORMANCE OF STRUCTURES EQUIPPED WITH BRB	3912
<i>Paolo Castaldo, Enrico Tubaldi, Laura Gioiella</i>	
EFFECT OF LEAD RUBBER BEARING (LRB) MODELING TECHNIQUE ON THE SEISMIC RESPONSE OF BASE-ISOLATED BRIDGES	3930
<i>Vahid Aghaeidoost, Ahm Muntasir Billah</i>	
AN ADVANCED MODEL FOR THE FLUID VISCOUS DAMPER BRITTLE FAILURE	3942
<i>Laura Gioiella, Fabrizio Scozzese, Enrico Tubaldi, Laura Ragni, Andrea Dall'Asta</i>	
SEISMIC PERFORMANCE OF STEEL MRFS RETROFITTED WITH BRBS: INFLUENCE OF THE DESIGN DECISIONS FOR THE DEVICES	3957
<i>Fernando Gutiérrez-Urzuá, Fabio Freddi</i>	

EXPERIMENTAL INVESTIGATION OF SPHERICAL RUBBER SEISMIC ISOLATION BEARINGS	3970
<i>Antonios Katsamakas, Gabriel Belser, Michalis Vassiliou, M. Blondet, Božidar Stojadinovic</i>	
EXPERIMENTAL SEISMIC POST-TENSIONING PERFORMANCE AND LONG-TERM EFFECTS OF A POST-TENSIONED TIMBER FRAMED MODEL WITH DISSIPATIVE SYSTEMS	3982
<i>Antonio Di Cesare, Felice Carlo Ponzo, Nicla Lamarucciola, Domenico Nigro</i>	
EXPERIMENTAL COMPARISON BETWEEN FLAT AND CURVED SLIDING CONDITIONS FOR THE RESPONSE EVALUATION OF CURVED SURFACE SLIDER DEVICES	3992
<i>Alberto Pavese, Marco Furinghetti</i>	
THE NEW CAMERINO UNIVERSITY RESEARCH CENTER: DESIGN OF THE BASE-ISOLATED BUILDING AND DYNAMIC TESTING	4005
<i>Andrea Dall'Asta, Graziano Leoni, Fabio Micozzi, Laura Gioiella, N. Ceccolini, Laura Ragni</i>	
VARIATION IN RESPONSE OF A BRIDGE SEISMICALLY ISOLATED WITH LRBS UNDER THE EFFECT OF LOW AMBIENT TEMPERATURE	4015
<i>Esengul Cavdar, Volkan Karuk, Gokhan Ozdemir</i>	
SEISMIC PROTECTION OF MULTI-STORY STRUCTURES WITH NOVEL VIBRATION ABSORPTION DEVICES COMBINING NEGATIVE STIFFNESS AND INERTER	4026
<i>Konstantinos Kapasakalis, Georgios Florakis, Ioannis Antoniadis, Evangelos Sapountzakis</i>	
MULTI-LEVEL OPTIMISATION OF NONLINEAR VISCOUS DAMPERS FOR SEISMIC RETROFIT OF SUBSTANDARD STEEL FRAMES	4046
<i>Dario De Domenico, Iman Hajirasouliha</i>	
SEISMIC RETROFIT OF EXISTING PRECAST RC BUILDINGS WITH DISSIPATIVE DEVICES BASED ON CARBON WRAPPED STEEL TUBES	4058
<i>Lucia Praticò, Andrea Vittorio Pollini, Devis Sonda, Nicola Buratti</i>	
METAMODELING CHOICES FOR SEISMIC VULNERABILITY ASSESSMENT OF BRB-RETROFITTED LOW-DUCTILITY RC FRAMES	4078
<i>Jayadipta Ghosh, Fabio Freddi</i>	
NUMERICAL INVESTIGATION OF RUBBER BEARINGS WITH LOW SHAPE FACTOR UNDER SEISMIC EXCITATION	4091
<i>Alessandra Orfeo, Enrico Tubaldi, Alan Muhr, Daniele Losanno</i>	
INELASTIC RESPONSE MODES OF SEISMICALLY ISOLATED STRUCTURES: FAILURE OF THE ISOLATORS OR DAMAGE IN THE ISOLATED STRUCTURE?	4100
<i>Anastasios Tsiavos, Tomislav Markić, David Schlatter, Božidar Stojadinović</i>	
 MS 42: ADVANCES IN MODEL REDUCTION TECHNIQUES OF COMPUTATIONAL AND STRUCTURAL DYNAMICS	
A NEW PARALLEL ALGORITHM FOR THE OPTIMUM EMBEDDED REBAR MESH GENERATION FOR LARGE-SCALE REINFORCED CONCRETE STRUCTURES	4111
<i>Dewald Gravett, George Markou</i>	

ON THE APPLICATION OF GENERALISED SCHUR COMPLEMENTS TO SUBSYSTEM-LEVEL VARIABILITY QUANTIFICATION	4120
<i>Vladimir Yotov</i>	

MS 43: ANALYSES AND DESIGN OF STEEL JOINTS UNDER CYCLIC ACTION

BEHAVIOUR OF LAP SHEAR RIVETED CONNECTIONS WITH CONSTRUCTIONAL IMPERFECTIONS	4134
<i>Aldo Milone, A. De Martino</i>	
BEHAVIOR OF INNO3D JOINTS UNDER MONOTONIC AND CYCLIC LOADING	4142
<i>Arash Poursadrollah, A. De Martino</i>	
DESIGN AND ANALYSIS OF FREEDAM FRAMES: COMPARISON WITH TRADITIONAL CONNECTIONS	4149
<i>Maria Maglio, Camilla Naddei, Elide Nastri, Rosaria Russo, Paolo Todisco</i>	
COMPONENT MODELLING OF CONNECTIONS BETWEEN CIRCULAR-HOLLOW-SECTIONS AND THROUGH- ALL MEMBERS	4177
<i>A. Saldutti, Sabatino Di Benedetto, Massimo Latour, Gianvittorio Rizzano</i>	
SEISMIC RESPONSE OF INNOVATIVE CFS WALLS BRACED WITH UHS STEEL BARS: EXPERIMENTAL INVESTIGATION	4185
<i>Alessia Campiche</i>	
VALIDATION OF NOVEL SEISMIC DESIGN CRITERIA FOR LIGHTWEIGHT STEEL BUILDING IN EUROPE	4199
<i>Sarmad Shakeel, Marica Navarra, Alessia Campiche</i>	
BEHAVIOUR OF T-STUB UNDER MODE 2 AND 3 WITH HV AND HR BOLTS	4212
<i>Roberto Tartaglia, Mario D'Aniello</i>	
INFLUENCE OF THE JOINT BEHAVIOUR ON THE PERFORMANCE OF ORTHOGONAL EXOSKELETONS FOR SEISMIC RETROFIT	4219
<i>Roberto Tartaglia, Gianmaria Di Lorenzo, Antonio Formisano, Raffaele Landolfo</i>	

Thematic Sessions

TS 5: DYNAMICS OF CONCRETE AND MASONRY STRUCTURES

EVALUATION OF THE SEISMIC BEHAVIOR OF HISTORICAL CHURCHES REINFORCED BY CROSS-LAM ROOF- STRUCTURES	4226
<i>Nicola Longarini, Pietro Crespi, Marco Zucca</i>	
SEISMIC RESPONSE OF SEVEN EXISTING REINFORCED CONCRETE CHIMNEYS EQUIPPED WITH TUNED MASS DAMPERS UNDER FIVE STRONG SEISMIC EVENTS	4248
<i>Pietro Giuseppe Crespi, Nicola Longarini, Marco Valente, Marco Zucca</i>	

SHAKING TABLE TEST ON THE EFFECTS OF SHEAR WALLS FOR LONG-SPAN KOREAN TRADITIONAL TIMBER STRUCTURE	4262
<i>Yeong-Min Kim</i>	
INVESTIGATION OF THE IMPACT OF SEISMIC ZONE TO THE COST OF CONSTRUCTION OF A 5-STOREY R/C BUILDING	4272
<i>Theodoros Chrysanidis, Nikolaos Alamanis, Grigorios Papageorgiou, Georgia Kaouri</i>	
FLEXURAL PERFORMANCE OF CONCRETE BEAMS UNDER CYCLIC LOADING	4283
<i>Waseem Khan, Saleem Akhtar, Aruna Rawat, Anindya Basu</i>	
A MULTILAYER SHELL ELEMENT FOR NONLINEAR ANALYSIS OF R/C SHEAR WALLS	4294
<i>Vassilis Papanikolaou, Christos Karakostas, Konstantinos Morfidis, Emmanouil Baboukas</i>	
COMPARISON OF THE EFFICIENCY OF MINIMUM-THICKNESS CIRCULAR AND PARABOLIC ARCHES FOR VARIOUS GRAVITY CONDITIONS	4302
<i>Nicos Kalapodis, Georgios Kampas, Thomas McLean, Christian Malaga-Chuquitaype</i>	
LARGE-DISPLACEMENT RESPONSE OF UNREINFORCED MASONRY STRUCTURES: COMPARISON BETWEEN ANALYTICAL SOLUTIONS AND DEM MODELS INCLUDING OPEN-SOURCE SOFTWARE	4317
<i>Igor Bouckaert, Michele Godio, João Pacheco de Almeida</i>	
TS 14: NUMERICAL SIMULATION METHODS FOR DYNAMIC PROBLEMS	
NONLINEAR FINITE ELEMENT MODELS FOR EMBEDDED BASE CONNECTIONS	4331
<i>Nicolas Mora Bowen, Pablo Torres Rodas</i>	
LOCAL SCALE DAMPING MODEL FOR REINFORCED CONCRETE ELEMENTS	4341
<i>Clotilde Chambreuil, Cédric Giry, Frédéric Ragueneau, Pierre Léger</i>	
NUMERICAL STUDY ON THE DAMPING CHARACTERISTICS OF A SHOCK ABSORBER VALVE UTILIZING DIFFERENT VELOCITIES THROUGH CFD ANALYSIS	4353
<i>Yousif Badri, Thaer Syam, Sadok Sassi, Mohammed Hussein, Jamil Renno, Saud Ghani</i>	
ENERGY HARVESTING FROM RAILWAY VIBRATIONS – A NUMERICAL STUDY BASED ON BEAM-ON-ELASTIC-FOUNDATION UNDER QUASI-STATIC LOADING	4363
<i>Shahd Elshafei, Mohammed Hussein, Jamil Renno, Asan Mutalif</i>	
IMPACT FACTORS DERIVED FROM INTERNAL FORCES IN TIMOSHENKO BEAMS SUBJECTED TO CONCENTRATED MOVING LOADS	4373
<i>Benjamín Pinazo, Salvador Monleón, Carlos Lázaro, Pedro Museros</i>	
ON THE DEVELOPMENT OF A NOVEL APPROACH FOR SIMULATING ELASTIC BEAMS IN DUALSPHYSICS WITH THE USE OF THE PROJECT CHRONO LIBRARY	4385
<i>Salvatore Capasso, Bonaventura Tagliafierro, Iván Martínez-Estévez, José M. Domínguez, Joe El Rahi, Vasiliki Stratigaki, Alejandro J.C. Crespo, Rosario Montuori, Peter Troch, Moncho Gómez-Gesteira, Giacomo Viccione</i>	

DIGITAL SIMULATION OF WIND FIELD VELOCITY FOR EVALUATING PROPER STIFFNESS INDICATORS OF WINDOW MULLIONS	4400
<i>Gian Felice Giaccu, Antonio Cazzani</i>	
ANALYTICAL/NUMERICAL SOLUTIONS TO THE PROBLEM OF THE DYNAMIC RESPONSE OF AN ELASTIC PLATE ON A CONTINUOUSLY NON-HOMOGENEOUS CROSS-ANISOTROPIC VISCOELASTIC SOIL TO A MOVING LOAD	4407
<i>Niki D. Beskou, Edmond V. Muho</i>	
 TS 15: OPTIMUM DESIGN AND CONTROL IN STRUCTURAL DYNAMICS AND EARTHQUAKE ENGINEERING	
OPTIMAL DESIGN OF TID-BASED SYSTEM FOR THE CONTROL OF WIND-INDUCED VIBRATION IN TALL BUILDINGS THROUGH CULTURAL ALGORITHM	4428
<i>Luis Lara-Valencia, Mateo Ramírez-Acevedo, José Brito, Daniel Caicedo, Yosef Farbiarz</i>	
A PARAMETRIC ANALYSIS OF THE SEISMIC PERFORMANCE OF BRIDGES AS A FUNCTION OF THE DCFP DEVICE PROPERTIES	4439
<i>Paolo Castaldo, Guglielmo Amendola</i>	
SEISMIC PERFORMANCE OF BRIDGES ISOLATED WITH FPS	4452
<i>Paolo Castaldo, Guglielmo Amendola</i>	
CRITICAL ACCELERATION, SEISMIC SLIDING DISPLACEMENT AND SMART DESIGN OF CANTILEVER WALLS	4467
<i>Loukas C. Katsenlis, Constantine A. Stamatopoulos, Vassilis P. Panoskaltsis</i>	
COMPARISON OF CONTROL ALGORITHMS APPLIED TO AN HYBRID MASS DAMPER ATTACHED TO AN WIND TURBINE TOWER	4481
<i>Pedro Rocha, Suzana Avila</i>	
PRELIMINARY STUDY OF AN ARDUINO CONTROLLED SHAKE TABLE TO LOW-FREQUENCY TEST	4494
<i>Ledyamar F. Moreno, Marcus V. G. de Moraes, Suzana M. Avila</i>	
EFFICIENT DAMPER DESIGN METHOD FOR ELASTIC-PLASTIC MDOF STRUCTURES UNDER CONSECUTIVE-LEVEL EARTHQUAKES	4508
<i>Hiroki Akehashi, Izuru Takewaki</i>	
DIFFERENTIATION OF THE CONSTRUCTION COST OF A FIFTEEN STOREY R/C BUILDING DEPENDING ON THE SEISMIC HAZARD ZONE	4520
<i>Paulina Tselempi, Theodoros Chrysanidis</i>	
DOES THE SEISMICITY OF THE AREA HAVE AN IMPACT ON THE CONSTRUCTION COST OF THE LOAD-BEARING STRUCTURE OF R/C BUILDINGS?	4535
<i>Thomas-Erik Makris, Theodoros Chrysanidis</i>	

IMPROVING ENERGY DISSIPATION CAPACITY OF NATURALLY BUCKLING BRACES UNDER LOW-CYCLE FATIGUE LOADS	4547
<i>Shadiya Jamshiyas, Kazuhiro Hayashi, Xiaopo Yang, Konstantinos Skalomenos</i>	

TS 17: PERFORMANCE-BASED EARTHQUAKE ENGINEERING

NUMERICAL MODELING OF SLIP RESPONSE OF LATERALLY SWAYING BRIDGE PIERS' TENSILE REINFORCEMENT	4558
<i>Konstantinos G. Megalooikonomou</i>	

SEISMIC RISK ASSESSMENT OF A PROCESS PLANT UNIT ACCOUNTING FOR DYNAMIC INTERACTION	4568
<i>George Karagiannakis, Luigi di Sarno</i>	

A COMPARATIVE STUDY ON SEISMIC RESPONSE OF A SUPER HIGH-RISE BUILDING USING CONVENTIONAL AND MODAL PUSHOVER ANALYSIS	4582
<i>Xianlong Zhang, Hao Wu, Qiao Yu, Yang Liu, Lingzhi Li, Wannan Xu, Junyan Zhou</i>	

NUMERICAL PARAMETRIC STUDY OF GRILLE-TYPE STEEL CONCRETE COMPOSITE SHEAR WALL FOR SEISMIC REGIONS	4593
<i>Tian Wang, Qiao Yu, Hao Wu, Yang Liu, Lingzhi Li, Xianlong Zhang</i>	

SEISMIC RELIABILITY OF BRIDGES ISOLATED WITH FPS	4607
<i>Paolo Castaldo, Guglielmo Amendola, Luca Giordano, Diego Gino, Elena Miceli</i>	

INTENSITY MEASURES PROPERTIES AND SELECTION FOR RISK ANALYSIS ON STRUCTURES SUBJECTED TO EARTHQUAKE INDUCED BUILDING POUNDING WITH A NON SMOOTH CONTACT DYNAMICS METHOD	4621
<i>Thomas Langlade, David Bertrand, Stéphane Grange, Gabriel Candia, Juan Carlos de la Llera</i>	

ESTIMATION OF DUCTILITY IN ASYMMETRIC-PLAN STRUCTURES	4633
<i>Kaan Kaatsiz, Halûk Sucuoğlu</i>	

A MULTI-OBJECTIVE DISPLACEMENT-BASED DESIGN PROCEDURE OF VISCOUS AND HYSTERETIC DAMPED BRACES FOR THE SEISMIC PROTECTION OF RC BUILDINGS	4646
<i>Fabio Mazza, Carlo Pasceri</i>	

EFFECT OF THE DAMPING RATIO OF THE NON-STRUCTURAL COMPONENTS ON FLOOR ACCELERATION DEMANDS IN TORSIONALLY IRREGULAR BUILDINGS	4660
<i>Ankur Jain, Mitesh Surana</i>	

EXPLORING THE EXPECTED INCREASE OF COSTS AND LOSS REDUCTION BY RAISING THE BAR IN SEISMIC DESIGN: COMPARISON OF ALTERNATIVE DESIGN METHODOLOGIES AND EARTHQUAKE-RESISTANT TECHNOLOGIES	4670
<i>Francesca Gentili, Jonathan Ciurlanti, Simona Bianchi, Stefano Pampanin</i>	

SEISMIC RESPONSE OF A TRANSPARENT PAVILION MADE OF STRUCTURAL GLASS	4688
<i>Dimitra V. Achillopoulou, Nikoleta K. Stamataki</i>	

ON THE USE OF INSTANTANEOUS POWER FOR NEAR-FAULT RECORD MODIFICATION	4697
<i>Esra Zengin, Norman Abrahamson</i>	
SEISMIC DESIGN OF STEEL FRAMES WITH INTENTIONALLY ECCENTRIC INDUCTION-HEAT TREATED STEEL BRACES	4706
<i>Thomas Whittall, Konstantinos A. Skalomenos</i>	
AN EFFICIENT RECORD-TRUNCATION SCHEME FOR PULSE-LIKE RECORDS USING A WAVELET-BASED APPROACH	4720
<i>Vicky Dimakopoulou, Michalis Fragiadakis, Ioannis Taflampas</i>	
 TS 19: REPAIR AND RETROFIT OF STRUCTURES	
NUMERICAL MODELLING OF SHEAR BOND TESTS ON EXTERNALLY STRENGTHENED MASONRY SPECIMENS	4729
<i>Ottavio Tamborrino, Daniele Perrone, Marianovella Leone</i>	
A DISPLACEMENT-BASED DESIGN PROCEDURE OF VISCOUS DAMPED STEEL EXOSKELETONS FOR THE SEISMIC RETROFITTING OF RC FRAMED BUILDINGS	4742
<i>Fabio Mazza, Egidio Mollo</i>	
DEBONDING ANALYSIS OF FRCM COMPOSITES FOR STRUCTURAL UPGRADING OF RC STRUCTURES	4758
<i>Maria Teresa Cristofaro, Angelo D'Ambrisi, Francesco Focacci, Raffaele Nudo, Gianfranco Stipo, Marco Tanganelli, Mario De Stefano</i>	
NODAL DISSIPATIVE DEVICES FOR SEISMIC PROTECTION OF PRECAST RC STRUCTURES	4772
<i>Fabrizio Comodini, Angelo D'Ambrisi, Marco Mezzi</i>	
INVESTIGATION OF THE RESPONSE OF INTERFACES OF CFRP SHEET STRENGTHENING SCHEMES ENHANCED WITH TOUGHENED EPOXY ADHESIVE LAYERS APPLIED IN CORRODED CONCRETE SUBSTRATES	4782
<i>Dimitra Achillopoulou</i>	
SEISMIC RETROFITTING OF SINGLE-STORY RC PRECAST BUILDINGS THROUGH A NOVEL METALLIC HYSTERETIC DEVICE	4789
<i>Chiara Di Salvatore, Gennaro Magliulo, Maria G. Castellano, Nicola Caterino</i>	
COMPRESSIVE STRENGTH EVALUATION OF BLUE MOSQUE MINARET STONES WITH ULTRASONIC TESTING	4800
<i>Gulen Uncu, Şahin Dede, Eser Çaktı</i>	
EXPERIMENTAL INVESTIGATION OF SHEAR STRENGTH OF SOLID BRICK URM WALLS RETROFITTED WITH TRM JACKET	4808
<i>Athanasia Thomoglou, Athanasios Karabinis</i>	

TS 20: SEISMIC ISOLATION

METAFoundation AS A NEW APPROACH FOR SEISMIC ISOLATION OF BUILDINGS	4816
<i>Stefania Fiore, Domenico Magisano, Giovanni Finocchio, Massimo Chiappini</i>	

SEISMIC PERFORMANCE OF DOUBLE FRICTION PENDULUM BEARINGS UNDER HORIZONTAL AND VERTICAL EXCITATION	4824
<i>Ioannis E. Kavvadias</i>	

SEISMIC DEVICES FOR STEEL STORAGE STRUCTURES	4834
<i>Marco Simoncelli, Bonaventura Tagliaferro, Rosario Montuori</i>	

ANALYSIS OF THE PARTICLES DISTRIBUTION INFLUENCE ON THE RECYCLED RUBBER PROPERTIES TO BE USED AS A MATRIX OF LOW-COST SEISMIC ISOLATORS	4845

Abstract

The present contribution deals with an innovative evaluation of the vulnerability and static seismic behavior of existing masonry structures and monumental buildings. For a given masonry construction, a discretization through few NURBS surfaces is realized. NURBS surfaces are converted into shell elements which are assumed rigid and infinitely resistant. The non-linearities typical of the masonry material (almost no tensile strength, frictional behavior in shear, and relatively larger resistance in compression) are imposed at interfaces between adjacent elements, which represent in this way possible fracture lines. Once defined a horizontal load configuration, an adaptive upper bound limit analysis is applied. As final result, the collapse mechanism and the collapse load multiplier are found. Then, to provide the complete non-linear structural response, a FE model composed of elastic elements representing macro-blocks and non-linear contact-based interfaces or plastic damaging strips corresponding to the cracks is derived. On such model, static non-linear analyses can be performed easily at a fraction of the computational burden needed by standard approaches. Several examples including masonry churches, vaults, and buildings are presented. Finally, a novel limit analysis computational technique based on a discretization through NURBS solid elements is introduced and future perspectives of the research are drawn.

Keywords: Masonry, seismic vulnerability, NURBS, limit analysis, non-linear analysis.

1 INTRODUCTION

The prediction of the load bearing capacity and ultimate displacements in the framework of a displacement-based design for existing masonry structures and monumental buildings is a very difficult task and at present a hot topic for the specialized scientific community, especially for earthquake prone masonry countries.

As a matter of fact, a huge amount of different modelling strategies have been developed in the last decades [1] to deal with the multitude of challenges that characterize the analysis of such structures in the non-linear range. Indeed, masonry is characterized by heterogeneity, strongly non-linear behavior even at low levels of both horizontal and vertical loads, anisotropic response, complex geometries and an infinite variability of the textures.

Classically, we can distinguish two main analysis approaches for masonry structures subjected to horizontal loads [2], namely (i) limit analysis-based and (ii) incremental-evolutionary approaches.

Numerical techniques based on limit analysis are quite diffused nowadays because it is well-known their reliability for the realistic determination of both collapse mechanisms and ultimate load carrying capacity. Limit analysis applied to masonry has a long tradition and is basically due to the seminal work by Heyman [3]. In the last four decades, many different approaches have been developed grounded on the utilization of both the lower bound [4]-[8] and the upper bound [9]-[11] theorem, removing also in some cases the associativity of the flow rule. When embedded in a FE formulation, limit analysis becomes very intuitive in its upper bound formulation and kinematic approaches are generally preferred in the literature [12]-[14]. Within the FE upper bound formulation, different models have been proposed, assuming that the inelastic deformation occurs only inside elements, only at the interfaces between adjoining elements or on both interfaces and elements, as firstly proposed in [15] for geotechnical problems. When the plastic dissipation is constrained to occur only on interfaces, then the problem becomes strongly mesh dependent and either remeshing or mesh adaptation algorithms are needed [16]. The advantage is that the number of variables is limited and, if the adaptation scheme is efficient, the computational burden remains rather limited [17]-[19]. However, as well known limit analysis typically does not provide any information regarding displacements, although this would be essential in a displacement-based design, which is considered the standard for any seismic analysis [20].

Incremental-evolutionary approaches are widely utilized tools for the step-by-step investigation of the structural equilibrium in nonlinear iterative analysis frameworks, often used in pushover analyses for the seismic assessment of masonry structures [21]. These approaches can be used within three classic modelling strategies that proved to be effective for masonry structures:

- Macro-element models or simplified models in general (see e.g. [22]-[27]), widely used in common engineering practice due to their simplicity, although typically limited to ordinary buildings and not applicable for complex monumental structures;
- Block-based models (see e.g. [28]-[32]) where masonry is modelled block-by-block (typically into Finite Elements) and the interaction between blocks can be accounted for through various formulations, being the most diffused the utilization of mortar interfaces. Although potentially highly accurate, their main drawback is the huge computational effort needed even for small and medium size structures;
- Continuum models (see e.g. [33]-[35]) where masonry is modelled through a deformable continuum and the constitutive law can be defined directly or through a multi-scale framework. These models, although interesting and potentially very effective, could be computationally expensive or could find difficulties in representing the post-peak response due to

convergence issues, as well as the collapse mechanism predicted could be, in general, not fully clear and somewhat smeared [35].

- Discrete element models -or restricting the family of the approaches proposed, Distinct Element Methods DEMs- (as for instance those presented in [36]-[44] without being exhaustive) where masonry is modelled with rigid or elastic blocks and all non-linearity is lumped on joints typically assumed with a cohesive frictional behaviour [43][44]. Such approach is conceived mainly for Non Linear Dynamic Analyses NLDAs [45]-[47] but it can be adapted also to static non linear analyses, or in presence of foundation settlements, albeit requiring typically huge computational efforts. There are obviously other important drawbacks that cannot be summarized in few words in this introduction, but it is interesting to point out how they have recently inspired the implementation of FEM combined with DEM for large scale computations (see for instance [48]-[49]).

Accordingly, both limit analysis-based and incremental-evolutive approaches present either advantages or disadvantages, and their coupling would represent a favourable solution. The research initially conceived by one of the authors of this paper [50] represented a first attempt to couple limit analysis to displacement-based strategies. In particular, in [50] the collapse mechanism deduced by a genetic algorithm-based GA adaptive limit analysis has been used in a pushover-based framework using two different approaches to introduce nonlinearities in the model. The first one considered 3D plastic damaging strips governed by a nonlinear continuum constitutive law, while the second exploited zero-thickness contact-based interfaces governed by a cohesive-frictional contact behaviour. Both approaches proved a good performance in simulating not only the separate in- and out-of-plane behaviour of masonry structures, but also than of full 3D buildings, having the advantage of requiring for such analyses a considerably low computational demand.

Returning to deal with classic limit analysis, it can be affirmed that its adoption, when the procedure grounds basically on the pioneering paper by Heyman [3] is still very suitable; it is not a case indeed that it has been recently applied in a very successful manner, because the approach is very straightforward, relatively simple and quite accurate in predicting load carrying capacities and failure mechanisms. This is probably the reason why many other researchers developed in the last four decades interesting different limit-analysis procedures, in the majority of the cases basing on a FE discretization (that goes well with limit analysis) -both homogeneous and heterogeneous-, using less the static theorem [4]-[8] and slightly more the kinematic theorem [51]-[56] approach. This is not a case; it is indeed opinion of the authors that, from an implementation point of view, limit analysis procedures which use finite elements (FEs) are typically easier to implement when based on the upper bound theorem, i.e. in a kinematic framework. For cohesive-frictional materials (e.g. masonry) the solution can be found easily also in presence of a non associated flow rule and therefore it appears particularly flexible, especially in all those cases where dissipation occurs only on interfaces between contiguous elements, i.e. failure is due to the formation of a kinematic chain formed by large rigid blocks, an intuition which follows the idea originally proposed in [57]. Nowadays, limit analysis-based solutions are considered trustworthy to investigate collapse mechanisms and the ultimate load in masonry structures [3].

The present paper discusses the following important key issues related to an adaptive limit analysis of existing masonry buildings in general (including also masonry aggregates), masonry curved structures and monumental buildings;

- 1) The most suitable and stable adaptive limit analysis algorithm to use to obtain results quickly with a high confidence on the correctness of the estimated collapse accelerations and failure mechanisms.

- 2) The flexibility of the approach, intended as its utilization in a variety of different limit analysis problems, which includes also the possibility to take into account the orthotropy of the material (when present), the possible presence of multi-leaf walls, double curvature structures or the analysis of complex masonry aggregates exhibiting good or bad interlocking at the intersection between perpendicular walls, also in presence of any kind of strengthening device, such as tie rods, FRP strips, continuous FRCM reinforcement, etc.
- 3) The extension to non-linear static analyses, i.e. a newly conceived two-step methodology where ultimate displacements can be predicted after a preliminary limit analysis. The main idea of the procedure proposed is shown schematically in Figure 1. For a given masonry construction, a discretization through few NURBS surfaces is realized. NURBS surfaces are converted into shell elements which are assumed rigid and infinitely resistant. The non-linearities typical of the masonry material (almost no tensile strength, frictional behavior in shear, and relatively larger resistance in compression) are imposed at interfaces between adjacent elements, which represent in this way possible fracture lines. Once defined a horizontal load configuration, an adaptive upper bound limit analysis is applied. As final result, the collapse mechanism and the collapse load multiplier are found. Then, to provide the complete non-linear structural response, a FE model composed of elastic elements representing macro-blocks and non-linear contact-based interfaces or plastic damaging strips corresponding to the cracks is derived. On such model, static non-linear analyses can be performed easily at a fraction of the computational burden needed by standard approaches.

Figure 1. two-step approach used to provide quickly pushover curves for complex masonry structures.

In the present paper, several examples including masonry churches, vaults, and buildings are discussed in detail. Finally, a novel limit analysis computational technique based on a discretization through NURBS solid elements is introduced and future perspectives of the research are drawn.

2 THE THEORETICAL METHOD ADOPTED

In the present Section, the main features of the theoretical model adopted for the adaptive limit analysis and the subsequent simplified pushover analysis are recalled and commented, discussing also the efficiency of different meta-heuristic approaches used for the mesh adaptation.

2.1 Adaptive NURBS-based upper bound limit analysis

For a given masonry structure, a model composed by curved or planar NURBS surfaces is realized within the Rhinoceros environment. NURBS surfaces (Non-Uniform Rational Bezier Spline [58]) are parametric surfaces whose basis functions are piecewise polynomial rational functions obtained starting from the traditional spline basis function. In this approach, NURBS properties are used to both represent exactly curved geometries and facilitate mesh adaptation procedures.

The NURBS model of the whole masonry structure is imported within MATLAB, where each surface is here converted into a 3D shell element through the definition of a thickness value. By using the properties of NURBS, a mesh can be defined by subdividing each initial surface into few trimmed surfaces: each one generates a single element that is still a NURBS surface and the overall geometry is not altered. Elements are supposed to behave as rigid blocks with internal dissipation allowed only along their interfaces. With the aim of finding a failure mechanism constituted exclusively by macro-blocks, the NURBS elements constitute the macro-blocks involved in the mechanism and interfaces are possible fracture lines or hinges.

An upper bound limit analysis is applied. Given a load configuration $[\mathbf{q}_0, \lambda \mathbf{q}]$, in which \mathbf{q}_0 are permanent loads and \mathbf{q} are live loads depending on a multiplier λ , a mechanism involving the few rigid elements composing the initial mesh can be identified by solving a linear programming problem. The mechanism is described by a velocity field $\dot{\mathbf{u}}$ that contains the six velocity components (three translational and three rotational) of each centroid of a NURBS macro-block, which at the edges exhibits discontinuities (i.e. velocity jumps) with respect to the contiguous elements. To properly quantify the velocity jumps, rigid-plastic interfaces are defined at the common boundaries between adjacent elements. Each interface is discretized through collocation points to which the associative flow rule is imposed:

$$\Delta \tilde{\mathbf{u}} = \dot{\lambda} \frac{\partial f}{\partial \boldsymbol{\sigma}} \quad (1)$$

where $\Delta \tilde{\mathbf{u}}$ are the velocity jumps defined in the local reference system, $\dot{\lambda}$ are the non-negative plastic multipliers, $\boldsymbol{\sigma}$ is the stress vector, and f is the linearized three-dimensional yield domain defined in the space of the local stress. For the masonry material, f can be represented by using a three-dimensional Mohr-Coulomb failure criterion defined through a cohesion value c and a friction angle φ . A tension cut-off and a linear cap in compression are included to limit respectively the maximum tensile strength f_t , otherwise equal to $c/\tan(\varphi)$, and the maximum compression strength f_c that masonry can undergo. The failure surface can be in any case changed at user's discretion, for instance utilizing the homogenization theory in the rigid plastic case to take into account in a rigorous manner orthotropy [59]. Alternatively, to reproduce the orthotropic behavior of masonry, a much more straightforward strategy is to

assign two different sets of resistance values along two orthogonal directions of each NURBS surface (e.g. following the directions of bed and head joints): for each inclined interface, a Mohr-Coulomb domain is thus determined by combining the resistance values proportionally to the inclination angle.

Once defined the internal and the external power in reference to the overall vector of unknowns $\mathbf{x} = [\dot{\mathbf{u}}, \dot{\boldsymbol{\lambda}}]$, the linear programming problem that solves the upper-bound formulation is summarized as follows:

$$\min \lambda = \mathbf{c}^T \mathbf{x} \text{ such that } \begin{cases} \mathbf{A}\mathbf{x} = \mathbf{b} \\ \dot{\boldsymbol{\lambda}} \geq \mathbf{0} \end{cases} \quad (2)$$

in which \mathbf{A} is the global matrix of constraints (geometric, compatibility, and normality condition), \mathbf{b} is the vector of known terms in the equality equations (basically a zero-vector with a unitary value as the last term), and \mathbf{c} is the vector of coefficients derived from the Principle of Virtual Powers. The solution vector \mathbf{x} contains the discontinuous velocity field that describes the mechanism obtained starting from the adopted mesh. Eventually, the linear programming problem can be modified into a sequential linear programming to take into account a non-associative behavior in shear (see [51]).

However, the use of a reduced number of macro-elements makes the problem highly mesh-dependent. According to the upper bound theorem of limit analysis, the collapse load multiplier is the minimum of the kinematic load multipliers and it is associated to the real collapse mechanism, which is properly identified only if the interfaces between adjacent elements coincide with the real position of fracture lines. Therefore, a procedure of mesh adaptation is finally applied: the initial mesh is iteratively adjusted until the absolute minimum of the kinematic load is found. For this operation, a meta-heuristic approach is used. Among the several available meta-heuristic algorithm [52], a Genetic Algorithm (GA) is generally applied, because considered sufficiently stable and reliable, as demonstrated in the following Section.

A representative scheme of adaptive limit analysis procedure (step 1 of Figure 1) is depicted schematically in Figure 2. This limit analysis procedure has been used to study several typologies of masonry structures in the last years by the authors, ranging from in-plane and out-of-plane loaded panels to double curvature structures and masonry aggregates [18][19][51]-[56].

Figure 2. Adaptive upper bound limit analysis tool: (a) original geometry and load condition, (b) NURBS model with initial mesh, (c) collapse mechanism and collapse load multiplier.

2.2 Efficiency test for different meta-heuristic approaches for double curvature structures

The adaptive meta-heuristic approach previously mentioned has been tested on 4 double curvature structures utilizing 4 different algorithms in [52], namely using a specifically devised Prey Predator Algorithm (PPA), a Particle Swarm Optimization (PSO) Algorithm, a Firefly Algorithm (FA) and a specifically crafted Genetic Algorithm (GA). The reader interested into the details of the procedures adopted is referred to [52] for the sake of conciseness. In particular, here it is worth mentioning that the 4 benchmarks considered are a circular skew arch (test #1), a parabolic straight arch (test #2), a parabolic skew barrel vault (test #3) and a ribbed cross vault (test #4). Here we focus almost exclusively on test #3, i.e. on the parabolic skew barrel vault, see Figure 3, for the sake of conciseness. The skew geometry forces the vault to fail non-symmetrically, displaying a mixed interaction of bending and torsional deformation modes. Therefore, the NURBS mesh of the vaulted surface is generated by four moving interfaces in the parameters space. As it can be easily predicted, the failure mechanism is more complex than a failure mechanism formed by four hinges as it occurs for straight arches. In particular, interfaces are not anymore constrained to remain orthogonal to the vault shape: in fact, they can rotate, so that the placement of each interface in the parameters space is governed by two parameters (i.e. the location of the yield lines extremes). It follows that the problem at hand is governed by eight parameters, as depicted in Figure 3(b). Therefore, the NURBS mesh of the vaulted surface is generated by eight moving interfaces in the parameters space. Nonlinear finite element analyses on this case study have been performed in [60] and they are used for comparison purposes. A population of 40 individuals has been adopted in all the meta-heuristics approaches. The number of total iterations is 50. Figure 4(a) depicts convergence plots for the 4 discussed meta-heuristic algorithms, whereas Figure 4 (b-c) illustrate the computational time needed to solve the problem. Similarly to the other benchmarks treated in [52] (i.e tests #1, 2 and 4), PPA seems to guarantee a slightly faster convergence to the optimal solution when compared to the other three proposed meta-heuristic algorithms; furthermore, the error in the estimation of the collapse load multiplier is less than 5% after only 7 iterations, computed in 82 seconds. However, in general and also in this case, the performance of PPA is approximately equivalent to that provided by GA algorithm, which is able to furnish a very good approximation of the final solution after only 11 iterations. Table 1 summarizes the results in terms of computational time, number of iterations and number of function evaluations required for all the benchmarks discussed in [52]. Finally Figure 5 and Figure 6 show respectively the last iteration crack patterns associated to the collapse mechanisms for the four examples discussed in [52] and a comparison between the collapse mechanisms obtained by means of the proposed meta-heuristic NURBS-based limit analysis schemes and the ones obtained in the literature through both homogenized finite element limit analysis and experiments.

From the numerical tests carried out in [52], it can be affirmed that all meta-heuristic approaches are able to furnish engineering meaningful results at a fraction of standard FE limit analysis computations carried out with many elements. However, GA seems globally slightly more efficient and always in agreement with experimental evidences: such reasons are at the base of the preference given to GA in the two-step numerical procedure proposed in this work.

2.3 FE model with few DOFS and non-linear analyses

Once the optimized position of fracture lines has been found, the NURBS mesh is imported in a FE software where non-linear static and dynamic analyses can be performed. A FE model governed by few degrees of freedom (dofs) is built starting from the NURBS geometry by using a properly defined subroutine [61]. Each shell rigid element is converted into a mesh of elastic tetrahedral finite elements (12 dofs for each one). Then, cohesive-frictional contact-based interfaces are automatically inserted in the cracks of the collapse mechanism formerly obtained. In alternative, plastic damaging strips can be used as well, according to the general scheme depicted in Figure 1. Such failure criterion has been implemented in Abaqus through an automatic user-defined subroutine but any FE code can be utilized for such purpose. In this way, a non-linear constitutive law under interface tangential and tensile stresses is imposed along the contact-based interfaces. Moreover, the potential effects of masonry crushing failure

can be accounted for inside the macro-blocks assuming for their constituent material any non-linear continuum plastic-damage constitutive law. For Abaqus, for instance, the standard concrete damaged plasticity (CDP) model appears very suited and has been considered in the simulations reported in this paper, see [62][63] for the constitutive laws adopted.

An incremental-evolutive approach is adopted to derive the full load-displacement curves of any kind of masonry structure. It is important to observe that, having non-linearities mainly imposed just at the contact-based interfaces, the computational burden required by this FE model is much lower in comparison with fully non-linear FE models. At the same time, any mesh dependency effect is avoided thanks to the previous adaptive limit analysis that allows defining the exact position of the cracks. The procedure, initially proposed for out-of-plane loaded walls, has been recently extended to in-plane loaded walls and 3D buildings [61]. Figure 7 shows a schematization of the proposed procedure (corresponding to step 2 of the full procedure depicted in Figure 1).

Alternatively, the FE model can be realized by following an approach [50] based on discrete elements recently proposed for masonry vaults in [64]. This allows extending the two-steps procedure for double curvature masonry elements.

3 NUMERICAL EXAMPLES

Some numerical examples involving monumental masonry constructions are here presented.

The first structure considered is the Church of Natività di Maria Vergine, in Bondeno (Italy), a single nave church with lateral chapels (Figure 8a), approximately 36 meters long and 22 meters wide. The façade is 19 meters high and is built with a typical Romanesque style. The original plant dates back to the Middle Age (1100), but exception made for the apse and the bell tower, the rest was re-built more recently, from the end of 1600 to the end of 1800. The medieval semi-octagonal apse is covered by irregular ribbed gothic cross vaults, which are original of that period. Vaults are realized with thin single leaf common clay bricks.

Numerical results can be obtained by representing the whole construction with few NURBS elements. Mechanical properties for clay bricks and mortar joints masonry have been adopted according to prescriptions contained in the Italian code: in particular, a vanishing tensile stress is adopted, with a cohesion of the non-linear interfaces and friction angle equal to 0.06 MPa and 22° (corresponding to a friction coefficient equal to 0.4) respectively.

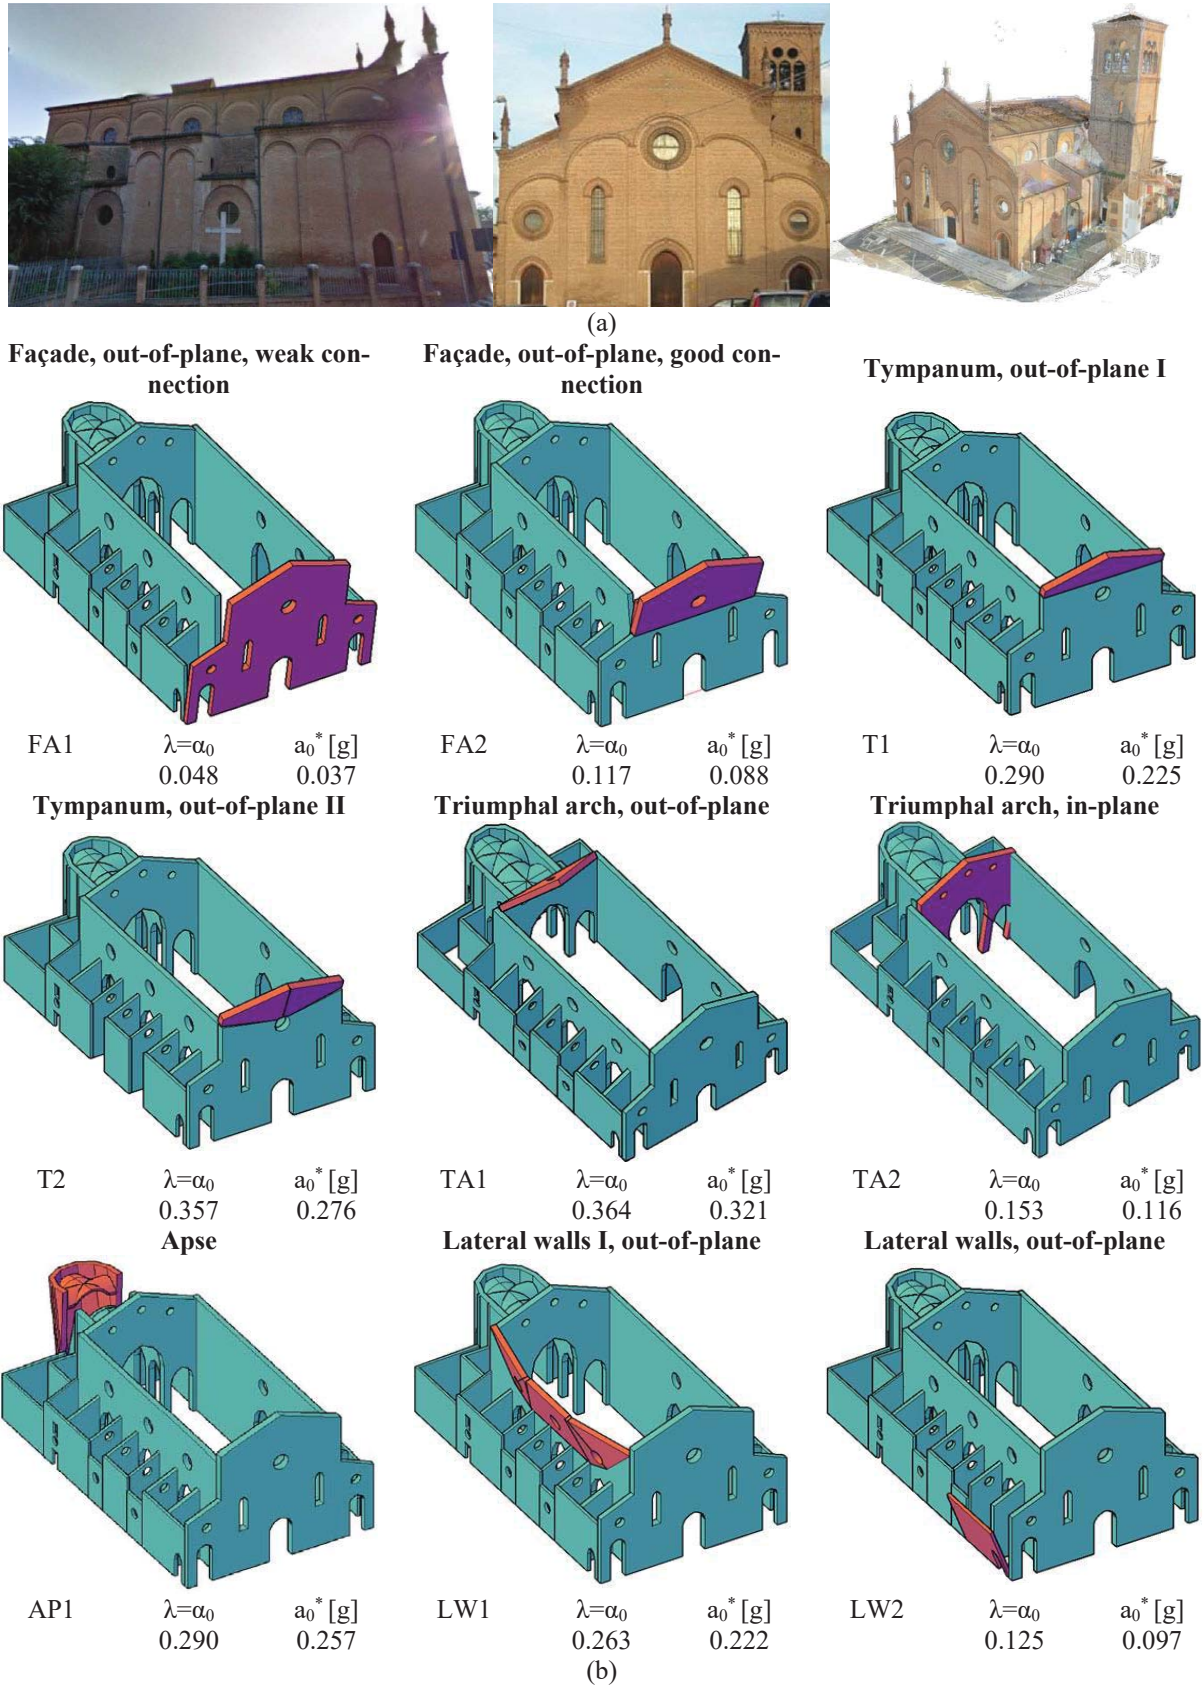

Figure 8. (a) The Church of Natività di Maria Vergine in Bondeno (Italy), (b) failure mechanisms obtained through adaptive limit analysis assuming different directions of the seismic action and interlocking between walls.

A compression strength cap equal to 2.4 MPa has been also used. As prescribed, these values have been furtherly reduced according to a factor equal to 1.35. In the present simulations, a constant horizontal force distribution along the height of the building is assumed.

The resultant failure mechanisms are depicted in Figure 8b. In the same figure, for the sake of completeness, values of α_0 and a_0^* are also reported, where α_0 is the horizontal load multiplier λ from limit analysis and a_0^* the corresponding spectral acceleration (normalized against g). In general, the obtained mechanisms are in good agreement with the pre-assigned failures suggested by the Italian Guidelines for the Cultural Heritage.

The second example here presented is the seismic behavior of the dome of the Church of Anime Sante, which was severely damaged on 6th April 2009 during the L'Aquila seismic sequence (maximum seismic event with the following characteristic: $M_w = 6.3$, $ML = 5.8$). Attributed to Giuseppe Valadier, the dome (Figure 9a) was completed in parallel with the realization of the church in 1805. After the earthquake, both the lantern and the dome collapsed, and the still standing parts of the drum and the dome are visible from photos reported in Figure 9b.

Some simulation results under the application of two distributions of horizontal loads, one linear and the other constant along the height, are here presented. Even in this case, in absence of specific data to assign to masonry mechanical properties, resistance values have been chosen in agreement with the Italian code for existing buildings: null value of tensile stress, 2.4 MPa for compression strength, 0.06 MPa for cohesion and 22° degrees for interfaces friction angle.

The results obtained in terms of both collapse mechanisms and normalized acceleration are reported in Figure 9c. The failure mechanism does not change too much with the distribution of horizontal loads applied, conversely the collapse acceleration is very sensitive to the actual distribution of accelerations. It is interesting to observe that the still standing portion of dome and drum obtained through the NURBS limit analysis reproduces quite closely the situation observed after L'Aquila earthquake.

The identification of such a clear collapse mechanism is also useful to perform non-linear static analyses by simply re-meshing the structure with elastic elements and non-linear interfaces where the yield lines are located (as described in the previous Section). This procedure is followed in the benchmark discussed next.

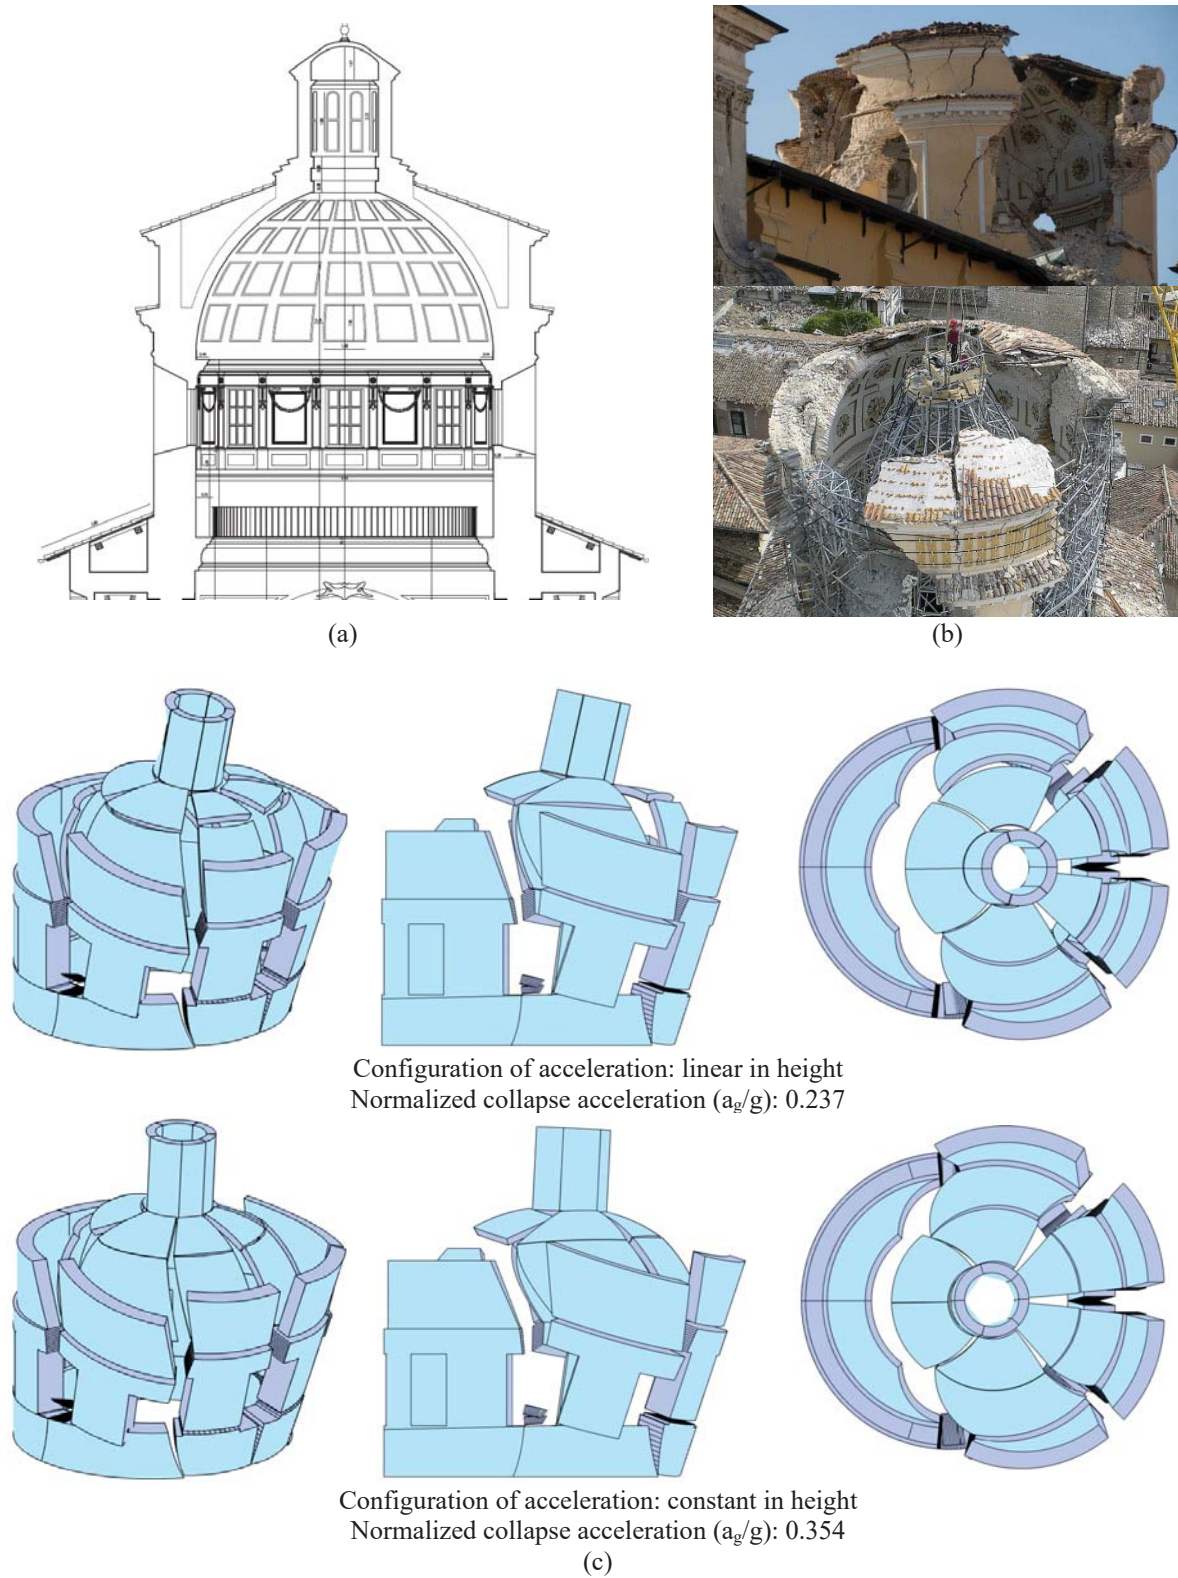

Figure 9. Dome of the Anime Sante Church, in L'Aquila (Italy): (a) geometry before the earthquake, (b) still standing parts after the collapse, (c) collapse mechanisms obtained under linear and constant in height horizontal acceleration (perspective, lateral and plan views).

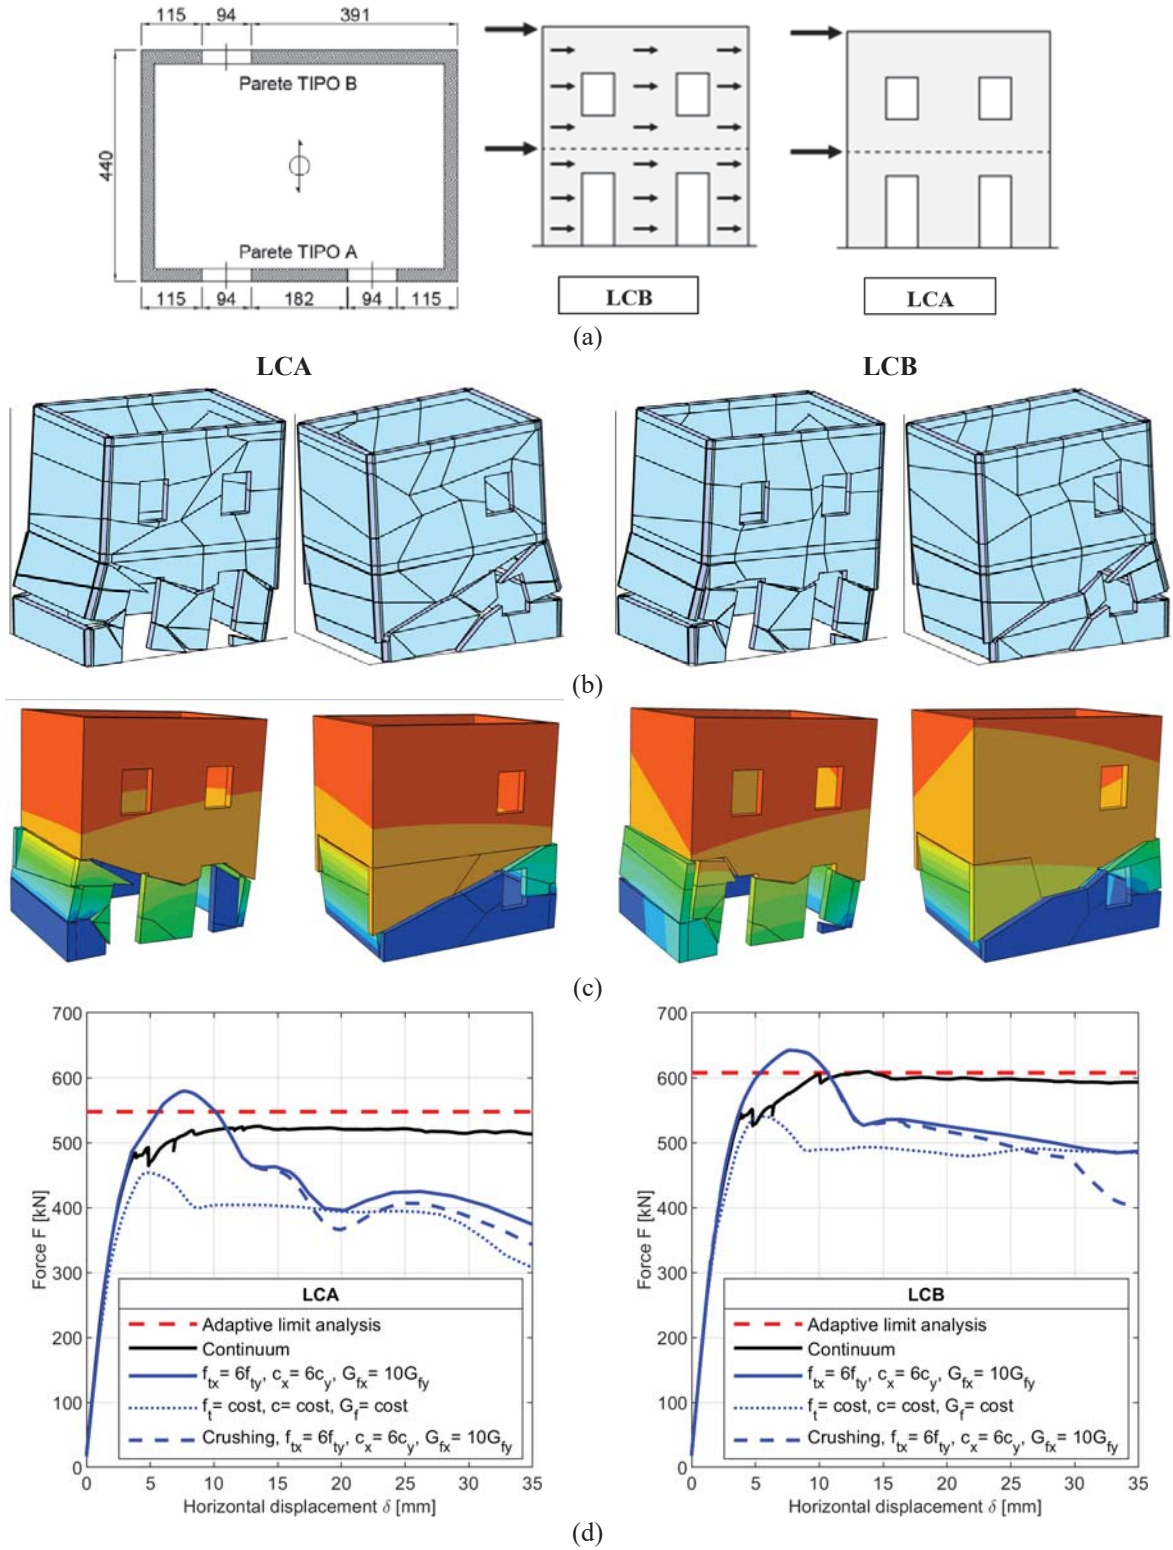

Figure 10. Two-storey masonry building: (a) geometry and load conditions, (b) collapse mechanisms obtained through limit analysis, (c) non-linear static deformed shape, and (d) comparison of results (in b-d, LCA on the left and LCB on the right).

Such benchmark relies on the application of the aforementioned two-step procedure to a simple laboratory two-storey masonry building. As depicted in Figure 10a, the horizontal projection of the construction is completely described by the 4 perimeter walls, each one 0.25 m

thick. Some openings are present on the two longitudinal walls. Both storeys are characterized by rigid horizontal floors, carried by the longitudinal walls and connected by concrete edgings. From here on the longitudinal direction term will be referred to that direction parallel to the long walls (i.e. the horizontal direction in Figure 10a). The vertical load given by the floors is equal to 10 kN/m^2 . It is worth mentioning that this benchmark has been extensively analyzed by the authors within a research project supported by the Italian network of University laboratories of seismic engineering (ReLUIIS).

The small two-storey house is analyzed under the application of two different horizontal load distributions, directed along the longitudinal direction (i.e. parallelly to the longest walls) and labelled as LCA and LCB. LCA is characterized by horizontal forces concentrated at floor levels, whereas LCB by distributed forces along the height of the structure (see Figure 10a). A NURBS model of this full-scale 3D case study has been realized. Limit analyses have been performed by assuming 0.04 MPa as tensile strength f_t , 6.2 MPa as compression strength f_c , a cohesion c equal to 0.163 MPa and a friction coefficient for the interfaces equal to 0.58 . Moreover, a specific weight equal to 17.5 kN/m^3 has been also adopted. With the aim of providing a more realistic representation of the masonry behavior in shear, a non-associative flow rule has been used in this example. The final results obtained are depicted in Figure 10b-d in terms of collapse mechanism and collapse base shear. It can be observed that cracks spread mainly on piers at the ground floor, where both flexural damage and sliding cracks appear on all four perimeter walls.

Non-linear static analyses on the derived FE model are now presented. Four hypotheses have been considered as regards material properties: (i) linear material with constant contact properties, i.e. the same resistance values assigned in limit analysis plus contact fracture energy $G_f = 500 \text{ N/m}$, (ii) linear material with variable contact properties, for which $f_{tx} = 6f_t$, $f_{ty} = f_t$, $G_{fx} = 6G_f$, $G_{fy} = G_f$, $c_x = 6c$, $c_y = c$, (iii) variable contact properties as above and material with finite compressive strength (called “crushing” model in what follows), and (iv) continuum approach introduced for comparison.

The results of the present modeling procedure (Figure 10c) show a good agreement with the base shear values obtained with limit analysis and with those obtained through a continuum approach, in terms of both pushover curves (presented in Figure 10d) and damage pattern (the continuum damage pattern is not shown here for sake of brevity). Concerning the post-peak response, the continuum model exhibits a plateau, while a considerable softening is shown by the variants of the proposed approach, which is further accentuated in the case with crushing. Accordingly, the proposed approach appears significantly robust and able to account for a softening behavior without particular numerical issues.

The proposed procedure resulted computationally efficient, particularly if compared to standard continuum FE models. Therefore, the adaptive NURBS limit analysis combined suitably with a FE non-linear static analysis can be considered an effective and efficient tool for the seismic assessment of historic and monumental masonry buildings.

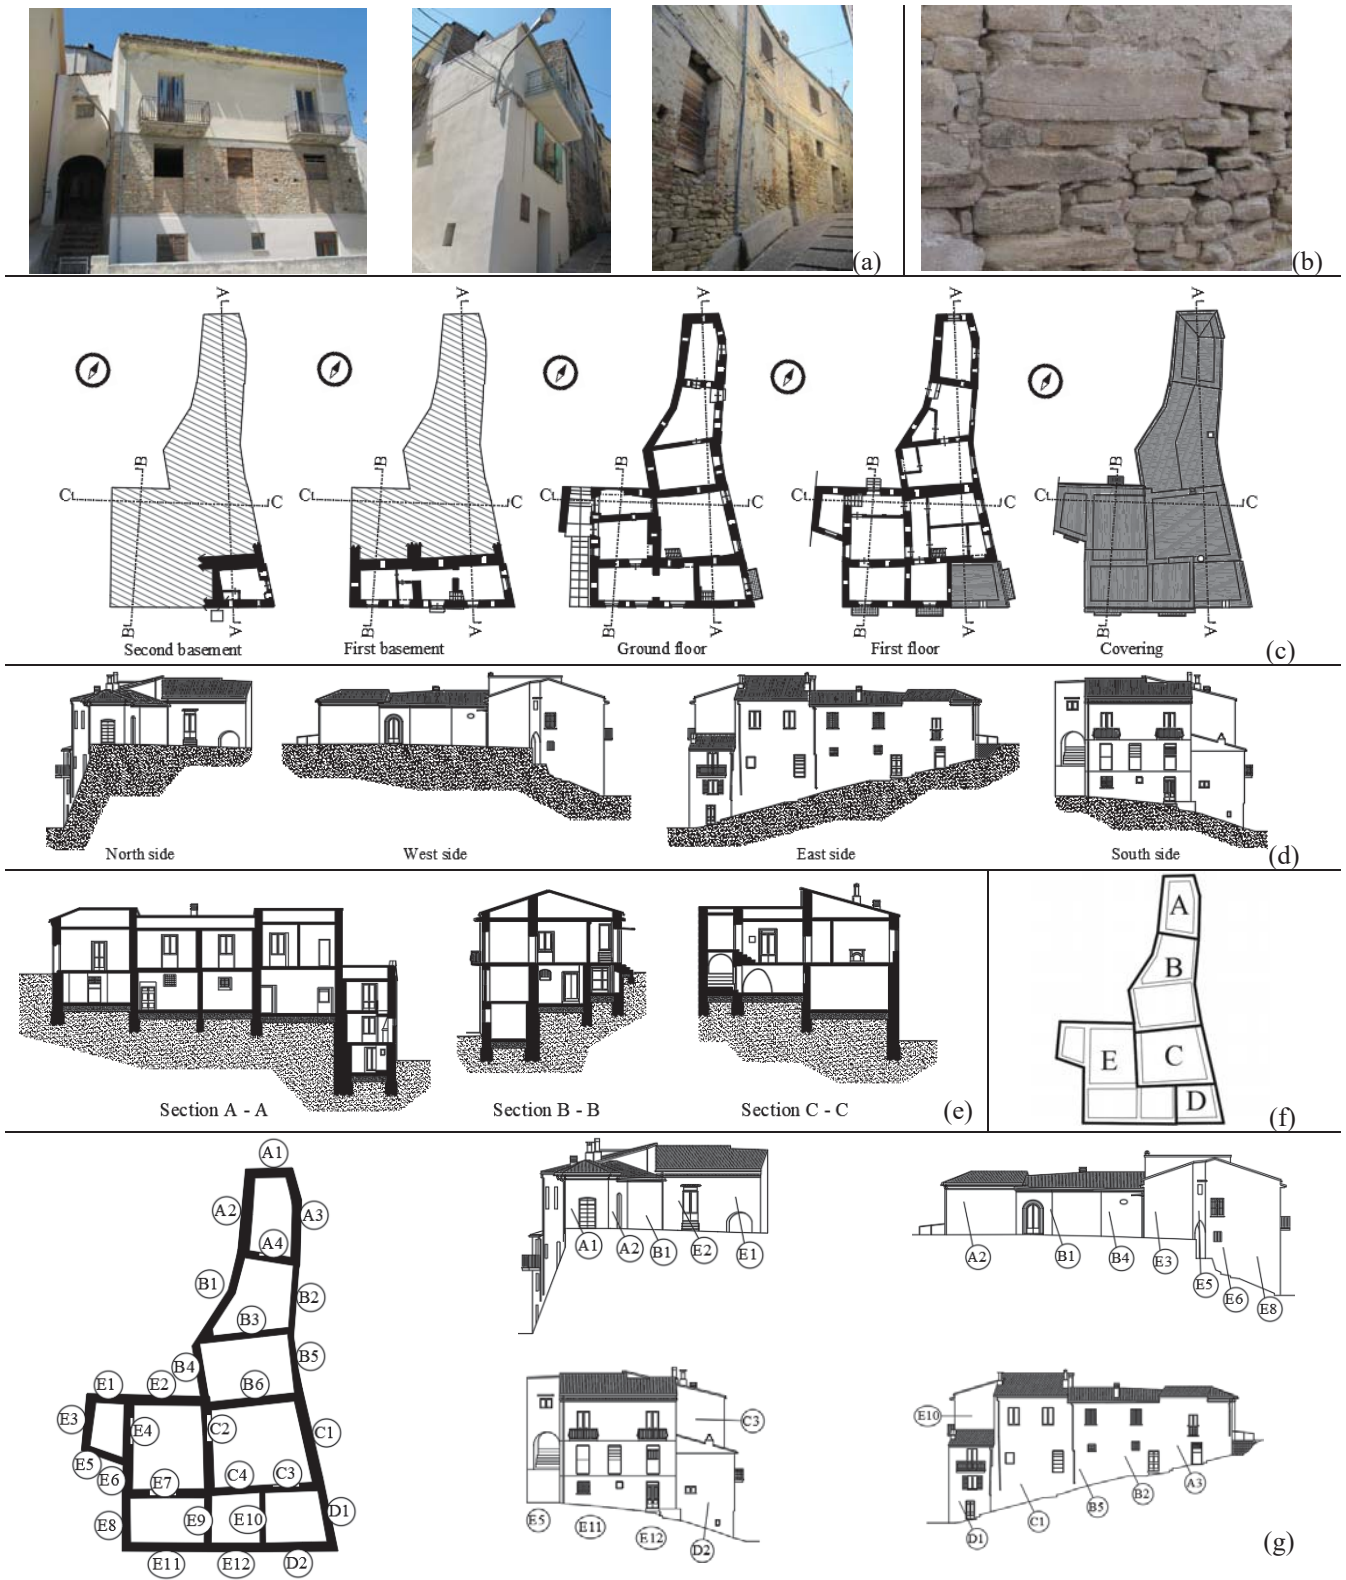

Figure 11. Aggregate “La Vecchia Forestale”: (a) pictures of South and East sides, (b) particular of the irregular masonry texture, (c) plan views, (d) perspective views, (e) sections, (f) identification and notation of structural units, and (g) nomenclature here adopted for each wall.

The fourth numerical example deals with a masonry aggregate called “La Vecchia Forestale” (Figure 11). In Figure 11 (a) some pictures of the aggregate are reported. The

building is characterized by an irregular masonry texture, composed of irregular stones and low quality mortar, as it can be seen on several masonry walls (see Figure 11(b)). The maximum length is about 25 m, which is referred to the East side, whereas, in the orthogonal direction, the width is almost equal to 14.2 m for the South side and 3.8 m for the North side. Strong irregularities can be observed both in plan and elevation. There is a total of four floors, two of which are basements defining different foundation levels. The maximum and the minimum height are respectively equal to 11.8 m on the East side and 3.9 m in the North-West corner, both measured in relation to the local ground level. The plan of different levels, perspective views, and some sections are reported in Figure 11(c-e). Five different structural units, which have been named by using the letters from A to E, have been identified. In Figure 11(f), the distinction of each structural unit is depicted: only units C, D, and E are residential, whereas units A and B are used as storage rooms. Different types of horizontal floors are present and no chains or concrete edgings are reported: the roof is made with light wood elements.

Finally, in Figure 11(g) the notation here adopted for each wall is reported. Basically, each wall is named with a letter, representing the unit to which it belongs, and a number: therefore, for example, A1 is the wall number 1 belonging to structural unit A.

Figure 12 shows the analyses on structural unit A considering two directions of the horizontal load; a relatively good interlocking between perpendicular walls is considered. In Figure 12(a) the horizontal load has been applied along the North direction. As it can be seen, the collapse occurs through the overturning of wall A1 together with some triangular portions of the transversal walls A2 and A3. Moreover, a vertical fracture line opens on wall A1: such a fracture line is probably due to the different geometries of walls A2 and A3, resulting in a non-symmetrical contribution to the failure mechanism. A value of α_0 equal to 0.772 has been obtained for the horizontal load multiplier, which is much higher when compared with the simple overturning of wall A1. Such a result is mainly due to the internal dissipation in tension and shear related to the formation of inclined fracture lines, a consequence of the good interlocking hypothesis. In Figure 12(b) the horizontal load has been applied along the East direction. In this case, the final result mainly consists of an overturning of the out-of-plane loaded wall including a single triangular portion of the transversal wall A1. Since wall A4 is thinner than wall A1, the fracture line is almost vertical and therefore no triangular blocks from this element are involved in the mechanism. Despite the similarities with the simple overturning of wall A3 evaluated in [56], a value of α_0 equal to 0.319 has been obtained: such higher value is due to the internal dissipation included in the computations.

In Figure 13 the analysis of structural unit B is reported. A total of 4 walls has been selected, as it can be seen in the plan view. The walls adjacent to other structural units have been supposed as disconnected in the contact-edge. Therefore, only one of the out-of-plane loaded walls is involved in the collapse mechanisms. The collapse takes place through an overturning of wall B2 along an inclined fracture line, due to the different constraint conditions applied on the vertical edges of wall B2 (good connection with walls B3 and B5, no connection with walls A4 and A3). The associated α_0 is equal to 0.156.

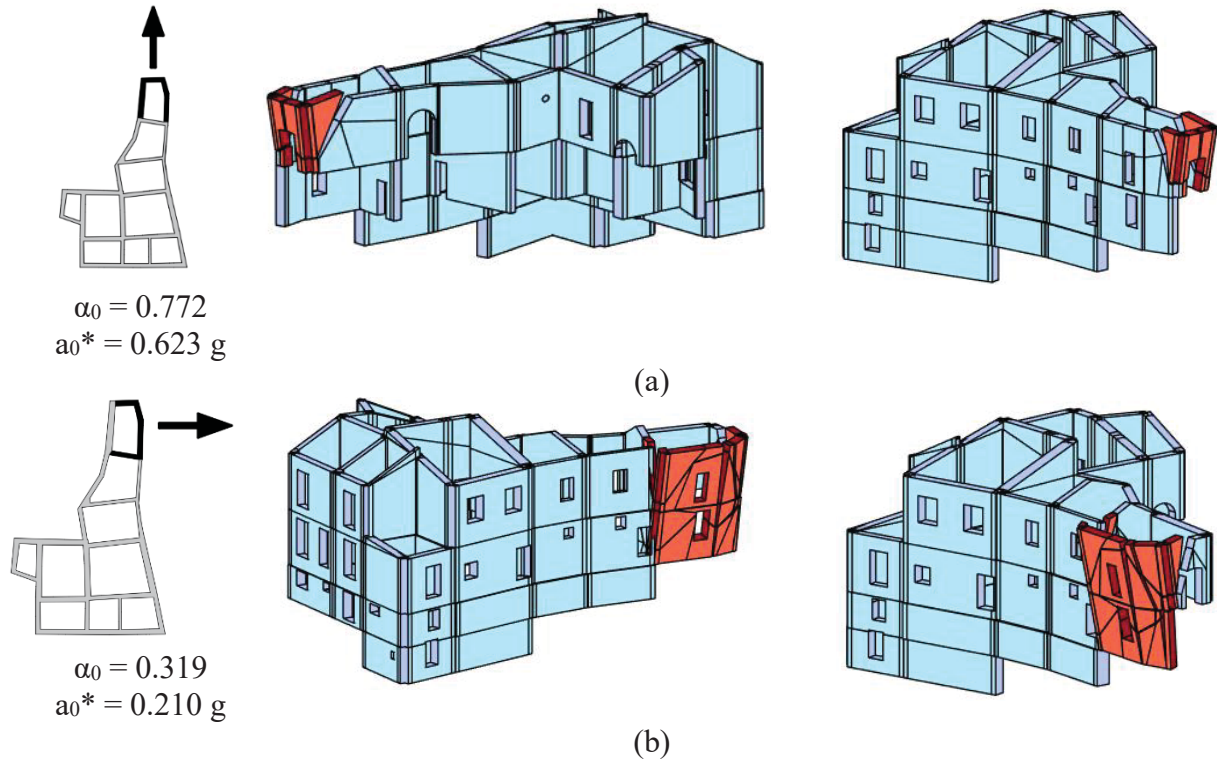

Figure 12. Aggregate, unit A, analyses with good interlocking: horizontal load applied along (a) the North and (b) the East directions.

A similar behavior has been observed for wall C1, as it can be seen in Figure 14. Even in this case, wall C1 is well connected only to the transversal wall C3. The collapse mechanism is again an overturning with inclined fracture line: however, in this case the fracture line starts at the bottom of the last storey. This is due to the lower thickness of wall C3 at the last storey with respect to the bottom part, resulting in a partial participation of this weaker portion of wall C3 in the failure mechanism.

Figure 13. Aggregate, unit B, analyses with good interlocking.

Similar results are obtained for units D and E, not reported here for the sake of conciseness. The interested reader is referred to [56] for further details.

Figure 14. Aggregate, unit C, analyses with good interlocking.

As final example, a quite complex 3D limit analysis approach conceived for monumental constructions characterized by complex curved shapes is here presented. This approach consists of a limit analysis in which the structure is discretized through NURBS solids. A NURBS solid is a closed region of space delimited by NURBS boundary surfaces. NURBS solids are used to represent the rigid elements involved in the mechanism. By using NURBS surfaces to describe the external boundary of each block, this approach allows extending the study to structures that do not behave as shell-like elements, thus resulting as a generalization of the kinematic limit analysis for curved three-dimensional rigid block structures.

The Carmo Convent, in Lisbon (Portugal), is here analyzed through the NURBS solids-based limit analysis. The conventual church, see Figure 15a, presents a Gothic style composed of a nave, two longitudinal aisles, one transept, a main chapel and four side chapels, distributed onto a Latin cross. Considering the huge complexity of the case, the analysis is here focused on the triumphal arch located in the transept. Some structural elements cannot be properly represented without a NURBS solid representation: Gothic arches present a non-rectangular and curved cross-section, whereas limestone columns have a multi-circular cross-section.

The transept is analyzed under the application of an out-of-plane directed horizontal load. A comparison with FE non-linear static analyses previously presented by Scacco and colleagues [65] is also shown. Materials parameters have been assumed in agreement with those indicated in [65]. In particular a compression strength equal to 27 MPa, a friction angle equal to 30° , a cohesion equal to 0.05 MPa, and null tensile strength are adopted. Similarly to the example of the masonry dome, a constant (Load Case 1, LC1) and a linear along the height (Load Case 2, LC2) distribution of horizontal accelerations are considered. In addition, kinematic non-linear analyses aimed at including a softening behavior in tension (initial tensile strength of 0.15 MPa, fracture energy equal to 0.015 N/mm) are performed using a sequential linear programming approach where displacements at the end of the simulations are found with a procedure fully described in [66].

The results obtained are reported in Figure 15b. The failure mechanism involves the overturning of the central columns with the participation of arches at the top. Moreover, arches at the top show a combined in- and out-of-plane mechanism. A load multiplier equal to $1.19 \cdot 10^{-1}$ has been found for LC1 distribution. The resultant horizontal loads at collapse normalized for the total weight (i.e. the load multiplier) are compared with the pushover curve derived in [65], finding again a very good agreement even in such very complex case where the geometry reproduction of the sections is particularly demanding.

With this last example, it can be affirmed that the presented approach is promising in terms of efficiency and reliability to perform limit and non-linear static analysis for complex exist-

ing masonry buildings, historical structures and monumental constructions, even when very complex 3D massive curved geometries are present.

4 CONCLUSIONS

The present research paper was intended to show a short synopsis of the results obtained by the authors in the evaluation of the ultimate load bearing capacity and the non-linear static behavior of complex historical or existing masonry structures using non conventional software. Such approach is based on a two-step procedure, where the structures are first analyzed in the limit analysis case with adaptive 2D and 3D NURBS meshes and then with non-linear FEs where non linearity is lumped on the crack patterns found using the adaptive limit analysis. A particularly interesting recent improvement of the approach proposed is the utilization of 3D NURBS and Sequential Linear programming to predict also displacements during the formation of the failure mechanism, as shown in the last example (Carmo Convent in Lisbon). Future research streams will include (but they will not limited to) the adaptive NURBS limit analysis of massive historical masonry structures (e.g. towers and pagodas) and the extension

to non-linear dynamic loads, which include not only seismic actions but also extreme events such as explosions and floods.

Keywords: Wave Finite Element, Periodic Structures, Structural Dynamics, Distributed Loads, Numerical Methods, Time Response, Absorbing Boundary Conditions.

Abstract. *The wave finite element (WFE) method is now an established numerical method for obtaining the structural response of periodic structures. From a model of a substructure obtained from any finite element software, it allows to get dispersion curves and responses of finite periodic structures with a low calculation cost. Here, we consider some recent improvements of the method. First of all, the original WFE is often formulated with some point loads on the structure, but we show that it is possible to extend this to the consideration of general loads as pressure waves or moving loads for which external loads are applied on each substructure. Second, the classical WFE deals with structures in the frequency domain. It would be interesting to consider the analysis of periodic structures in the time domain, for instance to deal with blast loads. We present here one possibility to do so by computing absorbing boundary conditions in the time domain. By considering supplementary variables at the boundary, a new formulation can be obtained and a classical equation with extended mass, damping and stiffness matrices can be formulated in the time domain and solved by classical algorithms like the Newmark scheme.*

1 INTRODUCTION

The wave finite element method (WFE) is often used to predict the dynamic response of periodic structures under harmonic loading like railway tracks, pipelines, ribbed plates, tires, reinforced panels or metamaterials. This consists in computing wave modes (propagation constants, wave shapes) of a periodic structure from the finite element (FE) model of a substructure and its related mass, damping and stiffness matrices which can be obtained from any FE software. Afterwards, these wave modes can be used to calculate the harmonic response of periodic structures in an efficient way, i.e., by computing small matrix systems for one substructure, or a few of them, see for instance the works in [1, 2, 3, 4].

First of all, the original WFE considers mainly some points loads on the structure, but we show here that it is possible to extend this to the consideration of general loads as pressure waves or moving loads for which external loads are applied on each substructure. Several applications of this are possible. At first is the computation of civil engineering structures such as bridges which have extended loads and various displacement and reaction forces at supports, or the computation of structures under moving loads such as railways tracks under the dynamic loads of a train.

Second, it is a matter of fact that the classical WFE deals with structures in the frequency domain. But it would also be interesting to consider the analysis of periodic structures in the time domain, for instance to deal with shocks or blast loads. We present here one possibility to do so by computing absorbing boundary conditions in the time domain. For dispersive media like beams [5], multi-layered systems [6] or general periodic structures [7], absorbing BCs can be formulated in terms of boundary operators involving complicated functions of the frequency — e.g., square roots of the frequency — which, as such, cannot be converted to simple functions of time after inverse Fourier transforms. To solve this issue, the impedance relation at the boundary of a periodic structure is first written in the frequency domain, then this impedance frequency function is decomposed as a rational function for which poles and residues are computed. By considering supplementary variables at the boundary, a formulation in the time domain can be obtained. Finally, a classical equation with extended mass, damping and stiffness matrices can be formulated in the time domain and solved by classical algorithms like the Newmark scheme.

The rest of this paper is organized as follows. In section 2, the main steps of the WFE method are recalled. In section 3, the case of complex and moving loads are considered. Then section 4 is concerned with the formulation of time domain absorbing boundary conditions for periodic structures and the solution of time domain structural dynamics problems. Numerical comparisons with analytical or an equivalent infinite full FE model are presented. Concluding remarks are finally brought in section 5.

2 WFE method

The present paper investigates the dynamic response of infinite 1D periodic structures subject to harmonic or time-dependent loadings. For instance, a schematic of a periodic structure made up of identical substructures is shown in Fig. 1. The substructures under concern can be of arbitrary shape and are supposed to be linear, elastic, isotropic and damped (viscous damping). Also, the excitations are applied on the structure encompassing those substructures which can be infinite or bounded by two left and right boundaries.

The wave propagation analysis in 1D periodic structures can be conducted with the WFE method [2, 4, 8]. The basics of the method are recalled hereafter. Let us consider infinite structures under harmonic disturbance $e^{i\omega t}$ which are built from identical substructures as shown

Figure 1: Periodic structure of infinite length, and FE mesh of a substructure.

in Fig. 1, are supposed to share the same FE mesh, and are modelled by means of identical mass, damping and stiffness matrices \mathbf{M} , \mathbf{C} and \mathbf{K} . The related dynamic equilibrium equation is given by:

$$\begin{bmatrix} \mathbf{D}_{II} & \mathbf{D}_{IL} & \mathbf{D}_{IR} \\ \mathbf{D}_{LI} & \mathbf{D}_{LL} & \mathbf{D}_{LR} \\ \mathbf{D}_{RI} & \mathbf{D}_{RL} & \mathbf{D}_{RR} \end{bmatrix} \begin{bmatrix} \mathbf{q}_I \\ \mathbf{q}_L \\ \mathbf{q}_R \end{bmatrix} = \begin{bmatrix} \mathbf{F}_I \\ \mathbf{F}_L \\ \mathbf{F}_R \end{bmatrix} \quad (1)$$

where \mathbf{q} and \mathbf{F} refer to the displacement vector and the force vector (respectively), and where \mathbf{D} is the dynamic stiffness matrix of the substructures (similar for all the substructures) expressed by $\mathbf{D} = -\omega^2 \mathbf{M} + i\omega \mathbf{C} + \mathbf{K}$. The FE mesh of a substructure is shown in Fig. 1, and involves internal (I) degrees of freedom (DOFs), left (L) and right (R) boundaries which are described with the same number n of DOFs. If we assume that the internal DOFs are free from excitation, e.g., $\mathbf{F}_I = \mathbf{0}$, we can remove \mathbf{q}_I and rearrange Eq. (1) to yield the following transfer matrix relation between the right and left boundaries of the substructure:

$$\mathbf{u}_R = \mathbf{S} \mathbf{u}_L, \quad (2)$$

where \mathbf{u}_R and \mathbf{u}_L are $2n \times 1$ state vectors expressed by:

$$\mathbf{u}_R = \begin{bmatrix} \mathbf{q}_R \\ \mathbf{F}_R \end{bmatrix}, \quad \mathbf{u}_L = \begin{bmatrix} \mathbf{q}_L \\ -\mathbf{F}_L \end{bmatrix}. \quad (3)$$

Also, \mathbf{S} is a symplectic $2n \times 2n$ matrix (also called transfer matrix) expressed by:

$$\mathbf{S} = \left[\begin{array}{c|c} -(\mathbf{D}_{LR}^*)^{-1} \mathbf{D}_{LL}^* & -(\mathbf{D}_{LR}^*)^{-1} \\ \hline \mathbf{D}_{RL}^* - \mathbf{D}_{RR}^* (\mathbf{D}_{LR}^*)^{-1} \mathbf{D}_{LL}^* & -\mathbf{D}_{RR}^* (\mathbf{D}_{LR}^*)^{-1} \end{array} \right], \quad (4)$$

where \mathbf{D}^* refers to the dynamic stiffness matrix of the substructure condensed on the left and right boundaries [9].

The eigenvalues and eigenvectors of the transfer matrix \mathbf{S} occur in pairs as (μ_j, ϕ_j) and $(\mu_j^* = 1/\mu_j, \phi_j^*)$ with $|\mu_j| < 1$ (see [3] for further details about the computation of the eigensolutions of \mathbf{S}). Also, the eigenvectors ϕ_j (resp. ϕ_j^*) have the meaning of wave shapes, for the waves traveling to the right and left directions (respectively) of the periodic structure. Those vectors of wave shapes are of size $2n \times 1$ and are usually partitioned as follows:

$$\phi_j = \begin{bmatrix} \phi_{qj} \\ \phi_{Fj} \end{bmatrix}, \quad \phi_j^* = \begin{bmatrix} \phi_{qj}^* \\ \phi_{Fj}^* \end{bmatrix}, \quad (5)$$

where ϕ_{qj} and ϕ_{qj}^* (resp. ϕ_{Fj} and ϕ_{Fj}^*) are $n \times 1$ vectors involving displacement (resp. force) components. The related $n \times n$ matrices of wave shapes — namely, Φ_q , Φ_q^* , Φ_F and Φ_F^* — are given by:

$$\Phi_q = [\phi_{q1} \cdots \phi_{qn}], \quad \Phi_q^* = [\phi_{q1}^* \cdots \phi_{qn}^*], \quad \Phi_F = [\phi_{F1} \cdots \phi_{Fn}], \quad \Phi_F^* = [\phi_{F1}^* \cdots \phi_{Fn}^*]. \quad (6)$$

A state vector at any substructure interface can then be decomposed on these wave modes by

$$\mathbf{u} = \sum_{j=1}^{j=n} Q_j \phi_j + \sum_{j=1}^{j=n} Q_j^* \phi_j^* \quad (7)$$

where Q_j and Q_j^* are respectively the amplitudes of the right and left propagating waves in the considered section.

3 WFE with complex loads

3.1 Equations

We consider now the case where the structure is under a distributed load that can be applied on each substructure. For loads inside a substructure, relation (1) yields

$$\mathbf{q}_I = \mathbf{D}_{II}^{-1} [\mathbf{F}_I - \mathbf{D}_{IL}\mathbf{q}_L - \mathbf{D}_{IR}\mathbf{q}_R] \quad (8)$$

and so relation (2) is transformed to a relation linking the state vector in sections n (between substructures $n - 1$ and n) and the state vector in section $n + 1$ (see [10] for details)

$$\mathbf{u}^{(n+1)} = \mathbf{S}\mathbf{u}^{(n)} + \mathbf{b}^{(n)}, \quad (9)$$

with

$$\mathbf{u}^{(n)} = \begin{bmatrix} \mathbf{q}^{(n)} \\ -\mathbf{F}_L^{(n)} \end{bmatrix}, \quad \mathbf{b}^{(n)} = \begin{bmatrix} \mathbf{D}_{qI}\mathbf{F}_I \\ \mathbf{D}_{fI}\mathbf{F}_I - \mathbf{F}_R^{ext} \end{bmatrix} \quad (10)$$

where \mathbf{F}_R^{ext} is the external load applied in section $n + 1$ and

$$\begin{bmatrix} \mathbf{D}_{qI} \\ \mathbf{D}_{fI} \end{bmatrix} = \begin{bmatrix} -(\mathbf{D}_{LR}^*)^{-1}\mathbf{D}_{LI}^* \\ \mathbf{D}_{RI}^* - \mathbf{D}_{RR}^*(\mathbf{D}_{LR}^*)^{-1}\mathbf{D}_{LI}^* \end{bmatrix} \quad (11)$$

where the superscript $*$ means that the matrix is condensed on the boundary, for instance,

$$\begin{aligned} \mathbf{D}_{LR}^* &= \mathbf{D}_{LR} - \mathbf{D}_{LI}\mathbf{D}_{II}^{-1}\mathbf{D}_{IR} \\ \mathbf{D}_{LI}^* &= \mathbf{D}_{LI}\mathbf{D}_{II}^{-1} \end{aligned} \quad (12)$$

Finally, the state vector in section n is related to the state vectors of sections 1 and $N + 1$ by

$$\mathbf{u}^{(n)} = \mathbf{S}^{n-1}\mathbf{u}^{(1)} + \sum_{k=1}^{n-1} \mathbf{S}^{n-k-1}\mathbf{b}^{(k)} \quad (13)$$

or

$$\mathbf{u}^{(N+1)} = \mathbf{S}^{N-n+1}\mathbf{u}^{(n)} + \sum_{k=n}^N \mathbf{S}^{N-k}\mathbf{b}^{(k)} \quad (14)$$

where the sum including $\mathbf{b}^{(k)}$ allows to take into account all the loads applied between the two sections. Projecting on the wave modes, the state vector $\mathbf{u}^{(n)}$ in section n and load vector $\mathbf{b}^{(k)}$ in section k can also be written in terms of wave amplitudes by

$$\begin{aligned} \mathbf{u}^{(n)} &= \Phi \mathbf{Q}^{(n)} + \Phi^* \mathbf{Q}^{*(n)} \\ \mathbf{b}^{(k)} &= \Phi \mathbf{Q}_E^{(k)} + \Phi^* \mathbf{Q}_E^{*(k)} \end{aligned} \quad (15)$$

3.2 Case of moving loads

An interesting case concerns moving loads. For a moving load at speed v , with a substructure of length L , the amplitude of the load in section (k) is related to the amplitude of the load in section (0) by

$$\begin{aligned} \mathbf{Q}_E^{*(k)} &= e^{-ik\frac{\omega L}{v}} \mathbf{Q}_E^{*(0)} \\ \mathbf{Q}_E^{(-k)} &= e^{ik\frac{\omega L}{v}} \mathbf{Q}_E^{(0)} \end{aligned} \quad (16)$$

because the loads on the different substructures are related by $f_n(t) = f_{n-1}(t - L/v)$. From relations (13) and (15), one gets

$$\begin{aligned} \mathbf{u}^{(n)} &= \Phi \mathbf{Q}^{(n)} + \Phi^* \mathbf{Q}^{*(n)} \\ &= \Phi \mu^n \left(\mathbf{Q} + \sum_{k=0}^{n-1} \mu^{k+1} \mathbf{Q}_E^{(k)} \right) + \Phi^* \mu^{-n} \left(\mathbf{Q}^* + \sum_{k=0}^{n-1} \mu^{k+1} \mathbf{Q}_E^{*(k)} \right) \end{aligned} \quad (17)$$

with μ the diagonal matrix made of the propagation constants μ_j on the diagonal and \mathbf{Q} , \mathbf{Q}^* are free wave amplitudes in the structure determined by the boundary conditions. As the precedent relation should be bounded for $n \rightarrow \infty$, we get

$$\mathbf{Q}^* = - \sum_{k=0}^{\infty} \mu^{k+1} \mathbf{Q}_E^{*(k)} = - \frac{\mu}{1 - \mu e^{-i\frac{\omega L}{v}}} \mathbf{Q}_E^{*(0)} \quad (18)$$

For the left side, we get

$$\mathbf{Q} = \sum_{k=1}^{\infty} \mu^{k-1} \mathbf{Q}_E^{(-k)} = \frac{e^{i\frac{\omega L}{v}}}{1 - \mu e^{i\frac{\omega L}{v}}} \mathbf{Q}_E^{(0)} \quad (19)$$

Finally, one gets

$$\mathbf{u}^{(0)} = \frac{e^{i\frac{\omega L}{v}}}{1 - \mu e^{i\frac{\omega L}{v}}} \mathbf{Q}_E^{(0)} \Phi - \frac{\mu}{1 - \mu e^{-i\frac{\omega L}{v}}} \mathbf{Q}_E^{*(0)} \Phi^* \quad (20)$$

3.3 A simple example

Consider the very simple example of a bar undergoing a longitudinal displacement subject to a moving force

$$\rho \frac{\partial^2 u}{\partial t^2} = E u'' + f \quad (21)$$

We have $k = \sqrt{\frac{\rho \omega^2}{E}} = \frac{\omega}{c}$, $c = \sqrt{\frac{E}{\rho}}$, $f(x, t) = \delta(x - vt)$ and the wave modes are

$$\Phi = \begin{bmatrix} 1 \\ -ikE \end{bmatrix}, \quad \Phi^* = \begin{bmatrix} 1 \\ ikE \end{bmatrix} \quad (22)$$

The propagation constant is $\mu = e^{-ikL}$ and the load amplitudes are obtained from the load in the period $[0, L]$. The solution of (21) such that $u(0) = u'(0) = 0$ is given by

$$u(x) = - \int_0^x \frac{1}{kE} \sin(k(x-t)) f(t) dt \quad (23)$$

So that for $x = L$ and $f(t) = \frac{1}{v}e^{-i\omega t/v}$, one gets

$$\begin{aligned} u(L) &= -\frac{1}{2ikEv} \int_0^L (e^{ik(L-t)} - e^{-ik(L-t)}) e^{-i\omega t/v} dt \\ &= -\frac{1}{2ikEv} \left(\frac{e^{-i\omega L/v} - e^{ikL}}{-ik - i\omega/v} - \frac{e^{-i\omega L/v} - e^{-ikL}}{ik - i\omega/v} \right) \end{aligned} \quad (24)$$

and

$$Eu'(L) = -\frac{1}{2ikv} \left(\frac{\frac{-i\omega}{v} e^{-i\omega L/v} - ik e^{ikL}}{-ik - i\omega/v} - \frac{\frac{-i\omega}{v} e^{-i\omega L/v} + ik e^{-ikL}}{ik - i\omega/v} \right) \quad (25)$$

Using relation (9) and the solution of (21) such that $\mathbf{b} = {}^T[u(L) \quad Eu'(L)]$, the load amplitudes are obtained by decomposing the solution at $x = L$ on the wave modes by

$$\begin{aligned} Q_E^{(0)} &= \frac{{}^T\Phi^* \mathbf{J} \mathbf{b}}{{}^T\Phi^* \mathbf{J} \Phi} \\ &= -\frac{e^{-i\omega \frac{L}{v}} - e^{-ikL}}{2kEv(k - \frac{\omega}{v})} \\ Q_E^{*(0)} &= \frac{{}^T\Phi \mathbf{J} \mathbf{b}}{{}^T\Phi \mathbf{J} \Phi^*} \\ &= -\frac{e^{-i\omega \frac{L}{v}} - e^{ikL}}{2kEv(k + \frac{\omega}{v})} \end{aligned} \quad (26)$$

with

$$\mathbf{J} = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \quad (27)$$

The amplitudes of the right-going and left-going waves are thus given by, using (20),

$$\begin{aligned} Q &= -\frac{1}{2kEv(k - \frac{\omega}{v})} \\ Q^* &= -\frac{1}{2kEv(k + \frac{\omega}{v})} \end{aligned} \quad (28)$$

and we recover the displacement at $x = 0$ by

$$\begin{aligned} u &= -\frac{1}{2kEv(k - \frac{\omega}{v})} - \frac{1}{2kEv(k + \frac{\omega}{v})} \\ &= -\frac{1}{Ev(k^2 - \frac{\omega^2}{v^2})} \\ &= -\frac{1}{Ev\omega^2(\frac{1}{c^2} - \frac{1}{v^2})} \end{aligned} \quad (29)$$

which is the analytical solution of (21). Following the same procedure, this can be extended to more complex structures with many DOFs in each section.

4 Absorbing boundary conditions in the time domain

4.1 WFE formulation

Consider now a periodic structure involving a finite number N of substructures which is enclosed between two left and right boundaries S_L and S_R where absorbing BCs are considered (see Fig. 2). Such BCs are used to describe the coupling effect between the periodic structure and two semi-infinite periodic structures, that would expand to the left and right directions. The related impedance matrices for the left and right boundaries S_L and S_R — namely, \mathbf{Z}_L and \mathbf{Z}_R — can be defined, in the frequency domain, as follows:

$$\mathbf{F}_L = \mathbf{Z}_L \mathbf{q}_L, \quad \mathbf{F}_R = \mathbf{Z}_R \mathbf{q}_R, \quad (30)$$

where \mathbf{q}_L and \mathbf{q}_R (resp. \mathbf{F}_L and \mathbf{F}_R) are the displacement (resp. force) vectors (size $n \times 1$) for the periodic structure on S_L and S_R . Following the WFE procedure and expanding those vectors on the basis of wave shapes, this yields [9]:

$$\mathbf{q}_L = \Phi_q^* \mathbf{Q}_L^*, \quad \mathbf{q}_R = \Phi_q \mathbf{Q}_R, \quad (31)$$

and

$$\mathbf{F}_L = -\Phi_F^* \mathbf{Q}_L^*, \quad \mathbf{F}_R = \Phi_F \mathbf{Q}_R, \quad (32)$$

where \mathbf{Q}_L^* (resp. \mathbf{Q}_R) is the vector of wave amplitudes, at position S_L (resp. S_R), for the waves traveling to the left (resp. right) direction of the structure. The fact that left-going (resp. right-going) waves are only considered at S_L (resp. S_R) results from the absorbing BC, i.e., the fact that no wave comes from infinity. So we get the following expressions for the impedance matrices:

$$\mathbf{Z}_L = -\Phi_F^* (\Phi_q^*)^{-1}, \quad \mathbf{Z}_R = \Phi_F (\Phi_q)^{-1}. \quad (33)$$

Let us decompose the impedance matrices \mathbf{Z}_L and \mathbf{Z}_R which are complicated functions of frequency that do not generally possess an analytical expression, via rational approximations like in [7]:

$$\mathbf{Z}_L = \sum_{k=1}^P \frac{\mathbf{R}_{Lk}}{i\omega - p_{Lk}} + \mathbf{K}_L, \quad \mathbf{Z}_R = \sum_{k=1}^P \frac{\mathbf{R}_{Rk}}{i\omega - p_{Rk}} + \mathbf{K}_R, \quad (34)$$

where p_{Lk} and p_{Rk} denote poles ($k = 1, \dots, P$), and \mathbf{R}_{Lk} and \mathbf{R}_{Rk} denote matrices of residues. Some of these usually appear in conjugate pairs, i.e., $(p_{Lk}, \overline{p_{Lk}})$ and $(p_{Rk}, \overline{p_{Rk}})$, and $(\mathbf{R}_{Lk}, \overline{\mathbf{R}_{Lk}})$ and $(\mathbf{R}_{Rk}, \overline{\mathbf{R}_{Rk}})$. As a result, Eq. (34) leads to:

$$\mathbf{Z}_L = \sum_{k=1}^Q 2 \frac{i\omega \Re\{\mathbf{R}_{L(2k)}\} - \Re\{\overline{p_{L(2k)}} \mathbf{R}_{L(2k)}\}}{-\omega^2 - 2i\omega \Re\{p_{L(2k)}\} + |p_{L(2k)}|^2} + \sum_{k=2Q+1}^P \frac{\mathbf{R}_{Lk}}{i\omega - p_{Lk}} + \mathbf{K}_L \quad (35)$$

where $2Q < P$. Only the left impedance is described as the right impedance follows similar expression by replacing the subscript L by R . To remove the denominator terms in Eq. (35), let us introduce $n \times 1$ vectors of supplementary variables \mathbf{X}_{Lk} and \mathbf{X}_{Rk} , and let us rewrite Eq. (30) by means of Eq. (35) as follows:

$$\mathbf{F}_L = \sum_{k=1}^Q 2 (i\omega \Re\{\mathbf{R}_{L(2k)}\} - \Re\{\overline{p_{L(2k)}} \mathbf{R}_{L(2k)}\}) \mathbf{X}_{Lk} + \sum_{k=2Q+1}^P \mathbf{R}_{Lk} (i\omega) \mathbf{X}_{L(k-Q)} + \mathbf{K}_L \mathbf{q}_L \quad (36)$$

where:

$$\begin{aligned} (-\omega^2 - 2i\omega\Re\{p_{L(2k)}\} + |p_{L(2k)}|^2) \mathbf{X}_{Lk} &= \mathbf{q}_L & \text{for } k = 1, \dots, Q, \\ (-\omega^2 - i\omega p_{Lk}) \mathbf{X}_{L(k-Q)} &= \mathbf{q}_L & \text{for } k = (2Q+1), \dots, P, \end{aligned} \quad (37)$$

Finally, let us introduce the following $(P-Q)n \times 1$ vector \mathbf{X}_L defined by:

$$\mathbf{X}_L = \begin{bmatrix} \mathbf{X}_{L1} \\ \vdots \\ \mathbf{X}_{LQ} \\ \mathbf{X}_{L(Q+1)} \\ \vdots \\ \mathbf{X}_{L(P-Q)} \end{bmatrix}. \quad (38)$$

The block components of the matrices occurring in Eqs. (36) and (37) represent polynomials of $i\omega$ of orders 0, 1 or 2, which as such can be simply and quickly converted to the time domain (see hereafter). By separating the terms of identical powers of $i\omega$, and by invoking the classical time-frequency transforms $\mathbf{q}(\omega) \rightarrow \mathbf{q}(t)$, $i\omega\mathbf{q} \rightarrow \dot{\mathbf{q}}$, $-\omega^2\mathbf{q} \rightarrow \ddot{\mathbf{q}}$ and $\mathbf{X}(\omega) \rightarrow \mathbf{X}(t)$, $i\omega\mathbf{X} \rightarrow \dot{\mathbf{X}}$, $-\omega^2\mathbf{X} \rightarrow \ddot{\mathbf{X}}$ (where dot and double-dot notations mean single and double time derivatives, respectively), this yields:

$$\mathbb{M}_L \begin{bmatrix} \ddot{\mathbf{X}}_L \\ \dot{\mathbf{X}}_L \\ \mathbf{X}_L \end{bmatrix} + \mathbb{C}_L \begin{bmatrix} \dot{\mathbf{X}}_L \\ \mathbf{X}_L \end{bmatrix} + \mathbb{K}_L \begin{bmatrix} \mathbf{q}_L \\ \mathbf{X}_L \end{bmatrix} = \begin{bmatrix} \mathbf{F}_L \\ \mathbf{0} \end{bmatrix} \quad (39)$$

where:

$$\begin{aligned} \mathbb{M}_L &= \begin{bmatrix} \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \text{blkdiag}\{\mathbf{I}_n\}_{k=1}^Q & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \text{blkdiag}\{\mathbf{I}_n\}_{k=2Q+1}^P \end{bmatrix}, \\ \mathbb{C}_L &= \begin{bmatrix} \mathbf{0} & 2\Re\{\mathbf{R}_{L(2)} \cdots \mathbf{R}_{L(2Q)}\} & [\mathbf{R}_{L(2Q+1)} \cdots \mathbf{R}_{LP}] \\ \mathbf{0} & \text{blkdiag}\{-2\Re\{p_{L(2k)}\}\mathbf{I}_n\}_{k=1}^Q & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \text{blkdiag}\{-p_{Lk}\mathbf{I}_n\}_{k=2Q+1}^P \end{bmatrix}, \\ \mathbb{K}_L &= \begin{bmatrix} \mathbf{K}_L & -2\Re\{\overline{p_{L(2)}}\mathbf{R}_{L(2)} \cdots \overline{p_{L(2Q)}}\mathbf{R}_{L(2Q)}\} & \mathbf{0} \\ -\mathbb{1}_{Q \times 1} \otimes \mathbf{I}_n & \text{blkdiag}\{|p_{L(2k)}|^2\mathbf{I}_n\}_{k=1}^Q & \mathbf{0} \\ -\mathbb{1}_{(P-2Q) \times 1} \otimes \mathbf{I}_n & \mathbf{0} & \mathbf{0} \end{bmatrix}, \end{aligned} \quad (40)$$

where \otimes denotes the Kronecker product.

Let us denote by \mathbf{M} , \mathbf{C} and \mathbf{K} the mass, damping and stiffness matrices of the periodic structure (N substructures), and let us write the related equation of motion as follows:

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \mathbf{K}\mathbf{q} = \mathbf{F}, \quad (41)$$

where $\mathbf{q} = \mathbf{q}(t)$ and $\mathbf{F} = \mathbf{F}(t)$ are the displacement and force vectors, respectively. In this case, the force vector is expressed by $\mathbf{F} = [\mathbf{F}_I^T \mathbf{F}_L^T \mathbf{F}_R^T]^T$ where \mathbf{F}_L and \mathbf{F}_R refer to the force vectors on S_L and S_R (absorbing BCs), and \mathbf{F}_I refers the force vector for the internal DOFs (I) of the structure. Also, the displacement vector is expressed by $\mathbf{q} = [\mathbf{q}_I^T \mathbf{q}_L^T \mathbf{q}_R^T]^T$ where \mathbf{q}_I is the displacement vector for the internal DOFs. By considering the absorbing BCs (Eq. (39)), this yields:

$$\mathbf{M}_{\text{tot}} \ddot{\mathbf{y}} + \mathbf{C}_{\text{tot}} \dot{\mathbf{y}} + \mathbf{K}_{\text{tot}} \mathbf{y} = \mathbf{f}. \quad (42)$$

with

$$\mathbf{y} = \begin{bmatrix} \mathbf{q}_I \\ \mathbf{q}_L \\ \mathbf{q}_R \\ \mathbf{X}_L \\ \mathbf{X}_R \end{bmatrix}, \quad \mathbf{f} = \begin{bmatrix} \mathbf{F}_I \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \end{bmatrix} \quad (43)$$

In (42), the matrices \mathbf{M}_{tot} , \mathbf{C}_{tot} and \mathbf{K}_{tot} are given by:

$$\begin{aligned} \mathbf{M}_{\text{tot}} &= \begin{bmatrix} \mathbf{M}_{II} & \mathbf{M}_{IL} & \mathbf{M}_{IR} & \mathbf{0} & \mathbf{0} \\ \mathbf{M}_{LI} & \mathbf{M}_{LL} & \mathbf{M}_{LR} & \mathbf{0} & \mathbf{0} \\ \mathbf{M}_{RI} & \mathbf{M}_{RL} & \mathbf{M}_{RR} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbb{M}_{L(XX)} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbb{M}_{R(XX)} \end{bmatrix}, \\ \mathbf{C}_{\text{tot}} &= \begin{bmatrix} \mathbf{C}_{II} & \mathbf{C}_{IL} & \mathbf{C}_{IR} & \mathbf{0} & \mathbf{0} \\ \mathbf{C}_{LI} & \mathbf{C}_{LL} & \mathbf{C}_{LR} & -\mathbb{C}_{L(qX)} & \mathbf{0} \\ \mathbf{C}_{RI} & \mathbf{C}_{RL} & \mathbf{C}_{RR} & \mathbf{0} & -\mathbb{C}_{R(qX)} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbb{C}_{L(XX)} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbb{C}_{R(XX)} \end{bmatrix}, \\ \mathbf{K}_{\text{tot}} &= \begin{bmatrix} \mathbf{K}_{II} & \mathbf{K}_{IL} & \mathbf{K}_{IR} & \mathbf{0} & \mathbf{0} \\ \mathbf{K}_{LI} & \mathbf{K}_{LL} - \mathbb{K}_{L(qq)} & \mathbf{K}_{LR} & -\mathbb{K}_{L(qX)} & \mathbf{0} \\ \mathbf{K}_{RI} & \mathbf{K}_{RL} & \mathbf{K}_{RR} - \mathbb{K}_{R(qq)} & \mathbf{0} & -\mathbb{K}_{R(qX)} \\ \mathbf{0} & \mathbb{K}_{L(Xq)} & \mathbf{0} & \mathbb{K}_{L(XX)} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbb{K}_{R(Xq)} & \mathbf{0} & \mathbb{K}_{R(XX)} \end{bmatrix}, \end{aligned} \quad (44)$$

where:

$$\begin{aligned}
\mathbb{M}_{L(XX)} &= \left[\begin{array}{c|c} \text{blkdiag} \{ \mathbf{I}_n \}_{k=1}^Q & \mathbf{0} \\ \hline \mathbf{0} & \text{blkdiag} \{ \mathbf{I}_n \}_{k=2Q+1}^P \end{array} \right], \\
\mathbb{C}_{L(qX)} &= \left[\begin{array}{c} 2\Re \{ [\mathbf{R}_{L(2)} \cdots \mathbf{R}_{L(2Q)}] \} \\ \hline [\mathbf{R}_{L(2Q+1)} \cdots \mathbf{R}_{LN}] \end{array} \right], \\
\mathbb{C}_{L(XX)} &= \left[\begin{array}{c|c} \text{blkdiag} \{ -2\Re \{ p_{L(2k)} \} \mathbf{I}_n \}_{k=1}^Q & \mathbf{0} \\ \hline \mathbf{0} & \text{blkdiag} \{ -p_{Lk} \mathbf{I}_n \}_{k=2Q+1}^P \end{array} \right], \\
\mathbb{K}_{L(qq)} &= \mathbf{K}_L, \\
\mathbb{K}_{L(qX)} &= \left[\begin{array}{c} -2\Re \{ [\overline{p_{L(2)}} \mathbf{R}_{L(2)} \cdots \overline{p_{L(2Q)}} \mathbf{R}_{L(2Q)}] \} \\ \hline \mathbf{0} \end{array} \right], \\
\mathbb{K}_{L(Xq)} &= \left[\begin{array}{c} -\mathbb{1}_{Q \times 1} \otimes \mathbf{I}_n \\ \hline -\mathbb{1}_{(P-2Q) \times 1} \otimes \mathbf{I}_n \end{array} \right], \\
\mathbb{K}_{L(XX)} &= \left[\begin{array}{c|c} \text{blkdiag} \{ |p_{L(2k)}|^2 \mathbf{I}_n \}_{k=1}^Q & \mathbf{0} \\ \hline \mathbf{0} & \mathbf{0} \end{array} \right], \tag{45}
\end{aligned}$$

and similar expressions for the right boundary.

Eq. (42) represents a second-order differential matrix equation for the displacement vector \mathbf{q} and the vector of supplementary variables $\mathbf{X} = [\mathbf{X}_L^T \mathbf{X}_R^T]^T$. This indeed represents a classical dynamic equation, in the time domain, of a structure with absorbing BCs and subject to an input force vector $\mathbf{F}_I = \mathbf{F}_I(t)$, with the only modification that supplementary DOFs are added at the boundaries. Therefore, this equation can be solved in a standard way via a time integration numerical scheme (e.g., Newmark scheme).

4.2 Euler-Bernoulli beam on an elastic foundation

We consider the example of the dynamic response of an infinite Euler-Bernoulli beam lying on an elastic foundation as shown in Fig. 2 and subject to some forces $f(x, t)$. The governing equation of motion of the beam is given by:

$$\rho S \ddot{v} + EI \left(\frac{\partial^4 v}{\partial x^4} + \xi \frac{\partial^4 \dot{v}}{\partial x^4} \right) + k_F v = f(x, t), \tag{46}$$

where $v = v(x, t)$ represents the transverse displacement, ρ is the density, S is the cross-sectional area, E is the Young's modulus, I is the inertia moment, and ξ is a damping parameter. For harmonic disturbance of the form $f(x) e^{i\omega t}$, Eq. (46) leads to:

$$(-\rho S \omega^2 + k_F) v + EI(1 + i\omega \xi) \frac{\partial^4 v}{\partial x^4} = f(x), \tag{47}$$

For this simple case, there exist analytical expressions of the matrices of wave shapes Φ_q , Φ_q^* , Φ_F and Φ_F^* , see Eq. (6). Hence, by expressing the transverse displacement v together with the rotation $\theta = \partial v / \partial x$, this yields:

$$\begin{bmatrix} v \\ \theta \end{bmatrix} = \Phi_q \begin{bmatrix} e^{-ikx} & 0 \\ 0 & e^{-kx} \end{bmatrix} \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix} + \Phi_q^* \begin{bmatrix} e^{ikx} & 0 \\ 0 & e^{kx} \end{bmatrix} \begin{bmatrix} Q_1^* \\ Q_2^* \end{bmatrix}, \tag{48}$$

Figure 2: Infinite flexural beam on an elastic foundation.

where:

$$\Phi_q = \begin{bmatrix} 1 & 1 \\ -ik & -k \end{bmatrix}, \quad \Phi_q^* = \begin{bmatrix} 1 & 1 \\ ik & k \end{bmatrix}, \quad k = \left(\frac{\rho S \omega^2 - k_F}{EI(1 + i\omega\xi)} \right)^{1/4}. \quad (49)$$

Also, by expressing the shearing force $V = -EI(\partial^3 v / \partial x^3)$ and the bending moment $M = EI(\partial^2 v / \partial x^2)$, this yields:

$$\Phi_F = EI k^2 \begin{bmatrix} -ik & k \\ -1 & 1 \end{bmatrix}, \quad \Phi_F^* = EI k^2 \begin{bmatrix} ik & -k \\ -1 & 1 \end{bmatrix}. \quad (50)$$

Therefore, the impedance matrices are written as:

$$\mathbf{Z}_L = -\Phi_F^* (\Phi_q^*)^{-1} = -\frac{EI k^2}{1 - i} \begin{bmatrix} 2ik & -(1 + i) \\ -(1 + i) & \frac{2}{k} \end{bmatrix}, \quad (51)$$

and

$$\mathbf{Z}_R = \Phi_F (\Phi_q)^{-1} = -\frac{EI k^2}{1 - i} \begin{bmatrix} 2ik & 1 + i \\ 1 + i & \frac{2}{k} \end{bmatrix}. \quad (52)$$

These are analytical expressions of the impedance matrices that could also have been obtained numerically by means of the WFE method.

Consider an infinite beam of rectangular cross-section having the following parameters: height $h = 0.001$ m, width $b = 0.01$ m, Young's modulus $E = 2.2 \times 10^{11}$ Pa, density $\rho = 7800$ kg/m³, damping parameter $\xi = 0.001$ s. Also, the lineic stiffness of the elastic foundation is $k_F = 1$ N/m². The system is at rest at time $t = 0$ — i.e., $v(x, 0) = 0$ and $\dot{v}(x, 0) = 0$ — and, for $t \geq 0$, it is excited by a point harmonic force of frequency $f_0 = 5$ Hz (at $x = 0$):

$$f(x, t) = \cos(2\pi f_0 t) \delta(x) \quad \text{for } t \geq 0. \quad (53)$$

A beam of finite length L — i.e., $x \in [-L/2, L/2]$ where, for instance, $L = 5$ m — excited at $x = 0$ (Eq. (53)) is considered as shown in Fig. 2. Here, the system beam-foundation is modeled by means of 500 identical substructures that represent identical two-node Hermitian beam elements of length $d = 0.01$ m. The rational approximations of the impedance matrices \mathbf{Z}_L and \mathbf{Z}_R with $P = 12$ poles/residues (see Eqs. (34)) are computed with the MATLAB rationalfit function.

The differential matrix equation (42) is solved with the Newmark algorithm where $\Delta t = 0.01$ s, $\mathbf{y}^0 = \mathbf{0}$ and $\dot{\mathbf{y}}^0 = \mathbf{0}$. The related transverse displacement field, at $t = 20$ s, is shown in the left of Fig. 3 along with the analytical harmonic solution. In this case, the proposed solution closely matches the analytical one, as expected. Finally, the right of Fig. 3 shows the history of the displacement solution at position $x = L/2$. Again, it is seen that, after a certain time (transient period), the solution issued from the proposed approach stabilizes towards the harmonic solution.

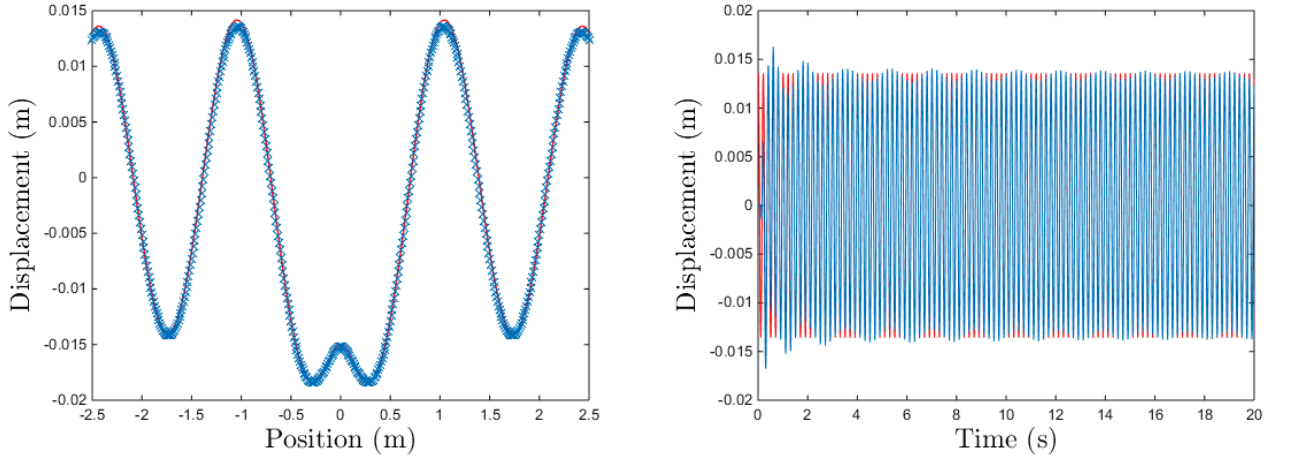

Figure 3: Transverse displacement field of the beam on the elastic foundation at $t = 20$ s (left): (blue crosses) Proposed approach; (red line) analytical harmonic solution and time response at $x=L/2$ for $t \in [0, 20]$ s (right) (blue line and crosses) Proposed approach; (red line) analytical theory, harmonic response.

4.3 Periodic structure with 2D substructures

We consider now a 2D beam with periodic distributions of holes and elastic supports (springs of stiffness K_s) as shown in Fig. 4. Here, square substructures of dimensions 2×2 m² with holes of radius 0.4 m are considered which are similar to those depicted in Fig. 1. Regarding the modeling of the periodic supports, a nodal stiffness of $K_s/2$ (vertical direction) is added to the FE model of the substructures at the left and right boundaries (bottom node). Other substructure parameters are: thickness $e = 0.005$ m, Young's modulus $E = 7 \times 10^{10}$ Pa, Poisson's ratio $\nu = 0.35$, density $\rho = 2700$ kg/m³, and stiffness $K_s = 10^5$ N/m. Rayleigh-type damping matrices $\mathbf{C} = a\mathbf{M} + b\mathbf{K}$ are also considered where $a = 0.01$ s⁻¹ and $b = 5 \times 10^{-5}$ s.

Figure 4: Schematic of an infinite periodic structure with periodic elastic supports.

The time response of the infinite periodic structure subject to a vertical point force $F_0(t)$ at $x = 0$ (top node) is analyzed. Within the framework of the proposed approach, a periodic structure involving $N = 20$ substructures and absorbing BCs is considered as shown in Fig. 4. In this case, the structure has a length of $L = 40$ m. The rational approximations of the impedance matrices \mathbf{Z}_L and \mathbf{Z}_R (Eq. (34)) are expressed by means of $P = 15$ poles/residues. The time response of the structure is computed over a time range of $[0, 0.1]$ s by solving the differential matrix equation (42) with the Newmark algorithm where $\Delta t = 10^{-4}$ s, $\mathbf{y}^0 = \mathbf{0}$ and $\dot{\mathbf{y}}^0 = \mathbf{0}$. For comparison purpose, an equivalent FE model of an “infinite” structure with a larger number of substructures (200) is considered and simulated over the time range $[0, 0.1]$ s which is supposed to be small enough to prevent wave reflections (free boundaries). Consider a harmonic point force of magnitude $F_0(t) = 10^4 \cos(2\pi \times 100t)$ acting at $x = 0$, and assume that the structure is at rest at $t = 0$. The time response is analyzed over a time range of $[0, 0.1]$ s which is supposed to be broad enough to include several oscillations (10 in this case) and cover

the transient phase. Especially, the time variation of the transverse displacement at $x = 20$ m (right boundary, top node) can be computed as shown in Fig. 5. It is shown that the proposed solution perfectly matches the reference one over the whole time range. It is also numerically stable, i.e., a smooth curve that well predicts the oscillating nature of the signal.

Figure 5: Harmonic force: time response at $x=L/2$ (top node, vertical displacement). (blue crosses) Proposed approach; (red line) reference FE method.

5 Conclusion

A FE procedure has been proposed to model infinite periodic structures subject to distributed or moving loads, or localized time-dependent excitations. For instance, in the case of moving loads, the load is applied on each substructure. Concerning time domain problems, first, using the WFE method to express the absorbing BCs by means of impedance matrices, in the frequency domain, impedance matrices have been rewritten in terms of polynomials of the frequency $i\omega$ up to order 2. Then, they are simply converted to the time domain and the global dynamic equation is solved by the Newmark algorithm. Follow-on works could include the analysis of infinite periodic structures with localized nonlinear effects.

Abstract. *Two kinds of numerical approaches able to predict the dynamic response of periodic structures and metamaterials are presented. Both of them are model reduction techniques which can be used to obtain the response functions of the structures at a low computational cost. The first kind of approaches employs the wave finite element (WFE) method for modeling 1D periodic structures made up of complex substructures, e.g., 2D cells of arbitrary shapes. Resonant metamaterials are particular cases of periodic structures where the substructures possess local resonances — e.g., layered substructures involving soft layers and heavy layers/core —, which in turn lead to band gap effects and low vibration levels. Although well-suited for modeling periodic structures in the frequency domain, the WFE method also works for periodic structures subject to time-dependent excitations. The second kind of approaches employs finite element (FE) procedures for modeling 2D periodic structures, and 2D nearly periodic structures involving substructures with slightly varying (random) geometrical properties. For nearly periodic structures like plates with disordered resonant 2D cells, results show that the vibrational energy is localized around the excitation sources.*

1 INTRODUCTION

Periodic structures are frequently encountered in engineering applications, e.g., in the aeronautic (fuselages, turbines) and railway industries. Also, they appear interesting to passively control the vibration levels of mechanical systems. Metamaterials are periodic structures which possess such interesting features, i.e., the fact that they do not convey vibrational energies on some frequency bands (band gaps) which as such yield low vibration levels. Well-known examples of metamaterials are periodic structures made up of resonant cells where band gaps occur in the vicinity of the resonance frequencies of the cells. There exist plenty of works in the literature about the analysis of the wave propagation in 1D or 2D periodic structures and the related band gap effects [11, 10, 9, 12, 29, 25, 4, 28]. However, the forced response analysis of periodic structures is much less reported. This especially means developing numerical models able to predict the dynamic response of periodic structures of finite dimensions with various kinds of boundary conditions, or assemblies of finite dimensions involving several periodic structures and other non-periodic components which are systems of practical interest in engineering applications. In this case, the analysis of the band gap effects does not only rely on the wave propagation properties, but also on the boundary and coupling conditions which induce energy conversion between waves.

This paper aims at investigating the modeling of 1D and 2D periodic structures, of finite dimensions, subject to various kinds of excitations and boundary conditions. Periodic structures made up of complex cells — i.e., substructures which can be of various shapes and which are modeled with a moderately high number of degrees of freedom (DOFs) — are especially dealt with. Numerical results are brought which concern the dynamic response of periodic structures and resonant metamaterials.

The paper starts with an overview of the wave finite element (WFE) method and its recent applications. The method is well suited for modeling 1D periodic structures, i.e., structures made up of identical substructures which are connected to each other along a straight or circumferential direction. The WFE method works by considering the FE model of a substructure, and computing the eigenvalues and eigenvectors of the related transfer matrix to determine the waves traveling along a periodic structure. To predict the forced response of periodic structures, the WFE method involves expanding the displacement and force vectors on the basis of the eigenvectors (wave shapes) of the transfer matrix of a substructure. The methodology is detailed in [16, 18] (see also [30, 6, 32, 15]). Among the recent extensions of the method are: the development of model reduction strategies based on reduced wave bases to target substructures with large-sized FE models [22]; the modeling of periodic structures with cyclic symmetry, such as turbines [19]; the time response analysis of periodic structures via wave-based absorbing boundary conditions [7].

Aside from the study of 1D periodic structures, 2D periodic structures with resonant substructures are well-known examples of metamaterials to passively control the vibration levels of mechanical systems. As mentioned earlier, the analysis of the wave propagation (e.g., Bloch waves) in 2D periodic structures is well documented in the literature. However, contrary to the study of 1D periodic structures, the forced response analysis of 2D periodic structures of finite dimensions, based on wave expansion (displacement and force vectors), is prone to tough theoretical and numerical modeling issues which make it difficult even impossible to carry out. The issue is linked to the multi-directional behavior of the propagating waves, and the description of the wave reflection at boundaries that arise from these multi-directional waves. Here, two FE-based approaches are proposed as alternative model reduction techniques. The first

one is standard and makes use of the Craig-Bampton (CB) method and the related fixed interface modes of the substructures for modeling purely periodic structures. The second approach targets the modeling of 2D nearly periodic structures made up of resonant substructures with slightly varying geometrical properties [20]. Plates with disordered resonant 2D cells, made up of soft layers and heavy layers/core with random geometrical properties, are examples of 2D nearly periodic structures. Such structures possess interesting features, e.g., the fact that the vibrational energy remains localized around the excitation points. The proposed strategy involves computing the reduced matrices of the substructures for some particular distorted FE meshes (a few number), and interpolating these matrices between these “interpolation points” for modeling substructures with random FE meshes.

2 WFE METHOD FOR 1D PERIODIC STRUCTURES

2.1 Wave propagation

The WFE method originates from the transfer matrix theory and the Bloch’s theorem. Let us first consider an infinite periodic structure under harmonic disturbance $e^{i\omega t}$ made up of identical substructures with similar FE meshes as shown in Fig. 1. Also, let us denote by \mathbf{M} , \mathbf{C} and \mathbf{K} the conventional mass, damping and stiffness matrices of the substructures (identical for all the substructures). From the practical point of view, these matrices can be obtained via usual FE softwares, Matlab FE mesh generators (e.g., DistMesh [27]) or Matlab in-house FE codes. The related dynamic equilibrium equation, for a given substructure k , is given by:

$$\mathbf{D}\mathbf{q}^k = \mathbf{F}^k, \quad (1)$$

where \mathbf{q}^k and \mathbf{F}^k refer to the displacement vector and the force vector (respectively) of the substructure k ; \mathbf{D} is the dynamic stiffness matrix expressed by $\mathbf{D} = -\omega^2\mathbf{M} + i\omega\mathbf{C} + \mathbf{K}$.

Figure 1: Periodic structure of infinite length, and FE mesh of a substructure.

The FE mesh of the substructure involves left (L) and right (R) boundaries (see Fig. 1) which are here assumed to be described with a same number n of DOFs. From Eq. (1), the following transfer matrix relation between the right and left boundaries can be proposed:

$$\begin{bmatrix} \mathbf{q}_R^k \\ \mathbf{F}_R^k \end{bmatrix} = \mathbf{S} \begin{bmatrix} \mathbf{q}_L^k \\ -\mathbf{F}_L^k \end{bmatrix}, \quad (2)$$

where \mathbf{S} is the so-called transfer matrix (size of $2n \times 2n$), expressed by:

$$\mathbf{S} = \left[\begin{array}{c|c} -(\mathbf{D}_{\text{LR}}^*)^{-1}\mathbf{D}_{\text{LL}}^* & -(\mathbf{D}_{\text{LR}}^*)^{-1} \\ \hline \mathbf{D}_{\text{RL}}^* - \mathbf{D}_{\text{RR}}^*(\mathbf{D}_{\text{LR}}^*)^{-1}\mathbf{D}_{\text{LL}}^* & -\mathbf{D}_{\text{RR}}^*(\mathbf{D}_{\text{LR}}^*)^{-1} \end{array} \right]. \quad (3)$$

Here, \mathbf{D}^* represents the condensed dynamic stiffness matrix, i.e., on the left and right boundaries of the substructure [18]. Let us consider two consecutive substructures k and $k+1$ which are rigidly connected at a common interface. In this case, the coupling conditions write $\mathbf{q}_{\text{R}}^k = \mathbf{q}_{\text{L}}^{k+1}$ and $\mathbf{F}_{\text{R}}^k = -\mathbf{F}_{\text{L}}^{k+1}$, and Eq. (2) gives:

$$\begin{bmatrix} \mathbf{q}_{\text{L}}^{k+1} \\ -\mathbf{F}_{\text{L}}^{k+1} \end{bmatrix} = \mathbf{S} \begin{bmatrix} \mathbf{q}_{\text{L}}^k \\ -\mathbf{F}_{\text{L}}^k \end{bmatrix} \quad \text{and also} \quad \begin{bmatrix} \mathbf{q}_{\text{R}}^{k+1} \\ \mathbf{F}_{\text{R}}^{k+1} \end{bmatrix} = \mathbf{S} \begin{bmatrix} \mathbf{q}_{\text{R}}^k \\ \mathbf{F}_{\text{R}}^k \end{bmatrix}, \quad (4)$$

which relates the displacement and force vectors between two consecutive substructures k and $k+1$.

It can be proven that the transfer matrix \mathbf{S} is symplectic [23], which means that its eigenvalues and eigenvectors come in pairs (μ_j, ϕ_j) and $(\mu_j^* = 1/\mu_j, \phi_j^*)$ with $|\mu_j| < 1$. Numerical issues about the computation of the eigensolutions of \mathbf{S} are discussed in [22, 32, 36]. According to the Bloch's theorem [34], the eigenvalues of \mathbf{S} have the meaning of wave parameters which are given by $\mu_j = e^{-i\beta_j d}$ for the waves traveling to the right direction (β_j : wave number for a wave j ; d : substructure length) and $\mu_j^* = e^{i\beta_j d}$ for the waves traveling to the left direction. Also, the eigenvectors ϕ_j and ϕ_j^* have the meaning of wave shapes for the waves traveling to the right and left directions, respectively. These are vectors of size $2n \times 1$, expressed by:

$$\phi_j = \begin{bmatrix} \phi_{\text{q}j} \\ \phi_{\text{F}j} \end{bmatrix}, \quad \phi_j^* = \begin{bmatrix} \phi_{\text{q}j}^* \\ \phi_{\text{F}j}^* \end{bmatrix}, \quad (5)$$

where $\phi_{\text{q}j}$ and $\phi_{\text{q}j}^*$ (resp. $\phi_{\text{F}j}$ and $\phi_{\text{F}j}^*$) are $n \times 1$ displacement (resp. force) component vectors for the right-going and left-going waves. In matrix form, these vectors give:

$$\Phi_{\text{q}} = [\phi_{\text{q}1} \cdots \phi_{\text{q}n}], \quad \Phi_{\text{q}}^* = [\phi_{\text{q}1}^* \cdots \phi_{\text{q}n}^*], \quad \Phi_{\text{F}} = [\phi_{\text{F}1} \cdots \phi_{\text{F}n}], \quad \Phi_{\text{F}}^* = [\phi_{\text{F}1}^* \cdots \phi_{\text{F}n}^*]. \quad (6)$$

2.2 Forced response

The analysis of the harmonic response of periodic structures of finite length — i.e., with a finite number N of substructures — can be easily performed with the WFE method. The advantage, against the conventional FE method, is in the modeling of a whole periodic structure via a small matrix system of size $2n \times 2n$ that is linked to the number of DOFs on the left and right boundaries of a substructure. In comparison, the FE method would involve assembling the condensed dynamic stiffness matrices of all the substructures, yielding a bigger matrix system of size $(N+1)n \times (N+1)n$ whose computation is likely to take much more time. The main idea behind the WFE modeling is to expand the displacement and force vectors, on a particular interface (k) connecting two substructures $k-1$ and k , on the wave shapes $\phi_{\text{q}j}$ and $\phi_{\text{q}j}^*$, and $\phi_{\text{F}j}$ and $\phi_{\text{F}j}^*$, of a periodic structure [16, 18]:

$$\mathbf{q}_{\text{L}}^{(k)} = \mathbf{q}_{\text{R}}^{(k)} = \Phi_{\text{q}} \boldsymbol{\mu}^{k-1} \mathbf{Q} + \Phi_{\text{q}}^* \boldsymbol{\mu}^{N-k+1} \mathbf{Q}^* \quad k = 1, \dots, N+1, \quad (7)$$

$$-\mathbf{F}_{\text{L}}^{(k)} = \mathbf{F}_{\text{R}}^{(k)} = \Phi_{\text{F}} \boldsymbol{\mu}^{k-1} \mathbf{Q} + \Phi_{\text{F}}^* \boldsymbol{\mu}^{N-k+1} \mathbf{Q}^* \quad k = 1, \dots, N+1. \quad (8)$$

Here, $\mathbf{q}_L^{(k)}$ and $\mathbf{F}_L^{(k)}$ represent the displacement and force vectors at the left boundary of the substructure k for $k = 1, \dots, N$; $\mathbf{q}_R^{(k)}$ and $\mathbf{F}_R^{(k)}$ represent the displacement and force vectors at the right boundary of the substructure $k-1$ for $k = 2, \dots, N+1$; \mathbf{Q} is the wave amplitude vector for the right-going waves at the substructure interface (1) (left end of the periodic structure); \mathbf{Q}^* is the wave amplitude vector for the left-going waves at the substructure interface ($N+1$) (right end of the periodic structure). Finally, $\boldsymbol{\mu} = \text{diag}\{\mu_j\}_{j=1}^n$ is the diagonal matrix of the wave parameters μ_j for the right-going waves, with the property that $\|\boldsymbol{\mu}\|_2 < 1$ [16].

Consider for the sake of clarity a finite periodic structure as shown in Fig. 2 whose left end is excited by some forces (vector \mathbf{F}_0), and whose right end is constrained by prescribed displacement vector \mathbf{q}_0^* . In this case, by considering Eqs. (7) and (8), the boundary conditions write $-\mathbf{F}_0 = \boldsymbol{\Phi}_F \mathbf{Q} + \boldsymbol{\Phi}_F^* \boldsymbol{\mu}^N \mathbf{Q}^*$ and $\mathbf{q}_0^* = \boldsymbol{\Phi}_q \boldsymbol{\mu}^N \mathbf{Q} + \boldsymbol{\Phi}_q^* \mathbf{Q}^*$ which, after some simple manipulations, yield the following wave-based matrix equation (size $2n \times 2n$):

$$\begin{bmatrix} \mathbf{I}_n & (\boldsymbol{\Phi}_F)^{-1} \boldsymbol{\Phi}_F^* \boldsymbol{\mu}^N \\ (\boldsymbol{\Phi}_q^*)^{-1} \boldsymbol{\Phi}_q \boldsymbol{\mu}^N & \mathbf{I}_n \end{bmatrix} \begin{bmatrix} \mathbf{Q} \\ \mathbf{Q}^* \end{bmatrix} = \begin{bmatrix} -(\boldsymbol{\Phi}_F)^{-1} \mathbf{F}_0 \\ (\boldsymbol{\Phi}_q^*)^{-1} \mathbf{q}_0^* \end{bmatrix}. \quad (9)$$

Solving the wave-based matrix equation (9) yields the wave amplitude vectors \mathbf{Q} and \mathbf{Q}^* . The determination of the displacement and force vectors, at any substructure interface (k), follows from Eqs. (7) and (8). If needed, the displacements at the internal nodes (I) of the substructures can be retrieved by considering the full dynamic stiffness matrix, i.e., $\mathbf{q}_I = -(\mathbf{D}_{II})^{-1}(\mathbf{D}_{IL} \mathbf{q}_L^{(k)} + \mathbf{D}_{IR} \mathbf{q}_R^{(k+1)})$ for a substructure enclosed between two interfaces (k) and ($k+1$).

Figure 2: Finite periodic structure with prescribed forces \mathbf{F}_0 (left end) and prescribed displacements \mathbf{q}_0^* (right end).

The main numerical tasks involved in the WFE method may be summed up as follows:

- (i) Computation of the condensed dynamic stiffness matrix \mathbf{D}^* of a substructure;
- (ii) Computation of the eigensolutions of the transfer matrix \mathbf{S} ;
- (iii) Computation of the matrix system (9).

Task (iii) is not computationally cumbersome given that the matrix system (9) has a small size, as explained earlier. As for the computation of the condensed dynamic stiffness matrix \mathbf{D}^* (task (i)), this can be easily performed via the CB method [18]. For periodic structures involving substructures whose number of boundary DOFs is not excessive (e.g., smaller than 300), task (ii) is not cumbersome too. Things are more complicated for substructures with large-sized FE models, and in this case, it is advised to only compute a few low-order waves (rather than all the waves) using appropriate eigensolvers like the Lanczos algorithm [22].

The WFE method can be advantageously applied to structural assemblies made up of different periodic structures and other non-periodic structural components, i.e., mechanical systems which are of practical interest in engineering. The reader is referred to [23, 24, 17, 30]. The

WFE modeling of those structural assemblies involves considering coupling conditions between periodic structures (two or more), across a rigid interface c or a non-periodic structural component c (coupling element), which in wave-based form are written as:

$$\mathbf{Q}^{c*} = \mathbb{C}^c \mathbf{Q}^c + \mathbb{F}^c, \quad (10)$$

where \mathbf{Q}^c and \mathbf{Q}^{c*} represent the wave amplitudes vectors for the outgoing waves and incoming waves, respectively, for the periodic structures connected at interface c or coupling element c ; \mathbb{C}^c is the so-called scattering matrix (reflection and transmission coefficients); \mathbb{F}^c is a vector representing the excitation sources imposed at the interface or inside the coupling element. Hence, a global wave-based matrix equation which takes into account coupling conditions between several periodic structures, and classical boundary conditions (prescribed forces or displacements), can be proposed whose size is not big, i.e., linked to the numbers of boundary DOFs of the substructures used for modeling the periodic structures.

2.3 Some recent and ongoing works

1D periodic structures are often considered as straight structures, made up of simple or more complicated substructures, vibrating under harmonic disturbance. The purpose here is to show that the WFE method can handle more sophisticated engineering problems. Two examples of recent WFE strategies are proposed. The purpose is to give the main ideas and outlines of these strategies rather than fully detailing all the theoretical developments (see [19, 7]).

2.3.1 Periodic structures with cyclic symmetry

The first kind of problems concerns the analysis of multi-stage bladed disks, which is well known in the aeronautic industry. The proposed approach involves computing the dynamic flexibility modes of a given periodic structure (cyclic symmetry) via the WFE method, and modeling assemblies made up of several periodic structures via dynamic substructuring [19].

Figure 3: (left) Periodic structure with one of its substructures subject to one unit force on the boundary. (right) Two connected periodic structures with arbitrary forces applied to the coupling interface.

A dynamic flexibility mode of a periodic structure (N substructures) represents the displacement vector that results from applying one unit force to a given DOF of the boundary, the others being free (see Fig. 3). For instance, assume that the unit force (force vector \mathbf{F}_B) is applied to a boundary DOF i of a substructure enclosed between two substructure interfaces (N) and (1).

The resulting dynamic flexibility mode is given by:

$$\mathbf{x}_i^{(N)} = \begin{bmatrix} (\mathbf{I}_{(n+n_{\text{I|B}})/3} \otimes \mathcal{R}) \mathbf{q}^{(1)} \\ (\mathbf{I}_{(n+n_{\text{I|B}})/3} \otimes \mathcal{R}^2) \mathbf{q}^{(2)} \\ \vdots \\ (\mathbf{I}_{(n+n_{\text{I|B}})/3} \otimes \mathcal{R}^N) \mathbf{q}^{(N)} \end{bmatrix}, \quad (11)$$

where $\mathbf{q}^{(k)}$ ($k = 1, \dots, N-1$) represents the displacement vector of a substructure enclosed between two substructure interfaces (k) and ($k+1$) and expressed in the local cartesian coordinate system of the substructure; \mathcal{R} is the 3×3 rotation matrix for the angle $-2\pi/N$, with $\mathcal{R}^N = \mathbf{I}_3$; n is the number of interface DOFs (between the substructures), and $n_{\text{I|B}}$ is the number of internal DOFs which belong to the boundary. Recall that the unit force is applied to the boundary of a substructure enclosed between interfaces (N) and (1). The displacement vector of this substructure is denoted by $\mathbf{q}^{(N)}$ and is given by:

$$\mathbf{q}^{(N)} = \begin{bmatrix} \mathbf{I}_n & \mathbf{0} \\ \mathbf{X}_{\text{st|B}} - \tilde{\mathbf{X}}_{\text{el|B}} \tilde{\mathbf{D}}_{\text{el-e1}}^{-1} \tilde{\mathbf{D}}_{\text{st-e1}}^T \end{bmatrix} \mathcal{H}^T \begin{bmatrix} \Phi_{\mathbf{q}} \boldsymbol{\mu}^{N-1} & \Phi_{\mathbf{q}}^* \boldsymbol{\mu}^{N-1} \\ \Phi_{\mathbf{q}} & \Phi_{\mathbf{q}}^* \boldsymbol{\mu}^{N-1} \end{bmatrix} \begin{bmatrix} \mathbf{Q} \\ \mathbf{Q}^* \end{bmatrix} + \begin{bmatrix} \mathbf{0} \\ \tilde{\mathbf{X}}_{\text{el|B}} \tilde{\mathbf{D}}_{\text{el-e1}}^{-1} \tilde{\mathbf{X}}_{\text{el}}^T \mathcal{L}_{\text{IB}} \end{bmatrix} \mathbf{F}_{\text{B}}. \quad (12)$$

Here, \mathbf{X}_{st} and $\tilde{\mathbf{X}}_{\text{el}}$ are, respectively, the matrices of static modes and fixed interface modes of the substructure (CB method), $\tilde{\mathbf{D}}_{\text{el-e1}}$ represents the dynamic stiffness matrix of the substructure “projected” on $\tilde{\mathbf{X}}_{\text{el}}$, and \mathcal{H} is a transformation matrix which relates the unit vectors in cylindrical coordinates (i.e., \vec{e}_r , \vec{e}_θ and \vec{e}_z) to those in cartesian coordinates (i.e., \vec{e}_x , \vec{e}_y and \vec{e}_z) at the interface nodes of the substructure. Also, for a non-excited substructure, one has:

$$\mathbf{q}^{(k)} = \begin{bmatrix} \mathbf{I}_n & \mathbf{0} \\ \mathbf{X}_{\text{st|B}} - \tilde{\mathbf{X}}_{\text{el|B}} \tilde{\mathbf{D}}_{\text{el-e1}}^{-1} \tilde{\mathbf{D}}_{\text{st-e1}}^T \end{bmatrix} \mathcal{H}^T \begin{bmatrix} \Phi_{\mathbf{q}} \boldsymbol{\mu}^{k-1} & \Phi_{\mathbf{q}}^* \boldsymbol{\mu}^{N-k} \\ \Phi_{\mathbf{q}} \boldsymbol{\mu}^k & \Phi_{\mathbf{q}}^* \boldsymbol{\mu}^{N-k-1} \end{bmatrix} \begin{bmatrix} \mathbf{Q} \\ \mathbf{Q}^* \end{bmatrix} \quad \text{for } k \neq N. \quad (13)$$

In Eqs. (12) and (13), $\mathbf{Q} = \mathbf{Q}^{(1)}$ and $\mathbf{Q}^* = \mathbf{Q}^{*(N)}$ are wave amplitude vectors, expressed at substructure boundaries (1) and (N) (see Fig. 3) and obtained via WFE procedure. The matrix of flexibility modes which results from applying successive unit forces to the boundary DOFs of the substructure enclosed between interfaces (N) and (1) is given by $\mathbf{X}^{(N)} = [\mathbf{x}_1^{(N)} \mathbf{x}_2^{(N)} \dots \mathbf{x}_{n_{\text{B}}}^{(N)}]$ where n_{B} is the number of boundary DOFs of a substructure. The whole matrix of flexibility modes which results from applying successive unit forces to the boundary DOFs of the whole periodic structure follows as $\mathbf{X} = [\mathbf{X}^{(1)} \mathbf{X}^{(2)} \dots \mathbf{X}^{(N)}]$, where:

$$\mathbf{X}^{(k)} = (\mathbf{I}_{n_{\text{T}}/3} \otimes \mathcal{R}^k) \mathcal{P}^{(k)} \mathbf{X}^{(N)} (\mathbf{I}_{n_{\text{B}}/3} \otimes \mathcal{R}^k)^T, \quad (14)$$

where $\mathcal{P}^{(k)}$ is a permutation matrix, and $n_{\text{T}} = N(n + n_{\text{I|B}})$. The modeling of several periodic structures with cyclic symmetry follows from domain decomposition procedure. For instance, for two structures (displacement vectors \mathbf{q}_1 and \mathbf{q}_2) subject to force vectors \mathbf{F}_{B1} and \mathbf{F}_{B2} on their boundaries, this yields:

$$\begin{bmatrix} \mathbf{I} & \mathbf{0} & -\mathbf{X}_1 \mathcal{L}_{\text{B1}}^T \\ \mathbf{0} & \mathbf{I} & \mathbf{X}_2 \mathcal{L}_{\text{B2}}^T \\ \mathcal{L}_1 & -\mathcal{L}_2 & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{q}_1 \\ \mathbf{q}_2 \\ \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} \mathbf{X}_1 \mathbf{F}_{\text{B1}} \\ \mathbf{X}_2 \mathbf{F}_{\text{B2}} \\ \mathbf{0} \end{bmatrix}, \quad (15)$$

where \mathbf{X}_1 and \mathbf{X}_2 are the matrices of flexibility modes of the structures, and $\mathcal{L}_1, \mathcal{L}_2, \mathcal{L}_{B1}, \mathcal{L}_{B2}$ are localization matrices. Also, $\boldsymbol{\lambda}$ represents a vector of Lagrange multipliers to enforce the displacement continuity conditions (i.e., $\mathcal{L}_1 \mathbf{q}_1 - \mathcal{L}_2 \mathbf{q}_2 = \mathbf{0}$) for some nodes of the boundaries of the structures. Solving Eq. (15) yields:

$$\boldsymbol{\lambda} = -(\mathcal{L}_1 \mathbf{X}_1 \mathcal{L}_{B1}^T + \mathcal{L}_2 \mathbf{X}_2 \mathcal{L}_{B2}^T)^{-1}(\mathcal{L}_1 \mathbf{X}_1 \mathbf{F}_{B1} - \mathcal{L}_2 \mathbf{X}_2 \mathbf{F}_{B2}). \quad (16)$$

The displacement vectors of the structures follow as $\mathbf{q}_1 = \mathbf{X}_1(\mathbf{F}_{B1} + \mathcal{L}_{B1}^T \boldsymbol{\lambda})$ and $\mathbf{q}_2 = \mathbf{X}_2(\mathbf{F}_{B2} - \mathcal{L}_{B2}^T \boldsymbol{\lambda})$.

Some results are proposed hereafter which concern two coupled bladed disks 1 and 2 (two stages) with $N_1 = 36$ and $N_2 = 60$ substructures (respectively), excited by non-symmetric forces. Here, the harmonic response function (transverse displacement) at some node at the tip of one blade of structure 1 is assessed up to 10,000 Hz (see Fig. 4), which is high enough to include local resonance effects for each blade. Those results show that the proposed approach perfectly agrees with the conventional FE method.

Figure 4: (left) Two periodic structures and FE meshes of the related substructures (Γ_- and Γ_+ are coupling interfaces with previous and subsequent substructures). (right) Response functions, conventional FE (black solid line) and WFE (pink dotted line).

2.3.2 Time response of periodic structures via wave-based absorbing boundary conditions

The second kind of problems concerns the modeling of infinite periodic structures (or periodic structures which are supposed to be long enough) subject to localized time-dependent loadings. Potential applications could be, for instance, structures like pipelines or tanks subject to shocks. A periodic structure with a finite number N of substructures and subject to time dependent forces (vector $\mathbf{F}(t)$) is shown in Fig. 5. The semi-infinite behavior at the left and right ends — i.e., the fact that no wave is coming from infinity — is described by means of absorbing boundary conditions expressed in the time domain [7]. Although easy to understand in the frequency domain, the determination of absorbing conditions for time response analysis is not a straightforward task and, for this reason, this study hasn't been conducted extensively so far.

The proposed approach can be summarized as follows. Let us start with the impedance matrices (frequency domain) at the left (L) and right (R) ends of a periodic structure (N substructures), which can be simply obtained via the WFE method as follows:

$$\mathbf{Z}_L = -\Phi_F^*(\Phi_q^*)^{-1}, \quad \mathbf{Z}_R = \Phi_F(\Phi_q)^{-1}. \quad (17)$$

Figure 5: Schematic of a periodic structure with N substructures subject to time-dependent forces and semi-infinite boundary conditions.

Then, decompose the impedance matrices \mathbf{Z}_L and \mathbf{Z}_R via rational approximations:

$$\begin{aligned}\mathbf{Z}_L &= \sum_{k=1}^Q 2 \frac{i\omega \Re\{\mathbf{R}_{L(2k)}\} - \Re\{\overline{p_{L(2k)}} \mathbf{R}_{L(2k)}\}}{-\omega^2 - 2i\omega \Re\{p_{L(2k)}\} + |p_{L(2k)}|^2} + \sum_{k=2Q+1}^P \frac{\mathbf{R}_{Lk}}{i\omega - p_{Lk}} + \mathbf{K}_L, \\ \mathbf{Z}_R &= \sum_{k=1}^Q 2 \frac{i\omega \Re\{\mathbf{R}_{R(2k)}\} - \Re\{\overline{p_{R(2k)}} \mathbf{R}_{R(2k)}\}}{-\omega^2 - 2i\omega \Re\{p_{R(2k)}\} + |p_{R(2k)}|^2} + \sum_{k=2Q+1}^P \frac{\mathbf{R}_{Rk}}{i\omega - p_{Rk}} + \mathbf{K}_R,\end{aligned}\quad (18)$$

where (p_{Lk}, p_{Rk}) and $(\mathbf{R}_{Lk}, \mathbf{R}_{Rk})$ denote poles and matrices of residues ($k = 1, \dots, P$), respectively. Usually, some of these terms appear in conjugate pairs, say, for $k = 1, \dots, Q$. In the frequency domain, the absorbing boundary conditions are expressed by $\mathbf{F}_L = \mathbf{Z}_L \mathbf{q}_L$ and $\mathbf{F}_R = \mathbf{Z}_R \mathbf{q}_R$ where \mathbf{q}_L (resp. \mathbf{q}_R) and \mathbf{F}_L (resp. \mathbf{F}_R) are the displacement vector and force vector at the left (resp. right) end of the structure, respectively. By considering vectors of supplementary variables \mathbf{X}_{Lk} and \mathbf{X}_{Rk} together with Eq. (18), it can be shown that the absorbing conditions can be rewritten as follows:

$$\begin{aligned}\mathbf{F}_L &= \sum_{k=1}^Q 2 (i\omega \Re\{\mathbf{R}_{L(2k)}\} - \Re\{\overline{p_{L(2k)}} \mathbf{R}_{L(2k)}\}) \mathbf{X}_{Lk} + \sum_{k=2Q+1}^P \mathbf{R}_{Lk}(i\omega) \mathbf{X}_{L(k-Q)} + \mathbf{K}_L \mathbf{q}_L, \\ \mathbf{F}_R &= \sum_{k=1}^Q 2 (i\omega \Re\{\mathbf{R}_{R(2k)}\} - \Re\{\overline{p_{R(2k)}} \mathbf{R}_{R(2k)}\}) \mathbf{X}_{Rk} + \sum_{k=2Q+1}^P \mathbf{R}_{Rk}(i\omega) \mathbf{X}_{R(k-Q)} + \mathbf{K}_R \mathbf{q}_R,\end{aligned}\quad (19)$$

where:

$$\begin{aligned}(-\omega^2 - 2i\omega \Re\{p_{L(2k)}\} + |p_{L(2k)}|^2) \mathbf{X}_{Lk} &= \mathbf{q}_L & \text{for } k = 1, \dots, Q, \\ (-\omega^2 - 2i\omega \Re\{p_{R(2k)}\} + |p_{R(2k)}|^2) \mathbf{X}_{Rk} &= \mathbf{q}_R & \text{for } k = 1, \dots, Q, \\ (-\omega^2 - i\omega p_{Lk}) \mathbf{X}_{L(k-Q)} &= \mathbf{q}_L & \text{for } k = (2Q+1), \dots, P, \\ (-\omega^2 - i\omega p_{Rk}) \mathbf{X}_{R(k-Q)} &= \mathbf{q}_R & \text{for } k = (2Q+1), \dots, P.\end{aligned}\quad (20)$$

The interesting feature of Eq. (19) is that the force vectors are described in terms of polynomials of $i\omega$, of order 1. In comparison, Eq. (18) is more complicated with rational terms of $i\omega$. As for Eq. (20) — i.e., the relations between the displacement vectors and the vectors of supplementary variables — it also involves polynomials of $i\omega$ (up to order 2). By separating the terms of identical powers of $i\omega$ in Eqs. (19) and (20), and by invoking the classical time-frequency transforms $\mathbf{q}(\omega) \rightarrow \mathbf{q}(t)$, $i\omega \mathbf{q} \rightarrow \dot{\mathbf{q}}$, $-\omega^2 \mathbf{q} \rightarrow \ddot{\mathbf{q}}$ and $\mathbf{X}(\omega) \rightarrow \mathbf{X}(t)$, $i\omega \mathbf{X} \rightarrow \dot{\mathbf{X}}$, $-\omega^2 \mathbf{X} \rightarrow \ddot{\mathbf{X}}$

(where dot and double-dot notations mean single and double time derivatives, respectively), two classical second-order differential equations can be obtained:

$$\mathbb{M}_L \begin{bmatrix} \ddot{\mathbf{q}}_L \\ \ddot{\mathbf{x}}_L \end{bmatrix} + \mathbb{C}_L \begin{bmatrix} \dot{\mathbf{q}}_L \\ \dot{\mathbf{x}}_L \end{bmatrix} + \mathbb{K}_L \begin{bmatrix} \mathbf{q}_L \\ \mathbf{x}_L \end{bmatrix} = \begin{bmatrix} \mathbf{F}_L \\ \mathbf{0} \end{bmatrix}, \quad \mathbb{M}_R \begin{bmatrix} \ddot{\mathbf{q}}_R \\ \ddot{\mathbf{x}}_R \end{bmatrix} + \mathbb{C}_R \begin{bmatrix} \dot{\mathbf{q}}_R \\ \dot{\mathbf{x}}_R \end{bmatrix} + \mathbb{K}_R \begin{bmatrix} \mathbf{q}_R \\ \mathbf{x}_R \end{bmatrix} = \begin{bmatrix} \mathbf{F}_R \\ \mathbf{0} \end{bmatrix}, \quad (21)$$

where \mathbf{X}_L and \mathbf{X}_R are vectors built from all the vectors of supplementary variables \mathbf{X}_{Lk} and \mathbf{X}_{Rk} . Eq. (21) can be simply integrated into a FE model of a periodic structure (N substructures). Thus, the FE model of a periodic structure with absorbing boundary conditions can be written in the time domain as follows:

$$\mathbf{M}_{\text{tot}} \ddot{\mathbf{y}} + \mathbf{C}_{\text{tot}} \dot{\mathbf{y}} + \mathbf{K}_{\text{tot}} \mathbf{y} = \mathbf{F}_{\text{tot}}, \quad (22)$$

where

$$\mathbf{y} = \mathbf{y}(t) = \begin{bmatrix} \mathbf{q}_I(t) \\ \mathbf{q}_L(t) \\ \mathbf{q}_R(t) \\ \mathbf{X}_L(t) \\ \mathbf{X}_R(t) \end{bmatrix}, \quad \mathbf{F}_{\text{tot}} = \mathbf{F}_{\text{tot}}(t) = \begin{bmatrix} \mathbf{F}_I(t) \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \end{bmatrix}, \quad (23)$$

where \mathbf{q}_I and \mathbf{F}_I represent the displacement vector and force vector (time loadings) for the internal DOFs (between the left and right ends). Eq. (22) is a classical second-order differential equation which can be solved in a standard way via time integration numerical schemes (e.g., Newmark scheme). For instance, the time response of an infinite periodic structure, with 2D substructures, subject at its center to a shock (transverse Ricker wavelet force pulse) is analyzed. Here, a periodic structure consisting of only 20 substructures (squares with holes, meshed with 2D plane stress triangular elements) is considered. Absorbing boundary conditions are invoked at the left and right ends of the periodic structure, as discussed earlier. For comparison purposes, a FE model of a much longer periodic structure with free ends and 200 substructures, aiming at modeling an infinite structure, is simulated. Results are shown in Fig. 6 for the time history and the displacement field at $t = 0.01$ s, which fully validate the proposed approach.

Figure 6: Time response of the periodic structure: (left) time history at the right end (reference FE: red line; proposed approach: blue crosses); (right) deformed shape.

2.4 Some results about locally resonant metamaterials

The analysis and design of locally resonant metamaterials is a research topic of growing interest, which is mostly due to their ability to create band gaps and strongly attenuate the vibration levels of structures [31, 1, 35, 8, 33]. Band gaps refer to frequency bands in which

one or several waves do not propagate, and which are here induced by the local resonances of the substructures (cells).

Among the resonant metamaterials are those made up of multi-layered continuous substructures combining soft and heavy materials (e.g., soft and stiff/heavy layers/core) which behave like a single or multi-DOF mass-spring system. For instance, a periodic structure with periodic inclusions of viscoelastic layers (spring and damping effects) and heavy parts (mass effect) is shown in Fig. 7. The goal of the present study is to analyze the band gap effect in such periodic structures. Also, it aims at investigating whether periodic structures with viscoelastic properties can be used to create band gaps with larger bandwidths (compared to when purely elastic properties are considered), to make them useful for a wider range of engineering applications.

Figure 7: Periodic structure with $N = 10$ squared substructures with two viscoelastic layers (rubber), a heavy layer and a heavy core (tungsten).

Following the WFE procedure, the wave properties of the periodic structure and the related forced response can be obtained straightforwardly. Attention must be paid, however, to the FE modeling of the viscoelastic layers and the fact that their stiffness matrices depend on the frequency (see [21] for further details):

$$\mathbf{K}_v^{\text{vel}}(\omega) = \mathbf{K}_{v\infty} + \sum_{i=1}^{n_v} \mathbf{K}_{vi} \left(\frac{\omega^2 \tau_i^2}{1 + \omega^2 \tau_i^2} + i \frac{\omega \tau_i}{1 + \omega^2 \tau_i^2} \right), \quad (24)$$

where τ_i are relaxation times with $\tau_i = 10^{-i}$ s for $i = 1, 2, \dots, n_v$. The stiffness matrix of a whole substructure involves assembling several FE viscoelastic layers (v) together with FE elastic layers (e), i.e.:

$$\mathbf{K}(\omega) = \mathbf{K}_1 + \mathbf{K}_2(\omega), \quad (25)$$

where

$$\mathbf{K}_1 = \sum_{e=1}^{N^{\text{el}}} (1 + i\eta_e^{\text{el}}) (\mathcal{L}_e^{\text{el}})^T \mathbf{K}_e^{\text{el}} \mathcal{L}_e^{\text{el}} + \sum_{v=1}^{N^{\text{vel}}} (\mathcal{L}_v^{\text{vel}})^T \mathbf{K}_{v\infty} \mathcal{L}_v^{\text{vel}}, \quad (26)$$

and

$$\mathbf{K}_2(\omega) = \sum_{v=1}^{N^{\text{vel}}} \sum_{i=1}^{n_v} (\mathcal{L}_v^{\text{vel}})^T \mathbf{K}_{vi} \mathcal{L}_v^{\text{vel}} \left(\frac{\omega^2 \tau_i^2}{1 + \omega^2 \tau_i^2} + i \frac{\omega \tau_i}{1 + \omega^2 \tau_i^2} \right), \quad (27)$$

where $\mathcal{L}_e^{\text{el}}$ and $\mathcal{L}_v^{\text{vel}}$ are localization (Boolean) matrices, and η_e^{el} denotes the loss factors of the elastic parts. As it turns out, the dynamic stiffness matrix of the substructure is expressed by $\mathbf{D} = -\omega^2 \mathbf{M} + \mathbf{K}_1 + \mathbf{K}_2(\omega)$. Numerical issues about the condensation of the dynamic stiffness matrix on the left and right boundaries of the substructure (see Sec. 2.1) are discussed in [21]. Results about the dispersion curves of the bending wave are shown in Fig. 8, e.g., when $n_v = 5$

(number of terms in the series in Eq. (24)) and $\mathbf{K}_{vi} = 0.05 \times \mathbf{K}_{v\infty}$ ($i = 1, \dots, 5$). The structure of interest is shown in Fig. 7. Here, squared substructures with two viscoelastic layers (rubber, $N^{\text{ve}1} = 2$) and elastic parts including an external layer in aluminum, a central layer and a core in tungsten ($N^{\text{el}} = 3$), are considered. Here, each substructure is meshed using 20×20 eight-node plane stress quad elements. For comparison purposes, a purely equivalent elastic structure, when $\mathbf{K}_v^{\text{ve}1} = \mathbf{K}_{v\infty}(1 + 5 \times 0.05)$, is also considered.

Band gaps occur when the real parts of the wavenumbers are equal to 0 or π/d (d being the substructure length). The dispersion curves displayed in Fig. 8 represent plots of the functions $\omega \mapsto \Re\{\beta d\}$ and $\omega \mapsto \Im\{\beta d\}$ where β is the wavenumber for the bending wave. Associated to the band gap behavior — when $\Re\{\beta d\} = 0$ or $\Re\{\beta d\} = \pi$ — are local increases of the magnitude of the imaginary part of the wavenumber, which means that the wave is becoming evanescent. The band gap effect in resonant metamaterials mostly relies on the presence of substructure local modes. For instance, the fixed interface mode shapes of a purely equivalent elastic substructure are shown in Fig. 8, which could help understand the physical behavior of the structure in the vicinity of band gaps. As expected, band gap phenomena yield strong reduction of the vibration levels of the structure. Here, a structure with $N = 10$ substructures with prescribed transverse harmonic displacement at the right end is considered. For instance, two locally resonant band gaps appear at 742 Hz and 984 Hz which are close to each other. In the purely elastic case, the vibration levels show two local minima around these frequencies which appear to be well separated to each other. The interesting feature in the viscoelastic case is that these frequency bands with minimum vibration levels tend to merge to produce a wide frequency band (i.e., between 700 Hz and 1100 Hz) where, overall, the vibration levels remain low. This opens interesting prospects for the passive vibration control of structures.

Additional results about 1D periodic structures and resonant or non-resonant (Bragg) band gaps can be found in [30] (aircraft structures) and [2] (rotating phononic crystal ring).

3 2D PERIODIC STRUCTURES

3.1 Wave approaches and the modeling of structures of finite dimensions

The dynamic analysis of 2D periodic structures like metamaterial plates with resonant substructures constitutes a research topic of growing interest which mostly rely, with the era of 3D printing, on the ability to design and manufacture such structures at a low cost. A schematic of a 2D periodic structure made up of resonant layered substructures (soft layer and heavy core) is shown in Fig. 9. From the FE point of view, there exist plenty of works analyzing the propagation of Bloch waves in infinite 2D periodic structures and the related band gap effects. These approaches can be classified in two ways:

1. Those where a Bloch solution $\mathbf{u}(\mathbf{x}, \boldsymbol{\beta}, t) = \tilde{\mathbf{u}}(\mathbf{x}, \boldsymbol{\beta})e^{i(\omega t - \boldsymbol{\beta}^T \mathbf{x})}$ ($\boldsymbol{\beta} = [\beta_x \beta_y 0]^T$: wavenumber vector with $\beta_x = \beta \cos(\theta)$ and $\beta_y = \beta \sin(\theta)$; $\mathbf{x} = [x \ y \ z]^T$: position vector; $\tilde{\mathbf{u}}(\mathbf{x}, \boldsymbol{\beta})$: periodic function) is considered in the dynamic equilibrium equation of a cell (see for instance [9, 4]). The resulting dynamic equation of the cell together with the periodicity conditions for $\tilde{\mathbf{u}}(\mathbf{x}, \boldsymbol{\beta})$ are then converted into a FE model (Galerkin method), yielding a generalized eigenproblem of the form $\mathbf{A}(\beta_x, \beta_y)\tilde{\mathbf{q}} = \omega^2 \mathbf{B}(\beta_x, \beta_y)\tilde{\mathbf{q}}$ for the eigenvalue ω^2 and the eigenvector $\tilde{\mathbf{q}}$. The computation of the so-called band diagrams then involves plotting the pulsation ω for some pre-determined values of β_x and β_y following the first irreducible Brillouin zone.
2. Those where a FE model of a substructure is considered and where pseudo-periodic conditions are applied to its boundary. For substructures with rectangular boundaries (e.g., of lengths L_x and L_y), the pseudo-periodic conditions write $\mathbf{q}_R = e^{-i\beta_x L_x} \mathbf{q}_L$ between the left (L) and right (R) edges, $\mathbf{q}_T = e^{-i\beta_y L_y} \mathbf{q}_B$ between the bottom (B) and top (T) edges, $\mathbf{q}_{RB} = e^{-i\beta_x L_x} \mathbf{q}_{LB}$ between the left-bottom and right-bottom corners, $\mathbf{q}_{LT} = e^{-i\beta_y L_y} \mathbf{q}_{LB}$ between the left-bottom and left-top corners, and $\mathbf{q}_{RT} = e^{-i(\beta_x L_x + \beta_y L_y)} \mathbf{q}_{LB}$ between the left-bottom and right-top corners (see for instance [14, 25]). By considering the FE model of a substructure together with these pseudo-periodic conditions, a generalized eigenproblem of the form $\mathbf{A}(\beta_x, \beta_y)\tilde{\mathbf{q}} = \omega^2 \mathbf{B}(\beta_x, \beta_y)\tilde{\mathbf{q}}$ can be proposed (again) for computing the band diagrams of the structure.

Figure 9: 2D periodic structure and FE mesh of a substructure (red spots highlight boundary nodes).

Although well detailed in the literature, the dynamic analysis of 2D periodic structures that uses wave approaches appears quite restricted to infinite systems where waves are supposed to

propagate freely, or infinite systems subject to point forces (see for instance [5]). In contrast, the analysis of 2D periodic structures of finite dimensions — i.e., systems which are frequently encountered in engineering applications — is not well reported. The thing is, the modeling of 2D periodic structures of finite dimensions via wave approaches appears to be a tough task (as opposed to the 1D periodic case) mostly due to the multi-directional behavior of the propagating waves, and the description of the boundary conditions (or coupling conditions) using these multi-directional waves.

Fortunately, there remain several FE-based reduced models which can be used to simulate the dynamic behavior of finite periodic structures, at a low computational cost. Indeed, by considering the periodicity hypothesis into account, the FE models of the substructures are identical and, therefore, they can be efficiently reduced via component mode synthesis like the Craig Bampton (CB) method. In fact, since the substructures are identical, their component modes are identical too which means that they only have to be computed once, i.e., regardless of the number of substructures considered. Hence, the following transformation matrix, for all the substructures, can be proposed [20]:

$$\tilde{\mathbf{T}} = \begin{bmatrix} \mathbf{I}_{N_B} & \mathbf{0} \\ -(\mathbf{K}_{II})^{-1}\mathbf{K}_{IB} & \tilde{\mathbf{X}} \end{bmatrix}, \quad (28)$$

where $-(\mathbf{K}_{II})^{-1}\mathbf{K}_{IB}$ and $\tilde{\mathbf{X}}$ are the matrix of static modes and the matrix of fixed interface modes (a reduced set) of the substructures, respectively; N_B is the number of boundary DOFs of the substructures. The reduced dynamic equation of a substructure s follows as:

$$\left[(-\omega^2 + i\omega a)\tilde{\mathbf{M}} + (i\omega b + 1)\tilde{\mathbf{K}} \right] \begin{bmatrix} \tilde{\mathbf{u}}_B^s \\ \tilde{\boldsymbol{\alpha}}^s \end{bmatrix} = \begin{bmatrix} \mathbf{F}_B^s - \mathbf{K}_{BI}(\mathbf{K}_{II})^{-1}\mathbf{F}_I^s \\ \tilde{\mathbf{X}}^T \mathbf{F}_I^s \end{bmatrix}, \quad (29)$$

where notation “ \mathbf{u} ” is used to denote displacement vectors (instead of “ \mathbf{q} ”); $\tilde{\mathbf{u}}_B^s$ is the approximated displacement vector for the boundary nodes; $\tilde{\boldsymbol{\alpha}}^s$ is a vector of generalized coordinates; \mathbf{F}_B^s and \mathbf{F}_I^s are force vectors for the boundary and internal nodes (respectively); a and b are damping coefficients (Rayleigh damping). Also, $\tilde{\mathbf{M}}$ and $\tilde{\mathbf{K}}$ are the reduced mass and stiffness matrices of the substructure (similar for all the substructures), expressed by:

$$\tilde{\mathbf{M}} = \tilde{\mathbf{T}}^T \mathbf{M} \tilde{\mathbf{T}}, \quad \tilde{\mathbf{K}} = \tilde{\mathbf{T}}^T \mathbf{K} \tilde{\mathbf{T}}. \quad (30)$$

The reduced global mass and stiffness matrices of a whole 2D periodic structure — namely, $\tilde{\mathbf{M}}_{\text{per}}$ and $\tilde{\mathbf{K}}_{\text{per}}$ — follow from conventional FE assembly procedures by considering the displacement continuity conditions at the boundary DOFs. The global dynamic equation of the periodic structure follows as:

$$\left[(-\omega^2 + i\omega a)\tilde{\mathbf{M}}_{\text{per}} + (i\omega b + 1)\tilde{\mathbf{K}}_{\text{per}} \right] \begin{bmatrix} (\tilde{\mathbf{u}}_B)_{\text{per}} \\ \tilde{\boldsymbol{\alpha}}_{\text{per}} \end{bmatrix} = \tilde{\mathbf{F}}_{\text{per}}, \quad (31)$$

where $(\tilde{\mathbf{u}}_B)_{\text{per}}$ is the displacement vector of the boundary/interface nodes of the substructures. In addition, the boundary conditions of the periodic structure may be written in a general way as:

$$\mathbf{Y}_B(\tilde{\mathbf{u}}_B)_{\text{per}} + \mathbf{Z}_B(\tilde{\mathbf{F}}_B)_{\text{per}} = \mathbf{Y}_B^0(\tilde{\mathbf{u}}_B)_{\text{per}}^0 + \mathbf{Z}_B^0(\tilde{\mathbf{F}}_B)_{\text{per}}^0, \quad (32)$$

where $(\tilde{\mathbf{u}}_B)_{\text{per}}^0$ and $(\tilde{\mathbf{F}}_B)_{\text{per}}^0$ are vectors of prescribed displacements and prescribed forces, respectively, and where \mathbf{Y}_B , \mathbf{Z}_B , \mathbf{Y}_B^0 and \mathbf{Z}_B^0 are matrices whose expressions depend on the kind of applications considered. A second reduced mode expansion can be proposed to speed up the computation of the matrix system (31) by expressing the displacement vector $(\tilde{\mathbf{u}}_B)_{\text{per}}$ on some “boundary modes” (eigenvectors) for the matrix pencil $((\tilde{\mathbf{K}}_{BB})_{\text{per}}, (\tilde{\mathbf{M}}_{BB})_{\text{per}})$.

3.2 2D nearly periodic structures

It is well known that nearly periodic structures — e.g., periodic structures with disordered resonant substructures with slightly varying geometrical properties — possess interesting properties, e.g., the fact that the vibrational energy is localized around the excitation points [3, 13]. For instance, a schematic of a nearly periodic plate with layered substructures (soft layer and heavy core), embedded in a floor panel, is shown in Fig. 10.

Figure 10: 2D nearly periodic plate embedded in a floor panel, and related transverse displacement field resulting from harmonic excitations.

A strategy for modeling such nearly periodic structures has been recently proposed in [20] and is briefly summarized here. The key idea for describing disordered substructures is to make use of distorted FE meshes, with node positions which randomly vary around a baseline (undistorted) mesh:

$$x_j^{se} = x_j^e + \epsilon_x^s f_x(x_j^e, y_j^e) \quad , \quad y_j^{se} = y_j^e + \epsilon_y^s f_y(x_j^e, y_j^e), \quad (33)$$

where (x_j^{se}, y_j^{se}) and (x_j^e, y_j^e) are the node coordinates of the distorted and undistorted meshes, respectively; ϵ_x^s and ϵ_y^s are uniform random variables with support $[-\delta, \delta]$ where δ is a dispersion parameter; $f_x(x, y)$ and $f_y(x, y)$ are two arbitrary deterministic functions of (x, y) , identical for all the substructures, which are supposed to cancel out on the boundary. Examples of distorted substructures are highlighted in Fig. 10.

When it comes to nearly periodic structures, the modeling of substructures raises two main issues compared to the purely periodic case. First, since the substructures are not identical, their mass and stiffness matrices \mathbf{M}^s and \mathbf{K}^s have to be computed several times (as many times as the number of substructures considered); second, the matrices of static modes and fixed interface modes $-(\mathbf{K}_{II}^s)^{-1}\mathbf{K}_{IB}^s$ and $\tilde{\mathbf{X}}^s$, and also the reduced mass and stiffness matrices $\tilde{\mathbf{M}}^s$ and $\tilde{\mathbf{K}}^s$ (matrix multiplications with the transformation matrix, see Eq. (30)), have to be computed several times. For structures with many substructures, this makes the CB method ineffective. To address these issues — i.e., to avoid computing the reduced mass and stiffness matrices many times — it is proposed to compute these matrices at some points $\epsilon_x^s = (\epsilon_x)_p$ and $\epsilon_y^s = (\epsilon_y)_p$ (a small number) for some particular distorted FE meshes of the substructures, and approximate these matrices between these points via matrix interpolation for any distortion ϵ_x^s and ϵ_y^s . Although easy to understand, the procedure for interpolating matrices is not straightforward, however, and requires the reduced matrices to be expressed using coordinate systems which are

compatible to each other [26]. For this task, the following alternative reduced matrices of fixed interface modes, at the interpolation points, can be considered [20]:

$$\widehat{\mathbf{X}}_p = \widetilde{\mathbf{X}}_p (\Psi^T \widetilde{\mathbf{X}}_p)^{-1}, \quad (34)$$

where

$$\Psi = \left((\mathbf{M}_{\text{II}}^0)^{\frac{1}{2}} \right)^T \widetilde{\mathbf{X}}^0. \quad (35)$$

Here, notations \mathbf{M}_{II}^0 and $\widetilde{\mathbf{X}}^0$ mean that the matrices \mathbf{M}_{II}^s and $\widetilde{\mathbf{X}}^s$ are expressed at $\epsilon_x^s = 0$ and $\epsilon_y^s = 0$. As a result, the following transformation matrix, reduced mass matrix and reduced stiffness matrix can be proposed:

$$\widehat{\mathbf{T}}_p = \begin{bmatrix} \mathbf{I}_{N_B} & \mathbf{0} \\ -(\mathbf{K}_{\text{II}})_p^{-1} (\mathbf{K}_{\text{IB}})_p & \widehat{\mathbf{X}}_p \end{bmatrix}, \quad (36)$$

$$\widehat{\mathbf{M}}_p = \widehat{\mathbf{T}}_p^T \mathbf{M}_p \widehat{\mathbf{T}}_p, \quad \widehat{\mathbf{K}}_p = \widehat{\mathbf{T}}_p^T \mathbf{K}_p \widehat{\mathbf{T}}_p. \quad (37)$$

The determination of the interpolated reduced mass and stiffness matrices — namely, $\widehat{\mathbf{M}}^s$ and $\widehat{\mathbf{K}}^s$ — for any substructure s with mesh parameters (ξ^s, η^s) follows from classic interpolation, e.g., using an interpolation scheme based on eight interpolation points (ξ_p, η_p) and eight Serendipity interpolation functions $N_p(\xi^s, \eta^s)$, as shown in Fig. 11. Thus:

$$\widehat{\mathbf{M}}^s = \sum_{p=1}^8 N_p(\xi^s, \eta^s) \widehat{\mathbf{M}}_p, \quad \widehat{\mathbf{K}}^s = \sum_{p=1}^8 N_p(\xi^s, \eta^s) \widehat{\mathbf{K}}_p, \quad (38)$$

where :

$$\xi^s = \sqrt{2} \frac{\epsilon_x^s}{\delta}, \quad \eta^s = \sqrt{2} \frac{\epsilon_y^s}{\delta}. \quad (39)$$

The modeling of a whole 2D nearly periodic structure follows from classic FE assembly procedure, as reported earlier.

Numerical experiments can be carried out to validate the proposed strategy. Let us consider, for instance, a nearly periodic plate with 8×4 substructures embedded in a floor panel and subject to random forces, as shown in Fig. 12 where simply supported boundary conditions are considered. Typical distorted substructures are shown in Fig. 10 and are meshed using 20×20 isoparametric quadratic Mindlin elements. Concerning the distorted meshes of the substructures, $f_x(x_j^e, y_j^e)$ and $f_y(x_j^e, y_j^e)$ are chosen as trigonometric functions, while $\delta = 0.01$ m (mesh dispersion).

The frequency responses of the structure (quadratic velocities at the location of the excitation points) over a frequency band of $[0, 150]$ Hz, obtained from the interpolation strategy and the conventional FE modeling, are shown in Fig. 13 where good matches are observed. The eigenfrequencies of the undistorted substructures (fixed interfaces) are shown with dotted vertical red lines. For the purely periodic case, these frequencies correspond to band gap effects where vibration levels are low.

Also, the transverse displacement fields of the plate/panel at 125 Hz are shown in Fig. 14 for the nearly and purely periodic cases. For the nearly periodic case, the displacement field shows localized peaks of high magnitude in the plate, and small displacement levels in the floor. In comparison, the periodic case involves uniform (diffuse) field in the plate, and higher displacement levels in the floor. In this sense, the nearly periodic plate appears to be a suitable means to passively control the vibration levels of the floor. Finally, in terms of computational times, the interpolation strategy provides an overall time reduction of 82% compared to the FE method.

4 CONCLUSION

An overview of some wave approaches and FE-based procedures, for modeling periodic structures and metamaterials, has been proposed. For 1D periodic structures, the WFE method has been investigated and some recent advances in this field have been presented. For 2D periodic structures, a reduced FE modeling of the substructures based on the CB method has been proposed. The procedure has been extended to the dynamic analysis of 2D nearly periodic structures (with substructures having randomly varying geometrical properties) via the use of distorted FE meshes and the interpolation of the reduced matrices of the substructures between “interpolation points” (some particular distorted meshes). Those wave approaches and FE procedures have been proven relevant for predicting the dynamic behavior of periodic structures including metamaterials with resonant cells that could be of various shapes. The dynamic analysis of periodic structures is a research topic in constant progress. This concerns the wave

propagation analysis in infinite systems, but also, the study of systems of finite dimensions (one or several, possibly coupled together). Follow-on works could include the analysis of periodic structures with localized nonlinear effects, e.g., metamaterials with local nonlinear resonant devices, or structures locally subject to fast loadings of high magnitudes (shocks, blast).

Abstract

Although the seismic performance of non-structural elements is currently recognised as a key issue in the seismic behaviour and loss estimation of buildings, both at the individual and portfolio level, the accurate evaluation of the seismic demand to which the former are subjected is still an open issue. Code formulations, as well as simplified methodologies for regional scale applications, are often based on inaccurate distributions of peak floor accelerations and floor spectral accelerations. In this respect, one of the main shortcomings in the formulations available in the literature is related to the effect of masonry infills on Floor Response Spectra (FRS), which is generally neglected, even in recently proposed design/assessment-oriented simplified methodologies. This study highlights and quantifies the impact of different masonry infill typologies on FRS estimates in existing infilled reinforced concrete (RC) frames. Nonlinear time history analyses are carried out for different case-study RC frames, selected from a fully integrated building portfolio, representative of buildings designed according to the Italian codes in force between 1970 and 1980. To account for the infill-related uncertainty, a macro-level distinction of common infill types, in terms of shear strength, was used. Moreover, the influence of the geometrical configuration and the number of storeys was also investigated. Acceleration FRS were then computed and statistically characterised, based on the observed infill-to-infill-related variability.

1 INTRODUCTION

The earthquake related economic losses observed in the last decades were often attributed, for a good share, to damage to non-structural elements (NSEs), as reported in post-earthquake surveys [1,2]. NSEs represent all the systems and elements attached to the floors and walls of a building that are not part of the vertical and lateral load-bearing structural systems [3] but that are subjected to the same dynamic excitation during a seismic event. As reported by Miranda and Taghavi [4], NSEs represent the largest portion of the total investment in typical buildings. At the same time, the damage to NSEs can also represent a threat to life mostly because of falling hazards. Due to the numerous typologies of NSEs installed in a building, their vulnerability could significantly affect the immediate functionality because they generally exhibit damage at low (serviceability) seismic intensities, while the supporting structures respond mainly in the elastic range. This issue is paramount for strategic facilities, such as hospitals and schools that should remain operational in post-earthquake emergency situations. In Italy, for instance, the actual repair costs of reinforced concrete (RC) residential buildings damaged by the 2009 L'Aquila Earthquake, involved majorly the repair of infills and partitions [1,5-7]. Indeed, hollow clay brick walls, typical of Mediterranean construction standards, are characterised by brittle behaviour, which resulted in significant earthquake damage [5]. In particular, the costs related to structural elements did not exceed the 10% of the total repair costs; the remaining 90% was related to NSEs, such as infill walls and partitions (about 47%), plumbing and electrical systems, which are commonly incorporated in hollow clay brick (around 16%), windows and doors (around 22%), and other elements (15% approximately). Similar observations were made following the 2012 Emilia Earthquake and the 2016 Amatrice Earthquake [1,5-7], where it was reported that most of the NSE failures were related to partition walls experiencing large in-plane drifts and/or out-of-plane collapse (OOP), as well as damage to storage rack systems and ceiling systems [1,8].

NSEs are generally classified into different performance groups, according to their sensitivity to a specific engineering demand parameter (EDP); the main distinction is between acceleration-sensitive and drift-sensitive NSEs. For example, infill walls, partition walls and glazing systems are vulnerable to storey drifts whereas bookshelves, suspended ceilings, light fixtures, piping systems and rigidly attached elements are examples of acceleration sensitive NSEs. It is worth mentioning that infill and partition walls are also vulnerable to OOP collapse, which could be caused by floor accelerations. Consequently, the seismic performance assessment of NSEs requires the characterisation of the structural response in terms of inter-storey drifts and absolute acceleration floor response spectra (FRS), respectively, for drift-sensitive and acceleration-sensitive NSEs.

The lack, or in some cases the questionable accuracy, of code prescriptions and code-compliant guidelines [9,10], has oriented the recent past research efforts towards the development of simplified methodologies to predict absolute acceleration and displacement FRS for elastic and inelastic single-degree-of-freedom (SDOF) and multi-degree-of-freedom (MDOF) systems [11–18]. Such methodologies are particularly useful, given that accurate FRS estimates require complex and demanding nonlinear time-history analysis (NLTHA). Petrone et al. [11] proposed a methodology to predict absolute acceleration FRS calibrated using a set of RC moment resisting frames designed according to Eurocode 8 [9] and subjected to frequent (serviceability-level) earthquake ground motions. Sullivan et al. [12] proposed a simplified approach to predict absolute acceleration FRS for linear and nonlinear SDOF structures, which was subsequently extended to linear and nonlinear MDOF systems [13,14]. Another approach, proposed by Vukobratovic and Fajfar [15], was calibrated for both elastic and inelastic SDOF and MDOF structures. In the case of MDOF structural systems, the resulting FRS were obtained

by a combination of the FRS obtained for individual vibration modes; a significant influence of higher modes on FRS was observed. Recently, other methodologies were also developed by Calvi [16] to evaluate relative-displacement FRS and by Merino et al. [17] to predict consistent absolute acceleration and relative displacement FRS, which can be used within displacement-based seismic design of NSEs [18].

2 RESEARCH METHODOLOGY

It was highlighted in the Introduction how the performance of new and existing buildings is strictly related to that of NSEs and how, for such reasons, research efforts have been made with the aim to develop simplified methodologies to predict absolute acceleration and displacement FRS for elastic and inelastic SDOF and MDOF systems [11–18]. As also previously discussed, some simplified methods are available in the literature to predict the FRS of RC buildings [11,14,15] but the influence of masonry infills, which are typically present in Italy and other Mediterranean countries, was not considered in any of them.

Few studies have investigated the influence of masonry infills on FRS in RC buildings [19,20]. Lucchini et al. [19] investigated the influence of masonry infills and damping models on FRS in nonlinearly analysed buildings, pointing out how the infill walls can significantly affect the peak floor acceleration profile at a given intensity, as well as the FRS at all storeys in terms of spectral acceleration and shape. More recently, Surana et al. [20] studied the effect of unreinforced masonry infills on the inelastic FRS of RC frame buildings; the outcomes demonstrated that the influence of masonry infills cannot be neglected in the evaluation of FRS in RC frames, especially for frequent earthquakes, for which cracking developing in the masonry is generally not expected and the uncracked stiffness of the infills tends to be considered. Recently, Perrone et al. [21], by means of Monte Carlo simulation, analysed a database of European masonry-infilled RC frames and computed absolute acceleration and relative displacement FRS at different floor levels for both bare and infilled frame archetypes using NLTHA. As a result, a first model was proposed for regional scale application, to evaluate the seismic demand to which the NSEs are subjected, taking the effect of masonry infills explicitly into account.

With such considerations in mind, this paper deals with the evaluation of absolute acceleration FRS of bare and infilled frames, with the aim of (i) highlighting the difference between the results for these two structural configurations and (ii) quantifying the impact of masonry infills on the FRS. A fully integrated building stock, recently assessed by means of nonlinear static analysis in [22], is considered as case-study. In particular, the RC buildings built between 1970 and 1980, one of the decades with massive construction in Italy, are focused on. Figure 1 presents the research approach workflow of the study, while more information related to the case-study building portfolio can be found in [22]. Once the building stock was defined, NLTHAs were performed to record the accelerations at two different floor levels (first and roof floor) and the FRS were then computed from floor acceleration time-histories recorded along the structure's height. Finally, the comparison of FRS at two intensity levels, corresponding to Serviceability Limit State (SLS) and Life Safety Limit State (LSLS), are presented for both infilled and bare frames.

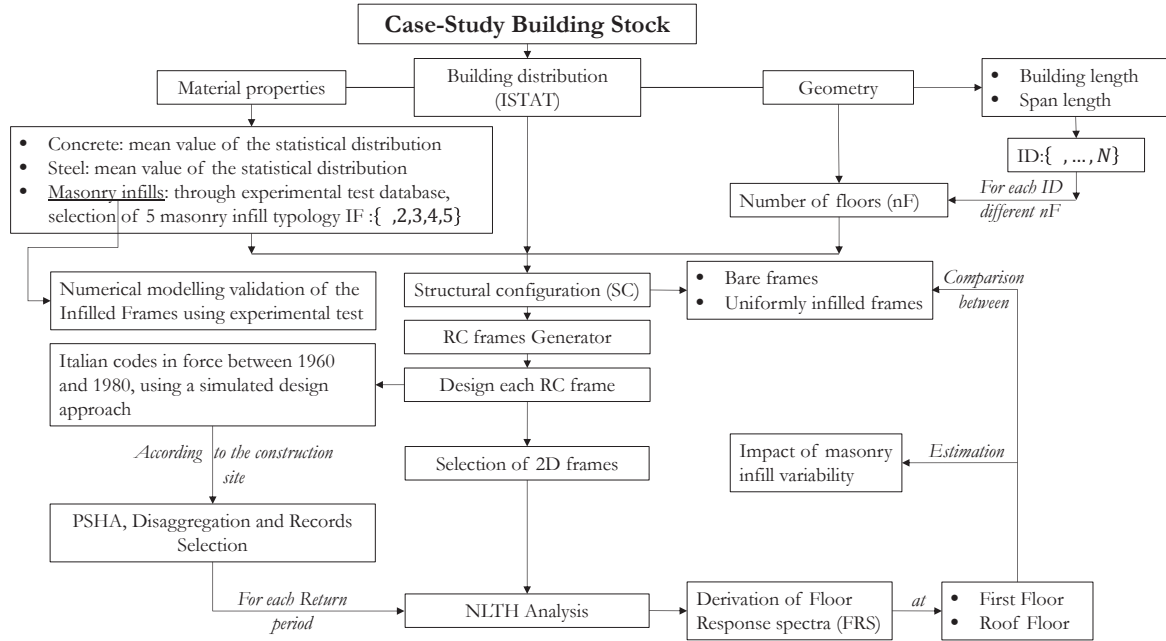

Figure 1: Research approach workflow.

3 RESEARCH METHODOLOGY

A building portfolio representing existing masonry-infilled RC residential buildings in Italy has been analysed in this study. It accounts for both the building geometrical layout and infills variability, characterised from statistical data collected from ISTAT [23] and from databases comprising information regarding experimental tests carried out on different masonry infill typologies [24-26]. According to the data provided by ISTAT [23], in Italy, there are 3 594 695 RC residential buildings, representing around 30% of the entire building stock, whereas 57% are in masonry and 13% correspond to other structural typologies (e.g. steel, precast). These buildings can be disaggregated as a function of the construction year, which allows to identify the building codes employed for their design, the material properties, the construction practice and the structural detailing. Most of the RC residential buildings in Italy were built before 1990 and, analysing the ISTAT database, no correlation between period of construction and geographical area has been found, demonstrating a quasi-uniform building construction trend over the national territory. Following such a preliminary analysis, this study is focused on RC buildings built between 1960 and 1980, decades with massive construction of such a building typology and during which an update of the seismic design guidelines was introduced. In order to fully develop the building portfolio, the variability in the following parameters has been considered: plan dimension, number of floors, inter-storey height, span length, material properties of RC elements and of masonry infills.

3.1 Building stock

In this section, the development of the building portfolio is summarised while interested readers can refer to Mucedero et al. [22] for full details. With the aim to define a statistically representative building stock, the data provided by ISTAT [23] was used, however, specific information, such as the material properties, number of floors, building height and plan dimensions, were aggregated or were not reported. For example, the ISTAT database does not provide information about the buildings' plan dimension; however, for residential buildings, it could be estimated using data from urbanistic directives and population distribution. Combining

this information with satellite images [27] for different geographical areas in Italy, a more precise and accurate definition of the plan dimensions was achieved. In particular, the range of variation of the plan dimensions in the longest and shortest dimensions (L_x and L_y) was estimated as in between 10-50 m and 8-25 m, respectively. Regarding the number of floors, including the ground floor, almost half of the buildings consist of two storeys, whilst only 10% have four or more storeys. Furthermore, the data provided by ISTAT [23] aggregated all the buildings with more than four storeys into a single class, making a further disaggregation difficult. As such, the defined building stock consists of RC frames with a number of storeys varying from one to six. Considering the design practice and common architectural trends, the inter-storey height was fixed at 3.0 m and span lengths were limited to the range of 3.0-5.0 m. Since no information is provided in ISTAT [23] about structural element properties, additional information was collected analysing the codes in force during the selected construction period, as well as original drawings of residential buildings from different geographical areas in Italy.

The mechanical properties of the materials used in the selected construction period (1970-1980) were obtained from the results of in-situ tests on existing buildings or from data collected in laboratory archives [28,29]. Considering the wide range of steel properties adopted in the reference construction period, it was chosen to use a yielding strength of 350 MPa. The ratio between the ultimate and the yielding strength was assumed as 1.4 [28]. Regarding the diameter of the longitudinal bars, 14 mm was chosen according to the mean value provided in Verderame *et al.* [28]. For what concerns the concrete strength, exhaustive information is presented in Masi *et al.* [29], from a large database of test results on concrete cores extracted from about 300 RC public buildings located in the Basilicata region (Italy), for which the mean strength and dispersion for different construction periods were provided. The test results showed mean values of concrete strength in the construction periods 1961–1971 and 1972–1981 of 19.53 MPa and 21.03 MPa, respectively. Although these tests were based on concrete strength of hospital and school buildings, this information was deemed suitable for residential buildings thus 20 MPa was considered as mean concrete strength in the period 1970-1980. The assumption of mean values for the concrete strength and for the ultimate and yielding strength of steel reinforcements is in accordance with the results pointed out in Celarec *et al.* [30], Dolšek [31], Mohammad *et al.* [32], in which it was showed that those parameters have limited effect on the dispersion when compared to other sources of uncertainty.

Despite the high-level of uncertainty surrounding the masonry infill properties, constant mechanical and geometrical properties of the masonry infills are typically assumed in seismic risk assessment studies of single buildings or at regional scale. To the authors' best knowledge, results of in-situ tests on masonry infills are not available; hence, the results of experimental studies [33-36], also reported in recent databases dealing with the definition of the mechanical properties of masonry infills [24,26], are taken into account to define a range of variability. Such variability is related to many parameters, such as the maximum shear strength of the panel, the stiffness of the panel, the relative stiffness between the panel and the surrounding frame, the vertical/horizontal compressive strength of the masonry, vertical/horizontal modulus of elasticity and thickness of the masonry.

This study considered, firstly, based on the results provided by Mucedero *et al.* [37], a macro-level distinction of the infills in terms of shear strength, which, according to the results of the works by Blasi *et al.* [38] and Mohammad *et al.* [32], is one of the most important, affecting the lateral capacity of RC frames and that could also lead to local shear failure (e.g. shear failure of columns that were built without particular construction details). Five masonry infill typologies, from weak to strong, classified according to the shear strength (Table 1) were thus selected as representative of the existing masonry infill typologies used in RC residential buildings built between 1970 and 1980 in Italy.

References	Type	Macro classification	t_w [mm]	E_{wv} [MPa]	E_{wh} [MPa]	G_w [MPa]	f_{wv} [MPa]	f_{wlat} [MPa]	f_{wu} [MPa]

Table 1: Representative masonry infills.

Considering the wide spectrum of characteristics of the selected infill typologies, it is believed that, even if some typologies that can be found in existing buildings are not represented, due for example to the variation in the thickness of the panels, the combination of five different masonry infill typologies is representative enough. Moreover, comparing the ranges of minimum and maximum values of the main mechanical properties (Young's modulus (E_w), shear modulus (G_w), peak load (F_{peak}) and the cracking strength (F_{cr})) provided in the database by De Risi *et al.* [26], it is possible to see that the selected masonry infill typologies cover the entire range of variation.

The design of the buildings was then carried out using a simulated design approach, according to the codes in force between 1970 and 1980 [39,40]. Table 2 summarises the main geometrical and material parameters considered in this study to define the building portfolio. The results of the simulated design are in good agreement with those provided in Bal *et al.* [41] and Silva *et al.* [42].

The case-study building portfolio comprised a total of 108 geometrical configurations, given by the combination of the different variables. In specific, the number of bays and the length of the analysed 2D masonry infilled RC frames vary according to the data reported in Table 2 for L_y (8-25 m). The span length varies between 3 m and 5 m, with increments of 1 m, while the height of the buildings varies between 3 m and 18 m, with increments of 3 m (the inter-storey height). Seven discrete building lengths were selected from the range of L_y (8-25 m) and combined with equally discrete possible different span lengths, leading to 18 different geometrical configurations (labelled as ID-1 to ID-18). Each of these was then combined with six different building heights, leading to 108 geometrical configurations, and with the five masonry infill typologies, leading to a total of 648 RC frames, subdivided as follows: 108 bare frames and 540 uniformly infilled frames.

<i>Description</i>	<i>Variable</i>	<i>Range</i>
Building length X direction	L_x	[10-50] m
Building length Y direction	L_y	[8-25] m
Span length	b_x or b_y	[3-5] m
Number of storeys	n	[1-6]
Interstorey height	h	3.0 m
Steel yield strength	f_y	350 MPa
Longitudinal rebar diameter	ϕ_l	14 mm
Stirrup diameter	ϕ_s	8 mm
Concrete compressive strength	f_c	20 MPa
Concrete cover	c	20 mm
Column height	h_c	[300-550] mm
Beam height	h_b	[300-400] mm
Column or beam width	b_c or b_b	300 mm
Masonry infill	IF	Type: [1-5]

Table 2: Geometrical and material parameters, together with corresponding ranges, considered for the definition of the case-study building portfolio.

3.2 Numerical Modelling

An advanced nonlinear numerical model was developed to account for the many phenomena that may occur in the buildings during an earthquake, such as: material and geometrical nonlinearity, bar slippage, flexible joints with likely shear failure, behaviour of poorly detailed and non-ductile RC frame members, premature shear failure, deficiencies in concrete core confinement due to stirrup spacing, inelasticity concentrated in the structural element ends, amongst others. To account for any potential structural deficiencies, the modelling approach proposed by O'Reilly *et al.* [43] and Perrone *et al.* [44] for older RC frames was followed, as shown in Figure 2. The numerical models were developed using OpenSees [45]. The flexural elements (i.e. beams and columns) were modelled through force-based beam-column elements with a modified Radau plastic hinge integration scheme, as suggested by Scott & Fenves [46], where the nonlinearity is lumped at the ends of the element and an aggregation section [45], V- γ and M- Θ , was introduced. The flexural behaviour was thus defined through the moment-curvature relationships proposed in [47], whereas the shear behaviour was modelled according to Zimos *et al.* [48], in which the backbone shear deformation curve consists of four phases, namely: initial elastic behaviour, post-cracking, peak response and strength degradation. To capture the nonlinear behaviour of joints, a zero-length spring coupled with a rotational hinge was adopted, which represents the shear joint behaviour; its hysteretic behaviour was calibrated according to different experimental tests [49-52]. Regarding damping, 5% tangent stiffness proportional Rayleigh damping at the fundamental periods was adopted.

The uniaxial nonlinear Pinching4 Material model has been adopted to simulate the hysteretic behaviour of the masonry infills; all the parameters defining the equivalent strut's hysteretic behaviour were not selected a priori but rather calibrated considering the specific features of each masonry infill typology, defined according to the numerical modelling validation recently carried out by Mucedero *et al.* [37]. More details on the numerical modelling approach and validation of the response of both bare and masonry infilled RC frames using experimental testing results are provided in [37].

Figure 2: Numerical modelling of RC members, beam-column joints and masonry infills.

3.3 Seismic Hazard modelling and ground motion Record Selection

The OpenQuake [53] software was used to perform the seismic hazard computations, adopting the SHARE Project [54] source model and the GMPE proposed by Boore & Atkinson [55]. The hazard curve corresponding to the average spectral acceleration (AvgSa), the chosen intensity measure (IM), for the period range 0.01-2.0 s for the city of L'Aquila (Italy) was derived and, accordingly, a total of 30 pairs of ground motion records were selected, for each IM level, from the PEER NGA-West database [56]. Two IM levels were selected according to the limit states defined in [57], namely Serviceability Limit State (SLS) and Life Safety Limit State (LSLS), corresponding to return periods (T_r) of 50 and 475 years, respectively. Figure 3 illustrates the two target spectra and the corresponding empirically derived conditional spectra (CS) of the selected record ensembles based on CS(AvgSa). It is worth mentioning that the two presented limit states are of paramount importance in the Italian “Guidelines for the seismic risk classification of constructions,” in which technical principles for exploiting tax deductions with respect to seismic strengthening interventions on existing buildings (Sismabonus) have been defined [58].

Figure 3: Comparison between the two target spectra and the corresponding empirically derived conditional spectra of the selected record ensembles based on CS(AvgSa): (left) Serviceability Limit State (SLS) and (right) Life Safety Limit State (LSLS)

4 DERIVATION OF FLOOR RESPONSE SPECTRA

The results of NLTHAs of the 2D frame buildings were used to derive absolute acceleration FRS (AFRS). The 5%-damped AFRS were evaluated by subjecting the building portfolio to the selected set of ground motions and then using numerical techniques to compute the FRS from floor acceleration time-histories recorded along the structure's height, for the two structural configurations (i.e. bare and infilled frames). For the sake of brevity, only the AFRS of the first and roof storeys, for the two selected IM levels, are presented; in the case of the one-storey RC frames, the AFRS are not plotted for the first storey because the first and roof storeys coincide.

4.1 Bare frames

Figure 4 plots the AFRS for the bare frames for the SLS return period. The dynamic properties of the RC frames in the case-study building portfolio are comprehensively presented in [22], in particular, the median, 16th and 84th percentile of the first elastic period of vibration (T_1). For the complete building portfolio, T_1 varies in the range of [0.44-1.99 s]. For each plot in Figure 4, the median acceleration floor response spectra (MAFRS) taken across the ground motions ensemble are presented in bold, while the grey-filled area represents the envelope defined by the 16th and 84th percentiles, representing both the record-to-record variability and the geometrical layout variability.

Analysing the first storey AFRS (Figure 4a), it is possible to observe that the floor spectral acceleration (S_a) in correspondence of higher modes is governing the response, except for the two-storey buildings, in which S_a at the fundamental period is still relevant. As regards the AFRS at the roof level (Figure 4b), one-storey buildings are characterised by a single peak that lies at a period close to the fundamental period of the structure, whereas when increasing the number of storeys, the higher modes have a significant impact on the shape of MAFRS. In the MAFRS, the S_a values are higher in correspondence of higher modes, except for the two-storey buildings for which S_a at the fundamental period is still higher than the ones due to the higher modes. For three- to six-storey buildings, the shape of the MAFRS is quite similar and the peaks are less pronounced. For all the buildings, for periods longer than the fundamental period, the S_a tends to reduce and it is close to zero for long periods. For both first and roof levels the record-to-record-related variability and the geometrical layout variability is low and quite similar when varying the number of storeys, as would be somehow expected for such a low return period.

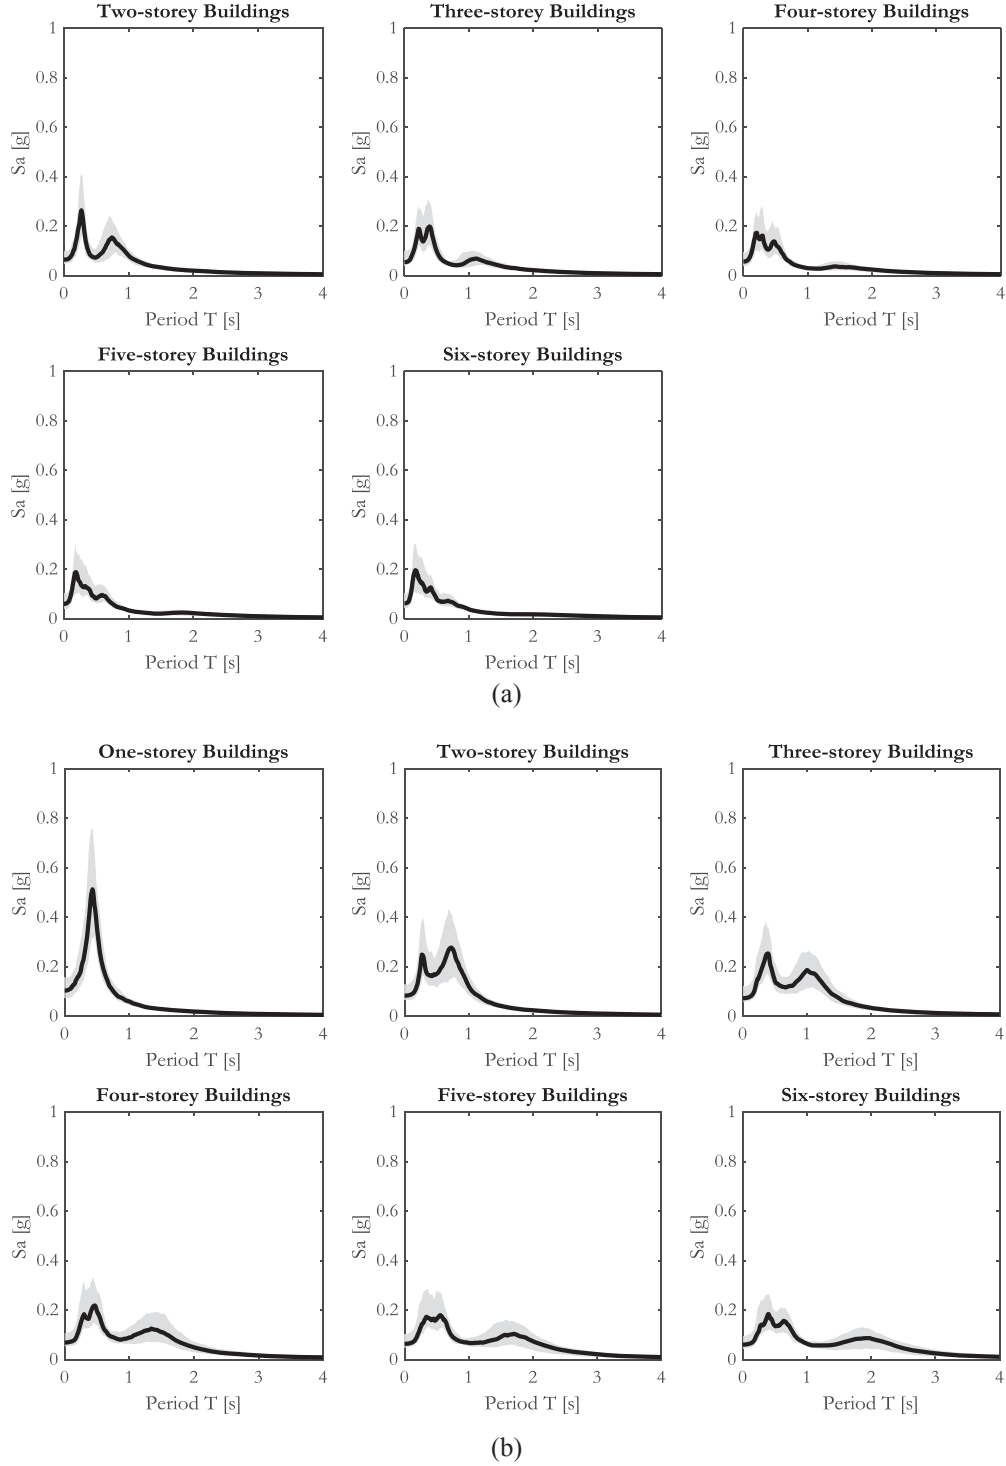

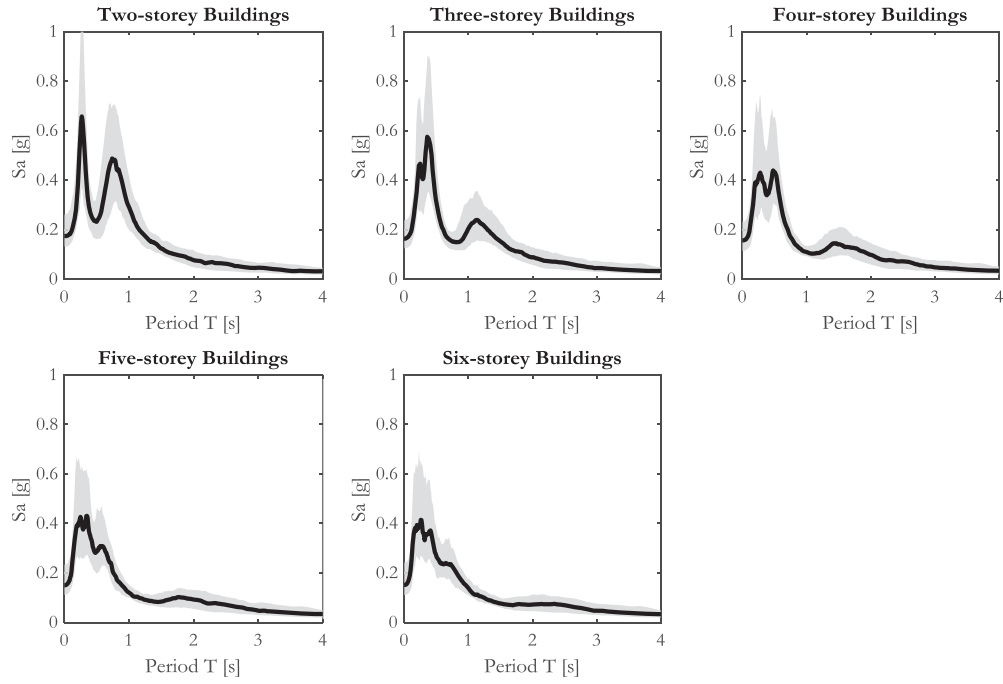

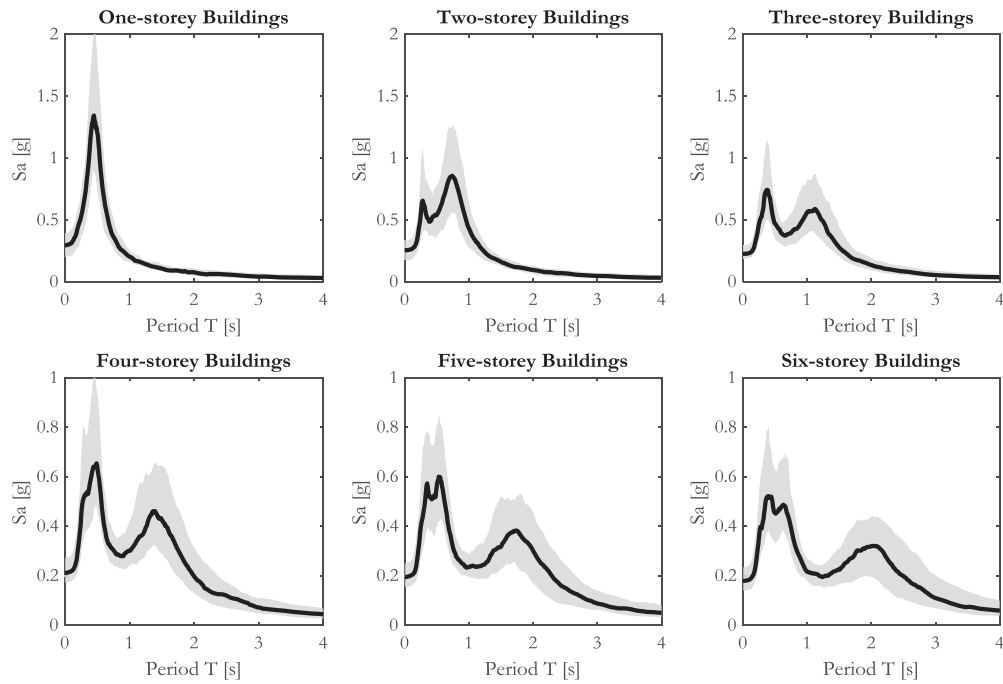

Figure 4: Acceleration floor response spectra, $\xi=5\%$, at (a) first level and (b) roof level for the bare frame structural typology at SLS ($T_r = 50$ years). Median values (black line), envelope (grey-filled area) of 16th and 84th percentile of AFRS over the entire building portfolio, by aggregating the IDs.

Increasing the ground motion IM level, considerations similar to those reported for the SLS can be made (see Figure 5), albeit the surrounding variability is higher. As expected, the amplitudes of S_a significantly increase, whereas the MAFRS shape is almost unaffected. Also, for LSLs, the MAFRS of the five- and six-storey buildings at the roof level exhibit a smoother shape with a plateau in correspondence of the higher modes, in contrast to the other

configurations, for which a well-defined peak is obtained. The large influence of the higher modes is the consequence of the long fundamental periods associated with the bare configurations, in particular for RC frames with more than three storeys.

(a)

(b)

Figure 5: Acceleration floor response spectra, $\xi=5\%$, at (a) first level and (b) roof level for the bare frame structural typology at SLSL ($T_r = 475$ years). Median values (black line), envelope (grey filled area) of 16th and 84th percentile of AFRS over the entire building portfolio, by aggregating the IDs.

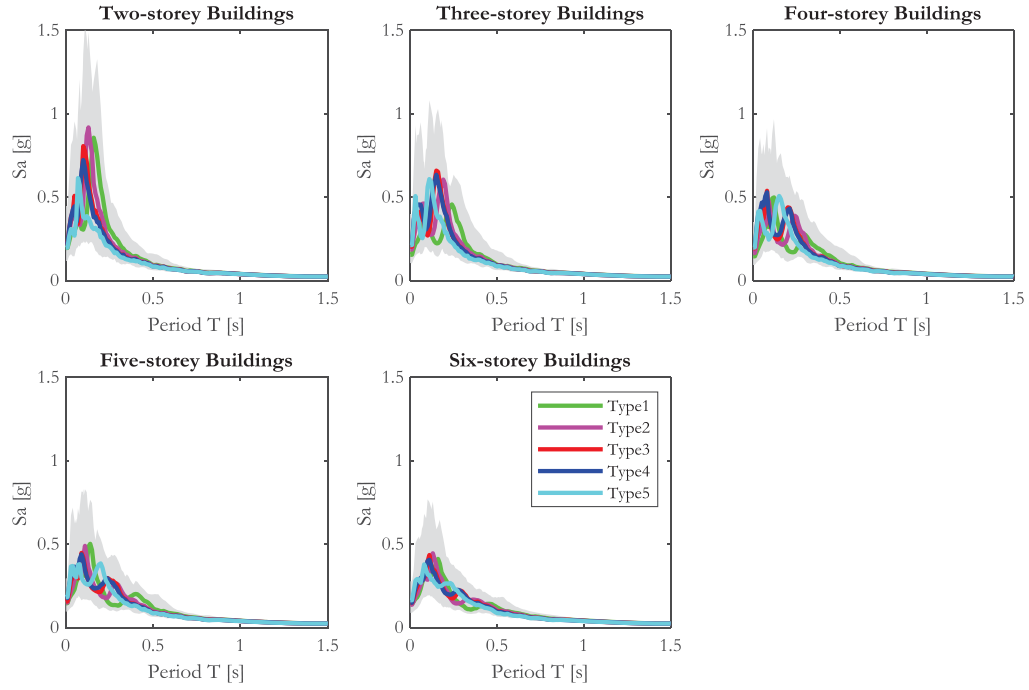

4.2 Infilled frames

For what concerns the AFRS for the infilled configurations, the macro-level distinction of the infills in terms of shear strength, based on the results provided in Mucedero *et al.* [22], is used. The results of the eigenvalue analyses carried out to characterise the dynamic properties of the case-study building portfolio, as well as the variability due to different typologies of masonry infills, are comprehensively presented in [22], through median, 16th and 84th percentiles of the first elastic period of vibration, T_1 . This period varies in the range [0.04-0.075 s] and [0.194-0.374 s] for single-storey and six-storey buildings, respectively. This highlights the significant impact of the masonry infills and their variability on the fundamental period of the case-study RC frames. Figures 6 and 7 plot the MAFRS and the area defined by the 16th and 84th percentiles for the first (Figures 6a and 7a) and roof (Figure 6b and 7b) levels, considering both seismic intensity levels (SLS in Figure 6 and SLSL in Figure 7). The MAFRS are reported for all considered masonry infill typologies. In contrast to Figure 4, the grey-filled areas in Figure 6 and Figure 7 are representative of the record-to-record variability, the geometry variability and the variability due to the masonry infill typology.

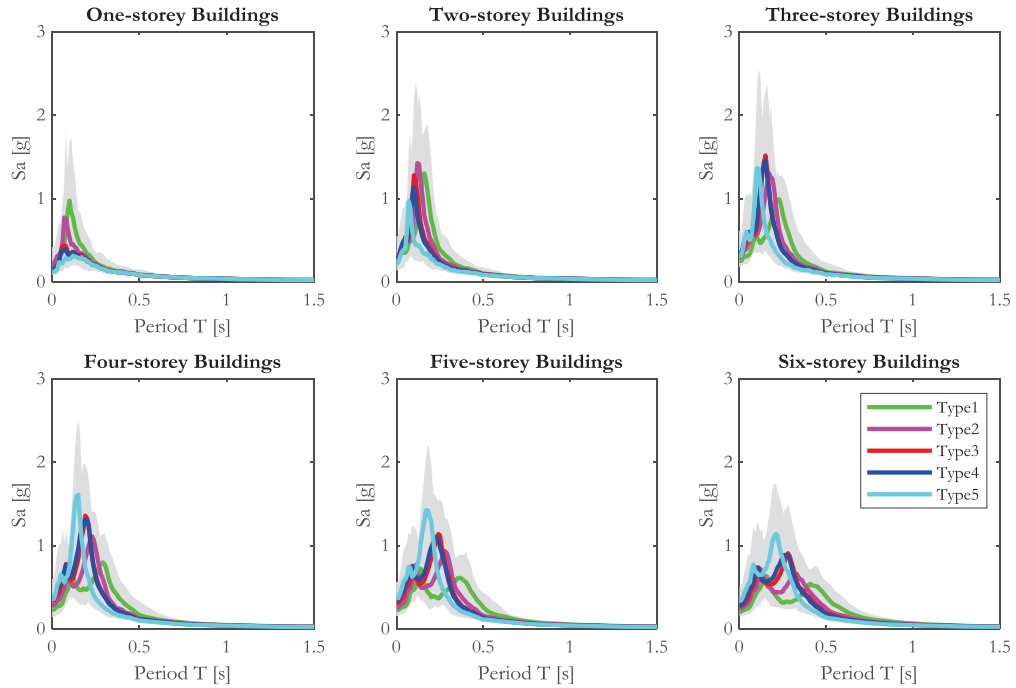

Looking at the first-storey AFRS (Figure 6a), the S_a values in correspondence of the higher modes are well evident, exception made for the two- and three-storey buildings, in which S_a at the fundamental period is also relevant. The impact of different masonry infill typologies is quite evident for low-rise buildings, whereas, for taller buildings, the AFRS at the first storey are less affected by the masonry infill typology, resulting in more similar trends and comparable values. Considering the AFRS at the roof level (Figure 6b), the influence of higher modes, in terms of maximum S_a , is reduced with respect to the AFRS at the first storey, whereas the higher S_a values are close to T_1 . Moreover, the differences coming from the masonry infill typology are more remarkable. For lower buildings, the higher S_a values are due to the weak and weak-to-medium masonry infills, whereas increasing the number of storeys, this trend is reversed, with the higher S_a values observed for the medium-to-strong and strong masonry infills.

In both cases, the envelope of the 16th and 84th percentiles, is quite wide; the differences of median MAFRS values, as a function of the masonry infill typology, are higher at the roof level than those at the first storey. For instance, considering the four-storey buildings, when changing infill type 5 to infill type 1, the median values of MAFRS at first storey decrease of only 4%, whereas the decrease is close to 50% when the roof-level MAFRS are taken as reference.

Moreover, considering the six-storey buildings, the peak value of MAFRS at roof level decreases of almost 44%, when comparing infill type 5 (strong) with infill type 1 (weak). This trend is quite similar also in case of four- and five-storey buildings, with the peak value of MAFRS that decreases of almost 48÷50%, when comparing the aforementioned infill typologies. For three-storey buildings, the MAFRS decreases of almost 27%, changing infill type 5 to infill type 1. The trend is reversed for lower buildings: for one- and two-storey buildings, comparing infill type 1 with infill type 5, the MAFRS ordinates decrease of almost 68% and 26%, respectively. The median S_a , as a function of the considered masonry infills, is in the range of [0.37÷0.85g] and [0.3÷1.61g] for AFRS at first and roof levels, respectively.

(a)

(b)

Figure 6: Acceleration floor response spectra, $\xi=5\%$, at (a) first level and (b) roof level for the infilled frame structural typology at SLS ($T_r = 50$ years). Median values of FRS for each infill typology over the entire buildings, by aggregating all the IDs, and envelope (grey-filled area) of 16th and 84th percentile for each infill typology.

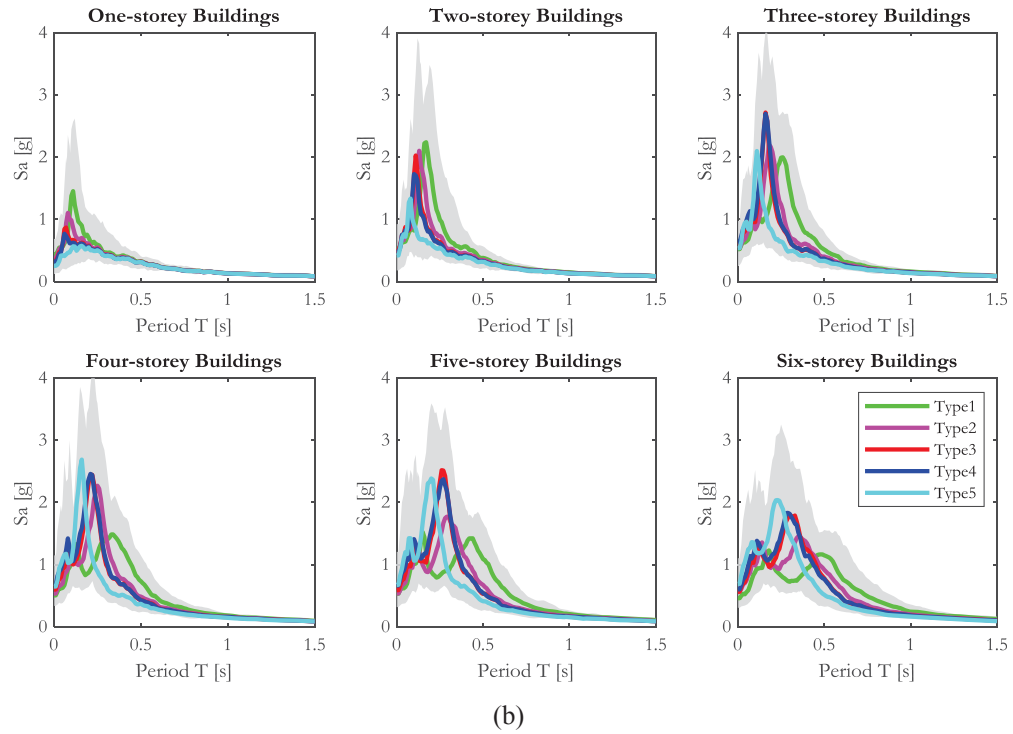

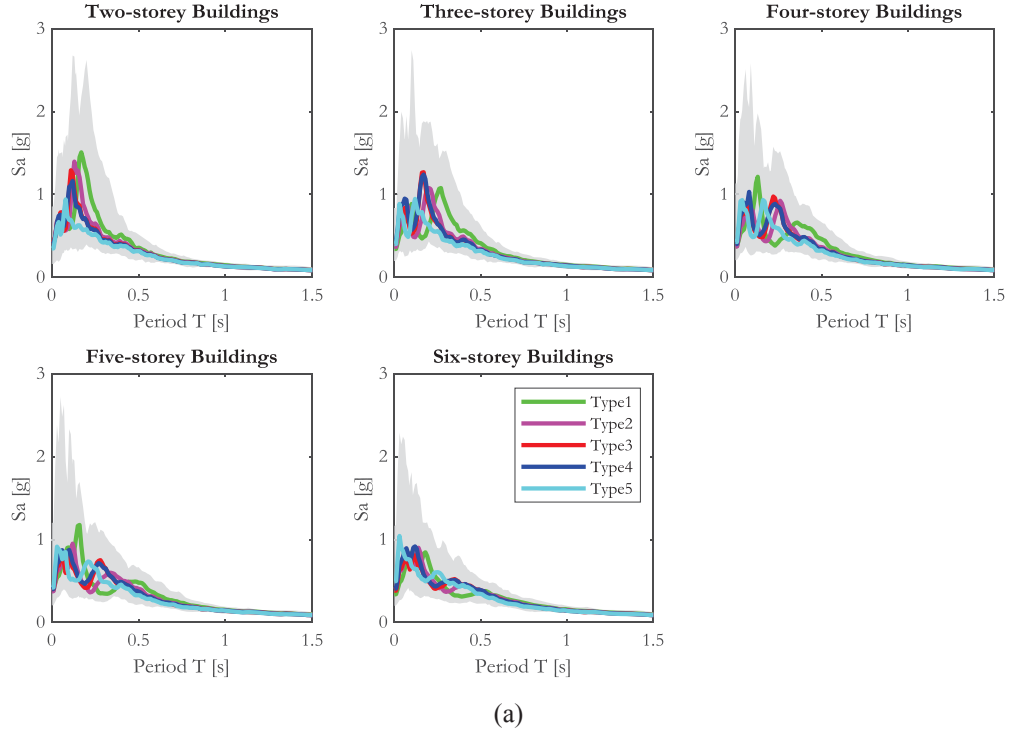

Figure 7: Acceleration floor response spectra, $\xi=5\%$, at (a) first level and (b) roof level for the infilled frame structural typology at SLSL ($T_r = 475$ years). Median values of FRS for each infill typology over the entire building portfolio, by aggregating all the IDs, and envelope (grey-filled area) of 16th and 84th percentile for each infill typology.

Regarding the AFRS at LSLs (Figure 7), with respect to the results at SLS, no significant changes are observed in terms of AFRS shape. As expected, the median S_a values are higher than those at the SLS. Also for the LSLs, the impact of masonry infill properties is less significant for the AFRS at first storey, except for one- and two-storey RC frames, while it is

significant at roof level. Also in this case, for lower-rise buildings, the higher values of the S_a are due to weak and weak-to-medium masonry infills, whereas for taller buildings the trend is reversed, with the higher values generated by medium-to-strong and strong masonry infills. The median S_a , as a function of infill typology, is in the range of $[0.91 \div 1.51g]$ and $[0.57 \div 2.69g]$, respectively, for AFRS at first and roof level. Moreover, as regards the envelope of the 16th and 84th percentiles, the variability is quite different as a function of the period of the NSEs considered. Given three different periods T and considering the AFRS recorded at roof level for the SLSL, the maximum differences between the 16th and 84th percentiles are in the following ranges: (i) $[0.74 \div 3.02g]$ for $S_a(T=0.2s)$, (ii) $[0.19 \div 1.4g]$ for $S_a(T=0.5s)$, and (iii) $[0.007 \div 0.23g]$ for $S_a(T=1.0s)$. This variability also increases with the number of storeys, particularly for the shorter periods.

Considering the six-storey buildings, the peak value of MAFRS at the roof level decreases of almost 43%, when comparing infill type 5 (strong) with infill type 1 (weak). This trend is quite similar also in the case of four- and five-storey buildings, with peak values of MAFRS that decrease almost 40÷44%, when comparing infill type 5 with infill type 1. For three-storey buildings, the MAFRS peak decreases of around 5%, going from infill type 5 to infill type 1. Conversely, for lower buildings (one- and two-storey buildings), when changing infill type 1 to infill type 5, the MAFRS peak decreases of almost 60% and 40%, respectively. Regardless of the LS considered, for both first and roof storeys, the variability surrounding the MAFRS is quite significant. Additionally, regardless of the IM investigated, the variability due to masonry infills' properties is less significant for periods longer than 1 s.

4.3 Comparison of MAFRS for bare and infilled frame configurations

For completeness, and to further highlight the differences in the shape and on the S_a intensity at different periods between the two structural configurations, the results of MAFRS for infilled and bare frames are compared herein. Figure 8 illustrates the 5%-damped MAFRS at the first and roof levels for SLSL, for both structural configurations. Regardless of the selected masonry infill type, the shape of the FRS for the infilled frames is quite different from the ones derived for the bare frame configurations. The S_a peaks are in the range of $0 \div 0.5$ [s] in the case of infilled frames, whereas in case of bare frames, due to a longer first elastic period, the S_a peaks are not restricted to a limited range of periods but are rather associated with a wider period range of $0.2 \div 2$ [s]. Moreover, it is noteworthy that for the bare frame's portfolio analysed, the S_a peaks, due to higher mode effects, are in the range of $0 \div 0.7$ [s], depending on the number of storeys. In the latter range, the S_a intensity of the bare frame configuration is lower than the one of the infilled frame configurations for the vast majority of cases.

As regards the S_a at different periods, a quite relevant impact of the masonry infills on the AFRS is observed, especially until 0.5 s, whereas for higher periods the S_a of bare frames are most often higher than those of the infilled frames. There are some expected implications of such differences in terms of seismic risk, at both single-building and portfolio scale. For instance, if for an infilled frame the acceleration sensitive non-structural components are characterised by a period of vibration in the range of $0 \div 0.5$ [s], the seismic demand in terms of acceleration on those components would be completely different and much higher than that derived from a bare frame configuration. Moreover, since the simplified methods available in the literature do not account for the presence of masonry infills, the impact of the latter on the shape and on the S_a magnitude itself could be underestimated, even significantly, in comparison with NLTHA-driven counterparts.

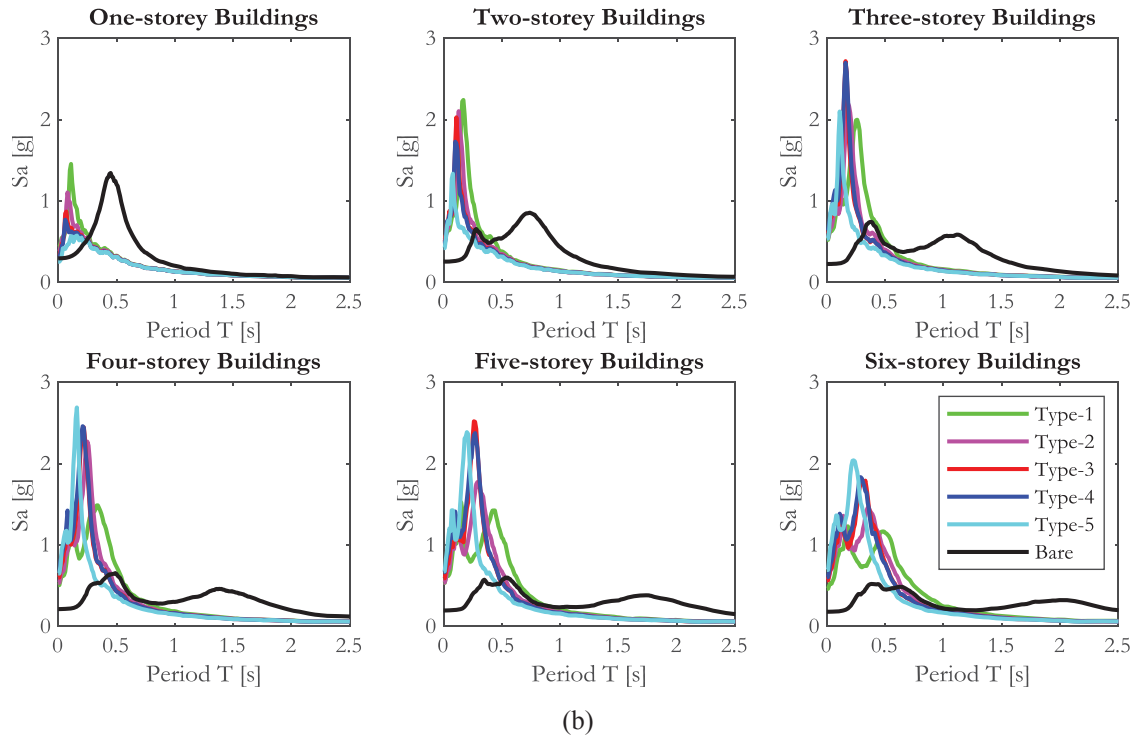

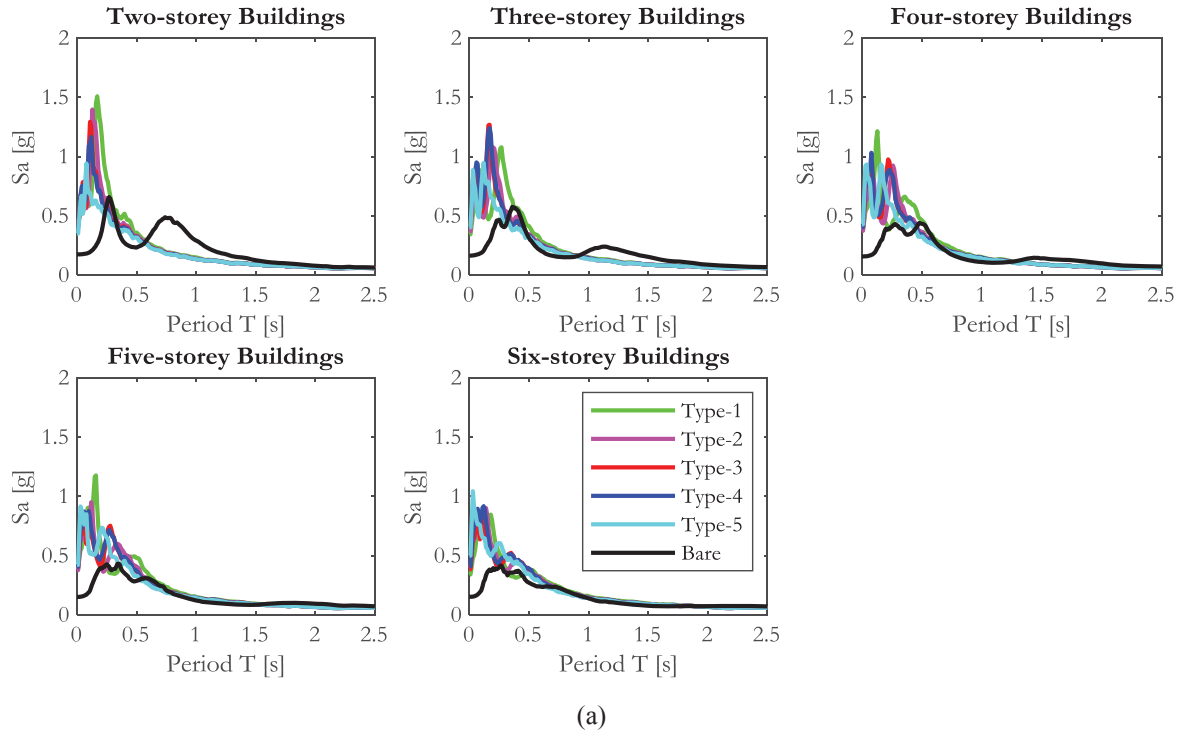

Figure 8:MAFRS for both infilled and bare frame structural typology, $\xi=5\%$, at (a) first level and (b) roof level for SLSL.

5 CONCLUSIONS

Significant efforts have been made in the recent past to investigate the influence of masonry infills on the seismic performance of existing RC buildings. However, less attention has been paid to the evaluation of the role of their variability on peak floor accelerations and floor response spectra. To address this gap, this study investigates the influence of different typologies of masonry infills on the acceleration floor response spectra (AFRS), as well as the differences in terms of S_a intensity and shape of AFRS between infilled and bare frames. In particular, a macro-level distinction of masonry infills that defines five typologies, representative of the infill properties commonly adopted in the European context, has been used.

The results of this study quantitatively pointed out how the seismic demand to which the NSEs are subjected is significantly affected by the interaction of the masonry infills with the surrounding RC frames and by the variability in their mechanical properties. Neglecting the masonry infills in the numerical modelling should therefore be avoided, paying careful attention to the structural details of the analysed building (i.e. masonry infills connected or disconnected to surrounding frame). The AFRS have been compared in detail for two different storeys and considering two seismic intensity levels. The floor spectral accelerations (S_a) recorded in the infilled frames are significantly higher than those observed in the bare frames, for both considered storey levels and seismic intensities. In terms of AFRS shape, the ones for bare frame are generally smoother, while in the infilled frames the S_a peaks that lay at the fundamental periods of the RC frames are more evident. The impact of the variability in the masonry infills is evident, although different trends are observed for low-rise and medium-rise buildings. In particular, for lower buildings, the higher S_a values are due to weak and weak-to-medium masonry infills, whereas for taller buildings the trend is reversed, with the higher values generated by medium-to-strong and strong masonry infills.

These results can be used, for instance, to correctly define the seismic demand imposed on NSEs and, consequently, to realistically perform the design or assess expected annual losses. Moreover, this study further demonstrates that the variability related to the masonry infills induces significant dispersion on the AFRS and sheds light into how neglecting the masonry infill variability can be highly misleading and lead to results that are not realistic, particularly for seismic demand on NSEs in regional-scale frameworks. Although some simplified methods are available in the literature and codes to predict the FRS of RC buildings, the influence of masonry infills, which are typically present in the Italian and European building portfolios, has not yet been comprehensively accounted for. For this reason, it is evident that further efforts are still required to improve such simplified methodologies.

Abstract

Currently, in the framework of performance-based earthquake engineering, the seismic assessment of buildings should be performed by considering the safety of non-structural components. This is necessary to protect human life safety from their collapse, as well as to limit the economic losses associated with their damage. Typically, the safety assessment of non-structural components is performed with a force-based approach, i.e., by comparing their force/acceleration capacity with the expected force/acceleration demand under the design earthquake scenario, i.e., with reference to different limit states.

Different acceleration demand models, i.e., floor response spectra, exist, but relatively few of them were defined by considering the influence on the structural response of the in-plane response of infill walls, and none of them by considering the so-called “in-plane/out-of-plane interaction” effects. In other words, it is nowadays well known that the out-of-plane damage of unreinforced masonry infills affects their in-plane response, thus influencing the seismic response (and the floor response spectra) of the supporting structure.

In this paper, non-linear time-history analyses are performed on reinforced concrete framed buildings with different number of storeys, design level, and infill wall layout. The analyses are performed on the bare structure as well as on the infilled structure by considering and by not considering the in-plane/out-of-plane interaction effects in the infill wall model. The acceleration floor spectra derived from the analyses are compared, thus investigating the potential effect of the in-plane/out-of-plane interaction effect on the expected acceleration demand acting on infill walls.

Keywords: RC structure, infill wall, out-of-plane, seismic assessment, floor spectrum.

1 INTRODUCTION

In the framework of performance-based earthquake engineering, the seismic assessment of nonstructural components is a paramount issue: in fact, most of the earthquake-induced damage to buildings and the consequent economic losses is related to the response of nonstructural elements. Nonetheless, the heavy damage of certain nonstructural components, such as infill walls, may even threaten human life safety. For these reasons, there is need for the development of robust and reliable models for the assessment of capacity and demand associated with nonstructural elements. This work is focused on the definition of the acceleration demand acting on them, i.e., on floor response spectra.

Floor response spectra are a useful tool for the assessment of the pseudo-acceleration demand acting on acceleration-sensitive nonstructural components within a linear force-based approach, which is typical of the design process of new buildings. To understand what a floor spectrum is, the simplest way is considering the usual approach to the seismic analysis of a building. It is well-known that a structure subjected to a certain earthquake, i.e., to a certain ground motion acceleration time-history, will experience a certain maximum acceleration demand which is different from the maximum acceleration demand at its base, which is also known as Peak Ground Acceleration (PGA). This occurs since the ground motion is filtered by the structure through its mass, deformability and damping properties, thus resulting in an acceleration response history of the structure different from that applied to the base and in a maximum pseudo-acceleration demand named pseudo-spectral acceleration (S_a) different from PGA. The S_a acting on a certain structure represented by an equivalent Single Degree of Freedom (SDOF) system characterized by vibration period T and damping ratio ξ can be simply calculated through the pseudo-acceleration response spectrum of the ground motion. Similarly, the maximum pseudo-spectral acceleration, herein identified as PSA, acting on a nonstructural component represented by an SDOF system with vibration period T_a and damping ratio ξ_a supported by a certain floor of a structure can be calculated through the pseudo-acceleration response spectrum of the acceleration time-history of the supporting floor. This pseudo-acceleration response spectrum is known as floor response spectrum.

In other words, a stiff nonstructural component (i.e., a nonstructural component with $T_a=0$) attached to a certain floor of a structure will experience a PSA equal to the maximum acceleration demand of that floor, which is named Peak Floor Acceleration (PFA) and is different from the PGA. If T_a is higher than zero, the PSA will be different from the PFA dependently on T_a and ξ_a . These concepts are summarized in Figure 1.

So, based on the above discussion, the seismic demand acting on a certain nonstructural component supported by a certain floor of the structure can be known if the PFA of that floor and the floor spectral shape are known. In addition, based on the above discussion, it is possible to define some parameters that, intuitively, are expected to have an influence on the PFA and on the spectral shape. Regarding the PFA, one can expect its dependence on the PGA value (the higher the PGA, the higher the PFA) and on the height of the specific floor considered, z , potentially normalized with respect to the total building height, H . Regarding the spectral shape, one can expect that the PSA is amplified or de-amplified with respect to the PFA, with the maximum amplification expected due to resonance of the nonstructural component and of the structure, i.e., when T_a is closer to the fundamental vibration period(s) of the supporting structure. As will be shown later in this paper, further parameters may have a paramount influence on both the PFA distribution along the building height and the floor spectral shape.

Figure 1: Concept of floor response spectrum.

In this study, the state-of-the-art of current code and literature formulations is presented, mainly to define a systematic review of the geometric and mechanical structural parameters which are expected to influence the PFA distribution along the building height and the floor spectral shape. Second, nonlinear models of bare and infilled case-study reinforced concrete framed buildings with 2, 4, 6 and 8 storeys designed for different PGA levels (0.05 g, 0.15 g, 0.25 g and 0.35 g) according to Eurocodes are defined. Then, nonlinear time history analyses are performed on the case-study buildings to evaluate floor response spectra. The numerical outcomes are compared in order to analyze the effect of the presence of infill walls on floor response spectra considering and not considering the out-of-plane response of infill walls and the mutual interaction between their in-plane and out-of-plane response (i.e., the in-plane/out-of-plane interaction). To this aim, a recent out-of-plane and in-plane/out-of-plane interaction model proposed by the Authors of this study is updated in order to account for the potential softening and cyclic degradation of the out-of-plane response of infill walls. Note that modelling the out-of-plane response of infills and the in-plane/out-of-plane interaction is a novelty element for studies dedicated to floor spectra assessment, which rarely have been dedicated to infilled buildings in general.

2 SUMMARY OF EXISTING FORMULATIONS

Several studies have been dedicated to floor response spectra in past and recent times. Comprehensive state-of-the-art reviews are proposed by Rodriguez et al. [1] and by Vukobratović [2]. In this section, for the sake of conciseness, the discussion is focused on recent practice-oriented proposals available in the literature, as well as on main code prescriptions regarding this topic.

2.1 Code proposals

Eurocode 8 [3], in section 4.3.5, proposes an expression for the PSA as shown, with some manipulation in the nomenclature, in Equation 1.

$$PSA = PGA \left[\frac{3(1 + z/H)}{1 + (1 - T_a/T_1)^2} - 0.5 \right] \quad (1)$$

In Equation 1, T_a is the non-structural element vibration period and T_1 is the fundamental vibration period of the structure. If T_a equals zero, a linear PFA distribution along the building height is obtained at varying z/H ratio. PFA ranges from PGA (at z equal to zero) to 2.5PGA (at z equal to H). On the other hand, the maximum PSA is obtained if T_a equals T_1 . In this case, the maximum PSA ranges from 2.5PGA (at z equal to zero) to 5.5PGA (at z equal to H). It should be noted that this formulation returns a maximum PSA/PFA ratio different for each floor. This will be observed also from the numerical analyses performed in this study.

ASCE/SEI 7-10 [4], in section 13.3.1, proposes an expression for the PSA as shown, with some manipulation in the nomenclature, in Equation 2.

$$PSA = PGA \left(1 + 2 \frac{z}{H} \right) a_p \quad (2)$$

In Equation 2, a_p is a factor accounting for the amplification of accelerations due to the deformability of the non-structural element reported in Table 13.5-1 of the code. It is worth noting that the American approach, with this factor, simplifies the calculation of the seismic demand acting on non-structural elements, as there is no need of a more or less detailed dynamic characterization of the nonstructural element required for the determination of its period, T_a , which enters Eurocode 8 [3] formulation. Exterior non-structural wall elements, such as unreinforced masonry infills, are associated with an a_p factor equal to 1.00.

Also according to the ASCE/SEI 7-10 [4] approach, the PFA varies linearly along the building height. It ranges from PGA (at z equal to zero) to 3PGA (at z equal to H). The maximum value of a_p reported in Table 13.5-1 of the code is equal to 2.5. Hence, the maximum possible PSA value is always equal to 2.5PFA, independently on the floor considered.

The New Zealand code NZSEE2017 [5], in section C7.6.2, refers to the loading code NZS 1170.5 [6] for the calculation of floor response spectra. NZS 1170.5 [6], in section 8.5.1, provides the formulation reported, with some manipulation in the nomenclature, in Equation 3 to calculate the PSA.

$$PSA = PGAC_{Hi}C_i(T_a) \quad (3)$$

C_{Hi} is calculated through the formulations reported in Equation 4 and defines the PFA distribution along the building height which is, in this case, multilinear. The PFA ranges from PGA (at z equal to zero) to 3PGA (at z equal to H).

$$C_{Hi} = \left(1 + \frac{z}{6} \right) \quad \text{for all } z < 12 \text{ m} \quad (4a)$$

$$C_{Hi} = \left(1 + 10 \frac{z}{H} \right) \quad \text{for } z < 0.2H \quad (4b)$$

$$C_{Hi} = 3.0 \quad \text{for } z \geq 0.2H \quad (4c)$$

In Equation 3, $C_i(T_a)$ is the spectral shape coefficient. $C_i(T_a)$ is expressed as a function of the period T_a and ranges from 0.5 for T_a higher than 1.50 s to 2.0 for T_a lower than 0.75 s. Hence, the maximum possible PSA value is always equal to 2PFA, independently on the floor considered. It is worth noting that, in this case, the maximum PSA value depends on the “absolute” value of T_a , i.e., it does not depend on T_a/T_1 ratio.

As above shown, the previous code prescriptions generally relate the PFA linear or multilinear distribution along the building height to the floor height normalized with respect to the building height (i.e., the higher z/H , the higher the PFA) and the PSA spectral shape to the ratio between the T_a and T_1 . From both these features, it can be assumed that they relate the floor response spectra to the elastic response of the structure to its first vibration mode.

The commentary (Circolare 2019, [7]) to the current Italian building code (NTC2018, [8]) defines a “rigorous” approach for the assessment of floor response spectra as well a simplified approach specific for framed reinforced concrete structures. Both account for multi-modal contributions and for the effect on floor response spectra of structural nonlinearity. In fact, structural nonlinearity limits the maximum force acting on a structure: hence, it also may limit the maximum acceleration acting at its floors. Both topics have been also highlighted in recent literature, as will be shown in the next subsection.

The rigorous approach accounts for multi-modal contributions based on simple considerations related to structural dynamics. In fact, the PFA_{ij} acting at the j -th floor of the structure associated with its i -th vibration mode is determined by means of Equation 5.

$$PFA_{ij} = \Gamma_i \varphi_{ij} S_a(T_i) \quad (5)$$

In Equation 5, Γ_i is the modal participation factor of the i -th vibration mode, φ_{ij} is the modal displacement of the j -th storey for the i -th vibration mode, $S_a(T_i)$ is the spectral acceleration of the structure associated with its i -th vibration period, potentially reduced by means of the structure behaviour factor. The PSA is obtained, for each floor and for each vibration mode contribution, by amplifying or de-amplifying the PFA through an R factor (which equals PSA_{ij}/PFA_{ij}) calculated by means of Equation 6.

$$R_{ij} = \frac{PSA_{ij}}{PFA_{ij}} = \left(\sqrt{\left(2\xi_a \frac{T_a}{T_i} \right)^2 + \left(1 - \frac{T_a}{T_i} \right)^2} \right)^{-1} \quad (6)$$

Equation 6 returns a PSA_{ij} value equal to $1/2\xi_a$ times PFA_{ij} for $T_a=T_i$. The value of the maximum amplification is a classical result of the dynamic of the damped SDOF system (Chopra [9]). For each storey, the floor spectrum can be obtained by combining multi-modal contributions through the SRSS rule, thus resulting in a spectral shape with multiple peaks corresponding to the number of significant modes considered. Implicitly, also the PFA at the j -th floor can be obtained through the SRSS combination of the different modal contributions, thus resulting in a potentially non-monotonic distribution along the building height. Both circumstances will be observed also from the analyses results presented in this study.

Regarding the PFA distribution, it is worth noting that Equation 6 may yield to a de-amplification of the PFA with respect to the PGA value, especially in bottom floors of high-rise structures. This circumstance has been observed by some authors (e.g., Rodriguez et al. [1], Petrone et al. [10], Surana et al. [11]), especially when analyzing elastic models, but not by other authors and never in the analyses performed in this study. A comment to this issue will be given in the next subsection, when describing the approach proposed by Calvi and Sullivan [12].

The simplified approach proposed by the Italian regulation for framed reinforced concrete structures is borrowed by the work by Petrone et al [10]. Since this proposal is based on numerical analyses on nonlinear models of reinforced concrete framed structures, it implicitly account

for both multi-modal contributions and structural nonlinearity effect. The proposed formulations are reported, with some manipulation in the nomenclature, in Equation 7.

$$PSA = \begin{cases} PGA \left(1 + \frac{z}{H}\right) \left[\frac{a_p}{1 + (a_p - 1) \left(1 - \frac{T_a}{aT_1}\right)^2} \right] \geq PGA & \text{for } T_a < aT_1 \\ PGA \left(1 + \frac{z}{H}\right) a_p & \text{for } aT_1 \leq T_a < bT_1 \\ PGA \left(1 + \frac{z}{H}\right) \left[\frac{a_p}{1 + (a_p - 1) \left(1 - \frac{T_a}{bT_1}\right)^2} \right] \geq PGA & \text{for } T_a \geq bT_1 \end{cases} \quad (7)$$

In Equation 7, a , b , and a_p are coefficients depending on T_1 that account for higher modes effects (a), resonance period elongation due to nonlinearity (b) and effect of nonlinearity of the maximum PSA value (a_p). If T_a equals zero, a linear PFA distribution along the building height is obtained. PFA ranges from PGA (at z equal to zero) to 2PGA (at z equal to H). On the other hand, the maximum PSA is obtained if T_a is between aT_1 and bT_1 . In this case, the floor spectral acceleration ranges from 2.5PFA to 5PFA, dependently on a_p value.

It is worth noting that none of the proposals discussed in this subsection explicitly refers to infilled buildings, as if the presence of infills may be considered only through T_1 value, i.e., as if the presence of infills only affects the resonance period at which the maximum PSA is attained, except for the simplified proposal of the Italian regulation, in which also the maximum PSA value depends on T_1 and attains its maximum potential value for small values of the period (i.e., $a_p=5$ when T_1 is lower than 0.5 s). In other words, based on this approach, an infilled building is expected to experience an equal or higher maximum PSA value, at a certain floor, with respect to an identical but bare structure. This is also generally observed in the numerical analyses shown in this paper.

2.2 Literature formulations

Calvi and Sullivan [12] propose an approach for the assessment of floor response spectra for SDOF systems extended to Multi-Degree of Freedom systems and validated against the results of numerical time-history analyses on reinforced concrete wall structures. The PSA value for each floor and for each modal contribution is calculated by means of Equation 8.

$$PSA_{ij} = \Gamma_i \varphi_{ij} a_{m,i} \quad (8)$$

In Equation 8, $a_{m,i}$ is a spectral shape function given by Equation 9.

$$a_{m,i}(T_a) = \begin{cases} \frac{T_a}{T_i} [a_{max,i}(DAF_{max} - 1) + a_{max,i}] & \text{for } T_a < T_i \\ a_{max,i} DAF_{max} & \text{for } T_i \leq T_a < T_{i,eff} \\ a_{max,i} DAF_i & \text{for } T_a \geq T_{i,eff} \end{cases} \quad (9)$$

In Equation 9, $a_{\max,i}$ is the minimum between $S_a(T_i)$ and the S_a corresponding to global yielding of the structure (S_{ay} , potentially determined by means of a nonlinear static analysis), DAF is given by Equation 10, with DAF_{\max} obtained for $T_a=T_{i,eff}$.

$$DAF_i = \left(\sqrt{\left(1 - \frac{T_a}{T_{i,eff}}\right)^2 + \xi_a} \right)^{-1} \quad (10)$$

In Equations 9 and 10, $T_{i,eff}$ is the effective period of the structure (which is assumed potentially different from the elastic vibration period only for the first vibration mode), potentially evaluated through a nonlinear static analysis.

This approach accounts for the effect of multiple vibration modes contributions, which can be combined through the SRSS rule. Also, it accounts for structural nonlinearity effects in terms of resonance period elongation and limitation of the maximum PSA. Also in this case, as highlighted when discussing the Italian regulation “rigorous” approach, the PFA value may result lower than PGA. Since this is only seldom observed as a result of numerical analyses, due to, according to Calvi and Sullivan [12], the interaction between the ground motion typical frequency content and the structure dynamic properties, they suggest that the PFA value should never be assumed lower than PGA at bottom floors and that, at the same floors, the floor response spectrum should never return PSA values lower than those associated with the ground motion response spectrum.

Vukobratović and Fajfar [13, 14] propose a theoretical-based (except for the determination of the maximum PSA value, which is empirical) approach for the assessment of floor response spectra validated against the results of numerical time-history analyses on reinforced concrete frames. The PSA value for each floor and for each modal contribution is calculated by means of Equation 11.

$$PSA_{ij} = \frac{F_i \varphi_{ij}}{\left| \left(\frac{T_a}{T_{i,eff}} \right)^2 - 1 \right|} \sqrt{\left(\frac{S_a(T_{i,eff})}{R_{\mu,i}} \right)^2 + \left(\left(\frac{T_a}{T_{i,eff}} \right)^2 S_a(T_a) \right)^2} \leq AMP_i F_i \varphi_{ij} \frac{S_a(T_{i,eff})}{R_{\mu,i}} \quad (11)$$

In Equation 11, $T_{i,eff}$ is different from the elastic period only for the first vibration mode and can be calculated by means of a nonlinear static analysis; $R_{\mu,i}$ is the reduction factor due to the nonlinear behaviour of the structure and is equal to the maximum between 1 and the ratio between $S_a(T_{i,eff})$ and S_{ay} (potentially determined by means of a nonlinear static analysis) for the first vibration mode, while it is equal to 1 for higher vibration modes; AMP_i is the maximum PSA_{ij}/PFA_{ij} value and is expressed as a function of the damping ratio similarly to the approach proposed by Calvi and Sullivan [12]. The effects of multiple modes are combined by applying ALGSUM combination rule in the post-resonance region, with the SRSS rule otherwise.

3 DESIGN AND MODELLING OF THE CASE-STUDY STRUCTURES

The 2-, 4-, 6-, and 8-storey case-study reinforced concrete moment resisting frames have regular rectangular plan defined by five and three bays in the longitudinal and transverse direction, respectively. Beams are 4.5 m long; columns are 3.0 m high. The buildings were designed according to Eurocode 2 [15] and Eurocode 8 [3] for four different design PGA values at Life Safety Limit State (0.05 g, 0.15 g, 0.25 g and 0.35 g) in “High” Ductility Class (DCH). The materials used for design are class C28/35 concrete with characteristic compressive strength of

the cylinder equal to 28 N/mm² and steel rebars with characteristic yielding stress equal to 450 N/mm². It is assumed that floor slabs have a diaphragmatic behaviour. During the design and the analysis process, second-order geometric effects are neglected. Further details on the design of the case-study RC frames are available in Di Domenico [16] and in Ricci et al. [17]. For the analyses, the reinforced concrete elements' non-linearity is modelled by adopting a lumped-plasticity approach in OpenSees [18] by using ModIMKPeakOriented Material with response parameters determined according to Haselton et al. [19] and with the introduction of the cracking point. In the modelling process, average material properties are used, namely a compressive strength for concrete equal to 36 N/mm² determined according to Eurocode 2 [15], and a steel yielding stress equal to 517.5 N/mm² determined according to Fardis et al. [20].

Two different unreinforced masonry infill layouts are considered. The first is constituted by a two-leaf (thickness: 80+120 mm) 'weak' infill wall (weak layout, WL), the second is constituted by a one-leaf (thickness: 300 mm) 'strong' infill wall (strong layout, SL). Note that the two-leaf infills are constituted by independent non-interacting panels. In other words, the in-plane and the out-of-plane responses of each leaf are determined (and modelled) independently on those associated with the other leaf.

The mechanical properties of these infills are those calculated for the masonry wallets tested by Calvi and Bolognini [21] for the WL and those by Guidi et al. [22] for the SL. Each infill leaf is introduced in the structural model by using a couple of equivalent no-tension struts.

The in-plane non-linear behaviour is modelled, separately for each leaf, based on the proposal by Panagiotakos and Fardis [23]. According to this modelling approach, only the slope of the softening branch of the force-displacement in-plane behaviour relationship is an open parameter, and it should be set to a fraction α of the infill initial elastic stiffness. In Fardis [24] it is suggested to set α to a value between -1.5% and -5%. For the 80-, 120-mm thick leaves α is set to -1.6% while for the 300-mm thick leaf it is set to -3.6% in order to reproduce the experimental evidences shown by Calvi and Bolognini [21] and by Guidi et al. [22]. The two layouts analyzed are characterized by similar elastic in-plane stiffness but by different in-plane and out-of-plane strength capacity. In other words, buildings with WL and SL infills have similar elastic period, but those with WL infills are more likely to experience nonlinearity due to infills' cracking.

Regarding the out-of-plane response, the modelling strategy proposed by Ricci et al. [25] is adopted in order to account for the in-plane/out-of-plane interaction effects, i.e., the degradation of the out-of-plane strength and stiffness due to in-plane damage and of the in-plane strength and stiffness due to out-of-plane damage. The equations adopted for modelling the out-of-plane response are those proposed in Ricci et al. [17] for infills in which the out-of-plane response is governed by two-way arching effect strength mechanism, except for those associated with some response parameters. In fact, for this study, the out-of-plane response model is improved and updated.

First, the empirical equation for the assessment of the out-of-plane first macro-cracking force, F_{crack} , is updated to account for recent experimental evidences proposed by De Risi et al. [26] and by Di Domenico et al. [27] The new formulation is reported in Equation 12.

$$F_{crack} = 5.90 f_{mv}^{0.11} \frac{t^{0.83}}{h^{1.44}} wh \quad (12)$$

In Equation 12, forces are expressed in Newtons and lengths are expressed in millimeters. In addition, the formulations proposed by Di Domenico et al. [27] are used to model the in-plane/out-of-plane interaction effects. In these formulations, the reduction of the out-of-plane strength and stiffness capacity is related not only to the in-plane interstorey drift ratio demand

and to the infill wall vertical slenderness (i.e., the h/t ratio), but also to the infill wall aspect ratio w/h .

However, the most important and significant improvement of the out-of-plane response model is the introduction of the softening branch in the out-of-plane response backbone, as shown in Figure 2a, and the assessment of the cyclic degradation of the response envelope. As shown in Figure 2a, the out-of-plane response backbone adopted in Ricci et al. [17] was trilinear with a plastic branch after the peak load point up to the attainment of the displacement, equal to 0.30 times the infill thickness, corresponding, on average and based on experimental tests, to the 20% degradation of the maximum out-of-plane strength, which is a usual threshold associated with conventional collapse of structural members. In this study, the “conventional” ultimate point is retained at a displacement equal to 0.30 times the infill thickness. However, a bilinear softening branch is modelled. The first part of the softening branch goes from the peak load point to the “conventional” ultimate point set at a force equal to 80% of the predicted maximum strength capacity. The second part goes from the “conventional” ultimate point to the “collapse displacement” point corresponding to zero out-of-plane strength capacity, i.e., at vanishing of arching action strength mechanism. As demonstrated in Angel et al. [28] and further explained in Di Domenico et al. [29], vanishing of both vertical and horizontal arching effect is expected, based on geometrical considerations, at an out-of-plane central displacement of the infill wall equal to 0.80 times the infill thickness. So, the out-of-plane collapse displacement is set, in this study, to this value.

The quadri-linear response envelope shown in Figure 2a is modelled in OpenSees [18] by adopting Pinching4 Material. Pinching4 Material also allows modelling the hysteretic degradation of strength, unloading and reloading stiffness, as well as the so-called “pinching” effect. Further details on the nature and meaning of the hysteretic parameters governing Pinching4 Material response are available in Lowes et al. [30]. A preliminary calibration of these parameters has been performed by carrying out at the laboratory of the Department of Structures for Engineering and Architecture of University of Naples Federico II (DIST-UNINA) a cyclic out-of-plane test on an unreinforced masonry infill with thickness equal to 120 mm and poor mechanical properties (i.e., nominally identical to those monotonically tested in Di Domenico et al., [31]), whose out-of-plane force (F_{OOP})-displacement (d_{OOP}) response is shown in Figure 2b. Further details on this experimental test are available in [16].

Figure 2: Updating of the out-of-plane response model: (a) new response envelope and (b) calibration of Pinching4 Material hysteretic parameters based on the cyclic test performed at DIST-UNINA.

The Pinching4 Material hysteretic parameters have been calibrated by setting damage degradation type to “energy” and in order to minimize the distance between the experimental and the predicted energy dissipation history during the entire experimental test. They have been calibrated by neglecting the force cyclic degradation, since the limited number of comparisons between monotonic and cyclic experimental tests available (e.g., [16, 32]) shows that no significant strength degradation is observed when comparing monotonic and cyclic out-of-plane tests. The calibrated parameters are $gK1=2.00$, $gK2=0.55$; $gK3=1.50$; $gK4=0$; $gD1=0.45$; $gD2=0.85$; $gD3=0.45$; $gD4=0.50$; $gF1=gF2=gF3=gF4=0$; $gKLim=1$; $gDLim=1$; $gFLim=0$; $gE=100$; $rDispP=rDispN=-0.40$; $rForceP=rForceN=-1.00$; $uForceP=uForceN=-0.40$. As already highlighted, the number of cyclic out-of-plane experimental tests is very limited. Further experimentation is needed to achieve a more robust and reliable calibration of the hysteretic parameters of the out-of-plane response of unreinforced masonry infills, also characterized by different geometric and mechanical properties.

4 NONLINEAR ANALYSIS PROCEDURE

The nonlinear time-history analyses have been performed by scaling up to the design PGA of each case-study building ten bidirectional ground motions selected in the European Strong Motion (ESM) Database [33]. The selected records were registered on stiff and horizontal soils (i.e., type A soils according to Eurocode 8 [3]). Both components of the selected records were simultaneously matched to the 5%-damped design spectrum at Life Safety Limit State by using wavelets and the RspMatchBi software [34]. The record component registered in the NS direction was applied along the longitudinal global direction, while the component registered in the EW direction was applied along the transverse global direction. Further details on record selection are available in [16].

Nonlinear time-history analyses were performed on the Bare Frame (BF) models, on the infilled frame models with WL infills and SL infills but modelling only their in-plane response (WL and SL models), and on the infilled frame models with WL infills and SL infills with modelling both the out-of-plane response and the in-plane/out-of-plane interaction effects (WLOOP and SLOOP models). In the following, each case-study building is identified using an acronym, such as XPY_Z , in which X is the number of storeys, Y the design PGA at Life Safety Limit State expressed in $g/100$, Z the model identifier (BF, WL, SL, WLOOP, and SLOOP).

Consistently with the design process, a 5% damping ratio was used to calculate damping forces during the analyses. More specifically, mass- and tangent stiffness-proportional Rayleigh damping model was adopted.

5 TIME-HISTORY ANALYSIS RESULTS

In this section, the results of the time-history analyses are presented and discussed. Namely, the outcomes in terms of PFA/PGA profiles and PSA/PFA spectral shapes are shown. The spectral shapes are calculated by assuming a code-consistent value of the damping ratio equal to 5%. For each case-study building, the results shown are obtained as the average of the results obtained from the ten time-history analyses performed under the action of the ten bidirectional ground motions selected. For the sake of brevity, only some significant results are shown. These results can be considered representative of the general trends observed from the outcomes of all the numerical analyses. Then, these outcomes are compared with the results of the application of code and literature proposals previously described.

5.1 PFA/PGA profiles

The PFA/PGA profiles along the longitudinal direction for a selection of case-study buildings are shown in Figure 3.

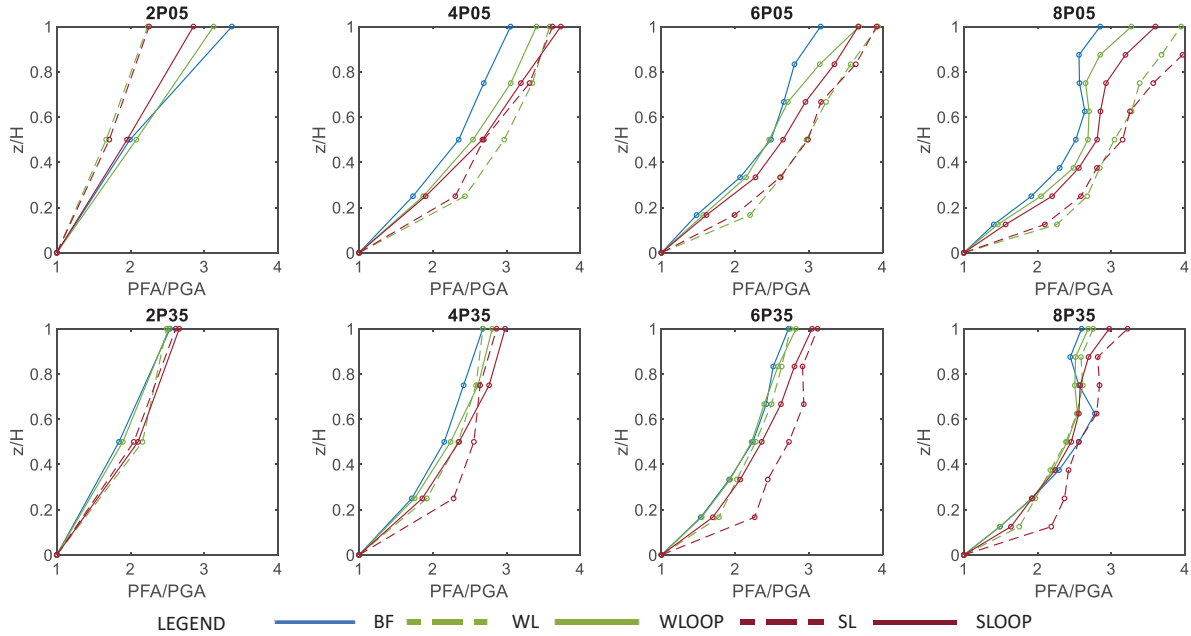

Figure 3: PFA/PGA profile along the longitudinal direction of a selection of case-study buildings.

Some considerations can be drawn:

- i. The maximum value of PFA/PGA is generally between 3 and 4, it is registered at top floors and is lower for buildings designed and analyzed for higher PGA (see point v. for comments on this). Among code and literature formulations, NZSEE2017 [5] approach returns a maximum PFA/PGA value equal to 3 at the top floors of buildings; in addition, a maximum PFA/PGA ratio equal to 4 was expected at top storeys according to Uniform Building Code [35]. Hence, the PFA/PGA maximum values obtained from the analyses can be deemed reasonable.
- ii. The shape of the profiles is roughly linear for 2-storey buildings, while it becomes multilinear for the other buildings and non-monotonic for taller (6- and 8-storey) buildings. This is an effect of the influence of higher vibration modes, which, as it is well-known, is more significant in high-rise structures. This is expected based on the more refined code and literature proposals discussed in section 2. The effect of higher modes appears also more visible and significant for infilled structures than for bare structures, as well as in presence of higher nonlinearity (i.e., for higher PGA demand).
- iii. Generally, at fixed building and at fixed floor, the maximum PFA/PGA value is registered for infilled buildings without modelling of out-of-plane response and in-plane/out-of-plane interaction, except for the 2-storey buildings. This occurs due to the dependence of the PFA on $S_a(T_1)$. In fact, in 4-, 6-, and 8-storey buildings, $S_a(T_1)$ is generally higher for infilled buildings, since T_1 is lower for infilled buildings and T_1 for bare frames is higher than the corner period T_C equal to 0.40 s; on the contrary, T_1 for 2-storey bare structures is lower than T_C , so, infilled buildings, which are always characterized by lower T_1 than bare buildings, are characterized, in this case,

- also by lower $S_a(T_1)$. The dependency of the PFA values on $S_a(T)$ is expected based on the more refined code and literature proposals discussed in section 2.
- iv. Generally, at fixed building, the PFA/PGA profiles for infilled buildings with out-of-plane response of infills and in-plane/out-of-plane interaction modelled tend to approach the profile obtained for the bare structures. This is expected, since when the in-plane/out-of-plane interaction is modelled, the in-plane response of the infill deteriorates, in terms of both stiffness and strength capacity, due to the out-of-plane displacement demand. So, the general behaviour of the building results intermediate between those of the bare and of the infilled (with in-plane response only of infills modelled) buildings.
 - v. Generally, the trends described above are confirmed when passing from the buildings designed and analyzed for PGA equal to 0.05 g to those designed and analyzed for PGA equal to 0.35 g. However, they are sometimes disturbed due to structural nonlinearity, which in general, yields to a reduction of the PFA/PGA demand in the case-study buildings. This is expected based on the more refined code and literature proposals discussed in section 2. Note that due to the modelling approach adopted (see section 3.1), the case-study buildings experience nonlinearity (in terms of tangent stiffness variation during the analysis) due to elements'/infills' cracking, while their elements do not yield. In other words, the reduction of PFA at increasing demand PGA and, as will be shown in the following, period elongation and PSA reduction at increasing demand PGA is mainly due to elements'/infills' cracking. This has been observed also by Petrone et al. [10].

Based on the above considerations, which are corroborated by the discussion of literature and code proposals presented in section 2, it can be concluded that, with reference to the set of case-study buildings analyzed for this study, the significant parameters influencing the values of PFA/PGA ratios are the $S_a(T)$ acting on the structure and on the PGA value itself (which is representative of the level of expected nonlinearity in the structure), both referred to the ground motion. On the other hand, the shape of the PFA/PGA profile depends on the importance of higher modes, which is higher for taller buildings than for lower buildings, as well as for infilled buildings than for bare buildings.

5.2 PSA/PFA spectral shapes

The PSA/PFA spectral shapes obtained along the longitudinal direction for a selection of floors of a selection of case-study buildings are shown in Figure 4. The value of T_1 used to normalize the period T_a is the period of the bare frame for WLOOP and SLOOP models: in fact, as previously discussed, due to the in-plane/out-of-plane interaction effects, the behaviour of models in which the out-of-plane response of infills is modelled is intermediate between the behaviour of the bare structural model and that of the infilled structural model with only the in-plane response of infills considered; for bare and WL/SL models, the period adopted for normalization is the one calculated by means of modal analysis of the elastic uncracked model.

Some considerations can be drawn:

- i. The maximum value of PSA/PFA is significantly variable from floor to floor, as some of the code and literature models described in section 2 show. In general, it appears dependent on the PFA/PGA value: the higher the PFA/PGA, the higher the maximum value of PSA/PFA. The maximum observed value of the PSA/PFA ratio is roughly equal to 5.5, which is consistent with the maximum value, equal to 5, predicted by the proposal by Petrone et al. [10] adopted also by the Italian code.

- ii. The spectral shapes are characterized, in general, by multiple peaks corresponding to the different vibration modes of the structure. This is quite evident in taller buildings, in which the maximum value of PSA/PFA associated with the higher modes (i.e., at T_a/T_1 significantly lower than the unit) may be even higher than that associated with the first vibration mode (i.e., at T_a similar to T_1). In 2-storey buildings, the effect of higher modes is visible only at the first floor, at which, actually, the maximum influence of the second vibration mode is expected. On the other hand, in the 8-storey buildings, peaks of PSA/PFA associated with higher modes are visible at different T_a/T_1 values dependently on the floor considered. This occurs because at bottom floors the predominant effect among higher modes may be associated with different higher modes from floor to floor (e.g., the second or the third vibration mode of the structure).
- iii. In general, infilled buildings are characterized by higher values of the maximum PSA/PFA ratio associated with the first vibration mode with respect to bare buildings, except for the 2-storey buildings. This occurs, most likely, because $S_a(T_a=T_1)$ is higher for infilled buildings with respect to $S_a(T_a=T_1)$ for bare buildings, since T_1 of the infilled building is lower than T_1 of the bare building, which, in tune, is higher than T_C . As already explained when discussing maximum PFA/PGA trends, this is not true for 2-storey buildings, since in this case $S_a(T_a=T_1)$ is lower for infilled buildings than for bare buildings. This occurs because T_1 of the infilled building is still lower than T_1 of the bare building, but T_1 of the bare building is lower than T_C . The dependence of the maximum PSA/PFA value on $S_a(T_a=T_1)$ may be also expressed by relating it directly to the period T_1 , as done by Petrone et al. [10].
- iv. As also shown when discussing the PFA/PGA profiles, also the spectral shapes for infilled buildings with modelling of the out-of-plane response of infills and of the in-plane/out-of-plane interaction effects are intermediate between those obtained for the bare models and those obtained for the infilled models with modelling of the in-plane response only of the infill walls. The fact that for WLOOP and SLOOP models the peak of PSA/PFA due to resonance with the first vibration mode occurs at $T_a/T_1 < 1$ is due to the fact that, in this case, T_a is normalized with respect to T_1 of the bare frame, while the real resonance period is lower than it, being intermediate between the bare and the infilled structure elastic vibration period.
- v. Generally, the trends described above are confirmed when passing from the buildings designed and analyzed for PGA equal to 0.05 g to those designed and analyzed for PGA equal to 0.35 g. However, the peak PSA/PFA associated with the first vibration mode of the structure is noticeably reduced due to the effect of structural nonlinearity; in addition, the resonance period is higher than T_1 for the period elongation due to structural nonlinearity. Remember that, as previously highlighted, this effect is mainly due to elements'/infills' cracking. Both effects of structural nonlinearity are expected also by applying the more refined literature proposals discussed in section 2. Also note that, even if with a lower impact, also the peaks associated with higher vibration modes may be reduced due to structural nonlinearity. This was observed also by Surana et al. [11].

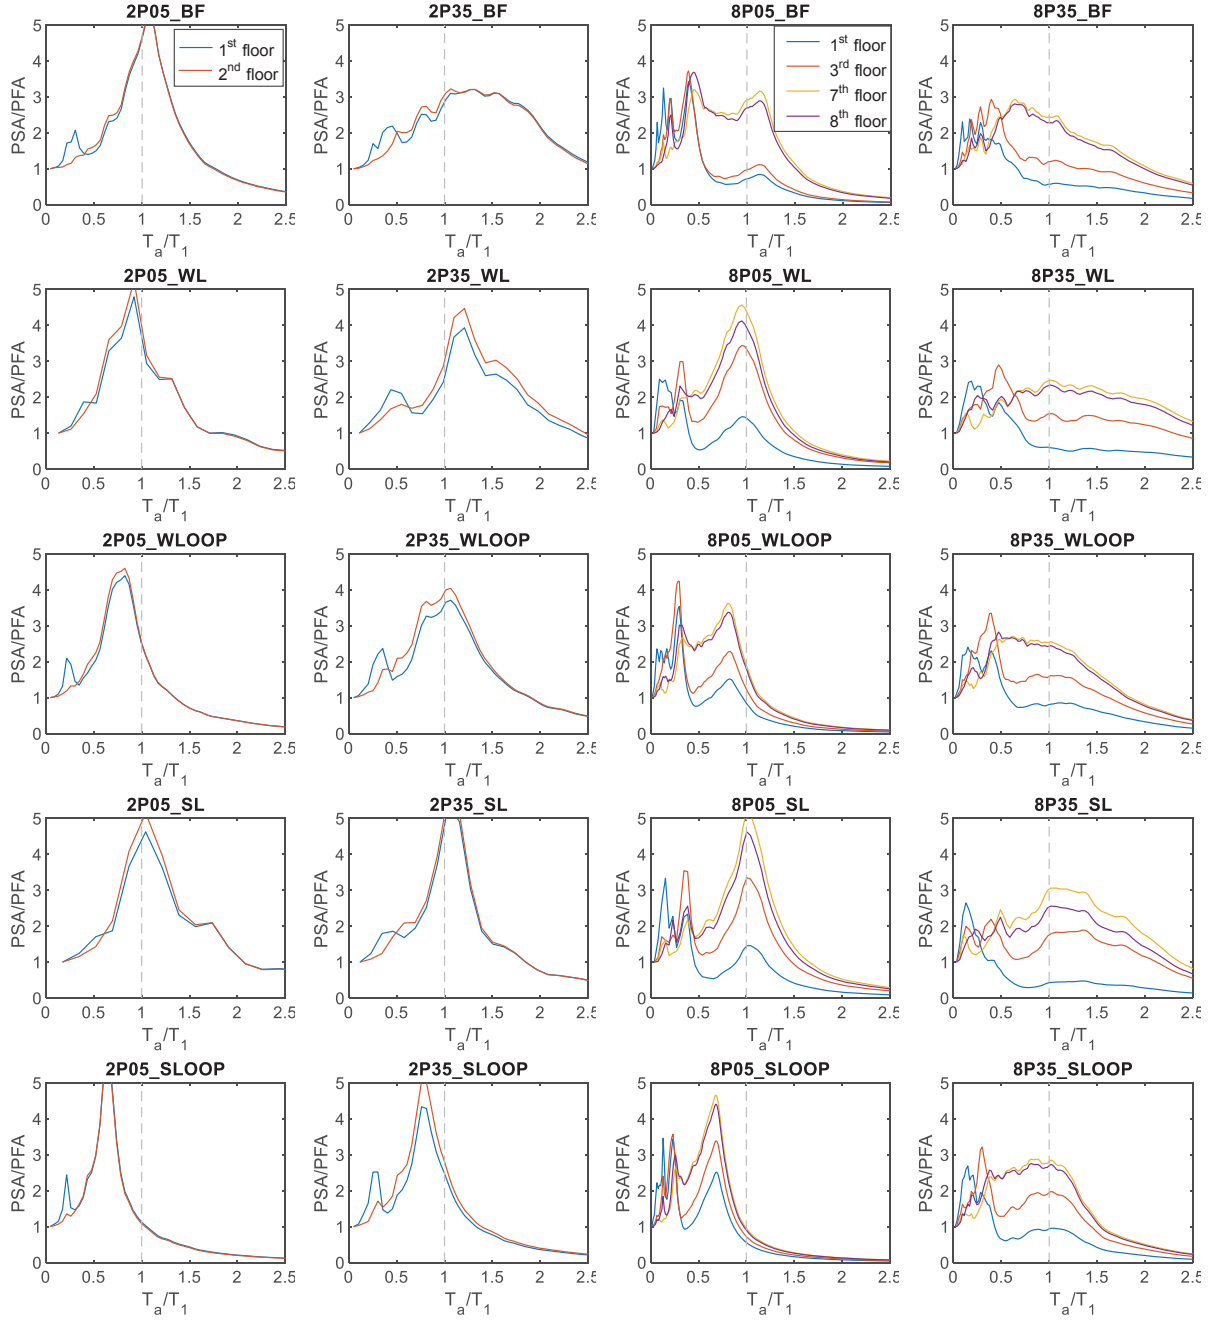

Figure 4: PSA/PFA spectral shapes along the longitudinal direction of a selection of case-study buildings.

Based on the above considerations, which are corroborated by the discussion of literature and code proposals presented in section 2, it can be concluded that, with reference to the set of case-study buildings analyzed for this study, the significant parameters influencing the values of the maximum PSA/PFA ratios associated with the resonance with the i -th vibration mode at a certain floor are the PFA/PGA value at that floor, the $S_a(T_a=T_i)$ value, potentially substituted directly by T_i , and the PGA value (which is representative of the level of expected nonlinearity in the structure). On the other hand, the shape of the PSA/PFA profile is characterized by a peak associated with the resonance with the structure first vibration mode and with a group of close peaks associated with the resonance with the structure higher modes.

6 CONCLUSIONS

- Floor response spectra are a useful tool for the assessment of the seismic demand on non-structural components, whose safety check is a paramount issue in performance-based earthquake engineering. This study was dedicated to the assessment via nonlinear time-history analyses of floor response spectra of case-study reinforced concrete framed structures designed according to Eurocodes for four different levels of design peak ground acceleration at Life Safety Limit State. The case-study bare structures have also been analyzed by including in the model two different kinds of uniformly-distributed infill walls. The main novelty of this study is not only the assessment of floor spectra for infilled reinforced concrete buildings, which has been rarely addressed in the past, but above all the fact that infill walls are modelled by considering their in-plane response, as usual, and their out-of-plane response, as well as the in-plane/out-of-plane interaction, i.e., the degradation of the in-plane response due to the out-of-plane seismic demand and vice-versa.
- Based on literature and code existing formulations, the main parameters which are expected to influence floor response spectra have been identified, namely the floor height normalized with respect to the building height, the pseudo-spectral accelerations acting on the considered building, the vibration periods of the considered building and the shape of its vibration modes, the building height, the expected peak ground acceleration demand. Moreover, floor spectra shape is strongly influenced by higher vibration modes and by the nonlinearity demand experienced by the structure.
- Generally, at fixed building, the PFA/PGA profiles for infilled buildings with out-of-plane response of infills and in-plane/out-of-plane interaction modelled tend to approach the profile obtained for the bare structures. This is expected, since when the in-plane/out-of-plane interaction is modelled, the in-plane response of the infill deteriorates, in terms of both stiffness and strength capacity, due to the out-of-plane displacement demand. So, the general behaviour of the building results intermediate between those of the bare and of the infilled (with in-plane response only of infills modelled) buildings.
- Also the spectral shapes for infilled buildings with modelling of the out-of-plane response of infills and of the in-plane/out-of-plane interaction effects are intermediate between those obtained for the bare models and those obtained for the infilled models with modelling of the in-plane response only of the infill walls.
- Based on the above discussion, formulations for the assessment of floor response spectra have will be proposed for both bare and infilled buildings in future studies.

Abstract

Several sources of uncertainty affect seismic loss analysis results, and investigating their influence is crucial to obtain reliable quantitative estimates of the building performance under seismic excitations. The present study propagates uncertainties from seismic hazard to annualized seismic losses of a code-designed unreinforced masonry infilled reinforced concrete moment resisting frame building. Uncertainties were considered in the ground motion record-to-record variability and in model class uncertainty of masonry infill walls that originates from two equivalent strut macro-model classes used and uncertainties in their backbone model parameters. A large set of finite element models (FEMs) was generated for each infill strut model class by Latin hypercube sampling (LHS) of the statistical distribution of experimentally fitted backbone parameters. Each finite element model was subjected to multiple-stripe based nonlinear response history analyses to estimate the structural response parameters of interest. The propagation of uncertainties from structural response to repair costs was evaluated considering mean values and dispersion in repair cost at the selected seismic hazard levels for two building performance models. Moreover, the contribution of different structural and non-structural elements of the studied building to the expected annualized losses was evaluated.

Keywords: expected annual losses; FEMA P-58; model class uncertainty; seismic risk analysis; URM infill.

1 INTRODUCTION

Reinforced concrete (RC) moment-resisting frames with unreinforced masonry (URM) infills represent a predominant typology of buildings worldwide. Understanding the performance of such building typology to seismic actions is crucial to assess the impact of their potential damage on the economic and societal losses [1–6]. To this end, performance-based earthquake engineering (PBEE) methods and tools can be used to evaluate the seismic risk of existing or newly designed structures through targeted seismic loss analysis. Seismic loss analysis is a very complex process, whereby a robust assessment of the seismic performance is needed and requires propagation of relevant sources of uncertainty [7]. In particular, uncertainties in numerical modeling of structural and non-structural elements and damage mechanisms considerably affect the seismic response, such as those related to the modeling of infill panels. Even though, several research efforts addressed the effect of modeling parameter uncertainty of URM infill walls on the seismic structural response of RC buildings [8–10], only a limited number of studies focused on the impact of model class uncertainty on estimated losses. Model class uncertainty [11, 12] incorporates the uncertainty in modeling parameters and the uncertainty in the selection of appropriate models to describe a general physical phenomenon.

This paper deals with the impact of incorporating model class uncertainty related to URM infills on seismic loss assessment results. Model class uncertainty is described via two equivalent infill strut models and considering the uncertainty in their backbone parameters by generating 200 realizations of the infill strut backbone for each infill model. Nonlinear response history analyses (NRHAs) were carried out using the multiple-stripe analysis (MSA) approach [13], with a different set of 30 ground motion (GM) records selected for each seismic intensity level. The FEMA P-58 methodology [14], which finds several applications in the literature for building-specific seismic loss analyses [15, 16], was adopted to evaluate the monetary performance of the considered building. This was achieved through the building performance models developed incorporating the NRHAs results of the two selected infill model classes and considering necessary information on elements damage and loss characteristics. In particular, the recently validated SP3 web-tool [17] has been used for the seismic loss analysis. Results highlight the impact of model class uncertainty for URM walls by comparing mean repair costs and mean annualized costs obtained for the two selected model classes.

2 DESCRIPTION OF BUILDING

An existing code-conforming RC URM building is selected to evaluate the effect of infill-strut model class uncertainty on seismic loss assessment. The building is an irregular six-story structure infilled with URM walls, with three bays in the Y-direction (transverse) and five bays in the X-direction (longitudinal), as shown in Figure 1(a). The lateral force resisting system consists of RC special moment-resisting frames in both longitudinal and transverse directions. The concrete used has expected compressive strength of $f'_{ce} = 30$ MPa, and the reinforcing steel with expected yield strength of $f_y = 496$ MPa. Figure 1(b) shows the elevation view of the internal frames for grid lines B to E, where infill walls are used as partitions in second and third stories. Solid clay bricks are used for infill wall panels. Detailed information regarding the building description is reported in [18].

3 NUMERICAL MODELING AND STRUCTURAL ANALYSIS

3.1 RC frame and infill strut modeling

A two-dimensional model of the building internal RC frame in the transverse direction is developed in OpenSees [19]. The graphical representation of the numerical modeling scheme is presented in Figure 2. Beams and columns of the RC frame are modeled as fiber-section force-based finite length plastic hinge elements [1, 2, 5, 6]. The uniaxial stress-strain response of the concrete fibers is modeled using the model by Yassin [20], while the reinforcing steel bars are modeled with an elastoplastic with linear hardening model. Geometric nonlinearity ($P - \Delta$) are explicitly considered. A strength-based nonlinear zero-length shear spring is considered near the column end offsets to capture potential column shear failures due to infill-frame interaction. The details of the shear-spring model implemented are described elsewhere [21].

Infill panels are modeled through equivalent strut macro-models. Among the numerous infill strut macro models available in the literature to model infill panels [22–25], the infill strut models proposed by (1) Sattar and Liel [26], and (2) Burton and Deierlein [27] are adopted and hereafter referred to as SL10 and BD14, respectively. The SL10 is composed of a single diagonal concentric strut. In contrast, the BD14 model consists of a diagonal concentric strut and an off-diagonal strut, the latter connected at the end of the column end offsets. Figure 2(c) shows the two-infill strut model backbone curves, based on expected infill model parameters. The differences in the infill strut backbones arise from the different failure mechanisms considered by each infill strut model and the relative strength of the infill and surrounding RC frame.

To account for uncertainty in infill model constitutive parameters, 200 finite element model (FEM) realizations of the infill strut backbones are generated for each infill model, considering five models to experiment bias ratio parameters for the infill strut backbones as basic random variables, including: (1) bias in peak strength, $V_{cap,model}/V_{cap,exp}$, (2) bias in initial stiffness, $K_{e,model}/K_{e,exp}$, (3) ratio of experiment measured peak strength to yield strength, $V_{cap,exp}/V_{y,exp}$, (4) ratio of experiment measured capping drift to yield drift, $\Delta_{cap,exp}/\Delta_{y,exp}$, and (5) ratio of experiment measured residual strength to peak strength, $V_{r,exp}/V_{cap,exp}$. Statistics on model bias are determined based on the approach and results presented in Burton and Deierlein [27] and FEMA 307 [28].

Figure 2: Infilled RC frame modeling: (a) SL10; (b) BD14; (c) infill strut backbone parameters.

3.2 Structural analysis results

The uncertainty in ground shaking is considered by simulating nonlinear response history analyses (NRHAs) with 30 natural GM records at eight seismic intensity levels, corresponding to exceedance probabilities of 50%, 30%, 10%, 5%, 2%, and 1% in 50 years, 1% in 100 years, and 1% in 200 years, respectively. Within the MSA approach [13], for each seismic hazard level (HL), a different GM records suite is selected for a soil site class D in Salem, Oregon, USA. Two-dimensional structural analyses are performed on the 200 FEM realizations of the two considered model classes representing an internal building RC frame. The suite of analyses is carried out by using high-performance parallel computing [29].

The summary of the results of NRHAs is presented in Figure 3, in which median profiles for peak interstory drift ratio (PIDR) are reported. It can be seen from Figure 3 that there is a notable reduction of the drift demands at the second and third stories, which are the stories in which the infill panels are located. The comparison between the results for the two model classes indicates a lower PIDR demand in lower stories when the BD14 infill strut model is adopted.

Figure 3: Median PIDR profiles for the two selected model classes, SL10 and BD14, at 30%, 10%, 2% in 50 years HLs and 1% in 200 years hazard levels.

4 LOSS ANALYSIS RESULTS

The building seismic loss analysis is evaluated via the FEMA P-58 loss methodology on a three-dimensional performance model of the building, where the information related to the geometrical building characteristics, the structural response results, as well as the damage and loss description of the elements, is required. In particular, the demand distribution generated from the NRHAs is used as input data for the damage analysis of damageable structural and non-structural elements at each selected HL. In this paper, the seismic loss analysis is carried out for two building performance models, each one corresponding to one of the two selected infill

strut model classes. The correspondence is expressed using the specific PIDR demand resulting from the NRHAs of the 200 FEM realizations of that infill strut model class. In other words, the two performance models have a different PIDR distribution, reported in the previous section in Figure 3. In order to appreciate the influence of infill modeling uncertainty, the fragility and loss functions of the structural and nonstructural elements are the same for the two performance models. Figure 4 reports the mean repair cost values at the selected seismic intensities for the two performance models, normalized by the total replacement cost of the building. The element category deaggregation of mean repair cost is also reported. The seismic risk due to collapse is much less relevant than those from element damage analysis, which is partly explained by the fact that a modern code-designed building is considered in this study. The figure shows that the most substantial contribution to the risk is from the masonry infill walls, whereas repair costs from MEP (mechanical, electric, and plumbing) elements are less relevant at higher HLs. In addition, repair costs due to collapse for the BD14 model class become progressively more important with increasing HLs and even though a similar trend is observed for the SL10 model class, the contribution of collapse to the risk is less for the latter model class.

Figure 4: Effect of model class uncertainty on the mean total repair cost, deaggregated by the different structural and nonstructural elements contribution, for the two implemented performance models, SL10 and BD14.

To illustrate the propagation of the uncertainty from the structural response to losses, the dispersions of the maximum PIDR over all the building stories ($MIDR$), β_{MIDR} , and repair cost dispersions, β_{RC} , are compared at the selected HLs. Figure 5 reveals an amplification of repair cost dispersions compared to $MIDR$ dispersions, and results in Figure 5(b) indicate that dispersions of seismic loss in terms of repair costs decrease as seismic intensity increases, probably because higher values of the EDP imply that elements damage condition tend to concentrate at the higher damage states, hence the same for subsequent elements loss. This observation is consistent with the results presented in Kohrangi et al. [30].

Within a more comprehensive seismic loss analysis, the expected annualized losses (EAL) are computed as a percentage of the total replacement cost. The estimated EAL values are very similar, 0.0728 % and 0.0738% for the SL10 model class and BD14 model class, respectively, revealing a negligible influence of infill strut model class uncertainty on annualized losses for the present case-study modern RC building. Moreover, these values are relatively low when compared with studies on older RC frame buildings [15, 31, 32].

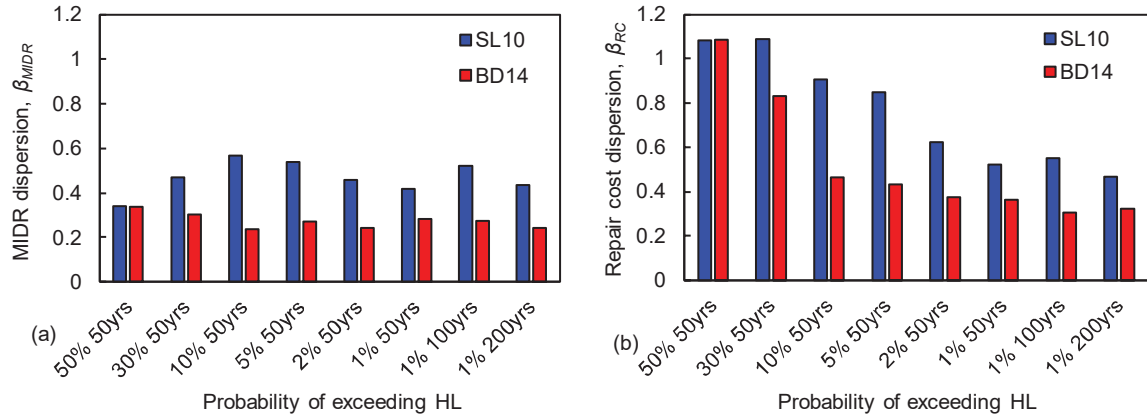

Figure 5: Logarithmic standard deviation for the two implemented performance models, SL10 and BD14: (a) maximum peak inter-story drift ratio, β_{MIDR} ; (b) repair cost, β_{RC}

The EAL percentage deaggregation in terms of replacement losses and damageable element category losses reported in the bar chart in Figure 6 confirms the predominant contribution from masonry infill walls, whereas MEP elements contributed to approximately 15% of EAL. The structural damage contribution to the risk is negligible, highlighting the importance of using modern building codes to reduce seismic risk.

Figure 6: Contributions of collapse and damageable element losses to expected annualized loss for the two implemented performance models, SL10 and BD14.

5 CONCLUSIONS

This paper aims to assess the effect of model class uncertainty related to URM infills modeling on seismic risk of a modern RC building by using two different equivalent strut models, namely SL10 and DB14, and the uncertainty in the infill strut backbone parameters. NRHAs were performed at eight hazard levels for 200 FEM realizations of each of the two selected infill strut backbones, obtained through Latin hypercube sampling of the backbone parameters. The key findings of the study are as follows:

- Comparison between uncertainties in NRHAs results and loss analysis results shows a strong amplification of repair cost dispersions compared to maximum PIDR (MIDR) dispersion at low and medium HLs, which reduce at higher HLs, for both the infill-strut model class used.

- The results of the loss analysis reveal the influence of model class selection for URM walls on mean repair costs; in fact, the SL10 model class experiences larger losses at low and medium HLs, whereas repair costs for the BD14 model class become progressively predominant at increasing HLs due to the higher contribution of collapse losses.
- The EAL values for the two implemented performance models are very similar. Moreover, the EAL deaggregation indicates the predominant contribution from the masonry infill walls and other nonstructural elements, while the contribution from RC frames and collapse is negligible.

Summarizing, model class uncertainty for URM infills has significant effects on repair costs and mostly on repair costs dispersions, whereas the impact on annualized costs is less relevant. Such consideration is valid for the present case-study modern RC building, and further work should be performed to validate the results.

Abstract

In earthquake prone areas, columns of many relatively old RC (reinforced concrete) structures do not comply with the current seismic design codes, particularly in developing countries. Low concrete strength, improper seismic detailing of transverse reinforcement and high axial stresses on the columns are common problems causing lack of sufficient ductility under seismic forces. External jacketing of substandard columns by spraying GFRM (glass fiber reinforced mortar) is a new, practical and feasible method to overcome these deficiencies, particularly for the cases where access to the structural members is limited. In this study, the effects of cross-sectional aspect ratio (h/b) of columns on effectiveness of external jacketing with sprayed GFRM are investigated experimentally. For this purpose, four full scale RC columns were tested under constant axial load ($0.35f_c A_g$) and cyclic lateral displacement reversals before and after seismic retrofit with sprayed GFRM jacket. The cross-sectional aspect ratios of two columns were 2.0, whereas the cross-sectional aspect ratio was 4.0 for the other two columns. The structural responses of the columns are discussed through hysteretic and envelope load-displacement curves. The test results show that sprayed GFRM jacketing improves lateral ductility of the substandard columns significantly. It is also shown that the method is effective for the columns with high cross-sectional aspect ratios.

Keywords: Column, GFRM, Reinforced Concrete, Seismic

1 INTRODUCTION

There are many buildings all over the world that do not comply with the requirements of current seismic design codes or with the requirements of their construction times. The poor seismic performance of buildings with typical deficiencies of structural members (i.e. columns) such as low strength concrete, inadequate detailing and insufficient transverse reinforcement may cause a considerable number of casualties and economic losses during severe earthquakes. Previous devastating earthquakes (i.e. 1994 Northridge, 1995 Kobe, 1999 Kocaeli, 2011 Van, 2020 Elazig and Izmir earthquakes) have also demonstrated the vulnerability of substandard RC columns exposed to seismic actions demanding large inelastic deformations [1-2]. To mitigate this risk, many studies on seismic retrofitting of substandard columns were conducted in the last decades. Because the major problem for the substandard building stock stems from the lack of lateral strength, ductility and stiffness, the external jacketing method using fiber reinforced polymers (FRPs) has gained popularity for the enhancement of the seismic performance of substandard RC members [e.g. 3-9]. The proven efficiency of this innovative solution in terms of providing additional confinement, leads to improved seismic resistance in terms of lateral load capacity and inelastic deformation capabilities of substandard RC members. Recent researches have shown that usage of other innovative materials such as textile reinforced mortar [e.g. 10-11] or fiber reinforced mortar [12] for external confinement is also a promising retrofitting solution for reinforced concrete and masonry members [13].

Therefore, this paper is aimed at improving the seismic resistance of extended rectangular substandard RC columns through sprayed GFRM (glass fiber reinforced mortar) jacketing. Towards this aim, preliminary results of an experimental study conducted on full-scale substandard RC columns of different cross-sectional aspect ratios (2.0 and 4.0) are presented in this paper. The study examines the impact of reversed cyclic lateral loading on the columns before and after application of proposed external jacketing method.

2 EXPERIMENTAL WORK

2.1 Specimen details and test setup

In the scope of the study, a total of 4 cantilever columns were cast to assess the efficiency of sprayed GFRM jacketing on seismic behavior of substandard RC columns. The columns had dimensions of 200 mm×400 mm and 200 mm×800 mm, corresponding to cross-sectional aspect ratio (h/b) of 2.0 and 4.0, respectively. The columns with h/b of 2.0 and 4.0 were cast having a height of 1750 and 2100 mm, respectively. For each aspect ratio, two columns were cast, one to be a reference column and the other with purpose of retrofitting. Each column incorporated an RC foundation block with dimensions of 900 mm×1300 mm ($h/b=2.0$) or 1300 mm×1700 mm ($h/b=4.0$) and height of 700 mm. Columns were reinforced with 4 of 16 mm ($h/b=2.0$) or 8 of 16 mm ($h/b=4.0$) diameter longitudinal steel plain bars placed at the corners with a 30 mm concrete cover from the edge of the specimen to the outside of the longitudinal bars (Fig. 1). These bars had a yield strength of 292 MPa. Transverse reinforcement was provided in the form of plain bars with 10 mm diameter, which had a yield strength of 312 MPa. These bars were formed at 200 mm spacing center-to-center with 90 degrees hook angle at the test region representing existing substandard building stock. The geometric ratio of longitudinal reinforcement ratio was 1% and volumetric ratio of transverse reinforcements was 0.22% ($h/b=2.0$) or 0.1% ($h/b=4.0$), respectively, which were calculated according to current Turkish Building Earthquake Code [14]. All columns were constructed so as to be representative of

the substandard columns not complying to any design codes. Concrete compressive strength at 28th day after casting was around 12 MPa, and at around the seismic test day (six months after casting) it was 14.1 MPa, which were obtained from 150 mm×300 mm standard cylinders. The columns were tagged as C2 (reference specimen with $h/b=2.0$), C2-R (retrofitted specimen with $h/b=2.0$), C4 (reference specimen with $h/b=4.0$) and C4-R (retrofitted specimen with $h/b=4.0$). The columns were strengthened with sprayed GFRM that had 4.5% glass fiber content by weight. The average 28-day compressive strength of five standard 50 mm cubic GFRM specimens was obtained in accordance with ASTM C109 [15] as 41.4 MPa.

Figure 1: Reinforcement details of the columns. Note: All dimensions are in mm

The general view of the test setup and measurement system consisting of load cells, potentiometers and strain gauges are shown in Fig. 2. The data from the potentiometers, load cells, and electrical resistance strain gauges were collected by means of a data logger. TML YFLA-5 post-yield strain-gauges and TML FLA-5 foil strain-gauges were mounted on longitudinal and transverse reinforcements, respectively. The types and measurement lengths of potentiometers are shown in Fig. 2. In this figure, for instance, SLPS 50 denotes the potentiometer with a 50 mm stroke length. Specimens were fixed to the strong floor of the laboratory by means of six high strength 36 mm diameter bolts. Prior to the seismic tests, the axial load was applied by means of a manually force-controlled hydraulic jack with 2200 kN capacity. After application of vertical constant load, reversed cyclic lateral displacement protocol was applied to the column by means of a horizontal hydraulic actuator with a ± 300 kN and ± 400 mm force and displacement capacity, respectively. Each target displacement had two repeated cycles. The reversed cyclic lateral loading was applied considering increasing drift ratios in pushing and pulling directions that corresponded to ± 0.0005 , ± 0.001 , ± 0.002 , ± 0.003 , ± 0.004 , ± 0.005 , ± 0.0075 , ± 0.01 , ± 0.015 , ± 0.02 , ± 0.025 , ± 0.03 , ± 0.04 , ± 0.05 , ± 0.06 and ± 0.07 drift ratios according to ACI 374.2R-13 [16]. Tests were not terminated until the failure (at least 25% loss of axial and/or lateral load capacities) was observed.

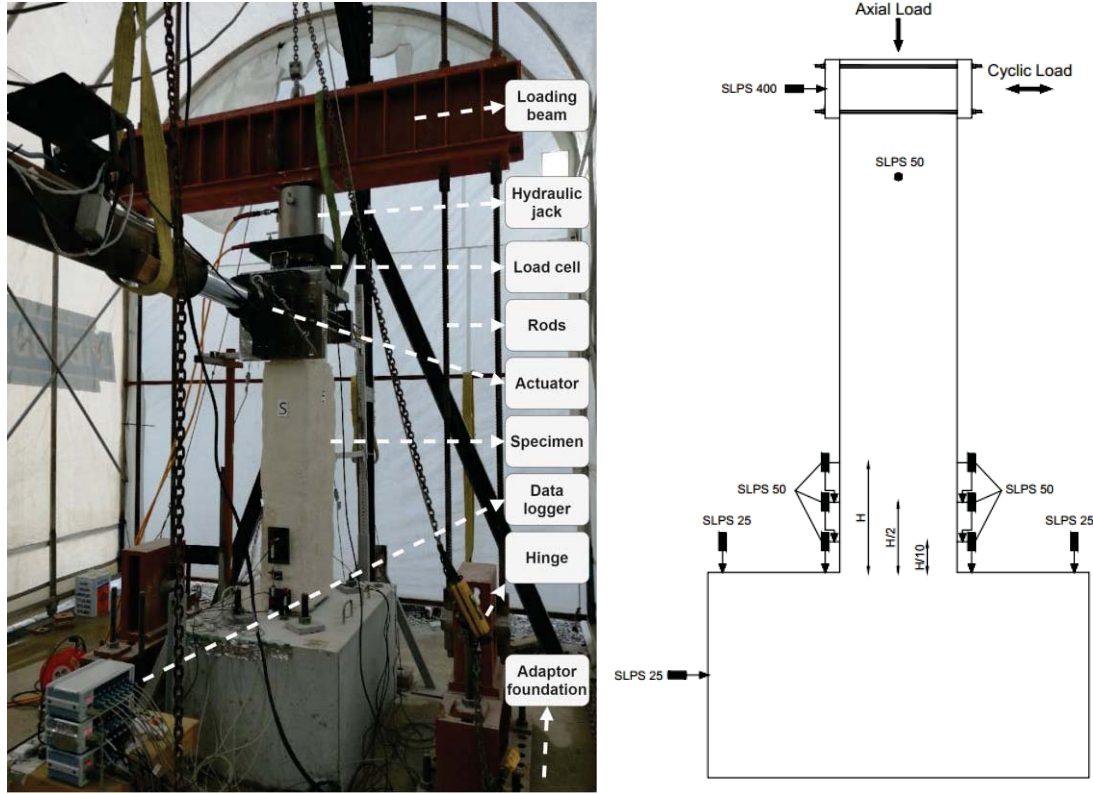

Figure 2: Seismic test setup and instrumentation

2.2 Retrofitting procedure

The columns C2-R and C4-R were prepared to be strengthened by rounding off their corners with a radius of 30 mm. After preparing the surface by cleaning the dust to provide saturation between concrete and GFRM, spraying of GFRM started. Then, GFRM was sprayed by using a spraying gun to the surface of the column. The thickness of GFRM jacket for the column C2-R varied between 25 mm and 35 mm, whereas for the column C4-R, this thickness was between 25 mm and 45 mm. This enlarging thicknesses towards the center of the column edges were proposed to enhance the lateral confinement pressure provided by the jacket. Chopped glass fibers of 32 mm length were used in this composite material. Technical properties of the fibers provided by the manufacturer are shown in Table 1. In order to avoid local damages in the GFRM near the column foundation, a 30 mm of vertical gap was left between the GFRM and the column-foundation interface. The process of strengthening is shown in Fig. 3.

Table 1: Chopped glass fiber technical properties

Properties	Value
Average Filament Diameter (μm)	19
Specific Gravity (gr/m^3)	2.68
Thickness (mm)	0.8-0.9
Tensile Strength (MPa)	1000-1700
Elastic Modulus (GPa)	72

2.3 Test results

The columns were tested under constant axial load and reversal cyclic lateral loading about six months after casting. During the tests, axial load was kept constant at $0.35f'_c b h$ for all specimens, where f'_c is the compressive strength of concrete, b and h are the width and depth of the column cross-sections. The lateral load-displacement hysteretic curves of the columns and their envelopes are shown in Figs. 4 and 5. The maximum lateral load capacities in pushing and pulling directions are shown in Table 2. For the reference columns C2 and C4, peak lateral loads were achieved at around 1% and 0.75% drift ratio, respectively. The damage progressed for these columns sequentially with crushing and spalling of concrete cover which was followed by buckling of longitudinal rebars. Yielding of longitudinal reinforcement did not occur in these columns. For the reference columns, tests were terminated with 68% and 77% loss of lateral strength, respectively. On the other hand, due to the additional confinement provided by sprayed GFRM, retrofitted columns C2-R and C4-R exhibited a more ductile behavior with respect to their reference counterparts. This additional confinement led to delayed buckling of longitudinal bars which results with more ductility. Moreover, longitudinal reinforcements of strengthened specimens yielded before strength degradation, indicating that failure was not governed by crushing of concrete merely. For retrofitted columns C2-R and C4-R, peak loads were achieved at 1% drift ratio and 0.75% drift ratio, respectively. After this point, strength loss initiated due to an increase in crack widths at the edges of the GFRM jacket. Finally, these cracks extended along the height up to the middle of the column leading to the failure of the column. Jacketing of the specimens with sprayed GFRM enhanced the lateral load capacity of the columns with aspect ratio 2.0 and 4.0, around 6% and 10%, respectively. On the other hand, maximum drift ratio experienced in the seismic tests for these columns were 7% and 4%, respectively. The increase in maximum drift of the columns C2-R and C4-R were around 250% and 166%, respectively, with respect to their reference columns. The damages of the columns after tests are shown in Fig. 6.

Table 2: Summary of the test results

Specimen	Failure drift ^a (%)	Maximum lateral load in pushing (kN)	Maximum lateral load in pulling (kN)	Yield displacement, Δ_1 (mm)	Ultimate displacement, Δ_2 (mm)	Ductility factor, μ_Δ
C2	1.8	58.1	53.2	5.8	28.9	5.0
C2-R	3.6	60.2	58.6	6.6	59.4	9.0
C4	1.5	168.7	170.0	4.4	30	6.8
C4-R	3	181.7	191.4	4.0	60	15.0

^a drift corresponding to ultimate displacement (when the lateral strength was reduced to 80% of the peak value)

For a better comparison of the column performances in terms of ductility, displacement ductility factors (μ_Δ) are calculated as an indicator of deformability. Displacement ductility factors are defined in this study as the ratio of ultimate displacement to the yield displacement. Yield displacement, Δ_y , is the lateral displacement obtained from lateral load-lateral displacement ($P-\Delta$) curve corresponding to the maximum lateral load on straight line joining origin and the point at 75% of the peak lateral load on ascending portion of the average envelope curve, and Δ_u is the ultimate lateral displacement obtained from $P-\Delta$ curve corresponding to 80% of the peak load on descending portion of average envelope curve. The yield and ultimate displacements are shown in Table 2 as well as corresponding displacement ductility factors. As seen in this table, sprayed GFRM jacketing of the columns doubled the ductility of the columns irrespective of the cross-sectional aspect ratio.

3 CONCLUSIONS

The main objective of this study is to investigate the efficiency of sprayed GFRM jacketing in terms of improving seismic performance of substandard columns with extended rectangular cross-sections. In accordance with this purpose, the preliminary results of an ongoing study are presented herein. Two reference and two sprayed GFRM jacketed sub-standard RC columns were tested under seismic loading with cross-sectional aspect ratios of 2.0 and 4.0. The following conclusions can be drawn from the study.

- Application of sprayed GFRM jacketing resulted with a 6-10% increase in lateral load capacity of the substandard columns.
- Due to the effective confinement provided by sprayed GFRM jacketing, the drift capacities of the columns were approximately doubled corresponding to 80 and 120% increase of displacement ductility for the columns with cross-sectional aspect ratios of 2.0 and 4.0, respectively.

Further numerical and experimental studies are under progress for different cross-sections to shed some more light on the behavior of sprayed GFRM strengthening for substandard extended rectangular columns. The current results show that this cost-effective and easily-applicable technique is promising for future practical applications.

ACKNOWLEDGMENTS

This research was granted in the scope of the bilateral collaboration between the research councils of Turkey (TUBITAK) and the Pakistan (PSF) under the grant number 118M261. The authors are most thankful to the Fibrobeton company for their continuous support from the construction phase of the specimens to the testing stage. The contributions of Dr. Cem Demir, Alihan Baltaci, Safiye Gundogan and Erkan Tore are also gratefully acknowledged.

Abstract

Substandard reinforced concrete (RC) joints often exhibited poor seismic performance even under moderate intensity earthquakes, which is due to the lack of earthquake-resistant design detailing. Premature joint cracking often compromises the seismic performance of the entire building, initiating local collapses or global failure mechanisms. The quantification of the joint repairability in terms of reduction of the structural damage as well as expected economic losses is still a challenging task. This is due to the uncertainties in the assessment of residual and maximum crack widths. This study deals with the evaluation of crack by the increasing drift level. To this end, available numerical and experimental cyclic data on the substandard beam-column joints are collected. The variability in material properties is considered and the correlation between residual and maximum crack width is obtained. These data are then used to obtain residual-to-maximum crack width ratio by increasing drift level. The available repairability thresholds are then compared with the residual-to-maximum crack width ratio curve.

Keywords: Crack width, Repair, Probabilistic, Beam-column joints, Substandard

1 INTRODUCTION

Existing reinforced concrete buildings designed according to former code provisions lack several earthquake-resistant design detailing. This makes these buildings vulnerable to seismic actions. The poor energy dissipation and sudden strength and stiffness degradation are the main consequences of the brittle failures of such vulnerable structural members. Beam-column joints deserve special interest in existing buildings because they can be the critical and possibly the weakest link according to the capacity design principles or hierarchy of strength considerations [1]. Such an unfavorable seismic behavior of joints obviously compromises the structural integrity of the whole system. Therefore, the experimental performance of the deficient joints has attracted considerable research interest [2–7]. The response of beam-column joints under a multi-axial complex stress field is also reproduced by the computer-aided nonlinear analysis [8–12]. The refined and validated numerical models are also combined with the stochastic approach requiring a solution with randomized material properties to improve the accuracy of the analysis results [13–15]. The repair of deficient joints has attracted considerable research interest [16–20]. However, the building repair is usually limited by the high repair cost of drift-sensitive members [21], and massive reconstruction and intrusive repair procedures [22]. Besides, the repair procedure and type are fairly sensitive to damage level (i.e., light, moderate or severe damage). The damage indicators characterizing the severity and extent are usually associated with the crack width for light/moderate damage level and macroscopic concrete and reinforcing bar damage for severe damage state [23–29]. Therefore, the selection of a suitable repair procedure usually depends on damage level and crack width. The evolution of the crack width by the increasing drift level, the correlation between maximum and residual crack width are important parameters in assessing the level of damage (and the repair actions). The effect of randomness at the material level should be also considered when obtaining such engineering demand parameters (EDPs). This study mainly deals with the evolution of crack at imposed drift and residual crack width by the increasing drift level. The residual-to-maximum crack width ratio at imposed drift ratio is obtained to show the crack closure effect. Then, this ratio is compared with current repairability thresholds to obtain proper relationships suitable for on-site engineering applications.

2 METHODOLOGY

The deformation limit of serviceability and its corresponding crack width are usually considered as a threshold for the building repairability considering conventional repair actions (i.e., crack filling, concrete patching, or cover replacement). On the other hand, it should not be beyond economical repair. FEMA P-58 [30] specifies a threshold value of 50% of building cost when contemplating whether a damaged structure should be replaced or repaired. Light to moderate damage can be identified as the threshold for the feasibility of repair. Here, light damage corresponds to hairline cracks or cracks that can be repaired with surface finishing/epoxy resin while moderate damage refers to remarkable wide cracks, concrete cover spalling, local concrete crushing, and reinforcement yielding [30, 31]. The use of fiber-reinforced polymers (FRP) for the repair and rehabilitation of heavily damaged RC members is an efficient solution [23–28]. The indicators for the detection of damage at light to moderate damage levels are also identified for in-situ inspections in terms of residual crack width. Therefore, the residual crack width can be useful for the detection of the damage during post-earthquake damage inspections for the feasible repair action. The available standards and guidelines also refer to the use of residual crack width for repairability [23, 25, 27, 32]. On the other hand, special attention should be given to assess the residual crack width as the scatter in the residual crack width is high.

Note that, Maximum Inter-story Drift Ratio (IDR) is commonly accepted to be a key engineering demand parameter. The residual story drift is also one of the global acceptance criteria for repairability [32], however large variability could be associated to this parameter and residual crack width. Besides, it is more sensitive to hysteretic unloading and reloading response in moderately damaged reinforced concrete plastic hinges [31]. In the case of brittle behavior of joint, limiting the residual displacements (and so the residual crack width) as a means of increasing the probability that the building can be repaired following earthquake ground shaking is also an efficient solution. Therefore, the damage evolution could be represented by the crack width at maximum and residual IDR.

This research proposes relationships between residual crack width and maximum crack width together with the correlation to maximum drift. This allows the reader to obtain the relationship between residual and maximum crack width together with the evolution of the crack width by the increasing drift level. To address this scope, the outcomes of stochastic analyses developed on validated FEM numerical models are used. The substandard beam-column joint specimen with low strength concrete and plain round bar is first tested (i.e., specimen EJ_R) [22]. Then, the progress of crack developments, its patterns, and global hysteretic response is reproduced in ATENA Science [33] finite element method (FEM) software. The modeling approach, the constitutive law of the materials and its parameters suitable for application to substandard beam-column joint, modeling accuracy and effectiveness in reproducing the experimental behavior, modeling advantages-disadvantages, difficulties in the modeling of substandard joints are discussed in detail in Yurdakul *et al.* [12]. The simulation of the randomness at the material level (i.e., concrete and reinforcing steel) is accounted by computational stochastic mechanics. The mechanical properties of concrete and reinforcing steel are described as random variables to consider the variability in material properties [14]. Thus, the effect of material parameters on the cracking response is found. The residual crack width and maximum crack width at the imposed drift with their scatter are obtained from the numerical analyses. In many cases, the cracking mechanism at the joint back, joint core and interface occur simultaneously. The most critical cases for the most unfavorable situation are taken into account when evaluating the crack width at each location of the joint region. More detailed information about the cracking response can be found in Yurdakul *et al.* [13].

3 RESULTS AND DISCUSSION

The outcomes of numerical analyses in terms of the crack width vs. maximum or residual IDR are reported in Figure 1a and b, respectively. The data can be fitted with a linear relationship with an acceptable level of accuracy. The correlation among datasets (i.e., imposed/residual drift and imposed/residual crack width), referred as the coefficient of determination R^2 in the graphs is high, demonstrating the accuracy of the fitting. When both imposed and residual crack widths at the interface are considered, a higher scatter in fitting the data can be observed.

As mentioned in the previous section, the uncertainty in the residual crack width is high. Therefore, the reliability of setting a crack repairability limit based on the residual drift (and so crack width) should be further investigated. The correlation between the residual crack widths and maximum crack widths is presented to validate the range of application of the considerations for joint repairability based on residual crack width. For this purpose, the data are fitted with a linear relationship, and the correlation between the residual crack widths and crack widths at imposed drift is obtained for 30 samples (see Figure 2). The graph indicates the correlation at each imposed and residual drift ratio.

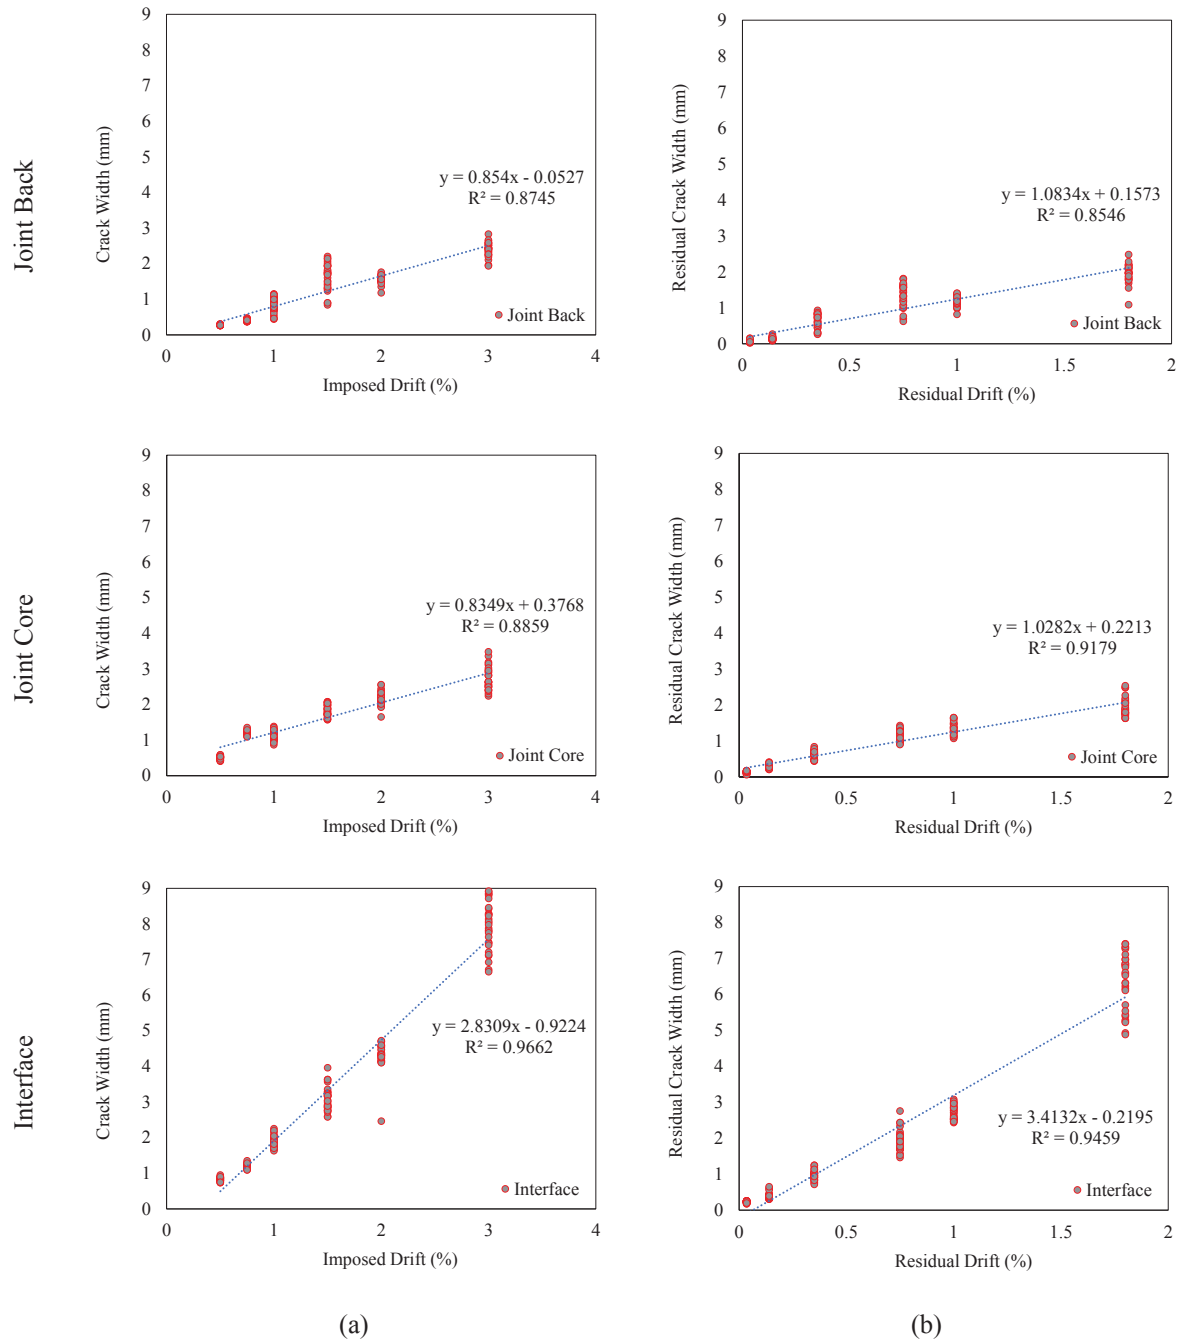

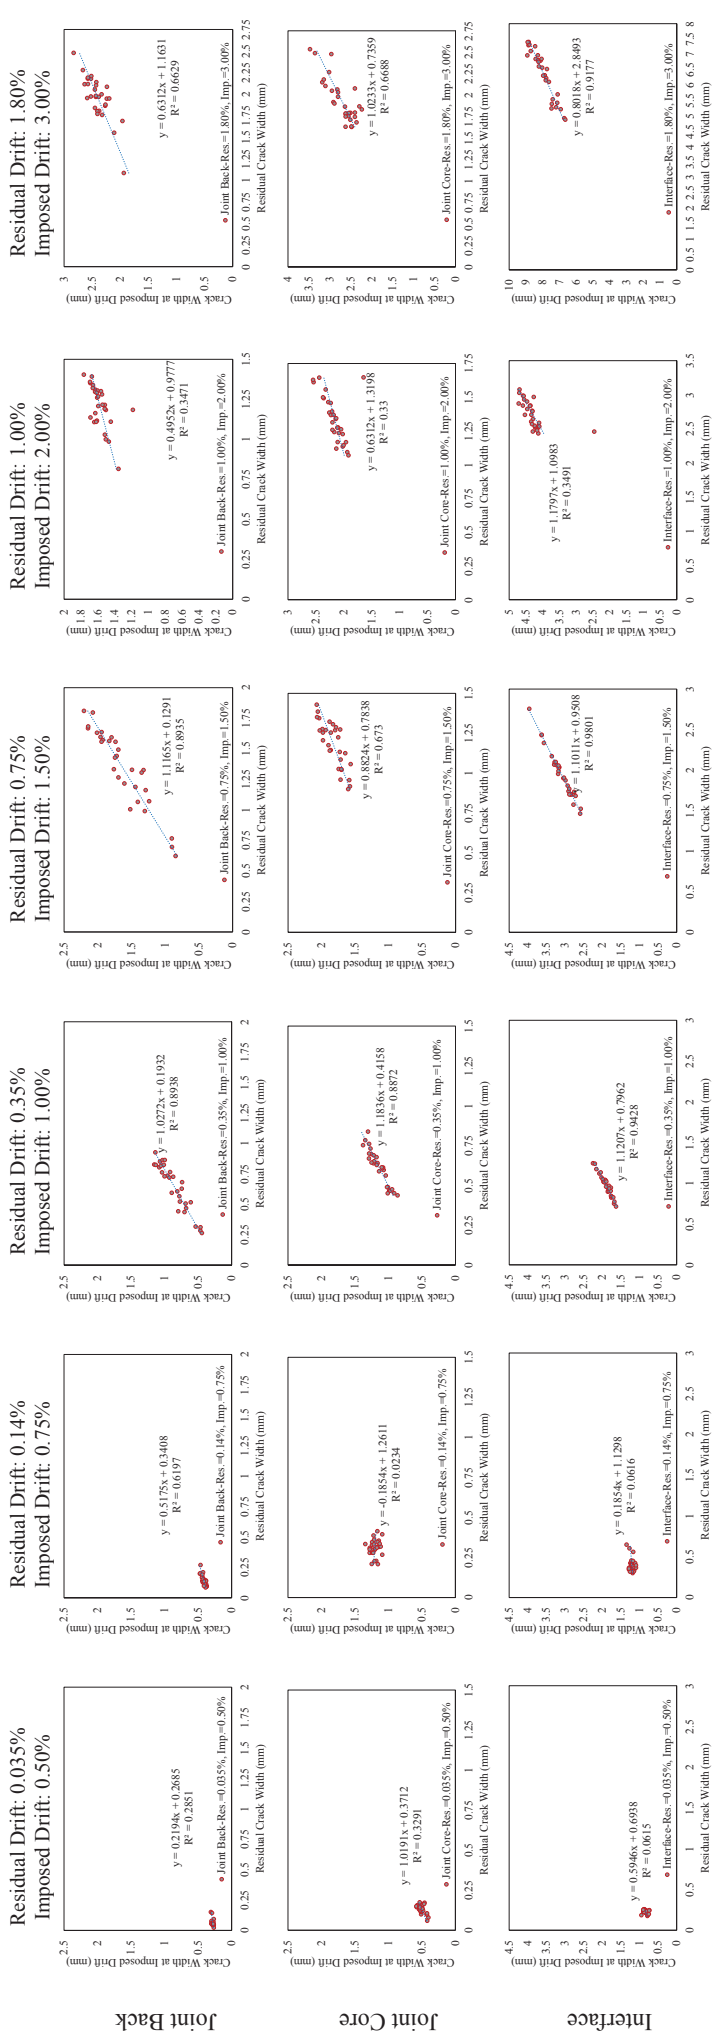

Figure 1. Correlation between (a) maximum crack width and imposed drift (b) residual crack width and residual drift (EJ_R)

Res: Residual Drift, Imp: Imposed Drift

Figure 2. Correlation between imposed/residual crack width (specimen EJ-R)

The evolution of the correlation coefficient, referred as a coefficient of determination R^2 , at each drift level in Figure 2 is presented in Figure 3. A low correlation between peak and residual crack width is found at low imposed drifts (i.e., 0.50 and 0.75%). This is due to the sensitivity of the crack width to the tensile strength of concrete at low joint shear stress demand [14]. Indeed, a high variability of concrete tensile strength is widely recognized [34, 35]. The R^2 values indicate the acceptable level of correlation between the residual crack widths and crack widths at imposed drift at 0.35% residual drift (corresponding to the imposed drift of 1.00%) and 0.75% residual drift (corresponding to the imposed drift of 1.50%). It should be noted that FEMA P58 [30] refers to the residual drift ratio of 0.5% as a threshold for the feasible repair action. The residual drifts of 0.35% and 0.75% are the closest values to 0.5% residual drift ratio representing the threshold limit as per FEMA P58 [30]. The correlation then drops to a certain level in the subsequent drift levels. This could be due to excessive damage in subsequent drift levels.

Figure 3. Coefficient of determination R^2 of the linear fitting of maximum vs residual crack width at increasing drift demand.

The change in the residual-to-maximum crack width ratio by the increasing imposed drift is presented in Figure 4a-c. If one of the parameters in Figure 4a-c is known, the other parameters can be estimated from the presented equations. For instance, the proposed relationships allow the calculation of the maximum crack width by knowing the residual crack width and maximum inter-story drift (that can be estimated with a numerical model). Thus, it allows correlating two of the most important EDP to assess building reparability.

An in-depth analysis of the results reported in Figure 4a-c allows to draw important consideration on the feasible reparability and crack closure effect for RC beam-column joints. An ascending linear trend is followed by a second linear trend with a lower steepness. The change of steepness approximately takes place between 1.00% and 1.50% imposed drift. With the less steep curve, the residual-to-maximum crack width ratio gets close to 1.00. Namely, the cracks become large enough, which are not closing, and exhibit large residual cracks. Therefore, the breakpoint of the curve where it changes the characteristics can be assumed as a feasible reparability threshold value. Note that the residual drifts of 0.35% (corresponding to 1.00% imposed drift) and 0.75% (corresponding to 1.50% imposed drift) are the closest values to residual drift ratio of 0.5% being a threshold for feasible repair according to FEMA P58 [30]. Overall, the change in the characteristics of the multilinear curve takes place between 1.00% and 1.50% drift ratio, being the corresponding imposed drifts closest to the feasible repair threshold.

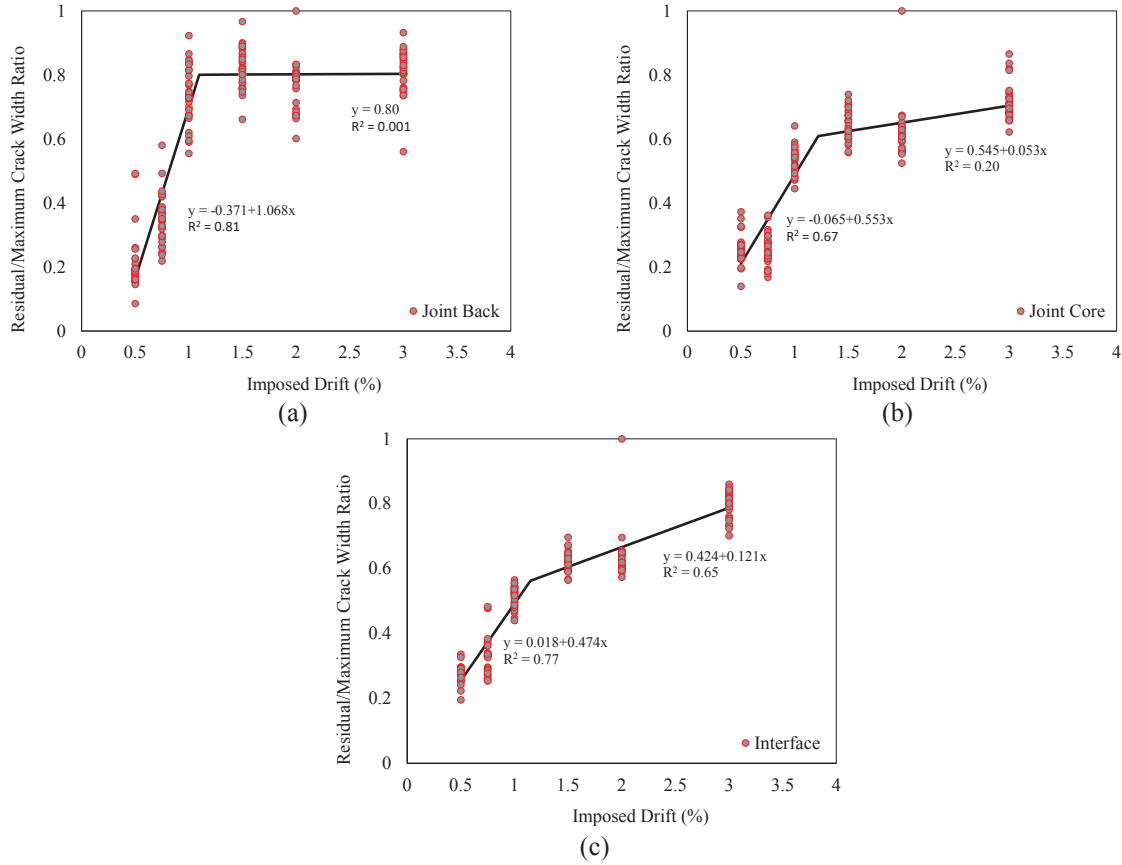

Figure 4. Residual to maximum crack width ratio at different residual drift levels

The proposed residual-to-maximum crack width curves are compared with each other as well as with the curve available in the literature (Figure 5). The trend of the proposed curve for the joint back crack is far from the experimental observations of Chen *et al.* [36]. That of interface predicts the experimental observations of Chen *et al.* [36] with a rather low accuracy, in turn, the proposed curve for joint core closely characterizes the experimental observations of Chen *et al.* [36]. The trend obtained for the joint core is best among all data in reproducing the experimental observations of Chen *et al.* [36].

Data retrieved from Chen *et al.* [36]

4 COMMENTS ON REPAIRABILITY

The apparent macroscopic damage at RC components, which covers wide cracks, the onset of concrete spalling, and local concrete crushing, is usually associated to the repairability threshold. Proper repair actions can restore the strength and stiffness of the component that experienced such a damage level. A comprehensive literature review of codes, standards, and guidelines [30, 37] showed a high scatter in the definition of the repairability threshold. FEMA P-58 [30] refers to DS1 (with corresponding maximum drift ratio of 1.75%) for non-conforming beam-column joints (under the condition that residual crack width is smaller than 1.50 mm) while HAZUS MR4 [37] associates the imposed drift with 0.60% for moderate structural damage. Besides, FEMA P-58 [30] also refers to residual drift ratio of 0.5% for the repairability threshold. As mentioned previously, the residual drifts of 0.35% and 0.75% are the closest values to 0.5% residual drift ratio representing the threshold limit as per FEMA P58 [30]. The imposed drifts are 1.00% and 1.50%, respectively. The change in the curve characteristics lies between imposed drifts of 1.00% and 1.50%, corresponding to the threshold value of residual drifts in FEMA P-58 [30] (Figure 6). To conclude, the breakpoint of the curve where it changes the characteristics can be assumed as a feasible repairability threshold value, which is between 1.00% and 1.50% imposed drift.

The correlated most important EDPs, which are residual and maximum crack width, allows the calculation of the maximum crack width. The maximum crack width can be calculated by the proposed curves if the residual crack width (which is a quantifiable parameter after an earthquake) and maximum inter-story drift (which can be estimated with a numerical model) are known. It should be also noted that this study relies on the numerical and stochastic assessment of the substandard beam-column joint. The specimen represents the substandard RC member with low strength concrete and plain round bar. The scatter in the stochastic analysis is considered only for material uncertainties. Besides, the resulting failure mode is shear failure together with slippage of the beam longitudinal reinforcement. A further study is required accounting for geometrical uncertainties together with different failure modes.

Figure 6. Repairability thresholds on residual-to-maximum crack width plots

5 CONCLUSION

Existing reinforced concrete buildings are vulnerable to seismic actions due to lack of earthquake-resistant design detailing. The poor energy dissipation and sudden strength and stiffness degradation may result in devastating brittle failure for beam-column joints. Furthermore, the lack of transverse reinforcement does not allow to keep the integrity of joint panel, often resulting in marked cracking difficult to repair. Determining widely recognized acceptance criteria for feasible repair is challenging. Limiting the residual drift is commonly accepted since it is a measurable quantity after an earthquake (i.e., the residual story drift and so residual crack). On the other hand, the maximum inter-story drift allows making proper consideration on the achieved damage state by using available fragility curves. However, this requires a reliable numerical model. Based on the results of numerical analyses by using a validated numerical FEM model, this study proposes a correlation between residual and maximum crack width as well as evaluation of both maximum and residual crack width.

Based on the obtained results, the following preliminary conclusions can be drawn;

- The reliability of setting a crack reparability limit based on the residual drift (and so crack width) is validated via the correlation between the residual crack widths and maximum crack widths.
- The data fitted with a linear relationship has enough accuracy. The correlation among datasets (i.e., imposed/residual drift and imposed/residual crack width), referred as the coefficient of determination R^2 in the graphs, is high demonstrating an acceptable level of accuracy of the data fitting at 1.00% and 1.50% imposed drifts corresponding to 0.35% and 0.75% residual drifts, respectively. Those are the closest values to 0.5% which is considered a feasible threshold value for repair according to FEMA P-58 [30].
- The residual-to-maximum crack width ratio graphs allow to draw important consideration on the feasible reparability and crack closure effect for RC beam-column joints. The change of steepness approximately takes place between 1.00% and 1.50% imposed drift. With the less steep curve, the residual-to-maximum crack width ratio gets close to 1.00. Namely, the cracks become large enough, which are not closing, and exhibit large residual cracks. Therefore, the breakpoint of the curve where it changes the characteristics can be assumed as the feasible reparability threshold value.
- The study relies on the numerical and stochastic assessment of the substandard beam-column joint with low strength concrete and plain round bar. The shear failure together with slippage of the beam longitudinal reinforcement is the resulting failure mode. A further study is required accounting for geometrical uncertainties together with different failure modes.

Abstract

Recent devastating earthquakes pointed out the high vulnerability of existing reinforced concrete (RC) buildings and the critical role of infills. The presence of stiff infills may significantly modify the lateral response of RC moment resisting frame buildings and cause severe damage on the surrounding RC members due to seismic actions transmitted at level of beam-column joints. Furthermore, due to their brittle response, they commonly exhibited severe damage often leading to high economic losses. In this context, effective seismic retrofit strategies should aim at both increasing the shear strength of RC members and reducing the damage to infills. However only few tests are available in literature addressing the seismic strengthening of existing RC frames accounting for the infill-to-structure interaction. To fill this gap a comprehensive experimental program of pseudo-dynamic tests on full-scale two-storey infilled RC frames has been designed and is currently ongoing at the full-scale laboratory testing of the University of Napoli Federico II.

This paper reports the preliminary experimental results and numerical analyses carried out by using available non-linear models accounting for the infills contribution. The comparison between theoretical predictions and experimental results provides useful insights to improve the numerical models to reproduce the infill-to-strut interaction. Finally, a retrofit strategy to improve the seismic performance of the structural system and reducing the expected damage to infills is herein outlined.

Keywords: pseudo-dynamic, full-scale, shear failure, FRP

1 INTRODUCTION

Recent devastating earthquake pointed out the high vulnerability of existing reinforced concrete (RC) buildings designed with obsolete code provisions. This resulted in number of fatalities, injuries and massive economic losses [1]. Severe damage were commonly found on hollow clay brick infills (see Figure 1a) [2] and at level of beam-column joints with marked shear cracks involving in many cases also the top end of the columns; this latter effect is caused by the interaction with stiff infills (see Figure 1b). Thus, stiff infills have a crucial role in the seismic response of existing RC buildings, modifying their dynamic response [3–5], increasing the shear actions transmitted to surrounding RC members [6], and, last but not least, experiencing significant damage and high economic losses due to their brittle response [7]. This remarks the need to properly account for the infill contribution to the lateral response of RC buildings and for the infill-to-structure interaction that may lead to premature shear failure of poorly detailed columns.

Figure 1: Case study building: front view (a); damage to RC column due to infill-to-structure interaction (b).

In the last decades, a significant research effort was devoted to the experimental testing [3,6,8–10] and numerical modelling of RC building or frames with hollow clay brick infill and partitions [5,6,11,12]. This resulted in number of analytical and numerical approaches to assess the infill contribution to the lateral response of RC buildings. Nowadays different numerical models are available [3,6,9,13–16]. They can be used to assess the damage state of the infills and the action transmitted to the surrounding frames. Furthermore, refined analytical models are recently proposed to capture the column shear failure due to the infill-to-frame interaction.

Although number of studies can be found in literature to assess the contribution of infills to the lateral response of RC buildings, only few researches addressed the experimental behavior of full-scale RC frames and their seismic strengthening to resist the infill action [17,18]. This paper presents the preliminary results of pseudo-dynamic experimental tests carried out on infilled full-scale RC frames. The experimental outcomes are reported and compared with the preliminary results of a numerical model. Then, the model is used to assess internal actions in RC members that can be used for the design of suitable strengthening solutions.

2 EXPERIMENTAL PROGRAM

The experimental program consists of pseudo-dynamic tests on a full-scale two storey infilled RC frame (see Figure 2). The frame reproduces a perimetral frame of a real building damaged during the L'Aquila earthquake (2009), see Figure 1, and re-built due economic inconvenience of repair and structural retrofit [1]. Indeed, the severe damage to structural and non-structural components (see Figure 1) resulted in very high repair costs.

Figure 2: Front view of the prototype infilled RC frame.

The selected frame is extracted from the building depicted in Figure 1. It is 6.86 m high and 4.50 m long. The interstorey height is about 3.10 m and the foundation block is 0.56 m high. The square columns, 0.40 m side, are reinforced with 8 ϕ 16 mm longitudinal bars and ϕ 8 mm transverse reinforcement 250 mm spaced. The beam is 0.55 m high and 0.40 m width reinforced with 6 ϕ 16 mm and 4 ϕ 16 mm bars at top and bottom side, respectively. The joint panel have no transverse reinforcements as commonly observed in existing buildings built in the last century in the Mediterranean area.

The concrete compressive strength of the tested frame is about 8 MPa corresponding to a very poor-quality concrete as often found in many existing buildings in the Mediterranean area [19].

Hollow clay brick stiff infills are used at both floors. Square bricks with 250 mm side and 200 mm thick are used. Furthermore, 10 mm joints of M10 class mortar are used to build the infill walls. The mechanical characterization tests on wall samples showed a shear strength of about 0.35 MPa.

The experimental program consists of pseudo-dynamic tests at increasing intensities. In particular, the AQG record in the Est direction ($PGA=0.45$ g) of the 2009 L'Aquila earthquake is used as input acceleration. The Alpha-OS [20] integration algorithm is used for the numerical solution of the equation of motion and calculate step-by-step the displacement profile to apply at the different floors. The mass matrix is defined considering two lumped mass at the level of

the two floors. They are calculated making simple considerations on the substructuring of the test. In particular, it is assumed that the portion of the floor mass belonging to each frame is function of the elastic stiffness of the frame. In this case, exterior frames are considered infilled and interior frame bare. The test results in terms of recorded displacement histories at the two floors as well as in terms of global hysteretic response are reported in the following and compared with the numerical predictions.

3 NUMERICAL MODELLING

A non-linear FEM model has been developed in the SAP2000 environment [21]. An overview of the adopted model is reported in Figure 3 along with the selected capacity models used to characterize the structural members and the infill walls.

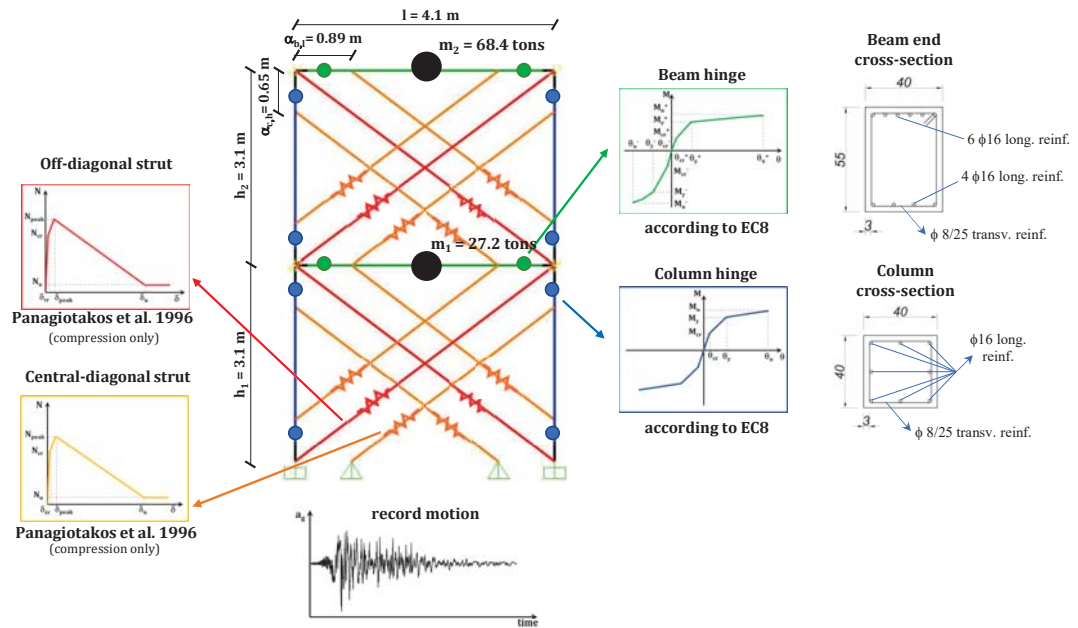

Figure 3: Overview of the adopted numerical model.

The frame is represented by using the member axis. All the nonlinearities are lumped at the member ends. The plastic hinge properties are characterized by using the capacity models suggested by the Eurocode 8 [22] and Italian building code [23,24] for the plastic hinge rotation at the yielding and at the ultimate limit state. The contribution of the joint non-linear response to the building lateral deformation is neglected at this stage. The infill walls are included in the model by means of diagonal compression struts in the perimetral frames. A three-strut model is considered for this study. Indeed, it is demonstrated that this model can reproduce the actual force distribution transmitted by the infills to the surrounding frame members [6]. The mechanical properties of the strut are defined according to the Panagiotakos and Fardis model [3]. The mechanical properties of the hollow clay brick masonry wall are assumed according to mechanical characterization tests (i.e. $\tau_{cr} = 0.35$ Mpa). The distribution of the portion of the infill lateral load absorbed by each strut assumed in this work is compliant with the proposal by Jeon, Park, and DesRoches [25], while the mechanical characterization of the off-diagonal struts have been reproduced according to the proposal by Chrysostomou et al. [26]. Furthermore, the use of a three-strut model allow to identify the ac-

tual distribution of shear on the column due to the interaction of the RC frame with the infill walls [6]. Nonlinear time-history analyses (NLTH) are carried out imposing the input motion at the base and concentrating the masses in the center of the beam. A mass of about 27.2 tons is applied at the first level, while a mass of 68.4 tons at the second level. The reference mass of the selected frame is calculated distributing the total floor mass of the reference building (see Figure 1) as function of the elastic stiffness of the frame respect to the total floor stiffness of the building. The masses of the third and forth floor are lumped at the second level assuming that they behaved as rigid floor. This assumption is made according to those made in the substructuring of the pseudo-dynamic test as discussed in the previous section.

4 COMPARISON OF EXPERIMENTAL AND NUMERICAL RESULTS

A direct comparison of the experimental and numerical response in terms of measured top displacement, d_2 , during the pseudo-dynamic test at 50% and 100% of the 2009 L'Aquila earthquake is depicted in Figure 4.

Figure 4: Comparison of experimental and numerical results in terms of top displacement: 50% of the selected record motion (a); 100% of the selected record motion (b).

The comparison outlines the accuracy of the proposed modelling procedure that is capable of providing reliable estimations of the top displacement at all the steps of the test. In particular, the best match between experimental response and theoretical model at 50% of the earthquake intensity (Figure 4b) is attained in the first 5 seconds of the test. Also, the peak displacement of about 3 mm is well captured by the model. In the following time steps, the model predicts a displacement lower than the experimental one as a consequence of a theoretical stiffness higher than the actual one. This can be clearly observed comparing the experimental and

global stiffness expressed as the ratio of the base shear and the top displacement showed in Figure 5a. Although a quite good matching can be observed also in the hysteretic response, the numerical model have a post peak degraded stiffness higher than the experimental one in the range 0-1 mm. This results in an underestimation of the top displacement in the post peak after 5 s in the time-history response.

Figure 5: Comparison of experimental and numerical results in terms of global hysteretic response: 50% of the selected record motion (a); 100% of the selected record motion (b).

With reference to the test at 100% intensity of the L'Aquila 2009 earthquake, a top displacement of about 13.5 mm is achieved. It is significantly larger than the double of the one achieved at 50% due to the stiffness degradation in the infill walls. This can be clearly observed comparing the two responses in Figure 5, where a drop of the experimental secant stiffness of about 1/3 to 1/4 can be observed. The numerical model well captures both the displacement time history and hysteretic response resulting in an good accuracy of the predicted displacement and base shear during the test.

5 STRUCTURAL DAMAGE AND RETROFIT STRATEGY

During the test at 100% of the earthquake intensity a significant shear cracking at top of the ground floor columns was observed. This is related to the infill-to-structure interaction and could be triggering of a shear failure and collapse as observed in the post-earthquake inspections in many exiting RC buildings. In order to assess the reliability of the proposed modelling procedure to assess the shear failure at the top of the columns due to the infill-to-structure interaction, the model proposed by Verderame et al. [6] is used to evaluate the shear strength. According to experimental evidences and other available literature models [27,28], the shear strength degrades as function of the inelastic demand at the top of the column. Despite other degrading models, it allows to account for the actual internal force distribution due to the interaction with the off-diagonal infill strut insisting on the column. The overlapping of the shear strength with the shear demand at the top of the column due to the infill action is depicted in Figure 6. The intersection between capacity and demand allows to recognize the shear failure detected at a top displacement at the ground column of about 4.15 mm corresponding to about 0.2% drift. This result clearly remarks the key role of such failure mode to properly assess the seismic response and the structural safety of existing infilled RC buildings. In order to avoid such a kind of failure, different strengthening solutions can be found in literature [17,29,30]. However, it should be considered that recent financial incentives provided by the

Italian government, consisting in 100% tax deduction of the cost of seismic strengthening interventions, exacerbated the need to have light strengthening intervention that can be applied to the structural system with a minimum level of disruption [31,32].

Figure 6: Comparison of the shear demand at the ground floor column top end and shear capacity

This will help the widespread of seismic strengthening interventions to large scale and may fulfill the needs to significantly improve the seismic response with the low disruption to occupants. In this context composite materials may represent a sound solution because they combine the advantage related to the easy installation procedure with their high performances to increase the shear capacity of RC members and beam column joint panels [33]. In light of the observed damage and the structural weaknesses outlined from numerical analyses, the strengthening layout proposed in Figure 7 is initially outlined.

Figure 7: Strengthening system for the RC frame.

It consists of the column end shear strengthening by using Quadriaxial or uniaxial CFRP wrapped around the column on the two sides. This is in line with the strengthening system proposed in the ReLUIIS guidelines [29] to resist the infill action. Then quadriaxial fabric is

also outlined on the joint panel serving as joint shear strengthening to avoid the joint panel shear cracking, which are commonly observed in poorly detailed subassemblies. Number of layers of quadriaxial fabric on the joint panel can be designed according to the formulation proposed in the fib bulletin 90 [34] properly developed and validated on experimental data [29]. The novelty of this new proposal consists in the use of FRP mechanical anchors to replace the commonly adopted U-wrap on beams and columns useful to avoid end-debonding. This may further reduce the disruption to occupants in real field applications. This is a promising technique [32] that requires further experimental investigation to validate its use at large scale. Ongoing experimental tests will show the advantages and limitations of such strengthening solution.

6 CONCLUSIONS

This research focuses on the design and analysis of an experimental pseudodynamic tests on a full scale infilled RC frame representative of a portion of an existing RC building damaged by the L'Aquila 2009 earthquake. The analytical modelling of the specimen behavior under seismic actions is also presented. In particular, the experimental results in terms of time histories of the top displacement and global hysteretic response are showed and compared with the results of a non-linear FEM model. The following preliminary conclusions can be drawn:

- the experimental tests remarked the role of stiff infills in the lateral response of existing RC frames. They increase the stiffness of the building resulting in a reduction of the displacement demand and in an increase of the seismic forces that will be transmitted to surrounding RC members;
- the proposed non-linear numerical model consisting in a lumped plasticity model for the RC frame and in a three-strut model to reproduce the infill contribution well captured the global displacement and hysteretic response occurred in the experimental tests;
- the proposed numerical model allowed to quantify the actual internal force distribution with particular emphasis on the shear actions transferred from the infill to the RC columns;
- literature shear strength capacity models properly developed to account for the top column shear failure due to infill-to-structure interaction allows to accurately predict the failure mechanism and to provide useful insights for the design of an effective strengthening intervention.

Keywords: Heritage, FRCM, Retrofit, Composite Materials, Masonry.

Abstract. *In this contribution are reported the first results of an experimental campaign conceived to evaluate the performance of FRCM (Fiber Reinforced Cementitious Matrix) composite materials for the recovery and restoration field of heritage buildings. With reference to the risks of seismic collapse concerning ancient masonry buildings, the peculiar structural behaviour of “in falso” walls, a typology of load-bearing masonries built without a direct load path to the foundations, has been examined. The tests have been conducted, through an experimental set-up specially designed, on two rectangular walls characterized by the same basic traits: the first one in unreinforced masonry, the second presenting a non-canonical “truss-like” application of bands of composites. Alongside the progression of the experimental campaign - delayed due to the COVID outbreak - that in the near future will engage other two masonry panels enhanced by different applications of the FRCM, the creation of a FEM will be achieved gathering data from the new tests in order to replicate the complex mechanical behaviour of the FRCM composites with reference to the skills and time required for different installation modalities.*

1 INTRODUCTION

For any country, the conservation of heritage buildings is a primary goal: it is a reflection of the society and a basic tool to transfer its cultural and educational values. These purposes require an inclusive and interdisciplinary approach to masonry structures' reinforcement that involves, among the others, structural engineering, non-destructive techniques of survey, numerical modelling and architectural design [1, 3, 4]. In this regard, as part of an ongoing research, a peculiar focus is dedicated to the study of the mechanical behaviour of natural FRCM composite materials in the field of the innovative strengthening techniques, since they are compatible with the architectural value of historic surfaces and are, to a large extent, reversible, biodegradable and eco-friendly; however, their numerical modelling represents a complex task, due to the interactions between fibers, matrix and masonry. Moreover, a previous experience, that covered the seismic assessment and the restoration plan of an architectural complex designed by Luigi Vanvitelli, pointed out a recurrent feature affecting the structural safety of Italian heritage architectures: the presence of "in falso" walls, consisting of load bearing walls built without a direct load path to the ground and standing on top of masonry vaults [2, 5]. That occurrence, in case of seismic action, could trigger a "domino effect", due to the possible collapse of underlying masonry vaults, then compromising the safety of the entire heritage structure. However, it should be noted that the investigation for the mechanical behaviour of the such walls, that struggle to perform like masonry beam structures, is not adequately investigated by the scientific literature. In order to improve the knowledge about such topic and to investigate new applications of FRCM technology, an experimental campaign has been started in partnership with a company, the Kimia S.p.a., to evaluate the effectiveness of composites regarding the prevention of in-plane collapses described above.

2 THE EXPERIMENTAL CAMPAIGN

2.1 The setup implementation: an experimental test designed "ad hoc"

The FRCM systems represent an innovative class of fiber-reinforced composites, which are becoming broadly used concerning heritage constructions. The key feature of this emergent technology is the replacement of the classical polymeric matrix with an inorganic one, making them particularly effective in retrofitting of historical masonries given their chemical, physical, and mechanical compatibility to the ancient substrates. Such new-gen. methodologies allow to fulfil the strengthening and the architectural reconfiguration of historical masonry buildings in compliance with the cultural and social context. On this, the benefits of FRCM materials are the following:

- Good mechanical properties in the face of low thickness and little weight;
- Easy installation modalities ensuring the continuity of the building's activities;
- Use of inorganic mortar (less aggressive than the epoxy resins) that is useful in order to apply first aid enhancements whilst and at the same time permits a better transpiration to masonry;
- Chance to recycle, considering the natural origin of nets and the matrix characteristics.

Several experimental investigations have been carried out so far - during previous experiences - both at the scale of the composite material and of the single components, reaching an adequate level of experimental mechanical characterization of the materials used for the campaign

in question; for further details refer to such data [6]. Even so, in this contribution the beneficial effects of composites on walls subjected to gravity loads and earthquake actions in peculiar conditions are highlighted, also with reference to the installation modalities. Indeed, the outcomes deriving from an experimental test on an ordinary masonry wall and another one retrofitted according to non-canonical criteria are compared. In order to evaluate the influence of FRCM in the prevention of knock-on collapses a specific experimental set-up has been conceived, and realized, to engage life-sized masonry walls with action similar to the ones ascribed in case of collapse of the below vaults on which they rest: masonry panels inferiorly suspended, except for lateral supports of reduced length, Figure 1. Therefore, with the aim of bringing a single brick wall to failure, a steel contrast portal has been designed - and realized - to make a self-balanced closed system.

2.2 Preparation of the specimens

The masonry specimens are walls of the dimensions 2.4m wide for 1.2m high, made of a single wythe of solid bricks, of dimensions 12x24x5.5 (respectively thickness, width and height), and recalling the wall's dimensions provided by the Italian Building Code for the shear verification [7]. Concerning the materials' features of the walls, solid bricks and lime mortar were used and with reference to the latter a "shoddy" lime inorganic mortar (M 2.5) with poor mechanical properties was created from the company in order to simulate the structural behaviour of a historical masonry.

Concerning the composite materials, the fiber net *Kimitech BS ST 200* and the matrix *MALTA M15/F* have been used. In particular, has been used a bidirectional basaltic fiber net characterized by a size of the square knitting interaxle spacing of 20mm between the strands (of 4mm wide). The matrix is a lime inorganic mortar with maximum 1.20 mm particle size distribution. The samples' preparation, concerning the application of the composites, required:

- the cleaning of the surface of the masonry substrate and its saturation and wetting (condition s.s.a.);
- application of a first layer of mortar Basic MALTA M15/F;
- positioning of the fiber net Kimitech BS ST 200;
- application of a second layer of mortar Basic MALTA M15/F.

As mentioned so far regarding the reinforced wall, for this non-conventional reinforcement a specific intervention was designed - since generally this type of composite material is applied evenly on the wall's surface - devising the application of FRCM bands each 20cm wide, a measure that represents a multiple of one meter, the dimension with which the meshes in basaltic fiber are produced [8].

The goal was to reinforce the weakest areas of the wall thus using less composite material than in the classic applications: the diagonals subject to traction, two shorter diagonals parallel to the main ones but placed below, the lower band of the masonry panel and, moreover, three vertical bands useful for maintaining adhered to the wall the ends of the other strips of composite material. The reinforcement intervention was applied with the same criteria on both sides of the wall. After the curing period exceeding 56 days - 28 days for the walls plus the same duration for the FRCM - the experimental tests were performed. All the material's mechanical features are available in the aforementioned contribution [6].

Figure 1: On the right, the “in falso” walls of Palazzo Murena. On the left, a schematization of the walls in the vault’s collapse scenario.

2.3 Boundary conditions and acquisition systems

In the scientific literature there are several references to experimental tests, both codified and innovative ones for these materials, but there is no one similar to the one presented in such contribution [9, 10]. The specimens were built directly on top of steel temporary supports, designed with a dual function: the first reason to facilitate their movement on the portal-shaped steel frame, the other to prop-up the walls themselves until the beginning of the test; in both cases without causing damages or deformations to the samples. Thanks to a forklift it was possible to remove the support - separated from the rest thanks to plastic sheets - and begin the test with the walls, already equipped with sensors, resting only on the remaining permanent lateral supports (Figures 2 and 3); such constraint condition is addressing the described above damage scenario (Figure 1). Concerning the load conditions, the load was applied gradually by means of a hydraulic jack placed on the top of a load cell. About the modalities, force distribution steel beams were used to create a load concentrated in two points, by means of two steel plates, similar to an equivalent distributed load. Moreover, an active sensor system has been implemented. A total of 8 Linear Variable Displacement Transducer (LVDT) sensors was installed on the wall - 4 for each side - as indicated in Figure 4. The measured lengths were extended by means of diagonal support rods anchored to the specimens through rocker like constraints. Those sensors along with the load cell, aimed at measure the applied load, were connected to an acquisition system.

3 THE TWO EXPERIMENTAL TESTS

In this Section will be discussed, and finally compared, the results of the aforementioned first two tests, in the order: ordinary masonry and masonry reinforced on both faces with a truss-like application of FRCM designed to reinforce the diagonals subjected to tension and other significant parts [11].

3.1 Experimental test on the ordinary wall

Both tests lasted less than 15 minutes. The breakage, as can be seen in Figure 3, occurred due to the separation and breakage of the mortar joints. In test led to breaking the masonry sample with the damages starting at a load of about 40KN.

As far as possible, the load was applied gradually with the hydraulic jack by controlling the load cell connected to the acquisition system.

Due to the structural relaxation, even before the removal of the sensor's support rods, a further collapse and the effective damage pattern came forward. From the critical interpretation of this latter, a “arched” stress redistribution mechanism is observable, comparable to the one to which are subject the weakly reinforced concrete beams, Figure 3. Moreover, concerning the data acquisitions, it is observable that the sensors sg2 with sg6 and sg3 with sg7 record consistently even if, however they mate on opposite faces, not all manifest the same trend. For example, it is noted that, possibly due to a manufacturing defects on the wall, the sensors sg1 and sg4 were in traction (negative sign on the acquisitions), Figures 4 and 5, perhaps implies a flexural behaviour out of plane of the wall. Considering that is an innovative and non-codified type of test, such results have been used as a basis for the subsequent test which, except for the application of the composite materials, in every part has been analogous to this one. The purpose is to evaluate, by comparison, the influence of FRCM on the structural behaviour due to seismic damages to the vaulted underlying masonry elements. Therefore, the same procedure will always be respected also in the future tests, also in terms of points of view for the photos.

Figure 2: On the right starting with the top row, the ordinary wall ready to be moved, handling of the same and the subsequent removal of the steel support, zoom on one of the two remaining supports. On the left, masonry wall reinforced with truss-like application of FRCM at the start of the test, all components of the setup.

3.2 Experimental test on the wall reinforced with FRCM

In this case it was possible to witness a peculiar collapse phenomenon which manifested itself first with partial lesions on the composite reinforcements and then led to the collapse through the breaking of bricks (and not by the separation of the courses, as seen in the first test). Moreover, were necessary about 140KN to break this wall, compared to the 40KN needed to breach the unreinforced one in the very first test.

Figure 3: On the right, tearing of the wall at the end of the test. On the left, photo of the experimental setup at few minutes later the completion of the test.

Although the beginning of a fracture in the lower left reinforcement band has been observed during the test, the presence of the vertical strip in composite probably led to an asymmetry in the damage pattern of the wall that has collapsed because of a large crack located on the right side of the wall, that evidently was weaker (Figure 6). It is observed how the instruments that match each other on the opposite faces of the reinforced wall (sg1-sg5, sg2-sg6, sg3-sg7, sg4-sg8) seem to acquire data consistently and in parallel. In particular the diagonals with sensors sg1, sg4, sg5 and sg8 worked at traction, Figure 7. From the previous and further data processing (Figure 8) it is clear that during such test the expected behaviour of the diagonals, in terms of displacements related to compressive and tensile deformations, was confirmed. Among the readings of the instruments, the one of inferior quality this time concerned only that of the sensor marked as sg1. For purposes of comparison, the averages of the sensor readings with positions sg3 and sg7 (Figures 5 and 8) were plotted in relation to the applied load path, which in the authors' opinion represent reliable measurements in both the experimental tests, Figure 9.

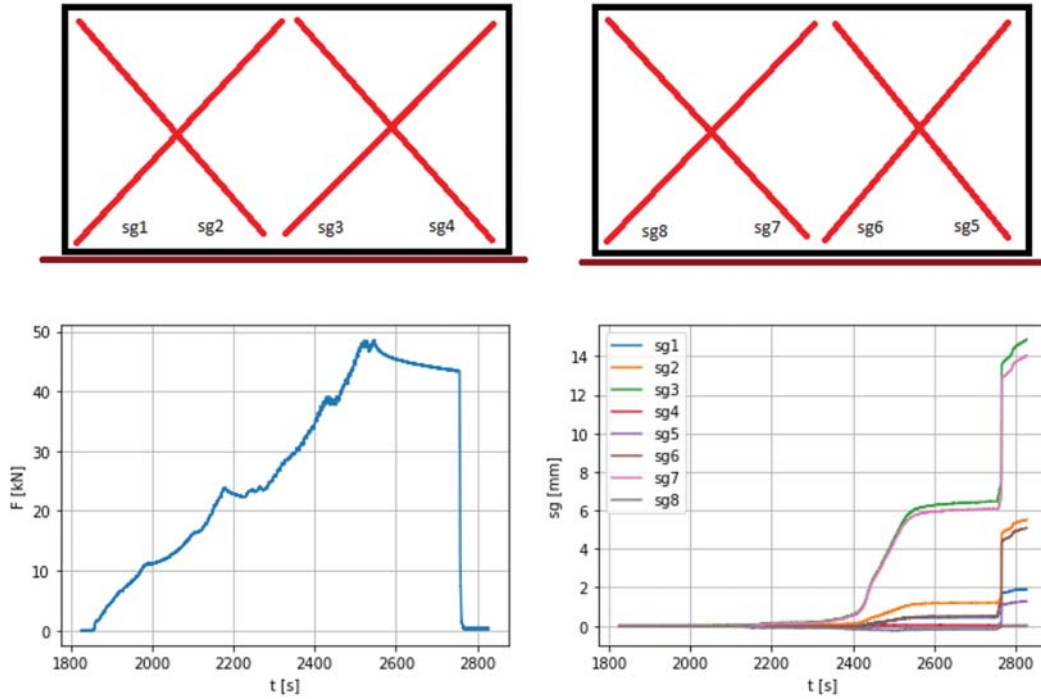

Figure 4: On the top the positions of the sensors on the wall (the picture on the right presents the same point of view of the photos reported in Figure 3). Below, respectively the force and displacement diagrams against time.

Figure 5: For the sensors subjected to tension, force-displacement graphs for collapse incipient.

Figure 9: A comparison diagram between the two tests: unreinforced masonry in blue lines, the reinforced wall in orange lines.

4 CONCLUSIONS

- A focus on the study of the mechanical behaviour of natural FRCM composite materials was carried out in the field of the innovative strengthening techniques on masonry structures, since they are more compatible with the architectural value and specificities of heritage buildings;
- A experimental setup has been designed and realized in order to evaluate the influence of FRCM in the prevention of knock-on collapses in heritage buildings and to, in a future perspective, achieve the creation of a Finite Element Model gathering data from the tests;
- The first two tests have been made, involving an unreinforced masonry panel and a reinforced one, whose allowed to analyse the good functioning of the experimental setup designed and to evaluate the loads necessary to break the prototype and observe the stress redistribution mechanism due to the peculiar constraint conditions.

Abstract

Eccentric steel bracing with a vertical shear link is a type of seismic force resisting system that could be selected for seismic retrofitting or upgrading of existing structures. Previous studies have shown that short links with relatively small sections could develop peak shear forces larger than usually predicted values, because of a combination of geometrical characteristics of the link cross section, the link length and the boundary conditions. The peak shear force could be limited by the ductility demand as well as by the occurrence of local and/or global buckling phenomena. This paper explores the response of eccentric bracing comprising the link as well as the diagonal members, looking for the overall behavior. To this end, realistic eccentric bracing systems have been first designed. The case studies were generated starting from the analysis of an existing RC school building in Italy. The existing building was selected within an Italian research project sponsored by the ReLUIS consortium and the Department of Civil Protection in Italy. The response of the existing RC structure was upgraded by designing a steel eccentric bracing system to fulfil the design criteria of the Italian seismic code. Then, the steel bracing system was modelled by means of the finite element (FE) method. This paper describes shortly the design criteria and the consequent results. Then, the FE models and the analyses are described in detail, especially discussing the global behavior in terms of steel strain hardening and overall system stability at the peak inelastic deformation demand estimated at the design stage.

Keywords: Building, brace, buckling, FEM, link, upgrading.

1 INTRODUCTION

Older reinforced concrete (RC) buildings usually suffer from known structural deficiencies which typically lead to poor seismic performance. In fact, several structural and non-structural damages were observed during past and more recent earthquakes [1]. Nowadays, because of the severe difficulties in upgrading existing buildings, the Italian seismic code allows designing for a minimum performance. In fact, the code introduces a conventional risk measuring parameter (ζ_E), defined as the ratio between the maximum seismic intensity that the building is predicted to resist and the design intensity that it should resist if it were a new building. The ratio ζ_E is accepted to be less than unity, but not less than a minimum value; for example, in case of school buildings $\zeta_E \geq 0.60$. In this context, retrofit solutions which maximize the building resistance and ductility while increasing the lateral stiffness are worth to be studied, addressing designers in using less conservative assessment procedures and designing structural details for which one can have both numerical and experimental validations. The technical literature has proposed several technical solutions based on using additional steel elements. Y-bracing with vertical shear links is one possibility, allowing to increase the building lateral stiffness, resistance and being inherently ductile [2,3,4]. In fact, steel braces do generally provide significant increase of the global system stiffness, thus contributing to reduce the deformation demand to existing members and joints. Besides, the use of yielding links allows the additional forces introduced into the existing system to be limited to selected upper bounds, so that the existing structure could sustain the change in the loading system. In case of eccentric bracing, the use of short links is usually preferable, because short links allow maximizing the increase of global system stiffness while minimizing the moment demand to the connections between the link and the existing RC frame members.

Therefore, the paper describes an investigation into a few design and analysis issues for Y-bracing systems with short links, by adopting an existing school building as a case study. Numerical modelling issues are discussed concerning both global and local behaviors, especially referring to the out-of-plane stability of the bracing system.

2 CASE STUDY STRUCTURE AND DESIGN OF THE BRACING SYSTEM

The case study structure is taken from an existing school building located in a small town in Italy (Loro Piceno, MC). Figure 1 summarizes the structural layout with plan and elevation views. The building has moment-resisting (MR) frames in the transverse (X-) direction, while both MR frames and RC walls exist in the longitudinal (Y-) direction. The RC walls evidently originate some irregular dynamic response. In fact, the modal analysis results for the as-built structure show that the first vibration mode is mainly torsional, while the second mode was a combination of translation in the X-direction and torsion. On the contrary, because of the relatively large lateral stiffness of the RC walls, the Y-translational mode of vibration was essentially uncoupled from the torsional response. Structural deficiencies were found in beams and columns, as well as in beam-to-column joints, leading to premature shear failures. Therefore, the need for some local reinforcements to ensure a global ductile failure mode was apparent from the analysis of the as-built structure [5, 6]. However, to improve the overall system performance (i.e., to reduce damage to non-structural elements), a global bracing system was also needed to keep the displacement demand into an acceptable range.

Figure 1 shows an overall view of the designed bracing system. The figure highlights also the plan location of the braces. Design of the additional steel members was carried out according to [7, 8, 9]. Two alternative design solutions were analyzed: (i) short links with HE cross sections and (ii) short links with built-up square hollow sections (B-SHS). In both cases, diagonal members were designed using HE cross sections. In Figure 1, information concerning

the RC beam and column dimensions are also summarized. Eventually, the figure shows the link and brace cross sections.

Figure 1: Plan and elevation views of the structural layout.

The design of connections was carried out according to [10]. Capacity design rules and strain hardening of the steel links, as well as uncertainties in the definition of the link yielding strength, were considered according to [7, 8]. Figure 2 shows examples of typical connection details for the considered case study. Particularly, Figure 2(a) and Figure 2(b) show examples of link to RC beam connections, for the HE and the B-SHS design solutions respectively. In both cases, link to RC beam connections were strongly affected by the concrete edge failure mode [11, 12], thus resulting in multiple anchors to allow for sufficient connection overstrength, especially for the HE links (Figure 2(a)). A smaller number of connectors was needed for the B-SHS links because of the smaller link length producing smaller moment demand to the connection (Figure 2(b)).

Figure 2: Link-to-beam connections: (a) HE; (b) B-SHS.

Figure 3(a) shows the connection between the brace and the RC beam-column joint, while Figure 3(b) shows the brace connection to the RC column and foundation beam. In every case, brace connections were designed assuming fixed ends for the diagonal members, thus conservatively evaluating the bending moment demand.

Figure 3: Brace to frame connections: (a) at a beam to column joint, (b) at a foundation beam joint.

3 ASSESSMENT OF THE EXISTING STRUCTURE AND DESIGN OF THE BRACING SYSTEM

3.1 Numerical models

The global seismic response assessment was carried out by developing a 3D non-linear model in SAP2000 [13]. All the RC members were modelled non-linearly with a concentrated plasticity approach [6]. Diagonal brace members were modelled as elastic beam-column elements, while a shear plastic hinge was used to consider link yielding and cyclic hardening. Figure 4 shows the link shear force (V_l) vs. link chord rotation (θ) relationship adopted for the global structural assessment. The link shear force was normalized by the design resistance of the link ($V_{l,Rd}$). Other backbone parameters were obtained by applying the ASCE-SEI standard rules [14]. According to the Italian code [7], the maximum link rotation should not exceed $\theta_u = 0.08 \text{ rad}$.

Figure 4: Modelling the shear links for design purposes.

3.2 Analysis results

Pushover analysis results are summarized in Figure 5. Two force distributions were used for the analysis: (i) a modal force pattern (MP) and (ii) a uniform force pattern (UP). The worst structural response was always observed in the Y-direction. The ratios between the lateral stiffness considering the EBs and the bare RC frame model resulted equal to 2.4 and 1.3 for the X- and Y-direction, respectively. The ratio between the base shear force resistance of the structure equipped with EBs and that of the bare RC frame was equal to approximately 1.5 for every building directions and link sections. In the figure, ductile failures of members are highlighted with empty circles ($\zeta_{E,min} > 1$). Empty triangles in the plots highlight brittle shear failure of RC columns. In the case of the structure with EBs, such condition was reached with a value of $\zeta_E = 1$, i.e. with a fully satisfactory performance.

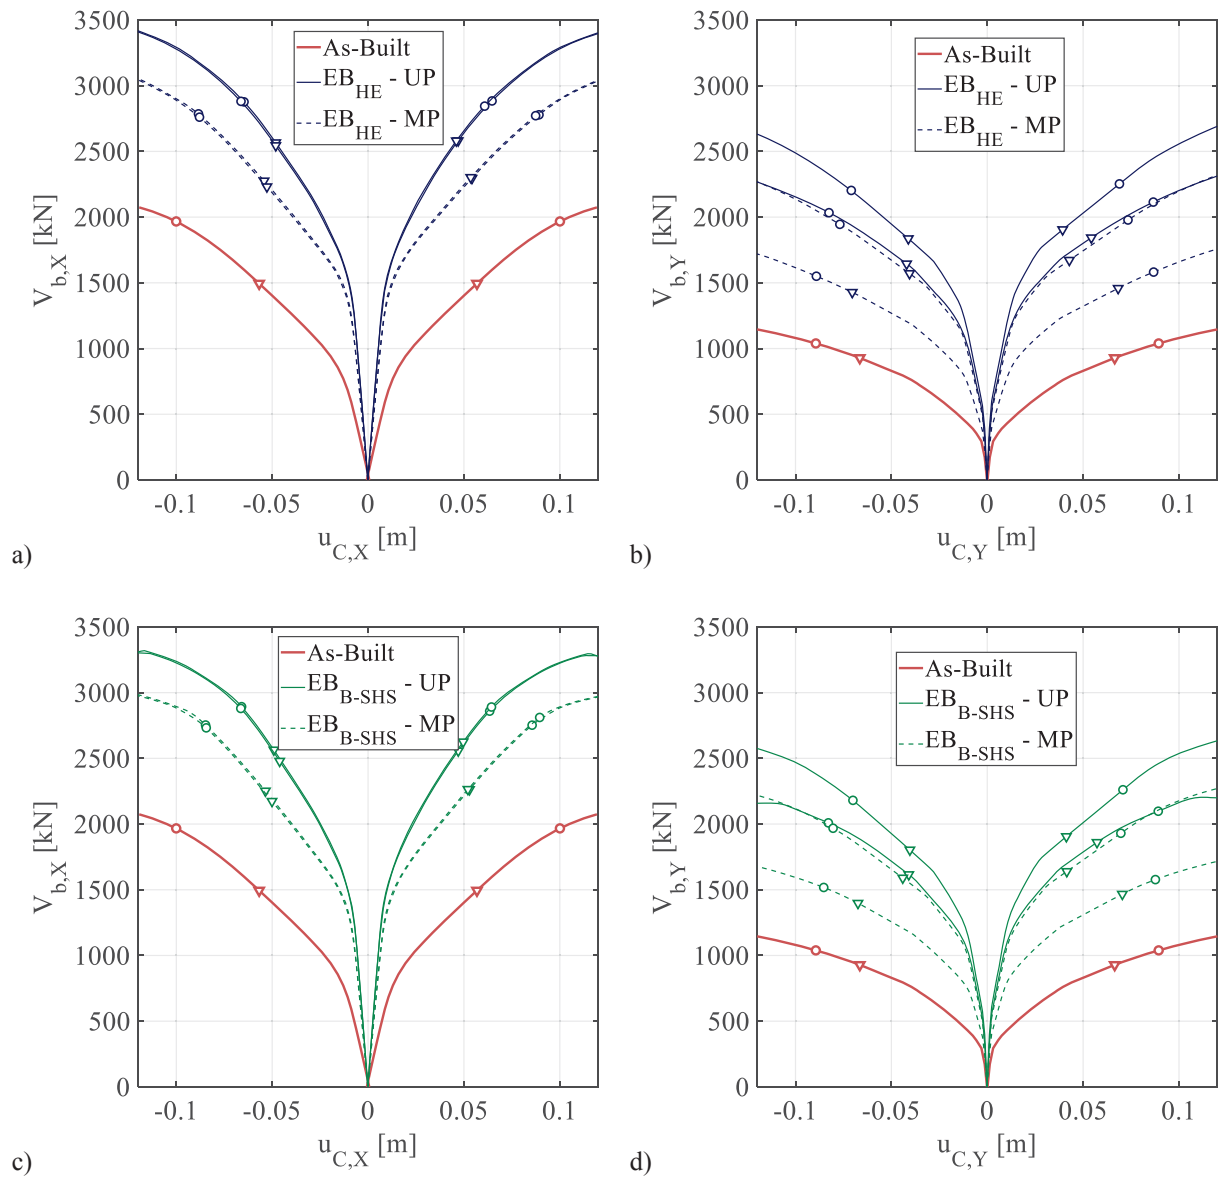

Figure 5: Pushover analysis results:

4 ANALYSIS OF THE BRACING SYSTEM RESPONSE

4.1 Numerical models

The out-of-plane (OoP) stability of the bracing system and the effects of various models for the steel strain-hardening response were investigated using finite element (FE) models of a couple of braces and the corresponding vertical link. The models were built by using non-linear shell elements. Two FE software packages were adopted to perform the analysis and compare the results: (i) *SAP2000* and (ii) the open-source software *Code_Aster* [15]. The two software packages were used to perform elastic, linear buckling and non-linear static analyses. The assumed in-plane boundary conditions are shown in Figure 6(a). Both out-of-plane displacements and rotations were fixed at the boundaries. Regarding the length of the brace members, two models were considered: (i) a node-to-node length (N, Figure 6(b)); (ii) a shorter brace member, considering the RC beam and column sizes (C, Figure 6(c)). The analyses were carried out for the EBs with links having the HE cross sections.

Figure 6: EB model: (a) boundary conditions; (b) Node-to-node (N) model; (c) model considering the finite size of the concrete (C) members.

Three steel stress-strain relationships were used to investigate the role of the steel strain hardening model. First, a simple bilinear stress-strain relationship with kinematic hardening (KH) was considered. The yielding strength was assumed equal to the expected value ($f_{ym} = 343.75$ MPa), while the ultimate strength and strain were assumed equal to the design nominal values ($f_u = 430$ MPa, $\varepsilon_u = 0.20$). Such bilinear relationship was implemented for all the brace geometries both in *SAP2000* and *Code_Aster*. The KH model is shown in Figure 8(a). Second, the numerical data used by Della Corte *et al.* [4] were adopted to fit a numerical stress-strain relationship to the stress-strain experimental data. The considered experimental stress-strain relationships are shown in Figure 8(a), where both monotonic (M, dashed line) and cyclic (C, dotted line) test data are reported according to [4]. The numerical calibration was carried out

using the cyclic response data, because the non-linear static analysis was used to assess the envelope response for a cyclic loading history (i.e., to properly include the steel cyclic strain hardening). The non-linear isotropic saturation hardening (SH) model available in *SAP2000* was used. The SH model has two parameters: (i) the ratio of the ultimate stress to the yield stress (k); (ii) the hardening rate (δ), which controls the rate of approaching the ultimate stress with an exponential decay function. Equation (1) shows the SH model for the uniaxial stress-strain case, in which ε_p represents the uniaxial plastic strain.

$$\sigma(\varepsilon_p) = f_y + f_y \cdot (k - 1) \cdot (1 - e^{-\delta \varepsilon_p}) \quad (1)$$

In Figure 8(a), the curve labelled as SH1 assumes $k = 1.78$ and $\delta = 20$. This curve was taken as a best fit of the non-linear behavior for strain values larger than 0.10. The curve labelled as SH2 assumes $k = 1.60$ and $\delta = 50$, which was taken as a best fit of the non-linear behavior for strain values smaller than 0.10.

In the *SAP2000* model, both the shell “thick” and shell “thin” mechanical formulations were used, which do respectively consider or exclude the deformability to shear forces transverse to the shell thickness. Within *Code_Aster*, similar mechanical formulations are available (called DST and DKT respectively). Two different meshing strategies were considered for the *SAP2000* and *Code_Aster* models as shown for example in Figure 7 with reference to one of the examined links. The mesh for the *SAP2000* model was manually generated, to minimize the number of triangular elements needed to mesh locally the geometry at the intersections of the link and the two diagonal members (Figure 7(a)). On the contrary, within *Code_Aster* the mesh was generated automatically by one of the algorithms available within the graphical pre-processor *Salome* [16] (*NETGEN 1D-2D*). Consequently, the number of triangular elements is automatically generated by the software (Figure 7(b)).

Figure 7: Example of generated meshes with (a) *SAP2000* and (b) *Code_Aster*.

An analysis of the sensitivity to the mesh density was carried out, to select the maximum permissible size of the finite elements and to evaluate the effect of the different mechanical formulations (“thin” or “thick” elements). Results are summarized in Figure 8(b) by plotting the horizontal displacement at the top end cross section of the link (u_{top}) as a function of the mesh geometrical parameter (i.e., the characteristic size of the generic shell element). The hor-

horizontal displacement was calculated by performing a static analysis of the bracing system subjected to a horizontal force equal to the link plastic shear resistance. To have a reference solution, a geometrically equivalent frame model (i.e., with only beam-column elements) was also built and analyzed in *SAP2000*. The frame model had the same boundary conditions as the refined shell model (Figure 6(a)). The solution from the frame model is depicted in the plot with a dashed line. As one can see, analysis results show a small increase of the elastic displacement varying the mesh size. A relatively small difference is also shown by varying the shell mechanical formulation, as well as the considered FE software. In every case, the frame model was found to be stiffer than the corresponding shell models. A mesh characteristic size equal to 20 mm was chosen for the subsequent nonlinear analysis.

Three different bracing were extracted from the design results, to evaluate any change in response due to changes in the diagonal member inclinations and lengths.

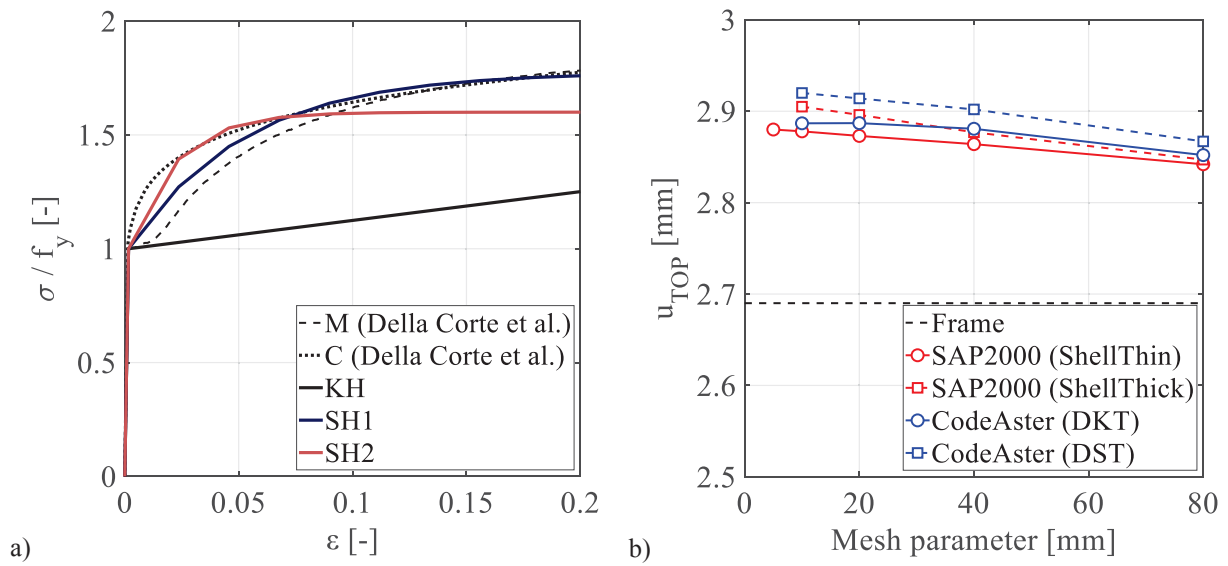

Figure 8: (a) Steel stress-strain relationship; (b) mesh sensitivity analysis.

4.2 Linear buckling analysis results

The linear buckling analyses were carried out to investigate the OoP stability of the bracing system, as well as to identify the shape of the imperfections to use for the non-linear static analyses.

Numerical results from *SAP2000* are summarized in Table 1 for all the examined cases. Particularly, the table provides information concerning the brace length (L_{br}), the brace inclination with respect to the horizontal axis (α , as shown in Figure 4), the (elastic) critical link shear force (V_{cr}), and the global slenderness for OoP buckling (λ_{op}) which was evaluated according to EC3 [9]. In the worst examined case, the elastic critical load multiplier was equal to 18, with respect to the shear yielding strength of the link. The corresponding global slenderness λ_{op} was equal to 0.23 for the N model and 0.22 for the C model. Such values are slightly larger than the EC3-stipulated limit (0.2) for predicting yielding prior to buckling.

Figure 9(a) and Figure 9(b) show first-mode buckling shapes, for the N1 and C1 models respectively, with respect to a sample geometry among all the examined cases. Similar results were obtained for the other geometries. The first buckling modes show lateral-torsional buck-

ling of the compressed brace, along with some out-of-plane (OoP) link displacements mainly concentrated at its bottom end cross section.

For the N1 case study, a linear buckling analysis was performed also using *Code_Aster* for comparison purposes. The analysis results from the *Code_Aster* model shows the same first mode of buckling as obtained with *SAP2000* (Figure 10), thus confirming the lateral-torsional buckling of the compressed brace.

MODEL	L_{br} [m]	α [°]	V_{cr} [kN]	λ_{op} [-]
N1	3.60	42	3896.64	0.19
N2	4.52	46	2598.87	0.23
N3	3.66	57	2924.13	0.22
C1	3.16	42	4619.4	0.18
C2	4.30	46	2876.35	0.22
C3	3.30	57	3468.39	0.20

Figure 10: First mode buckling shape with *Code_Aster* for the N1-EB model.

4.3 Non-linear static analysis results

Non-linear static analyses were performed to investigate the OoP stability and the non-linear link behavior. The previously described FE model based on shell elements was used for these analyses. An imperfect geometry was considered, by using the buckling shape obtained by means of the linear buckling analysis results previously discussed. The amplitude of the imperfection was assumed equal to 1/1000 of the brace length. Results are summarized in Figure 11 by plotting the link shear force, normalized with respect to the expected plastic shear resistance, $V/V_{l,Re}$, as a function of horizontal displacement of the top end cross section of the link (u_{top}). Particularly, Figure 11(a) shows a comparison between the results obtained by using either *SAP2000* or *Code_Aster* with the KH non-linear stress-strain model. In *Code_Aster*, the analysis was performed either considering or neglecting non-linear geometrical effects (NLG). Analysis shows identical results up to yielding of the link. After such non-linear event, non-linear geometrical effects took place along with the strain hardening, thus increasing the shear strength. Results suggest minor differences between *Code_Aster* and *SAP2000* in the non-linear branch of the curve.

Figure 11: Non-linear static analysis results: (a) *SAP2000* vs. *Code_Aster*; (b) strain hardening model.

Figure 11(b) shows all the numerical analyses carried out with *SAP2000* by using the three previously described stress-strain relationships (i.e., KH, SH1 and SH2) and, by varying the considered model geometry (C and N models, Figure 6). The results are shown by plotting the normalized link shear force as a function of the link chord rotation (θ). All the performed numerical analyses show that both link and brace stability are ensured up to drift angles equal to at least $\theta_u = 0.08$ rad. Therefore, the results from the linear buckling analyses appear to provide conservative results for the assessment of the brace stability. In fact, the global slenderness for OoP stability was slightly larger than 0.2, that is the code stipulated limit to avoid OoP buckling. Besides, the non-linear static analysis results show negligible differences between the N and C geometrical modelling options. Particularly, the pushover curves were practically coincident in the elastic response range, whilst negligible differences were observed in the inelastic response range.

Focusing on the link overstrength, the analysis results show that the KH model significantly underestimates the inelastic link shear forces. In fact, the ratio between the link peak shear force developed for $\theta = 0.08 \text{ rad}$ and the expected plastic shear resistance is equal to 1.30 for the KH model, 1.67 for the SH1 model, and 1.77 for the SH2 model (the values reported here are the mean values among the six examined structures per each considered non-linear stress strain relationship). The basic link overstrength factor that is stipulated by the current Italian code is 1.50, which the code increases to 1.65 (multiplying 1.5 by a factor of 1.1) for capacity design of “non-dissipative” members and connections adjacent to the yielding link. Since the analysis results predicted peak strains smaller than 0.10 for $\theta = 0.08 \text{ rad}$, the SH2 model should be considered in comparing the code-stipulated overstrength factors with those obtained by the numerical analysis. Therefore, the ratios between the code-stipulated overstrength factors and the numerical results are equal to $1.65/1.77=0.93$ and $1.5/1.77=0.85$.

Figure 12(a) shows an example of a contour plot of the equivalent Von-Mises stresses in the link and the plates connecting the braces to the link. Considering that very close results were obtained by varying the brace geometry, the C1 model was selected as an example. The results in Figure 14(a) are for a link rotation $\theta = 0.01 \text{ rad}$, which approximately corresponds to $V_l = V_{l,Re}$. The Von Mises stresses show that yielding develops almost uniformly within the link web. Yielding occurs also in the link flanges close to the bottom and top end cross sections. On the contrary, the Von Mises stresses were always smaller than the yielding strength in the horizontal and vertical plates, as well as in the brace members.

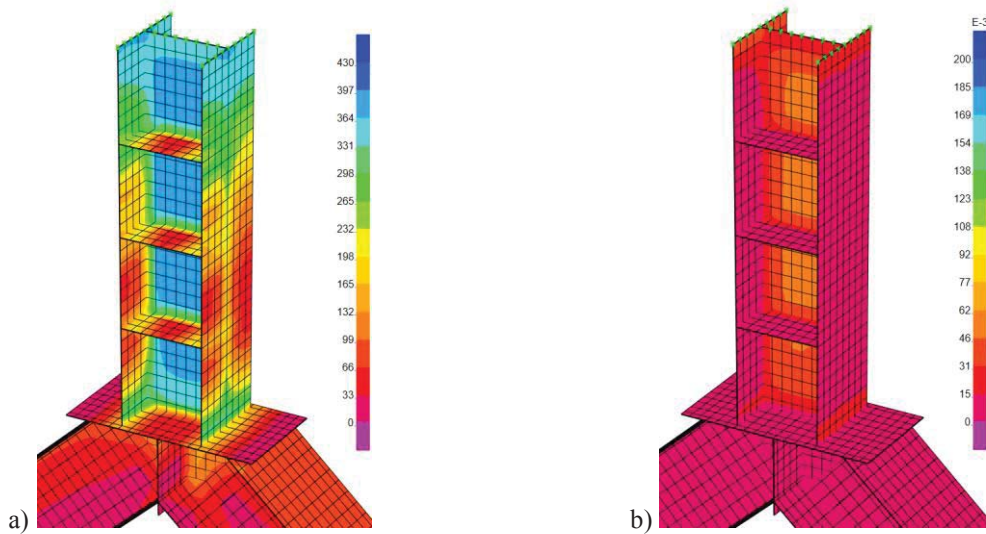

Figure 12: Example of (a) Von-Mises equivalent stresses and (b) equivalent strains in the link.

Figure 12(b) shows an example of the equivalent Von Mises strains in the link and the plates connecting the braces to the link. The equivalent Von Mises strains are used in *SAP2000* as a measure of the plastic deformation intensity. Again, the C1 model was selected as an example. The analysis step corresponds to a link rotation equal to $\theta = 0.08 \text{ rad}$, i.e. considering the ultimate limit state for the link element according to the Italian code. Values of the equivalent strains are smaller than 0.10 everywhere in the link web. Plastic strains can be observed also in the link flanges at its top and bottom cross sections, consistently with the Von Mises stresses depicted in Figure 12(a).

Figure 13 shows examples of deformed shape for the considered C1 model. Hence, Figure 13(a) shows the deformed shape corresponding to a link rotation equal to $\theta = 0.01 \text{ rad}$. The

contour plot highlights out-of-plane displacements (values in the plot are in mm). The compressed brace on the left-side shows OoP displacements with a maximum value approximately equal to 0.3 mm . On the contrary, the tensile brace on the right-side shows negligible OoP displacements if compared with the compressed brace (the maximum value is smaller than 0.07 mm). Figure 13(b) shows the deformed shape corresponding to a link rotation equal to $\theta = 0.08\text{ rad}$. The results show the same distribution of OoP displacements as previously discussed, thus confirming the brace stability for the whole range of the investigated structural response.

Figure 13: Example of deformed shapes with out-of-plane displacement contour plot:
(a) $\theta = 0.01\text{ rad}$; (b) $\theta = 0.08\text{ rad}$.

Overall, the static non-linear analysis results confirm the validity of the assumed design procedure which adopted member-based buckling checks and capacity design rules for the design of both braces and connections. Further studies with FE models explicitly including connections between brace members will be considered to evaluate the influence on the OoP stability.

5 CONCLUSIONS

The paper presented a numerical study on steel eccentric braces with vertical shear links used for seismic retrofitting of older reinforced concrete (RC) structures. The study mainly focused on the numerical modelling and analysis of the bracing members. Particularly, the paper presented an investigation into the out-of-plane stability of the bracing system, and the peak inelastic forces developed by the link. The investigation was carried out by means of various finite element (FE) models analyzed with different FE software packages. The out-of-plane stability was assessed by performing two types of analysis: 1) linear buckling analysis, coupled with the general method for stability verification proposed by Eurocode 3; 2) non-linear static analyses with imperfect geometrical models. The first analysis method yielded conservative results compared with the static non-linear analysis. The non-linear static analysis has shown a stable behavior of the bracing system up to the ultimate link chord rotation stipulated by the current Italian code. Regarding the plastic overstrength of the shear links, the numerical results indicates that the currently suggested rules by the Italian code could underestimate the peak shear strength. However, effects such as the loading history and the steel strain hardening models still need further investigations to make conclusive comments on this aspect of the code.

Abstract

The present analytical work deals with the assessment of the performances of Reinforced Concrete (RC) Deck Arch Bridges under the non-seismic loading conditions required by the current mandatory Italian codes. In particular, the attention is focused on a specific RC deck arch bridge typology, better known as the “Maillart Type Arch Bridge”, which is characterized by a very stiff deck beam and a slender and wide vault. As well as other existing RC structures which were designed under only gravity loads and without specific structural details, such as lower limits for longitudinal and transverse reinforcement bars, these bridges could be damaged by loading conditions not considered at the time of design. For the evaluation of the main critical issues related to the current performance of such bridges under the current non-seismic loading conditions, it has been defined a large inventory of simulated arch bridges in accordance to the design procedures usually adopted in 1950s which considered only gravitational loads, i.e. self-weight and moving loads. Each bridge of the inventory is modelled and studied by means of a Linear Gravitational analysis implemented in the structural software SAP2000, with support of an Application Programming Interface (API), such as Matlab.

Due to the differences between the current loads and those considered at the design time and to the approximations of the design strategies of the time, a performance – based analysis of the existing bridges under non-seismic loads is important for the stakeholders as much as for the decision – makers in order to plan risk mitigation programs and prioritize eventual retrofit interventions for risk reduction.

Keywords: RC Arch Bridges, Maillart Bridges, Gravitational loads, Vulnerability Analysis.

1 INTRODUCTION

In recent years, considerations and rehabilitations of existing bridges have been an ongoing problem for the bridge administrations and for their owners in almost all countries. The performance level of an existing bridge is often inadequate: indeed, the always increasing number of vehicles and of traffic and the heavier weight loads, have made the structural safety of existing infrastructure system progressively insufficient even under vertical loads only.

In Italy, the Reinforced Concrete (RC) arch bridges are today still one of the most important part of the transportation system. Such bridges, designed and built around 50s, and in most cases under-designed for the nowadays serviceability conditions, require particularly attention due to their specific peculiarities that make exceptionally complex the assessment of their behavior under both static and dynamic actions. In addition to the previous “vulnerabilities”, most of these structures were designed only for gravitational loads: indeed, the seismic hazard has only recently been recognized by national structural codes ([1], [2]) and this means that their current vulnerability may be much more important.

In this study, the attention is focused on a specific arch bridge typology: the “Maillart-Type Arch Bridges” or “Deck Stiffened Arch Bridges” ([3], [4], [5]), which are characterized by a very stiff deck beam and a slender and wide vault (with a low moment of inertia), connected the one to the other by means of slender piers, often wall-like and lightened by central windows (Figure 1). The name of this bridge typology comes from the Swiss civil engineer Robert Maillart, who first introduced a very revolutionary concept: he reversed the classic arch-to-deck stiffness ratio, realizing in this way a significant reduction of the bending moment and of the shear forces in the arch in favor of a mainly compression stress status in the arch. This led to the fact that, being the structure hyperstatic, the stiffest element also bears the highest stresses and, thus, the deck beam becomes the key element of the whole bridge, since it has to bear the most bending moments and shear forces ([6], [7]).

Nowadays, as mentioned previously, some of RC Deck Stiffened Arch Bridges built in the last century need a structural strengthening due to several environmental factors such as corrosion and degradation of materials and/or anthropological factors such as the always increasing traffic loads under serviceability conditions and/or poor maintenance [8].

Figure 1: General view of a RC Deck Stiffened Arch Bridge.

It is worth to note that a fundamental problem in Italy is represented by the absence of a detailed database of existing infrastructures; indeed, the lack of exact information makes the role of managing entities even more difficult. An example of the particularity of the Italian

scenario is that, in February 2019, there were about 1000 bridges whose ownership was not even known [9].

Therefore, information about damage and/or structural deficiencies of bridges is also quite rare and, additionally, details about dimensions, type and amount of materials of real structures are not available for a large number of these bridges.

The present study focusses attention on the assessment of the safety conditions of RC Deck Stiffened Arch Bridges under the current static loading conditions defined by the Italian codes ([10], [11]). Despite several bridges of this typology have been recognized in Italy, due to the lack of detailed information about them, the structural analyses herein presented have been performed with reference to a large building inventory of simulated “Maillart – Type” Arch Bridges, characterized by geometry and material properties varying in the ranges typical of the real structures. Firstly, a simulated design procedure according to the current codes at the age of construction has been used for creating the geometrical models and define the internal steel reinforcements. Then, structural analysis and safety verifications have been carried out for the samples of the collected inventory under the static loads provided by the current Italian codes ([10], [11]).

2 CREATION OF THE BRIDGES INVENTORY

2.1 Characteristics of existing “Maillart – Type” Arch Bridges in Italy

Although the typology of girder bridges is certainly the most widespread in Italy, examples of arch bridges are also frequent. In Crisci et al., 2021 [12], after careful investigations based on examination of old projects, books and online resources, several existing RC arch bridges (about 90) were collected and recognized on the Italian territory. Unfortunately for most of them, it was only possible to retrieve general information on geometry, such as span length L_{arch} and the rise of arch f_{arch} . This study allowed to identify the variability of the main geometric parameters of such structures; indeed, most of the bridges are characterized by an arch span L_{arch} ranging between 50 and 90 m, while a low percentage is found for the case 90-110 m (Figure 2a). It is worth noting that these distributions are representative of the only collected available data and, thus, they might be not fully representative of the real situation in Italy or worldwide.

Similar considerations can be summarized for the arch rise f_{arch} : a good percentage of bridges, approximately 50%, are characterized by an arch rise ranging between 10-20 m, whereas a lower percentage is concentrated around the values of 20-30 m and 30-40 m (Figure 2b). In Figure 2c, the frequency distribution of the ratio f_{arch}/L is also plotted.

In addition to the arch, the structural elements of each bridge consist of a regular grid of main and secondary RC beams with rectangular cross sections, connected the one to the other by means of a slab. Finally, slender piers connect the vault to the deck beam. Detailed information about the dimensions of the various structural elements or the reinforcement ratios are more difficult to determine or collect, and they would require ad hoc investigations and inspections. For such reason, in Crisci et al. 2021 [12], thanks to historical documents and old designs, the typical variability of the secondary geometric characteristics has been presented, such as the dimensions of piers, beams, reinforcement ratios for the vault, piers, etc...

Thus, for the generation of the inventory, the following ranges were fixed for the main geometrical parameters:

- 50 - 120 m for the arch span, L ;
- 10 - 40 m for the arch rise, f_{arch} ;
- 0.2 - 0.3 for the ratio, f_{arch}/L ;

- 0.30 - 0.45 m for the base of piers, B_p ;
- 0.30 - 0.45 m for the base of the main beams, $B_{b,I}$;
- 1.0 - 1.6 m for the height of the main beams, $H_{b,I}$;

Note that for the parameters plotted in Figure 2, the ranges have been defined by considering the minimum and maximum values relative to the cases with greater frequency.

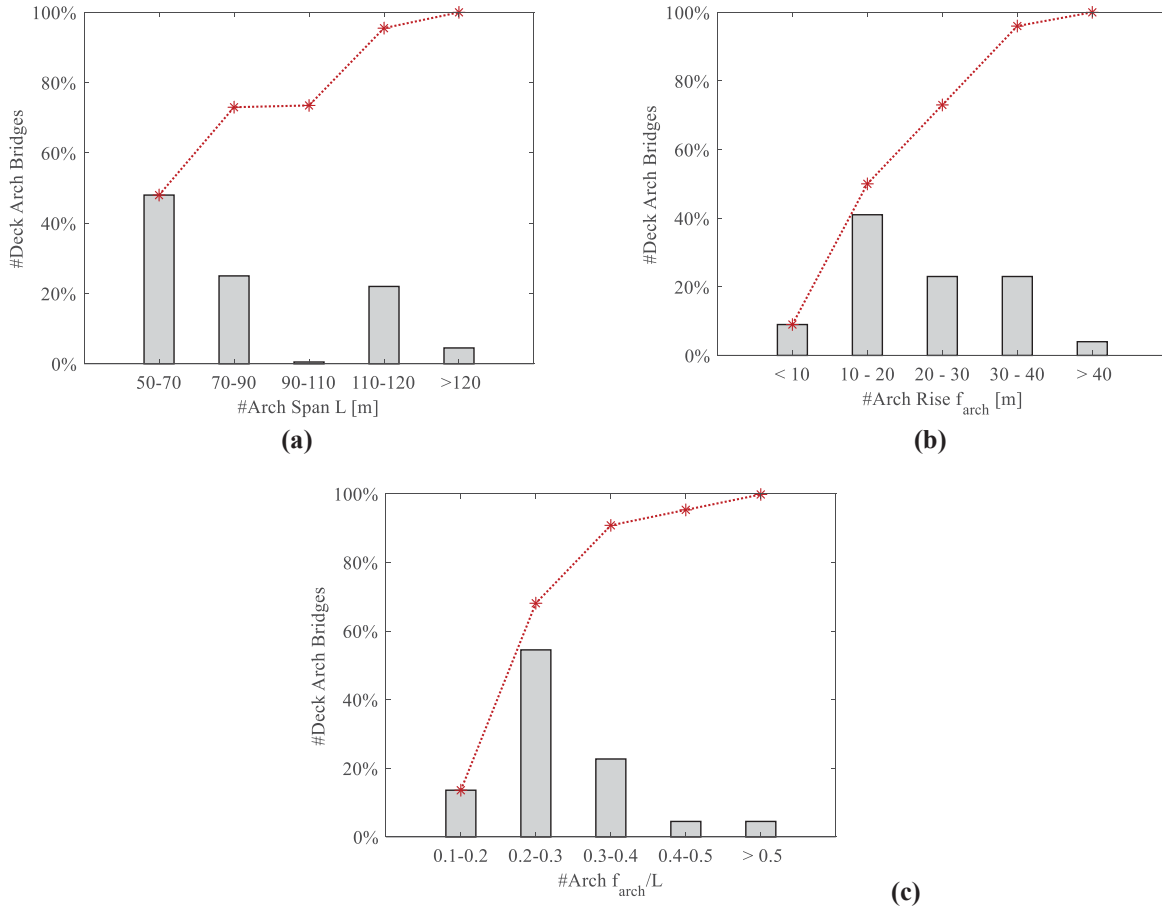

Figure 2: Distribution and cumulative percentage of bridges as: (a) function of Arch Span, L ; (b) function of Arch Rise, f_{arch} ; (c) function of ratio between f_{arch}/L .

About the mechanical characteristics of the materials, historical and documented sources evidenced that it was customary to use concrete with a cubic characteristic compressive strength R_{ck} of at least 36 MPa, whereas for the steel reinforcement, usually the one known as TOR60 was adopted with an average yielding stress of about 600 MPa.

A proper Bridge Inventory of more than 1500 structures has been, thus, defined by means of the Monte Carlo simulation procedure ([13]). The generation of a proper dataset is, indeed, very useful in order to study the average behaviour of a homogeneous class of structures at large scale with regards to a certain demand, that for the present study will be represented by the static loads provided by the current Italian codes.

The bridge inventory was, thus, built by changing some significant parameters such as geometrical data, mechanical and reinforcement percentages in the fixed ranges discussed previously. As regard the reinforcement percentages, they were established in accordance with the minimum values indicated by the mandatory codes of the time ([14]) and with reference to a few designs of real bridges. In particular, for the vault and the piers, the minimum

reinforcement percentage was, on average, equal to 0.8% of the area of the concrete cross section. For the elements subjected to bending moment, on average, the reinforcement percentage varied between 0.1% and 2%. Moreover, it was customary to use a transverse reinforcement (e.g. stirrups) with a very scattered distance, i.e. variable between 150 and 250 mm.

In particular, with regard to the dimensions of the piers, it is worth to note that only the lower dimension of the vertical piers has been defined, because it is linked to the base of the main beams for geometric reasons. As regard the larger dimension, e.g. the one parallel to the longitudinal direction of the bridge, it has been obtained as a function of the slenderness, λ , of the structural element. Indeed, in order to reduce the effects of the second order, it was usual at the time to set the slenderness of the piers to a limit value of 50.

Generally, the extraction of the parameters should take place with reference to a probability distribution, but, due to the limited number of known reference structures and, thus, to the limited knowledge of the actual distribution of each parameter in the real structures, the parameters have been drawn assuming a uniform probability distribution for each of them.

Moreover, in order to exclude the combinations of geometric and mechanical parameters which could lead to bridges structurally not verified nor realistic, each generated arch bridge was subsequently verified with reference to the vertical loads of the time, i.e. according to the mandatory codes of the time. These verifications, explained in the following, have been carried out according to the structural schemes and analysis procedures of the time that were simpler in comparison with those adopted nowadays thanks to the aid of numerical software.

2.2 Verifications of “Maillart – Type” Arch Bridges according to the codes of the time

Once the bridge inventory has been defined, the geometric and mechanical characteristics of each structure are known, such as arch span and rise, dimensions of piers, principal and secondary beams, steel reinforcement ratio, and so on. For each bridge, a simulated design has been carried out according to the mandatory codes at the time of design in order to verify the correct size and the reinforcement layers assigned to the various structural elements (Crisci et al. 2021 [12]) and to exclude non-realistic combinations of geometric and mechanical parameters. In this section the steps followed for carrying out these verifications are described.

The starting point for building the geometry of a deck arch bridge is the definition of its arch; a common practice of the time consisted into design the axis of the arch in order to be funicular of the gravitational loads corresponding to the self-weight only of the entire structure. This means that the arch is subjected to axial compression force only, without any bending moment and shear force. The calculation of the stresses acting on each arch has been done considering a simplified model in agreement with the assumptions commonly done by the designers of the time, i.e., an equivalent two-dimensional structure, characterized by a continuous deck beam supported by the piers, a hinged arch at both springings, and axially rigid piers connected to both the arch and the deck beam by means of hinges.

The load combinations were fixed with reference to the mandatory codes in force at the time, in particular the Royal Decree of 1939 [14] and the Circular n. 6018 concerning the loads on bridges of 1945 [15]. In particular, two different types of loading schemes were adopted:

1. Two or more undefined trains of trucks weighing 12 tons (about 120 kN) side by side;
2. Two compressor rollers weighing 18 tons each (about 180 kN) side by side.

In addition, a compact crowd was expected on the sidewalks next to the driveway.

The assessment of maximum stresses was carried out by placing the moving loads, given by the loading condition 1 [15], in the most unfavourable position on the deck, which was

found by means of the Influence Lines. Figure 3 shows some of the influence lines adopted for the verification of the structural elements of bridges, i.e. the influence lines of bending moments for moving vertical loads in one cross section of the deck (magenta line) and of the horizontal thrust in the arch (yellow line).

Figure 3: Examples of influence line of bending moment on the deck, horizontal thrust and position of moving loads able to maximize the bending stress.

It is worth to note that the position of the moving loads giving the maximum bending moment on the deck does not yield the maximum horizontal thrust in the arch as well. Indeed, in order to maximize the horizontal thrust, H , and so the compression force, N , in the arch as well, the moving loads must be applied on the whole entire deck. Under this latter load condition, the piers were verified as well.

The envelope of all the positive and negative peaks of each magenta line represents the diagram of the maximum and minimum bending moments from which it is possible to identify the cross section and, therefore, the position of the moving loads able to maximize the bending moment on the deck beam. For simplicity, in Figure 3, the only envelope of the maximum positive bending moments is plotted (red line); the envelope of the minimum negative bending moments is, indeed, mirrored to this one.

Conversely, the secondary beams have been verified with reference to their tributary area to define the entity of the gravitational loads (uniformly distributed loads) and with reference to the worst condition for the moving loads, i.e. when the axis of the vehicle is just on the secondary beam. Moreover, the constraint conditions at the ends of the secondary beams have been assumed as ranging between a simple supported beam and a fully fixed beam, in order to maximize the positive and negative bending moments along the element.

According to the Royal Decree of 1939 [14], the design of steel reinforcement in the beams was made with respect to “*Allowable Stress Method (ASM)*” [16], where the working stress is defined as the 5% percentile strength divided by a safety factor, equal to 3 for concrete and 2 for steel. On the basis of the stress distributions in each element under the previously cited load combinations, each generated arch bridge has been verified with reference to both flexural, normal and shear stresses. If some verifications are not satisfied, the bridge has been excluded from the database under the assumption that the casual combinations of the parameters have led to hypothesize a structure not in agreement with design rules and loads of the time and, thus, not representative of an existing bridge. Clearly, for the not verified

samples, a different choice of some parameters, as, for example, the reinforcement percentage or the dimensions of some structural elements, might lead to a representative structure, but lacking more detailed information on these parameters, this option was not pursued. Therefore, in place of the excluded cases, other bridges were extracted, as long as the sample size was satisfactory and the geometrical parameters assumed for the generation of the sample were equally distributed.

2.3 Creation of 3D Finite Element Models

Once each geometric model has been designed and verified according to a simplified methodology and in agreement with the loads and rules of the time, a 3D Finite Element Model (FEM) is implemented using the software SAP2000 [17]. Two node – frame elements, i.e. beam elements with three translational and three rotational degrees-of-freedom (DOF) at each node have been used to model the beams, the piers and the arch. Moreover, the eccentricities of the piers with regard to the axis of the vault have been taken into account by means of rigid offsets and massless links. In Crisci et al., 2020 [6] it was, indeed, verified that no significant differences in the stresses in all structural elements occur if the vault is modelled by two-dimensional elements instead of frame elements with offsets. This latter solution was preferred in order to reduce the computational effort also in view of the analyses under seismic actions.

About the constraint conditions of the piers, it is worth to remember that usually at the time of design the piers were modelled as pendulums, i.e. simply hinged at both ends, under the gravitational loads and, thus, they resulted subjected to axial loads only. The choice of modelling the piers as pendulums was related to the reduction of the hyperstatic unknowns and, thus, of the complexity of the solution of the structural scheme of the bridge, but, at the same time, led also to a reduction of the differences in stiffness of the deck beam and the vault. However, some design documents of the time have evidenced that in many cases the piers were realized as fixed at the end, as testified by constructive details, and were, thus, subjected to some shear and bending actions as well. For this reason, in the SAP2000 model the piers have been considered fixed constrained at their both ends and not connected by simple hinges to the arch and the deck. It is worth noting that the entity of the shear and bending actions transferred to the piers under gravitational loads was limited due to the high difference of stiffness between the deck and the arch and, thus, between deck and piers [6].

The deck slab, on the contrary, has been considered only in terms of loads acting on the main beams, while a “diaphragm” constraint has been used to simulate its behaviour on the bridge deck. Fixed supports at ends of the arch have been assumed; this assumption is well accepted when bridge foundation is over bedrock sites, i.e. ground type A [10], as it is the case for the majority of this type of bridges. With reference to the deck constraints, the generic bridge was assumed to be constrained along the longitudinal direction in order to simulate the presence of abutments or of other roads which could limit its displacement, whereas it was considered free along the out – of – plane direction.

Each structural element is modelled as elastic and, in order to take into account the development of cracking phenomena in the concrete, the effective moment of inertia of the beams has been reduced by 50%, while by only 25% for the vertical piers and the arch according to the prevalent compression forces in the elements ([10], [18]). No reduction of the transverse area, torsion and shear area has been considered [19]. This procedure was automatized adopting specific software such as MATLAB [20], where by means of Open Application Programming Interface (OAPI), it is possible to integrate with structural software, such as SAP2000 [17], to run analysis on a multitude of several models.

Figure 4: (a) Geometric model of RC Deck Stiffened Arch Bridge; (b) Three Dimensional (3D) FEM.

3 ASSESSEMENT OF TRAFFIC LOADS ACCORDING TO ITALIAN CODES

As reported in section 1, the demand in terms of traffic loading is very different nowadays if compared to the past. This study is, indeed, aimed to highlight which are the main structural deficiencies of existing bridges, especially for arch bridges designed and built with regards to the rules of 40s, under the non-seismic loads prescribed by the current codes, i.e. the new guidelines for existing bridges [11] and the Italian code for structures [10]. This is a fundamental aspect that has to be investigated prior to proceed with the verifications under seismic actions. It is worth to note that, for structural purposes, according to new guidelines [11], each generated arch bridge was assumed to be classified as CC3, i.e. Consequences Class 3, that means “*high consequence for loss of human life, or economic, social or environmental consequences very great, such as bridges, public buildings, where consequences of failure are high*”. The structural verifications were carried out considering the loads according to the new guidelines for bridges [11], that entail to assume the same partial safety coefficients prescribed by [10].

The structural analyses were performed considering, in addition to the structural and non - structural weights, e.g. road pavement, the moving loads schemes in accordance with [10]. The latter, shown in Figure 5, also include the dynamic effects due to the passage of vehicles on the structures, and they are the reference schemes that have to be used for the global structural verifications of the bridge structures.

Q_{ik} Q_{ik} q_{ik}		
		Lane 1
		$Q_{1k}=300\text{kN}$ $q_{1k}=9\text{kN/m}^2$
		Lane 2
		$Q_{2k}=200\text{kN}$ $q_{2k}=2.5\text{kN/m}^2$
		Lane 3
		$Q_{3k}=100\text{kN}$ $q_{3k}=2.5\text{kN/m}^2$
		Remaining part $q_k=2.5\text{kN/m}^2$

Figure 5: Moving loads according to Italian Building Code 2018 [10].

Moreover, it has been considered the braking actions of the vehicles, which are applied as uniformly distributed loads on the axis of the lane. In addition to the moving loads, the loads

related to temperature, wind and snow have been considered as well, assuming for simplicity a climatic zone III and an altitude of less than 200m [10].

In order to define the characteristic values (i.e. the 5% percentile values) of the traffic loads, the loading schemes have been combined by considering two groups of actions, respectively the group 1 and the group 2a, as reported in [10]. The first group considers the characteristic values of the moving loads without taking into account the braking actions. The group 2a, on the other hand, considers the frequent values of the moving loads and takes into account the characteristic values of the braking actions. Finally, the various actions have been combined with the fundamental combination at the Ultimate Limit State, obtaining a total of 9 individual load combinations, as Table 1 shows.

Tab 1: Load combinations at the Ultimate Limit State according to ([10], [11])

ID	G _{k1}	G _{k2}	Q _k			Wind	Snow	Temperature
			Q _{ik}	q _{ik}	Braking			
1	1.35	1.5	1.35	1.35	-	0.9	-	0.72
2	1.35	1.5	1.01	0.54	1.35	0.9	-	0.72
3	1.35	1.5	1.01	0.54	-	1.5	-	0.72
4	1.35	1.5	1.01	0.54	0.54	1.5	-	0.72
5	1.35	1.5	1.01	0.54	-	0.9	1.5	0.72
6	1.35	1.5	1.01	0.54	0.54	0.9	1.5	0.72
7	1.35	1.5	1.01	0.54	-	0.9	-	1.20
8	1.35	1.5	1.01	0.54	0.54	0.9	-	1.20
9	1.35	1.5	-	-	-	0.9	-	0.72

The structural verifications have been carried out with reference to both the ductile (flexural verifications) and brittle mechanisms (shear verifications) in terms of capacity at the Ultimate Limit State (ULS), in accordance to [10]. For the flexural capacity, in order to take into account the presence of biaxial bending moments, the following Bresler's equation has been adopted:

$$\left(\frac{M_{Ed,x}}{M_{Rd,x}}\right)^{\alpha} + \left(\frac{M_{Ed,y}}{M_{Rd,y}}\right)^{\beta} \leq 1 \quad (1)$$

being $M_{Ed,x}$ and $M_{Ed,y}$ the bending moments around the two principal axes, x and y, of the cross sections and come from the 9 loads combinations, $M_{Rd,x}$ and $M_{Rd,y}$ the flexural capacity of the section evaluated with respect to the x and y axis respectively, α and β two shape coefficients, which for rectangular cross section have been assumed equal to 1.5.

As regard the shear capacity, two different approaches have been considered for the arch and for the beams. Due to the presence of longitudinal steel reinforcement only, for the arch the shear strength for members without shear reinforcement given by ([10], [18]) has been used, while for the piers and the beams, which are supposed to have steel stirrups, the shear capacity has been evaluated according to the strength model proposed by [21] in order to take into account the significant benefit of the compression force in the piers on their ultimate shear capacity.

4 DISCUSSION OF RESULTS

Each simulated bridge has been studied with reference to the several combinations of loads discussed above; in particular, the results are represented in terms of DCR, i.e. Demand over

Capacity Ratio, where the Demand and the Capacity are represented by bending moment, shear or axial force. It is worth to point out that, as more than 1500 Maillart-Type Arch Bridges have been generated and verified, the results will be represented in the following in terms of maximum DCR ratio for each bridge with reference to the main stress acting in the various structural elements, e.g. arch, piers and beams, and with reference to the considered load combinations. This means that for each structural element the worst safety condition is represented.

The Figure 6 shows the trend of the maximum DCR for the arch, in the case of flexural and shear verifications, as a function of the span (6a and 6b) and the rise of the arch (6c and 6d); it is clear that structural problems do not arise in any case for the arch. In particular, the maximum DCR, for flexural verifications, is about 0.8, whereas it is about 0.5 for shear verifications. In order to better read the trend of DCR, a linear regression line has been represented too: it is observed that the average trend, as function of both the span and the rise, is increasing in the case of flexural verifications (minimum value of about 0.2 and maximum value of about 0.6), while it is rather constant for shear verifications (approximately 0.4).

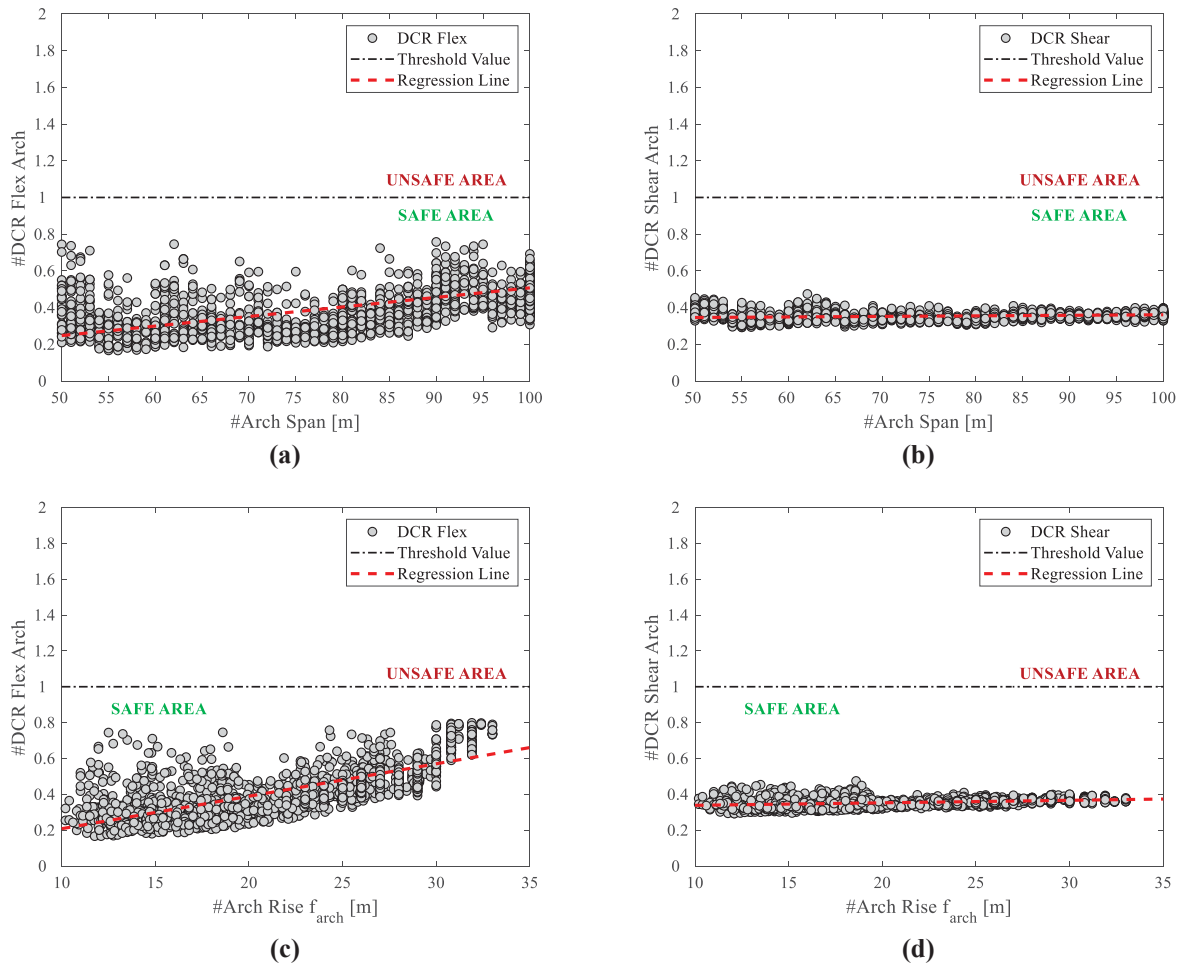

Figure 6: Demand over Capacity Ratio (DCR) distribution in the arch for flexural and shear failure, respectively, vs. : a)-b) Arch Span, L ; c)-d) Arch Rise, f_{arch} .

Figure 7 shows the trend of the maximum DCR for the piers in function of arch span length and arch rise with reference to flexural (Figure 7a-c) and shear (Figure 7b-d) failures. It can be noted that the flexural problems are very prominent if compared to the shear ones,

especially as the span and the rise of the arch increases. This is due to the fact that the piers, as previously mentioned, were verified in section 2.2 under axial forces only due to the assumption of simple hinges at their ends, according to a common practise of the time. This means that, under only axial forces, a fairly lower percentage of steel was required to satisfy the verifications if compared to the case of elements subjected to shear and bending moment.

However, in many real cases details were built at the ends in order to let the piers work as fixed elements and not as pendulums. As previously discussed, the presence of the pendulums drastically reduced, indeed, the hyperstatic unknowns and, thus, the complexity of the solution of the structural scheme of the bridge, but, at the same time, the relevant differences in the stiffness of the deck beam and the vault ensured that, under gravitational loads only, the neglected stresses were however limited even considering the hinges at the ends.

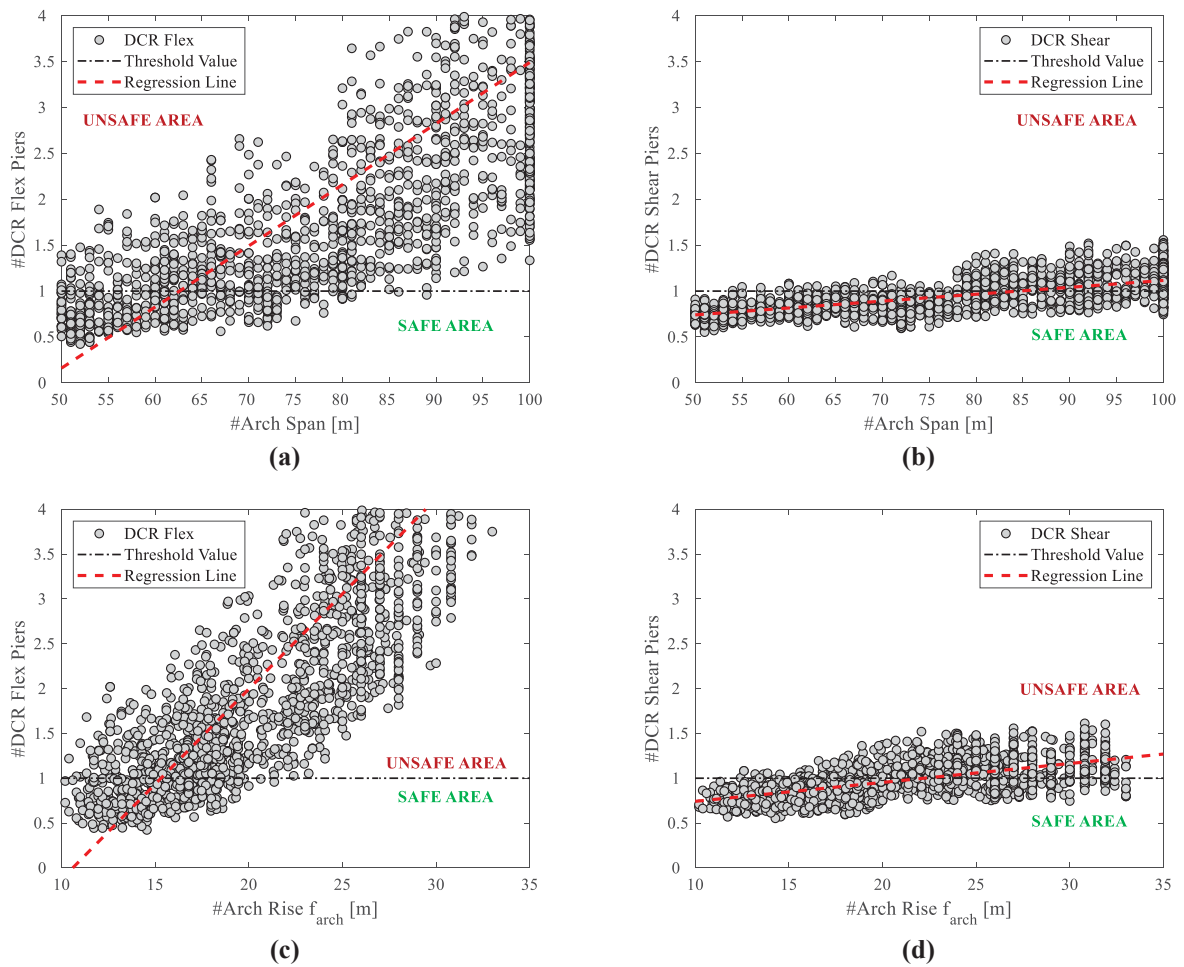

Figure 7: Demand over Capacity Ratio distribution in the piers for flexural and shear failure vs.: a)-b) Arch Span, L ; c)-d) Arch Rise, f_{arch} .

Clearly, in addition to the different constraining conditions introduced in the SAP model, the loads combinations adopted in the verifications herein presented, being more demanding than those considered at the design time both in terms of gravitational loads and of presence of horizontal actions, as the braking and acceleration forces, not considered in the past, have also contributed to have values of DCR in the piers higher than 1. This topic will become even more important for the verifications of the piers under seismic actions because they

became mandatory only in the most modern regulatory codes and, thus, it is expected that higher stresses would be present in the piers for the acceleration loads provided by the current codes. Therefore, under the design seismic actions, the constraint conditions at the ends of the piers will make even more the difference. For the beams of the deck, for the sake of simplicity, the distributions of the maximum DCR have not been reported, because, as for the arch, there aren't criticisms related to bending or shear failures. It is worth to remember that the deck of these bridges, and therefore the beams, are characterized by a high flexural stiffness in comparison with the arch. Thus, if the moment of inertia of the deck and of the vault cross section are denoted as I_d and I_a , for a "Maillart – Type" Arch Bridge, the ratio I_d/I_a is very large: in particular, manuals and historical sources indicate that the minimum value of this parameter has to be about 50 ([4]) for such a bridge typology.

Finally, the analysis of the Demand-to-Capacity ratios highlighted that, under the current vertical loading conditions, for "Maillart – Type" Arch Bridge the piers are the most vulnerable structural elements. In particular, the maximum DCR ratio is attained for flexural failure in the outermost piers with respect to the crown of the arch, i.e., the slenderest ones. It is worth noting that, although the ratios f_{arch}/L range in 0.2-0.3, for spans of 80-100 m, there are piers with a length of about 20 m, which are characterized by a very important bending demand. These piers, on the contrary, are characterized by a flexural capacity not very adequate, because, as previously discussed, they were designed to bear only compression force.

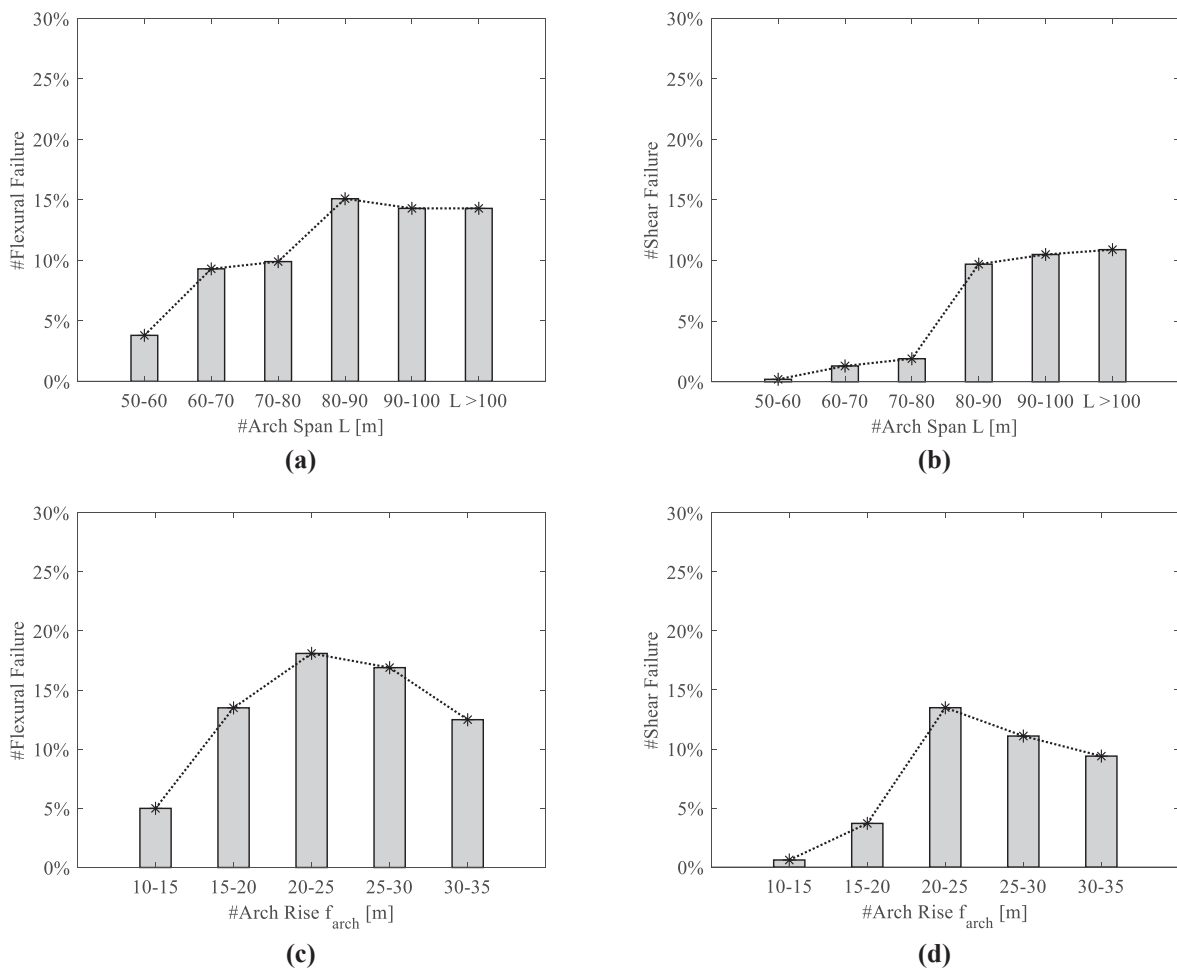

Figure 8: Distribution of failures for flexural and shear failure vs. a)-b) Arch Span L ; c)-d) Arch Rise, f_{arch} .

A global view of the obtained results for the examined numerical database of 1500 bridges can be represented by the percentages of failures, differentiated according to the type of failure and distributed in the variation ranges of span and arch rise in the inventory. Figures 8a and 8b report, indeed, the failure percentage with reference to flexural and shear failures, respectively, versus the arch span, L . Analogously, Figures 8c and 8d report the failure percentage versus the arch rise. It is worth noting that the number of analysed structures, for each subclass of the rise and span of arch within the selected ranges, is fairly uniform, as it is evidenced in the diagrams of Figures 9 and 10 that report the number of failed bridges (for flexure in Figure 9 and for shear in Figure 10) and the number of the generated ones for the fixed ranges of arch rise and arch span.

Representations shown in Figures 8, 9 and 10 are very useful to highlight how many structures, for each subclass, have showed at least one failure on the total number of bridges of the subclass. It is worth to remember, once again, that the sample of bridges was generated and verified through a simulated design, adopting, thus, reinforcement ratios indicated in the regulations of the time, defined and controlled also according to some original designs and drawings. Therefore, such results necessarily reflect the characteristics of the inventory of bridges defined in the previous section, and provide, for that inventory, an idea of damages that may affect such typology of bridges.

Figure 9: Distribution of failed bridges compared to generated bridges (flexural failure).

Figure 10: Distribution of failed bridges compared to generated bridges (shear failures).

The study of the behaviour of these structures at large scale is, indeed, a crucial point for planning risk mitigation programs and for understanding how to prioritise the interventions for risk reduction. Moreover, since the failures are localized at the piers, above all at their ends for flexural problems and along the element for the short piers at the arch keystone, the structural reinforcement of these bridges through the use of FRP, i.e. Fiber Reinforced Polymers, could represent an efficient solution that would allow to realize non-invasive and reversible interventions for improving the structural performance ([22], [23]). Clearly, further studies are in progress aimed to assess the performance of the same inventory of bridges under the design seismic actions provided by the current codes and verify if the critical elements are the same identified in the analysis under the load combinations herein presented.

5 CONCLUSIONS

The paper presents the performance of Reinforced Concrete “Maillart-Type” Arch Bridges, also known as “RC Deck – Stiffened” Arch Bridges, under the gravitational and the moving loads prescribed by the current mandatory codes for bridges.

The structural performance has been evaluated by means of a linear analysis implemented in a Finite Element (FE) model for a Bridge Inventory made of more than 1500 structures, which have been generated by means of the Monte Carlo simulation method considering fixed variation ranges of several geometrical parameters. Each bridge within the inventory has been verified based on the typical design approaches adopted in the 50s and under the loading conditions required by the Codes of the time (i.e. only gravitational loads). Successively, according to current guidelines (Italian Building Code and New Guidelines for existing bridges), the performance of the designed bridges has been assessed considering the current non seismic design actions.

The analyses evidenced that at the Ultimate Limit State, flexural failures occur in the most external piers, which are also the slenderest ones, while shear failures occur mainly in the short piers at the arch keystone. This is due to the fact that the piers were designed only for axial forces and schematized as pendulums even if, in many cases, they were built as fixed elements at both ends and with some additional steel reinforcements. Therefore, the design assumption of pendulum scheme led to a fairly lower percentage of steel if compared to elements subjected to shear and bending moment. Conversely, no flexural or shear failures occur in the arch and in the beams of the deck.

This study allowed to identify the main vulnerabilities of this type of bridge under the current gravitational and moving loads and to highlight the opportunity for future developments, which could include the definition of different structural strengthening systems in order to improve the structural capabilities of such bridges. Further studies will investigate the same bridge inventory, herein defined, under the seismic actions provided by the current Italian codes to better understand the global vulnerability of such bridges under both static and seismic loading conditions.

Abstract

The large number of existing buildings for which seismic rehabilitation interventions are required highlights the need of sustainable techniques able to reduce costs and downtime. To this purpose, a new strengthening technique named High-Performance Dissipating Frame (HPDF) was developed. It consists of new framed structures applied from the outside thus reducing the impact and relocation needs of tenants. This is even more important for strategic (e.g. hospitals) and other public buildings (e.g. schools) due to the social and economic effects deriving from their interruption of use. HPDF system consists of external precast RC frames (i.e. exoskeletons) rigidly connected to the existing structure and equipped with both shear and flexural damper devices to provide a high dissipation capacity in case of seismic actions and then to protect existing building. In the paper, the HPDF system has been applied to a Reinforced Concrete (RC) school building designed only to gravity loads. After a brief description of the building under study and the HPDF system, the stiffness, strength, and dissipation properties have been determined using an iterative displacement-based design procedure purposely set up. Results show that the considered strengthening technique increases seismic performance of the existing building according to different targets involving both structural and non-structural components, also avoiding any other local intervention.

Keywords: Seismic Strengthening, Existing Buildings, RC Structures, Exoskeleton System, Energy Dissipation.

1 INTRODUCTION

The large number of existing buildings in Italy without adequate seismic protection [1] requires the definition of sustainable intervention techniques, able to reduce time and costs, and to limit the interruption of use. Specifically, regarding existing reinforced concrete (RC) structures, most of the gap is due to inadequate detailing and poor behavior of fragile elements like beam-column joints [2] as clearly demonstrated by recent earthquakes [3].

Sustainable strengthening techniques were and are being developed, at both local and global level, within the activities of the Work Package 5 “Integrated and Sustainable Interventions for the Requalification of Existing Buildings” (WP5) carried out in the framework of the 2019-21 research program funded by the Italian Dept. of Civil Protection (DPC) and carried out by the Network of Laboratories of Earthquake Engineering (ReLUIS). Among others, a patented local seismic strengthening system was developed in order to allow cheap interventions only from the outside [4].

Also, new techniques were developed to perform upgrading interventions at global level as for example that based on RC exoskeletons [5, 6, 7]. This solution is frequently coupled with further interventions devoted to reducing energy consumption of buildings, thus increasing their sustainability [8, 9].

In [10] a strengthening solution based on the use of precast RC exoskeletons connected to the existing structure to provide it with additional seismic capacity, is proposed. Further, the possibility of adding dissipative capacity to this kind of intervention technique has been studied [11, 12], in order to enhance global performance and therefore optimize the required intervention costs. The strengthening solution named HPDF (High Performing Dissipation Frame) was developed in order to optimize the position of dissipative elements coinciding with the centreline of the beams. This makes it possible to maximise the deformation to which the dissipative elements are subjected, which is amplified with respect to the inter-storey displacement. Therefore, an increased effectiveness is expected with respect to dissipative bracing systems, where hysteretic dissipation elements work on the interstorey displacement due to seismic actions.

As a first step of the development process, the HPDF frames were applied to simple structural models [11] in order to identify the parameters that most influence their behaviour and effectiveness in increasing the seismic capacity of the structure under intervention. Moreover, the iterative design process was outlined starting from the push-over curve of the existing structure and the identification of the seismic capacity gap to be covered by the strengthening technique.

The present study, relying on the design method set-up in [11], is devoted to applying the strengthening solution to a real case study represented by the “Santini school building” located in the small town of Loro Piceno town, province of Macerata, Italy. The building is an old RC structure dating back to early ‘60s designed only to gravity loads. The application of the HPDF system to a real case study is helpful in identifying the potential advantages and disadvantages of the technique and to better evaluate its effectiveness.

2 DESCRIPTION OF THE STRENGTHENING SYSTEM

As can be seen in Figure 1a, the HPDF system is made up of two main components each one made up of a column and a half beam. At the beam end, the shear dissipative devices are placed to work under the relative displacements (S hinges). Moreover, at the base of the column, flexural dissipative hinges are inserted working under the rotation of column members. It can be noted that when the span length is two times the interstorey height, the relative dis-

placement of the S hinge is equal to 2Δ , where Δ is the interstorey displacement. This highlights the advantage with respect to other devices whose dissipative capacity is related to the interstorey displacement Δ as, for example, in the case of bracing systems.

A suitable working mechanism of the HPDF system is obtained when the framing elements behave in a suitably stiff manner. In fact, in order to maximize the relative displacement of the S hinge, small or no deformations of the beam members are needed. This is strongly dependent on the bay length and makes the system not effectively applicable in case of large values of the span length, which would require large cross-sections of beams and columns. In these cases, an additional bracing system may be introduced to reduce RC members deformations thus increasing the effectiveness of the HPDF system (see Fig. 1b)

The new frames of the HPDF system have to be connected to the existing structure by means of shear connectors, grouted with epoxy resin and designed to resist the (inertial) shear forces that are transferred from the existing structure to the new frames. In order to allow the dissipative kinematics, the connections must be such that only vertical displacements are allowed.

Figure 1: Position of the bending (F) and shear (S) hinges for a single-bay frame a); HPDF system with addition bracing members b).

The connection between the HPDF system and the existing structure must be present only at beam column joints in order to allow a rigid body behavior of new frames with respect to the existing one. Details of the connection system are reported in [11].

3 DESCRIPTION AND ASSESMENT OF THE CASE STUDY

In order to apply a reinforcement technique from the outside, by means of an exoskeleton, the Primary School "Pietro Santini" (Fig. 2a) in Loro Piceno (Macerata) was selected as a case study. The building was damaged by the 2016-2017 Central Italy seismic sequence.

The school building has RC structure, rectangular plan with three stories (Fig. 2b), two of which are below the ground level (south side), while only one storey is visible on the north side, which faces the main road. The building has a floor area of about 400 m² and it reaches a total height of about 12 m. The structure has a regular mesh of columns, with the exception of a small plan irregularity. The structural arrangement shows the presence of a series of one-way frames (Fig. 2b). The staircase, made of two RC walls, is eccentric with respect to the building's center of mass. In order to verify the effectiveness of the proposed technique, the modelling activity first focused on the development and calibration of the FEM model of the building in SAP2000 for assessment purposes.

Figure 3: 3D finite element model and dynamic characteristics of the structure.

The material properties were determined through destructive and non-destructive tests in accordance with the code NTC 2018 [13]. In particular, the mechanical characterisation of the compressive strength of concrete was obtained from compressive tests on cores drilled from the structure. From these tests a mean cylindrical compressive strength $f_{cm} = 10.9$ MPa has been found. The yield strength of the reinforcing steel was obtained from tensile tests on reinforcement bars. These tests resulted in an average yield strength $f_{ym} = 370$ MPa. It is worth noting that the material properties found in the Santini school are essentially consistent with the expected values reported in [14] for the same construction period.

Figure 4 shows the reinforcement arrangement and moment-rotation relationships of typical column (Fig. 4a) and beam (Fig. 4b) members. The column cross-section dimension is generally 46x46 cm (related to column P1 in Fig. 3), while beams have 40x65 cm section (beam T1 in Fig. 3).

Figure 4: Plastic hinge modelling of column (P1) and beam (T1).

Figure 5 shows the capacity curve of the structure, determined through push-over analysis in the X direction considering a pseudo-triangular eccentric load distribution. The analysis was pushed up to a displacement of 120mm (evaluated at the top of the structure) where the seismic capacity/demand ratio is equal to $\zeta_E=1$. The capacity curve does not account for possible brittle failures but only for ductile ones related to the exceedance of the rotation capacity of flexural hinges in RC members. The identification of brittle failures in RC members was made *ex-post* by comparing shear stresses on beams, columns and beam-column joints with the related capacity. Therefore, the displacement (and related base shear) that causes the first fragile crisis was determined equal to $d=11$ mm to which a $\zeta_E=0.12$ is obtained.

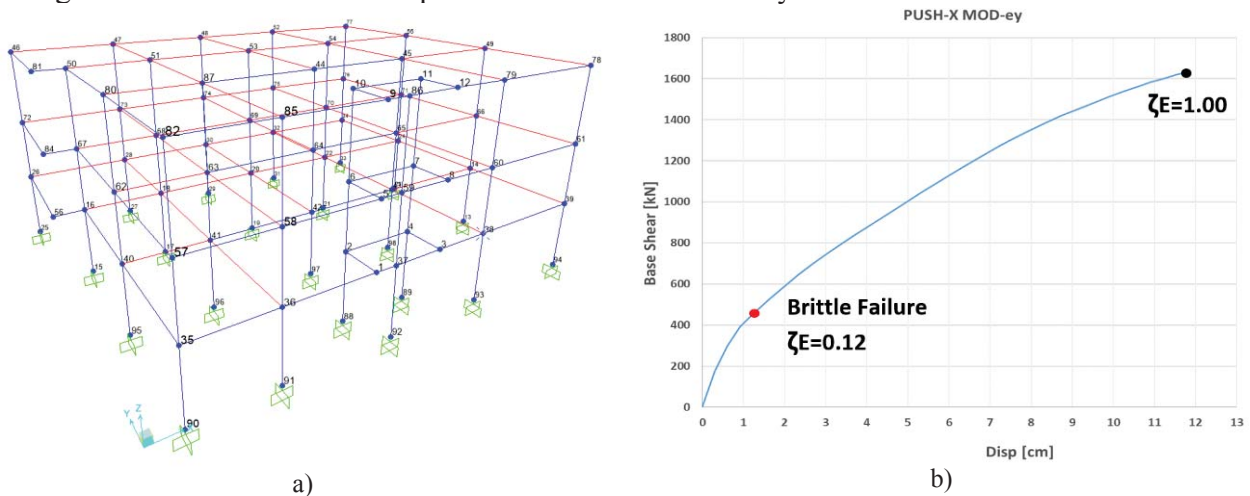

Figure 5: Structural model a); Push-over analysis in the X direction b).

4 THE STRENGTHENING INTERVENTION

In order to design the strengthening intervention, all the HPDF frame elements were considered as elastic and substantially rigid, while the dampers were modelled as elasto-plastic, without hardening behaviour. Starting from the push-over (PO) curve [15, 16], obtained for the X-direction (Fig. 5), the equivalent bilinear behaviour was reported in the ADRS format along with the 5% damping demand spectrum, according to the current code NTC-2018 [13]. In the first design phase, the achievement of seismic upgrading (conventionally related to a value $\zeta_E=0.6$) was set for the structure, therefore the demand spectrum was properly reduced. The target displacement was assumed to be equal to the displacement at which the existing structure achieves the first fragile collapse ($d_{y,EX} = 11\text{mm}$ $d_{y,EY} = 13\text{mm}$, for the X and Y directions respectively). This latter means that the HPDF system is designed to prevent any fragile collapse in the existing structure, in order to also avoid local interventions to strengthen RC members. The displacement value is reported on the demand spectrum to evaluate the stiffness value of the complete dissipative frame structure ($K_{EX} + K_{HPDF}$). The stiffness is given by the slope of the straight line connecting the origin of the ADRS plane and the intercept on the demand spectrum (Fig. 6). By reporting the target displacement on the reduced spectrum (damping $\xi=30\%$), both the force and the yield displacement of the HPDF-frame reinforced structure are determined. In this case the ductility demand is approximately equal to 2.0.

After defining the $K_{EX} + K_{HPDF}$ stiffness of the coupled system (green line in Fig. 6), the stiffness of the dissipative system alone (1) is obtained as follows:

$$K_{HPDF} = K_{(EX+HPDF)} - K_{EX} \quad (1)$$

The stiffness and strength properties of shear (S) and flexural (F) hinges are linked together and contribute to the global stiffness K_{HPDF} according to equation (2).

As reported in [11] the contribution to the global stiffness and strength of F hinges is lower than that of S hinges which are usually more numerous. In some cases, the contribution of F hinges could be also neglected by realizing a pinned connection at bottom end of the first story columns.

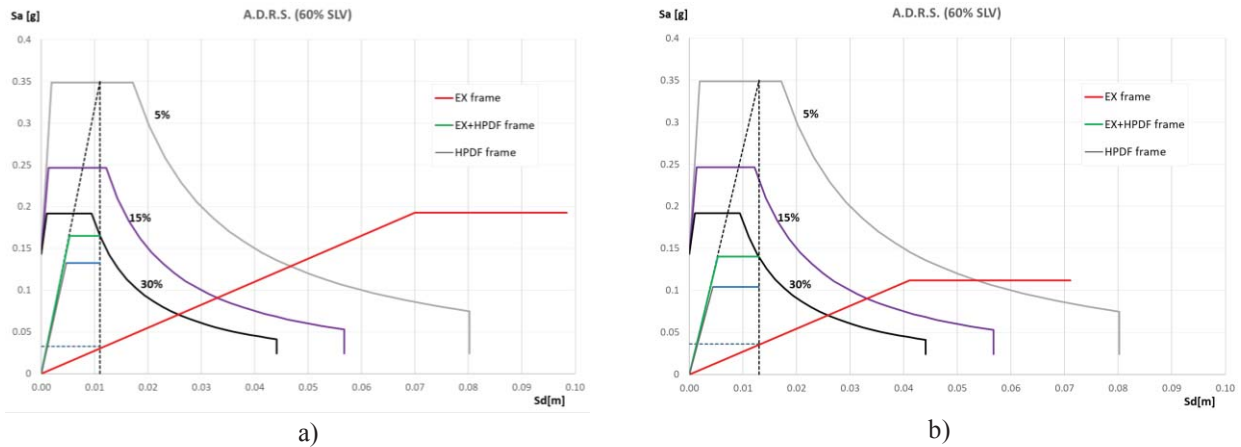

Figure 6: Demand and capacity spectra according to ADRS format for x-direction a) and y-direction b).

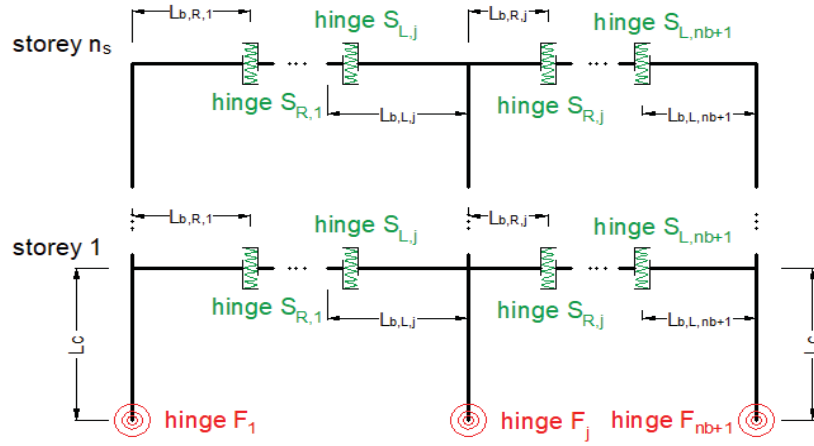

Figure 7: Stiffness of the dissipative system as a function of the stiffnesses of the individual devices in shear and bending.

$$K_{HPDF,i} = \sum_{j=1}^{n_b+1} \frac{K_{F,j,i}}{n_s^2 \cdot L_c^2} + 2 \cdot \frac{K_{SL,i,j} \cdot L_{bL,j,i}^2}{n_s \cdot L_c^2} + 2 \cdot \frac{K_{SR,i,j} \cdot L_{bR,j,i}^2}{n_s \cdot L_c^2} \quad (2)$$

4.1 Assessment of the upgraded structure

The new HPDF frames are placed only externally, along the existing structure perimeter (Fig. 8). The upgraded structure is made of two RC frames working in parallel. New frames are devoted to subtracting seismic action from the existing ones in order to limit their stresses and deformations. However, frames along one side only work in their own plane, so their contribution is negligible in orthogonal direction. Therefore, post-intervention structural assessment can be made by means of separate PO analyses for the two plan directions.

Figure 8: Exoskeleton defined by four HPDF frames.

The proposed methodology, which refers to the N2 method [17], is applied for each of the two main directions of analysis and is based on an iterative procedure [11]. That procedure allows the stiffness of dissipative elements to be calibrated according to the stiffness of the system (HPDF+existing structure) and the equivalent damping ξ . For each step of the analysis, the damping value must be compared to that one assumed, and to this purpose, the expression provided by Mazza and Vulcano [18] was adopted. Figure 6 shows the results in the final configuration at 30% damping.

The first results showed that the flexural dampers provide a small contribution, so the frames were considered to have a pinned connection at the base. The characteristics of the shear dampers are shown in Figure 9.

Figure 9: Shear hinges on X frames a); Load-deformation relations of shear hinges b).

The four HPDF frames (Fig. 8) are defined by RC beam and column elements (concrete class C28/35) with a 40x60cm rectangular cross-section. The braces are HEB300 and HEB240 steel profiles (structural steel of class S275), for the X-direction and Y-direction frames, respectively.

Figure 10 shows the capacity curves ante and post intervention for the X and Y plan directions. As can be seen, a large stiffness increase for both directions and a consequent increase in the base shear capacity at the target displacement are visible.

Figure 10: Push-over pre and post intervention in x-direction a) and y-direction b).

Figure 11 shows the capacity-demand comparison in the ADSSR format for the X and Y directions. As can be seen, a clearly larger stiffness is provided by the upgraded structure (HPDF + existing structure). The base shear has a higher value with respect to the assumption made in the design phase. This latter could be attributed to the existing structure irregularity that behave in a little different way when upgraded with the HPDF system, modifying the assumed distribution of base shear between the existing and the upgrading frames. However, this does not affect the effectiveness of the HPDF system, which relying on a 30% damping is able to lead the structure to the wanted performance displacement.

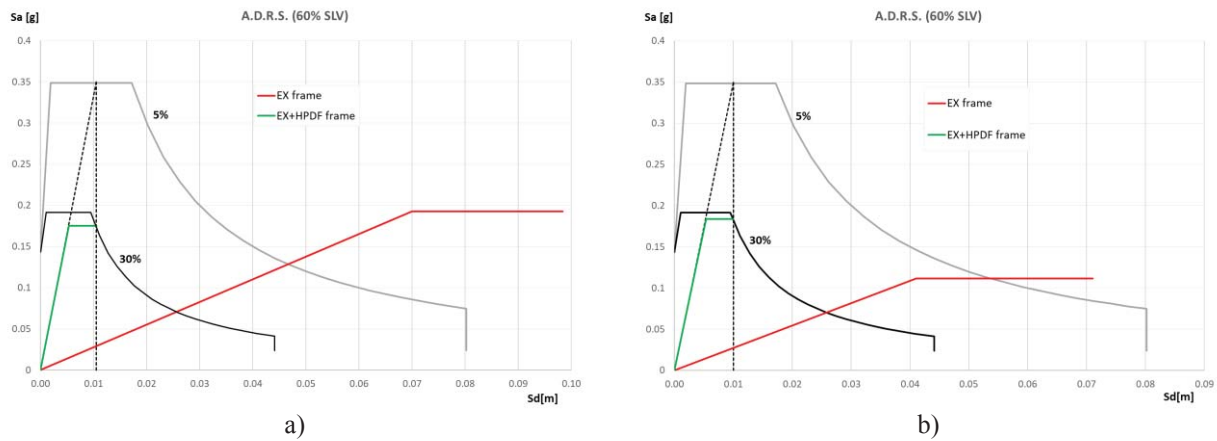

Figure 11: Post-intervention structure capacity according to ADRS format in x-direction a) and y-direction b).

5 CONCLUSIONS

Seismic strengthening techniques based on exoskeletons allow to operate only from the outside without interrupting the building use. Moreover, the demolition and restoration of non-structural elements (e.g. plugging, flooring, infills, etc.) which cause considerable inconvenience to the occupants of the buildings is avoided.

The main aim of this study was to apply the HPDF system to a real case study building, which was so far developed and applied to simple structural schemes. The mentioned case study allowed to recognize that in case of large span length of the existing structures it appears advisable modifying the basic configuration adopted for the HPDF system. In fact, to increase the system effectiveness, it is suggested the installation of steel braces to reduce the beam and column deformability. This allows to fully exploit the relative displacement between beam ends, maximizing the global seismic performance. Moreover, in such a way, the RC members' cross section can be kept under dimensions more suitable from both the economic and aesthetic point of view.

The intervention was designed to upgrade the seismic capacity of the case study building that, in the as-built condition, was equal to 12% of the seismic demand ($\zeta_E = 0.12$). The entire assessment process was performed in accordance to the current Italian seismic code with respect to the life safety limit state. The existing structure capacity is referred to the first fragile collapse and the upgrading system was designed to prevent it. This intervention approach favourably allows to apply only the HPDF system without any other local intervention to achieve the strengthening target.

Using an iterative design procedure, all the elements of the upgrading system were designed starting from the dissipative hinges up to the RC members and bracing steel members. The needed performance point was attained by providing a damping value of 30%, which is usual for hysteretic devices like those used in the HPDF system.

The case study analysed in the present paper contributed to optimise the HPDF system for its application to real buildings showing the need of some layout modifications under the occurrence of specific structural configurations like, for example, the presence of long frame spans.

Abstract

The effectiveness of externally applied Carbon Fiber-Reinforced-Polymer (C-FRP) sheets for the retrofitting of damaged Reinforced Concrete (RC) beam-column connections is experimentally investigated. Two real-scale exterior RC beam-column connection specimens are tested under reverse cyclic deformation. The damaged specimens have been repaired using C-FRP sheets superficial placed as surface reinforcement after the sealing of the developed cracks with high strength resin paste. The retrofitted joints re-tested under the same reverse cyclic deformation loading. The retrofitted specimens in comparison with the original ones exhibited more or less similar load capacity and stiffness level with respect to the original ones.

Keywords: Reinforced Concrete, Beam-column connections, C-FRP sheets, Cyclic tests, Hysteretic response.

1 INTRODUCTION

Structural repair and upgrading of Reinforced Concrete (RC) beam-column joints in damaged RC frame structures after seismic excitations is a common problem in seismic prone regions. Researchers have published during the last decades valuable research on the post-earthquake rehabilitation procedures of damaged beam column joints [1], [2]. Many efforts have been done so far for the introduction and the establishment of techniques that are based on the promising material of Fiber-Reinforced Plastics (FRP) sheets [3], [4], [5], [6], [7].

A well-known efficient rehabilitation technique of RC beam-column joints damaged during earthquake excitations is the application of FRP sheets in combination with resin injections. It includes thin resin infusion under pressure in the cracks of the damaged area prior to the application of FRP sheets on the damaged body. The efficacy of this combined procedure of resin injection and FRP sheets for the strengthening of damaged beam-column connections has also been the subject of the experimental project by Karayannis and Sirkelis (2008) [4] and Tsonos et al (2017) [2]. Nevertheless, the increasing interest in the use of FRP sheets, due to the immediate and easy-to-apply nature of the required intervention, was the main motive behind the simplification of the rehabilitation technique by omitting the use of resin injections prior to the application of the FRP sheets [8]. Addressing the issue of the efficiency of any strengthening technique it is important to remember that the seismic behavior of reinforced concrete connections involves the interaction of complex phenomena such as bond, shear, confinement, fatigue which have not been yet well understood [9], [10], [11]. Since many unanswered questions remain about the traditionally reinforced connections it is justifiable to consent for a certain measure of uncertainty for the mechanics of joints with superficially applied C-FRP sheets as external strengthening reinforcement [12], [13]. Despite all the uncertainties and based on the justified thought that a structural member can adequately be re-designed and strengthened to resist seismic loading even without full knowledge of all the involving interacting phenomena, this easy-to-apply technique is experimentally investigated.

This simplified technique is usually adopted in areas after damaging earthquakes due to the fast and easy-to-apply required procedure. This treatment of the damaged beam column joints has been mainly based on the generally accepted concept that in all reported cases the application of FRP sheets has been proved rather successful. In this direction, the experimental study presented herein investigates the efficacy of the rehabilitation of damaged beam-column connections using FRP sheets after a meticulous but superficial repair of the cavities and cracks of the damaged area using resin paste. The investigation presents experimental results of 4 real-scale beam column specimens; two original specimens and two retrofitted ones. The original two joint specimens first were subjected to cyclic loading and then repaired with C-FRP sheets. The reteofitted specimens were re-subjected to the same cyclic loading and the observed results are used for the evaluation of the efficiency of the applied repair technique.

2 CHARACTERISTICS OF THE SPECIMENS

Cross-sections, dimensions, materials and reinforcement arrangements of the specimens were chosen in the way that the first specimen (BJB-S1) represents common RC buildings designed according to earlier codes without the proper shear reinforcement in the joint body (only one stirrup in the joint area) whereas the second specimen (BJB-BX) represents cases with X-type reinforcement in the joint without stirrups.

The maximum joint shear that can be developed in the joint body by the steel bars of the beam is 0.32 MN and consequently shear stress equal to 3.67MPa. The ratio $\Sigma M_c / \Sigma M_b$ is almost 1.40 (a little higher) and therefore cracks are expected to be developed both in the joint body and the part of the beam near the joint (ACI 318).

Name	Geometry and Reinforcement (in mm)				
	Joint area	Beam		Column	
	Steel	Cross-section	Steel	Cross-section	Steel
BJB-S1	Ø8	{350×250}	$\left\{ \begin{array}{l} 4\text{Ø}14 \text{ up} \\ 4\text{Ø}14 \text{ bot.} \\ \text{Ø}8/100 \end{array} \right\}$	{350×350}	$\left\{ \begin{array}{l} 4\text{Ø}14 \\ \text{Ø}8/100 \end{array} \right\}$
BJB-S1-R	Ø8 + FRP				
BJB-XV	X2Ø12	{350×250}	$\left\{ \begin{array}{l} 4\text{Ø}12 \text{ up} \\ 4\text{Ø}12 \text{ bot.} \\ \text{Ø}8/100 \end{array} \right\}$	{350×250}	$\left\{ \begin{array}{l} 4\text{Ø}14 \\ \text{Ø}8/100 \end{array} \right\}$
BJB-XV-R	X2Ø12 + FRP				

Table 1: Geometrical and reinforcement characteristics of the tested exterior beam-column joint specimens.

The total length and cross-section of the column are 3.0m and 350/250cm, respectively, whereas the free length and the cross-section of the beam are 1.875m and 350/250cm, respectively. The list of the tested beam column specimens, their names, the geometrical characteristics and the reinforcement arrangements are presented in Table 1.

Figure 1: Damage of the joint (a, b). Cleaning (c) of the damage area and removal of loose material.

2.1 Application of the C-FRP sheets

The FRP sheets are applied to the body of the damaged joints after a superficial repair of the damage. First, cleaning and removal of the loose concrete material takes place (Figure 1). Right

after, meticulous filling of the cavities and the developed cracks is performed with high strength resin paste (Figure 2). Prior to the application of the C-FRP sheets abrasion of the surfaces is absolutely necessary (Figure 2c).

Figure 2: Filling of the developed cavities and cracks with high strength resin paste (a, b) and meticulous abrasion of the surfaces (c) prior to the C-FRP application.

The positions of the applied C-FRP sheets are schematically shown in Figure 3a and application works in Figures 3b and c. As presented in Figure 3a the C-FRP sheets are placed round the joint body and round the critical parts of the upper and down column and the beam.

2.2 Materials

The concrete's cylinder compressive strength was 34MPa whereas the yield tensile strength of the longitudinal steel bars and the stirrups was 550MPa. The type of the fiber-reinforced plastics sheets was Carbon FRP sheets. The characteristics of the used C-FRP sheets as given by the manufacturer were: Thickness of the sheets 0.168mm, tensile strength 4300MPa and tensile modulus of elasticity 240GPa.

2.3 Loading procedure and test setup

The loading procedure of the specimens includes full reverse cyclic deformations that are applied near the free end of the beam. The examined beam column subassemblages are subjected to seven loading steps and each step comprised three full cycles as shown in Figure 4. The used loading program permits the evaluation of the structural performance parameters of the specimens.

The experimental setup and the instrumentation are shown in Figure 5. Each beam-column joint specimen is placed after 90° counter clockwise rotation in the way that the column is in the horizontal direction whereas the beam is in the vertical direction. The specimen is supported by rotational devices that allow rotation to simulate the inflection points of the real columns in the middle of their heights.

Compressive axial load equal to 150kN is applied to the horizontally placed column element throughout the testing procedure. This loading is almost equal to 5% of the nominal strength of the concrete section of the column ($0.05A_c f_c$).

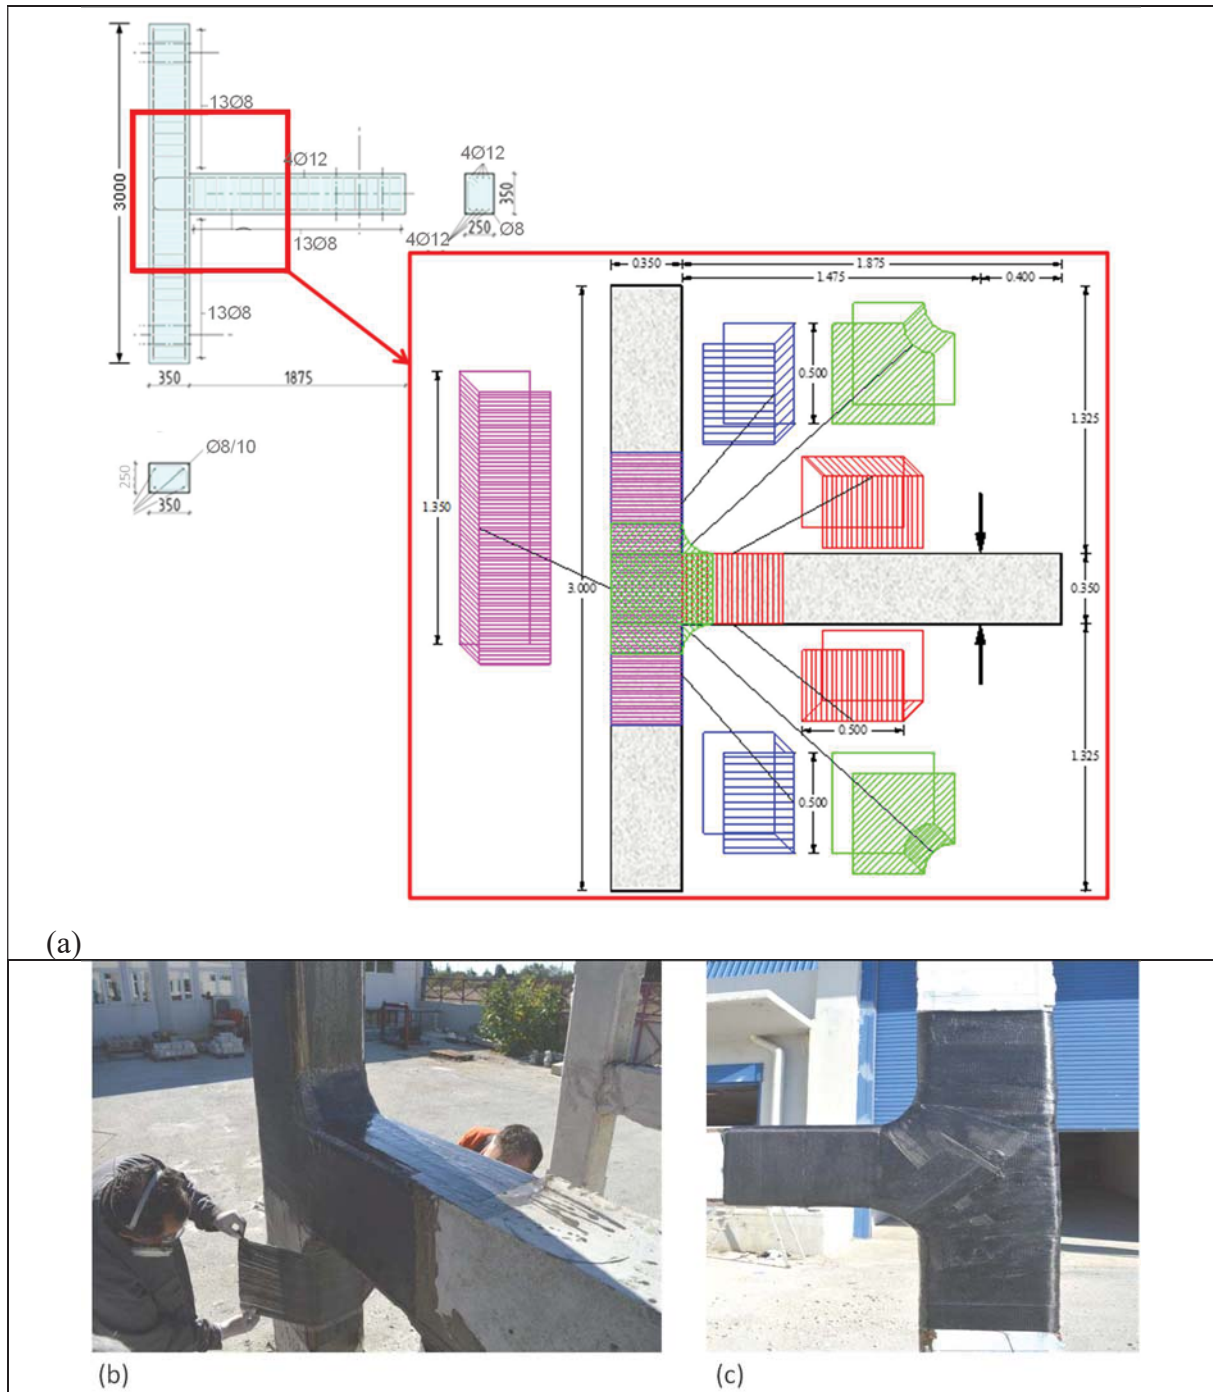

Figure 3: Schematic application of the C-FRP sheets (a) and application works of the C-FRP sheets (b, c).

Figure 4: Loading procedure

Figure 5: Test setup.

3 TEST RESULTS AND DISCUSSION

For the evaluation of the efficiency of the studied retrofitting procedure the overall performance of each original beam column joint is examined and compared to the performance of the corresponding retrofitted one in terms of hysteretic responses and energy dissipation curves.

3.1 Hysteretic responses - Load carrying capacity

The hysteretic responses of the original joint BJB-S1 and the corresponding retrofitted one BJB-S1-R are presented in Figures 6a and 6b, respectively. Further, the cracking patterns of these specimens at the end of the loading sequence are presented in Figures 6c and 6d, respectively. For comparisons purposes the envelope curves for the three full cycles per loading step, of these two tested specimens, BJB-S1 and BJB-S1-R, are shown in Figures 7a and 7b, respectively. The comparison of the hysteretic curves and the envelope curves obtained from the original joint and the corresponding ones obtained from the testing of retrofitted joint indicates that the application of C-FRP sheets restored the capacity values of the damaged joint in respect to those of the original specimen, to a great degree.

The hysteretic responses of the original joint BJB-XV and the corresponding retrofitted one BJB-XV-R are presented in Figures 8a and 8b, respectively. Further, the cracking patterns of these specimens at the end of the loading sequence are presented in Figures 8c and 8d, respectively. For comparisons purposes the envelope curves for the three full cycles per loading step, of these two tested specimens, BJB-XV and BJB-XV-R, are shown in Figures 9a and 9b, respectively. The comparison of the hysteretic curves and the envelope curves obtained from the original joint and the corresponding ones obtained from the testing of retrofitted joint indicates that the application of C-FRP sheets restored the capacity values of the damaged joint in respect to those of the original specimen, to a great degree.

Nevertheless, from the observations it is concluded that there are some reservations for the efficiency of the technique in the restoration of the load bearing capacity in cases of high levels of loading or high levels of initial damage.

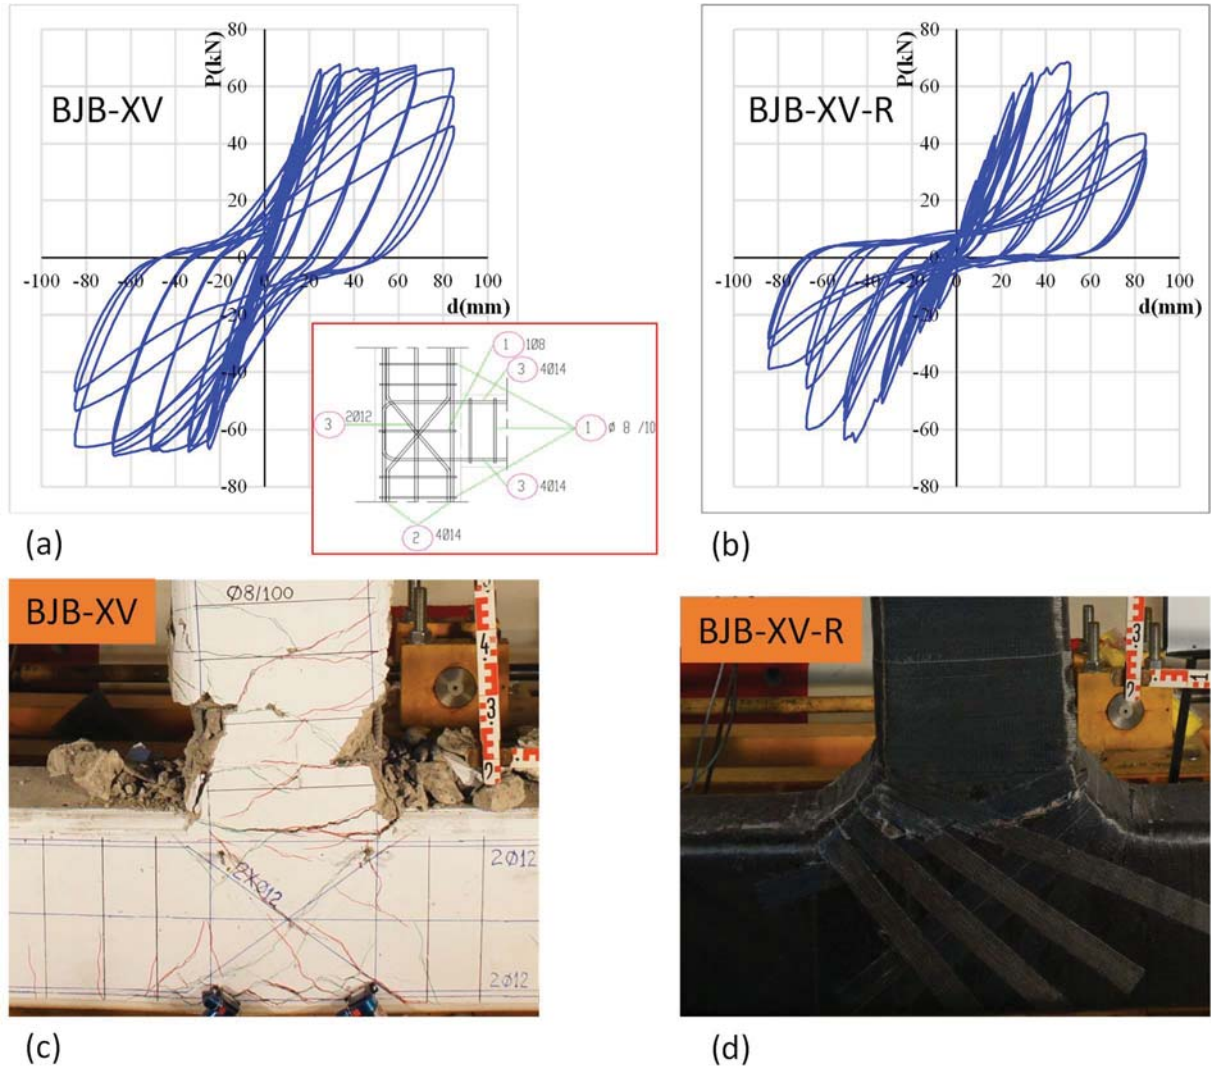

Figure 8: Hysteretic response (a) of the specimen BJB-XV and hysteretic response (b) of the corresponding repaired specimen BJB-XV-R and cracking pattern at the end of loading of the same specimens (c, d).

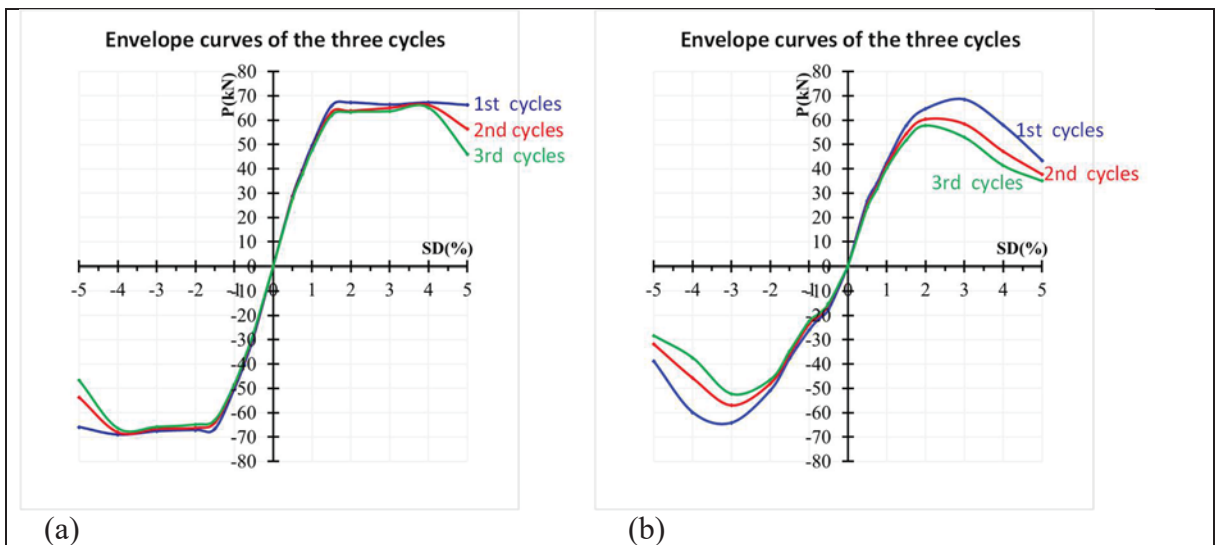

Figure 9: Envelope curves of the hysteretic responses (a) of the specimen BJB-XV and (b) of the corresponding repaired specimen BJB-XV-R.

3.2 Dissipated energy capacity

A measurement for the assessment of the efficacy of the applied retrofitting technique can be the observed dissipated energy capacity in terms of the area of the hysteresis loops. Energy dissipation is an indication of the structural element capacity to be strained and it defines the energy that can be absorbed before the loss of the system stability.

The dissipated energy at 1st, 2nd and 3rd cycles of each loading step as measured in terms of the area of the corresponding hysteresis loops of the original specimen BJB-S1 are presented in Figure 10a. Further, the dissipated energy at 1st, 2nd and 3rd cycles of each loading step as measured in terms of the area of the corresponding hysteresis loops of the retrofitted specimen BJB-S1-R are presented in Figure 10b. Comparing the diagrams of retrofitted specimen with the corresponding diagrams of the original specimen it is deduced that the applied technique can rather adequately restore the energy dissipating capacity for the specimen designed according to earlier codes without the proper shear reinforcement in the joint body (only one stirrup in the joint area).

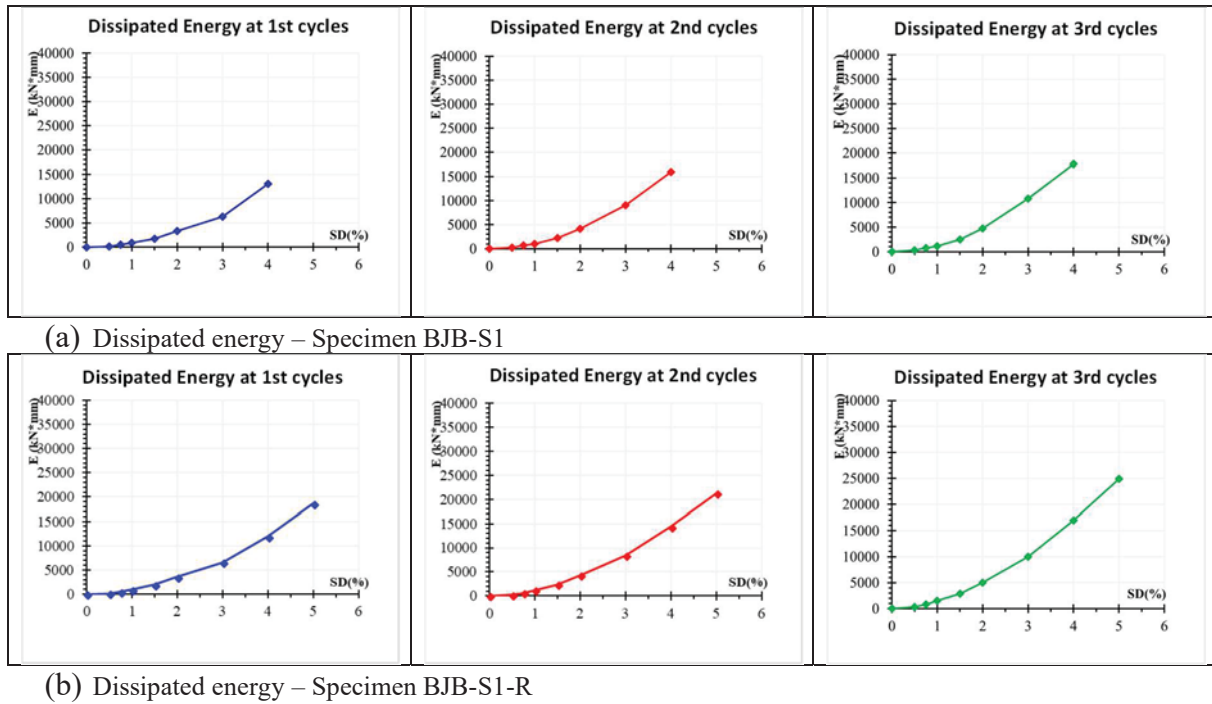

Figure 10: Energy dissipation per each loading step (a) of the specimen BJB-S1 and (b) of the corresponding retrofitted specimen BJB-S1-R.

The dissipated energy at 1st, 2nd and 3rd cycles of each loading step as measured in terms of the area of the corresponding hysteresis loops of the original specimen BJB-XV are presented in Figure 11a. Further, the dissipated energy at 1st, 2nd and 3rd cycles of each loading step as measured in terms of the area of the corresponding hysteresis loops of the retrofitted specimen BJB-XV-R are presented in Figure 11b. Comparing the diagrams of retrofitted specimen with the corresponding diagrams of the original specimen it is deduced that the applied technique can rather adequately restore the energy dissipating capacity for the specimen with X-type reinforcement in the joint (without stirrups).

However, from Figures 9 and 10 it can be observed that there are reservations about the efficiency of the technique in the restoration of the energy dissipation capacity in high levels of loading or high degree of initial damage.

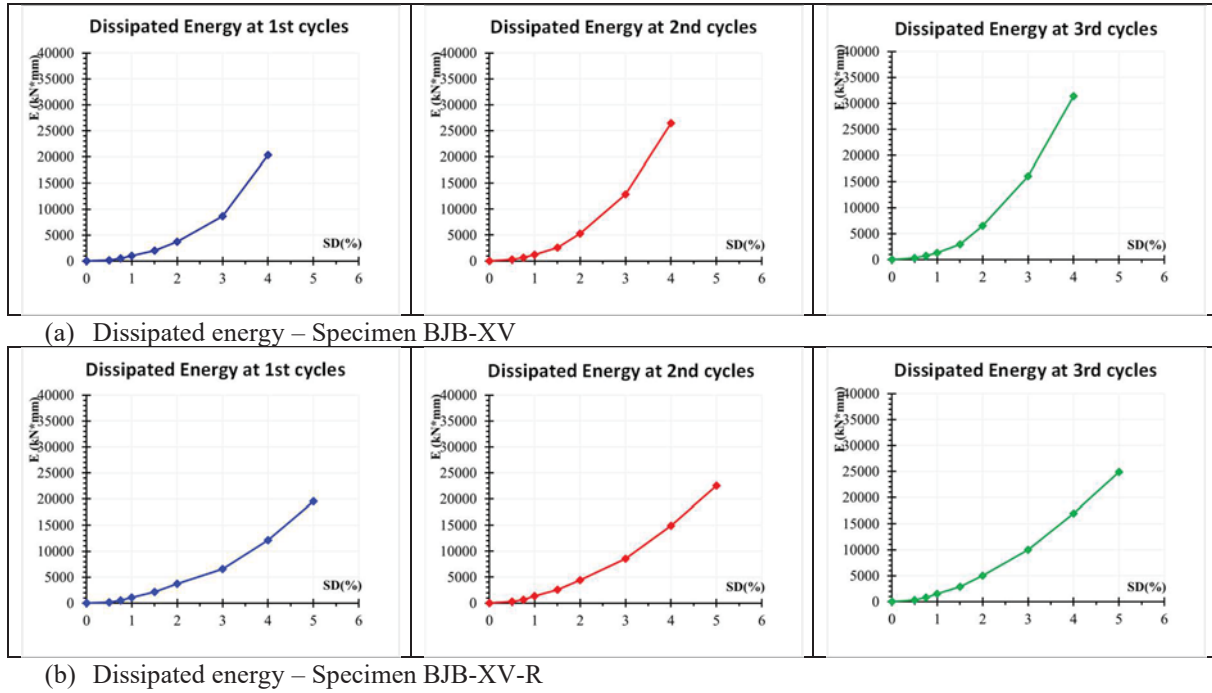

Figure 11: Energy dissipation per each loading step (a) of the specimen BJB-XV and (b) of the corresponding retrofitted specimen BJB-XV-R.

4 CONCLUSIONS

The efficacy of using C-FRP sheets for the retrofitting of damaged external beam column joints after seismic excitations is experimental studied. In the repair technique under investigation in this work, the C-FRP sheets are applied after a meticulous filling of the developing cavities and cracks but without the infusion of thin resin into the cracking system of the damaged area.

From the comparisons of the hysteretic responses of the original specimens with the hysteretic responses of the retrofitted ones it is deduced that in both cases the load bearing capacity values of all the retrofitted joints were almost equal to the ones of the original specimens in every loading step of the loading history.

Further, from the comparisons of the dissipated energy at 1st, 2nd and 3rd cycles of each loading step of the original specimens with the dissipated energy at 1st, 2nd and 3rd cycles of each loading step of the corresponding retrofitted ones it is deduced that the applied technique has rather adequately restored the energy dissipating capacity in the examined cases.

Finally, there are reservations for the efficiency of the technique in the restoration of the load bearing capacity and energy dissipation in cases of high level of loading or high degree of initial damage.

Abstract

The instability risk of underground cavities is issue of concern particularly for areas densely urbanized as the case of many historical centers in Italy. Among the possible causes of the cavity damages up to collapse, the proposed work considers a particular triggering factor that is the dynamic loading induced by an earthquake. Thus, the seismic vulnerability of shallow cavities in soft rock is addressed by proposing a methodology based on an extensive parametric two-dimensional finite element analysis. The proposed methodology is extended to a significant number of realistic cases, considering the effect of the variability of some predisposing and triggering factors on the cavity stability like roof thickness and cavity width, presence of overburden on the top of the rock layer, seismic signal intensity. The seismic vulnerability of the studied cases is assessed through the minimum Factor of Safety calculated during the whole length of the dynamic analysis. Finally, the results of the parametric study are rearranged into 'seismic stability charts for cavities in soft rock' proposed to be adopted as preliminary level of screening, to assess the seismic vulnerability of shallow underground cavities in soft rock. The results of screening enable to identify the critical zones that need a detailed analysis, in consideration of their possible interaction with above-ground structures, infrastructures and human activities.

Keywords: FEM, full dynamic analysis, underground cavities, soft rock, Factor of Safety

1 INTRODUCTION

Shallow underground anthropogenic cavities are frequently spread over the most urbanized areas in many Italian regions whereby their stability represents matter of concern leading to potential risk for buildings, infrastructures, and population. Different causes can induce cavity instability: starting from their excavation, the initial static stability can worsen over time due to an unexpected overloading, water recharge, water table fluctuation and other particular conditions that can result in progressive damage up to the global collapse. Furthermore, seismic actions can represent source of instability for underground cavities as documented by numerical studies in literature [1, 2] and historic observations in some Italian database of co-seismic effects (CFTI5Med, <http://storing.ingv.it/cfti/cfti5/> [3]; CEDIT, http://www.ceri.uniroma1.it/index_cedit.html, [4]).

In the present work we focused our attention on the seismic behavior of cavities, proposing a methodology to assess their stability. The proposal was tested in a specific soft rock type, that is the Neapolitan Yellow Tuff where it is very recurrent to find anthropogenic cavities excavated for different needs during years and with different features (e.g. cavity shape, dimension, cover, other loads). Some studies in the technical literature are dedicated to such cavities, that consider their stability under static and seismic actions [5, 6, 7, 8, 9, 10].

The proposed methodology, described in detail afterwards, is extended to a significant number of realistic cases, taking into account the variability of some different predisposing and triggering factors of the cavity instability (*i.e.* the width and depth of cavity, the overburden stress, the intensity of the seismic action). A parametric study via numerical dynamic analyses was conducted in plane strain conditions using the finite element code Plaxis 2D, on simplified rectangular shapes of shallow cavity. The ground shaking was simulated by applying several time histories of acceleration at the base of the numerical model.

The cavity stability was evaluated by assuming the rock cover above the cavity roof as a beam and quantifying the so-called Factor of Safety (FoS) calculated as the ratio between the resistant moment (M_r) and the loading moment (M_{load}) in correspondence of the most critical vertical sections. The considered FoS is the lowest one experienced during each shaking. The obtained results are presented and discussed in terms of variation of FoS as a function of the ratio L/H (with 'L' equal to cavity width and 'H' equal to the depth of the cavity roof, or rock cover), of PGA_{input} and of the overburden above the rock cover, q .

Although the analyzed conditions are simplified, the parametric study provides a methodological approach to be adopted as a preliminary level of screening to assess the seismic vulnerability of shallow underground cavities in soft rock. The results of screening enable to identify the critical zones that need a detailed analysis, in consideration of their possible interaction with the above structures, infrastructures and human activities.

2 METHODOLOGY

The preliminary stability assessment of underground cavities in soft rock under seismic actions is proposed upon the results of a significant number of parametric two-dimensional finite-element analyses carried out for realistic cases of underground cavities. A rectangular shape cavity was adopted for the analyses that is, with good approximation, representative of many shallow cavities excavated in soft rock. Therefore, for the specific case of rectangular shallow cavities, the parametric study was built considering: *i*) the effect of varying the width of the cavity (L); *ii*) the effect of stress acting in the rock, by varying the depth of the cavity roof (H) and the entity of the load applied above the rock cover (q); *iii*) the intensity of the seismic action by varying the PGA and the frequency content of the input signals selected

among unscaled records of real earthquakes. Table 1 shows all the geometries considered for the analyses: in total 10 geometrical layouts were analysed, defined by varying H from a minimum of 2 m up to a maximum of 10 m, and L from a minimum of 2 m up to a maximum of 10 m. For each layout, two loading conditions were considered ($q_1=50$ kN/m, $q_2=150$ kN/m), reaching a total number of cases equal to 20. The minimum cavity dimensions were selected to obtain a value of the slenderness of the roof, L/H , higher or at least equal to 1 while the maximum dimensions were set in order to guarantee the static stability of the cavity. The vertical load applied at the model surface intends to simulate the presence of soil layers and fills and above the rock cover and structures or infrastructures at the ground surface.

layout #	H (m)	L (m)	L/H (-)	q_1, q_2 (kN/m)
1.1	2	2	1	50, 150
1.2		5	2.5	
1.3		10	5	
2.1	5	5	1	
2.2		10	2	
2.3		15	3	
2.4		20	4	
3.1	10	10	1	
3.2		15	1.5	
3.3		20	2	

Table 1: Geometric and loading properties of realistic cavity models.

The variability of the seismic action was considered by varying the peak ground acceleration and the frequency content of the input signals as shown in Table 2: 12 unscaled accelerograms of real earthquakes were extracted from the Italian database ITACA (<http://itaca.mi.ingv.it/>) and, for the classes with higher energy content, from the international PEER database (<https://ngawest2.berkeley.edu/>), considering PGA_{max} values ranging from a minimum of 0.118g up to a maximum equal to 0.367g and f_{max} values ranging from a minimum of 0.51Hz up to a maximum equal to 11.26Hz. The signals were subjected to a band-pass filtering in the range of 0.1–25 Hz prior to the seismic response analyses.

Finally, 240 analyses (10 cavity geometries x 2 load conditions x 12 signals) were performed.

Figure 1 shows, as an example, the numerical model implemented in Plaxis 2D for the layout #3.1 (see Table 1). The cavity was excavated in Neapolitan Yellow Tuff that was modelled with a simple linear elastic-perfectly plastic model with a Mohr-Coulomb failure envelope [5]: the tuff unit weight (γ_t) equal to 16 kN/m³, the cohesion (c') equal to 866 kPa, the friction angle (ϕ') equal to 30°, the angle of dilatancy (ψ) equal to 0°, the uniaxial compressive strength (σ_c) equal to 3 MPa, the Poisson ratio (ν) equal to 0.3, the Young modulus (E) equal to 2000 MPa, a tension cut-off of σ_t equal to $0.1\sigma_c$.

An amount of viscous damping equal to 5% was added to the model through the well-known Rayleigh formulation, calibrating the mass and stiffness matrix coefficients by means of the double frequency approach. Moreover, the hysteretic behavior of tuff under dynamic loading was not modelled, given the high linearity threshold measured experimentally by [11].

Figure 1: Example of numerical mesh for layout #3.1 implemented in Plaxis 2D.

Table 2: Natural accelerograms selected for the seismic analyses.

The numerical analyses consist of three calculation stages [12, 13]:

- first stage: initialization of the initial stress state within the soft rock mass domain;
- second stage: simulation of the cavity excavation by means of the deactivation of the cavity volume. When possible, generally for lower value of L/H , single step excavation solution was assumed as conservative assumption, while for higher values of L/H multiple steps excavation solution were adopted;
- third stage: full dynamic analyses in the time domain, simulating all the selected earthquake recordings in Table 2.

It is worth noting that the same FE mesh used for static analysis (see Fig. 1) was used for the full dynamic analysis. The width of such numerical model in fact, was originally optimized by a series of sensitivity analyses, in order to reach a true free-field condition at the lateral borders and to minimize the influence of vertical boundaries [13]. Also, the mesh was refined to achieve a reliable propagation of the minimum significant wavelength of the input

signals [14]. The lateral boundary conditions consist of fixed displacements in the horizontal direction perpendicular to the vertical sides of the mesh in static condition; viscous dashpots are applied during dynamic stages of analysis [14]; the base of the model, 50 m deep, is fixed both in vertical and in horizontal directions; the nodes at the top surface are free.

The cavity stability was assessed by means of the Factor of Safety (FoS), calculated as the ratio between the ultimate resistant moment ($M_{r,ULS}$) corresponding to the achievement of the compressive, σ_c , and tensile, σ_t , strengths in the compression and tensile zones and the loading moment (M_{load}) acting in correspondence of the most critical vertical section of the roof beam and calculated by integrating the horizontal stress component, σ_{xx} , acting on the considered sections. The FoS_{static} is computed at the end of the second stage of analysis, while FoS_{dyn} is computed at the end of the full dynamic analyses at stage three, as the lower value experienced during the dynamic analysis under each input signal.

3 RESULTS

Figures 2 and 3 show, for the case of layout #3.1, the horizontal stress distribution acting around the cavity (assuming negative the compressive stress) in correspondence of three reference sections of the roof beam (central section in red, the right and left sections at pillars edges in green and light blue, respectively) after its excavation and during Loma Prieta earthquake considered as example.

After the cavity excavation (Figure 2), the roof tends to behave as a beam subjected to uniform distributed load, not completely bounded at the edges of the pillars: in the upper portion of the vault, the compression area assumes the typical arched profile over the underlying tension area; the separation curve between the compression and tension zones represents the location of the neutral axes of the different sections of the roof beam that assumes an approximately parabolic shape. Definitely, the central section is stretched in the bottom, in correspondence of the roof cavity extrados, and compressed at the top while the lateral reference sections at the intersection with pillars are totally compressed. Similar behavior was observed also in the other cavity layouts (see Table 1); a tensile zone in correspondence of the lateral section in the upper portion closer to the ground surface has been sometimes calculated for shallower cavities, depending on the roof slenderness (the ratio between the cavity width and cover).

For the proposed example in Figure 2, the horizontal stress distributions in correspondence on the central and the lateral sections produce a value of loading moment equal to $M_{load,cx}=3432$ kNm and $M_{load,left=right}=1144$ kNm respectively. By comparing the loading moments with the resistant moment $M_{r,ULS}=13727$ kNm of the roof resistant section, FoS_{static} equal to 4 and 12 was calculated for the central and the lateral section respectively. As expected, after the cavity excavation, the central roof section is the most loaded one exhibiting the lowest value of FoS.

Starting from this stress distribution induced by the cavity excavation, thus from this initial equilibrium condition, the seismic excitation starts, producing in the surrounding cavity a continuous redistribution of the stresses during ground shaking. As example of the time history of σ_{xx} in some points of the cavity roof—selected each 1 m along the central and the right sections of the roof beam—is shown in Figure 3,

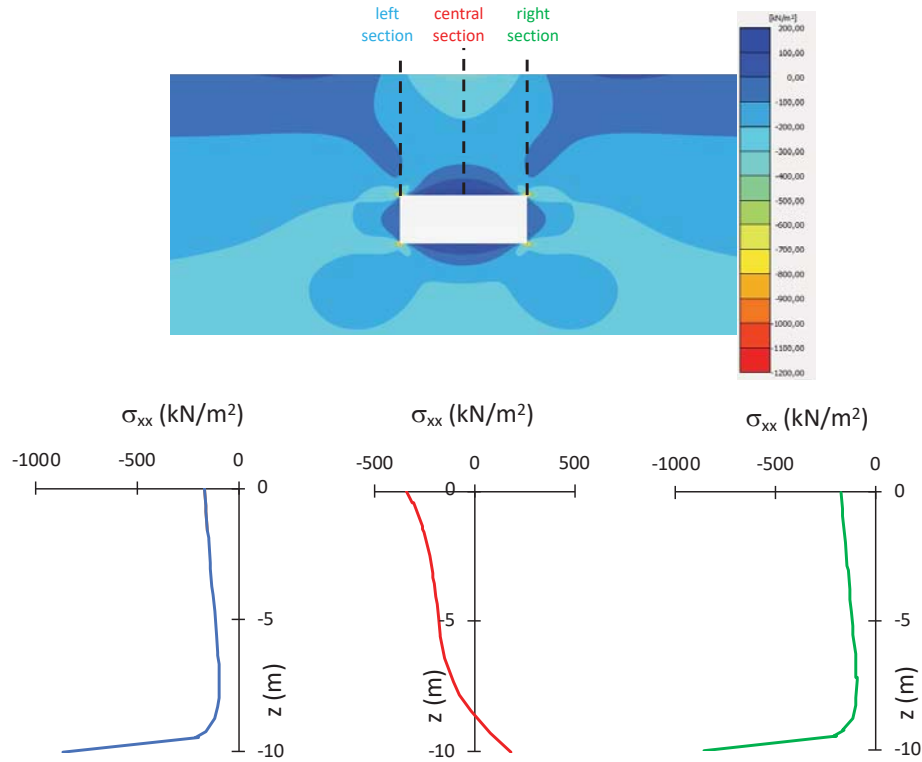

Figure 2: Horizontal stress distribution after the cavity (layout #3.1) excavation.

Consistently with the expected ground deformation under shaking, the lateral sections of the cavity roof experience higher stress variation than the central section. This implies a different modification of the FoS in the considered sections during shaking.

In the central section, starting from $FoS_{static} = 4$, a minimum value of $FoS_{dyn_min} = 3.6$ occurred at the instant $t = 6.15$ s of the time history and a value of $FoS_{dyn_final} = 4.3$ is computed at the end of the shaking; in the left and right sections, starting from $FoS_{static} = 12$, a minimum value of $FoS_{dyn_min} = 1.6$ occurred at the instant $t = 6.15$ s of the time history and a value of $FoS_{dyn_final} = 8$ is computed at the end of the shaking.

Therefore, the initial static conditions of the central section do not change substantially during the shaking, actually a slight increase of FoS occurs at the end shaking due to the redistribution of stress. Such aspect was already observed with reference to a more complex case study by [10]. Conversely, an important reduction of FoS is observed in the lateral sections both during and at the end of the shaking (a reduction of FoS_{static} about equal to 86% and 25% is calculated respectively) due to the high seismic intensity of the selected earthquake, highlighting the effect of earthquake-induced modifications of the static equilibrium under gravity loads. Fortunately, the FoS after earthquake increases in the section (the central) where FoS_{static} was lower and does not reduce down to unity in the lateral sections, hence the roof stability of the selected cavity is not compromised.

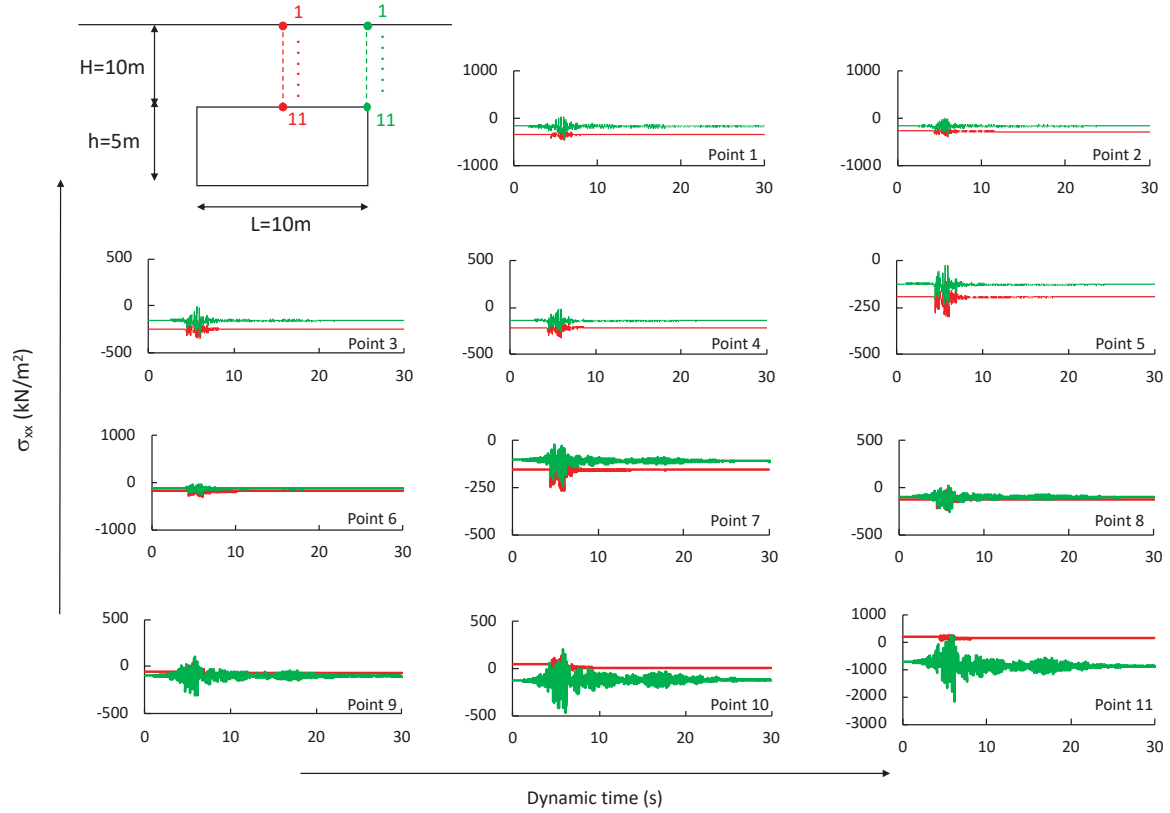

Figure 3: Horizontal stress time history in correspondence of selected points of the cavity roof (layout #3.1) during Loma Prieta earthquake 1989 earthquake.

To generalize the outcome of the proposed parametric study, the FoS values calculated for all cases as the minimum between the central and lateral sections, were processed as function of the increasing intensity of PGA in the proposed Seismic Stability Charts for Cavities, SSCCs (Figure 4). Each chart refers to a specific cavity geometry including both considered loading combinations (q_1 black lines/points, q_2 grey lines/points). In particular, the first row of Figure 4 represents the three cases in which H is set equal to 2 m while L varies from 2 m to 10 m (Figs 4a,b,c respectively), the second row of Figure 4 represents the four cases in which H is set equal to 5 m while L varies from 5 m to 20 m (Figs 4d,e,f,g respectively), the third row of Figure 4 represents the three cases in which H is set equal to 10 m while L varies from 10 m to 20 m (Figs 4h,i,j respectively).

The general trend of the results shown in the figure leads to the following considerations:

1. FoS tends to decrease with the increasing of the seismic loading intensity, here expressed as function of PGA;
2. higher FoS is expected for q_1 loading combination compared to q_2 , because a lower vertical stress is initially induced by a lower overburden; however, with increasing cavity depth such effect vanishes as expected;
3. shallower (lower depth H with same width L) and wider (larger width L with same depth H) cavities exhibit a lower level of safety (FoS) compared with the deeper and narrower ones, when the seismic intensity (PGA) increases.

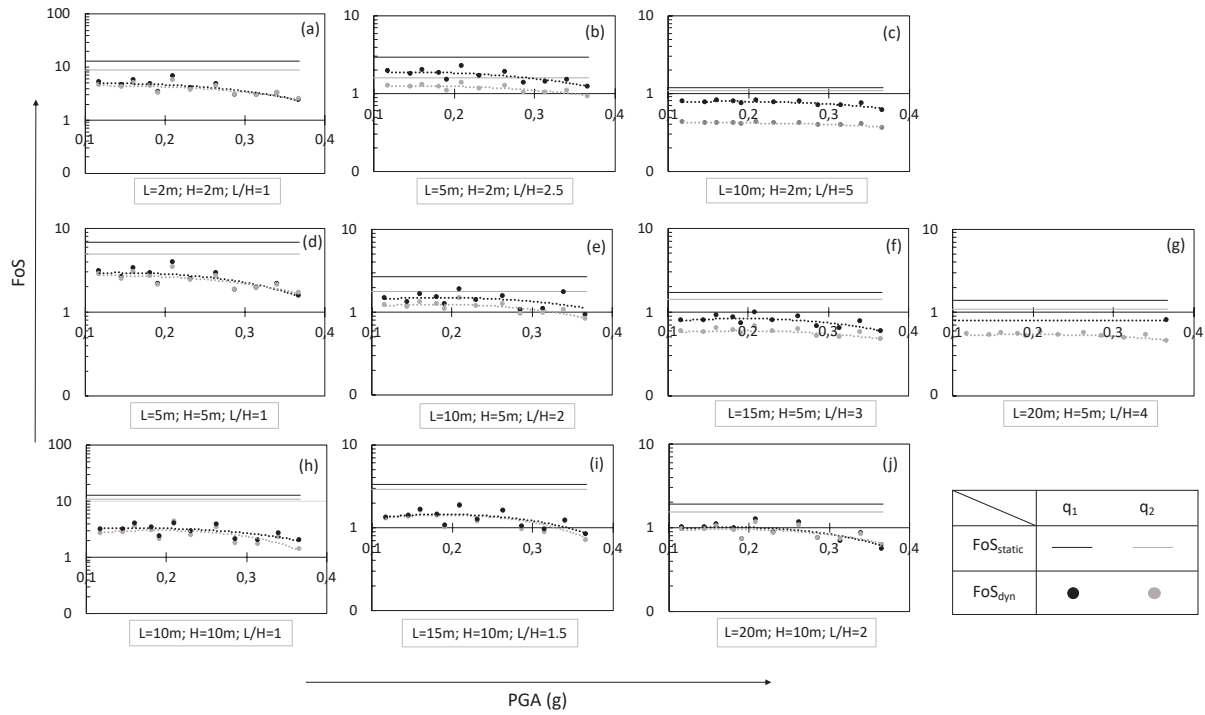

Figure 4: Seismic Stability Charts for Cavities (SSCCs) when $H=2$ m (a,b,c), $H=5$ m (d,e,f,g), $H=10$ m (h,i,j).

It is worth noting that, for the considered layouts, instability conditions (i.e. $FoS < 1$) are achieved, independently of the amplitude of the input motion, when $H=2$ m and $L/H > 5$, $H=5$ m and $L/H > 3$, while failure occurs only under the highest PGA when $H=10$ m and $L/H > 1.5$.

The proposed charts can be adopted as a preliminary level of screening to assess the seismic vulnerability of shallow underground cavities in soft rock, by comparing the so calculated FoS values with a threshold expressing the accepted damage level (i.e. the well-known limit state): “damage limit state” occurring when the FoS is lower than 3; “collapse limit state” associated to FoS lower than 1.5 [10]. In this way, a reconnaissance of possible critical zones that need a more detailed and site-specific analysis can be accomplished.

However, the basic hypotheses of the present study – that constrain the use of the proposed charts to a specific field of applicability – should be here underlined: i) the charts are valid for cavities with approximate flat roof, which are the most widespread in urban areas, hence their applications to arch roof could lead to an underestimation of FoS; ii) the charts are valid in presence of cavity excavated into a homogeneous lithotype rock, therefore they are not strictly applicable in presence of multiple lithotypes that may imply different site effects [15]. Any simplification in the use of the proposed charts outside the hypotheses under which they were obtained, can reduce their reliability.

4 CONCLUSIONS

The seismic actions represent a source of instability for underground cavities, bringing to their damage up to the global collapse. This possibility represents matter of concern leading to potential risk situations for buildings, infrastructures and population. In this scenario the present work represents an attempt to frame the problem at large scale, proposing a methodologi-

cal approach that provides stability charts to assess the seismic vulnerability of shallow underground cavities in soft rock, as preliminary level of screening.

The charts evaluate the cavity seismic stability by means of the proposed Factor of Safety ($FoS = M_{r,ULS}/M_{load}$ of the most vulnerable roof beam sections) as a function of some controlling parameters: the width of the cavity, the depth of the cavity roof, the PGA of the earthquake and the overburden stress on the top of the rock layer. By comparing the estimated FoS values with threshold values expressing the admissible damage level, possible instable cavities can be identified, that require a detailed site analysis.

The discussed results represent a preliminary outcome of a larger ongoing research project that is aimed to extend the methodological approach proposed in this paper to study a large number of cases, including different geometrical layouts and rock mechanical characteristics, in order to widen the applicability of the proposed charts.

Abstract

This paper investigates numerically the seismic liquefaction-induced "failure" mechanisms of elongated structures founded on the ground surface of a liquefiable sandy layer, which is first considered horizontal and then having a mild inclination angle of 2°. In accordance with the literature, the paper shows that if the layer is horizontal, the structure suffers from accumulation of settlement. It also shows that even such a mild inclination leads to the additional hazard of horizontal displacement and rotation of the structure due to lateral spreading of its foundation soil. The paper continues with an investigation of the beneficial effects of implementing rows of prefabricated drains or diaphragm walls at the perimeter of the foundation soil of these structures. The former mitigation method aims at reducing the developing excess pore pressures, while the latter targets at increasing the equivalent stiffness of the foundation system. The study is performed via non-linear dynamic fully coupled plane strain analyses with the finite-difference method, while the soil response is modeled with NTUA-SAND, a sophisticated bounding surface plasticity model with verified ability of simulating the response of liquefiable granular soils. It shows that diaphragm walls are much more efficient in reducing settlements, horizontal displacements and rotations than prefabricated drains. However, this efficiency is fully attained only if their depth reaches the bottom of the liquefiable layer.

1 INTRODUCTION

Since 1964 when the Alaska and Niigata earthquakes occurred, liquefaction has been treated as one of the most severe geo-hazards for civil engineering structures. Nowadays, there exists a large number of soil improvement techniques for liquefaction mitigation, which can be easily used prior to construction in many variants (e.g., densification by vibro-flotation or dynamic compaction, grouting/mixing by deep soil mixing or compaction grouting, drainage and stiffening by gravel piles). Yet, at already developed sites, the majority of these techniques cannot be applied due to the inability to perform improvement works under the structure footprint, as well as due to the possibility of severely affecting the infrastructures or neighboring structures during these works (e.g., due to vibrations from densification techniques). More importantly, there is a significant gap of knowledge for the applicability of existing mitigation techniques in cases where lateral spreading of liquefied ground is anticipated, either due to small inclination of the ground surface (angles of 0.5° to 6°), or due to free face proximity.

In this paper, a numerical investigation of the behavior of strip footings founded directly on a liquefiable soil layer is being presented, focusing initially on the differences between having a horizontal and a mildly inclined ground surface (angle of 2°). Then, the effectiveness of two different liquefaction mitigation techniques is being analyzed for horizontal and inclined ground surface conditions. Particularly, the investigation focuses on the application of rows of prefabricated drains or narrow diaphragm walls solely at the perimeter of the foundation. Such configurations may not sound ideal for mitigating the liquefaction hazard since they do not cover the footprint of the structures. However, they are the only configurations that may be readily implemented in existing structures that is our primary concern here. Moreover, there exist limited experimental evidence of the efficiency of such configurations, and this comes from dynamic centrifuge studies for drains [1] and diaphragm walls [2] only for horizontal ground conditions.

2 NUMERICAL METHODOLOGY

The numerical investigation is performed with the finite difference code FLAC [3] and its User-Defined-Model capability. Particularly, the constitutive model NTUA-SAND ([4], [5]) is used for the simulation of the liquefiable soil layer after its implementation in FLAC. It is a well-established bounding surface Critical State plasticity model, which has proven ability to simulate the cyclic behavior of non-cohesive soils (sands and silts), under any (small-medium-large) cyclic shear strain amplitude using a single (sand-specific) set of constants, irrespective of the initial stress and density conditions. It is based on a previously proposed model ([6], [7]), but in its current form it is characterized by a vanished elastic region. In addition, it incorporates three (3) open cone-type surfaces with apex at the origin of stress space: (i) the Critical State surface at which deformation develops for fixed stresses and zero volumetric strain, (ii) the Bounding surface which locates the (ever-current) peak stress ratio states and (iii) the Dilatancy surface which dictates the sign of the plastic volumetric strain rate during loading. The NTUA-SAND model has been extensively validated against centrifuge experiments related to a number of different liquefaction-related problems: lateral spreading ([8]), foundation settlement ([9]), pile response ([10]), use of drains for liquefaction mitigation ([11]). As such it is considered very reliable for the task at hand in this paper.

As shown in Figure 1, the liquefiable soil layer has a thickness $H = 10\text{m}$, while the strip footing width is $B = 5\text{m}$. In order to ensure no effects from the boundaries, the soil layer has a total width of 100m . This soil domain is discretized into 1000 rectangular zones (the “elements” in FLAC terminology). The mesh is denser in the vicinity of the footing (for an ap-

proximate width of $2.0B = 10\text{m}$), reaching a zone thickness equal to 0.5m . The footing is considered massless, rigid and rough, and is simulated by beam elements on the top of the mesh. The same mesh is also used for the analyses that considered improvements at the perimeter of the footing. Specifically, a row of elements (of 0.5m thickness) has either a permeability coefficient 1000 times larger than that of the natural soil (prefabricated drains) or was considered elastic with very increased stiffness (diaphragm walls, made of reinforced concrete). As also shown in Figure 1, this row of elements was considered at a distance of 0.5m from the edge of both sides of the footing, while the effects of the depth of the improvement H_{imp} was studied parametrically as part of this study.

Figure 1: Basic definitions and dimensions of the numerical simulation model (horizontal ground).

The liquefiable soil is (fine) Nevada sand of relative density $D_r=45\%$, dry density 1.53Mgr/m^3 , void ratio 0.718 and permeability $k=6.5 \times 10^{-5}\text{m/s}$. This is considered in the analyses via the values of the NTUA-SAND model constants, as adopted from numerous successful simulations using this sand in the literature (e.g., [3], [4], [8], [9], [10], [11]). A uniform vertical load of 100kPa is applied to the footing in all numerical analyses presented herein. The base excitation is an acceleration time history that is sinusoidal, consisting of ten (10) main cycles with period $T=0.35\text{s}$ and maximum acceleration $a_{\text{max}}=0.20g$. Two (2) additional cycles of variable acceleration have been added to the start and the end of the acceleration time-history to ensure gradual increase and decrease of the acceleration. The lateral boundaries of the model that are at the same altitude are tied to one-another to ensure that they will have the same horizontal displacements throughout the excitation, thus simulating the shaking behavior of a laminar box container, or the free field response insitu.

For the numerical simulation of footings resting on mildly inclined ground (angle $i=2^\circ$), the same grid has been used with the following adjustments:

- the gravity vector has been rotated by 2° to simulate the sloping ground (see [8] for details)
- a minor “excavation” has been modeled at the footing location, to ensure the footing rests on horizontal ground, despite the inclination of the sloping ground

In addition, for reference purposes, the inclined ground response analysis without the existence of footing (lateral spreading of soil at the free-field) is also performed and denoted as free-field (FF) herein.

3 TYPICAL STRUCTURAL RESPONSE ON LIQUEFIABLE SAND

As it was expected, the performed numerical analyses verify the severe problems caused by the existence of a liquefied sand layer of significant thickness underneath existing structures. The developed “failure” mechanism of each footing in the liquefied soil can be deduced from Figure 2, where the accumulated shear strains in the soil underneath the footing at the end of shaking are shown, both for horizontal (subplot 2a) and (mildly) inclined (subplot 2b) ground conditions.

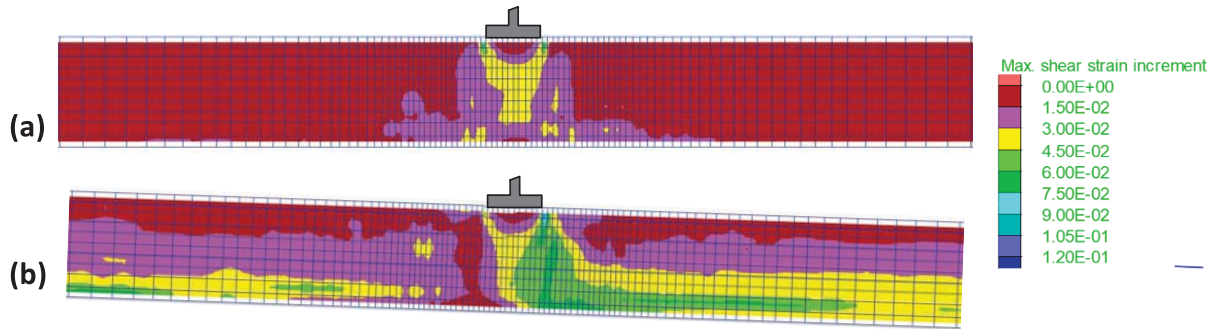

Figure 2: Accumulated shear strains underneath strip footings of width $B=5\text{m}$ (at the end of shaking) resting on liquefied ground of thickness $H=10\text{m}$ that is: (a) horizontal and (b) inclined by 2°

In horizontal ground conditions (Figure 2a) the shear strains concentrate in the area beneath the strip footing, creating a “punching” failure mechanism that reaches the bottom of the liquefied layer (at depth $2.0B$ here) without extending laterally. This “failure” mechanism is narrower and deeper than the well-known bearing capacity mechanism of footings in non-liquefied soils (generalized failure in the shape of a logarithmic spiral), which extends to distances up to $3.5B$ to $5.0B$ laterally and down to $1.5B$ in depth. When the same footing rests on a mildly inclined ground surface, the punching “failure” mechanism reaches again the bottom of the liquefied layer, but is no longer symmetrical (see Figure 2b). Particularly, the zone of intense shearing is more pronounced towards the downslope side and is connected to the shear band that appears at the base of the liquefied layer due to lateral spreading.

In order to gain further insight into the structural response, Figure 3 presents the time-histories of footing displacement (horizontal x and vertical z) and rotation (θ) during the excitation, for both horizontal and inclined ground conditions. Particularly, in Figure 3a the horizontal displacement of the footing resting on inclined ground is being presented (blue line) in comparison with the horizontal displacement of the ground surface of the corresponding free-field laterally spreading layer (dashed green line), under the same excitation. The positive sign depicts downslope displacements. The figure shows that in both cases the horizontal displacements accumulate linearly with time, or with the number of sinusoidal excitation cycles. In quantitative terms, the footing is carried away by the laterally spreading of the liquefied ground, since the footing displacement is practically identical to that of the free field displacement. Hence, despite that the footing increases the vertical stresses in the ground below its footprint, the procuring local increase of shear strength does not suffice for reducing the horizontal drift of the footing. It is believed that this response is the worst-case scenario for a footing and it is due to its relatively small width B in comparison to the thickness H of the liquefied layer, that takes a value of $B/H = 0.5$ here. In other cases where $B/H > 1$, it is expected that the footing drift would be smaller than the horizontal displacement of the ground surface of the corresponding free-field laterally spreading layer.

In addition, Figure 3b presents the accumulated settlement of the (centerline of the) footings in both horizontal (purple line) and inclined (blue line) ground conditions, under the same excitation. It is observed that the settlement of the footing on the inclined layer is of the same magnitude (actually slightly larger) with that of the same footing if the layer is horizontal. This means that the existence of a mild ground inclination does not significantly affect the settlement response. Note also that the final settlement value is in the order of 25-27cm, i.e., much smaller than the 48cm of horizontal displacement of the footing. Finally, Figure 3c presents the rotation of the rigid footing resting on the inclined layer during the excitation, with the negative value of θ depicting downslope rotation, i.e., clockwise rotation for the case of Figure 2b.

Figure 3: Time-histories of response characteristics of strip footing of width $B = 5\text{m}$ on liquefied ground with $H=10\text{m}$ that is horizontal or inclined, in terms of: (a) horizontal displacement, (b) settlement, and (c) rotation.

There is no other curve in Figure 3c for comparison purposes, since the footing in horizontal ground does not rotate (due to zero static eccentricity). Observe that the rotation also accumulates linearly with time and its final value of $\theta = 2.2^\circ$ is quite significant, i.e., slightly larger than the ground inclination of 2° . As was the case for horizontal displacements, this large value of θ is also due to the small B/H ratio that allows for easier rotations, in comparison to cases with $B/H > 1$ that are expected to rotate less under the same excitation.

Overall, Figure 3 shows that the existence of a mild ground inclination (just 2° in our case) leads to the added hazard of (significant) horizontal displacement and rotation of the structure due to the lateral spreading of the liquefied layer. Hence, such large combined rigid body translations of the structure cannot be safely accommodated by any structural system and the need for soil improvement is more pronounced than for horizontal ground conditions.

4 MITIGATION WITH PERIMETRICAL PREFABRICATED DRAINS

The first improvement technique for existing structures examined here is the application of dense rows of prefabricated drains at the perimeter of an existing footing, which for a strip footing corresponds to the area denoted with green color in Figure 1. This configuration is inspired by pertinent centrifuge tests [1] and aims at reducing the developing excess pore pressures beneath the footing. In our analyses, the drains are considered to extend to the bottom of the liquefied layer, i.e., $H_{\text{imp}}=H=10\text{m}$. For the purpose of the numerical simulation, the permeability of the elements at the improved zone has been considered to be 1000 times higher than that of the natural sand, i.e., it is considered equal to $k=6.5 \times 10^{-2}\text{m/s}$. Note that the improvement area of width 0.5m simulates the effective area of dense series of prefabricated drains (each one of which has a small diameter of a few cm), which as a system offers the foregoing drainage capability to the natural sand. Since the drains are not made of gravel, the response is only affected in terms of drainage. Hence, the constitutive model for the improvement area is still the NTUA-SAND model calibrated identically to the natural sand.

In order to study the effectiveness of this liquefaction mitigation technique, Figure 4 presents the time-histories for the footing displacements x and z and rotations θ with and without the perimetrical prefabricated drains. The results for the cases with drains are different when the liquefiable layer is horizontal (khaki line with spikes) and inclined (green line with crosses). More specifically, Figure 4a presents the comparison in terms of horizontal displacement x of the footing, where only a minor decrease is obtained (approximately 10%) with the installation of the perimetrical drains. Similar conclusions are derived in Figure 4b for the footing settlements, only that the reduction in seismic settlements is approximately 20% for both horizontal and inclined ground surface conditions.

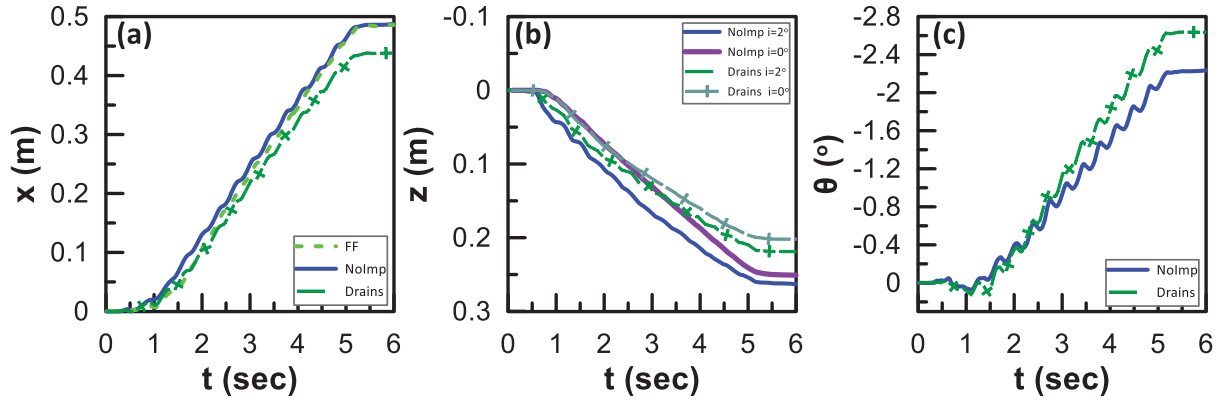

Figure 4: Effect of perimetrical drains on time-histories of response characteristics of strip footing of width $B = 5\text{m}$ on liquefiable ground with $H=10\text{m}$ that is horizontal or inclined, in terms of: (a) horizontal displacement, (b) settlement and (c) rotation.

Unfortunately, these small benefits in reduced footing displacements come at a price of increased footing rotations (in the order of 20%) in the case of laterally spreading inclined sand, as depicted in Figure 4c.

Overall, solely perimetrical drains do not seem to offer any significant benefit in the footing response, while they may even be considered unfavorable if rotations are of primary concern. Either positive or negative, the effects of such drains on the footing response are quantitatively small. This is corroborated by the images of accumulated shear strains in the foundation soil at the end of shaking, that are presented in Figure 5, for both horizontal (in subplot 5a) and inclined (in subplot 5b) ground conditions in the presence of perimetrical drains. Specifically, if one compares these images with the respective plots in Figure 2, a great resemblance is depicted. For example, observe the “punching” failure mechanism when the soil is horizontal in both cases for horizontal ground (subplots 2a and 5a). Also observe that when the soil is mildly inclined, the foregoing failure mechanism becomes asymmetrical and (roughly) connected to the shear band at the base of the liquefied layer due to lateral spreading in the downslope side of the footing, regardless of whether perimetrical drains are implemented (subplot 5b) or not (subplot 2b).

In closing, it is underlined here that this inefficient liquefaction mitigation is a result of the inability of the solely perimetrical drains to effectively reduce the excess pore pressures below the footing. If it was possible to implement drains throughout the area below the footing, the resulting liquefaction mitigation would be more efficient. However, such configuration can only be implemented before the construction of a new footing, and not below existing structures that is the aim of this investigation.

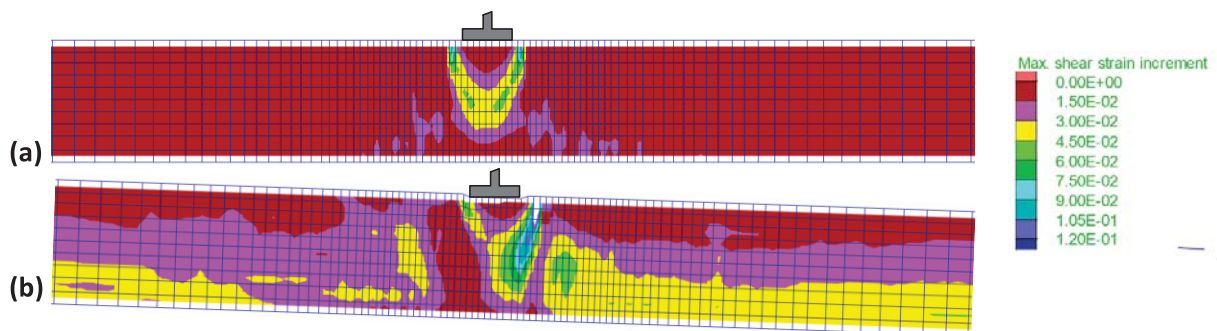

Figure 5: Accumulated shear strains underneath strip footings of width $B=5\text{m}$ with perimetrical drains (at the end of shaking) resting on liquefiable sand of thickness $H=10\text{m}$ that is: (a) horizontal and (b) inclined by 2°

5 MITIGATION WITH PERIMETRICAL DIAPHRAGM WALLS

The second technique investigated for the mitigation of liquefaction underneath an existing structure is the construction a stiff containment wall at its perimeter and within the foundation soil (see concept in Figure 1, as inspired by [2]). This wall retains the soil underneath the structure in place, while increasing the overall stiffness of the foundation system. The construction material of this wall may vary, but in the analyses presented herein it is considered to be reinforced concrete. In this respect, these containment walls are named diaphragm walls. Two different wall lengths are examined, a) full-depth wall, from the ground surface to the bottom of the liquefiable layer ($H_{imp} = H = 10\text{m}$), b) half-depth wall, from the ground surface to the mid-depth of the liquefiable layer ($H_{imp} = H/2 = 5\text{m}$). The full-depth walls are considered pinned to the base of the mesh, thus following the base excitation, while the mid-depth walls are considered floating inside the liquefiable layer. The retaining wall of 0.5m thickness is simulated with an elastic model of bulk modulus equal to 16.7GPa, shear modulus equal to 12.5GPa, mass density 2.50Mgr/m³ and are practically impermeable (in our analyses a permeability of $6.7 \times 10^{-7}\text{m/s}$ is considered, i.e., 100 times lower than that of the surrounding soil).

In order to study the effectiveness of this liquefaction mitigation technique, Figure 6 presents the time-histories for the footing displacements x and z and rotations θ with and without the perimetrical full-depth diaphragm walls. In order to distinguish the results for the cases with these walls, those pertaining to the horizontal liquefiable layer are depicted by a red line with quotations, while those that refer to the inclined layer with a purple line with squares. Interestingly, the construction of the walls seems to offer maximum improvement, since all footing response characteristics (displacements x , z and rotation θ) become essentially zero, regardless of whether the liquefiable layer is horizontal or not.

Figure 6: Effect of full-depth ($H_{imp}=10\text{m}$) perimetrical diaphragm walls on time-histories of response characteristics of strip footing of width $B = 5\text{m}$ on liquefiable ground with $H=10\text{m}$ that is horizontal or inclined, in terms of: (a) horizontal displacement, (b) settlement and (c) rotation.

This impressive performance of the full-depth diaphragm walls is corroborated by the images of accumulated shear strains in the foundation soil at the end of shaking, that are presented in Figure 7 for both horizontal (in subplot 7a) and inclined (in subplot 7b) ground conditions in the presence of such walls. Specifically, if one compares these images with the respective plots in Figure 2, a totally different response is depicted. For horizontal ground, there are no shear bands formed underneath the footing, thus explaining the zero footing settlements. On the contrary, shear bands are formed in the inclined ground. Specifically, the uphill shear band is related to the laterally spreading sand layer that drifts towards the footing area. This soil movement is hindered by the uphill rigid wall, thus leading to upward relative movement of the soil against it, which in turn creates a shear band at the interface.

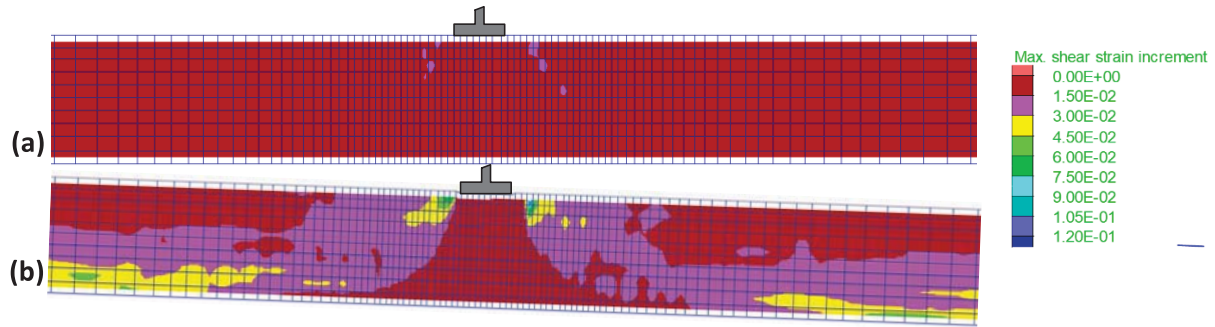

Figure 7: Accumulated shear strains underneath strip footings of width $B=5\text{m}$ with (full-depth $H_{\text{imp}}=10\text{m}$) perimetrical diaphragm walls (at the end of shaking) resting on liquefiable sand of thickness $H=10\text{m}$ that is: (a) horizontal and (b) inclined by 2°

Similarly, the downhill shear band is related to the laterally spreading sand layer that drifts away from the footing area. As this soil mass moves, there is downward relative movement of the soil versus the downhill rigid wall, thus creating the pertinent shear band at their interface. It becomes evident that these shear bands have no effect on the footing response itself since they are formed outside the walls and not underneath the footing. As such, zero displacements and rotation appear in the unaffected footing.

It has to be underlined here that the rigidity of the diaphragm walls is key for this excellent performance. In other words, if these full-depth containment walls are constructed with a less stiff material (e.g., deep soil mixing with cement, or lime), then their performance is not expected to be as excellent, i.e., some settlements or rotations of the footing may persist. Another issue of importance is how the depth of the diaphragm walls affects the footing response. This is the reason that analyses with half-depth perimetrical diaphragm walls are performed herein. Their efficiency is explored in Figure 8 that presents the time-histories for the footing displacements x and z and rotations θ with and without these half-depth walls in the format of Figure 6. Interestingly, the operation of these half-depth walls does not seem as effective as that of its full-depth counterparts. Specifically, these half-depth walls manage to reduce horizontal displacement x (in subplot 8a) by just 10%, settlements z by 20% (in subplot 8b) and downhill rotations by 75% (in subplot 8c). In other words, the half-depth walls seem significantly effective only for the reduction of footing rotations in cases that the sand layer is mildly inclined. For the footing (horizontal and vertical) displacements, these walls appear to offer improvement that is comparable to that of full-depth perimetrical drains.

In order to understand the reasons behind this significantly reduced effectiveness of half-depth diaphragm walls, images of accumulated shear strains in the foundation soil at the end of shaking are presented in Figure 9 for both horizontal (in subplot 9a) and inclined (in subplot 9b) ground conditions. Observe in subplot 9a that the soil mass in between the diaphragm walls and under the footing seems to move downwards as a rigid block (creating shear bands in the inner interfaces of the walls), thus translating the “punching” bearing capacity failure in the lower half of the liquefied layer where the diaphragm walls do not reach. Similarly, in subplot 9b, the shear band at the bottom of the laterally spreading soil layer seems little affected by the existence of the half-depth walls, thus explaining their inability to reduce the horizontal drift of the footing. In addition, the clear asymmetry of the failure mechanism under the footing that appears in the untreated case (see Figure 2b) seems less pronounced in the case of the half-depth walls of subplot 9b, an observation that may explain the smaller (yet non-zero) rotations of the footing when half-depth walls are in place.

Figure 8: Effect of half-depth ($H_{imp}=5m$) perimetrical diaphragm walls on time-histories of response characteristics of strip footing of width $B = 5m$ on liquefiable ground with $H=10m$ that is horizontal or inclined, in terms of: (a) horizontal displacement, (b) settlement and (c) rotation.

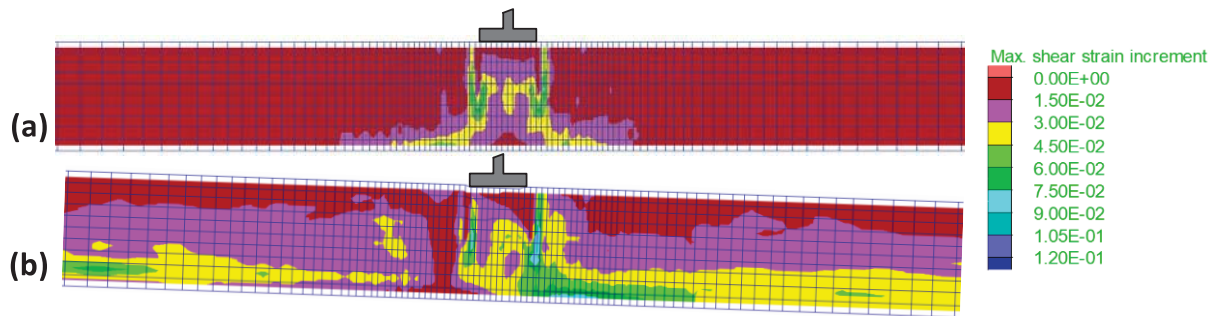

Figure 9: Accumulated shear strains underneath strip footings of width $B=5m$ with (half-depth $H_{imp}=5m$) perimetrical diaphragm walls (at the end of shaking) resting on liquefiable sand of thickness $H=10m$ that is: (a) horizontal and (b) inclined by 2° .

6 CONCLUSIONS

Fully coupled numerical analyses are performed in order to examine the response of shallow-founded structures on horizontal and/or mildly inclined liquefiable layers of relatively significant thickness. The results show that besides significant settlements, even a very mild slope (2° here) creates lateral spreading, which in turn causes the additional hazard of similarly large horizontal displacements and rigid body downhill rotations of the structure.

Then, the efficiency of two liquefaction mitigation methods that can be readily implemented in existing structures resting on the foregoing layers is examined numerically. Specifically, the use of prefabricated drains at the perimeter of the structure does not prove efficient, since it reduces by 10-20% its horizontal displacements and settlements, but may even increase slightly its rotations. On the contrary, the implementation of reinforced concrete perimetrical walls with depth until the bottom of the liquefiable layer proves exceptionally efficient, since all structural displacements and rotations become zero. The investigation also shows that this efficiency disappears if the perimetrical walls are shallower than the bottom of the liquefiable layer. For example, if these walls reach the mid-depth of the liquefiable layer, the perimetrical diaphragm walls become similarly efficient as the perimetrical drains.

Abstract

The prediction of railway track displacements is a topic of great interest in railway engineering. Different constitutive models of the materials (ballast, sub-ballast and ground) have been applied, from the linear elastic model to non-linear models based on the Equivalent Linear approach. In the technical literature, it is shown how non-linear models enhance the prediction of the displacements of the railway track, especially when the train's running speed approaches the critical speed. In this paper and for the first time to the authors' knowledge, the Hardening Soil Small Strain model is applied and experimentally validated to the study of track displacements near critical speed. Specifically, the well-known case at Ledsgaard (Sweden) has been used for its evaluation, showing numerical results very similar to those measured experimentally. Moreover, the critical speed is calculated, showing values significantly lower than those calculated with the linear elastic model. This is relevant for practical geotechnical engineers, even assuming a certain complexity of the model, because its use is increasingly widespread in commercial finite element codes.

1 INTRODUCTION

The study and conceptualization of the phenomenon of critical speed in railway lines have been developed since the 1990s, after the problems arising from the increase in the speed of train operation following the rehabilitation of the railway line in Ledsgard [1-4]. This increase in speed led to a considerable increase in the track displacements.

From a theoretical point of view, the critical speed is the speed of a non-oscillating moving load that implies the greatest amplification of the dynamic response. It is the properties of wave propagation in the embankment-ground system and the bending wave propagation in the track that completely determine this phenomenon [5-8]. This is associated with a considerable increase in ground deformations, which may even be permanent [9-10], which can be of great importance in high-speed lines [11-12] and be critical in soft soils.

When a train travels at lower speeds and speeds far from those of Rayleigh wave propagation on the ground, the level of strains induced in it is low and may be in the range of small deformations. It is known that here the behavior of the ground is elastic and linear, where G does not undergo any significant degradation. In this sense, when the train runs on stiff soils, the geotechnical safety associated with the behavior of the ground is practically guaranteed and the calculation of the track displacements can be carried out with a simple and numerically highly efficient model such as the linear elastic model. However, when the speed of the train approaches the speed of propagation of Rayleigh waves in the ground, the deformations in the ground increase considerably causing a degradation of the stiffness of the ground that becomes totally relevant and that has an important influence both on the magnitude of the track displacements and on the value of the critical speed. In these cases, the accuracy and suitability of the linear elastic model is lower and non-linear cyclic models with degradations of the value of G are required to satisfy the strain conditions of the ground. In this respect, [13] has shown how the use of an Equivalent Linear approach (ELA) has led to reductions of between 10-20% in the value of the critical speed with respect to that obtained with the linear elastic model. Similar values have been found in the studies presented by [2,14].

The constitutive soil model known as the Hardening Soil Small Strain model (HSsmall) [15] is an advanced ground behavior model which takes into consideration the full degradation curve of G , from the very small strains to the large strains associated with the failure of the soil. It forms part of the package of constitutive software models for commercial use such as Plaxis or Zsoil. Although it is a complex model, it is within the reach of all geotechnical engineers, making it a good tool of analysis for this type of cases. However, to the knowledge of the authors, it has never been experimentally validated in cases of critical speed in railway lines. For this reason and for the advance that this might lead to in the practice of geotechnical railway engineering, this study is presented with the aim of verifying whether the HSsmall model is a reliable tool for the prediction of displacements undergone by the track near critical speed and for the prediction of the critical speed. To do this, a numerical simulation of the famous Ledsgard case[1-4] has been performed, comparing the numerical results (with the HSsmall and Elastic Linear model) with those measured in reality.

2 CASE STUDY OF LEDSGARD

2.1 Generalities

The Ledsgard site is located 25 km to the south of Gothenburg. In the 1990s, excessive vibrations were detected all along the track and this led to an intense investigation on the geotechnical properties of this site [2]. Both the properties of the ground and those of the track have been shown in the many studies made of this case [1-4,16] and the reader is advised to

consult them. In this study, the data proposed by [2] have been used. These are summarized below, thus avoiding a reiterative description of the data found in the technical literature.

2.2 Soil and track properties

The geotechnical profile and a detail of the ballasted track is shown in fig. 1.

Figure 1: Soil (left) and ballasted track geometry (right)

The elastic properties of the ground are shown in Table 1, taken from the data provided by [2].

Layer	Thickness (m)	Specific weight (kN/m ³)	G ₀ (kN/m ²)	Poisson's ratio
Embankment	1.2	18.00	79.51·10 ³	0.19
Dry crust	1.1	15.00	5.95·10 ³	0.49
Organic Clay	3.5	12.60	2.17·10 ³	0.49
Clay 1	4.5	14.75	5.31·10 ³	0.49
Clay 2	6	14.75	11.18·10 ³	0.49
Clay 3	14.9	14.75	14.75·10 ³	0.49

Table 1: Soil elastic properties

As regards the degradation curves of G and the damping considered in the HSsmall model, these have the following equations [17] and are shown in fig.2:

$$G_s/G_0 = \frac{1}{1 + \frac{0.385 \cdot \gamma}{\gamma_{0.7}}} \quad (1)$$

$$\xi = \frac{E_D}{4\pi E_s} \quad (2)$$

$$E_D = \frac{4 \cdot G_0 \cdot \gamma_{0.7}}{0.385} \left(2 \cdot \gamma - \frac{\gamma}{1 + \gamma_{0.7}/0.385 \cdot \gamma} - \frac{2 \cdot \gamma_{0.7}}{0.385} \cdot \ln \left(1 + \frac{0.385 \cdot \gamma}{\gamma_{0.7}} \right) \right) \quad (3)$$

$$E_s = \frac{G_0 \cdot \gamma^2}{2 + 2 \cdot 0.385 \cdot \gamma / \gamma_{0.7}} \quad (4)$$

where $\gamma_{0.7}$ is the shear strain for $G_s/G_0 = 0.722$

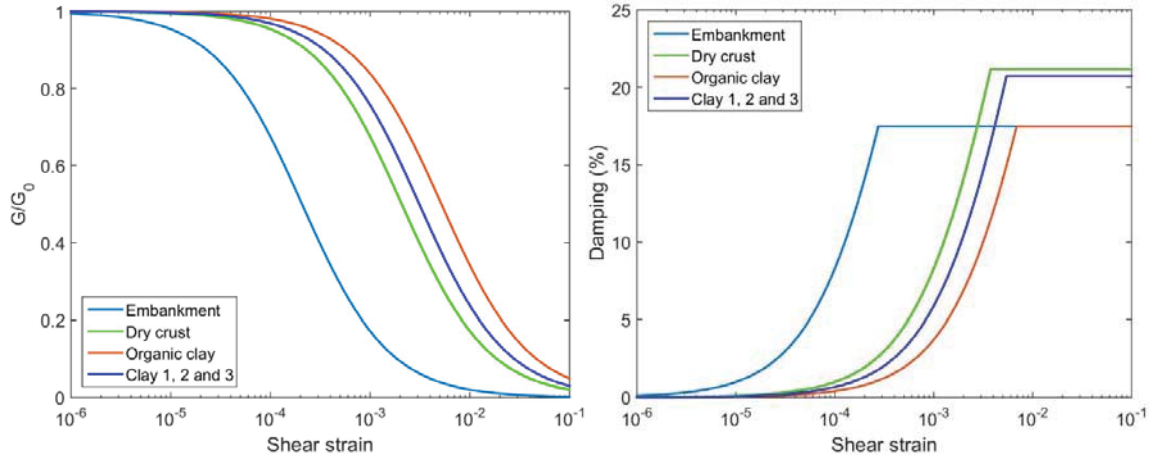

Figure 2: Shear modulus reduction (left) and damping ratio (right) (adapted [2])

Given that numerical simulations have also been made considering a linear elastic behavior of the ground, a Rayleigh damping has been considered. As regards the characteristics of the railway track, this corresponds to a ballasted track, with a rail type UIC60 which is seated on railpads of a stiffness of 250 kN/mm. The sleepers have a length of 2.6 m, a height of 0.2 m and are separated by 0.67m. Their elastic properties are mass density 2,500 kg/m³, Young's modulus 3x10⁷ kN/m² and Poisson's ratio 0.2. The ballast is included in the embankment shown in fig. 1, this being made up both of ballast and of gravels and sands [2]. The measurement of the track response during train passage was made with the X2000 train at different speeds. The geometry and axle load of this train are shown in fig. 3. The tests were performed in both directions, i.e. Northbound and Southbound but in this study only the Southbound direction is considered.

Figure 3: Geometry and axle load of X2000 train

3 EXPERIMENTAL VALIDATION

3.1 Numerical model

To validate the HSsmall model experimentally, a dynamic 3D model formulated in the time domain has been developed in Plaxis software [15]. The geometry of the numerical model is shown in detail in fig. 4 and as can be seen it corresponds to a symmetric case, so that only half of it has been modeled. The dimensions of the model are 70x40x30 m in the longitudinal, horizontal and vertical directions respectively, which are values considered and experimentally validated in 3D models of finite elements formulated in the time domain similar to those used here [16,18-21]. The railpad is modeled as a linear spring, whereas the rail has been simulated as a beam, with the normalized properties of the UIC-60 type. The rest of the track components (sleeper, ballast and subballast) and ground were modeled using 3D solid elements.

Figure 4: Numerical model: 3D view mode (left) and track detail (right)

The numerical model is made up of 370,181 elements and 523,961 nodes. Quadratic tetrahedral elements (10 node elements) are used for solid elements. The boundary conditions correspond to viscous dampers [15] in all boundaries except the plane of symmetry, where horizontal movements are impeded, and the ground surface, which is a free boundary.

As for the numerical modeling of the moving load, this has been applied using the equivalent nodal force method, in keeping with that described in [22] and the time step has been considered according to the criteria of Courant-Friedrichs-Lewy [16,22], with an implicit Newmark integration scheme, as shown below:

$$C_n = \frac{\Delta t \times C}{L_{min}} < 1 \quad (5)$$

where C_n is the Courant number, Δt is the time step, C is the moving load speed and L_{min} is the distance between two adjacent loading nodes.

3.2 Experimental validation

Fig. 5 shows the experimental validation for four different train speeds: 70, 140, 180 and 204 km/h. As can be seen, the results obtained with the Linear Elastic model show relevant differences from those actually measured for the four speeds, these differences becoming

more evident the higher the speed of the train. The Linear Elastic model tends to underestimate the dynamic response, and in quantitative terms it predicts only half of the actual displacement of the sleeper. These differences are important.

As for the results obtained by the HSsmall model, these are quite close to those actually measured for the four speeds studied. It is worth noting that the adjustment is quite acceptable and that it is more precise when the train speed is higher. In fact, for speeds of 180 and 204 km/h the accuracy of the model is quite good while for the lower speeds (70 and 140 km/h), the results are also very close but with slightly greater differences than for the high speeds.

In this case, the critical speed is approximately 200 km/h. Around these speeds, the results of the HSsmall model are highly accurate, showing that the constitutive model is correctly reproducing the behavior of the different ground layers.

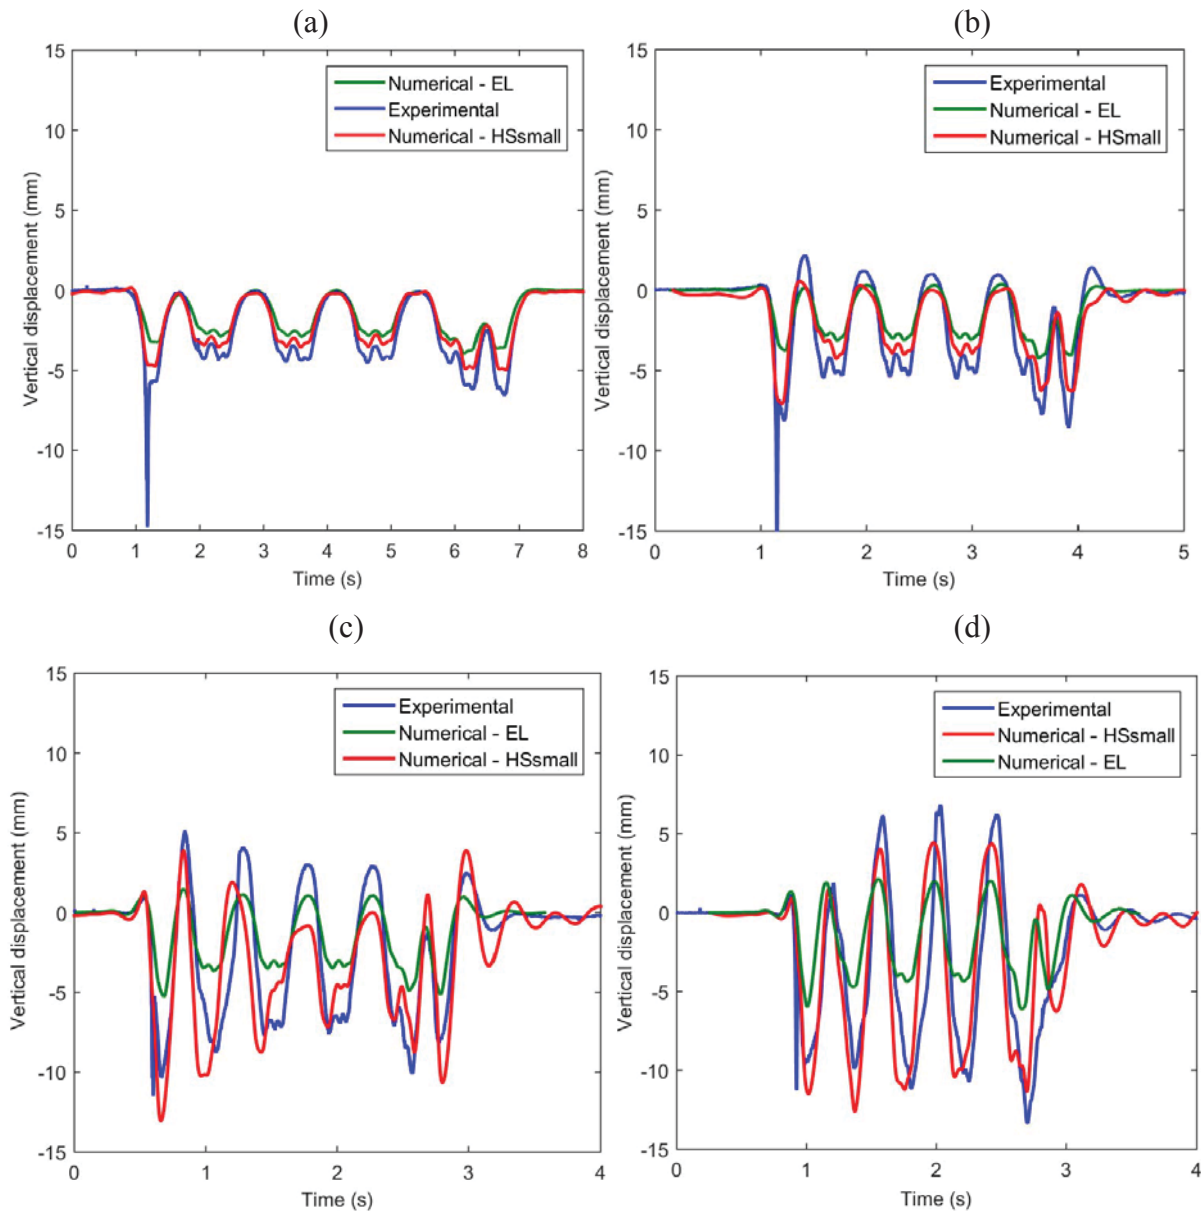

Figure 5: Measured and computed time histories of sleeper displacements for different train speeds (Southbound direction): (a) $V=70$ km/h; (b) $V=140$ km/h; (c) $V=180$ km/h and (d) $V=204$ km/h

Comparing the results between the HSsmall and LE models at low speeds, it can be observed that there is also an appreciable degradation of the stiffness of the ground layers, which the HSsmall model is also correctly simulating but which is obviously not being simulated correctly with the Linear Elastic model. This fact shows that the degradation of the stiffness of the ground is not only substantial near the critical speed, but that for speeds considerably lower than the critical speed there is also a significant degradation of the stiffness. It is likely that at low speeds the degradation of stiffness is more important in the structural layers of the track: ballast and subballast, while at speeds close to the critical speed, the degradation of the stiffness of the underlying ground plays a more important role than at low speeds.

3.3 Critical speed for a single moving point load

It has been considered of interest, once the HSsmall model has been experimentally validated, to calculate the critical speed of the Ledsgard case for a single moving point load. For this, the same numerical model has been considered, but with only one moving load. Two scenarios have been considered: Linear Elastic model and HSsmall model. The displacements of the sleeper and the Dynamic Amplification Factor (DAF) as a function of the speed of the load are shown in figure 6, where it can be seen how the HSsmall model gives a critical speed value of 47 m/s, while for the Linear Elastic model it is 53 m/s. Therefore, the use of the HSsmall model results in a critical speed which is 12% lower than that of the Linear Elastic model. These differences are relevant and demonstrate the suitability of the HSsmall model for predicting the critical speed of the train.

Regarding the displacements and the DAF, the HSsmall model yields higher values than the Linear Elastic model, so for the prediction of the track movements, the HSsmall model is more suitable, both for low speeds and those close to the critical speed, as shown above.

Figure 6: Sleeper displacements vs velocity (left); DAF in sleeper vs velocity (right)

4 CONCLUSIONS

This research has studied the applicability of the HSsmall constitutive model to the prediction of the movements of the track in railway lines. Numerical values have been obtained which are very close to those actually measured in the Ledsgard case, both for speeds close to the critical speed and for low speeds. In this respect, the HSsmall model has proven to be a reliable tool for the prediction of the movements of the track with a very acceptable level of accuracy. Moreover, it has been shown how the critical speed is 12% lower when analyzed

with the HSsmall model with respect to that obtained by the Linear Elastic model. Hence, the use of the HSsmall model may be of greater use when in-depth studies are made of the critical speed.

Abstract

The conservation of ancient masonry structures requires knowledge of their structural behavior. At the same time, the possibility to perform standard mechanical tests on heritage structures is limited by the need for the preservation of the cultural heritage.

This paper presents the results of a deep experimental program aimed at the mechanical characterization of masonry panels reproducing the ancient technique opus incertum found at the Pompeii archaeological site. They were built based on the traditional technique by using original rock units and a typical mortar mixture. The experimental program firstly involved sonic pulse velocity tests and diagonal compression tests on three masonry panels, 1.20m x 1.20m x 0.45m. Then, axial compression tests on five masonry specimens extracted from the three panels were carried out.

In the following, the main results of the experimental program are presented and discussed and relevant correlations among the results of non-destructive tests and destructive tests are defined to provide a useful tool for a preliminary assessment of the structural behavior of similar ancient masonries.

Pompeii archaeological site; Masonry Panels, Rubble Stone Masonry, Non-destructive tests, Axial Compression Test, Mechanical Properties

1 INTRODUCTION

The conservation of heritage masonry structures set specific issues from a structural point of view concerning the achievement of adequate knowledge of the mechanical parameters of the structural elements and their components [1,2]. Despite different methodologies are available for the investigation of the mechanical properties of existing building materials and masonry assemblages, several limitations may occur in heritage contexts. Indeed, the execution of destructive and minor-destructive tests, DTs and MDTs (e.g. diagonal compression tests, axial compression tests, single or double flat-jack tests), which is required for a direct estimation of fundamental mechanical parameters, is strongly restricted in such a context. This is related to the need for conservation of the heritage structures and technical challenges related to the extraction of undamaged and adequate size test specimens. On the other hand, non-destructive tests, NDTs (e.g. sonic tests, tomography, radar, thermography), can provide only a qualitative evaluation of structures (i.e. homogeneity and consistency of the specimens, presence of voids or material alterations) or indirect estimation of the mechanical parameters based on empirical correlations with DTs results. Moreover, their results are strongly affected by the structural state of conservation and by test conditions. For these reasons, the implementation of appropriate databases containing the results of different types of tests related to specific material and structural typologies can be very useful tools for the definition, by analogy, of the mechanical properties of similar elements.

A possible approach for the structural knowledge of heritage masonry structures is the realization and testing of new masonry panels representing the old typologies. This would allow performing a comprehensive experimental program involving the execution of DTs to obtain essential information on the structural behavior of traditional masonry typologies. Moreover, the execution of NDTs on reproduced panels would allow a comparison with the results obtained on the ancient structures. Stone masonries with irregular arrangements are typical of historical and archaeological contexts. Several studies involving the characterization through DTs of irregular stone masonry panels reproducing old typologies (particularly diagonal compression tests and axial compression tests) are available in the technical literature [3–5]. Few other studies focused on the definition of proper relationships between the results of DTs and NDTs obtained on the same masonry specimens, particularly focusing on the use of sonic pulse velocity tests (STs) [6–9]. Indeed, ST is considered an effective method for a qualitative structural assessment of existing masonry structures, and few applications of STs on the archaeological structures at the Pompeii site are also available [10,11]. However, the available set of data is still limited and robust empirical correlations are still lacking.

This paper presents a wide experimental program aimed at the characterization of rubble stone masonry panels reproducing one of the most common masonry typologies at the archaeological Pompeii site (Italy), the ancient building technique *opus incertum*. The masonry panels were produced based on a deep survey of the ancient technique and using original rock units and new mortar compliant with the ancient one. This latter was produced with precious volcanic sand coming from the same volcanic region where the ancient builders collected their *pulvis puteolanus*, i.e. the Phlegrean area, next to the Bay of Naples. The characterization involved extensive sonic pulse velocity tests, three diagonal compression tests carried out in an open space laboratory equipped at the Pompeii site, and five axial compression tests conducted in the laboratory of the University of Naples.

In the following, the experimental program is presented along with the results provided by tests. Moreover, a discussion and comparison of the results obtained from the different NDTs and DTs performed and a comparison with available data from literature is presented.

2 EXPERIMENTAL PROGRAMME

Given the impossibility of performing DTs or MDTs on archaeological structures, this experimental program involved the realization and characterization through NDTs and DTs of Pompeii-like rubble stone masonry panels compliant with the ancient building technique *opus*

incertum. The panels were built by using original stone units collected within the archaeological excavations started at *Regio V* in 2018 and mortar compatible with the ancient one, i.e. made with lime putty and pozzolan with a binder to aggregate ratio 1:3 by volume. The pozzolan used in the mortar was precious volcanic sand coming from the same volcanic region where the ancient builders collected their *pulvis puteolanus*, i.e. the Phlegrean area, next to the Bay of Naples. The masonry panels were constructed by experienced masons inside a specifically dedicated test area at *Regio V* (Figure 1). Indeed, a first part of the experimental program was carried out in the on-site test area, involving: i) realization and storage of the panels; ii) execution of NDTs, i.e. sonic pulse velocity tests (STs) at different ages; iii) execution of DTs, i.e. diagonal compression tests. After that, the final phase of the experimental program was carried out in the laboratory of the University of Naples, involving the execution of axial compression tests on masonry specimens extracted from the undamaged portions of the panels after the diagonal compression tests. In the following, details of the experimental program are reported.

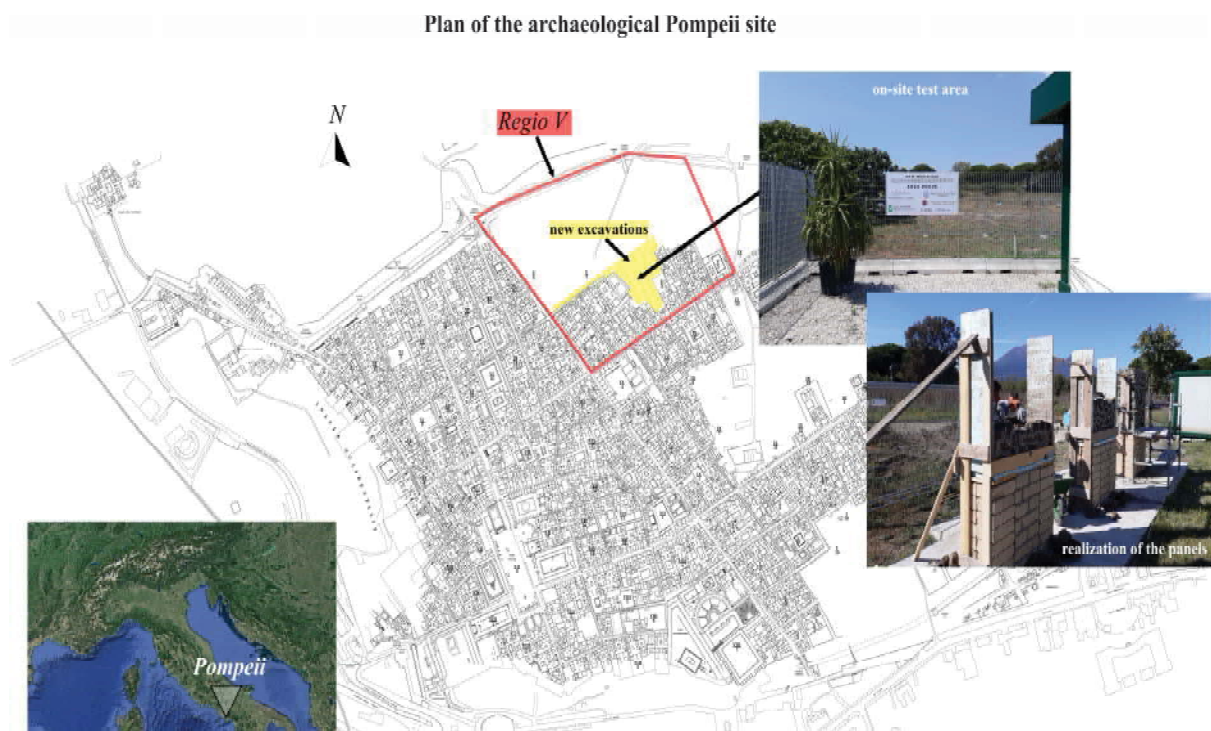

Figure 1: Plan of the archaeological Pompeii site with the indication of the localization of the city of Pompeii in Italy; the borders of the *Regio V*; the area of the new excavations at the *Regio V*; the localization and pictures of the on-site test area.

2.1 Pompeii-like masonry panels

For the production of the panels, detailed geometric and material surveys of archaeological *opus incertum* masonry structures were firstly carried out (Figure 2 (a)), then stone units belonging to collapsed masonry structures found throughout the excavations at *Regio V* were collected (Figure 2 (b)). According to this preliminary study, the panels were realized with two external leaves made of about 30% of mortar and 70% of irregularly shaped units of lava, travertine, and foam lava, with few fragments of other materials. The internal core was made of abundant mortar and stone fragments and smaller units (Figure 2 (c)). The wall thickness was defined as equal to 0.45m, based on the values detected on similar walls, and no transversal connecting elements between the external leaves were inserted. The panels had a size of 1.20m x 1.20m x 0.45m, according to the standard ASTM E 519-02 regarding the execution of diagonal compression tests on masonry wall panels [12]. They were progressively identified as S1, S2, and S3 (Figure 6Figure 2 d) [13]. Mechanical characterization of the stone units and mortar constituting the panels was also performed [14,15]. The tests performed

on the stone units resulted in mean bulk density and compressive strength equal to 2358 kg/m³ and 38 MPa, 1380 kg/m³ and 6 MPa, 859 kg/m³ and 4 MPa, for the lava, travertine and foam lava, respectively. The tests performed on the mortar specimens resulted in mean bulk density and compressive strength equal to 1105 kg/m³ and 3 MPa, at two months of curing.

Figure 2: Pompeii-like masonry panels: view of archaeological *opus incertum* masonry structure (a); typologies of the stone units used to make the panels (b); cross-section of a panel during the construction phase (c) and view of the completed panels (from the right S1, S2, and S3) (d).

2.2 Non-destructive testing

An extensive program of STs was carried out on the new masonry panels to provide useful data for comparison with archaeological *opus incertum* at the site, to monitor the hardening process in the panels, and to assess the presence of any correlation with results of DTs. The tests were performed by transparency, employing a piezoelectric hammer transducer and a piezoelectric broadband receiver, with 55 KHz resonance frequency and internal pre-amplification of 20 dB, and a coupling material between the receiver and the masonry surface. The tests were carried out at 12, 44 and 148 days from the realization of the panels; a modular mesh, 0.10m spaced, with 121 acquisition points was investigated on each panel (Figure 3). For each point, the velocity was calculated from the conventional path length, equal to the thickness of the panel, divided by the mean of three recorded values of travel time. Thus, the mean velocity for each panel at each age was calculated as the mean of the points.

Figure 3: Modular mesh 1.00m x 1.00m, 0.10m spaced, on the masonry panels S1.

2.3 Destructive testing

After the Sts, the experimental program involving DTs started with the in-situ diagonal compression tests (these were carried out after 5 days from the last STs, i.e. 153 days from the production of the panels), to obtain essential information on the shear behavior of the *opus incertum* masonry and to correlate these results with those provided by DTs. The tests were performed with a specific custom-designed set-up for the outdoor tests. According to the standard ASTM E 519-02 [12], the shear stress, τ , the shear strain, γ , and the shear modulus of elasticity, G , were derived from the tests. In this formulation, a uniform shear stress state is assumed and the tensile strength is equal to the shear capacity, τ_{\max} . The tests were carried out with single loading ramps under displacement control with a rate of 0.02mm/s. Devices for the measurement of the in-plane displacements were applied on the two leaves of each panel [13].

Once diagonal tests were completed, five masonry specimens were extracted from the undamaged portion of the panels for the execution of axial compression tests in the laboratory. The masonry specimens were identified as C1, C2, C3, C4 and C5. The first test, performed on C1, was carried out with a single loading ramp to determine the specimen capacity, the following ones involved cyclic testing protocols set between 10% and 50% of the maximum load attained in the first test. This to investigate the elastic behavior of the specimen, according to what is suggested in the standard EN 1052-1 [16]. Note that two cycles were performed with C2, then three cycles were performed with C3, C4 and C5. For each test, the axial compressive strength, f_c , was evaluated as the maximum compressive stress achieved by the panel, σ_{\max} , i.e. the maximum compression load recorded divided by the area of the loaded cross-section. The elastic modulus, E , was evaluated by making a linear least-squares fit the loading ramp of the cycle in the stress-strain curves and calculating the mean of the slopes of the three obtained lines, as shown in Figure 4.

Figure 4: Scheme of determination of the mean elastic modulus of the three loading/unloading cycles of each test.

Considering the anisotropy of masonry specimens, two different Poisson ratios were also calculated for each specimen: in the horizontal, v_h (1), and transversal, v_t (2), direction.

$$v_h = \frac{\varepsilon_h \left(\frac{l}{3} \right)}{\varepsilon_v \left(\frac{l}{3} \right)} \quad (1)$$

$$v_t = \frac{\varepsilon_t \left(\frac{l}{3} \right)}{\varepsilon_v \left(\frac{l}{3} \right)} \quad (2)$$

where $\varepsilon_v (1/3)$, $\varepsilon_h (1/3)$ and $\varepsilon_t (1/3)$ are the vertical, horizontal and transversal strain corresponding to one-third of the maximum compressive stress, being each of them calculated as the mean of the values recorded on loading ramps of the loading/unloading cycles.

3 EXPERIMENTAL RESULTS

3.1 Sonic pulse velocity tests

Figure 5 summarizes the results of the STs for each panel at 12, 44 and 148 days in terms of probability density distributions of the velocities and mean velocities with their coefficients of variation, CoV. The velocities detected on the panels increased with time, consistently with the evolution of the hardening process in the mortar. The mean velocity at 144 days resulted equal to 2428m/s, 2923m/s and 2767m/s, for S1, S2 and S3 respectively.

Specimen	$V_{t=12}$ [m/s]	$V_{t=44}$ [m/s]	$V_{t=148}$ [m/s]
S1	1673 (CoV = 19%)	2297 (CoV = 20%)	2428 (CoV = 25%)
S2	1919 (CoV = 23%)	2163 (CoV = 19%)	2923 (CoV = 23%)
S3	2070 (CoV = 23%)	2381 (CoV = 16%)	2918 (CoV = 23%)
mean	1890 (CoV = 11%)	2280 (CoV = 5%)	2767 (CoV = 11%)

Figure 5: Probability density distributions of the velocities recorded at 12, 44 and 148 days for each panel and summary of the mean velocities with their coefficients of variation.

3.2 Diagonal compression tests

Table 1 reports the main outcomes of the diagonal compression tests, in terms of maximum shear stress attained, τ_{max} , shear strain corresponding to the maximum shear stress, γ_{tmax} , shear strain corresponding to the conventional failure assumed as strength degradation of 20% of the peak force, γ_u , and the shear modulus of elasticity, G . This latter was not derived for S3 due to inaccurate local recordings. Different values of the shear capacities were detected, with the maximum stress attained by S2 (i.e. 0.27 MPa) and the minimum one attained by S1 (i.e. 0.19 MPa). The values of the shear strain corresponding to the maximum shear stress and of the shear modulus of elasticity were similar among the panels, while a certain variability was again detected in terms of shear strain at the conventional failure. The variability detected in the outcomes was probably related to the different specific arrangements and quantities of the single building materials in each panel.

Table 1: Main outcomes of the on-site diagonal compression tests.

Specimen	τ_{\max} [MPa]	$\gamma_{\tau\max}$ [%]	γ_u [%]	G [MPa]
S1	0.19	0.16	0.90	522
S2	0.27	0.17	2.13	520
S3	0.25	0.16	1.24	-
mean	0.23 (CoV=16%)	0.16 (CoV=3%)	1.42 (CoV=44%)	521

The failure mode was consistent among the panels. It resulted in the development of the main crack along the compressed diagonal dividing each panel into two almost symmetric parts. The crack pattern mainly developed in the mortar, but occasionally involved rock units, particularly travertine and foam lava. Indeed, this latter had a lower compressive strength compared to the lava. Figure 6 shows each panel at the end of the diagonal compression test with the indication of the final crack pattern and the masonry specimens extracted from the undamaged portions for the execution of the axial compression tests.

Figure 6: Crack pattern of the masonry panels S1 (a), S2 (b) and S3 (c) with the indication (red boxes) of the masonry specimens extracted for the execution of the axial compression tests.

3.3 Axial compression tests

Table 2 reports the main outcomes of the axial compression tests, in terms of maximum compressive stress attained, σ_{\max} , vertical, horizontal and transversal strain corresponding to the maximum compressive stress, $\varepsilon_{\sigma\max}$, $\varepsilon_{h\sigma\max}$ and $\varepsilon_{t\sigma\max}$, vertical strain corresponding to the conventional failure assumed as a strength degradation of 20% of the peak force, ε_u , modulus of elasticity, E, Poisson ratios in the horizontal, ν_h , and transversal, ν_t , directions. Note missing values of ε_u are related to the fact that the conventional failure was not achieved and missing values of ν_h and ν_t are related to inaccurate local recordings. The outcomes of the axial compression tests are also summarized in Figure 7, which plots the compressive stress-vertical strain relationships for C1, C2, C3, C4 and C5. Specimen C4 showed the highest values of compressive stress and corresponding vertical strain, while C3 showed the lowest ones. C3 also showed the lowest elastic modulus, while the highest value was showed by C2. The highest variability of the results was detected for the Poisson ratios. However, the overall dispersion of these results has been considered acceptable considering the proper inhomogeneity of the masonry typology and consistent with what was found from the sonic tests and diagonal compression tests.

Table 2: Main outcomes of the axial compression tests.

Specimen	σ_{\max} [MPa]	$\varepsilon_{\sigma\max}$ [%]	ε_u [%]	E [MPa]	ν_h [-]	ν_t [-]
C1	1.52	0.59	-	-	0.08	-
C2	1.49	0.52	-	1253	0.24	0.03
C3	0.96	0.40	-	843	-	-
C4	1.95	1.17	2.77	1053	0.07	0.08
C5	1.46	0.89	2.37	862	-	-
mean	1.48	0.71	2.57	1003	0.13	0.05
	(CoV=24%)	(CoV=44%)	(CoV=11%)	(CoV=19%)	(CoV=75%)	(CoV=66%)

Figure 7. Compressive stress-vertical strain curves.

Figure 8 shows the specimens at failure. For all the specimens, the first cracks were vertical and thin and involved the mortar matrix, finally, the expulsion of material outward occurred and several stone units were also damaged. The units involved in the cracks were travertine and foam lava, consistently with what was found in the diagonal compression tests. In many cases, the first cracks developed in the central part of the cross-section of the specimens. However, clear detachments of the external leaves from the internal core were not detected on the final crack pattern but cracks distributed over the entire cross-section of the wall. Indeed, due to the irregular arrangement of the masonry assemblage along with its thickness, the separation between the core and the leaves was not sharply defined.

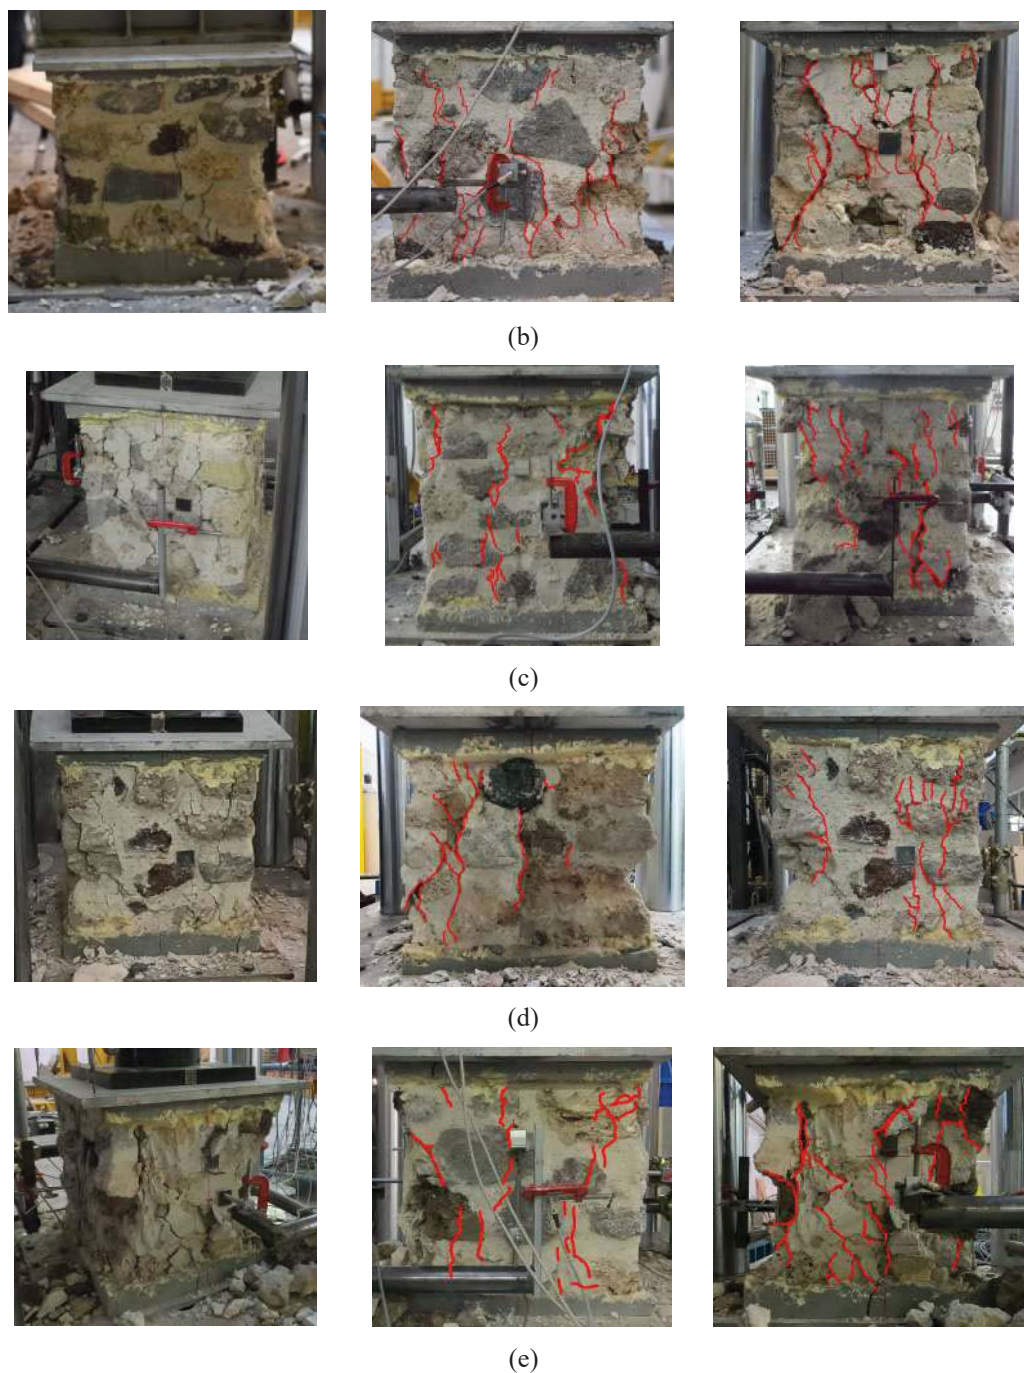

Figure 8. Specimens crack pattern on two orthogonal sides of the panel C1 (a), C2 (b), C3 (c), C4 (d) and C5 (e).

4 DISCUSSION OF THE RESULTS AND COMPARISONS

Table 3 summarizes the main results of the mechanical characterization through NDTs and DTs of the Pompeii-like masonry panels.

Table 3. Main experimental outcomes of sonic pulse velocity tests, diagonal compression tests and axial compression tests.

	V	τ_{\max}	G		σ_{\max}	E	v_h	v_t
3 masonry panels 1.20m x 1.20m x 0.45m	[m/s]	[MPa]	[MPa]	5 masonry specimens 0.45m x 0.45m x 0.45m (average sizes)	[MPa]	[MPa]	[-]	[-]
	2767	0.23	521		1.48	1003	0.13	0.05
	11%	16%	-		24%	19%	75%	-

The final mean velocity achieved by the panels ($V=2767\text{m/s}$, $\text{CoV}=11\%$) can be associated with good-quality stone masonry, according to a common classification found in the literature [17] (Table 4). This result is consistent with what was found in similar experimentations on stone masonry panels reproducing historical typologies, with good compactness [18,19]. Instead, lower values of velocity were found for historical or archaeological masonry structures [6,10,11] or reproduced panels incorporating flaws or inclusions [20]. Indeed, the sonic pulse velocity is greatly affected by differences in the building materials and inner and superficial conditions of the structure.

Table 4. Relations between the masonry overall conditions and the mean sonic pulse velocity value.

	Poor-quality masonry	Medium-quality masonry	Good-quality masonry
Range of velocities [17]	< 1500m/s	1500m/s - 2500m/s	2500m/s <

Table 5 reports a literature review of the main results obtained from diagonal compression tests and axial compression tests on stone masonry panels reproducing traditional typologies. Despite the general scatter, the obtained results are comparable with the available data from the literature. In particular, the obtained shear strength is comparable with the experiments by Milosevic et al., Gattesco et al. and Magenes et al., and lower value of the shear modulus compared to Gattesco et al. and Magenes et al. was probably related to a lower amount of mortar and more regular textures in the specimens investigated in these latter [3–5]. Moreover, as regards the compressive strength and modulus of elasticity lower values found in this study compared to available literature data were probably related to relatively low capacity, deterioration and pre-existing damage of several of the archaeological stone units used in this work.

Table 5. Literature review of experimental outcomes of diagonal compression tests and axial compression tests on reproduced stone masonry panels.

<i>*results were adapted to the ASTM formulation for the comparison with the results of the present study</i>							

Despite the number of data collected in this investigation is not enough to define reliable correlations, a preliminary correlation between STs and DTs results can be formulated using the obtained experimental results. Indeed, the results of the last STs were in good agreement with the results of the diagonal compression tests, with the maximum shear stress achieved being higher for

the panels which showed the higher mean sonic velocity (i.e. $V=2923\text{m/s}$ and $\tau_{\max}=0.27$ for S2, $V=2918\text{m/s}$ and $\tau_{\max}=0.25$ for S3, and $V=2428\text{m/s}$ and $\tau_{\max}=0.19$ for S1) (Figure 9).

Figure 9: Values of the mean sonic pulse velocity at 148 days and maximum shear stress achieved by the masonry panels 1.20m x 1.20m x 0.45m with diagonal compression tests.

On the contrary, the results obtained from STs in terms of modulus of elasticity of the masonry did not comply with the one obtained from the DTs. Indeed, from the well-known formula defined for homogeneous materials and also applied to concrete [21] (3):

$$E_d = V^2 \frac{\rho(1-2\nu)(1+\nu)}{(1-\nu)} \quad (3)$$

with V equal to the mean sonic velocity of the specimen at 148 days, ν equal to the mean horizontal Poisson ratio resulting from the axial compression tests and ρ equal to the bulk density of the masonry calculated with a simplified homogenization procedure from the bulk density of the single building materials (i.e. equal to 1406 kg/m^3), the resulting dynamic modulus of elasticity, E_d , is equal to 10058 MPa, i.e. ten times higher than the mean value obtained from the axial compression tests. This result shows that eq. (3) is not reliable to predict the elastic modulus of rubble masonry.

5 CONCLUSIONS

This paper presents the results of a wide experimental program aimed at the mechanical characterization of masonry panels reproducing the ancient technique *opus incertum* found at the Pompeii archaeological site. Non-destructive tests (NDTs) and destructive tests (DTs) were carried out on masonry panels built according to the traditional technique by using original rock units and a typical mortar mixture. The experimental program firstly involved sonic pulse velocity tests and diagonal compression tests on three masonry panels, 1.20m x 1.20m x 0.45m. Then, axial compression tests on five masonry specimens extracted from the three panels were carried out.

The following main conclusions may be drawn:

- The panels showed a mean sonic pulse velocity at 148 days after their construction equal to 2767, $\text{CoV} = 11\%$;
- The on-site diagonal compression test resulted in a mean shear strength equal to 0.23 MPa, $\text{CoV} = 16\%$, and a mean shear modulus of elasticity equal to 521 MPa. These results are comparable with what found in similar experiments on other typologies of reproduced stone masonry structures;
- The axial compression tests resulted in a mean compressive strength of 1.48 MPa, $\text{CoV} = 24\%$, and mean modulus of elasticity equal to 1003 MPa, $\text{CoV} = 0.19\%$;

- The Poisson ratios in the horizontal and transversal direction derived from the axial compression tests resulted equal to 0.13, CoV = 75%, and 0.05, respectively. High scattering of these values was also found in other studies;
- The final mean velocity resulting from the sonic tests was consistent with the results of the diagonal compression tests, with the higher velocities showed by the panels that also achieved the maximum shear strength;
- The mean dynamic elastic modulus calculated from the sonic pulse velocity was found to be ten times higher than the one obtained from the axial compression tests.

The information here provided could support the assessment of several archaeological masonry structures in the exceptional context of the Pompeii site and similar archaeological and historical contexts.

Abstract

Huaca de la Luna is a monumental earthen complex located near Trujillo in the North coast of Peru built from 200 AD to 850 AD by the Moche civilization on the slopes of the Cerro Blanco mountain. The principal structure is a massive stepped pyramid built with millions of adobe bricks. The pyramid presents severe structural damage near the NW corner. The static and dynamic response of the pyramid is analyzed using 2D plane strain nonlinear FE models representing the east-west middle section together with the underlying soil profiles. We perform a sensitivity analysis of the static and dynamic response to (a) the pyramid stepped west side profile, (b) the underlying soil and bedrock configuration, and (c) the adobe material tensile strength. Under static conditions the models develop internal fractures but in none of the cases considered these grow to cause the structural collapse of the west side. The west side suffers complete collapse under horizontal accelerations as low as 0.135g.

Keywords: massive earthen construction, archaeological heritage, dynamic analysis, structural failure, non-linear explicit FE analysis, soil-structure interaction.

1 INTRODUCTION AND OBJECTIVES

1.1 Historical introduction

The archaeological site of Huaca de la Luna, or Temple of the Moon, is a monumental earthen complex built by the Moche civilization approximately from 200 AD to 850 AD and located near the modern city of Trujillo in the North coast of Peru. Huaca de la Luna was erected on the lower slopes of the Cerro Blanco as part of a sprawling urban center considered to be the capital of the Moche state. The Moche is one of the most important pre-Inca culture, recognized for its distinctive ceramics and architectural decorations [1]. Huaca de la Luna is considered one of the best examples of the Moche cultural achievements because of its well-preserved mural bas-reliefs particularly on the north façade of its main pyramid [2]. After extinction of the Moche culture, circa 850 A.D., the complex was naturally buried under eolian sand deposits, which reduced exposure to seismic loading demands during possible historical earthquakes in that region of Peru. The sand deposits also protected the extensive bas-relief on the north façade from the erosion caused by El Niño torrential rains. The archaeological works that started in the beginning of the 90s has systematically unearthed and exposed the entire Huaca de la Luna complex [2]. Archeologists working at the site interpret Huaca de la Luna as consisting of three pyramids composed by large platforms at various levels, connected by open spaces as reconstructed in Fig. 1(a). Typical of Moche monumental architecture, the complex was entirely built using millions of adobe bricks connected with mud mortar.

The principal structure is a massive stepped pyramid – shown in its present state in Fig. 1(b) – which served for leading political and religious ceremonial events including human sacrifices and elite burials. This pyramid is the result of a succession of construction stages, each consisting in a taller and larger building erected on top of the previous one, so that the new structure encapsulates in its interior all preceding constructions. Each stage was built by erecting adjacent vertical piers of well textured adobe masonry. The pyramid shows signs of extensive anthropogenic and natural damage, primarily in the north and west façade and in the built-up area unearthed by the archaeological excavations on top of the pyramid [2]. A large excavation, attributed to treasure hunting digging during colonial time, cuts deeply in the north façade – Fig. 1(b), while several tunnels dug by treasure hunters pierce the west façade at different levels – Fig. 2(b). Structural damage is mainly present in the NW sector of the pyramid including the substantial collapse of the NW corner – Fig. 2(a) - and large cracks in the upper areas which penetrate deeply in the structural system.

1.2 Research objectives

The main pyramid is the long term objective of a multidisciplinary study focused on determining the structural behavior of its massive core as well as the built up areas on the top of the pyramid under static and dynamic conditions. Previous work has included a detailed laser-scan survey and 3D reconstruction of the pyramid [3], the mechanical characterization of adobe brick and mud mortar construction through lab testing [4, 5] and the geotechnical and geophysical exploration of the foundation soils along the northern façade [6]. These results have been incorporated into a series of preliminary nonlinear FE models of increasing complexity in order to understand how the soil-structure interaction affects the static and dynamic stability of the pyramid. Taking into account the location of the Huaca on the slope of the Cerro Blanco and the results of the geotechnical and geophysical exploration, the FE models assume that the east side of the pyramid is supported on solid bedrock while the west side is built directly on layers of soft sand, with large adobe blocks serving as the foundation layer. Previous research has investigated the relationship between the observed damage and the soft soil support under static

conditions using a simplified 2D plane strain model derived from the geometry and the ground level of the north façade [7]. In the present research we turn our attention to west side of the pyramid to capture the effect of the original ground level, located 5.5 m below the north side. To this end, we develop a refined 2D geometry which includes all superimposed construction layers down to the original ground level as revealed by the archaeological excavations along the west side of the pyramid. Adopting a plane strain formulation, this geometry is used to model the structural behavior of an EW cross section positioned in the middle of the pyramid. We then perform a sensitivity analysis of the static and dynamic response to variations in (a) the pyramid stepped west side profile, (b) the underlying soil and bedrock configuration, and (c) the adobe material tensile strength. In each case, the dynamic response is evaluated by applying lateral and vertical ground accelerations leading to the structural collapse of the stepped (west) side of the 2D model. Following a macro-modeling strategy [8, 9], the analysis is performed in Abaqus CAE/Explicit using the concrete damaged plasticity formulation to represent a continuum with the mechanical properties of adobe [10]. The soil layers are modelled using the Mohr-Coulomb formulation [11]. The specific material parameters are given below in the modeling section.

Figure 1: (a) 3D model of Huaca de la Luna [2] and (b) Laser scanning of main pyramid of Huaca de la Luna [3].

Figure 2: (a) Damaged NW corner of the main pyramid, and (b) West façade of the main pyramid (remaining of the buttress system is highlighted) [7].

2 METHODOLOGY

In order to determine the formation of local damage and its evolution into structural failure in the cross-sectional model under static and dynamic conditions, we apply the energy based

approach previously developed for the failure analysis of other concrete damaged plasticity models [12, 13]. In brief, the time-evolution of strain (SE), kinetic (KE), and dissipative energy (PD – due to plastic deformations simulating internal fractures) is used to identify the development of local damage conditions up to structural collapse. Consider a simple vertical wall under lateral acceleration normal to the wall – Fig. 3. After gravitational loading, a uniform monotonically increasing horizontal acceleration is applied to the model using the explicit FE formulation available in Abaqus. The desired quasi-static condition is enforced by adopting long time intervals for the application of both gravitation and lateral accelerations: in the example shown, five seconds for gravitation to increase linearly from 0 to 1 g followed by ten seconds for lateral acceleration to go from 0 to 0.8 g. As long as structural integrity is maintained under increasing lateral acceleration, KE remains negligible during the evolution of quasi-static structural response. Structural failure is associated with the sudden transition from quasi-static to a fully dynamic state and is detected by the accompanying asymptotic growth of KE. PD follows an identical growth pattern, becoming asymptotic at collapse. Notice also that the viscous dissipative energy (VD) produced by the fictitious viscosity parameter used in Abaqus/CAE Explicit to dampen possible oscillatory behavior remains negligible during static conditions and then goes asymptotic at failure.

The examination of the energy plots in Figure 4 suggests complementary ways to associate a specific time interval to failure. KE begins to develop at 7.3 s and becomes asymptotic at 7.9 s, reaching the 10% value of the total internal energy (i.e. SE + PD + KE) at 7.7 s. PD, which can be taken to represent the work necessary to propagate the fractures at the base of the wall, begins to appear at 6.6 s and crosses the SE at 7.85 s. Thus, purely on energy considerations, total failure can be reasonably defined to happen between $t = 7.7$ s (when the loading process cannot anymore be regarded as static) and $t = 7.85$ s (when the PD equals the SE).

Figure 3: Wall under normal acceleration: energy curves versus analysis time [13].

In the present work, after gravitational loading, lateral accelerations are applied directly to the boundary conditions at bedrock level. In this case, since the entire model is accelerating under inertial forces, KE develops rapidly well before collapse conditions and cannot be used to detect collapse. Under these circumstances, we can still depend on PD to trace the evolution of damage to full collapse, with the latter taken to be the time at which PD equals SE.

The explicit (dynamic) nonlinear FE formulation is preferred over the implicit one because of its capability to sustain large deformations and attendant local material failures, and to capture unequivocally the collapse condition due to lateral accelerations. In fact, in most of the

cases of the present study, it may be not possible to detect the actual failure condition using an implicit nonlinear FE formulation because the analysis terminates due to numerical error (e.g., the stiffness matrix becomes singular) before the actual structural failure occurs. On the negative side, dynamic explicit models are computationally costly. In order to ensure algorithmic convergences, Abaqus Explicit requires the time increments of the order of 10^{-6} second for both gravitation and lateral acceleration.

3 DESIGN OF MODELS

The sensitivity analysis of the static and dynamic response of the EW cross section is based on twenty seven models derived from the combination of three variations of the west side stepped profile, three underlying soil and bedrock configuration, and three adobe material tensile strength.

3.1 West side stepped profile

Based on the archaeological reconstruction, the original platform level on the west side of the pyramid can be located at approximately 25.2 m from the ground [14]. Of relevance for interpreting the geotechnical data, we notice that the ground level on the west side is approximately 5.5 m lower than level of the plaza in front of the north façade. The architecture of the upper west side is well defined in terms of step dimensions. However, due to higher level of damage, less is known with certainty about the original configuration of the lower steps [15, 16]. Thus, working from the archeological cross sections, the upper five steps – extending approximately the 17.1 m in elevation – can be reasonably reconstructed and matched with the identical steps on the north façade. However, the architectural configuration for the remaining 8.1 m is ambiguous and can be interpreted as consisting of either three equally spaced steps, or the combination of two irregular steps (a single higher step replacing the two lowest ones from the previous configuration), or even including a triangular buttress at ground level. The resulting three geometrical configurations – hereafter labelled C1, C2, and C3 – are shown in Fig. 4. Notice that the footprint of the stepped west side changes according to the configuration, with C2 resulting in a substantially smaller footprint than C1 or C3.

3.2 Soil and bedrock configurations

The reconstruction of the foundation soil configuration below the EW cross section is based on the geotechnical data produced during the exploration conducted in front and to the west of the north façade [6, 7]. Figure 5 shows the location where cone penetration tests (CPT) were performed and the resulting EW soil stratigraphy configuration with the ground level set at the base of the north façade, i.e., 5.5 m above the ground level on the west side. Based on additional geological considerations, the stratigraphy illustrated in Fig. 6 is assumed for a NS section taken to the west of the pyramid in correspondence of the CPT02 location (Fig. 5). Starting from these data we construct three alternative bedrock configurations for the EW cross section taken in the middle of the pyramid and referred to the west ground level, see Fig. 6. Configuration B1 assumes the same bedrock position as determined in front of the north façade. For configuration B2, the bedrock layer is shifted uniformly 5 m down. Configuration B3 is derived from B1 by positioning the bedrock 5 m lower only in correspondence of second CPT location. As a result, the amount of soft soil below the pyramid in B2 and B3 is larger than B1, while the contact surface between the pyramid and the soft soil is essentially unchanged between B1 and B3 but increases markedly in B2.

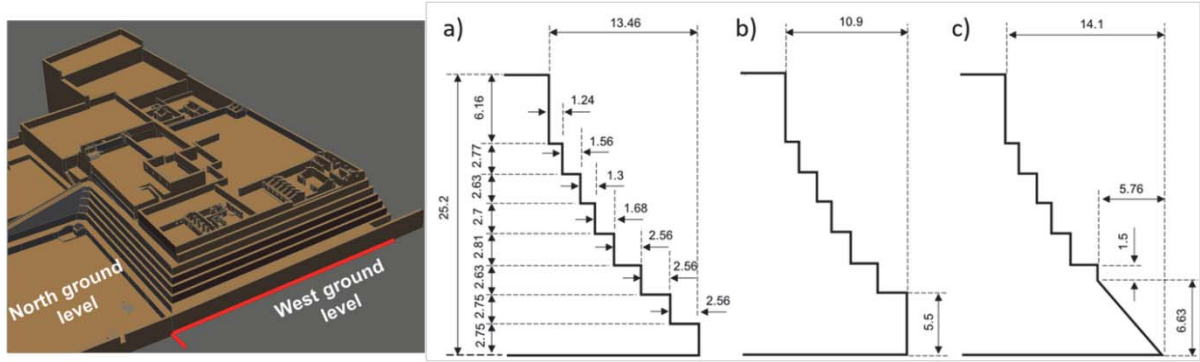

Figure 4: 3D solid model with north and west ground elevation difference on the left, (a) C1 configuration - regular steps, (b) C2 configuration - higher lower step, and (c) C3 configuration - buttress system.

3.3 Adobe tensile strength

In quasi-brittle materials such as adobe masonry, performing tensile tests are extremely difficult. In this case, tensile properties are derived from the compressive strength σ_c [8, 9]. For the present case we consider three adobe materials characterized by the same compressive behavior but with tensile strength set as $1/10 \sigma_c$ (M1), $1/20 \sigma_c$ (M2), and $1/30 \sigma_c$ (M3). The post-critical tensile stress versus displacement input for the three cases are shown in Fig.7.

4 MATERIAL CHARACTERIZATION

We use the material parameters for the adobe masonry and the soft soil stratification experimentally given in [4, 5] and [6, 7], respectively.

4.1 Concrete damaged plasticity parameters (adobe)

The concrete damaged plasticity in Abaqus/CAE Explicit requires separate characterization for the elastic, plastic, and inelastic behavior. For the elastic part, the density is $\rho = 1735 \text{ kg/m}^3$, the Young's modulus $E = 123 \text{ MPa}$, and the Poisson ratio $\nu = 0.2$. The plastic properties are given in Table 1.

Dilation Angle (°)	Eccentricity	f_b/f_c0	K	Viscosity Parameter
1	0.1	1.16	0.67	1E-8

Table 1: Plastic properties for the adobe material

The inelastic behavior is defined separately for tension and compression. While in [7] the compressive curve is expressed as stress versus total strain, Abaqus requires that the uniaxial compressive response be given in terms of stress versus inelastic strain [10]. The following equation is used to convert the strain data:

$$\varepsilon_i = \varepsilon_t - \sigma/E \quad (1)$$

where ε_i denotes the inelastic strain, ε_t the total strain, E the elastic modulus, and σ the compressive stress. As in [7] the postcritical tensile response is expressed in terms of stress versus crack-opening displacement. The resulting material curves for inelastic compression and tension are given in Fig. 7. The tensile curves for M2 and M3 are derived by scaling the M1 curve by 1/2 and 1/3, respectively.

Figure 7: Compressive behavior stress versus inelastic strain (left), material variation on tensile strength as M1, M2 and M3 (right).

4.2 Mohr-Coulomb parameters (soft soils)

For the B1, B2 and B3 soil and bedrock configurations defined above, the soil stratification and related properties follow the CPT data given in [6, 7]. The foundation soils are comprised of layers of eolian sands that range from medium dense near the surface to very dense at deeper depths approaching the bedrock. Each of the four layer shown in Figures 5 and 6 is assumed to behave like a Mohr-Coulomb material with properties given in Table 2. To take into account the marginal cohesion of eolian sand, the cohesion strength of each layer is set to 10 Pa.

Parameter	Layer 1	Layer 2	Layer 3	Layer 4
Mass density (kg/m ³)	1900	2000	2000	2250
Elastic modulus (MPa)	17	43	57	58
Poisson ratio	0.43	0.43	0.42	0.41
Friction angle	40°	42°	43°	43°

Table 2: Material properties of soil layers under Huaca de la Luna [6, 7].

5 RESULTS

Although none of the twenty seven M-B-C pyramid configurations reaches structural failing conditions under static loading, all of them exhibit some level of adobe plasticity at the soil-structure interface in proximity to the west edge. The size and intensity of this damage, the additional development of vertically penetrating fractures originating from the top of the pyramid and of damage along the west steps are all affected by the variation in adobe tensile strength and bedrock configuration, and, in a lesser measure, by the step architecture.

We begin by considering how the variation of underlaying bedrock configurations and adobe tensile strength affect material damage under static conditions. Shown in Fig. 8 is the plastic dissipation energy (PD) measured in the adobe mass at the end of gravitational loading. PD increases with bedrock configurations from B1 to B3 and also, as expected, with the adobe tensile strength decreasing from M1 to M3. It is clear that the bedrock configuration has the highest effect on the plastic dissipation energy. Thus, the combined effect of steeper bedrock angle and deeper soft soil foundation - configuration B3 - produces the highest plastic dissipation on the main pyramid. Considering that, as explained earlier, plastic dissipation is directly proportional to the formation of fracture damage in the adobe material, it can be concluded that the bedrock layout makes the most important contribution to material damage under static conditions. This consideration will be further explored by analyzing the results of the various models built with combination of bedrock layout, step architecture, and material tensile strength.

Figure 8: Plastic dissipation energy for material and bedrock variations.

The distribution of maximum principal plastic strains on bedrock configurations B1, B2, and B3 with the highest tensile strength of adobe (M1) are shown in Fig. 9 (a)-(c). These are compared with the results for the same configurations but with the lowest tensile strength (M3), Fig. 9 (d-f). The black zones indicate areas where the strains are above the 10^{-3} threshold, and thus where fracture damage can be predicted. For all the M1 cases, compressive stresses – although remaining below compressive strength – produce a nucleus of low level tensile plastic strains at the base of the pyramid in proximity of the west edge – see B3, Fig. 9(c). For B1 and B2 their

magnitude is below $2.5e^{-4}$ and thus not visible in Fig. 9(a) and (b). While there is no fracture development on the top level of the pyramid for B1, a downward vertical fracture forms at the angle between the top platforms for B2 and B3.

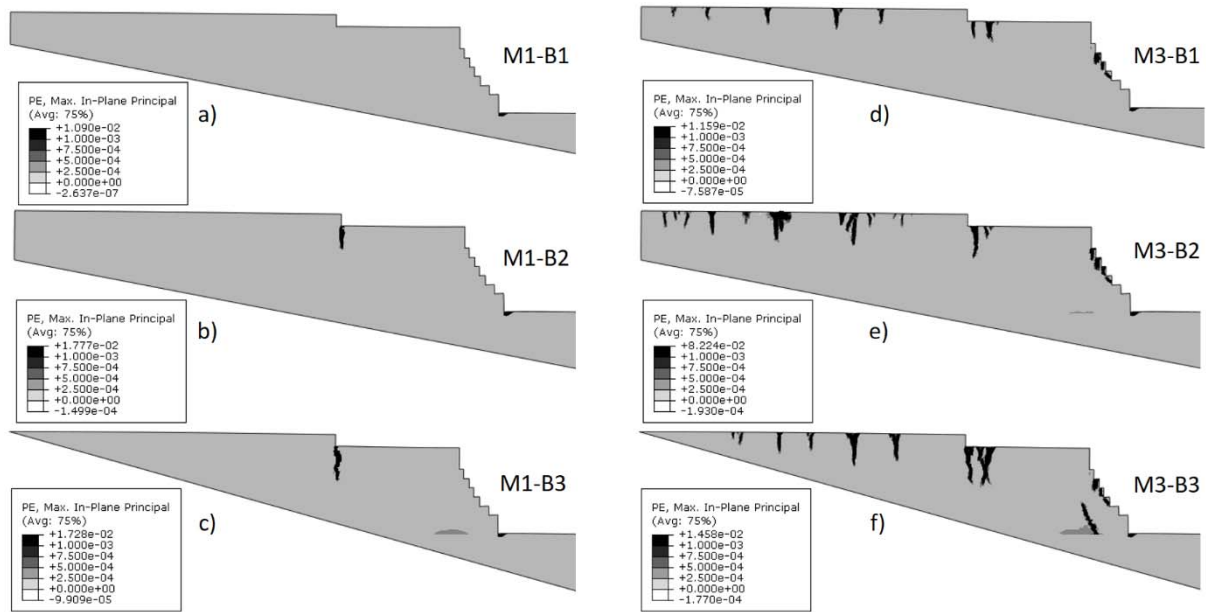

Figure 9: Plastic strain results of bedrock variation for M1 (a-c) and M3 (d-f).

As shown in Fig. 9(d)-(f), the M3 models under static conditions exhibit similar damage patterns at the base of the pyramid. In all three bedrock configurations, however, the downward fractures on the top level increase noticeably in number and in depth and damage appears along the steps on the west side of the pyramid. For M3-B3, a substantial fracture propagates upward from the base near the west corner – Fig. 9(f).

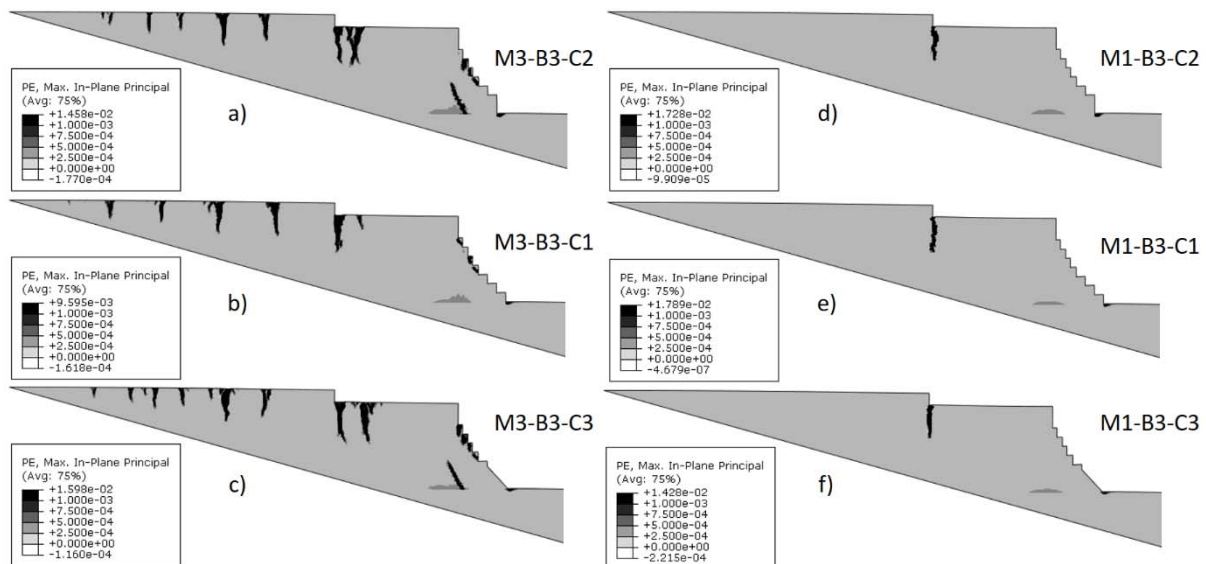

Figure 10: Plastic strain results of step architecture variation for M1-B3 (a-c) and M3-B3 (d-f).

Figure 10 shows the effect of the step architecture on the B3 configurations with material M1 and M3 under static conditions. The regular step architecture (C1) produces the least damaged conditions. For the M3 cases, C1 appears to stabilize the west façade by containing the

expansion of the fracture zone at the base, while for the M1 cases, it produces the least plastic dissipation energy. The downward fractures at the top platforms are consistent with those shown in Fig. 9 for M1 and M3. For the M1 cases, there is a single fracture at top of the pyramid, which is not affected by the step architecture. All M3 cases show several downward penetrating fractures at the same location. In addition, the M3-B3-C2 and M3-B3-C3 cases show more extensive damage along and in the proximity of the west steps.

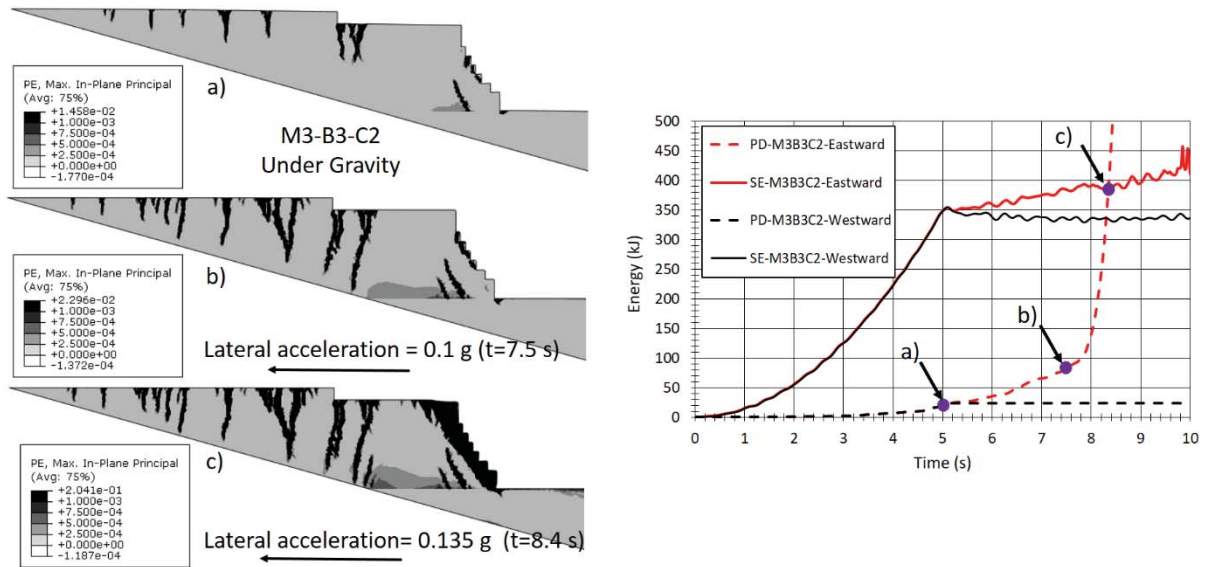

Figure 11: Plastic strain results of M3-B3-C2 configuration under gravity and eastward acceleration (a-c) on the left, energy results of both eastward and westward acceleration cases on the right.

We now examine the effect of horizontal acceleration on the M3-B3-C2 configuration, which exhibits the highest level of structural damage under gravitational loading. The horizontal acceleration is applied at the bedrock level after gravitational loading as a linear function of time, gradually increasing from 0.0 g to 0.2 g over 5 seconds. In order to account for the asymmetry of the model, two separate tests are performed with the acceleration applied eastward in one case and then westward in the other. As expected, the results indicate that the pyramid is critically vulnerable under the eastward acceleration as clearly shown by the difference in PD energy curves for the two cases – Fig. 11. The effect of the eastward acceleration is shown in Fig. 11 in terms of damage progression starting at 5 s (at the end of gravitational loading, Fig 11(a)), at the beginning of collapse at 7.5 s (horizontal acceleration 0.1 g, Fig. 11(b)), and at full collapse at 8.4 s (horizontal acceleration 0.135 g, Fig. 11(c)). The structural collapse involves the separation of the entire west side of the pyramid. In contrast, the energy curves for the westward case reveal that the structural situation remains essentially unchanged from the static condition through the following 5 s of increasing horizontal acceleration.

To explore the effect of horizontal and vertical accelerations applied simultaneously to the M3-B3-C2 model after gravitational loading, a downward acceleration is also added as a ramp increasing from 0.0 g to 0.1 g over the same 5 s. The vertical acceleration is selected as half of the horizontal one in consideration that earthquake vertical peak ground accelerations in this area are generally significantly lower than the horizontal component. As shown in Figure 12, the results demonstrate that the addition of downward acceleration changes the structural failure condition only marginally, with the horizontal acceleration at failure shifting from 0.135 g to 0.139 g.

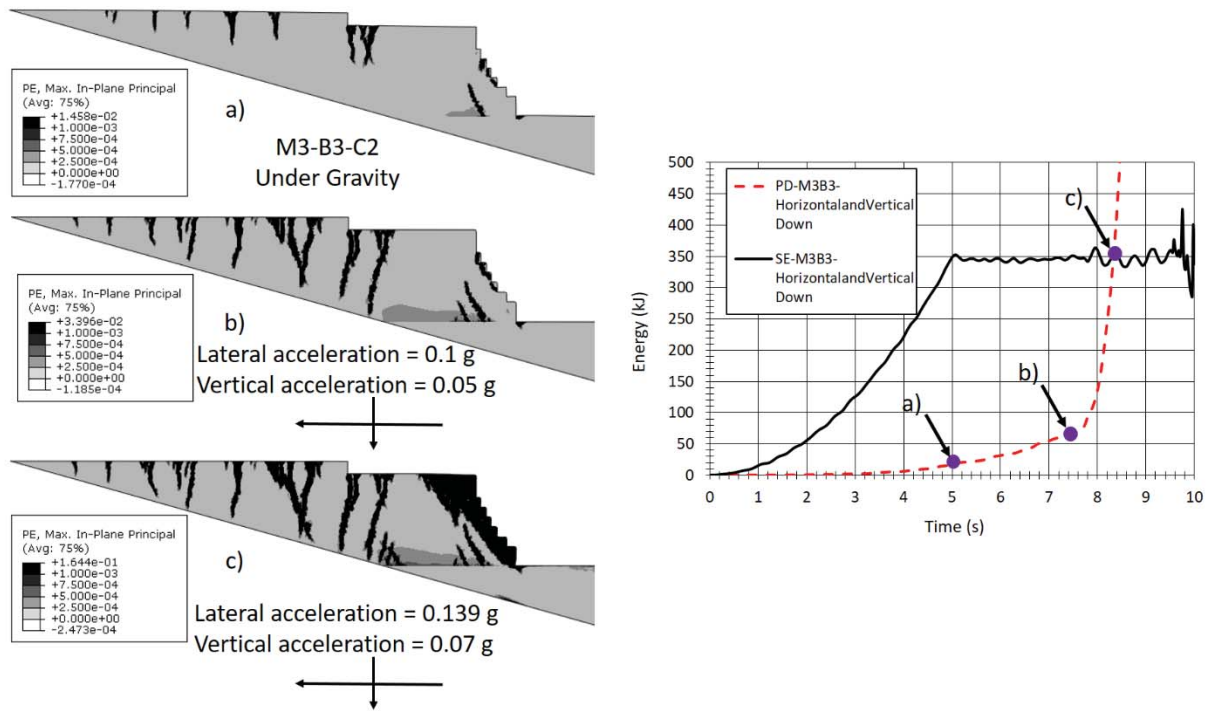

Figure 12: Plastic strain results of M3-B3-C2 configuration under gravity and eastward and downward acceleration (a-c) on the left, energy results on the right.

Figure 13 illustrates the effect of maximum adobe tensile strength as in the M1-B3-C1 case under eastward horizontal accelerations. The lateral capacity of the structure is further increased from 0.135 g to 0.24 g (78% more than M3-B3-C2). Finally, Fig. 14 illustrates the effect of the step configuration on the M3-B3 model under horizontal accelerations. The comparison with Fig. 11 is revealing. The presence at the ground level of a buttress (C3) or an addition step (C1) increases the lateral capacity by 33% and 45%, respectively.

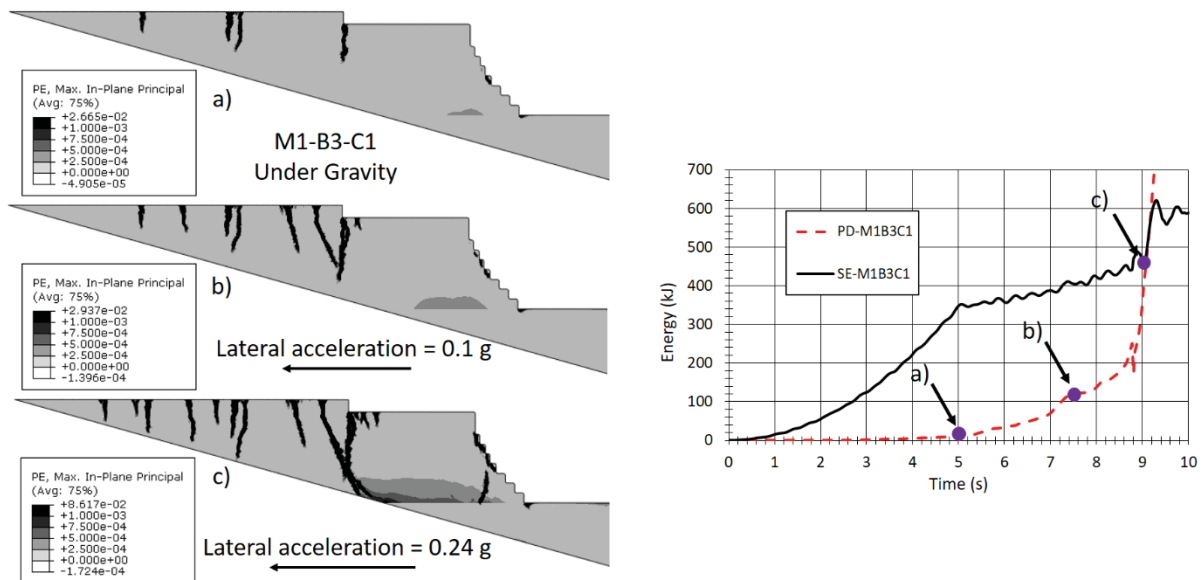

Figure 13: Plastic strain results for M1-B3-C1 configuration under gravity and eastward acceleration (a-c) on the left, energy results on the right.

It is worth noting the similarity in the failure pattern along the west side between all the M3-B3 model and the actual collapse present on the NW corner of the pyramid, Fig. 14.

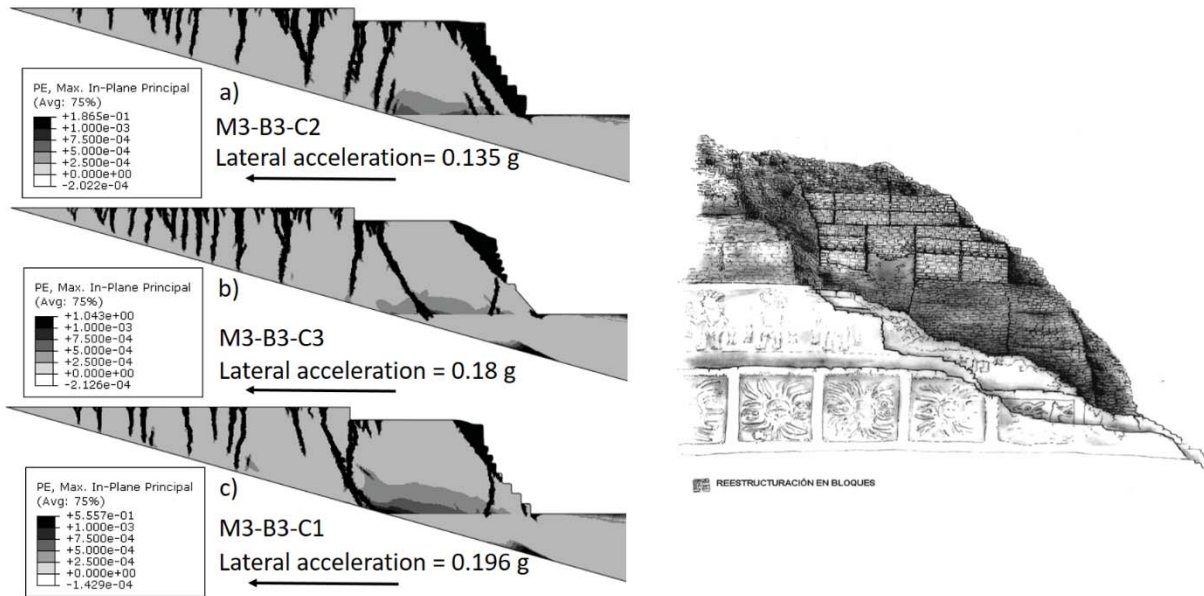

Figure 14: Lateral resistance of M3-B3 cases for step architecture variation (left), damage status of the NW corner of the main pyramid (right) [16].

6 DISCUSSION

Results indicate that under the assumptions made for material properties, bedrock and soil stratification, and architectural configuration, the 2D plane strain model shows localized material damage but does not collapse under gravitational loading. For each adobe tensile strength considered the bedrock configuration produces a major effect on the extension of the damaged areas, while the step architecture affects damage only marginally. Within the bedrock configurations, B2 is characterized by the largest structure-soil contact, thus inducing higher displacements and strain energy for the pyramid, but less damage than the B3 configuration. Although B3 yields less structure-soil contact, it assumes a steeper bedrock angle than B1 and B2, resulting in a deeper amount of soft soil under the west side of the pyramid.

The lateral acceleration tests indicate that the pyramid will reach failure conditions characterized by the extensive collapse of the west side under eastward accelerations ranging from 0.135 g to 0.24 g. The lowest value is due to the combined effect of lowest adobe tensile strength (M3) with steeper bedrock angle (B3) and shorter step footprint on the west side (C2). Although for the M3-B3 set the step architecture appears to contribute marginally to structural stability under gravitation, it affects significantly its lateral capacity. The C3 and C1 configurations increase lateral capacity from 0.135 g under C2 to 0.18 g and 0.196 g for C3 and C1, respectively. As expected in the case of a massive earthen structure, the material tensile strength plays a major – if not dominant – role in determining the lateral capacity. Replacing the lowest tensile strength (M3) adobe in the B3-C2 configuration with the highest tensile strength (M1) increases the lateral capacity from 0.135 g to 0.24 g (a 78% increment).

In conclusion, the results of the present preliminary study can be tentatively extrapolated to the actual pyramid to suggest that the uneven structure/soft soil/ bedrock interaction due to the pyramid location is not likely to cause the west side structural collapse under static conditions. Under this perspective, the extensive structural damage present in the NW corner could be at-

tributed to lateral accelerations produced by seismic actions rather than soft soil support conditions as initially suspected. However, given the inherent limitations of the 2D plane strain formulation, the characteristic features of Moche building techniques ignored in the present continuum model, and, most importantly, the uncertainties of the actual NS soil stratifications, these are still tentative considerations to be used as a point of departure for future in depth studies.

Abstract

Italian building heritage is widely composed of masonry buildings, whose characteristics largely vary depending on geographical location, construction techniques and materials typology. This type of structures has shown a high vulnerability to horizontal loads that must not be ignored, especially due to the high seismic hazard of Italian territory. Hence, appropriate numerical models are required to assess the complex structural behavior of unreinforced masonry (URM) existing structures, implementing the non-linear behavior of both materials and structure.

In this framework, two different approaches have been widely acknowledged: the Equivalent Frame Model (EFM) and the continuum Finite Element Model (FEM). This paper presents the application and comparison of these modeling strategies to an URM building dating back to XVII century, located in the Italian Alpine region (Roana, Vicenza). Non-linear static analyses were carried out by means of the software 3Muri (EFM), DIANA FEA and Midas FEA-NX (FEM). Results were compared in terms of ultimate resistance, capacity, ductility, and evolution of the damage state. Finally, assessment of the global behavior was carried out according to the Italian seismic code, pointing out the differences of the two approaches. Results showed that the EFM appears to be more conservative than FEM.

Keywords: Masonry buildings, Seismic vulnerability assessment, Non-linear static analysis, Finite Element Model, Equivalent Frame Model.

1 INTRODUCTION

The importance of preserving the Cultural Heritage in Italy has become more and more important, even due to the seismic events, which interested Italian territory [1]. The complexity of masonry structures, which widely compose built heritage, derives from its nature, being an extremely non-homogeneous material, whose properties vary depending on units and binder characteristics, assembling techniques, geometric layout. Computational methods can be helpful for taking into account some uncertainties, which affect the structural behavior and therefore are becoming more and more essential for the seismic assessment of unreinforced masonry (URM) structures.

This paper aims to compare various modelling strategies applied to an existing URM building in north Italy (Veneto region). The models, based on different approaches for the non-linear behavior of both materials and structure, were compared through pushover analyses, which are able to represent the global structural behavior, providing an estimation for the structure's capacity. For this approach to be valid, the assumption of "box behavior" has to be made, thus considering only in-plane resistance for masonry panels and excluding the activation of out-of-plane mechanisms, which could lead to local collapses.

The results were also processed in terms of Near-Collapse PGA capacity, in order to evaluate how the different modelling strategies can affect seismic assessment.

1.1 Numerical modeling of masonry structures

Two of the most acknowledged modeling strategies for masonry structures are the Equivalent Frame Model (EFM) and the Finite Element Model (FEM) approaches [2]. EFM is based on the discretization of masonry walls through three different macro-elements: piers, spandrels, and rigid nodes. This subdivision idealizes a frame structure where piers and spandrels are connected through un-deformable elements (rigid nodes), while non-linear properties are lumped at hinge elements. This method is subject to multiple uncertainties, regarding the frame schematization and non-linear hinges behavior [3]. It is indicated for the in-plane analysis of regular structures [4], since the out-of-plane behavior is not considered [5].

FEM can provide more detailed discretization, yet it presents a higher computational cost. Different approaches can be used in FE masonry modeling [6], depending on the complexity and purposes of the analyses. A relatively simple yet effective approach is the continuum modeling, in which the heterogeneous characteristics of masonry (i.e., resistant units and binder) are merged into a homogeneous one, and non-linearities are uniformly distributed. This method allows creating complex models able to identify out-of-plane mechanisms and more accurate crack patterns [7].

1.2 "La Cattedra" Case Study

The case study is part of "La Cattedra" complex, located in Canove di Roana (province of Vicenza), in the Italian Alpine region, about 1000 m AMSL. It corresponds to the older portion of the complex (Figure 1a), dating back to XVI century and it is characterized by a rectangular layout of about 10 m x 13 m, split in half by a central wall (Figure 1b). The building is adjacent to the remaining complex on the north side. It is a regular three-story building with the arrangement of the windows on three distinct rows. The main entrance is centered on the eastern façade, whereas the inner stairs are placed on the opposite side.

Due to the lack of a particular economic value, the complex underwent numerous renovations, which altered the original layout. For this reason, experimental investigations had to be carried out to identify the structural elements of the building and determine their physical parameters.

Figure 1: a) Picture of 'La Cattedra' case study, b) plan scheme of the case study.

The experimental investigation campaign was carried out in 2019 implementing semi-destructive and non-destructive tests. Firstly, scarifications were realized on different spots of the main walls, to identify the masonry type, detecting a stratigraphic composition; the lower portion is characterized by a local calcareous stone block (*Biancone*) masonry, whereas the upper section presents a hollow clay block one, due to a superelevation intervention realized on the last century. Walls' thickness varies from about 70 cm on the bottom to 60 cm on top of the building.

Two types of horizontal structures were detected: RC with slab for the first two floors, and RC without slabs for the third floor and the roof.

For the identification of masonry properties, both IQM (masonry quality index) analyses [8] and penetrometer tests on mortar samples were carried out: a very poor mortar was detected, especially for the stone masonry, while the characteristics improve for the block one.

2 MODEL GENERATION

The numerical models were developed via 3MURI (EFM), DIANA FEA and MIDAS FEA NX+ (FEA) (Figure 3), which represent some of the most common tools for EFM and FEM analyses of URM structures.

Figure 3: Numerical models: 3MURI (a), DIANA (b) and MIDAS (c)

2.1 EFM model

3MURI software [9] was used for the EFM modeling [10], allowing the automatic mesh generation. Material's properties assigned for masonry elements (Table 1) were defined from the Italian seismic code [11] and the experimental investigations previously described. The non-linear properties, different for piers and spandrels, were described by two collapse criteria, related to a flexural and a shear behavior. The constitutive laws adopted for each criterion presents a bilinear behavior without hardening, followed by progressive resistance softening (Figure 4). A 50% reduced stiffness is generally suggested [11] to simulate the cracked conditions of masonry elements. However, this assumption strongly affects the initial global stiffness, and it's commonly accepted the use of un-reduced values, since adopted parameters are already conservative, deriving from code tables and being already reduced by safety factors [12]. Hence, having to compare different modelling strategies, uncracked stiffness was considered.

Floors were modeled as 4-noded orthotropic plane strain elements, whose elastic properties for both types are listed in Table 2.

Figure 4: Constitutive laws adopted for EFM in 3MURI: a) flexural and b) shear behavior for piers, c) lintel model for spandrels (DL: Damage Level) [13].

2.2 FEM model

FEM analyses were carried out by means of two software: DIANA FEA [14] and MIDAS FEA NX+ [15], referring to a continuum approach. In both cases, masonry walls were modeled through curved shell elements, considering the material as nonlinear isotropic. For the non-linear behavior of masonry, the smeared crack approach was chosen, originally developed for concrete [16] and later adapted to masonry. The parameters which characterize this model (*Total Strain Based Crack* for DIANA, *Concrete Smeared Crack* for MIDAS) are the tensile (f_t) and compressive (f_c) ultimate stresses and the fracture energy values (G_t and G_c) to define the post-peak of the stress-strain curve. The behavior is described by a linear softening function in tension and a parabolic function in compression. In addition, a shear retention factor (β) was defined. The parameters implemented for each masonry type in the FE model (Table 1), are equal for both FE models. As for the EF model, the reference values derive from Italian seismic code [11], in accordance with the results of experimental tests, while fracture energy values were suggested by scientific literature [17].

Floors were modeled as elastic orthotropic shell element and elastic properties, equal for EF model, are reported in Table 2.

	EFM		FEM	
Parameter	SB Masonry	HCB Masonry	SB Masonry	HCB Masonry
E [MPa]	1740	4550	1740	4550
ν	0.25	0.25	0.25	0.25

3 RESULTS

The seismic assessment was carried out through modal and pushover analyses. These last, as stated by the Italian code [11], were performed for both principal directions, following two load profiles: proportional to mass distribution and proportional to mode shape. The results, consisting in four capacity curves for each model, permitted to evaluate the seismic vulnerability for the global structure in terms of peak ground acceleration (PGA).

3.1 Modal analyses

The models were firstly compared through eigenvalue analyses. Table 3 reports the results for the three models in terms of modal frequencies and participant mass percentage for each principal direction. The comparison shows a good correlation for the first modes, especially between the two FE models, whose frequencies are close. For higher modes, differences become more significant, although less important than former ones.

Observing mass participation percentages, the FE models present similar values (about 75%), for the first two modes, corresponding to the main bending modes in Y and X direction, respectively. Major differences can be observed for the EF model, especially on the second and third modes, which both are oriented in X direction, although involving less dynamic mass. Thus, while FE models shows a global dynamic behavior, with participating masses lumped in the first modes, EF model does not.

Table 3: Results of modal analyses

Figure 5: Comparison between modal frequencies

3.2 Pushover analyses

The capacity curves deriving from pushover analyses pointed out significant differences among the three models (Figure 6). The EF curves were characterized by two very distinct sections: the first elastic and the second almost perfectly horizontal. On the FE curves, instead, the transition between elastic and post-elastic behavior was less defined. This difference is due to the nature of non-linearities in the models. On the EF model, the behavior is ruled by few idealized elements (plastic hinges), while on FE model the non-linearities are spread to all the elements; therefore, the transition between the linear and nonlinear phase is much more dilatated, depending on the status of more elements.

Differences can be noticed even in the post-elastic phase, thus inducing major divergencies on displacement capacity, as the FEM analyses provide higher values for ultimate displacement and peak shear capacity, which brings to a brittle failure of the structure. Significant differences can be observed even between the FE models: while the curves coincided in the elastic section due to the equal elastic properties of the materials' model, the post-elastic behavior changed, due to the different non-linear model implemented by the two software: MIDAS curves were characterized by a higher post-elastic stiffness, leading to higher maximum shear values.

The models were also compared on damage evolution (Figure 7). For the EF model, the damage is represented by a color scale legend of the status reached by every element based on the related plastic hinges status, while for FE model, the damage is represented by major principal strain. Firstly, a correspondence between the rigid node elements of EF model and the un-damaged portion of FEM walls can be noticed, thus validating the assumptions of the EF approach. Secondly, all the three models pointed out the major damage located at the piers of the first floor, suggesting the activation of a soft story mechanism, which led to the collapse

of the structure. The main difference can be observed on the damage at upper levels, as the FE model led to the damage located on the piers of the second floor, while the EF on the third one.

3.3 Seismic capacity assessment

Verifications were carried out following the Italian seismic code [10][18], obtaining the capacity in terms of Near-Collapse PGA (PGA_C) for every pushover curve. Resulting PGA capacities of FE models were compared to EF ones (Δ_{PGA}) and reported in Table 4. Results pointed out that the Y direction is the most vulnerable one, providing lower values of Near-Collapse PGA (PGA_C). Comparing the modeling strategies, lower values can be observed for the EF model, especially for the transversal direction analyses, suggesting a more conservative approach. The FE models deliver similar PGA values for Y-direction analyses, while dif-

ferences emerge from X-direction ones, as MIDAS values are significantly higher than DIANA ones.

Analysis	3MURI	DIANA FEA		MIDAS FEA NX+	
	PGA _C [g]	PGA _C [g]	ΔPGA [%]	PGA _C [g]	ΔPGA [%]
X Mass	0.220	0.222	+0.9	0.289	+31.3
Y Mass	0.125	0.187	+49.6	0.189	+51.2
X Modal	0.194	0.174	-10.4	0.200	+3.1
Y Modal	0.104	0.114	+9.6	0.118	+13.5

4 CONCLUSIONS

In this contribution, different modeling strategies for existing URM buildings have been applied to a representative case study.

The case study was a three-story URM building located in the Italian Alpine region. It has a rectangular plan shape, as well as it is regular in elevation. Lower portion was built using local calcareous stone blocks, while the upper portion was made of hollow clay blocks.

Equivalent Frame (EF) and Finite Element (FE) models were implemented using different software [9,14,15]. The comparison of analyses results showed that:

- differences related to the various approaches can be observed, especially in damage evolution and post elastic behavior;
- both EFM and FEM approaches identified the same soft story mechanism involving the first floor's piers, even if differences can be observed in damage pattern among the strategies;

In this study, EFM approach produced more conservative results than FEM ones, providing lower capacity PGA values. Other examples led to controversial results [2][4][7], suggesting that one or other strategy has to be carefully chosen, depending on case study characteristics and analysis purposes; besides its low computational effort, the EFM approach appears to be suitable for seismic assessment of regular building. FE approach is indicated for more irregular structures, which cannot be easily schematized with EF method. They even provide more detailed results, allowing local damage patterns to be better identified, however they require way more computational time.

Abstract

This paper investigates whether it is possible to identify the influence of soil conditions on the modal parameters of the structure for damage detection and overall structural health monitoring. To do so, the data gathered on a large monumental building damaged by differential settlements are analyzed. In particular, the dynamic response of the case study, a large monumental masonry building, was experimentally investigated within an operational modal analysis (OMA) campaign. Mechanical data obtained from the geophysical tests were in turn employed to build and characterize a numerical model of the soil underlying and surrounding the building. The resulting model was then used to study the sensitivity of the modal characteristics of the building with respect to variations of external environmental factors (e.g., the water table level) which affect the underlying soil.

The results obtained from this numerical study is deemed to represent a starting point for future experimental tests and investigations, whose final aim is relating ambient vibration measurement to the occurrence of differential settlements or subsidence, in order to detect progressive, and possibly pathological, behaviors.

Keywords: soil-structure interaction, degree of saturation, environmental data series, FEM, foundation settlements, Operational Modal Analysis, Structural Health Monitoring, ground-water table.

1 INTRODUCTION

It is well-known that soil conditions may affect the response of a building. This is especially true for monumental buildings in masonry, which are unable to bear strong flexural internal stresses caused by differential settlements or subsidence [1]. Cyclic oscillations of water table levels may alter the soil characteristics and potentially activate or worsen these phenomena, damaging the superimposed structures. Dynamic monitoring systems are a widespread tool for Structural Health Monitoring (SHM) and consist of accelerometers installed on the superstructure [2]. However, alterations occurring at the foundation level are difficult to understand from the outputs of these systems. Moreover, the systems dedicated to dynamic SHM are usually not equipped with sensors dedicated to controlling the effects of the soil, as they are set to capture responses from the superstructure only.

The present paper wants to investigate how the modal behavior of the structure is affected by the variation of the soil characteristics, such as the degree of saturation and the water table evolution. The aim is to study how a dynamic sensing system mounted only on the structure would capture the evolution of these parameters correlated to the structure response. To this aim, the case study of the Chiarugi building in Racconigi (Piedmont, Italy) is presented as a benchmark. The “Chiarugi” pavilion is a monumental three-story masonry structure presenting a double quadrangular plan with two inner courtyards overlooking the walkways loggias at the various floors. The building, which has been used as a psychiatric hospital for over a century, is distributed in various wings, a common design solution adopted at the time for hospice and hospital in general, and it includes a baroque chapel dedicated to the Madonna del Buon Consiglio. The building covers about 4.000 m², with a total usable area of about 17.000 m² distributed between the basement and the various floors and reaches a maximum height of 21 m. The building, whose construction is dated between the end of the 18th century and the beginning of the 19th century, has been in disuse for more than twenty years and has been in a latent danger state. Currently, the building is affected by a condition of widespread degradation and severe damaging phenomena: internal collapse, local deformations, wide cracks scattered on the whole building. These damaging phenomena, documented for over 50 years, are distributed differently in the various wings in which the building is subdivided. The structural problems of the “Chiarugi” pavilion are essentially due to two main causes mentioned in all the static surveys carried out since 1972: the maintenance problems and the soil characteristics [3]. In fact, the structural damage affecting the building is caused by the hydrogeological conditions and the seasonal oscillations of the groundwater layer. Moreover, the maintenance problems had led to the deterioration of the roofs, causing infiltration and percolation of the meteoric waters into the walls, sometimes worsened by the absence or inefficiency of the gutters in the structure [4].

Figure 1: (a-b) some cracks on the various facade of the building (2015); (c) collapse of a portion of the southern façade (2016).

In 2016 a portion of the southern façade suddenly collapsed. The collapse is presumably due to the collapse of the masonry pillars that supported the vaults of the underlying plan. Another collapse followed in 2019.

2 MODELING STRATEGY

The building is located on a plane with a slight slope of about -0.15% to the north, in an area concentric to the city of Racconigi (259 m above sea level in the northern part of the "Pianura Cuneese"), historically influenced by the depositional process of the Maira torrent whose riverbed is currently spaced about 800 m west of the building. The first stratigraphic indications of the soil were obtained from the documentation on the hospital's thermal power plant; however, specific analyses were subsequently carried out, which determined the characteristics of the soils more precisely [3].

Given the complexity of the problem, in a first approach to the study, the superimposed structure has been modeled through a low fidelity approach, essentially using finite shell elements and without considering the opening. Instead, for the soil-foundation system, brick and shell elements with 8 and 4 nodes, respectively (3 Degree of Freedom – DoF and 6 DoF at each node) have been used.

The superimposed structure has been modeled to consider in a simplified way the effect of its mass and stiffness distribution along the foundations. To this aim, the soil-foundation-structure system has been calibrated, going to update the equivalent values of Young's moduli of floors and masonry walls for the different sleeves. The updating was possible thanks to the availability of the experimental modes identified after an intensive experimental campaign carried out in situ by the authors. The results of the calibration, reported in Table 1, demonstrate how the grey-box representation of the updated superimposed structure is able to satisfactorily trace the first two modes of the building, providing a good estimate of the global stiffness/mass distribution of the system, which is the aim of the low-fidelity representation of the superimposed structure.

Table 1: Results of the numerical calibration of the superimposed structure: (a) natural frequencies. (b) Modal Assurance Criterion (MAC).

The Finite Element (FE) model of the soil counts 219716 elements and 41754 nodes, with a maximum mesh size of 2 m. The main dimensions of the soil volume in the vertical and horizontal direction have been chosen starting from the geotechnical campaign results carried out by [3]. Starting from these data, the total depth of the volume was fixed to 18 m, while the distance between the soil edge and the foundation was fixed to 5 m in each direction. The total dimensions of the soil volume resulted in being 127 m in the East-West direction (X direction in the FE model), 88 m in the North-South direction (Y direction in the FE model), and 18 m in the vertical direction (Z direction in the FE model). The total number of soil layers follows the experimental findings (see Figure 2 for clarity). Finally, the foundations are laid at a depth of 3 m from the surface. The data of the elastic properties of the soil obtained by the geotechnical investigation are reported in Table 2.

Table 2: Available elastic properties of the soil used to build the FE model.

Layer 3 was divided into 2 sub-layers because of the presence of the water table, which oscillates from a minimum of -5 m up to a maximum of -3 m, where it touches the building's foundations [3], [5]. In the absence of more information, the Poisson ratio was set to uniform in the model and equal to 0.33 at the time of the geotechnical investigations. For the foundations, Young's modulus of 2 GPa and a density of 1800 kg/m³ were then assumed. The vertical faces of the soil volume were then fixed in the horizontal direction, while a total restraint was given to the bottom face (at -18 m).

3 SIMULATIONS AND RESULTS

The simulations are aimed to numerically study the influence of soil conditions on the modal and the static response of the structure for Structural Health Monitoring (SHM) of the building. The structure is known to be affected by the water table oscillation, which affects the elastic

properties of layer 3 of the FE model. The oscillation of the water table affects the saturation of the overlying layers, as demonstrated by several literature studies, e.g. [6], [7], [8], [9]. This is mainly due to the capillary rise of water in the soils (in this case, mainly sands) and obviously to the infiltration properties of the surface layers, which allow the access of meteoric rains to the depth. Thus, the rain contributes not only to the direct modification of the degree of saturation on the surface but also to the modification of the height of the aquifer, and therefore (indirectly) to the modification of the capillary rise and the degree of saturation of the soil above the aquifer. Then, the elastic properties of the soil are affected by the degree of saturation as demonstrated by several studies, e.g. [10], [11], [12], [13], [14]. In this study, the elastic properties of layer 3 are supposed to vary in accordance to the wave speed laws derived and experimentally validated by [10] starting from the Van Genuchten relation [15]:

$$V_p(S_r) = V_p^s + \frac{V_p^d - V_p^s}{[1 + (a_p S_r)^{n_p}]^{m_p}} \quad (1)$$

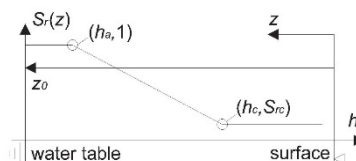

$$V_s(S_r) = V_s^s + \frac{V_s^d - V_s^s}{[1 + (a_s S_r)^{n_s}]^{m_s}} \quad (2)$$

where V_p^s , V_p^d , V_s^s , V_s^d and S_r are the *saturated* and *dry* P-wave and S-wave velocity and degree of saturation respectively, while a_p , n_p , m_p , a_s , n_s , m_s , are empirical model parameters. Starting from the P-wave and S-wave velocity it is possible to evaluate the Poisson ratio, ν , [13] by combining the theoretical formulations for the oedometric modulus M , Young's modulus E and shear modulus G :

$$M = V_p^2 \rho; G = V_s^2 \rho; E = M \frac{(1 + \nu)(1 - 2\nu)}{(1 - \nu)} = 2G(1 + \nu) \quad (3)$$

$$\nu(S_r) = \frac{V_p^2(S_r) - 2V_s^2(S_r)}{2(V_p^2(S_r) - V_s^2(S_r))} \quad (4)$$

where ρ denotes density. From equations (3) and (4), it is possible to conclude that having $V_p(S_r)$, $V_s(S_r)$ and ρ it is possible to derive the elastic properties of the soil as a function of the degree of saturation. In the present paper the laws (1) and (2) are those reported in [10] for sand (see [10] for the model parameters). Then the laws have been normalized to the values obtained from the geotechnical campaign in order to maintain a consistency of the analyses with the case study. Regarding the degree of saturation in the soil layer, it was assumed to be linearly variable between the *air entry height* region h_a , and the *maximum capillary height* region h_c , evaluated starting from the water table depth [6], [9]. For height lower than h_a the soil is known to be saturated (i.e., $S_r=1$), while for height over h_c the degree of saturation tends to be uniform, and in the first approximation it was assumed to be constant and equal to S_{rc} . Thus, the model that describes the variation of S_r along the soil depth z from the surface (positive downwards) is:

$$S_r(z, z_0) = \begin{cases} 1; & \text{for } h(z, z_0) \leq h_a \\ 1 + \frac{1 - S_{rc}}{h_c - h_a} (h_a - h(z, z_0)); & \text{for } h_a < h(z, z_0) < h_c \\ S_{rc}; & \text{for } h(z, z_0) \geq h_c \end{cases} \quad (5)$$

Figure 3: Scheme of the linear model assumed for the degree of saturation S_r along the depth z .

where $h_c > h_a$. In the equation, $h = z_0 - z$ and z_0 represents the depth of the water table (i.e., variable from 5 m to 3 m in the present study), while z varies from 5 m to 2 m in the present application (thickness of the 3rd soil layer). For the study, the average values for sand reported in [9], [16], [17] have been used for the air entry height and the maximum capillary height ($h_a = 0.22$ m and $h_c = 0.59$ m). Figure 3 depicts a schematization of the model defined by equation (5). Finally, to practically cast the results of (5) in the FE model, which is discretized in uniform soil layers, the average degree of saturation $S_{r,avg}$ along the 3 m of thickness of layer 3 has been calculated and used for the evaluation of the elastic properties with equations (3) and (4).

The aforementioned methods have been applied to carrying out a parametric analysis focusing the attention on the effect of soil characteristics on the modal response (in terms of the first two identified natural frequencies) and the static response (in terms of the standard deviation of foundation settlements). In the study, only the elastic characteristics of layer 3 have been changed, maintaining constant the properties of the first two soil layers.

Figure 4 shows the variation of the first two natural frequencies of the model as a function of z_0 and S_{rc} . The figure demonstrates as a sudden decrease in frequency is detected when the soil saturation increases (decrease of water table depth or increase of S_{rc}). Extremely dry condition of the soil, such those one caused by extreme warm seasons, will thus result in an increase of natural frequency. The absolute variations are however very low and without intelligent feature extractions the effect of the alteration of the third soil layer in the "Chiarugi" pavilion could be confused with other Environmental and Operational Variations (EOVs).

Figure 4: (a) First natural frequency of the calibrated FE model as a function of the degree of saturation of superficial layers S_{rc} and the water table depth z_0 . (b) second natural frequency of the calibrated FE model.

Figure 5 reports the results of the static analysis. In Figure 5a, the standard deviation of the foundation settlements is reported. From the figure, it is also clear that an increase of the saturation in the soil produces an increase of the standard deviation of the settlements. Figure 5b, instead, depicts the settlement profiles at the foundation's depth in case of dry ($z_0=5$ m and $S_{rc}=0$) and saturated ($z_0=3$ m and $S_{rc}=1$) conditions of the third layer. Comparing Figure 5b with Figure 5c (which depicts the actual condition of the building), it is possible to note how the corroboration of the FE model with the experimental data gathered during the geotechnical campaign can positively produce fitting results since the maximum depression zone foreseen by the model coincides with the area below the collapsed portion of the structure.

Figure 5: (a) Standard deviation of the foundation settlements as a function of the degree of saturation of superficial layers S_{rc} and the water table depth z_0 . (b) foundation settlements for the dry (red) and saturated (blue) condition of the 3rd soil layer. (c) Google Maps picture of the structure (lat. 44.765470, long. 7.678842) on March 3rd, 2021 with highlighted (see the red circle) the collapsed portion of the building <https://www.google.it/maps>.

Figure 6: Results in terms of normalized values.

The previous results demonstrate as the modal and the static response of the building are quite correlated. In particular, the standard deviation of the foundation settlements has been considered in this study since it is related to the potential damage of the superimposed structure.

The results of the study are presented in Figure 6 in a normalized scale. In Figure 6, the following quantities are depicted:

$$n_{f,j}(S_{r,avg}) = \frac{f_j(S_{r,avg})}{f_{j,s}} \quad (6)$$

$$n_{\sigma}(S_{r,avg}) = \frac{\sigma_c(S_{r,avg})}{\sigma_{c,s}} \quad (7)$$

$$r_{12}(S_{r,avg}) = \frac{f_1(S_{r,avg})f_{2,s} - f_2(S_{r,avg})f_{1,s}}{f_{1,d}f_{2,s} - f_{2,d}f_{1,s}} \quad (8)$$

with $j=1,2$; f_j j -th natural frequency; $f_{j,s}$ j -th natural frequency at saturation; $f_{1,d}$ and $f_{2,d}$ 1st and 2nd natural frequency in dry conditions; σ_c , standard deviation of the foundation settlements; $\sigma_{c,s}$, standard deviation of the foundation settlements at saturation, while $n_{f,j}$, n_{σ} , and r_{12} are the j -th natural frequency normalized to the saturated value, the standard deviation of the foundation settlements normalized to the saturated values, and the difference between $n_{f,1}$ and $n_{f,2}$ normalized to the difference between the values taken in $S_{r,avg} = 0$. From Figure 6a, the relative variation of the first two natural frequencies demonstrates as the main variations are detected for the first mode and are in the order of 0.4%. On the other hand, Figure 6b depicts a relative variation of the standard deviation of the settlements of about 6%. Despite the fact that these variations are not worrying for the immediate stability of the building, their cyclic nature can determine damage accumulation in the superimposed structure, bringing in time to brittle collapses such as those occurred in the South façade of the "Chiarugi" pavilion. It is worth stressing that data and parameters extracted from real dynamic monitoring systems would be affected by several EOVs (such as the temperature effect) that could hide variations due to soil conditions. Commonly these EOVs, acting on the whole system, do not affect only the first natural frequency. Thus instead of focusing the attention on the variation of single frequencies, intelligent algorithms could be applied to the relative variations of these parameters (see, for example [18]). In these terms, Figure 6c conceptually shows as the normalized difference of the normalized frequencies can provide a correlation to the static response that is more amplified.

4 CONCLUSIONS

The paper investigated the influence of soil conditions, in terms of water table depth and degree of saturation, on the modal parameters of the "Chiarugi" pavilion. The modal response of the soil-foundation-structure system has also been correlated to variables potentially associated with the occurrence of damage in the superstructure (i.e., the standard deviation of the foundation settlements). The results of the study can be summarized in the following points:

- The absolute variations of the natural frequencies with respect to the variation of the degree of saturation of the third soil layer are quite low (maximum variations of about 0.4%);
- A variation in the first natural frequency value is reflected on a variation of the standard deviation of the settlements, which is an order of magnitude higher than that of the frequency (i.e., about 6%);
- Despite the low variations of natural frequency, the cyclic oscillation of the water table and the meteoric phenomena in Racconigi can change the degree of saturation

of the 3rd soil layer between 0.13 to 1 (under the made assumptions), and this results in a slow material deterioration that can lead to the sudden collapse of the masonry structure, as happened for the "Chiarugi" pavilion in 2016 and 2019;

- The low variations in natural frequency can be amplified if relative variations of the modal parameters of the structure are considered instead of absolute ones and if intelligent algorithms are used to separate the effects of other EOVs.

It is worth underlining that the results of this study are valid under the made hypotheses. For example, in a real scenario, the actual behavior of the soil with respect to the water table oscillation could diverge from linearity. Then, due to the infiltration processes also the soil characteristics of the surface soil layers will be affected by the changes in the degree of saturation, and thus the frequency variations could be even higher than those one reported in the study. These and other aspects (such as a full physical representation of the superimposed structure) will be addressed in future works, which might also focus on the prognosis of the "Chiarugi" pavilion thanks to nonlinear representation of the time degradation of the soil-foundation-structure system and the availability of some experimental variables in time, such as the time histories of water table depth and the degree of saturation of surface soil layers.

Abstract

The seismic vulnerability of unreinforced masonry structures is a relevant topic as they stand for one of the most typical building typologies in the world. Despite the effort carried out by researchers, further experimental campaigns can help to increase the level of knowledge on the most frequent collapse mechanism and to suggest the most adequate reinforcement technique for the specific case. In this context, we address here a study on a mixed construction technique, in particular a type of building with masonry walls and concrete slabs, the so-called “Placa” buildings. Such buildings are typical of the Lisbon region and were mainly erected from 1930 to 1960. In this period, there was low awareness about the effects of adding heavy slabs to the global and local behavior of masonry structures. The seismic vulnerability of such structures is high, which is relevant in a medium-high seismic hazard region such as Lisbon.

An experimental campaign will be performed at the University of Minho. The set-up comprises a U-shaped brick wall tested subjected to an out-of-plane load and three tests are planned to perform: an unreinforced and two (different) reinforced configurations.

In this paper, sensitivity analyses concerning the unreinforced wall are shown. The primary goal is the identification of the correct set-up that would allow the exploitation of the energy at the orthogonal connection without leading to undesirable rocking phenomena of the wall. In such a way, the subsequent application of the reinforcement will have a major role in vulnerability reduction.

Keywords: “Placa” buildings, brick walls, out-of-plane, micro-modeling, concrete damage plasticity.

1 INTRODUCTION

Masonry structures are one of the most typical building typologies all over the world. Despite their great efficacy for sustaining gravity loads, they may suffer severe damage when subjected to horizontal loads coming from destructive events like earthquakes [1][2][3]. In recent years, several efforts were made to reduce the seismic vulnerability of such structures [4][5]. Indeed, not only for historical structures, but also for schools [6], hospitals and palaces that assume strategic importance during possible emergency management. Many of these buildings are relatively recent and can present a mixed technology, in which both masonry brick walls and reinforced concrete slabs are combined. A remarkable example of such construction typology is represented by the so-called “Placa” buildings, typical of the urban expansion of Lisbon in the period from 1930 to 1960.

In the progressive trend of introducing the reinforced concrete as the main structural element, the “Placa” buildings are characterized by brick walls, which stand as structural elements and reinforced concrete (RC) slabs. However, such a combination was realized in a period of insufficient awareness of the consequence of adding heavy concrete slabs (if compared to the timber ones) for the local and overall response of the buildings. Many deficiencies, along with inadequate construction details, can be typically found in “Placa” buildings, namely: i) internal structural irregularities, ii) limited capacity of the vertical elements against shear forces and bending, iii) a low number of vertical elements, iv) interruption between floor slabs and masonry walls affecting the rigid diaphragm behavior. All these aspects, combined with the increase of inertia loads because of concrete slabs, might lead to a marked seismic vulnerability, enhanced by the relevant seismic exposition of Lisbon.

An experimental campaign has been planned to investigate the local structural capacity of such buildings. The primary focus is the investigation of the out-of-plane capacity of the brick masonry walls that rarely have enough resistance against forces acting perpendicular, causing local collapse mechanism. Three U-shaped brick walls will be tested by applying a uniform pressure on the internal side of the wall (as done in [7]). The first configuration (unreinforced wall) will serve as a reference for the two subsequent reinforced configurations. To get a damage pattern that resembles what is observed in “Placa” buildings, particular care has been addressed in the design process of the experimental set-up. Indeed, in order to define the most effective strengthening solution and provide a fair comparison, the damage should spread mainly at the connection with the orthogonal walls. For this reason, it is necessary to avoid, or significantly postpone, any rocking of the U-shaped wall. In such a way, the improvements ensured by the reinforcement technique will be more noticeable. To this end, this paper summarizes distinct hypotheses for the geometry, load and boundary conditions on the unreinforced configuration. Damage patterns and load-displacement curves are presented in order to provide a comparison of the results.

2 EXPERIMENTAL PLAN: AN OVERVIEW

In this section, the experimental plan is exposed in each step. I will include: i) material characterization tests, ii) test on one scaled unreinforced configuration, iii) test on two different scaled reinforced configurations. Regarding the firsts, masonry wallets with an English-bond arrangement (the same as the U-shaped walls) have been built and will be tested according to the recommendations given in EN 1052-1:1998 [8] and EN 1052-2 [9]. In particular, 3 wallets will be tested under compression and 3 wallets under diagonal compression in order to define the in-plane behavior. The out-plane behavior will be investigated by testing 5 wallets under

horizontal flexural tests and 5 wallets under vertical flexural tests. Along with these tests, a mechanical characterization of the mortar will be provided.

The geometric configuration of the walls has been defined to represent a typical façade and corresponding transversal walls of a ‘Placa’ building. As mentioned, bricks are arranged according to an English-bond arrangement with dimensions $250\text{mm} \times 120\text{mm} \times 60\text{mm}$. The initial geometric dimensions of the set-up are: 3.24m of façade wall length, walls’ height of 1.40m, transversal walls’ length of 1.20m and thickness of 0.25m. However, as it will be clearer in the next Sections, such initial assumption resulted to not be sufficient for avoiding a rocking of all systems. So, a slight modification of such configuration is later justified.

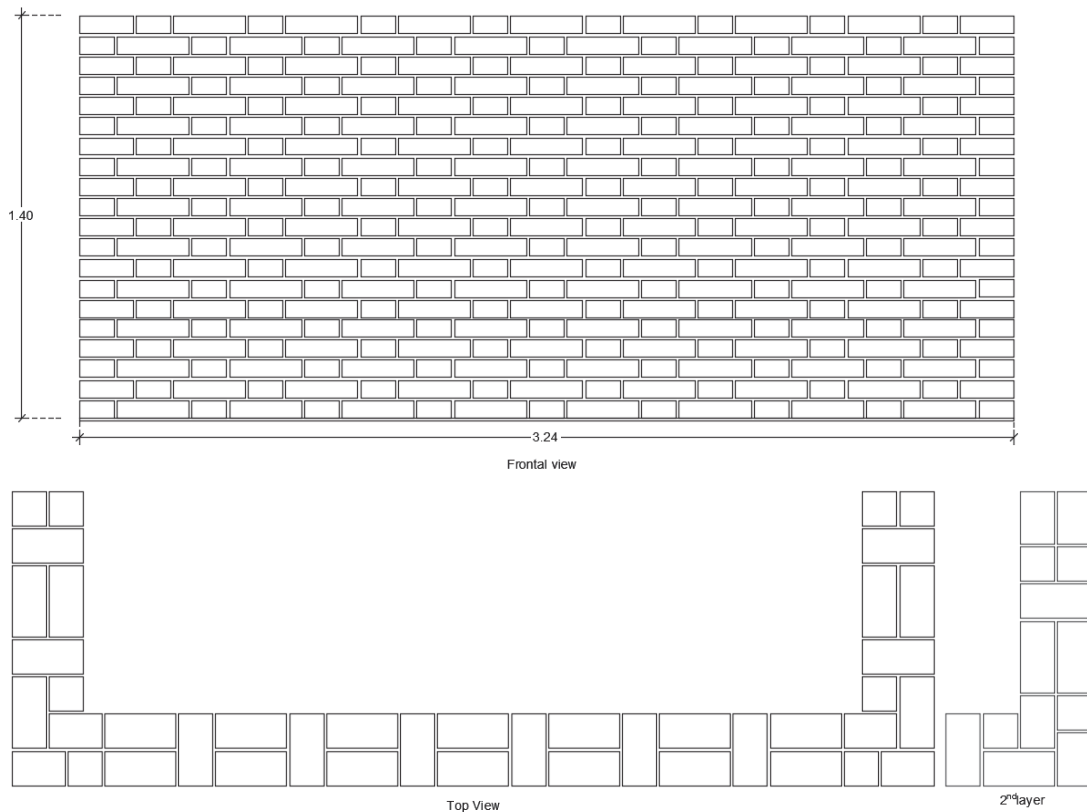

Figure 1 Frontal view (top) and top view (bottom) of the planned configuration.

The plan includes two different strengthening solutions are planned to be carried out: i) an anchored system between façade and transversal walls; ii) a textile reinforced mortar on the outer façade eventually coupled with the anchored system. In order to provide a further reference, the unreinforced wall will be reinforced after the damage and led to the collapse.

3 NUMERICAL STRATEGY: A MICRO-MODELING APPROACH

In the current prediction stage of the experimental campaign, a detailed heterogonous approach has been picked to reproduce accurately the failure modes. In such an approach, the bricks and mortar joints are modeled separately with contiguous 3D elements. No interfaces are interposed between them and the non-linear mechanical properties are exclusively lumped at the joints, addressing only elastic properties to the bricks (as done in [10–12]). Such simplification is reasonable as the good mechanical properties of bricks and the weak capacity of the mortar. Specifically, the mortar intended to be used in the tests is characterized as Mortar5, with a compressive strength equal to 5 MPa. All the analyses are carried out in the FE-based software Abaqus and non-linearities are addressed through the already available constitutive

model Concrete Damage Plasticity. In such a way, it is possible to input a differential behavior in compression and tension and define a specific softening law. In this predictive stage, a tensile strength equal to 0.2 MPa has been addressed to the mortar along with fracture energy of 0.02 N/mm. Regarding the mesh, taking advantage of the symmetry of the setup, a half wall has been modeled. The average size of the 3D brick elements is around 10-20 mm leading to an overall number of nodes around 140000.

Figure 2 Model in Abaqus of half wall and mesh detail.

The analyses are carried out by applying a perpendicular uniform pressure on the internal side of the main wall in order to simulate the load transferred from the airbag that will be used in the experimentation (same procedure followed in [7]). In this way, the analyses are all performed under load control and the arch-length algorithm is employed for obtaining the softening response of the structure. Fixed boundary conditions are imposed at the bottom of the wall where a mortar layer (with the same mechanical properties used for the joints) is posed.

4 NUMERICAL RESPONSE OF THE U-SHAPED URM WALL: PARAMETRIC ANALYSES

The sensitivity (in terms of geometry, pre-stress level and boundary conditions) numerical analyses that will be shown in the next Sections are applied only at the unreinforced masonry case. Indeed, the main goal of the present work is the definition of the correct set-up with the view of applying different strengthening techniques on the same configuration in a subsequent step.

The first parametric analysis concerns the amount of pre-stress that is necessary to impose on the side walls in order to avoid or postpone any rocking phenomena. In Figure 3a it is provided a comparison of the load-displacement curves related to different values of the imposed pre-stress. The control point is picked exactly at the top middle of the wall (red circle in Figure 1). It is important to highlight that the global loads to which reference is made are related to the half specimen. As it is noticeable, the U-shaped wall tested with no pressure on the top of the side walls is characterized by a marked softening behavior. However, as shown in Figure 3b, such behavior is associated with a rocking phenomenon that is not desirable. The softening branch is strongly reduced at the increase of the pre-stress applied, reaching a plateau when a pre-stress of 100 kPa is considered. In fact, in Figure 3c, it is possible to appreciate the reduction of the damage at the bottom of the wall. However, its extent is still too clear and further sensitivity analyses are required.

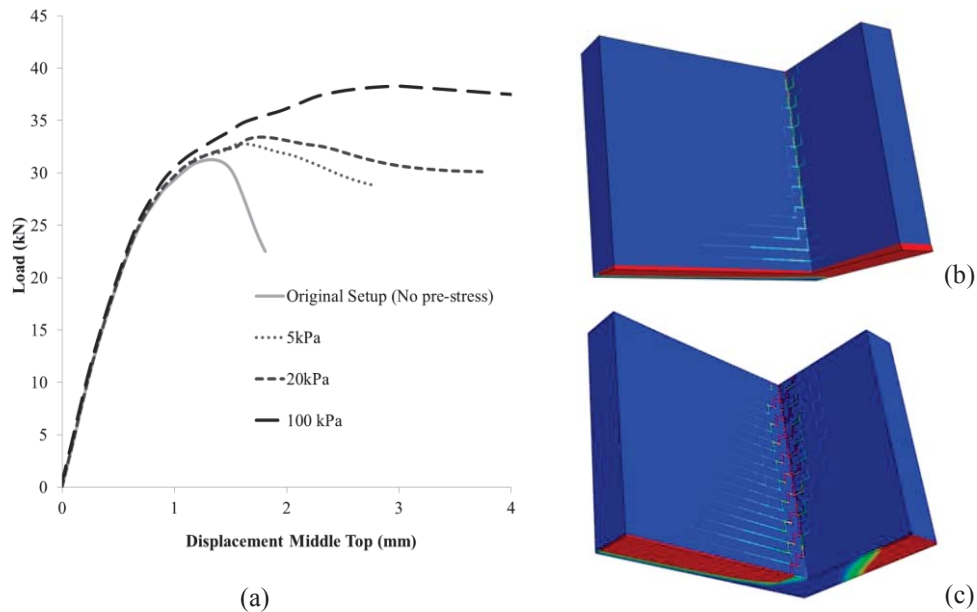

Figure 3 Load-displacement curves related to the wall in its original configuration by applying different values of pressure (a); damage configuration of the wall without pre-stress(b); damage configuration of the wall subjected to a pressure of 100 kPa (c).

The next sensitivity analyses are focused on the possibility to impose further constraints. In Figure 4 it is provided a qualitative overview of the results obtained. In particular, in Figure 4a the back face of the side wall is constrained. This hypothesis can be implemented by embedding the back portion of the lateral wall in U-shaped steel beams (a similar setup can be found in [13]). In such a way, the rotation of the side walls is prevented and the damage spread mostly at the connection as required. A similar result can be achieved by imposing a steel beam above the top back corner of the lateral walls. As it is noticeable in Figure 4b the damage pattern can be superimposed to the previous case. These strategies are highly efficient but, on the other hand, the control of the load attained by such constraints might be complicated.

In Figure 4c-d it is shown an attempt of modifying the boundary conditions at the base of the wall. In Figure 4c, the first layer of brick and mortar is furtherly constrained, but in such a way the rocking trend is only delayed. In Figure 4d, a different hypothesis has been made. In this case, the central wall is considered only supported at the base (a layer of sand can serve the purpose) leading to a single curvature bending moment. However, the damage pattern is concentrated mainly at the connection at the base of the walls

Figure 4 Boundary condition applied at the back face of the side wall and related damage pattern (a); boundary condition applied at the top of the side wall and related damage pattern (b); boundary condition applied at the bottom (fixing two layers of bricks) of the side wall and related damage pattern (c); boundary condition released at the bottom of the main wall and related damage pattern (d).

From the previous analyses, it seems evident the necessity to change the original geometric configuration presented in Section 2. So, a parametric analysis is conducted on the length of the main wall and side walls. These lengths are increased to 25 cm (model “SWL_25cm” that stands for Side Wall Longer of 25 cm) and to 50 cm (model “SWL_50cm”). The main wall is modified by adding 80 cm and 120 cm (model “402_SWO”) that stands for the main wall of 402 cm and the Side Wall Original and model “442_SWO”). Also, a combination of both modifications is provided in the models “402_SWL_25cm” and “442_SWL_25cm”. In all the cases a vertical pre-stress of 20 kPa is imposed.

In Figure 5 the global responses of all the models are reported. It is interesting to notice the strong enhancement that the extension of the side walls can provide (Fig. 5a). From a comparison of the capacity curves, the outcomes are very similar to the one obtained when a vertical pre-stress of 100 kPa is imposed. However, comparing the damage pattern (Fig. 6a-b), the rocking behavior is much less evident. Moreover, no evident differences can be noticed among the curves related to the models SWL_25cm and SWL_50cm but as shown in Figures 6a and 6b the damage at the base of the side wall is almost absent in this case. This might have huge relevance when the reinforced configurations will be treated.

Figure 5b provides the results related to the extension of the main wall (also in combination with an extension of 25 cm of the side walls). It is quite evident how increasing the length of the side walls is much more effective than extending the longitudinal dimension of the main wall. Moreover, this strategy would require much more material for the construction of the walls without leading to further improvements (see the comparison of the damage pattern in Figure 6a and Figure 6c).

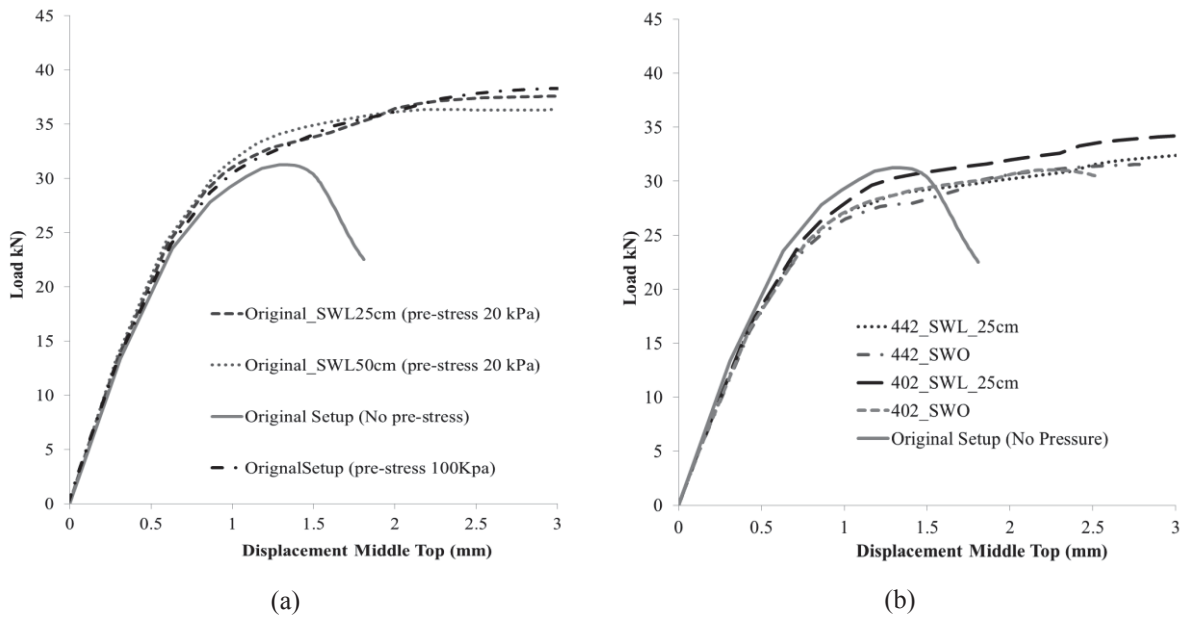

Figure 5 Load-displacement curves related to the original setup by changing the length of the side walls (a); Load-displacement curves of the original setup by changing the length of the main and of the side walls.

5 CONCLUSIONS

The paper summarizes preliminary analyses conducted on an unreinforced brick masonry wall. The main scope was the definition of the correct set-up in terms of geometric configuration, the load applied and boundary conditions for upcoming experimental tests that will be performed at the facilities of the University of Minho in Guimarães.

The experimental campaign will focus on the seismic vulnerability and possible strengthening solutions for building realized with a mixed technology: masonry walls and RC slabs. The so-called “Placa” buildings are a typical example of such configuration, and particularly vulnerable as mainly spread in the Lisbon region. In order to resemble this structural typology, a U-shaped brick wall has been conceived. Several parametric analyses have been carried out to highlight the parameters that have more influence on both the global behavior and collapse mechanism. The different proposed scenarios revealed the necessity to adapt the initially planned configuration to prevent any rocking mechanism of the structure that would be undesirable. In fact, the occurrence of such a collapse mechanism would prevent the spread of damage at the connection between transversal walls, which will be the point of more interest when defining the strengthening solutions will be discussed. In the upcoming numerical analyses concerning the reinforced scenarios, the

composite materials might be added using a detailed micro-modeling [10][14] or through a simplified approach [15]. Whereas, the anchors might be introduced explicitly in the model or through truss FEs [7] avoiding an increase in the computational demand.

Abstract

Unreinforced masonry (URM) buildings are one of the most common constructions in developing countries and are usually constructed based on traditional knowledge without engineering intervention. Due to poor seismic performance of URM buildings, the development of seismic protection systems can play a key role in the mitigation of losses in future earthquakes. Despite the availability of different interventions for seismic strengthening of URM buildings, the quest for a cost-effective technique still exists. On the basis of recent outcomes by these authors, this study presents the design of low-cost base isolation systems for a class of URM buildings deemed representative of the building stock of developing countries. The proposed base-isolation system is made by recycled-rubber fibre-reinforced elastomeric isolators (RR-FREIs). Building classes were defined by properly selecting those parameters which are expected to mostly affect the seismic behaviour of the building such as number of storeys, masonry type and in-plan irregularity. Three-dimensional numerical models of URM buildings were developed in SAP2000 using nonlinear layered shell elements and bilinear models for RR-FREIs. Nonlinear time history analyses were carried out for a set of ground motion records to investigate the performance of both fixed-base (FB) and base-isolated (BI) configurations of URM buildings. The comparison of results shows a significant reduction of inter-storey drift ratios for BI configuration, thus demonstrating the effectiveness of RR-FREIs.

Keywords: Unreinforced masonry buildings, base isolation system, recycled rubber, fiber reinforced elastomeric isolators, finite element analysis.

1 INTRODUCTION

Unreinforced masonry (URM) buildings are usually constructed using locally available bricks, based on traditional knowledge without engineering intervention. Such non-engineered constructions (NEC) are highly susceptible to damage when subjected to lateral loads like seismic motion. This is mainly due to the lack of seismic design, low strength construction materials and poor structural detailing [1]. The common URM buildings found in developing nations of the world are constructed using masonry walls with roofs made up of reinforced concrete. Such type of buildings tends to develop deep cracks and undergo significant damage even under moderate earthquakes [2]. The collapse of such non-engineered and semi-engineered buildings during seismic events had resulted in huge losses especially in developing nations like India, Nepal, Philippines, Pakistan, Mexico, and Indonesia. Notable events include the 2006 Yogyakarta earthquake and 2005 Kashmir earthquake in India and Pakistan, respectively [3].

Considering the economic impact, the complete replacement of NECs with earthquake-resistant buildings is unfeasible. Hence, there is a need for a sustainable control strategy with reduced cost. One of the promising solutions is the base isolation technology in which the seismic response of the superstructure is reduced by introducing isolation bearings between the superstructure and the foundation of the building [4,5,6]. However, the cost of the base isolation system being high, the application is usually limited to important structures such as hospitals and historic buildings. The continuous development in this field had led to the development of novel configurations of elastomeric bearings for base isolation. Among these, fibre-reinforced elastomeric isolators (FREIs) have been developed in the recent years as an alternative to conventional laminated rubber bearings [7,8]. The replacement of internal shims with flexible reinforcement makes FREIs less heavy and easier to install in comparison with conventional isolators.

In order to further reduce the cost of FREIs, significant research effort is being dedicated currently to developing a novel elastomeric bearing using recycled rubber. The extremely low cost of recycled-rubber fibre-reinforced elastomeric isolators (RR-FREIs) would make them highly suitable for application in developing nations [9,10,11,12]. However, research on the suitability and effectiveness of the novel RR-FREIs for base isolation of URM buildings is scarce in the literature [13]. A recent study by Losanno et al. investigated the effectiveness of RR-FREIs for a box-type URM building in developing nations [14]. The study assessed the response of fixed-base (FB) and base-isolated (BI) building models developed based on macro-modelling approach using SAP2000 [15]. The use of such simplified macro-modelling approach for nonlinear analysis of base-isolated structures can be widely seen in the literature [16, 17]. Developing a suitable modelling approach with acceptable accuracy is necessary to capture the exact response of the masonry structures [14,18,19,20].

In this context, the present study aims at investigating the effect of low-cost base isolation system on typical URM buildings from the stock of developing nations. Three building types were chosen in order to address the effect of plan variability, wall density and number of storeys on effectiveness of base isolation under a set of earthquake records. Nonlinear time history analyses of the FB and BI-URM buildings were carried out using a simplified three-dimensional numerical model developed in SAP2000.

2 SELECTION OF CASE STUDIES

Three different masonry buildings representing URM buildings in developing nations are considered for the aim of the study. The first building prototype (URM1) is a single-story building reported by Shahzada et al. (2012) with plan dimensions 4.115 m \times 3.505 m, built

with 0.228-m-thick walls as shown in Figure 1a. The experimental and numerical analysis results of URM1 are available in the literature [14,21,22]. The second building prototype (URM2) is selected based on a detailed investigation on the URM building stock in developing nations and the building plan with dimensions 8.0 m \times 6.0 m is shown in Figure 1b. The building plan is framed by also considering the Indian Standards for earthquake design [23]. The third building prototype (URM3) considered in the study is a two-storey building with the same building plan of URM2.

Figure 1: Plan view of URM buildings: (a) URM1; (b) URM2 and URM3.

The wall thickness is constant in plan and elevation, and equal to 0.228 m; the roof of the URM buildings was considered to be made up of 0.152 m reinforced concrete slab. Further, the buildings were also provided with a 0.152 m thick RC lintel above the openings to improve the building resistance to gravity loads. The inter-storey height of the structures was taken equal to 3.3 m. Mohr-Coulomb failure criterion with associated flow rule was used for simulating the inelastic shear behaviour and failure of the masonry. The RC elements were assumed as linear elastic and a rigid diaphragm constraint was assigned to the roof level of the buildings.

In order to consider the variability of mechanical properties, the material properties of the masonry structures considered in the present study were selected from previous studies on URM buildings located in developing nations such as India, Nepal, Pakistan and Iran [21,24,25,26,27]. The statistical distributions, mean value and coefficient of variation (CoV) of the main material properties are listed in Table 1.

Material properties	Distribution	Mean	CoV
Mass density [kg/m^3]	Lognormal	1707.5	0.13
Compressive strength [MPa]		4.2	0.43
Tensile strength [MPa]		0.16	0.56
Shear strength [MPa]		0.24	0.66
Young's modulus [MPa]		1302	0.68

Table 1: Material properties of URM buildings.

3 DESIGN OF BASE ISOLATION SYSTEM

Detailed research on RR-FREIs has been carried out in the recent years both numerically and experimentally. The RR-FREI sample and its experimental shear behaviour obtained from Losanno et al. (2020) is shown in Figure 2 [12]. These bearings are made up of rubber grains from used tires and industrial leftovers that are crumbled and glued together. The devices are installed in unbounded configuration in order to achieve an easier installation and significantly releasing internal stress within the isolator. The cost of this innovative RR-FREIs has been estimated in the order of 10% of the cost of conventional laminated rubber bearings.

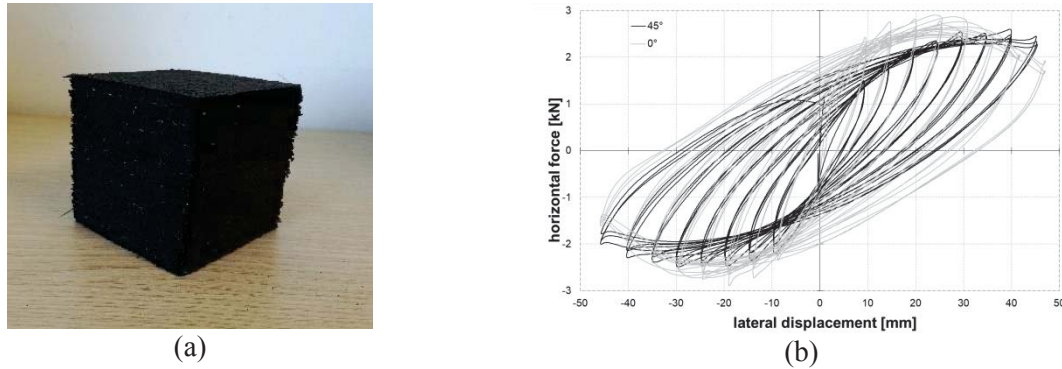

Figure 2: RR-FREI prototype: (a) picture; (b) experimental shear behaviour [12].

The weight of the building plays a major role in the design of rubber-based isolation systems. Considering the low weight of single-story URM buildings, only a smaller number of bearings would be required to achieve a conventional target period in the range of 2.00 to 2.50 s. But the requirement of a deep beam spanning over the whole length of the masonry walls poses a major challenge. In order to maintain the overall lateral stiffness of the system, a suitable trade-off needs to be identified while designing the base isolation systems with a limited number of bearings trying to avoid a deep base-beam. In the present study, the reinforced concrete base beam was designed in accordance with Indian code provisions confirming minimum concrete strength and internal reinforcement for URM buildings. The width of the base bond beam is maintained same as that of the wall thickness. Dead load analysis of finite element model was carried out with varying support locations to identify the most suitable position of the least number of isolators while satisfying the requirements in terms of both stress and deformation limits provided by the code. The number of isolators used in the three BI-URM buildings considered in the present study is equal to 8 (URM1) and 15 (URM2 and URM3), respectively. The layout of the isolation bearings is shown in Figure 3.

The properties of the square RR-FREIs used in the building prototypes are listed in Table 2. Square-shaped devices are considered for the possibility of easy cutting RR-FREIs from larger size rubber pads. The width of the bearing is defined according to stability requirements. The target period of BI-URM buildings is obtained as a trade-off between the longer period range for a more significant mitigation of spectral accelerations and the lower period value corresponding to limited displacement demand of the isolation system.

According to previous studies by the authors, the stability limit and damping capacity of RR-FREIs were set equal to 50% shear strain and 15% of critical damping, respectively [11]. Shear modulus for URM1 was set equal to 0.70 MPa [14]. A lower value of that modulus, i.e. 0.40 MPa, was selected for URM2 and URM3 in order to obtain a more stable geometry of the bearings. A laboratory investigation is being developed in order to reduce the shear modulus to a value which is typical of a softer compound.

Figure 3: Location of RR-FREIs in URM buildings: (a) URM1; (b) URM2 and URM3.

Building model	FB fundamental period (s)	Target BI	Target displacement (mm)	Equivalent damping (%)	Shear modulus (MPa)	Rubber height (mm)
URM1	0.12	1.30	60	15	0.70	120
URM2	0.10	1.50	150	15	0.40	300
URM3	0.14	1.70	170	15	0.40	340

Table 2: Properties of RR-FREIs used in BI-URM buildings.

Due to increasing weight, a higher target period can be achieved with larger URM buildings, i.e. URM2 and URM3 in comparison with URM1. The variability associated with the properties of the isolators is not considered in the present study.

4 NUMERICAL MODELLING OF URM BUILDINGS

Masonry being a complex material demands extensive computational effort and experienced users in order to model the exact characteristics of the structure. Further, the inclusion of orthotropic properties of masonry requires additional material properties that are not readily available. Thus, a detailed experimental study on the masonry structure under investigation is necessary to reproduce the realistic behaviour of the masonry through numerical modelling. Hence, simplified macro-modelling techniques are preferred when the aim of the research is mainly focussed on the global behaviour of the structure. In macro-modelling techniques, masonry is modelled as a homogeneous material with equivalent mechanical properties.

The numerical model of the buildings was developed using this simplified macro-modelling approach in SAP2000 software package with nonlinear layered shell elements. In this macro-modelling approach, masonry was considered as an isotropic material. The shell layers are defined with different constitutive law in the thickness direction. Two stress-strain curves corresponding to normal and shear stresses were used to represent the nonlinear behaviour of the masonry [1,16]. The uniaxial compressive strength of the masonry was defined based on the analytical model developed by Kaushik et al. [28]. The uniaxial tensile strength of the masonry was defined based on the relationship suggested by Akhaveissy and Milani

[29]. The presented numerical approach had also been proven to be accurate and computationally efficient compared to other micro modelling approaches used in masonry modelling. The comparison of numerical and experimental results of the box-type structure can be seen in Losanno et al. [14]. Furthermore, a detailed research article on the comparison of different macro-modelling approaches for URM buildings highlights the suitability of this method [30]. In case of base-isolated buildings, the RC base beam is modelled using linear elastic frame elements. The RR-FREIs are modelled using a simplified bilinear model to account for non-linear behaviour of the bearings. The initial and post-yielding stiffness values were used in order to provide the effective stiffness and equivalent damping ratio obtained with the base isolation system design according to values listed in Table 2. The numerical models of the base-isolated buildings along with their first mode of vibration are shown in Figure 4. The first mode of BI-URM buildings clearly shows the rigid-body motion in the superstructure.

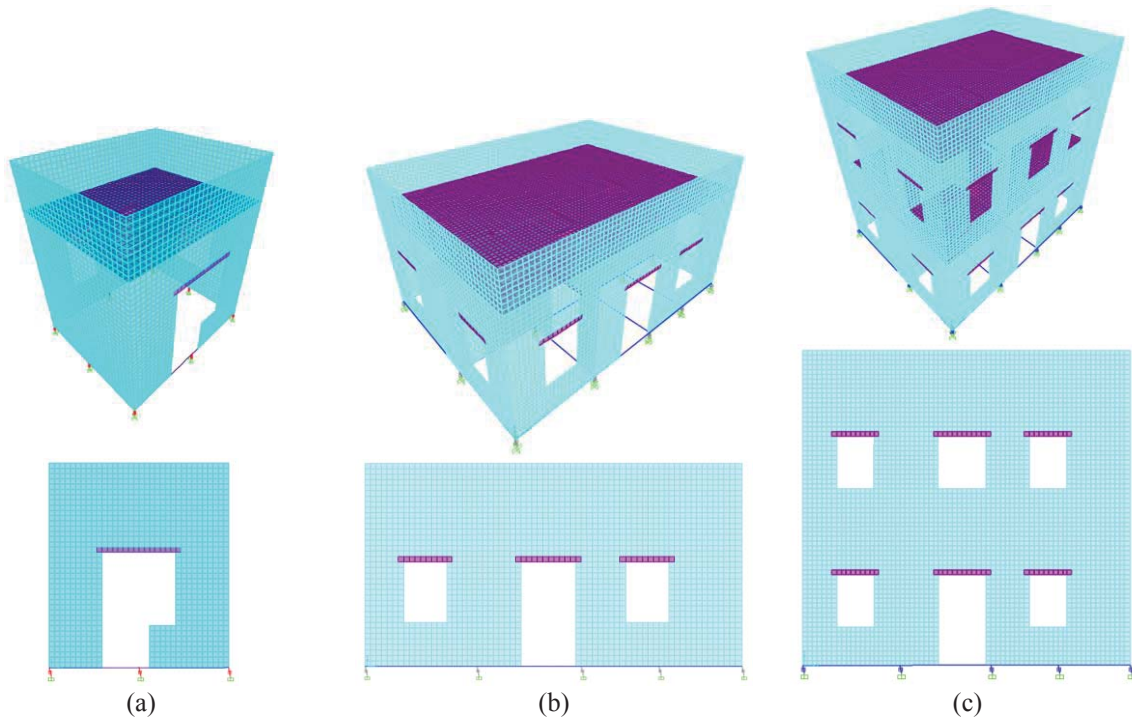

Figure 4: Numerical model (first mode of vibration) of base-isolated buildings using RR-FREIs: (a) URM1; (b) URM2; (c) URM3.

5 SEISMIC ANALYSIS OF URM BUILDINGS

In order to consider the uncertainties associated with earthquake ground motion (i.e. record-to-record variability), the response of the FB- and BI-URM buildings was studied under 20 ground motions recorded in several developing nations all around the world. The peak ground acceleration (PGA) of the selected records ranges from 0.01g to 1.78g. The moment magnitude and epicentral distance of the earthquakes associated with those ground motions range from 5.2 to 7.9 and 2.2 to 190 km, respectively. The variation of PGA with moment magnitude and epicentral distance of the ground motions is shown in Figure 5.

In order to model uncertainties associated both with the ground motions and material properties, Latin hypercube sampling (LHS) technique is used in the present study to select the random variables. Using this technique, 20 sets of random parameters were selected and randomly combined with 20 ground motion records. Then, direct integration nonlinear time-history analysis (NLTHA) of FB- and BI-URM buildings was carried out and the structural

response is obtained. Thus, a total of 120 NLTHAs were carried out over the different cases considered in the study.

Figure 5: Selected input ground motion records: (a) PGA vs. moment magnitude; (b) PGA vs. epicentral distance.

6 RESULTS AND DISCUSSION

Structural response in terms of inter-storey drift ratio (IDR), which is the ratio between relative lateral displacement measured at the roof level and inter-story height, was computed for all case studies. IDR values were studied due to their direct correlation with the damage of the masonry buildings. The range of IDR corresponding to different damage levels varies in accordance with the building type and material strengths [31]. Previous studies suggest that IDR values greater than 0.2% usually correspond to extensive damage and significant strengthening interventions would be necessary. As far as isolators' displacements are concerned, a maximum response value was not explicitly given since the present study mainly focused on effectiveness of base isolation on seismic response of URM buildings. As a further development of the subject, the authors will study the fragility of the different structural components including base isolators.

6.1 URM1 building

The comparison between FB and BI configurations of URM1 building is shown in Figure 6. The results clearly highlight the effectiveness of base isolation. Under $PGA = 1.78g$, the reduction in IDR in the BI-URM building reaches approximately 91% whereas the reduction corresponding to the lowest PGA level, i.e. $0.04g$, is about 40%. It is also important to note that the IDR values of BI-URM1 building under all the earthquake excitations would be less than 0.2%, which demonstrates the absence of extensive damage. Furthermore, comparatively higher reduction in IDR is observed under seismic excitations with $PGA > 1g$. The percentage reduction of IDR in BI-URM1 in comparison with FB-URM1 building is shown in Figure 7, with average value equal to 63% over all shaking intensities. For ground motion records with $PGA \approx 1g$, a wide variation in the building response is observed due to the combined variation in material properties and record characteristics. It can be noted that a linear regression model would be poorly accurate in providing an estimate of IDR reduction versus PGA due to significant non-linear behaviour in both FB- and BI-URM buildings.

Figure 6: Seismic response of URM1 building.

Figure 7: Percentage reduction in IDR of base isolated URM1 building.

6.2 URM2 building

URM2 building prototype is considered to identify the effect of base isolation with the variation in wall density along the direction of excitation (X-axis) and plan area in comparison with URM1 building. The response of URM2 building under earthquake excitations is shown in Figure 8. A significant reduction in IDR is observed in BI-URM2 building.

Figure 8: Seismic response of URM2 building.

Similar to URM1 building, the base isolation technique is found to be more effective under seismic excitations with $PGA > 1g$. The reduction in IDR due to base isolation under earthquake ground motion with $PGA = 1.78g$ is around 98% and response reduction in BI-URM2 building under varying PGA is shown in Figure 9. The average percentage reduction in IDR is about 66%, i.e. a higher value in comparison with URM1 building.

Figure 9: Percentage reduction in IDR of base isolated URM2 building.

6.3 URM3 building

URM3 building is considered in the present study to assess the effect of an increased number of storeys. The two-storey URM building is deemed more representative of a common building type found in developing nations, classified under low-to-medium income socio-economic people. The building response in terms of IDR is shown in Figure 10 and the percentage reduction is given in Figure 11. The properly designed base isolation system offers a great reduction in terms of structural response, thus avoiding severe damage even under higher PGA levels. The average percentage reduction in IDR of URM3 building is about 81%, which is significantly higher than that predicted on others URM buildings due to increased mass of the building. Differently from previous cases, a linear regression model would result more accurate in predicting IDR reduction. These outcomes confirm the effectiveness of RR-FREIs under medium-size URM buildings, laying the basis for a further development of the subject.

7 CONCLUSIONS

In the present study, a low-cost base isolation system using recycled-rubber fibre-reinforced bearings for URM buildings in developing countries is assessed. Three URM buildings are selected as representative of nonengineered constructions and the numerical models are developed in SAP2000 using nonlinear layered shell elements. The base isolation system is designed for all the selected buildings and modelled using a simplified bilinear model. Statistical distributions of material properties were calibrated from previous studies available in the literature. Then, the nonlinear time history analyses of the URM buildings were carried out under both fixed-base and base-isolated configurations. In order to consider the variability associated with both material properties and earthquake excitation, 20 sets of random variables were obtained through Latin hypercube sampling technique and each combined with a different earthquake ground motion recorded in developing countries. The results show a significant reduction in the IDR of the base-isolated URM buildings in comparison with their fixed-base counterparts under all selected ground motions. Furthermore, the reduction in IDR due to base isolation is more effective in URM2 and URM3 buildings in comparison with URM1 building due to their higher mass, i.e. a longer base isolation period is achieved due to a more stable geometry of the isolators. These promising results confirm the suitability of a novel low-cost base isolation concept for URM buildings in developing nations. The lower IDRs of the BI configuration are a major proxy of a significant reduction in the conditional probability of damage to the URM structure under seismic events. In next studies, the authors will thus investigate the seismic fragility of base isolated URM buildings, explicitly accounting for the limited displacement capacity of base isolators as additional critical parameter.

Abstract

Seismic performance assessment of masonry buildings requires a nonlinear response analysis to achieve a reliable understanding of the possible effects of future earthquakes in terms of damage and losses. Equivalent frame (EF) modelling combined with nonlinear static procedures has been recognized as an efficient tool, which was validated in several studies through both experimental data and post-earthquake damage inspections.

In this paper, a new macroelement based on a fibre formulation is implemented into a matrix analysis approach to build up a nonlinear EF model and to perform incremental static (push-over) analysis with response control. For each step of the analysis, the stiffness matrix of the structure is updated using the novel macroelement model, accounting for geometric and mechanical nonlinearities both in terms of flexural and shear behaviour. Floor systems are modelled with truss elements, the stiffness of which can be varied in order to consider either rigid or flexible floors. In addition, the capacity model can simulate different degrees of connection at wall intersections and can easily be adapted to consider structural elements made of reinforced concrete, steel, wood, or other materials.

The capacity modelling procedure proposed in this study was first validated by simulating the in-plane lateral behaviour of a full-scale masonry wall with opening, and then, implemented to run pushover analysis of existing masonry buildings representative of those located in the Campania region (southern Italy).

Keywords: Masonry buildings, Macroelement modelling, Fibre formulation, Experimental validation, Nonlinear static analysis, Seismic performance.

1 INTRODUCTION

Post-earthquake reconnaissance missions and experimental programs have shown a significant vulnerability of unreinforced masonry (URM) structures to earthquakes, resulting in huge losses of life and money [1]. Despite the wide use of masonry as the oldest construction technology worldwide, the simulation of the seismic behaviour of URM structures and their retrofitting still need to be further investigated.

Over the years, various approaches have been proposed for simulation of URM structures, simplifying the problem differently according to the type of construction (e.g., modern or historical building, church, castle, bridge), specific purpose of the analysis (e.g., structural performance assessment under gravity loads, seismic actions, settlements), and the expected accuracy level and resolution of mechanical behaviour. Accurate results can be obtained through finite element (FE) simulation based on micro-modelling techniques, where masonry units, mortar joints and, if any, unit-mortar interfaces are distinctly modelled with nonlinear finite elements [2–5]. Several authors have proposed simplified micro-models in which only masonry units and joints are considered [6,7]. Even though micro-modelling techniques allow accurate simulations of masonry structures, they require a detailed knowledge of masonry constituents and have a considerable computational cost. This is a major drawback that makes FE micro-modelling rather difficult to apply in engineering practice and/or in structural assessments based on few data. In this respect, the macro-modelling approach [2] based on the assumption of masonry as equivalent homogeneous material allows a good trade-off between computational accuracy and cost, hence being applicable to real constructions and/or structures with few known properties.

An alternative computational strategy for structural response analysis of URM constructions, particularly in the case of buildings for their global seismic performance assessment, is based on macroelement modelling of walls with openings, i.e., the idealization of each wall as an equivalent frame (EF) with vertical and horizontal elements simulating pier and spandrel panels, respectively [8,9]. Macroelements with different behavioural modes can be used to model such types of masonry panels, which have comparable size with respect to openings. Pier-spandrel joint panels can be implicitly considered within the EF model, making use of macroelements with rigid parts at their ends. Macroelement modelling was validated on several structures, including those having an irregular layout of openings [10].

This paper presents a novel macroelement modelling procedure that permits the seismic analysis of masonry buildings, simulating the in-plane nonlinear response of load-bearing walls. The proposed macroelement, which is based on a fibre formulation, was validated in a previous study against experimental tests on single piers. In this study, the macroelement is implemented into a matrix-based formulation for development of EF models and their seismic performance assessment via nonlinear incremental static (pushover) analysis with response control. The overall approach is then validated at the system scale by comparing numerical results to experimental data of a lateral loading test on a full-scale masonry wall with central opening. The final part of this paper describes the application of the fibre-based macroelement approach to an URM structure representative of real buildings located in Campania (Italy), for their seismic fragility assessment.

2 MACROELEMENT ANALYSIS PROCEDURE

This study builds upon a fibre-based macroelement that was recently developed and experimentally validated by Parisi and Acconcia [11,12]. The aim was to develop a matrix-based procedure for nonlinear incremental static (pushover) analysis of masonry walls and buildings.

The macroelement allows the simulation of flexural, shear and rocking contributions to deformations associated with in-plane lateral loading, considering geometric and mechanical nonlinearity sources as well as the macroscopic constitutive behaviour of masonry.

The pushover analysis procedure is based on a nonlinear incremental algorithm with response control, namely, where the structure is subjected to increasing horizontal displacement of a control point located at the roof level. The macroelement proposed by Parisi and Acconcia [12] is modified to incorporate the presence of possible rigid end parts, simulating the presence of pier-spandrel joint panels. Each macroelement is formulated according to Timoshenko's beam theory and its stiffness matrix is defined by accounting for axial, flexural, shear, and torsional behaviour. The stiffness matrix of the structure is then assembled and updated according to the secant method during pushover analysis. The stiffness matrix coefficients are indeed a function of the displacement components at the two ends of the macroelement. In each analysis step, the secant stiffness matrix is evaluated through an iterative procedure that can be summarized in the following phases:

- linearized solution of the structure under the displacements imposed in the current step;
- evaluation of the displacements experienced by each macroelement and corresponding stresses and strains throughout fibres;
- computation of the secant stiffness for each macroelement;
- linearized solution of the structure based on the updated stiffness matrix;
- convergence check in terms of internal forces for each macroelement;
- iteration of previous steps or termination of stiffness matrix updating.

In the following sections, the EF modelling and analysis algorithm is validated by comparing pushover analysis results to experimental data in the case of a full-scale tuff stone masonry wall [13]. The procedure is then used to build up the EF model of an URM building, the seismic vulnerability of which is evaluated through fragility analysis.

3 EXPERIMENTAL VALIDATION AT SYSTEM SCALE

The EF modelling approach and pushover analysis procedure was validated against a lateral loading test on a full-scale URM wall with central opening [13]. The wall specimen consisted of two piers connected to each other by a spandrel with timber lintel above the opening (Fig. 1). The wall was made of tuff stone masonry with running bond and 10-mm-thick mortar joints. Overall, the wall was 5.10-m-long, 3.62-m-high, and 310-mm-thick. The piers were 1.70-m-long, whereas the spandrel was 1-m-high. The specimen was first subjected to vertical loads on top of the piers and then to horizontal loading with displacement control. Vertical loads had an intensity of 200 kN. The horizontal load consisted of a displacement-controlled force that was applied to the wall at a height of approximately 3.00 m from the base of the piers. The tuff masonry was composed of yellow tuff stones and a pozzolanic mortar, having the mechanical properties listed in Table 1.

Figure 1: Experimental setup of lateral loading test on full-scale URM wall with opening [13].

Material	Tensile strength f_t [MPa]	Compressive strength f_c [MPa]	Young's modulus E [GPa]	Shear modulus G [GPa]
Tuff masonry under compression parallel to mortar bed joints (case of spandrel)	0.192	3.85	2.07	0.86
Tuff masonry under compression perpendicular to mortar bed joints (case of piers)	0.198	3.96	2.22	0.92

Table 1: Mechanical properties of tuff stone masonry.

Figures 2a and 2b show the EF model of the wall specimen and a numerical-experimental comparison in terms of base shear versus top displacement curves, respectively. The numerical procedure allows a satisfactory reproduction of the initial stiffness, the peak base shear (experimental value of 184.31 kN against numerical value of 182.96 kN), and maximum lateral displacement. The damage observed on the wall specimen at the end of test was also well simulated, indicating a flexural failure of both piers and a diagonal shear cracking in the spandrel.

Figure 2: (a) EF model of wall specimen; (b) numerical-experimental comparison in terms of base shear versus top displacement curve.

4 FRAGILITY ANALYSIS OF CASE-STUDY BUILDINGS

The definition of case studies was based upon typological-structural data regarding existing URM buildings in the Campania region (Italy), in order to generate a sample of archetype buildings representative of residential buildings surveyed in that area. In detail, reference was made to real data from the CARTIS database [15], which collects information on typological and geometric characteristics of Italian buildings. Based on the 2011 Italian census data [16], the Campania region is characterized for more than 47% by masonry buildings, 94% of which were built before the first Italian code on masonry structures, namely DM 20/11/1987 [17]. In terms of size distribution, the masonry buildings in the area are composed of single-storey buildings (19%), two-storey buildings (45%), three-storey buildings (22%), and buildings with more than three storeys (14%).

By querying the CARTIS database [15], the pre-code building class in the area under study was characterized in more detail. It was found that 57.9% of existing buildings are made of tuff stone masonry with load-bearing walls having the following distribution of thickness at the ground floor: 700 mm in 32.9% of cases and 800 mm in 39.4%, with remaining values equal to 400, 500 and 600 mm. The mean thickness of load-bearing walls at the ground floor is 660 mm. In plan, the on-centre distance between walls was found to be 4.50 m in 80.2% of cases, 5.0 m in 15.3%, and 4.0 m in 4.5%, with a mean value of 4.64 m. The mean floor area of buildings falls in the interval $[100 \text{ m}^2, 150 \text{ m}^2]$ in 41% of cases, $[60 \text{ m}^2, 100 \text{ m}^2]$ in 24%, $[150 \text{ m}^2, 250 \text{ m}^2]$ in 28%, and $[250 \text{ m}^2, 350 \text{ m}^2]$ in 3%, with the remaining 4% of buildings having an area larger than 350 m^2 . The mean floor area is 159 m^2 . It was also found that 79% of tuff stone masonry buildings have flat floors, whereas the remaining 21% of them is characterized by vaults. Among flat floors, there are 68% of them consisting of steel I-beams and hollow tiles, 14% made of wooden beams, 12% made of concrete and hollow tiles, 5% consisting of wooden beams and tiles, and 1% made of SAP-type prefabricated systems with steel-reinforced tiles. The selected building has a rectangular plan with 3 walls in the X direction and 5 walls in the Y direction and consists of 2 floors (Fig. 3). The geometric characteristics agree with statistics reported above, so the distance between walls is approximately 4.60 m, the thickness of walls

at the ground floor is 660 mm, reducing to 500 mm at the first floor. The floors have an area of 246 m² and consist of steel I-beams and hollow clay tiles.

Figure 3: Plan of the building (longitudinal and transverse walls in the X and Y directions, respectively).

As regards the mechanical characteristics, the tuff stone masonry under study was regarded as ‘regular soft stone masonry’ according to the Italian building code NTC 2018 [18]. The mean values of mechanical properties assumed here were set to the average of those provided by the Italian building code commentary CS.LL.PP. 21/01/2019 n.7 [19]. According to CNR-DT 212-2013 guidelines on seismic reliability assessment of existing buildings [20] and previous studies [7,14], uncertainties in material properties were modelled as outlined in Table 2, defining the dispersion of lognormally distributed variables as follows:

$$\beta = \frac{X_{\max} - X_{\min}}{2} \quad (1)$$

where X_{\min} and X_{\max} are the minimum and maximum values of the natural logarithms of the property.

Property	Symbol	Unit	Range		Distribution	μ	β
			min	max			
Compressive strength	f_m	MPa	2.00	3.20	Lognormal	2.60	0.24
Diagonal shear strength	τ_0	MPa	0.04	0.08	Lognormal	0.06	0.35
Sliding shear strength	f_{v0}	MPa	0.10	0.19	Deterministic	0.145	-
Young’s modulus	E	MPa	1200	1620	Lognormal	1410	0.15
Shear modulus	G	MPa	400	500	Lognormal	$0.33E$	-

Table 2: Uncertainty modelling of material properties.

As regards the mechanical modelling of masonry, the compressive behaviour was simulated by assigning the constitutive model proposed by Augenti and Parisi [21]. That model is defined by the peak compressive strength f_m and the corresponding axial strain, which was assumed so that the secant modulus of elasticity at $0.3f_m$ was equal to Young’s modulus E provided in [19]. The tensile behaviour of masonry was assumed to be linear elastic up to the peak strength f_t and

followed by an exponential post-peak phase, assuming $f_t = 0.05f_m$ and a deterministic value of tensile fracture energy $G_{ft} = 0.0025$ N/mm.

The selected building was analysed through an equivalent frame model (Fig. 4) in which macro-elements were equipped with rigid offsets suitably sized to take into account the pier-spandrel joint flexibility and interaction according to previous studies [10,22]. Floor systems were modelled through linear truss elements with axial stiffness derived from size and material properties. That modus operandi allowed on one hand the floor flexibility to be considered in the distribution of horizontal actions between walls, and on the other, the axial force in spandrels to be computed. By the way, the flange effect due to wall-to-wall connections was taken into account in the structural model. It is also noted that one-way floors were assumed to span in the Y direction of the building plan, hence transmitting gravity loads to walls oriented in the X direction. Therefore, the gravity loads on walls in the Y direction were barely associated with self-weight of structural elements. Pushover analysis was performed with response control under two lateral load profiles, namely, the ‘modal profile’ with lateral forces proportional to the first vibration mode times inertia masses and the ‘mass profile’ proportional to inertia masses only. The centre of mass at the roof level was assumed as control point for nonlinear seismic analysis.

Figure 4: Equivalent frame model of the cases-study building.

Fragility analysis was carried out on 27 structural models of the building, corresponding to as many samples of material properties assumed to be lognormally distributed according to Table 2. More specifically, three possible values equal to μ , $\mu e^{-\beta}$ (16th percentile) and $\mu e^{+\beta}$ (84th percentile) were assigned to f_m , σ and E , resulting in 3^3 combinations of those material properties. Figure 4 shows the capacity curves corresponding to each direction and profile of horizontal forces.

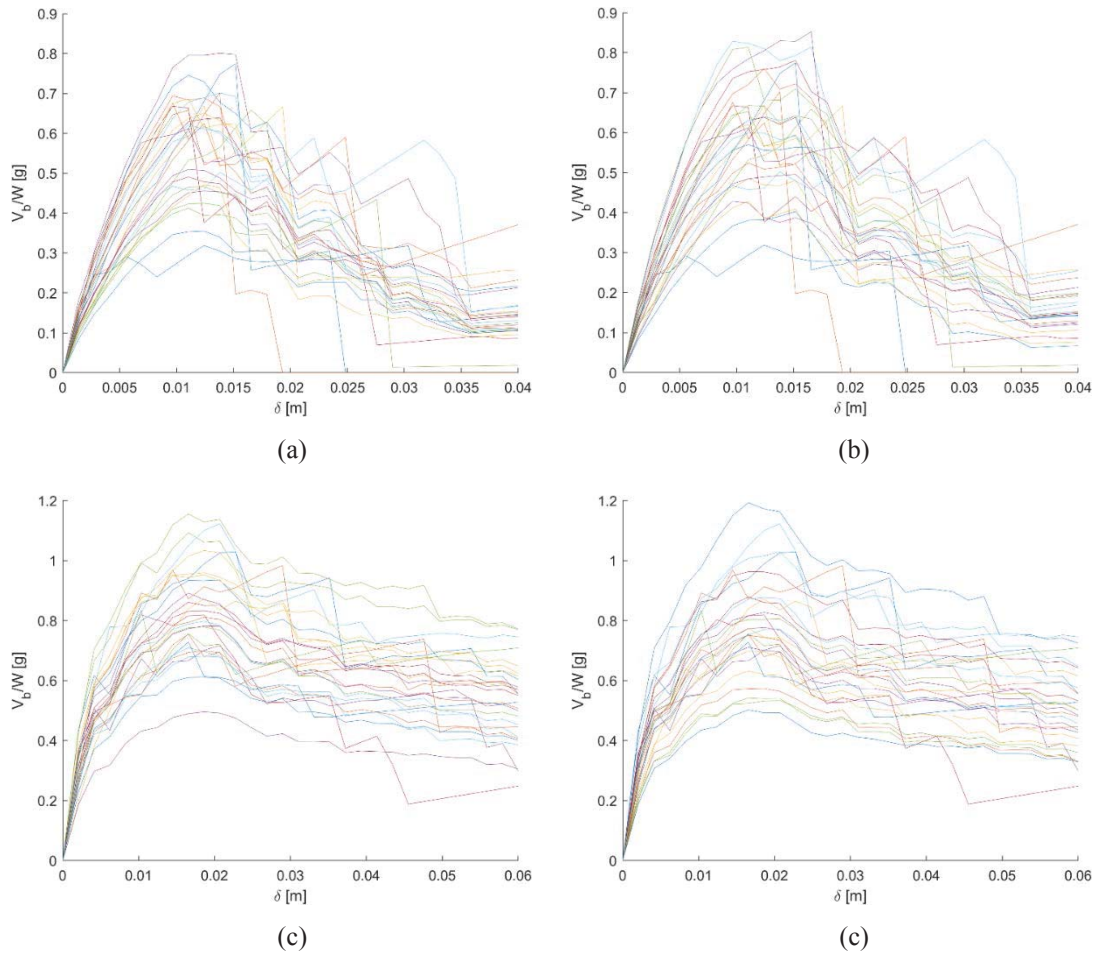

Figure 4: Pushover capacity curves of case-study building: (a) X direction and modal profile; (b) X direction and mass profile; (c) Y direction and modal profile; (d) Y direction and mass profile.

Seismic demand was evaluated in accordance with the N2 method [23], allowing global safety checking in terms of displacement. The building was assumed to be located on ground type A, i.e., rock or rock-like soil. Damage assessment was then performed with respect to four damage states (DSs), allowing seismic fragility associated with each DS to be computed under varying peak ground acceleration (PGA) that was assumed as intensity measure. The following DSs were considered: slight damage (DS1) associated with 60% of the maximum base shear; moderate damage (DS2) associated with the maximum base shear; extensive damage (DS3) associated with 20% post-peak degradation of base shear; collapse (DS4) corresponding to 50% post-peak degradation of base shear.

After that fragility points were individually derived, a lognormal probability distribution was fitted to them. The total dispersion was computed as square root of the sum of squares of dispersion associated with capacity (i.e., dispersion derived via fitting) and dispersion associated with demand, the latter set equal to 0.4.

Figures 5 and 6 show that the seismic fragility of the building was rather insensitive to the lateral load profile, while highlighting a significant sensitivity to the orientation of seismic actions. Indeed, the highest fragility of the structure is related to the Y direction, as expected according to the lowest intensity of gravity loads on walls parallel to one-way floors.

Figure 4: Fragility curves in the Y direction: (a) modal profile; (b) mass profile.

5 CONCLUSIONS

In this paper, a novel macroelement modelling procedure for masonry buildings has been presented and experimentally validated, creating the basis for efficient computation of seismic fragility through pushover analysis with response control. The macroelement modelling procedure is based on the fibre modelling approach and is framed within a matrix analysis approach, allowing consideration of material nonlinearities and real construction features (e.g. wall-to-wall connections, floor flexibility, presence of lintels). The macroelement modelling procedure build upon a macroelement that was originally validated against an experimental test on piers, and then it was extended to the structural system scale. Therefore, the matrix-based analysis procedure was validated against experimental data of a lateral load test on a full-scale masonry wall with central opening, highlighting a satisfactory numerical-experimental agreement.

The final part of this paper has presented the implementation of the proposed procedure in the seismic vulnerability assessment of a masonry building. The building geometry was modelled according to statistical data on existing masonry buildings located in the Campania region, Italy. Uncertainties in material properties were modelled and propagated through pushover

analysis, considering 27 samples of the building. Assuming four damage states corresponding to as many performance levels of the building, fragility curves were obtained to provide the conditional probability of exceeding each damage state given seismic intensity, which was measured in terms of peak ground acceleration.

The output of this study can be of interest for seismic risk assessments at regional scale and can be extended to other geometric configurations, types, and classes of masonry buildings at national scale. The fragility curves presented in this paper will be compared to those derived through Monte Carlo simulation, assessing the influence of the uncertainty in capacity that is usually of paramount importance particularly in the case of existing masonry buildings. Further developments of this study will also include a computationally efficient computation of the uncertainty in seismic demand, using nonlinear time history analysis of equivalent elastic-plastic oscillators associated with the pushover curves of the building samples.

Abstract

Recent earthquakes demonstrated the vulnerability of existing and historical masonry constructions. Many strengthening techniques for the seismic retrofitting of these structures have been introduced in the literature. Among these, FRCM strategies, based on the application of fibre-reinforced composite materials on the masonry surface through inorganic mortar layers, has become rather popular due to their physic and mechanic compatibility with historical masonries, low invasiveness and capacity to improve both the in-plane and the out of plane masonry behaviour. In this paper, a simplified discrete model, working at the material macroscale, is proposed to simulate the in-plane behaviour of masonry panels strengthened by FRCM systems. The proposed modelling approach is based on the DMEM model, whose calibration is enhanced to encompass the properties of the externally bonded strengthening system. According to the proposed strategy, the masonry support and the FRCM layers are simulated by an equivalent homogeneous material, discretised by a mesh of shear-deformable articulated quadrilaterals interacting along their edges by means of 2D unilateral cohesive-friction links. The model is implemented in OpenSees and validated by simulating experimental shear-diagonal tests, available in literature.

Keywords: FRCM, Composite material, Masonry structures, DMEM, in-plane behaviour, non-linear analysis.

1 INTRODUCTION

The numerical description of the mechanical behavior of masonry elements strengthened with externally bonded systems, such as Fabric Reinforce Polymer (FRP) or Fabric Reinforced Cementitious Matrix (FRCM) systems, represent a current complex task and requires complex mathematical models due to the non-linearity and anisotropy of masonry and the non-linear interaction between the reinforcement and the masonry support [1,2]. An effective modelling approaches to simulate unreinforced and reinforced masonry panels are represented by mesoscale finite element models [3-7] which explicitly simulate masonry, brick-block, units and mortar joints. According to these strategies, nonlinear zero-thickness interfaces describe both the behaviour of mortar joints and the masonry-reinforcement layer. However, these models require high computational costs; especially for external reinforced masonry elements where the matrix, the reinforce and the interfaces are detailed represented [8]. Consequently, these methods are not suitable for engineering applications.

Then the challenging problem of the scientific community is to simulate the complex mechanical behavior of unreinforced/strengthened masonry constructions with a limited computational cost and with sufficient accuracy. Is the case of simplified continuum finite element models where the masonry is represented as an equivalent homogenized continuum material [9,10]. Simplified structural macro-models aiming at drastically reduce the computational effort by describing each structural element through a single computational element (macro-element) or a coarse mesh of them, are largely used both in engineering practice and research [11,12]. Two of the most popular structural macro-models are represented by Equivalent Frame Model (EFM), in which the masonry building is represented by an equivalent nonlinear frame structure constituted by nonlinear beam element and rigid offsets [13,14], and the Macro-Element Model (DMEM), in which masonry panels are represented by shear-deformable 2D macro-elements interacting by discrete nonlinear interfaces [15-18]. The latter model guarantees a geometrically consistent description of masonry panels thanks to its 2D kinematics also allowing a more accurate simulation of the interaction between masonry panels and beam/column elements [19].

In this paper, a new simplified numerical strategy for the simulation of the in-plane FRCM strengthened masonry walls is proposed. This approach is based on the subdivision of a FRCM-strengthened masonry panel in a macro-mesh of shear-deformable elements interacting by discrete interfaces, according to the DMEM modeling strategy. Each interface is composed of a set of 2D links which describe the flexural/axial and shear behavior of masonry and the reinforcement layer. The proposed model is applied to simulate some experimental diagonal-compression tests performed on unreinforced and FRCM-strengthened masonry panels. The comparisons are presented in terms of load-force capacity curves and distribution of damage at the failure of the panel. The results of the analyses confirmed that the proposed model is able to simulate the response of the specimens with a satisfactory level of accuracy.

2 DESCRIPTION OF THE NUMERICAL STRATEGY

According to the proposed strategy, the masonry panel is subdivided in a mesh of shear-deformable panels (*shear panel*) that simulate the shear deformability of masonry portion represented. It is worth pointing out that, contrary to mesoscale approaches, the mesh discretization is not directly related to the brick-masonry arrangement which is taken into account by the calibration procedures of the interfaces. Following the DMEM approach, each shear panel can be described by an articulated

quadrilateral with rigid edges which are used to connect the interface links allowing the interaction between the shear panel and the adjacent elements. . Each interface (horizontal and vertical interfaces in Figure 1) is constituted by m nonlinear 2D links which model the flexural and shear-sliding behaviours of masonry and their coupling.

Figure 1 Real masonry wall (left); numerical representation with discrete elements (center); Single discrete element (right)

Each interface link, as depicted in Figure 2, is constituted by two one-dimension springs arranged in-series. One spring is oriented along the direction perpendicular to the connected panel edge (normal spring) and one spring is parallel to the edge (shear spring). The normal spring simulating the masonry axial behaviour is character by the normal displacement U_N and force F_N while the shear spring is characterized by the shear displacement U_T and force F_T . The two springs behaviour is coupled according to the Mohr coulomb failure criterion, based on the friction coefficient (μ) and the cohesive force (F_0). $K_{N,0}$ and $K_{T,0}$ are the initial values of the stiffness respectively in normal and in tangential direction.

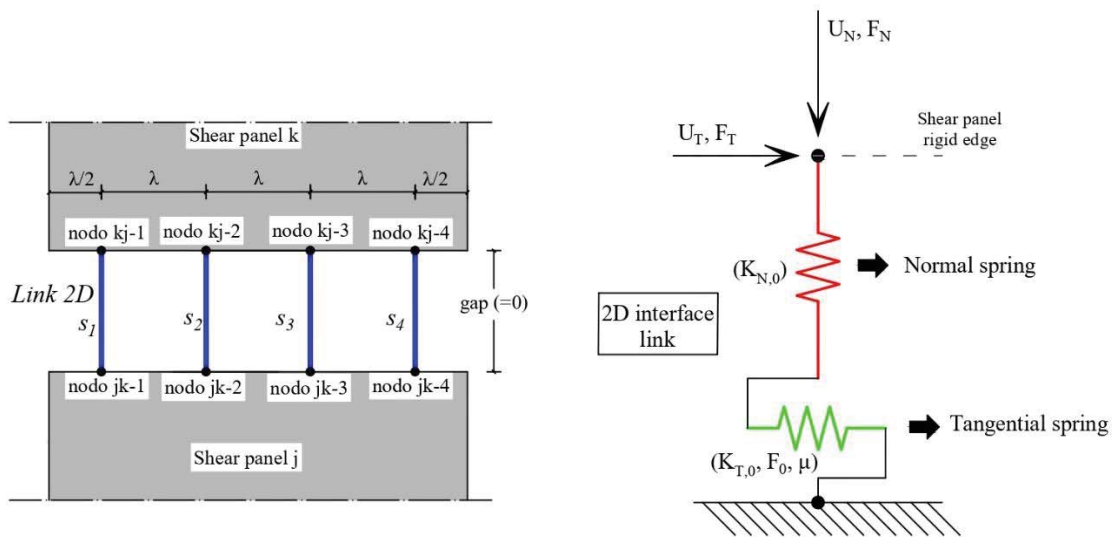

Figure 2 Discrete element interface with representation of all the nodes that are connected with 2D links (left); single 2D link numerical representation (right)

3 MODEL CALIBRATION

3.1 Calibration of the 2D masonry links

The constitutive law of the normal spring in compression is characterized by a parabolic relationship until the peak-strength, followed by a linear-softening and a residual strength (Figure 3a). The tensile behavior is linear elastic until the material strength after a linear softening is considered. When the displacement $U_{N,tu}$ is reached the material is considered cracked and the residual tensile strength is equal to zero. This model considers the masonry material in two conditions: cracked and uncracked considering two different force-displacement curves as shown in Figure 3b and in Figure 3c.

Figure 3 Constitutive law of the normal spring: backbone curve in compression and tension and unload-reload rules in compression; unloading behaviour in tension before cracking (b); behaviour in tension after material cracked (c)

The initial stiffness $K_{N,0}$ calibration is obtained assigning to each link the axial rigidity of the corresponding masonry strip. The same process is applied to assign to the normal material the compression and tensile yielding force $F_{N,cy}$, $F_{N,ty}$. In the case of the calibration of the interface link that connect two shear panels we have:

$$K_{N,0} = \frac{E \cdot \lambda \cdot s}{h_{infl,tot}} \quad (1)$$

$$F_{N,cy} = s \cdot \lambda \cdot \sigma_c \quad (2)$$

$$F_{N,ty} = s \cdot \lambda \cdot \sigma_t \quad (3)$$

Where: E is the Young modulus of the masonry, λ is the distance between two 2D links, s is the thickness of the represented masonry panel, $h_{infl,tot}$ is the sum of the two semi length of the adjacent shear panels, measured in the direction orthogonal to the direction of the interface; σ_c and σ_t are the compressive and tensile yielding stresses. The compressive yielding displacement $U_{N,cy}$ and the tensile yielding displacement $U_{N,ty}$ are calculated considering rigidity, force and the constitutive law.

The shear spring are characterized by an elasto-plastic constitutive law with linear softening (Figure 4), governed by a Mohr Coulomb yielding surface. The sliding occurs when the force in the direction tangential reaches its limit value, F_{lim} , calculated as reported in Eq. (4) in which μ is the friction coefficient, F_N is the force acting in the normal spring of the 2D link and $F_0 = c \cdot \lambda \cdot s$, and c is the cohesive strength of the masonry.

$$F_{T,lim} = \mu \cdot F_N + F_0 \quad (4)$$

Figure 4 Shear behaviour of the 2D link (left); influence of the normal force agent in the 2D link to the limit shear force $F_{T,lim}$ (right)

3.2 Calibration of FRCM strengthening system

The FRCM matrix is represented by an additional 2D links in parallel with the 2D masonry links and distributed along the panel edge with the same interval. The shear spring of the reinforcement link is characterized by the same constitutive law of the shear spring of the masonry links (figure 3b), calibrated considering the experimental shear strength of the mortar layer or the reinforcement [21-25]. The normal spring is characterized by an arbitrary multi-linear force-slip ($\sigma-U_N$) relationship in tension, calibrated according to the force-slip relationship determined by a shear lap test [21-25] (Figure 5), and zero compression strength.

Figure 5 Comparison between the experimental result of the single shear lap test and the behaviour of the multilinear material to assign to the element that represent the fibers. In the graph σ stands for the tension in the fibers area, without the matrix; U_N is the sliding between fibers and matrix.

4 NUMERICAL SIMULATIONS OF DIAGONAL COMPRESSION TESTS FRCM STRENGTHENED MASONRY WALL

This case study considers the results of the diagonal compression test brick masonry walls, executed experimentally [20]. The wall tested in laboratory (129x129x25 cm³) were built using standard clay bricks and hydraulic lime-based mortar for the bed joints.

The tests are executed at displacement control, applying the vertical load along the principal diagonal direction of the square panel. Deformations along the two principal directions were recorded by using linear potentiometric transducers. The results are reported using τ - γ diagrams, considering γ as the sum of the deformations along the principal diagonals ($\varepsilon_c, \varepsilon_t$); τ is the tangential stress calculated as $\tau = P/A_d$, in which P is the load applied and A_d is the section of the wall measured on the principal diagonal of the specimen. These tests are reproduced numerically with a mesh 10x10 of discrete elements (Figure 6).

Figure 6 Comparison between the experimental and numerical results (left) and deformed shape registered after the first peak in the numerical strengthened wall, considering an amplification factor of 50 (right)

5 DISCUSSION OF THE RESULTS

The proposed procedure well simulates the nonlinear behavior of the URM wall in terms of initial stiffness, peak load and residual load. Moreover, observing the numerical deformation, is evident the formation of a single diagonal cracking. This collapse mechanism reflects the failure mode experimentally observed.

In the case of the strengthened panel, some differences are observed between the experimental and numerical capacity curves, mainly in the peak-strength phase. However, the global trend of the experimental curve is reproduced with a satisfactory approximation, moreover the failure mechanism is well reproduced (Figure 6). Analyzing the stress and deformations of the Links representing masonry, mortar matrix and fibers, it is possible to determine the failure points of each element, as reported in Figure 7. The first part of the curve corresponds to the linear part, in which masonry and matrix aren't cracked. In this phase the tensile stresses in the fibers are lower than 200 MPa. The first peak corresponds to the cracking of the masonry in the central part of the panel, followed by the cracking of the matrix along the loaded diagonal. After this point, the external force decreases due to opening of the diagonal crack, that can be clearly seen in the deformed shape. The tensile deformations in the cracked interfaces continue to increase, allowing the fibers to increase tensile deformations and stresses, which result much higher than those registered during the uncracked phase. The second increase in strength is due indeed to the contribution of the elements that represents the fibers. The second peak corresponds to the yield of the fibers in the central part of the panel.

Figure 7 Numerical result with the indication of collapse of every material

6 CONCLUSION

This paper introduces a simplified model for the simulation of the nonlinear in-plane response of masonry panels strengthened by FRCM systems. The masonry is described by a mesh of discrete elements able to simulate the main collapse modes of masonry material. The FRCM reinforcement is simulated by a simple and efficient method. The calibration of the model is immediate and based on the materials parameters. As a numerical case study, a diagonal compression test has been simulated. The comparison between experimental and numerical results highlights the efficiency of the method in reproducing the global collapse modalities of the mixed system constituted by the masonry and the reinforcement. In the numerical simulation, according to the experiments, the matrix contributed to the first peak of the capacity curve while the contribution of the fibers resulted predominant in the post-peak phase where the capacity curve showed a second peak, after a main diagonal crack was developed.

Abstract

Fiber Reinforced Cementitious Matrices (FRCM) are innovative materials currently adopted for the structural strengthening of existing masonry structures. With reference to the in-plane behavior of masonry, FRCM systems are effective in enhancing the shear capacity and in influencing the failure mode of masonry panels, which moves from a very brittle failure, typical of unreinforced masonry walls, to a less brittle failure mode. The main objective of this paper is to study the structural behavior of masonry panels strengthened with a FRCM system through nonlinear numerical analyses of diagonal compression tests performed on an unreinforced and a reinforced panel. With reference to the masonry substrate, a brick-to-brick modelling approach is adopted. According to this approach, the non-linearities are all concentrated in the mortar joints and in correspondence with potential crack surfaces located in the middle of each brick. The FRCM strengthening system is discretized by means of a continuous bi-directional fiber grid constituted by trusses embedded into the mortar matrix, which is bonded to the masonry substrate. A calibrated bond-slip relationship is assigned to the matrix-fiber interface, assuming an idealized bilinear law. The nonlinear analyses allow to capture the typical experimental shear response of a reinforced masonry panel, characterized by a load-displacement curve in which three principal phases can be identified, corresponding with different failure mechanisms: masonry cracking, mortar matrix cracking and ultimate failure of the panel. The numerical results are, indeed, compared with experimental results, showing a good agreement and confirming the suitability of the modelling approach in reproducing the described experimental behavior. Parametric studies on both the material and the geometrical parameters of the FRCM system are also performed.

1 INTRODUCTION

The damages caused by the most severe earthquakes in recent decades have drawn attention to the problem of the vulnerability of the built cultural heritage, mostly consisting of masonry buildings [1,2]. In this framework, the use of composite materials, such as Fiber Reinforced Cementitious Matrix (FRCM), to strengthen masonry panels became very popular due to the extremely low weight-to-strength ratio, the ease of application, and the capability of maintaining the original stiffness of the unreinforced element unchanged [3,4]. These materials proved to be very effective for the enhancement of the shear behavior of masonry structural elements, both in terms of load bearing capacity and failure mode [5,6].

Significant research has been also devoted to the numerical simulation of the behavior of FRCM strengthened structural elements, adding to the specific aspects of the masonry modelling, further issues related to the FRCM systems, considering all the possible failure modes [3]. In literature, the FRCM systems are often modeled as homogenized materials, under the assumption of having the mortar matrix layers homogenized with a distributed reinforcement, fully embedded inside the matrix elements [7-10]. Moreover, the hypothesis of a perfect bond between the FRCM systems and the masonry substrate is usually introduced. Some research works have introduced simplified analytical-numerical approaches to model the interaction between the fibers and the mortar matrix to analyze the debonding/delamination phenomena of the FRCM system from the substrate [11,12]. According to these models, the interface behavior between the mortar matrix and the fibers is based on the stress vs slip curves deduced from experimental tests.

The objective of the paper is the numerical investigation of the in-plane behavior of FRCM strengthened masonry panels subject to diagonal compression test by proposing a specific modelling approach. In more detail, the masonry is modelled using a brick-to-brick model, based on the simplified micro-modelling approach developed in the past and also known in literature as meso-scale approach [13,14]. With reference to the FRCM system, each component (i.e. mortar matrix, fiber, matrix-fiber interface) is specifically modelled and the constitutive laws are purposely calibrated on the basis of experimental results to account for several possible failure modes. For the validation of the proposed model, the comparisons between the results of nonlinear numerical simulations and the experimental results of previous experimental campaigns [15,16] are discussed, together with the results of several parametric analyses.

2 NUMERICAL MODEL

In this paper, the in-plane shear behavior of an unreinforced (URM) and a FRCM strengthened panel is simulated by means of nonlinear numerical analyses of diagonal compression tests. The geometry of the panels ($1210 \times 1210 \times 120$ mm³), the setup and the boundary conditions (Figure 1a) are chosen to reproduce the ones used in previous experimental campaigns on masonry panels built with clay bricks and 10-mm thick cementitious mortar layers, then strengthened by a FRCM system composed of a bidirectional carbon fiber grid embedded in a lime-based mortar, having a total thickness of 6 mm per side [15,16]. The bidirectional carbon grid is characterized by a weight density of 170 g/m², a grid spacing of 10 mm, an equivalent thickness of 0.047 mm and a yarn perimeter equal to 4 mm. The masonry components and the FRCM system were subject to experimental tests for the determination of their mechanical properties, which are here used as input parameters in the numerical model, as will be explained in the following.

A 2D numerical description of the problem is considered: this is consistent with the fact that the tested masonry panels are single-wythe walls, characterized by a regular bond pattern.

The numerical analyses are carried out by using the finite element software DIANA FEA 10.1. The quality and refinement of the mesh adopted both for the URM panel and the FRCM strengthened one (Figure 1b,c) is the result of a mesh sensitivity analysis. Numerical analyses are carried out under displacement control, applying the displacement to the top steel cradle.

To include the presence of the FRCM strengthening system over the masonry panel, an improved modelling approach is here proposed. More in detail, the approach consists of modelling masonry with a brick-to-brick model, where the nonlinearities are all concentrated in the zero-thickness interface elements modelling the mortar joints and in correspondence with potential crack surfaces located in the middle of each brick. The mortar matrix presents discrete cracks at the same locations of the masonry substrate and it is considered perfectly bonded to the substrate. Then, the single fiber bundles are individually modelled as embedded in the mortar matrix through a bond-slip law. In more detail, the bond-slip law of the considered carbon FRCM system is calibrated based on experimental bond tests, performed in a Round Robin test of the RILEM 250-CSM Technical Committee [4]. The graphical representation of the adopted modelling approach is shown in Figure 2.

2.1 Masonry

According to the brick-to-brick modelling approach, each mortar joint, consisting of mortar and two brick-mortar interfaces, is lumped into a zero-thickness interface element, while the bricks, modelled with continuum elements, are expanded to keep the overall geometry un-

changed. Interface elements are also used in the middle of each brick to model its potential cracking. The bricks are modelled as a linear elastic material and all the nonlinearities of the problem are lumped in the interface elements. The purpose of this approach is to concentrate all the damages in the mortar joints and in the brick interfaces. The adopted mesh includes eight-node quadratic elements for the bricks and six-node quadratic elements for brick-mortar and potential brick crack interfaces.

Large values of normal (k_n) and tangential (k_s) stiffness are adopted for the interfaces located in the middle of the bricks to ensure material continuity and to avoid the interpenetration. An exponential tension softening model was used for these elements without a specified shear or compression failure criteria. The elastic stiffness parameters for the zero-thickness interfaces modelling the mortar joints are determined starting from the elastic properties of brick and mortar, as reported in [14].

The nonlinear behavior of the mortar joint interface elements is introduced by considering the combined cracking-shearing-crushing model available in the software DIANA FEA, which was developed and improved in past research works [13,17]. This model includes the failure mechanisms that characterize masonry: cracking of the joints, sliding along bed or head joints at low values of normal stress, cracking of the bricks in direct tension, brick diagonal tensile cracking and masonry crushing. In more detail, the adopted model is based on multi-surface plasticity and it includes a Coulomb friction model combined with a tension cut-off and an elliptical compression cap.

Equations 1-3 describe the Coulomb friction yielding criterion, the yield value and the coupling between cohesion and friction softening, respectively:

$$f_1(\sigma, \kappa_1) = |\tau| + \sigma \tan \phi(\kappa_1) - \bar{\sigma}_1(\kappa_1) \quad (1)$$

$$\bar{\sigma}_1(\kappa_1) = ce^{-\frac{c}{G_f^{II}} \kappa_1} \quad (2)$$

$$\tan \phi = \tan \phi_0 + (\tan \phi_r - \tan \phi_0) \frac{c - \bar{\sigma}_1(\kappa_1)}{c}, \quad (3)$$

where c is the cohesion of the brick-mortar interface, ϕ_0 and ϕ_r are the initial and the residual friction angles, respectively, G_f^{II} is the mode-II fracture energy and κ_1 is an internal softening parameter that controls the softening behavior. Non constant mode-II fracture energy is considered since the softening of the friction angle is taken proportional to the exponential cohesion softening. The dilatancy effect is also included in the model [17] by using the parameter:

$$u_p = \frac{\Psi_0}{\delta} \left\langle 1 - \frac{\sigma}{\sigma_u} \right\rangle \left(1 - e^{-\delta v_p} \right), \quad (4)$$

where Ψ_0 is the dilatancy at zero confining stress and shear slip, σ_u is the confining stress at which the dilatancy becomes zero, and δ is the dilatancy shear slip degradation coefficient.

For the tension mode, the yield function reads:

$$f_2(\sigma, \kappa_2) = \sigma - \bar{\sigma}_2(\kappa_2) \quad (5)$$

$$\bar{\sigma}_2(\kappa_2) = f_t e^{-\frac{f_t}{G_f^I} \kappa_2},$$

with f_t tensile strength of the brick-mortar interface and G_f^I mode-I fracture energy.

The yield function for the cap model is given by:

$$f_3(\sigma, \kappa_3) = C_{mm}\sigma^2 + C_{ss}\tau_2 + C_n\sigma - (\bar{\sigma}_3(\kappa_3))^2, \quad (6)$$

where C_{mm} , C_{ss} , and C_n are a set of material parameters, controlling the center of the cap and its intersection with the tensile part of the normal stress axis, and $\bar{\sigma}_3$ is the yield value. The cap mode is described by a parabolic hardening rule, until the peak compressive strength of the masonry f_c is reached at the plastic strain κ_p . After the peak, the softening behavior under compression is described by a parabolic/exponential softening rule and depends on the fracture energy $G_{f,c}$, considered according to Eq. 7 [18]:

$$G_{f,c} = 15 + 0.43f_c - 0.0036f_c^2. \quad (7)$$

The introduced geometrical and mechanical properties are reported in Table 1 and Table 2, together with the properties of the FRCM system described in Section 2.2, and they are derived mainly from experimental results or calibrated by considering data found in literature.

The vertical displacement along the compressed diagonal is assigned through two steel cradles placed at two opposite corners of the panels. The contact surfaces between the panel and the cradles are also modelled: the normal stiffness of the interface was high (10^8 N/mm³) to avoid interpenetration while a small tangential stiffness value (450 N/mm³) was calibrated to allow relative displacements and to properly simulate the confinement at the corners.

2.2 FRCM

The modelling approach here introduced to describe the FRCM strengthening system behavior allows for relative slips between the fiber bundles and the mortar matrix. The formers are introduced as a grid of 1D elements, connected to the 2D continuum elements, representing the mortar matrix, through bond-slip reinforcement interfaces. In more detail, the fiber bundles are modelled as 2-noded linear trusses connected by line-shell interface elements to the mortar matrix in which they are located (Figure 2). Trusses representing the fibers are considered elastic in tension and not effective in compression. The use of a linear elastic behavior for the truss elements is a simplification verified and supported by experimental evidence [19]. The bond-slip model adopted within the software DIANA FEA sets a nonlinear

relation between the shear stress and the shear slip, while the relation between normal traction and normal relative displacement is maintained linear.

The mortar matrix, composed of 2D elements, is introduced in the model as perfectly bonded to the masonry panel. This hypothesis is consistent with the experimental failure modes [15,16], never characterized by detachment or shear slip between the mortar matrix and the masonry substrate. Accordingly, the mortar matrix is allowed to crack together with the masonry substrate, in correspondence of the same weak locations, i.e. mortar bed joints and in the middle of the bricks. Therefore, the mesh of the mortar matrix is considered coincident with the mesh of the masonry, and the same potential discontinuities are introduced through zero-thickness nonlinear interfaces (Figure 2), modelled by adopting the combined cracking-shearing-crushing material model, already introduced. Only the definition of the normal and the tangential interface stiffness is modified, considering the presence of one material only: $k_n=E/t$ and $k_s=G/t$, being E , G and t the elastic modulus, the shear modulus and the thickness of the mortar matrix, respectively. Since a 2D mesh is used for the mortar matrix, t is introduced as the overall thickness of the mortar, including both the inner and the outer layers.

In FRCM strengthened masonry panels, the interaction between the reinforcement system and the substrate is highly complex and different failure modes are possible. In this work, for reasons of simplicity, all the delamination and slippage phenomena are concentrated at the matrix-fiber interface. This is indeed the most frequent mechanism leading to failure, after the rupture of the fibers, which can be explicitly taken into account by the fiber model.

The potential slippage of the fiber bundles with respect to the mortar matrix is described by zero-thickness interface elements with six-nodes, a quadratic displacement field and a plane stress assumption. Since they connect 1D elements (fiber bundles) to 2D shell elements (mortar matrix layer), two separate interface laws are assigned along the longitudinal direction and along the direction orthogonal to the fiber bundle alignment. The adopted constitutive laws are based on a total deformation theory, which expresses the stresses as a function of the total relative displacements. The relation between the normal traction and the normal relative displacement is assumed to be linear elastic and characterized by the k_n stiffness. The large deformability of fibers along the direction orthogonal to their alignment and the possibility of relative slippage between orthogonal bundles, suggest that a negligible value of the stiffness should be considered. Therefore, a very weak stiffness is given to the bond-slip interface elements along the direction orthogonal to the fiber bundles, to neglect their contribution along that direction. A bilinear shear stress vs slip curve is considered along the longitudinal direction; this is a simple but common choice for FRCM systems [9]. Given the purpose to perform structural analyses with a large number of interface elements and the growing difficulty of calibrating increasingly complex laws, the choice seems appropriate. Shear laws for positive and negative values of slips are equal.

To calibrate the bond-slip interface laws and to verify the simplified assumptions introduced, preliminary numerical simulations of bond tests are carried out using the software DIANA FEA 10.1. In more detail, experimental bond tests [4] performed on the same carbon FRCM system considered for the diagonal compression tests are numerically modelled. The prevalent experimental failure modes were the delamination at the matrix-fiber interface and the slippage of the fibers within the mortar matrix. In the numerical simulations, the brick is considered as a linear elastic material and the FRCM system is modelled as previously described. To simulate the bond tests, the free edges of the fiber bundles (truss elements) were pulled horizontally by imposing a common displacement, while restraining the brick substrate. The numerical results of the bond tests in terms of axial stress vs slip curves are shown in Figure 3a. The axial stress is evaluated as the applied force divided by the cross section of the

dry fibers. The calibration of the bilinear bond-slip law is performed by direct comparison and fitting of the experimental results. Figure 3a shows a good matching between the numerical axial stress *vs* slip curve and the experimental envelope. This finding confirms the suitability of the adopted modelling choices. The parameters describing the bilinear bond-slip law are reported in Figure 3b.

3 NUMERICAL RESULTS

The results of the nonlinear numerical analyses are presented in this Section for both the URM and the FRCM strengthened panels. They are compared with the experimental results obtained in a previous experimental campaign [15,16], in which two unreinforced and two FRCM strengthened panels were tested, to validate the proposed approach and understand the capabilities and limitations of the model. In more detail, the load *vs* vertical displacement (δv) curves are shown in Figure 4a.

With regards to the URM panels, a good agreement can be noticed between the numerical curve and the experimental ones, both in terms of peak load and corresponding displacement. The initial stiffness of the system is properly captured as well as the stiffness decrease registered around the 85% of the peak load. The experimental post-peak behavior was not properly registered due to the fragility of the experimental failure.

The experimental behavior of the FRCM strengthened panels is well described by the numerical load *vs* vertical displacement curve: the initial stiffness and the load bearing capacity increment (+30%) with respect to the URM panels are properly captured. In terms of vertical displacements, the prediction is realistic and inside the experimental range.

From the numerical results, the mechanical contribution of each single component of the FRCM strengthened panel (i.e masonry, mortar matrix and fibers) can be observed and described. In more detail, the reference points highlighted in Figure 4b can be identified, corresponding to the following phases of the diagonal compression tests:

- Point A: end of the elastic phase for the masonry panel. The first crack appears locally inside the substrate while the external mortar matrix layer is still uncracked.
- Point B: diffused masonry cracking, while the FRCM layers are still uncracked.
- Point C: presence of macro-cracks within the mortar matrix. Along the cracking lines, the fibers reach the peak shear stress and the onset of local delamination. In this phase, the load reduction between points B and C can be related to the amount and type of mortar matrix and fibers.

- Point D: the crack opening with the fiber slippage determines the significant load drop, until the stress redistribution allows for a proper bonding of fibers, working alone bridging the cracks. Until this condition is stable, the system can recover the load.
- Point E: the peak shear stress is reached for few further fiber alignments.
- Point F: bond failure of a significant number of fibers: the extent of stress redistribution is so diffused that fibers do not have the needed minimum bond length. This phase corresponds to the final failure of the FRCM system (due to delamination).

These findings confirm that the crack pattern and failure mechanism of the FRCM strengthened panels are directly affected by both the fibers and the mortar matrix characteristics. The mortar matrix gives stiffness and peak stress contributions, while the fibers allow to reseal the crack of the masonry panel and then determine a less brittle post-peak behavior and eventual force recovery (if the bond is effective).

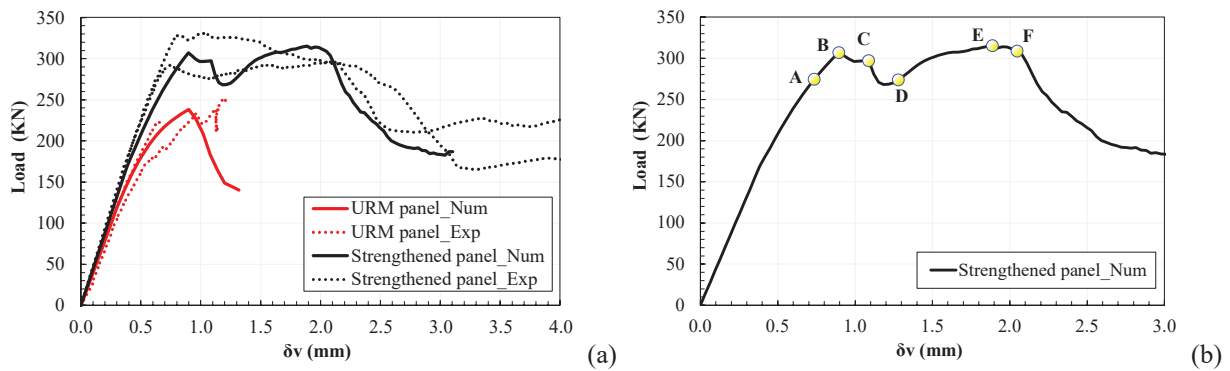

Figure 4: Load vs vertical displacement curves: (a) numerical vs experimental results; (b) strengthened panel.

The vertical stress and the interface normal stress are reported in Figure 5 and Figure 6 for the URM panel at peak and for the FRCM strengthened panel in correspondence with Point C of Figure 4b, respectively. Moreover, to better investigate the delamination process of the fibers within the mortar matrix during the diagonal compression tests, two representative fiber bundles are considered, in the positions denoted in Figure 1c. The shear stress distribution along the two fibers at different vertical displacements (B-F points of Figure 4b) is shown in Figure 7. The potential cracking lines, in correspondence of mortar joint interfaces and of the middle of the bricks are represented with vertical black lines. For the fiber bundle 170 (Figure 7a), an increase in the shear stress, even leading to the reaching of the bond strength, can be observed along some section when the mortar matrix starts to crack (lines B-C). In the following steps, a shift of the peak shear stress can be noticed due to the development of the delamination process. In correspondence with the formation of new cracks (e.g. position at 293.8 mm), a sudden failure (delamination) and a subsequent stress redistribution towards less stressed portions are observed, until the reaching of the minimum bond length, when the bundle fully delaminates. An analogous behavior can be noticed for the fiber bundle 174, even if the trend of the shear stress is influenced by the different position of the bundle within the masonry panel. Indeed, the delamination process starts later with respect to the fiber bundle 170, but the shift of the stress diagram is much larger. Starting from these observations and considering that the fully delamination can be reached at different time instants for the bundles, it can be observed that a stress redistribution is allowed between the bundles (beyond point F of Figure 4b). A FRCM strengthened masonry panel can exploit this important resource in the post-peak phase, depending on the quality of the matrix-fiber bond.

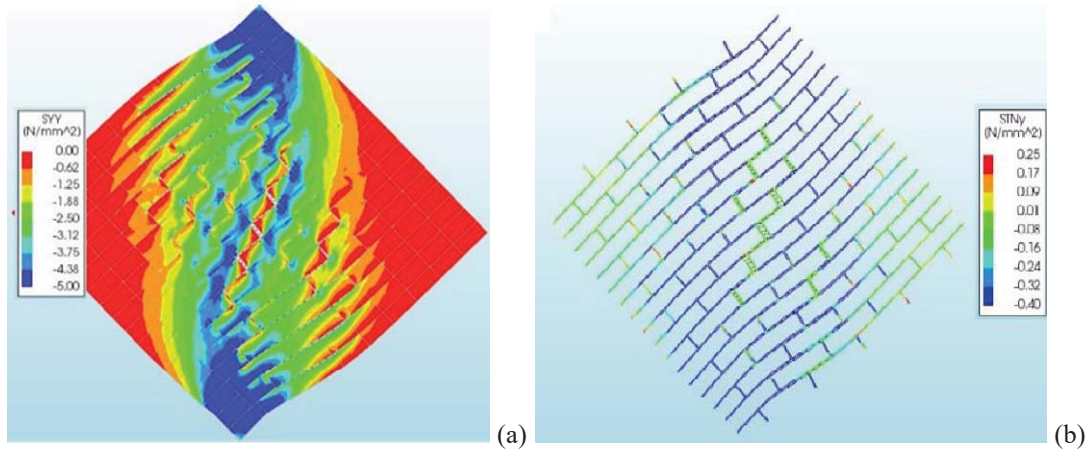

Figure 5: Numerical results for the URM panel at peak: a) vertical stresses on the brick elements, b) interface normal stresses.

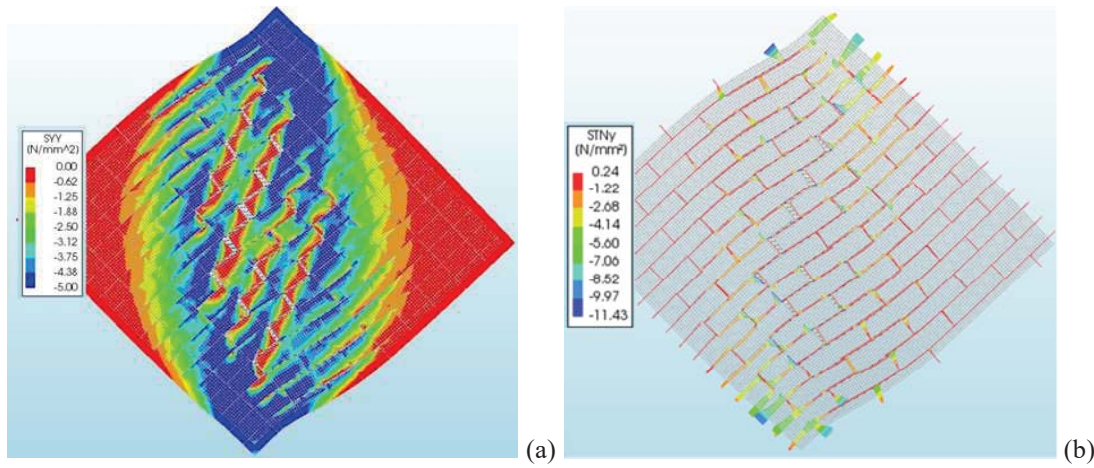

Figure 6: Numerical results for the FRCM strengthened panel: a) vertical stresses on the bricks, b) interface normal stresses.

Figure 7: Tangential stress distributions along: a) fiber bundle 170, b) fiber bundle 174.

The numerical and experimental results are also compared in terms of failure mode. For the URM panel, the numerical failure is governed by the formation and development of one main crack along the compressed diagonal, in good accordance with experimental evidence (Figure 8a). For the FRCM strengthened panel, the presence of the composite system improves the failure mechanism, bridging the main crack and allowing for an effective stress

redistribution, which leads to the formation of multiple cracks before failure (Figure 8b). Correspondingly, the sample is allowed to reach much greater deformations before failure, with respect to the URM panel.

Figure 8: Typical failure modes of (a) URM panel and (b) FRCM strengthened panel.

4 PARAMETRIC ANALYSES

After the validation of the proposed numerical model by comparison with experimental diagonal compression tests, parametric analyses are performed to investigate some of the parameters which could affect the structural response. The variations here considered regards the mortar matrix properties, i.e. elastic modulus and tensile strength, and the amount of fibers embedded within the mortar matrix, according to Table 3. In more detail, the considered range of variability of the elastic modulus of the mortar matrix covers adoption of soft mortars and of thick mortar layers: the cross section of the mortar matrix is indeed kept constant in the model and the membrane stiffness is properly modified through the variation of the elastic modulus only. Concerning the variation of the amount of fibers, different cross sections and perimeters are considered, selecting appropriate ranges according to the products available in the market.

Model	E_{matrix} [MPa]	$f_{t,matrix}$ [MPa]	Area [mm ²]	Perimeter [mm]
Reference	17	3	0.47	4
Soft matrix	5.5	3	0.47	4
Stiff matrix	51	3	0.47	4
Weak matrix	17	1	0.47	4
Strong matrix	17	6	0.47	4
Matrix only	17	3	-	-
Double density	17	3	0.92	5.64
High density	17	3	1.38	6.92
Light density	17	3	0.23	2.83
Double layer	17	3	0.92	4

Table 3: Parametric analyses on mortar matrix properties and amount of fibers.

The results of the parametric analyses are reported in Figure 9 in terms of load vs vertical displacements. In particular, from Figure 9a it can be noticed that the value of the elastic modulus of the mortar matrix affects the stiffness of the initial uncracked branch, as expected.

A large deformability of the mortar matrix (soft curve) leaves the masonry alone in the definition of the first peak, which is then remarkably reduced with respect to other cases (ref., and stiff); on the contrary, a too stiff mortar matrix (stiff) cracks before the masonry, leaving almost unaffected the stress at first peak. After the first peak, the mortar matrix stiffness also affects the possibility of having a force recovery, due to a possible tension stiffening mechanism allowing for an effective distribution of the cracks around the central portion of the panel. Figure 9a shows also the effect of the mortar matrix tensile strength on the shear behavior: a weak mortar matrix cracks before the masonry and it produces a sudden stiffness reduction. Correspondingly, the first peak is significantly lower with respect to the Reference case. On the other side, a high value of tensile strength seems partially not effective without a coherent increase of elastic modulus, since the first peak is shifted towards larger deformations and crack openings, where the larger mortar matrix force contribution is balanced by the smaller masonry counterpart, clearly inside its softening behavior. Moreover, once the tensile strength is locally reached, the post-peak stress behavior is more brittle and, correspondingly, the global force redistribution capability is reduced. Once the mortar matrix is cracked, the second peak is mainly governed by the amount of fibers and their strength. These findings are also confirmed by recent research works [6].

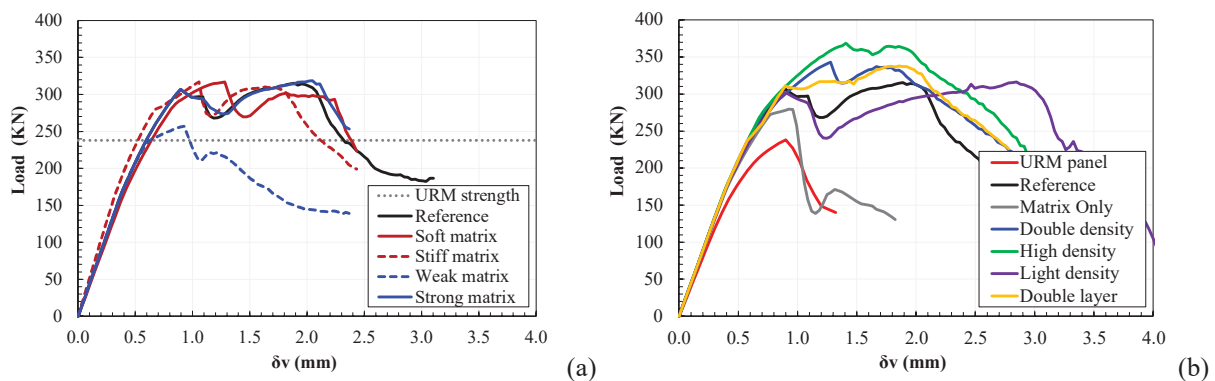

Figure 9: Load vs vertical displacement curves: (a) numerical vs experimental results; (b) strengthened panel.

The effect of the use of different amounts of fibers is presented in Figure 9b. It can be noticed that a growing amount of fibers inside the mortar matrix does not improve the first peak so much, since before cracking mortar matrix is more effective than fibers. Only when the amount of fibers is relevant (double density and high density) and properly bonded, the initial capacity is remarkably enhanced, even because the mortar matrix is thin. In fact, when two layers of strengthening grids are considered (double layer), first peak is not so affected and the effect of fibers can be observed only later, because of the limited bond between mortar matrix and fibers. The force drop after the first peak and the slope of the following force recovery branch (tension stiffening effect) are strongly related to the amount of fibers: the former being inversely dependent and the latter being proportional to it. This can be explained by considering the better stress redistribution which takes place around the main cracks with growing amount of fibers. As a consequence, a stronger reinforcement tends to merge the two peaks into one. Finally, as expected, the application of a layer of mortar matrix only produces an increase of stiffness and shear strength with respect to the URM panel but a very brittle failure occurs.

5 CONCLUSIONS

In the present paper, the in-plane shear behavior of FRCM strengthened masonry panels subject to diagonal compression tests is investigated by means of nonlinear numerical analyses. A novel modelling strategy is proposed to include the contribution of each component of the FRCM system. In more detail, the FRCM system is discretized by using linear trusses embedded into the mortar matrix and a proper bond-slip law is calibrated from experimental bond tests.

The numerical simulations allow to identify the different phases, characterizing the improved shear behavior of a FRCM strengthened panel, highlighting the role of each component, i.e. masonry substrate, mortar matrix and fibers. In particular, it is observed that, in most of the cases, the masonry cracks before the external mortar matrix, without introducing a sudden change of slope of the force vs vertical displacement curve. Then, the presence of the mortar matrix mostly influences the first peak load, while the presence of the fibers has an impact in the post-peak branch and in the determination of a second load peak. Parametric analyses on the mortar matrix properties and on the amount of fiber are performed to better analyze the influence of these parameters on the overall structural response.

It can be concluded that the described modelling approach can determine a satisfactory match between numerical and experimental results both for the unreinforced and the FRCM strengthened masonry panel. It could be extended to different typologies of FRCM systems, with a proper calibration of the mechanical properties of the materials and of the matrix-fiber bond-slip interface laws.

Abstract

Presently, in historical centres, it is very difficult to analyse buildings as independent structures, since they share the same boundary walls with adjacent structural units. These constructions of the building aggregate interact among themselves under seismic actions, so that their behaviour differs from that of the individual buildings considered as isolated structures. Therefore, it is emerging the need to assess seismic vulnerability of building aggregates. Thus, in this paper both simple empirical and mechanical refined vulnerability evaluation methods of masonry building aggregates are examined in general terms and illustrated in detail through the application on a case study in Mirandola, a district of Modena. On one hand, two empirical assessment methodologies, mainly based on the basic observational data of masonry constructions and properly calibrated on macro-element analysis results on a significant number of clustered buildings, are proposed taking properly into account the interactions among adjacent constructions. On the other hand, a mechanical analysis method at the individual building scale is also applied to evaluate more realistically the seismic behaviour of clustered structural units through the development of appropriate capacity curves.

Keywords: Seismic Vulnerability, Masonry Aggregates, Empirical Methods, Quick evaluation, Mechanical Methods, Capacity curves.

1 INTRODUCTION

The seismic safety of existing masonry buildings represents, as it is known, one of the main priorities for reducing the seismic risk of historical centres and is conditioned from multiple geometrical and mechanical factors that influence their behaviour against earthquakes [1].

Nowadays, in most Italian centres, it is easy to find a building heritage characterized by historic masonry constructions without an adequate structural apparatus to resist the increasingly frequent and disastrous seismic actions. This structural inadequacy generates a drastic increase of the global vulnerability and, therefore, of the seismic risk of entire urbanized sectors.

Buildings erected in aggregate conditions are often made up according to the traditional constructive practice with very variable types of vertical structure (i.e. heterogeneous or multi-leaf masonry walls) and deficient construction details (bad connections between orthogonal walls and between walls and floors, variation in the thickness of the walls along with the building height, etc.), which implicitly involve behavioural deficiencies in terms of stability in areas characterized by considerable seismicity. Furthermore, the interactions among the contiguous structural cells must be appropriately considered in the study of the vulnerability of the whole aggregate, since the dynamic response of each cell is strongly influenced by both the number of aggregate units and the position within the clustered building [2].

Based on these considerations, the present study aims to focus on the seismic response of a masonry aggregate located in the historical Centre of Mirandola, a municipality within the province of Modena. The selected masonry aggregate is made of brick walls with deformable floors, which is a typical structural typology representative of the building classes present in the examined urban area. The main objective of the present research is to study seismic vulnerability through empirical and mechanical procedures in order to provide a judgement on the effectiveness of simple analysis methods in predicting seismic vulnerability of masonry structural units of clustered buildings.

2 CASE STUDY MASONRY AGGREGATE

The case study historical building is a row masonry aggregate (Figure 1) composed of different structural units (SUs), mutually interacting to each other, which occupy different positions (heading or intermediate) within the examined clustered compound.

Figure 1: Case study aggregate placed in the historical centre of Mirandola.

From a structural point of view, the height of the structural units varies from 2 to 4 floors above ground, with an average inter-storey height of 2.80 m. The vertical structures, characterized by solid brick walls, have an average thickness ranging from 0.24 m to 0.50 m.

The horizontal structures are mainly made of wooden beams with double planking. The street views of the study building compound, together with the division of the masonry aggregate in different SUs, are depicted in Figure 2.

Figure 2: Structural layout and identification of the SUs.

Concerning the physical conditions, it has been observed that the main facades along Franciacorta street do not show, globally, a marked deterioration of the materials. Nevertheless, there are evident spots of humidity and partial detachment of the plaster, which, however, do not alter the static behaviour of buildings. Similarly, the façade facing Dei Quartieri street does not display signs of structural decay or cracks.

3 EMPIRICAL VULNERABILITY ASSESSMENT

To estimate the seismic vulnerability of the reference case study aggregate, firstly, it is adopted a specific vulnerability index method (V.I.M.) proposed in [3], which is appropriately conceived for historical buildings aggregates. The proposed survey form takes into account the effects of mutual interaction among SUs under seismic actions with suitable five parameters accurately calibrated on mechanical analyses. So, the vulnerability index of each SU is achieved as the weighted sum of the score of each parameter multiplied by the respective weight. Consequently, the seismic vulnerability of the entire aggregate is estimated as the weighted mean of the vulnerability indices of each SUs, considering the ratio between the cell volume and that of the entire aggregate, as shown in the following Equation 1:

$$V_{I,agg.} = \sum_{i=1}^n \left(V_I^{SU_i} \cdot \frac{Vol_{SU^i}}{Vol_{agg.}} \right) \quad (1)$$

Subsequently, the methodology proposed in [4] is applied. This seismic vulnerability assessment procedure is essentially based on specific vulnerability indices, which describe, according to various constructive and functional parameters (geometric characteristics, construction period, collapse mechanisms, etc.), the seismic criticality degree of each aggregate.

This methodology allows estimating the seismic vulnerability based on a global analytical vulnerability index (V_{GA}) of the aggregate, providing an immediate quantification of the haz-

ard of the single aggregate. Mathematically, the used analytic expression is shown in the following Equation 2:

$$V_{GA} = DM \cdot P_{DM} + RF \cdot P_{RF} + RT \cdot P_{RT} + LP \cdot P_{LP} + VT \cdot P_{VT} + MRC \cdot P_{MRC} + MSS \cdot P_{MSS} \quad (2)$$

where: DM is the masonry disconnection index, RF is the index of façades overturning, RT is the index of the gable overturning, LP is the index of strut-cracks, VT is the shear index, MRC is the R.C. hammering index and MSS is the hammering index due to staggered floor. The above mentioned factors are vulnerability indices identifying the portion of the aggregate, which results to be exposed at seismic damage. Moreover, the coefficients P_i (P_{DM} , P_{RF} , ..., P_{MSS}) are the weights associated to the previously defined indices, whose numerical values are assigned proportionally to the corresponding collapse mechanism activated [4].

The two assessment methods are applied to the case study building aggregate. Figure 3 shows the comparison between the analytical indices assessed using the applied methodologies and the respective typological vulnerability curves [5] of the entire aggregate case study.

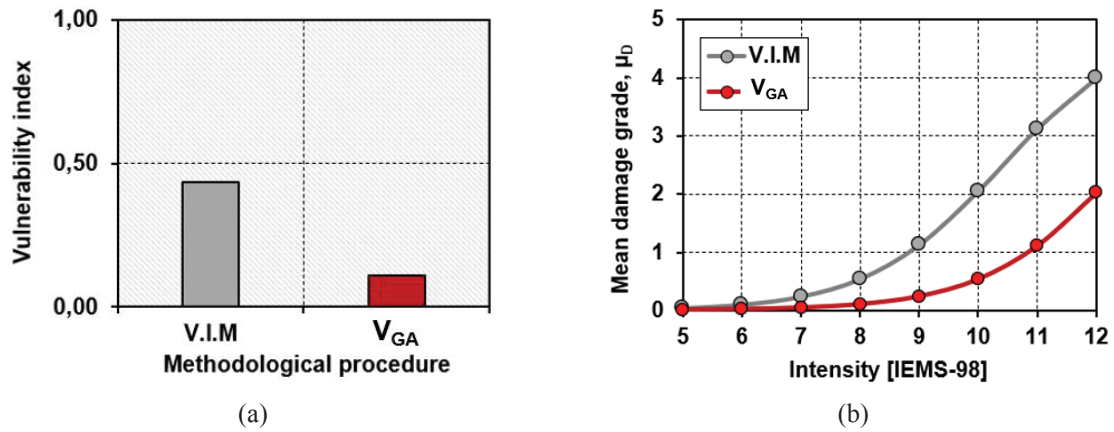

Figure 3: Comparison between the proposed methodologies in terms of vulnerability index (a) and vulnerability curves (b).

From the results acquired, it is shown how the V.I.M shows a significant increase in vulnerability (+ 26%) compared to the V_{GA} method (Figure 3a). This discrepancy is essentially due to the parameters monitored in the two methods used. The V.I.M. establishes its applicability mainly on the interactions of structural units, considering the incidence of the plane-altimetric configuration of the single SUs. On the contrary, the V_{GA} method is based on the definition of a set of indices, that affect the behaviour of the façades of the building examined. The comparison results are also presented in terms of vulnerability curves in Figure 3b, where it is seen that, starting from a macro-seismic intensity of nine, the V_{GA} method tends to underestimate of one level the expected damage compared to that of the other method proposed.

4 MECHANICAL VULNERABILITY ASSESSMENT

The numerical analyses are performed according to the 3Muri software [6] based on the Frame Macro-Elements (FME) theory. In this analysis method, it is assumed that masonry walls are considered as a set of single-dimensional macro-elements suitably interconnected to each other by rigid nodes.

The strength criteria of deformable elements are assumed based on EN 1998-3 provisions [7], which establish as maximum drifts for shear and flexural collapse failures the values of

0.4% and 0.6%, respectively. Furthermore, to consider the confinement effect of the structural units contiguous to the reference one, the SUs are modelled with the 3Muri software considering half part of adjacent structural cells accounting for their contribution in terms of stiffness and mass. In Figure 4, the most representative SUs extrapolated from the whole aggregate, namely head unit (SU1) confined on one side only, intermediate unit (SU7) confined on three sides and intermediate unit (SU13) confined on two sides, are depicted.

Figure 4: Numerical models of some structural cells: head SU (a) intermediate SU confined on 3 sides (b) and intermediate SU confined on 2 sides (c).

Subsequently, the above-presented structural configurations are compared in terms of capacity curves, as reported in Figure 5.

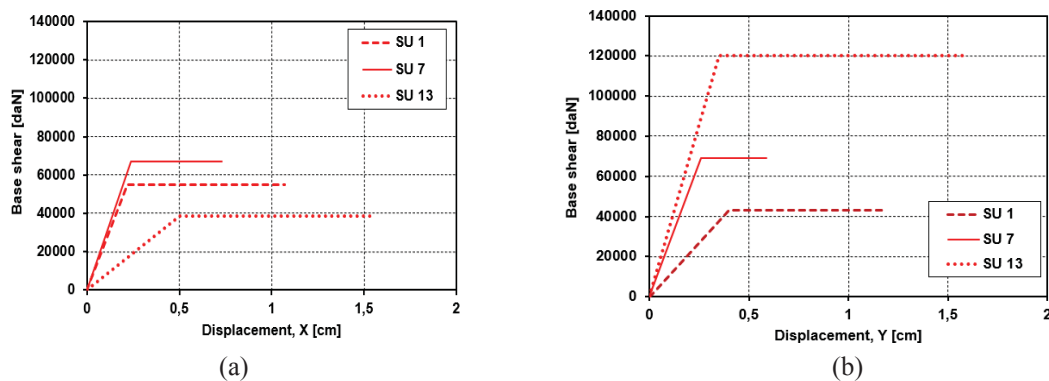

Figure 5: Capacity curves of the inspected SUs in X (a) and Y (b) analysis directions.

From the analysis of the achieved results, it is possible to appreciate how the structural behaviour of the examined SUs in the two analysis directions is very different to each other.

In particular, it is observed that in the transverse direction (X) the SU1 (head) and SU7 (intermediate, confined on three sides) provide an increase of strength about of 42% and 72%, respectively, with respect to the SU13 (intermediate, confined on two sides). Moreover, considering the comparison in terms of the ultimate displacement, d_u , the SU13 exhibits the best performance, with a value from 1.5 to 2.0 times greater than that of the other above-mentioned SUs. Conversely, in the longitudinal direction (Y), the examined structural cells display a different structural behaviour. In fact, as it is seen from the results attained in Figure 5b, the SU13 shows strength of about 3 and 2 times greater than that of SU1 and SU7, respectively. In addition, by comparing the ultimate displacements of the examined clustered units, it is noticed how the SU13 provides a value about 1.5 and 2.5 times greater than those of SU1 and SU7, respectively. Finally, the V.I.M method is applied to each of the SUS of the building compound to highlight the differences detected with the results gotten from the mechani-

cal analyses applied to each of the SUS of the whole buildings aggregate. The comparison of results deriving from the used analysis procedures are shown in Figure 6.

Figure 6: Comparison between V.I.M. results and mechanical method ones.

From the comparison presented, it is clear how, globally, the vulnerability level obtained by the empirical method is not very dissimilar from what is obtained by mechanical analysis. In particular, in the direction X, the mechanical analysis indices differ on average by +25% (estimated dispersion concerning the entire sample of data examined) compared to the mean value of the empirical procedure. On the contrary, in the direction Y, the data obtained by the mechanical approach differ on average by -10% compared to the average empirical one. This circumstance leads to consider that the proposed V.I.M. method is almost effective for the simplified estimation of the seismic vulnerability of SUs of masonry building compounds.

5 CONCLUSIONS

The present research applied different analysis procedures for seismic vulnerability evaluation of historical buildings in aggregate condition. In particular, two different approaches, namely empirical (V.I.M. and A.V.I.) and mechanical, were used to determine the seismic vulnerability of a clustered building located in the municipality of Mirandola. From the application of empirical methods, based on specific and synthetic survey forms, it was found that:

- The V.I.M method, specifically conceived for cluster buildings, allowed to estimate the vulnerability of the whole building aggregate as a weighted average of the indices of the individual structural units (SUs), providing a medium-low vulnerability level equal to 0.43;
- The method proposed by Gulli et al., which was derived as a weighted sum of specific local vulnerability indices, mainly taking into consideration the behaviour of the façade walls, provided a synthetic vulnerability index equal to 0.106 (low vulnerability);
- The comparison between the empirical methodologies showed how the V_{GA} index underestimates, on average, the expected vulnerability by + 26% compared to the V.I.M. one. This discrepancy was reflected in the evaluation of the average damage degree too. In fact, starting from a macroseismic intensity equal to nine, a mean underestimation of the expected damage degree of 33% was found by applying the methodology proposed by Gulli et al.

Subsequently, mechanical analysis was carried out on each of the SUs composing the aggregate to compare the achieved results with the corresponding ones deriving from the empirical V.I.M. method. From comparison, it was noticed that:

- In the two analysis directions, a variation of the seismic capacity was observed for the SUs examined. In particular, in the direction X, the monitored base shear provided by the SU1 and SU7 was 42% and 72% higher than those of the corresponding SU13, respectively.

Moreover, the SU13 exhibited a significant increase of the capacity displacement, with a value from 1.5 to 2.0 times greater than that of the other above-mentioned SUs. On the contrary, in direction Y, it was observed how the SU13 provided a shear strength about 3 and 2 times higher than that of SU1 and SU7, respectively. In addition, by comparing the ultimate displacements of the examined clustered units, it has been noticed how the SU13 provided a value about 1.5 and 2.5 times greater than those of SU1 and SU7, respectively.

- The vulnerability level attained by the empirical V.I.M. method did not result dissimilar from what was obtained by the mechanical approach. In particular, in the direction X, the mechanical simulation overestimated by +25% the mean index of empirical procedure. On the contrary, in the direction Y, the vulnerability index obtained by the mechanical approach underestimated on average by 10% the seismic safety condition deriving from the simple empirical method.
- In conclusion, based on the above-mentioned results, it was found that the V.I.M. method is quite suitable in predicting, through a simple analysis tool, the seismic vulnerability of SUs of clustered buildings.

Keywords: Masonry, arch bridge, seismic behaviour, Piecewise Rigid Displacement approach.

Abstract. Settlements severely affect historic masonry structures, and in fact, settlement-induced structural failures are common worldwide. This paper describes a rigid block detection and identification procedure of the crack pattern in masonry-like structures subjected to dead loads and finite displacements (e.g., settlements). The procedure is based on the Piecewise Rigid Displacements (PRD) approach. The equilibrium problem is formulated in the framework of Limit Analysis by means of a suitable variational formulation for the Boundary Value Problem (BVP) of Normal Linear Elastic No-Tension material (NENT). The equilibrium states of masonry-like structures are obtained as an optimization of Total Potential Energy (TPE). The application of the proposed method to real case studies highlights its potential in the field of mechanics and the mechanisms of fracture.

1 INTRODUCTION

Masonry arch bridges are susceptible to extensive structural damage, failure, and even collapse when subjected to exceptional loading or massive differential settlements induced by floods, ship-worm infestations of wooden foundations, scouring, and other natural or man-made events. The Scrivia River, Trigno, and Rubianello bridges in Italy (2002, 2003, 2013), the Ballynameen and Bishopsford Road bridges in England (2015, 2019), the Deba bridge in Spain (2018) are just some examples of recent spread world wide masonry bridges failures under scour-induced settlements [1]-[6] are just a few examples of recent worldwide masonry bridges failures under scour-induced settlements. These events are further proof of the urgent need for the analysis and assessment of the load-carrying capacity of masonry bridges. The number of scientific research papers dealing with this topic is impressive. The main methods of structural analysis of masonry construction are:

- FEM-based approaches, which are subdivided into three main categories depending on the representative scale: macro-modeling [7]-[9], discontinuous models [10] and micro-modeling [11]. Moving from the macro- to the micro-scale, the level of accuracy increases, but the modeling and numerical implementation challenges and the computational efforts also significantly increase;
- homogenization approaches [12, 13], in which a structural elementary cell (consisting of different components such as mortar and blocks) is modeled as an equivalent homogeneous medium (i.e., a continuum) with mechanical parameters that are derived from each of its individual components; and
- Limit Analysis-based approaches, modern approaches that support the classical methods employing thrust line theory, graphic statics, and Limit Analysis. Their origins date to the English school in the late 1600s, with the theory of the chain having firstly been proposed by Robert Hooke (1676) and used later by Christopher Wren in Saint Paul's dome (1675), by Giovanni Poleni in St. Peter's dome in Vatican (1743), and, more recently, by Antoni Gaudí i Cornet for the design of the church of Colònia Güell in Barcelona (c. 1900) [14, 15]. Their modern formulation, due to Anthony Kooch, Jacques Heyman and Olgierd Cecil Zienkiewicz [16]-[18], is based on the No-Tension assumption. The material is modeled as a no-tension rigid or elastic material, with unilateral no-friction contact conditions [19]-[22].

Nonetheless, the issue is far from being exhausted because each of these three methods yields results only within its own bounds. There is to date no generally accepted way to assess masonry structures.

This paper focuses on analyzing and predicting crack patterns in masonry arch bridges subjected to dead loads and finite displacements. In the framework of the modern Limit Analysis-based approaches, the equilibrium problem is reformulated with a classical variational inequality form or equivalently as a constrained minimization problem of a non-differentiable functional (i.e., the Total Potential Energy) over the set of admissible displacements [23]-[?]. The main novelty is the consideration of a fictitious elasticity of the material to guarantee the convergence of the proposed method. The solution is then obtained by making the elastic deformation tensor tend to zero. This procedure is based on the Piecewise Rigid Displacements approach [21], which consists of restricting the minimization problem by a finite class of piecewise rigid displacements with support on a

finite partition of the whole structural domain. This reduces the equilibrium problem to a convex optimization problem for which existence and uniqueness are ensured. The case study of the Deba Bridge failure in Spain is also considered to capture the essence of the proposed method and its effectiveness.

The structure of the paper is as follows: Section 2 focuses on the Deba Bridge and its failure occurred in 2018, Section 3 presents the mathematical model and theoretical framework of the proposed numerical approach, Section 4 applies such a procedure to the case study of Deba Bridge. The results show a satisfactory agreement between the numerical-based crack pattern and the observed one, proving to be a powerful and versatile tool for the study of the mechanisms of fracture of No-Tension materials. The proposed method can be usefully exploited for the study of collapse mechanisms and ultimate load capacity of a wide range of masonry-like structures as it is emphasized in the concluding remarks drawn in Section 5.

2 The Deba Bridge

The Deba Bridge is a four-span stone bridge connecting the city of Deba with Mutriku in the Basque Country of Spain. It was built from 1865 and 1866 as part of a larger coastal motorways project that aimed to link the cities of San Sebastián and Bilbao. For its artistic and historic value, the Deba Bridge has special protection within the Monumental Complex of the Camino de Santiago. The underlying geology of the Deba riverbed is mainly composed of alluvial soil mixed with silt, sand, and gravel that constantly experiences landslides, dolines, and rockfalls. This is reflected in many episodes of settlement-induced bridge failures over the years. The latest occurred at the beginning of July 2018, when the central pier experienced a vertical settlement of about 0.80-0.90m, resulting in a great depression in the road, damage and cracking of the two central bridge vaults, and, consequently, closure of the bridge (Figure 1).

Figure 1: Views of the Deba Bridge (Debako Zubia kaltetuta)

3 Mathematical model

Let us consider an elastic body that occupies, in its undeformed state, an open and bounded subset $\Omega \in \mathbb{R}^2$ with a sufficiently smooth boundary (i.e., $\mathcal{C}^{1,1}$ -regular curve $\partial\Omega$), consisting of two open disjoint parts $\partial\Omega = \partial\Omega_D \cup \partial\Omega_N$. They are bound to first-type (i.e., Dirichlet) and second-type (i.e., Neumann) boundary conditions (i.e., here, the displacements and the surface forces are prescribed), respectively:

$$\mathbf{u} = \bar{\mathbf{u}} \quad \text{on } \partial\Omega_D, \quad \mathbf{T}^{(n)} = \mathbf{p}, \mathbf{b} \quad \text{on } \partial\Omega_N. \quad (1)$$

Here, $\bar{\mathbf{u}}$ denotes the vector field of prescribed surface displacements; $\mathbf{p} = \{p_i\}$ and $\mathbf{b} = \{b_i\}$ denote the prescribed forces and the body forces; and $\mathbf{T}^{(n)} = \mathbf{T}\mathbf{n}$, where \mathbf{n} is the outward normal vector on the boundary of Ω . Let $\mathbf{E} = \boldsymbol{\varepsilon} + \boldsymbol{\lambda}$ denote the infinitesimal strain tensor, additively decomposed into an elastic ($\boldsymbol{\varepsilon}$) and an anelastic part ($\boldsymbol{\lambda}$); \mathbf{T} the stress tensor; and \mathbb{C} , the positive-definite elasticity tensor. The constitutive equations for the NENT material we investigate are described by the set of relations:

$$\text{strain-stress relation:} \quad \mathbf{E} = \mathbb{C}^{-1}\mathbf{T} + \boldsymbol{\lambda}, \quad (2)$$

$$\text{internal constraint:} \quad \mathbf{T} \in \text{Sym}^-, \quad (3)$$

$$\text{normality law:} \quad \boldsymbol{\lambda} \in \text{Sym}^+ \wedge \mathbf{T} \cdot \boldsymbol{\lambda} = 0. \quad (4)$$

The Boundary Value Problem (BVP) for a NENT material is given by:

Problem 3.1 Find an admissible state $(\mathbf{u}, \boldsymbol{\lambda}, \mathbf{T})$ (i.e., displacement, anelastic strain and stress fields):

1. equilibrium

$$\text{div}\mathbf{T} + \mathbf{b} = \mathbf{0}, \quad \text{on } \Omega \quad (5)$$

2. stress-strain constitutive law

$$\mathbf{T} = \mathbb{C}(\mathbf{E} - \boldsymbol{\lambda}), \quad (6)$$

3. internal constraint and normality law

$$\mathbf{T} \in \text{Sym}^-, \quad \boldsymbol{\lambda} \in \text{Sym}^+, \quad \mathbf{T} \cdot \boldsymbol{\lambda} = 0, \quad (7)$$

4. boundary conditions

$$\mathbf{T}\mathbf{n} = \mathbf{p}, \quad \mathbf{u} = \bar{\mathbf{u}}|_{\partial\Omega_N}, \quad \text{on } \partial\Omega_N. \quad (8)$$

The resulting weak formulation, i.e., the variational formulation of such a problem, can be formulated as follows:

Problem 3.2

$$\text{minimize}_{\mathbf{u} \in \mathcal{K}, \boldsymbol{\varepsilon}} : \quad \mathcal{E}_p(\boldsymbol{\varepsilon}) = \int_{\Omega} \phi_{\mathbb{E}i}(\boldsymbol{\varepsilon}) da - \int_{\Omega} \mathbf{b} \cdot \mathbf{u} da - \int_{\partial\Omega_N} \mathbf{p} \cdot \mathbf{u} ds, \quad (9)$$

$$\text{subject to :} \quad \mathbf{A}\mathbf{U} \geq 0, \quad \mathbf{B}\mathbf{U} = 0 \quad (10)$$

where \mathcal{K} is a proper finite class of piece-wise rigid displacements obeying material conditions and having support on a finite partition of the whole domain $\Omega = \bigcup_1^m \Omega_i$

$$\mathcal{K} \subset \{\mathbf{u} \in \mathcal{S}(\Omega) : \boldsymbol{\lambda} \in \text{Sym}^+ \text{ and } \mathbf{u} = \bar{\mathbf{u}} \text{ on } \partial\Omega_N\} \quad (11)$$

$\phi_{\mathbb{E}_i}$ denotes the strain energy density, $\mathbf{U} \in \mathbb{R}^{3m}$ is the vector collecting the three Lagrangian parameters of the elementary mesh element Ω_i , and the matrices \mathbf{AU} and \mathbf{BU} collect the no-concentration and no-sliding conditions, respectively (See ... for more details). Note that the resulting optimization problem involves a quadratic functional subjected to linear constraints. By minimizing the TPE with respect to both displacements and elastic deformation, we are forcing the elastic part of the strain tensor to vanish. It is equivalent to coupling the initial rigid structure, characterized by a positive semi-definite stiffness \mathbf{K} , with a fictitious elastic structure, characterized by a positive-definite stiffness \mathbf{K}_s . It can be proven that the problem of finding an admissible state of displacement for the initial structure is equivalent to the same problem formulated for a structure having a positive-definite stiffness, $\mathbf{K}_\delta = \mathbf{K} + \delta\mathbf{K}_s$, because regularization parameter δ tends to zero [30].

4 Numerical analysis

The proposed method is validated by analyzing the case study of the Deba Bridge failure. The convex optimization problem related with the proposed approach was solved here by the Interior Point method [31, 32], which is particularly advantageous when the problem involves a large number of variables ($3 \cdot 1012$ in the case analyzed here). The bridge domain is discretized into 1012 quadrilateral elements and a vertical displacement of 0.9m and a counterclockwise rotation of 1.13 is imposed on the central pier of the bridge. The obtained results, both in terms of displacements and macro-block identification, show good agreement with the failure geometrical survey. On the basis of blocks rigid roto-translations, six macroblocks have been identified. The two on the outside (the light blue blocks in Figure 2) are fixed. Then a four-block isostatic substructure can be identified, the kinematic motion of which is closer to that seen in the bridge failure (Figure 2).

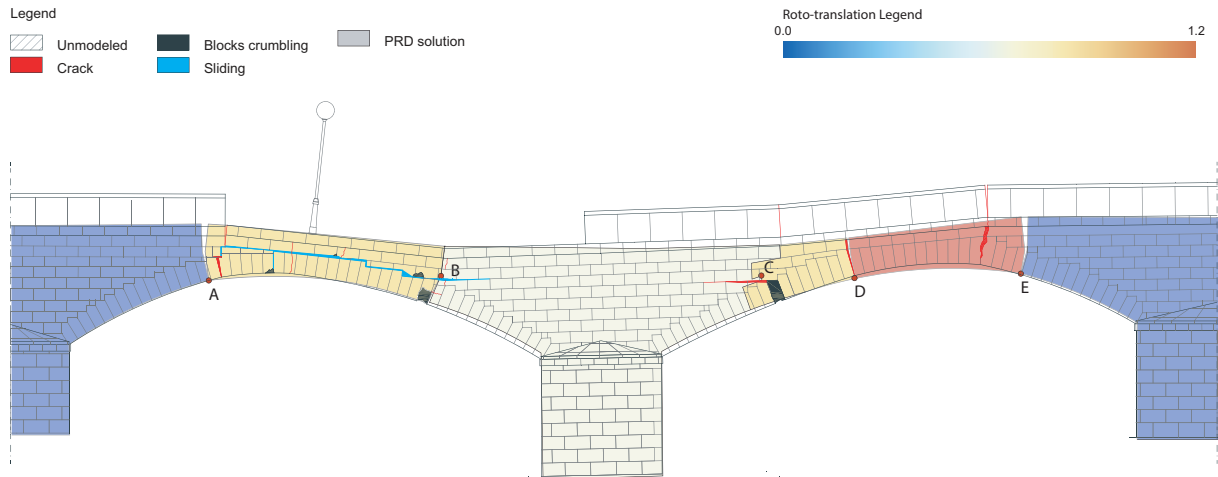

Figure 2: Superposition of PRD numerical results and failure geometrical survey (red dots A, B, C, D, and E mark the hinges location between two adjacent macroblocks).

5 CONCLUSIONS

A preliminary study of the mechanics of fracture mechanisms in unilateral no-tension bridge structures subjected to pier settlements is proposed here. This approach falls into

the so-called block-based Limit Analysis methods. The equilibrium problem is formulated by a convex optimization problem with a quadratic objective function and linear inequality constraints. The main innovation introduced by this approach is consideration of a Normal Linear Elastic No-Tension material in which the elastic part of the strain tensor is considered only fictitious. By minimizing the TPE with respect to both displacements and elastic deformation, we force the elastic part of the strain tensor to vanish. In this way, the problem of finding an admissible state of displacement for the NENT structure became equivalent to the same problem formulated for a No-Tension No Rigid material. The proposed approach is applied to a case study of the Deba Bridge failure (2018). The obtained results indicate very good agreement between the numerical model and the failure survey. The method is simple, effective, and promising. The range of applicability of this method can be broadened to facade and complex NENT structures. It provides a good starting point for the study of the collapse mechanisms and ultimate load capacity of masonry-like structures.

Keywords: Structural Health Monitoring, Digital Twin, Incremental Dynamic Analysis, Surrogate model, Post-earthquake damage assessment, Cultural Heritage.

Abstract. *This paper presents the introduction of Digital Twins in the case of an historic masonry tower for rapidly addressing earthquake-induced damage identification. In the context of the present paper, a digital twin is a model or a suite of models of the considered structure that are updated/modified during time based on monitoring data. In particular, the proposed approach combines Operational Modal Analysis (OMA), Surrogate Modeling (SM) and non-linear Incremental Dynamic Analysis (IDA). On the one hand, OMA-based Structural Health Monitoring (SHM) systems successfully allow the detection of small structural damages occurring during earthquakes, and on the other, SM exploits the correlation between continuous vibration data and structural stiffnesses while IDA is carried out from a tuned model together with in situ recorded seismic data. The San Pietro bell tower has been considered for the validation of the proposed methodology. The tower is a monumental medieval masterpiece, located in Perugia, Italy, and it represents a relevant case study in the scientific literature due to its important experience during the 2016-2017 seismic sequence that occurred in Central Italy. While the OMA-vibration data processing assessed distinct earthquake-induced changes in its global dynamic behavior, the focus of the present work is the results on the use of linear as well as non-linear modeling, i.e. SM and IDA, respectively, aimed for post-earthquake damage localization and quantification.*

1 INTRODUCTION

Vibration-based SHM methods based on unsupervised learning techniques have been recently demonstrated in the literature as eminently efficient for early-stage damage detection [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13]. Due to their limitation to detection only, more advanced approaches are required in order to address higher levels of damage identification for Cultural Heritage (CH) masonry structures.

The introduction of Digital Twin (DT) in civil engineering in the case of historic masonry constructions is a recent concept of scientific interest [14]. DT can be defined as a model or a suite of models of the structure that continuously exchanges information with the physical reality through experimental/field data, thus providing evidence of novelties or changes, for instance, related to a faulty or damage conditions.

Surrogate models (SM) have been lately investigated as computationally efficient tools to reproduce the behavior of a numerical model, potentially allowing a continuous model updating procedure for damage identification that is compatible with continuous SHM systems in historic masonry structures [15, 16, 17]. The damage localization task is performed through the inverse calibration problem on a surrogate of the linear FE model where equivalent elastic properties of macrostructural elements are considered as uncertain parameters, and by using long-term vibration data.

Other approaches are adapted given the strong development of computer processing power and advanced structural analysis software packages, aiming at more accurate analysis methods for the assessment of masonry buildings. Noteworthy to mention, non-linear dynamic analysis (NLDA) can provide a reliable assessment of the structural response of masonry constructions [18, 19, 20, 21]. In particular for NLDA, Incremental Dynamic Analysis (IDA) [22] considers the selection of time histories to be scaled at increasing seismic intensities. The application of IDA to CH masonry structures is comparatively less common with respect to RC structures. The recent research carried out in [21] proposed the use of an IDA-based approach for damage localization and quantification in the case of a laboratory masonry structure, but still, further investigations can be carried out in the case of full-scale historic masonry constructions.

The methodology proposed in this paper combines OMA, SM and IDA for earthquake-induced damage identification in historic masonry towers. It is applied to the San Pietro bell tower, an iconic Cultural Heritage masonry building that was hit by the three main shocks of the 2016 Central Italy seismic sequence: (i) Accumoli Mw6.0 earthquake of August 24th and the following shocks, (ii) Ussita Mw5.9 earthquake of October 26th and (iii) Norcia Mw6.5 of October 30th [4, 23, 24]. Fig. 1 illustrates a schematic view of the monitoring system and the FE model constructed in the ABAQUS platform [25]. With concern to the proposed methodology, the tower is ideally subdivided into three distinct structural parts: the shaft, the belfry and the cusp.

The paper is organized as follows. Section 2 describes the proposed methodology, while Section 3 reports the results and its validation. Finally, Section 4 summarizes the main conclusions of the work.

2 METHODOLOGY

This paper investigates a new methodology for rapid damage detection, localization and quantification in long-term monitored historic masonry towers subjected to earthquakes. It merges the data-driven OMA-based approach for a rapid and automated damage detection with two combined Digital Twins for damage localization and quantification: (i) SM-based damage

Figure 1: The monitoring system installed on the San Pietro bell tower (a) and view of the calibrated FE model (b).

identification based on linear numerical modeling and long-term vibration monitoring data and (ii) IDA-based damage identification relying on a non-linear model and seismic response to earthquakes.

The OMA is based on a Stochastic Subspace Identification (SSI) technique. Concerning the SM, among different SM models available in the literature, the Response Surface Method (RSM) has been proposed to be used here. Finally, the IDA approach investigates tensile damage (d_t) as a Damage Measure (DM) versus significant uncorrelated Intensity Measures (IMs).

Main theoretical aspects about SM and IDA can be found in [16, 17] and [21], respectively.

3 VALIDATION RESULTS

The OMA-based damage detection has been applied using 5 years of vibration-based monitoring data, from December 2014 onwards. Time series of identified natural frequencies have been used for the novelty analysis. Fig. 2 illustrates the control chart where earthquake-induced damage has been identified in correspondence to the seismic events. It is clear from the plot that it represents anomalous deviations from normal conditions due to small permanent changes of the structural behavior of the bell tower, highlighted right after the Accumoli earthquake, as well as after Ussita and Norcia shocks.

The SM of the San Pietro bell tower has been constructed considering the FEM ideally subdivided into three distinctive macroelements and thus parametrized by means of a set of damage-sensitive features. A training population of $N=2048$ individuals has been uniformly generated by using a Latin Hypercube Sampling (LHS) method. The design variables are represented by the stiffness multipliers k_i of the shaft, belfry and cusp, respectively ($\mathbf{x} = [k_1, k_2, k_3]^T$).

Figure 2: OMA-based damage detection: 5-year control chart with main seismic events highlighted.

Subsequently, the SM-based damage identification approach has been applied before and after the 2016 seismic sequence for localizing and quantifying earthquake-induced damage, whereby time series of cleansed natural frequencies and experimental eigenvector components have been used as input for solving the inverse FE model calibration problem on the RSM-type SM.

A first investigation on the time histories of the stiffness multipliers k_i has been carried out, where instant decays have been quantitatively evaluated for each macroelement by comparing values identified before and after each shock. The k_2 multiplier experiences the highest variation, denoting that damage has occurred in the belfry macroelement, while the shaft and the cusp show insignificant values. Subsequently, the k_i vectors have been independently used to build the statistical models for novelty analysis. The control charts are illustrated in Fig. 3, where the damage can be clearly localized in the belfry macroelement. The relative frequency

Figure 3: SM-based damage identification: 5-year control charts obtained with stiffness multipliers k_i .

of outliers in the case of the belfry "jumps" from 2.21% before the earthquake sequence to 36.41% after the sequence, while for the shaft and the cusp it remains under 2.5%.

As reported by the statistical correlation analysis carried out in [21], nineteen weakly correlated IMs have been investigated for the construction of the IDA curves, independently from the case study. These IMs have been exploited in the present paper for the San Pietro bell tower, while tensile damage (d_t) has been used as DM (computed as a volume-averaged damage parameter). Local damage conditions have been investigated for the three distinct macroelements: shaft, belfry and cusp. Figs. 4a-b depict IDA curve sets obtained from spectral accelerations $S_a(T1)$ and Peak Ground Velocity (PGV), while other curves can be found in [24]. From the plots, the belfry can be immediately identified as the most vulnerable macroelement where the maximum numerically obtained tensile damage d_t is equal to about 0.85.

The recordings of the main earthquakes of the 2016 Central Italy seismic sequence have been used in the IDA-based damage identification approach. Once all the IDA curve sets have been

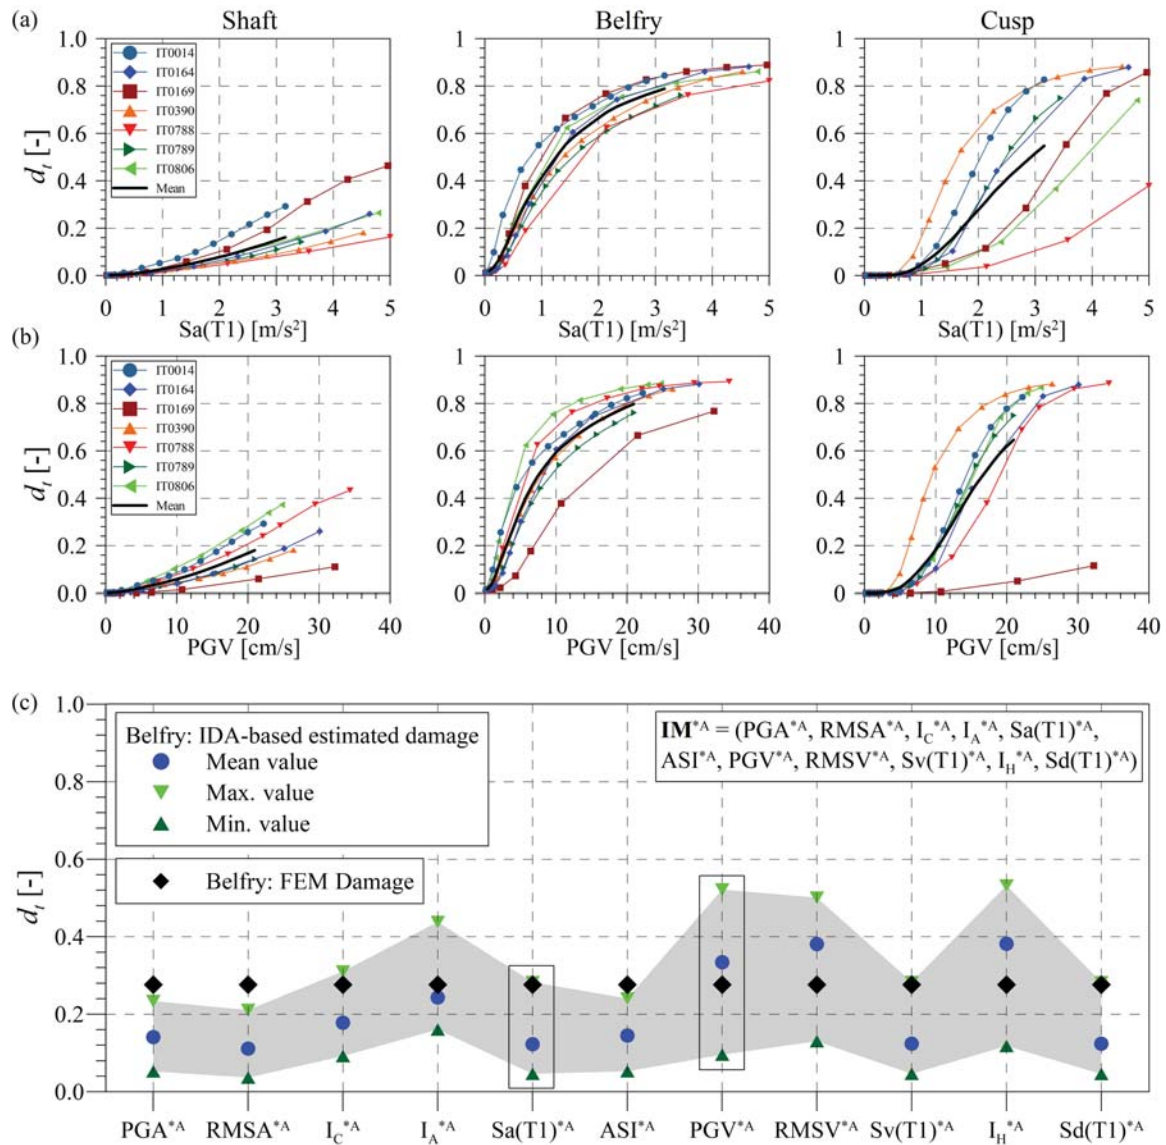

Figure 4: The IDA curve sets obtained with tensile damage, d_t , versus $S_a(T1)$ (a) and PGV (b), and IDA-based tensile damage estimated for the belfry macroelement by means of eleven input IMs calculated from Accumoli earthquake (c).

constructed and their dispersion investigated, local damage conditions have been assessed by using seismic input and response IMs of the real aforementioned seismic events. Eleven seismic input IMs have been computed from the base seismic records and seven seismic response IMs have been calculated from the top seismic records. Fig. 4 illustrates damages estimated in the belfry macroelement by applying all eighteen IMs that are computed from Accumoli, Ussita and Norcia earthquakes, respectively. Besides IDA-based damages that are reported in terms of minimum, maximum and mean values, damage predicted through a direct non-linear FEM simulation is also reported for comparative purposes. It can be seen that there is relatively good consistency, whereby d_t values fall within the corresponding estimated ranges.

4 CONCLUSIONS

The paper presented the validation results of the proposed methodology for earthquake-induced damage identification in historic masonry towers. The San Pietro bell tower (Perugia, Italy) that was hit by the 2016 Central Italy seismic sequence has been considered as the case study.

The main concluding remarks are listed below.

- The OMA-based data-driven method is extended through the introduction and implementation of Digital Twins, in particular SM and IDA, for localization and quantification of earthquake-induced damage.
- Both SM and IDA are comparatively combined for higher accuracy of the method: (i) the former uses a linear model while the latter a non-linear one, (ii) IDA uses the recorded seismic response of an earthquake, whereas OMA and SM are based on long-term vibration monitoring data in operational conditions.
- Five years of continuous monitoring data of the San Pietro bell tower have been used in the SM-based procedure for earthquake-induced damage detection and localization and damage has been localized mainly in the belfry macroelement.
- Non-linear seismic IDA procedure has also identified the belfry as the most significantly vulnerable and damaged macroelement of the bell tower. In addition, top recorded seismic responses during earthquakes have allowed the introduction of seismic response IMs.
- Both Digital Twins have localized and consistently quantified earthquake-induced damage in the belfry macroelement.

The successful validation of the Digital Twins can result potentially useful in more severe future earthquake scenarios due to the precious information provided for needed first inspections, retrofit and strengthening interventions.

Keywords: Micromechanical modeling, Finite element, Masonry arch, Reinforcement.

Abstract. *This work analyzes the in-plane response of unreinforced and reinforced masonry arches by adopting micromechanical finite element (FE) models. These allow to describe onset and evolution of degrading mechanisms until failure, including the accurate characterization of the pre- and post-peak behavior. Two different models are adopted: the first considers each masonry component, brick and mortar, as continuous material discretized with quadrilateral FEs; the second connects properly resized bricks through interfaces representing both mortar and mortar-units interaction. Linear elastic behavior is assumed for bricks, whereas a coupled damage-friction constitutive law is adopted for mortar to account for typical arch collapse mechanisms involving flexural hinges and shear sliding. As concerns the modeling of the reinforcements, these are considered as truss elements with bilinear response in tension. In such a way the debonding and delamination phenomena are accounted in a simplified way.*

Results obtained with the proposed models are validated through comparison with experimental data and solutions obtained from other numerical approaches. It emerges that the response of both the unreinforced and reinforced elements are satisfactorily described, as well as the positive effect of the introduction of the reinforcement on the collapse load and failure mechanism.

1 INTRODUCTION

Most of historical masonry constructions, including monuments, urban buildings and bridges, are based on arch systems. These typically show high carrying capacity under gravity loads, but under point loads or seismic actions the thrust line falls outside the arch central core, inducing tensile stresses with the onset and growth of microcracks which, eventually, lead to the structural collapse. A traditional strengthening technique consists of the insertion of tie-rods which, however, have a strong visual impact and in some cases are not accepted. The scientific community proposed and developed several types of alternative strengthening techniques aimed at improving the arch performance with no visual impact and with negligible added mass. These are based on innovative composite materials consisting of glass fibers, carbon fibers, steel rod or other materials embedded in polymer or mortar matrices. Several experimental campaigns proved the efficiency of such strengthening systems [1], which usually increase the structural capacity in terms of both ductility and maximum strength. Apparently, the type of reinforcement and matrix [2, 3] and the reinforcement location [4, 5] significantly affect the overall response. Moreover, the classical collapse mechanism of unreinforced arches, involving the formation of four flexural hinges, is modified for strengthened structures. The failure modes are, in fact, usually characterized by shear sliding, masonry crushing, reinforcement rupture, debonding and delamination phenomena [1].

The experimental research is developed together with the formulation of efficient numerical models to reproduce and predict the arch structural response. In this framework, limit analysis approach is a consolidated tool for the assessment of the arch safety. Starting from the first applications of Heyman [6], many other enriched models have been proposed, where Heyman's hypotheses are partially or all removed [7, 8, 9]. The success of these models is mainly due to their simplicity and the reduced number of material parameters required in the analysis. The main limit is that no information is given on the pre- and post-peak response as well as the evolution process of the nonlinear mechanisms. To overcome these restrictions, accurate nonlinear finite element (FE) models have been developed [10, 11, 12]. Most of these are typically based on micromechanical, multiscale and macromechanical approaches [13, 14] and introduce nonlinear constitutive laws to describe the onset and evolution of degrading mechanisms. In particular, detailed micromechanical finite element formulations model each masonry constituent, brick and mortar, and their interaction. However, some simplified hypotheses are usually assumed to reduce the computational complexity, still ensuring enough accurate results. Neglecting the explicit modeling of the unit-mortar interfaces, the composite masonry material is regarded as the assembly of bricks/units and mortar joints which simultaneously describe mortar material and interfaces. According to this approach, in this work two strategies are adopted and compared to analyze the in-plane response of masonry arches. The first model, recently presented in [15], considers masonry components, units and mortar, as continuous materials discretized with quadrilateral FEs. Conversely, in the second model, masonry is modeled as the assembly of expanded units and interface elements representing both mortar and unit-mortar interaction. The two models are based on the same constitutive hypotheses, i.e. linear elastic and nonlinear behavior are assumed for bricks and mortar, respectively. The damage-friction law originally proposed in [16] is employed for joints. This allows to capture the typical failure modes of arches due to fracture mode I and II, and has been recently extended to mortar joints modeled as 2D [17] or 3D [18] interfaces. Moreover, when dealing with strengthened arch systems, reinforcements are modeled with truss elements, whose constitutive response is properly identified to also reproduce the debonding and delamination phenomena in a simplified

and conventional way [8, 10, 19].

To prove the capability of the proposed models to reproduce the response of unreinforced and reinforced arches, some numerical applications are performed on properly selected experimental tests. The results, in terms of global response curves and failure mechanisms, are compared with the experimental outcomes, as well as with those obtained by means of different FE numerical approaches.

2 MICROMECHANICAL FINITE ELEMENT MODELS

Two micromechanical FE models are presented to investigate the response of masonry arches. Both adopt isoparametric quadrilater FEs to discretize the bricks, but differ in the way the mortar joints are modeled. The first (Figure 1(a)), named as *continuous model* (CM), also uses isoparametric quadrilater FEs to describe mortar as continuous materials. The second (Figure 1(b)), later called as *interface model* (IM), adopts interface elements to model the mortar joints. Moreover, truss elements are used to introduce in a simple but effective way the strengthening material.

In the following, details about the constitutive assumptions made for brick, mortar and reinforcement are provided. Figure 2 gives a summary of the modeling choices.

Figure 1: Micromechanical models: masonry as the assembly of (a) bricks and mortar joints, (b) interfaces and expanded bricks.

2.1 Constitutive laws of masonry constituent materials and reinforcement

Similar constitutive hypotheses hold for the two micromechanical models CM and IM, as both assume nonlinear mechanisms only occurring in the mortar and linear-elastic response for units. Plane stress conditions are considered. Hence, the linear elastic relation between stresses, $\boldsymbol{\sigma}^b = \{\sigma_1^b \sigma_2^b \tau_{12}^b\}^T$, and strains $\boldsymbol{\varepsilon}^b = \{\varepsilon_1^b \varepsilon_2^b \gamma_{12}^b\}^T$, holds for bricks:

$$\boldsymbol{\sigma}^b = \mathbf{C}^b \boldsymbol{\varepsilon}^b \quad (1)$$

being \mathbf{C}^b the elastic constitutive matrix for 2D plane stress problems, depending on the Young's modulus E^b and Poisson coefficient ν^b .

As for the mortar, the damage-friction law proposed in [16, 17] is assumed. This is properly formulated to analyze the response of arbitrarily curved masonry elements with variable inclination of mortar joints [15]. The constitutive law accounts for the typical flexural and shear degrading mechanisms characterizing masonry nonlinear behavior, that is degradation due to the onset of microcracks, friction effects caused by closure of microcracks in compression and unilateral stiffness recovery.

Herein, the main governing equations are recalled, specializing them on the basis of the modeling approach, CM or IM, adopted for the mortar. Indeed, stresses, $\boldsymbol{\sigma}$, and strains, $\boldsymbol{\varepsilon}$, are the static and kinematic descriptors of the mortar as continuous material, whereas tractions,

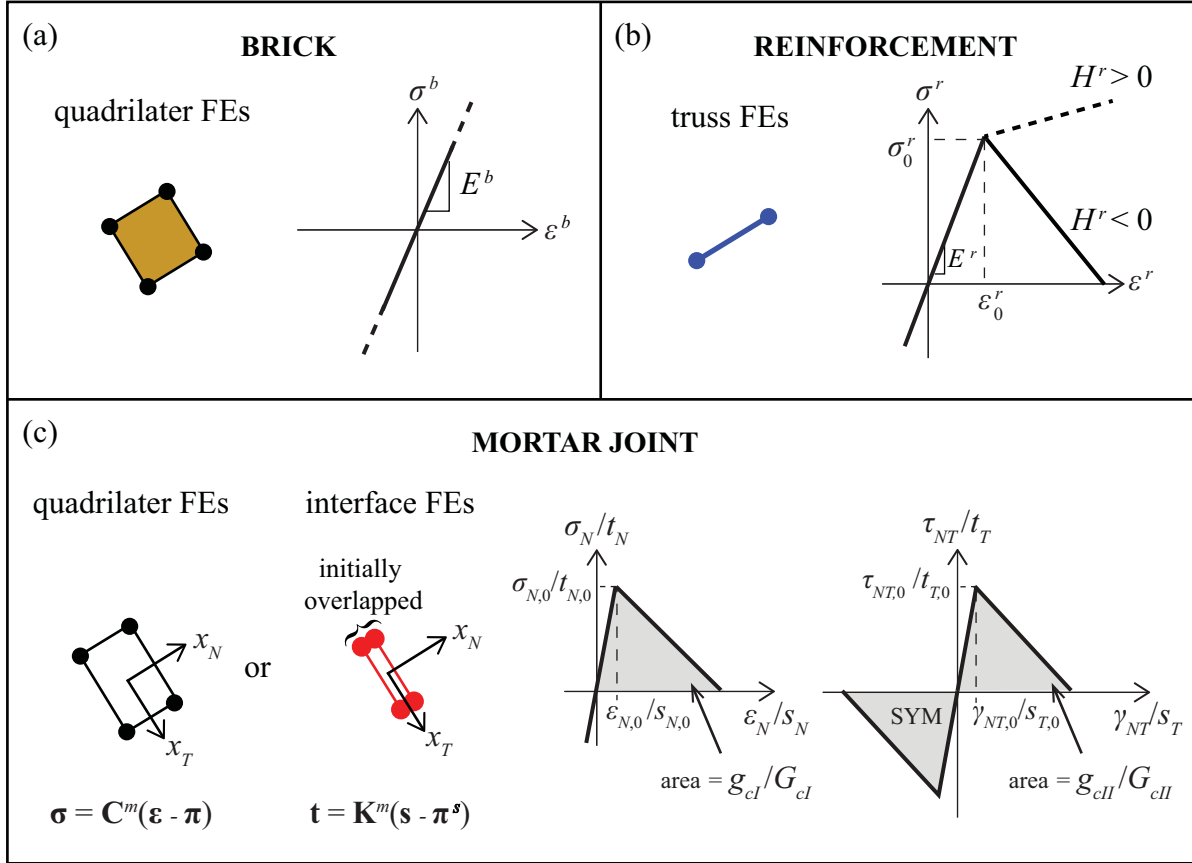

Figure 2: Types of finite elements and constitutive laws adopted for: (a) brick, (b) reinforcement and (c) mortar.

\mathbf{t} , and displacement jumps, \mathbf{s} , are the corresponding quantities in case of interfaces modeling mortar joints.

The constitutive law is firstly defined in the local reference system (x_T, x_N) of each mortar layer, being T and N the directions aligned with mortar joint width and thickness (Figure 1(c)). Then, it is expressed in the global system (x_1, x_2) by using standard transformation rules. The constitutive law for the CM is expressed as:

$$\underbrace{\begin{bmatrix} \sigma_T \\ \sigma_N \\ \tau_{NT} \end{bmatrix}}_{\boldsymbol{\sigma}} = \mathbf{C}^m \left(\underbrace{\begin{bmatrix} \varepsilon_T \\ \varepsilon_N \\ \gamma_{NT} \end{bmatrix}}_{\boldsymbol{\varepsilon}} - D \underbrace{\begin{bmatrix} h(\varepsilon_N)\varepsilon_T \\ h(\varepsilon_N)\varepsilon_N \\ \gamma_{NT}^p \end{bmatrix}}_{\boldsymbol{\pi}} \right) \quad (2)$$

where \mathbf{C}^m is the mortar elastic constitutive matrix for plane stress conditions and $\boldsymbol{\pi}$ is the inelastic strain vector accounting for damage D , unilateral contact and slip γ_{NT}^p .

Similarly, tractions \mathbf{t} at the interfaces are computed as:

$$\underbrace{\begin{bmatrix} t_T \\ t_N \end{bmatrix}}_{\mathbf{t}} = \mathbf{K}^m \left(\underbrace{\begin{bmatrix} s_T \\ s_N \end{bmatrix}}_{\mathbf{s}} - D \underbrace{\begin{bmatrix} s_T^p \\ h(s_N)s_N \end{bmatrix}}_{\boldsymbol{\pi}^s} \right) \quad (3)$$

being \mathbf{K}^m the diagonal matrix collecting the stiffness values, K_T and K_N , along the tangential and normal directions, respectively, to the interface. In Eqs. (2) and (3), $h(\bullet)$ denotes the Heaviside function ($h(\bullet) = 1$, if $\bullet \geq 0$ and $h(\bullet) = 0$ otherwise), describing the unilateral stiffness

recovery due to the re-closure of the tensile cracks in compression.

According to its physical meaning, the damage variable D can range between 0 and 1, representing virgin and fully degraded material states, respectively. Its evolution law is stated as:

$$D = \max_{history} \left\{ 0, \min \left\{ 1, \frac{1}{\eta} \left(\frac{\beta}{1 + \beta} \right) \right\} \right\} \quad (4)$$

where β is the damage associated variable which assumes the following forms for continuous and interface mortar, respectively:

$$\beta = \sqrt{\left(\frac{\langle \varepsilon_N \rangle_+}{\varepsilon_{N,0}} \right)^2 + \left(\frac{\gamma_{NT}}{\gamma_{NT,0}} \right)^2} - 1, \quad \beta = \sqrt{\left(\frac{\langle s_N \rangle_+}{s_{N,0}} \right)^2 + \left(\frac{s_T}{s_{T,0}} \right)^2} - 1 \quad (5)$$

In Eq. (5), the Macaulay's brackets $\langle \bullet \rangle_+$ select the positive part of the quantity; $\varepsilon_{N,0}$ and $\gamma_{NT,0}$ are the first crack strains, while $s_{N,0}$ and $s_{T,0}$ are the displacement jumps at the onset of the damaging mechanism (see Figure 2(c)).

Parameter η introduced in Eq. (4) rules the coupling of mode I and II of fracture, and assumes the following expression for CM:

$$\eta = 1 - \frac{1}{\alpha^2} [\langle \varepsilon_N \rangle_+^2 \eta_N + (\gamma_{NT})^2 \eta_{NT}] \quad \text{with} \quad \alpha = \sqrt{\langle \varepsilon_N \rangle_+^2 + (\gamma_{NT})^2} \quad (6)$$

being η_T and η_{NT} quantities defined on the basis of the peak values of the stresses, $\sigma_{N,0}$ and $\tau_{NT,0}$, and the mode I and II fracture energy densities, g_{cI} and g_{cII} , as:

$$\eta_N = \frac{\sigma_{N,0} \varepsilon_{N,0}}{2 g_{cI}}, \quad \eta_{NT} = \frac{\tau_{NT,0} \gamma_{NT,0}}{2 g_{cII}} \quad (7)$$

As for IM, the expressions corresponding to Eqs. (6) and (7) are obtained simply introducing the peak tractions, $t_{N,0}$ and $t_{T,0}$, the displacement jumps, $s_{N,0}$ and $s_{T,0}$, and the fracture energies for unit area, G_{cI} and G_{cII} .

Finally, the classical Mohr-Coulomb yield function is adopted to govern the evolution of the inelastic slip, γ_{NT}^p , modeling the frictional mechanisms at the interface between mortar and bricks for CM:

$$\varphi(\boldsymbol{\sigma}^d) = \mu \sigma_N^d + |\tau_{NT}^d| \quad (8)$$

or s_T^p for IM,

$$\varphi(\mathbf{t}^d) = \mu t_N^d + |t_T^d| \quad (9)$$

being μ the friction parameter. Then, the following non-associated flow rules are considered:

$$\dot{\gamma}_{NT}^p = \dot{\lambda} \frac{\tau_{NT}^d}{|\tau_{NT}^d|}, \quad \dot{s}_T^p = \dot{\lambda} \frac{t_T^d}{|t_T^d|} \quad (10)$$

together with the Kuhn-Tucker loading-unloading conditions. The resulting constitutive responses for mode I and mode II are schematically depicted in Figure 2(c).

As concerns the constitutive response in tension of the truss element modeling the reinforcement layer, the bilinear elastic-damage law proposed in [20] is adopted:

$$\sigma^r = (1 - D^r) E^r \varepsilon^r \quad (11)$$

where D^r is the damage variable evolving on the basis of the following rule:

$$D^r = \max_{history} \left\{ 0, \frac{|\varepsilon^r - \varepsilon_0^r|}{\varepsilon^r} \left(1 - \frac{H^r}{E^r} \right) \right\} \quad (12)$$

As emerges from Figure 2(b), the resulting stress-strain relationship in compression is linear elastic and in tension is bilinear, with the first elastic branch characterized by stiffness E^r and the second branch described by the reduced stiffness H^r . In case, the constitutive relationship in Eq. (11) and the damage evolution law in Eq. (12) could easily be modified and enriched to describe the typical trilinear responses of composite reinforcement under tensile loads [3, 21].

2.2 Regularization techniques

The constitutive relationships adopted for reinforcements and mortar joints exhibit strain softening branches, as clearly shown in Figure 2(b,c). This means that the typical pathological mesh-dependency would affect the numerical FE response, if no proper regularization techniques are applied in the case of the continuous models adopted for the mortar and the reinforcement. In this work, two different regularization strategies are assumed: the nonlocal integral approach and the fracture energy technique.

The evolution problem of damage in each mortar joint is ruled by nonlocal quantities. In particular, variables β , η and α in Eqs. (5)_a and (6) are evaluated on the basis of the nonlocal strain vector $\bar{\varepsilon}$. At the generic point \mathbf{x} of the k -th mortar joint, $\bar{\varepsilon}$ is defined as:

$$\bar{\varepsilon}(\mathbf{x}) = \frac{1}{\int_{\Omega^k} \psi(\mathbf{x}, \mathbf{y}) d\Omega^k(\mathbf{y})} \int_{\Omega^k} \psi(\mathbf{x}, \mathbf{y}) \varepsilon(\mathbf{y}) d\Omega^k(\mathbf{y}) \quad (13)$$

where Ω^k denotes the area of the mortar joint k . The weight function ψ , measuring the influence of the point placed at \mathbf{y} on the analyzed point located at \mathbf{x} , is assumed as the classical Gaussian function. This latter depends on the nonlocal radius l_c related to the characteristic length of the mortar. No interaction between different joints is accounted for.

The fracture energy approach is employed to regularize the numerical response of the reinforcement. This is a consolidated tool based on the adjustment of the post-peak slope of the stress-strain law depending on the size of the element. To this end, the stress-strain curve is properly modified. The energy dissipated in the finite element is equal to G^r , i.e. the assigned value in tension. A characteristic length l^e is defined for each truss element. The specific fracture energy g^r , defined in Eq. (14), is then scaled so that it results $g^r l^e = G^r$ for each truss element with:

$$g^r = \int_{\varepsilon_0^r}^{\varepsilon^r} \sigma^r(\varepsilon^r) d\varepsilon^r + \frac{1}{2} \sigma_0^r \varepsilon_0^r \quad (14)$$

For each scaled g^r , the corresponding value of the reduced stiffness H^r is defined, with the aim of evaluating the evolution of damage, as described in Eq. (12).

3 CORRELATION STUDIES: EXPERIMENTAL-NUMERICAL COMPARISON

Capability of the presented models in describing mechanical response of arch systems is evaluated with reference to the experimental campaign performed by Oliveira et al. [5]. The

tests investigated the response of twelve segmental half-scaled masonry arches subjected to increasing concentrated load applied at the quarter span up to failure. Two unreinforced arches, called US1 and US2, were tested and their reference response was used to evaluate the efficiency of strengthening techniques. The remaining samples were strengthened with different arrangements of GFRP (Glass Fiber-Reinforced polymer) strips. Continuous and localized strips were located at the intrados and/or extrados, also varying the reinforcement width.

Each arch was built with clay bricks (size $100 \times 50 \times 25 \text{ mm}^3$) assembled with 10 mm thick mortar joints. Figure 3(a) shows the resulting geometry characterized by an internal span and radius equal to 1467 mm and 750 mm, respectively, thickness 50 mm and out-of-plane width 450 mm.

In the following, the mechanical response of the arches is numerically reproduced and the results are compared with the experimental outcomes and those derived by other numerical approaches. Particular attention is devoted to the analysis of the onset and evolution of the degrading mechanisms and the variation of the maximum load and failure mode caused by the presence of the reinforcement.

3.1 Response of unreinforced arches

The response of the unreinforced arches US1 and US2 is analyzed adopting both CM and IM. The first model, CM, discretizes each brick and mortar joint with 5×3 and 5×1 quadrilateral isoparametric FEs, respectively. The last, IM, adopts a similar discretization for the resized units, but 5×1 zero-thickness interface elements for each joint. As for the mechanical parameters of the constituent materials, these are set according to the available experimental data [5] and the numerical analyses performed by Di Re et al. [11]. Tables 1 and 2 contain the mortar mechanical parameters assumed for CM and IM, respectively. In detail, Table 2 shows the same quantities of Table 1 but expressed for the interfaces, and derived assuming that each interface models a mortar joint with a constant thickness equal to $l^m = 10 \text{ mm}$. Consequently, $K_N = E^m/l^m$, $K_T = G^m/l^m$, $G_{cI} = g_{cI} \times l^m$ and $G_{cII} = g_{cII} \times l^m$ are set. Young's modulus $E^b = 5000 \text{ MPa}$ and Poisson ratio $\nu^b = 0.2$ are assumed for bricks when adopting the continuous model. Instead, a scaled value $E^{b*} = 7000 \text{ MPa}$ is considered for IM to account for brick scaling and, consequently, describe the correct initial stiffness of the arches. Considering that resized bricks have length $l = l^b + l^m$, E^{b*} is evaluated as $E^{b*} = \frac{l}{l^b} E^b$.

E^m [MPa]	G^m [MPa]	$\sigma_{N,0}$ [MPa]	$\tau_{NT,0}$ [MPa]	g_{cI} [MPa]	g_{cII} [MPa]	μ
1200	500	0.25	0.25	1.8×10^{-3}	1.25×10^{-3}	0.5774

Table 1: Mechanical properties adopted for the mortar (CM).

K_N [N/mm ³]	K_T [N/mm ³]	$t_{N,0}$ [MPa]	$t_{T,0}$ [MPa]	G_{cI} [N/mm]	G_{cII} [N/mm]	μ
120	50	0.25	0.25	1.8×10^{-2}	1.25×10^{-2}	0.5774

Table 2: Mechanical properties adopted for the mortar joint interfaces (IM).

The numerical simulations are performed assuming for both materials unit weight $\gamma = 17 \text{ kN/m}^3$ and imposing a concentrated monotonically increasing load under displacement control at the nineteenth brick counted from the left impost, mimicking the loading conditions in

Figure 3(a). The global response of the arch is depicted in Figure 3(b) in terms of vertical force F -vertical displacement s . The dashed blue lines correspond to the experimental outcomes, the green curve is that evaluated with the IM and the red line refers to the numerical results derived from the CM, and already presented in [15], assuming the nonlocal radius equal to the mortar characteristic length, that is $l_c = 10$ mm. Finally, for further comparison, the black curve shows the results of the multiscale model proposed by Di Re et al. [11], which adopts the same constitutive modeling assumptions but employs a force-based beam formulation in conjunction with the energy regularization technique. On the overall, a very good agreement is detected between

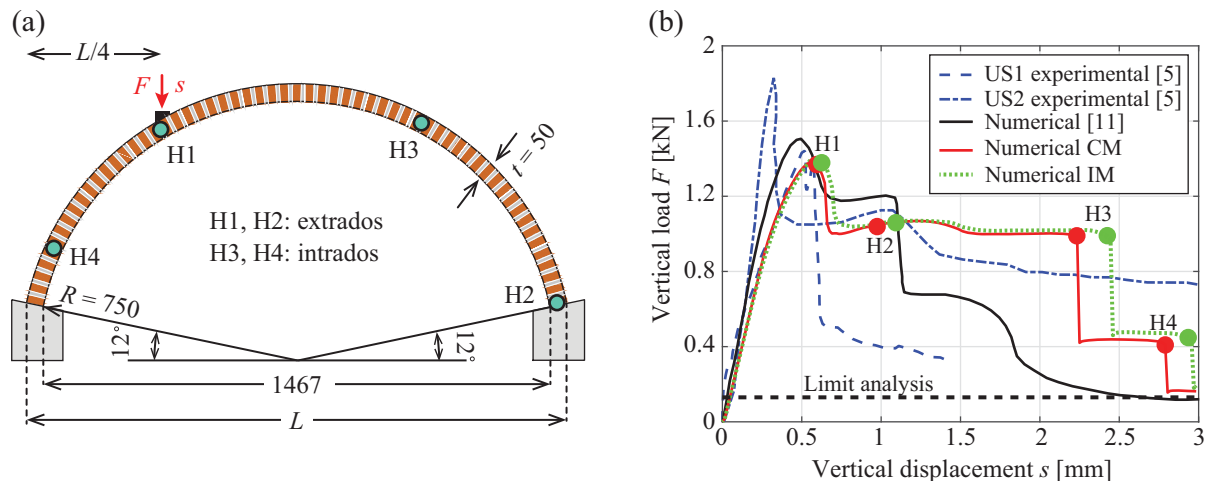

Figure 3: Unreinforced arches tested by Oliveira [5]: (a) geometry (dimensions in mm), loading conditions and experimental hinge (H) location, (b) experimental and numerical load-displacement global curves.

all solutions in terms of initial stiffness, collapse load and ductility. The curves referring to the CM and IM show slight discrepancies caused by the intrinsic differences between the two modeling assumptions. For instance, the mechanical characteristics assigned to each interface FEs are derived assuming, in a simplified manner, a constant mortar thickness of 10 mm, thus failing to describe the small variation of thickness characterizing each mortar joint starting from the intrados to the extrados of the arch. Moreover, unlike IM, CM adopts a nonlocal integral formulation which consistently affects the evolution of degrading mechanisms.

Moreover, in Figure 3(b), the collapse load value evaluated by the classical limit analysis is depicted with dashed black line. This is estimated following the three hypotheses of Heyman [6]: masonry has no tensile strength, masonry has infinite compressive strength and sliding cannot occur between joints. It is noted that both numerical and experimental response curves approach the limit value from above, thus predicting a higher peak load. This interesting aspect is caused by the not negligible tensile strength of the mortar, which moves away from the first Heyman's hypothesis, as more in detail investigated in [8, 15].

As for the failure mechanism, this experimentally involves the formation of the classical four flexural hinges located at the intrados and extrados, alternatively (Figure 3(a)). Same results are obtained with the proposed numerical models, as evident from Figure 4(a) and (b) which contain the arch deformed configurations at the end of the analyses for IM and CM, respectively. The distribution of the damage variable D defined in Eq. (4) is also illustrated in Figure 4(b), showing that damage variable, varying between 0 and 1 according to its physical meaning, is concentrated in the zones where tensile stresses are expected to be higher. The onset of fully

cracked sections, corresponding to the formation of nonlinear hinges, is the cause of the steep load drops characterizing the load-displacement global curve in Figure 3(b), as indicated by the green and red circle markers. Finally, it should be emphasized that the two models provide indistinguishable results in terms of deformed structural configuration and predict location and order of formation of the hinges in accordance with the experimental outcomes.

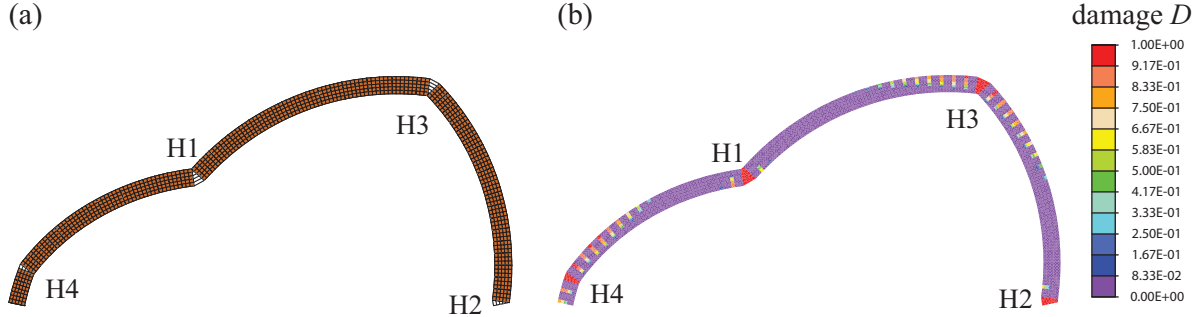

Figure 4: Numerical failure mode of the unreinforced arches tested by Oliveira [5]: (a) deformed shape obtained with IM, (b) deformed shape and distribution of the damage variable D obtained with CM.

3.2 Response of GFRM strengthened arches

The response of the GFRP strengthened arches is analyzed by employing the CM. As mentioned before, three main strengthening approaches were tested in [5]. Here, continuous configuration at the extrados is considered and numerically reproduced. The experimental set was composed of two arches (CSE1 and CSE2) strengthened with two continuous GFRP strips of 50 mm width, and the other two arches (CSE3 and CSE4) with two GFRP strips 80 mm width each. In Figure 5(a), the strengthening arrangement applied over the external substrate is schematically shown.

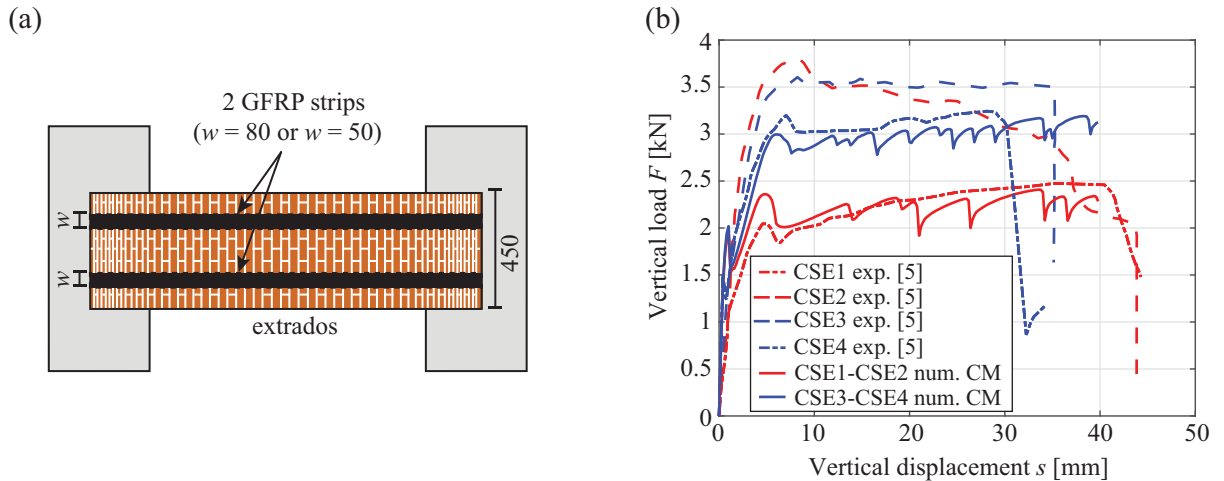

Figure 5: Strengthened arches tested by Oliveira [5]: (a) location of continuous extrados strengthening (dimension in mm), (b) experimental and numerical load-displacement global curves.

Two numerical models are considered to reproduce the different configurations by varying the size of the strips for the reinforcement and assuming the geometrical characteristic provided

in [22]. Young's modulus is set equal to $E^r = 80000$ MPa, according to the experimental results of the tensile tests performed on several GFRP samples [22]. The reduced stiffness, characterizing the second branch of the bilinear stress-strain relationship in tension, is assumed equal to $H^r = 0.01E^r$. The tensile strength, $\sigma_0^r = 200$ MPa, is calibrated to reproduce the experimental response and this is representative of both the reinforcement tensile strength and the reinforcement/masonry interaction behavior.

Figure 5(b) shows the comparison of the vertical load-vertical displacement global curves numerically and experimentally evaluated. Results referring to the configuration with 50 mm GFRP strips are depicted in red color, whereas those related to 80 mm GFRP strips are reported in blue color. Overall, a good agreement emerges between the experimental and numerical responses. The sliding failure characterized all the experimental specimens CSE, almost certainly due to their weak resistance against shear mode. The failure mechanism exhibited during testing is illustrated in Figure 6(a). It involves the formation of three hinges: in particular, a sliding hinge was located close to the right support. In Figure 6(b) the deformed numerical configuration is shown referring to the end of the analysis and to the case of strips 50 mm wide. According to the experimental outcomes, two sliding hinges appear. The first is located underneath the loading point, the second close to the right support. The numerical failure mechanism and the damage distribution shown in Figure 6(b) are representative of both the strengthening configurations. In fact, it is noted that the increase of the GFRP strips size from 50 mm to 80 mm did not produce significant variations in the structural response in terms of failure mechanism. Although this type of strengthening does not permit joint opening at the extrados, a widespread damage distribution seems to appear in the numerical model at the location opposite to the load application.

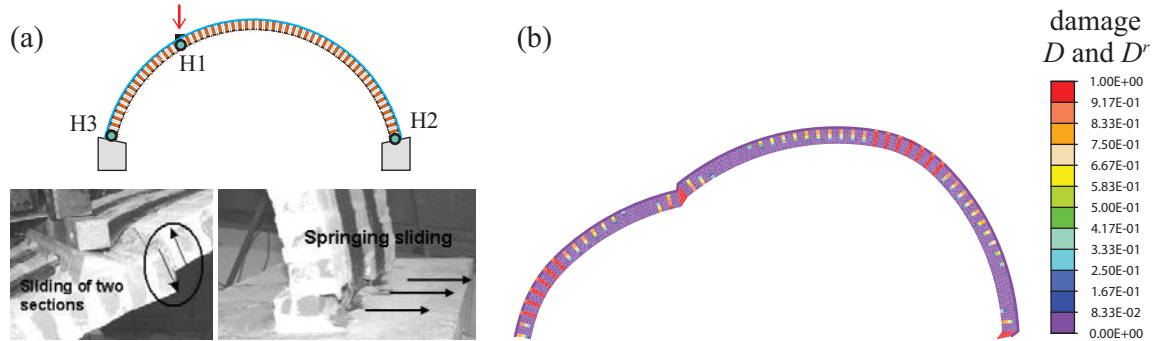

Figure 6: Externally strengthened masonry arches tested by Oliveira [5]: (a) experimental failure mechanism [5, 22], (b) numerical failure mechanism and distribution of the damage variables D and D^r obtained with CM.

4 CONCLUSIONS

- This paper presented two micromechanical FE models for the analysis of the in-plane response of masonry arches. These are based on the same constitutive assumptions, but adopt different strategies to model mortar joints. The CM considers the mortar as a continuous material modeled with 4-node isoparametric FEs, whereas the IM discretizes each mortar joint by means of 2+2 zero thickness interface elements. Linear elastic behavior is assumed for bricks, whereas a coupled damage-friction constitutive law is adopted for mortar to account for flexural and shear failure mechanisms.

- Effectiveness of the models in describing maximum strength and collapse modes of unreinforced and strengthened arches was proved by comparison with experimental outcomes.
- Satisfactory agreement is found between numerical and experimental results as regards the unreinforced case. The numerical load-displacement global curves, as well as the four hinge mechanism, well match the experimental counterpart. Moreover, the two numerical models provided very similar structural responses with only slight discrepancies caused by the different modeling assumptions. Hence, it emerged that the adoption of interface elements to model response of mortar joints is an efficient alternative to the use of continuum finite elements.
- The numerical results referring to strengthened arches with GFRP strips bonded at the extrados are encouraging. Despite the reinforcement was modeled in a simplified way by means of truss elements with mechanical properties representative of both reinforcement itself and its interaction behavior with the substrate, the change of the structural response with respect to the unreinforced case is well reproduced. The presence of the reinforcement prevented the hinge mechanism formation and let the shear sliding mechanism to prevail.
- Further improvements of the model could be performed by introducing the explicit modeling of the reinforcement-substrate interaction in order to distinguish failure mechanisms due to debonding and reinforcement rupture. To this end proper interface elements connecting masonry and reinforcement [23, 24] could be considered. Moreover, the constitutive assumptions could be modified and enriched to account for the nonlinear mechanisms involving the bricks, as masonry crushing is likely to occur in strengthened arches due to the onset of high compressive stresses.

Abstract

The seismic response of churches is peculiar due to the building typology, the structural features and the used materials. During last decades a great work of research on damages occurred on such structures after seismic events was performed and some insight of this behavior have pointed out suggesting different intervention techniques. This lead to apply, during past years, some interventions on churches already damaged. In particular, the Umbria-Marche region, has stroked by three relevant earthquakes: Norcia 1979 (Mw 5.8), Colfiorito-Annifo 1997 (Mw 6.0), Norcia 2016 (Mw 6.5). The last events occurred on structures already damaged in past and strengthened by interventions that aim at improving their seismic behavior. Starting from the conclusions of such extended survey campaign and analyzing the effect of interventions, the Church of S. Martino's dei Gualdesi in Castelsantangelo sul Nera (MC – Italy) was modelled and studied with both linear and non-linear methods. The paper presents the results of such analysis comparing also the observed damages and the effectiveness of some interventions performed in past years on the church.

Keywords: Masonry Churches, Seismic Vulnerability, Numerical Analysis, Limit Analysis.

1 INTRODUCTION

The study of structures damaged from earthquakes is the most interesting benchmark to evaluate the analytical and numerical tools available in the vulnerability analysis and commonly used to design retrofit or refurbishment interventions.

The study herein reported is a preliminary stage of a deeper project carried out on the San Martino's dei Gualdesi Church. The case-study selection derives from a wider observation on a dataset of about 900 churches stricken by the 2016 earthquake swarm [1] that recognize in Castelsantangelo sul Nera, an interesting opportunity to evaluate vulnerability and effect of interventions.

The paper presents a qualitative evaluation of interventions carried out in the municipality and reports the analysis carried out on San Martino. The presented analysis looks at the unreinforced church and aims at evaluating the seismic multiplier. Moreover, a non-linear static analysis has carried out to evaluate its reliability in predicting the damage pattern and to support the kinematic analysis.

2 RESPONSE OF CHURCHES IN CASTELSANTANGELO SUL NERA

The municipality of Castelsantangelo sul Nera, located in the Marche Region, was interested by numerous seismic events in past years and also by the 2016 Central Italy seismic swarm. This last caused severe damage to structures including the churches of the region [2].

In order to evaluate the vulnerability and the seismic response of such structures, a focus on the municipality cluster, composed by 19 cases, was carried out beginning from the enlarge database collected in the Centre of Italy [1]. All the churches in the cluster undergone a PGA between 0.52g and 0.54g evaluated by INGV shake-maps. Therefore, considering similar actions, the damage observed is mainly guided by the vulnerability of each structure.

The Damage Index (i_d) has evaluated by the A-DC form [3, 4] and the Vulnerability Index (i_v) was first defined according to the II level form for the church survey [5]. The i_d have shown an high heterogeneity, ranging from 0.33 to 0.85 (variation of 0.52, average of 0.52 and standard deviation of 0.14) that could be attributed to the vulnerability of the constructions since the seismic actions were quite similar. The analysis of i_v did not show significant variations varying between 0.36 and 0.57 (average of 0.48 and standard deviation of 0.06). This could lead to suggest a small representativeness of the i_v value to describe the different vulnerabilities, suggested also by the fact that the variation of the damage index calculated by formulation available in literature [6] would be 0.09, for the i_v and PGA values ranges herein described.

To better highlight the raised differences, a specific evaluation on each case has performed, also considering the consolidation interventions carried out in past years with the aim of obtaining insight into their effect on the seismic response.

From the observation of all cases, some intervention highlighted always a positive behavior such as tie rods applied for both goals: prevent the out-of-plane mechanisms of the walls and counterbalance the loads of arches and vaults. This intervention pointed out some issues only in case of poor masonry quality with the disaggregation of wall [7]. Another very positive intervention is the introduction of a metallic hopping system on the bell-tower. Indeed, two churches two hundred meters close, very similar in geometry and dimensions, like S. Stefano and San Martino's dei Gualdesi pointed out two emblematic boundaries in behavior (Figure 1) between the total collapse and only a cracking of the bell-tower due to the presence, in the case of St. Martino, of hooping interventions on the belfry that avoid the collapse after the mechanism activation. On the other hand, some interventions show generally worsening effects such as some concrete slab reinforcement of roofs, where due to the increase of loads and stiffnesses, masonry collapse or severe damage occurred. The task of containing the overturning of the

walls and distributing the vertical loads was entrusted to the ring beam. Sometimes, it was observed an overall achievement of the goal, whereas either in the case of reinforced concrete ring beam and in the steel beam sometimes some damage caused by this intervention were observed such as horizontal cracks at the height of the ring beam and the disintegration of the masonry below it. The causes can be associated with poor masonry quality as well as an ineffective or absent connection between the ring beam and the masonry.

The results obtained from this analysis have determined different responses in terms of local and global damages although the earthquake was the same. For these reasons, in order to understand which parameters have the greatest influence on the vulnerability, a seismic behavior analysis of a specific church, that may represent the cluster, has been implemented and herein presented.

Figure 1: S. Stefano's tower (left) and San Martino's bell tower (right) after the 30th of October 2016

3 SAN MARTINO'S DEI GUALDESI CHURCH

San Martino's dei Gualdesi church, in Castelsantangelo sul Nera (MC), was built in the 14th century. The structure is mostly made of local limestone (two leaves masonry 70-120 cm thick) and lime mortar. The structure is 30.60 x 7.40 m in plan and 6.87 m height for the nave with an height of 17 m for the tower and it is of medium size compared to those present in the region [1]. The church consists of a single nave, marked by four pointed arches arranged transversely, covered by a timber gable roof. Externally, the church has the same internal regularity: the longitudinal south-west facade is characterized by two entrance portals and by further secondary openings. The transversal gabled facade, located to the north-west side, is composed by a simple window in the central area.

The structural data were entirely deduced from the information collected during the on-site surveys and through some documentary additions provided by the Superintendence for Cultural Heritage of Ancona. To date, it has not been possible to carry out diagnostic campaigns for the characterization of construction details or materials. For this reason, the materials' mechanical properties were obtained from a critical analysis of masonry arrangements by the study of the masonry quality index (IQM) [8] of some panels and masonry sections. These investigations with its typological and qualitative definition helped in identify two different masonry typologies according to the Italian National Standard [9], whose mechanical properties [10] are summarized in Table 1.

In this case, since the investigations are limited, the confidence factor calculated according the Italian guidelines for cultural heritage [11] is equal to 1.24 and the level of knowledge reached is KL1.

Figure 2: Aerial view (a), and plan (b) of San Martino's dei Gualdesi church.

MASONRY TYPOLOGIES	$f_{m,d}$ (N/mm^2)	$\tau_{0,d}$ (N/mm^2)	E (N/mm^2)	G (N/mm^2)	w (kN/m^3)
Masonry: Roughly cut stone masonry with good texture - III	2.6	0.056	1740	580	21
Arches: Stone blocks squared masonry- V	5.8	0.090	2850	950	22

Table 1: Mechanical properties of the masonries used.

3.1 Interventions related to the past seismic events

The most significant earthquakes for the Castelsantangelo sul Nera area were the earthquakes of Norcia, M_w 5.8 in 1979, and the Umbria-Marche earthquake, M_w 6.0 in 1997. These seismic events had a strong impact with regard to both the identification of seismic damage and the implementation of series of interventions aimed at mitigating its effects (not always with real benefits). The church of San Martino's dei Gualdesi, entering into this context, was subjected to four intervention campaigns (in 1988, 1999, 2000 and in 2014). Some of the older interventions had been replaced in subsequent refurbishments. Therefore, a description of the present configuration of the church with the current interventions is presented below.

In general, two significant phases of intervention can be distinguished: one relating to the 2000 restorations, which mainly involved the bell tower, and a more recent restoration of 2014 regarding the structure of the nave.

In 2014 interventions, a systematic demolition of the top of the wall was carried out with subsequent reconstruction of it for a height of 30-50 cm. In addition, a UPN 220 metal profile

has been inserted and anchored with the underlying wall with a $\phi 16$ bar 85 cm long, every 50 cm. The bars were inserted inside perforations (with a diameter of 24 mm) and subsequently injected with lime mortar (blue line in Figure 3). A further intervention was the injection of a fluid hydraulic lime mortar on the walls. Four holes per square meter with a diameter of 22 mm were injected (red dot fill in Figure 3). A final and significant structural intervention performed on the nave concerns the execution of a series of steel bars reinforcement between the longitudinal walls of the nave and the internal arches. Twelve stainless steel bars with a diameter of 16 mm were inserted and injected with epoxy resin inside drillings of 24 mm of diameter (red strip hatch in Figure 3). Regarding the bell tower, in 2000, two orders of metal hooping beams have been inserted in elevation under the belfry and at the level of the mouldings (blue dashed line in Figure 3). Finally, about 20 perforations per wall were made on the tower's walls with subsequent insertion of steel bars presumably with a diameter of 20 mm (green dot mesh in Figure 3).

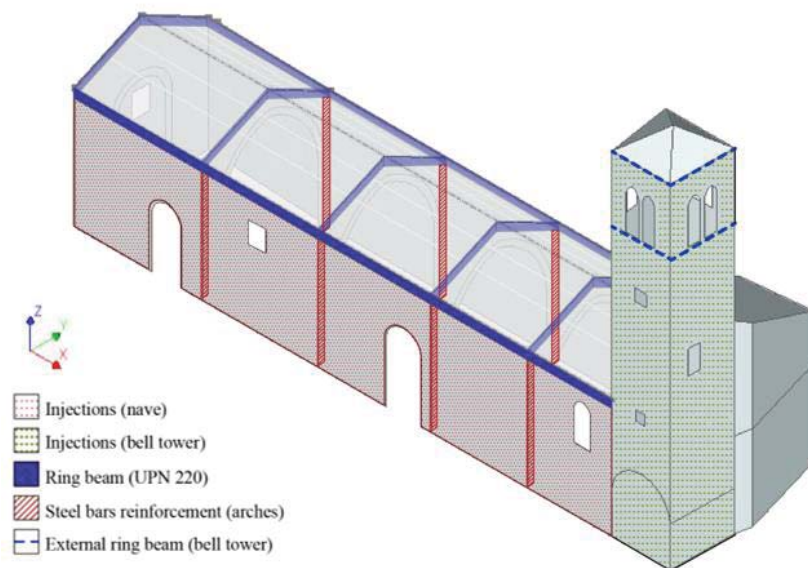

Figure 3: Representation of interventions implemented in 2014 and 2000 to the San Martino's dei Gualdesi church.

3.2 Analysis of damage

The church of San Martino's dei Gualdesi, referring to the A-DC form [3, 4], has an intermediate damage index ($i_d=0.60$). Although the i_d value is slightly higher than the average of the Castelsantangelo's cluster (see § 2), the church showed only a small collapse of the wall above the entrance (Figure 4d) but, any other structural element of the nave and the tower had not collapsed. The main damages are located in the internal part of the church, in particular near the pointed arches, in some parts of the perimeter wall and in the bell tower.

The cracks affecting the internal part of the church are mainly located between the longitudinal walls and the central arches. From the structure of the church, it is clear that the pointed arches, placed transversely to the nave, support the roof and transmit the loads to the side pillars and to the perimeter walls. Figure 4b highlights some cracks between pillars and the longitudinal wall probably due to the weak connection in shear between the two. Moreover, it seems that some interactions in traction are present since some sliding in first voussoirs is present, probably due to the introduction of rebars and a consequent movement of the pillar according to the out-of-plane of the lateral wall.

More cracks are located at the interface between the extrados of the arch and the masonry, due to the absence of connection between the two different materials. In the same pictures (Figure 4b), reduced cracks are observed even at the level of the roof, perhaps due to the insertion of the metallic ring beam that may have limited their opening but also promoted the detachment.

Other cracks were located in the transverse walls of the nave, in particular in the north-west facade, which still has the shape of the original door. The distribution of the cracks follows the intersection between the original wall and the added element showing the typical shear cross shape (Figure 4a).

Lastly, deep cracks were found on the bell tower (Figure 4c). The position of these cracks is related to the presence of windows and small openings. The windows and the little columns of the upper level represent the weakest. However, although characterized by widespread cracks, the bell tower did not show the collapse of masonry parts or other elements. This proves the effectiveness of the past hooping interventions, which have defined a better connection between the orthogonal walls ensuring the box behavior during the seismic events.

Unlike the other facades of the church, the longitudinal wall located to the south shows a loss of the curtain wall with the detachment of the upper portion of the masonry (Figure 4d). The collapse of this masonry portion seems to be promoted by the reinforcement (of the past interventions) at the top. Indeed, if the metallic beam presents excessive stiffness, it can generate damages related to the tangential stresses in the contact area with the masonry and therefore a detachment between the parts. Moreover, the entire wall suffered from an out-of-plane displacement in the order of 15-20 cm. The overall displacement of that seems to be provided by the monolithic behavior probably promoted and enhanced by injections.

Figure 4: Damages observed on the north-west facade (a), central arch (b), bell tower (c) and on the south-west facade.

4 STRUCTURAL ANALYSIS

The preliminary structural analysis of the church has focused on the pointed arch behavior and on the influence that this has on the overall behavior. With this aim, a kinematic study was performed together with a non-linear static analysis with a Finite Element Model in order to validate the assumptions made.

4.1 Definition of the seismic action

The seismic action used for the assessment of the church is determined by following the indications provided by the Italian Standard [12]. The design parameters used in the analysis are represented in Table 2. The return period, considering the ecclesiastical function, is of 712 years.

Parameters (DLS)				Parameters (ULS)			
a_g	0.120	q	1.00	a_g	0.283	q	2.000
F_0	2.305	S	1.80	F_0	2.400	S	1.554
T_c^*	0.288	η	1.00	T_c^*	0.339	η	1.000
S_S	1.500	T_B	0.15	S_S	1.295	T_B	0.170
C_C	1.584	T_C	0.45	C_C	1.500	T_C	0.510
S_T	1.200	T_D	2.08	S_T	1.200	T_D	2.726

Table 2: Design parameters used in the analysis

4.2 Kinematic analysis

The kinematic analysis is based on the limit analysis and the principle of virtual works and refers to the upper bound solution [13]. This, on one hand, make easier the analysis and, on the other, it requires defining the minimum multiplier to obtain the exact solution. Therefore, the Finite Element Model helps in defining the proper crack pattern and hinges location.

The out-of-plane limit analysis was guided by the actual crack pattern observed, and hence evaluating those mechanisms activated during the earthquake (Figure 5). In detail, the south-west wall of the nave and the north-west corner of the tower were analyzed as out-of-plane mechanisms, while the central arch as in-plane mechanisms.

Figure 5: In-plane (left) and out-of-plane (right) analysis of the church.

Table 3 shows the results of the kinematic analysis implementing linear methods. The factor ζ is the safety coefficient defined as the ratio between the seismic capacity and the demand for each macro-element. Values greater than one indicate that the mechanism is verified at the damage limit state (DLS) and at the ultimate limit state (ULS). As regards the out-of-plane kinematic mechanisms, the linear verification is not verified for any mechanisms. The activation multiplier was calculated accounting for the masonry compression hence considering the hinge in the middle of the stress-block. The lower multiplier refers to the wall overturning (C3 Figure 5) and it figures out that the restrain contribution of the roof is not negligible, since that mechanism does not reach the collapse although it has activated with an overall ultimate displacement of about 15-20 cm. The tower mechanism activated also on the real case but it was counteracted by the hooping system that avoided the collapse, as did not happen for the near church of S. Stefano. Lastly, the highest multiplier found (mechanism C2) of 0.535 has activated but not avoided by any interventions resulting in the collapse of the macro-element. That value is similar to the highest PGA recorded in the swarm of 0.541 the 26th of October 2016.

1° Mode			
Kinematics	α (t/2)	ζ (DLS)	ζ (ULS)
C1	0.266	0.38	0.44
C2	0.535	0.68	0.74
C3	0.143	0.58	0.57

Table 3: Results of the kinematic analysis for the out-of-plane mechanisms

Similar to what has been observed for the out-of-plane mechanism, the hypothesis of interaction among macro-elements may lead to significantly different solutions also for in-plane analysis. Due to this, different combinations (Table 4) have been defined.

For the in-plane analysis of the arch, which is placed in the transversal direction of the nave (Y direction), the hinges position was defined by the analysis of the principal traction strains. The latter were obtained by the non-linear static analysis of the church, considering that this comes from static considerations which belong to the lower bound solution. Therefore, the obtained multiplier should be the exact one also for the interaction among longitudinal walls and the arch.

	D1- All hinges as FEM	D2 – Hinge D on the impost	D3 – Hinge D in the wall
Case A Only arch			
Case B Only tension between the arch and the wall			
Case C Shear and tension between the arch and the wall			

Table 4: Type of kinematic analysis implemented

The possible variability may concerns the in-plane and out-of-plane interaction of the longitudinal wall and of the soil on the mountain side. Therefore, looking at Table 4, cases A, B, C considers different interactions among macro-elements whereas cases from D1 to D3 evaluate differently positions of the hinge on the mountain side (hinge D).

Table 5 reports the obtained activation multipliers α , always considering the hinge regression, and the factor ζ that report the structural verification. Due to the not symmetric geometry, the multiplier of both directions is reported.

In case A the arch is alone, neglecting the contributions of lateral walls, whereas in cases B and C walls are considered. In the latter the coupling between the arch and the wall is perfect,

with transmission of normal and shear stresses on the interface, while in case B only the normal action is considered.

2° Mode (+Y) North/mountain dir.					2° Mode (-Y) South/valley dir.				
	case	α (t/2)	ζ (DLS)	ζ (ULS)		case	α (t/2)	ζ (DLS)	ζ (ULS)
D1	A	-0.002	-	-	D1	A	0.079	0.34	0.34
	B	0.188	0.80	0.79		B	0.172	0.73	0.72
	C	0.189	0.80	0.79		C	0.184	0.78	0.77
D2	A	-1.030	-	-	D2	A	0.108	0.45	0.44
	B	0.065	0.28	0.28		B	0.137	0.59	0.59
	C	0.064	0.28	0.27		C	0.159	0.69	0.68
D3	A	-0.550	-	-	D3	A	0.107	0.44	0.44
	B	0.277	1.16	1.14		B	0.161	0.68	0.67
	C	0.306	1.28	1.26		C	0.198	0.83	0.82

Table 5: Results of the kinematics analysis for the in-plane mechanisms

In the case A, in the positive direction of Y, there is a negative multiplier that means that there is no equilibrium in the thrust of the arch without the lateral walls providing a counterbalancing effect even in static conditions. Therefore, the case A is not a reliable hypotheses of the actual behavior. Considering the fact that the FEM model reliably describes the hinge positions, and comparing with the actual observations, also cases D2 and D3 are not suitably describing the real situation because did not appear evident cracks next to the guessed hinge position D.

In conclusion, the cases more similar to the actual situation are B and C in conditions D1. Herein, case B is selected as the most reliable (Table 5 in bold) because even the intervention with rebars performed in 2014 could not guarantee the shear transfer, as pointed out by the crack pattern occurred (Figure 4b). Therefore the final multipliers selected are α 0.188 and 0.172 in the positive and negative Y direction respectively.

4.3 Fem analysis

The numerical analysis of San Martino's dei Gualdesi was performed using the DianaFea software. In detail, a linear and a non-linear static analysis were performed in order to obtain results consistent with the actual damages observed.

The church has modeled using two-dimensional elements. The roof analysis of weight has performed following the information obtained by documents on past interventions. The vertical elements of the model have defined as regular curved shells: quadrilateral elements with eight nodes and a quadratic behavior. The mesh has a size of 0.25 m. The linear elements such as beams have specified as beam elements curved and characterized by three nodes (Class-III 3D). Boundary conditions were defined to constrain all translations and two rotations except the out-of-plane. Finally, the material properties were defined following Table 1 for the linear properties. To account for the non linear behavior a total strain cracked model has been adopted with a parabolic behavior in compression and a exponential one for the softening in tension. The fracture energy has defined following the literature [14].

First, a linear static analysis was performed to evaluate the static conditions of the model. Regarding the reaction forces, the maximum vertical value is 74.9 kN. The vertical deformation (Z direction), due to its own weight, is located on the bell tower and is approximately 1.7 mm. Lastly, as regards the main stresses, the compression stress located at the base of the bell tower is 0.45 MPa.

Subsequently, the static non-linear analysis was implemented to analyze the non-linear behavior of the structure. The analysis concerns both the longitudinal (X) and transverse directions of the church (Y), with more attention to the transversal direction (east-west direction). The own weight of the structure was applied in a single load step, followed by the application of a global acceleration (proportional to the masses) into different load steps.

Results show greater deformations and displacements refer to the analysis with transverse direction of the seismic action (+Y, -Y). In the first case (+Y, mountain dir.), the displacements of the control nodes positioned at the top of the central arch are approximately equal to 0.20 m in agreement with the actual observations. Analyzing the results relating to strains, the main stresses are located on the transversal walls. However, high cracks are also located on the longitudinal facades of the church and on the tower's walls (Figure 6).

In the negative direction of Y (-Y, valley dir.), the greatest displacement is measured at the top of the bell tower (0.12 m) even the control nodes at the top of the central arch reach considerable displacements of 0.10 m.

Regarding the analysis in the longitudinal direction (+X, -X) the main deformations and displacements are located on the upper part of the bell tower.

Figure 6: Major principal strain for the analysis in the +Y direction (left) and -Y direction (right).

4.4 Comparison between the damages observed and the numerical analysis

The results obtained from the numerical analysis has been compared with the damages described in the previous paragraph (§3.2). The structural parts investigated are the north-west and the south-west facade of the nave, the walls of the bell tower and finally the internal arches of the nave.

Figure 7a shows that strains, and thus cracks concerning the internal arch, are mainly located between its lateral part and the longitudinal part of the south-western masonry and in the interface between the extrados of the arch and the masonry above. From this crack pattern, the four hinges location for the limit analysis presented above was defined (§4.2). Moreover, damages and cracks coincide with the damages observed in the on-site survey (Figure 4b), confirming the reliability of this type of analysis.

Less deformation and damages occurred in the north-east walls, again corresponding to the actual condition. In this case, the pillars are embedded in the wall itself, ensuring a better connection between them. The greatest displacements are reached in the analysis with transverse direction of the seismic action.

The longitudinal south-west wall showed significant damage due to the longitudinal action. Figure 7b shows cracks on the entire wall and in particular near the transverse arches and openings. More cracks are located in the interface between the wall of the bell tower and in the upper part of the nave facade. These damages coincide also with the current state of the church.

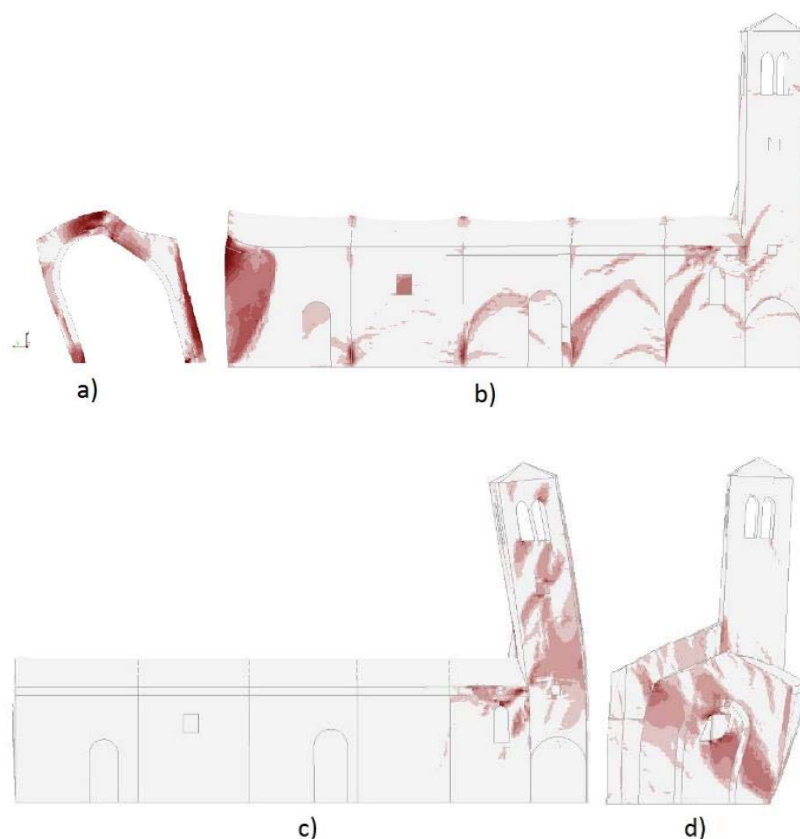

Figure 7: Localized deformations in the central arch (a), south-west wall (b), tower (c) and north-west wall (d).

The north-west facade is characterized by significant damages in the case of transverse seismic action. Cracks obtained from the numerical model provide almost the same pattern observed in the structure. The distribution of cracks follows the intersection between the original wall and the added element.

Lastly, the south-western wall of the bell tower shows significant deformations due to the longitudinal action (-X). The principal strains, obtained from the numerical model, are located near the mullioned windows, in the small openings below and lastly in the contact area between the roof of the church and the belfry. These critical points are also observed on the damage picture (Figure 4c).

5 CONCLUSIONS

- The paper presents the first stage of studies carried out on the San Martino's dei Gualdesi church, confirming that the integrated methodology among different type of analysis (i.e. kinematic and non-linear static analysis) lead to achieve reliable results compared to the real case observations.
- The kinematic analysis, supported by some non-linear analysis in the definition of the mechanisms, proved to be a valuable tool in the definition of the activating accelerations.

The evaluation of the interaction in-plane and out-of-plane may also be detrimental to obtain the correct value.

- The static non-linear analysis confirms to be a reliable method of structural modeling detecting a crack pattern very similar to the real one.
- Future works aim at evaluating through capacity curves the real performances of the structure, even compared with the real occurred earthquake, and furtherly improving analysis by the implementation of interventions.

Abstract

In this paper, we propose a NURBS-based adaptive approach to the three-dimensional analysis of masonry vaults undergoing foundation settlements. A given masonry vault of arbitrary geometry is described through its NURBS (Non-Uniform Rational B-Spline) parametric representation in the three-dimensional Euclidean space. The vault surface is then discretized into an initial set of rigid elements. Such discretization is obtained by suitably subdividing the NURBS parameters space. Jumps of displacement are allowed solely at the interfaces. Given a known displacement on the external boundary, which comprises possible settlements, the resulting displacement field is computed by minimizing the total potential energy of the system by means of a linear programming optimization algorithm. Moreover, a mesh adaptation scheme based on a suitable Genetic Algorithm (GA) is used to determine the crack pattern yielding the mechanism actually induced by the settlement. The procedure is here demonstrated through a numerical example.

Keywords: Masonry, Foundation Settlements, NURBS, Genetic Algorithm

1 INTRODUCTION

The interest in studying the crack patterns induced by foundation settlements in masonry structures is quite recent. In fact, differential settlements are one of the most frequent causes of cracks in historical masonry structures. When undergoing foundation settlements, masonry structures deform like mechanisms in order to be able to accommodate such settlements, accompanied by a pattern of cracks. The strong nonlinearities of the masonry material, which have been summarized by Heyman [1] by means of the no-tension material assumption, render masonry constructions quite unsuited to resist differential settlements. In the last decades, the problem of settlements on masonry structures has been studied by means of nonlinear analyses within the Finite Element Method (FEM) [2–4], the Discrete Element Method (DEM) [5], or, rigid blocks analyses under the hypothesis of unilateral contact and simple linear programming techniques [6–9].

The analysis of the response to settlements response using systems of rigid blocks entails procedures similar to the ones typical of limit analysis. Under the action of settlements, the above structure reaches a new configuration of equilibrium exhibiting small deformation [10]. However, since masonry cannot withstand deformations of any kind, cracks appear and propagate within the structure, transforming the initially continuous construction into an assembly of relatively big and approximately rigid blocks. The new configuration of equilibrium can be described through a discontinuous displacement field. As a result, the structure behaves like a mechanism and can be studied by using limit analysis techniques. The analogy between limit analysis and analysis of settlements for rigid blocks structures has been analyzed in detail in a recent publication [11]. Here, it is shown that the discontinuous displacement field can be obtained by solving a unilateral contact problem. The discrete formulation can be written in terms of a linear programming problem, in which the external work is maximized. The formulation by rigid blocks and linear programming allows a quick assessment of crack patterns with a sensibly reduced computational effort with respect to standard finite element nonlinear techniques and iterative procedures.

In this contribution, we present the study of masonry vaults undergoing differential settlements through a new adaptive GA-NURBS based approach. A masonry vault is modeled through NURBS rigid shell elements, which allow accurate reproduction of the actual geometry even with a small number of elements is used. Given an initial mesh of NURBS rigid element, the displacement field is found by maximizing the work of external loads. A Genetic Algorithm mesh adaptation search scheme is devised in order to find the actual displacement field induced by a given settlement. The procedure is illustrated by solving the historical vault previously analyzed in [13–14].

2 DISCRETE VARIATIONAL FORMULATION

The behavior of a masonry structures undergoing foundation settlements can be studied by idealizing it as an assembly of rigid blocks and applying unilateral contact conditions at the interfaces [11]. The solution \mathbf{u} of the variational contact problem, at the continuum level, is given by

$$\mathbf{u} = \arg \inf_{\mathbf{v} \in M^m} \Pi_r(\mathbf{v}), \quad (1)$$

where

$$\Pi_r(\mathbf{v}) = - \sum_{i=1}^{N_b} \ell_i(\mathbf{v}) \quad (2)$$

is the potential energy of external loads acting on each block and, M^{*m} is the convex set of rigid motions and $\ell(\cdot)$ is the linear form:

$$\ell(\mathbf{v}) = \int_{\Gamma_q} \mathbf{q}\mathbf{v} d\gamma. \quad (3)$$

In other words, a displacement field solution of the boundary value problem at hand, can be found by minimizing the potential energy of the external loads in the set M^{*m} of all the mechanisms satisfying the unilateral constraints in the normal direction and the no-sliding condition.

At the discrete level, a generic piecewise two-dimensional rigid displacement $\mathbf{v} \in M^{*m}$ is represented by a vector \mathbf{d} composed by $3N_b$ elements being the three barycentric components of rigid body motion (two translations and a rotation) for each block. Obviously, it is possible to define the potential energy associated to the rigid body motion \mathbf{v} represented by the vector \mathbf{d} as a linear function of \mathbf{d} :

$$\Pi_r(\mathbf{v}) = -\hat{\mathbf{q}}^T \mathbf{d}, \quad (4)$$

where $\hat{\mathbf{q}} \in \mathbb{R}^{3N_b}$ is a vector containing, for each body \mathcal{B}_i , the resultants – in terms of two translational forces and one moment – of the external load distribution $\mathbf{q}(\mathbf{x})$ on Γ_q . Therefore, the discrete linear programming problem associated to (1) can be written as follows:

$$\text{find } \mathbf{d} \text{ s.t. } \{\hat{\mathbf{q}}^T \mathbf{d}\} \text{ is maximum,} \quad (5)$$

under the following linear constraints:

$$\mathbf{A}\mathbf{d} \leq \mathbf{0} \quad (6)$$

$$\mathbf{B}\mathbf{d} = \mathbf{0} \quad (7)$$

$$\mathbf{C}\mathbf{d} = \hat{\mathbf{u}}_0, \quad (8)$$

where $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{N_{col,p} \times 3N_b}$, $\mathbf{C} \in \mathbb{R}^{N_{col,r} \times 3N_b}$ and $\hat{\mathbf{u}}_0$ is a vector whose elements are the values of the function $\mathbf{u}_0(\mathbf{x})$, representing the non-homogeneous essential boundary conditions, evaluated at collocation points on Γ . Constraints (6) and (7) represent the requirement that $v_n \leq 0$ on Γ_c and $v_t = 0$ on Γ_c respectively, Γ_c being the union of all the possible contact curves among the blocks. On the other hand, constraint (8) represents the non-homogeneous essential boundary conditions (i.e. foundation settlements) on Γ_u . It should be noticed that the objective function in (5) is the work of the assigned external loads.

3 ADAPTIVE GA-NURBS SCHEME

The structural response is described by roto-translations of the rigid blocks and jumps of displacement on the contact points. The overall displacement field can be obtained by solving problem (5), in which the external work is maximized under the constraints imposed by unilateral contact conditions, by means of an efficient linear programming.

In this work, a discretization through few NURBS shell rigid elements is adopted. The NURBS geometry description of the mesh allows to preserve the actual geometry of the structure even when using a small number of elements, avoiding the need for fine discretizations which would be otherwise required for masonry vaults. Thus, in place of modeling every single brick composing the structure, NURBS elements reproduce the curved macro-blocks

which determine the mechanism induced by the applied settlement, provided that the crack pattern is suitably adjusted by means of a suitable meta-heuristic optimization algorithm. On each interface, the unilateral contact conditions are applied. In case a rigid plastic behavior is to be accounted for, an associative flow rule can be adopted. As already discussed, the overall disposition of interfaces, i.e. the mesh adopted, represents only a possible crack pattern but, since the real crack pattern is not a-priori known, mesh adaptation is required. For this reason, in order to find the absolute maximum of the external work, we allow a Genetic Algorithm (GA) to adjust the initial mesh until a good approximation of the actual crack pattern is obtained. The procedure is very similar to the one used in the GA-NURBS limit analysis of masonry vaults proposed in [12], which was proven to be effective in the study of several typologies of masonry constructions [15–22].

4 NUMERICAL EXAMPLE

As an example, we study a reproduction of the historical barrel vault which constituting the roofing of the central nave of the Bothwell Parish Church (Glasgow, United Kingdom, see Fig. 1(a)). An in-depth geometrical survey revealed that the vault is slightly skewed, with cracks that has opened over the years due to settlement across the less braced South edge. In [14], this response of this vault under foundation settlements has been investigated by means of finite element analyses and several experimental test (also carried out in [13]) on a 1/12 scaled model (Fig. 1(b)). The actual vault geometry features an interior span of 6.1 m, a rise of 3.8 m, and a length of 16.8 m, and an average thickness of 36 cm. We assume a 520 kg/m³ density for masonry material. Finally, in order to better reproduce sliding deformations observed in the experimental test performed in [14], a 3D Mohr-Coulomb failure surface with tension cut-off and compression linear cap is assumed, with ultimate tensile and compression stresses equal to 0.03 MPa and 2.6 MPa respectively. Shear failures are controlled by a cohesion of 0.02 MPa and a tangent of the friction angle of 0.5. To replicate the experimental test, in the first numerical simulation, a vertical linear settlement has been applied (see Fig. 2), with a 1 cm maximum drop along the external edge.

Figure 1: (a) Bothwell Parish Church (Glasgow, UK) barrel vault [14] and (b) crack pattern observed in the experimental test [13].

Figure 2: Analysis of the displacement field under the action of non-uniform vertical settlement.

Figure 3: Analysis of the displacement field under the action of non-uniform horizontal settlement.

Each of the two NURBS surfaces describing half of the vault is discretized with 3×4 shell elements. Fig. 2 depicts the obtained displacement field. It can be noted that the crack pattern close to the external arch reproduces the typical hinges of the masonry arch undergoing a vertical differential settlement [11]. The shape of the crack pattern long the longitudinal direction of the vault is mainly due to settlements inducing torsional effects. The crack obtained with the proposed procedure is in good agreement with the results previously obtained both experimentally and numerically [13].

This barrel vault has been also studied under a horizontal linear settlement. Differential horizontal settlements are common in vaults used as roof elements in historical constructions, in which collapse during seismic events often occurs because of the differential movement of their supports, rather than because of the horizontal seismic actions applied to the vault. Fig. 3, represents the applied settlements and the obtained results. As in the previous case, it can be noted that the extremal part of the vault behaves like an arch. Also in this configuration, the proposed adaptive GA-NURBS scheme allows to accurately predict the 3D behavior of the vault.

5 CONCLUSIONS

In this paper, a NURBS-based adaptive approach to the three-dimensional analysis of masonry vaults undergoing foundation settlements is presented. A given masonry vault of arbitrary geometry is described through its NURBS parametric representation in the three-dimensional Euclidean space. The vault surface is then discretized into an initial set of rigid elements. Such discretization is obtained by suitably subdividing the NURBS parameters space. Jumps of displacement are allowed at the interfaces only. Given a known displacement on the external boundary, which comprises possible settlements, the resulting displacement field is computed by minimizing the total potential energy of the system by means of a linear programming optimization algorithm. Moreover, a GA-based mesh adaptation scheme is used to determine the crack pattern yielding the mechanism actually induced by the settlement. The example

Abstract

Bonded brickwork as loadbearing walls is widely found in the heritage structures worldwide. The bonded brickwork consists of two or more bricks in the thickness direction which causes them to behave differently to single leaf walls which are the basis of masonry design guidelines. The evaluation of bonded masonry structures under dynamic seismic actions therefore requires appropriate numerical modelling techniques accounting for the cyclic loading. Subsequently, a simplified 3D mesoscale numerical model has been developed in this paper to analysis different thicknesses of bonded brickwork under cyclic compression. Each masonry brick was defined using 3D solid elements with 8 nodes and 24 degree of freedom (DOF) representing an enlarged brick consists of a full-scale brick enveloped by half thickness of the mortar bedding layer all around. These masonry bricks were arranged in multiple layers using zero thickness cohesive interface elements to simulate the bond behaviour under shear, tension, and compression actions. A plasticity-based damage constitutive model to represent the damage in the masonry bricks under cyclic compression loading was employed. A threshold strain level was used to enact the element deletion technique for initiating the brittle crack opening in the masonry units. Whereas the joint interface failure between the masonry units was defined using a cohesive model represented by a simple bi-linear traction-separation constitutive law exhibiting an initial linear elastic behaviour at the interface followed by the initiation of the damage and evolution until the surface bonding degradation. The robustness of the developed model under cyclic compression loading has been proven by validating the test data presented for the clay brick selected to construct 9 masonry wallettes of single, double and triple brick thicknesses. The failure modes, cyclic stress-strain curves and stiffness degradation have been studied.

1 INTRODUCTION

Bonded masonry is invariably used as loadbearing elements in structures and the compressive strength characteristics of this masonry are of prime importance in the design of new and assessment of existing masonry structures. Subsequently, plenty of research efforts have been put in place to comprehend the compressive strength characteristics of various masonry assemblies in the past [1-4]. However, most of the studies in the past were dedicated to determining the monotonic compressive strength properties of masonry, where only limited studies were dedicated to understand the cyclic compression characteristics of masonry, which are needed to assess the performance of masonry elements against seismic or dynamic actions. Moreover, the non-loadbearing masonry infill walls in reinforced concrete or steel frames are also considered to act as diagonal compression struts under in-plane actions [5-6], thus analysing such infill frames under dynamic actions need cyclic compression properties of masonry.

The limited experimental studies on the cyclic compression behaviour of bonded masonry revealed that the characteristics of masonry under cyclic compression are different to monotonic compression in terms of the attainment of strength and deformation characteristics [7-9], where relatively low compressive strength and considerably larger deformation were depicted under cyclic compression than the monotonic loading. As a result of lack of cyclic compression experimental data on various assemblies, the development of constitutive models for masonry under cyclic compression was generally derived from the studies on concrete under cyclic compression [10-12]. While there are some similarities on the general characteristics between the masonry and concrete under cyclic compression, the damage evolution under cyclic compression is greatly different to concrete due to the anisotropic nature and interfacial incompatibility between unit and mortar in masonry. Recently, Thamboo et al. [13] compared the predictability of cyclic compression behaviour of the existing masonry models with the available experimental data and highlighted that most of the models were not able to predict one or other cyclic compression characteristics such as envelop response, plastic strain, unloading and reloading paths accurately. Nonetheless, experimental studies are not always viable to develop constitutive models for masonry under cyclic compression, owing to the diversity of masonry assemblies exist and difficulty in carrying out the cyclic testing. Therefore, numerical assessment of masonry under cyclic compression is a prudent solution.

Although plenty of progresses have been made to develop numerical methods to assess the masonry at different scales (micro, meso and macro) under various loading conditions [14-16], no systematic methodologies were developed to evaluate the cyclic compression behaviour of masonry in the past. Obviously, micro modelling technique is the most appropriate approach to assess the various assemblies of masonry under a localised loading situation. As an alternative to complex micro-modelling, simplified micro modelling of bonded masonry can save computational effort and avoid complexity of modelling additional mortar joints in the thickness of bonded brickwork. In this technique, mortar thickness is omitted by expanding the bricks into an equivalent masonry material which are joined to make assemblies of various patterns through zero thickness interfaces. Simplified micro-modelling based numerical assessment under cyclic compression could predict the characteristics of masonry reasonably,

especially in terms of damage evolution and localised stress-strain responses as it has been used earlier for the monotonic loading conditions [17-19].

This paper provides the details of a simplified 3D micro-scale modelling technique to assess the characteristics of bonded masonry under cyclic compression. The rationality of the developed modelling technique and outcome under cyclic compression loading simulation have been validated against the results from the experimental campaign carried out previously to assess the cyclic characteristics of bonded brickworks by the third author. Subsequently, Section 2 explains the simplified micro-modelling based numerical procedures established to simulate the cyclic compression behaviour of masonry. The validation of the numerical method against the experimental data is described in Section 3. Finally, the key conclusions derived from the study are mentioned in Section 4.

2 NUMERICAL MODELLING TECHNIQUE

An explicit finite element modelling method was developed to simulate the bonded brickwork response under cyclic compression loading. A simplified 3D mesoscale homogenised material model was adopted to analyse different thicknesses of bonded brickwork under cyclic compression. The material and contact non-linearities were incorporated in this model, and the parameters were calibrated using the datasets of the single brick thick wallette test specimens. Figure 1 shows the developed FE model of the brickwork constructed of single, double and triple bricks in their thickness.

Figure 1: Wallettes model details (a) Single brick (b) Double brick (c) Triple brick with detail of expanded bricks and (d) Mesh size

2.1 Geometry Details

In the simplified 3D mesoscale homogenised numerical modelling method, the homogenised units were modelled using 3D solid elements (C3D8R) with 8 nodes and 24 degrees of freedom. The selected mesh size (shown in Figure 1(d)) was 20 mm \times 20mm \times 20mm based on the mesh sensitivity analysis performed in [17]. The brick size representing an enlarged brick consists of full-scale brick enveloped by half-thickness of the mortar bedding layer all around,

was modelled as shown in Figure 1. These masonry bricks were arranged in multiple layers using zero thickness cohesive interface elements to simulate the bond behaviour under shear, tension, and compression actions. The sizes of single, double and triple brick thick brickwork samples were 410 (L) \times 740 (H) \times 95 (T) mm, 410 (L) \times 740 (H) \times 200 (T) mm, and 410 (L) \times 740 (H) \times 305 (T) mm, respectively. Loading plates were also modelled to distribute the compressive load uniformly over the specimens and to restrain the specimens against displacement from the bottom.

2.2 Material properties and constitutive model of expanded bricks

A plasticity-based damage constitutive model to represent the damage in the masonry bricks under cyclic compression loading was employed. The concrete damage plasticity (CDP) model in-built in ABAQUS was used to simulate homogenised brick and mortar behaviour. This model can predict two main failure modes: tensile cracking and compression crushing. Beyond the failure limit, the formation of minor and major cracks were represented with a softening stress-strain response, as shown in Figure 2. The stress-strain and other material data were taken from the experimental results of Thamboo & Dhanasekar [20], which were used in the calibration and validation of model results. A threshold strain level was used to enact the element deletion technique for initiating the brittle crack opening in the masonry units. The elastic modulus of the expanded clay bricks was input as 200 MPa. The Poisson's ratio was kept as 0.18 as was observed from the experiments [20]. In addition, the CDP model requires five main parameters: dilation angle (ψ) to account for the volume change caused by the inelastic behaviour of bricks, flow potential eccentricity (e) that defines the rate at which the hyperbolic flow potential approaches its asymptote, the ratio of the biaxial compressive strength of the material to its uniaxial compressive strength ratio (f_{b0}/f_{c0}), shape factor (K_c) which is the ratio of the tensile to the compressive meridian for describing the shape of the yield surface and viscosity (μ) that represents the relaxation time of the visco-plastic system, and is used for the visco-plastic regularisation. More details of these parameters can be found in [21]. The assigned CDP parameters are given in Table 1.

Figure 2: Stress-strain curve with damage properties of clay brick for CDP material model (a) Compression and (b) Tension

Parameter	Magnitude
Dilation angle (ψ)	30^0
Eccentricity (e)	0.1
Strength ratio (f_{b0}/f_{c0})	1.16
Shape factor (K_c)	0.66
Viscosity (μ)	0.001

Table 1: CDP model parameters for expanded bricks

2.3 Zero thickness interface: cohesive zone model

The zero-thickness interface between the homogenised expanded bricks was simulated using the cohesive zone model as shown in Figure 3(a). The interaction between the bricks was modelled using the simple bi-linear separation constitutive law, as shown in Figure 3 (b). The traction law is graphically represented using the traction force (τ) resulted in the opening displacement (δ). The interface allowed a damage initiation based on the threshold value which is followed by damage evolution until complete degradation of the surface bonding. The interface's elastic behaviour relates the normal and the shear (tractions) to the normal and shear displacements (separation) across the interface.

The normal stiffness matrix (K_n) is directly related to the thickness of the adhesive (cement) properties and the stiffness of the mortar (bedding layer). To evaluate the normal stiffness at the interface, a mathematical expression used for this relation is given in Equation (1).

$$K_n = \left(\frac{1}{\frac{t_{\text{mortar}}}{E_{\text{mortar}}} + \frac{t_{\text{ad}}}{E_{\text{ad}}}} \right) \quad (1)$$

Where t_{ad} represents the thickness of the adhesive found in the cement [22], t_{mortar} is the thickness of the mortar bedding layer and the E_{mortar} [20] and E_{ad} [22] are the young modulus of the mortar and the adhesive, respectively.

Similarly, the shear stiffness matrix (K_{ss} and K_{tt}) at the interface is mathematically expressed as shown in Equation (2).

$$K_0 = K_{ss} = K_{tt} = \left(\frac{1}{\frac{t_{\text{mortar}}}{G_{\text{mortar}}} + \frac{t_{\text{ad}}}{G_{\text{ad}}}} \right) \quad (2)$$

Where, G_{ad} and G_{mortar} are defined as the shear moduli of adhesion and mortar, respectively. The input values for the interface modelling are provided in Table 2.

The damage initiation in the interface was assumed to occur when a quadratic traction factors involving the combined normal stress and shear stress ratio reached to the value of 1 as shown in Equation (3). These criteria can be represented as

$$\left\{ \frac{\langle \sigma_n \rangle}{\sigma_n^0} \right\}^2 + \left\{ \frac{\langle \tau_s \rangle}{\tau_s^0} \right\}^2 + \left\{ \frac{\langle \tau_t \rangle}{\tau_t^0} \right\}^2 = 1 \quad (3)$$

Where σ_n is the cohesive tensile and the τ_s and τ_t are the shear stresses of the interfaces and n,s and t refers to the direction of the stress component as shown in Figure 3(c).

However, the interface damage evolution was expressed in terms of fracture energy release as shown in Equation (4).

$$G_n^c + (G_s^c - G_t^c) \left(\frac{G_s + G_t}{G_n + G_s + G_t} \right)^\eta = G^c \quad (4)$$

Where, G is the fracture energy; the superscript c represents the critical fracture energy and the dependency of the fracture energy η is a material parameter (Benzeggagah & Kenane [23]). The Benzeggagah- Kenane fracture criterion defines the critical fracture energies when the deformation along the first and the second shear directions are same. The properties of the zero-thickness interface to account for cohesion, traction separation law and friction are listed in Table 2.

Parameter	Magnitude
Normal stiffness, K_n (N/mm ³)	28
Shear stiffness, K_{ss} and K_{tt} (N/mm ³)	32
Friction coefficient	0.6
Maximum tensile stress, σ_n^0 (MPa)	0.68
Maximum shear stress, τ_s^0 and τ_t^0 (MPa)	0.82

3 VALIDATION RESULTS

This section presents the validation of the FE model using the experimental results of single, double and triple brick thick wallettes under cyclic compression loading presented in [20]. The validation includes the failure modes of bonded brickwork wallettes, stress-strain curves comparison with the experimental results and the strain variation in the region of damage.

3.1 Details of experimental programme

The experimental investigation on the cyclic response of the masonry wallettes was studied by the authors in the previous study [20]. The tested bonded brickwork samples in this experimental programme were constructed using clay bricks. The material properties and geometrical descriptions of types of bonded brickworks are presented in Figures 1 and 2. The properties of clay bricks varied mainly due to the manufacturing process depending on the controlled and uncontrolled firing in the kiln. However, the bricks used in this study with low strength and modulus of rupture are very common in practice in many developing countries. These bricks also have resemblance to the brick types mainly found in the historical masonry structures. In total, nine bonded brickwork wallettes were constructed with three different thickness (single, double, and triple) to assess their cyclic compression behaviour. The wallettes were built and tested according to BS EN 1052-1 provisions and loaded under the cyclic displacement-controlled protocol. The thickness of the mortar was restricted to 10 mm with the help of an experienced mason. The constructed masonry wallettes were air cured for 28 days under an ambient temperature of 34°C.

The wallettes were tested in a 1000 kN capacity servo-controlled Universal Testing Machine (UTM). A 5 mm thick plywood was used between the top and bottom platens of the UTM to uniformly distribute the compression loading on the surfaces. In total eight displacement transducers were attached to record the axial and lateral deformation in each wallette. Four transducers were attached vertically on both faces (two on each face) of the wallette to record the axial deformation. Similarly, four remaining transducers (two on each face) were placed horizontally to record lateral deformation on each face of the wallette. A typical cyclic loading protocol applied to the specimens is shown in Figure 4. The cyclic displacement procedure was taken from the load-displacement responses of the similar wallettes under monotonic testing [20]. The elastic, hardening and peak limits were identified from the load displacement response presented in [20]. The elastic limit point was observed at the one third of the peak load and the hardening limit was considered as 0.8 times the peak load. The number of cycles within each limit are reported in the Table 3.

Figure 4: Loading input for the cyclic test of the wallettes

Monotonic Loading	Cyclic Loading	
Load-Displacement Response	Number of Steps	Number of Cycles
Elastic Limit (one third of peak load)	4 steps	2 cycles at each step
Hardening Limit (0.8 times the peak load)	4 Steps	2 cycles at each step
Peak Limit	3 Steps	2 cycles at each step

Table 3: Typical Cyclic loading protocol

3.2 Failure modes

The failure modes of single, double and triple brick thick bonded brickwork models are shown in Figure 5 in terms of principal strain. The failure pattern observed in the numerical model for all wallettes was in close agreement with the experimental failure modes as shown in Figure 5. For single brickwork wallette, vertical cracks developed in the bricks, mainly on the central area and near the edges of the faces at about 50 to 70% of the peak force. After the peak load, these cracks propagated diagonally and opened leading to the spalling from the edges of the wallettes. However, for the double and triple brick wallettes, a single splitting crack through the thickness of the wallettes and the parallel tensile cracks were observed along the width of the wallettes. During the post-peak stage, the cyclic loading resulted in the wider crack propagation within small span of time associated with the spalling of brick-and-mortar pieces.

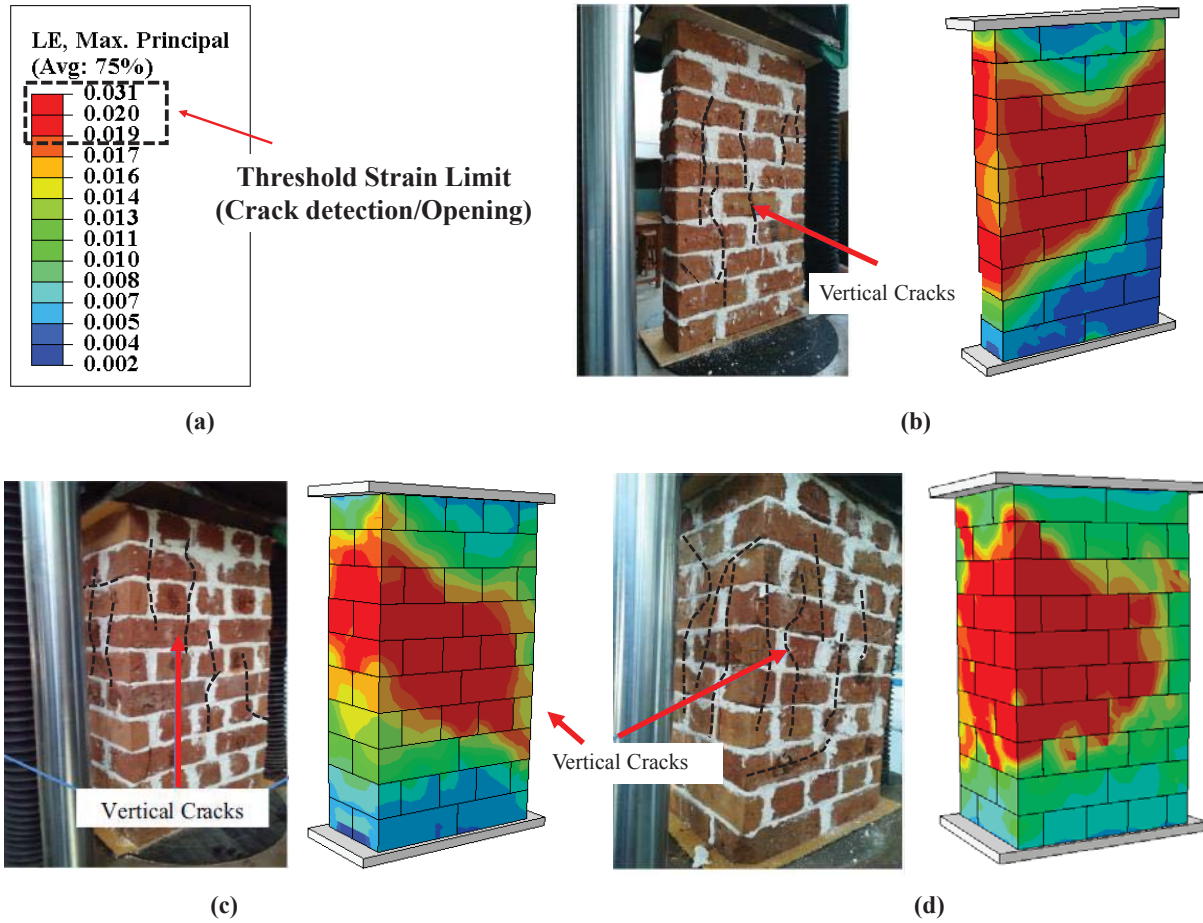

Figure 5: Numerical Failure modes of the brick wallettes: (a) Maximum Strain contour (b) Single brick (c) Double brick and (d) Triple brick

3.3 Stress-strain relationship

Figure 6 shows the compressive strength of single, double and triple brick thick bonded brickwork models under cyclic compression loading. The compressive strength predicted by the FE model of all three brickwork specimens matched well with the experimental data with only 5~10% approx. deviation. The experimental and numerical results show a 10% increase in the compressive strength of the double brick thick brickwork compared to the single- brick wallette. The marginal increase in the compressive strength can be attributed to the reduction in the slenderness ratio (height-to-thickness ratio). However, no significant enhancement in the compressive strength observed when compared double brick to triple brick wallettes. The reason for not increasing the compressive strength is the increase in the number of weak joints (more perpendicular joint) with the increase in the thickness of the wallettes.

Additionally, it was also observed that the compressive strength for the cyclic loading was lower than for the monotonic loading [20]. The compressive strength reduction observed in the cyclically loaded wallettes was mainly because of the accumulating lateral tractions and inelastic strains in the bonded brickwork. Hence, the accumulation of the strain over time history is significant for the compressive strength of the bonded brickworks as well as for defining the mitigating strategies under cyclic loading.

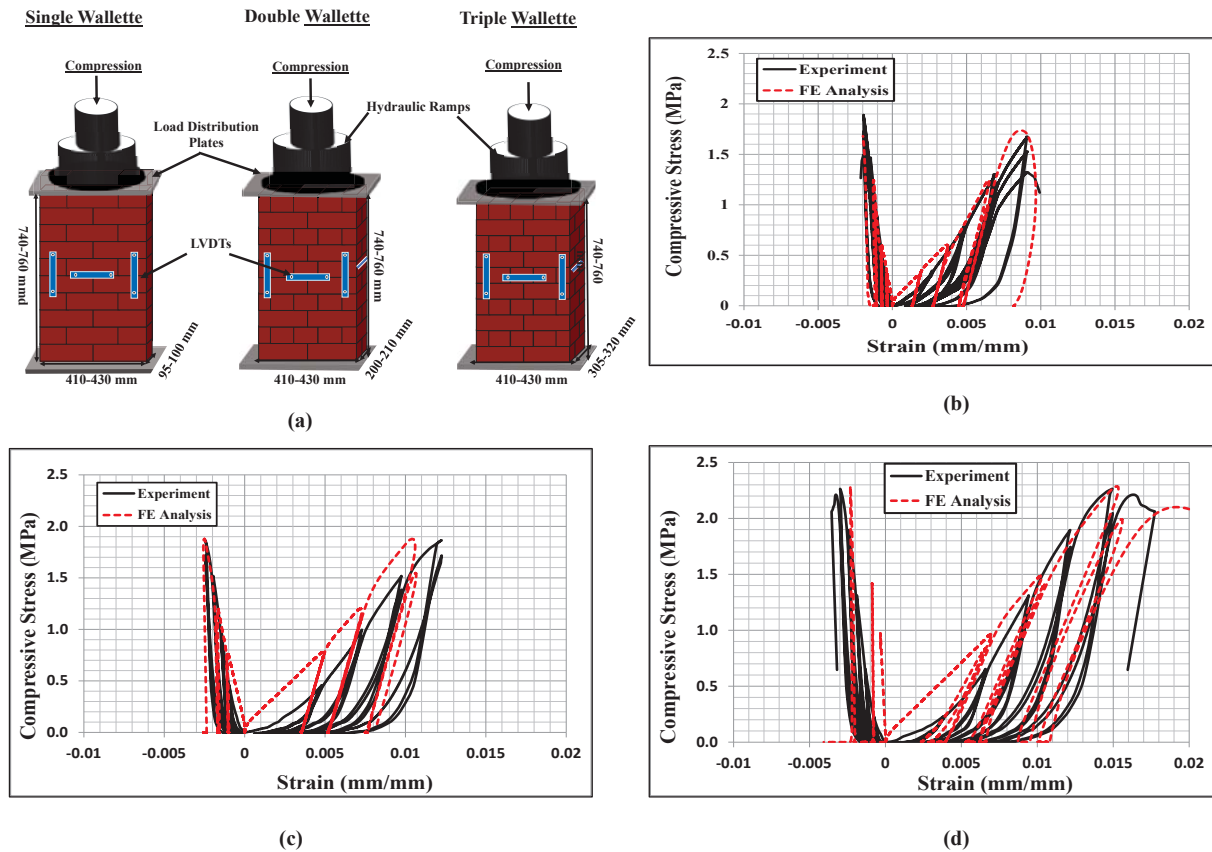

Figure 6: Stress-strain variation of the bonded brick wallettes (a) Experimental setup (b) Single brick (c) Double brick and (d) Triple brick

4 CONCLUSION

A simplified 3D finite element model incorporating expanded bricks with zero thickness cohesive interfaces, representing brick – mortar joints, has been developed for predicting the cyclic compression behaviour of different thicknesses of bonded brick masonry wallettes. The experimental results of bonded brickwork constructed with single, double and triple brick thickness were used for validating the developed model. The FE prediction of the failure modes and cyclic stress-strain curves under the cyclic loading matched well with the experimental results. The change in the thickness of the brickwork samples did not significantly alter the failure pattern of the bonded brickwork confirming the experimental findings that the effect of increase in the thickness of the bonded brickwork (or decrease in the slenderness) was insignificant on the compressive strength of the bonded brickwork.

Abstract

This paper adopts a very convenient 3D CAD method to quickly assess the seismic vulnerability of existing masonry towers. The study selected five typical collapse mechanisms, vertical splitting, base rocking, overturning with diagonal cracks (Heyman 1992), a combination of splitting and diagonal overturning and base sliding. The Longhu pagoda in China is selected as the research case. Based on the principle of virtual works, assuming that the masonry material is a no-tension material, and the collapse acceleration under loads G1 and G2 is calculated from the four main directions. The research results show that vertical splitting of collapse mechanism is the easiest to appear, which is in full compliance with the results of the on-site survey after the Longhu pagoda earthquake, further demonstrating the reliability of this method. This method does not require complex mathematical foundations, can be easily mastered by non-professionals, and at the same time greatly reduces the amount of simulation calculation, which is helpful for the promotion of seismic research of masonry structures.

Keywords: Masonry pagoda; limit analysis; Collapse mechanism, Collapse acceleration.

1 INTRODUCTION

As one of the four ancient civilizations, Chinese ancient buildings are a precious heritage left over from history. The ancient masonry pagoda is a typical representative, which combines the crystallization of the world's wisdom and the essence of architectural art. With the development and changes of the times, most of the ancient pagodas left behind have become historical sites, which not only brighten the city's scenery, but also promote Chinese culture and enrich tourism resources. The ancient pagoda is mainly located in the north and south of China, with many styles and characteristics. After going through the changes of the times, the existing masonry pagodas have extremely high historical and cultural, aesthetic art and scientific research value. Therefore, trying to protect and repair the ancient masonry pagoda has become an important mission for contemporary people.

Masonry pagoda has the advantages of high compressive strength, low cost, convenient construction, fire resistance, and good heat and sound insulation performance. It is a brittle material with relatively high tensile and shear strength. These pagodas have undergone a century of historical vicissitudes and changes, and have withstood countless baptisms of nature, with more or less damage to a certain degree. However, according to investigations and studies, most of the damage or collapse of ancient masonry pagodas structures are mainly caused by earthquakes. Once an earthquake occurs, it will cause great harm to human society [1]. China is located in the middle of the Eurasian seismic belt and the Pacific Rim seismic belt. There are many and strong earthquakes. The area of seismic belts is also very wide and scattered. It is one of the countries that suffer the most from earthquake disasters in the world [2]. In view of this, it is of extraordinary significance to understand and master the structural form and construction technology of ancient masonry towers, study its dynamic characteristics under earthquake action, find out the weak links of the structure, and reduce the losses caused by earthquake disasters.

After subjected to earthquakes, the accumulation of damage will lead to collapse of pagoda that is major threat of structural safety. The main damage characteristics of pagodas which were made by earthquake are following (Figure 1): 1) the tilt and collapse of pagoda spire, 2) the tilt and bend of pagoda body, 3) the break in the middle part of the pagoda, 4) the split of pagoda body along the central axis, 5) overall collapse [3].

Figure 1. Damage characteristics of pagodas [3].

Studying masonry towers seismic vulnerability is not a trivial task. The current research work of Chinese scholars on the ancient pagoda is mainly carried out in the three aspects of classical theory, test data and numerical simulation [4]. Among the others, a "cantilever rod model" has been proposed, combining different tools to simplify the structural analysis model,

and apply these theories to the study of real cases such as Quanzhou pagoda, Fawang pagoda, Wenfeng pagoda, etc. [5,6]. For example, Y. Shen et al. analyzed the dynamic characteristics and the seismic capacity of the ancient masonry Xiaoyan pagoda based on the historical survey and reinforcement data. They discussed its seismic performance [7]. F. Zhu et al. conducted a seismic simulation shaking table test of the China Dinosaur pagoda model structure to observe the weak links and failure mechanism of the model structure under the action of earthquakes. They conducted a comprehensive technical evaluation of the seismic capacity and the technical feasibility of the construction of the pagoda [8]. Seoul National University in Korea has cleverly built a five-story full-scale model to study the seismic performance of the masonry pagoda, conducted destructive tests on it. Through the actual test results, the earthquake effect of the prototype tower body was reversed [9].

Western scholars deeply studied the seismic vulnerability of ancient masonry towers in the past years applying even more sophisticated methods. Non-linear static and dynamic analyses have been widely used to apply the earthquake loads [10-13]. University of Minho, Portugal conducted material mechanical performance tests and ingenious static tests on 24 masonry walls, evaluated the earthquake resistance level of the masonry structure, and summarized the relevant non-destructive testing methods, which provided information for the improvement of its seismic resistance level [14]. A. Carpinteri, S. Invernizzi, G. Lacidogna et al. conducted non-disturbing non-destructive testing of two ancient masonry pagodas in Italy in the 13th century, and they also did preliminary linear analysis, which basically coincided with the measured stress level. Non-linear cracking and damage analysis was also carried out, the evolution of principal stress damage and damage distribution are predicted. It was found that the damage is mainly distributed in the local high strain area. The results of the numerical analysis provide meaningful guidance to the monitored parts and evaluate the seismic performance analysis [15]. S.T. Sperbeck et al. conducted on-site investigation and testing of ancient masonry pagodas, comprehensively analyzed the influencing factors, established an H-dimensional solid model, applied loads of different levels and directions, and changed boundary conditions [16]. The dynamic characteristics are evaluated, and the influence of the parameters on the test results was discussed in detail.

To sum up, based on meticulous field exploration and experimental research, it is possible to conduct dynamic characteristic testing and numerical calculation analysis on ancient masonry pagodas. In this way, the structural damage of the ancient masonry pagoda can be identified, and the seismic performance of the structure can be effectively evaluated, which provides a reference for the seismic resistance of the project.

However, all the above-mentioned researchers are based on strong mathematics, dynamics, and computer engineering. In the society where the seismic research of masonry buildings has become the common demand and desire of many people, such a professional research method is not conducive to the widespread dissemination of knowledge of ancient architectural heritage protection.

In order to overcome this drawback, Researchers have recently proposed a kinematic limit analysis where vulnerability can be estimated assuming that a tower fails for the formation of five possible different pre-assigned failure mechanisms, namely vertical splitting, base rocking, overturning with diagonal cracks (Heyman 1992), a combination of splitting and diagonal overturning and base sliding (Figure 2). G. Milani et al. has also used this method in the vulnerability assessment of a large number of Italian masonry buildings, which greatly proved the practical significance of this method [17,18].

This paper aims to apply a fast full 3D CAD limit analysis method to the seismic performance evaluation of Longhu pagoda. The research is based on the principle of virtual works, assuming that the masonry material is a no-tension material, and quickly assesses the

horizontal acceleration when the building collapses. The research only needs a detailed 3d model, basic mechanics knowledge and calculation ability, simple and easy to learn, can well adapt to the diversified requirements of research and protection of masonry structure buildings. At the same time, the amount of calculation for simulation research can be greatly reduced.

Figure 2. Collapse mechanism for masonry towers selected in [17] (images adapted from [17]).

2 INFORMATION ABOUT LONGHU PAGODA

Longhu pagoda (Figure 3) which was built in 1342 A.D. is located in Xiaoquan, Deyang, Sichuan province (East longitude $104^{\circ} 17'$, North latitude $31^{\circ} 15'$) and is the only preserved masonry pagoda made in Yuan dynasty [19,20]. It has a square plan with 13 layers of eaves outside it, and it is roughly 33 meters tall which contains 2 meters of stylobate and 31 meters of body.

Figure 3. Longhu pagoda.

Figure 4. Damage of longhu pagoda

On May 12, 2008, a 8.0 magnitude Richter earthquake occurred in Wenchuan, Sichuan province, China, and the epicenter was in a small town whose name is Yingxiu. Wenchuan earthquake is destructive and has a strong impact, its maximum acceleration peak value which appeared after the start of the crustal movement (65 s - 82 s) is nearly 424 cm/s^2 . According to incomplete statistics, the earthquake killed around 69227 people, injured 376443 people, and

17,923 people were missing. Large numbers of architectures were collapsed and cultural relics were severely damaged, which resulted immeasurable losses.

The position of Longhu pagoda is not very far away from the epicenter (about 100 km), and it was influenced by the east-west seismic wave. The post-earthquake disaster investigation showed that the Longhu pagoda had a north-south through crack from the bottom to the top of the body. The cracks developed along the height, and the higher the position, the larger its width. The pagoda body was shaken into two parts, east and west, and its integrity was severely damaged (Figure 4).

3 LIMIT ANALYSIS

In the previous literature, the kinematic theorem of limit analysis has been widely used to calculate the collapsed ground acceleration of a masonry structure, especially some masonry pagodas [21,22]. Compared with complex finite element simulation calculations, this method can predict the collapse mechanism and collapse acceleration of masonry pagodas more easily and conveniently. The calculation results are quite reliable and can be quickly grasped by non-professionals. At the same time, when conducting a more detailed and in-depth study of masonry structures, the results of limit analysis can be compared with pushover and nonlinear dynamic analysis to improve the accuracy of simulation calculations.

According to Figure 2, this paper applied the same research method in the limit analysis of Longhu pagoda. The collapse accelerations related to the five collapse mechanisms of Figure 1 have been computed on the real 3D geometric model, applying the kinematic theorem of limit analysis, and considering the masonry as a no-tension material with infinite compressive strength. It has been decided to do not optimize the position of the vertical cutting planes (as done in [22]) but to roughly position them as passing through the middle points of the base edges. The inclined planes of mechanisms n.3 and n.4 (Figure 2) have been posed with an inclination of 30° , 45° or 60° to the horizontal plane. Each collapse mechanism is simulated from four main directions (X^+ , X^- , Z^+ , Z^-). It is worth noting that a Mohr-Coulomb failure criterion has been used in mechanism n.5 calculation; and the friction angle has been taken equal to 30° following what stated in [23]. The analysis in load control, and the considered loading conditions are G1 and G2. G1: principal distribution of forces proportional to the mass and linearly proportional to the height of the structure (the so-called “inverted triangle”). G2: secondary distribution of forces proportional to the mass and constant along the height of the structure.

Figure 5. Collapse mechanism n.4 that considering the negative work done by the block n.2.

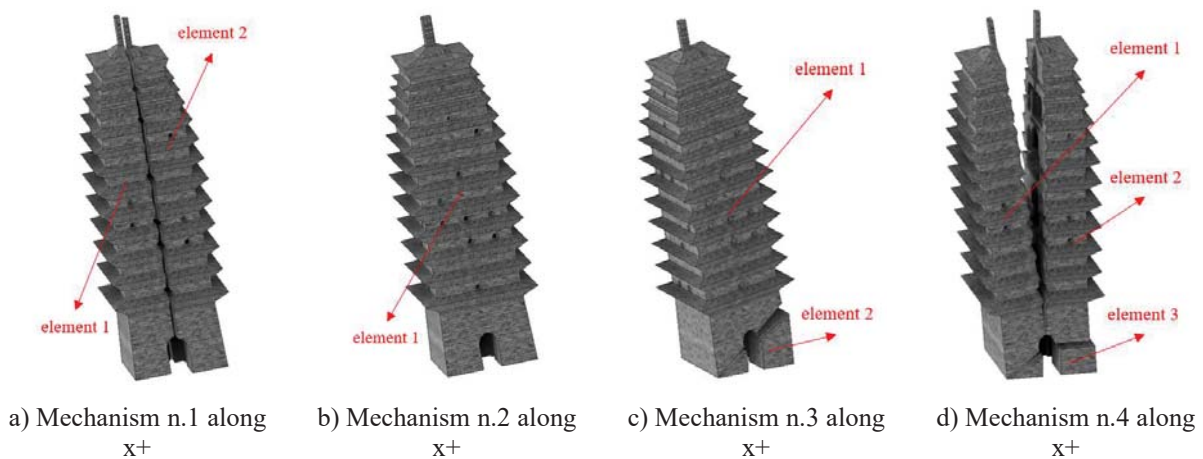

Figure 6. Some of the studied collapse mechanisms.

The mathematical basis of this method is very simple: only a first-order equation and basic geometry consideration are needed, and the collapse multiplier is easily computed for each mechanism. The kinematic theorem is applied through the equating of the work done by external forces (inertia forces) and internal forces (self-weight). However, some changes have been introduced in this paper with respect to reference [21,22] and they are here explained: the tensile strength has been considered as null (it was not in the reference research) and the mechanism n.4 (Figure 2) has been slightly modified by considering the negative work done by the block n.2 (Figure 5)

The collapse accelerations values for each mechanism are reported in Table 1, and Figure 6 represents some of the collapse mechanisms applied to the 3D model of the pagoda. The results have shown that the vertical splitting (mech. n.1) is always the most likely to occur.

Direction	Mechanism	Inclination Angle [°]	Collapse Acceleration G2 [g]	Collapse Acceleration G1 [g]

Table 1. Limit analysis results. The minimum of each direction is formatted in bold.

4 CONCLUSIONS

This paper uses a 3D CAD method to perform a quick limit analysis of the Longhu pagoda. It mainly calculated the collapse accelerations along the four main directions for four different collapse mechanisms under G1 and G2 loads. Under G1 load, a_g/g along the X direction is 0.155, and a_g/g along the Z direction is 0.124. Under G2 load, a_g/g along the X direction is 0.155, and a_g/g along the Z direction is 0.125. The research results show that collapse mechanism n.1 which is vertical splitting is the most likely occurrence. This is also consistent with the on-site survey of Longhu pagoda earthquake damage after the Wenchuan earthquake.

Abstract

The seismic assessment of two vaulted monuments made of Roman concrete is here presented. Both their structural forms and constituent materials are here explored, whose combination enabled to build such largescale structures, and whose knowledge is essential for assessing and maintaining the safety of the portions of such structures that still exist.

Specifically, two different monuments dating back to the Imperial age are analyzed: the Calidarium of the Baths of Caracalla and the Calidarium of the Diocletian's Baths. The two structures were built at a distance of less than one century one each other and both were erected with the same construction technique. Nowadays both Calidarium structures no longer exist: the first one still presents two not collapsed monumental pillars, whilst the ruins of the second were demolished in the Sixteenth Century. Therefore, the present work aims at investigating the causes behind their collapse and how their collapse occurred by performing advanced numerical simulations.

Keywords: seismic assessment, vaulted monuments, roman concrete, monuments, Imperial age, structural analyses.

1 INTRODUCTION

Roman vaulted structures belonging to the imperial age represent one of the most important contributions to the artistic, architectural and engineering heritage of the entire world and their extraordinary durability is an aspect that should make the whole scientific community reflect and inspire. These large spans and curvilinear forms are still visible in buildings such as the Pantheon, the thermal baths of Caracalla and Diocletian, the Trajan's Markets and the Basilica of Maxentius, but these are just some of the many monuments still preserved in an impressive way. The secret of the majesty of these monuments and their longevity lies in the combination of the use of monumental vaulted forms and Roman concrete [1].

Caracalla's and Diocletian's Calidaria were two of the largest vaulted structures built with unreinforced pozzolanic Roman concrete. The high complexity of such constructions requires advanced numerical techniques to be analyzed. The characteristics of the Roman concrete, poor tensile resistance compared with high compressive strength, provide it a quasi no-tension behavior [2] allowing to follow the numerical strategies proposed for vaulted masonry structures [3]. Among the methods currently available from the technical literature, we can mention the modern limit analysis tools based on the static [4–6] and the kinematic theorem [7–12] but also the recent numerical techniques relying on the Finite Element (FE) method [13–16].

In this paper, a numerical investigation behind the causes of the collapse of these vaulted structures is conducted. The seismic vulnerability is studied through non-linear dynamic simulations carried out on FE models in the software Abaqus/CAE, where the behavior of the pozzolanic concrete (*opus caementicium*) is represented by means of the concrete damage plasticity model [17] available within Abaqus. Finally, non-linear time-history analyses are carried out on both structures by applying an accelerogram compatible with the response spectrum of Rome.

2 ABOUT ROMAN CONCRETE “OPUS CAEMENTICIUM”

The material used in vaulted monuments such as Caracalla and Diocletian Baths consists in a composite masonry structure, called *opus latericium*, made of two external brick walls with a triangular shape and a concrete core composed by a pozzolanic lime mortar containing large pieces of stone, brick, marble and tufa (*opus caementicium*). The distribution of materials with decreasing density are observed: a distinct gradation of brick in the lower third (1800 kg/m^3), tufo lionato in the middle third (1600 kg/m^3), and Vesuvian scoria in the upper third (1400 kg/m^3).

The mechanical characterization of the Roman concrete was possible thanks to the analysis of the results obtained from a consistent test campaign carried out at the University of Rome “La Sapienza” (1996) and conducted by A. Samuelli Ferretti [18]. According to the experimental results, the elastic parameters adopted in the structural analyses are: elastic modulus $E = 3000 \text{ MPa}$, Poisson modulus $\nu = 0.5$, compression strength $f_c = 5 \text{ MPa}$ and tensile strength $f_t = 0.5 \text{ MPa}$. Post elastic non-linear behavior is taken into account through the Concrete Damaged Plasticity Model. Damage plasticity is a continuum macro-model for concrete, originally developed by Lubliner et al. [17] and modified by Lee and Fenves [19], which incorporates tensile cracking and compressive crushing as the primary failure mechanisms. Moreover, it assumes the fracture energy formulation for concrete developed in [20]. Regarding the post-elastic behavior on the Roman concrete, an innovative study was performed at the University of Rochester by Ivancic, Brune and Perucchio [21] which allowed to construct a nonlinear damage plasticity formulation for both compressive and tensile response of the *opus caementicium* suitable for 3D implementation in Abaqus (see Figure 1).

3 NON-LINEAR DYNAMIC ANALYSIS OF TWO CALIDARIA IN ROME

The dynamic non-linear analysis of the Calidaria of the Baths of Caracalla (216 A.D.) and the Baths of Diocletian (306 A.D.) are here presented.

The Calidarium of the Caracalla's baths (see Figure 2) was a circular room paved in marble and roofed with a dome of almost 36 m diameter, very similar to the dimension of the Pantheon. The weight of the dome was carried by eight pillars made in Roman concrete. The plan view shows a structure composed of an internal diameter of 36 m and pillars with a thickness of 6 m (1/6 of the external radius). Two levels of vaults can be observed from the cross-sections. The first one consists of vaults whose springers are located at a height of 11 m from the ground; conversely, those at the upper level have a particular shape that maximizes the light entering the structure. The thickness of the dome at the crown is assumed to be equal to 1.5 m, as in the dome of the Pantheon.

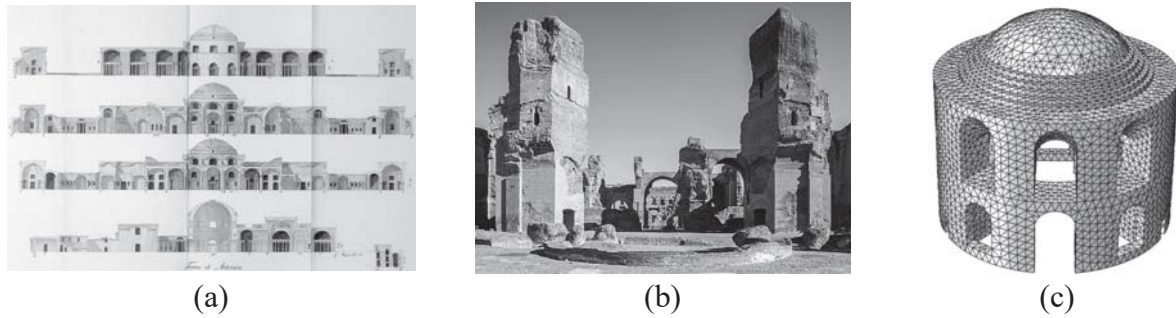

Figure 2: Baths of Caracalla: (a) drawings made by Palladio, (b) current state of the Calidarium, and (c) FE model.

By following the prescriptions given by the regional authority (Regione Lazio), an appropriate accelerogram compatible with the response spectrum was adopted and applied in both directions (x and y). The shape and the duration of the seismic input can be observed in Figure 3. Three meaningful instants indicated through the points A, B, and C, are defined in the accelerogram and highlighted in the results.

Figure 3: Accelerogram adopted in the dynamic non-linear analyses (points A: $t = 7.9$ s, B: $t = 11.3$ s, C: $t = 17$ s).

The level of damage suffered by the *Calidarium* is represented in terms of plastic strains in the different time instants, see Figure 4. The dark areas indicate the presence of plastic strains generated by traction, therefore they correspond to the areas where tensile cracks develop.

As it can be observed from Figure 4, after the first peaks of the accelerogram (point A), high plastic strains develop within the structure: fracture lines propagate from the vaults up to the top of the dome.

Figure 5 shows the trend of the strain energy and plastic dissipation energy during the analysis. It can be observed that point A (i.e. peak value of the accelerogram) coincides with the instant in which the plastic dissipation energy begins to increase, while in point C it has already assumed its final value. At the end of the analysis, the plastic dissipation energy and the strain energy have almost the same value. The energy plastically dissipated at the end of the strongest part of the accelerogram reaches a sort of plateau and its value remains stable until the end of the analysis. Therefore, it can be supposed that an accumulation of damage has been generated in the *Calidarium* but that the seismic action is not sufficient to cause the failure of the dome. Therefore, it can be stated that the collapse of the *Calidarium* is not associated with a single seismic event, but probably is due to the repetition of multiple earthquakes.

Figure 4: Plastic-strain maps for the Calidarium of the Bath of Caracalla.

Figure 5: Internal energy-time diagrams (accelerogram applied along both directions).

The Baths of Diocletian, see Figure 6, represent the largest thermal complex ever built in ancient Rome. Its Calidarium was a rectangular room paved in marble and roofed by a system of three cross vaults. The entire structure was made in Roman concrete with the exception of the entablature blocks and granite columns on which the cross vaults rested. Moreover, there were three lateral apses, also supported by granite columns. Nowadays only a small portion of the north-eastern side of the *Calidarium* is still standing (Figure 6b).

Figure 6: Baths of Diocletian: (a) transversal cross-section of the Calidarium (E. Paulin, 1880), (b) current state, and (c) FE model

The results of the non-linear dynamic analysis here presented are obtained by considering the same accelerogram used for the *Calidarium* of Caracalla (Figure 3) and applying it in both x and y directions. The analysis stops before the ending of the duration time of the accelerogram due to the collapse of the front apse that provoked the excessive distortion of the elements of the mesh. By observing the derived crack patterns depicted in Figure 7, the Calidarium appears totally intact, except for the front apse that at the time instant C presents a high level of plastic strains.

The trend of the internal energies evaluated in the roof of the *Calidarium* and in its central apse are reported in Figure 8. While the energy plastically dissipated in the roof is very low, in the apse it reaches very high values (Figure 8b). This result demonstrates that the collapse of the apse occurs before the roof suffers high damages. Deduction that is completely in accordance with the ruins of the structure represented in the drawing made by Dosio (1533-1611).

Figure 7: Plastic strain maps for the Calidarium of Diocletian.

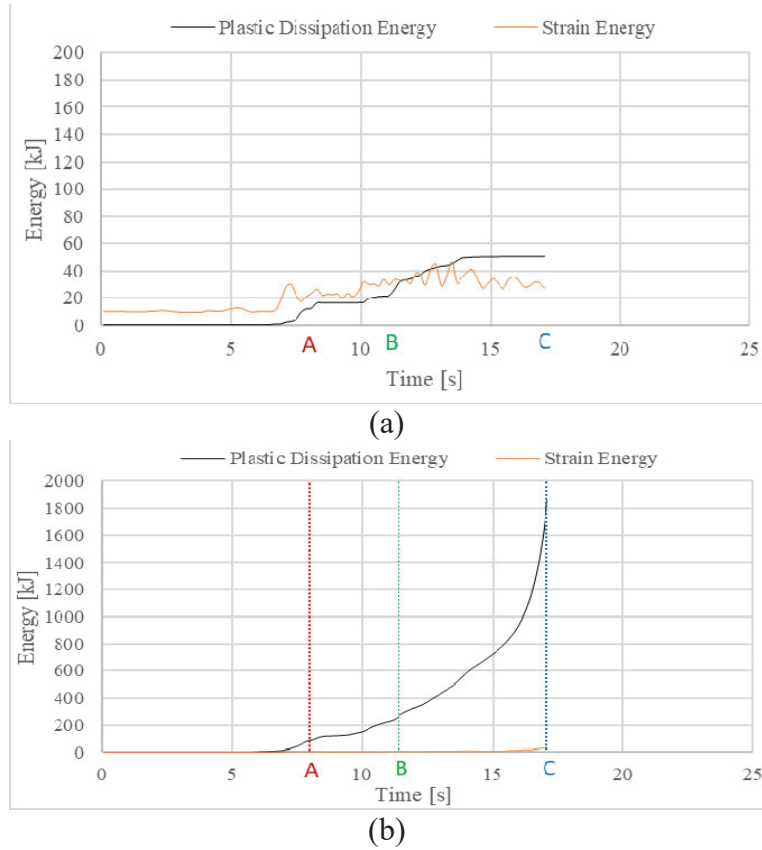

Figure 8: Internal energy-time diagrams: (a) roof and (b) apse.

4 CONCLUSIONS

In this paper, the collapse of two Roman concrete Calidaria in Rome has been investigated by means of advanced non-linear dynamic analyses performed in Abaqus. The behavior of the Roman concrete, the so-called *opus caementicium*, is represented by means of the concrete damage plasticity model. A non-linear damage plasticity law for both compressive and tensile response of the *opus caementicium* has been implemented in Abaqus to correctly reproduce the post-elastic behavior.

As far as the Calidarium of the Caracalla's Baths is concerned, the application of a single accelerogram is not sufficient to generate its collapse condition. However, at the end of the dynamic analysis, high plastic strains develop within the structure, indicating that the application of a further accelerogram may cause the collapse of its dome. Therefore, it can be argued that the seismic events occurring in Rome over the course of its post-Imperial history generated damages that had accumulated within the structure, greatly reducing its resistance. Consequently, the collapse may have occurred during or after one of those seismic events, just when the structure itself was already damaged.

The analyses carried out on the Calidarium of the Diocletian's Baths show that the front apse is the first structural part to have collapsed. Despite how reported by Dosio in its drawings, in which the Calidarium is represented without its front apse and its roof, at the end of the dynamic analysis the upper cross vaults appear poorly damaged.

Eventually, for both Calidaria it has been discovered that their collapse is not associated with a single seismic event, but with the repetition of multiple earthquakes.

Abstract

This paper presents the numerical results obtained simulating a 4x4mq masonry vault (unreinforced and reinforced with glass-TRM) tested at the Universitat Politècnica de Valencia (Spain). The vault was built using a traditional Catalan layered-construction technique and its structural behavior was analyzed when subjected to monotonic vertical displacements in one of its supports. The geometry and construction technique of the vault resembled those in a church on the outskirts of Valencia, which collapsed probably due to soil settlements. Indeed, due to their peculiar geometric and mechanical features, these structures are especially prone to damage from support movements produced by ground settlements or earthquakes.

Two advanced 3D numerical models were developed using the commercial software Abaqus to study the vault response with and without the application of an extrados layer of lime based TRM strengthening material. The FE software allowed the adoption of a concrete damage plasticity (CDP) material model which was employed to both masonry support and TRM strengthening material, after a preliminary tuning of the compressive and tensile mechanical properties of the constituent materials.

The outputs obtained with the FE models coupled with the results of the tests, provided valuable information to the scientific community on the available modelling strategies to be used to evaluate the behavior of ancient masonry double-curvature structures pre-damaged by vertical movements of the vault supports and repaired with TRM materials.

Keywords: Masonry vaults, Textile Reinforced Mortar (TRM) materials, Vertical Settlements.

1 INTRODUCTION

Textile Reinforced Mortar (TRM) materials represent a valid alternative to Fiber Reinforced Polymers (FRP) [1]-[7] for the reinforcement of ancient structures [8]-[12]. The advantages offered by TRM materials are mainly related to their compatibility with weak ancient substrates and their permeability. In addition, TRM materials offer some of the advantages of FRP composites, as their ease of installation and adaptability to complex geometries. Until now, TRM materials have been studied to characterize their mechanical properties which in turn have helped define guidelines and guide professionals during their design [10]. One of the most important features of this strengthening material, is represented by the mortar matrix, which is generally characterized by a low tensile strength. The adoption of TRM materials has been encouraged in the case of ancient masonries by leveraging their high compatibility and reversibility with respect to ancient supports. An obvious development therefore was the promotion of lime matrices instead of cementitious ones. Unfortunately, the adoption of low tensile strength matrices decreases the global performance of the strengthening solutions themselves which thus needed to be engineered by mixing them with reinforcing fibers. Unlike FRPs, engineered TRM materials usually fail due to slippage phenomena between the reinforcing textile and the mortar matrix [8][10].

Several research groups focused on this aspect, while few research works were developed to study their actual applicability to full-scale structures [13]-[16]. This aspect is particularly important when the support on which the reinforcement is applied is a weak material characterized by negligible tensile strength as in the case of old masonries. In fact, the suitability of a reinforcing solution needs to be evaluated taking into account possible adverse failure mechanisms that the reinforcing material could trigger. Several researches highlighted this aspect especially on isolated masonry panels subjected to diagonal compression or arches reinforced with different strengthening solutions [15]. Furthermore, advanced computational models and analytical approaches were developed mainly on a local scale to study the bonding performance of TRM materials, completely disregarding the effects these reinforcement solutions have on full-scale structures [17]-[22]. One of the first examples of a comprehensive study on the adoption of TRM materials is represented by [23][24]. This work shows the positive and negative effects of TRM solutions when applied on full-scale structures. The results obtained by the lab investigation were used in the present work to propose a 3D macro-modelling strategy to study the structural response of masonry layered vaults. The models were used to deduce important outcomes on the limitations of TRM strengthening materials.

2 EXPERIMENTAL CAMPAIGN

This section is devoted to the discussion of the results obtained by a unique laboratory investigation developed at the *Universitat Politècnica de Valencia* (Valencia, Spain) on one masonry timbered vault damaged by vertical settlements and repaired by an extrados radial TRM strengthening configuration. The vault had a square 4x4 m² shape and it was constructed on four concrete supports interconnected by a steel bracing frame. The vault was subjected to different settlements during two laboratory tests: a downward settlement up to 40 mm was applied to one support (I test), then the vault was repaired by applying an extrados layer of TRM materials and it was re-tested by imposing a total downward settlement up to 120 mm (II test). The vault geometry and displacement history are depicted in Figure 1 -a and -b respectively. The reader is referred to [23][24] for further details. The strengthening material was composed of a 10-15 mm thick fibre reinforced natural hydraulic lime and eco-pozzolan based mortar reinforced with a glass textile.

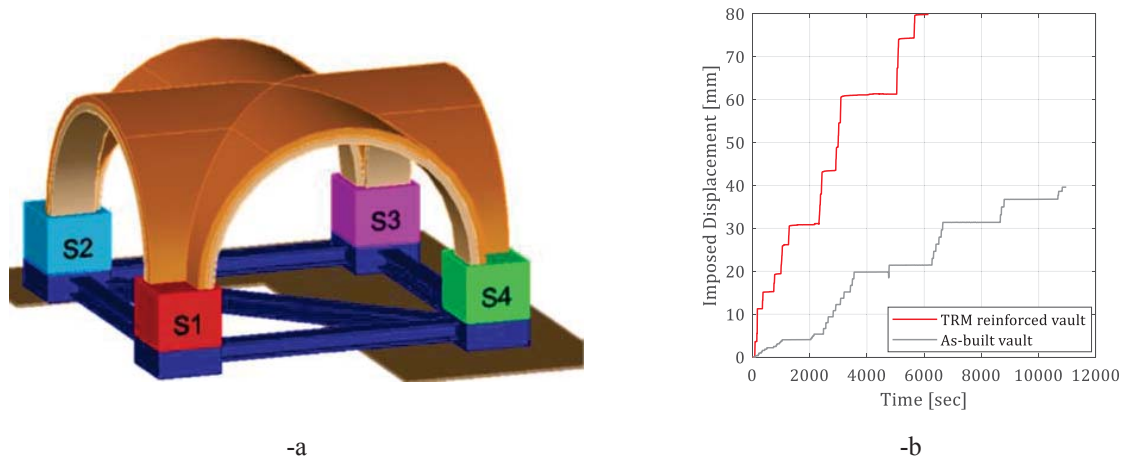

Figure 1: Geometry of the tested vault (-a) and downward settlement applied to one support (-b).

The vault was rested on four supports: the vertical settlement was applied in S1, the opposite counterpart (S3) was completely fixed while, the remaining two supports (S2 and S4) were only allowed to slide horizontally. The vertical downward displacement was applied by means of two mechanical jacks placed below S1. Similarly to S2 and S4, S1 was designed to slide horizontally. The vault behavior was monitored by means of different sensors, namely: Linear Variable Displacement Transducers and Fiber Optic sensors. In particular, Figure 2 -a and -b depicts the results obtained at the end of the experimental investigation in terms of reaction force vs. imposed settlement curves and damage patterns, respectively (test II).

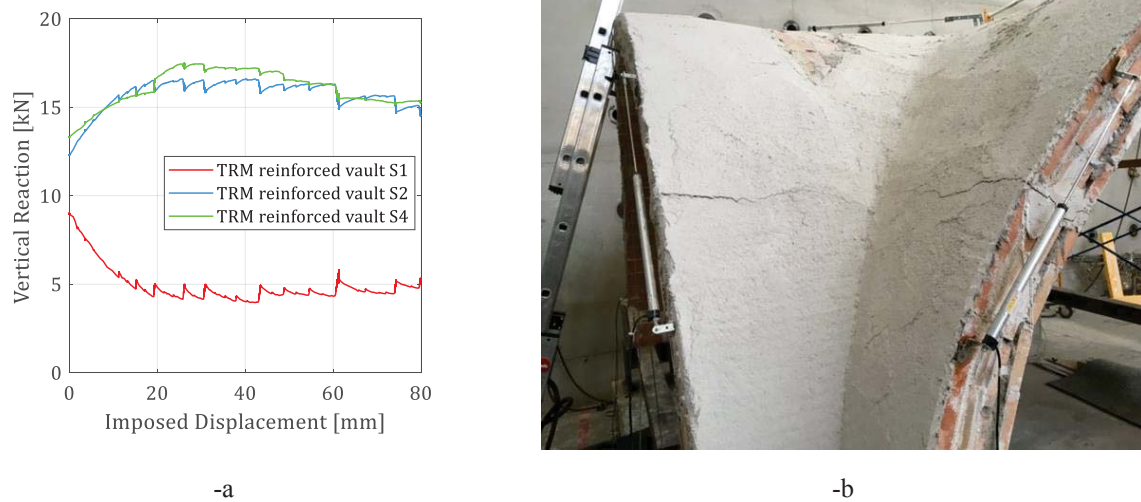

Figure 2: Experimental reaction force vs vertical settlement curves (-a) and crack patterns at the end of the investigation (-b).

As visible in Figure 2, the vault reinforced with TRM composites, experienced the formation of various cracks, namely an extrados diagonal crack connecting the two lateral supports S2-S4 and traditional hinged mechanisms in the lateral arches (S1-S2 and S1-S4). The application of TRM materials was able to restore the continuity of the masonry structure severely damaged by previous settlements. Also, the damage patterns showed that for extrados

reinforcements, the strengthening material experienced some mortar cracking without textile slippages or tensile failures.

3 NUMERICAL MODELLING

This section is provided to discuss the assumptions made during the FE analysis. The following hypotheses lie at the basis of the models developed in Abaqus:

- The masonry support was modeled as a homogeneous material. This simplification, not normally available for traditional masonry, is adopted here due to the peculiar characteristics of layered masonry structures. The layered support was in fact composed of a stacked sequence of tiles and joints arranged along two perpendicular directions.
- The longitudinal axis of symmetry was considered to reduce the computational cost of the simulations. In fact, the masonry structure should have behaved symmetrically during the entire experimental campaign. During the laboratory investigations some torsional effects were observed, due to geometric and material heterogeneity. These effects do not invalidate the initial hypothesis since they could hardly be considered in standard simulations.
- The vault behavior during the two-stage lab campaign was decoupled allowing the adoption of two models: one considering the unreinforced masonry and the other considering the TRM strengthening material applied on an undamaged support. This assumption holds considering that the masonry support was subjected to repointing and injections before applying the TRM material. Also, the reaction force-settlement curves showed that the initial stiffness of the vault was completely restored after the strengthening interventions.

3.1 Unreinforced and TRM Reinforced structure

The vault behavior was modeled using a 3D macro-modelling strategy using 4-noded shell elements representing the masonry support and strengthening material. The final models are depicted in Figure 3 -a and -b, respectively considering the unreinforced and TRM reinforced vaults.

Figure 3: 3D models of the timbrel vault: unreinforced structure (-a) and TRM reinforced structure (-b).

In details, the thickness of the masonry supports was considered equal to 70.5 mm for the vault and 159.5 mm in the lateral arches while, the TRM thickness was set to 10 mm. In order to realistically study the effect of vertical settlements, the masonry support and TRM materials were simulated using a Concrete Damage Plasticity (CDP) model available in Abaqus. The elastic modulus of the masonry support was set to 1700 MPa, with tensile and compressive strengths equal to 0.23 MPa and 10 MPa, respectively. The TRM mechanical properties were deduced according to the data provided by the manufacturer when available. In details, the authors assumed an elastic modulus equal to 3179 MPa and compressive strength equal to 17 MPa.

4 NUMERICAL RESULTS

4.1 Unreinforced Structure

This section discusses the results obtained using the Abaqus FE model and considering only the unreinforced vault. For the sake of brevity, the damage maps are briefly discussed in this section (see Figure 4). Figure 4-a and -b depicts the tensile damage maps (red stands for 90% damage whereas blue stands for 0% of damage) obtained at the end of the simulation and at the end of the first lab test, respectively.

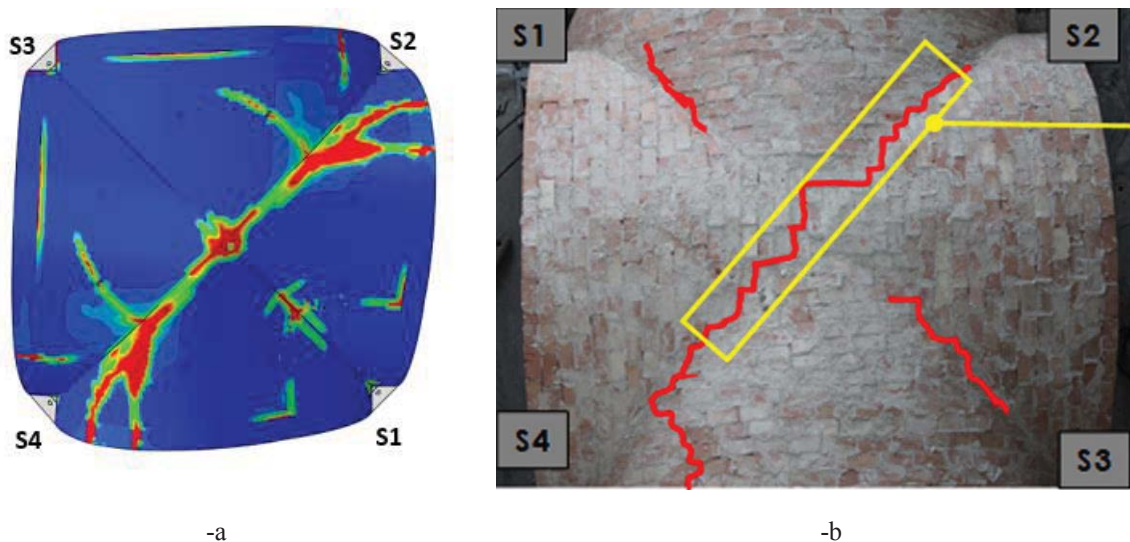

Figure 4: Tensile damage maps at the vault extrados: FE modelling (-a) and lab test (-b).

As visible comparing Figure 4-a and -b, the model was able to describe accurately the development of the failure mechanism found experimentally. The most important damage was observed along the diagonal connecting supports S2-S4 and along the lateral arches S1-S2 and S1-S4.

4.2 TRM Reinforced Structure

The TRM reinforced vault was modelled using the same approach discussed in the previous sections. In this section the most important numerical results are presented and discussed with respect to the experimental outcomes. Figure 5 -a depicts the numerical tensile damage maps plotted at the vault extrados at the end of the simulation while, Figure 5-b proposes a

comparison between the reaction forces-settlement curves obtained experimentally and numerically.

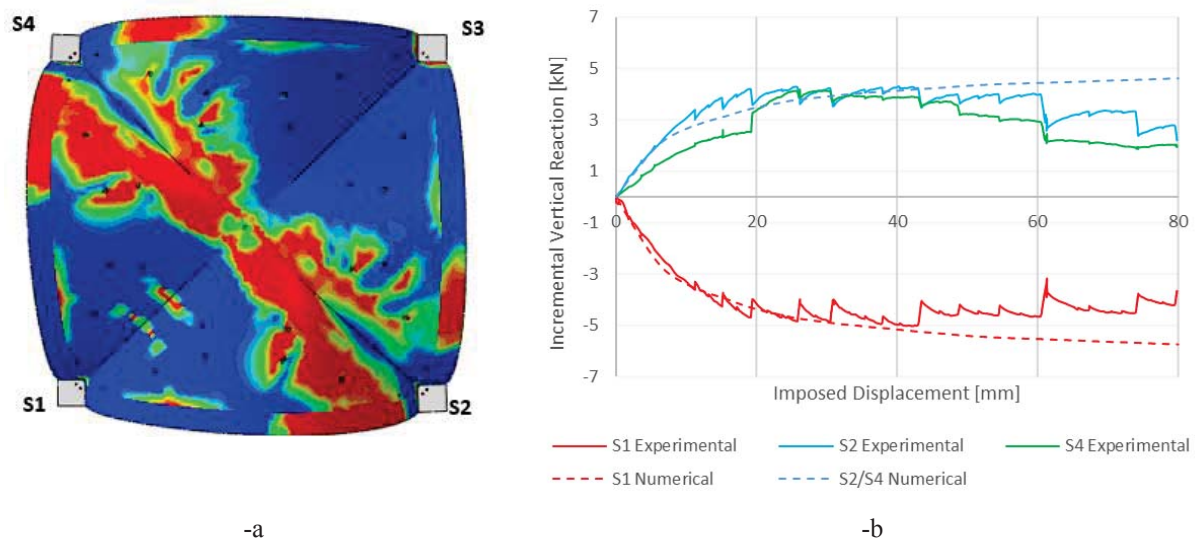

Figure 5: Experimental reaction force vs vertical settlement curves (-a) and crack patterns at the end of the investigation (-b).

As visible in Figure 5-b the model is able to capture the global structural response of the vault in terms of initial stiffness, peak reaction load and post peak behavior. Similarly, the adopted FE approach successfully described the failure mechanism which was characterized by spreading tensile damages on the masonry substrate in correspondence of the S2-S4 diagonal and mostly in the lateral arches S1-S4 and S1-S2.

5 CONCLUSIONS

The article discusses a series of numerical simulations developed using the commercial software Abaqus to study the structural response of masonry vaults damaged by vertical settlements. Based on the results obtained, the following conclusions could be drawn:

- A macro-modelling approach was successfully adopted to study the behavior of unreinforced and TRM reinforced masonry vaults.
- The model, although simplified, was able to capture the global structural response of the structure and the development of the failure mechanism.
- The TRM strengthening was successfully applied to restore the continuity of the vault also, extending the displacement capacity of the structure. Conversely, increasing the displacement capacity increases spreading the damages on the masonry support before failure of the strengthening material. This is particularly evident comparing Figure 4-a with Figure 5-a.
- This latter finding is particularly interesting as it suggests using the TRM materials cautiously especially for historic structures where the focus is on preserving the structural integrity. The results suggest to couple FE models to monitoring strategies in order to verify the behavior of the structure and implement soil improvement interventions before reaching a critical state of the masonry.

Abstract

In this contribution, a simple and effective Rigid Beam Model, recently introduced for simulating the dynamic behavior of slender freestanding masonry columns and walls, is adopted and improved for studying masonry chimneys. These structures represent a particular masonry building typology, characterized by a conical shape with a very large slenderness, they are prone to collapse in case of seismic actions due to poor material mechanical characteristics and poor state of conservation. The original model is improved by considering the chimney subdivided into several portions along its height, and each portion is modelled as a rigid beam element with an annular cross-section. Small displacements and no-sliding at the interfaces between the beam elements are the main adopted hypotheses, following the typical assumptions taken by Housner. Material nonlinearity is considered by means of a moment-rotation constitutive law at interface level, also accounting for masonry stiffness and tensile strength. Several numerical tests are performed by considering an existing case study and comparing the modal analysis results of the Rigid Beam Model with respect to those obtained with traditional FE models; then, harmonic tests with varying acceleration and frequency are performed.

Keywords: Masonry, chimneys, Rigid Beam Model, harmonic excitation.

1 INTRODUCTION

Unreinforced masonry chimneys are a particular building typology [1], characterized by a truncated-conical shape with a considerable height and a consequent large slenderness. Masonry chimneys were built in most of the industrial countries around the middle of the 19th century, for releasing combustion gases from the industrial plants. Due to the industrial technological improvements, masonry chimneys started to be dismissed in the middle of the 20th century and became part of the huge and various masonry-built environment. However, these structures turned out to be prone to earthquake effects because of their slenderness and their poor state of conservation, mostly motivated by atmospheric agents and due to the limited interest on their restoration. For these reasons, the seismic analysis of unreinforced masonry chimneys is an important challenge in the field of Earthquake Engineering, especially because of the non-standard shape and size of the structure with respect to ordinary monumental and minor masonry buildings.

In this contribution, the original rigid beam model, introduced by authors for modelling the dynamic behavior of monolithic and multi-drum freestanding columns [2] and recently extended for studying cantilever walls [3], is further improved for modelling the dynamic behavior of masonry chimneys. The updated model assumes the chimney subdivided into distinct portions, which are modelled as rigid beam elements with annular cross-section. The model keeps the hypotheses of small displacements and no sliding at interfaces, but it considers masonry mechanical properties for defining interface stiffness and strength into a moment-rotation constitutive law.

An existing case study, represented by a tall masonry chimney located in Ferrara (Italy), is taken into consideration for evaluating the effectiveness of the updated rigid beam model (Figure 1a). This chimney was hit by the Emilia earthquake in May 2012 and after the seismic sequence [4] it was shortened (Figure 1b) by removing an upper damaged portion for safety reasons, since the building is located into the Scientific Campus of University of Ferrara. Several numerical tests have been already performed by adopting accurate three-dimensional models [4,5]; in particular, modal analysis results are here taken as reference for setting the stiffness parameters of the rigid beam model of the chimney. Then, a set of dynamic analyses are performed for determining the safe-unsafe domains of both full and shortened case studies.

Figure 1: Masonry chimney in Ferrara before (a) and after (b) shortening [5].

2 RIGID BEAM MODEL FOR MASONRY CHIMNEYS

This work considers a generic masonry chimney with a simplified geometry, having overall height H , and characterized by varying outer diameter D and thickness t along the height (Figure 2a,b). The structure is subdivided into n portions having height h_i . The rigid beam model is then generated by considering n rigid beam elements and $n+1$ nodes as shown in Figure 2c. Each beam element represents a portion of the chimney and each node represents an interface between the portions. In particular, the first node/interface represents the contact between the foundation and the first portion of the chimney, whereas the last node represents the top of the chimney. Chimney diameter and thickness are defined at each interface level. Nodal horizontal translational degrees of freedom are considered, namely u_i , \dot{u}_i , and \ddot{u}_i represent, respectively, nodal horizontal translation, velocity, and acceleration (Figure 2c). Each i -th beam element is characterized by a mass m_i , which depends on material density γ and on the volume of the corresponding portion, which is considered for simplicity as the difference between the volumes of outer and inner cylinders (Figure 2d), assuming an average diameter \tilde{D}_i and an average thickness \tilde{t}_i with respect to upper and lower ones. Due to the rigid beam hypothesis, each element is subjected to a rigid rotation depending on the horizontal translations at beam ends and beam height, h_i (Figure 2e):

$$\theta_i = (u_{i+1} - u_i) / h_i \quad (1)$$

Figure 2: Masonry chimney subdivided into n portions (a), corresponding vertical section (b), corresponding rigid beam model (c), generic chimney portion with average diameter and thickness (d), corresponding rigid beam element (e).

Internal forces of the beam element are given by a normal force N_i , a shear force T_i , and a bending moment M_i , acting at each beam end (Figure 3d).

The translational and rotational equations of motion can be defined with the approach already adopted for multi-drum freestanding columns [2]. If a horizontal ground acceleration $a_g(t)$ acts at the base of the chimney and the top of the chimney is assumed free to move, equations of motion can be written for the entire structure by obtaining the following system of differential equations to be solved:

$$\mathbf{M}(\theta) = \mathbf{G}\mathbf{M}_a\ddot{\mathbf{u}} - \mathbf{G}\mathbf{A}_g + \mathbf{I}_G\ddot{\mathbf{u}} - \mathbf{B}_g \quad (2)$$

Where each bending moment M_i in \mathbf{M} depends on the rotation θ_i of the corresponding i -th drum (Eq. 1). Matrices \mathbf{M}_a , \mathbf{G} , and \mathbf{I}_G can be called, respectively, mass coefficient matrix, geometric coefficient matrix, and polar inertia coefficient matrix. Details of such matrices and vectors \mathbf{A}_g and \mathbf{B}_g can be found in [3].

The system of differential equations in (2) is solved by means of a Runge-Kutta ODE solver. At this stage, the nonlinear behavior that can affect the chimney is the bending failure at each interface between the portions, whereas, following Housner's hypothesis, shear failure cannot occur [6]. The bending moment M_i at each interface follows a bi- or tri-linear moment-rotation relationship, which represents the maximum stabilizing moment for varying block rotation (Figure 3), and it is slightly modified with respect to Housner's law by means of an initial elastic stiffness $K_{M,i}$ and a smoothing parameter $\xi \leq 1$.

Figure 3: Moment-rotation relationship.

The maximum stabilizing moment in Figure 3 on one hand accounts for the maximum eccentricity of the normal force acting at the i -th interface; on the other hand, it also accounts for the tensile strength F_t of the i -th interface, depending on masonry tensile strength f_t and chimney cross-section A_i :

$$M_{u,i} = \frac{d_i}{2} (N_i + F_{t,i}) = \frac{d_i}{2} \left(\sum_{j=i}^n P_j + A_i f_t \right) \quad (3)$$

At the moment, an infinite compressive strength for masonry is assumed, as it was done in the original rigid beam model [2]. Eq. 3 is also adopted into an existing rigid block model for evaluating the bending strength of masonry panel interfaces [7]. However, it can be demonstrated that in case of dead loads close to the 10% of masonry compressive strength, the stabilizing moment evaluated with Eq. 3 is overestimated of about 11% with respect to that accounting for masonry compressive strength.

In the original rigid block model defined for masonry columns or walls, the interface bending stiffness $K_{m,i}$ depends on the elastic modulus of the material E_m , on the interface thickness e_i and on the moment of inertia of interface cross-section J_i : $K_{m,i} = E_m e_i J_i$. In case of a masonry chimney, an interface does not actually represent a joint between masonry blocks or drums, hence an interface normal stiffness is introduced: $K_{m,i} = k_m J_i$.

3 NUMERICAL TESTS

As stated into introduction, the slender masonry chimney located in the old industrial facility that houses the Scientific-Technological Campus of the University of Ferrara, Italy (Figure 1), is taken into consideration for the numerical tests. The full chimney, 50 m high, suffered severe damages during the 2012 Emilia seismic sequence. Afterward, for security reasons, the upper damaged portion, 12.40 m high, was disassembled, leading to a shortened chimney 37.60 m high. Geometric characteristics of the structure are taken from [5] and resumed in

Figure 4a. It is worth noting that the data at only 4 and 3 levels for the full and shortened chimney, respectively, are adopted for the rigid beam model. Mechanical characteristics of masonry for the rigid beam model are material density $\gamma = 1800 \text{ kg/m}^3$, tensile strength $f_t = 0.1 \text{ MPa}$.

Figure 4: Masonry chimney in Ferrara before and after shortening [5], geometric characteristics (a) and corresponding rigid beam models (b).

Since the chimney is characterized by a thick base from 0 to 8 m, having a larger diameter with respect to the entire chimney, such a base portion is modelled by one rigid beam element. Then, the full chimney from 8 to 50 m is subdivided into 7 equal portions, whereas the shortened chimney from 8 to 37.60 m is subdivided into 5 equal portions, hence by removing the two upper beam elements from the full chimney (Figure 4b). The rotation at the base node of both models is fixed, whereas the stiffness of the interfaces is calibrated by means of a modal analysis of full and shortened chimneys, assuming as reference existing numerical results obtained with an accurate three-dimensional FE model [5].

3.1 Modal analysis

chimney	model	frequency	
		1st	2nd
full	rigid beam model	0.43 Hz	2.03 Hz
	FEM [5]	0.46 Hz	2.16 Hz
shortened	rigid beam model	0.93 Hz	-
	FEM [5]	0.85 Hz	-

Table 1: Comparison between frequencies of the full and shortened chimneys obtained with the proposed rigid beam model and with an accurate 3D FE model [5].

Considering the full chimney, assuming $k_m = 800 \text{ MPa/mm}$ for all the interfaces of the model, the first and second frequencies obtained with the rigid beam model turn out to be in excellent agreement with existing numerical results obtained with accurate 3D models [5]. Furthermore, the same stiffness parameter applied to the rigid beam model of the shortened chimney allows

to obtain at least the first frequency in good agreement with existing numerical results (Table 1).

3.2 Dynamic analysis, harmonic excitations

In order to evaluate the dynamic behavior of the full and shortened masonry chimney, with particular attention to their level of safety and to the potential collapse mechanisms that can be activated by dynamic excitations, a set of harmonic tests is performed by varying input frequency and acceleration amplitude at the base of the rigid beam models introduced and calibrated in the previous sub-section.

Starting with the full chimney, Figure 5 shows the deformed configurations obtained at the end of the harmonic tests by assuming several values of base acceleration and input frequency. The corresponding horizontal displacements versus time, evaluated at the top of the full chimney and at the 2nd node (after the thick base) of the rigid beam model are collected in Figure 6. Collapse mechanisms close to the top of the chimney, involving the last or the last two beam elements, are obtained several times: with 0.25g and 0.5 Hz, 0.5g and 1.0 Hz, 0.5g and 2 Hz. In some cases (0.25g with 0.5 Hz and 1.0 Hz) the deformed configurations are also characterized by a significant rigid rotation of a huge portion of the chimney over the thick base.

Figure 5: Deformed configurations of the full masonry chimney close to the end of several harmonic excitations.

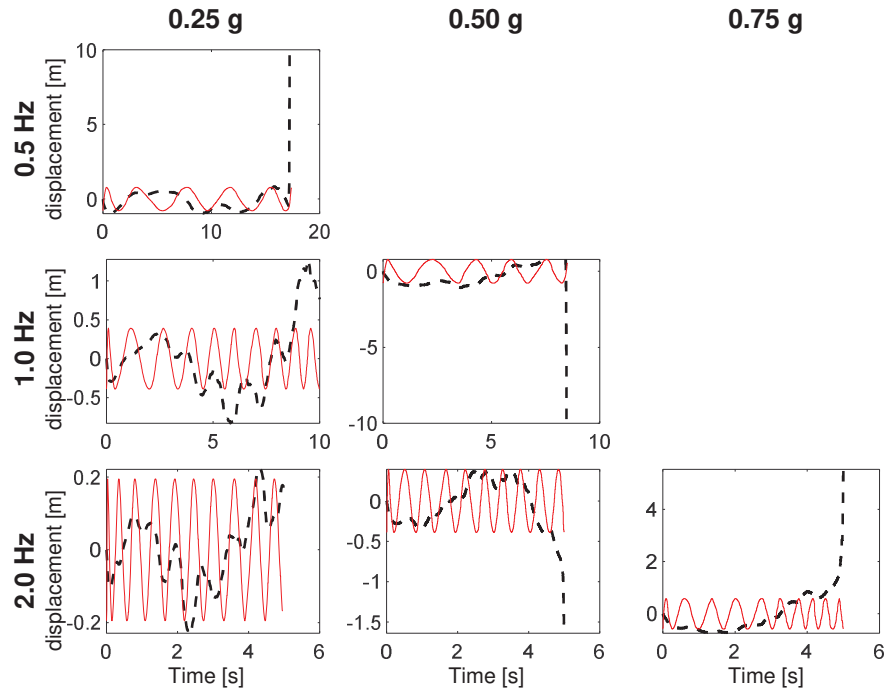

Figure 6: Base (red continuous line) and top (black dashed line) displacements for a of the full masonry chimney subjected to several harmonic excitations.

Figure 7: Deformed configurations of the shortened masonry chimney close to the end of several harmonic excitations.

Focusing on the shortened chimney, Figure 7 shows the deformed configurations obtained at the end of the harmonic tests by assuming several values of base acceleration and input frequency. The corresponding horizontal displacements versus time, evaluated at the top of the

full chimney and at the 2nd node (after the thick base) of the rigid beam model are collected in Figure 8.

Collapse mechanisms close to the top of the chimney, involving the last beam element, are obtained several times, with larger acceleration amplitudes and frequencies with respect to the full chimney: 0.5g and 1.0 Hz, 1g and 2 Hz. Similarly to the full chimney, in some cases (0.5g with 1.0 Hz) the deformed configurations are also characterized by a significant rigid rotation of a huge portion of the chimney over the thick base. However, with 0.25g and 0.5 Hz, the rigid rotation of the chimney with respect to the thick base involves the entire shortened chimney.

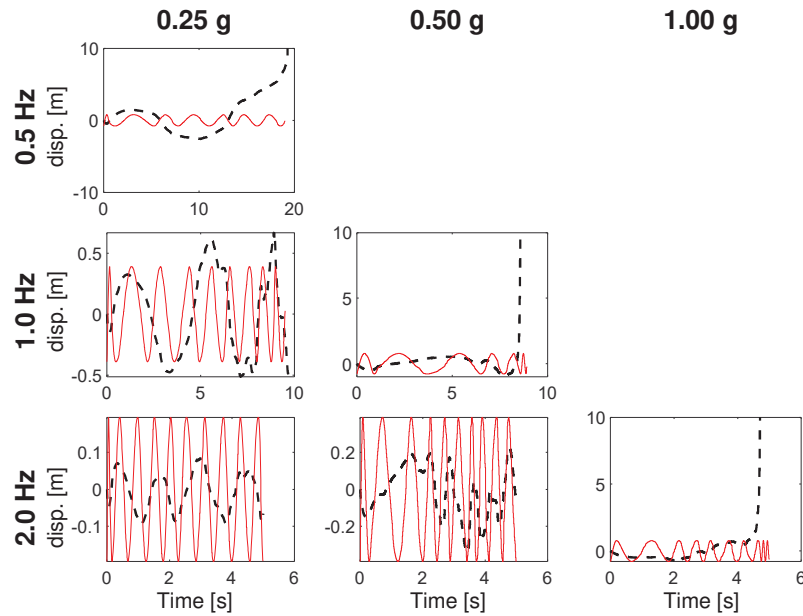

Figure 8: Base (red continuous line) and top (black dashed line) displacements for a of the shortened masonry chimney subjected to several harmonic excitations.

Figure 9: Safe-unsafe domain for the full (a) and shortened (b) chimneys subjected to harmonic excitations.

Figure 9a and b shows the final results of the campaign of numerical simulations on the full and shortened masonry chimneys, by highlighting safe and unsafe conditions at the end of the harmonic tests; a comparison between the two domains is presented in Figure 10. As ex-

pected, the shortened chimney is characterized by a larger safe domain with respect to the full one.

Figure 10: Comparison between the safe-unsafe domains of the full and shortened chimneys subjected to harmonic excitations.

4 CONCLUSIONS

This paper presents a simple and effective rigid beam model for studying the dynamic behavior of tall and slender chimneys. The model applied to a real case study i.e. the chimney located in the Scientific Campus of the University of Ferrara which was hit by the Emilia earthquake in May 2012. During the earthquake, the upper part of the chimney was severely damaged. For safety reasons, the chimney shortened (from 50 m which was originally to 37.5 m) by removing its upper damaged portion. In the proposed rigid model, both the original and shortened chimneys investigated. The chimney subdivided into several portions along its height, and each portion was modelled as a rigid beam element with an annular cross-section. In each model, material non-linearity allowed by means of a moment-rotation constitutive law at interfaces, which accounts for masonry stiffness and tensile strength. Initially, modal analysis results were used to obtain the stiffness parameters of the rigid beam model of the chimney. Later, a set of dynamic analysis were performed and the safe-unsafe domains of both full and shorten chimneys obtained. From the results analysis, it is shown:

- A comparison between frequencies of the full and shortened chimneys obtained from the proposed rigid beam model found to be in excellent agreement with existing numerical results obtained from 3D models.
- With respect to the dynamic behaviour of the full height chimney, harmonic excitations with low amplitude (i.e., 0.25g) resulted in rotations and collapse of the upper part of the chimney. On the other hand, harmonic excitations greater or equal to 0.75g caused collapse mechanism of the entire chimney.
- With respect to the dynamic behaviour of the shortened chimney, harmonic excitations with low amplitude (i.e., 0.25g) resulted in rotations and collapse of the upper part of the chimney. The harmonic excitation characterized by 0.75g causes a collapse mechanism involving the entire chimney.
- A comparison between the safe-unsafe domains of the full and shortened undertaken. As expected, the shortened chimney is characterized by a larger safe domain with respect to the full one.

Abstract

Masonry building compounds are sets of structural units having at least one common wall. The numerical analysis of the structural units grouped in aggregate, which are very diffused in Italian historical centres, is needed for identifying the structural interactions among them. Starting from these premises, in the current paper a masonry building aggregate built in the early twentieth century in the municipality of Cercola (district of Naples, Italy) and made of four structural units has been investigated as a case study. The structural behaviour under seismic forces has been investigated through non-linear static analyses. In particular, both the whole aggregate and the individual structural units have been modelled. Moreover, the single structural units have been considered both in the grouped and isolated conditions in order to assess either the beneficial or detrimental effect of the aggregated condition. The numerical models have been carried out with three different FEM software, namely 3MURI, CDS Win and Edilus, which schematise masonry buildings in different way. The analysis purpose has been to highlight the different results obtained with the three programs and to assess the most reliable seismic behaviour of investigated structural units. Finally, the susceptibility at damage of the case study aggregate has been evaluated through empirical fragility curves and mechanical vulnerability curves, which have been compared to each other and can be considered as preliminary tools to setup effective rehabilitation interventions.

Keywords: Seismic vulnerability, Building compounds, FEM analysis programs, Macro-element approach, Equivalent frame model.

1 INTRODUCTION

The structural heritage facing the most part of Italian historical centres is made of masonry buildings without adequate structural performance level against seismic actions. Therefore, these types of buildings have high seismic vulnerability [1,2]. For this reason, the seismic safety assessment of existing masonry buildings is needed by many researchers working in the field of Seismic Engineering [3,4].

Seismic vulnerability is the tendency of buildings to suffer a certain degree of damage during a seismic event. The vulnerability assessment methods proposed in current standards are often based on the knowledge of construction features, i.e. connections between orthogonal walls, floor types and presence of tie beams, which are difficult to detect in old urban centres. The existing masonry buildings in historic centres are often grouped in aggregates. So, clustered buildings are sets of independent structural units (SUs) which interact to each other under seismic actions. Since SUs are often characterized by masonry walls with poor mechanical properties, as well as by poor connections between orthogonal walls and between walls and floors, their seismic behaviour is no easy to be determined [5, 6].

However, the performance of clustered buildings is influenced by several factors, that mainly depend on the interactions between the individual SUs. Moreover, the presence of effective interconnections between SUs prevents the occurrence of local collapse mechanisms. Instead, the presence of geometrical irregularities in height and/or the lack of an effective connection between orthogonal walls can cause the activation of out-of-plane collapse mechanisms [1,7,8].

The bearing capacity of individual SUs may differ significantly from the whole aggregate one. A SU inside of a building aggregate has a highly non-linear and complex behaviour, which can lead to evaluation errors in the evaluation of its seismic behaviour. Therefore, it is essential to consider simplified, but reliable, structural models, which should foresee as well as possible the vulnerability level of the aggregated constructions [9-13].

The main vulnerability factors are the elevation discontinuities between adjacent units, the presence of staggered floors and the structural heterogeneity usually leading to disconnections of walls. All of these factors must be taken into account when studying the global seismic capacity of buildings, because they significantly affect the dynamic response of the structures. In this framework, in various studies many mechanical models accounting for uncertainties associated to the vulnerability factors have been developed to quantify the seismic response of the whole aggregate [14-16].

Based on these considerations, the present study focuses on the seismic response of a masonry aggregate located in Cercola, a municipality near the city of Naples, in the South of Italy. The selected aggregate consists of four SUs (two head units and two intermediate ones) arranged in line, which interact to each other under earthquake. These clustered buildings date back to the 19th century and they are representative of the most common building classes present in the Campania Region. In this study the influence of structural units on the global response of the whole aggregate is investigated. For this reason, non-linear static analyses are carried out to simulate the response of structural units in both isolated and aggregate conditions and their seismic responses are compared with those of the whole aggregate. Finally, by selecting the most unfavourable analysis conditions, the fragility curves proposed in [17] are developed and illustrated for all examined cases in order to estimate their propensity at seismic damage.

2 THE CASE STUDY

The case study is a masonry building aggregate located in the municipality of Cercola (Figure 1), an urban district located near Naples. This agglomerate of constructions was built at the end of the 19th century as one of the most representative example of the classic typology of clustered buildings of the Campania Region historical centres. From a structural point of view, it consists of 4 structural units, two in the head position and two in intermediate one. The head SUs have 3 floors, while the intermediate SUs develop on 4 floors. Buildings have commercial use at ground floor and residential use at other floors. Figure 2a shows the external view of the aggregate main façade, while the geometrical plan layouts of the clustered buildings are shown in Figures 2b, 2c and 2d. The head SUs have the first floor characterized by masonry vaults, while the remaining floors are made of wooden beams. The intermediate SUs have steel floors or RC ones at the first level. As the head SUs, the remaining floors are made of wooden beams. The masonry walls are characterised by Neapolitan yellow tuff stones and have an average thickness of 0.80 m at the first floor and 0.50 m at the other floors. Due to the absence of accurate on-site test procedures, wall mechanical properties are assumed according to the indications provided by the Italian Standard [18] by applying a confidence factor (FC) equal to 1.35, which corresponds to a knowledge level LC1 (limited knowledge) [18,19]. So, the wall mechanical features are as follows: average compressive strength (f_m)= 2.00 MPa; average shear strength (f_{v0})= 0.10 MPa; Young modulus (E)= 1410 MPa; Shear modulus (G) 450 MPa and dead weight (w)=16 kN/m³.

In order to estimate the aggregate seismic influence on single SUs, two different cases are studied: (i) the whole aggregate (Figure 2b) and the head structural unit (acronym HSU), both in aggregated (Figure 2e) and isolated (Figure 2f) configurations.

Figure 1: Identification of the case study.

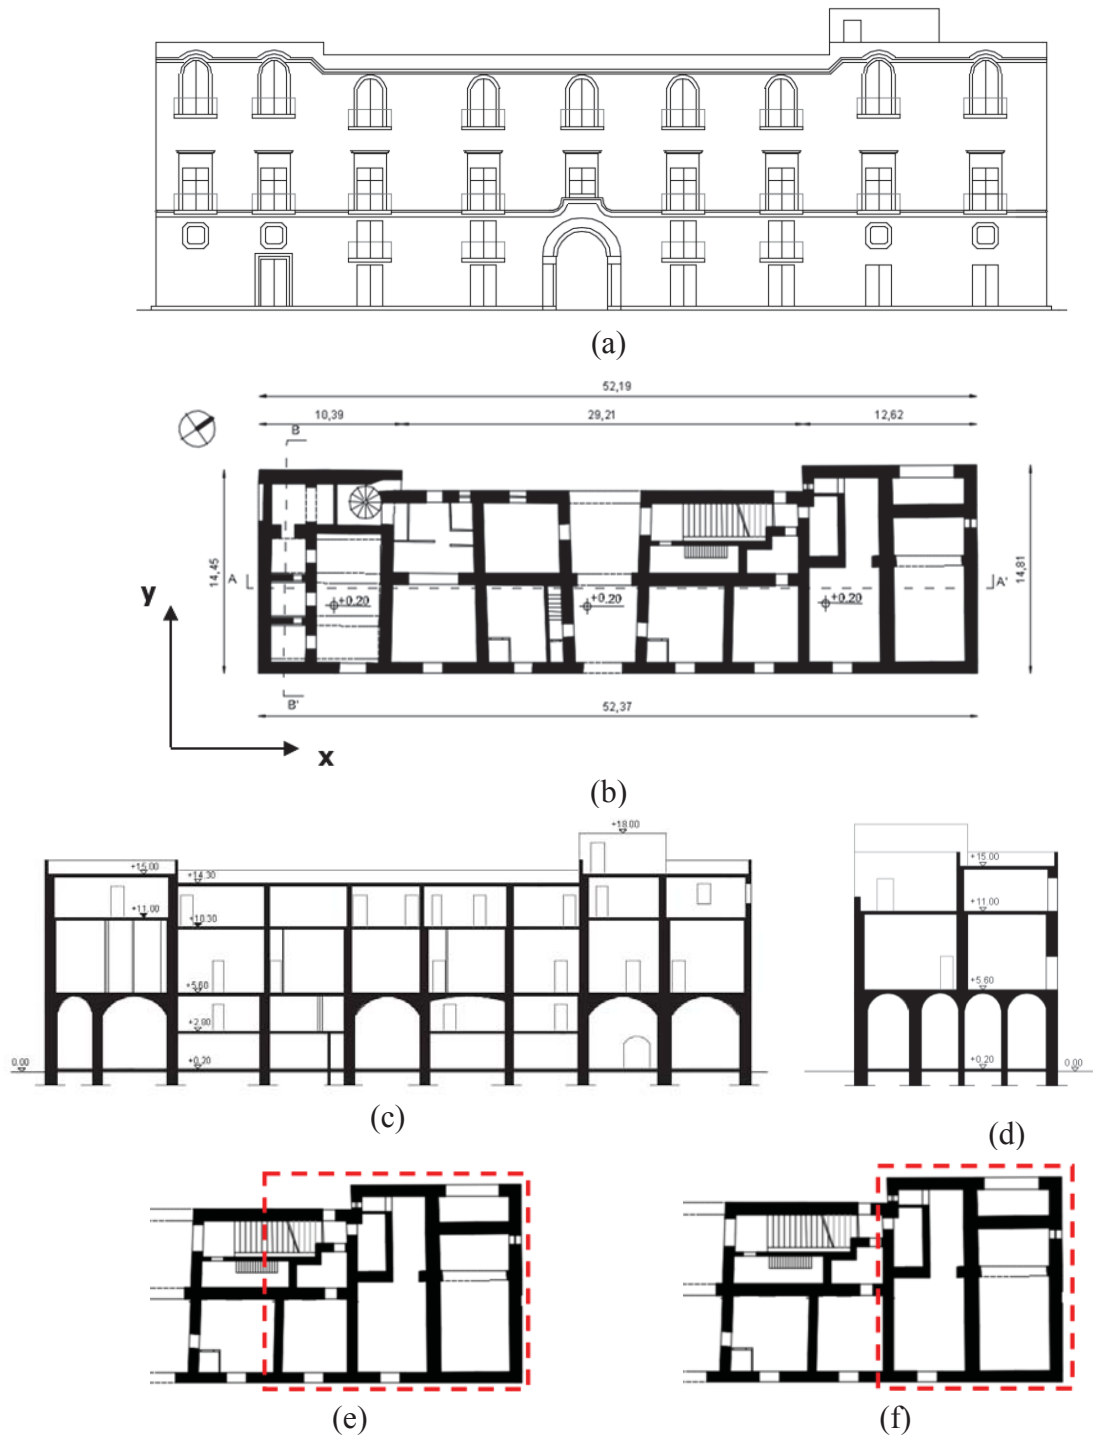

Figure 2: Graphic representation of the case study: main view (a), plan layout (b) and sections (c, d) of the building aggregate; aggregated (e) and isolated (f) HUS plan layouts.

3 NUMERICAL MODELS

The numerical models are carried out using three different FE analysis programs based on 2 different modelling approaches: from one side, the equivalent frame adopted by 3MURI and CDS win and, on the other side, the shell model adopted by Edilus. Figures 3,4 and 5 shows

numerical models developed by the three employed software packages. The basic modelling concepts of the implemented FEM models are shown in the following sections.

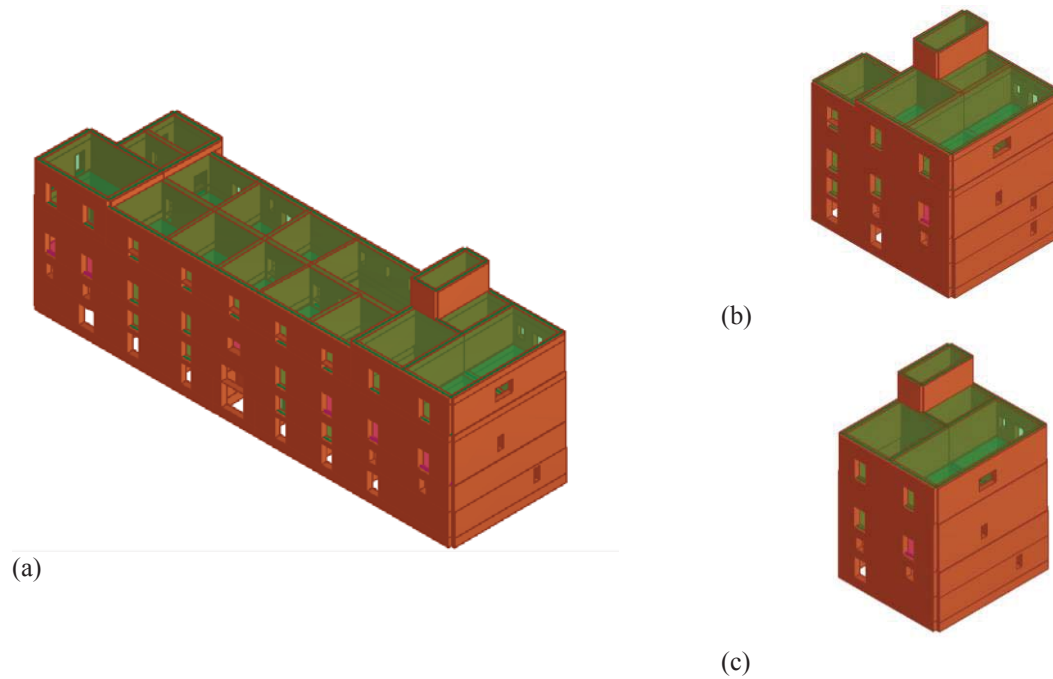

Figure 3: The 3MURI software numerical models: whole aggregate (a) and HSU in aggregated (b) and isolated (c) conditions.

Figure 4: The CDS Win software numerical models: whole aggregate (a) and HSU in aggregated (b) and isolated (c) conditions.

Figure 5: The Edilus software numerical models: whole aggregate (a) and HSU in aggregated (b) and isolated (c) conditions.

3.1 Equivalent frame model

3MURI and CDS analysis programs adopt a mathematical model based on Frame by Macro-Elements (FME) theory, which implements the Equivalent Frame Model approach (Figure 6). The reference model is a three-dimensional equivalent frame, where the walls represent the vertical elements able to resist both vertical and horizontal loads. The horizontal elements, namely the floors, transfer the horizontal forces to the walls according to the stiffness they have in their own plane. Therefore, the numerical modelling of a building is carried out by inserting walls, which are discretized into macro-elements representative of deformable components (piers and spandrels), while nodes (rigid links) are masonry portions typically less subjected at seismic damage. Usually, rigid links connect piers and spandrels which are contiguous to the openings. The numerical analyses allow to foresee the expected damage mechanism into masonry buildings, which can occur in deformable elements by either shear or compression-bending. So, each pier is composed by three parts: one deformable in the element central part, having a certain strength value, and other two placed at the element ends, having infinite strength and stiffness. Instead, spandrels are represented with frame elements having horizontal axis. It is assumed that the deformable part corresponds to the opening length, while the element remaining part is modelled with infinitely rigid beams. Floors are modelled as finite elements with 3-node orthotropic membrane, having 2 degrees of freedom per node and connected to the three-dimensional nodes of the building model.

Figure 6: Schematic representation of the Equivalent Frame Model.

3.2 Shell model

Edilus software adopts the *Shell60* model, which consists of high-performance shell elements composed of a membrane part and a flexural one, whose effects can be coupled in order to have plates having large thickness and different layers, which can be anyway oriented. The membrane element has stiffness to normal rotation, which allows for a more faithful schematization of shell structures not completely connected to a plane and linked with beam elements. The implemented elements have triangular or quadrangular shape with three and four nodes, respectively. The quadrangular elements are obtained by automatically assembling several triangular elements. The triangular elements are High Performance Elements (HPE). However, the use of only triangular elements has undoubted advantages. In fact, the triangular elements allow for a faster analysis execution. The subdivision of any surface is also easier and more accurate.

The *Shell60* element (Figure 7) has a formulation that makes it rather insensitive to distortion. This feature is particularly useful in a pre-processing phase, which generate the mesh automatically. The formulation of the HPE *Shell60* element is based on the composition of an *AnDeS* triangular membrane element with drilling degree of freedom with the *DKT* (Discrete Kirchhoff Triangle) element. The degree of freedom towards rotation (drilling DoF) is added by describing the deformation of each side.

Figure 7: Linear shell model definition.

4 PUSHOVER ANALYSES

The seismic behaviour of the buildings facing the case study is investigated through pushover analyses. Based on the provisions of the Italian standard [19], these analyses are performed along the two main directions “X” and “Y” of the building aggregate (see Figure 2b). For each direction, the positive and negative accidental eccentricities are considered. Furthermore, 4 different verses of the seismic forces ($\pm X$, $\pm Y$) and 2 dissimilar force distributions (proportional either to masses or to the first vibration mode of the building) are considered.

So, 24 pushover analyses are performed. Figures 8, 9 and 10 show the pushover analysis curves in the 'X' and 'Y' directions performed with 3MURI, CDS Win and Edilus programs, respectively. In particular, for the sake of representation, among the 24 combinations, the worst one, that is the analysis minimizing the capacity acceleration of the aggregate, is considered.

The analysis results show that the most deformable direction is the "Y" one for the whole aggregate and the "X" one for HSU, both in aggregated and isolated conditions. In general, strength and stiffness increase switching from the HSU isolated, passing through the HSU (aggregated), to the whole aggregate. With respect to ductility, an opposite behaviour occurs.

Figure 8: Pushover curves along X and Y directions carried out by the 3MURI software.

Figure 9: Pushover curves along X and Y directions carried out by the CDS Win software.

Figure 10: Pushover curves along X and Y directions carried out by the Edilus software.

The three models use different calculation solvers and the solutions obtained are not always like each other. Therefore, a comparison in terms of pushover curves is made. In this

case, only one curve for each software is taken into account. In particular, among the worst analyses performed with each analysis program, only the pushover curve proving the lowest resistance value of the aggregate is chosen. This curve is then compared with the corresponding curves of the other 2 programs, as shown in Figure 11.

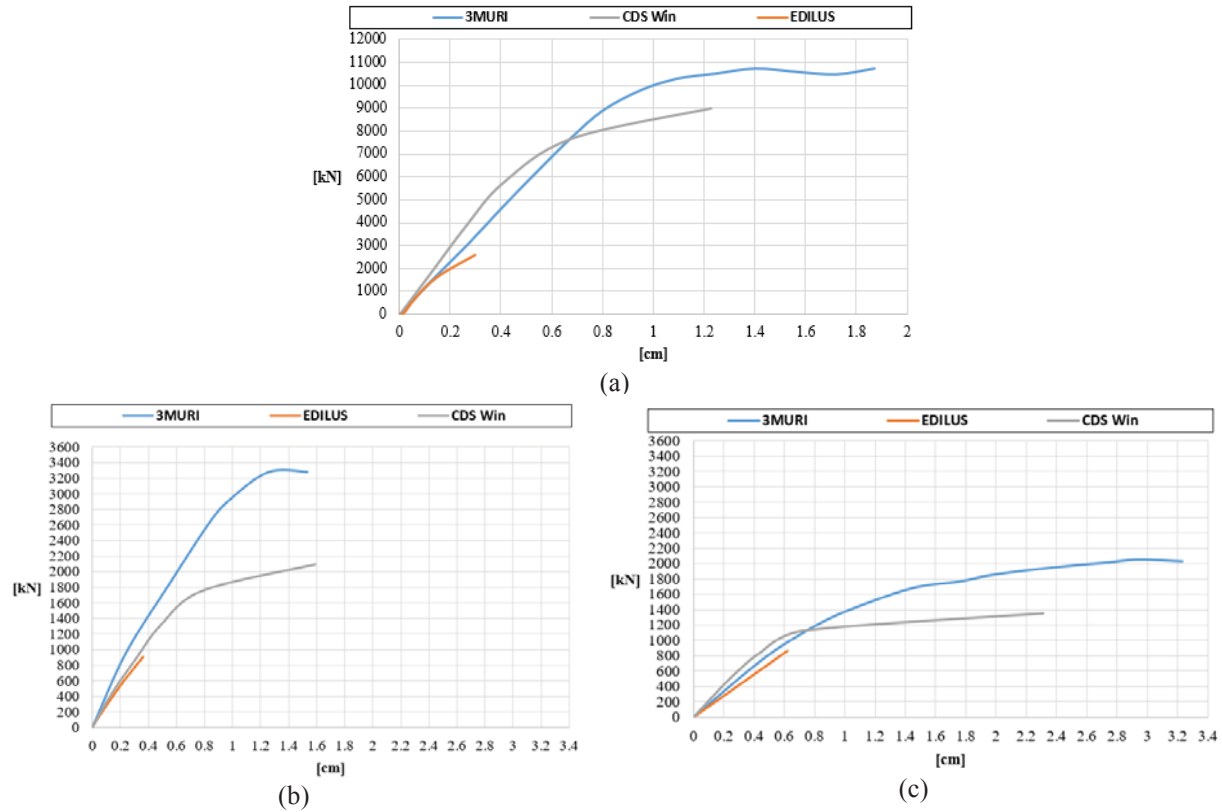

Figure 11: Comparison between analysis programs in terms of pushover curves: results for aggregate (a) and head structural unit in aggregated (b) and isolated (c) conditions.

From the analysis results presented in Figures from 8 to 11 it can be observed that the curves provided by the Edilus software have a different trend compared to the other ones. In fact, these pushover curves have an almost linear behaviour. This is because the software does not adopt a multi-collapse analysis procedure, but, when the first collapse mechanism occurs in the structure, the software stops the pushover curve. Conversely, 3MURI and CDS Win programs work with a multi-collapse analysis, where the analysis is not blocked when some elements attain the ultimate displacement, but the structure is pushed until collapse. This type of analysis is allowed by the Italian Standard [19] for existing masonry structures.

5 FRAGILITY ANALYSIS

In the last part of the study, the fragility curves of investigated buildings are derived. These curves represent the probability of exceeding a certain damage state varying the intensity measurement, generally represented by either the PGA or the spectral displacement. The evaluation of the fragility curves is carried out according to the methodology proposed in [17]. In particular, four damage levels, namely D1 (slight), D2 (moderate), D3 (near collapse), and D4 (collapse), are considered (Table 1). These damage states are defined starting from the yielding displacement (d_y) and ultimate displacement (d_u) of the SDoF system associated to the MDoF structural system. The fragility curves are analytically defined as follows:

$$P[DS|PGA]=\Phi\cdot\left[\frac{1}{\beta}\cdot\ln\left(\frac{PGA}{PGA_{DS}}\right)\right] \quad (1)$$

where Φ is the cumulative distribution function, PGA_{DS} is the median acceleration value associated to each damage threshold and β is the standard deviation of the log-normal distribution.

Damage thresholds, DS_i		
D1	$0.7 \cdot d_y$	Slight
D2	$1.5 \cdot d_y$	Moderate
D3	$0.5 \cdot (d_y + d_u)$	Near-collapse
D4-D5	d_u	Collapse

Table 1: Evaluated damage thresholds D_i [19]

Based on these above considerations, the fragility functions are plotted considering the most unfavourable structural analysis conditions both for the whole aggregate (Figure 12) and the head structural unit in aggregated (Figure 13) and isolated (Figure 14) conditions.

Figure 12: Comparison among fragility curves of the whole aggregate in “Y” direction based on the pushover curves deriving from the three used programs.

Figure 13: Comparison among fragility curves of the aggregated HSU in “X” direction based on the pushover curves deriving from the three used programs.

Figure 14: Comparison among fragility curves of the isolated HSU in “X” direction based on the pushover curves deriving from the three used programs.

From the acquired results it is observed that for all cases the probability of exceeding a certain threshold of damage D_i ($i = 1, \dots, 4$) is greater for the HSU in isolated condition. Fur-

thermore, the probability increases passing from the whole aggregate to the HSU in aggregated condition.

Finally, it is possible to make some considerations on the results achieved from different programs used. In particular, it is found that the Edilus software shows the most conservative results, while the CDS Win exhibits safety thresholds higher than those of the 3MURI Software. Considering that the PGA of Cercola at Collapse Limit State (CLS) is 0.263g [18], in Tables 2,3 and 4 the expected damages evaluated with the different programs for the whole aggregate, the aggregated HSU and the isolated HSU are respectively shown.

Whole aggregate				
Software	D₁	D₂	D₃	D₃
3MURI	99.35%	28.18%	25.07%	2.03%
CDS Win	99.95%	55.55%	55.55%	8.50%
Edilus	100%	86.85%	60%	56.88%

Table 2: Expected damages for the whole aggregate.

Aggregated HSU				
Software	D₁	D₂	D₃	D₃
3MURI	99.54%	64.76%	23.60%	3.36%
CDS Win	100%	80%	74.15%	40.16%
Edilus	100%	100%	100%	100%

Table 3: Expected damages for the aggregated HSU.

Isolated HSU				
Software	D₁	D₂	D₃	D₃
3MURI	100%	94.18%	86.75%	74.84%
CDS Win	100%	96.04%	92.55%	86.81%
Edilus	100%	100%	100%	100%

Table 4: Expected damages for the isolated HSU.

6 CONCLUSIONS

In this paper the seismic response of a masonry building aggregate located in Cercola, a municipality near the city of Naples, was investigated. The aggregate is made of four SUs, namely two in heading position and two in intermediate one. Both the whole aggregate and the single SUs, both in isolated and aggregate conditions, were analysed to estimate the influence of the mutual interaction among adjacent structural units. Non-linear static analyses were carried out according to the Italian standards using three Italian popular programs, namely 3MURI, CDS Win and EDILUS, which work with different modelling approaches to schematise the seismic behaviour of existing masonry buildings. From the non-linear analysis results it was observed that in most cases the maximum strength and stiffness are offered by the whole aggregate and they reduced with the aggregated SU and much more with the isolated SU. On the contrary, the structural ductility offered by the US in isolated condition is more pronounced than the one of the aggregated US, which exhibited greater ductility than that of the aggregate. Finally, the fragility curves of the buildings under study were plotted to estimate expected damages as a function of different PGA levels. The results achieved showed

that the Edilus software provides the most conservative results, while CDS Win exhibits safety thresholds higher than those of the 3MURI Software.

Abstract

In this paper two simplified methods are presented in order to assess the seismic performance of a set of Italian ancient churches. The methods applied are characterized by an increasing refinement level, requiring only some qualitative information in order to evaluate representative indexes of global seismic response. The methods considered may be applied for screening and identifying the current priorities at a territorial level and for planning, where necessary, more refined analysis for evaluating seismic response and required interventions (if necessary). Finally, applications to case studies are illustrated and compared with the aim of highlighting the limitations of the methods considered.

Keywords: Ancient masonry churches, cultural heritage, monuments, seismic risk, seismic vulnerability

1 INTRODUCTION

Recent earthquakes have revealed, due to significant damage encountered, high vulnerability of cultural heritage [1]-[2]. Therefore, to date several works have been proposed in the published literature in order to evaluate the actual seismic risk of existing structures, considering different cultural heritage assets, such as palaces, old buildings, churches, monuments, etc. [3]-[7].

Among these works, also fast appraisal methods for preliminary screening the seismic vulnerability at a territorial level have been proposed, too. They have the advantage of requiring, with limited costs, few and not quantitative information for estimating a global index (also indicated as score) useful, in relative terms, for comparing seismic performance of an entire territorial asset. At the end of this preliminary screening, more refined methods have to be applied for specific and more precise evaluations, and also for designing the interventions required [8]-[15].

Recently a multilevel approach is indicated by Italian Directive [16], where three Levels of Valuation (LV) are considered for seismic assessment. These levels, indicated as *LV1*, *LV2* and *LV3* have a different refinement level requiring an increasing information amount. Specifically, the first two levels (*LV1* and *LV2*) are established on simplified analyses for seismic assessment, while FEM analyses are possible through the *LV3* level. In addition, with particular reference to ancient churches, recently in accordance with the approach indicated by the Italian Directive, also a simplified method has been proposed in [14, 15] indicated as *Level of Evaluation 0 (LV0)*. This method is very simple to apply and, coherently with the multilevel approach indicated in [16], is simpler to use representing a fast appraisal method useful at a territorial scale as decision-making tool, and applicable with only qualitative and historical information.

This paper deals with a territorial analysis of seismic performance of an ancient churches set located in the historic centre of Matera (Italy), recognized as UNESCO site since 1993. In particular, the main results obtained are illustrated and commented by applying the *LV0* method proposed in [14, 15], and the *LV1* method proposed by the Italian Directive [16]. More details on the churches considered and on the obtained results are reported elsewhere [9, 14].

2 LV0 METHOD [14, 15]

This method, proposed and validated in [14, 15], is particularly devoted to territorial seismic analyses of ancient churches. It provides, for each church examined, *seismic risk score R*, by applying the symbolic risk equation [17, 18]:

$$R = H \times V \times E \quad (1)$$

where *H*, *V*, and *E* are, respectively, the scores assigned to hazard, vulnerability and exposed elements or assets at risk. The score for each factor is calculated by means of a specific tool, as specified in the following:

Tool 1 allows of rating the exposition *E*, through information gathered from classifications of investigated cultural heritage and any conservation document;

Tool 2 provides a scoring related to the seismic hazard considering many threats with the related hazard maps;

Tool 3 is referred to the seismic vulnerability assessment. It assigns a score starting from the available information provided in the other seismic vulnerability forms and any other historic documents archives.

This method may be also implemented for assessing the seismic vulnerability provided that, unless the exposition factor E , the higher the seismic risk the higher the seismic vulnerability. Therefore, under this assumption the *seismic risk score* R , may be calculated as:

$$R = [H + 1] \times V \quad (2)$$

where the score R , in accordance with the simplified method, may be calculated through the scores H and V , obtained with the *Tool 2* and *Tool 3*, respectively. Moreover, as proposed in this method the score is added to unity for obtaining the resulting score R greater than one. In the following *Tool 2* and *Tool 3* are briefly described since applied in this study. More details about the *Tool 1* may be found in [14, 15].

2.1 Tool 2

Tool 2 is addressed to provide a score regarding several threats including the seismic action. Threats are divided, according to the occurrence frequency, in “*sporadic events*” and “*continuous processes*”. The intensity assessment may be conducted by referring to existing documents where events occurred into past are reported. If no information is available, therefore a possible intensity estimation may be done considering also data available within the scientific literature. In the following sporadic and continuous processes considered are listed.

Sporadic events. This group considers:

- i. *earthquake*, expressed through the maximum Mercalli Intensity;
- ii. *landslide or rock fracture* as a consequence of an earthquake.

Continuous processes. The following processes are considered:

- iii. *rainfall erosion*, due to the precipitations amount depending on coastal distance, relative humidity, direction and speed of prevailing winds;
- iv. *physical stress*, to assess the material damage provoked by temperature oscillations as, for instance, particles water icing with a consequent disintegration or cracking of materials;
- v. *air pollution*, associated to traffic of vehicles, airplanes and boats, producing dissolution by acid rainfalls;
- vi. the *socio-organizational, threat* analysing the overload or damage on the monuments for the presence of intensive tourism and possible vandalism;
- vii. *demographic decline*, provoking monuments abandonment and maintenance lack.

The damage score $h_{k,i}$, assigned to the k -th threat, is reported in the Table 1 for three different intensities: *no hazard*, *low or gradual*, *catastrophic*.

The resulting *seismic hazard score*, that is a dimensionless parameter ranging between 0 and 1, is given by the expression:

$$H = \sum_{k=1}^7 h_{k,i} \quad (3)$$

Table 1–Seismic hazard scoring [14, 15].

Threats		Severity of damage $h_{k,i}$		
		No damage/ No hazard	Low or gradual	Catastrophic
<i>Sporadic events</i>	Seismic action	0	0.20	0.40
	Landslide or rock fracture	0	0.15	0.25
<i>Continuous processes</i>	Erosion	0	0.05	0.10
	Physical stress	0	0.05	0.10
	Air pollution	0	0.01	0.05
	Socio - organizational	0	0.01	0.05
	Demographic decline	0	0.01	0.05

2.2 Tool 3

Tool 3 provides a score related to the seismic vulnerability assessment. In order to provide a fast vulnerability estimation several factors are considered, including:

- foundation system and building position*, in order to consider potential weaknesses or deficiencies of foundations;
- plan and elevation irregularity*, that may increase, as known, the vulnerability of the building against earthquakes;
- distance between walls*, by considering wall slenderness, out of plumb, excessive length in plan between two transversal walls and other potential weaknesses;
- non-structural elements*, by considering potential failures of hanged elements or other accessories;
- roof configuration*, by evaluating the roof deformability, its connection to the walls and the effects of thrusts on the walls;
- conservation status*, by considering eventual existing damages and the global and local conservation situations;
- fire vulnerability*.

Four different vulnerability levels are considered for each parameter that are *A*, *B*, *C*, *D*, where *A* is assigned in the case of absent (or very low) vulnerability, while level *D* corresponds to the case of high vulnerability. The resulting *vulnerability score* V , may be calculated as weighted sum of the vulnerability scores assigned to each parameter considered:

$$V = \sum_{k=1}^{13} \rho_k v_{k,i} \quad (4)$$

where $v_{k,i}$ is the vulnerability score of the k -th parameter and ρ_k the associated weight (Table 2).

Table 2 – Parameters scores and weights for seismic vulnerability evaluation [14, 15].

Parameter		Vulnerability $v_{k,i}$				Weight ρ_k
		A	B	C	D	
1	Position of the building and foundations	0	1.35	6.73	12.12	0.75
2	Floor plan configuration or geometry	0	1.35	6.73	12.12	0.5
3	Elevation configuration	0	1.35	6.73	12.12	1.0
4	Distance between walls	0	1.35	6.73	12.12	0.25
5	Non-structural elements	0	1.35	6.73	12.12	0.25
6	Type and organization of the resistant system	0	1.35	6.73	12.12	1.5
7	Quality of the resistant system	0	1.35	6.73	12.12	0.25
8	Horizontal structures	0	1.35	6.73	12.12	1.0
9	Roof configuration	0	1.35	6.73	12.12	1.0
10	Conservation status	0	1.35	6.73	12.12	1.0
11	Environmental alterations	0	1.35	6.73	12.12	0.25
12	Construction system alterations	0	1.35	6.73	12.12	0.25
13	Fire Vulnerability	0	1.35	6.73	12.12	0.25

3 LV1 METHOD [16]

The Italian Directive [16] proposes a multilevel approach for evaluating the seismic performance of a cultural heritage. As introduced, this approach consists of three different Levels of Evaluation, namely *LV1*, *LV2* and *LV3* having an increasing refinement level.

In particular, this study focuses on the *LV1* related to the ancient masonry churches proposed in [16], indicated for preliminary evaluation at a territorial scale. This method is particularly simple to use since only qualitative information gathered with a visual inspection are

required. The method assigns a *vulnerability index* i_v , and then estimates the ground acceleration corresponding to the achievement of a certain limit state. This procedure does not allow of designing any structural intervention.

As for the i_v , it may be comprised between 0 and 1, and estimated through the expression:

$$i_v = \frac{1}{6} \frac{\sum_{k=1}^{28} \rho_k (v_{ki} - v_{kp})}{\sum_{k=1}^{28} \rho_k} + \frac{1}{2} \quad (5)$$

In the previous equation ρ_k is the k -th collapse mechanism weight, equal to: 0 if the mechanism is not present or not active, or else between 0.5 and 1 in the other cases. v_{ki} and v_{kp} are scores assigned to the k -th mechanism measuring, according to this method, vulnerability and to any seismic-resistant device, respectively. The weights are equal to 1 for the most important macro-elements regarding the seismic behaviour of a church (such as façade overturning, nave longitudinal transversal response, triumphal arch transversal response, etc.), while secondary mechanisms (such as prothyrum – narthex response, mechanisms of transepts and chapels) may have a weight varying between 0.5 and 1 [16].

Once the *vulnerability index* i_v is calculated, ground acceleration corresponding to achievement of *Damage Limit State (DLS)* and *Life-Safety Limit State (LSLS)* may be estimated with the equations reported in the following, established on a statistical basis:

$$a_{DLS}S = 0.025 \cdot 1.8^{2.75-3.44i_v} [g] \quad (6)$$

$$a_{LSLS}S = 0.025 \cdot 1.8^{5.1-3.44i_v} [g] \quad (7)$$

4 APPLICATION TO CASE STUDIES

4.1 Description of case studies chosen

The *LV0 method* [14, 15] and the *LV1 method* [16] are applied in order to perform a territorial scale evaluation regarding five ancient masonry churches. They fall within the historic centre of Matera (Italy), recognized UNESCO site since 1993. The case studies chosen are illustrated in Figure 1 where, for brevity, only a plan of each church considered is reported. The churches considered in this study are: *SS Maria della Bruna*, *San Giovanni Battista*, *San Pietro Caveoso*, *San Rocco*, *San Francesco d'Assisi*. They have in common the fact that they were constructed with the same masonry, composed by calcarenite units of sedimentary rock, improperly named ‘tufo’ (tuff) due to its apparent similarity to the volcanic rock properly denominated tuff, and lime mortar joints. This rock has the main property of being a very porous rock, very soft and characterized by low-compressive strength. This masonry is present with an extraordinary continuity for realizing walls and vaulted structures, and quite often is present in recurrent dimensions. Usually, mortar joints have a thickness varying from 0.5 cm up to 1.5 cm, while blocks have the following dimensions: 45-60 cm length, 25-27 cm height, 20-25 cm width. All the churches have a one-floor elevation configuration and, in some case, they have also more than one nave; the roof structures are made with vaulted structures in masonry, or with wood elements in the case *San Pietro Caveoso* and *San Francesco d'Assisi*. In none of the considered churches interventions are present for reducing seismic vulnerability. A detailed description of the churches considered may be found in [9, 14].

Figure 1 – Floor plan of the considered case studies

4.2 Application to case studies

The results of the application of the *LV0 method* are illustrated in the form of histogram in Figure 1. In particular: Figure 1a) reports the hazard assessment according to the Table 1 for obtaining the *seismic hazard score* H ; Figure 1b) illustrates the vulnerability assessment according to the Table 2 for obtaining the *vulnerability score* V ; and Figure 1c) summarizes the resulting *seismic risk score* R calculated with the Eq. (2). As one may see the lowest R score is obtained in the case of *SS Maria della Bruna* ($R=22.15$), while the highest one is obtained for *San Francesco church* (i.e. $R=30.46$). In the case of other churches (*San Giovanni Battista*, *San Pietro Caveoso*, *San Rocco*) similar R scores are found (25.00, 25.25, 25.39, respectively). The results of the seismic risk score reported in ascending order in the Figure 1c) are reported also into Figure 3, in terms of ratio R_i/R_{min} . R_i is the seismic risk score of each church, and R_{min} is the minimum score found, corresponding in this case to the *SS Maria della Bruna* score ($R=22.15$). The same figure also reports the results of the *LV1 method* as proposed by the Italian Directive [16]. As for the *LV1 method* results, the dimensionless return period $T_{i,LSLS}/T_{LSLSmin}$ and the dimensionless ground acceleration capacity $a_{i,LSLS}/a_{LSLSmin}$ for the *Life Safety Limit State (LSLS)* are reported. Details on these obtained results are reported in [9, 14]. Both these ratios express a measure of the seismic vulnerability resulting that the seismic vulnerability decreases as these ratios increase (in terms of acceleration or return period). By

comparing the results obtained with the *LV0* and *LV1 method*, it can be noted that both methods are in good agreement. Therefore, the *LV0 method* may be also used for ranking the seismic vulnerability of a certain sample at a territorial scale. It provides a seismic risk assessment having the same trend of the vulnerability assessment conducted with the *LV1 method*, resulting simpler to use since requires less information than the *LV1 method*.

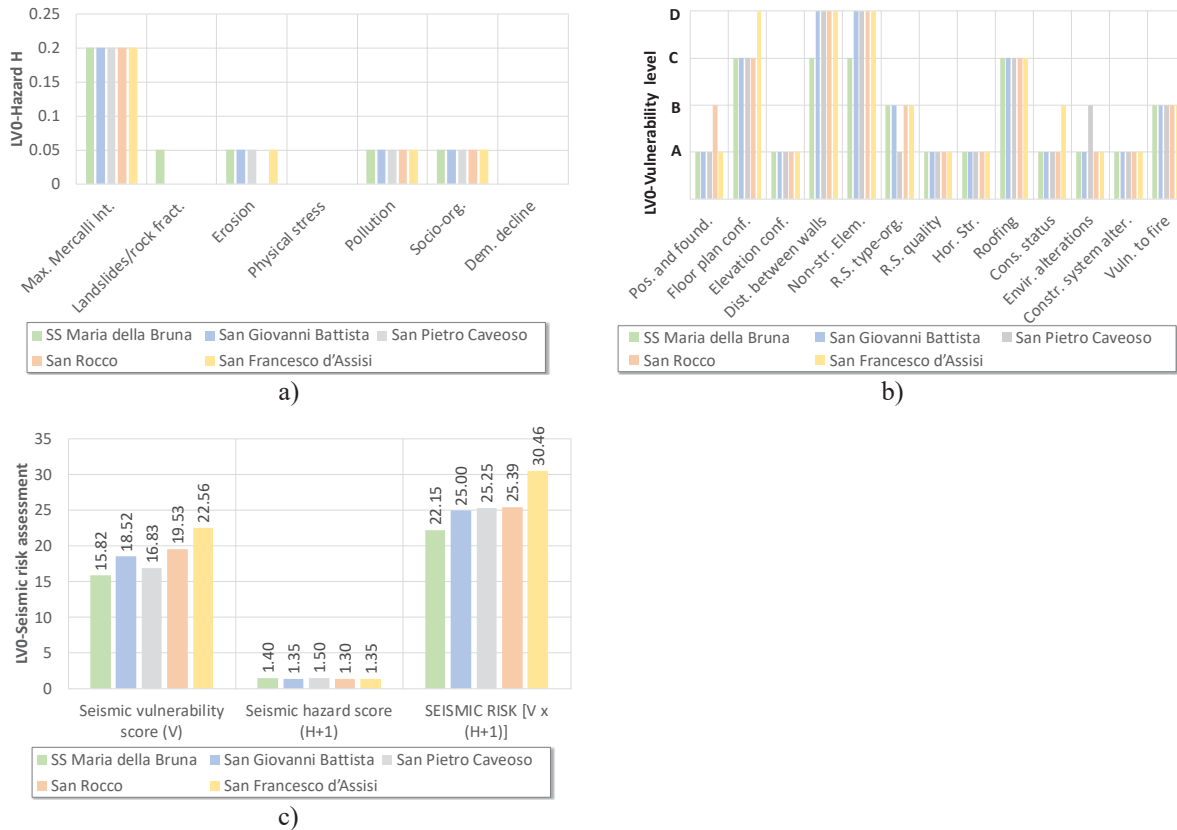

Figure 2 – Results of the LV0 method: a) Hazard assessment, b) vulnerability level assessment and c) resulting seismic risk

Figure 3 - Comparison of results obtained with the LV0 and LV1 method.

5 CONCLUSIONS

In this paper two simplified methods have been applied in order to assess the seismic performance of a sample of ancient churches. These methods are implemented within a multi-level approach, and result very simple to be applied since they require only qualitative information for obtaining a score to be applied within a territorial evaluation.

As shown, the *LV0 method* is a fast tool for ranking within a certain area the priorities needing to be investigated with more refined methods. While, the *LV1 method* provides in quantitative terms a first estimation of the seismic performance starting from few qualitative information that may be gathered with an in-situ survey. Both methods, are not capable of designing any intervention. To this aim, within the multi-level approach indicated in the Italian Directive [16], the *LV2* and *LV3 methods* may be applied. However, they require geometrical and mechanical information on structures and materials rarely available and, therefore, known only after specific survey campaigns.

Abstract

Losses and damages induced by strong earthquakes are a dramatic reality worldwide. As a consequence, the implementation of innovative protection strategies for both existing and new constructions is of key societal importance. Elastomeric isolators are special devices for seismic isolation of structures. Typically, they are made of alternate layers of steel or fiber reinforced laminas and rubber and they are interposed between the ground and the foundation in order to increase the natural period of the structure and reduce the inertia forces to apply in case of an earthquake. This study proposes a detailed 3D FE modelling of isolators conceived for low-rise masonry buildings in developing countries, carried out through the FE software code Abaqus. The isolator under study consists of an energy dissipation core made by relatively High Damping Rubber and an external EPDM ring. In addition, in order to reduce the production cost and allow its applicability in developing countries, it presents unbonded boundary conditions. In fact, the upper and lower edges do not exhibit any bond with the supports. The main feature of such a device is the large deformability thanks to the rollover deformation and the favorably lower lateral stiffness compared to the bonded isolator.

1 INTRODUCTION

Some commercial base elastomeric isolators have been introduced in the last four decades to protect buildings from vibration and earthquake. Typically, they are constituted by several alternating layers of rubber pads and steel, interposed by two continuous pads that limit vertical deformability (Steel Reinforced Elastomeric Isolator, SREI). This system reduces the seismic demand and isolates the energy transmission of the earthquakes to the structure. A very effective seismic isolator shall satisfy the following functions: good performance under all service loads (vertical and horizontal); provide enough horizontal flexibility to reach the natural target period for the isolated structure; recentering capability after the ground motion, so that no residual horizontal displacement can downgrade the serviceability of the structure; provide an adequate level of energy dissipation (damping) to control the displacement that could damage other structural members. Fiber-reinforced elastomeric isolator (FREI) is a new type of elastomeric isolator. Instead of steel lamina, it's constituted by thin fiber layers for the vertical reinforcement. Compared with SREIs, FREIs have considerably lower weight and can be manufactured through cold vulcanization. Furthermore, FREIs can be applied to the structure in unbonded conditions without steel supports [1, 2, 3, 4, 5]. So, the isolators can be installed between the upper structure and foundation without any bonding or fastening. The advantage is related to the low production cost, that makes the device suitable for the application in developing countries. The reduced quality of the rubber material used and the unbonded condition allow their utilization only for low-rise residential masonry buildings, which are however quite widespread in developing countries. From a technical point of view, the unbonded condition results in a stable rollover lateral deformation, which reduces the horizontal stiffness and increases the efficiency of the devices. Comparing to the identical specimen but in bonded conditions, the unbonded FREIs exhibit an interesting superior performance concerning the damping [6]. This paper proposes a novel typology of base seismic isolator, Unbonded Fiber Elastomeric Isolator (UFREI), made with a core made by a relatively High Damping Rubber and reactivated Ethylene Propylene Diene Monomer (EPDM) used as ring of each pad. In this way the ageing of the device is strongly reduced. Preliminary FE results of a non-linear 3D numerical analysis carried out on a single isolator subjected to cyclic tests are presented.

2 RUBBER MECHANICAL PROPERTIES

Two rubber compounds have been considered for the design of the unbonded fiber elastomeric isolator. The first one is a relatively high damping rubber [7], and it constitutes the damping core of the isolator. This type of rubber compound, made of natural rubber (NR), guarantees a good performance in terms of energy dissipation (Figure 1), but at the same time, it is vulnerable to quick aging.

Figure 1: Hysteretic curves for different deformation levels of High Damping Rubber [7]

To protect the HDR, it has been considered a second rubber compound used as ring for each pad, namely a reactivated EPDM made with 2/3 of regenerated rubber and 1/3 of virgin rubber [8, 9, 10] which shows good performances even under aging effects (Figure 2). In Figure 3 it's possible to see the single rubber pad, made of an EPDM frame (Green) with a thickness of 5 mm, and the core ($65 \times 65 \text{ mm}^2$) of HDR (Red).

Figure 2: Stretch-stress (a) and relaxation curves (b) of reactivated EPDM, before and after aging [9]

Figure 3: Rubber pad made of HDR and reactivated EPDM

3 HIGH DAMPING RUBBER BEARING

The device object of the study (Figure 4) is constituted by five pads of HDR and reactivated EPDM (10 mm thick), and four GFRP laminas (0.5 mm thick) with a square section of 75x75 mm². On the top and on the bottom, there are two pads of EPDM (3 mm thick) in direct contact with the superstructure and the foundation.

Figure 4: Design of Unbonded Fiber Elastomeric Isolator made of HDR and EPDM

4 3D FE MODEL - CYCLIC SHEAR ANALYSIS

In this section, detailed 3D FE analyses are performed on a single UFREI. In particular, the device is subjected to a 0.5 Hz cyclic horizontal displacement up to 60 mm applied at the top under a constant vertical pressure of 1 MPa.

4.1 3D FE Model

The isolator has been modeled using almost 18000 eight-node brick (C3D8RH) elements with dimensions 3.5 x 3.5 x 2 mm³. The final mesh is shown in Figure 2. Unbonded condition has been simulated. No bonding is present between the supports and the rubber pad. So, a penalty surface-interaction model has been introduced between the two surfaces and a friction coefficient of $\mu=1$ has been applied. On the contrary, a perfect bond using the surface-to-surface tie constraint between HDR, EPDM and GFRP has been adopted.

Figure 5: FE model of Unbonded Fiber Reinforce Elastomeric Isolator

4.2 Results

Effective horizontal stiffness $K_{H,eff}$ and damping ratio ξ have been evaluated on four cycles with maximum displacement equal to 15 mm, 30 mm, 50 mm, and 60 mm respectively. The computations are based on the equations (1)-(4):

$$K_{H,eff} = (F_{max} - F_{min}) / (\Delta_{max} - \Delta_{min}) \quad (1)$$

$$\xi = W_d / (4\pi W_s) \quad (2)$$

$$W_s = (1/2) * K_{H,eff} * \Delta_{max,ave}^2 \quad (3)$$

$$\Delta_{max,ave} = (\Delta_{max} + \Delta_{min}) / 2 \quad (4)$$

Cycle	Effective horizontal stiffness $K_{H,eff}$ [N/mm]	Damping ratio ξ [%]
Device cured at 130° for 40 minutes		
1°	39.69	5.60
2°	31.91	8.22
3°	22.48	11.65
4°	19.46	14.42

Table 1: Damping ratio and Effective horizontal stiffness for each cycle on the device.

Figure 6: Lateral force-displacement curve for the unbonded FREI.

In Figure 6, the lateral force-displacement curves of the device are shown. The effective horizontal stiffness decreases from the first to the last cycle, up to the final displacement equal to 60 mm (Table 1). This is a typical characteristic of unbonded application, rollover (Figure 7), which causes a nonlinear behavior, resulting in a softening behavior.

5 CONCLUSIONS

In this paper, preliminary FE analyses on a novel typology of Unbonded Fiber Reinforced Elastomeric Isolator have been presented.

Each pad of the isolator is constituted by two rubber compounds, HDR as core and EPDM as external layer; the aim is to obtain -at low cost- a base seismic isolator with good performance in terms of damping and good durability. Subsequently, a detailed 3D FE model of the isolator has been considered, carrying out the analyses through the FE software code Abaqus; in particular, cyclic shear tests with a maximum displacement of 60 mm have been performed. The preliminary numerical results obtained seem promising to consider this new device suitable to isolate low-rise masonry buildings in developing countries, where the low cost and the promotion of circular economy will be crucial in the future decades.

Abstract

Recent earthquakes have highlighted the high seismic vulnerability of the structures and the need of retrofitting interventions. Different seismic protection strategies and techniques can be used to increase the seismic capacity of existing masonry constructions. Common retrofitting techniques are generally based on a strengthening approach. Instead, innovative retrofitting strategies can be used to mitigate the effect of earthquakes, with the aim of decreasing the seismic demand on the structure or increasing its energy dissipation capacity. One of the most innovative devices is the Unbonded Fiber Reinforced Elastomeric Isolators. UFREIs are made of alternate layers of fiber and rubber and they are interposed between the ground and the foundation, with the particularity that no bonding or fastening is provided between the bearing and top-bottom supports. In this paper, through the FE software code Abaqus, a series of nonlinear dynamic analysis are performed to investigate the influence of crosslinking on the seismic performance of UFREI made of regenerated rubber. Numerical results show that the devices vulcanized at 130°C for 40 minutes, although having suboptimal crosslinking density, are suitable to properly isolate low-rise buildings.

Keywords: Base Isolation, Fiber Reinforced Elastomeric Isolator, Vulcanization, Regenerated Rubber, FE Analysis.

1 INTRODUCTION

The elastomeric isolators are the most used devices to seismically isolate the buildings. Applying the elastomeric isolators can restore the horizontal seismic force and does not cause residual displacements of the isolated building after an earthquake. Usually, they are constituted by several alternating layers of rubber pads and steel interposed by two continuous pads, having the role of limiting vertical deformability. At the same time, they exhibit good deformation capacity in the horizontal direction when subjected to a seismic load. This system isolates the energy transmission of the earthquake from the foundation to the upper structure. Fiber-reinforced elastomeric isolator (FREI) is a new type of elastomeric isolator. Instead of using steel lamina, thin fiber layers are utilized for the vertical reinforcement. FREIs can be applied to the structure in several methods: bonded [1], unbonded [2, 3, 4, 5], partially bonded [6], and friction (no-bonding between rubber and fiber layers). Without steel supports, the isolators can be simply installed between the upper structure and foundation without any bonding or fastening. So, the shear load is transferred through the friction generated between the isolator and the structure surfaces.

A fundamental part of the manufactory process is vulcanization. During this stage, rubber is heated with sulfur or peroxides, accelerators, and activators at around 140-160 °C. This process triggers the formation of crosslinks between long rubber molecules, creating the so called polymer network. Thanks to crosslinks, the chains are prevented from sliding along each other and the rubber becomes elastic. The final mechanical properties of rubber (such as elastic modulus, tensile strength, hardness, etc.) are strongly affected by the degree of curing [7]. Curing temperature and the exposition time are critical parameters to establish to obtain optimal and homogenously distributed mechanical properties of rubber items. This paper investigates the influence of vulcanization on the seismic performance of Unbonded Fiber Reinforced Elastomeric Isolator made of regenerated rubber [8, 9, 10], considering two types of vulcanization, one at 130°C for 40 minutes and one at 150°C for 40 minutes.

Figure 1: Design of the device object of the study

2 BASE SEISMIC ISOLATOR

The device object of the study is constituted by five pads (10 mm thick) of reactivated EPDM made with 2/3 of regenerated rubber and 1/3 of virgin rubber, and four GFRP lamina (0.5 mm thick) with a square section of 75x75 mm² (Figure 1). The results obtained in [11] show that the device cured with a temperature of 130° for 40 minutes exhibits a non-uniform curing level. So, rubber mechanical properties are non-homogenous within the isolator. On the other hand, the curing temperature of 150° leads to homogenous curing, with a homogenous distribution of mechanical properties. To investigate the distribution of curing level for the under-vulcanized device, knife-cuts on the middle vertical and diagonal sections (Figure 2)

have been done, and the Shore A hardness has been measured with a digital Shore A durometer. As expected, the hardness varies from inner to outer points from values of 48 ± 2 Shore A to 60 ± 2 Shore A (Figure 2).

Figure 2: Middle vertical (Red) and diagonal (Yellow) sections for the measurements of the Shore A hardness

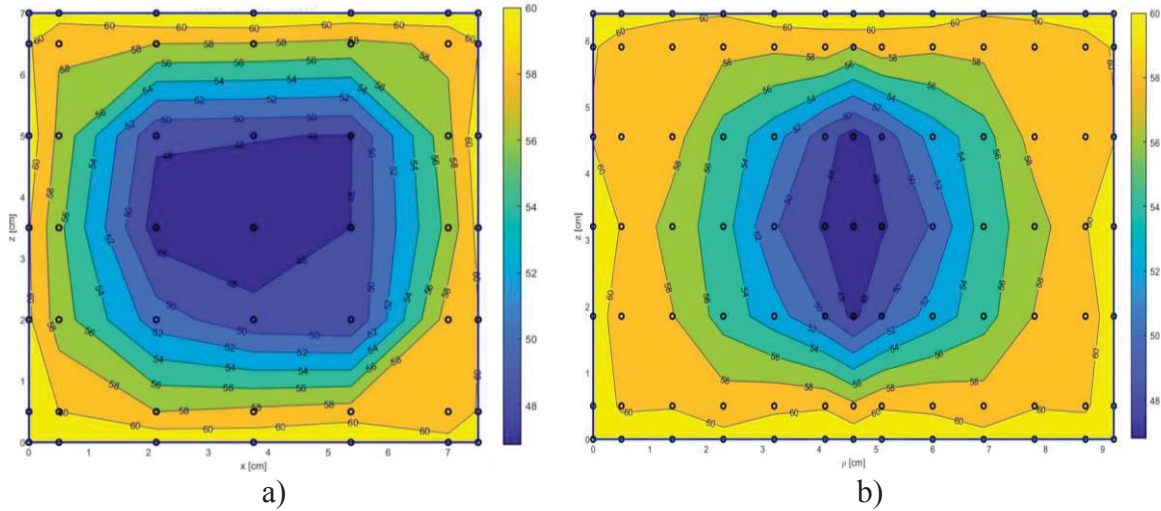

Figure 3: Shore A hardness measured on the middle vertical section (a) and along the diagonal (b) of a device cured at $T=130^\circ$ for 40 minutes

3 3D FE MODEL - CYCLIC SHEAR ANALYSIS

In this section, detailed 3D FE analyses are performed on a single UFREI. In particular, the device is subjected to a 0.5 Hz cyclic horizontal displacement up to 50 mm (Total rubber height) applied at the top under constant vertical pressure of 2 MPa.

Two devices are analyzed. The first one cured at 150°C for 40 minutes, with the rubber mechanical properties uniformly distributed, and the second cured at 130°C for 40 minutes, with a non-homogeneous distribution of rubber mechanical properties, which vary almost linearly within the isolator in accordance with the results shown in Section 2.

3.1 3D FE Model

The isolator has been modeled using almost 18000 eight-node brick (C3D8RH) elements with dimensions $3.5 \times 3.5 \times 2$ mm. The final mesh is shown in Figure 4. In this study, an unbonded condition has been simulated. There is no bonding between the supports and the rubber pad. For this purpose, a penalty surface-interaction model has been introduced between

the two surfaces, and a friction coefficient of $\mu=1$ has been applied. On the contrary, a perfect bond using the surface-to-surface tie constraint between rubber and GFRP has been adopted. As visible in Figure 3, rubber mechanical properties on the device cured at 130°C linearly changes within the isolator. So, in order to assign different mechanical properties to the model, the EPDM pad has been partitioned into several cubes (Figure 5).

Figure 4: FE model of UFREI75

Figure 5: EPDM pad subdivided into several cubes on ABAQUS

Then, three different pads have been considered: middle pad, intermediate pad, and external pad. On each pad, a different distribution of mechanical properties has been assigned as visible in Figure 6 and Figure 7, where the red part is linked to 50 Shore A rubber properties, the orange one to 54 Shore A, and the green one to 60 Shore A.

Figure 6: a) external pad section, b) intermediate pad section, c) middle pad section.

Figure 7: Middle horizontal section of FREI cured at T=130°.

3.2 Results

To compare devices' structural responses, effective horizontal stiffness $K_{H,eff}$ and damping ratio ξ have been evaluated on four cycles with maximum displacement equal to 5 mm, 15 mm, 30 mm and 50 mm respectively. The computations are based on the equations (1)-(4):

$$K_{H,eff} = (F_{max} - F_{min}) / (\Delta_{max} - \Delta_{min}) \quad (1)$$

$$\xi = W_d / (4\pi W_s) \quad (2)$$

$$W_s = (1/2) * K_{H,eff} * \Delta_{max,ave}^2 \quad (3)$$

$$\Delta_{max,ave} = (\Delta_{max} + \Delta_{min}) / 2 \quad (4)$$

Cycle	Effective horizontal stiffness $K_{H,eff}$ [N mm]	Damping ratio ξ [%]	Effective horizontal stiffness $K_{H,eff}$ [N mm]	Damping ratio ξ [%]
	Device cured at 130° for 40 minutes		Device cured at 150° for 40 minutes	
1°	67.59	6.38	87.65	7.86
2°	64.86	5.67	82.41	7.68
3°	50.30	7.73	65.34	10.01
4°	35.08	11.20	46.20	13.92

Table 1: Damping ratio and Effective horizontal stiffness for each cycle on the device cured at 130° for 40 minutes and at 150° for 40 minutes.

In Figure 8, the lateral force-displacement curves for the device cured at 130° and at 150° for 40 minutes are compared. In both cases, the effective horizontal stiffness decreases, passing from first to last cycle. This is a typical feature of unbonded application: the device experiences a rollover (Figure 9) which causes a nonlinear behavior, resulting in a softening behavior. Another remarkable feature appreciable in both the devices is the variation of damping ratio with the increase of lateral displacement.

The results summarized in Table 1 show how the device cured at 130° is characterized by lower effective horizontal stiffness compared to the one cured at 150°. The same holds for the damping ratio.

Figure 8: Lateral force-displacement curve for the unbonded FREI cured at 130° for 40 minutes (blue curve) and cured at 150° for 40 minutes (red curve).

Figure 9: Typical rollover deformation due to unbonding, which causes a softening behavior

4 CONCLUSIONS

In this paper, the seismic performance of under-vulcanized Unbonded Fiber Reinforced Elastomeric Isolators has been studied, and it has been compared with a well-vulcanized one.

Firstly, to investigate the distribution of curing level of the under-vulcanized device, the Shore A hardness has been measured with a digital Shore A durometer along two sections. Results have shown the non-homogeneous hardness distribution and the non-homogeneous rubber mechanical properties within the base isolator.

Subsequently, the device has been modeled through the FE software code Abaqus and cyclic shear tests have been performed, with a maximum displacement of 50 mm. Two different seismic performances of the under-vulcanized UFREI and the well-vulcanized one have been obtained. The device cured at 130° is characterized by lower effective horizontal stiffness and lower damping ratio than the one cured at 150°.

In conclusion, although the devices show different behavior in these cyclic shear tests, both are suitable to isolate low-rise buildings properly.

Abstract

Evolution of technologies both in the fields of in situ investigations and Finite Element (FE) modeling strongly enhanced the possibility to understand the structural dynamic behavior of masonry historical constructions, allowing a periodic or continuous analysis of their response to environmental, anthropic, and exceptional actions and the formulation of accurate hypotheses about their future behavior, which is fundamental for Cultural Heritage preservation. In order to improve the assessment of the health status of historical buildings, inverse methods re-sorting to dynamic identification techniques are often used to provide experimentally verified data for the accurate calibration of FE models representative of the investigated structures.

In this paper, vibration-based identification methods are coupled with an automatic FE model updating procedure to study the dynamic behavior of the Civic Tower of Ostra, Italy, and obtain baseline information for future comparative analyses. The experimental data obtained from two different campaigns of ambient vibration tests are used to update the mechanical characteristics of the detailed FE model of the tower. The updating process, unsolvable via common calibration procedures, is automatically managed through a powerful bio-inspired tool, i.e. the Genetic Algorithm (GA), allowing to closely reproduce the actual behavior of the tower.

1 INTRODUCTION

Masonry towers are one of the most widespread structural typologies among the various Italian Cultural Heritage (CH) buildings. The intrinsic characteristics and peculiarities of these artefacts make them unique objects but, at the same time, render these structures particularly vulnerable against seismic events [1–6], sometimes in irreparable way. Due to the historical, social and economic importance that CH plays in many countries of the world, it is crucial to guarantee appropriate maintenance plans and to undertake regular preventive actions in order to avoid irreversible damages to these iconic structures, and to historical buildings in general.

Early damage detection should be one of the primary tasks to ensure the integrity of ancient buildings and the safety of their users. To this end, several non-destructive techniques relying on the observation of the dynamic behavior of these structures, commonly known under the expression “Structural Health Monitoring (SHM)”, have been developed in the last decades [7–11]. Among these techniques, those exploiting vibration-based monitoring tools can be of great help in terms of dynamic characterization of heritage towers, allowing to improve the knowledge of the global behavior of these structures without resorting to any invasive method, which is necessary when the historical value of the construction must be respected. To this end, a grid of sensors, each one communicating with a central processing unit through wires or wirelessly, can be deployed across the structure and used to collect the vibration response of the system to ambient excitations. Such data are then post-processed to determine the modal parameters of the structure in operational conditions, applying the methodologies of Operational Modal Analysis (OMA). As widely known, modal features, if tracked on a regular basis, can provide useful information for the evaluation of the health status of the structures over time, also allowing the detection of possible changes associated to their dynamic behavior in case of exceptional events [12] as well as the estimation of future structural scenarios.

With the aim of providing reliable experimental data for the calibration of realistic numerical models (NMs), closely representative of the investigated buildings, ambient vibration testing (AVT) is often coupled with another essential tool in the dynamic assessment of historical structures: the Finite Element (FE) modeling. Various examples of synergy between these two techniques can be found in the literature [8,13,14], where the results obtained from OMA are employed in the process of FE model updating so that the unknown parameters of the structure (such as material properties, boundary conditions, quality of connections between elements, etc.) are iteratively updated until the difference between experimental and numerical modal results is minimized. This operation, if performed manually [15], as it often happens, can result unwieldy and onerous from a computational standpoint, making difficult to attain a precise calibration of the model in case of large and multi-dimensional problems. In order to overcome this limitation, a methodology for the automatic modal-based updating of Finite Element (FE) models is proposed hereafter making use of genetic algorithms.

The genetic algorithm (GA) is one of the oldest and most known metaheuristics used for optimization purposes [16–18]. The search for the solution space mimics, in a sense, the Darwinian theory of species evolution. In the present work, a GA provided by the open-source FE solver Code_Aster is properly exploited to automatically calibrate the elastic properties of the materials assigned to the model of the Clock Tower of Ostra, an emblematic historical tower located in Central Italy. To analyze in depth the GA potential, different mesh refinements of the tower’s geometry are examined along with the adoption of an isotropic constitutive law for the materials [19–24].

2 DESCRIPTION OF THE CASE STUDY: OSTRA CIVIC TOWER

The Civic Tower of Ostra (Figure 1), also known as “Clock Tower”, is the most characteristic historical structure located in the homonymous village of the Marche region, Central Italy.

Originally built in 1552 to serve as bell tower the adjacent church of San Giovanni (no longer existing today) and severely damaged during the aerial bombardments of 1944, in the second half of the XX century the Civic Tower underwent a profound intervention aimed at reinstating its sound condition. The works included the strengthening of the uncovered foundation and of the base walls as well as the restoration of some parts of the external walls and of the battlement, damaged by the bursts of artillery bullets.

Figure 1: Ostra Civic Tower: localization and external view.

2.1 Geometrical and material survey

The Ostra tower is a 30 m high masonry structure featuring four main parts: basement, central body or shaft, belfry, and top roof (Figure 2).

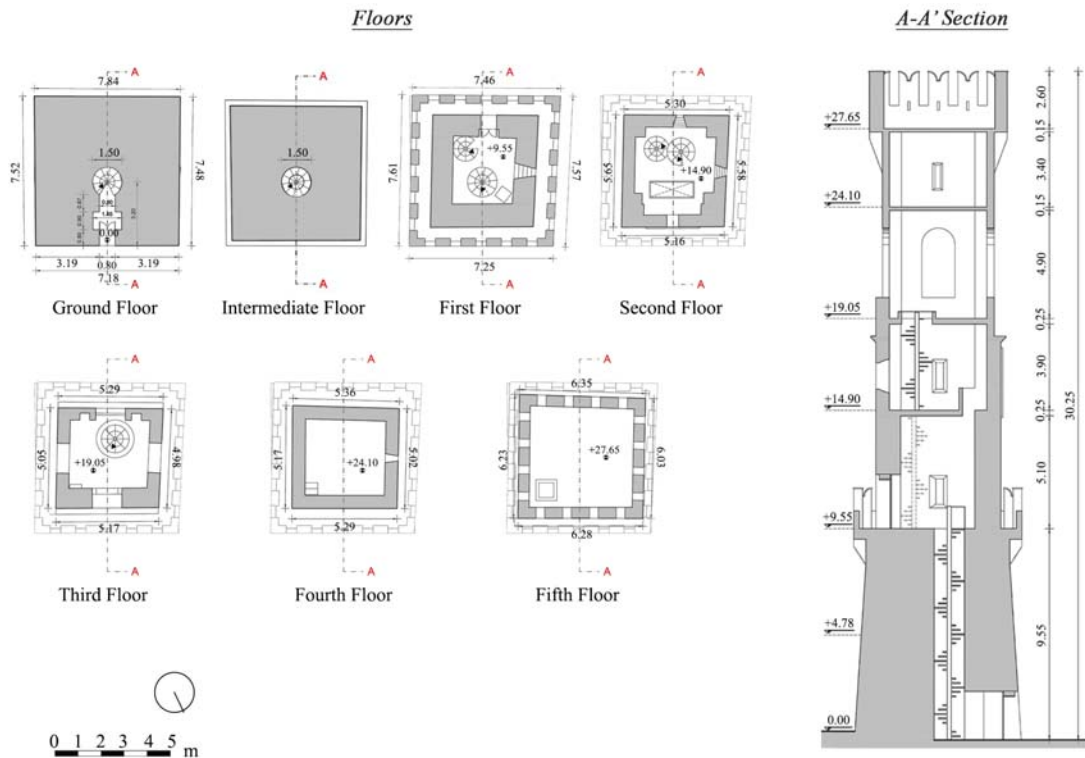

Figure 2: Geometrical survey of the investigated tower.

The basement resembles a truncated pyramid with a lower base of approximately 7.30 x 7.50 m² and an upper base of 5.30 x 5.60 m². This part is characterized by massive walls with outer brick wythes and develops upwards for a height of 9.95 m, ending with an embattled balcony. The shaft, partially reconstructed, starts from this height and keeps the same quadrilateral cross-section for additional 9.50 m. Then, at the level of the belfry, the tower's cross-section dimensions slightly reduce and remain unchanged till the top enlargement of the battlement. Likewise, the thickness of the brick masonry walls of both shaft and belfry progressively decreases upwards, passing from 1.1 m of the first floor to 0.6 m of the last floor.

The entrance door is located at the ground level, in correspondence of the main façade which overlooks Piazza dei Martiri. Five additional floors can be distinguished along the tower height: the first three are connected through spiral staircases, whereas the fourth (rebuilt in reinforced concrete during the intervention) and the last floor are accessible by means of an iron ladder. The clock mechanism is located on the second floor, while the bell is placed at the third level, being visible through the arch openings of the perimetral walls.

3 AMBIENT VIBRATION TESTING

Ambient vibration testing (AVT) has become a common technique in the world of non-destructive experimental characterization of the global behavior of historical constructions [13,25]: indeed, studying the full-scale response of structures to environmental and anthropic actions in real operational conditions, namely without interrupting the normal use of the building and based on its true boundary conditions, results extremely advantageous for many reasons, which go far beyond the economic aspects [11]. Moreover, the non-invasive character of the experiment makes AVTs particularly suited for CH buildings, as proven by the numerous works that in the last years have shown the potentialities of vibration-based monitoring through accelerometric sensors in the study of the dynamic behavior of historical buildings, both in the short-term and in the long-term [26,27].

3.1 Instrumentation, sensor layout and acquisition parameters

Two AVT campaigns were conducted on the Civic Tower of Ostra to assess its dynamic behavior: the first one on 29th June 2018 and the second one on 22nd February 2019.

The sensor network which was used to acquire the structural vibration response in eight specific points defined beforehand consisted of four triaxial MEMS-based piezoelectric accelerometers (model MonoDAQ-E-gMeter) embedded into a data acquisition device simply connected to the PC by a network cable using EtherCAT protocol. One of the major advantages of this sensing system is that analog to digital conversion is performed inside the device itself, thus eliminating any noise pickup in analog cabling. Sensors were placed across four levels (Figure 4), namely at the height of 9.55 m, 14.90 m, 19.05 m, and 27.65 m. At each level, two MEMS accelerometers were deployed at opposite corners, thereby allowing to catch also the expected torsional modes.

To comply with the time-window length requirements [28] and in order to avoid any possible influence from non-stochastic excitations, the duration set for the signal acquisition was far greater than 2000 times the structure's fundamental period: for each setup the registration lasted around 40 minutes and the nodal processes were recorded with a sampling rate of 1024 Hz, resulting in nearly two and a half million data points per channel.

Figure 3: Sensor layouts and corresponding acceleration time series for 2018 and 2019 dynamic testing campaigns.

3.2 Operational modal analysis: method and results

The elaboration of the acquired vibration data allowed the construction of an Experimental Model (EM) of the structure, whose estimated dynamic parameters were subsequently employed to calibrate the Numerical Model (NM) of the tower in order to realistically reproduce its structural behavior, as better discussed in the next Section. The dynamic feature extraction process was carried out and cross-validated through the application of two OMA techniques: the Enhanced Frequency Domain Decomposition (EFDD) [29] and the Stochastic Subspace Identification – Principal Components (SSI-PC) [30], both available in the commercial software ARTEMIS [31].

Modal frequencies (f), damping ratios (ξ) and mode shapes of the five vibration modes identified in each AVT campaign are reported and compared in Table 1 and Figure 4, respectively.

Mode	f_{EM18} [Hz]	ξ_{EM18} [%]	f_{EM19} [Hz]	ξ_{EM19} [%]	Δf [%]	$\Delta \xi$ [%]	MAC [%]
$\phi 1$	2.082	0.817	2.092	0.762	0.478	-7.218	99.2
$\phi 2$	2.156	0.893	2.165	0.787	0.416	-13.469	99.5
$\phi 3$	6.293	0.578	6.302	0.666	0.143	13.213	98.1
$\phi 4$	6.442	2.423	6.449	3.397	0.109	28.672	99.0
$\phi 5$	6.941	2.463	6.872	2.739	-1.004	10.077	97.1

Table 1: Modal frequencies and damping ratios estimated for EM2018 and EM2019 along with their corresponding percentage variation.

As expected, the first two identified frequency values correspond to the translational modes of the tower in x and y directions, respectively, thus resulting quite closely spaced (with a difference of just 3.43% in 2018 and 3.37% in 2019). The other three frequency values fall in the range 6-7 Hz and correspond to the torsion and double bending modes of the tower. The frequency results, sensibly higher if compared to commonly studied masonry towers, are not only affected by the low aspect ratio of the structure ($\lambda = 4$) but also highlight an elevated stiffness of the system which is likely imputable to past restoring interventions. No substantial variation in the dynamic behavior of the structure is recorded during the period elapsed between the dynamic campaigns.

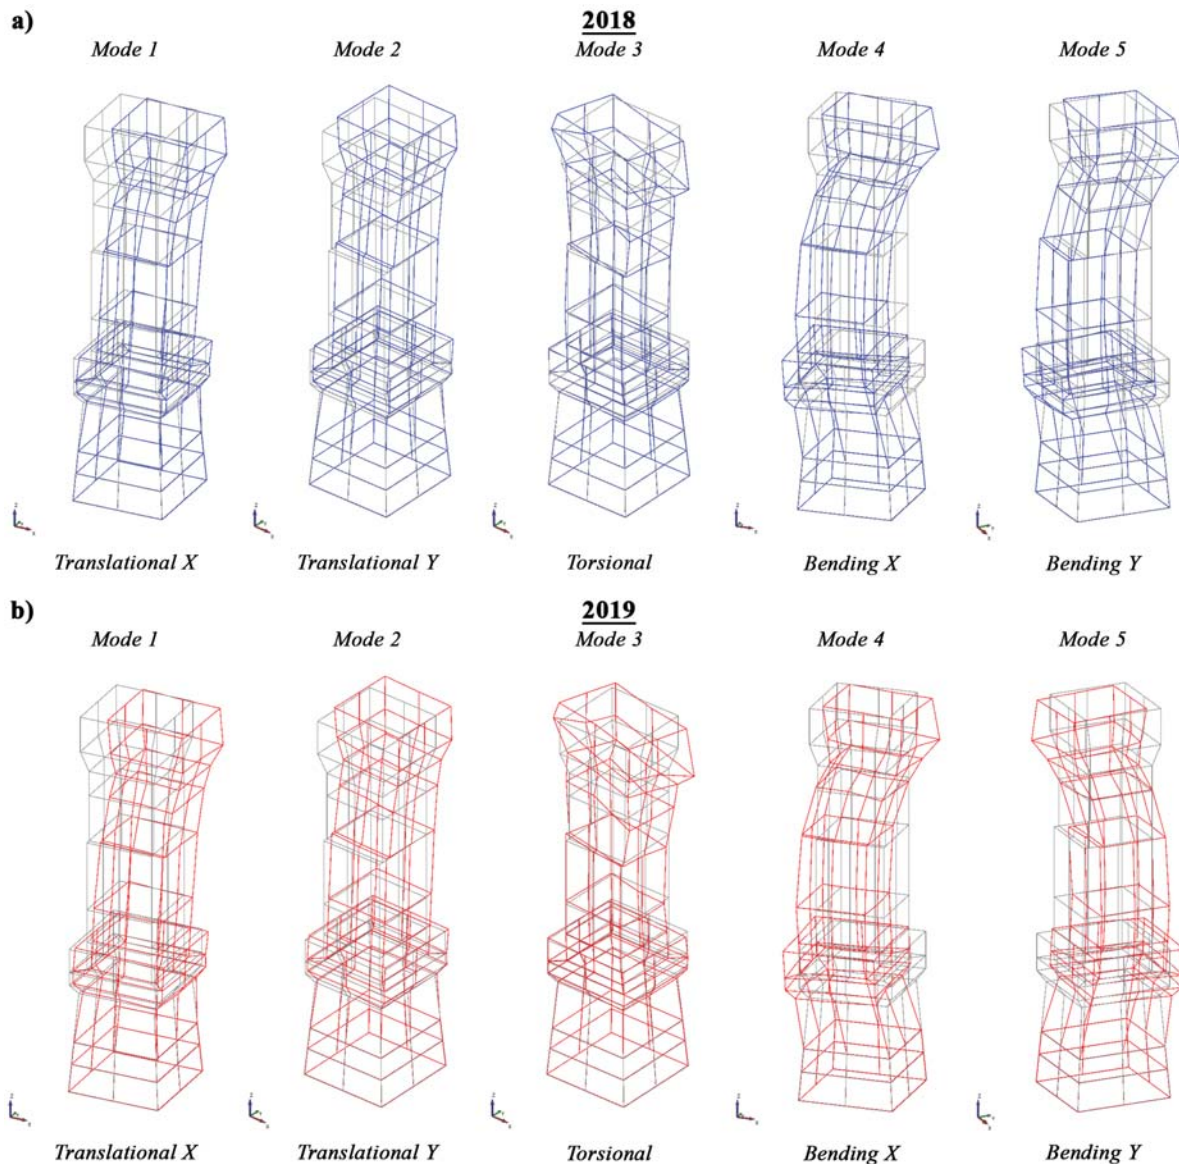

Figure 4: Comparison between the mode shapes of EM 2018 (a) and the corresponding ones of EM 2019 (b).

4 AUTOMATIC MODEL UPDATING WITH GENETIC ALGORITHM

4.1 Preliminary FE model and modal analysis results

A FE model of the tower was realized using MidasFea©. This NM was needed in the first stage to preliminary assess the dynamic characteristics of the tower and drive the setting of the acquisition parameters for the field-testing campaign.

Particular attention was paid to the geometrical features of the tower as well as to the modeling of the masonry infill walls present in the first two levels, given the nonnegligible influence of both aspects in the modal response of the structure. The reinforced concrete floors were considered as rigid in their plane, while secondary elements, like stairs, deformable wooden floors, clock mechanism and towers, were not explicitly modelled, but their presence was taken into account in the form of added masses.

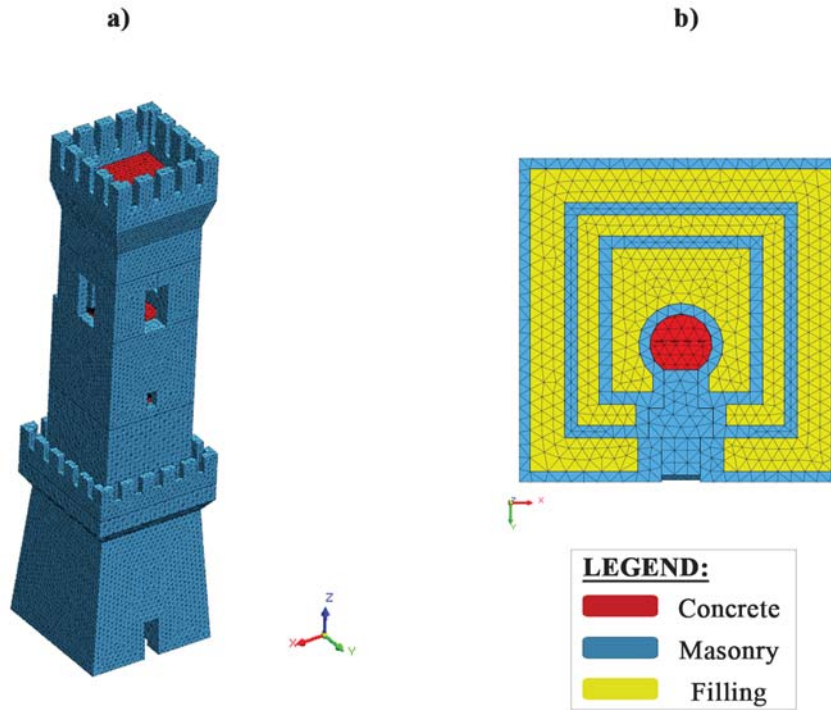

Figure 5: FE modeling of the Civic Tower of Ostra: (a) Assonometric view, (b) Bottom view at foundation level.

The FE model, shown in Figure 5, consisted of 78926 4-nodes tetrahedral elements and 21726 nodes. The mesh size was established equal to 0.3 m. The tower was assumed to be clamped at the base and constituted by three groups of homogeneous and isotropic materials (three-group discretization) whose initial mechanical properties, chosen in accordance to the Italian Technical Standards for Structures [32], are reported in Table 2.

Material	E [MPa]	ν [-]	γ [kN/m ³]
Masonry	1800	0.20	18
Concrete	18000	0.20	25
Filling	1100	0.20	18

Table 2: Mechanical properties of the initial FE model: Young's Modulus (E), Poisson's ratio (ν) and mass density (γ).

The results of the preliminary modal analysis, implemented through the Lanczos method [17,21,33,34], are resumed in Table 3 and Figure 6. A remarkable difference is found among the frequencies of the EM and those of the NM, being the latter not yet calibrated on the basis of the experimental outcome.

Mode	f_{NM0} [Hz]	Eff. Mass X dir [%]	Eff. Mass Y dir [%]	f_{EM18} [Hz]	f_{EM19} [Hz]	$ \Delta f_{EM18-NM0} $ [%]	$MAC_{EM18-NM0}$ [%]	$ \Delta f_{EM19-NM0} $ [%]	$MAC_{EM19-NM0}$ [%]
$\phi 1$	1.509	35.80	0.00	2.082	2.092	27.52	77.6	27.87	82.5
$\phi 2$	1.536	0.00	35.72	2.156	2.165	28.76	81.5	29.05	67.2
$\phi 3$	5.012	0.00	0.00	6.293	6.302	20.36	22.1	20.47	2.6

φ_4	5.821	21.21	0.00	6.442	6.449	9.64	52.2	9.74	47.6
φ_5	5.883	0.00	29.38	6.941	6.872	15.24	1.1	14.39	44.7

Table 3: Preliminary numerical results (NM0) and percentage error with the experimental frequencies (EM)

Analogous considerations can be drawn about the mode shapes (Figure 6), whose main displacement components are visually correlated with their experimental counterpart – being the first two modes translational in x and y direction, the third torsional, and the last two double bending modes in x and y direction – but a low degree of consistency is found between them when MAC values are computed (Table 3).

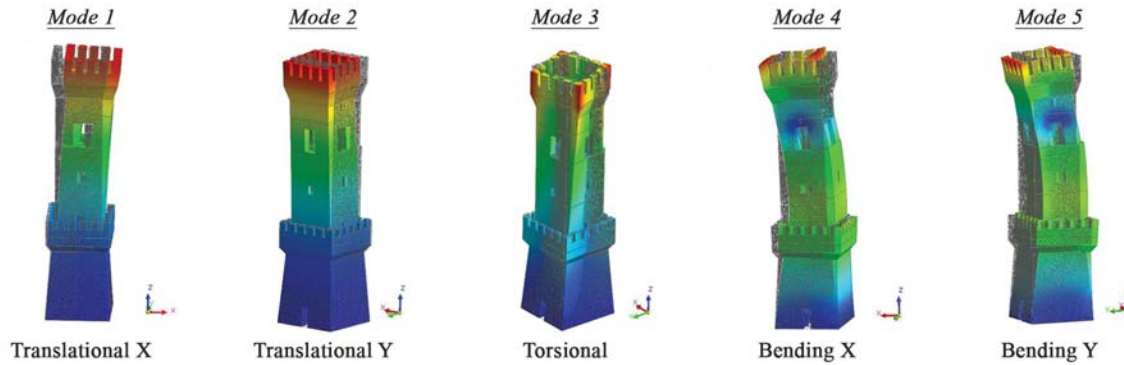

Figure 6: Mode shapes of the preliminary FE model.

4.2 Genetic Algorithms

The genetic algorithms (GAs) are heuristic techniques inspired by Darwin's theory and are based on the imitation of the natural selection process. These algorithms allow to solve optimization problems through an automatic procedure where the final set of optimal solutions is iteratively selected from an initial set of candidate solutions, based on their fitness score [35–38]. As for the present case, the initial population of solutions was represented by all the plausible values of material properties falling within pre-defined upper and lower bounds [17,18]. A two-term objective function considering both frequencies and mode shapes residuals between EM and NM was employed for the selection of the optimal values.

In order to avoid the limitations imposed by a manual calibration approach, the iterative process was implemented into Code_Aster© software environment. The procedure, summarized in Figure 7, started with the creation of a condensed model, carrying all the dynamic characteristics of the EM, and with its projection onto the NM. This operation allows scaling the EM DOFs up to those of the NM and, consequently, the creation of dependencies for calculating the gaps between their nodal displacements.

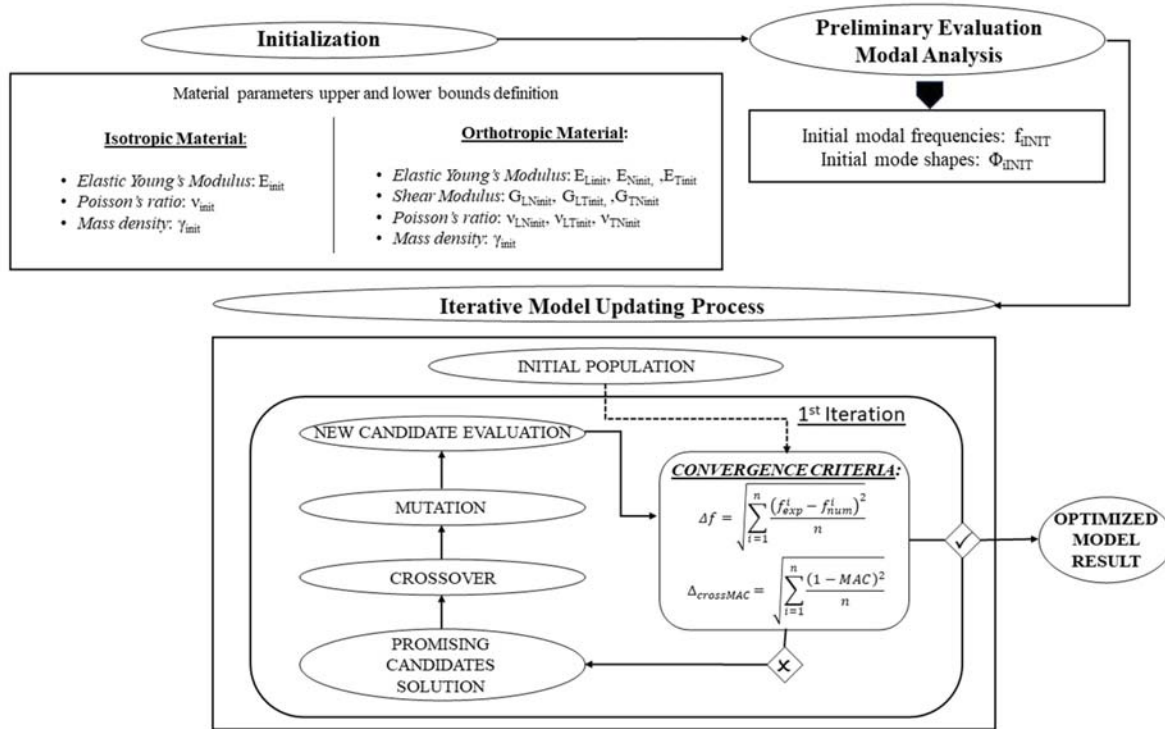

Figure 7: GA-based model updating flowchart.

The model updating process consisted of four phases (objective function, selection, crossover, mutation) and stopped only when the global optimum was located. Indeed, one of the main advantages of GA is the possibility to explore diverse regions of interest by running the same search problem on different conditions and finally locate the global optimum without getting trapped in local minima [16,17,39,40]. In the present work, these conditions are checked by resorting to the following objective function (1):

$$\Delta f = \sqrt{\sum_{i=1}^n \frac{(f_{exp}^i - f_{num}^i)^2}{n}} \quad (1)$$

$$\Delta_{crossMAC} = \sqrt{\sum_{i=1}^n \frac{(1 - MAC)^2}{n}}$$

Convergence criteria were satisfied when the residual tolerance of two consecutive steps reached $1e-4$ or after 1000 evaluations.

5 CALIBRATION PROCESS AND RESULTS

In order to improve control over the model dynamic response and to achieve a better tuning with the experimental data, the calibration process was performed operating a further discretization of the preliminary NM in terms of material properties distribution, while the mesh size remained unchanged. This operation was driven by the careful observation of the masonry appearance and morphology across the tower, which ultimately led to a twelve-group discretization of the updating variables (Figure 8).

Figure 8: Updating variables for the twelve-group discretization of the FE model. Each material group is named as “X” followed by a subscript composed by a number (00 to 12), which stands for the group, and a letter indicating the material (“M”: masonry, “C”: concrete, “F”: masonry infill).

For each group, properties were attributed considering an isotropic constitutive law for the materials, thus leading to a total number of 36 updating variables. The pre-defined ranges of variability for the material parameters, presented in Table 4, were again assigned in accordance with the Italian Technical Standards for Structures [32].

Material	E [MPa]	ν [-]	γ [kN/m ³]
	Min - Max	Min - Max	Min - Max
Masonry	600 - 3300	0.01 - 0.45	15 - 20
Filling	600 - 2400	0.01 - 0.45	15 - 20
Concrete	27000 - 32000	0.01 - 0.45	23 - 26

Table 4: Lower and upper bounds for isotropic elastic properties

The optimal mechanical properties resulting from the model updating are summarized in Table 5. It is worth noting that the obtained values, especially the Young’s Moduli, consistently reflect the masonry changes produced by the strengthening interventions that the

Tower underwent in the past: indeed, E first tends to decrease moving from the basement (restored during the 1950s) to the central body (partially restored) and the belfry, and then increases towards the top part of the tower (added afterwards).

Updating Parameter	NM 2018			NM 2019		
	E [MPa]	ν [-]	γ [kN/m ³]	E [MPa]	ν [-]	γ [kN/m ³]
X _{01M}	1909	0.11	15	1616	0.28	15
X _{02M}	2783	0.10	15	1886	0.15	15

Table 5: Optimal values for the material parameters of the isotropic FE model after calibration

The results of the modal analyses run over 2018 and 2019 NMs, both calibrated through the automatic GA-based procedure previously described, are exposed in Table 6 and Table 7. The comparison between EM and NM frequency values is satisfactory, being the relative error less than 3% in all cases, with the sole exception of the 4th mode that shows a slightly higher error for the pair EM18-NM18.

Mode	f_{EM18} [Hz]	f_{NM18} [Hz]	Eff. Mass X dir [%]	Eff. Mass Y dir [%]	$ \Delta f_{EM18-NM18} $ [%]	$MAC_{EM18-NM18}$ [%]
ϕ_1	2.082	2.087	34.14	0.01	0.24	97.9
ϕ_2	2.156	2.130	0.01	33.53	1.21	97.3

ϕ_3	6.302	6.275	0.41	0.06	0.43	95.7

$\varphi 4$	6.449	6.629	29.22	0.03	2.79	95.8
$\varphi 5$	6.872	6.761	0.02	28.48	1.62	95.8

Table 7: Comparison between 2019 experimental (EM) and numerical (NM) frequencies

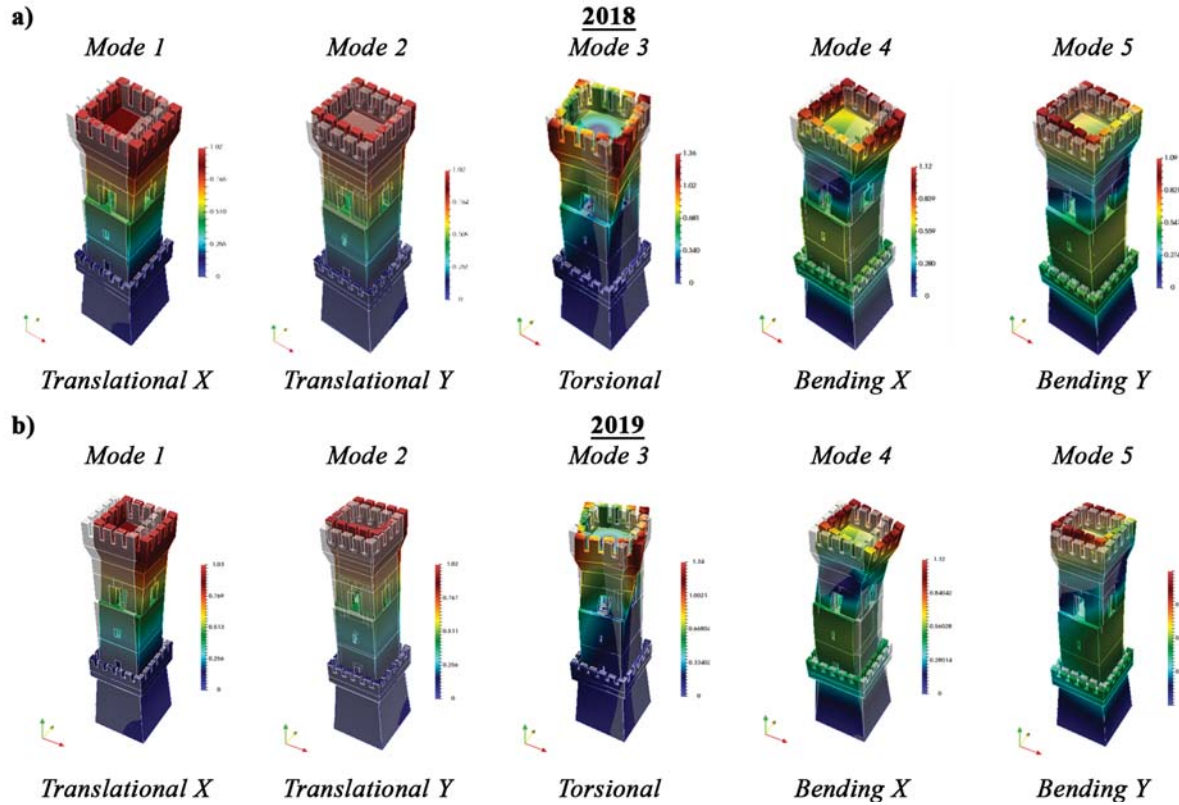

Figure 9: Numerical mode shapes after calibration of 2018 NM and 2019 NM.

Very good results are also achieved in terms of mode shapes (Figure 9), as confirmed by the optimal levels of correlation ($MAC > 95\%$) obtained from the comparison between experimental and calibrated modal vectors, proving the validity and robustness of the GA-based model updating when tackling optimization problems otherwise ungovernable with conventional approaches.

6 CONCLUSIONS

The paper showed and discussed the results obtained by combining AVT-based dynamic identification methodologies and FE model updating techniques, through the application of an automatic procedure based on GA for the assessment of the dynamic behavior of the Ostra Civic Tower (Italy).

After an initial geometrical and material survey to define the main morphological and structural characteristics necessary for the creation of a preliminary NM (over which more advanced non-linear analyses will be implemented in order to estimate the structural response against future scenarios), two modal testing campaigns were carried out to acquire the vibration response of the tower to ambient noise. Innovative sensing solutions based on MEMS were adopted for this purpose.

After extracting the main dynamic parameters of the tower (i.e. modal frequencies, modal damping and mode shapes) through well-known OMA techniques, the EM of the structure was implemented into Code_Aster© and used as a target reference for the calibration of the afore-mentioned finite element NM. In both campaigns, the same five vibration modes were identified, meaning that no changes in the structural condition of the tower occurred between 2018 and 2019.

All the eigenfrequencies and eigenvectors associated to these five modes were exploited for the subsequent automated calibration process, which consisted in a perturbation of the mass and stiffness matrices of the NM in order to find optimal yet physically meaningful values of the unknown material properties of the tower, so that the difference between estimated (OMA) and calculated (FEM) eigen-parameters was minimized. The search problem was solved by applying a metaheuristic inspired by the process of natural selection, namely the GA, to the OMA eigen-data projected onto the equivalent NM. The employment of such an algo-rithm was pivotal given the population of candidate solutions taken into account for the mod-al-based FE updating.

The results, obtained assuming an isotropic behavior for the materials, were satisfactory. Future developments will take into consideration orthotropic constitutive laws for the masonry in the attempt to further minimize the discrepancies between numerical and experimental models.

Abstract

Masonry cross vaults are common structural elements in historical buildings. They are largely diffused in all European countries, including those characterized by higher levels of seismicity. Although they have been constructed for centuries, they represent some of the most vulnerable elements of traditional architecture, especially with reference to horizontal loads. The understanding of their behaviour under seismic loading and the definition of their safety are crucial aspects for the accurate assessment of the global health conditions of historical buildings. In the present work, masonry cross vaults are analysed through the Finite Element Method (FEM) and static non-linear analyses are performed considering the effect of different brick pattern.

A simplified micro-modelling approach is adopted for the generation of the FEM models and two different brick arrangements are considered, i.e., radial bricks and diagonal bricks, which are the most widespread in European cross vaults. Static non-linear analyses are performed by monotonically incrementing a lateral acceleration until collapse. Results are analysed in terms of maximum load factor, crack pattern and damage mechanisms. The analysis of the results shows that the masonry apparatus strongly influences the vault seismic response both in terms of stiffness and ductility as well as in terms of global capacity.

Keywords: Cross vaults; Masonry apparatus; FEM model; Push-over analysis, Seismic behaviour.

1 INTRODUCTION

European historical masonry buildings are often characterized by the presence of vaulted structures of complex geometry and cross masonry vaults are among the most widespread types. They are largely diffused in all European countries, including those characterized by higher levels of seismicity. Although they have been constructed for centuries, they represent some of the most vulnerable elements of traditional architecture, especially with reference to horizontal loads when the construction site is characterized by high levels of seismicity. For this reason, the assessment of their behaviour under seismic loading, and consequently the definition of a safety level, is a crucial precondition for the accurate assessment of the global safety of historical buildings.

Compared to simple masonry walls, numerical modelling of masonry vaulted structures is particularly complex due to their three-dimensional curved geometry and articulated masonry pattern. As a matter of facts, vaults can be built according to different brick patterns, which, in historical building practices, were generally chosen for technical reasons.

In the present work, cross vaults of ideal geometry are modelled through the simplified micro-modelling approach in the framework of Finite Element Method (FEM) [1]. This modelling approach has already been used by the authors and successfully validated with physical in-scale models [2]. The use of micro-mechanical models allows to simulate block-to-block interactions and therefore the real interlocking of bricks. In this work, two different brick arrangements are considered, i.e., radial bricks and diagonal bricks, which are most found in European cross vaults. Static non-linear analyses are performed by monotonically incrementing a lateral acceleration until collapse. Results are analysed in terms of maximum load factor, crack pattern and damage mechanisms.

2 DESCRIPTION OF THE MODEL

In this section the main features of the FEM model are described in terms of geometry, mechanical parameters of materials and interface properties. Moreover, the load cases and the boundary conditions are illustrated.

2.1 Geometry and mechanical features

The geometry of the vault is obtained as intersection of two semi-circular barrel vaults. The base is squared with a net span of approximately 3.1 m and rise of 1.175 m. The volume is discretized into bricks of size 6x12x24 cm. The shape of the interlocked bricks along the diagonal arches is idealized and simplified. Four rigid corner supports are modelled at the base of the vault. Two different masonry apparatus are modelled, namely those which follow radial (R) and diagonal (D) path. More in detail, in the case of radial pattern, the longitudinal courses between bricks are disposed normal to the ring arches; conversely, in the case of diagonal pattern, the bed joints are oriented at a 45° angle. Figure 1 shows the details of the geometry and the discretization into bricks; as an example the vault with radial brick pattern is reported.

The discretization of the solid volume of the vault is conducted by means of a simplified micro-modelling approach which allows for the detailed definition of the brick pattern [1]. Such a method consists in the assemblage of a series of blocks connected with zero-thickness interfaces endowed with proper tangential and normal mechanical properties.

The mechanical properties of the blocks are defined through simple elastic behaviour, adopting the values suggested by [3] for historic brick-masonry. In particular, the density of the material ρ is assumed equal to 1800 kg/m³ while the elastic modulus E and the Poisson's ratio ν are equal to 1200 MPa and 0.2, respectively. The behaviour of the mortar joints is sim-

ulated through the insertion of an interaction property between all masonry surfaces into contact. The Authors have already validated this modelling approach in some previous research [2,4,5]. In the local tangential direction, the response is ruled by frictional behaviour in which the contribution of cohesion is neglected as suggested in [6]. In particular, a static friction coefficient μ equal to 0.5 is assumed. In the normal direction, detachment is allowed with zero stiffness while an almost infinite stiffness k_n is assumed in compression to simulate a rigid normal contact. Tangential and normal behaviour are assumed uncoupled. The mechanical parameters adopted in the model are reported in Table 1.

Figure 1: Geometry and discretization of the vault.

Blocks			Joints	
ρ [kg/m ³]	E [MPa]	ν [-]	μ [-]	k_n [N/m ³]
1800	1200	0.2	0.5	$5 \cdot 10^9$

Table 1: Mechanical parameters.

2.2 Load conditions

The seismic performance of the cross vault is analysed through pushover analyses, by applying a monotonic lateral load to the structure. The analysis is divided in two steps: first the gravitational acceleration is applied, then the horizontal acceleration is applied. Two different inclinations of the horizontal acceleration are considered, i.e., $\theta = 0^\circ$ and $\theta = 45^\circ$, the angle θ being defined in Figure 2. It is noted that, because of the symmetry of the model, there is no need to study both positive and negative directions.

The vault is confined by lateral Deformable Arches (DA) on three sides and by a rigid wall on one side (Figure 3). The boundary arches are 27 cm thick (i.e., about twice the vault thickness) and 50 cm depth. The mechanical properties adopted for the DAs are the same adopted for the masonry of the vault. Figure 3 also shows the fictitious plane which is introduced in the model to simulate the unilateral constraint of a rigid wall: the head arch of the vault in contact with the fictitious plane can detach from the plane, while it is prevented to compenetrare inside it. Similarly, contact between blocks of head arches and boundary structures is defined using the same interface behaviour adopted in the block-to-block contact definition. This means that normal compressive forces can arise, while no tension forces can develop.

Shear forces along the planes of the boundary structures can be generated, depending on the normal forces, according to the Mohr-Coulomb criterion.

Figure 3: Boundary conditions. Pinned supports in red.

3 PARAMETRIC ANALYSIS

A parametric numerical study is conducted with the aim of highlighting the effect of the masonry apparatus. Table 2 reports the list of the performed simulations. The results will be commented in the following sections.

ID	Pattern	Confinement	Angle [°]
1	R	DA	0
2	D	DA	0
3	R	DA	45
4	D	DA	45

Table 2: Parametric analysis.

4 RESULTS

By looking at the deformed shapes in Figure 4, it is possible to notice that the two vaults behave quite differently. Note that the deformed shapes are plotted without boundary arches, with the exception of plan and axonometric views, to better highlight the collapse mechanism of the vaults. When $\theta=0^\circ$, the radial vault collapses due to the formation of a global mechanism characterized by four parallel hinges normal to the direction of the seismic action. On the contrary, the diagonal vault does not experience a global collapse, but only one cap under-

goes instability. When the angle of the seismic action is $\theta=45^\circ$, the deformed shapes show an almost symmetric collapse mechanism on both radial and diagonal vaults, with respect to groins, as visible in Figure 5. In particular, the radial vault shows the formation of parallel hinges along the bed joints, once again denoting a global collapse mechanism. However, a local failure occurs in the region along the groins, where the sliding and detachment of few bricks take place. The diagonal vault shows a quite different crack pattern in comparison to the radial vault and a local failure occurs at the head arches of two opposite caps.

Figure 6 plots the load-displacement curves in the case of horizontal acceleration along the x -axis direction ($\theta=0^\circ$), for both considered masonry patterns. Two different control nodes have been chosen, in order to monitor the horizontal displacement in the x -direction: one node at the crown of the vault and one node at the key of the head arch of one cap, as shown in Figure 2. The load factor is obtained by normalizing the sum of the horizontal forces at the abutments to the vault's weight W , including the weight of the lateral confinement structures. The markers in Figure 6 and Figure 7 are referred to the values of imposed displacement $u_{c,Crown}$ and $u_{c,Key}$ that correspond to the activation of a failure mechanism.

Figure 4: Collapse shapes in Pushover analysis for $\theta = 0^\circ$: axonometric view (first row), x - z plane view (second row), y - z plane view (third row), planar view with contour plot of u_z displacement [m] (fourth row).

Figure 5: Collapse shapes in Pushover analysis for $\theta=45^\circ$: axonometric view (first row), y-z plane view (second row), x-z plane view (third row), planar view with contour plot of u_z displacement [m] (fourth row).

They have been identified by monitoring the reaction forces at each support, referring to a sudden decrease of force on the load-displacement curves, as visible in Figure 8.

In order to compare the capacity curves, the following quantities have been identified:

- R_{\max} , peak value of the load factor;
- $u_{c,Crown}$, maximum horizontal displacement at the crown of the vault before the activation of a collapse mechanism;
- $u_{c,Key}$, maximum horizontal displacement at the key of one head arch before the activation of a collapse mechanism;
- K_{el} , elastic stiffness, calculated as the ratio R_{60}/u_{60} between the 60% of R_{\max} and the corresponding settlement;
- u_{80}/u_{60} , ductility parameter where u_{80} is the settlement corresponding to R_{80} , i.e., to a post-peak 20% reduction of R_{\max} .

Table 3 reports the values of the above-defined quantities, while Table 4 reports their variation with respect to the radial pattern case for $\theta=0^\circ$. In particular, the table reports the variations in terms of $\Delta Q = (Q_{\text{pattern}} - Q_{\text{radial}})/Q_{\text{radial}} \cdot 100$, where Q is the generic quantity.

It can be observed that the two vaults have quite similar capacity, with variations below 20% with respect to the radial configuration for $\theta=0^\circ$. Also their behaviour in terms of elastic stiffness is similar, whereas the values of ductility differs greatly, depending on the considered pattern and value of θ . Specifically, when $\theta=0^\circ$ the diagonal vault is the one characterized by the lowest elastic stiffness (14.52% lower than the radial vault) and by the highest reduction of ductility with respect to the radial pattern (-53.08%). This last aspect is also visible in the load displacement curves in Figure 6, by looking at the values of displacement of the control nodes. As a matter of fact, in the radial vault, the horizontal displacement of the head arch is only 1.16 times greater than the horizontal displacement of the crown of the vault, whereas in the diagonal vault it is 2.65 times greater.

Figure 6: Capacity curves of confined radial and diagonal cross vaults for $\theta=0^\circ$.

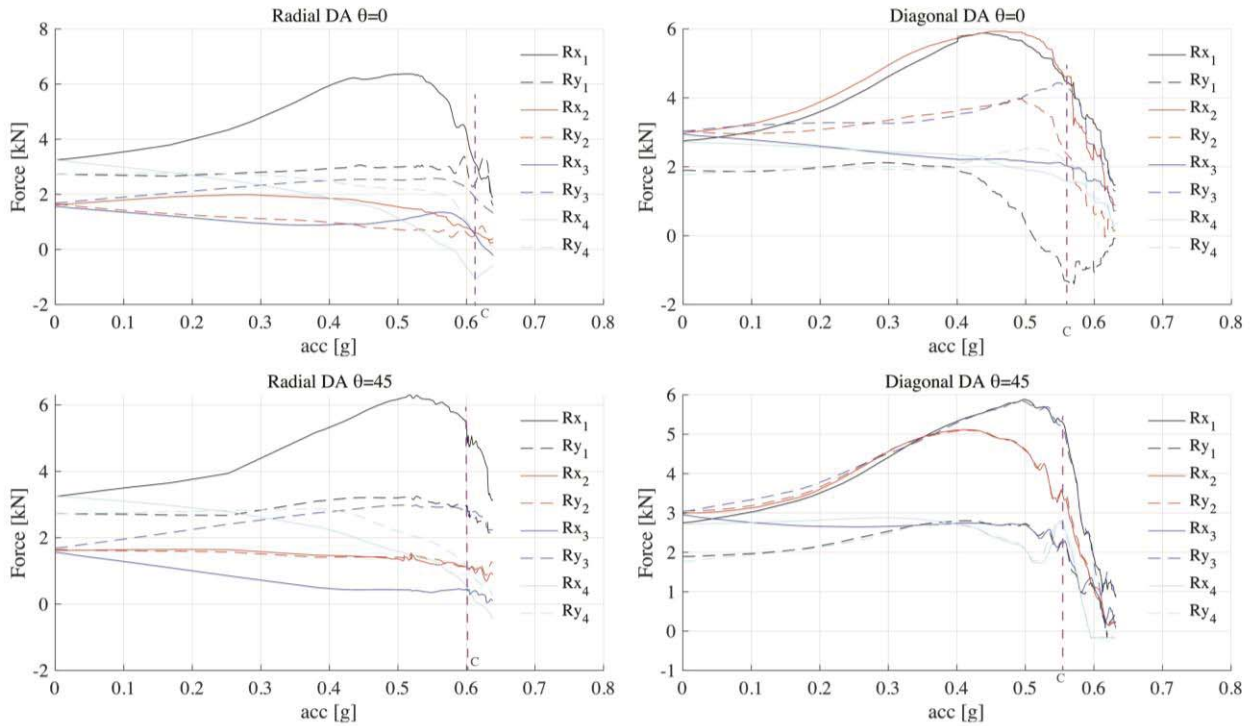

Figure 7: Capacity curves of confined radial and diagonal cross vaults for $\theta=45^\circ$.

Figure 8: Reaction forces R_x and R_y at the abutments vs. horizontal acceleration.

This means that the diagonal vault undergoes a partial collapse of one cap, but the crown of the vault is still stable. The different deformation mechanism induced by the two brick laying techniques is also highlighted by the vertical displacement field of the vaults, plotted before the activation of a collapse mechanism. In the case of the diagonal vault it is clearly visible how the damage is concentrated mostly in one cap, while the rest of the structure results almost undamaged.

When the direction of the seismic action is parallel to the groins, hence for $\theta=45^\circ$, the vault arranged with the diagonal pattern provides the greatest increase of ductility (+31.67%), while the radial vault suffers a decrease of ductility of about 8.84% if compared to the same vault with $\theta=0^\circ$. The radial vault also experiences the greatest increase of elastic stiffness, being 20.61% greater than the loading condition with $\theta=0^\circ$.

Pattern	R_{\max} [-]	$u_{c,Crown}$ [m]	$u_{c,Key}$ [m]	R_{60} [-]	$u_{60,Crown}$ [m]	K_{el} [N/m]·10 ⁶	$u_{80,Crown}$ [m]	u_{80} / u_{60} [-]
Radial $\theta=0^\circ$	0.469	0.131	0.169	0.282	0.0020	10.05	0.158	78.9
Diagonal $\theta=0^\circ$	0.394	0.064	0.233	0.236	0.0019	8.59	0.072	37.02

Pattern	ΔR_{\max} [%]	ΔK_{el} [%]	$\Delta(u_{80} / u_{60})$ [%]
Diagonal $\theta = 0^\circ$	-16.07	-14.52	-53.08
Radial $\theta = 45^\circ$	-10.68	20.61	-8.84
Diagonal $\theta = 45^\circ$	-20.22	10.21	31.67

Table 4: Variation of peak reaction force, elastic stiffness and ductility compared to the radial vault with $\theta = 0^\circ$.

5 CONCLUSIONS

- In this paper the results of a parametric analysis on the seismic response of cross masonry vaults are presented.
- The geometry of an ideal vault is considered taking into account its detailed brick pattern.
- The FEM simplified micro-modelling approach is adopted for the discretization of the volume of the structure, endowing the interfaces with tangential frictional behaviour and normal rigid compressive contact. Free detachment is allowed under traction. Linear elastic behaviour is assumed for the masonry blocks.
- Two different brick patterns are considered, i.e., radial and diagonal. Static non-linear analyses are performed, assuming two different directions of the seismic input in the horizontal plane, namely 0° and 45° .
- The results show that the influence of the brick pattern on the seismic response is limited in terms of seismic load capacity and elastic stiffness, while it highly affects the ductility. In particular, diagonal bed joints are able to provide the vault with almost twice displacement capacity.

Abstract

This paper outlines the characterization of masonry walls composed of “Scaglia Rossa”, a typical stone of the Apennine area between the Umbria and Marche Regions in Central Italy. The study focuses the assessment of the mechanical behavior by means of an experimental campaign carried out in the laboratory of the Polytechnic University of Marche, where the samples of “Scaglia Rossa” masonry, obtained from the controlled demolition of three school buildings, were reconstructed with the same techniques of the 1950s-‘60s, and then tested in order to identify both the constituent materials, stone and mortar, and the composite masonry. The experimental tests were prior to a numerical analysis implemented by the adoption of a nonlinear model capturing the cracking behavior. The main mechanical parameters were then calibrated by means of an optimization algorithm of Levenberg-Marquardt, considering a continuous approach in macro-modelling techniques and obtaining resistance parameters not deriving directly from the experimental tests. The comparison between the results obtained from the Levenberg - Marquardt algorithm by changing the parameters of the damage model based on data given by the experimental campaign allowed to confirm the validity of the approach used.

1 INTRODUCTION

In the recent years all over the world an elevated number of seismic events was seen, especially in the southern subregion of Europe [1]–[4]. These events caused important damages to the architectural heritage and lead to the need of in-depth investigation on the quality of materials and buildings. The features that complement a construction are, in fact, of fundamental importance in order to acquire a complete comprehension of how historical building heritage behaves under both static and dynamic loads. Italy, has been affected by diverse earthquakes (Friuli (1976), Irpinia (1980), Umbria-Marche (1996-1997), Molise (2002), L’Aquila (2009), Emilia-Romagna (2012), and Central Italy (2016-2017)) and the need to evaluate damage before a restoration project commenced was outlined. The occurred events characterized the damage and collapse of a great number of buildings demonstrating how fundamental is to assess adequately restoration works since the common ground between the various cases is made by poor quality mechanical characteristics of masonry, together with absence of connection between vertical and horizontal elements components that define the structures. The quality of masonry is determined by the features of both mortar and stone and presents in many cases the starting point of the investigation for the diagnosis, since the processes of rehabilitation and restoration are accomplished if the actual state is known. The behavior of masonry’s components (mortars and stones), becomes important since masonry is a composite material that is obtained by joining artificial or natural bricks by means of mortar layers. Due to this above-mentioned reason, stiffness and resistance have great variability but can still characterize masonry materials by means of average values that are not only provided through means of codes or manuals but also experimental campaigns. In most of the Italian Regions it was seen that the seismic activity was intense through the centuries and especially in the area that defines the Apennine region between Umbria and Marche where the heritage is characterized by rural, vernacular masonry [5]. The material mostly used to define the construction techniques of the area is called “Scaglia Rossa” and is the focus of the experimental campaign and numerical non-linear modelling approach of the present paper [6], [7]. In Section 2, the methodology for the experimental campaign is presented and it is explained also the numerical approach used to identify the results of the campaign numerically. Section 3 dwells in more detail on the construction technique utilized for the components that were used during the experiments and Section 4 gives more detail on the numerical approach and damage evaluation results that were defined. In Section 5 the summarized discussion and conclusions are found.

2 METHODOLOGY

The methodology that was followed for the present work is divided in three parts. The first part contains the research done in bibliography for the identification of the construction schemes that used the “Scaglia Rossa” material in the Apennine area and the in-situ campaign that was done in order to identify visually the constructions and select the sample materials that are to be used later in the laboratory experimental tests. The second part englobes the tests that followed to identify the mechanical properties of the samples were done in the the “*Laboratorio Prove Materiali e Strutture*” of the Polytechnic University of Marche (Ancona, Italy). The test considered were divided in two categories, the first for the mortar and the second for the stone samples. In summary, these tests consisted of three-point bending tests, load bearing tests for the mortar and “Scaglia Rossa” samples individually and shear - compression tests for matrices that were constructed in the laboratory, following the double leaves technique. The third part was initiated once the results of the experimental campaign were known. It was then that the numerical modelling began and was done in order to calibrate with the Levenberg-Marquardt algorithm present in the open source software Code_Aster, the non-

linear Mazars damage model parameters onto the experimental results, [8]–[12]. This was done to see if the algorithm can calibrate the parameters and to confirm numerically with a macro-model approach the evolution of the damage seen in the experimental campaign.

3 CASE STUDY

In the Apennine area, after the II World war, the zones between Marche and Umbria were built with a relatively new, compared to the older techniques, local material that was easily available and abundant called “Scaglia Rossa”. This material monopolized the market in the years between the 50’s and 60’s instead of bricks, tuff and concrete blocks that were also later introduced. Coming into more recent years and specifically concentrating attention on the 2016-2017 seismic sequence and the damages it caused in Central Italy, the examinations of engineers reported that the structures consisting of this limestone were considerably damaged. The damage reports consider at the end of the seismic sequence cases of disintegration of the masonry, and out-of-plane mechanisms were rare compared to frequent cracks encountered on the examined panel planes.

The experimental campaign was carried out in the “*Laboratorio Prove Materiali e Struttura*” of the Polytechnic University of Marche (Ancona, Italy), where the samples of “Scaglia Rossa” masonry were accumulated. The samples derived from three school buildings [13]–[15], where controlled demolitions were done. The samples then were assembled using the construction technique of 1950’s – 60’s and were tested in order to identify the mechanical properties of the constituent materials, stone and mortar, and the composite masonry. Initially, load bearing tests were carried out for the selected “Scaglia Rossa” specimens and tested to measure the compressive resistance of the limestones. Afterwards, four matrices were assembled with a cement mortar mixture with percentages that were found in literature to near the construction technique of the initial period (1950’s – 60’s). Mortar samples were extracted and tested with three-point bearing and load bearing tests (on the remaining portions), after 28 days of curing.

Diverse FE models were developed to reproduce the data acquired by the experimental campaign and a calibration process was executed with the Levenberg – Marquardt algorithm present in open source software Code Aster, developed by EDF (Electricité de France), in order to obtain the parameters that characterize the non-linear evolution and could not be directly measured from the experimental tests.

4 SPECIMENS SETUP AND MECHANICAL CHARACTERIZATION

The constructed walls for the masonry mechanical parameters evaluation are four in number and are made with samples of different sizes and shapes utilizing a double leaves technique (Figure 1). Two different kind of tests were performed: a load bearing test in order to establish the behavior under vertical static loads on one wall and load-bearing tests in order to establish the resistance to horizontal loads acting in the plane for all three walls. The dimensions of the four constructed walls are reported in Table 1.

Wall N.	Base (mm)	Length (mm)	Height (mm)
Wall matrix n.1	760	846	500
Wall matrix n.2	750	862	500
Wall matrix n.3	720	860	500
Wall matrix n.4	740	857	500

Table 1: Wall specimens’ geometrical properties

Figure 1: Construction process followed for the wall specimens with "Scaglia Rossa" limestone applying the double leaves technique.

The load bearing test for the wall matrix follows the Italian legislation and is provided by UNI EN 1052-1:2001. This experiment aimed to understand the level of axial force that can be supported by the composite specimen and to provide indications in presence of only vertical forces. The force-displacement curve was obtained by using two LVDT between the frame and the steel plate in the top of the specimen to gain the displacement (Figure 2).

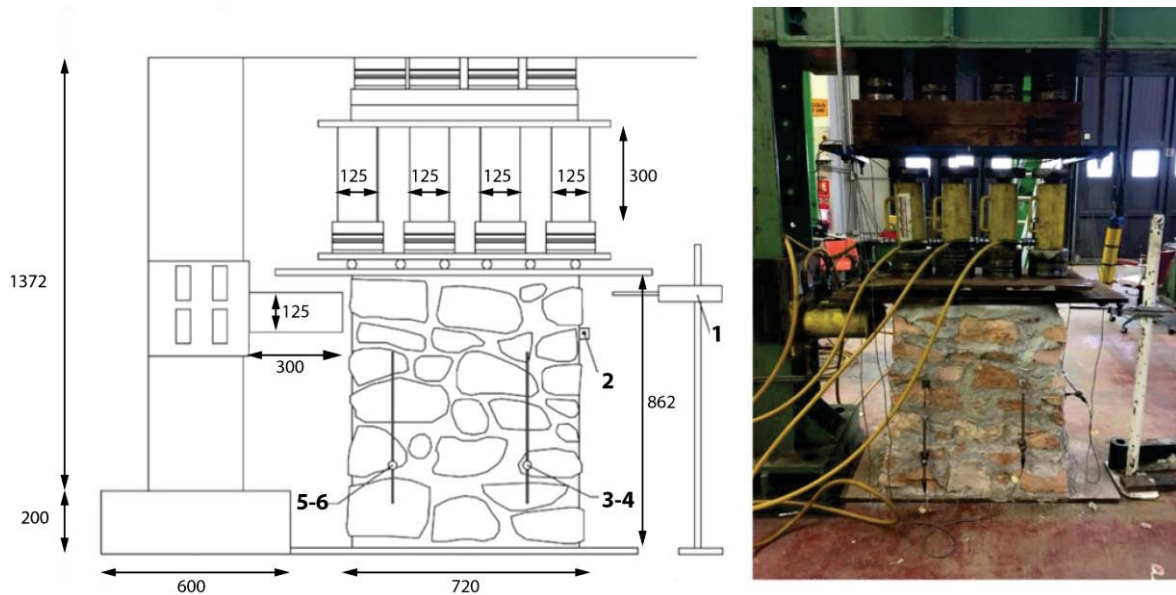

Figure 2: Load-bearing - shear apparatus with example of one matrix specimen. The numbers indicate the dimensions of the apparatus and the positioning of the strain gauges used to measure displacements (measures in mm).

Figure 3: Force - Displacement (kN - mm) evolution curve with the enveloped curve of the Wall#4 that was subjected to load-bearing test.

The results indicate that the range between 0 – 800 kN the displacement values are almost null, while the in the range between 900 – 1200 kN there is augmented displacement. The peak of the curves is found in the 1800 kN range where a clear plateau is visible (Figure 3). Once the horizontal evolution was observed, three ulterior cycles were applied to evaluate residual displacements and possible accumulated damage. The wall had reached its ultimate limit and is able to withstand numbers of cycles without a decrease in stiffness (Figure 4).

Figure 4: (a) Installed displacement transducers on the wall matrix, (b, c) damage on the specimen caused by the load - bearing test.

For the shear-compression tests a constant precompression load of 400 kN was applied and kept constant during the entirety of the procedure. Afterwards, the hydraulic actuators are activated once the stabilization of the vertical force has occurred. The resulting shear force-displacement curves of the three specimens are shown in Figure 5.

Figure 5: Summary of the horizontal force (kN -mm) curves of the specimens subjected to load-bearing-shear tests

All the performed tests showed homogeneity in their behavior, with a maximum resistance standing above 500 kN except for local criticalities. In more detail, Wall#1 retains the maximum force applied at 580 kN with the displacement arriving at 2.6 mm or the drift is 0.31%. For Wall#2, the maximum force stands at 500kN for a drift of 0.18% and Wall#3 a maximum force of 580kN is observed for a drift of 0.22%. The drift values are comparable with values encountered in National Standards for nonlinear analysis of masonry's walls. The absence of plateau is given to the highly fragile behavior of the specimens once the maximum force is reached. The damage observed indicates in all the specimens a diagonal rupture due to compression and shearing and in some cases panel disintegration when the maximum force applied was reached (Figure 6).

Figure 6: Damaged specimens at the end of the load-bearing-shear test for Wall#1, Wall#2 and Wall#3.

The non-monolithic behavior of such matrix is well represented and does confirm the behavior found commonly in stone walls made by substantially joined faces with diatones providing connections transversally.

5 NUMERICAL METHODOLOGICAL ANALYSIS AND RESULTS

Once the experimental campaign was concluded, with the geometrical information received, diverse Finite Element models were developed for each test of the campaign. To consider the material non linearities, Mazars damage model was considered, and a calibrations process was followed. The process had as its objective the calibration of Mazars damage model parameters (Isotropic scalar damage model), with the Levenberg – Marquardt algorithm,[16], in order to capture the force – displacement curves course and to visualize and evaluate the resulting damage coming of the specimens at the end of the experimental campaign on macro – models, [17]–[21].

The model for the analysis and calibration of Mazars damage model was constituted by 3887 nodes and 16930 tetrahedral elements. For the load-bearing model, the nodes number arrives at 4231 while the tetrahedral elements are 16445. The left side panel substitutes the place of the two hydraulic heads with an equivalent plate. The decision to model this part was to reduce possible errors of the calculation by mesh incompatibilities. The loading was given at the top and left face of the equivalent steel plates of the model while the bottom side is fixed (Figure 7).

Figure 7: Macromodel geometry and mesh representation

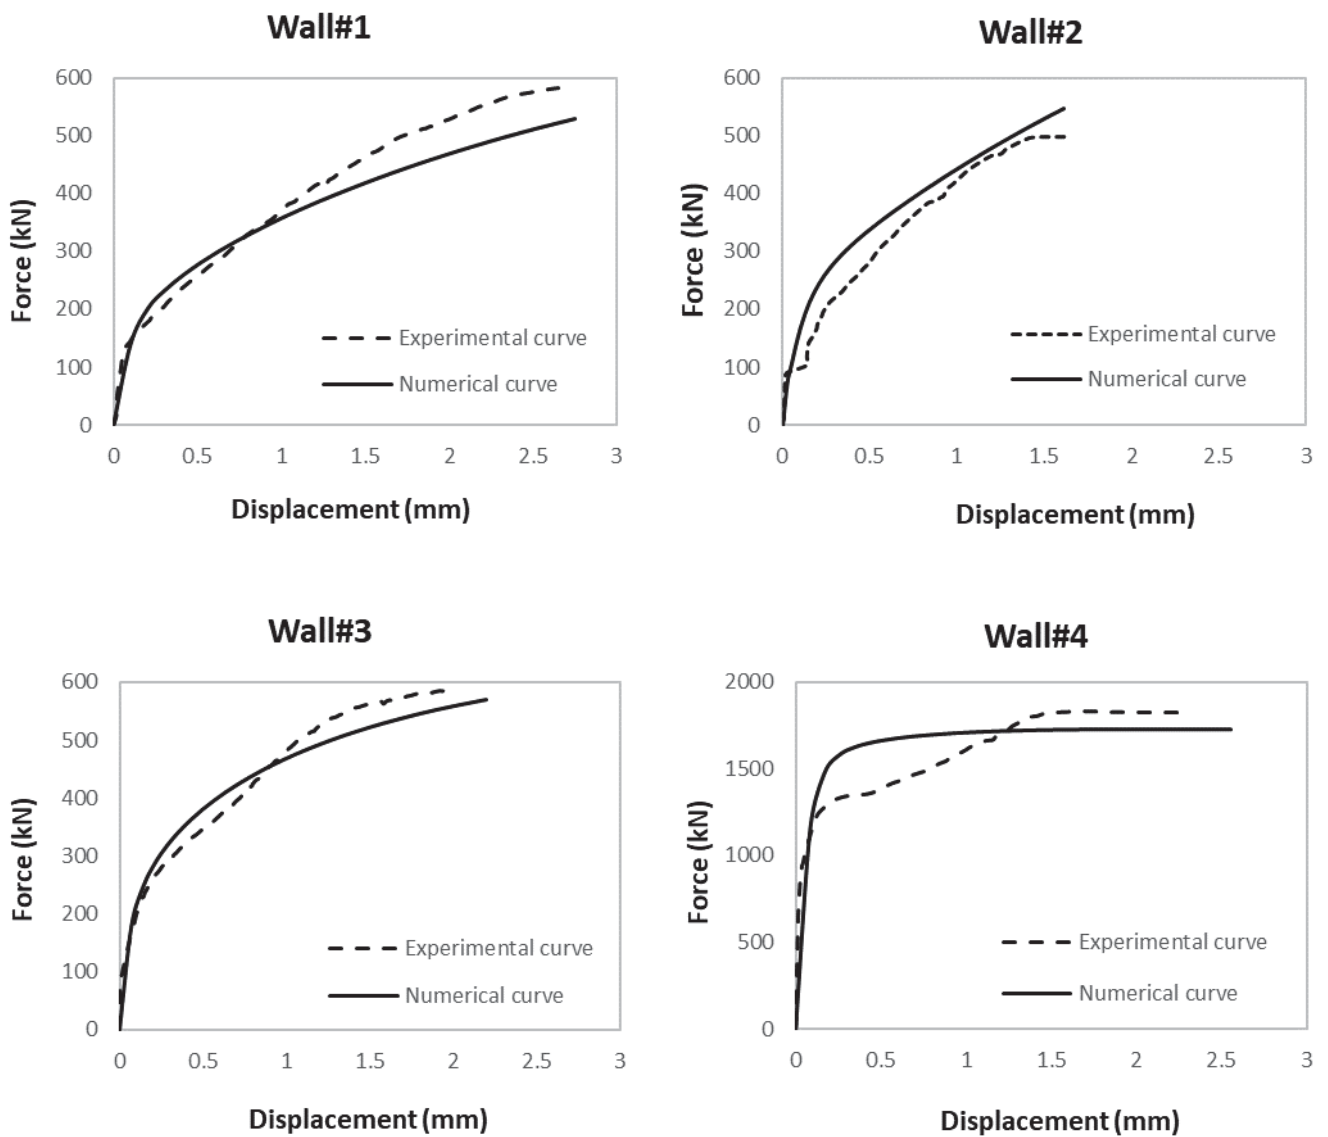

Figure 7: Comparison between the experimental and numerical force - displacement curves (kN - mm), results of the macro-modelling approach.

The results of the calibration by the Levenberg – Marquardt algorithm, obtained under the form of force – displacement curves and the fit with the experimental curves is shown in Figure 8 and the values product of the optimization process in Table 2. In all cases, it was possible to capture the progress of the compression – shearing with discrepancies shown for Wall#2 and Wall#3 that was caused by progressive disaggregation of the materials during the experimental tests.

Wall #	E (MPa)	ν	A_t	A_c	B_t	B_c	k	E_0 (10^{-5})	Error (%)
(1)	4049.3	0.243	1.120	0.158	5020	99.3	0.808	5.66	1.56
(2)	3000.0	0.400	1.170	0.843	6800	0.10	1.090	0.108	3.69
(3)	4843.8	0.150	0.460	0.223	7260	104.0	0.700	0.0276	3.94

Table 2: Calibration results of Mazars damage model parameters

Figure 8: Numerical damage evolution for (a) Wall#1, (b) Wall#2, (c) Wall#3, (d) Wall#4.

The damage of the numerical models is concentrated to the upper-right and lower-left sides of the specimens and evolves later in the middle part of the specimens where the diagonal

damage is evident. In comparison to the actual damaged state of the specimens, visually the damage is found to evolve diagonally and at the base of the specimen, so the numerical propagation in this point seems to be visually in good correspondence as can be seen in Figure 8. The damage evolution is initially concentrated in the inverse diagonal in respect to the experimental schemes. While the shearing process continues so does the damage in the correct diagonal direction and it is at that point that it corresponds to the results of the campaign.

6 CONCLUSIONS

The studies of the present work are carried out to assess the mechanical behavior of masonry walls build utilizing the “Scaglia Rossa” stone, a material typical of the area that encircles the Apennine regions between Umbria and Marche in Central Italy. Diverse experimental tests and numerical analyses by finite element method were performed with the aim to provide quantitative indications for the professionals that are involved in the reconstruction and rehabilitation works in the area affected by the renowned earthquake of Central Italy in 1997. The experimental campaign involved several tests on the constructed masonry composite that was reconstructed using techniques adopted in 1950’s and 1960’s. The specimens, in presence of shear loading, demonstrated an evident fragile behavior connected with the diagonal failure due to compression and shearing deformations. This characteristic mechanism was observed in all investigated cases. Also, several finite element models were developed aiming to reproduce the resulting data of the experimental campaign. This work was assisted by a calibration process by the Levenberg – Marquardt algorithm to fit the numerical process on the experimental results and validate if Mazars damage model can reproduce the specimen’s evolution of damage. The results obtain under the form of force – displacement curves on a macro – modelling approach and reproduced the experimental behavior visually. The summary of both experimental and numerical approaches appear to be of importance in order to define the non-linear and numerical behavior of the material “Scaglia Rossa” masonry, in order to be utilized under design orders for specific restoration projects whose focus is based on structural fragilities featuring the recent seismic activities.

Abstract

The seismic vulnerability of masonry towers is a critical research field and it has an important role in the preservation of worldwide conservation of such kind of masonry building. Indeed, masonry towers have a very high seismic vulnerability and are often located in high seismic hazard zones. Researches about this topic have become even more frequent in the last decades. However, the results about the seismic behaviour of the masonry towers are still limited and further researches are needed. This paper aims to study the value of the behaviour factor (usually called q -factor or R -factor) of ancient masonry tower-like structures. This parameter provides quantitative information about the ductility of the tower and it can be computed by the capacity curve of the structure. In particular, the pushover curve can be bilinearized, and the q -factor can be computed according to the equal displacement or equal energy rule. The bilinearization of the capacity curve implies the knowledge of the ultimate displacement, whose computation is not a trivial task for this kind of structures because the capacity curves usually computed for such structures are apparently infinite ductility curves and the ultimate displacement cannot be directly computed. Therefore, an innovative pushover method (called “manual” pushover) has been formulated and implemented in a Matlab® code to achieve the q -factor computation goal. The tower is modelled by a vertical cantilever beam with lumped plasticity and it is loaded by self-weight and a user-defined horizontal distributed load profile. The non-linearities are modelled by the Moment-Curvature diagram of the cross-section where the plasticity is lumped. These cross-sections are positioned along the height of the tower splitting it into parts as uniform as possible in material and geometry characteristics. It allows considering the influence of openings and irregularities. The capacity curve is built by curvature control; it is similar to a displacement control and it allows to

capture the softening branch and, consequently, to compute the ultimate displacement. This method is quick, computationally light and it has been properly benchmarked with FEM results. The obtained capacity curve fits the request of the q -factor computation method presented above. It is worth noting that the Moment-Curvature diagrams have been computed by a Matlab code based on digital image processing. In particular, it can read the geometry of a generic cross-section through its digital image representation and it automatically computes the diagram according to equilibrium, compatibility and energy considerations. Finally, the q -factor value has been computed for various real case-studies highlighting its strong variability on the tower geometry (e.g. slenderness and shear area). The results have been compared with the suggested behaviour factor given by the Italian Guidelines for Built Heritage (2011) and it has been found that the code suggestions overestimate the tower ductility and they are too limited.

Keywords: masonry towers; earthquake; simplified models; pushover; Matlab; behaviour factor.

1 INTRODUCTION

The seismic vulnerability of masonry towers is a critical research field and it has an important role in the preservation of worldwide conservation of such kind of masonry building. Indeed, masonry towers have a very high seismic vulnerability and are often located in high seismic hazard zones. Researches about this topic have become even more frequent in the last decades. However, the results about the seismic behaviour of the masonry towers are still limited and further researches are needed.

Masonry towers have usually shown high seismic vulnerability [1–6] and their seismic response is complex and depends on various parameters, both mechanical and geometrical. In [7,8], the authors have demonstrated that five collapse mechanisms (Figure 1) are the most likely to occur and they depend on both slenderness and shear area.

Figure 1 Collapse mechanism for masonry towers selected in [7] (images adapted from [7]).

Various analysis methods have been usually applied. Non-linear static and dynamic analysis are the most diffused analysis tools and they have been fully and successfully used in [1,2,9–12]. Also, simplified methods have been introduced, like the kinematic limit analysis has shown its accuracy and efficiency in various studies (e.g. in [7,8,13,14]). More sophisticated methods have been recently discovered, like the DEM modelling [7,15] or the Non-Smooth Contact Dynamic method [16].

Towers specific features have been analysed too. In [17–19] it has been demonstrated the importance of the tower inclination in their seismic assessment, while the influence of the surrounding buildings has been studied in [20].

This paper aims to study the value of the behaviour factor (usually called q -factor or R -factor) of ancient masonry tower-like structures. This parameter provides quantitative information about the ductility of the tower and it can be computed by the capacity curve of the structure. The capacity curve can be bi-linearized, and the behaviour factor may be computed according to the equal displacement rule or equal energy rule.

The bilinearization of the capacity curve implies the knowledge of the ultimate displacement, whose computation is not a trivial task for this kind of structures because the capacity curves usually computed by FE simulations for such structures are apparently infinite ductility curves and the ultimate displacement cannot be directly computed.

To achieve this goal, an innovative pushover method has been developed by the authors and it has been called "manual" pushover analysis. It is based on the modelling of the tower as a cantilever beam with lumped plasticity and it is loaded by self-weight and a user-defined horizontal distributed load profile.

The non-linearities are modelled by the Moment-Curvature diagram of the cross-section where the plasticity is lumped. These cross-sections are positioned along the height of the tower splitting it into parts as uniform as possible in material and geometry characteristics. It allows considering the influence of openings and irregularities.

The capacity curve is built by *curvature* control; it is similar to a displacement control and it allows to capture the softening branch and, consequently, to compute the ultimate displacement. This method is quick, computationally light and it has been properly benchmarked with FEM results. The obtained capacity curve fits the request of the q-factor computation method presented above. The Moment-Curvature diagrams have been computed by a Matlab code based on digital image processing. In particular, it can read the geometry of a generic cross-section through its digital image representation and it automatically computes the diagram according to equilibrium, compatibility and energy considerations.

Finally, the q-factor value has been computed for various real case-studies highlighting its strong variability on the tower geometry (e.g. slenderness and shear area). The results have been compared with the suggested behaviour factor given by the Italian Guidelines for Built Heritage (2011) and it has been found that the code suggestions overestimate the tower ductility and they are too limited. In particular, the suggestion made by the Italian Guidelines provides a double choice for the behaviour factor value: equal to 3.6 for regular towers and 2.8 for irregular ones. This value is used in the LV1 procedure proposed by guidelines, which is a method to quickly study the seismic vulnerability of such structures. The behaviour factor value is inversely proportional to the applied inertia horizontal forces; therefore its overestimation may lead to unsafe results. Similar final considerations have been produced also in [21].

A real case-study will be considered: a Chinese masonry pagoda (the *Longhu Pagoda*). It is the case study presented in [22], in which several FE pushover analyses have been carried out. These data will be used in this paper.

Figure 2 Lumped plasticity model for the "manual" PO applied to the Longhu Pagoda.

The structure of this paper is as follow. Section 2 will briefly present the “manual” pushover method and its validation. Finally, in Section 3 the assessment of the behaviour factor value is reported. Discussions and conclusions are drawn in Section 4.

2 THE “MANUAL” PUSHOVER ANALYSIS

Unfortunately, pushover analysis often needs sophisticated FE tools. Thus, a simplified pushover method is presented for masonry towers seismic assessment. The computational cost

is lower, and no FE software are needed. A similar method but with different algorithms and analysis tools has been proposed in [23].

The tower is modelled as a cantilever beam with lumped plasticity. The plastic properties are considered through the Moment-Curvature ($M-\chi$) diagram where the plasticity is lumped. The tower body is split into n parts, posing the horizontal cutting, particularly at openings and irregularities. Each part has to be as uniform as possible in geometry and materials, similarly to what is suggested by Italian guidelines [24] to apply the LV1 analysis. An example is represented in Figure 2.

The $M-\chi$ diagram has been computed by a Matlab subroutine the author has created that can compute specific cross-sections properties based on a digital image processing of cross-section itself and equilibrium equations (a specific study will be published on this algorithm by the authors, an example is shown in Figure 3). The diagram is computed by considering a compressive axial force equal to the weight of the tower above the cross-section itself. The material model is implemented through a non-linear stress-strain relationship with softening both in tension and compression. Figure 4 shows the implemented stress-strain relationship, while Table 1 reports the main mechanical parameters. The material properties have been supposed according to the usual values of masonry models.

Figure 3 Example of the implemented $M-\chi$ diagrams.

Figure 4 The implemented stress-strain relationship.

Density ρ [kg/m ³]	Young's Modulus E [MPa]	Poisson's Coeff. ν [-]	σ_c [MPa]	σ_t [MPa]
2000	1600	0.2	1.5	0.075

Table 1 Main mechanical parameters.

The proposed “Manual” pushover analysis is performed in *curvature* control. It is a sort of *displacement* control method that allows capturing the softening branch. The curvature is progressively increased in a chooses cross-section (i.e. the first one that would fail, named *controlled* cross-section). Both G1 and G2 (Figure 5) load distributions have been used. The structure is statically determined, thus the bending moment diagram depends only on equilibrium considerations and its expression will never lose its validity during the whole analysis procedure. The usual formulas used to compute the bending moment distribution on a cantilever beam have been used. The external horizontal load is progressively incremented

and the equilibrium at each step is achieved. Through the bending moment at each cross-section and the related $M-\chi$ diagrams, the curvature distribution is computed along the height and, subsequently the top displacement. Finally, the capacity curve is obtained by the base shear and the top displacement at each step.

Figure 5 G1 and G2 load distributions.

The horizontal load value decrease after that the structure strength reaches its pick and the same happen to the bending moment distribution. However, while in the *controlled* cross-section the *curvature* is continuously increased, the other cross-sections experience a decreasing in bending moment and the same happens to the curvature: linear unloading is implemented for them.

The method has been applied to real case-studies and its results have been compared to capacity curves obtained by FE simulations. It is the *Longhu Pagoda* which is a Chinese masonry pagoda and it is the case study presented in [22]. The data collected in this latter study are presented here to show the validity of the “manual” pushover method.

Figure 6 The pagoda models.

In [22] peculiar considerations have been made on the slenderness influence by building two fictitious models of the pagoda adding and removing two floors. In this way, the interiors

and mass distribution are still plausible. The three models are shown in Figure 6 and the interested reader is remanded to [22] for further details about them. Therefore, three case-studies will be presented in the following. The material model is reported in Figure 4 and Table 1. Both G1 and G2 load cases have been considered and the pushovers have been carried out along the z^+ direction only (Figure 6).

The “manual” pushover results have been compared with the FEM pushover capacity curves presented in [22] and carried in the Abaqus environment. The material models are similar in terms of a stress-strain relationship. Figures 7-9 shows the comparison between the capacity curves for the three models. The “Load Factor” is the ratio between the total base shear and the total weight of the structure. A new phenomenon is here present: the *snap-back* of the top displacement in the last phases of the analysis. This novelty has been possible to be caught only thanks to the special pushover control parameter used (i.e. the *curvature* control in the worst cross-section). Apart from the “+2 Model”, in which the predictions of the two methods differ, in the other cases good agreement is achieved. These results will be used to compute the behaviour factor of the pagoda.

Figure 7 Abaqus vs Manual POs: original model.

Figure 8 Abaqus vs Manual POs: “-2 Model”.

Figure 9 Abaqus vs Manual POs: “+2 Model”.

3 THE BEHAVIOUR FACTOR OF THE TOWER

To estimate the q -factor it has been decided to use the bi-linearization of the capacity curve and then to apply the equal displacement rule or the equal energy rule. The bi-linearization

procedure is taken from the Italian building code [25] and its schematization is shown in Figure 10. It is a function of the frequency content of the seismic action (its elastic-response spectrum) and the natural period of the structure.

Figure 10 Equivalent bi-linear curve (adapted from [25]).

Figure 11 Equal displacement criterion (adapted from [26]).

In particular, considering the elastic system and the elastic-plastic system (Figure 11), they are related between each other according to the value of the natural period of the structure and the period T_c , which is the upper limit of the period of the constant spectral acceleration branch in the elastic response spectrum that represents the seismic demand (as defined in the Eurocode 8 [27]). In this case $T_c = 0.4 \text{ s}$ (according to the spectrum defined by the Chinese Building Code [28] for the site of the pagoda and presented in [22]). Two cases can be defined:

- $T \geq T_c$: the ultimate displacement is the same between the elastic and the elastic-plastic system (Figure 11) (“equal displacement” criterion).
- $T < T_c$: the deformation energy is the same between the elastic and the elastic-plastic system (“equal energy” criterion).

The q-factor can be computed by Eq. (1).

$$\begin{aligned} q &= \mu & T &\geq T_c \\ q &= 1 + (\mu - 1) \frac{T}{T_c} & T &< T_c \end{aligned} \quad (1)$$

where $\mu = \frac{d_u^*}{d_y^*}$. Note that $\frac{F_e}{F_y^*} = \frac{d_u^*}{d_y^*}$ if $T \geq T_c$.

This method has been applied to the capacity curves obtained from the “manual” pushovers. As an example, the computations made on the capacity curve related to the “manual” pushover performed on the original model along the z+ direction with a G1 load distribution is shown in detail (Table 2 and Figure 12). Table 3 report the behaviour factors computed for each case. It is worth noting that the behaviour factor changes as the applied load and the height change. Moreover, the value computed for the “+2 Model” might be furtherly studied due to the discrepancy between the “manual” pushover and the FE capacity curves.

It is noticeable that the behaviour factor values presented in Table 3 are lower than the values proposed by the Italian guidelines [24] and they are different from each other. This means that what is suggested in [24] may lead to unsafe and unrealistic results in terms of seismic vulnerability. Indeed, the Italian guidelines [24] propose two values of the behaviour factor:

3.6 for regular towers and 2.8 for irregular ones and these suggestions are not confirmed by this research.

F_{MAX}	F_Y	d_Y	d_U	T	T_C	μ	q

+2	G2	1.485

Table 3 Behaviour factor's values

4 CONCLUSIONS

This paper has studied the value of the behaviour factor of masonry towers through an innovative pushover method that allows to capture the softening branch and thus, to apply the bi-linearization procedure to the capacity curve to compute the behaviour factor.

The behaviour factor values have been computed for some case-studies: three Chinese masonry pagodas with different slenderness. The behaviour factor has been computed by the capacity curves of these structures obtained from the application of the “manual” pushover method using both a G1 and G2 load distribution.

The computed values of the behaviour factors show that the suggestions of the Italian guidelines may underestimate it. Indeed, the Italian guidelines [24] propose two values of the

behaviour factor: 3.6 for regular towers and 2.8 for irregular ones and these suggestions are not confirmed by this research.

Therefore, further analysis of this topic may be useful to better quantify the behaviour factor of masonry towers and to propose new guidelines. Indeed, the simple and reliable formula may be very useful for practitioners for the safety assessment of the masonry towers. However, this study has shown that the behaviour factor may depend on several factors, among them the geometry of the structures. To assess these dependencies, further researches will be needed.

Abstract

The seismic vulnerability of masonry chimneys is a critical research topic, and it has an important role in the preservation of such kind of structural type. Indeed, masonry chimneys have a very high seismic vulnerability and are sometimes located in high seismic hazard zones. Researches about this topic have become even more frequent in the last decades. However, the results are still limited, and further studies are needed. This paper aims to study the seismic behaviour of a 20th-century masonry chimney located in Spain, focusing on its ultimate behaviour. In particular, various FE pushover analyses have been carried out in Abaqus/CAE using a quite accurate 3D model of the chimney. The pushover analyses have been made along the four principal directions, and both G1 and G2 load distributions have been applied. The material properties have been chosen according to previous studies carried out on similar structures because no specific experimental data were available. The obtained capacity curves have been compared with each other, and the main weak points of the chimney have been pointed out. Finally, a sensitivity analysis has been done to better understand the influence of the viscosity parameter on the pushover results in terms of ultimate capacity and computational effort. The latter one is an input value of the Concrete Damage Plasticity model, an Abaqus built-in material model, widely used to represent the non-linear behaviour of masonry structures.

Keywords: masonry chimneys; earthquake; pushover; Finite Element Method; CDP; viscosity parameter; computational effort

1 INTRODUCTION

The seismic vulnerability of masonry chimneys is a critical research topic, and it has an important role in the worldwide conservation of such kind of masonry structures. Indeed, masonry chimneys have a very high seismic vulnerability and are often located in high seismic hazard zones. Researches about this topic have become even more frequent in the last decades. However, the results about the seismic behaviour of the chimneys are still limited, and further research is needed.

Generally, masonry tower-like structures have usually shown high seismic vulnerability [1–6]; their seismic response is complex and depends on various parameters, both mechanical and geometrical. Different analysis methods have been usually applied. Non-linear static and dynamic analysis are the most used analysis tools, and they have been fully and successfully used in [1,2,7–10]. Also, simplified methods have been introduced, like the kinematic limit analysis has shown its accuracy and efficiency in various studies (e.g. in [11–14]). [15–17] have demonstrated the importance of the tower inclination in their seismic assessment, while the influence of the surrounding buildings has been studied in [18].

Chimneys are usually brickwork structures, and their typical high slenderness makes them very vulnerable when subjected to horizontal actions: it has been highlighted in [19] that such structures may be affected by several actions, and among them, earthquakes play a significant role. Therefore, their ductility against horizontal loads is crucial. Specific studies on these structures have been presented in [5,19–25].

This paper aims to study the ultimate behaviour of such structures by using some pushover analysis carried out with Abaqus/CAE and applied to a real case-study: a 20th-century masonry chimneys located in Villar del Arzobispo (Spain) (Figure 1). It is almost 28m high, and the base edge is 2.4m long. The base cross-section is a square and became octagonal after almost 5m from the ground. A small opening is present on one of the base facades, and it is directly connected with the flue, which runs from the base to the top of the chimney with the same shape as the exteriors. Figure 2 shows the 2D technical drawing of the chimney.

Figure 1: The chimney located in Villar del Arzobispo (Spain) used as a case-study of this research.

Figure 2: Technical drawing of the Villar del Arzobispo's chimney.

Different POs analyses have been produced, loading the chimney along the four principal directions and using both the G1 and G2 load distributions (Figure 3). The material properties have been chosen according to previous studies carried out on similar structures because no specific experimental data were available. The plastic properties have been considered through the Concrete Damage Plasticity (CDP) model, an Abaqus built-in material model, widely used to represent the non-linear behaviour of masonry structures. The results have been used to compare the capacity curves between each other and point out the chimney's main weak points. Finally, a sensitivity analysis has been done on the viscosity parameter. The latter one is a numerical input value of the CDP, and it helps the analysis's steps to converge by smoothing the yield surface. It has been often highlighted that the viscosity parameter increment tends to overestimate the ultimate capacity (e.g. in [26]). On the other hand, the decreasing of the viscosity parameter increase the computational effort; therefore, a sensitivity

analysis on this parameter may be helpful to better understand the influence of this parameter on the pushover results.

Figure 3: G1 and G2 load distributions.

The structure of this paper is as follow. Section 2 will briefly present the pushover results related to the analyses carried out on the four principal directions with fixed model properties, while, in Section 3, the influence of some numerical parameters has been presented. Discussions and conclusions are drawn in Section 4.

2 THE FE PUSHOVER RESULTS

The pushover analyses have been carried out on a 3D Finite Element model in Abaqus/CAE [27]. The FE model uses a 3D representation of the actual chimney geometry (Figure 4), which has been built in the Autodesk Inventor environment starting from the available 2D drawings.

Figure 4: 3D model of the chimney case-study.

It has been decided to adopt a macro-modelling approach, and, in light of this latter choice, solid, homogeneous, and isotropic properties have been applied to the whole chimney body. The material properties have been chosen following the study presented in [20], and the main

mechanical parameters are shown in Table 1. The material non-linearities have been modelled employing the Concrete Damage Plasticity (CDP) model, whose main parameters are reported in Table 1 Main mechanical parameters.

. The compressive behaviour has been modelled by a brickwork feasible stress-strain relationship (Figure 5), while the fracture energy approach has been used for the tensile behaviour (Figure 6). The fracture energy has been computed by Eq. (1) as suggested in [28], and it is equal to 8.1 N/m.

$$G=0.025 (2\sigma_t)^{0.7} \quad (1)$$

Density ρ [kg/m ³]	Young's Modulus E [MPa]	Poisson's ratio ν [-]	σ_c [MPa]	σ_t [MPa]
1800	1500	0.15	3.5	0.1

Table 1 Main mechanical parameters.

Dilatation Angle	Eccentricity	f_{b0}/f_{c0}	K_c	Viscosity parameter
10°	0.1	1.16	0.667	0.0005

Table 2 Main parameters for the CDP

Figure 5: Compressive stress-strain branch to define the compressive CDP part in Abaqus.

Figure 6: The post-failure tensile stress-fracture energy curve used to define the tensile CDP part in Abaqus.

The chimney body has been meshed through the Abaqus's automesh command. A seed dimension equal to 0.2m has been input, and linear tetrahedral elements of type C3D4 has been chosen. The model has a total number of 17289 nodes and 79666 elements. Figure 7 shows the meshed body, being possible to see that the discretisation is very refined. The element dimension may be considered adequate since the elements are linear.

The pushover analyses have been carried out along the four principal directions applying a G1 load distribution and along the z+ direction involving a G2 load distribution. The capacity curves have been built using the Load Factor (which is the ratio between the base shear and the total weight of the structure) and the horizontal displacement of a control point located at the top of the chimney. Both the latter quantities are related to the pushover direction. Furthermore, the tensile damage maps have been analysed.

Figure 8 shows the pushover analyses' capacity curves along the four principal directions using a G1 load distribution. It is worth noting that the four curves almost coincide; therefore, the singularities of the chimney body, i.e. the small opening at the base, doesn't play a crucial

role in the seismic response (differently from [26], in which it has been shown that the opening at the base of the case-study pagoda constitutes a weak point for the overall dynamic response). Figure 9, instead, presents a comparison between the G1 and the G2 loads' application along the z^+ direction. As expected, the ultimate capacity in the latter case is higher.

Figure 7: The meshed model .with 3D elements

Figure 8: Capacity curves of the pushovers along the four principal directions.

Figure 9: Comparison between the G1 and G2 loads' application along the z+ direction.

It could be interesting to highlight the phases of the damage spread. All the cases behave qualitatively similar due to the approximative axial symmetry of the structure; thus, the damage evolution of the z+ case is taken as an example and presented in Figure 10. It is shown how the loss of linearity is due to some horizontal cracks born on the tended fibres at a height between 5m and 9m; then, an additional horizontal crack born at the base. The plateau is approached when the aforementioned cracks spread and propagate as inclined along the faces parallel to the pushover load until collapse. Moreover, it is worth noting that the most critical sections are those at a quota between 5m and 9m. The damage maps suggest that a collapse mechanism based on a plastic hinge mechanism is activated. Based on [11], it is one of the most probable collapse mechanisms in tower-like structures under seismic actions when the structural slenderness is considerable.

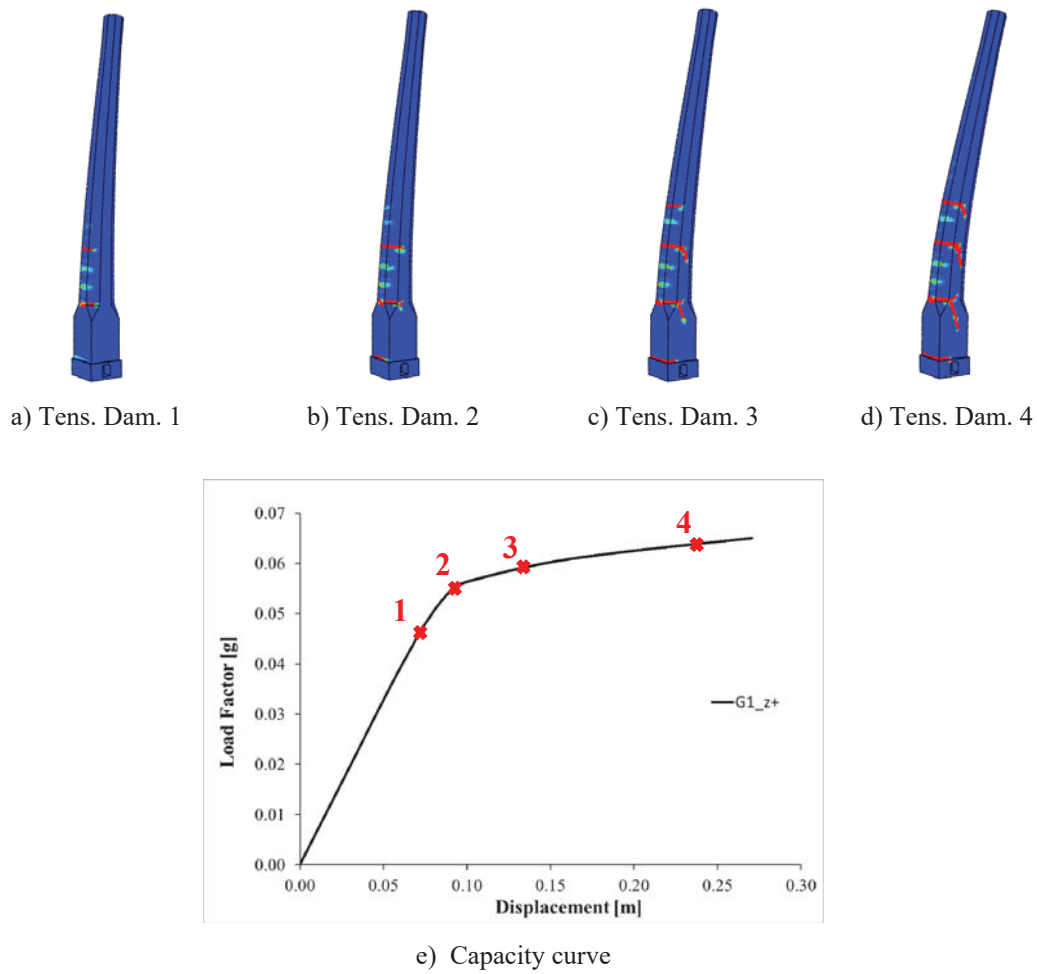

Figure 10: Damage evolution in z+ pushover.

3 SENSITIVITY ANALYSES ON THE VISCOSITY PARAMETER

A sensitivity analysis is proposed to highlight how the viscosity parameter value influences the analysis's results. The authors decided to select the G1 load and the z+ direction and varying the viscosity parameter only (the used values are shown in Table 3).

Viscosity parameter
0.001
0.0005
0.0001
0.00005

Table 3: Viscosity parameter's values used for the sensitivity analysis

Figure 11 shows the results of the sensitivity analysis. It is noticeable that the ultimate capacity significantly increases when the viscosity parameter is incremented. Moreover, the capacity curve's length is directly proportional to the viscosity parameter's value (the total load

increments number is fixed to 1200). The authors expected both the latter facts since the viscosity parameter smooth the yield surface and helps the steps' convergence and speed up. Increasing the viscosity parameter also increases the efficiency of the analysis by allowing larger load increments at each step but overestimate the ultimate capacity. Therefore, those who use the Concrete Damage Plasticity model in their studies must be aware of that and critically analyse the analyses' results also in light of the selected viscosity parameter's value.

Figure 11: Sensitivity analysis on the viscosity parameter value.

4 CONCLUSIONS

This study has presented some FE simulations carried out on a real 20th-century masonry chimney located in Villar del Arzobispo (Spain). Pushover analyses have been carried out using the FE software Abaqus/CAE on a quite accurate 3D model of the case-study. Different simulations have been presented: various pushover analyses along the chimney along the four principal directions, using both G1 and G2 load distributions. The material properties have been chosen according to previous studies carried out on similar structures because no specific experimental data were available, and the plastic properties have been represented through the Concrete Damage Plasticity (CDP) model, which is an Abaqus built-in material model, widely used to represent the non-linear behaviour of masonry structures.

The results have been used to compare the capacity curves between each other and point out that the main weak points of the chimney are the cross-sections at a quota between 5m and 9m. Finally, a sensitivity analysis has been done on the viscosity parameter. The latter one is a numerical input value of the CDP, and it helps the analysis's steps to converge by smoothing the yield surface. It has been often highlighted that the viscosity parameter increment tends to overestimate the ultimate capacity. On the other hand, the decreasing of the viscosity parameter increase the computational cost; therefore, a sensitivity analysis on this parameter may be helpful to better understand the influence of this parameter on the pushover results. Results confirmed that the viscosity parameter significantly affects the ultimate capacity.

This paper aims to present an overview of the seismic vulnerability of the selected case-study. These results allowed to estimate the order of magnitude of the collapse acceleration and the main weak points of the structure. Moreover, the results have shown the importance of the modelling choices in terms of numerical parameters of the material model. However,

different windows remain open, and the authors intend to continue the research work carrying out non-linear dynamic analyses with both real and artificial accelerogram and testing innovative and simplified methods that would allow fast analyses (which might be useful in case of scale campaigns) or the calculation of the ultimate displacements needed to carry out eventual Displacement Based Design procedures. In this framework, simplified beam models or kinematic limit analysis procedures might be applied.

Abstract

This paper highlights the main objectives and some of the results of an extensive structural health monitoring (SHM) project recently started in Khiva, Uzbekistan. The research team consisted of experts from the University of California, Berkeley (Berkeley, USA) and Urgench State University (Urgench, Uzbekistan). The paper presents results for the Juma Mosque in Itchan Kala. The structural health monitoring project was planned as a comprehensive study consisting of three major phases. In Phase 1, a terrestrial laser scanner was deployed to capture 3D geometry and identify anomalies in the monument's geometry. In this phase, the monument's geometry was captured as a collection of points, the so-called "point clouds". In Phase 2, a finite-element (FE) model based on the as-found geometry of the point clouds was generated. This model was generated to optimize placement of the conventional instruments to be used in Phase 3. A number of structural anomalies were discovered during Phase 1 and all of them are incorporated into the FE model. In Phase 3, there is a plan to monitor the monument by means of conventional instruments (accelerometers, displacement transducers, temperature gages and others). Accelerometers will be used to measure the resonant frequencies due to ambient vibrations. Displacement transducers will be used along with temperature gages to monitor the opening and closing of cracks under different thermal conditions and to measure the long-term growth trends of the cracks. The FE model will be updated based on the results of Phase 3. Preservation and restoration strategies will be developed based on the performance of the FE model under static and dynamic loads.

1 INTRODUCTION

This paper presents some of the results of the ongoing structural health monitoring program being conducted in Khiva, Uzbekistan. This paper focuses on the finite element (FE) modelling of the Juma Mosque in Itchan Kala, the inner city of Khiva. The main objective of the modelling is to develop an accurate representation of the actual monument so it can be investigated for seismic loading. The geometry of the FE model is based on the 3D point cloud collected during Phase 1 of the project. The main objective of Phase 2 is to generate a FE model with some assumptions about material properties. The next phase (Phase 3) will include field studies by means of conventional instruments: accelerometers, displacement transducers and thermocouples, to name a few. Since the number of instruments is limited and the access duration to the site is tight, the locations of the instruments need to be optimized to collect valuable information with the limited resources and within a reasonable timeframe. The results of this portion of the work are discussed herein. The model will be updated later based on the results of Phase 3.

2 GEOMETRY BASED ON POINT CLOUDS

The results of Phase 1 were published earlier [1]. As presented in Figure 1, the heritage structure consists of a courtyard surrounded by walls and a minaret incorporated into its north wall. The courtyard is covered by a roof that is supported by numerous timber columns. The heritage structure was scanned by ScanStation C10 from Leica Geosystems [2] and the so-called registration of the point clouds was conducted in Cyclone [3], also from Leica Geosystems.

Figure 1: Juma Mosque [1].

3 MODELLING OF MINARET

The minaret was modelled in SAP2000 [4] by utilizing solid 3D elements and some results were published earlier [5]. In this study of the minaret the interaction of the minaret with the walls was not considered and as such, the monument was studied as a stand-alone structure as presented in Figure 2. In this paper, the minaret's model is integrated into the walls of the heritage structure. From the analysis of the point clouds, it was observed that the minaret's axis is inclined in respect to the vertical gravitational axis. This imperfection is included into the model discussed herein.

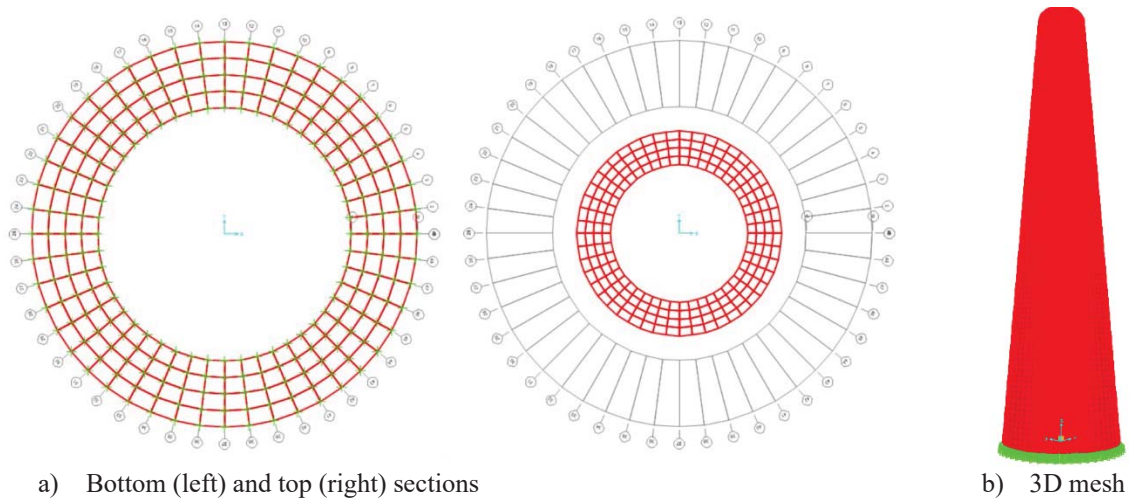

Figure 2: Model of minaret [5].

4 MODELLING OF WALLS

The walls of the heritage structure were also modelled in SAP2000 [4] by utilizing solid 3D elements. A global view of the heritage structure with a vertical reference plane crossing the wall is presented in Figure 3a. A plane view of the typical cross section of the wall's point cloud is presented in Figure 3b. In this image, a spacing between the grid lines is 0.25 m and one of the vertical grid lines is selected to be parallel to the inner wall. Based on the image, the following was concluded. First, the overall height of the wall is about 5 m and the roof starts at about 4 m. Second, the wall thickness at the very bottom is about 1.0 m and about 0.75 m at the roof level. Third, the outer surface of the wall has a slope in respect to a vertical line. Fourth, the inner surface of the wall is very close to vertical.

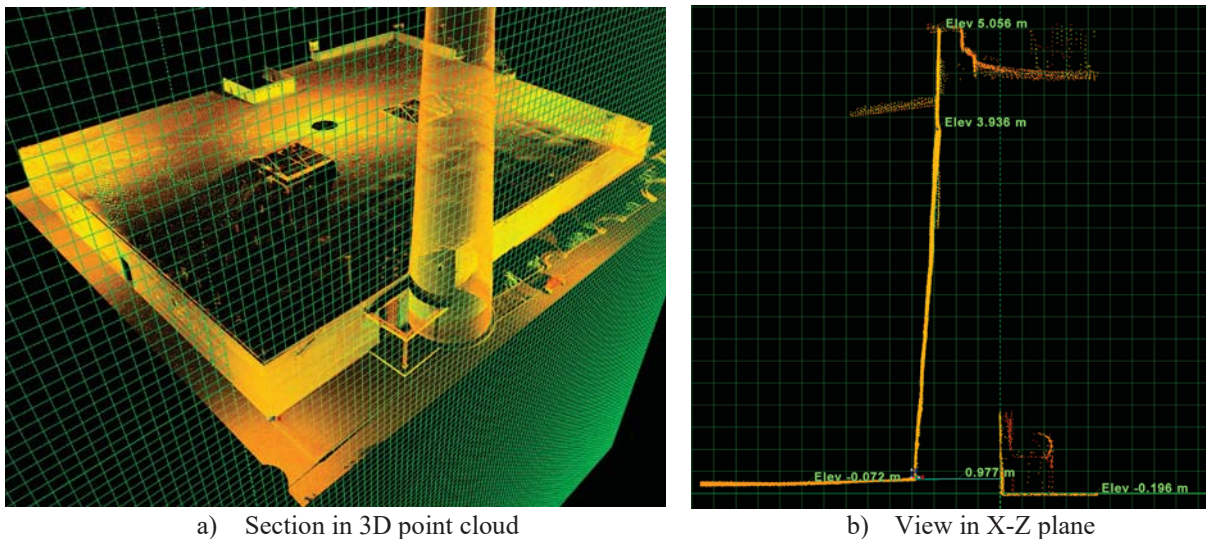

Figure 3: Typical geometry of wall's cross section.

The overall length of the north wall is presented in Figure 4. A length of each wall was published earlier [1] and the corner locations are shown in Figure 5. All of this information was used in the generation of the FE model.

Figure 4: Overall length of north wall.

Figure 5: Plan view at Z=4.85 m: corner locations.

The openings in the north and east walls shown in Figure 6 were also taken into account. The opening in the north wall right next to the minaret serves as the main entrance into the heritage structure.

b) North wall

Figure 6: Wall openings.

5 MODELLING OF ROOF DIAPHRAGM

The roof diaphragm was modelled by shell elements in SAP2000. Based on the measurements of the point clouds, the spacing between the columns was very close to 3 m as presented in Figure 7a. A typical view inside of the courtyard is presented in Figure 7b. A proper selection of the boundary conditions closely replicating the support columns is very important to ensure that the model closely represents the heritage structure. In the majority of cases the column has a narrow end at its bottom, which is installed into a stone or concrete footing as presented in Figure 8a. The interface between the narrow end and the concrete or stone is packed with a soft material as presented in Figure 8b. Therefore, it was assumed that the columns are free to rock and as such, roller type boundary conditions were assumed under the roof diaphragm at the locations of the columns.

a) Spacing between columns

b) Typical inside view in the courtyard

Figure 7: Support columns.

a) Typical layout of columns

b) Boundary conditions at bottom of columns

Figure 8: Support columns: details.

There are two skylights in the roof as presented in Figure 9. They were also introduced into the roof model as openings in the diaphragm.

b) Typical dimensions

Figure 9: Skylights in roof diaphragm.

6 FINITE ELEMENT MODEL

A final model of the heritage structure that consists of the walls, minaret and roof diaphragm is presented in Figure 10a. It was assumed that there is a rigid connection between these major components of the model. A modal analysis was performed. A typical result showing the first modal shape is presented in Figure 10b. The first modal shape is associated with the first flexural vibration mode of the minaret.

The second mode was also associated with the first flexural mode of the conical body in a horizontal plane orthogonal to the one of the first mode as presented in Figure 11a. The third mode was also associated with the minaret's vibrational mode and corresponded to a second mode of the conical body as presented in Figure 11b.

The fifth modal shape was associated with the minaret and represented the torsional mode of the vibrations of the conical body. The modal shapes 6, 7, and 8 corresponded to the higher modes of the minaret. Only starting from mode 9 a vibration mode of the walls was observed

as presented in Figure 12a. The modal shape of the east and west walls are shown in Figure 12b.

Figure 10: FE model and 1st modal shape.

Figure 11: Typical results of modal analysis: minaret modes.

Figure 12: Typical results of modal analysis: wall modes.

Estimates of the following frequencies were obtained for the assumed material properties. The first resonant frequency of the minaret is about 2.2 Hz. The estimates of the resonant frequencies of the walls were greater than 20 Hz. The resonant frequency of the roof is greater than 27 Hz. To capture the first three modes of the minaret the accelerometers in Phase 3 will be installed at the elevations shown in Figure 13.

Figure 11: Typical results of modal analysis: wall modes.

To capture the torsional mode of the minaret the accelerometers will be installed at diametrically opposite locations of Elevation 0 and Elevation 3.

7 CONCLUSIONS

A detailed finite element model of the Juma Mosque in Uzbekistan was generated. The geometry of the heritage structure was obtained from the point clouds captured by a laser scanner. Typical material properties for brick masonry and timber were assumed. The modal analysis of the FE revealed the following.

- The first eight resonant frequencies of the heritage structure are associated with various flexural modes of the minaret.
- The wall frequencies are greater than 20 Hz.
- The roof frequency is greater than 27 Hz.
- A placement of accelerometers in the upcoming Phase 3 of the project was optimized based on the analysis of modal shapes. The FE model will be updated after ambient vibration studies of the heritage structure which is the main objective of Phase 3.

8 ACKNOWLEDGMENTS

The project would not be possible without funding provided by the Central Asia University Partnerships Program (UniCEN). UniCEN is sponsored by the U.S. Embassy in Tashkent, Uzbekistan and administered by the American Councils for International Education. Special thanks are due to Mr. Brian Quigley of BNZ, Uzbekistan for providing access to a terrestrial laser scanner. The authors would like to acknowledge the Delta Group Max, Uzbekistan for logistical and technical support provided for the laser scanning project. The authors also

would like to acknowledge a large group of faculty and students of Urgench State University, Uzbekistan for active participation in this multi-phase project. Special thanks are due to Holly Halligan of UC Berkeley for editing the paper.

Abstract

Advanced numerical modelling of the masonry “Apennine Church” of Santissimo Crocifisso in Pretare, Arquata del Tronto (AP), was here utilized to have an insight into the dynamic properties and behavior of the structure under strong nonlinear dynamic excitations. The objectives were achieved by comparing nonlinear dynamic analyses through discontinuous and continuous approaches. In the discrete element approach, the Non-Smooth Contact Dynamics method, implemented in LMGC90©, was applied, adopting a full 3D detailed discretization. The Church was schematized as an arrangement of discrete rigid blocks, subjected to sliding by friction and perfect plastic collisions, governed by Signorini’s impenetrability condition and dry-friction Coulomb’s law, with a null restitution coefficient. In the finite element approach, the Concrete Damaged Plasticity model available in Midas FEA NX© was involved. This model allows reproducing the tensile cracking, the compressive crushing, and the degradation of the material under cyclic loads. At the end, the structure exhibited a complex dynamic behavior, because of the geometrical nonlinearity and the non-smooth nature of the contact laws. Finally, the numerical analyses provided a valuable picture of the actual behavior of the church, which is mandatory for future strengthening interventions.

1 INTRODUCTION

Over the years Italy has seen a succession of strong and frequent seismic events. This predisposition is because the peninsula is located on two tectonic plates, the Eurasian and the African, which by pushing themselves accumulate energy that causes earthquakes when released. The boundary line of these tectonic plates covers all the Apennines and the Alps, which are precisely the places where strong seismic events have developed most frequently. The most recent sequence took place between 2016 and 2017 and hit the mountain area of four regions of Central Italy: Abruzzo, Lazio, Marche, and Umbria. As visible in Figure 1, the first strong shock of magnitude 6.0 was recorded on 24th August 2016 with epicenter between the municipalities of Accumoli, Amatrice and Arquata del Tronto. This was the shock that caused most of the damage to the town of Arquata del Tronto, in fact there was a level of damage of the X degree of the European Macroseismic Scale (EMC). In the following days and months, nine thousand tremors were recorded, of which nine with a magnitude equal to or greater than 5 [1]. Relevant were those of 26th October 2016 with magnitude 5.4 and epicenter between Castelsantangelo sul Nera, Visso, Ussita and Preci and that of October 30th 2016 of magnitude 6.5 with epicenter between Norcia, Castelsantangelo sul Nera and Preci.

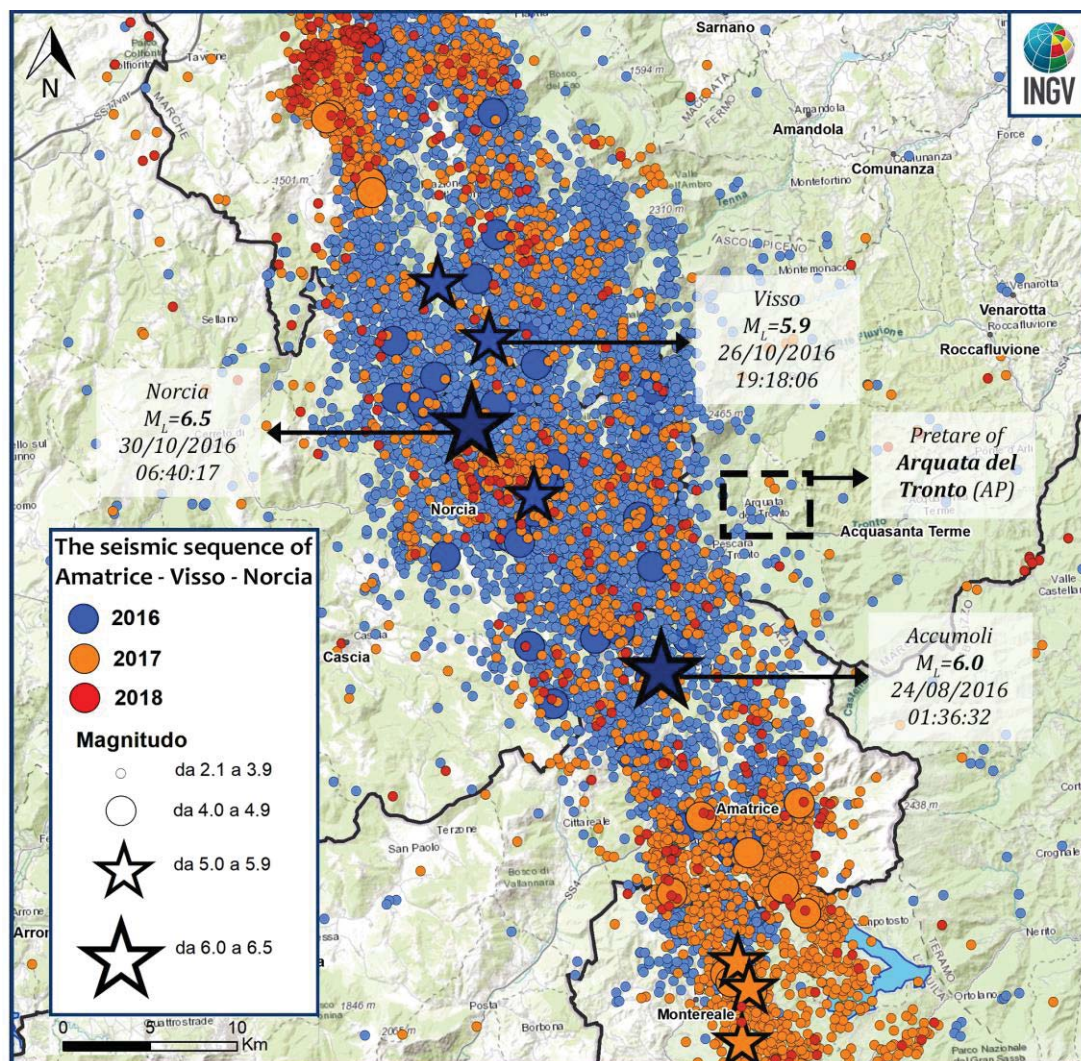

Figure 1: The Central Italy seismic sequence of 2016 (source: <http://itaca.mi.ingv.it>) and the geographic location of Pretare in the municipality of Arquata del Tronto (AP).

The case study analyzed in this research work is the Santissimo Crocifisso Church located in Pretare, municipality of Arquata del Tronto in the province of Ascoli Piceno (AP) (Marche region, Central Italy). For its position near the epicenters of the main strong motions, the structure suffered severe damages during the 2016 seismic sequence. To investigate in depth the nonlinear behavior of the structure, comparative work was carried out on continuous and discontinuous approaches applying the Concrete Damaged Plasticity (CDP) model and the Non-Smooth Contact Dynamics (NSCD) method, respectively. Other applications on towers [2–5] and churches [6–8] are introduced in the literature, but a comparison of these methods has not yet been developed.

2 HISTORICAL AND GEOMETRIC DESCRIPTION OF THE CHURCH

The origins of the Santissimo Crocifisso Church are not known and the first information showing its existence dates to the 15th century, when it was dedicated to Santa Maria della Cecca. During these years, the church was used sporadically and left in a state of neglect. The first restoration interventions were executed between 1910 and 1911. In these years, the church was almost completely rebuilt, the interior paintings were realized and the two niches on the lateral walls were created. After this restoration, the church was dedicated to the Santissimo Crocifisso in honor of an ancient wooden crucifix recovered from the old parish. In 1950 the church was deconsecrated and used as a parish theater. After the works of 1970 (reconstruction of the roof, reconstruction of the floor, and construction of the steeple in reinforced concrete (RC)) the church was reopened for worship. After the 1997 Umbria-Marche earthquake, the church presented extended damages. In the years 2014-2015 a new restoration was carried out, including interventions to improve the structural response. The masonry was reinforced with interventions of “scuci e cuci” and injection of mortar. A steel curb was inserted at the top main façade and the wooden roof was completely rebuilt. Finally, the church suffered severe damages following the 2016 Central Italy earthquakes, until its closure for safeguard reasons. Indeed, after these events, the church exhibited deep cracks and masonry disaggregation damages on the upper part of the main façade and extended cracks at the connections of the nave walls (see Figure 2). All of the masonry walls introduce the activation of overturning mechanisms.

Figure 2: Crack pattern of the Santissimo Crocifisso Church in Pretare (Arquata del Tronto, AP) after the earthquakes of 2016 on 1) the main façade and the 2) North and 3) West facades.

From a geometric point of view, the structure introduces a rectangular plan measuring 11.94 m x 7.24 m and it is covered by light vaults in camorcanna, as visible in **Errore. L'origine riferimento non è stata trovata.** The structure reaches a maximum height of 10.59 m in correspondence with the steeple. Two single arched openings are on the lateral sides of the nave and a semicircular opening is located above the portal of the main facade. The bearing masonry structure is characterized by local stone and travertine. The steeple and the curb at

the top of the main facade are built with reinforced concrete. Finally, the roof is made of chestnut wood.

Figure 3: Geometric configuration of the Santissimo Crocifisso Church in Pretare (Arquata del Tronto, AP).

3 COMPARISON OF THE FINITE AND DISCRETE ELEMENT

In this comparative work, the FEM and DEM modeling are used to analyze the case study. Both models were subjected to nonlinear dynamic analyses considering the three main shocks of the 2016 Central Italy sequence: 24th August 2016, 26th October 2016, and 30th October 2016. The events recorded in the surrounding area of the church and in the epicenters were applied at the base of the FE and DE models in Figure 4. Strong motions of 10 seconds were considered in sequence, with 5 seconds of rest among them.

Figure 4: a) FE and b) DE models of the Santissimo Crocifisso Church in Pretare (Arquata del Tronto, AP).

3.1 Finite Element model

The continuous model was accurately reproduced using tetrahedral 3D elements of average size 0.4 m. In total the model is composed of 23020 elements, 6283 nodes and 19782 degrees of freedom (see Figure 4a). The foundations were simulated by preventing both the displacements and the translations of the base nodes, while the presence of the camorcanna vaults was taken into consideration as an additional mass on the lateral walls of the nave.

To simulate the nonlinear behavior of the masonry, the Concrete Damage Plasticity Method (CDP) implemented in the Midas FEA NX© software was used. This type of modeling developed by Lubliner [9] and implemented by Lee & Fenves [10] was initially used for the study of reinforced concrete but subsequently proved to be optimal also for simulating fragile materials such as masonry [11,12].

Starting from the indications in the literature [13], it has been assumed that the masonry obeys a Drucker-Prager resistance criterion with an unassociated flow rule. The surface of this criterion was deformed through a coefficient K_c , to resemble that of Mohr-Coulomb, while the tip of the cone was beveled to avoid numerical convergence problems through an eccentricity parameter. To consider, the ratio between biaxial and mono axial ultimate compressive strength, it was considered with an appropriate ratio between f_{bo} and f_{co} . In addition, the dilatancy angle and the viscosity parameter were defined. The mechanical parameters applied in the CDP model are reported in Table 1. The nonlinear behavior of the masonry was defined assigning suitable inelastic mono-axial stress-strain curves in traction and compression.

Parameter	Value
Dilatancy angle (°)	10
Eccentricity	0.1
f_{bo}/f_{co}	1.16
K_c	0.667
Viscosity Parameter	0

Table 1: Mechanical parameters of CDP model

3.2 Discrete Element model

The discontinuous model reproduces the masonry structure through an assembly of 3D blocks modeled similarly to the existing masonry texture. The complex model is composed by a total of 7636 blocks (see Figure 4b).

The NSCD method belongs to the family of DE models, distinguishing from the classical Distinct Element Method (DEM) for three differences: (i) it integrates the non-smooth contact laws directly, (ii) it uses an implicit integration scheme, and (iii) it does not account for any structural damping. It is important to stress the fact that the NSCD method is based on some modelling simplifications. The main assumption is that bodies are rigid. Since the contact between blocks is governed by the Signorini's impenetrability condition and the dry-friction Coulomb's law, the churches exhibit discontinuous dynamics. Regarding the contacts between bodies, the above-mentioned relations imply perfectly plastic impact, i.e., the Newton law with restitution coefficient equal to zero, which does not account for bounces after impact. This presents two main advantages: (i) the contribution of impacts to the computational complexity is modest since they are modelled in a very basic and simple way; (ii) since the impact is perfectly plastic, it dissipates energy, and, from a mechanical viewpoint, this is a way to account for material damages and micro-cracks, which form in the stones at impact, and, from

a computational point of view, dissipation contributes to the stability of the numerical integration. In addition, the friction contributes to dissipation, but damping, a fundamental ingredient of continuum models, is not considered here.

3.3 Critical discussion

For brevity of the paper, the main results of the nonlinear dynamic analyses under the seismic actions recorded near the church location and performed with the CDP model and NSCD method are plotted Figure 5a and Figure 5b, respectively. A good match between the numerical damages and the existing crack pattern (see Figure 2) is reached. The resultant behaviors explain the relevant applicability of these methods in order to obtain similar failures despite the different laws that govern the two approaches.

Figure 5: Comparison of the numerical damages of the Santissimo Crocifisso Church in Pretare (Arquata del Tronto, AP) resulting from the nonlinear dynamic analyses with 1) the CDP model and 2) the NSCD method.

4 CONCLUSIONS

The numerical modeling of the Santissimo Crocifisso Church in Pretare, Arquata del Tronto (AP), was carried out by means of advanced FE and DE models. The relevance of the findings is related to the deep investigation of the masonry nonlinear response. The seismic actions registered near the church leads to the validation of both continuous and discontinuous methods through a good match with real cracks of the structure. The application of the epicentral seismic actions allows to obtain a development of the failure mechanisms with the amplification of the damages. All these numerical results appear to be interesting in light of design the retrofiting works. Indeed, the complex nonlinear behavior of the church is clearly pointed out with CDP model. Moreover, the NSCD method allows to investigate the local failure mechanisms, as the masonry disaggregation which is neglected in FEM.

Keywords: Out-of-Plane Behavior, Earthquake, Lattice Discrete Particle Model, Stone Irregular Masonry, Local Collapse Mechanisms, Global Collapse Mechanisms

Abstract. *Stone masonry buildings are known to be highly vulnerable to seismic actions. In this context, the analysis of the out-of-plane response of unreinforced masonry structures is crucial. For this purpose, the Lattice Discrete Particle Model (LDPM) was employed to simulate the mechanical behavior of stone masonries up to their failure. Unlike commonly used continuum-based methods or simplified analytical models, that are often limited in modeling correctly complex failure mechanisms, LDPM is able to capture accurately crack distributions and failure patterns. LDPM describes the masonry at the scale of stones and takes into account their interactions through tailored constitutive equations for tensile, compressive, shear, and frictional behaviors. First, LDPM was validated against experimental results on masonry panels subjected to out-of-plane loading. Next, the vertical bending mechanism was studied in the cases of one- and two-story walls with and without openings. Finally, more complex mechanisms were considered where the damage evolution and the fracture propagation were analyzed for a set of panels assumed to be placed within the continuity of a facade. The overall results presented in this paper show that LDPM can realistically predict the collapse mechanisms associated with out-of-plane loading for different structural configurations and geometries.*

1 INTRODUCTION

Unreinforced masonry structures often constitute a large part of the cultural and architectural heritage of historical cities, and they are known to be highly vulnerable to earthquakes. Commonly, masonry structures are made of multiple load-bearing walls placed in orthogonal planes and with flexible floor diaphragms [1]. When an earthquake occurs, masonry structures dissipate kinetic energy both at the structural and at the material levels [2, 3]. At the structural scale, several factors affect the global response: the slenderness of the load-bearing walls [4, 5], the connections between the walls and the horizontal members, which allows for the box behavior [6, 7, 8, 9], and the presence of specific rigid floor diaphragms [10, 11, 12, 13, 14, 15, 16]. At the material scale, the mechanical properties of the masonry constituents (mortar and stones) [17, 18, 19, 20] and the quality of the construction work [21, 22] greatly affect the overall response. During a seismic event, masonry walls are typically subjected to in-plane and out-of-plane motions. Whereas in-plane behavior is the topic of a large number of studies available in the literature, the out-of-plane behavior is often neglected. This paper focuses on the latter behavior, as one of the most common damage reported in post-seismic surveys is the failure of peripheral masonry walls. Indeed, the earthquake intensity required to obtain out-of-plane collapse of walls is lower than the one required for in-plane collapse [3].

Several analytical methods exist to analyze the out-of-plane behavior of masonry walls, namely force-equilibrium and displacement-based methods. The first type of formulation is based on the static equilibrium analysis of rigid body mechanisms and limit theorem of plasticity [23, 24, 25, 26, 27, 28, 29, 30, 31, 32]. Force-equilibrium methods are generally adopted for large scale analysis and are known to lead to rather conservative limit states [8]. On the other hand, displacement-based methods [33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44] appear to better estimate the limit values of masonry walls in out-of-plane loading. The rigid-block assumptions are often adopted within the postulates of limit theorem analysis (no-tensile strength, infinite compressive strength and absence of sliding between blocks) [23]. A capacity curve describing the horizontal multiplier α (limit equilibrium of the system) as a function of displacement d can then be obtained. When the displacement is zero, the value $\alpha(0) = \alpha_0$ represents the activation of the overturning. The loss of equilibrium is attained when $d = d_u$ where by definition $\alpha(d_u) = 0$. This curve can also be expressed in terms of spectral acceleration versus spectral displacement curve [45] or in terms of force-displacement curve. The rigid-block method within the displacement-based formulation is chosen in this paper for one part of the analysis of the out-of-plane behavior of masonry walls.

More advanced descriptions of the out-of-plane behavior of masonry walls and in general of the mechanical behavior of stone masonry require numerical models. Different methods are available and correspond to different levels of modeling resolution and computational costs [46, 47]. The finite element method is often used and allows micro-, meso-, or macro-modeling and the reader is referred to [48], [49], and [50], respectively. Although successful for regular masonry, the meshing complexity and the lack of accurate constitutive equations limit this method. Discrete element methods have also been employed [51, 52, 53, 54]. Multiple structures such as one or two-story buildings were modeled using 2D and 3D discrete element method [55], but limitations were found especially in capturing realistic out-of-plane responses. Moreover, these simulations were unable to correctly describe the fracture initiation and propagation. Indeed, in quasi-brittle materials such as masonry, understanding the development of the fracture process zone is crucial. An accurate model must also be able to capture the effect of stress parallel to cracks on the size of the fractured zone as shown recently in [56, 57], which

might be important in large masonry structures often under multiaxial state of stresses. To overcome these limitations, the Lattice Discrete Particle Model (LDPM) [58, 59] is here adopted for the numerical modeling. This model was originally conceived to simulate the behavior of concrete and other granular materials at the meso-scale level by modeling the interaction between coarse aggregate pieces. It was recently applied successfully for the modeling of stone masonry structures [60, 61]. LDPM is able to simulate accurately the fracturing behavior from crack trigger to localization, propagation, and to global failure, by taking into account the material heterogeneity. The interaction between stone aggregates embedded in the irregular matrix of lime or clay mortar is explicitly considered through dedicated constitutive equations, defined in a vectorial form to account for the correct state of stresses in the material.

In this study, the numerical model is first explained and validated against a set of experimental data relevant to masonry panels subjected to out-of-plane loading conditions. Next, the numerical model is used to assess its capability to simulate local collapse mechanisms, more specifically the bending mechanism. Finally, more complex mechanisms are analyzed with multiple structural configurations to simulate masonry walls within the continuity of the facade and to study the effect of transversal walls, floors and roofs on the overall behavior.

For a thorough investigation of the topic presented in this paper, the reader is referred to recent work of Mercuri and coworkers [61].

2 NUMERICAL MODEL AND VALIDATION

2.1 The Lattice Discrete Particle Model

The Lattice Discrete Particle Model (LDPM) was proposed by Cusatis and coworkers [58, 59] to simulate concrete at the coarse aggregate level. This model has a unique capability in capturing crack distribution and damage in granular quasi-brittle materials. It has been adopted to simulate the mechanical behavior of concrete [59, 62], mortar [63, 64], fiber reinforced concrete [65, 66], or to reproduce multi-physics phenomena such as hygro-thermo-chemical processes, alkali-silica reaction, and aging [63, 67, 68]. This lattice discrete model was also used to simulate the mechanical behavior of reinforced and unreinforced stone masonry [60, 61].

In the LDPM formulation, the masonry stones are simulated as spherical particles (see Fig. 1a and b). They are placed randomly from the largest to the smallest size in a given volume of material. The particle size distribution follows a Fuller sieve curve defined from a set of mix-design parameters: cement-mortar content c , water-to-mortar ratio w/c , maximum and minimum stone size d_a and d_0 , respectively, and Fuller coefficient n_f . Fig. 1e shows on an example the particle placement inside a dog-bone specimen. The geometry of the interaction between stone-particles is described as follows. First, a Delaunay tetrahedralization is performed with the centers of the particles to generate a lattice system (see Fig. 1c). Next, a domain tessellation is performed to identify the possible failure locations between adjacent stone-particles (see Fig. 1d). These two steps result in the generation of a system of polyhedral cells enclosing the particles (see Fig. 1f). These irregular cells idealize real textures and shapes of typical masonry stones and their surrounding mortar layer. The surface of each polyhedral cell is composed of triangular facets (see Fig. 1g) where the LDPM constitutive equations, facet stresses and strains are formulated in a vectorial form. The constitutive equations take into account the softening behavior for pure tension and shear-tension and the plastic hardening behavior for pure compression and shear-compression. For the complete set of constitutive equations, as well as the compatibility and equilibrium equations, and the numerical implementation, the reader is referred to the work of Cusatis and coworkers [58], and the recent work of Mercuri and coworkers [61].

2.2 Validation with experimental data

2.2.1 Description of experiments and numerical modeling

The Lattice Discrete Particle Model is here validated against experimental data reported in Degli Abbati and coworkers [69]. The experiments consisted in loading in out-of-plane direction three masonry panels of different dimensions. The sizes of the specimens and their slenderness ratios are shown in Table 1. Lime mortar was used as binder in the preparation of the specimens. The stones were irregular with an average block size of $180 \times 120 \times 120$ mm. All the panels were built on top of a masonry base with a larger thickness. For the testing setup, a steel cable was fixed at $2/3$ of the panel height at the center of the transverse section on one end and attached to a restraint frame on the other end. The cable was equipped with a load cell to measure the applied force along the cable. The displacement was measured at the location where the cable was fixed. The test was carried out in three phases. In Phase 1, the cable was pulled horizontally in order to form a cracked surface at the bottom of the specimen. In Phase 2, the cable was released to obtain a standing panel as in the initial configuration. Finally, in Phase 3, the cable was pulled horizontally and statically in displacement controlled conditions.

The LDPM parameters used in this study were calibrated in [60] on diagonal compression performed on a similar stone masonry mix composition. All the model parameters and the parameters related to the geometrical characterization can be found in details [60] and in [61], and are therefore not reported here for the sake of brevity. Fig. 2 shows the random stone-particle placement inside the three panels. One can note that the base of the specimen and the panel were modeled using one LDPM mesh. At the bottom of the base, the particles were fixed in translations and rotations. A velocity was applied directly to a set of particles at $2/3$ of the

Panel number	Width B [mm]	Height H [mm]	Thickness D [mm]	Slenderness λ [-]
P1	900	900	300	3
P2	900	1100	220	5
P3	900	1500	300	5

Table 1: Dimensions of the panels for model validation.

Figure 2: Spatial distribution of stone-particles in the three panels: (a) panel 1, (b) panel 2, (c) panel 3.

panel height to reproduce the experimental setup. Its magnitude was chosen low enough to obtain a quasi-static simulation. Two sets of simulations were performed. The first strategy was to reproduce the same testing procedure as in the experiments, i.e. in three phases. The second strategy, less computationally expensive, was to apply the static load directly to the uncracked specimen, from the beginning of the test, up to cracking and overturning of the panel. Finally, for all the simulations, three different stone distributions within the volume of the panels were used to capture the experimental scatter due to the spatial variability of stone size and distribution. Thus, the results shown afterwards are the average of the three individual results.

2.2.2 Numerical results and discussion

Fig. 3 refers to panel 2 and it shows the results of the two modeling strategies previously stated. One can see that replicating the experimental procedure (see Fig. 3a) and loading directly the sample from the initial uncracked configuration (see Fig. 3b) provide identical results. Fig. 3b shows clearly the fracturing part of the test followed by the overturning or rocking phenomenon once the fracture is formed. In order to save computational time, the second strategy was used to generate the results presented next.

Fig. 4 shows the load-displacement curves of for the three panels. One can see that the numerical results well predict the experimental data, especially for panels 1 and 2. In terms of fracture, all the three specimens failed at the base (see Fig. 5) as expected and observed in the experimental tests of panels 1 and 2. For panel 3, experimentally, the fracture formed at a height of 300 mm from the base, where the stones were not well interlocked. This unexpected failure

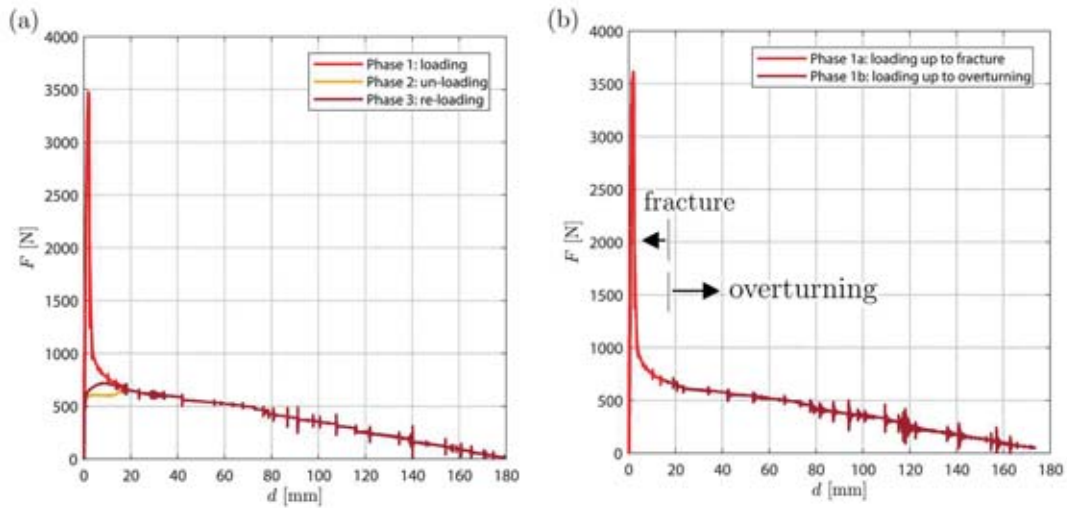

Figure 3: Force versus displacement curves for Panel 2: (a) Three phases loading; (b) Loading directly from the initial uncracked configuration

Figure 4: Force versus displacement curves in: (a) panel 1; (b) panel 2; (c) panel 3.

could be due to the preparation of the panels. The numerical response for panel 3 therefore overestimates the experimental results as the predicted failure occurred at the base.

For all the panels, the load-displacement trend is identical. First, the load increases linearly which represents the initial elastic phase. Next, a non-linear phase is reached while the load keeps increases which relates to the crack formation. In the post-peak regime, a softening behavior is observed and corresponds to the fracture propagation. Finally, a decreasing linear trend is observed for the load as the displacement increases. This phase characterizes the overturning process. One can analyze the latter phase using non-linear kinematic analysis, and more specifically the rigid-block displacement-based method.

Fig. 4 shows the results from the analytical method obtained from the kinematic analysis. The parameters used to perform the linear and non linear kinematic analyses are reported in Table 2. One can see that there is an excellent agreement with the numerical results. It is interesting to note that the horizontal force associated with the activation of the overturning F_0 are close to the kink point predicted by LDPM.

Figure 5: Total crack opening in: (a) panel 1; (b) panel 2; (c) panel 3.

Table 2: Parameters used to perform the linear and non linear kinematic analyses: initial horizontal multiplier α_0 , ultimate displacement d_u , participant mass fraction e^* , initial spectral acceleration a_0^* , initial horizontal force F_0 . The initial condition is referred to the activation of the overturning and the ultimate condition is associated with the loss of the overall equilibrium.

Panel Number	α_0 [-]	d_u [mm]	e^* [-]	a_0^* [m/s ²]	F_0 [N]

P3	0.200	240	1.0	3.270	1252

3 APPLICATION TO COMPLEX STRUCTURES

3.1 Local bending mechanism

3.1.1 Vertical bending mechanism

Design codes usually require the analysis of local collapse mechanism in unreinforced masonry walls for the assessment of seismic vulnerability [70]. Vertical bending mechanism was here considered as a first application of the numerical model and can be viewed as an alternative to kinematic analysis. The vertical bending mechanism is characterized by the fracture and the out-of-plane simultaneous rotation of two blocks of a facade with respect to the horizontal axis (often located at mid-height of the panel). This bending mechanism is observed for single or multi-story walls and the mechanical response depends on the effectiveness of the connection system with floors and the presence of openings or discontinuities.

For the simulation of vertical bending, two wall geometries were considered to be representative of real masonry walls. The first wall geometry was a one-story wall. It had a height of 3,000 mm, a thickness of 500 mm and a width 4,000 mm. Using this geometry, two cases were considered: case 1B-NO without openings and case 1B-O with openings. The dimensions of the openings were chosen to replicate the presence of windows (of 1,200 mm height, 500 mm thickness, 800 mm width) and doors (of 2,400 mm height, 50 mm thickness and 800 mm width). The second wall geometry was a two-story wall. It had a height of 6,000 mm, a thickness of 500 mm and a width 4,000 mm. Again, two cases were considered: case 2B-NO without openings and case 2B-O with openings. For all the walls, the translation and rotation of the stone-particles

were fixed on the bottom and the top sides. The load was applied in quasi-static conditions as a velocity prescribed to the surface particles at mid-height of the walls. Finally in order to consider self-weight, gravity load was applied prior to testing.

3.1.2 Results and discussion

Fig. 6 and Fig. 7 show the results of the simulations, for one-story and two-story walls, respectively.

Figure 6: Total crack opening: (a) one-story wall with no openings (1B-NO); (b) one-story wall with openings (1B-O); (c) Example of one-story bending mechanisms caused by the 2009 L'Aquila earthquake (Arch. Fot. Vice Comm. Del. Beni Culturali - Sisma Abruzzo 2009).

One can see that the main failure occurs at mid-height for the no-opening cases, with a secondary damage along the base (see Fig. 6a and Fig. 7a). In the cases with openings, one can notice that the crack occurs at about mid-height for the one-story wall (see Fig. 6b). For the two-story panel, the presence of windows affects the position of the main fracture, which is located close to the bottom of the windows and follows the discontinuity due to their inclusion (see Fig. 7b). Fig. 7d shows the load-displacement curves for the four cases. The trend is the same for all the walls. The load increases in an elastic phase and reaches a peak value. Next, a softening behavior is observed. As expected, the peak loads for the smaller walls are higher than the two-story panels. A reduction of the stiffness and the bearing capacity is observed when openings are considered. In particular, for the one-story bending mechanism, the stiffness and the bearing capacity decrease by 3.5% and 37.1%, respectively. For the two-story bending mechanism, the stiffness and the bearing capacity decrease of 6.9% and 16.4%, respectively.

3.2 Combined and Complex Mechanisms

3.2.1 Numerical modeling

In the analysis of local collapse mechanisms, all the possible failure mechanisms need first to be identified before being analyzed, for example using kinematic analysis. In more complex cases, such a process is impossible and simplified analytical methods are no longer satisfactory for an accurate study. In real structures, masonry walls are always in interaction with other structural elements. For example, the walls might be located within the continuity of a facade. There might also be transversal walls, floors and roofs attached to the main panel subjected

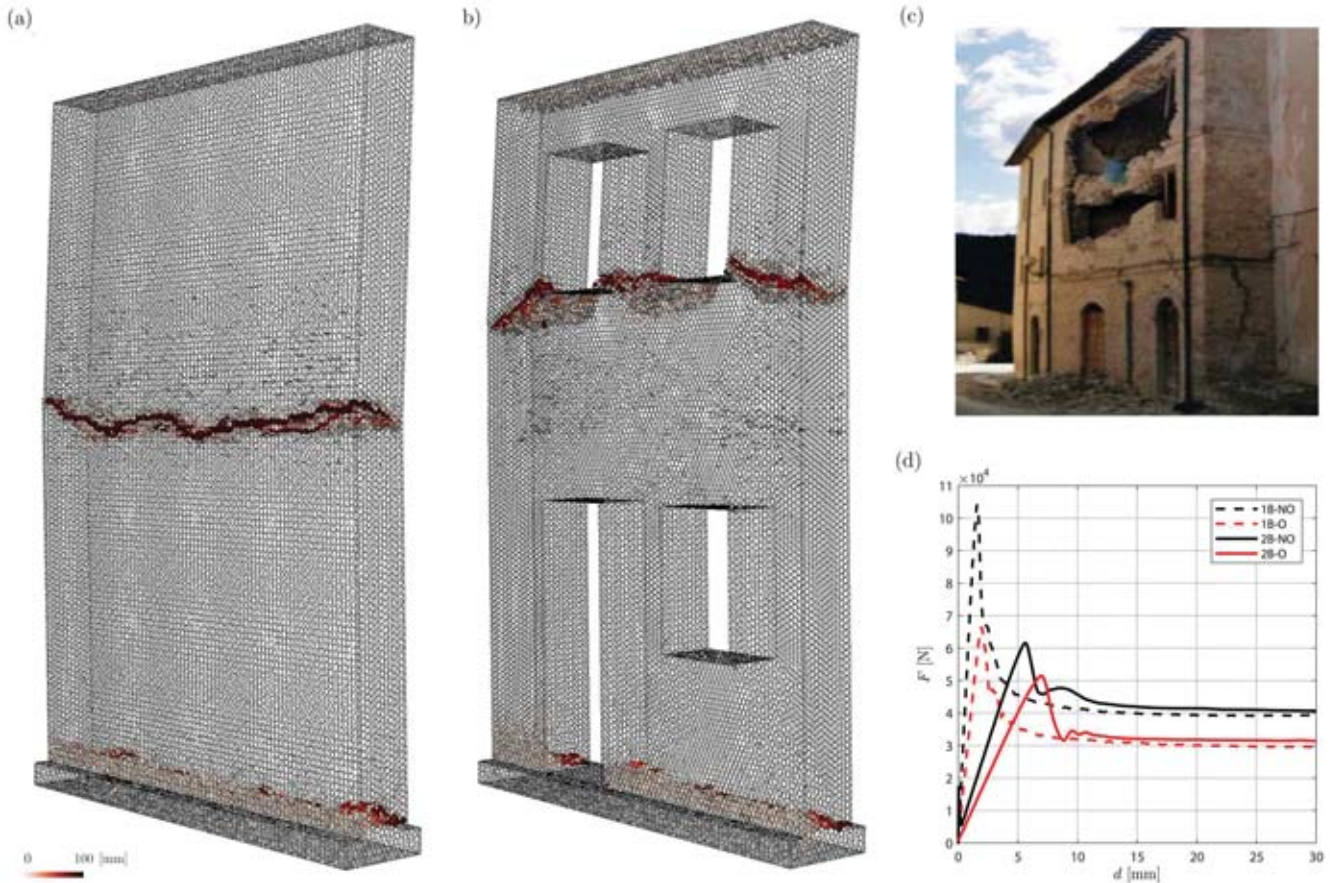

Figure 7: Total crack opening: (a) two-story wall with no openings (2B-NO); (b) two-story wall with openings (2B-O); (c) Example of two-story bending mechanisms caused by the 2009 L'Aquila earthquake (Arch. Fot. Vice Comm. Del. Beni Culturali - Sisma Abruzzo 2009); (d) force versus displacement curves for Cases 1B-NO, 1B-O, 2B-NO and 2B-O.

to out-of-plane loading. Moreover, masonry walls are usually the result of different stratification phases occurred over the course of many centuries. Here, three modeling strategies were adopted to reproduce different structural and time relations between the panels: (i) relation of contemporaneity (STRC), (ii) relation of anteriority (STRA) and (iii) relation of posteriority (STRP). In total, seven different cases were considered and they were based on the two-story bending wall with openings presented earlier.

STRC panels were modeled to replicate walls belonging to the same historical period. A single LDPM mesh was used and three sets of boundary conditions were considered to model different degrees of tothing between the walls. Fig. 8a, b, c show the models ordered by increasing level of constraint. The first model assumed the particles at the bottom surface to be fixed (see Fig. 8a). The second model assumed the particles at the bottom surface and the back surfaces of the transversal walls to be fixed (see Fig. 8b). The third model assumed the particles at the bottom surface, the back surfaces of the transversal walls and the lateral surfaces of the lateral walls to be fixed (see Fig. 8c).

STRP panels were modeled to replicate walls built after the adjacent structures. The main wall and the lateral-transversal walls were modeled using three separate LDPM meshes. All the particles at the bottom surface, the back surfaces of the transversal walls, and the lateral surfaces of the lateral walls were assumed to be fixed. A sliding with friction constraint model [59] was used at the interface between the panels. In order to simulate different levels of tothing

between the walls, two different friction conditions were adopted. High friction conditions were simulated using a static friction factor $s_{ff} = 0.13$ and a dynamic friction factor $d_{ff} = 0.015$ (see Fig. 8d), whereas low friction conditions were simulated with $s_{ff} = 0.03$ and a $d_{ff} = 0.0084$ (see Fig. 8e).

STRA panels were modeled to replicate walls built before the adjacent structures. The central-transversal walls and the lateral walls were modeled using three separate LDPM meshes. The structure composed by the main central panel and the transversal walls was assumed to belong to a previous historical period with respect to the lateral walls. The particles belonging to the bottom surface, to the back surfaces of the transversal walls and the lateral surfaces of the lateral walls were fixed. In order to simulate different levels of tothing between walls, the same sliding with friction algorithm was used and applied to the discontinuity surfaces between the panels. The same parameters for the friction mode were assumed, i.e. high friction (see Fig. 8f) and low friction (see Fig. 8g).

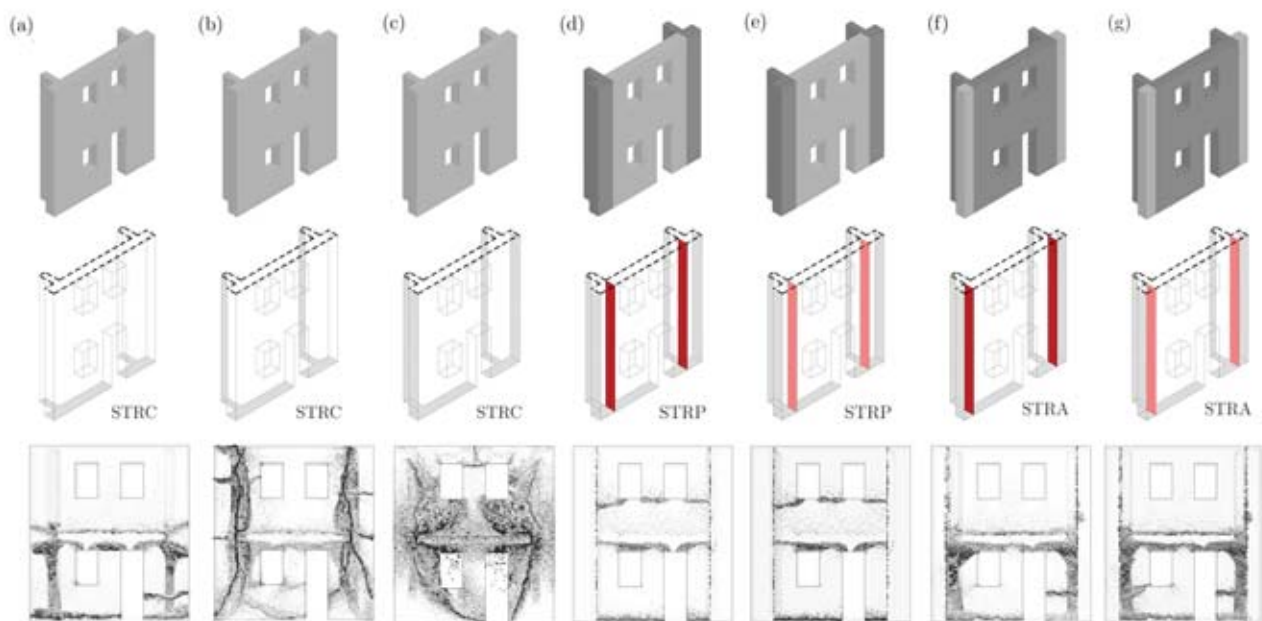

Figure 8: Geometry (top), boundary conditions (middle) and crack contours (bottom). In the middle row, the gray areas represent surfaces with all constrained displacements, the areas included within the black dotted lines represent the surfaces with horizontal displacements constrained in the out-of-plane direction and the red areas represent frictional interfaces (dark red for high friction and light red for low friction).

For all the simulated walls, the load was applied in quasi-static conditions by prescribing a velocity to particles of 300 mm height, between 2,700 mm and 3,000 mm, to reproduce the horizontal load of a floor activated by the seismic action. On top of the wall (at the second floor), the translations of the particles were constrained horizontally in the out-of-plane direction. The remaining boundary conditions and geometrical features of the structure are identical to the ones reported for the local bending mechanism case with opening case 2B-O.

3.2.2 Results and discussion

Fig. 8 and Fig. 9a, b, c, d, e, f show the damage distribution in the structures for the different configurations. Little similarities could be found with the local bending mechanism analyzed earlier. The fracture obviously depend on the boundary conditions and the connections between

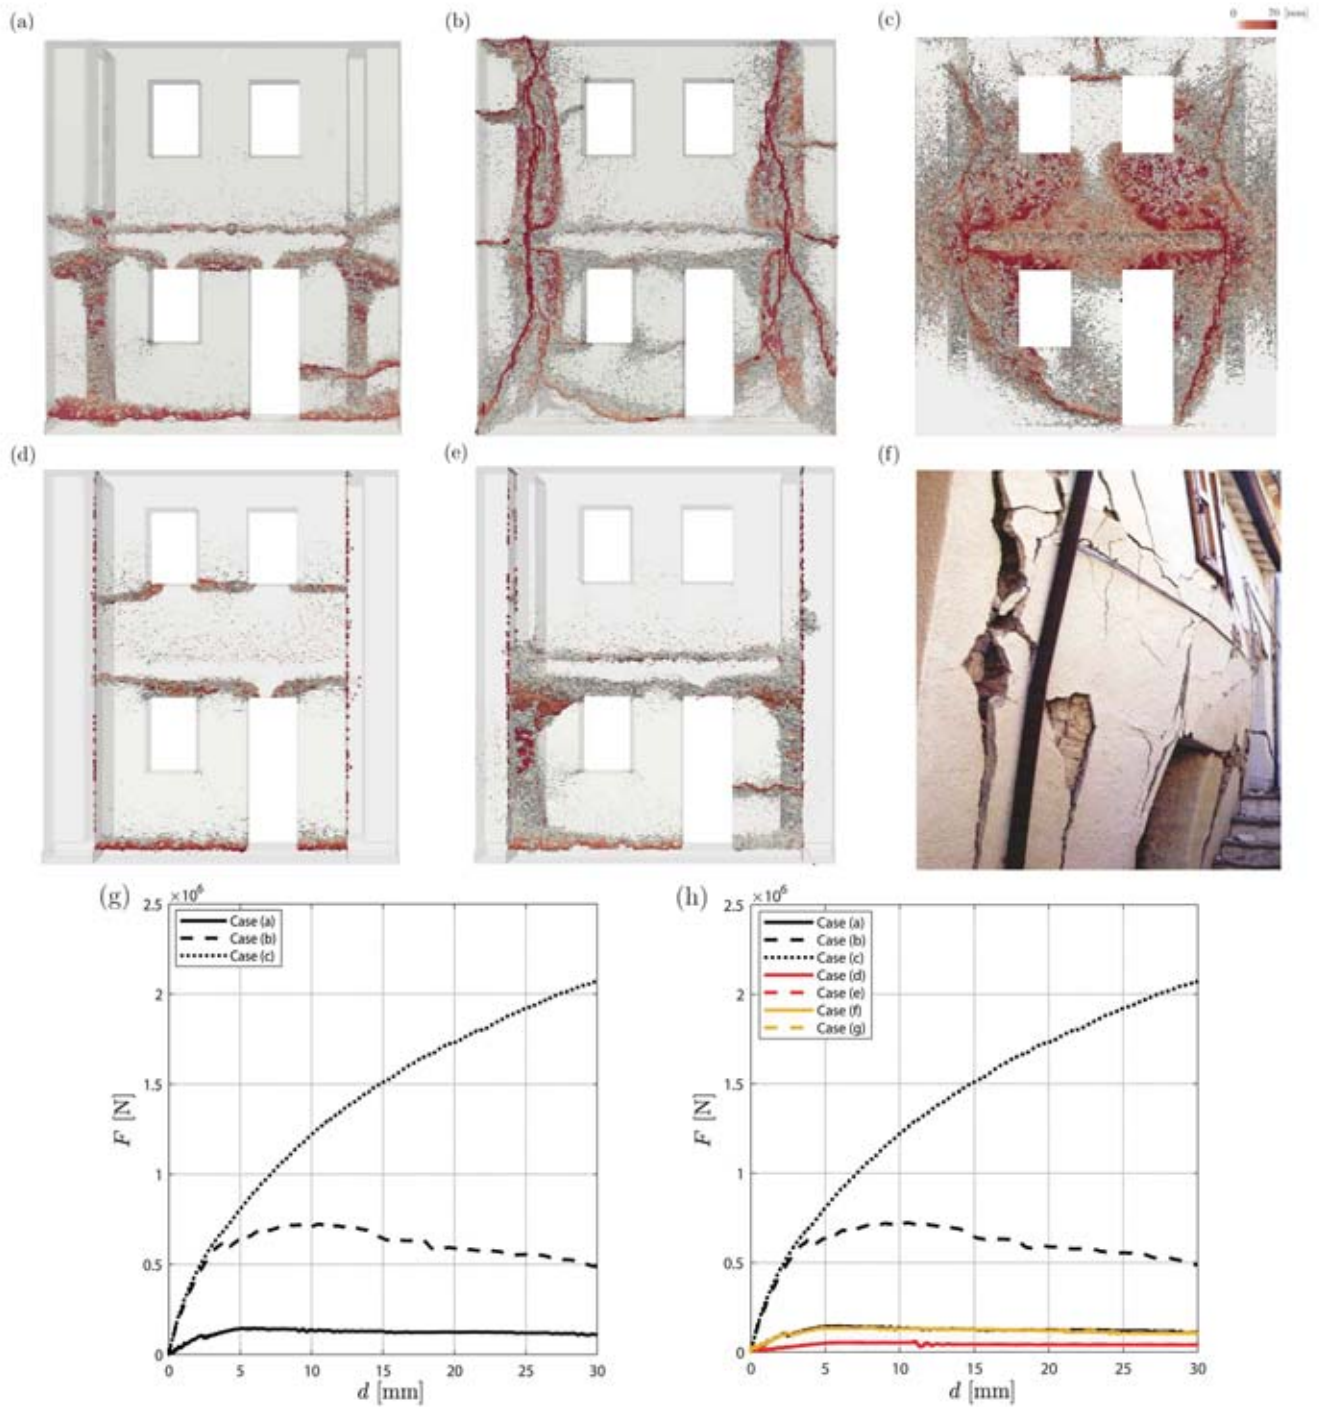

Figure 9: Total crack opening: (a), (b) and (c) STRC; (d) STRP; (e) STRA; (f) example of a complex mechanism (Arch. Fot. Vice Comm. Del. Beni Culturali - Sisma Abruzzo 2009). Force versus displacement curve: (g) for the cases (a), (b), (c); (h) for all the cases.

the central panel and the lateral and back walls. The damage in the case depicted in Fig. 8f, Fig. 8g and Fig. 9e is similar to the damage in the case shown in Fig. 8a and Fig. 9a. The reason might be that the continuity between the central and the transversal walls generates cracks in the lower floor as well as in the upper part. The main cracks in the cases depicted in Fig. 8b and Fig. 9b are vertical. On the contrary, the damage is distributed through the entire wall and are slightly concentrated in the central area (see Fig. 8c and Fig. 9c). In terms of quantitative analysis, Fig. 9g shows the load-displacement curves for the cases depicted in Fig. 8a, b, c. Fig. 9h shows all the curves. The more constrained case (see Fig. 8c) and the least constrained one (see Fig. 8d) define the upper and lower bound curves, respectively. One can deduce from these results that the choice of the correct boundary conditions in the analysis of such structures is complex and only a good estimation might be made. It also underlines the importance of performing accurate surveys to understand the architectural configuration and the historical evolution of the building.

4 CONCLUSIONS

The proposed Lattice Discrete Particle Model (LDPM) is presented, validated and used in the prediction of the mechanical behavior of unreinforced masonry structures in out-of-plane loading conditions. The model was first validated against experimental data and compared with nonlinear kinematic analysis (rigid-block displacement-based method). LDPM was then used to analyze more complex structures. Local bending mechanism was studied on walls with and without openings. The interaction between adjacent walls were also taken into account. The proposed numerical model is able to predict realistic fracture pattern in complex structures. On the basis of the results discussed in this paper, the following conclusions can be drawn.

- The damage distribution resulting from the collapse of masonry walls is well captured by LDPM.
- LDPM results were verified experimentally and with kinematic analysis. This suggests the use of this model to perform limit analysis for the assessment of local collapse mechanisms.
- Unlike typical kinematic analysis, LDPM does not require to identify a priori local collapse mechanisms. More complex configurations impossible to investigate analytically can also be considered.
- The presence of openings within walls and the application of adequate boundary conditions greatly affect the stiffness and bearing capacities of the walls.
- The results of this paper underlines the necessity to perform accurate in-field surveys in order to correctly model real masonry walls under out-of-plane loading.

Abstract

Unreinforced masonry (URM) buildings are characterized by high vulnerability to lateral loading, which is often manifested when an earthquake occurs. The present study investigates the effectiveness of a timber-based retrofit solution aimed at reducing the seismic vulnerability of existing URM structures. The retrofit technique consists of connecting timber-based panels, to the interior surface of the walls of a building using mechanical or adhesive point-to-point connections. The application of those panels allows to considerably increase both the in-plane and the out-of-plane capacity of the URM walls, while preserving the original external facades of the retrofitted building. This solution resulted to be relatively fast and easy to install and the reversible nature of the system allows to reduce the impact of the retrofit intervention.

In this work the in-plane behaviour of the retrofitted walls was investigated numerically, building on previous preliminary analyses and in the lights of the results of experimental evidence collected by the authors' research team. The effectiveness of this retrofit solution was analysed on several masonry types, considering different masonry properties and geometries. The influence of various parameters (such as masonry-to panel connection typology, connectors number and position) on the increase of lateral capacity of the retrofitted walls was studied by means of a series of non-linear quasi-static simulations.

Keywords: Unreinforced masonry, Seismic retrofit, Seismic rehabilitation, Timber panels.

1 INTRODUCTION

The retrofit solution studied herein aims at reducing the seismic vulnerability of existing masonry buildings while preserving the external facades. The retrofit consists of timber-based panels connected to the interior surfaces of the masonry walls of a building using mechanical or adhesive point to point connections. The use of the timber guarantees fast execution and reversibility of the system. A detailed description of this retrofit solution and the outcomes of numerical simulations were provided by Giongo et al. [1] while the effectiveness of this retrofit technique was experimentally investigated by Giongo et al. [2] via onsite testing of masonry shear walls strengthened with timber panels. Further experimental evidence on walls retrofitted with timber panels and timber-to-masonry connections can be found in Borri et al. [3], Pozza et al. [4], Riccadonna et al. [5] and Rizzi et al. [6].

Other examples of timber based retrofit techniques for masonry structures include the timber *strong-backs* retrofit solution and the timber *frames and sheathing* retrofit solution. The timber strong-backs retrofit solution aims to increase the out-of-plane capacity of the URM walls by connecting vertical timber elements to the masonry with mechanical screws or bolts. The effectiveness of this solution was investigated experimentally by Giaretton et al. [7], Dizhur et al. [8] and by Cassol et al. [9]. The timber *frames and sheathing* retrofit technique is instead a hybrid solution between the *strong-backs* and the *timber panels* retrofit techniques with the goal of increasing both the in-plane and the out-of-plane capacity of the URM walls. The effectiveness of this retrofit solution was recently tested by Guerrini et al. [10]. The use of timber panels as retrofit components was also studied for the seismic strengthening of reinforced concrete structures by Sustersic and Dujic [11] [12] and by Smiroldo et al. [13].

In this work the in-plane behaviour of walls retrofitted with cross-laminated timber (CLT) panels was investigated through non-linear quasi-static analysis. Starting from previous numerical analyses reported in [1], different modelling approach and type of analysis were adopted so as to improve the convergence and reach larger deformations. The properties of the connections (panel-to-masonry connections, panel-to-panel connections and anchoring system) were properly calibrated based the results of the aforementioned experimental testing campaigns carried out by the authors. The influence of different parameters on the effectiveness of the retrofit solution was investigated considering the behaviour of single piers, walls with openings and multi-storey walls. An example of retrofitted masonry wall is reported in Figure 1.

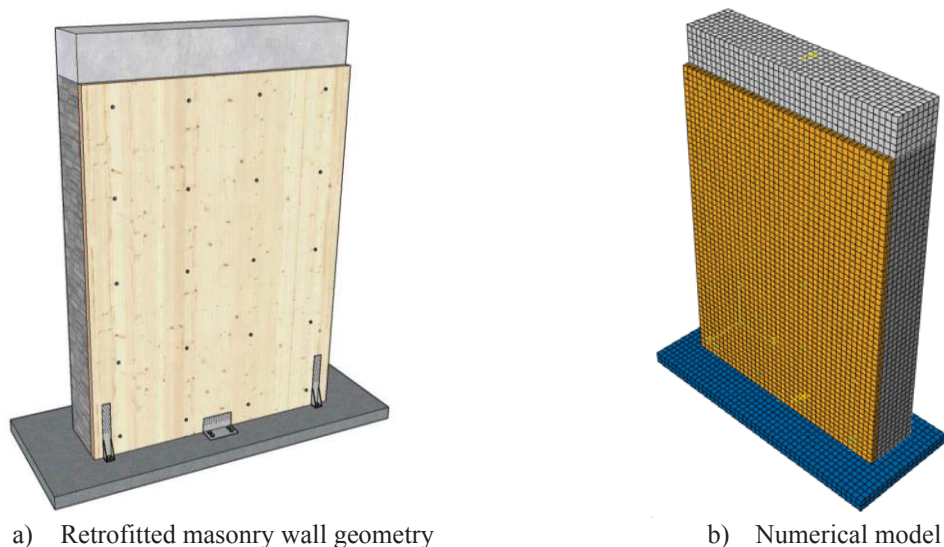

Figure 1: Retrofitted masonry wall.

2 NUMERICAL MODEL

The numerical models were realized using the finite element software Abaqus/Explicit [14]. The masonry was modelled as an equivalent, homogeneous and isotropic material. The post cracked behaviour was described with the Concrete Damage Plasticity (CDP) constitutive model. Such model was developed by Lubliner et al. [15] and improved with the modifications proposed by Lee and Fenves [16] and it is suitable to represent the behaviour of quasi-brittle materials such as masonry. The adopted yield surface function is a modified version of the Drucker-Prager model, which is governed by a parameter K_c . This parameter represents the ratio of the second stress invariant on the tensile meridian to that on the compressive meridian and it was assumed equal to 0.667. The dilatation angle, the flow potential eccentricity and the ratio of initial equibiaxial compressive yield stress to initial uniaxial compressive yield stress were assumed equal to 40° , 0.1 and 1.16 respectively, while visco-plastic phenomena were neglected. Parabolic and bilinear stress-strain relations were adopted to describe the compressive and tensile behaviours of the material under axial loading. The maximum values of the stress strain curves correspond to the compressive and tensile strengths while the post cracked behaviours are determined considering the fracture energy in tension and in compression. Such energy values were calculated as recommended by Lourenço [17].

The CLT panel was modelled as a three-layer solid, where the two external layers were defined with the principal direction oriented vertically while the inner layer was oriented horizontally. The timber was implemented as an orthotropic material where inelastic phenomena (such as local crushing at the panel's toe) were approximated using a plastic constitutive model. In this study the timber properties were selected considering timber grade C24 [18]. The point-to-point connections between the CLT panel and the masonry were modelled using one-dimensional connector elements. The properties of such elements were carefully calibrated on the experimental outcomes of different experimental campaigns. Cartesian and Radial thrust connectors were used and the connection between fastener extremities and masonry or timber was ensured by coupling constraints, considering adequate influence radii. Similar approach was adopted also for simulating the presence of anchoring devices such hold-downs (for tension forces) and angle-brackets (for shear forces). A concrete beam and a concrete base were also modelled using an indefinitely elastic and isotropic material with the aim of improving the transfer of the horizontal and the vertical loads to the masonry, and consistently with the load configuration of the experimental tests used as reference for the model validation. The surface-to-surface connections between the masonry and the concrete beam and the base were modelled using the tie constraint (no displacement allowed between coinciding nodes), while the interaction between the other elements was modelled with a hard contact constrain to avoid overlapping of materials.

A regular mesh pattern with eight nodes three dimensional elements (C3D8R) was used. The selected mesh size (i.e. 50 mm) is the maximum size that allowed to describe the material response close to the fasteners with adequate accuracy. Dynamic quasi-static analyses were performed to reduce the computational cost of simulations and to improve the convergence. The geometric nonlinearities were considered. The horizontal load was applied in the form of an imposed displacement while the vertical load was simulated as a uniform pressure. The loads were applied slowly (ranging between 0.05 and 0.2 mm/s) and the ratio between the kinetic and the internal energies of the system was monitored to verify the reliability of the analysis.

The model reproducing unreinforced masonry (URM) conditions was validated on the results from cyclic shear-compression testing of double-leaf rubble limestone masonry performed by Gattesco et al [19]. Figure 2 presents the comparison between the experimental

outcomes [19] and the numerical model employed in this work. It can be observed that the numerical results are consistent with the experimental data in terms of both *lateral load vs. displacement* curve and failure mechanism.

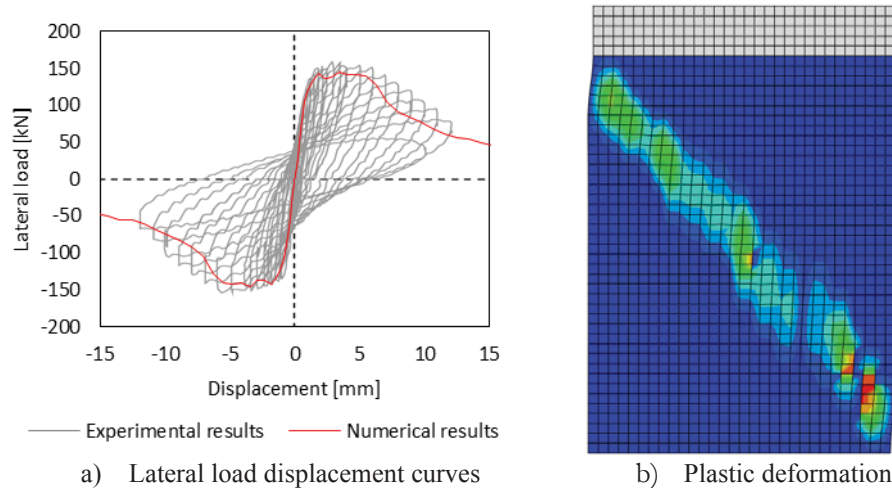

Figure 2: Model validation by means of a comparison between numerical and experimental results [19].

3 NUMERICAL ANALYSES

The effectiveness of the CLT panel retrofit solution was numerically investigated considering masonry piers retrofitted with one or more timber panels, walls with openings and multi-storey walls. The behaviour of the retrofitted walls was compared with the response of URM walls and parametric analyses were conducted.

3.1 Behaviour of retrofitted masonry piers

The first analyses were developed with the aim of testing the influence of different parameters on the response of the retrofitted walls. Different retrofit configurations were considered by changing the following parameters:

- Masonry properties (M1-M2-M3)
- Masonry thickness (T1-T2-T3)
- Masonry length (L1-L2-L3-L4-L5)
- Masonry overburden (Q1-Q2-Q3-Q4)
- Fastener configuration (C1-C2-C3-C4-C5-C6-C7)
- Connection properties (K1-K2-K3-KR)
- Hold-down properties (HD1-HD2-HD3-HDR)
- Angle bracket properties (AB1-AB2-AB3-ABR)

The mechanical properties of masonry vary widely and are greatly dependent on the properties of its components. Three masonry types were chosen to represent the masonry typologies that can be encountered when retrofitting existing masonry buildings. Table 1 reports the values of the adopted masonry properties. Three different thicknesses were selected with the aim of representing thin, medium and thick walls, see Table 2. All of the tested walls were characterized by the same height (2700 mm masonry + 300 mm concrete beam) while three different lengths were considered, see Table 3. The analysis was developed in displacement

control with the vertical load applied uniformly over the concrete beam. Four values of overburden were applied, see Table 4. Two boundary conditions were studied, assuming the wall's ends as either fixed-free (i.e. vertical cantilever) or double fixed. The real behaviour of the top constraint depends on several factors, such as the presence of the bond beam, the features of the lintels and the type of floor-diaphragm. The two selected boundary conditions represent the limit cases of weak and strong spandrels [20]. The combination of the previous properties (masonry properties, masonry thickness, overburden and boundary conditions) resulted in wall models characterized by different failure modes (e.g. rocking and diagonal cracking).

Masonry ID	M01	M02	M03
Elastic modulus E [MPa]	600	1200	1800
Compression strength f_c [MPa]	1.50	3.00	4.50
Compression fracture energy G_c [N/mm]	3.98	7.50	10.58
Tension strength f_t [MPa]	0.050	0.075	0.100
Tension fracture energy G_t [N/mm]	0.02	0.02	0.02

Note: for all the masonry types the density is 18 kN/m^3 and the Poisson ratio is 0.25.

Table 1: Masonry properties.

Thickness ID	T1	T2	T3
Thickness [mm]	250	400	600

Table 2: Masonry thicknesses.

Length ID	L1	L2	L3	L4	L5
Length [mm]	1500	2000	3000	4500	6000
Length to height ratio [-]	0.50	0.67	1.00	1.50	2.00

Table 3: Masonry lengths.

Overburden ID	Q1	Q2	Q3	Q4
Overburden [MPa]	0.10	0.15	0.20	0.25

Table 4: Overburdens.

The retrofit solution proposed herein consists of fixing a 60 mm CLT panel on the surface of the masonry wall. The point-to-point connection between the masonry wall and the timber panel is provided by mechanical or adhesive connections. Different retrofit configurations were analysed by changing the number and the position of the fasteners, see Table 5. The values of the connection stiffness and shear capacity were selected in accordance with the experimental results obtained in [5] and [6], where experimental testing of dry and adhesive connections under monotonic and cyclic shear loading was performed. The implemented load-displacement curves of the timber to masonry connections are reported in Figure 3a. The connection K1 represents a typical dry connection realised with screw-fasteners [5] and which was used to connect the timber elements (panels or strong-backs) to the wall in the experimental campaigns reported in [2] and [9]. Two adhesive connection types were also considered through K2 and K3 curves [6]. Additionally, a rigid connection (KR) was modelled to represent the limit case.

The timber panel was constrained to the ground by two hold-down devices positioned on either side of the timber panel at 100 mm from the lateral edge and by an angle bracket positioned at the middle of the base of the panel, see Figure 1. Three tensile and shear load dis-

placement curves were chosen to model the hold-down and the angle bracket connections based on the experimental outcomes presented in [21] and [22], see Figure 3b,c. The cases of rigid tensile and shear connections were also studied (HDR and ABR) to simulate the properties of high-stiffness connections such as the one presented in [23].

Configuration ID	C1	C2	C3	C4	C5	C6	C7
Connectors number [-]	12	15	16	20	24	28	35
Horizontal spacing [mm]	800	800	533	533	533	533	400
Vertical spacing [mm]	800	600	800	600	480	400	400
Connectors/m ² [-/m ²]	2.22	2.78	2.96	3.70	4.44	5.19	6.48

Table 5: Connector's configurations.

Note: It was also studied the case of rigid connections (KR, HDR, ABR).

Figure 3: Connection properties.

A base configuration was defined considering the retrofitted masonry wall reported in Figure 1 with the properties M1, T2, L2, Q1, C4, K1, HD2, AB3. Figure 4 presents the results obtained for this configuration in the unreinforced (URM) and retrofitted (R) states for two boundary conditions (fixed-free and double-fixed). It can be observed that in case of shear cracking behaviour (SB) the application of the retrofit allows to increase the lateral and the displacement capacities of the masonry wall considerably. The crack pattern of this model (R-SB) is characterized by the formation of a diagonal crack (point 1) followed by a further increase of load bearing capacity. The maximum capacity increase (56%) corresponds to the condition where the fasteners' shear capacity is reached. In case of rocking behaviour (RB), the application of the retrofit provides an increase in lateral capacity of 67%. The crack pattern is characterized by the formation of a first horizontal crack (point 2) next to the wall base, typical of the rocking behaviour, followed by the formation of second horizontal crack at mid-height of the tension side (point 3) and then, when the maximum lateral capacity is reached, a third crack developed (point 4). The second and the third cracks' formation is due to the tensile stress induced in the masonry by the fasteners. The URM-RB model exhibits a displacement capacity larger than 60 mm due to the properties of the URM wall. The displacement capacity limit imposed by the Italian code standard [24] is 30 mm for the URM-RB failure (1% wall's height) and 15 mm (0.5% wall's height) for the URM-SB failure, therefore in this work the behaviour of the masonry walls was studied within the displacement interval from 0 to 60 mm.

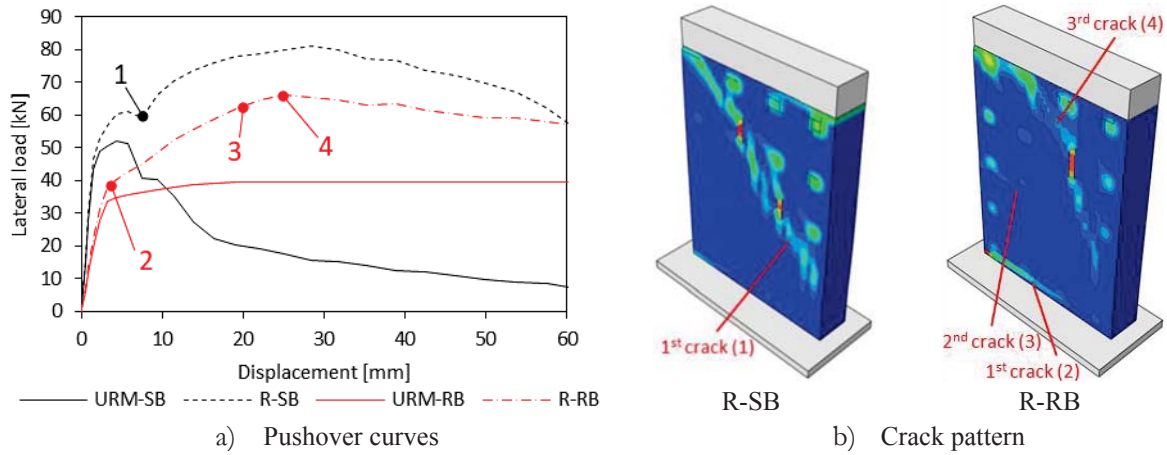

Figure 4: Standard configuration results (M1, T2, L2, Q1, C4, K1, HD2, AB3) (unreinforced masonry URM, retrofitted R, shear behaviour SB, rocking behaviour RB).

3.1.1. Timber panel anchoring connection

Four retrofit configurations were analysed considering different CLT panel anchoring connections: 1) a retrofit solution with no anchoring system to fix the panel to the foundation (CLT); 2) a solution with the connection provided by the sole hold-downs (HD); 3) a solution with just the angle bracket (AB) and 4) a solution with both the hold-downs and the angle bracket (HD+AB). Figure 5 presents the results for the two boundary conditions. It can be observed that in the first case (double-fixed condition and shear cracking behaviour), the application of the timber panel considerably increases the displacement capacity. As expected, the application of the hold-downs does not affect the performance of the retrofit while the constraint provided by the angle bracket produces a notable increase in the lateral capacity of the URM wall (AB and HD+AB). In the second case (cantilever and rocking behaviour), on the contrary, the hold-downs are of paramount importance in determining the effectiveness of the retrofit.

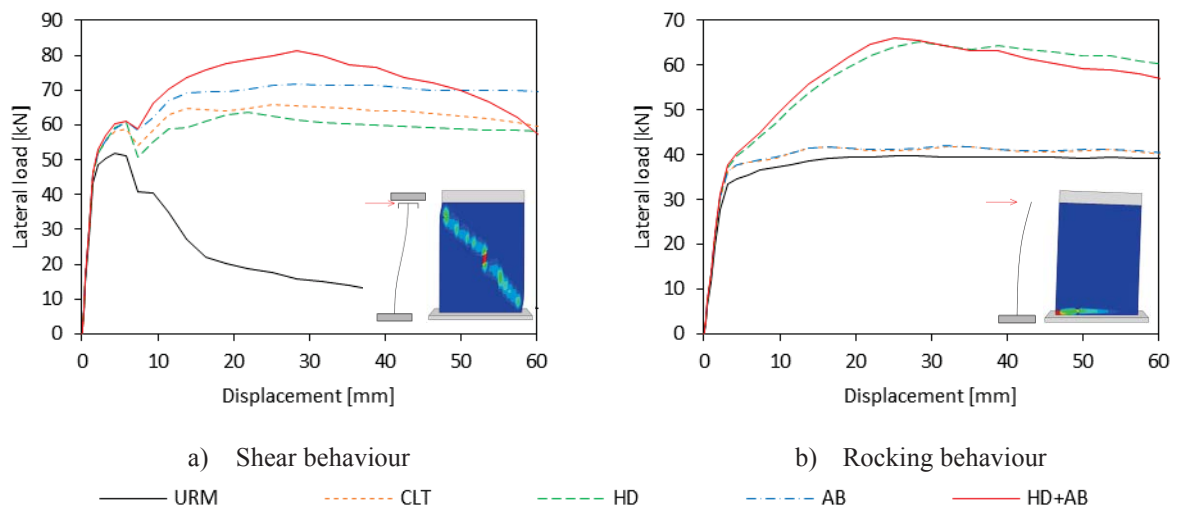

Figure 5: Effectiveness of the CLT panel to ground connection on the response of the retrofitted wall (base configuration M1, T2, L2, Q1, C4, K1, HD2, AB3).

Additional analyses were performed considering different hold-down and angle bracket properties, see Figure 6. The effect of the angle bracket properties was investigated considering the shear cracking behaviour (Figure 6a) and it was shown that the adoption of stiffer and

stronger angle brackets (AB3) appreciably increases the maximum capacity. Figure 6b shows the effect of different hold-downs on the response of the retrofitted wall in the case of rocking behaviour. The hold-down properties affect the stiffness of the second part of the response curves, when the first horizontal crack is already developed, while the lateral capacity of the retrofitted walls does not change. The shear load on the angle bracket was between 20 and 40 kN while the tensile load on the hold-downs ranged from 40 to 60 kN.

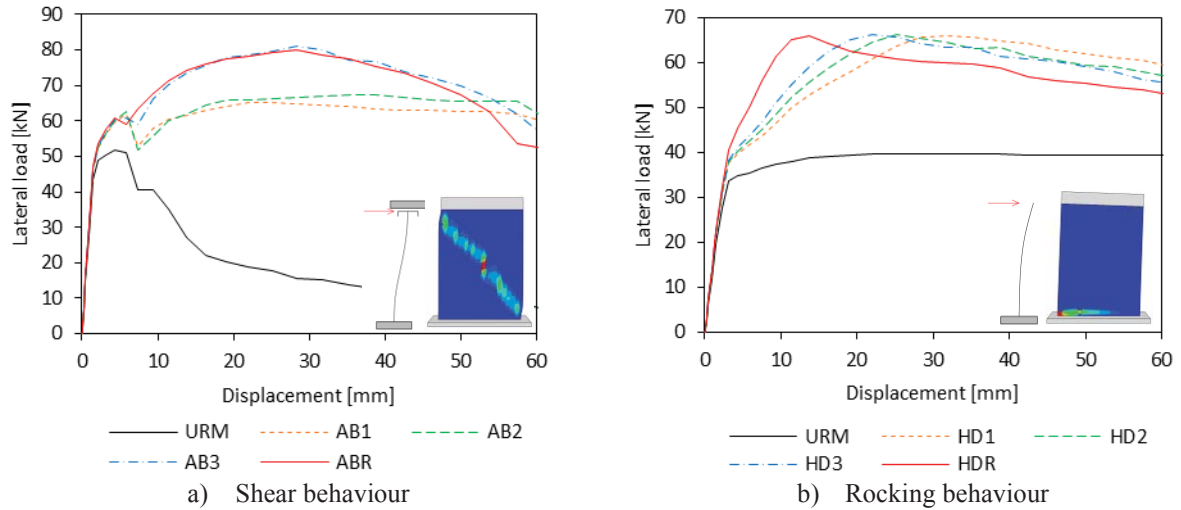

Figure 6: Effectiveness of angle bracket (SCB) and the hold-down (RB) properties on the response of the retrofitted wall (base configuration M1, T2, L2, Q1, C1, K1, HD2, AB3).

3.1.2. Timber panel to masonry wall connection

Figure 7 reports the behaviour of masonry walls retrofitted considering different types of CLT panel to masonry connections (see Figure 3a). The increase of connection stiffness slightly increases the effectiveness of the retrofit intervention for both failure modes. It can be noticed that in the shear cracking behaviour case, the response of the dry connection K1 presents a small decrease in the load bearing capacity as soon as the wall starts cracking followed then by a strength regain and a further increase. This phenomenon is due to the reduced stiffness of the connection, which requires the wall to displace 10 mm prior to engaging sufficient fasteners' shear to further increase the global lateral capacity.

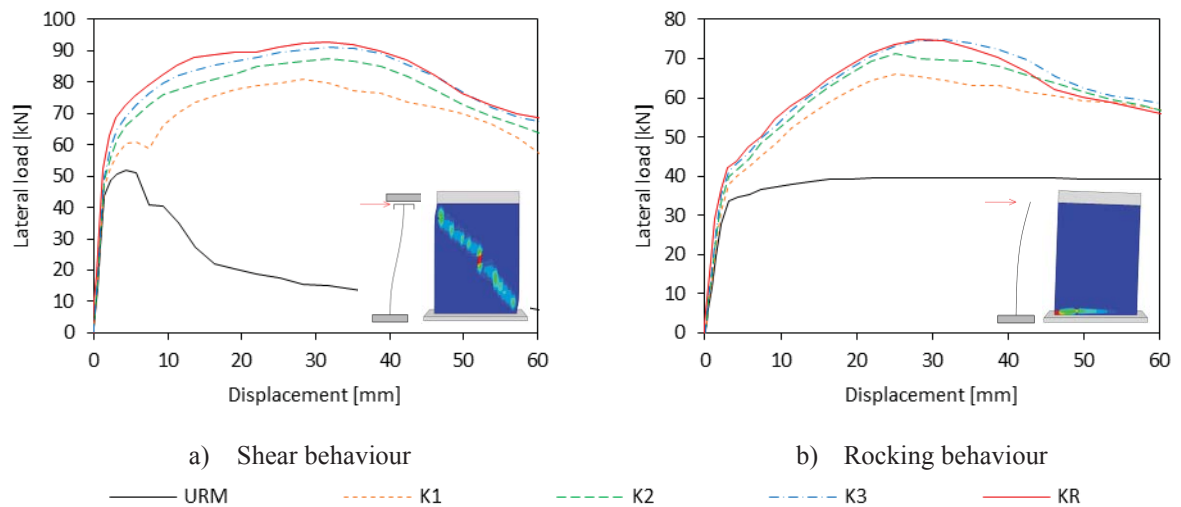

Figure 7: Effectiveness of the CLT panel to masonry connection on the response of the retrofitted wall (base configuration M1, T2, L2, Q1, C1, HD2, AB3).

The influence of the timber-to-masonry connection layout was analysed by varying the number and the position of the point-to-point fasteners, see Figure 8. Not surprisingly, the effectiveness of the retrofit solution grows when increasing the number of connectors, especially for the shear cracking behaviour. It can be observed that the pushover curves obtained from increasing the number of connectors are compatible with those obtained from increasing the fastener stiffness (Figure 7). The inevitable local stress-concentration associated with the stiffer fasteners appeared therefore not to be detrimental to the overall wall performance. As a result, the adoption of fewer fasteners of larger diameter seems a viable option to reduce costs, especially when adhesive fasteners are used.

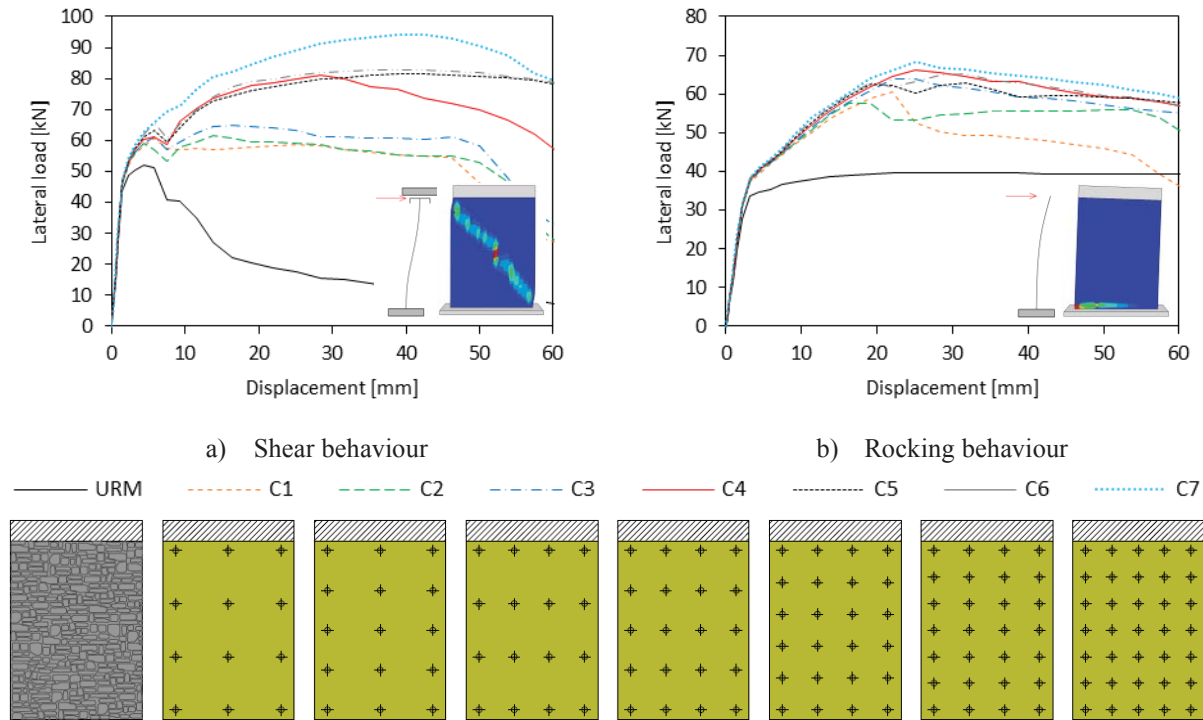

Figure 8: Effectiveness of the connector's configuration on the response of the retrofitted wall (base configuration M1, T2, L2, Q1, K1, HD2, AB3).

3.1.3. Overburden

Figure 9 reports the behaviour of retrofitted masonry walls for different overburden levels (see Table 4). As expected, the increase in overburden improves the load bearing capacity of both URM walls and retrofitted walls. Regarding the displacement capacity, when the wall response was governed by rocking (i.e. fixed-free walls), an increase in the vertical loading produced a reduction in the URM wall capacity due to toe crushing (URM-Q3 and URM-Q4). Conversely, when the walls responded in shear (i.e. double fixed-end walls) the displacement capacity was not appreciably affected by the overburden level. As concerns the retrofitted walls, the response appeared not to be influenced by variations in the vertical load independently from the boundary conditions.

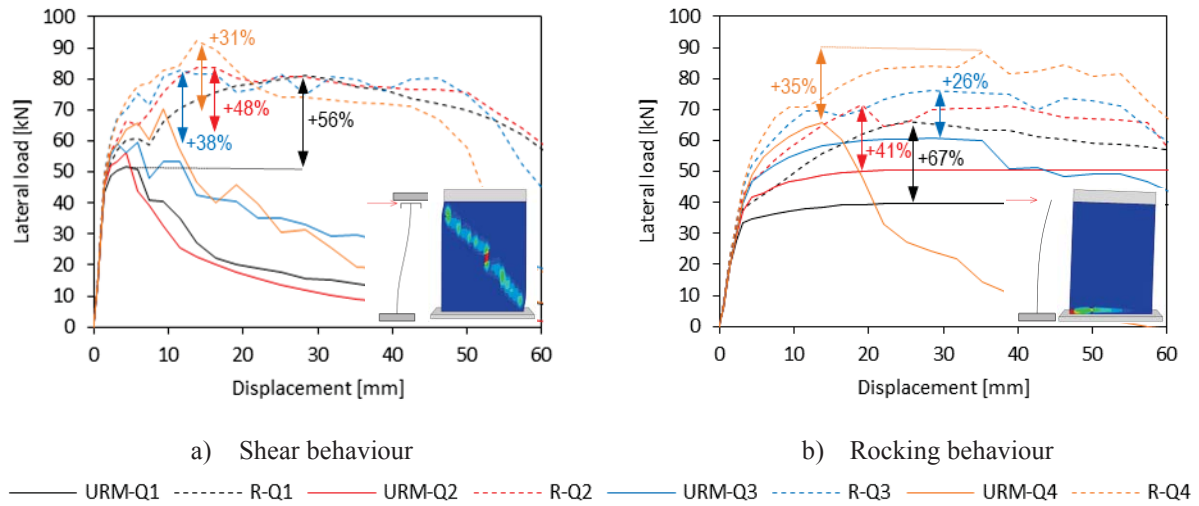

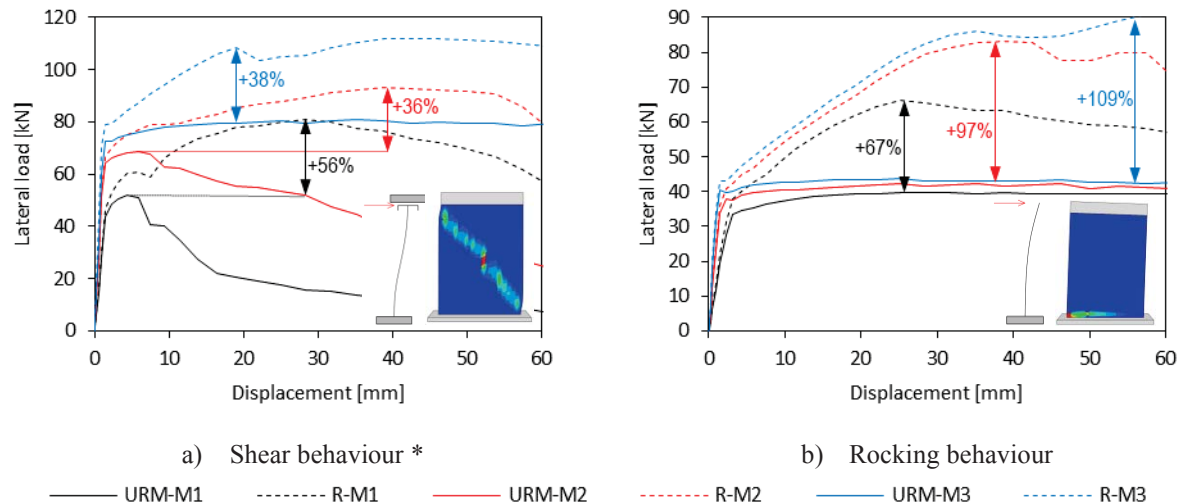

Figure 9: Effectiveness of the CLT panel retrofit on URM walls characterized by overburdens (base configuration M1, T2, L2, C1, K1, HD2, AB3).

3.1.4. Masonry wall characteristics

Figure 10 reports the behaviour of retrofitted masonry walls characterized by different masonry properties (see Table 1). It can be noticed that the application of the retrofit solution is effective for all the investigated configurations. Predictably, an increase in the elastic modulus affects the initial slope of the response curves while the improvement of tensile and compressive strength values impacts the behaviour of both the URM and retrofitted walls. The walls URM-M3 and R-M3 are characterized by rocking even in the case of double-fixed conditions. Such response is characterized by the formation of two horizontal cracks, one at the bottom and one at the top of the wall, and the retrofit solution resulted to be effective also in this case. For the RB cases, the effectiveness of the retrofit solution grows when improving the masonry properties. This phenomenon is mainly due to the increase of tensile strength which allows to transfer more load on the masonry wall before that the third diagonal crack occurs (Figure 4).

Note: * walls URM-M3 and R-M3 are characterized by a rocking behaviour for both boundary conditions.

Figure 10: Effectiveness of the CLT panel retrofit solution on URM walls characterized by different masonry properties (base configuration T2, L2, Q1, C1, K1, HD2, AB3).

Figure 11 reports the behaviour of retrofitted masonry walls characterized by different masonry thicknesses (see Table 2). It can be observed that the application of the retrofit solution considerably increases the shear and the displacement capacities of all the investigated configurations, except for case R-T3 (600 mm thickness) with double-fixed conditions, where the retrofit has an appreciable impact only over the displacement capacity that increases tenfold.

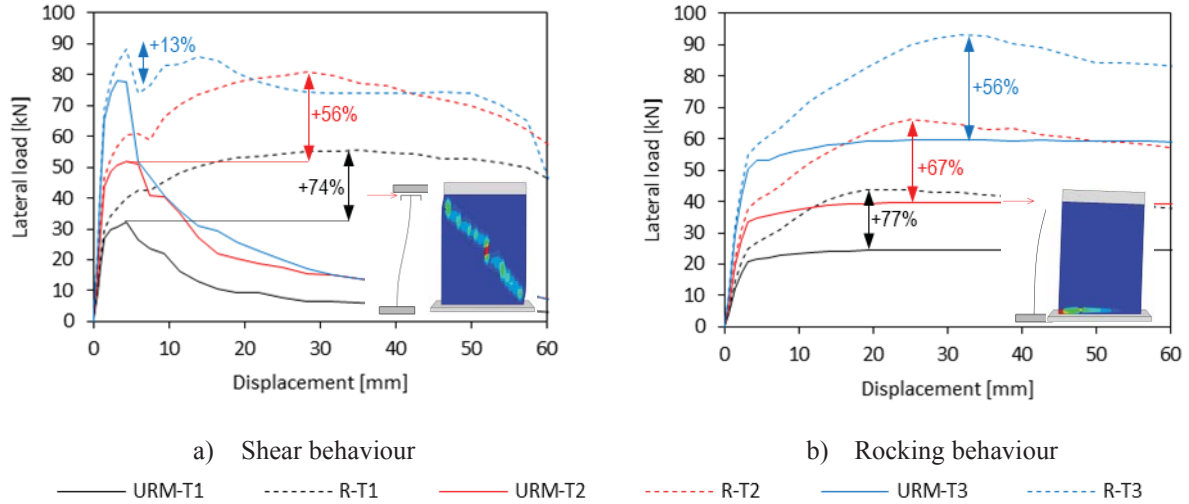

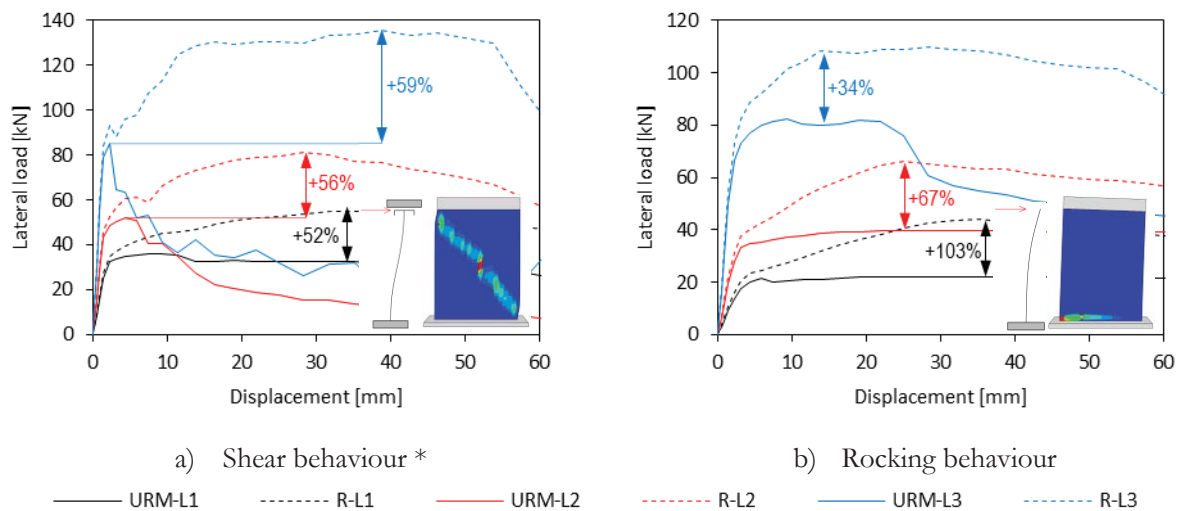

Figure 11: Effectiveness of the CLT panel retrofit solution on URM walls characterized by different thicknesses (base configuration M1, L2, Q1, C1, K1, HD2, AB3).

Figure 12 shows the behaviour of retrofitted masonry walls characterized by different masonry height to length ratios (see Table 3). The retrofit solution resulted to be effective for all the investigated configurations. As expected, the increase of the length to height ratio reduces displacement capacity of the URM walls in the cantilever condition, but it does not affect the displacement capacity of the retrofitted walls. The shorter walls URM-L1 and R-L1 are characterized by rocking failure independently from the boundary conditions adopted, with the retrofit proving to be effective for both wall configurations. The cases L4 and L5 are described in the following section when considering a multi-panel retrofit.

Note: * walls URM-L1 and R-L1 are characterized by a rocking behaviour for both boundary conditions.

Figure 12: Effectiveness of the CLT panel retrofit on URM walls characterized by different aspect-ratios (base configuration M1, T2, Q1, C1, K1, HD2, AB3).

3.2 Behaviour of URM walls retrofitted with multiple timber sub-panels

The dimensions of the CLT panels employed for the wall-retrofit are often subjected to limitation due to transport issue inside the buildings and, consequently, the strengthening of a single wall can be obtained by using two or more “sub-panels” shorter than the wall. In such case, the panel-to-panel connection and the anchoring connections are key aspects in determining the effectiveness of the retrofit solution. The panel-to-panel connection could be achieved by inserting fully threaded timber screws at an angle of 45° to the joint line (e.g. 8 mm diameter screws spaced at 200 mm). This connection was modelled using one-dimensional connector elements calibrated on the experimental outcomes obtained by Hossain et al. [25]. Two panel behaviours were analysed considering different anchoring conditions: the “single panel behaviour” (SPB) (Figure 13a) and the “multi-panel behaviour” (MPB) (Figure 13b). The SPB is characterized by the presence of a hold-down positioned at the two corners of the wall. In such case, the CLT sub-panels behave as a single panel with some interface slip at the panel-to-panel joint due to the screw connection deformability. In the second case (MPB), instead, each sub-panel is anchored at its base with two hold-downs and the CLT panels’ response is more similar to that of independent single panels.

Figure 14 and Figure 15 report the pushover curves of a 3000 mm long URM wall retrofitted with two panels 1500 mm wide, for the SPB and the MPB. Three panel-to-panel connections were studied: no panel-to-panel connection (J0), panel-to-panel screwed connection [25] (shear stiffness 3000 N/mm, tension stiffness 3000 N/mm, shear capacity 6000 N) and rigid connection (JR). As visible from the graphs, the adoption of connection J1 resulted in a higher peak capacity if compared to the case with J0, comparable to the performance obtained with the rigid connection JR. In previous analyses reported in [1], the influence of the panel-to-panel connection was found to be less pronounced. It is worth noting that the analyses in the preliminary study reached drift ratios (≈ 0.2 - 0.3%) smaller than those at which the impact of the panel-to-panel connection observed herein became appreciable. The multi-panel solution was then applied to two squat walls, with length to height ratios of 1.5 and 2.0 (L4 and L5), using respectively 3 and 4 CLT panels 1500 mm wide. The panel retrofit was modelled assuming a SPB which resulted in improvements of the walls’ maximum load-bearing capacities larger than 30%. As expected, the squat walls responded mainly in shear with formation of diagonal cracks. As a consequence, rocking was a secondary mechanism, with the tension forces in the “SPB hold-downs” being smaller than 35 kN for all three configurations L3, L4 and L5. The maximum shear force measured in the angle-brackets was also small (< 30 kN) because of the increased number of angle-brackets (one for each CLT panel).

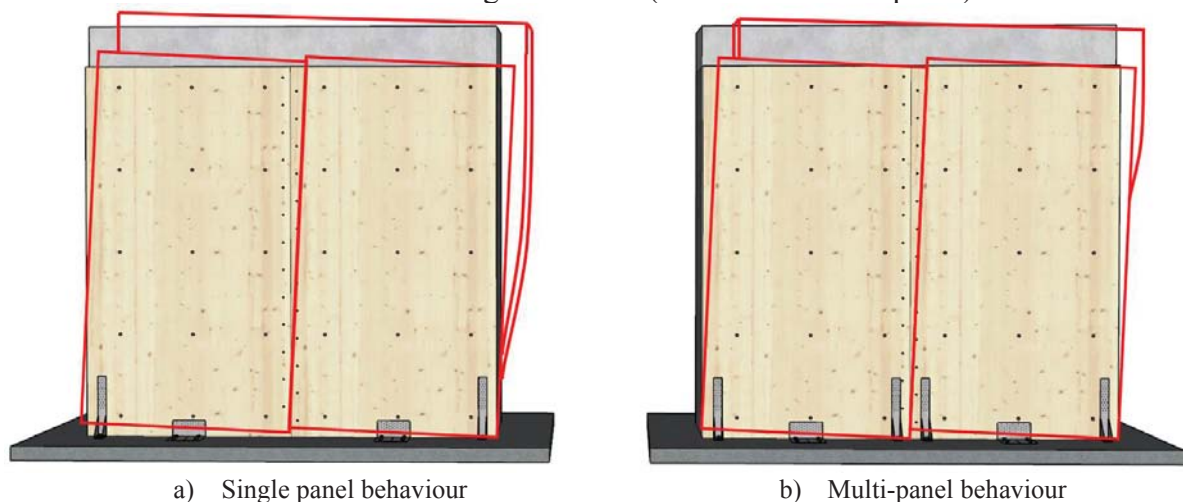

Figure 13: Multi-panel retrofit solutions.

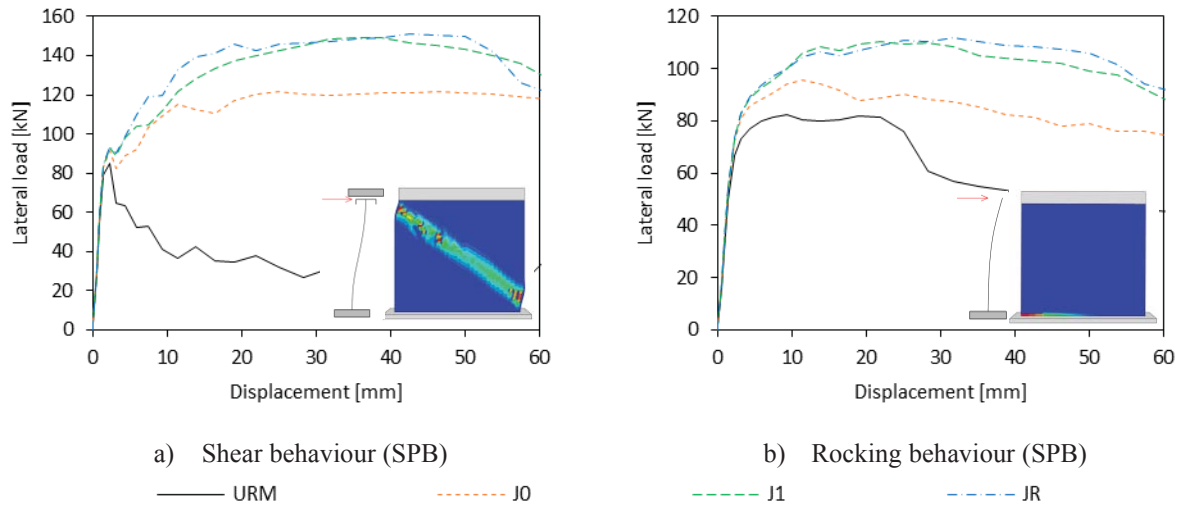

Figure 14: Effectiveness of the CLT panel retrofit solution on URM walls, single panel behaviour (SPB) (base configuration M1, T2, L3, Q1, C1, K1, HD2, AB3).

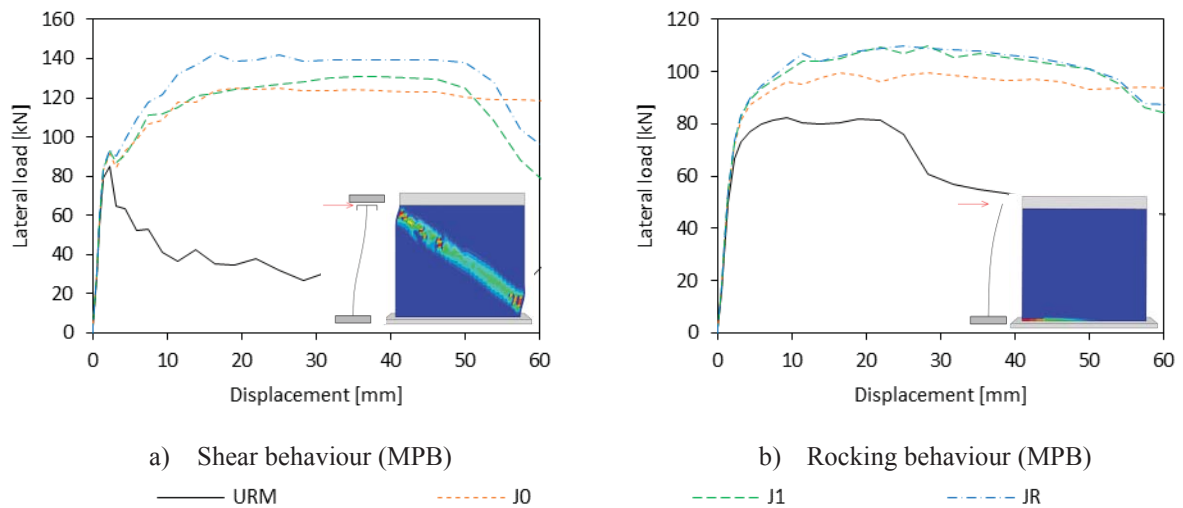

Figure 15: Effectiveness of the CLT panel retrofit solution on URM walls, multi panel behaviour (MPB) (base configuration M1, T2, L3, Q1, C1, K1, HD2, AB3).

3.3 Behaviour of retrofitted masonry walls with openings

The effectiveness of the retrofit when applied to masonry walls with openings was also studied. Two cases were modelled, consisting of two-pier walls with a door opening ($900 \times 2100 \text{ mm}^2$) or a window opening ($900 \times 1000 \text{ mm}^2$, sill height 1100 mm). The piers had the same characteristics of those described previously (M1, T2, L2, Q1, C1, K1, HD2, AB3). The spandrel was modelled without any additional tension-resisting element (no lintel nor concrete ring-beam). Figure 16 gives the response curves of the retrofitted walls. Three retrofit conditions were modelled: 1) R1, where the reinforcement was applied only to the masonry piers; 2) R2 that sees also the reinforcements of the spandrels, but without any connection between the CLT panels, and 3) R3, where the connection between the CLT panels strengthening the piers and the ones fixed to the spandrels was ensured by inclined timber screws, similarly to what reported in the previous section for the panel-to-panel connection. All three

retrofit solutions produced a remarkable increase in the shear capacity of the masonry walls (increase $> 30\%$) with the contribution of the spandrel retrofit being more effective, expectedly, when the panel-to-panel connection is present.

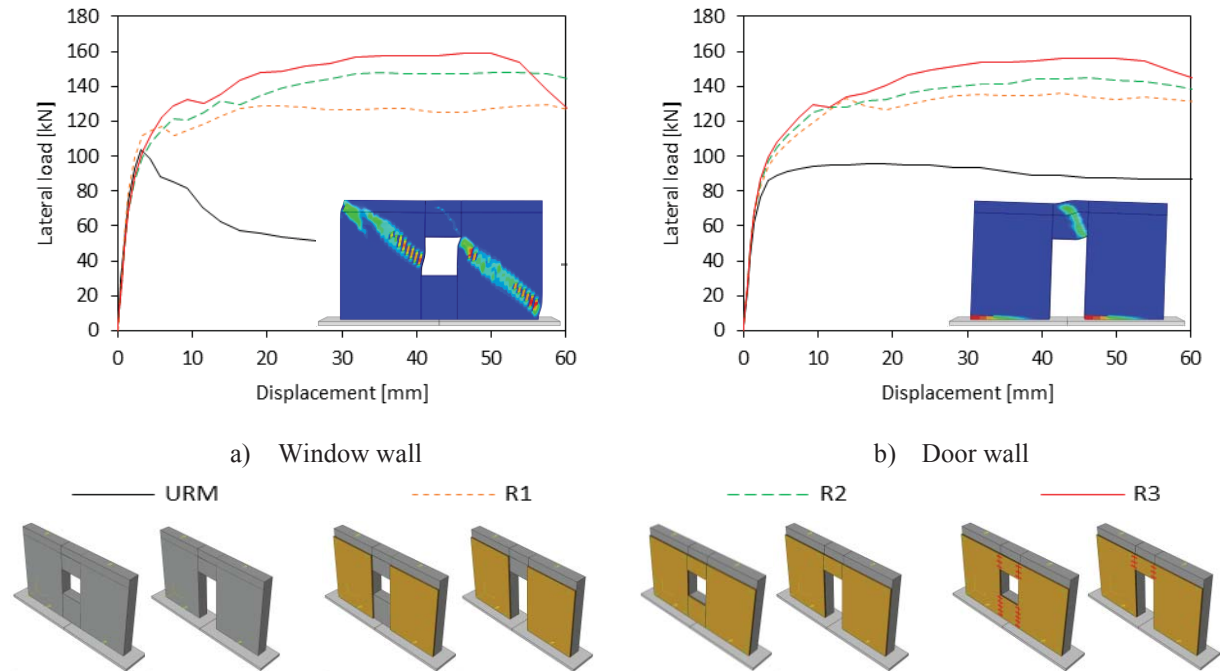

Figure 16: Effectiveness of the CLT panel retrofit solution on URM walls with openings (base configuration M1, T2, Q1, C1, K1, HD2, AB3).

3.4 Behaviour of two-storey retrofitted masonry walls with openings

Figure 17 shows the behaviour of two-storey retrofitted masonry walls. The geometry of such walls was derived from the “Door wall” and the “Window wall” analysed in the previous section, respectively for the first and the second level. The horizontal loading was applied at the diaphragm levels assuming a uniform distribution. The three retrofit configurations R1, R2 and R3 previously introduced for the one-storey walls were evaluated also for the two-storey walls. Three inter-storey force transfer mechanisms were analysed: 1) compression only (IS1); 2) compression and tension (IS2); and 3) compression, tension and shear (IS3). The condition IS1 can be obtained by creating slots in the bottom portion of the CLT panels at the second level, so that direct panel-to-panel contact is possible despite the presence of the diaphragm joists (see Figure 17), while the conditions IS2 and IS3 can be achieved by adding steel plates to transfer the tensile and shear forces. The tension and the shear inter-storey anchors were modelled adopting the force displacement curves of HD2 and AB3. The retrofit solution R3-IS3 resulted to be the most effective (increase of lateral load bearing capacity $> 70\%$) while the response curves of the other cases provided an increase of lateral capacity larger than 25%. All the retrofit solutions also guaranteed a noticeable increase in the displacement capacity.

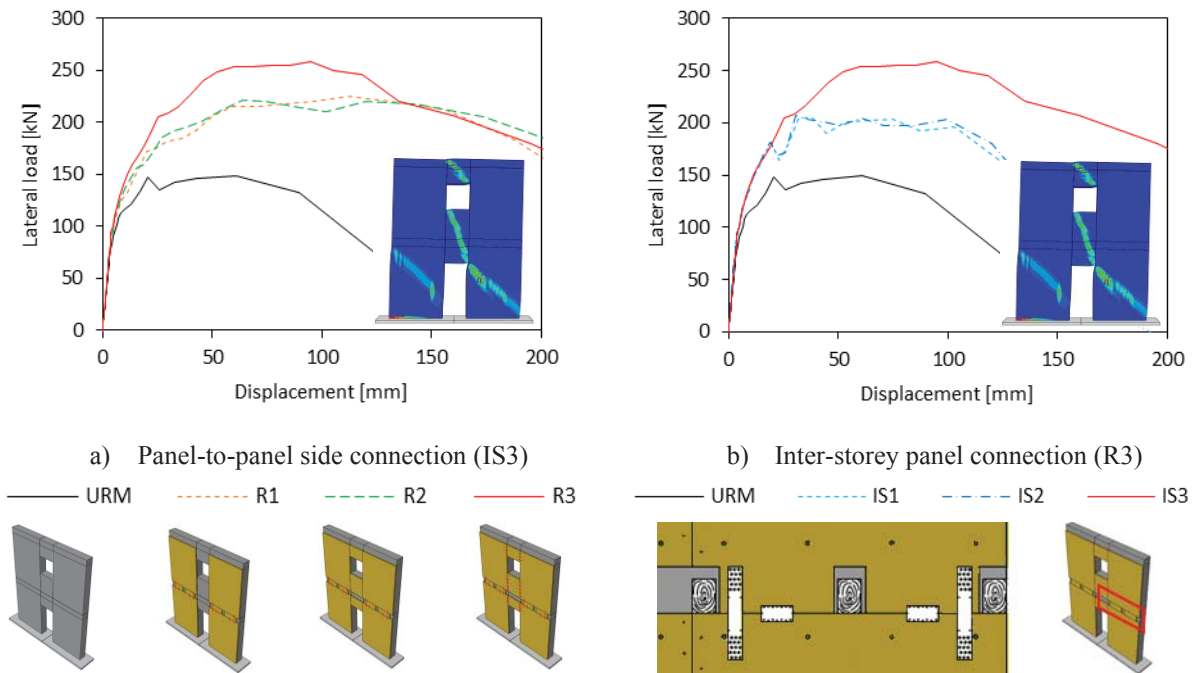

Figure 17: Effectiveness of the CLT panel retrofit solution on two-storey URM walls with openings (base configuration M1, T2, Q1, C1, K1, HD2, AB3).

4 CONCLUSIONS

The effectiveness of a timber based retrofit solution where timber panels are connected to the masonry walls through distributed point-to-point connection was numerically investigated. The parametric study addressed several aspects including masonry properties, wall geometry and boundary conditions, and various retrofit configurations. The results obtained herein confirmed and extended the outcomes of a preliminary numerical study previously reported by the authors. The adoption of a quasi-static approach allowed to investigate the behaviour of the retrofitted walls for a wider deformation range and to obtain further information about the lateral load and displacement capacity. The models described herein, benefitted from the outcomes of recent experimental campaigns that were relied to for the calibration of the properties of the connections and that enabled to obtain more refined results. The following conclusions can be drawn:

- The application of the retrofit technique under study can produce a considerable increase in the in-plane strength and displacement capacity of the masonry walls. The timber panel retrofit resulted to be effective for all the studied URM wall configurations characterized by different masonry properties, geometries, stress levels and boundary conditions. The increase in load bearing capacity of masonry walls up to 40 cm thick, ranged from $\approx 25\%$ to $\approx 100\%$. Regarding the displacement capacity, all wall-configurations reached drift values (top displacement/wall height) larger than 1.5%.
- The connection system to anchor the panels to the foundation or to transfer inter-storey forces was confirmed to play a major role in determining the retrofit effectiveness. The best performance was achieved in those configurations where the anchoring/interstorey connection system allowed transferring of compressive, tensile and shear loads (increase of wall shear capacity up to 90%). Expectedly, the properties of the hold-downs (tension anchors) were most influential when the walls showed a rocking behaviour, while the

properties of the angle brackets (shear anchors) were most relevant for squat walls with marked shear behaviour. In the case of walls exhibiting diagonal cracking, the timber panel strengthening generated a noticeable increase in the wall displacement capacity even in the absence of any anchoring device.

- An effective *timber panel-to-masonry* connection can be achieved by installing both dry and adhesive point-to-point fasteners. Fasteners with higher stiffness were found to produce minor yet visible improvements to the intervention effectiveness independently from the wall failure mode. However, the choice of the type of fastener should not prescind from considerations on the masonry type, with adhesive connections being recommended for irregular masonry with thick mortar joints. The parametric study on the fastener numbers and layout showed that 4 connectors per square meter of wall-surface can be considered as sufficient.
- In case of long walls, the application of the timber-based strengthening can be facilitated by installing multiple sub-panels shorter than the wall, without any detriment to the overall effectiveness. In fact, when screwed panel-to-panel connection was provided and when the “timber coating” was anchored at its base by two hold-downs and by an angle-bracket for every timber sub-panel the result was consistent with that obtained employing a single CLT panel as long as the masonry wall.
- Predictably, the strengthening of the spandrels can further increase the performance of the retrofit solution (+50-70% in wall strength with reference to the configuration where only the piers are strengthened) especially when a *spandrel-panel to wall-panel* connection is ensured, and when the number of storeys increases and accentuates the spandrel role in coupling the piers.

Abstract

Timisoara is the most important city located in Banat seismic area, characterized by shallow earthquakes of crustal type and was selected to be European Capital of Culture 2021. The majority of the historical buildings are made in masonry, with masonry vaults and wooden floors.

First part of the paper presents a quick and simplified empirical methodology based on European studies. The second part presents a detailed mechanical nonlinear analysis obtained for some of the most important historical buildings in Timisoara, based on complete survey and site inspection. Moreover, the authors present a direct correlation between the empirical and the mechanical seismic vulnerabilities. In the end, based on the correlation results, there is presented the proposed empirical seismic vulnerability assessment methodology for the near-field events. The methodology considers the specific failure mechanism for buildings with same characteristics and the particularities of Banat seismic area.

The proposed methodology aims to adapt the quick and simplified empirical methodology to the near-field earthquakes effects. This could serve for quick and simplified assessment of seismic vulnerability for any building with similar mechanical, geometrical, architectural and urbanistic characteristics as the case study buildings, in areas with earthquakes similar to those specific to Banat seismic area. This kind of study could provide a better knowledge for the local authorities, helping them to develop or improve earthquake mitigation plan and to define new earthquake engineering design recommendations.

Keywords: masonry, earthquake, vulnerability assessment, history, nonlinear analysis

1 INTRODUCTION

1.1 Case study area

Seismic vulnerability assessment represents an interdisciplinary task than can offer valuable tools for the risk reduction policies at a municipal level. The lack of seismic design rules at the moment of design or the lack of proper consolidation work during the lifetime of the buildings has led to an increase in the seismic risk of historic urban centers. The seismic risk can be divided into the sum of three elements, such as hazard, vulnerability, and exposure [1]. This paper aims to evaluate the seismic vulnerability of some historical masonry building and adapt an existing European vulnerability assessment methodology to the particularities of the site.

The Banat region represents an important area located in the western part of Romania. The biggest city in the Banat region is Timisoara, that was first recognized in 1177 as the “Fortress of Timis,” after the main nearby river [2]. After several administrations, such as Ottoman, Habsburgic, and Austro-Hungarian, the city developed into an important commercial and defensive pole, presenting a bastionary fortification system in Vauban architectural style, as shown in Figure 1 [2].

Figure 1: The bastionary fortification system for Timisoara city [2]

The most important historical area of the town is the Cetate district, located in the interior contour of the fortification, followed by two other districts, Iosefin and Fabric, which appeared outside the defensive walls, as presented in Figure 2 [3].

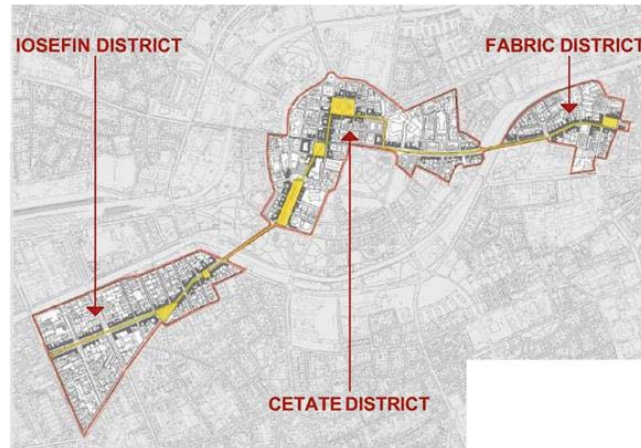

Figure 2: The three historic districts of Timisoara city [3]

The case study area in this paper is Fabric historic district, which appeared at first as a residential area for the craftsman. The streets are both rectangular and organic, with widths between 10 and 16 meters, and the buildings are made in masonry. Despite the industrial aspect of the area, the existing succession of public squares increases the quality of life in the area. An image from 1901 with the character of the district is illustrated in Figure 3 [2].

Figure 3: The spirit of Fabric district in 1901 [2]

1.2 Seismicity of the area

The determination of the seismic hazard for a specific area represents a difficult task, than can be achieved through both probabilistic and deterministic methods. At a global level, there was made a seismic hazard map, as presented in Figure 4 [4].

Figure 4: Seismic hazard map at a global level [4]

In Romania, there are two seismic areas, Vrancea and Banat. Vrancea is the most important seismic region, characterized by strong earthquakes with magnitudes around $M_w = 7.0$ of intermediate depth. Less dangerous earthquakes characterize the Banat region, with magnitudes around $M_w = 5.6$ of crustal type, with focal depths between 1 and 35 km [5]. The general seismicity of Romania, faults, and past seismic events is presented in Figure 5 [6].

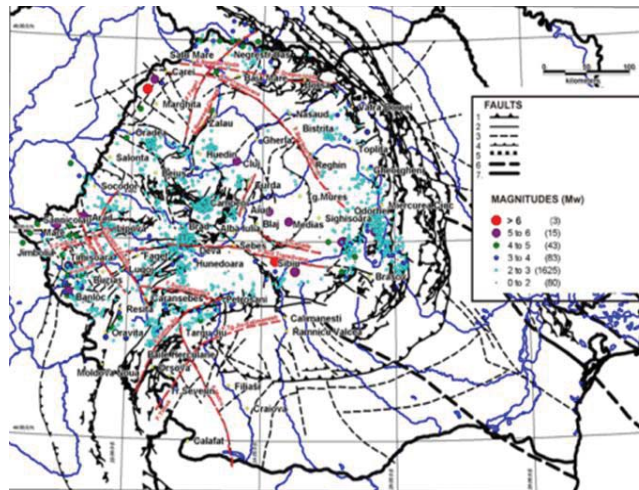

Figure 5: The location of the seismic faults and past earthquakes in Romania [6]

In Timisoara city, there are two active seismic faults located at less than 10 km from the city center, as shown in Figure 6 [3].

Figure 6: The location of the two active seismic faults in Timisoara [3]

The strongest seismic event registered in Banat area was the earthquake from 1991, in Banloc city, at less than 40 km from Timisoara, with a magnitude $M_w = 5.5$ and a focal depth of 11 km, followed by a strong aftershock of a magnitude $M_w = 5.3$ and a focal depth of 5 km [7]. After the event, there were registered damages, especially to attics, arches, lintels, and chimneys, as presented in Figure 7 [3],[8].

Figure 7: Damages to masonry buildings in the epicenter after Banloc earthquake, 1991 [3], [8]

There were observed both in-plane and out-of-plane failure mechanisms. The in-plane mechanism that can be noticed is mostly the diagonal shear cracking, especially in the façade masonry walls. Also, the vertical cracks can be seen due to the presence of strong vertical forces and L and R surface waves. Following the on-site observation, there was defined a specific failure mechanism for historic masonry buildings located in the near-field areas, after earthquakes of crustal type, as illustrated in Figure 8 [9].

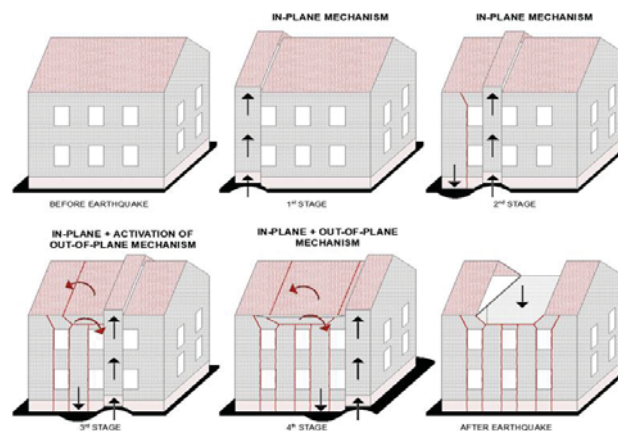

Figure 8: The specific failure mechanism for historic masonry buildings in the near-field areas similar to Banloc seismic region [9]

When the real observed damages were compared with the EMS-98 damage scale for masonry buildings [10], there was noticed the fact that the real damage was around damage state D2-D3, as shown in Figure 9 [9].

Figure 9: Correlation between EMS-98 damage scale and real damage observed after Banloc earthquake, 1991 [9]

For Timisoara city, there can be generated an expected damage scenario, similar to the one that occurred in Banloc area. The peak ground acceleration for Timisoara is considered to be 0.20g after the Romanian design code [11]. Following a simplified correlation law presented in Equation (1), there was determined that the most probable macroseismic intensity for the area is IX EMS-98, as shown in Figure 10 [12].

$$\ln(\text{PGA}) = 0.24 \times I_{\text{EMS-98}} - 3.9 \quad (1)$$

Figure 10: Correlation between EMS-98 damage scale and real damage observed after Banloc earthquake, 1991 [12]

1.3 Case study buildings

The investigated buildings are considered to be representative of the area, from all existing height regimes. Their location is presented in Figure 11 [13].

Figure 11: Location of the case study buildings [13]

In the area, there can be noticed that almost all buildings present the basement, while the minimum height regime is basement and ground floor, and the biggest is a basement, ground floor and two levels. The structural system of all investigated buildings is the masonry of burnt clay brick and lime. The buildings are located with the longest dimension along the main street, presenting massive façade and intermediate walls with thicknesses from 80 centimeters in the basement and 40 centimeters on the last floor. The transversal walls are not connected with the façade walls in most of the cases and are much thinner, around 15 centimeters [3], [14].

The horizontal structural systems are masonry vaults above the basement and sometimes ground floor and wooden floors for the other levels. There can be noticed, in many cases, a very tall complex wooden framework for the roof structure [3], [14].

The six selected buildings for investigation are presented in Figure 12 [13].

Figure 12: The six selected buildings for further investigation [13]

2 EMPIRICAL SEISMIC VULNERABILITY ASSESSMENT

2.1 Description of the existing methodology

The empirical methodologies represent a useful tool for a quick and simplified seismic vulnerability assessment that can also be applied at an urban scale [15].

The existing methodology that is used in this paper was proposed at first by Benedetti and Petrini [16] and was later developed by Mazzolani and Formisano [17].

The procedure is simple, based on visual inspection that leads to the fulfillment of an investigation form (Fig. 13), in which for several parameters, there is assigned a score for each possible situation. The parameters are in a number of 10 when the building is considered as isolated structural unit and 15 when there is also considered the influence of the adjacent buildings from the aggregate. For each parameter, there is also assigned a weight that illustrates its importance. All parameters and their associated weight are used following the existing Italian methodology [17]. The vulnerability index represents the sum of each parameter, whit the class score and weight assigned, following Equation (2) [9].

$$I_v = \sum s_i \times w_i \quad (2)$$

No	Factor	Class				Weight
		A	B	C	D	
1	Organization of vertical structures	0	5	20	45	1
2	Nature of vertical structures	0	5	25	45	0.25
3	Location of the building and type of foundation	0	5	25	45	0.75
4	Distribution of plan resisting elements	0	5	25	45	1.5
5	Plain regularity	0	5	25	45	0.5
6	Vertical regularity	0	5	25	45	1
7	Type of floors	0	5	15	45	1
8	Roofing	0	15	25	45	0.75
9	Details	0	0	25	45	0.25
10	Physical conditions	0	5	25	45	1
11	Presence of adjacent buildings with different height	-20	0	15	45	1
12	Position of the buildings in the aggregate	-45	-25	-15	0	1.5
13	Presence and number of staggered floors	0	15	25	45	0.5
14	Effect of either structural or typological heterogeneity among adjacent structural unit	-15	-10	0	45	1.2
15	Percentage difference of opening area among adjacent façade	-20	0	25	45	1

Figure 13: Empirical vulnerability form [9]

After the determination of the vulnerability index, the index is normalized in the range of 0÷1, following Equation (3) [9].

$$V = (I_V - I_{V \text{ MIN}}) / (I_{V \text{ MAX}} - I_{V \text{ MIN}}) \quad (3)$$

The last step in the process of determination of the empirical seismic vulnerability is the damage estimation, where following the normalized vulnerability index, there can be estimated the mean damage grade and the expected damage state, following Equation (4). The correlation between the mean damage grade and expected damage level is illustrated in Figure 14 [18].

$$\mu_D = 2.5 \{1 + \tanh[(I + 6.25V - 13.1)/\Phi]\} \quad (4),$$

where I represents the macroseismic intensity, V is the normalized vulnerability index and Φ is the factor that modifies the vulnerability curve slope and is considered equal to 2.3 for residential buildings [19].

μ_D	Damage state	Most probable degradation level
0.0-1.5	D1	Slight (no structural damage, slight non-structural damage)
1.5-2.5	D2	Moderate (slight structural damage, moderate non-structural damage)
2.5-3.5	D3	Substantial to heavy (moderate structural damage, heavy non-structural damage)
3.5-4.5	D4	Very heavy (heavy structural damage, very heavy non-structural damage)
4.5-5.0	D5	Destruction (very heavy structural damage)

Figure 14: Correlation between mean damage grade and expected level of damage [18]

2.2 Results of the applied existing methodology

The application of the empirical seismic vulnerability has led to a series of vulnerability indexes for ten and 15 parameters, as presented in Table 1.

Building	I_{V10}	I_{V15}
1	68.75	98.75
2	108.75	110.25
3	98.75	61.25
4	93.75	118.75
5	113.75	66.75
6	130	160

Table 1. Vulnerability indexes for the six investigated buildings

Following the determined vulnerability indexes, there were also designed the vulnerability curves, as presented in Figure 15 for buildings considered as isolated and in Figure 16 for buildings considered in aggregate. The comparison between the mean vulnerability curves for both situations is illustrated in Figure 17.

Figure 15: Empirical vulnerability curve for the six investigated buildings considered as isolated structural units

Figure 16: Empirical vulnerability curve for the six investigated buildings considered in aggregate

Figure 17: Comparison between mean vulnerability curves for both isolated and aggregate situations

The results illustrate a low vulnerability for a macroseismic intensity IX EMS-98, according to the most probable seismic scenario, in the range of damage state D1 for both situations, which means no expected damages.

Considering the real damages observed in Banloc in a similar situation, in the ranges of D2-D3, there is highlighted the need for performing nonlinear analysis to adapt the empirical methodology for near-field effect.

3 MECHANICAL SEISMIC VULNERABILITY ASSESSMENT

3.1 Nonlinear analysis

The numerical analysis represents a more precise tool in the process of seismic vulnerability assessment, indicating the weakest points of the structure [20].

The pushover analysis was obtained with Tremuri software and investigated the in-plane failure mechanism for the six investigated buildings, considered as isolated structural units. There was used the local seismic spectrum for Banat region, as illustrated in Figure 18 [21] while the mechanical proprieties for the masonry structures were determined following experimental tests and other technical expertise for similar buildings, as illustrated in Table 2 [3].

Figure 18: The local spectrum for Banat seismic region [21]

	f_k [N/mm ²]	f_{vk0} [N/mm ²]	E [N/mm ²]	G [N/mm ²]	Density [kg/m ³]
URM	2.35	0.06	2350	940	1800

Table 2. Mechanical proprieties for the masonry structures

The analysis made with Tremuri is a simplified analysis, appropriate for the investigation of more than one building, and can be used for historical masonry buildings. It has revealed the expected cracks damage distribution, as presented in Figure 19 [13].

Figure 19: Cracks and failures to the six investigated buildings after pushover analysis [13]

The pushover analysis has revealed that the buildings would suffer both nonstructural and structural damages for the considered seismic scenario, around damage states D2-D3. In Table 3, there are presented the yielding and ultimate displacement and also the maximum shear forces [13].

Bld. No.	Yielding displacement Δ_y [cm]	Maximum shear force V [kN]	Ultimate displacement Δ_u [cm]	Interstorey drift [%]
1	0.08	3482	0.28	0.040
2	0.14	966	0.62	0.107
3	0.04	4006	0.12	0.113
4	0.79	2735	2.84	0.318
5	0.60	5309	1.74	0.160
6	0.54	15096	1.74	0.220

Table 3. Displacements, shear forces and interstorey drift for the six investigated buildings [13]

According to the interstorey drift values, there can also be estimated the most probable damage state for each investigated building, following Table 4 [13].

URM	Damage state D2	Damage state D3	Damage state D4	Damage state D5
	$ID < 0.1\%$	$0.1\% < ID < 0.3\%$	$0.3\% < ID < 0.6\%$	$0.6\% < ID$

Table 4. Correlation between interstorey drift values and most probable damage state [13]

3.2 Conclusion of the numerical analysis

The results indicated by the pushover analysis highlight the possibility of an appearance of cracks and failures due to bending forces, especially to the lintels at the upper part of the buildings. Also, there can be noticed, in some cases, cracks and failures due to shear forces at the spandrels also located on the top floors. These aspects indicate a general damage state of D2-D3 for all six investigated buildings.

Also, the investigation of the interstorey drift values indicates the same damage states D2-D3 for all six investigated buildings.

The two aspects previously presented suggest that the existing empirical seismic vulnerability assessment methodology tends to underestimate the real vulnerability of historic masonry buildings located in the near-field areas.

In this case, an adaptation is necessary to be able to provide precise and quick results at an urban scale for similar buildings located in seismic regions with characteristics similar to Banloc region.

Because the existing methodology is well-used at the European scale, there is proposed to keep it in the original form and modify only the damage estimation formula.

4 NEW PROPOSED EMPIRICAL METHDOLOGY FOLLOWING NONLINEAR ANALYSIS

4.1 New proposed damage estimation formula

The investigation of real damages after past earthquakes in similar areas and on similar buildings have illustrated considerable damages to structural elements, without affecting the bearing capacity of the structure, so a damage state of D2-D3.

The same probable damage state was indicated by the nonlinear analysis obtained with Tremuri software and also, by the investigation of the interstorey drift values obtained following the pushover analysis.

Both visual and numerical investigation revealed the fact that, for a macroseismic intensity of IX EMS-98, there is the need to adapt the damage estimation formula.

This adaptation could provide the necessary tools for correctly assessing the seismic vulnerability of historic masonry buildings in the near-field areas, similar to Banloc region, in a quick and simplified way.

The first part of the methodology, regarding the fulfillment of the vulnerability form and determination of the vulnerability index and implicitly the normalized vulnerability index, are proposed to remain precisely in the original structure. There is recommended to modify just one parameter from the damage distribution formula (Equation 4), the parameter that influences the slope of the vulnerability curve. The new proposed damage estimation formula is presented in Equation (5) [13].

$$\mu_D = 2.5 \{1 + \tanh[(I + 12.5V - 13.1)/\Phi]\} \quad (5),$$

where I represents the macroseismic intensity, V is the normalized vulnerability index and Φ represents the parameter of the curve's slope, equal with 2.3 for residential buildings.

4.2 New vulnerability curves following the proposed damage estimation formula

Following the new proposed damage estimation formula, there were redesigned the vulnerability curves for the six investigated buildings, as illustrated in Figure 20 and Figure 21.

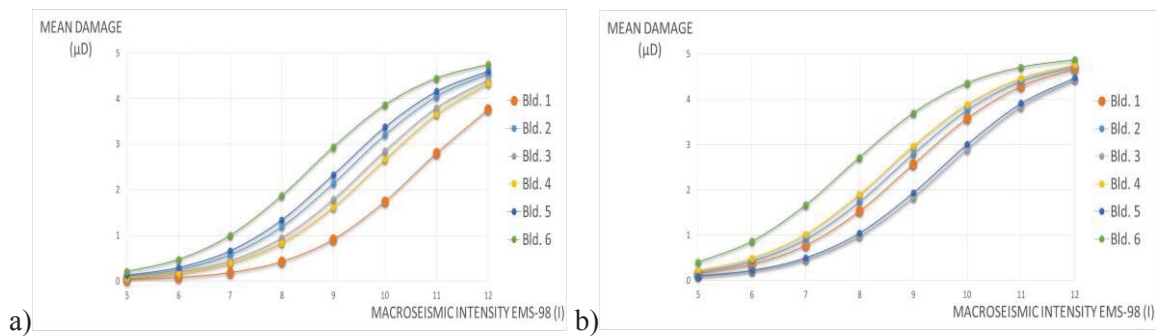

Figure 20: New empirical vulnerability curve for the six investigated buildings after proposed damage estimation formula considered: a) as isolated structural units; b) in aggregate condition

Figure 21: New comparison between mean vulnerability curves for both isolated and aggregate situations, following proposed damage estimation formula

5 CONCLUSION

The new results are in accordance with the real damages observed after the Banloc earthquake from 1991 and also with the results of the numerical analysis.

This aspect indicates the fact that the proposed damage estimation formula is appropriate for assessing the seismic vulnerability for historic masonry buildings located in the near-field areas similar to Banloc seismic region.

The most probable damage states of D2-D3 indicates a medium vulnerability for the investigated buildings that can be dangerous for the historic areas of Timisoara city. There is a high possibility of having significant damages to nonstructural elements and moderate damages to structural ones, but without affecting the bearing capacity of the structures. Because all the buildings are in protected areas, there is highlighted the possibility of losing irreplaceable cultural, architectural-artistic and urbanistic valuable elements.

The new proposed damage estimation formula could help provide quick and accurate vulnerability curves for historic masonry building with similar characteristics to the ones in Timisoara city, that are located in seismic regions with the same proprieties with Banloc area.

Abstract

Masonry vaults are present in a large number of historical structures and often used as flooring and roofing systems in monumental palaces and religious buildings, typically incorporating no backfill. Many of these structures are located in seismic regions and have been shown to be particularly vulnerable during recent earthquakes, with a need for accurate modelling to avoid future losses. Masonry vaults are often analysed using limit analysis procedures under the hypotheses of no-tension material and absence of sliding along the masonry joints. However, this method can be inaccurate for barrel vaults found in buildings, which are typically slender with no backfill. In this case, the masonry tensile strength and the progressive damage propagation play an important role in the nonlinear behaviour and ultimate strength of the vault. In this study, a detailed mesoscale finite element mesoscale approach is used to model slender unreinforced barrel vaults subjected to cyclic quasi-static and dynamic loading. According to this approach, 3D solid elements connected by 2D damage-plasticity interfaces are used to represent the arrangement of bricks and mortar present in the masonry. The proposed numerical description is first validated against the results from physical tests on a barrel vault under quasi-static cyclic loading. Subsequently, the shear response of a prototype vault is analysed by performing nonlinear simulations under prescribed horizontal displacements at the supports, considering also the influence of previous damage induced by earthquakes with different magnitudes.

Keywords: Seismic risk, Historical masonry structures, Cyclic analyses, Nonlinear time-history analyses, Discrete FEM approach, Mesoscale models.

1 INTRODUCTION

Several existing buildings worldwide of historical, cultural and architectural significance incorporate vaulted masonry components. A high percentage of these buildings is located in high-seismic regions, and masonry vaults and domes have been observed to be particularly vulnerable under lateral loading imposed by earthquakes [1]. Hence, to prevent the potential loss of cultural heritage assets, there is a need to model both unreinforced masonry vaults and potential strengthening measures accurately to ensure protection of vaulted structures against future seismic events.

Masonry vaults are usually analysed using limit analysis procedures [2][3]. However, this approach provides only ultimate load predictions but no description of the behaviour of the structure up to failure. Furthermore, the assumptions of no-tension material and no-sliding along the mortar joints [4], often made in these methods, may lead to unrealistic results in the case of barrel vaults in buildings, which are typically slender, with high span to thickness ratios, and which do not include backfill thus sustaining very low compressive stresses [5].

To achieve accurate response predictions at different loading levels up to collapse, detailed finite element (FE) models based on mesoscale or macroscale masonry models can be used. The first strategy allows for the specific masonry bond utilising nonlinear zero-thickness interface elements [6] to predict the development of cracks at the mortar joints within brick units. This accurate modelling strategy has been previously adopted in [7] to investigate the cyclic behaviour of masonry structures under cyclic loading. Detailed work using the mesoscale approach has been carried out on masonry arched structures by Zhang et al. [8] and on multi-span masonry arch bridges by Tubaldi et al. [9].

The alternative is a macroscale smeared crack approach [10] in which masonry is assumed as a homogeneous isotropic material, and specific nonlinear material models based on damage and plasticity frameworks are typically utilised to represent the development and propagation of damage in the brickwork. An example of the latter is the use of a damage model proposed in [11], which uses homogenised mechanical parameters. Smeared crack models have also been used by Stablon et al. [12] and by Gattesco et al. [13, 14] to model masonry vaults also in presence of strengthening systems.

A modelling approach, alternative to FE analysis, has been proposed in [15] and applied to simulate unreinforced and reinforced arches and vaults [15, 16]. The model is composed of shear deformable macro-elements, interacting by means of non-linear zero-thickness interface elements which simulate the masonry flexural behaviour and potential shear sliding.

This study proposes a detailed FE mesoscale approach to model typical barrel vaults of religious buildings. The model allows for the inhomogeneity of masonry and the damage accumulated in reverse cycles of loading. The numerical results are validated against experimental results obtained through a new testing layout in which the vault is subjected to horizontal forces proportional to the structural self-mass [17]. Further numerical simulations have been conducted to investigate the ability of a representative barrel vault to transfer shear forces acting as a floor diaphragm in a building structure subjected to earthquake loading.

2 THE MESOSCALE MODELING APPROACH

The mesoscale approach used here has been developed at Imperial College [6] and applied to different extreme loading conditions [7-9]. According to this approach, the masonry is discretised into 3D solid brick elements separated by 2D zero thickness non-linear interface elements representing the mortar joints. As the thickness of the mortar joints is generally much smaller than the scale of the bricks, the collapsing of the mortar joints into interfaces is a suit-

able simplification, but still captures the inherently nonlinear character of masonry as a material. This restricts the cracking to the predefined interfaces, which again is realistic in the context of masonry, where the joints act as preferential fracture planes. The interfaces are hence positioned to coincide with the mortar joints. Additional interfaces are placed in the midplane of each brick, in line with the head joints of adjacent bricks, to allow the propagation of cracks through the brick units themselves as observed in real masonry structures. This results in a regular, structured mesh, where the properties of the interfaces allow a physical representation of the 3D bond arrangement. This is important especially where 3D behaviour is of interest, in which case plane stress or plane strain assumptions can be unrepresentative of the true structure.

Specifically, for the vaults considered in this study, the bricks are modelled as 20-noded quadratic solid elements which for which the constitutive material response is linear elastic. All the material nonlinearity is captured by the 16-noded interface elements described by [6], hence the material model for these becomes of prime importance. Figure 1 shows the placement of joints to represent bed joints, head joints and brick failure surfaces. This allows the simulation of hinge formation, shear sliding and ring separation which are typical failure mechanisms for vaults and arches. A damage-plasticity constitutive law, proposed in [7], is employed for the interface elements. The plastic yield surface consists of three yield functions: two planar surfaces for mode I (tensile) and mode III (crushing) fracture which cap the ends of a conical Coulomb surface for mode II (shear) fracture. The level of damage in each mode is a function of the ratios the plastic work in tension ($W_{pl,t}$), shear ($W_{pl,s}$) and compression ($W_{pl,c}$). Based on physical observations, the damage in tension is influenced by the plastic work in both tension and shear, the damage in shear is influenced by plastic work in all three modes, while damage in compression is only related to the plastic work in compression. Numerical results obtained by this model were found to be close to those of experimental data, with the main drawback of the approach being its high computational cost. This was eased by using a partitioning approach which allowed parallel computing to reduce run time [8, 18].

Figure 1: Brick and interface elements used in the mesoscale model [6,7]

3 THE EXPERIMENTAL TESTS

The numerical model applied in this study is validated against experimental results from [17] which used a novel bench setup to apply cyclic horizontal forces proportional to the mass of the arch. To elaborate, a quasi-static cyclic load was applied as a prescribed displacement by a hydraulic actuator and distributed evenly to 8 points either side of the vault by the frame shown in Figure 2a. The load was increased each cycle up to the failure of the vault.

The abutments were fixed during the test allowing no relative displacement. Two geometric layouts have been tested (Figure 2b): V75-NR (rise 1540mm, rise/span 0.75) and V50-NR (rise 1030mm, rise/span 0.5). Both were 120mm thick and 770mm wide, with a common ra-

dius of 2060mm. The mortar joints were 10mm thick on average. Differing lime mortars were used for each vault, with Young's Module tested as 9632 MPa and 11790 MPa for the V75-NR and V50-NR tests, respectively. Flexural tests on masonry samples resulted in strengths of 0.42 MPa (V75-NR) and 0.84 MPa (V50-NR). Solid brick units with self-weight 15.64kN/m^3 were used for both vaults. The main results of interest were that collapse occurred via the formation of a hinge mechanism in all cases, with most specimens forming four hinges at failure [17].

Figure 2: Test layout (a) and geometry of vaults (b) used in the experimental study [17].

4 MODEL VALIDATION

The full arrangement of bricks around the circumference is modelled using 20-noded solid brick elements for each brick, connected by 16-noded interface elements representing the mortar bed joints, following the modelling approach described in Section 2. As displacement perpendicular to the span was prevented in the test, the arrangement of head joints through the width of the arch is not modelled. Instead, a strip model is assumed, comprised of a single solid brick element for the width of strip. The reactions obtained are then scaled up accordingly by the ratio of the vault width to the strip thickness. The final brick at each skewback is not explicitly included in the numerical model, rather interface elements are placed at the end of each vault and fully fixed to represent the mortar joint to this fixed brick.

The experiment employed devices to prevent the inward or outward slip of the vault at the skewbacks and this is simulated by giving the interfaces at each skewback arbitrarily high shear strength and stiffness values, preventing shear sliding. In the experiment a device was used to oppose the uplift at each skewback. It is modelled by a linear spring with normal stiffness of 1.1 N/mm arranged in parallel with the skewback interfaces. This value was obtained with reference to a subsequent numerical study performed in [17]. The model mesh is shown in Figure 3, with the zero-thickness interfaces shown as the full thickness of the mortar joints

for clarity. To simulate the experimental loading arrangement, 3D dynamic analyses are performed employing spreader elements available in ADAPTIC [19] which allow an acceleration time history to be applied at a ‘master’ node and the resulting forces to be distributed according to predefined ratios at a number of ‘slave’ nodes. In the analyses, according to the experimental findings, the same ratio is applied to all “slave” nodes.

Figure 3: Mesh used for the vault V75-NR

Figure 4: Displacement (a) and force (b) time-histories of the hydraulic actuator in the test and at the master node of the model.

Figure 4 shows the displacement history registered by the hydraulic actuator and those considered in the numerical analysis. Each analysis is performed in two separated phases: the self-weight of the vault is applied first as an initial load, then the lateral loads are applied by means of a displacement-control procedure. No viscous damping is considered in the analyses since it is expected negligible when compared to the hysteretic energy dissipation.

For both vaults, the interface tensile strength is calculated from the masonry tensile strength at the macroscopic scale according to [20]. The Young’s modulus of the bricks is estimated applying a simple homogenization procedure and fixing arbitrary high values for the tangential and normal stiffness (k_t and k_n) according to [21]. The resulting Young’s moduli are 4260MPa and 5280MPa for the V75-NR and V50-NR specimens, respectively. Finally, Poisson’s ratio 0.2 and specific weight 1664kN/m³ are considered for both the two tests.

The parameters for the Coulomb model are taken from values obtained with reference a numerical study performed on the same experimental results [14], resulting a friction coefficient of 0.58 for both vaults and cohesion of 0.19MPa and 0.38MPa for vaults V75 and V50, respectively. The fracture energy for modes I and II are assumed in line with values from previous studies [21,22] where it was found that values for mode I (tensile) were typically in the

range 0.01 to 0.08 N/mm and for mode II (shear) from 0.1 to 0.2 N/mm. The fracture energy in mode I is assumed at a low value to reflect the brittle response observed experimentally. The set of parameters adopted for each vault are summarised in Tables 1, where k_n and k_t are the normal and tangential elastic stiffness; f_t , f_c and c are the tensile strength, compression strength and cohesion; $\tan(\phi)$ and $\tan(\phi_g)$ are the friction and dilatancy coefficients; $G_{f,t}$, $G_{f,s}$ and $G_{f,c}$ are the fracture energy in tension, shear and compression, respectively.

Test	k_n [N/mm ³]	K_t	f_t	F_c [MPa]	c	$G_{f,t}$	$G_{f,s}$ [N/mm]	$G_{f,c}$	$\tan(\phi)$	$\tan(\phi_g)$ [-]	μ
V75-NR	1000	1000	0.14	5.00	0.19	0.01	0.125	1.0	0.58	0.00	0.1

Table 1: Mechanical parameters of the mortar joint interfaces.

5 CYCLIC QUASI-STATIC ANALYSIS

All analyses are performed using the general nonlinear Finite Element software ADAPTIC [19]. The total horizontal force applied (F_h) plotted against the horizontal displacement at the crown section (δ_h) is shown in Figure 5 and compared to the experimental hysteresis loops for both tests. The experiment on vault V75-NR exhibited an early hinge forming at one haunch in one loading direction, which is attributed to an imperfection in the mortar bond. This resulted in one skewback not cracking and led to an asymmetric response. To simulate this aspect, one artificially weakened skewback is introduced in the model considering a reduced tensile strength ($f_{t,skewl}=0.01\text{MPa}$). Moreover, it is noted that for both vaults the experimental results recorded a very high initial stiffness and very high unloading stiffnesses during cycles. This was a by-product of the testing rig arrangement and not representative of the physical behaviour of the vault. The numerical collapse mechanisms are shown in Figure 6, where the normal stress along the span (s_{xx} MPa) is represented. For the vault V75-NR, the model captured the formation of the 2 hinges at both skewbacks and then the third at the haunch. After this point, convergence was lost (Figure 6a). For the vault V50-NR, the first hinge occurred at the right skewback. Subsequently, the second and third hinges formed near simultaneously at the left skewback and right mid-span, then the 4th hinge opened at the remaining haunch (Figure 6b). After 4 hinges are formed, a rocking motion involving the three uncracked spans sustained a residual load which increased to around 5 kN, at which point additional damage occurred near the skewbacks and the blocks lost shear strength, with the final sliding failure occurring at approximately 24 mm. This mechanism was also observed experimentally, confirming the reliability and robustness of the interface model. Table 2 summarises the behaviour of each vault alongside the experimental results.

Test	F_{max} [kN]	$F_{max,exp}$ [kN]	$(F_{max} - F_{max,exp})/F_{max,exp}$ [kN]
V75-NR	3.37	3.76	-10%
V50-NR	12.23	13.01	-6%

6 NUMERICAL SIMULATIONS UNDER EARTHQUAKE LOADING

In this section, the behaviour of the V75-NR prototype, subjected to a time-history acceleration, applied at each skewback, is investigated. The full mortar bond arrangement is modelled using two different types of interfaces to represent the mortar-brick head joints and the brick-brick joints. The later allowing cracks to form through the centre of each brick. By alternating the placement of these interfaces in the y direction, the realistic arrangement of bricks and mortar can be simulated. The brick-brick joint interfaces are calibrated, according to specific literature referring to similar masonry units [6], as no direct information was available experimentally on the specific brick properties required. These are presented in Table 3.

The earthquake record from Southern Italy Irpina earthquake (1980), Sturmo station, is selected from the European Strong-Motion Database (ISESD) [23] with the linear baseline of the acceleration time history corrected. Two horizontal components (Figure 7) are simultaneously applied to the vault to observe the full 3D behaviour. The direction with the higher peak ground acceleration of 0.32g is applied parallel to the span of the vault (x direction), while the record with PGA 0.22g is applied perpendicular to the span (y direction). The original record is scaled up and down by 50%. The resulting acceleration time histories scale the original record by factors of 0.5 (EQ0.5), 1.0 (EQ1.0) and 1.5 (EQ1.5), and the peak ground accelerations for each simulation are shown in the first two rows of Table 4. A further test used the unscaled record with peak ground acceleration 0.32g applied only in the x-direction (EQ1.0x) to explore the influence of the shaking in the y direction.

The numerical response under EQ1.0, in terms of horizontal displacement at the crown section versus the horizontal base shear, is plotted in Figure 8a, superposed onto the experimental

results. Collapse is evidenced for cases EQ1.0 and EQ1.5, while the structure remains almost elastic for case of EQ0.5. These collapses correspond to the activation of four hinges.

k_n	K_t	f_t	F_c	c	$G_{f,t}$	$G_{f,s}$	$G_{f,c}$	$\tan(\phi)$	$\tan(\phi_g)$	μ
[N/mm ³]			[MPa]			[N/mm]			[-]	
1E+5	1E+5	1.67	20.77	2.8	0.05	0.125	1.0	1.0	1.0	0.1

Table 3: Mechanical parameters of the brick-to-brick interfaces

In the three simulations EQ1.0, EQ1.5 and EQ1.0x, a four-hinge mechanism forms in the x-direction, with two hinges at each skewback forming first, followed by hinges at the two haunches of each vault. In terms of the failure mechanism, the x-direction was dominant, with cracks forming along the full width of the bed joints. This is partially explained by the peak acceleration in the x direction being approximately 1.5 times that in the y-direction and considering the limited width of the vault.

Hinge locations are close to those obtained from the cyclic simulations. For the vaults accelerated in both directions, up until the formation of four hinges little deformation in the y-direction is observed, but once forms the vault lost shear stiffness along the cracked bed joints. Typically, a fifth hinge forms near the crown, and rotation of the uncracked blocks is observed, as shown in Figure 8b for simulation EQ1.5.

Figure 7: Earthquake signals applied along the longitudinal (a) and transversal (b) directions of the arch.

The study shows damage tending to be uniform along each bed joint, with damage being of a smaller magnitude along the head joints. Generally, up to the point of collapse, the behaviour under earthquake acceleration can be observed to be similar to that of cyclic loading, with the 3rd hinge tending to form at a similar load and displacement as that experimentally. As the fourth hinge begins to form, and collapse begins, the base shear varies sharply and at times is observed to be larger than at the formation of the hinges. This is in part due to the collapsing vault imparting large forces on its supports as the mechanism was formed. The main results of the analyses are summarised in Table 4. Comparing the results from the two simulations EQ1.0 and EQ1.0x, it can be seen that there is minimal difference in the load capacities obtained, with the vault accelerated in both directions (EQ1.0) actually reaching a slightly higher load at collapse of 4.32kN compared with 4.23kN for EQ1.0x. This demonstrates that the acceleration in the y-direction does not contribute significantly to the collapse load in x or to the failure mechanism observed. As discussed above, past the formation of 4 hinges, the rotation of blocks due to the y acceleration becomes noticeable. This indicates testing in only one directing and using a strip model in the previous section is justified for this type of barrel vault. The load at the formation of 4 hinges tended to be slightly higher than that obtained experimentally, which could be related to the dynamic effects of base acceleration.

Parameter		EQ0.5	EQ1.0	EQ1.5	EQ1.0x	Experiments
PGA x direction	[g]	0.16	0.32	0.48	0.32	-
PGA y direction	[g]	0.11	0.22	0.33	0.00	-
Peak base shear x	[kN]	1.78	4.32	4.78 (3.89)	4.23	3.76
Peak base shear y	[kN]	1.15	2.67	4.29	0.00	-
Max displacement x	[mm]	0.28	1.96	7.29 (2.31)	3.57	0.84
Max displacement y	[mm]	0.10	0.43	1.26 (0.73)	0.00	-

6.1 The shear stiffness of barrel vaults

Masonry barrel vaults represent the floor diaphragms of numerous historical buildings. Their shear behaviour influences the local and global response of the structure and its seismic performance. In this section, the performance of a barrel vault specimen under shear loading is numerically investigated considering the effects of accumulated damage caused by earthquake motions.

The same geometrical layout of the barrel vault investigated in Section 5 but with a width equal to the arch span (3980mm) is considered. The nonlinear model is first subjected to the X and Z component of the Irpinia earthquake. At the end the motion, a quasi-static shear drift is applied at the base of the two skewbacks. Four amplification factors, 50% and 75%, 85% and 100% are chosen to scale the original signal in order to cause plastic damage but no structural collapse.

In Figure 9, the relative displacement between the two skewbacks is plotted for each model versus the external shear load. In the graph, the curve of the undamaged vault is also plotted for the comparison. The damaged models show a brittle behaviour with a lower displacement capacity when compared to the undamaged vault. The ultimate shear displacement of the vault decreases as the PGA of the seismic input increases.

The failure mechanisms of the undamaged vault and the damaged vault (75% of signal) are reported in Figure 10a and Figure 10b, respectively. The undamaged model shows a failure mechanism characterised by the formation of 4 significant cracks along the mortar joints developing from the lateral faces of vaults. The cracks propagate towards the middle of the vault following a diagonal path (Figure 10a). The damaged vaults show a different failure mechanism, characterised by the sliding at the skewbacks leading to a rigid rotation of the vault (Figure 10b).

7 CONCLUSIONS

This study applies a detailed meso-scale model to simulate unreinforced masonry vaults subjected to earthquake loading. Both quasi-static cyclic loads and base accelerations are considered. The model simulates each brick by means of 20-noded elastic solid brick elements interacting by means of 16-noded interface elements. The effective mortar bond is modelled using two different types of interfaces to represent either the mortar bed joints or to simulate the cracks passing the bricks. The numerical results are compared to experimental findings obtained by means of a novel test setup to apply cyclic horizontal forces proportional to the mass of the vault. The meso-scale model is found to be effective in capturing the complex failure modes and predicting crack locations in unreinforced vaults. In the last part of the paper, the influence of different magnitudes of earthquake, including the resulting damage, on the shear deformability and shear strength of the investigated vault specimen is evaluated. The results show that previous damage can reduce significantly the shear displacement capacity of the vault potentially hindering its ability to act as an effective floor/roof diaphragm.

Abstract

In recent years the concept of recycling and reuse is a popular issue faced in many fields. During manufacturing processes a huge amount of materials is recovered to minimize waste. In particular, this study investigates the possibility of reuse materials recovered during the production of rubber in standard industrial practice, for the realization of low-cost rubber compounds for fiber-reinforced elastomeric isolators. To cope with this task, a new composition is developed basing on the past experience of the research group and in particular with reference to a previous study by A. B. Habieb et al, where a part of virgin rubber was replaced by regenerated one. Subsequently, a comparison between the two compositions in terms of rheometer curves, uniaxial tensile curves, hardness and compression sets, before and after the process of aging is provided. It is found that the new composition exhibits attractive performances with economic advantages and environmental benefits.

Keywords: Rubber compounds, Regenerated rubber, Elastomeric isolator.

1 INTRODUCTION

The rubber material is widely used either for household or industrial needs. Since the pre-historic era, rubber has been involved in human life by exploiting the latex from specific trees. The first use of rubber in the industrial sector occurred at the beginning of the 18th century [1]. Nowadays, rubber is commonly used for tires, vibration or seismic isolators, impermeable layers, and sports equipment. It can be in the natural or synthetic form of material. Some popular synthetic rubber types include Hypalon, Ethylene Propylene Diene Monomer (EPDM), Nitrile-Butadiene Rubber (NBR), Viton, Neoprene, Silicone rubber (SiR), and Styrene-Butadiene Rubber (SBR).

For elastomeric isolators, rubber pads have a main role. Damping performance is a prerequisite for isolation bearing materials. Besides, the materials must have an excellent overall performance, such as high strength to resist damage [2, 3]. Natural Rubber (NR) exhibits desirable physical and mechanical properties, good processing properties, and excellent flexibility, and it is an indispensable material for industrial applications. However, NR has a quite poor damping performance, which greatly limits its application in the field of anti-seismic materials [4] [5]. Artificial rubber seems promising for the fabrication of isolators since NR is vulnerable to quick aging and its industrial production capability is limited. Less frequently it is EPDM or an NBR-EPDM blend vulcanized with an increasing amount in weight of carbon black [6]. To be ready for application, rubber should be processed through several stages; mixing or milling, and vulcanization [7, 8]. In the mixing process, some additives are added to obtain the expected behavior of the rubber compound. In the vulcanization process, the rubber is heated with sulfur, accelerator, and activator at around 140-160 °C. The process triggers the formation of cross-links between long rubber molecules, thus improving tensile strength, hardness, and weather resistance.

Rubber waste recycling is one of the most critical emergencies in terms of sustainability, considering that massive rubber waste has polluted the environment. According to the literature, regenerative rubber and powdered rubber are important forms of recycled rubber used to combat the rubber industry's expanding demand for raw material. Studies proposed by A. B. Habieb et al. [9, 10, 11] validate the possibility of use regenerated EPDM compounds for the production of unbonded Fiber Reinforced Elastomeric Isolators. The utilization of regenerated EPDM appears very interesting because the EPDM backbone is essentially the same as the starting material.

The present study investigates the possibility of using recovered powder and oils from rubber manufacturing to fabricate rubber pads for low-cost seismic isolation systems. A new composition is developed basing on the past experience of the re-search group and in particular with reference to a previous study by A. B. Habieb et al. [12, 13].

In addition to the environmental benefits, the research wants to reveal remarkable ones of using recycled rubber waste from industries to drop down the cost of the isolation system. Such a consideration is particularly essential when dealing with seismic protection in developing countries (Indonesia, The Philippines, Thailand, for instance) where the cost of the commercial isolation system is considered too expensive for massive applications.

2 REGENERATED EPDM COMPOUND

The reference regenerated EPDM compound is the Batch 4 developed by A. B. Habieb et al. [14]. Commercial virgin rubber is blended with regenerated EPDM. Final rubber specimens are composed for 2/3 of regenerated EPDM and 1/3 of virgin rubber. In the following figures and tables are shown the mechanical properties of the recycled rubber.

3 RUBBER COMPOUND WITH RECOVERED POWDERS AND OILS

Respect the original composition of the rubber compound, carbon black and paraffinic oil have been totally replaced by recovered powders and oils (Table 3). Both replacements are obtained by recovering materials during the rubber manufacturing process, in particular, during the mixing process. In the following figures and tables are shown the mechanical properties of the new rubber compound.

4 COMPARISON BETWEEN THE RUBBER COMPOUNDS

The new rubber compound exhibits similar behavior to the original one. In figure 3 and in tables 1 and 4, it's possible to appreciate the same characteristic rheometer curves (Table 1, Table 4).

Figure 3: Rheometer curves of "Batch 4" (a) and "Recovered" (b) at different temperatures

For the stretch-strain test, the results obtained have shown that the new rubber compound presents a higher elongation at break and almost the same breaking stress of the original composition (Figure 4a). For the relaxation curves, the original rubber compound reaches a plateau at a value of normalized stress, of 0.57, while the new one reaches a plateau at a value of 0.79.

Furthermore, a comparison of densities, Shore A Hardnesses and Compression Sets has been made. As it is possible to see in Table 6, only the compression set exhibits a different behavior, with a difference percentage of 177.04% lower than the original one.

Figure 4: Comparison of stretch-stress (a) and relaxation curves (b) of the two rubber compounds

5 CONCLUSIONS

This paper has investigated the possibility of reuse materials recovered during the production of rubber in standard industrial practice to realize low-cost rubber compounds for fiber-reinforced elastomeric isolators.

Firstly, from a previous study of A.B. Habieb et al., a rubber compound made of reactivated EPDM has been considered. From the original composition, carbon black and paraffinic oils have been totally replaced by recovered powder and oils. A comparison between the new rubber compound and the original one in terms of rheometer curves, uniaxial tensile curves, relaxation curves, hardness, and compression set has been done. The new rubber compound exhibits a good overall performance, except for the compression set. In fact, it has shown a percentage difference of 177.04% lower than the original one.

So, for the production of rubber compounds for the low-cost elastomeric isolator, the recovered materials can't be used in total replacement of ingredients. Still, the results of rheometer curves, uniaxial tensile curves, relaxation curves, and hardness seem promising for future developments of this research where new compositions with partial replacements of recovered powder and waste oils will be proposed.

Abstract. The assessment of the ultimate load capacity of masonry domes and vaults is a complex open issue of both professional and research concern. 3D curved geometry of such structures entails biaxial stress states and highly nonlinear mechanical behaviors which require advanced computational strategies to be rigorously dealt with.

This study focuses on the assessment of the capacity of masonry hemispherical domes subjected to horizontal forces (such as those produced by wind and earthquake). In the framework of Limit Analysis (LA), a parametric Membrane Equilibrium Analysis (MEA) is proposed based on No-Tension (NT) material assumptions in the sense of Heyman: the unilateral membrane must lay inside the boundary surfaces of the dome and the membrane stress must have a non-positive concave potential. The membrane equilibrium problem for the dome is then formulated in Pucher form and controlled by a few parameters to be optimized. Two elementary examples are also provided to illustrate the method.

1 INTRODUCTION

The assessment of the structural capacity under horizontal forces (e.g., wind, inertial forces induced by earthquake etc.) of masonry domes or vaults is a challenging issue of structural engineering of relevant practical importance [1]-[9]. This is a very complicated problem, due to the interaction between biaxial stress on curved geometries and the highly non-linear mechanical behavior of masonry material. A number of researchers over the years have tried to develop complex Finite or Discrete Element (FEM, DEM) numerical strategies, often with very sophisticated material models mimicking the actual properties of masonry (such as anisotropy, plasticity, viscosity, damage and degradation processes, non-linear behavior etc.) in some detail. The precision and the accuracy of these models depend on the amount and quality of geometric and mechanical data used for the simulations [10]-[17]. However, the number of uncertainties and randomness related to the definition of such geometric and mechanical parameters make it arduous, not to say impossible, to draw definite and correct masonry models. This observation opened the way to a number of experimental approaches based, for example, on tilting tests on scale models [18]-[21].

Many papers have appeared in recent years setting a new promising approach in the framework of Limit Analysis, based on the application of the static and kinematic theorems to admissible stress and strain fields [22]-[31]. They exploit the unilateral masonry-like material model, also known as No-Tension (NT) model, dating back to the pioneering works of Heyman [32] and Zienkiewicz [33]. The key advantage of such approach is that no mechanical properties are required.

Inspired by the pioneering works of Angelillo and Fortunato and Angelillo et al. [34]-[36], the present paper proposes an innovative and promising parametric approach based on the Membrane Equilibrium Analysis (MEA) [37, 40]. The key idea is to extend the Thrust Line Analysis (TLA), widely used for 2D equilibrium problems concerning arches, to 3D dome or vault equilibrium problems. Equilibrium states of masonry domes can be thought of as carried by an ideal membrane that due to Heyman's assumptions, must be compressed (i.e. the generalized stress is negative semi-definite) and entirely contained within the dome volume. The membrane equilibrium is formulated in Pucher form [41] in terms of two unknown scalar functions, namely the stress potential and the elevation of the membrane. Then, the equilibrium equations are reduced to the transverse equilibrium only by introducing the Airy stress potential function. On adopting a form-finding strategy, the shape on which the membrane stress acts is assumed as unknown in the Pucher equation and tuned by a number of geometric parameters to be optimized. The constrained optimization procedure consists in maximizing the value of the load factor under the unilateral constraints related to the NT material assumption. The lines along which the membrane surface approaches or crosses the limit surfaces of the dome (i.e. the intrados or extrados surfaces) provide candidate lines of hinging at collapse. Such a prediction can be easily cross checked with predictions obtained with experimental results.

The paper is organized as follows: Section 2 provides the mathematical preliminaries on the membrane equilibrium problem and its formulation in terms of Pucher stress, Section 3 presents the proposed parametric procedure and the adopted form-finding strategy, Section 4 gives two trivial application of the proposed method to a hemi-spherical dome with the sole aim of illustrating the method, finally concluding remarks and future prospects are summarized in Section 5.

2 MEMBRANE EQUILIBRIUM OF A DOME

2.1 Geometry: "a la Monge" description

Let us consider a masonry dome subjected to its own weight and to the action of horizontal body forces controlled by a load factor $\lambda = (\lambda_1, \lambda_2)$ (Fig.1). With respect to a right-hand orthogonal coordinate system $O(x_1, x_2, x_3)$, the geometry of membrane surfaces can be conveniently represented by a Monge patch:

$$\{\mathbf{x} = (x_1, x_2, f(x_1, x_2)), (x_1, x_2) \in \Omega\} \quad (1)$$

where $f(x_1, x_2)$ is, in general, an arbitrary continuous function of its arguments (x_1, x_2) and Ω is the so-called planform of the membrane, namely a connected plane region obtained as projection of the inner or outer membrane surfaces (i.e. S_i and S_e) on the x_1x_2 -transverse plane.

Figure 1: Section of a typical hemispherical dome in the x_1x_3 -coronal plane.

The surface forces per unit projected membrane area, applied to the dome are

$$\mathbf{p} = \{\lambda_1 p, \lambda_2 p, -p\} \quad (2)$$

where $p = btJ^*$ is the dome self-load per unit projected area; t is the dome thickness and J^* is the area ratio between the loading surface and the planform. For the sake of simplicity, we suppose that such forces are lumped to a conveniently chosen loading surface S_p all contained in the dome thickness.

When the body force p is given, by tuning the load factor λ we search for a thrust surface S (i.e. a membrane surface) which carries the applied loads and lays entirely within the limit surfaces S_i , S_e of the masonry dome and capable of sustaining the applied loads through purely compressive stresses.

2.2 Equilibrium

The equilibrium problem of the membrane S subjected to the surface force per unit platform area p can be described through a Differential Geometry (DG) approach [34] based on the Pucher formulation [41] as follow

$$\begin{cases} S_{11,1} + S_{12,2} + \lambda_1 p = 0 \\ S_{21,1} + S_{22,2} + \lambda_2 p = 0 \\ S_{11}f_{,11} + S_{22}f_{,22} + 2S_{12}f_{,12} - f_{,1}\lambda_1 p - f_{,2}\lambda_2 p + p = 0 \end{cases} \quad (3)$$

where S_{ij} is the ij Pucher stress component. Hereafter, we use the subscript notation $(*)_{,i}$ to describe the partial differentiation of $(*)$ with respect to x_i , and the subscript notation $(*)_{,ij}$ to describe the second derivative of $(*)$ with respect to x_i and x_j ($i, j = 1, 2$).

The equilibrium of the Pucher stress in the planform can be solved on introducing a stress potential, in the following way

$$\begin{cases} \tilde{S}_{11} = S_{11} + \int \lambda_1 p dx_1 = F_{,22} \\ \tilde{S}_{12} = S_{21} = -F_{,12} \\ \tilde{S}_{22} = S_{22} + \int \lambda_2 p dx_2 = F_{,11} \end{cases} \quad (4)$$

were $F(x_1, x_2)$ is the so called Airy stress function, which here is assumed to be only continuous (more detailed information with regard to the underlying assumptions can be found in [34]). Based on the Airy solution (4) and setting $h_i(\lambda_i) = \int \lambda_i p dx_i$ ($i = 1, 2$), the equilibrium equations (3) reduce to a single linear equation in the unknown stress potential function $F(x_1, x_2)$

$$(F_{,22} - h_1(\lambda_1))f_{,11} + (F_{,11} - h_2(\lambda_2))f_{,22} - 2F_{,12}f_{,12} - f_{,1}\lambda_1 p - f_{,2}\lambda_2 p + p = 0 \quad (5)$$

This is a second order Partial Differential Equation (PDE) in which the components of the second fundamental form of the surface $f(x_1, x_2)$ represent non-constant coefficients. Depending on the definiteness of the Hessian of the shape function f the equation (5) can be elliptic, hyperbolic or parabolic.

2.3 Constitutive restrictions

By assuming a Normal Rigid No-Tension (NRNT) material, the membrane stress tensor $\tilde{\mathbf{S}}$ must be negative semi-definite ($\tilde{\mathbf{S}} \in \text{Sym}^-$) (see [34]), namely, in 3D Euclidian space

$$\text{tr} \tilde{\mathbf{S}} \leq 0 \wedge \det \tilde{\mathbf{S}} \geq 0 \quad (6)$$

These conditions, in terms of the stress function $F(x_1, x_2)$ read

$$F_{,11} + F_{,22} \leq 0 \wedge F_{,11}F_{,22} - F_{,12}^2 \geq 0 \quad (7)$$

which means that the stress surface described by $F(x_1, x_2)$ has to be concave.

3 METHODOLOGY: FORM-FINDING PROBLEM

By assuming that the shape $f(x_1, x_2)$ of the membrane is known, the Boundary Value Problem (BVP) for the unilateral membrane S consists in finding an admissible (i.e. concave) stress function $F(x_1, x_2)$ (i.e. compressive membrane stresses) satisfying the equation (5) and either Dirichlet or Neumann boundary conditions:

$$F|_{\partial\Omega} = g \vee \left. \frac{dF}{dn} \right|_{\partial\Omega} = h \quad (8)$$

where, $\partial\Omega$ is the projected boundary, i.e. the closed boundary of the platform Ω ; $g(x_1, x_2)$ and $h(x_1, x_2)$ are the moment and the shear forces generated by applying the projected tractions on a 1D beam with the same form as $\partial\Omega$. In other words, since the PDE (5) is a second-order equation (rather than a fourth-order equation as happens in plane linear

elasticity) we can choose to prescribe the normal or the tangential component (i.e. F or $\frac{dF}{dn}$) of the stress or even any combination of the two at the projected boundary, in a quite equivalent manner.

At any fixed value of the load factor λ , the BVP problem formulated in these terms admits a unique solution which, however, disregards the constitutive restrictions (7). Then the equilibrium problem of the unilateral membrane S governed by Pucher's equation (5) can be reduced to a form-finding problem. We search in an assigned n -parameter family of shape functions $f(x_1, x_2, \alpha_1, \alpha_2, \dots, \alpha_n)$, constrained to be entirely contained within the dome volume and such that the Hessian is definite (i.e. a convex polynomial function), the only one that provides a solution of the transverse equilibrium equation (5) which fulfills the BVP as well as the concavity conditions (7). The parameters α_i can represent, for example, the size, the position or the asymmetry of the stress membrane S . The restriction on the Hessian ensures that transverse equilibrium equation (5) is elliptic and then easy to solve by a FEM-like numerical strategy. Then, to assess the ultimate load capacity of the dome, i.e. the load factor λ , we can search for the maximum value of $\|\lambda\|$ within the feasible region such that a concave solution of the BVP so defined exists (i.e. $F \in Sym^-$).

4 Numerical applications

The goal of this section is to illustrate how the method works through two trivial examples. All examples consider a hemispherical dome with thickness-radius ratio (t/L) equal to 0.2. It is also assumed that, without loss of generality, the horizontal load \mathbf{p} is settled to be constant per projected area and equal to $\{\lambda p, 0, -p\}$ defining the loading surface S_p as

$$S_p = \{(x_1, x_2, f_p(x_1, x_2)), (x_1, x_2) \in \Omega\}; \quad (9)$$

where $f_p(x_1, x_2)$ is the paraboloid (Fig. 2)

$$f_p(x_1, x_2) = L \left(1 - \frac{x_1^2 + x_2^2}{t^2} \right); \quad (10)$$

L is the middle radius of the dome. Note that, for convenience purposes, all the geometrical dimensions are adimensionalized with respect to the reference length L .

Figure 2: Loading surface S_p

The Pucher's equation governing the equilibrium problem (5) is parametrically solved for the shape $f(x_1, x_2, \alpha_1, \alpha_2, \dots)$ by using the PDEs tool implemented in Mathematica© (Version 12) [42] and based on a triangular Finite Element discretization (Please refer to [27] for more details).

4.1 Example 1

In the first example we choose an initial membrane shape corresponding to the paraboloid (10). This shape is fully contained within the dome thickness but it is not dependent on the geometrical parameters α_i . The maximum value of λ at which the stress ceases to be a negative semi-definite concave surface is $\lambda = 0.35$. Fig. 3 shows the principal stresses

Figure 3: Thrust surface S_p inside the dome (a) and principal stresses profile in the sagittal plane for $\lambda = 0.38$ (b)

profile in the x_2x_3 -sagittal plane for a value of $\lambda = 0.38$ that leads to tensile stresses upwind with respect to the direction of the horizontal force.

In order to optimize the membrane shape $f(x_1, x_2) = S_p$, we have added to f_p a convenient shape function $\Delta f(x_1, x_2, \alpha_1, \alpha_2, \dots, \alpha_n)$, that is a cubic interpolating spline function with an appropriate set of control points $\alpha_1, \alpha_2, \dots, \alpha_n$ (i.e. maximum height, middle radius and inflexion point of membrane shape). By numerically solving the parametric equilibrium equation 5 we obtain a class of membrane forms depending on the load factor λ . By regarding the load factor λ as the objective function, the parameters $\alpha_1, \alpha_2, \dots, \alpha_n$ are finally optimized by maximizing $\lambda(\alpha_1, \alpha_2, \dots, \alpha_n)$.

The so optimized membrane shape $f(x_1, x_2, \alpha_1, \alpha_2, \dots, \alpha_n)$ enables a significant increase in the maximum value of λ at which the thrust surface is contained entirely inside the dome and conditions (7) hold, namely $\lambda = 0.42$.

Fig. 4 shows the corresponding profile of the principal stresses corresponding to the optimized solution in the x_1x_3 -coronal and in the x_2x_3 -sagittal planes. The contour plot of the principal (minimum and maximum) projected stress values and the corresponding isostatic lines are also reported.

4.2 Example 2

In this example we analyze a dome which displays a certain pattern of crack, due to horizontal actions which exceed the limit value. In such a case the stress membrane is not contained entirely in the dome (Figs. 5). Therefore, we allow for a small enlargement of the extrados surface and look for the intersection of the membrane surface with the original extrados surface S_e . In this case, the maximum load factor such that the stress is negative semi-definite is $\lambda = 0.45$. The contour plot of the minimum and maximum principal stresses and the corresponding isostatic lines are reported in Figs. 5, in particular the maximum principal stress almost vanish for $x_1 \in (-17, -5)$, leeward with respect to the horizontal action. Notice that the isostatic lines corresponding to zero principal stresses, are almost straight, meaning that the surface profile in such directions consists of funicular lines. In Fig. 5b the profile of the curve of intersection of the optimized membrane surface with the original extrados surface S_i is shown (black lines).

5 CONCLUDING REMARKS

This paper presents a new parametric approach, based on the Membrane Equilibrium Analysis, to the assessment of the load carrying capacity of masonry domes or vaults under horizontal body forces. By using the MEA the load applied to a dome composed of

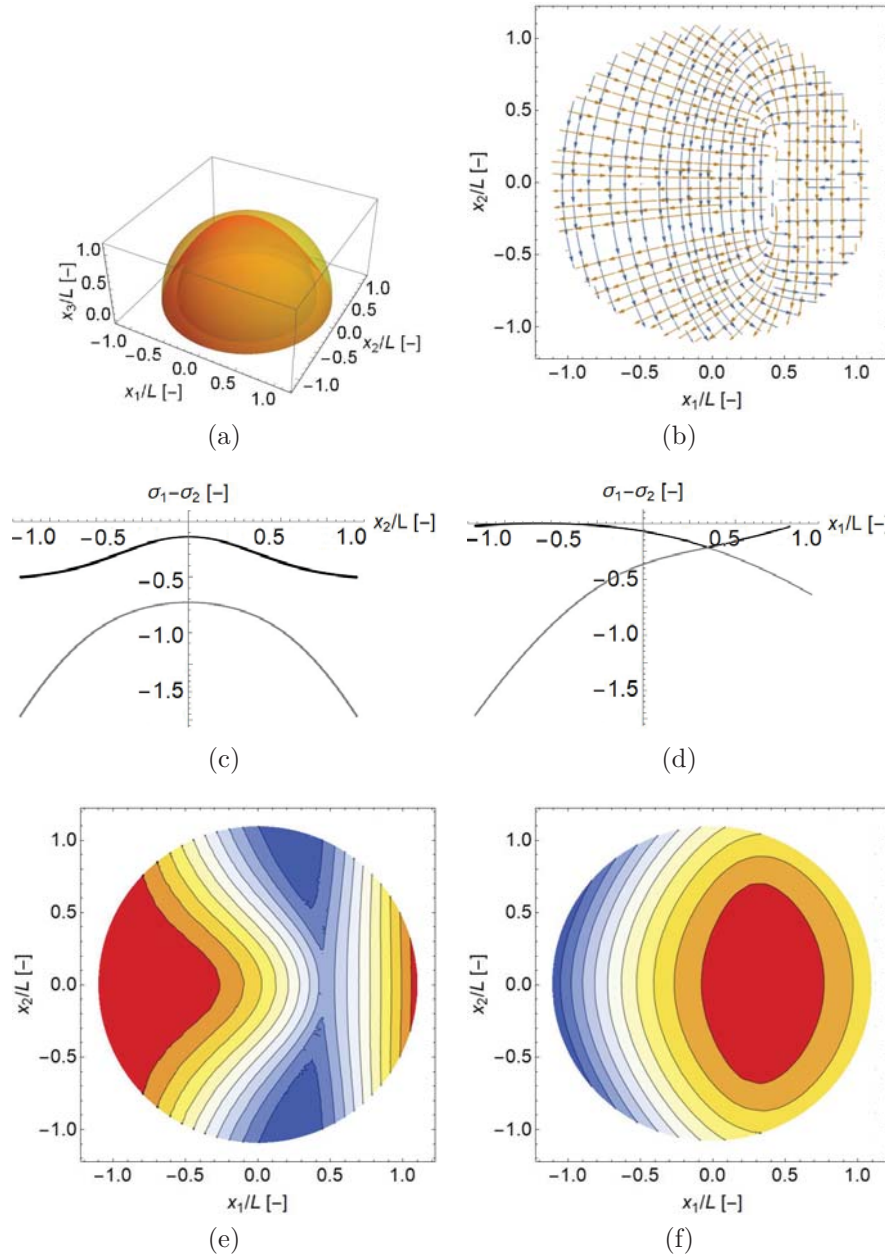

Figure 4: Optimized thrust surface S corresponding to the optimal value of λ (a); principal lines of curvature (b); principal stress profile in the coronal plane (c); principal stress profile in the sagittal plane (d); contour plot of minimum and maximum principal projected stress values (e,f)

unilateral Heyman material is lumped to a loading surface S_p and is carried by a thrust surface S contained inside the masonry. By changing its shape f through the tuning of a finite number of geometric parameters, the generalized membrane stress balancing the loads as well as its projection on the planform change. The optimal value of the geometric parameters, i.e. the optimal shape function of the stress membrane, is obtained by maximizing the horizontal load multiplier λ , with the constraints that the generalized stress is non-positive definite, the surface S is fully contained inside the dome volume and the Hessian of the shape function f is positive definite (i.e. f belongs to a n -parameter

function family of convex polinomia). The latter condition guarantees that the Pucher's equilibrium equation is elliptic and then easy to solve though a FEM-like numerical strategy. The proposed approach can be applied to either design or assessment of ultimate load capacity and can be easily extended to more complex geometries (i.e. thin-thick, flatted or pointed domes and semi-circular, cross, Rib or Fan vaults) even though it needs a substantial effort in terms of implementation.

Keywords: Masonry, homogenization, seismic behaviour, retrofitting techniques.

Abstract. In many seismically active regions of the world there are large numbers of masonry buildings. Most of these buildings have not been designed for seismic loads. Recent earthquakes have shown that many of these buildings are seismically vulnerable and should be considered for retrofitting. Different conventional and unconventional retrofitting techniques are available to increase the strength and/or ductility of unreinforced masonry (URM) walls. This paper reviews and discusses seismic retrofitting of masonry walls with emphasis on the conventional techniques. Retrofitting procedures are discussed with regard to a case study: a stone masonry building in Irpinia region, damaged by the 1980 earthquake. The interventions are evaluated by means of finite elements with a macroelement obtained with an homogenization technique. Linear and nonlinear procedures are compared, and peculiarities of each procedure are shown.

1 INTRODUCTION

Masonry structures are prone to extensive damage followed by failure and collapse when subjected to loads resulting from wind, earthquake and other natural or man-made events. Recent earthquakes and terrorist acts have clearly demonstrated that the development of effective and affordable strategies for the analysis and strengthening of masonry is urgently needed. Many older masonry structures currently in use were in fact designed and constructed with little or no consideration of these aggressive factors. In addition, recent changes in seismic requirements have left many URM buildings in need of strengthening. In many cases, these natural effects were not considered in ancient time [1]. Very few masonry buildings have been built in modern times, and knowledge of the related design methods is no longer part of a civil engineer's training [2]. Despite a growing need for rehabilitation and conservation of these structures, understanding of their behavior has been declining in the first decades of last century, and the available methods for assessing them are of questionable reliability. In recent times the strong need of rehabilitation, together with the development of numerical tools, has improved knowledge about assessment methods for masonry buildings [3]-[12]. As a response to the challenges offered by the assessment of URM, several intervention methods have been proposed [13]. Nevertheless the first step toward a complete assessment of an intervention method is the understanding of constitutive behaviour of both URM and reinforcement [15]-[26].

One of the reliable tools developed in the last years are the homogenization techniques. The development of these techniques in the field of composite materials has induced a similar approach in the field of masonry structures, in which the masonry material is the result of two different elements, spacially arranged in different geometries [27]. Since it is a key point in the bulk behaviour of masonry, careful attention must be posed on the behaviour of block-masonry interface [28, 29] and in the spatial arrangement of the blocks. Differently from fiber reinforced materials, in which a periodic structure can be often recognized, homogenization of non-periodic structures is a complex process [30]. Based on classical homogenization methods [31, 32], this paper presents an analysis of a stone masonry building performed before and after the reinforcement with grout injections. The basic cell of the homogenized medium is a non-standard one, with stone elements irregularly arranged in the representative Volume Element (RVE). Elementary load cases were developed in order to obtain the constitutive bulk parameters of the homogenized medium [33, 34]. According to the above considerations, the model has been developed by means of finite element analysis, since a closed form for the homogenization problem in this case is not available. A numerical finite element analysis was performed on this existing building taking into account the bulk parameters derived in the homogenization procedure. The case study is a stone masonry building with simple and irregular shape in Irpinia (a seismic region of Southern Italy), severely damaged by the 1980 earthquake.

2 THE STRUCTURAL MODEL

2.1 Homogenization

It is well known that the mechanical characteristics of masonry should be detected in order to define the constitutive laws of the material for the mathematical model assumptions. Nevertheless all the parameters defining these characteristics cannot be measured on site. The only parameters that can be measured at the moment on site are the modulus of elasticity, the Poisson ratio in the direction parallel to the bed joints, the value of

the stress at onset of cracking on the external face of a wall. A masonry wall has in fact different properties along different axes according to the units texture and the directions and geometry of the mortar joints. To evaluate the different properties according the directions, an homogenization procedure has been performed to describe masonry as a composite medium in terms of macro or average properties so that it can be assumed to be an homogeneous material. The first problem to solve was the choice of RVE, i.e. the minimum material to evaluate the macro-parameters of masonry. In the case of periodic structure of masonry it is in general a simple problem to consider the basic cell as RVE. In Southern Italy irregular stone masonry is widely diffused, so that basic cells are not simple to recognize. In this paper an iterative method, based on test windows, was taken into account [35, 36] considering a linear elastic behaviour for both mortar and stone units. A 3D model was built for the RVE (Figure 1a), performig linear and non linear analyses and considering two different types of bonding between the mortar and the stone unit:

1. perfect bonding: in this case a bulk linear elastic behaviour for masonry was obtained as a result;
2. unperfect bonding: in this case an unilateral frictional contact with Mohr-Coulomb constitutive law for the interface mortar-stone unit was taken into account. A nonlinear elastic bulk behaviour was obtained for masonry.

Figure 1: Representative volume element (a), discretized stone units (b) and mortar matrix (c).

In Figures 1 the discretized model of the basic cell is shown: it is a $110 \times 150 \times 60$ cm block in which 20 irregular stone units are embedded in a mortar matrix. The spatial distribution of the stones is irregular too. A finite element analysis was performed on the block, in order to evaluate the mechanical bulk properties to be employed in the numerical analysis of the entire building. Both the constituents were considered isotropic elastic [37]. Their mechanical properties are reported in Table 1.

A picture of the discretized basic cell is represented in Figure 2a. Numerical analyses have shown that negligible changes in the mechanical homogenized parameters were observed in masonry panels with larger dimensions with respect to the chosen one, so that the above block can be considered as a representative volume element.

Several sensitive analyses were carried out on different, more chaotic spatial distributions of stones in a masonry panel having the same bulk dimensions, as that reported in

Material	Elasticity Modulus	Poisson coefficient	Friction coefficient
Stone	6000 MPa	0.23	0.60
Mortar	2500 MPa	0.20	

Table 1: Values of mechanical parameters.

Figure 2: Discretized masonry block: basic cell (a) and tentative discretized cells (b).

Figure 2b. The analyses have shown that a transversal isotropic behaviour can be recognized in these last cases. The symmetry axis is that one orthogonal to the medium plane of the masonry panel. The anisotropic case has been chosen for the case study, both for the similarity of the stone arrangement with the real case and for the generality of the constitutive behaviour.

2.2 Numerical analysis

The results of the analysis performed by means of the ANSYS program [38] on the masonry block are shown in the following. Standard CONTA173 and TARGE170 were used to model the unperfect bonding, while elements SOLID45 were used to discretize both mortar and stone units.

Different load conditions were analyzed in order to obtain the compliance tensor for the homogenized medium. The stiffness tensor was obtained as the inverse matrix of the compliance one. As a synthesis of the results, the stiffness tensor for the homogenized medium is given in the two analyzed cases, with or without frictional contact. The stiffness tensor in the elastic case without frictional contact is reported in Tables 2a. As it can be seen, the stiffness matrix of the material modelled without frictional contact corresponds, as expected, to that of an orthotropic material, so that the symmetry of the matrix is preserved.

(a)

(b)

Table 2: Stiffness elastic tensor (no frictional contact).

In this case, in fact, the existence of an elastic potential can be demonstrated. Table 2 refers to the constitutive model of the block without interventions, while Table 2b reports the same data in case of grout interventions.

The case in which frictional contact is taken into account is different: an unsymmetric constitutive matrix is the result of the dissipative behaviour due to the unilateral frictional contact. In this case, in fact, the dissipation cannot assure the existence of an elastic potential function for the material behaviour, which corresponds to a symmetric constitutive matrix.

The above symmetry cannot be observed in fact in the case of frictional contact, shown in Tables 3a. In this case too Table 3a refers to the constitutive model of the block without interventions, while Table 3b reports the same data in case of grout interventions.

As it can be seen, the homogenized material shows more deformability in the case of frictional contact with respect to the perfect bonding.

(a)
(b)

Table 3: Stiffness elastic tensor (frictional contact).

This can be explained with the possibility of relative displacement between mortar and stones, due to chosen model of friction, which involves unilateral contact. To complete the set of data obtained by the homogenized procedure performed, the elastic bulk parameters in the two cases analyzed are reported in the following Tables 4a and 4b.

No interventions			Grout injections			No interventions			Grout injections

(a) No frictional contact
(b) Frictional contact

Table 4: Mechanical parameters.

In the two cases examined the elastic modulus increase is significant, while a less significant decrease can be observed in the Poisson coefficients. The expected overall increase of stiffness in the injected homogenized medium with respect to that without interventions is confirmed.

2.3 Structural analysis

A stone masonry building in Irpinia was chosen as a case study. It was built in 1930, with a planar L shape, and sort of regularity in the z -direction, being x and y the directions of the two external walls of the building (Figure 3a) and z the vertical one.

Figure 3: Pictures of the building with reference axes (a)-(b). Discretized model of the building (c).

The stiffness in the y -direction is higher to that in the x -direction as it can be seen in Figure 3b. The masonry walls were modelled with the bulk properties examined above, while floors and roofs were considered as plate elements with high in-plane stiffness (Figure 3c). The homogenized properties evaluated in the previous sections have been considered as the properties of the building masonry walls. The numerical analysis was performed by means of the numerical code ANSYS, with tetrahedral four-node solid elements SOLID45.

In the following a discussion about the displacements results is provided, in order to assess the reliability of the method proposed. Figure 4a presents the distribution of displacements for an earthquake loading along x -direction in the case of orthotropic behaviour. The constitutive model without frictional contact was taken into account. As it can be seen, the displacement evaluated at the top of the building is about 0.4 cm, better represented in Figure 4b. If the seismic loading is directed along the y -direction, the maximum displacement at the top of the building is about 0% of the previous, as expected according to the building geometry (Figure 4c).

The reduction of the displacement amount due to the contribute of grout injections in the case of orthotropic behaviour is represented in Figure 4d and 4e. As it can be seen, there is a similarity of overall behaviour of the structure, with increased stiffness due to the injections. The analysis performed and shown above involves orthotropic behaviour with a stiffness matrix in which the non-zero terms are derived from the stiffness matrix developed in the case of frictional contact. The isotropic model could not represent the behaviour of the real case study, as it can be seen in the following table, in which the results of a finite element analysis, involving both isotropic and orthotropic behaviour, has been reported.

Tables 5 and 6 show that an elevate stiffness can be recognized in the isotropic case, so that the maximum displacements in the four load cases examined for the isotropic behaviour are about 15% of the displacements obtained in the corresponding orthotropic

(a) Total displacements for earthquake x-loading (no interventions, orthotropic behaviour)

(e) Displacements y-direction for earthquake y-loading (with grout injections, orthotropic behaviour)

Figure 4: Results.

ones. Usually the isotropic models represent the different behaviour according the load directions only with reference to structural geometry, without considering the influence of the material geometry.

A similar finite element analysis has been performed and the displacements in the same four load cases for the orthotropic behaviour have been compared in three different cases: no interventions, grout injections and connections between the two wythes. This last case has been considered to evaluate the influence of transversal connections in masonry. In general, a good quality masonry presents different leaves with transversal connections, made in general by overlapped stones or long regular stones transversally placed. In the

	Isotropic case	Orthotropic case

Table 6: Maximum displacements in the intervention cases, orthotropic behaviour (cm).

cases in which the leafs that constitute the wall are not connected, a retrofitting connection is needed. Traditional interventions involve the placement of transversal stones. Recently local interventions by means of steel bars have been considered. Due both to the cost and to the difficulties connected with the insertion of the bars, usually these last interventions are taken into account if the portion of the masonry wall requiring a retrofit intervention is limited. The analyses show that the performance of the building subjected to a retrofitting intervention made with grout injections is comparable with that of a good quality masonry building.

3 CONCLUSIONS

The geometric and physical-mechanical characterization of the masonry texture is a key point in the homogenization of historical buildings. The numerical homogenization analysis can be focused as a standard procedure to identify the fundamental parameter to correctly model a masonry structure. The outcomes of the proposed approach point out that the anisotropic analysis is accurately formulated and are strongly influenced by the modeling parameters. It has also been shown that isotropic analysis provides different results from the anisotropic one.

Abstract

This paper proposes a simple analytical system that can be used to describe the dynamics of Negative Stiffness Bilinear Elastic (NSBE) systems, and consequently design them in a simpler manner. The NSBE oscillator is a mathematical idealization, which can be used to describe rocking structures with or without flexible restraining systems or curved extension at their bases. The paper defines the characteristic quantities to make the bilinear system and actual rocking structures equivalent.

A simpler “equivalent” system to describe the behavior of NSBE systems is proposed: The equivalent system is the Zero Stiffness Bilinear Elastic (ZSBE) system, which is a bilinear system with zero stiffness in the second branch. The ZSBE system is useful and simpler because it needs one parameter less than the NSBE to be defined. The paper proceeds by defining the “Equal Displacement” and “Equal Energy” rules that provide estimates of the maximum displacement of the NSBE based on the response of the ZSBE. Using a simpler system to predict the response of a more complicated one, is a concept similar to the $R_{\mu}T$ relations that provide estimates of the response of bilinear yielding systems based on the response of an equivalent linear elastic system. However, the method should not be confused with the approach of FEMA 356: it does not resort to a linear elastic system but to the ZSBE.

Finally, the preliminary design of a real rocking structure is presented, as a case of study. The paper compares the response predicted by the proposed methodology to the one predicted by a more accurate numerical analysis.

Keywords: negative stiffness systems, dimensional analysis, non-linear dynamics, bilinear systems

1 INTRODUCTION

Rocking has been proposed as a seismic isolation method for both bridges [1-20] and buildings [21–23], because uplift works as a mechanical fuse and limits the design forces of both the superstructure and the foundation. Unlike structures designed to yield, the free rocking rigid block exhibits negative post-uplift stiffness [24]. In particular, this paper focuses on negative stiffness systems that are designed to sustain rocking motion without sliding [25–32], and do not exhibit hysteretic damping. Thus, it loads and unloads on the same branch. These systems do not accumulate displacements as negative stiffness hysteretic systems would. To avoid confusion, note that this paper uses the term “elastic” to describe not only linear elastic systems but all systems that unload on the same branch, linear or nonlinear. Therefore, an unrestrained rocking system is a negative stiffness elastic system.

Plastic design has found its way to practice, partially because a simplified design methodology that is based on the linear elastic response spectrum has been developed. For most structures designed to yield, a time history analysis is not required and an approach based on linear elastic spectra is allowed. This convenient design approach was originally developed for elastoplastic systems, including the ones exhibiting post-yield hardening. It has been extended to include recentering (rocking) systems exhibiting positive post-uplift stiffness [33, 34]. However, it is not applicable to negative stiffness rocking systems, because there is no “equivalent linear elastic system” for them [35]. Therefore, time-consuming time history analysis is required and the linear elastic response spectra that are defined by codes become useless for such structures.

This paper suggests that there can be a simplified design method for Negative Stiffness Bilinear Elastic (NSBE) systems (Fig.1a), based not on an equivalent linear elastic system, but on an equivalent bilinear elastic system of constant restoring force (i.e., zero post-uplift stiffness)—a Zero Stiffness Bilinear Elastic (ZSBE) system (Fig.1b). Even though the equivalent ZSBE system does not present the convenience of a linear elastic system where the response scales proportionally to the excitation, it is useful because it reduces the dimensionality of the problem and it allows the development of design spectra (not linear elastic) for negative stiffness systems.

Figure 1: a) Characteristic pushover curve of the Negative Stiffness Bilinear Elastic (NSBE) system; b) Proposed bilinear elastic system of constant restoring force (Zero Stiffness Bilinear Elastic [ZSBE]) system.

It should be noted that the results of this study are not directly applicable to design procedures. However, they suggest approaches that might be used to develop a rational design procedure for earthquake resistance of rocking structures.

2 EQUIVALENT DESCRIPTION OF ROCKING SYSTEMS WITH NSBE SYSTEMS

One of the challenges in designing a rocking structure is that for a given height of a flat-based unrestrained rocking structure, usually defined by architectural considerations, its displacement capacity (i.e., the displacement that would cause overturn) is coupled to its uplifting force, because they both depend on its slenderness α (or, equivalently, on its base width $2b$). Therefore, extending the base to increase the displacement capacity of the structure causes an increase in the design forces of both the superstructure and the foundation.

In an effort to isolate buildings via a rocking story, Soviet engineers [36] were the first to suggest a way to decouple the displacement capacity from the uplift acceleration: They extended the base of the block by a curved part. This increases the displacement capacity while keeping the uplifting acceleration constant [8]. The post-uplift stiffness can be positive or negative depending on the curvature of the extension. A similar behavior can be obtained by using a flexible restraining system [14, 16].

The idealized systems presented above assume that the structure is rigid – a questionable assumption as the size of the blocks increase. Fig.1a shows the force-deformation curve of a rocking structure, when its deformability is considered [37–44]. In this case, the pre-uplift displacement is not zero but takes a finite value u_{up} . Therefore, all systems cited above can be described by an elastic bilinear system, up to a linear approximation.

The SDOF NSBE studied here is shown in Fig.1a. It has a mass m and a restoring force described by Fig.1a. The initial positive stiffness (k_{pos}) branch represents any pre-uplift deformability. The second branch has negative stiffness (k_{neg}), and it starts at the uplift displacement (u_{up}). The system displacement capacity (u_{cap}) is defined as the displacement that results to zero restoring force, even though there are rare cases where a system can dynamically exceed this displacement without collapsing.

Based on its characteristic pushover curve, the oscillator's equation of motion is:

$$m \cdot \ddot{u}(t) + f_{up} \cdot \frac{u(t)}{u_{up}} = -m \cdot \ddot{u}_g(t), \quad |u(t)| \leq u_{up} \quad (1)$$

$$m \cdot \ddot{u}(t) + f_{up} \cdot \left(\frac{u_{cap} - u(t)}{u_{cap} - u_{up}} \right) = -m \cdot \ddot{u}_g(t), \quad |u(t)| > u_{up} \quad (2)$$

The upper sign in Eq. 2 corresponds to a positive displacement and the lower to a negative displacement.

The main source of energy dissipation in rocking structures with protected ends is impact damping—unless extra damping is provided. For this reason, this paper assumes that the proposed NSBE model dissipates energy instantaneously. When the displacement is equal to the uplift displacement (i.e., when there is impact in the case of rocking structures), the integration is halted, and the post impact velocity is computed by a coefficient of restitution:

$$r_c = \frac{\dot{u}_{postimpact}}{\dot{u}_{preimpact}} \quad (3)$$

Herein, the ratio of the preimpact to postimpact velocities will be assumed equal to 0.95. Notably, the system unloads on the same branch and does not dissipate energy while unloading (apart from the instantaneous energy loss when it reaches the yielding displacement).

For the case of rigid systems, the parameters of the system of Fig.1a that make it mathematically equivalent to a variety of rocking systems are given in Table 1 and named \tilde{m} , \tilde{f}_{up} ,

and \tilde{u}_{cap} . Note that in order for the system of Fig.1a to be equivalent to these rocking systems, the excitation used for the equivalent bilinear system needs to be multiplied by a factor Γ , also given in Table 1. Then, the equation for the equivalent bilinear system becomes:

$$\tilde{m} \cdot \ddot{u}(t) + \tilde{f}_{up} \cdot \left(1 - \frac{u(t)}{\tilde{u}_{cap}}\right) = -\Gamma \tilde{m} \cdot \ddot{u}_g(t) \quad (4)$$

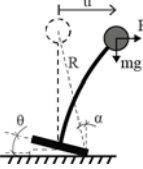

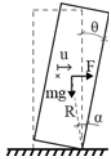

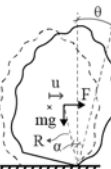

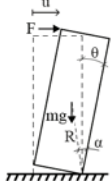

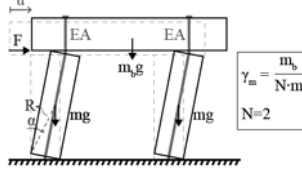

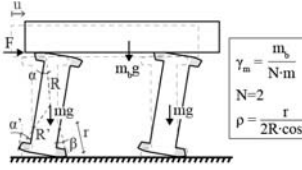

#		\tilde{m}	\tilde{f}_{up}	\tilde{u}_{cap}	Γ
1		m	$mg\alpha$	$R\sin\alpha$	1
2		$\frac{4}{3}m$	$mg\alpha$	$R\sin\alpha$	$\frac{3}{4}$
3		$\frac{I_o}{R^2}$	$mg\alpha$	$R\sin\alpha$	$\frac{mR^2}{I_o}$
4		$\frac{m}{3}$	$\frac{mg\alpha}{2}$	$2R\sin\alpha$	$\frac{3}{2}$
5		$\frac{(1+3\gamma_m)Nm}{3}$	$\frac{Nmg}{2}(1+2\gamma_m)\alpha$	$\frac{\left(\frac{1}{2}+\gamma_m\right)}{\left(\frac{1}{2}+\gamma_m\right)-\frac{EA}{mg}\alpha^2}2b$	$\frac{3(1+2\gamma_m)}{2(1+3\gamma_m)}$
6		$\frac{(1+3\gamma_m)m}{3}$	Rolling: $\frac{mg}{2}(1+2\gamma_m)\alpha$	$\frac{2R\sin\alpha}{(1-2\rho)} \leq 2R'\sin\alpha'$	$\frac{3(1+2\gamma_m)}{2(1+3\gamma_m)}$

Table 1: Parameters of the bilinear elastic system for different rocking systems

3 EQUAL DISPLACEMENT AND EQUAL ENERGY RULE

Using the elastic spectrum for the analysis of negative stiffness structures would have been very convenient as engineers are used to it and as elastic spectra for design already exist and are included in codes. However, this is not feasible for NSBE systems, because their response has been proven to be uncorrelated to any “equivalent” elastic system [35].

Therefore, this section defines Equal Displacement and Equal Energy rules that are applied not on an equivalent elastic system but on an equivalent ZSBE system (Fig.1b). We refer to it as “equivalent,” but this does not imply that it is *linear* elastic. It is a *bilinear* elastic system with finite pre-uplift displacement and zero post-uplift stiffness system.

To correlate the responses of the NSBE and of the ZSBE, the quantity of interest is the ratio:

$$\gamma = \frac{u_{dem,NS}}{u_{dem,ZS}} \quad (5)$$

where $u_{dem,NS}$ and $u_{dem,ZS}$ are the maximum displacements of the NSBE and ZSBE systems, respectively.

The Equal Displacement rule assumes that the NSBE and the equivalent ZSBE system will experience the same maximum displacement (Fig.2a):

$$u_{dem,NS} = u_{dem,ZS} \rightarrow \gamma_{ED} = 1 \quad (6)$$

The Equal Energy rule assumes that the monotonic loading curves of the NSBE and the ZSBE system will produce the same work, that is, the two shaded areas in Fig.2b are equal. Based on Fig.2b, one can compute that the Equal Energy rule gives:

$$\gamma_{EE} = \frac{u_{dem,NS}}{u_{dem,ZS}} = \frac{u_{cap}}{u_{dem,ZS}} - \sqrt{\frac{(u_{cap} - u_{up})}{u_{dem,ZS}} \cdot \frac{(u_{cap} - 2 \cdot u_{dem,ZS} + u_{up})}{u_{dem,ZS}}} \quad (7)$$

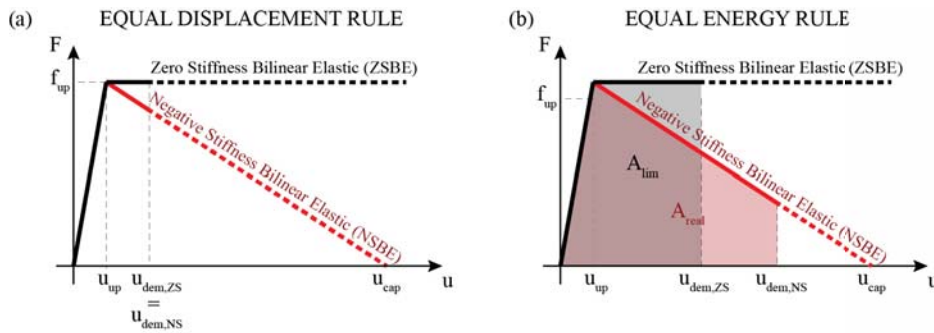

Figure 2: a) Equal Displacement, and b) Equal Energy rules for NSBE systems

4 RESPONSE OF RIGID-NEGATIVE STIFFNESSES SYSTEMS TO RECORDED GROUND MOTIONS

This section explores the accuracy of the rules defined in the section above, when applied to NSBE systems that present minimal pre-uplift displacement, i.e. systems with small u_{up} .

4.1 FEMA P695 Ground Motions

There is no consensus in the engineering community on what ground motions should be used in time history analysis. This paper focuses on the far-field set of ground motions proposed by FEMA P695 [45].

4.2 Median displacement spectra

Seismic design does not involve a single excitation, but a set of excitations that characterize the seismic hazard at a given site. Thus, this paper compares NSBE and ZSBE not by comparing their responses to individual ground motions, but by comparing the statistics of the responses to ensembles of ground motions [46]. The Equal Displacement and Equal Energy rules are assessed by focusing on the median displacement spectra for three variations of the set: scaled so that their PGV is equal to $0.5 \overline{\text{PGV}}$, or $1.0 \overline{\text{PGV}}$, or $2.0 \overline{\text{PGV}}$. $\overline{\text{PGV}}$ is defined as:

$$\overline{\text{PGV}} = \text{median}_{i=1 \dots N} \left(\sqrt{\text{PGV}_{i_x} \cdot \text{PGV}_{i_y}} \right) \quad (8)$$

where N is the number of ground motions and x and y are their two components.

4.3 Equal Displacement Rule for NSBE systems

Fig.3a plots the median of the maximum displacement of the NSBE stiffness system as a function of its strength normalized by the system's self-weight (f_{up}/mg) for several values of the displacement capacity. The uplift displacement is set to $u_{up}=5 \times 10^{-4}$ m to study quasi-rigid systems. For reasons of plot clarity, each line is plotted only for $f_{up}/mg > (f_{up}/mg)_{crit}$, where $(f_{up}/mg)_{crit}$ is the maximum uplift strength for which there is failure. The figure shows that:

- As long as the system is not close to failure, the displacement only loosely depends on the displacement capacity. So, when the system is not close to failure, instead of computing a different spectrum for each displacement capacity, one can compute the spectrum for the ZSBE system (i.e. for an NSBE with $u_{cap} \rightarrow \infty$) and use it to calculate the displacement demand on any NSBE of the same strength.
- As the system gets closer to collapse, the "Equal Displacement rule" does not apply and is unconservative: Systems with smaller displacement capacity exhibit larger displacements than the ones with larger displacement capacity. Moreover, close to failure the slope of the spectrum increases dramatically, i.e. a small decrease of the system strength would lead to a tremendous increase of the maximum displacement. This is not in agreement with a rational design, in which it would be required that this steep part is avoided.

4.4 Equal Energy rule for NSBE systems

Fig.3a show that the Equal Displacement rule is on the unconservative side, especially as the displacement demand approaches the capacity. To examine the performance of the Equal Energy rule, Fig.3b presents the median of the maximum displacement u_{max} divided by the factor γ_{EE} (Eq.7) as a function of the system normalized strength f_{up}/mg . The plots are constructed for several values of displacement capacity u_{cap} and for uplift displacement $u_{up}=5 \times 10^{-4}$ m.

The curves almost collapse to a unique curve, the one that represents the ZSBE system. Notably, this happens for all 3 different scalings of the ground motions. Hence, the Equal Energy rule gives a good estimate of the maximum displacement of NSBE systems with a finite displacement capacity. Comparing the Equal Displacement to the Equal Energy rule, the

former is simpler, but the latter is overall more conservative, especially for larger displacements. Therefore, unless there is a reason to opt for simplicity, the use of the Equal Energy rule is proposed.

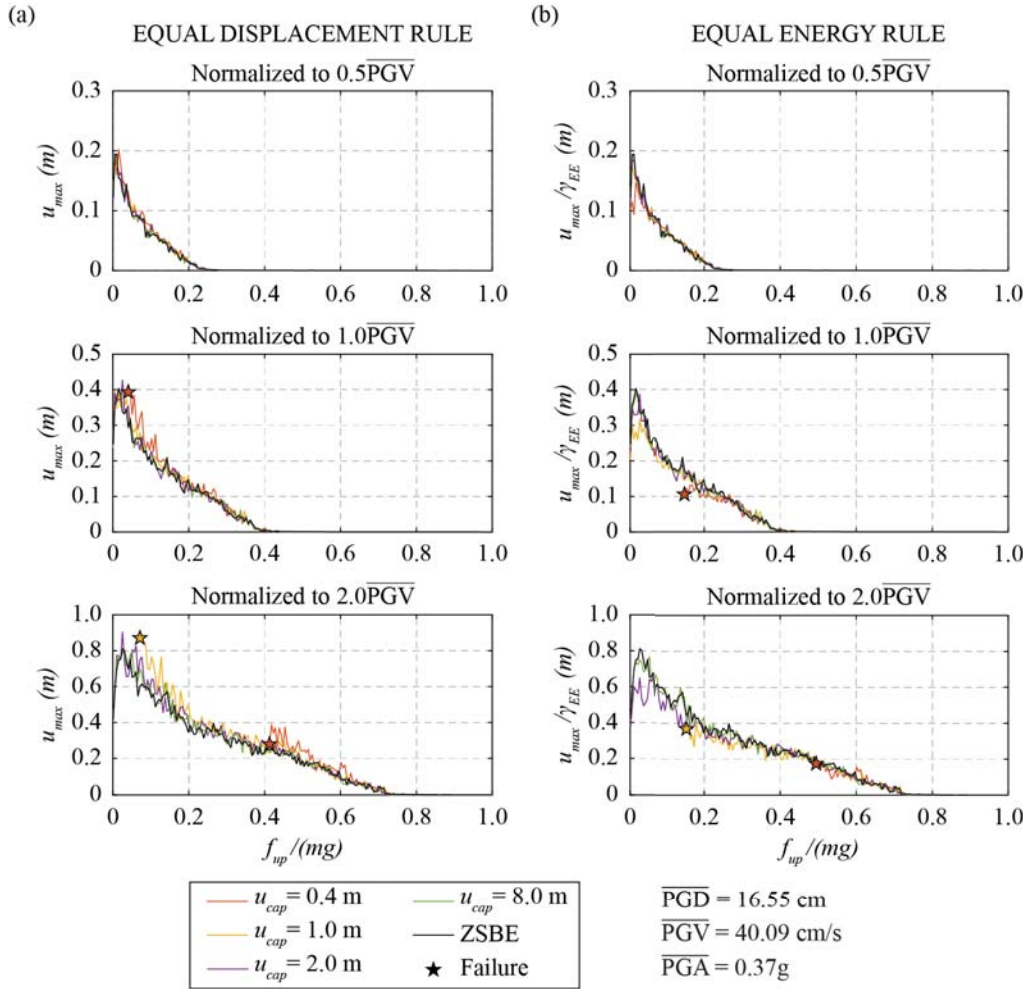

Figure 3: a) Median displacement spectra; b) Median displacement spectra normalized by γ_{EE}

The above conclusions also hold for the near-field pulse-like and near-field no pulse-like FEMA ground motion sets [47].

4.5 Design Example

Next, a case study is used to illustrate a design method based on the Equal Displacement and Equal Energy rules. The method is applied for the design of a rocking bridge equipped with a restraining system that increases the displacement capacity, while keeping the post-uplift stiffness negative.

The geometry of the bridge is typical of overpass bridges. The columns have a height of 9.6 m and a diameter of 1.6 m, whereas the deck is much heavier than the columns ($\gamma_m \rightarrow \infty$). Planar rocking (i.e., one directional excitation) is assumed as a first approximation (even though this has been proven unconservative [3, 20]). Then, the proposed design steps are:

1. Calculate the normalized yielding strength of the system ($f_{up}/(mg)$). If the restraining tendon is not prestressed, this depends solely on the column geometry, and is equal to α .
2. Obtain the displacement demand for the infinite capacity curve ($u_{dem,ZS}$) using the ZSBE curves. The ZSBE curves are the median response of the system subjected to ensembles of ground motions.
3. Calculate the design displacement capacity of the system, as:

$$u_{cap} = FS \cdot u_{dem,NS} = FS \cdot \gamma \cdot u_{dem,ZS} \quad (9)$$

in which FS is a safety factor and γ is defined by Eq. 9. Two alternative approaches were evaluated: One based on the Equal Displacement ($\gamma = 1$) and one on the Equal Energy ($\gamma = \gamma_{EE}$, Eq.7) rule.

Table 2 presents the design values when the two rules are applied on the set of ground motions under the three different scalings. u_{cap} is the capacity required for a $FS=2.5$ (Eq.9). For a system with a displacement capacity u_{cap} , $u_{dem,TH}$ is the median displacement demand of each set computed with time history analysis. $u_{dem,ED}$ and $u_{dem,EE}$ are equal to $\gamma_{ED} \cdot u_{dem,ZS}$ and $\gamma_{EE} \cdot u_{dem,ZS}$, respectively. $u_{dem,ZS}$ is the median response of the ZSBE system. The error is defined as $error = (u_{dem,ED/EE} - u_{dem,TH})/u_{dem,TH}$.

	Equal Displacement			Equal Energy		
	0.5 PGV	1.0 PGV	2.0 PGV	0.5 PGV	1.0 PGV	2.0 PGV
u_{cap} (m)	1.60	1.60	1.60	1.60	1.60	1.60
$u_{dem,TH}$ (m)	0.031	0.169	0.447	0.031	0.169	0.447
$u_{dem,ED}$ (m)	0.030	0.152	0.449	0.030	0.159	0.540
Error (%)	-2.65	-10.56	0.41	-8.61	-5.87	20.78

Table 2: Design Values for the Equal Displacement ($\gamma=1$) and Equal Energy rule ($\gamma = \gamma_{EE}$)

The Equal Displacement rule, in general, underpredicts the result, with a maximum under-prediction error of 10%. The Equal Energy rule is conservative in 1 out of 3 cases. None of the rules led to collapse, because of the safety factor $FS = 2.5$.

5 CONCLUSIONS

Rocking systems (free, restrained, or with curved extensions) that exhibit negative post-uplift stiffness can be described as elastic bilinear oscillators with a negative stiffness second branch, herein denoted as NSBE. This description can also take into account their pre-uplift deformability.

In this paper, it was proposed that these systems can be described by an equivalent bilinear elastic system that has the same strength, zero post-uplift stiffness, and zero uplift displacement, i.e. a one-parameter system, a ZSBE system with zero uplift displacement. Based on this equivalent system, the response of the original negative stiffness oscillator can be obtained by either an “Equal Displacement rule” or an “Equal Energy rule”, the former being simpler, the latter being more accurate. The above methodology is similar to the “ $R\mu T$ ” concept for elastoplastic structures with one fundamental difference: The equivalent system is not linear elastic, but a bilinear elastic system with zero stiffness of the second branch (ZSBE).

This equivalence suggests that the ZSBE oscillator should be extensively studied under a larger database of recorded ground motions to derive non-linear spectra describing its behavior. This will provide the engineering community with a tool to easily design rocking (or any other negative stiffness bilinear elastic) structures, without having to perform time consuming time history analysis.

Abstract

Prefabricated Reinforced Concrete (RC) cladding panels are often adopted in industrial facilities. While they are usually characterized by high strength and easiness of construction, their supports can represent a weak point. Indeed, the connections between the panel and the structure play a key role for the cladding safety. Without an appropriate design the connection can presents a brittle behaviour. High stress concentration, aging and exposure to aggressive environmental conditions that can accelerate the materials degradation represent some of the critical aspects in the connection design. This work, starting from a real case study describing the collapse of a RC cladding panel of a cooling tower, presents new simple design approaches for the supports. An accurate numerical analysis of the mechanical behaviour is also performed with a nonlinear Finite Element model developed in ANSYS environment.

Keywords: reinforced concrete, supports, durability, connections, fragility

1 INTRODUCTION

Prefabricated Reinforced Concrete (PRC) elements exhibit in some cases a brittle failure. The technology of precast concrete elements has become wide-spread particular from the 70s. Its main advantages are the reduced costs, the high quality of construction products and the speed of the entire construction process. Prefabricated buildings have been widely used in industrial/production plants. Their modular solutions, with shorter execution times and the possibility to use a reduced number of components have been adopted in several cases. The technology of extrusion consent to furnish low-cost panels with the same cross sections and different length. The designer of PRC elements preferred in time the application of quasi-isostatic structure with punctual connection. The reasons must be found in the possibility to absorb the viscous deformation. So, the joints between the various components are often represented by punctual elements (bars, plugs etc.) and so the support areas are reduced to the possible minimum value to better exploit the materials and to reduce the overall dimensions and costs of the connections and of the structure.

Recent earthquakes and, in particular, those that recently hit Italy (Abruzzo in 2009 and Emilia 2012 [1–3]), have highlighted the high vulnerability of the connections: numerous collapses or disasters occurred because of their fragility and inadequate capacity. The consequence, in Italy, was the development of specific guidelines and research activities for structural retrofitting of the joints [4–7]. Another relevant point are the ongoing changes in climate that produces significant effects, sometimes unexpected, on environmental actions [8–10]

However, the seismic event is not the only trigger for collapses or instability in such structures: in many cases the degradation of the material accompanied by a reduced maintenance activity non exhaustive code indication and improper structural design has produced situations of instability even in the presence of service loads only [11]. This is due to the reduced redundancy with which the support was conceived. This elements, joined to degradation due to aging [12–14], uncertain mechanical property of materials [15, 16] and poor cure of structural details [17, 18] produce dangerous static and seismic vulnerability. Indeed, without a conservative approach, there is an high sensitive to construction, material, installation or maintenance imperfections that can lead to failure [19–21]. From this the strategic relevance of specific survey and on site investigation to detect signals [22, 23].

This work reports on fall of RC cladding of a cooling tower located in an Italian industrial plant built in the early 2000s. This case is representative of the brittle behavior worsen by micro-climate conditions (marine salt vapors) reducing the durability of the elements, due to inadequate structural design. Indeed, in the original design the possibility of imperfections in the supports has not been considered, nor any strength or residual bearing capacity have been attributed to the connection [24, 25].

The examined collapse happened on the north-western Italian coast which, for reasons of privacy, are not explained here. The examination of the deficit conditions put in lights some elements of weakens in the conception of the structure, which is the result of the culture of “allowable stress”, the precedent design criteria that provide a limitation in the stress. Indeed, this approach do not paying attention to aspects of redundancy and sensitivity to imperfection.

Consolidation strategies are presented together with a proposal of a simple design criteria. In addition, a numerical model, in view to extend the results of the example in other similar situations, is developed with Ansys rel 18.1.

2 COOLING TOWER CLADDING PANEL COLLAPSE

A collapse of some cladding panels (Figure 1) is happened in a cooling tower of an energy production facility (47 x 32 m plant dimensions and 15.7 m height) built in the early 2000s. This event was triggered by the failure of the edge of one of the support cantilevers of the panels, on the south-west corner of the building. The damaged condition of the corner appears in a visible defect in the panels support (Figure 2). The small dimension of collapsed support is the main cause of the collapse. The microclimatic condition of nebulized sea water, percolating into the cooling tower, had a not negligible influence. This sea water, insinuated in the porosities of the concrete, has accelerated the structural degradation in a detail in which the sensitivity to imperfection plays a significant role.

A survey was carried to obtain proper information about the:

- mechanical characterization of the concrete of the various components (panels, columns, support);
- reinforcements emerging from the collapsed panels and cantilever;
- cracks on the lower edge panels still in position.

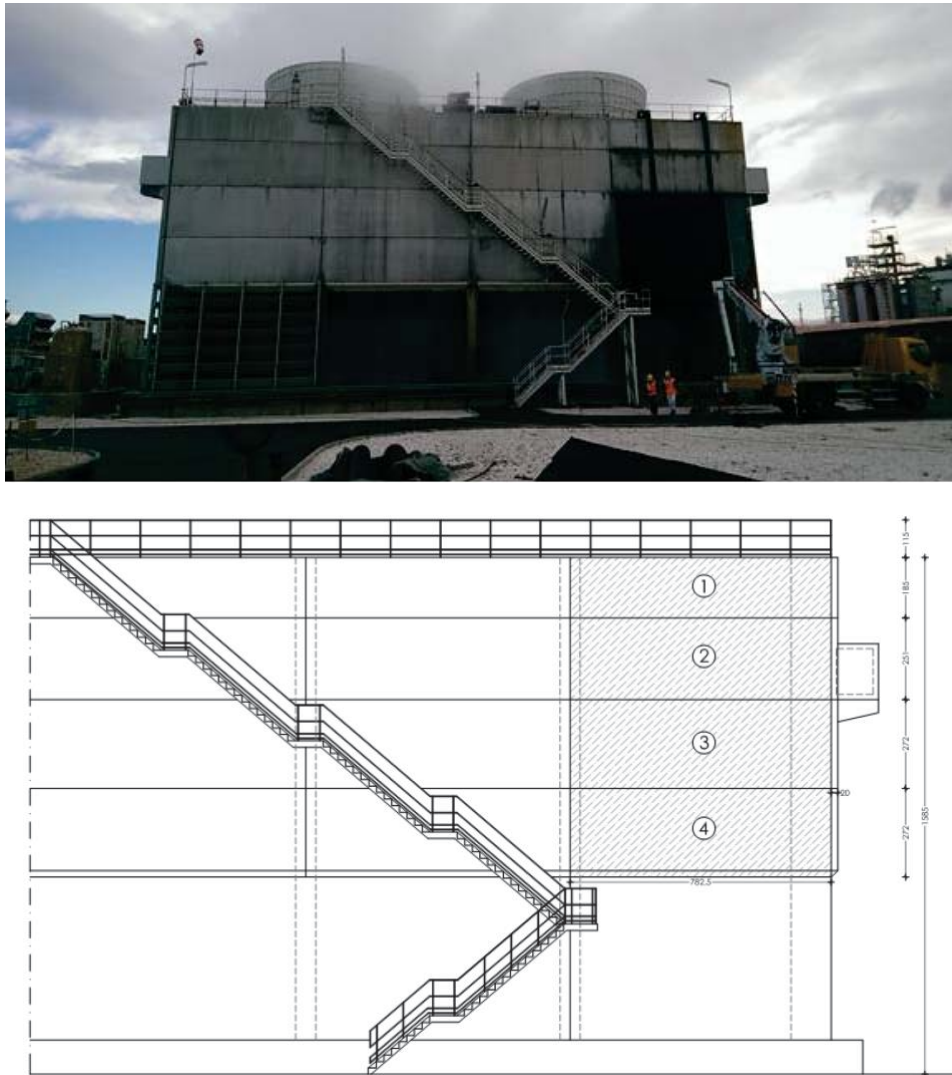

Figure 1: Cooling tower view with collapsed panels (top), drawing with highlighted collapsed panels (bottom).

The concrete of panels, cantilever and columns is characterized by cubic compressive strength equal to 50 MPa. This has been assessed using rebound hammer, pull out tests and destructive compressive strength tests on cores. The analysis of the reinforcements emerging from the concrete cantilever confirms that the collapse was triggered by the failure of concrete cover and of a 16 mm diameter steel threaded bar designed just to enable an accurate assembly of the panels but without structural role. The analysis of the cracks on the other corner panels (Figure 3) showed how all the corners not yet affected by collapses present visible cracks (up to almost 1.0 mm wide). This highlights that the conditions of the other panels support are not safe. In addition, the support zone of all the panels is very small.

A simple explanation of the collapse can be obtained with elementary equilibrium evaluation. On the concrete cover of the RC cantilever there is a permanent load of about $P=106.35$ kN. Indeed, the density of concrete is 25 kN/m^3 while the volume of the collapsed panel is 8.51 m^3 .

The reinforcements of the cantilever could not offer any resistance to shear. Indeed, Figure 4 show that the collapse crack developed quite far from the reinforcement. Thus, the 16 mm diameter threaded bar, designed just to place the cladding panel, was hugely deformed and cannot bear the panel load. Indeed, its cross section A_{res} is too small to bear the load. The force P , representing the panel load, induces an average shear stress τ equal to:

$$\tau = P/A_{res} = 106350/154 = 705 \text{ MPa} \quad (1)$$

This stress is beyond the material limit (360 MPa) even without considering any additional bending. To further adjust and make more uniform the stress between panel and cantilever a polymeric foam, based on polyurethane, was applied. However, this produced an imperfect contact between the panel and the cantilever.

Figure 2: South-West corner before (left) and after (right) the collapse.

Figure 3: Cracks on the remaining panels.

2.1 Retrofitting

To improve the safety of the other RC panels several additional connectors, realized with AISI 316 L steel ($\phi 27$ mm, $L=500$ mm), were applied throughout an injection with epoxy resins. These elements can guarantee structural integrity over time even in aggressive microclimatic conditions (Figure 4). Their external position (Figure 5) allows to carry out periodic maintenance inspections and to keep the support condition under control. The philosophy of intervention is to introduce redundancy in the system. Instead, the original detail did not have structural robustness, and, in case of material degradation, the failure is incipient.

Figure 4: Details of additional steel connectors

Figure 5: Details of on-site installation of the connectors.

3 DESIGN CRITERIA PROPOSAL

To reduce this kind of fragile collapse new design approach should be introduced in a stochastic framework [26]. In the following two of them are described.

3.1 Effective trace

The effective trace of the support surface a_{ef} should be evaluated as:

$$a_{ef} = a - (s + \sum d_i) \quad (2)$$

Where s is the horizontal gap between the panel and the column, while d_i are the distances presented in Figure 6.

Figure 6: Details of effective trace approach.

Considering that a can be measured in a deterministic way, the uncertainties are in $(s + \sum d_i)$. The latter expression can be described with a stochastic approach. Indeed, it is possible to assume that this term it is defined by a log-normal probability distribution. For example,

considering the case described in Section 2 $s_k = 1.3$ cm, $d_{i,k} = 1.3$ cm the following characteristic value of the effective trace is obtained:

$$a_{ef,k} = a - 1.3(s + \sum d_i) \quad (3)$$

Now it is interesting to point out that for the previous case $a = 15$ cm, while $a_{ef} = 2$ cm and $a_{ef,k} < 0$.

Equation (3) allows to develop a probabilistic reliability analysis of this structural detail.

3.2 Sliding surface

Considering the common “sliding surface” approach a simple geometric safety criterion. The fracture line is here characterized by an inclination of 45° with respect to the horizontal plane. Then it is overlapped on the reinforcement details of the support cantilever. If this line crosses the horizontal distance between the reinforcement, (Figure 7), it is possible sustain the load. Vice versa if it cannot cross this horizontal line the collapse is expected.

Clearly this graphical criterion can be expressed through a mathematical formulation, see equation (4) and Figure 7 for the symbols meaning.

Figure 7: Details of sliding surface approach.

$$a > t + \sum d_i \quad (4)$$

Considering a log-normal probability distribution is assumed for each geometrical variable it is possible to obtain also in this case a stochastic value of the safety coefficient.

4 NUMERICAL MODEL

A fem model of the structural detail is carried out with Ansys (rel 18.1). Three different conditions with different values of the horizontal distance between the bar in the cantilever and the bar in the panel (a_{ef} see equation (2)) have been analyzed. The geometrical description with loads and boundary conditions is reported in Figure 8. The cantilever is fixed in the back and in the bottom surface while the load is applied on the top of a panel section. The whole model is constrained in the z direction (transversal to the cantilever plane) to consider a plain problem. In any case a 3D modelling strategy has been developed to model the transversal rebars inside the concrete mesh.

The numerical model has been developed in ANSYS environment using SOLID65 elements for concrete and LINK180 for rebars. Concrete class is C20/25 while steel for rebars is B450C, see NTC18 [27]. The nonlinear behaviour of concrete and its progressive failure has been modelled with the Willam e Warnke

criterion [28] while the steel rebars behavior is always linear elastic. Two transversal rebars ($\phi 10$ mm) have been modelled following the scheme presented in Figure 6: one in the bottom right corner of the panel and one in the top left corner of the cantilever.

A nonlinear quasi-static analysis has been performed with a progressive load applied as a uniform pressure on the panel top surface. This load has been varied to test what is the ultimate capacity for the three different geometrical configurations (denoted Left, Central and Right) characterized by different a_{ef} parameter values, see Figure 6 and Table 1.

Figure 8: Model mesh, loading and boundary conditions.

	Left	Central	Right
a_{ef} (cm)	0	2.4	4.4
P_u/P_{MAX}	0.05	0.60	1.00

Table 1: Geometrical parameter a and relative ultimate load for different configurations.

Figure 9: Displacement Contour vertical direction, measures are in m.

Figure 10: Displacement Contour horizontal direction, measures are in m.

Both displacement and convergence criteria has been enforced with a Newton-Raphson approach to solve the nonlinear problem. When is not possible to find an equilibrium configuration the simulation is stopped and the maximum load is measured P_u . Its relative values are reported in Table 1. As expected, the configuration with the maximum a_{ef} (denoted as Right) presents the maximum load P_{MAX} , the left and central configuration instead produced a reduced ultimate load respectively equal to the 5% and 60% of the P_{MAX} .

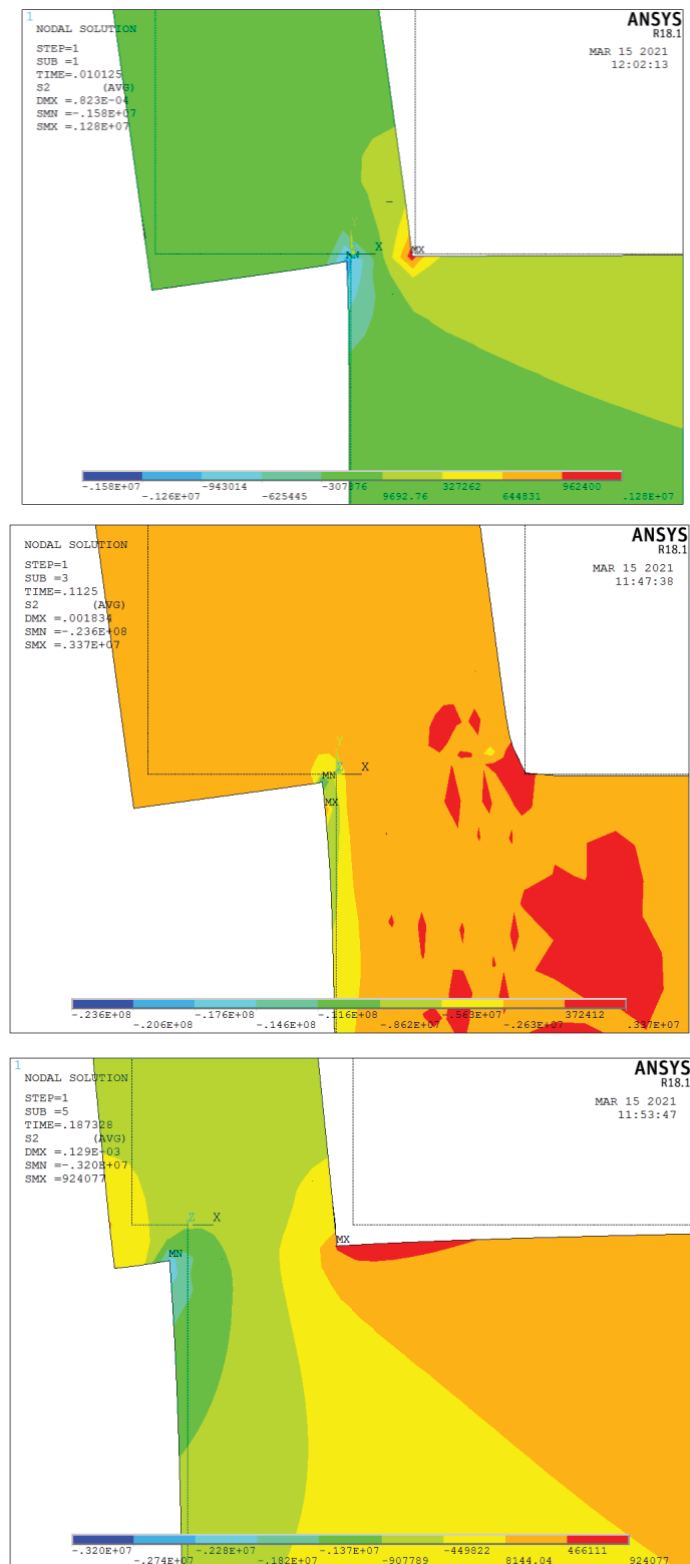

Figure 11: 2nd principal stress contour.

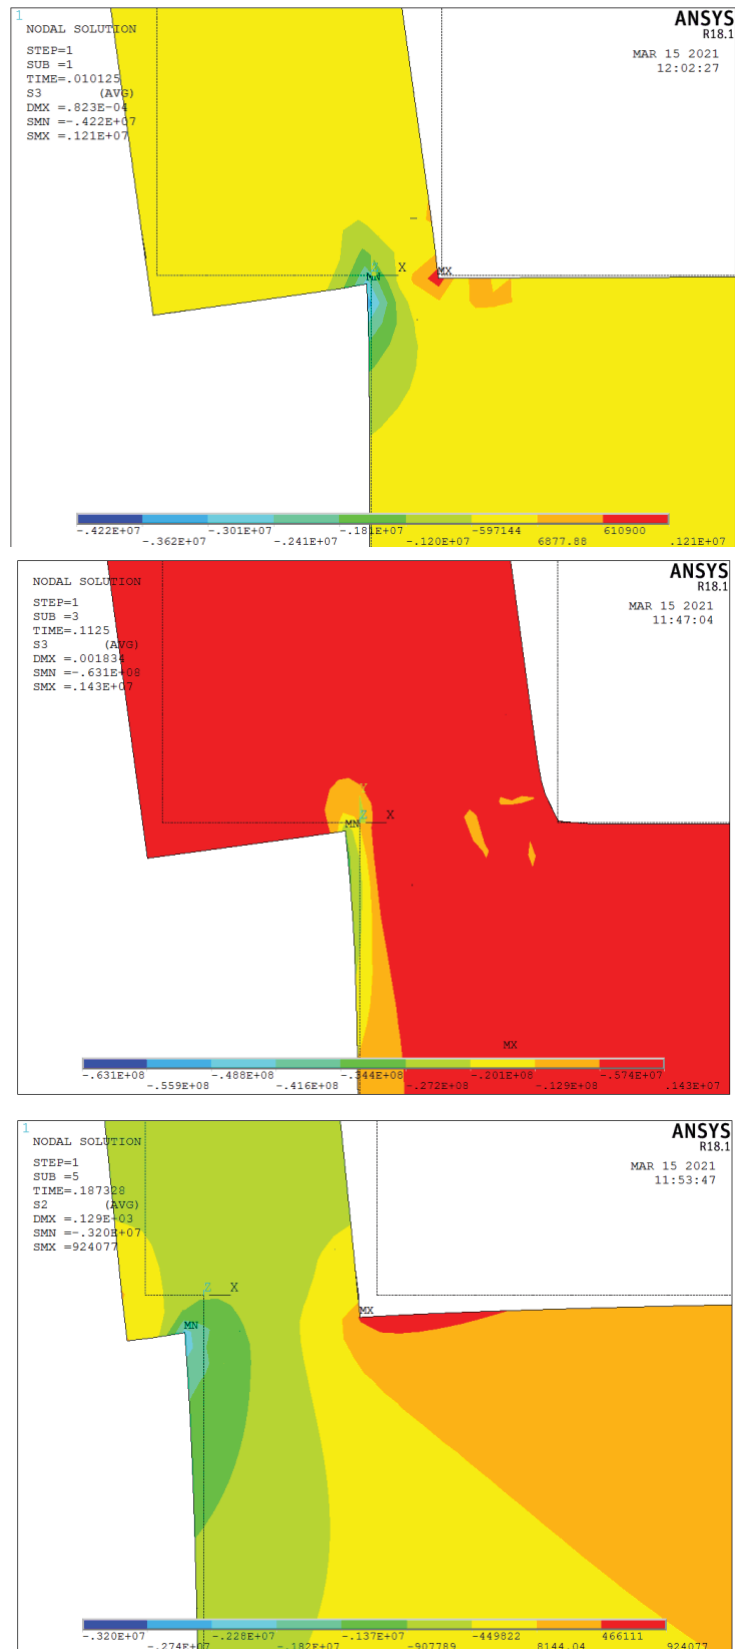

Figure 12: 3rd principal stress contour.

The vertical and horizontal displacement contours in the ultimate load step are reported in Figure 8 and 9 for the three configurations. It is clear that the left configuration ($a_{ef}=0$ cm) arrive at collapse with most of the deformation concentrated in the panel while the cantilever is still almost undeformed. Instead, the right configuration ($a_{ef}=4.4$ cm) requires that also the cantilever is deformed to reach the collapse condition.

Figures 10 and 11 presents the contours of 2nd and 3rd principal stress highlighting that the edge of the contact surfaces between the panel and the cantilever are the most stressed part of the element. Maximum compression is generally reached on the left part while maximum tension can be found on the right part.

The failure mechanism is almost the same for the three cases: the tensile crack appears in the top part of the cantilever on the right side of the contact edge between panel and cantilever. A representative picture of the crack propagation can be found in Figure 13 that points with red marks the tensile cracks. Clearly the crack pattern starts on the right and it develops toward left till the structure is not capable of finding an equilibrium condition.

Figure 13: Typical Crack pattern.

5 CONCLUSIONS

This paper reports on recurrent situations typical of a poor concept of the prefabricated elements supports. In the modern performance-based design ductility, robustness hierarchy of structural element importance are key aspects. The possibility that a local collapse can trigger macroscopic collapses must be considered in existing PRC Structure. A structural retrofitting as well as proper sealing strategy of the existing joints must be taken into account [29].

The numerical model showed how a bigger contact surface and a bigger distance between the transversal rebars a_{ef} yield to high load capacity. In addition, the failure mechanism highlights how it is critical the left end of the contact between the panel and the cantilever suggesting improving the resistance of this mechanism using appropriate reinforcements.

A modern trend is nowadays to evaluate also minor details in a resilience perspective. Thus, also the design of constructive details [30] should take into account the needs of inspection, the

possible faults or malfunctions warning signs, and should avoid that any local collapse does spread in an uncontrolled global collapse.

Further developments of this research are expected for a stochastic evolution of the proposed design criteria or considering the effect of material irregularities.

Abstract

Rocking analysis is a powerful tool to assess the seismic vulnerability assessment of masonry walls subjected to out-of-plane modes, especially when in view of checking the efficiency of traditional retrofitting solutions, such as steel tie-rods restraining rocking blocks. The study focuses on a probabilistic approach for the seismic assessment of the out-of-plane behavior of masonry walls, mainly aiming to reliably predict fragility and seismic demand hazard curves in case steel tie rods are used as anti-seismic device. To identify the most appropriate steel tie-rod device, more than thousand multistripe analyses have been performed considering the Italian site with highest seismic hazard (Carlentini, Sicily), duly modifying ductility and strength of the tie rods themselves. The resulting fragility curves and seismic demand hazard curves are critically discussed, so allowing the definition of the most efficient and proficient intensity measures referring to five relevant limit states. As expected, remarkable changes in the response are recorded by passing from a brittle to a ductile tie-rod, but when the ultimate strain is bigger than 2%, an increased tie-rod ductility does not sensitively improve the response even for high-intensity earthquakes. The probabilistic approaches show that even low-ductility tie-rods can sensibly reduce the probability of exceedance of limited and moderate rocking limit states, up to an order of magnitude. As for the influence of the tie-rod strength, even low-medium values produce a remarkable reduction of annual exceedance rate. For instance, a severe rocking limit state occurs for the unrestrained monumental wall every 450 years and every 2000 years for the wall restrained by a tie rod of strength just fitting the minimum required design value.

Keywords: rocking, brittle tie-rod, ductile tie-rod, historic masonry, annual exceedance rate, restrained walls, out-of-plane.

1 INTRODUCTION

Masonry structures can be seen as an assembly of macro-elements. Independently on the masonry type [1] and mechanical properties [2], these macro-elements that can be considered as a rigid system, provided that the masonry is monolithic. The rocking analysis of rigid blocks is a non-linear dynamic analysis capable of simulating the behavior of masonry walls rocking out-of-plane. The out-of-plane behavior is undesired for masonry buildings but unfortunately very common for the lack of proper connections between walls and between walls and horizontal diaphragms. Owing the fact that many types of such connections were developed over the centuries, ad hoc detailed studies are necessary to understand their effectiveness [3].

Nowadays, a wide literature is available on rocking analyses of free-standing walls as well as vertically/horizontally restrained walls, including analytical formulations [4]–[9], experimental outcomes [10]–[13] and numerical approaches [5], [14]–[18]. All these contributions are aimed at reliably representing the dynamic behavior of a masonry wall rocking out-of-plane during an earthquake.

Horizontal restraints are often provided by steel tie-rods, traditionally used in historic masonry buildings [19]–[21]. The response of free-standing blocks is strongly influenced by the size and slenderness ratio of the wall, besides the frequency content and numerous intensity measures associated to the seismic input. In addition to these parameters, the dynamic response of blocks restrained by horizontal tie-rods depends on the position and on the mechanical properties of the tie-rods themselves, as discussed in [22]. In [22] it was demonstrated on one hand that, as expected, tie-rods reduce the maxima amplitude rotations, but on the other hand that tied walls behavior is not significantly dependent on the aspect ratio of two walls of comparable size. The latter remark is still valid for walls restrained by tie-rods at different heights; more generally, it can be observed that the influence of tie-rod length as well as of normalized pre-stress is very limited. As for the influence of the mechanical properties, the role of the axial stiffness appears to be negligible. The yield strength was the most relevant parameter that influences the response, besides the brittle or ductile behavior of the tie-rod.

This contribution takes inspiration from the cited work but it considers different geometries and assumptions for the tie-rods. Moreover, this paper adopts a full stochastic approach for the seismic vulnerability assessment [23]–[26], whereas in [22] a semi-probabilistic approach is considered. After the presentation of the analytical formulation (Section 2) and the assumptions (Section 3) taken into account in the analysis, the work discusses the results in terms of fragility curves (Section 4) and seismic hazard curves (Section 5), which is a new frontier in the probabilistic assessment of seismic vulnerability [27].

2 ANALYTICAL FORMULATION

2.1 Mechanical model and equation of motion

The out-of-plane behavior of existing masonry structures can be investigated through non-linear dynamic analyses also called rocking analyses. This section describes the model considered for analyzing the one-sided motion of masonry walls restrained by steel tie-rods, displayed in Figure 1. In it, the wall is assumed as single degree of freedom rigid block of mass m and of perpendicular shape. Its size and slenderness are respectively given by R and $\alpha = \arctan\left(\frac{h}{b}\right)$. The equation of motion, found in previous works of the Authors [14], [15], [17], is the following:

$$I_0 \ddot{\vartheta} + \text{sgn}(\vartheta) m g R \sin A_\vartheta + T_t + T_L = m \ddot{u}_g R \cos A_\vartheta \quad (1)$$

The right hand side contains the seismic input term as acceleration time history $\ddot{u}_g(t)$ of the earthquake. The terms on the left hand side are related to the inertia forces, the self-weight stabilizing the response up to a rotation threshold equal to α , the tie-rod of stiffness K (T_t) and the transverse walls simulated by a spring bed of unitary stiffness K'_c (T_L). As for the symbols, I_0 is the polar inertia moment with respect to the pivot point O or O' equal to $\frac{4}{3}mR^2$, whereas $A_\vartheta = \alpha - \text{sgn}(\vartheta)\vartheta$.

Figure 1: schematics of the model considered in the rocking analyses.

The term T_t assumes the form:

$$T_t = \text{sgn}(\vartheta) K \beta^2 R^2 \cos A_{r,\vartheta} [\sin \alpha_r - \sin A_{r,\vartheta}] \quad (2)$$

in which $A_{r,\vartheta} = \alpha_r - \text{sgn}(\vartheta)\vartheta$ where α_r is a position angle dependent on the position coefficient $\beta = R_r/R$ (Figure 1). The tie-rod can behave either as elastic or as plasticized. If the tie-rod is in the elastic field, the corresponding term can be simply calculated from the external work made by it, obtaining:

$$T_{t,e} = [\text{sgn}(\vartheta) K R_r (\sin \alpha_r - \sin A_{r,\vartheta}) + F_0] R_r \cos A_{r,\vartheta} \quad (3)$$

$T_{t,e}$ is considered in the equation of motion if the tie-rod displacement d_t is in the range of $0 \leq d_t \leq d_y$ (the sub-index y stands for yielding) or $d_r \leq d_t \leq d_{max}$ (the sub-index max stands for ultimate displacement). The tie-rod can be subjected to a prestress F_0 . Once yielding is attained, $d_t > d_{max}$ or equivalently $d_t > d_{max}$, the spring exerts the constant yielding force F_y . The term related to the plastic tie-rod contribution is then:

$$T_{t,p} = \text{sgn}(\vartheta) F_y R_r \cos A_{r,\vartheta} \quad (4)$$

As usual, a compressed tie-rod is considered inactive. In case of unloading, the constitutive law follows the elastic branch. Anyway, the constitutive model is fully described in [28]. The tie-rod influence can be controlled through the following parameters: stiffness, yielding, ductility and strength associated to it.

T_L is different from zero only for counterclockwise rotations (spring bed in compression, Figure 1). In that case it is expressed by[29]:

$$T_L = \operatorname{sgn}(\vartheta) K'_c h' \left(A + \frac{Bh'}{2} + \frac{Ch'^2}{3} \right), \quad (5)$$

where:

$$A = \operatorname{sgn}(\vartheta) 4b^2 \sin \vartheta \cos \vartheta (1 - \cos \vartheta); \quad (6)$$

$$B = 2b (\sin^2 \vartheta \cos \vartheta - \cos^3 \vartheta + \cos^2 \vartheta);$$

$$C = \operatorname{sgn}(\vartheta) \sin \vartheta \cos^2 \vartheta.$$

h' is the extension of the spring bed, $2b$ is the wall thickness and K'_c is the stiffness of the spring bed. K'_c can be calculated as function of the horizontal elastic modulus of masonry E_x , actual transverse wall length $L_{L,eff}$ and transverse wall thickness t_t according to the multi-struts model presented in [29].

The solution of the equation of motion (Eq. (1)) gives the rotation time history $\vartheta(t)$ of the block and all the other parameters (acceleration, velocity, displacement) related to the center of mass and to the other significant points of the wall. The solution of the differential equation is performed by means of the ODE45 solver available in MATLAB [30], which uses a 4th-5th order Runge-Kutta integration technique.

2.2 Probabilistic model for the determination of fragility curves and seismic hazard curves

The probabilistic model employed for calculating the fragility curves is extensively described in [31] and that for obtaining the seismic hazard curves is illustrated in [23]. To be concise, only a general description of them is given in the following. The fragility curves are plotted by calculating the conditional probability of exceedance of specific limit states defined by the engineering demand parameter EDP ϑ/α . The EDPs, taken as maximum normalized rotation of each response time-history, clearly depend on the seismic input, in turn defined by specific intensity measures IMs. The conditional probability $P(EDP > C|IM)$ that the EDP overcomes a capacity threshold C conditioned to an IM is expressed by:

$$P_{ex}(EDP > C|IM) = \Phi \left(\frac{\ln D - \ln C}{\beta_{D|IM}} \right). \quad (7)$$

The capacity thresholds C considered for the corresponding limit states are:

1. LS0, rocking initiation, $EDP > 0.0$;
2. LS1, limited rocking, $EDP = 0.1$;
3. LS2, moderate rocking, $EDP = 0.4$;
4. LS3, severe rocking, $EDP = 1.0$.
5. LS4, near-collapse rocking, $EDP = 1.5$.

Φ is the standard cumulative distribution function Φ , $\beta_{D|IM}$ is the logarithmic standard deviation, or dispersion, of the demand conditioned on the IM level. D is the median structural demand which for univariate fragility curves is equal to:

$$D = a IM^b. \quad (8)$$

D coincides with the EDP coming from the rocking analyses, while a and b are the two correlation coefficients which derive from the post-processing of the results expressing D in logarithmic terms.

Preliminarily, the results of a set of rocking analyses with variable seismic inputs should be obtained. Each output of the rocking analysis, for a fixed geometry and fixed boundary conditions (mechanical properties of the tie-rods) is a single realization. These realizations are then elaborated to obtain the correlation coefficients. The larger is the correlation coefficient b , the more practical is the correlation with the intensity measure. The lower the dispersion coefficient $\beta_{D|IM}$, the more efficient is the correlation. A third correlation coefficient is $\zeta = \beta_{D|IM}/b$ to assess proficiency. The realizations are then used for calculating the fragility as conditional probability of failure [32], where the demand D is represented by the EDPs calculated from the rocking analyses and the capacity C is defined by the five limit states also expressed in [31], [33]. Different fragility curves can be plotted, depending on the fact that the case is categorical (rocking-non rocking) or a specific limit state is exceeded. In this paper the so-called “final probability” P_f is plotted combining the probability of exceedance P_{ex} to the probability of overturning P_{RO} . The complete procedure is described in [34].

3 ASSUMPTIONS OF THE ANALYSIS

This section illustrates the assumptions of the analysis in terms of choice of geometries, seismic inputs and mechanical properties of tie-rods. Indeed, all these parameters have an impact on the dynamic response.

3.1 Wall geometries

Two wall geometries are selected to give a first glimpse of their influence on the response. A medium-high slenderness ratio of $\alpha = 0.1$ is chosen, corresponding to a ratio of wall height/thickness (conventional slenderness) equal to 10. Upper limit values of conventional slenderness are fixed to 12 for unreinforced brick masonry (10 for stone masonry). These limit values are valid for earthquake resistant walls [35]. For what concerns the wall size, two thickness values are considered: 30 cm and 60 cm. Consequently, being $\alpha = 0.1$, the two respective heights are 300 cm and 600 cm. The walls have unit width and specific weight of 19 kN/m³. For the sake of clarity, one can define the first wall as ordinary wall, and the second one as monumental wall, since its greater size is similar to that of the main façades of historic or monumental buildings.

3.2 Mechanical properties of the tie-rods and transverse walls

This paper is mainly aimed at assessing the influence of the tie-rods in the dynamic response. The variability of mechanical properties is taken into account in terms of:

- Yield stress f_y (which assumes the values 142-235-294 MPa);
- Area A (calculated according to the procedures of kinematic linear analyses [35] assuming $PGA=0.278g$);
- Yielding force $F_y = f_y \cdot A$;
- Ultimate strain ϵ_u (which assumes the values 0-2-10%).

The yielding strength is that typical of existing tie-rods in unreinforced masonry structures, also historical [36]. The last parameter is related to the ductility of the tie-rod. This investigation has the purpose of analyzing its effect on the response depending on the level of ductility of the

tie-rod material. It is physically expectable that a brittle tie-rod behaves differently from a ductile tie-rod, but the quantitative difference can be assessed only through a comparison of non-linear dynamic analyses. Moreover, deterministic analyses are not fully reliable due to the fact that the response is input-dependent.

The response is reported in terms of a dimensionless parameter called *restraining efficiency coefficient* $\rho_{M,e}$. This parameter reads as ratio of a resisting moment M_r to a seismic demand moment M_d . In particular, the resisting moment can be expressed as:

$$M_r = F_y \cdot h_r \quad (9)$$

where h_r is the lever arm of the tie-rod, that is the distance of the tie-rod from the rocking hinge on the wall foundation. The seismic demand moment is calculated assuming an acceleration variable with the block height based on its first modal shape, whose maximum acceleration a_d is assumed to be equal to the gravity acceleration:

$$a_d = \ddot{\theta}(z = 2h) \cdot z = \frac{g}{2h} z \quad (10)$$

Considering the distance z of the mass per unit of length μ from the rocking base hinge, the corresponding force is:

$$dF_d = \mu \cdot a_d dz \quad (11)$$

The seismic demand moment reads, considering Eq. (11) and Eq. (12):

$$M_d = \int_0^{2h} dF_d \cdot z = \int_0^{2h} \mu \frac{g}{2h} \cdot z^2 dz. \quad (12)$$

In the present case, being μ constant, it results:

$$M_d = \frac{4}{3} Wh \quad (13)$$

where W is the wall weight. Finally, when the tie is installed at the top of the wall, namely $h_r = 2h$, the restraining efficiency coefficient $\rho_{M,e}$ assumes the following expression:

$$\rho_{M,e} = \frac{M_r}{M_d} = \frac{3 F_y}{2 W} \quad (14)$$

In the present case, since the diameter of the tie-rod is calculated from the design criterion of the kinematic linear analysis [35], $\rho_{M,e}$ is constant for both cases (Table 1). By contrast, the consequent tie-rod diameter φ varies as reported in Table 2, because the yielding strength changes.

	W [kN]	F_y [kN]	$\rho_{M,e}$ [-]
ordinary wall	17.1	5.7	0.5
monumental wall	68.4	22.9	0.5

Table 1: Weight of the analyzed walls, yielding force and restraining efficiency coefficient of the tied configuration.

f_y [MPa]	142	235	294
ordinary wall	7.2	5.6	5
monumental wall	14	11	10

Table 2: Variation of tie-rod diameter (in mm) with the yielding strength.

As for the transverse walls, the following parameters are considered: extension of the spring bed $h' = 2h$, horizontal elastic modulus of masonry $E_x = 690 \text{ MPa}$, actual transverse wall length $L_{L,eff} = 1.2 \text{ m}$ and transverse wall thickness $t_t = 2b$. By substituting the values for the two wall cases, one has $K'_c = 172.5 \text{ MN/m}^2$ and $K'_c = 345.0 \text{ MN/m}^2$ respectively for the ordinary wall and for the monumental wall.

3.3 Seismic inputs

A number of 48+48 seismic records, taken from the ESM database [37], has been considered for the stochastic analyses. The number is doubled because each of the 48 seismic records has been also changed in sign and used as second set of inputs. Among the 48 accelerograms, 24 were registered in Central Italy, whereas 24 were taken from [31]. Several significant intensity measures (IMs) can be associated to each accelerogram. It is important to point out that numerous IMs - acceleration, velocity and energy based - can be calculated for each of them. Nevertheless, in this contribution the focus is on peak ground acceleration (PGA), on Arias intensity (I_a) and on peak ground velocity (PGV), the most common IMs referred to in seismic vulnerability analysis. PGV is in particular an IM very significant for rocking blocks. The seismic inputs considered in the analysis are listed in Table 3.

3.4 Single realizations of the non-linear dynamic analyses and correlation coefficients

The single realizations coming from the rocking analyses are performed for both geometries and for the ten cases (free-standing and nine types of tie-rods as described in 3.2). A multistripe analysis [23] is carried out considering six values of PGA (hazard site: Carlentini, Italy [38], [39]). For each PGA value 1920 analyses have been performed, so that 11520 runs resulted in total. An extract of the graphs for the free-standing and tied case of the monumental façade ($f_y = 235$, $\varphi = 11$ mm, $\varepsilon_u = 10\%$) is reported in Figure 2. In the vertical axis of the graphs the maximum engineering demand parameter is reported for each rocking analysis with fixed seismic input. Each circle represents the maximum response of single realization obtained from each seismic input. Each accelerogram has a corresponding pair of PGA and PGV displayed in the abscissa axes; each one is scaled for six values of PGA corresponding to specific return periods of the selected construction site. It is evident that when the wall is not restrained by any tie-rod the normalized rotation is greater, and overturning frequently attained (Figure 2a). In case the wall is horizontally restrained by a ductile tie-rod of medium strength ($\varepsilon_u = 10\%$, $f_y = 235$ MPa, $\varphi = 11$ mm), the non-rocking cases are more numerous and the number of overturning cases is only three. Analyzing the results, the correlations coefficients can be easily calculated.

The best correlation is always obtained considering the PGA, with the exception of the monumental unrestrained wall, for which the best IM is the Arias Intensity I_a .

For the same cases displayed in Figure 2, Figure 3 reports the estimated curve with the correlation coefficients:

- b -coefficient (Eq. (8)), for the practicality;
- dispersion coefficient $\beta_{D|IM}$, for the efficiency;
- $\zeta = \beta_{D|IM}/b$, for the proficiency;
- Coefficient of determination R^2 , defined as $1 - \frac{\sum(\ln D - \ln S_D)^2}{\sum(\ln D - \text{mean}(\ln D))^2}$;

The correlation is made only for the cases of safe rocking, namely for $1e-4 < \vartheta/\alpha < 1.5$. That is the reason why Figure 3b shows only two values of PGA for multistripe analysis (see also for comparison the blue circles in Figure 2b). Therefore, the probability of exceedance of a specific limit state is calculated only for the safe-rocking cases.

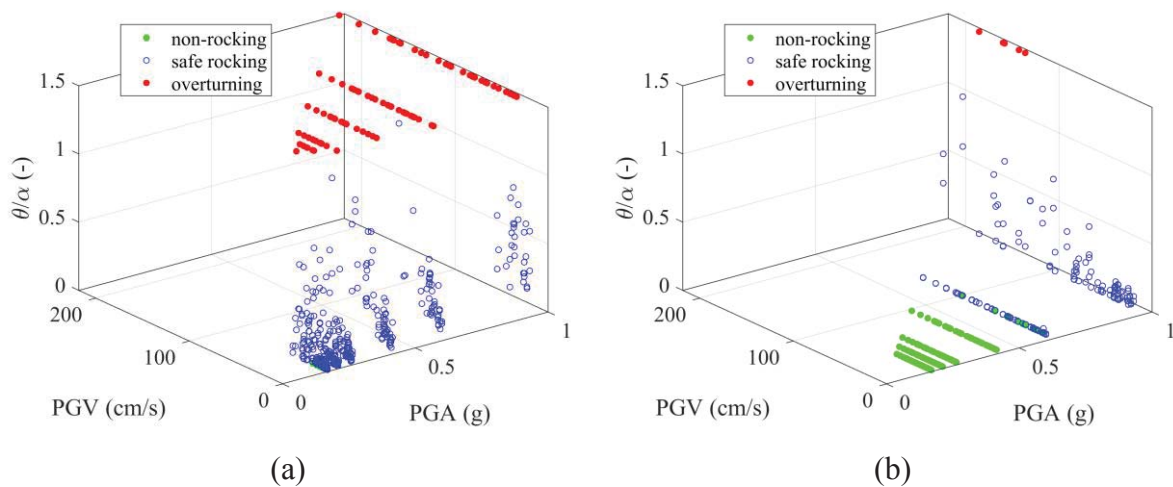

Figure 2: Realizations of the rocking analysis for specific values of PGA and PGV for unrestrained (a) and tied (b) monumental wall.

Looking at the results, it is possible to observe that, when the correlation is made towards the PGA (Figure 3a, b), the unrestrained case is worse correlated than the tied case in terms of efficiency and proficiency. As for practicality, the unrestrained case is better correlated. The results in terms of Arias Intensity, for which the correlation is the most efficient for the unrestrained case, are scattered because this intensity measure is calculated after that the PGA of each accelerogram is scaled according to the formula given in [31]. the unrestrained case is worse correlated than the tied case in terms of efficiency and proficiency (Figure 3c, d). Concerning practicality – and also proficiency – the unrestrained case is again better correlated than the restrained case. Since the dispersion coefficient for the unrestrained case is slightly greater than that for the tied case, the correlation of the first one is more efficient. The maximum coefficient of determination is observed for the correlation of PGA (restrained case) and of I_a (unrestrained case) and is equal to 0.57 for both scenarios (Figure 3b, c).

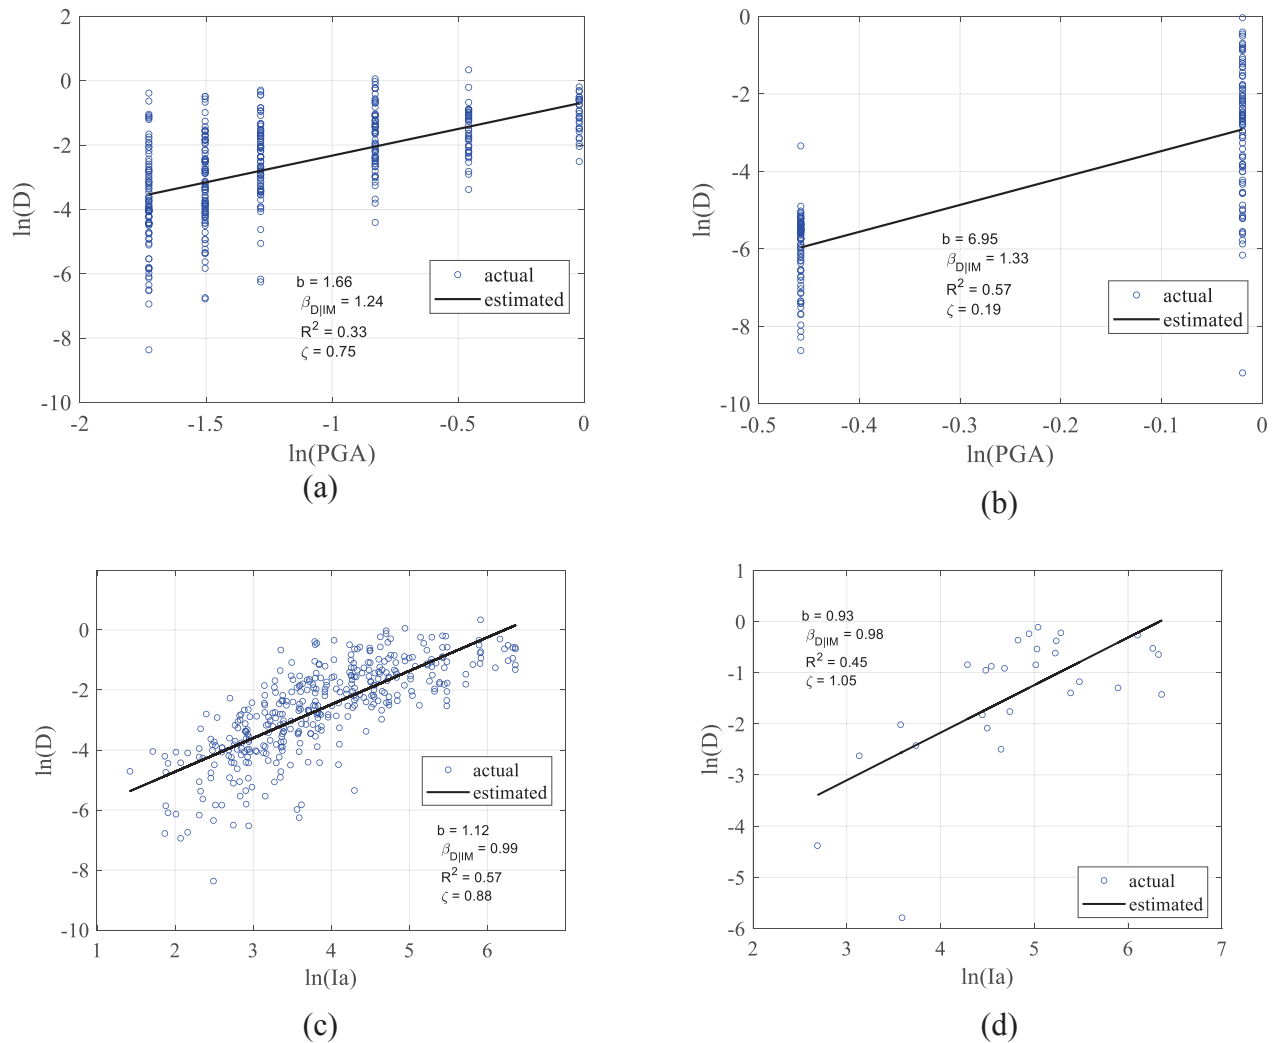

Figure 3: Structural demand and correlation coefficients for unrestrained (a, c) and tied (b,d) monumental wall.

4 FRAGILITY CURVES

This section discusses the fragility curves obtained for all the cases with the calculation process described in section 2.2. A first comparison can be made between the ordinary and the monumental wall. Their slenderness value is the same (height to thickness = 10) but the size of

the ordinary wall is half of that monumental. The fragility curves representing the conditional probability of the EDP conditioned to PGA are reported in Figure 4 for all the five limit states. The probability of occurrence of the rocking initiation state is much less for the ordinary wall rather than that of the monumental wall. For the ordinary wall, of small size, there is a narrower difference between probability of occurrence of the limit states, from the rocking initiation to the near-collapse. The ordinary wall appears more stable than the monumental wall, although the slenderness values are the same. In this case, therefore, the common scale effect usually exhibited by free rocking blocks is not observed.

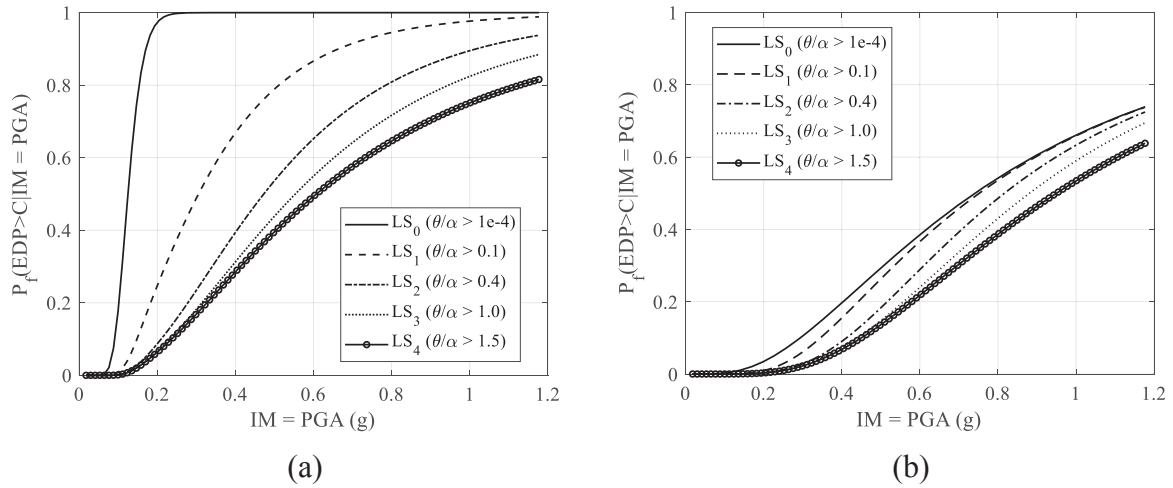

Figure 4: Fragility curves for the unrestrained monumental (a) and ordinary (b) wall.

Considering the monumental wall, the fragility curves considering again the five limit states but with different values of ductility capacity of the tie-rod are displayed in Figure 5. The sub-figures respectively indicate the response for the unrestrained wall (a), the wall restrained by a brittle tie-rod with $\varepsilon_u=0\%$ (b), by a low ductility tie-rod with $\varepsilon_u=2\%$ (c), by a high ductility tie-rod with $\varepsilon_u=10\%$ (d). It is evident that a more ductile tie-rod reduces the probability of overcoming the attainment of an EDP threshold. The case with the most ductile tie-rod results in flatter fragility curves which lose their typical s-shape, which indicate greater uncertainty.

For the medium steel axial strength (235 MPa, $\varphi = 11$ mm), the probability of exceedance for the limited rocking state (LS₁) is reported in Figure 6a: the most dangerous case is the brittle tie-rod, as expected. The probability of exceedance of the limited rocking state is respectively by 85%, 30%, 8% and 3% for unrestrained wall, wall restrained by brittle, ductile and low-ductile tie rod for PGA=0.8 g. PGA values lower than it, no remarkable difference is observed in terms of probability of exceedance, since the tie-rod impedes a considerable wall rocking. The trend of reduction of probability of exceedance above mentioned, not fully expected for ductile and low-ductile tie-rod, depends on the higher uncertainty that affects the probability of exceedance of a ductile tie-rod. So, even though the curve related to the ductile tie-rod is not considered, the reduction of probability of exceedance is sensitively strong being an order of magnitude lower for the low-ductile tie-rod (Figure 6a). Therefore, it is extremely beneficial to restrain the wall even with a low-ductile (but also a brittle) tie-rod. The choice will depend on the assumed probability of exceedance depending on the return periods established by the standards.

Figure 5: Fragility curves for the monumental wall: unrestrained (a); brittle (b); low ductility (c) and ductile (d) tie-rod.

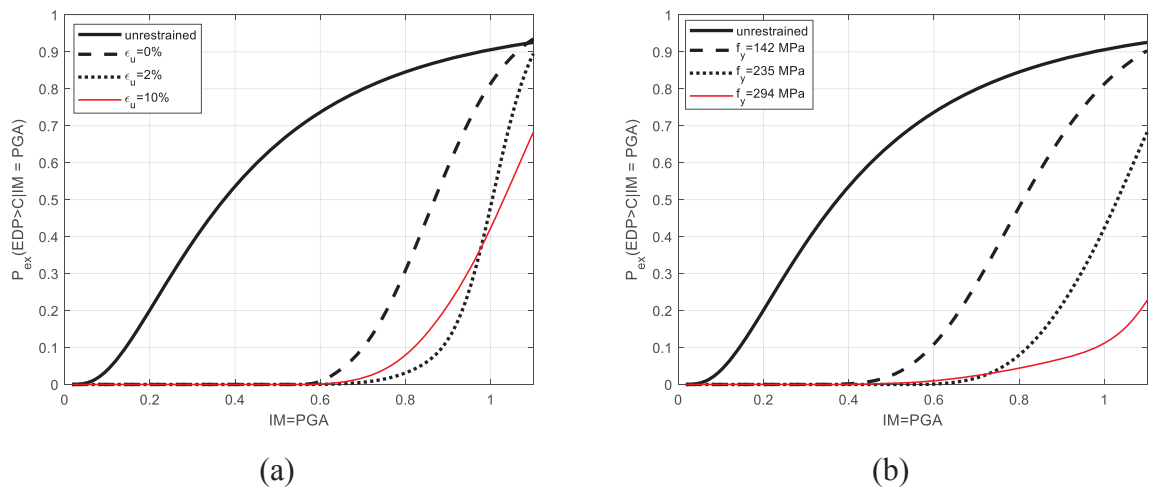

Figure 6: Fragility curves for monumental wall: parametric analyses in terms of (a) steel ductility and (b) axial strength for the limited rocking state (LS1).

As for the variation of steel strength, keeping constant the tie-rod ultimate strain to 10%, the weaker material has an increased probability of exceedance that anyway remains low (about 10% for $\text{PGA}=0.6\text{ g}$) even for medium-high intensity earthquakes. As a consequence, in many cases even a weak tie steel can be really beneficial for the reduction of the probability of exceedance of the limited rocking state. The cases of medium-high strength ties (235 MPa, $\varphi = 11\text{ mm}$ and 294 MPa, $\varphi = 10\text{ mm}$) give coincident fragility curves since the stress of 235 MPa is never overcome.

5 SEISMIC DEMAND HAZARD CURVES

The seismic demand hazard curves are obtained by following the procedure described in [23]. The output is readable as annual exceedance rate $\lambda_{EDP}(edp)$ for the five limit states indicated in the abscissa axis ($\vartheta/\alpha = 1\text{E-}4, 0.1, 0.4, 1.0, 1.5$). This information is more complete than the mere fragility curves, as the demand hazard is considered in the probabilistic assessment. The seismic demand hazard curve is much more conservative in case of restrained condition than for the unrestrained monumental wall (Figure 7a). Considering the same steel strength (235 MPa, $\varphi = 11\text{ mm}$) and varying the ultimate strain of the tie-rod (Figure 7b), it is clear that the annual exceedance rate is the lowest in case of low ductile tie-rod behavior than in case of brittle behavior. Moreover, a brittle behavior of the tie-rod could lead to unexpected performance of the tie-rod especially in case of historical ties, where localized failures can occur [36]. Thus, it is recommended to prefer even a low-ductile behavior that strongly reduces the seismic demand hazard curves. Indeed, for instance considering the moderate rocking limit state ($\vartheta/\alpha = 0.4$), the annual exceedance rate decreases by over 60% passing from a brittle to a low-ductile tie rod. Again the red curve, related to a highly ductile tie-rod, for same ranges of EDP exhibits unexpected performance. In any case, such a behavior can be neglected being the corresponding fragility curves characterized by greater uncertainties.

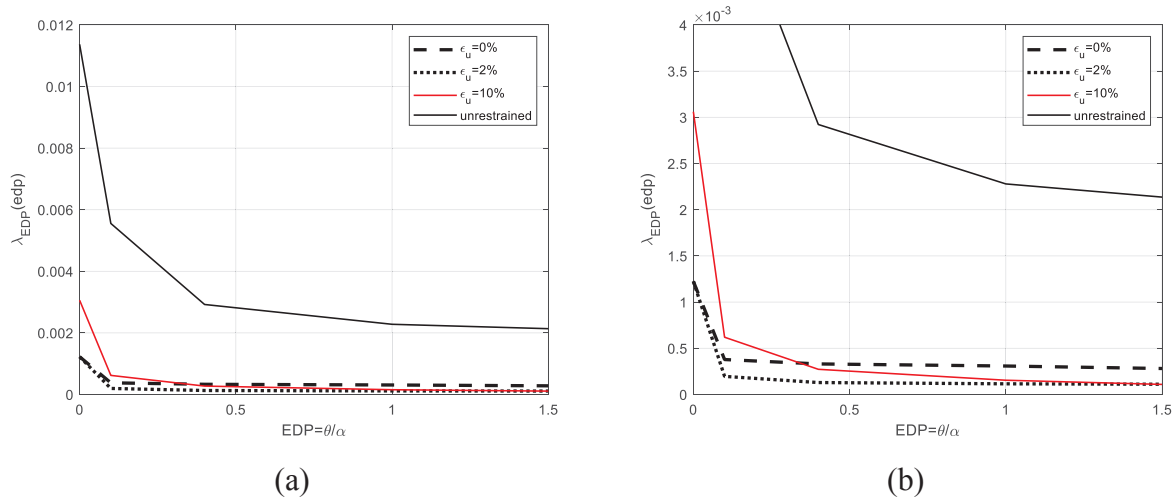

Figure 7: Seismic hazard curves for the monumental wall: parametric analyses in terms of steel ductility (a) with a detail for the restrained case (b).

Discussing how the tie-rod strength influences the seismic risk, it is evident that, as observed for the fragility curves, there is not a sensitive change in the annual rate of exceedance whether a high-strength tie-rod is assumed or a medium strength is considered (Figure 8).

Referring to the moderate rocking limit state ($\vartheta/\alpha = 0.4$), the annual exceedance rates are:

- $1.8\text{e-}5$ for the strength values of 294 MPa, $\varphi = 10\text{ mm}$;

- $7.7 \cdot 10^{-5}$ for 235 MPa;
- $2.7 \cdot 10^{-4}$ for 142 MPa;
- $2.9 \cdot 10^{-3}$ for the unrestrained case.

They respectively correspond to the fact that this limit state is exceeded once every 56000 years (high tie-rod strength) 13000 (medium), 3700 (low) and 345 years. Therefore, even with a low-strength tie-rod, the rate of occurrence is reduced.

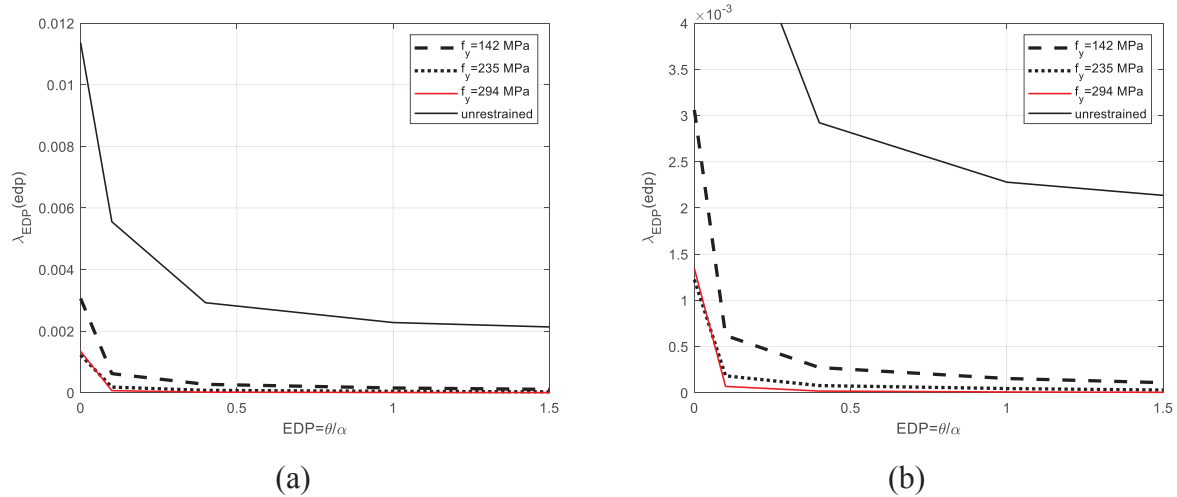

Figure 8: Seismic hazard curves for the monumental wall: parametric analyses in terms of steel strength (a) with a detail for the restrained case (b).

Taking into account the severe rocking ($\theta/\alpha = 1.0$), the annual exceedance rates are:

- $8 \cdot 10^{-6}$ for the strength value of 294 MPa, $\varphi = 10$ mm (one occurrence every 125000 years);
- $4.5 \cdot 10^{-5}$ for 235 MPa (22000 years);
- $1.5 \cdot 10^{-4}$ for 142 MPa (2000 years);
- $2.2 \cdot 10^{-3}$ for the unrestrained case (450 years).

Obviously, the two latter cases are over-conservative considering the life cycle of a masonry building, therefore even small strength values are sufficient to guarantee a remarkable increase of safety. For the severe rocking limit state, the reduction of annual exceedance rate is less evident than that for the moderate rocking limit state.

6 CONCLUSIONS

This paper discussed the role of tie-rods in the dynamic response of restrained masonry walls subjected to earthquakes. The analysis was performed by following a fully probabilistic approach with a multi-stripe analysis obtaining seismic fragility and hazard curves. Two typical masonry wall, one ordinary and the other of monumental type, were taken into account as unrestrained and restrained by tie-rods of different mechanical properties. Considering the results of over 11500 analyses, the best correlated intensity measures were observed to be peak ground acceleration and Arias Intensity.

Observing the fragility curves, the most dangerous case is the brittle tie-rod, as expected. The probability of exceedance of the limited rocking state is respectively by 85%, 30%, 8% and 3% for unrestrained wall, wall restrained by brittle, ductile and low-ductile tie rod for $PGA=0.8$

g. The reduction of probability of exceedance is significant being an order of magnitude lower for the case of low-ductile tie-rod with respect to the case of brittle tie-rod. Therefore, it is extremely beneficial to restrain the wall even with a low-ductile (but also a brittle, in comparison with an unrestrained wall) tie-rod. The choice of a specific tie-rod will depend on the admissible probability of exceedance depending on the return periods established by the standards.

As for the variation of steel strength, keeping constant the tie rod ultimate strain to 10%, the weaker material has an increased probability of exceedance that anyway keeps low (about 10% for $PGA=0.6$ g) even for medium-high intensity earthquakes. As a consequence, in many cases even a weak steel can be really beneficial for the reduction of the probability of exceedance of the limited rocking state.

For what concerns the seismic hazard demand curves, it is preferable for the tie-rod a low-ductile rather than a brittle behavior that strongly reduces the seismic demand hazard curves. A highly ductile performance could cause more uncertainties in the results. Considering the moderate rocking limit state, the annual exceedance rate decreases by over 60% passing from a brittle to a low-ductile tie rod. As for the influence of the tie-rod strength, even a low-medium values produce a remarkable reduction of annual exceedance rate. For instance, a sever rocking limit state occurs for the unrestrained monumental wall every 450 years and every 2000 years for the wall restrained by a tie rod of strength 142 MPa and a diameter of 14 mm. The return period of the same event increases to 22000 years for a strength of 235 MPa (and diameter 11 mm) and to 125000 years for 292 MPa (diameter 10 mm). Obviously, the two latter cases are over-conservative considering the life cycle of a masonry building, therefore even small strength values are sufficient to guarantee a remarkable increase of safety.

Finally, the probabilistic approach described here for the seismic assessment of the out-of-plane of masonry walls is able to reliably predict the seismic demand hazard curves to define the most appropriate type of steel tie rod to use as anti-seismic device.

Abstract

This paper presents the results of static and seismic vulnerability analyses performed on a single-span masonry bridge located in Northern Italy. The structure, dated back to the 17th century, is a bridge with single-span of about 16 meters and height of 8 meters, built with rubble and irregular masonry. A preliminary static analysis was performed on the bridge through traditional graphic approaches such as the Méry's rule and the Durand-Claye's method. Afterwards, a kinematic non-linear analysis was executed once the collapse mechanism under horizontal earthquake-type actions was identified. Finally, a static finite element analysis with brick elements was performed to state the seismic vulnerability of the bridge, by changing its mechanical properties to evaluate their influence on the structural response. Collapse load factors have been also computed considering non-uniform gravitational loads and horizontal settlements at the bridge foundations.

Keywords: masonry bridge, graphical methods, plastic hinge, arch bridge, seismic vulnerability; pushover analysis.

1 INTRODUCTION

Masonry Arch Bridges (MAB) represent a considerable portion of the ancient road infrastructures. The main characteristics of this artwork is a massive structure with significant stiffness and resistance. This aspect allows these infrastructures being less prone to vibration and deformation with respect to the modern structures. Furthermore, masonry bridges, as other historical structures, are characterized by a significant durability that permits their survival over the centuries.

MAB have an ancient origin. The first application of masonry in river overpasses are probably abutments and architraves of elementary bridges, made by simply supported wooden decks. The diffusion of arches in Mesopotamia and in Egypt gave a significant impulse to their use. The first stone arch can be dated back to the 4th millennium BC. Here the substitution of a previous slab made of intertwined reeds with dry stones and sun-dried bricks created the first documented arch of the history.

The first MAB was probably built in China, in the 3rd millennium BC. Later the Romans, famous road builders, massively used arches for the construction of bridges and aqueducts, some of which still survive nowadays [1].

For what concerns the computational modelling of MAB, from simplified methods to complex nonlinear finite element or discrete elements, interesting contributions can be found in [2–4]. For a proper computational modelling, the definition of geometry and mechanical properties of MAB is essential. In [5], the significant role of geometrical and mechanical parameters like arch thickness and filling is highlighted. In the same paper, a geometrical survey of 59 segmental MABs located in Portugal and Spain is reported. Thus, an accurate geometrical and mechanical survey is crucial in the safety evaluation; modern techniques can be very precious in this sense [6], especially when the internal core is not accessible. Specific techniques can be applied to limit the uncertainties in the composition of internal cores [7, 8]. When performing a structural assessment, it is important to vary the masonry and soil mechanical properties in case of uncertainties in their definition [9]. Sensitivity analyses are then often proposed to investigate the impact of the most important parameters such as the tensile strength of masonry [10–12]. Moreover, when dealing with uncertainties, it could be relevant to perform probabilistic analysis. For example, Casas [13] proposes a probabilistic assessment of MAB at the Serviceability and Ultimate Limit States. This work also illustrates recurring failure modes: four-hinge mechanism, the ring separation in multi-ring arches and the slip-page at the foundations. In [14] a simplified approach is proposed for the evaluation of fragility curves of MAB in case of seismic action. The study is carried out on numerous structures and broadened to a stock of roadway and railway bridge networks in dangerous condition to provide stakeholders a management tool.

There are diverse methodologies to study the static and the dynamic behavior of MAB. Very interesting graphical and numerical methods were developed in the past (from the 18th century) to study the static behavior of arch, in particular from the French Engineering Grand Écoles. This paper has the aim of performing all the possible analysis methods usually performed for MAB and of proposing qualitative comparisons.

In Section 2 a review of traditional and modern techniques is presented and applied to a representative case of study. The MAB selected for the investigation, reported in Section 3, is the *Premilcuore bridge* located in the District of Forlì-Cesena, Central Italy. The graphical methods and the numerical analyses are illustrated in Section 4.

2 BACKGROUND

2.1 Traditional graphical methods

In order to carry out a first simplified study of the stability of the vault, two different traditional methods have been employed: the so-called Mèry's Rule and Durand-Claye's Method.

Mèry's Rule, to which the credit for formalising the concept of thrust line is attributed, has risen to fame in the technical field particularly thanks to its ease of application. Indeed, it is interesting to observe how it is the only method still quoted in today's textbooks. Even though it was based on arbitrary assumptions [15], this method was applied for over a century for the design of arches and vaults. The foundation of this procedure is the personal criterium according to which the ideal condition for the arch can be identified by a thrust line that is entirely contained in the area defined by the middle third of the sections, intending to guarantee that the latter are completely reactive and the arch is not subjected to failure.

In accordance with Méry's studies, among the infinite curves of this type, which are able to ensure the arch equilibrium, the definition of the design line relies on the hypothesis that this thrust line passes through three pre-defined points: the lower middle third of the two sections in close proximity to the springers and the upper middle third in the keystone, where the direction of normal force is horizontal, according to the premise of symmetry of the applied load.

The second method, which is a more refined form from the theoretical point of view, is the one studied by Durand-Claye. It was conceived as a method to assess the stability of a symmetrical arch, symmetrically loaded by vertical forces under the condition that the material has finite value of the compressive strength and that it has a negligible tensile resistance.

This method essentially consists in defining the set of all the possible values of the internal forces in the keystone, the normal force N and the bending moment M , or, alternatively, the normal force and its eccentricity in relation to the axis curve, which ensure equilibrium and are compatible with the material strength. According to the assumptions, through each cross-section, possibly partialized, the compressive stresses vary with a linear law. The result of this procedure gives the graphical representation of the envelope of the aforementioned forces.

This method, unlike the previous one, allows to identify all the possible thrust lines capable of ensuring the balance in compliance with the limits of the material strength. Its value resides in checking the existence of admissible solutions without requiring to find the true one, which could be reached only by bringing into play the elastic properties of the material and the compatibility conditions. Assuming that the true solution exists, it is definitely included among these ones.

The Durand-Claye's method does not require either special hypotheses regarding the shape of the thrust line or regarding a predefined position of rupture joints, allowing to obtain several advantages. In particular, it allows to evaluate the degree of safety of the arch, the possible trend of the thrust line and the identification of the most stressed sections of the structure. This method is well suited to various types of arches, having different geometries and made with different materials.

2.2 Rigid block and arch models for kinematic analyses

A more modern approach to investigate the structural behavior of masonry buildings and bridges refers to limit analysis and non-linear dynamic analysis of rigid block models. Often, masonry structures - and especially historic constructions - can be regarded as composed by structurally independent parts or rigid blocks connected by ideal hinges. This occurs particularly when the connections between vertical members and between horizontal dia-

phragms/roof and walls are not effective [16]. In order to avoid such an undesirable behavior, tie-rods [17, 18], fiber composite stripes [19, 20] and strength anchors [21, 22] of suitable characteristics can be used. An extensive review on kinematic and rocking approaches for monolithic masonry walls, specifically regarded as rigid blocks on rigid foundations is reported in [23]. Among the methodologies based on limit analysis, recently many contributions were proposed considering the frictional forces [24–29] playing a crucial role in the assessment of the mechanism evolution. Evidently, these frictional forces should be determined through proper experimental testing [30]. Among the methods based on non-linear dynamic MAB (rocking) analysis, there exist models of walls connected with different types of horizontal diaphragms [31], but also of the corner mechanism as typical out-of-plane mode of masonry buildings [32]. A comparative study between the kinematic and non-linear dynamic methods investigating the 3D corner failure mechanism, also considering the thrusting roof and the stabilizing contribution of frictional resistances exerted within interlocked walls, is reported in [33]. One of the main issues arisen in these analyses is the output variability observed when input and boundary conditions change. Thus, probabilistic approaches suitable to describe the behavior of rocking structures have been defined [34, 35]. Moreover, rocking can be also seen as seismic dissipation technique for slender structures [36] and masonry walls [37]. Referring to arch-type structures, the rocking arch model assumes rigid blocks and rigid supports and is therefore only dependent on geometric properties similarly to the rocking block model. The susceptibility of masonry arches to earthquake loading is analytically and experimentally evaluated in [38] where the rocking arch model is a four-hinge mechanism. However, the approach currently most used in the professional practice for rigid block models is the kinematic analysis based on the displacement-based method. In it, the capacity in terms of both forces and displacements is compared with the seismic demand through the construction of acceleration-displacement response spectra. The standards from different countries (e.g. New Zealand [22] and Italy [39]) give specific indications about the way of calculating the collapse multipliers for each collapse mechanism and the methods to assess the seismic vulnerability through the acceleration-displacement curves. The *Premilcuore* bridge is here analyzed considering different single degree of freedom four-hinge mechanisms originated by different positions of the ideal hinges along the arch. The first aim of the kinematic analysis is to identify the most probable collapse mechanism, which corresponds to the lowest collapse multiplier according to the kinematic theorem of the limit analysis. Afterwards, the capacity curve is computed by following the Italian standards [40] and the safety verification is made through a kinematic non-linear analysis, namely by comparing the displacement demand with the displacement capacity.

2.3 Finite element and discrete element models

More refined approaches model masonry structures using micro and macro-modelling techniques. The formers separately consider the mechanical properties of the single components (bricks/blocks and mortar joints); the latter use simplified elements with homogenized properties. A consolidated model is represented by discrete macro-elements able to reproduce typical failures of masonry walls [41, 42]. A comparison between discrete macro-element and rigid block models used to assess the seismic vulnerability of a church façade is presented in [43]. An alternative method to discrete macro-element models regards the well-known finite element models, where masonry is modelled by means of planar (shell-plate type) or tridimensional (brick) elements with homogenized mechanical properties. A crucial issue of this modelling strategy consists in the correct selection of the masonry non-linear constitutive law and of the domain failure. These models offer a wide range of output, in terms of stress, strain, displacement, forces and energy [44], which have to be properly treated. Recently, some au-

thors developed discrete element models for the structural analysis of bridges [45, 46], whereas refined finite element models of multi-span masonry bridges were proposed in [47] performing nonlinear static, nonlinear dynamic, and incremental dynamic analyses under 14 earthquake records. This paper proposes the modeling of the *Premilcuore* bridge through a finite element model made of brick elements, whose features are illustrated in Section 3.2. The different modelling and analysis procedures, including the graphical methods and the kinematic analyses, are then discussed analogously to what is done in [48] in Section 5.

3 CASE OF STUDY

3.1 Geometry and masonry type

The *Ponte Nuovo (New Bridge)* of *Premilcuore* is named from the rebuilding (in 1650-1656) of a previous roman bridge, probably dated to the 2nd century AD [49]. The reconstruction of the New Bridge (Figure 1) was made after the collapse of the previous one, whose right abutment was kept (Figure 2a). The infrastructure is placed along the historical Florentine roads, which connected the two Italian regions Tuscany and Emilia Romagna across the *Rabbi* stream.

Figure 1: Aerial view of the bridge

The structure is characterized by a segmental arch with a length of 15.90 m and a maximum rise of 4.35 m. The deck is built with a “donkey back” shape with a slope of the ramp of about 22 degrees according to the canons of the medieval period.

The masonry of the abutments, of the wing walls and of the parapets is made of irregular stones except for the ring stone and the lower part of the abutment, which is built with regular stone. The river-bed appears irregular and the lithotype of the foundation has a predominant rock component. A large cracking under the bridge highlights a hypogea cavity that collects the runoff water.

The three metallic ties that appear under the arch (Figure 2b) are installed in the 1930's, after some seismic events that affected the area producing damages in the adjacent building (1818-1819).

(a) (b)
Figure 2: Details of the bridge: wing wall (a) and intrados (b)

3.2 Assumptions of the analysis

A detailed survey of the geometry is carried out according to [50]. A literary review allowed to define a part of the geometry that was not directly measured on site, by means of the design criteria used when the reconstruction took place [15, 51, 52]. The extension of the abutment and the thickness of the arch are in line with the 17th century design rules.

At the time of the construction of *Premilcuore bridge* there was no technical distinction between the part of the backfill that had or not a static rule in the bridge conception, so all the filling placed over the masonry vault is considered as non-structural [1, 53].

An identification of the mechanical properties of the bridge is carried out according to [54, 55]. The material variability, in existing buildings, is considered to be one of the most significant causes of uncertainties particularly affecting the structural response [56–58]. To consider the uncertainties in masonry properties a sensitivity analysis is carried out considering a variation of the mechanical properties in the range $\pm 40\%$ with respect to the average values reported in Table 1. The tensile strength is assumed to be 1/10 of the compressive strength.

The Max Stress criterion, also known as *Galileo-Rankine's criterion*, was assumed in the analysis.

Material	Elements	c [MPa]	ϕ [Deg]	E [MPa]
1	Vaults, spandrel walls	0.253	54.9	975
2	Arch ring, abutment	0.411	54.9	1320
3	Backfill	0.05	21.8	500

Table 1: Mechanical properties of the bridge components.

For all the elements a uniform specific weight of 18 kN/m^3 is assumed. The live load assumed is a distributed load of 5 kN/m^2 ; this value is indicated in [59] and in CNR Guidelines [60] for the masonry carter bridges of the 19th and 20th century and represents the same value that is currently used for the design of a pedestrian footbridge.

3.3 Finite element model

A tridimensional model of the central segment of the bridges is implemented in the software Straus 7 (r2.3.3). The model is composed by 8242 nodes, 7908 brick and 288 beam elements (Figure 3). The beam properties are *cut-off bars* with no tensile strength to model the interface with the soil foundation. The parapets are modelled as *non-structural masses*.

The material properties of Table 1 are assigned to the different parts of the bridge. In Magenta the material 1, in Yellow the material 2 and in Cyan the material 3 (Figure 3).

The lateral portions of the abutments adjacent to the soil of the access ramp (parallel to plane y-z) are restrained only in x-direction. The nodes under the foundations (parallel to plane x-y) are completely fixed.

Figure 3: Three-dim model, for Static (a) and Seismic (b) analysis.

4 ANALYSIS OF THE PREMILCUORE BRIDGE

4.1 Traditional / Graphical methods

In order to assess the stability of the arch, the Mery's Rule has been firstly applied. Preliminarily, the arch between the springer and the keystone has been divided into ten voussoirs with the same length, Δs . Then, the study has been focused on the section of the arch between the intermediate rupture joint and the keystone. In accordance with well-established assumptions [51], the lower section can be located halfway, in terms of height, between the springing line and the highest point of the intrados, meaning between the voussoirs 7 and 8.

Self-weight and traffic loads have been considered, and the latter has been schematized as a uniform load acting longitudinally along the entire bridge. Its intensity was set equal to 5 kN/m². The different loads acting on each element of the structure are shown in Table 2.

Voussoirs	Specific weight $\gamma = 18 \text{ kN/m}^3$				Equivalent Traffic Load $q_k = 5 \text{ kN/m}^2$		Resultant Force
	Voussoirs Self-Weight Load	Filling Load	Parapet of the bridge Load	Resultant Load	Length of the voussoirs	Traffic load	R
	[kN]	[kN]	[kN]	[kN]	[kN]	[kN]	[kN]
1	45.4	0.0	12.8	58.2	106.3	15.4	73.6

2	45.4	0.0	11.0	56.4	105.4	15.3	71.7
3	45.4	0.0	10.6	56.0	104.3	15.1	71.1
4	45.4	1.8	10.9	58.1	102.8	14.9	73.0
5	45.4	9.8	11.1	66.4	100.1	14.5	80.9
6	45.4	24.0	11.1	80.5	95.9	13.9	94.4
7	45.4	43.5	10.7	99.6	89.2	12.9	112.5
8	45.4	64.7	9.7	119.9	77.6	11.3	131.1
9	45.4	74.7	7.4	127.5	56.9	8.3	135.7
10	45.4	41.0	2.9	89.4	20.9	3.0	92.4
Total							936.4

Table 2 – Discretization of the Arch.

Applying the loads on each segment, the funicular polygon passing through the upper middle third of the keystone and the lower middle third of the previously mentioned section has been drawn. Thus, the thrust line of the arch has been graphically obtained, together with the magnitude of the forces at the extremities, H and S (Figure 4).

Figure 4: Thrust line according to Mery's Rule.

Subsequently, with the purpose of assessing in a different way the stability property of the vault, the Durand-Claye's method has been applied. The arch has been schematized in the same way, with ten voussoirs between the springer section and the keystone. The same loads have also been considered (Figure 5).

Figure 5: Mechanical model for the arch – Durand-Claye's method.

The rectangular cross section has a width of 3.65 m and a height of 0.65 m. The resistance of the material was evaluated considering the average value referred to the various parts of the structure; it has been assumed equal to $f_c=2.10$ MPa.

By applying the Durand-Claye's method for three different control sections, the same number of areas of stability at the keystone have been identified (Figure 6), hence, their intersection has been found (Figure 7).

Figure 6: Durand-Claye's stability areas

Figure 7: Intersection among the stability areas

The thrust lines corresponding to the four vertices of the stability curve identify the area within which the actual pressure thrust will be included. The latter satisfies the conditions of balance and strength of the material. Each line can be associated with the value of the force acting on the arch (Figure 8). The arch is more vulnerable where the area containing the pressure curve is outside the middle third of the section.

Having identified the solutions related to the two simplified methods, Mery and Durand-Claye, their comparison shows that the values obtained using the Mery's rule fall within the range identified with the Durand-Claye's method, as expected (Figure 9).

Figure 8: Thrust line according to Durand-Claye's Method.

Figure 9: Comparison between Méry's and Durand-Claye's graphical solution

4.2 Identification of the collapse mechanism and non-linear kinematic analysis

Let us assume that the single span bridge is made of rigid blocks whose contact surfaces have null tensile strength, infinite compressive strength and sliding impeded. These three conditions are the well-known Heyman's hypotheses [53]. From a static point of view, the bridge is subjected to its self-weight and to the permanent loads of backfill and bridge deck with parapets. According to the Heyman's safe theorem, "if a line of thrust can be found which is in equilibrium with the external loads and which lies wholly within the masonry, then the structure is safe". The rigid block analysis is aimed at assessing the seismic vulnerability of the bridge arch and consists in two steps:

- 1) identification of the more likely failure (four-hinge) mechanism;
- 2) non-linear kinematic analysis in which the displacement capacity is compared to the displacement demand.

When the seismic action is considered, the arch is subjected to inertial forces which modify the line of thrust. The distribution of inertial forces q_i is not unique as the interaction between arch and backfill is complex. Four possible models, schematically displayed in Figure 10 considering a horizontal ground acceleration from right to left, are considered [61]:

- (M1): only the sub-blocks of the left semi-arch are subjected to the inertial force q_i , equal to the horizontal acceleration multiplied by the mass of the block itself and that

of the tributary individual horizontal strip of the backfill included between the extrados and the vertical line passing from the corresponding arch springer. The semi-arch on the right is not interested by inertial forces as here the backfill is supposed to be detached from the extrados.

- (M2): analogous to (M1), but with the sub-blocks of the semi-arch on the right subjected to the inertial force q_i ;
- (M3): each sub-block is subjected to a horizontal force equal to the gravitational load that it is bearing;
- (M4): the inertial forces applied as uniform horizontal load only act on the semi-arch on the right. The resulting force of q_h is equal to the total vertical load (self-weight and backfill weight).

Considering all four models, the process to identify the four-hinge mechanism is iterative. Firstly, an attempt position of the four hinge is assumed considering only the arch since the bridge piles are stocky (Figure 10). The principle of virtual work allows calculating the collapse multiplier α by dividing the external work made by the vertical forces with that made by the horizontal forces. Once α is calculated, the reaction and internal forces between each sub-block are computed and the line of thrust, passing through the assumed hinges, can be drawn. If this line of thrust lies wholly within the masonry, α is also a statically admissible multiplier according to the limit analysis theorem and therefore the actual collapse multiplier. Otherwise, the procedure should be repeated by moving the hinges where the eccentricity (given by the ratio of bending moment to normal force on each block) is maximum, up to the condition for which the line of thrust lies wholly within the masonry. M4-m2-m3-m1

Comparing the results obtained by applying this procedure, (M1) and (M4) provide the highest and lowest estimation of the collapse multiplier respectively. (M3) corresponds to a collapse multiplier between that of (M1) and (M2). The most conservative model is therefore (M4) but the assumption of a constant horizontal load (Figure 10) is not fully realistic. On the contrary, (M3) is the simplest model and, as already illustrated in [61], can be accepted for a reliable estimation of the collapse multiplier.

Figure 10: Models with different distribution of inertial forces (from [61]).

Its collapse multiplier is close to that of M1 and therefore such a different assumption does not markedly change the final result. For these reasons, model (M3) is considered in the following calculations. By performing the described iterative procedure, the eccentricity trend

shown in Figure 11.a is obtained at the third attempt and the corresponding deformed shape is displayed in Figure 11.b.

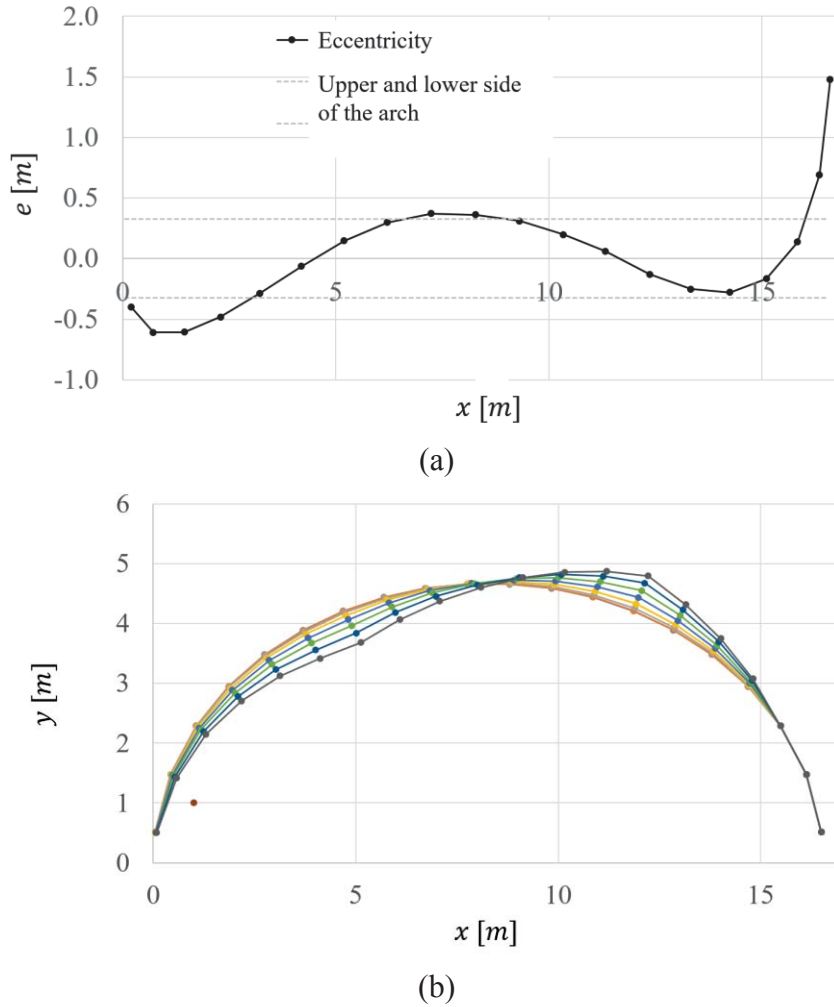

Figure 11: Eccentricity of the line of thrust obtained with the third attempt of hinge position change (a); evolution of deformed shape in the construction of the acceleration-displacement curve (b).

For this collapse mechanism, the capacity curve is firstly drawn by monotonically increasing the rotational angles between the rigid blocks constituting the arch. The displacements in x and y directions can be calculated through trivial geometric considerations from these rotational angles. This results in a progressive change of the deformed shape visible in Figure 11.b. The capacity curve is obtained by calculating through the principle of virtual work the acceleration corresponding to each imposed displacement (black curve of Figure 12).

The control point is selected as the center of mass of the key-stone and the confidence factor required to compute the acceleration is $CF = 1.35$ [40]. The ultimate displacement, corresponding to the zero acceleration capacity, is (Figure 12):

$$d_0 = S_{d,0} = 8.90 \text{ cm} \quad (1)$$

And the corresponding displacement capacity d_{ULS} is, for the ultimate limit state ULS [40]:

$$d_{ULS} = 0.4 \times S_{d,0} = 3.56 \text{ cm} \quad (2)$$

The displacement demand has to be computed by considering the secant period T_{SL} corresponding to the ultimate limit state from the expression found in the Italian standards [40]:

$$T_{SL} = 1.68\pi \sqrt{\frac{d_{ULS}}{a(d_{ULS})}} = 0.62 \text{ s} \quad (3)$$

The intersection between the dotted line of Figure 3 identified by T_{SL} and the elastic acceleration demand response spectrum (ADRS) gives the displacement demand:

$$S_d(T_{SL}) = 2.01 \text{ cm} \quad (4)$$

to compare with the displacement capacity. The verification is satisfied, being the capacity higher than the demand:

$$d_{ULS} = 3.56 \text{ cm} > S_d(T_{SL}) = 2.01 \text{ cm} \quad (5)$$

Resulting in a safety factor SF of:

$$SF = \frac{d_{ULS}}{S_d(T_{SLV})} = \frac{3.56}{2.01} = 1.77 > 1. \quad (6)$$

The bridge therefore results in a safe condition, which results even safer by considering a design ADRS with a behavior factor q [39]. This aspect confirms that these arches are rarely vulnerable to such mechanism, as already discussed in [61].

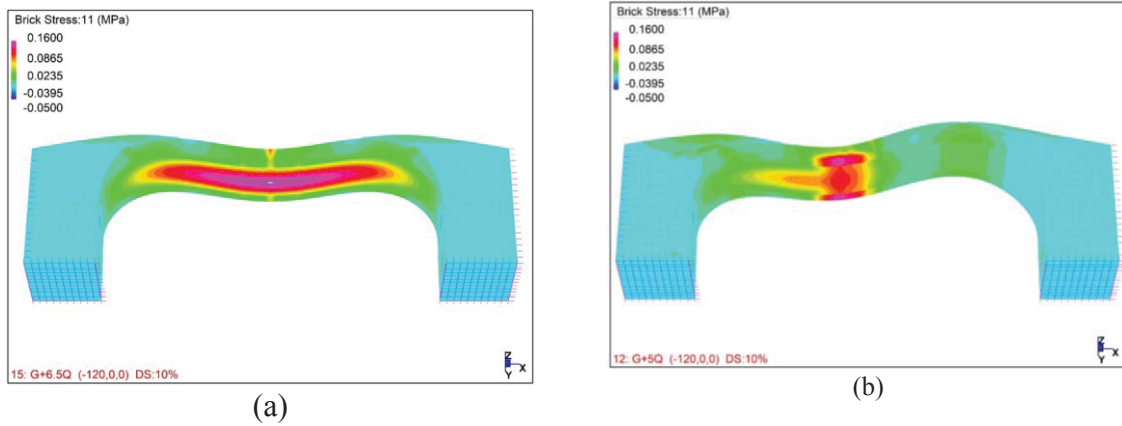

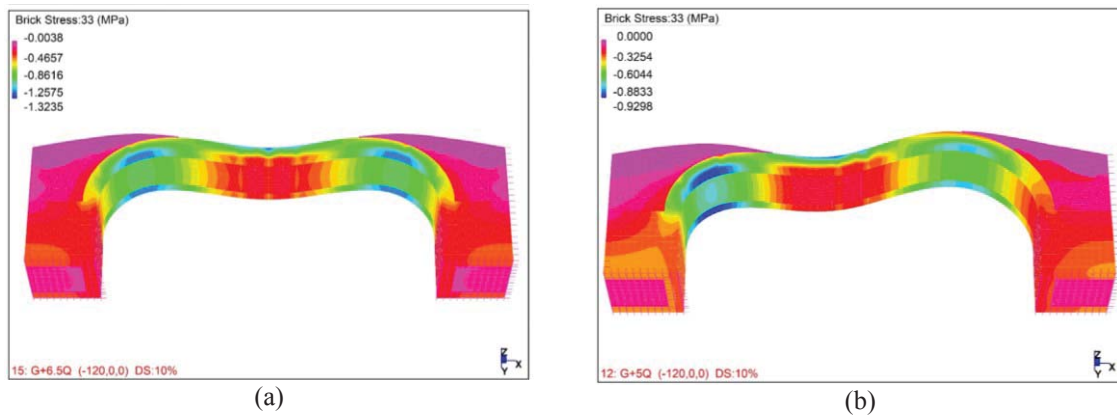

Figure 12: Seismic vulnerability assessment through non-linear kinematic analysis.

4.3 FEM analysis

4.3.1. Nonlinear static analysis (gravitational loads)

Nonlinear static analysis is carried out considering both symmetric and asymmetric incremental live loads. The gravitational load is applied into the two first steps. After that, an increasing live load is applied to identify the collapse multiplier (λ) with respect to 5 kN/m². The collapse is identified considering the numerical divergencies of the model. In Figure 13 and in Figure 14 the maximum principal stresses are displayed. The collapse multipliers λ are illustrated in Table 3. The bridge is safe with respect to the static live load, also considering a non-uniform distribution, and the worse resistance for masonry.

Figure 13: Contour of σ_{11} in case of symmetric (a) and asymmetric live load (b).Figure 14: Contour of σ_{33} in case of symmetric (a) and asymmetric live load (b).

Material	$\lambda_{uniform}$	$\lambda_{non-uniform}$
Average – 40%	4.0	4.5
Average	6.5	5.0
Average + 40%	9.0	6.0

Table 3: Collapse multiplier for static analysis.

4.3.1. Nonlinear static analysis (seismic actions)

A seismic push-over analysis is performed on the model of Figure 3 (b). The analysis is set applying first the gravitational load and after introducing the seismic action in transverse direction (Y-direction in Figure 3). The transverse direction is chosen since kinematic analyses are performed in the longitudinal section of the arch. The effect of transverse ties is neglected for the sake of safety.

The pushover curves are shown in Figure 15, considering the control displacement of a node in the middle of the arch (node 716). In these curves, the ultimate displacement depends on the material quality. It is interesting to highlight that all the curves end up at $V_b=1585$ kN that corresponds to a shear value of about the 90 % of the design seismic action. The overturning (joined to a crushing of masonry at the foundation) is the cause of this behavior. The hypothesis of smooth constraints (without friction) on the lateral face of the bridge consents the global

overturning. The analysis, made this prudential assumption, shows a good performance of the structure with respect to transverse action. This result is in line with the main indication in literature, which considers the kinematic approach as the most interesting for MAB.

Figure 15 – Capacity curves.

5 CONCLUSIONS

The present work dealt with the static and seismic analyses of an historical masonry bridge placed in *Premilcuore*, a small village in Central Italy. The vulnerability analysis was tackled with several methods, considering both the traditional static approaches and the modern types of seismic analysis.

Considering the hypotheses, which are based on different structural aspects, it is very difficult to carry out a rational comparison of the numerical results. The different approach moreover produced different results that is hard to merge to a common factor.

However, the following conclusions can be drawn. As for the graphical methods, their graphical comparison shows that the values obtained using the Mèry's rule fall within the range identified with the Durand-Claye's method.

These methods show how the shape of the arch and the mechanical properties of the material are able to ensure the stability of the structure for the vertical loads considered above. In the analysis, the shear actions have been neglected. Therefore, the structure resulted to be safe under vertical gravitational loads.

With the purpose of analysing the bridge through other numerical methods, the non-linear kinematic analysis, based on rigid block model and limit analysis, the estimation of the collapse multiplier of the arch considered as set of rigid blocks was made. The analysis shows that the bridge arch, assumed subjected to inertial forces computed by the gravitational loads, is safe even with an elastic acceleration demand response spectrum. This aspect confirms the low vulnerability of these types of arch mechanisms to horizontal seismic actions, confirming

literature results. Finally, the *Premilcuore bridge* was subjected to a FEM sensitivity analysis considering three materials and two different models, for static and seismic actions.

The static analysis, with an incremental live load, allowed to evaluate the collapse factors. Both the load scenarios investigated are safe also considering precautionary hypotheses on the bridge material.

The seismic analysis identified the collapse loads and the most likely failure modes in presence of transverse seismic actions. The transverse direction is chosen here as complementary of the natural direction of kinematic analysis of the arch, in the transverse direction of the bridge. The more severe scenarios, approximately obtained in correspondence of the 80-90% of the design seismic actions, highlights a failure mode with a crushing on the foot of the foundation, with a mechanism that recalls to an incipient overturning of the bridge.

Summarizing, a comparison of the different methods, highlights that the bridge is structurally safe from a static point of view, as confirmed by FE analysis and graphical methods, whereas it presents some critical vulnerabilities in case of seismic actions acting along the river direction when FE models are adopted.

Abstract

The out-of-plane dynamics of masonry walls is strongly influenced by seismic input, mass, wall geometry and boundary conditions. Nevertheless, the parameter that mostly affects the dynamic response of a rocking wall is the coefficient of restitution, defined by Housner as ratio of angular velocity after and before an impact on the ground. Such a parameter defines the amount of energy dissipated over motion and is of paramount importance in assessing the seismic vulnerability of a rocking wall, due to the sensitivity of the dynamic response to small changes of it. This paper critically illustrates the preliminary results of an experimental campaign performed on a masonry wall subjected to one-sided rocking. These results are presented in terms of experimental ratios of coefficients of restitution. Two methods for calculating the experimental ratios of coefficients of restitution are described according to whether rocking is one-sided or two-sided. In addition, the paper compares these ratios with those of other experimental tests on two sided rocking and horizontally restrained masonry walls available in the literature. A numerical example is provided by showing that the assumption of a correct coefficient of restitution is crucial for a realistic and correct seismic vulnerability assessment.

Keywords: rocking, one-sided, two-sided, coefficient of restitution, masonry, out-of-plane.

1 INTRODUCTION

The appropriate types of analysis that can be carried out on masonry buildings under earthquakes depend on the degree of connection between walls and between walls and horizontal diaphragms, including arches, vaults and roofs [1]–[3]. Seismic retrofitting interventions are generally needed to ensure the box-type behavior; nowadays, seismic consolidation techniques are coupled with low-impact solutions also from an environmental point of view [4], [5]. Nevertheless, when the connection is poor, only local analyses are meaningful for a proper seismic vulnerability assessment. In that case, the most common approach consists in computing collapse loads of local rigid block mechanisms [6]–[10], properly considering floor spectra [11]. An alternative approach, which can be seen as complementary to the mentioned kinematic non-linear analysis, is the non-linear dynamic analysis or rocking analysis. This investigates the dynamic behavior of the rigid block according to the Housner's equation [12], duly considering the energy dissipated over motion. A synthetic parameter describing this energy dissipation is the coefficient of restitution [13], [14]. The coefficient of restitution can be defined in several ways [8], but they are equivalent only in case of frictionless impact [9].

The coefficient of restitution has a relevant influence on the free damped vibration of a rigid block [15] as well as on its resonance conditions [16], [17]. In the present paper, the coefficient of restitution proposed by Housner is considered, which is defined as ratio of the square root of kinetic energies after and before each impact [12]. Yet, the values of the coefficient of restitution analytically found by Housner [12] as a function of the block slenderness generally overestimate experimental values.

Actually, tests executed on blocks of different materials (e.g. stone, masonry, concrete, etc.) showed scattered values of the coefficient of restitution. For example, tests on rectangular concrete blocks with aluminum base reported [18] were in satisfactory agreement with the Housner predictions ratio: in fact, ratio between experimental and analytical value of coefficient of restitution e_{Exp}/e_H was respectively 101% and 98%. But similar tests performed on non-rectangular blocks [19] and prismatic steel blocks [20] exhibited not recognizable trends. By contrast, at least a qualitative trend of coefficient of restitution with respect to the analytical one can be appreciated when dealing with masonry blocks. Indeed, in general rocking masonry/stone elements dissipate more energy than that is predicted by the Housner's formulation. Literature values refer to ratios of experimental to analytical coefficient of restitution percentage of 85% – 95% for free walls [21], [22] and of about 80% for horizontally restrained walls [22].

This paper analyzes the preliminary experimental results of free-vibration tests executed on an unrestrained masonry wall made of clay brick and cementitious mortar. The dynamics of one sided rocking can be analytically and numerically studied through a modified equation of motion (Section 2). Section 3 illustrates the general features of the experimental campaign and the results in terms of coefficients of restitution, whilst Section 4 compares the so-obtained results with literature values valid for walls of the same typology in two-sided rocking.

2 ANALYTICAL FORMULATION

The mechanical model considered for a classical non-linear dynamic analysis is displayed in Figure 1. The wall is assimilated to a perpendicular rigid block of mass m , size R , polar inertia moment I_0 rocking around its base. The rigid block is subjected to an acceleration time history $\ddot{u}_g(t)$ which can be registered or artificial (spectrum compatible). The rocking wall might be connected to transverse walls of unitary stiffness K'_c (acting only in compression for

the sake of simplicity) and to horizontal tie-rods of stiffness K . Using the Euler-Lagrange formulation, it is simple to obtain the corresponding terms of the equation of motion (T_L and T_t respectively) as described in detail in [23].

The equation of motion reads:

$$I_0 \ddot{\vartheta} + \text{sgn}(\vartheta) mgR \sin A_\vartheta + T_t + T_L = m \ddot{u}_g R \cos A_\vartheta \quad (1)$$

$$A_\vartheta = \alpha - \text{sgn}(\vartheta) \vartheta$$

Figure 1: Mechanical model assumed for a rigid block masonry wall.

The energy dissipation is not directly visible in Eq. (1) since it is introduced during the resolution of the equation of motion as change of boundary condition when the block rotation passes from zero to a negative/positive value. Generally, in the dynamics of slender and rectangular rigid blocks the coefficient of restitution as defined by Housner [12] is considered:

$$e_H = 1 - \frac{3}{2} \sin^2 \alpha \quad (2)$$

Where $\alpha = \text{atan}\left(\frac{h}{b}\right)$ (Figure 1). This expression is obtained by equating the moment of momentum about O' immediately before impact to that immediately after impact on the ground. The coefficient of restitution is expressed as ratio of the square root of the two kinetic energies after and before each impact. As it will be illustrated in Section 3.2, there are different manners to express the coefficient of restitution, depending on whether the rocking is symmetric or not.

3 EXPERIMENTAL CAMPAIGN ON A MASONRY WALL IN ONE-SIDED ROCKING

3.1 Features of the rocking wall and testing set-up

This section illustrates the tests executed on a clay brick and cementitious mortar wall. The wall, tested in free-vibration, has the following dimensions: height 2.70 m, thickness 0.36 m and width 1.68 m. Its weight is 29.4 kN and its slenderness ratio, given by the arctangent of

thickness to height, is 0.133. The wall is pulled out-of-plane through a tie-rod up to attain a specific displacement (50 mm, 100 mm and 150 mm) of the wall at 2.56 m from the base. A detailed description of the experimental tests and of the mechanical features of the wall can be found in [24], [25]. The only difference with the tests already performed is that the hinge is in this case formed at 0.23 m above the wall base, and not at the wall foundation. This makes the wall stockier as its height diminishes.

Once the wall attains the specified displacement, a quick release system frees it making it rocking. The motion is one-sided, namely the wall impacts against two transverse walls (Figure 2) of length 1.50 m and thickness 0.12 m each. The transverse walls have the same mechanical properties as the rocking wall. The displacement and acceleration time-histories are recorded by potentiometric displacement transducers and accelerometers respectively, positioned on the tested wall as shown in [25]. An example of the experimental outputs is reported in Figure 3, where also the velocity time histories, obtained by derivation of the displacement time-histories, are plotted.

Figure 2: Masonry wall tested in one-sided rocking.

Figure 3: Selection of experimental results: displacement and velocity time-histories of a point located at 2.56 m from the wall base: imposed displacement of 50 mm (a) and of 150 mm (b).

3.2 Computation of coefficient of restitution from experimental results

These outputs are furtherly elaborated to obtain the experimental coefficients of restitution by two alternative approaches:

1. The traditional one, which computes the experimental coefficient of restitution considering consecutive peaks of velocity. Referring to Figure 4, the coefficient of restitution is calculated as mere ratio of velocity at peak (i+1)-th to velocity at peak i-th:

$$e_{exp} = \left| \frac{v_{i+1}}{v_i} \right| < 1 \quad (3)$$

regardless of the rotation sign.

2. A more refined one, where two coefficients of restitution are calculated, considering the asymmetric behavior due to the one-sided rocking caused by the impact on transverse walls:

$$e_{exp}^+ = \sqrt{\frac{v_{i+3}^+}{v_{i+1}^+}}; \quad e_{exp}^- = \sqrt{\frac{v_{i+2}^-}{v_i^-}} \quad (4)$$

The need of shifting from Eqn. (3) to Eqn. (4) is due to the fact that, for one-sided rocking, the consecutive negative and positive peaks of velocity are strongly different and the behavior depends on the rotation. Therefore, the calculation of the coefficient of restitution, function of the velocity peaks, should consider such a relevant aspect. This issue was already highlighted for diverse properties of horizontal restraints in [25] and for non-homogeneous walls in [22].

We call “experimental ratio of coefficient of restitution” the term:

$$r = \frac{e_{exp}}{e_H} \quad (5)$$

in which e_{exp} is the experimental value of the coefficient of restitution and e_H the analytical value as defined by Housner [12] and recalled in Eq. (2). Three ratios can be therefore defined to calculate the coefficient of restitution:

$$r = \frac{e_{exp}}{e_H} \text{ (method 1); } r^+ = \frac{e_{exp}^+}{e_H} \text{ and } r^- = \frac{e_{exp}^-}{e_H} \text{ (method 2)} \quad (6)$$

The wall under examination has a slenderness ratio $\alpha = 0.133$, therefore according to Eq. (2) the analytical Housner's coefficient of restitution is $e_H = 0.974$.

Figure 4: Labels of velocity peaks.

3.3 Experimental values of coefficients of restitution

The results in terms of ratios of coefficient of restitution (Eqns. (5)-(6)) are reported in Table 1. Each value is labelled with the imposed displacement and the progressive number of the test. So, for example, test # 150_2 indicates the second consecutive test where an initial imposed displacement of 150 mm at the top of the wall has been released. These values are calculated as mean considering the first six impacts, since after them the motion amplitude is negligible. Thus, the two ratios r^+ and r^- are computed as average of two values, whereas r is computed by considering five values. It is worthy to observe that the average values of r do not sensitively differ from r^+ or r^- only because the differences between experimental coefficients of restitution are smoothed when the overall average is considered. This aspect is shown in Figure 5: this diagram evidently shows that the average for test #50_1 is very close to $r^+ = 62\%$ or $r^- = 59\%$ (Table 1), although each individual coefficient of restitution markedly change (from 35% to 88%) considering the actual ratios. The difference between r^+ and r^- is by about 10%. This means that, when the wall impacts against the transverse walls (inward rotation), there is a dissipation of energy by 10% greater than what occurs in the condition of out-of-plane rocking (outward rotation).

It should be noticed that is not a huge difference, because the length of the transverse walls (2.0 m) is not enough to produce a rebound effect. Indeed, the oscillations are bilateral as visible in Figure 3 and not unilateral as it should be in actual rocking walls, where the transverse walls are much longer and therefore more rigid. On the contrary, the difference between r^+ and r^- is only by 3% for the test #50_1, owing the fact that the initial displacement amplitude is only 50 mm and therefore the condition of bilateral oscillations is more pronounced. This difference is then not considered as representative, due to the small initial displacement. Consequently, excluding test #50_1, from Table 1 an average value of 59% can be estimated for r_1^- , which is a reduction by about 40% with respect to $r = 95\%$, evaluated for one-sided rocking walls.

test#	r^+	r^-	r
150_1	67%	59%	57%
150_2	65%	57%	59%
150_3	71%	61%	66%
100_1	68%	58%	63%
50_1	62%	59%	59%

Table 1: Mean experimental ratios of coefficients of restitution for the unrestrained wall in one-sided rocking (r^+ = outward rotation, r^- = inward rotation).

Figure 5: Local values of experimental ratios and average (blue line) for test #50_1.

4 COMPARISON BETWEEN ONE-SIDED AND TWO-SIDED ROCKING WALLS

This section illustrates a comparison in terms of experimental ratios of coefficient of restitution found for:

- (i) unrestrained walls, in bilateral (two-sided) rocking;
- (ii) unrestrained walls, in unilateral (one-sided) rocking;
- (iii) walls restrained by dissipative and non-dissipative horizontal restraints.

The first and third condition refer to the experimental tests described in [22], [25], whereas the second condition regards the experimental tests illustrated here.

4.1 Unrestrained walls in one- and two-sided rocking

As for the unrestrained walls in two-sided rocking, the mean coefficients of restitution do not vary considering either consecutive peaks or consecutive peaks of the same sign (second and third column of Table 2. In the first test (A_T0_1), there is a greater dissipation of energy, probably because the first impacts, breaking small parts of the mortar joints on the wall base, “smoothen” the rocking surface. For the tested wall, the values of coefficient of restitution range from 88% to 98%. In [25] the tests were executed also for a slenderer wall of equal characteristics: for it, the results were less scattered, being the minimum r 95% and the maximum r 96%. A reference value of 95% can be then assumed for the unrestrained walls in two-sided rocking. This ratio is different to that found for *in-situ* tests performed on historic rubble masonry [22]. This aspect can be explained considering that the *in-situ* conditions, such as imperfect foundation surface and interference of the rocking wall with the adjacent walls, undoubtedly imply an increase of energy dissipation. The results found in [25] are instead in agreement with the literature results of solid clay brick walls tested in two sided rocking [21], for which an average ratio of 95% was found.

test#	r^+	r^-	r	r (2 impacts)
A_T0_1	93%	93%	92%	97%
A_T0_2	97%	97%	94%	94%
A_T0_3	97%	97%	94%	99%

A_T0_4	97%	98%	95%	99%
A_T0_5	91%	92%	90%	88%

Table 2: Mean experimental ratios of coefficients of restitution obtained from experimental tests on the unrestrained wall in two-sided rocking illustrated in [25].

Comparing the results reported in Table 2 and in Table 1, it is clear that the one-sided motion presents much more scattered value of the experimental coefficients of restitution, while their difference increases by 10% passing from outward rotation to inward rotation (section 3.3). Obviously, in the two-sided rocking the coefficient of restitution does not change significantly when the rotation sign changes.

As described in section 3.3, the average value of r_1^- is 59%, corresponding to a reduction by about 40% from the value, $r = 95\%$, calculated for two-sided rocking walls. It is therefore of interest to distinguish the amount of energy dissipated by the impact at the ground from that originated by the impact on transverse walls.

Moreover, the presence of transverse walls introduces a non-linearity in the coefficient of restitution as it immediately influences the value of the coefficient of restitution itself. This aspect can be observed by considering the ratios pertaining the first impact only (r_1), or the first two impacts (r_1^+ and r_1^-). Indeed, the so calculated coefficients of restitution in the inward rotation (r_1^- in Table 3) are about 55%, that is almost 50% of the corresponding coefficients of restitution for the two-sided rocking wall (Table 2).

test#	r_1^+	r_1^-	r_1
150_1	65%	52%	32%
150_2	66%	53%	34%
150_3	69%	59%	37%
100_1	60%	52%	34%
50_1	64%	56%	35%

Table 3: Experimental ratios of coefficients of restitution for the first impact of the unrestrained wall in one-sided rocking (r_1^+ = outward rotation, r_1^- = inward rotation).

4.2 Restrained walls in one-sided and two-sided rocking

For what concerns the same wall restrained by a damped and stiff horizontal device, a reduction by 5% of the coefficient of restitution in unrestrained rocking was found in [25]. Therefore, the coefficient of restitution to assume for rocking analysis should be equal (on average) to 90%. The same reduction by 5% was computed in [22] passing from an unrestrained rubble masonry wall to the same wall restrained by an undamped elastic element. It must be stressed that such a reduction mainly depends on the horizontal restraint type and position, while the influence of masonry texture, material or age, seems negligible.

5 CASE STUDY: FAÇADE OF A THREE-NAVE CHURCH

Numerical analyses are performed in this Section to investigate the relevance of the coefficient of restitution in one-sided rocking motion. The selected case study is the façade of the San Filippo church (Figure 6a) located in Central Italy and struck by the 2016-2017 Central Italy earthquake. During the seismic swarm, a horizontal hinge formed at about 14 meters from the ground, causing the façade to rock and, finally, to overturn and collapse (Figure 6b).

5.1 Geometric and mechanical properties

The façade is made of clay brick and cementitious mortar masonry, having a specific weight around 18 kN/m^3 . The façade is assimilated to a rocking rectangular block of equivalent height 7.64 m (obtained considering the equivalence with center of mass and inertia moment of the original geometry), thickness 0.80 m and width 12.00 m (Table 4).

The parameters necessary to perform the rocking analysis are the radius vector R , the slenderness ratio α , the inertia moment I_0 and the compression spring bed stiffness K'_c reported in Table 4.

Figure 6: Case of study: San Filippo Neri's church in Camerino (Macerata): main façade before (a) and after (b) collapse.

Figure 7: Geometrical dimensions of the case of study (from [26]).

Equivalent height [m]	Thickness [m]	Width [m]	R [m]	α [rad]	I_0	K'_c [MN/m ²]
					[m ⁴]	
7.64	0.80	12.00	3.84	0.10	$2.36 \cdot 10^6$	750

Table 4: Geometric characteristics of the rocking façade.

5.2 Analysis method

As already said, the main façade of the church is assumed as rigid block with a compression spring bed simulating the transverse walls. The 40 seismic excitations considered in the study were selected among the most intense ground motions of the 2016-2017 Central Italy earthquake: these earthquakes, belonging to the entire seismic swarm, occurred between August 2016 and January 2017 [26]. Among them, the four that caused the highest rotation amplitudes of the masonry façade – and also its overturning – are here considered.

Their features in terms of Peak Ground Acceleration (PGA) and Peak Ground Velocity (PGV), obtained from the Engineering Strong Motion Database [27], are summarized in Table 5.

Seismic record	PGA	PGV
(date and station)	(g)	(cm/s)
20160824_AMT	1.10	55.31
20160824_NRC	0.46	37.79
20161030_CLO	0.54	66.33
20161030_NRC	0.62	61.33

Table 5: Peak Ground Acceleration and Peak Ground Velocity of the considered seismic records [27].

The equation of motion (Eqn. (1)), described in detail in [23], is solved with a MATLAB code to analyze the dynamic behavior of the façade. Since the rocking hinge is not formed at the wall base, the seismic records should be applied after a filtering process, duly taking into account the vibration effects of the substructure. Here, considering the wall geometry, a magnification factor of 1.27 is adopted, as explained in [26], [28].

Two values of coefficients of restitution are considered in the analyses:

- 1) The Housner's analytical value, labelled with $e_H = 0.980$ and calculated with Eq. (2).
- 2) The experimental value of coefficient of restitution, evaluated, as said before, considering the average of the values reported in Table 1, and excluding the test #50_1. This process results in considering, for the inward rotation, an average coefficient of restitution $e_e = 0.59$, whereas for the outward rotation the coefficient of restitution is $e_e = 0.68$.

5.3 Discussion of results

Firstly, the strongest records in terms of normalized rotation (θ/α) amplitude are considered. They occurred in 2016, October 30th and, as visible in Table 5, are associated to the highest PGV values. This aspect confirms the seismic vulnerability of rocking walls to high PGVs [29].

Figure 8 displays the time-histories of the normalized rotational response together with the ground acceleration (scaled by the magnification factor of 1.27). At first sight, the adoption of the experimental values of the coefficients of restitution instead of the analytical ones suggested by Housner, leads to generally unsafe-sided results. But it should be considered that an additional dissipation of energy takes undoubtedly place when transverse walls are present and that disregarding it would lead to over conservative results. Seismic vulnerability assessment executed by neglecting the transverse walls could suggest retrofitting interventions that are actually not needed. This aspect is particularly relevant in case of historic buildings, where it is recommended to avoid unnecessary interventions for the preservation of the cultural heritage. In any case, under the 20161030_NRC, which is not characterized by the highest PGA and PGV, in both cases the overturning is delayed, but not prevented if the reduced experimental value of the coefficient of restitution (e_e) is considered. By contrast, under the 20161030_CLO, adopting e_e the façade survives, although its normalized rotation is quite high ($\theta/\alpha > 0.5$).

Figure 8: Rocking response to 20161030_NRC (a) and to 20161030_CLO (b).

Considering the less intense earthquake occurred in 2016, August 24th, the passage from the analytical to the experimental value of coefficient of restitution implies a reduction of the amplitude peaks, as evident from Figure 9. In particular, under the earthquake with highest PGA and PGV, the rocking wall experiences a maximum normalized rotation about 60% that of the maximum rotation computed with the analytical coefficient of restitution.

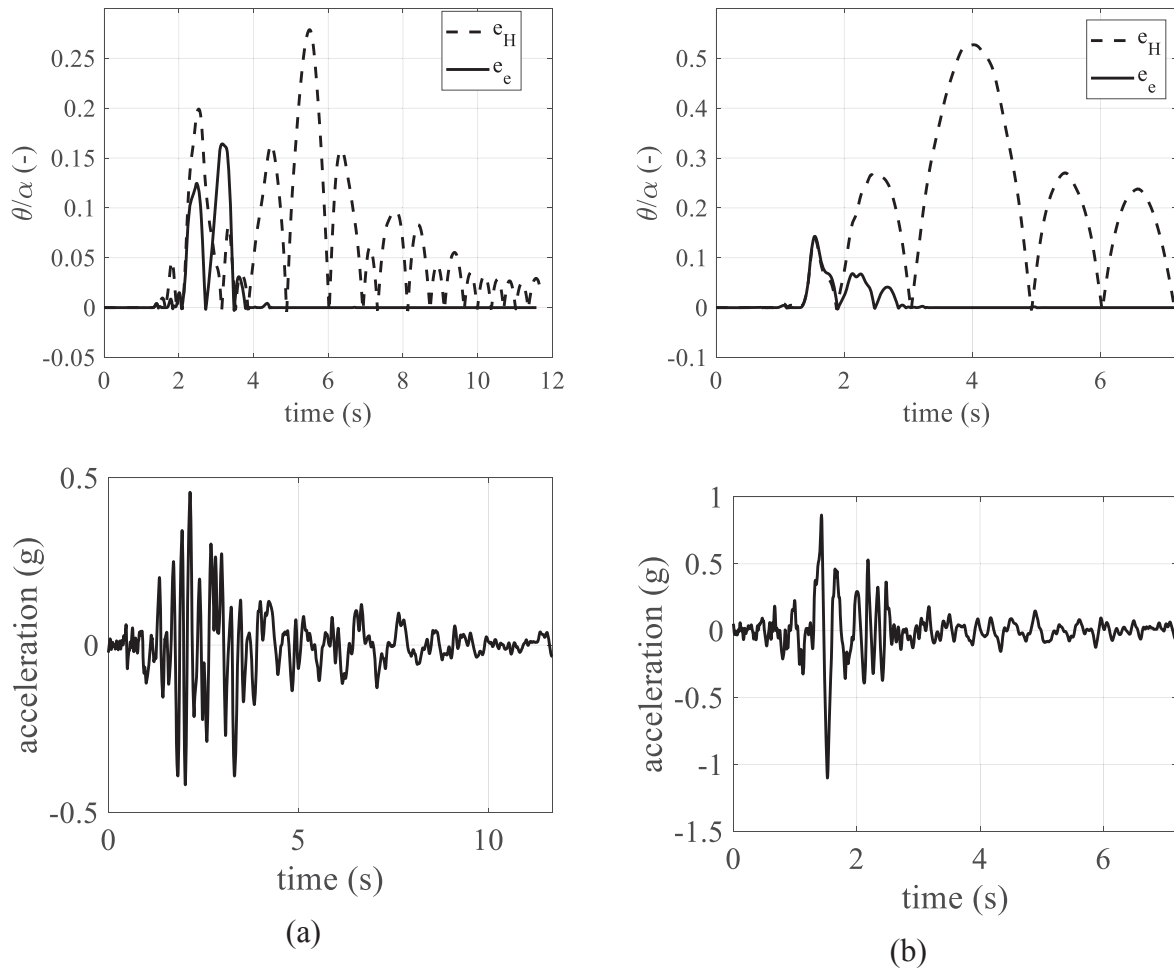

Figure 9: Rocking response to 20160824_NRC (a) and to 20160824_AMT (b).

Moreover, the maximum response is strongly reduced when the experimental coefficient of restitution is used, indeed it is about 25% of the maximum rotation computed with its analytical expression. In both cases, the peaks do not occur at the same time, but with the analytical coefficient of restitution the peak is delayed.

6 CONCLUSIONS

This paper discussed the experimental results of a set of rocking tests performed on a clay brick and cementitious mortar masonry wall tested in free vibration. The ratios of experimental to analytical coefficients of restitution were computed by the peaks of velocity time histories. Afterwards, their average values were used to perform numerical analyses on a church façade struck by the 2016-2017 Central Italy earthquake. The experimental results of the one-sided rocking wall were compared with those obtained on similar unrestrained and restrained walls in the two-sided rocking condition. The comparison shows that relevant parameters are more scattered in the one-sided rocking condition. Regarding the coefficient of restitution, it can be remarked that it is nearly independent on the rotation sign in the two-sided rocking condition; on the contrary, in the one-sided rocking condition it decreases by about 15% passing from the outward rotation to the inward rotation.

The outcomes of the numerical analyses demonstrate that, since the actual experimental values of the coefficient of restitution are generally sensibly lower than the ones estimated according to Housner expression, indirectly considering the influence of transverse walls, their adoption leads to less demanding responses. Consequently, assumption of the Housner coefficients can result too much safe-sided, so implying needs of interventions not always justified. Moreover, the substitution of the Housner coefficients of restitution with more realistic ones, on the one hand, delays but not prevents overturning under the stronger earthquakes, on the other hand maximizes the differences between the stable responses under earthquakes characterized by lower PGAs and PGVs.

In conclusion, since a realistic and critical evaluation of the coefficient of restitution is a key topic in order to avoid unnecessary and expensive retrofitting interventions especially regarding heritage structures, further studies are ongoing.

Abstract

Masonry structures have been observed to display a high vulnerability to failure under seismic action. This stems from the fact that their structural configurations usually lack adequate connections among the distinct elements, resulting in the formation of local mechanisms experiencing Out-Of-Plane (OOP) collapse. In this context, rocking dynamics has proven to be a valuable methodology for the analysis of masonry walls. Classical rocking theory can provide a fast solution to the dynamic phenomena taking place if simple configurations are examined. Nevertheless, as the degrees of freedom and the boundary conditions increase, the complexity increases, and thus the classical rocking theory becomes impractical. In the meantime, recent developments in computational modelling of masonry structures are gaining significant attraction. This includes block-based models which inherently consider the complexity of the problem and enable the solution to be obtained easily in the discretised spatial and time domains. However, despite their widespread use, applications of such models usually lack a reliable treatment of damping.

The present work attempts to bridge the gap between the well-established energy loss of the classical rocking theory and the treatment of damping of block-based computational models. To do so, the dynamics of the problem are reviewed and an equivalent viscous damping model is proposed. A unilateral dashpot formulation allows the replication of the impulsive nature of the energy loss at impact. Afterwards, a calibration methodology is adopted for the practical range of the problem's parameters and a ready-to-use equation is provided, which respects energy equivalence. The performance of the proposed damping model is also evaluated through comparisons with experimental results.

Keywords: rocking, coefficient of restitution, viscous damping, numerical modelling, out-of-plane.

1 INTRODUCTION

Masonry structures constitute a significant part of our built heritage, with earthquakes representing a severe threat to their integrity [1]. During seismic events, such structures tend to fail via specific collapse mechanisms, with out-of-plane (OOP) collapse recognised to be the most frequent and destructive – especially in the case of façade walls inadequately connected with the rest of the structural elements [2]. Static approaches have been widely used to assess the collapse of the OOP mechanisms, resorting either to limit analysis methods [3], or to advanced numerical techniques [4]. However, static approaches display inherent limitations, since the inertial effects are neglected and the dynamic reserve of stability is disregarded. Therefore, over-conservatism characterises the static approaches [5], while dynamic techniques suggest a more reliable modelling solution [6].

In this context, rocking dynamics has been proposed to simulate the response of OOP mechanisms [7]. In the classical work of Housner [8], the equations of motion of a rigid body rocking over its base have been developed. Since then, extensive research has evaluated the influence on the rocking response of both seismological characteristics [9], and structural features, such as the presence of transverse walls [10, 11], horizontal elements [12–14] and restraints [13, 15–17]. Rocking dynamics assumes that energy is lost at every impact, and is captured by the Coefficient of Restitution (CoR) which correlates the angular velocity of the structure before and after impact. The CoR may be computed analytically by assuming conservation of angular momentum [8]. Despite small discrepancies, experimental campaigns have confirmed the validity of the analytical approach [18–20], particularly from a statistical perspective [21]. Nevertheless, as the Degrees-Of-Freedom (DOFs) and the Boundary-Conditions (BCs) of the problem increase, the complexity introduced transforms the method to one of impractical interest [22, 23].

In the meanwhile, recent developments in numerical simulation methods with block-based models are gaining momentum, especially due to the ease in representing complex masonry textures, BCs, interactions between the contacting bodies, and material nonlinearities. Among them, the most commonly used are the Finite Element Method (FEM) [24], the Discrete Element Method (DEM) [25], and the multi-body dynamics [26, 27]. However, despite their widespread use, block-based numerical modelling techniques lack a reliable method of replicating energy loss at impact [28, 29]. Usually, viscous damping models are employed [30–32], yet, without confidence about their equivalence with the overall more consistent rocking theory.

The present work aims to bridge the gap between the treatment of energy loss of the statistically-accurate classical rocking theory and the widely used numerical block-based modelling. This is achieved by “tuning” a viscous damping model to replicate both the manner and extent of energy loss indicated by the rocking theory based on the CoR. To this end, the main dynamic and modelling characteristics of both the theoretical and numerical modelling techniques are described in Section 2. Subsequently, Section 3 presents the calibration methodology, resulting in the proposal of a pertinent ready-to-use equation which respects energy loss equivalence between the examined methods. Finally, the performance of the numerical viscous damping model is assessed in Section 4, where an experimental campaign from the literature is employed as a reference.

2 STRATEGIES FOR MODELLING ROCKING STRUCTURES

2.1 Analytical modelling

Consider a rigid block exhibiting planar rocking motion over its rigid base, as shown in Figure 1 (a). In this case, the equation of motion can be written as [8]:

$$\ddot{\theta} = -p^2 \left[\sin(\pm\alpha - \theta) + \frac{\ddot{u}_g}{g} \cos(\pm\alpha - \theta) \right] \quad (1)$$

where α is the slenderness of the block, θ describes the rocking response and \ddot{u}_g denotes the seismic ground acceleration. The positive and negative signs in Eq. (1) depend on the sign of θ , while p is defined as $p = \sqrt{mgR / I_0}$, with m referring to the mass of the block, and I_0 the rotational moment of inertia with respect to the pivot points. The moment-rotation diagram of the rigid system is indicated by the solid line in Figure 1 (c).

The equation of motion (Eq. (1)) describes the smooth part of the rocking motion, i.e. when pivoting, while nonsmooth impacts interrupt the response. Impacts are treated as instantaneous events that lead to energy loss in the form of radiation damping. Assuming no bouncing or sliding, the CoR e sufficiently describes the contact event, by connecting the pre-impact and post-impact angular velocities. Then, conservation of angular momentum yields [8]:

$$e = 1 - \frac{3}{2} \sin^2 \alpha \quad (2)$$

Clearly, the energy loss, in this case, relies solely upon the slenderness of the block and not its material characteristics.

The solution of the analytical problem herein is obtained by solving the differential Eq. (1) interrupted by event-based impacts, using mathematical programming in MATLAB.

2.2 Numerical modelling

Numerical block-based models introduce an interface stiffness to describe the interaction of the contact bodies (in this case, the block and the base, see Figure 1 (b)), working on the normal (k_n) and tangential (k_s) directions of contact. Importantly, the interface stiffness might be used to replicate actual stiffness properties of contacting bodies [33], simulate macro characteristics such as mortar flexibility [19] and degradation [34], or foundation flexibility

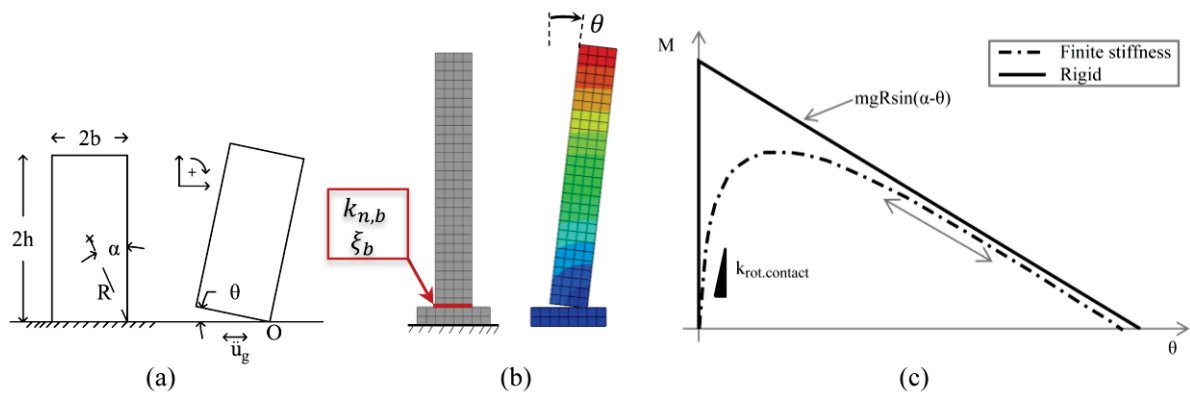

Figure 1: (a) Scheme of the classical rocking rigid block; (b) Numerical modelling of the rocking block with finite stiffness; and (c) Moment-rotation diagram of rigid and finite stiffness modelling techniques.

[35]. Consequently, the finite stiffness of the system ($k_{rot.contact}$, the moment-rotation curve for which is also shown also in Figure 1 (c)), results in impacts that occur over finite displacement and time, in contrast with the instantaneous behaviour of the analytical model.

Concerning energy loss, numerical block-based models commonly adopt viscous damping formulations, which are mathematical “artifices” used to simulate dissipative phenomena not considered explicitly [36]. Note that viscous damping models have a continuous nature, seemingly in contrast with the event-based CoR theory. A variety of viscous damping formulations are available depending on: i) the degrees of freedom used, ii) the response of the model during the time-history, and iii) the methods used to calibrate them [37]. Among them, a stiffness-proportional dashpot definition acting at the contact interfaces seems the most appropriate for simulation of the instantaneous features of the rocking impacts [38].

In the present work, the finite element environment of ABAQUS CAE [39] is used, where the solution is obtained using an explicit time-stepping integration. The rocking block is set to interact with its base through the normal k_n and tangential k_s interface stiffnesses. Moreover, a unilateral dashpot viscous damping model governs the interacting bodies, with a damping ratio ξ . It is worth noting that the validity of the adopted modelling technique has been confirmed also in other block-based simulation software [38], including implicit FEM and explicit DEM methods. This indicates universal applicability of the proposed numerical viscous damping model.

3 A VISCOUS DAMPING MODEL PROPOSAL

3.1 Calibration methodology

Since all viscous damping models need to be “tuned” to reproduce the desired energy dissipation, a phenomenological calibration methodology is adopted. More specifically, the energy loss of the classic rocking dynamics is considered as a reference, and the numerical viscous damping model is adjusted to mimic the former. In essence, the objective is to find a correlation among the CoR e and the damping ratio ξ . Evidently, the free-rocking problem is examined, where dissipation phenomena have a major impact on the response.

To this end, both modelling techniques are used to solve the rocking problem and pairs of $\xi - e$ are generated based on which response-histories match the best. This is done after comparing the rocking response of the two modelling techniques and minimising their root mean square difference. During the calibration process, all parameters possibly affecting the response are examined, i.e. i) the scale R , ii) the slenderness H/B , iii) the rocking amplitude θ_0/α , and iv) the normal interface stiffness k_n . In addition, the influence of the CoR e is also varied, independently of the slenderness of the block, i.e. Eq. (2) is disregarded. This choice allows the viscous damping proposal to be adaptable to any CoR correction suggestions, based either on experimental [10, 19], or theoretical basis [40, 41]. The ranges of the independent parameters that are varied during the calibration process are shown in Table 1. Among them, the scale has been found not to affect the viscous damping model, while non-significant influence is caused by the variations of the rocking amplitude (for more details, see [38]). Therefore, only the slenderness and the normal interface stiffness are essential to be included in the viscous damping model proposal.

Parameter	Range	Reference value
Scale: R [m]	1.4 – 2.8	2.1
Slenderness: h/b [-]	4.0 – 15.0	7.0
Amplitude: θ_0/α [-]	0.3 – 0.8	0.5
Normal interface stiffness: k_n [N/m^3]	$0.5 \cdot 10^8$ – $30 \cdot 10^8$	$5 \cdot 10^8$

Table 1: Independent parameters considered for calibration.

3.2 Proposed viscous damping model

The generated $\xi - e$ pairs of all the previously mentioned variations, 245 in total, are fitted through a multivariable nonlinear regression analysis. As a result, the following predictive equation is proposed which correlates the CoR e with the damping ratio of the viscous model ξ :

$$\xi_b = -0.000292 \cdot \left(\frac{H}{B} \right)^{0.935} \cdot k_n^{0.343} \cdot \ln e \quad (3)$$

Note that Eq. (3) is characterised by a coefficient of determination of $R^2 = 0.978$ over the 245 data $\xi - e$ pairs, showing a noteworthy estimation capability.

To illustrate the phenomenological calibration, one exemplary case of the predictive performance of Eq. (3) is shown in Figure 2. The comparison examines a rocking block with dimensions $2h = 4.2$ m and $2b = 0.6$ m, CoR $e = 0.97$, normal interface stiffness $k_n = 5 \cdot 10^8$ [N/m^3] and damping ratio $\xi = 5.9$ % according to Eq. (3). More specifically, Figure 2 (a) shows the rocking response of both the numerical viscous model and the analytical CoR based model, while Figure 2 (b) illustrates the corresponding energy content of both models. Clearly, a very good agreement is observed between the two methods. Importantly, the numerical viscous model presents a step-like response similar to that of the analytical CoR-based model: significant energy is lost only at impacts, gradually dissipating the free-rocking response. A small divergence is noticed only at smaller rocking amplitudes, i.e. $\theta_0/\alpha \leq 0.1$, which, however, are not expected to be decisive for the rocking stability of the structure, and thus assumed acceptable. Overall, the numerical viscous damping model shows a similar dissipative nature with that of the analytical CoR-based model, and the fitted relationship Eq. (3) a good predictive capability.

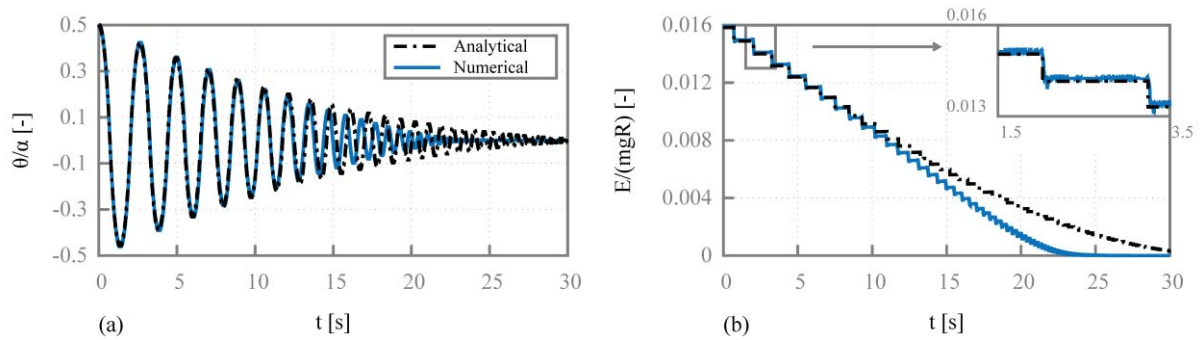

Figure 2: Behaviour of the viscous damping model. Comparison with the analytical model, in terms of variation of the (a) rocking angle and (b) total energy content over time. Details of the examined structure: $2h = 4.2$ [m],

$2b = 0.6$ m, $e = 0.97$, $k_n = 5 \cdot 10^8$ [N/m^3] and $\xi = 5.9$ %.

4 EVALUATION OF THE PROPOSED VISCOUS MODEL

Finally, the performance of the proposed numerical viscous damping model is assessed. While its calibration has been based on the analytical rocking model, its robustness is tested using actual experimental results. To this end, the experimental campaign reported by Peña [42] is used, where granite rocking blocks were tested under free- and forced-rocking vibrations. Details regarding the specimens' and excitation characteristics can be found in Table 2 and [42]. Given the fact that the proposed model has been calibrated independently of Eq. (2), the experimentally measured CoRs can be inserted in Eq. (3) to get the damping ratio ξ of the viscous damping model.

Specimen	$2h$ [m]	$2b$ [m]	e_{exp} [-]	Tests examined
1	1.0	0.25	0.936	i) Free rocking, ii) Hanning sine with $f = 3.3$ Hz and $a_p = 7$ mm
2	1.0	0.17	0.973	i) Free rocking
3	1.0	0.12	0.978	i) Synthetic ground excitation record 18, load factor 0.5, [42] for details

Table 2: Details of the specimens and examined tests [42].

4.1 Free rocking

Figure 3 (a) compares the free-rocking response of Specimen 1, while Figure 3 (b) the free-rocking response of Specimen 2, respectively. The results of the numerical simulations show a very good match with the experimental response both in terms of rocking phase and amplitude. Slight differences appear after several cycles, yet, given the experimental uncertainties and the simplicity of the problem, the overall dissipative phenomena are very well captured.

4.2 Forced rocking

To further evaluate the numerical viscous damping model, results of forced-rocking tests are compared in Figure 4. More specifically, Figure 4 (a) shows Specimen 1 under a hanning-sine excitation, while Figure 4 (b) illustrates Specimen 3 under a synthetic ground motion excitation [42]. For both cases, the numerical viscous damping model presents a rather good estimation of the experimental response. Slight differences are also observed, most notably the earlier collapse of the numerical model of Specimen 3. Nevertheless, considering the non-deterministic and bifurcating behaviour of the rocking problem, the performance of the nu-

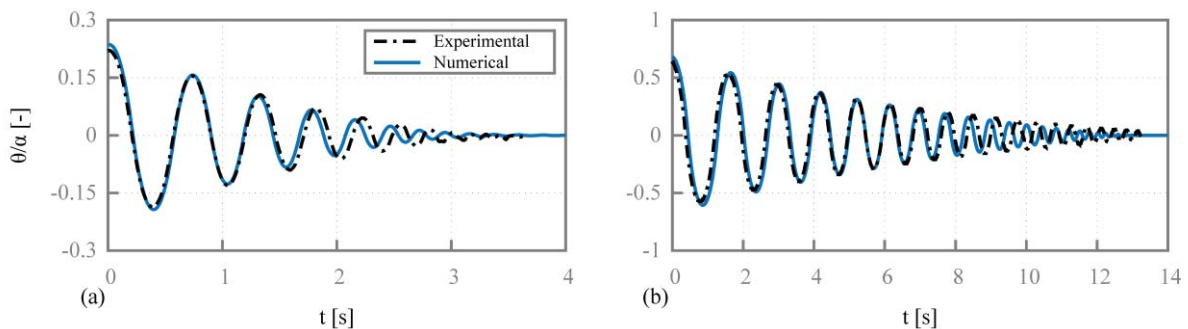

Figure 3: Free-rocking response of the proposed numerical viscous damping model compared to the experimental response reported in [42] of (a) Specimen 1 and (b) Specimen 2.

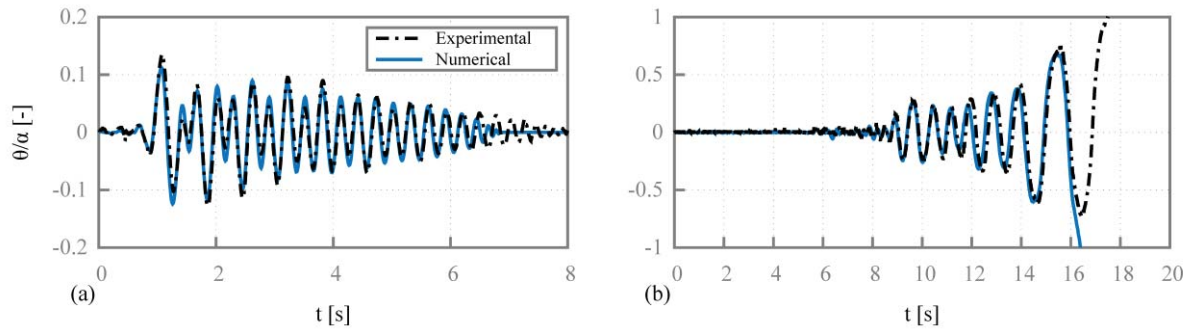

Figure 4: Forced-rocking response of the proposed numerical viscous damping model compared to the experimental response reported in [42] of (a) Specimen 1 under hanning-sine excitation and (b) Specimen 3 under synthetic ground excitation (Table 2).

merical viscous damping model is regarded as satisfactory.

5 CONCLUSIONS

This work proposes a numerical viscous damping model, aimed at simulation of the energy losses of the rocking problem using numerical block-based modelling techniques. This is achieved by following a phenomenological calibration methodology, where the analytical CoR-based rocking model is assumed as a reference and the viscous damping model is tuned accordingly. It is noteworthy that the suggestion of using a stiffness-proportional unilateral dashpot model results in impulsive energy losses, similarly to that of the CoR method. The performance of the proposed viscous damping model has been evaluated against experimental results from the literature, both under free- and forced-rocking vibrations, where its adequacy is highlighted.

In conclusion, the present paper suggests a reliable and consistent way to model energy losses when using numerical block-based models. This offers the possibility of modelling the rocking phenomena of more complex structures, with many DOFs or varying BCs, while additional material nonlinearities can be also easily included. Moreover, the proposed viscous damping model is universal and adaptable, as it can be used with any block-based numerical method and with any experimental or theoretical corrections on the used CoR.

Abstract

The seismic performance of masonry churches is mainly governed by the out-of-plane mechanisms. Among them, the greater seismic vulnerability can be associated to the out-of-plane mechanism of the façade. If the masonry quality ensures a monolithic out-of-plane behaviour, the dynamic analysis of a rigid rocking block allows a reliable estimation of the seismic capacity of the façade, provided that the element boundary conditions are well assessed. In the present paper, the literature rocking models are adopted for a vulnerability assessment of churches' masonry façades characterized by different geometries. At this aim, fragility curves are defined by means of the Cloud Analysis approach considering earthquakes recorded in the Central Italy area to account for the record-to-record variability.

Keywords: Rocking; masonry façades; cloud analysis; fragility curves.

1 INTRODUCTION

The seismic performance of historic masonry churches is governed by the local out-of-plane response of the single structural components (i.e., façades, transverse walls, etc.). Among all the macro-elements, the post-earthquake surveys highlight the greatest vulnerability of the façade [1]-[6], which dynamic performance is typically characterized by a rigid-body behaviour.

A common methodology for the dynamic simulation of simple overturning mechanisms is based on rocking motion models where the impacts occurring at the base of the block or against elements preventing inward rotation (i.e. transverse walls or roofings) are accounted for by means of a kinetic energy dampening. The dynamic analysis of the “two-sided rocking” –occurring in the case of isolated elements– was firstly studied by Housner [7]. Subsequently, Yim et al. [8] observed a great sensitivity by the dimensional characteristics of the block or by the

ground motion shapes, whilst Makris & Roussos [9] found a dependence of the block overturning on both the earthquake intensity and the pulse length. The first studies on the “*one-sided rocking*” –developing if the inward rotations are prevented– were performed by Hogan [10], lately the issue was more extensively addressed: the energy dissipation phenomena were experimentally and theoretically investigated by Sorrentino et al. [11]-[12], while a different mechanical model to study the unilateral rocking motion was proposed by Giresini et al. [13]-[14]. All the theoretical models proposed in the scientific literature were applied to investigate the vulnerability of different masonry macro-elements, among which the church façades [15]-[16].

In this paper, the classic rocking models are employed to define fragility curves for five geometries of masonry church façades subjected to unscaled ground motions recorded in the Central Italy area. Aim of the work is the application of a non-linear dynamic procedure, known as Cloud Analysis [17], in which a structural response parameter (i.e. the maximum rotation of the rocking block) and the intensity measures of an as-recorded ground motion are fitted in the logarithmic scale to obtain a linear regression model. The approach was employed for its simplicity and the limited number of required analyses. In the paper, both the two-sided and the one-sided rocking motion are considered. The obtained fragility curves are finally compared to evaluate the influence of the geometrical features of the blocks and of the kinematic mechanism (one-sided or two-sided) on the seismic vulnerability of masonry churches’ façades.

2 MODEL FOR THE ROCKING MOTION OF A MASONRY FAÇADE

If the masonry can be regarded as a no-tension monolithic material characterized by an infinite compressive strength, a masonry church façade can be studied as a rigid block involved into a rocking motion as a consequence of an earthquake over a certain magnitude.

The analytical model of the rocking mechanism starts from the Lagrange equation and reaches the formulation proposed by Housner in 1963 [7], if the body deformability is neglected and the occurrence of rotations without sliding is assumed:

$$\ddot{\theta} = -p^2 \cdot [\operatorname{sgn}\theta \cdot \sin(\alpha - |\theta|) + a_g(t) \cdot \cos(\alpha - |\theta|)] \quad (1)$$

where θ is the rotation of the block, $p^2 = (m \cdot g \cdot R) / I_0$ is the dynamic coefficient of the block, $I_0 = I_G + m \cdot R^2$ is the moment of inertia about the two centres of rotation (points O and O' in Fig. 1), I_G is the moment of inertia about the centre of gravity, m and R are the mass and the half-diagonal of the block respectively, α is the inverse of the block slenderness and $a_g(t)$ is the ground motion acceleration.

The rocking motion starts if the seismic acceleration exceeds the kinematic acceleration a_{RM} :

$$a_{RM} = g \tan \alpha \quad (2)$$

and the overturning condition defines the failure when a rotation of the block under the seismic motion higher than the angle α is attained. This statement may be overcome in the case of forced oscillatory motion: consecutive contrary pulses can in fact bring the system again in an equilibrium condition even if the rotation of the block exceeds the angle α .

Eq. (1) can be employed for any simple out-of-plane mechanism, on the condition to properly account for the dissipative phenomena taking place at each impact. Therefore, at the theoretical level, the difference between the one-sided and two-sided rocking behaviour is related only to the kinetic energy damped due to the different boundary conditions. The issue can be assessed considering the velocity reduction experienced by the element after each impact during the two-sided or the one-sided rocking motion.

FIGURE 1. Models of the rocking block (the geometrical features are expressed by the base B , the height H , the radius vector R , the angle α , the center of gravity G): a) initial position; b) two sided model; c) one sided model.

In the case of two-sided motion (Fig. 1), the behaviour is governed by the rotation θ around the two corners O and O' , those alternatively become the centers of block rotation. After each oscillation, the element comes back into the vertical position and an impact on the base occurs. Such rebound effect implies a reduction of the kinetic energy after the impact, with a consequent energy damping. According to the model proposed by Housner in 1963 [7], the reduction in angular velocity due to an impact of infinitesimal duration can be evaluated by means of the velocity reduction factor $e_{an,2s}$, given by the ratio between the velocities experienced by the block after and before the impact. By imposing the conservation of the angular momentum about the center of rotation before and after the impact, the velocity reduction factor can be evaluated for a rectangular block as:

$$e_{an,2s} = 1 - \frac{3}{2} \sin^2 \alpha \quad (5)$$

With Eq. (5) the initial conditions after each impact can be evaluated and the amplitude of the oscillation during the rocking motion can be still estimated by using Eq. (1). The higher the velocity reduction factor, the smaller is the energy loss due to impact and consequently the damping of the rocking motion of the element.

When the rocking motion is admitted only in one direction, as shown in the Figure 1, the block will oscillate around the corner O , and after reaching the maximum rotation it comes back again to its initial position and will impact to the restraint, which prevents the rotation around the opposite corner. In this case the motion is defined *one-sided rocking*. The influence of the sidewalls on the rocking motion can be studied according to Sorrentino et al. 2011 [12]. In this model the transverse wall is modelled as a fixed restraint. Admitting that there is a little gap between façade and transverse walls, after the first impact against the base, the block experiences an infinitesimal counter-clockwise rotation and a subsequent impact against the upper corner. The latter condition involves an initial change in the rocking hinge and a rotation reversal of the element: the clockwise rotation around O will cause a third impact, against the base, after which the block has returned to vertical position. According to this approach [12], the analytic transversal velocity reduction factor for the one-sided rocking motion $e_{an,1s}$, is:

$$e_{an,1s} = \left(1 - \frac{3}{2} \sin^2 \alpha\right)^2 \left(1 - \frac{3}{2} \cos^2 \alpha\right) \quad (6)$$

Of course, in the case of one-sided rocking the velocity reduction factor is smaller than the two-sided ones, due to the higher dissipation occurring at each impact.

3 DYNAMIC ANALYSES

The seismic performance of typical Italian masonry churches' façades or portion of them have been investigated by means of rocking dynamic analysis. The overturning conditions of masonry churches' façades, involved in earthquake events, is here evaluated with reference to five rigid blocks. In table 1 are reported the principal features of the investigated elements: typology, height (H), base (B), slenderness $\lambda = H/B$, kinematic accelerations a_{rm} (minimum acceleration that causes rocking). With the first set of geometries (1, 2 and 3), the incidence of the variation in slenderness is investigated. For the second set (1, 4 and 5), it is analyzed the influence of the base dimension fixed the slenderness. The selected geometries are subjected to the unscaled natural ground motions described in the following.

<i>Geometry</i>	<i>Typology</i>	<i>Height</i>	<i>Base</i>	λ	a_{rm}
[-]	[-]	[m]	[m]	[-]	[m/s ²]
F1	Façade of small church	6	0.6	10	0.98
F2	Intermediate façade between 1 and 3	4.5	0.6	7.5	1.31
F3	Façade of uppermost story	3	0.6	5	1.98
F4	Façade of big church	12	1.2	10	0.98
F5	Plane belfry	3	0.3	10	0.98

TABLE 1. Principal features of the walls: typology, height, base, slenderness and kinematic acceleration.

With the aim to simulate the performance of the Apennine Churches stricken by the Central Italy seismic sequence, 89 natural accelerograms recorded during the last twenty years in the Central Italy area are considered to account for the record-to-record variability.

89 time-histories characterized by magnitude between 4 and 6.5 has been collected into a database; according to [18], moment magnitude M_L lower than 3.5 are excluded. The adopted database covers intervals of peak ground acceleration (PGA) up to 1g, peak ground velocity (PGV) up to 0.85 m/s, Housner Intensity (H_I) up to 2.8 cm and Arias Intensity (I_A) up to 7 m/s.

ID	Station	Date	Time	Epicentral Distance	PGA	PGV	I_A	H_I
				[km]	[g]	[m/s]	[m/s]	[cm]
MZ30 ₂	Amatrice	30/10/2016	06:40:18	27.2	0.48	0.48	1.54	1.22
T1201 ₂	Domo	30/10/2016	06:40:18	22.6	0.48	0.87	2.24	2.12

Table 2. Seismic Characteristics of the Selected Natural Ground Motion.

In order to analyze the sensitivity of the selected masonry churches' façades on the shape of the natural ground motion, two records with the same peak ground acceleration were selected. Consequently, the other seismic intensity measures (Peak Ground Velocity, PGV, Arias Intensity, I_A ; Housner Intensity, H_I) differ as reported in Table 2. In Figure 5 the time-histories of the selected ground-motions are shown.

FIGURE 2: Selected ground-motions (the second one is shifted by 35 seconds).

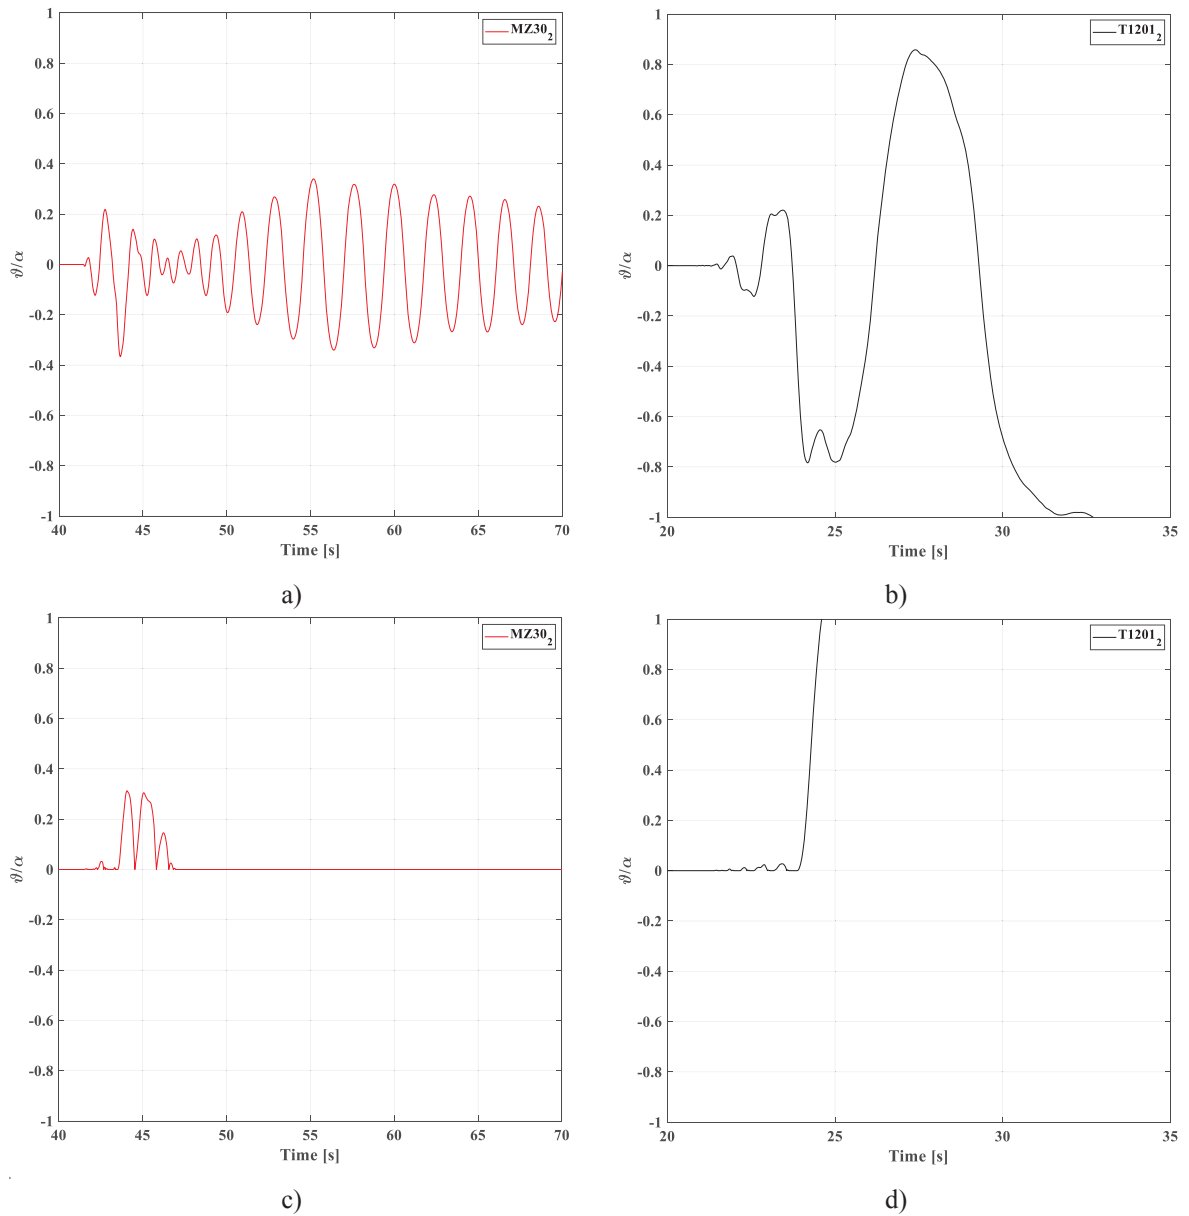

FIGURE 3: Seismic response of faades GEO1 involved in the two-sided rocking motion: a) MZ30₂ earthquake rocking-inducing; b) T1201₂ earthquake overturning-inducing; c) MZ30₂ earthquake rocking-inducing; d) T1201₂ earthquake overturning-inducing.

The seismic response of the façades in two-sided rocking motion characterized by slenderness $\lambda=10$ (F1) subjected to the MZ30₂ (Fig.3a) or to the T1201₂ (Fig.3b) earthquakes is firstly investigated. It is important to observe the different response of the façades to the earthquakes: the MZ30₂ time-history induces the rocking motion, while the T1201₂ ground motion –characterized by higher PGV, Arias Intensity and Housner intensity– causes the failure of the element, i.e. the block overturning. Similarly, the one-sided seismic response of the façades with $\lambda=10$ (GEO1) to the MZ30₂ (Fig.3c) or to the T1201₂ (Fig.3d) ground-motions shows the dependence of the façade performance by the earthquake's shape.

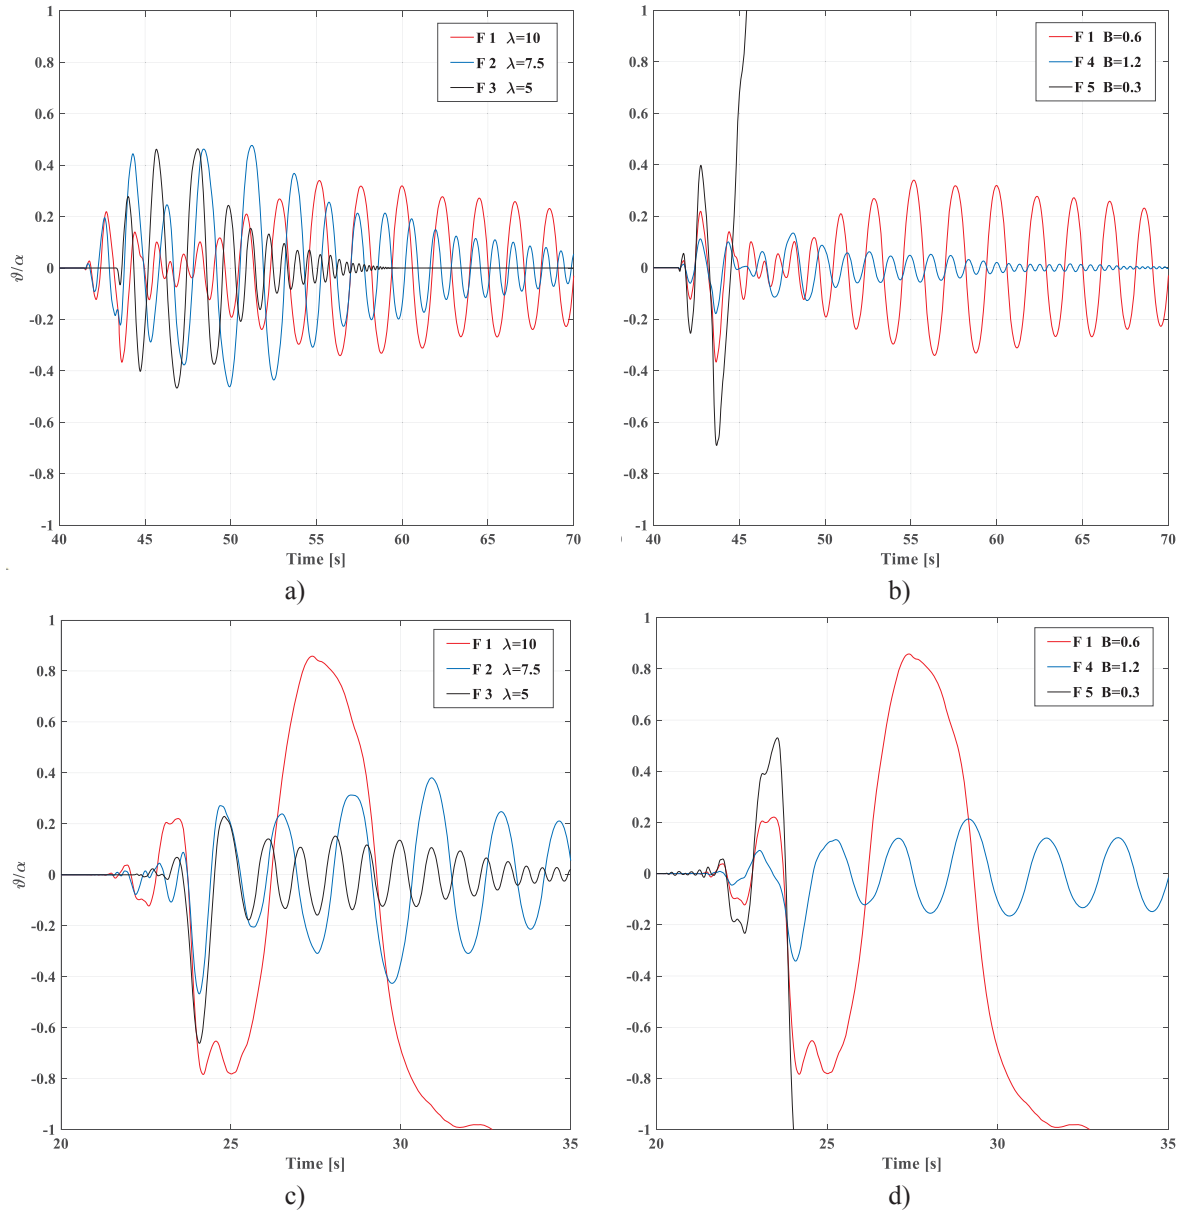

FIGURE 4: Two-sided seismic response of all façades subjected to MZ30₂: a) influence of the slenderness λ for $b=0.6$; b) influence of the base b for $\lambda=10$, and subjected to T1201₂: c) influence of the slenderness λ ; d) influence of the base b .

Finally, the results obtained by the parametric analysis are represented. In Figure 4 the influence of both the façade slenderness and thickness on the dynamic response in two-sided motion is represented. It can be noted that increasing the slenderness (Fig.4a and Fig.4c) the

rocking motion is delayed, due to the different value of the kinematic acceleration a_{RM} . Additionally, once the rocking motion begins, stockier blocks with similar slenderness (F2 and F3) are characterized by similar responses, while the slender block collapses under the heavier earthquake (T1201₂). With equal slenderness (Fig.4b and Fig.4d) the stabilizing effect due to the base dimension is clear: smaller the base, higher is the block rotations. Therefore, the block with the smaller base (F5) can collapse also under the lighter earthquake (MZ30₂).

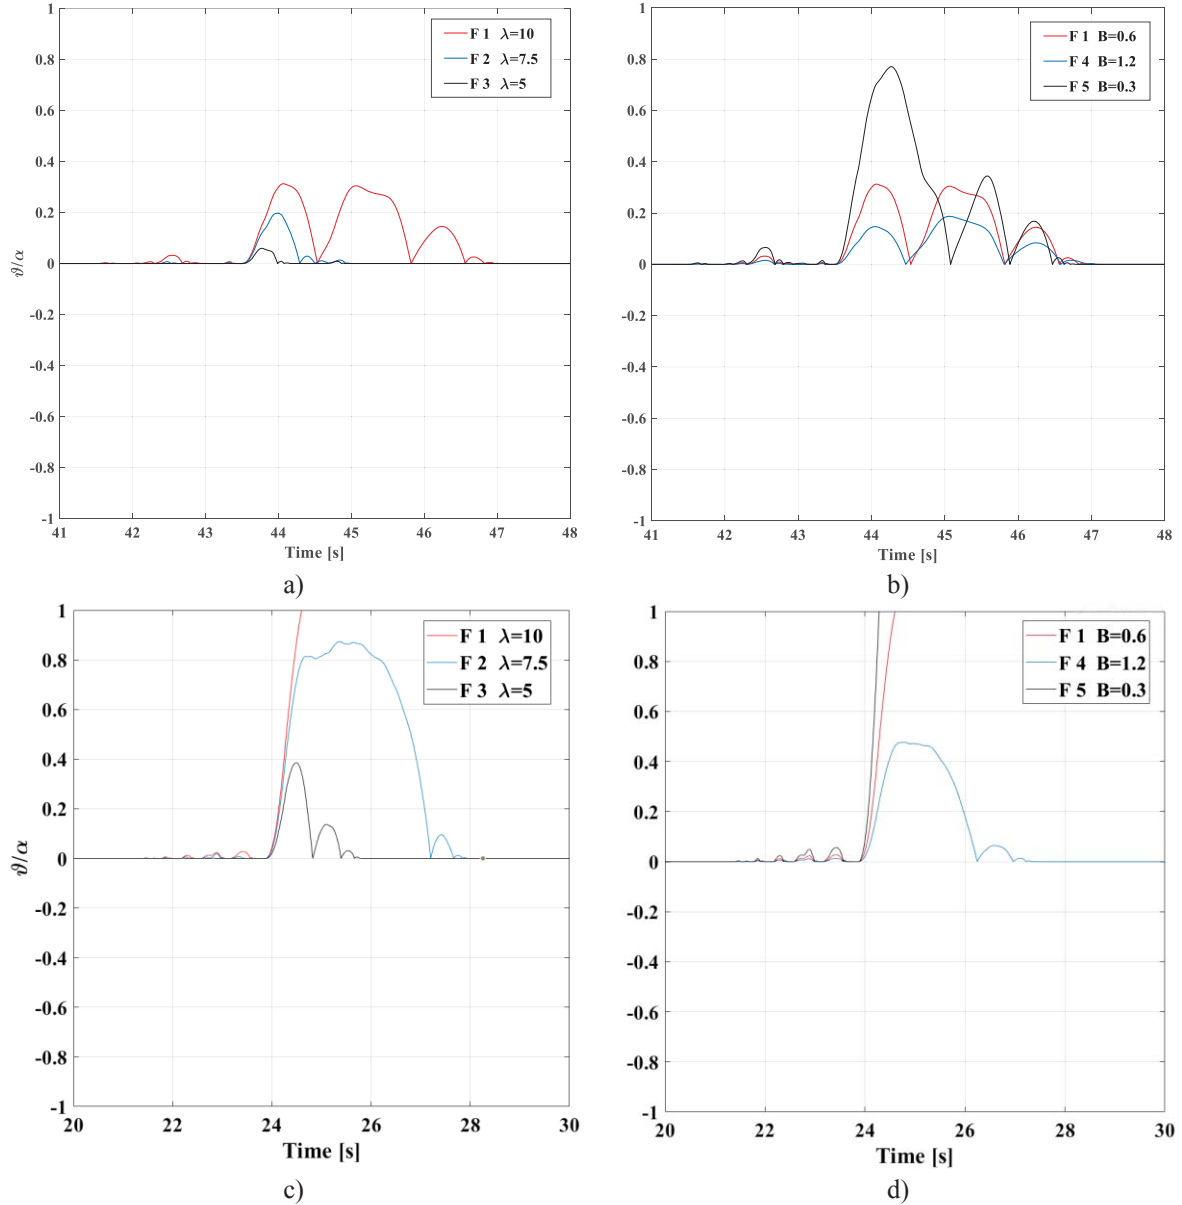

FIGURE 5: One-sided seismic response of all façades subjected to MZ30₂: a) influence of the slenderness λ for $b=0.6$; b) influence of the base b for $\lambda=10$, and subjected to T1201₂; c) influence of the slenderness; d) influence of the base.

Concerning the one-sided rocking response, a similar trend can be observed (Fig. 5). Nevertheless, the dynamic response in the one-sided can be more dampened than the two-sided rocking, depending on the ground motion shape as well as for the dissipative effect of the impacts against the sidewalls. In detail, the rocking motion is delayed increasing the slenderness (Fig.5a and Fig.5c), and the slender block collapses under the heavier earthquake (T1201₂) once the

rocking motion begins. Moreover, with equal slenderness (Fig.5b and Fig.5d) the dimension of the base has a stabilizing effect on the dynamic response: smaller the base, higher the rotations.

4 PROBABILISTIC SEISMIC ANALYSIS

The vulnerability of the selected masonry churches' façades is assessed by estimating the conditional probability P that the seismic demand D (measured with a specific engineering demand parameter, EDP) is higher than its capacity C for a given value of a seismic intensity (IM). Conventionally, the capacity C is derived by the results of incremental dynamic analysis (IDA) or multi stripe analysis (MSA). In the present work, instead, the Modified Cloud Analysis [17], an innovative and at the same time simple approach, is employed. The effectiveness of the proposed approach has been already established in other structural applications [19].

The structural fragility obtained by a modified cloud analysis in order to include the "collapse cases" [17] can be expressed as the probability that D exceeding the unity for a given IM :

$$P(EPD > 1|IM) = \Phi\left(\frac{\ln\eta_{D|IM}}{\beta_{\ln D|IM}}\right) \cdot \frac{e^{-(\alpha_0 + \alpha_1 \ln(IM))}}{1 + e^{-(\alpha_0 + \alpha_1 \ln(IM))}} + \frac{1}{1 + e^{-(\alpha_0 + \alpha_1 \ln(IM))}} \quad (9)$$

where Φ is the standardized Gaussian cumulative distribution function (CDF), and $\eta_{D|IM}$ and $\beta_{D|IM}$ are the conditional median and logarithmic standard deviation (dispersion) of the natural logarithm of D given IM for the No Collapse data. Based on the Cloud Analysis, these two parameters are obtained by performing a logarithmic linear regression on the No-Collapse data.

The parameter α_0 and α_1 have been instead evaluated through the logistic regression model applied to all records, distinguishing 1 or 0 depending on the collapse attainment or not [17].

The EPD assumed for the rigid block is the maximum normalized rotation, i.e. the ratio of the maximum rotation θ_{max} attained during the dynamic rocking analysis for each ground motion and the overturning limit condition $\alpha = \tan(B/H)$, corresponding to the loss of equilibrium.

Therefore, the EDP can assume the following values: the element is stationary (non-rocking), $|\theta_{max}|/\alpha = 0$; the rocking motion is enabled, $0 < |\theta_{max}|/\alpha < 1$; the element fails (rocking overturning), $|\theta_{max}|/\alpha > 1$. A percentage of the rocking blocks overturn, in such a case the EPD attains an arbitrarily large value $|\theta_{max}|/\alpha \rightarrow \infty$. The remaining dynamic analyses terminate without overturning, and finite (nonzero) values of $|\theta_{max}|/\alpha$ are observed.

In this study, the fragility curves at limit state corresponding to the rocking overturn, is developed. The Figure 6a illustrates the obtained fragility curves at collapse for the façades with different slenderness given $IM=PGA$. As already observed by the outcomes of dynamic analyses, slender façades are more vulnerable with respect to the squatter one. The Figure 6b illustrates the probability of overturning for the façades with different value of B . Although the slenderness of the façades is the same, the fragility curve shows an increment in collapse probability decreasing the base dimension. It is worth to note that the fragility curves obtained with the Cloud Analysis for the façades F1, F4 and F5 are comparable to those obtained by Lagomarsino et al. [20] performing the conventional IDA; therefore, the Cloud Fragility approach is reliable for the fragility assessment of elements involved in the two-sided rocking motion.

Concerning the one-sided rocking motion, the fragility curves given $IM=PGA$ are evaluated considering a set of 178 ground motion, 89 in positive direction and 89 in negative direction. In detail, Figure 6c illustrates the probability of overturning for the façades with different slenderness λ . It is worth to note that the obtained fragility curve for F1 (slenderness $\lambda=10$), is similar to that obtained by Giresini et al. [15] by adopting the conventional IDA approach, therefore the Cloud Fragility is feasible also for the one-sided rocking.

As already observed for the two-sided case, the façade vulnerability increases with increasing the slenderness. Considering the façades with the same slenderness and different base (Fig. 6d), the greater vulnerability decreasing the base can be observed, as for the two-sided motion. Comparing the fragility curves for one-sided and two-sided case, in the case of the one-sided rocking motion the fragility curves show higher mean and standard deviation with respect to the two-sided oscillation.

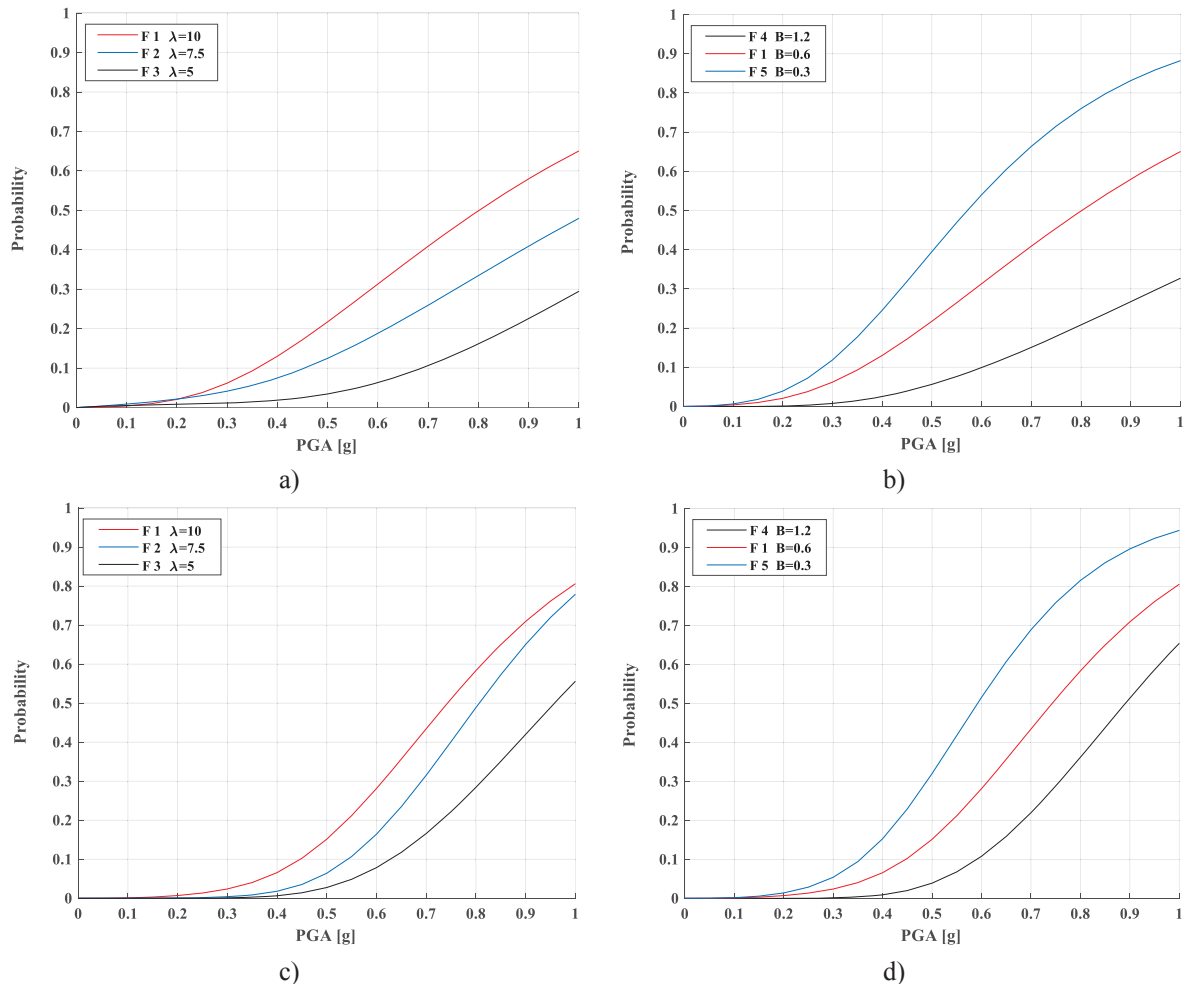

FIGURE 6. Cloud fragility in the two-sided motion: a) influence of the slenderness; b) influence of the base, and Cloud fragility in the one-sided motion: c) influence of the slenderness; d) influence of the base.

The presented fragility curves are developed adopting the PGA as *IM*, because it is in general the most used *IM* for various structural typologies. Nevertheless, the PGA is not always the most efficient *IM* for the analyzed structural typologies [14][21][22][23]. In particular, the most efficient *IM* can be different for the case of two-sided oscillation with respect to the one-side oscillation as already observed in previous studies. Further developing will be devoted in evaluating the fragility curves for the most efficient *IM* for each rocking motion.

5 CONCLUSIONS

The goal of this study is the estimation of the fragility curves at collapse for masonry church façades through a Cloud Analysis. At this aim, numerical nonlinear dynamic analyses, performed according to classical literature models, has been performed by applying more than

89 unscaled records of past earthquakes occurred in the area stricken by the 2016 Central Italy Earthquake. Therefore, the effects of record-to-record variability on the dynamic response was considered. Five different façade geometries were considered, defined observing the masonry churches' façades recurrent in the Central Italy. The obtained fragility curves, that are in line with those derived by other authors adopting different numerical approaches, clearly highlight the influence of the geometry on the seismic vulnerability of façades. Even if it is not meaningful to simply compare the fragility curves for the two-sided and the one-sided rocking motion, since the most efficient seismic intensity measure parameter differ for the two kinematic mechanisms, it should be noted the higher vulnerability for the one-sided compared to the two-sided rocking motion for higher values of PGA. This aspect, already observed by other authors in the past, requires a deeper investigation.

Abstract

Existing unreinforced masonry (URM) buildings, including historical and monumental structures, represent an important architectural and cultural heritage for several countries worldwide. The response of URM, subjected to earthquake excitations, is strongly governed by the out-of-plane (OOP) response of masonry walls, which can lead to local failure mechanisms, even at low levels of seismic loading. The OOP failure conditions are mainly controlled by the geometry of the structure and the masonry quality. Different strategies are used for modelling the OOP response of URM structures including limit analysis and nonlinear FEM. A further recently proposed strategy is based on the discrete macro-element method (DMEM) which allows the simulation of the in-plane and the OOP response of masonry walls with a reduced computational cost compared to the other numerical strategies. In this paper, the DMEM is applied to simulate a masonry wall rocking experimental campaign for which other numerical strategies have already been applied. The dissipation effects, related to the rocking motion and the repetitive impacts, are taken into account according to an equivalent viscous damping approach. Furthermore, the role of masonry deformability is investigated by comparing the results obtained by the DMEM model, for different value of masonry elastic modulus, with those obtained by typical rigid-block based models. The results clearly demonstrate that the DMEM can be efficiently adopted to accurately predict the dynamic response of monumental structures.

Keywords: URM structure, OOP failure mechanism, Modelling strategies, DMEM approach, Rigid-block models, FEM analysis.

1 INTRODUCTION

The existing buildings stock in several seismic area world around includes historical and monumental unreinforced masonry buildings (URM) which possess, in some cases, an important architectural and cultural value. The dynamic response of URM subjected to earthquake excitations is governed by the in-plane (IP) and out-of-plane (OOP) response of masonry walls. When the connections between vertical and horizontal structural elements do not guarantee a box-type behavior, the OOP failure mechanisms are the main source of seismic vulnerability of the building and the failure conditions are mainly controlled by the geometry and gravity loads directly applied to the wall. Due to the low tensile strength, cylindrical hinges tend to separate macro-portion of masonry leading to relative rotations between the different parts. If the number of hinges is such that a kinematic mechanism is allowed the corresponding equilibrium limit condition can be evaluated and a limit value of load multiplier leading to the incipient collapse condition can be determined. Due to the negligible tensile strength of masonry and the slenderness that generally characterise masonry walls, masonry walls can lose the equilibrium and overturn even under low values of seismic loadings. However, damage observation after strong earthquakes have proved that dynamic equilibrium can take place even after the rocking mechanism has been activated [1].

The simplified macro-block limit analysis approach is commonly adopted to assess the rocking behavior of masonry walls, according to the original Heyman's hypotheses [2]: no-tension material, rigid behavior in compression and absence of sliding. Consistently with these assumptions, a number of selected potential local mechanisms are selected whose ultimate load-multipliers correspond to upper-bound prediction of the effective load-multiplier, according to the limit analysis static theorem. Hence the lower load-multiplier represents the best prediction of the actual collapse mechanism within the investigated ones.

Upon the results of the limit analysis, the rocking capacity is evaluated by following the force-based or displacement-based approaches [3]. The force-based approach, consisting in comparing the load multiplier to the attendend in-situ PGA, represents the easiest tool to assess the seismic capacity of rocking blocks [4]. The displacement-based approach aims at comparing the displacement capacity of the assumed OOP mechanism with the corresponding displacement demand evaluated on an equivalent bi-linear or tri-linear single degree of freedom system [5]. Another simplified analysis method to assess the OOP response of masonry walls is based upon the hypothesis of tilting rigid block [6] according to which non-linear dynamic analyses are performed on a rigid block scheme assumed representative of the rocking behavior of the masonry wall. The dissipations sources involved in the OOP behavior of the wall are considered by means of a *coefficient of restitution* ruling the velocity of the rocking system after each impact. An extensive review on rigid block dynamics, when applied to URM structures, can be found in [7].

The main sources of approximation of limit analysis and rigid block models are related to the fact that they totally neglect the effects of masonry deformability and do not properly take into account the interaction between the portion of structure subjected to the overturning motion and the remaining part of the structure that is also subjected to the earthquake loadings and represents the source of loading and the constraint at the same time.

More recently, refined advanced discrete models have been applied to assess OOP rocking mechanisms such as the Distinct Element Methods (DEM) according to which masonry units are explicitly modelled by rigid irregular blocks while joints are modelled as a contact unilateral-friction links [8]. It is worth noting that these methods, difficult to calibrate, are quite computational expensive in the case of large structures and for these reasons although promising are currently limited to academic researches.

An alternative strategy of analysis to assess the OOP rocking mechanisms [CompDyn2017] is based on the discrete macro-element method (DMEM) which allows the simulation of the in-plane and the OOP response of masonry walls [Pantò et al 2017]. This innovative method has been firstly proposed and validated in the non-linear static field ([9] [10]), and more recently has been extended in dynamic field and validated through the comparison with experimental tests and refined FE simulation [11], [12]. According to DMEM, masonry walls are discretized as a mesh of shear deformable spatial macro-elements interacting through zero-thickness interfaces whose discretization follows a straightforward fiber calibration strategy. The single macro-element has a shear deformability governed by a single degree of freedom. The capability of the proposed DMEM to account for the IP and OOP behavior of masonry structure has been already numerical and experimental investigated [13], [14].

In this paper, the DMEM methods is applied to simulate the experimental response of masonry walls obtained by free-vibration and shake table tests already presented in the literature. Some parametric analyses are also performed to evaluate the influence of energy dissipation and the masonry deformability, comparing the results obtained by the DMEM model to the closed form solution of the classical rocking theory developed by Housner [6].

2 ANALYSIS METHODOLOGY AND OBJECTIVES

In this paper the rocking behavior of isolated walls exhibiting a cantilever mechanism, parapet wall (PW), or a simple supported wall (SSW) mechanism, is numerically investigated by using the DMEM approach and the classical rocking theory developed by Housner in 1963 [6]. The static schemes of the two considered mechanisms are reported in Figure 1. The main research goal of the present study is to identify and investigate critical issues related to the use of the DMEM model to describe the rocking motion of masonry walls. To reach this objective, the paper aim at:

- validating an equivalent viscous damping model for the DMEM, consistent to the contact-damping of the rigid model and experimental observations.
- estimating the effects on the rocking response of the masonry deformability, neglected in all the rigid-block-based approaches.

A brief description of the two methodologies of analysis is reported in the following subsection showing the main hypotheses according to which they are based on and highlighting their differences.

Figure 1: Rocking motion of isolated wall exhibiting a cantilever mechanism (a) and a simply supported mechanism (b) (from Doherty et al. 2002).

2.1 Classical Theoretical Model of Housner and the main Geometric Parameters influencing rocking

The dynamic behavior of a single rigid rectangular block, $2h$ height and $2b$ width, standing on a rigid base, with the assumption that friction between the block and the base is high enough to prevent sliding and neglecting bouncing, was first described by Housner in [6], hereinafter referred as the classical theory. When the rocking is activated, the rigid block can pivot on one of the two base vertexes. The main geometric features influencing the rocking response are the slenderness ratio $\alpha = \tan^{-1}(b/h)$ and the radius vector R connecting the pivot point to the center of mass of the block. A relevant finding of the classical theory is that, between two rigid rectangular blocks of the same slenderness, the block with the higher radius vector is more stable [15]. The equation governing the rocking motion under horizontal, $\ddot{u}_g(t)$, and vertical, $\ddot{v}_g(t)$, ground acceleration is reported in (1) where the rotation θ is the rotation angle of the block, assumed as the Lagrangian parameter, I_0 the moment of inertia of the block about an axis perpendicular to the plane of the wall and passing through its barycenter and g is the gravity acceleration.

$$(mR^2 + I_0)\ddot{\theta} + m(h \cdot \cos(\theta) + \operatorname{sgn}(\theta)b \cdot \sin(\theta))\ddot{u}_g + m(\operatorname{sgn}(\theta)b \cdot \cos(\theta) - h \cdot \sin(\theta))(g + \ddot{v}_g) = 0 \quad (1)$$

The rocking motion of the block $\theta(t)$, can be evaluated by integrating equation (1), within each time interval between two consecutive impacts, considering as initial conditions $\theta(t_i) = 0$; $\dot{\theta}(t_i) = \dot{\theta}_i$, where t_i is the time of the last impact and $\dot{\theta}_i$ the rotational velocity of the block after the impact. Considering a free-vibration motion of the block with maximum amplitude θ_0 , the periods of oscillation of the block (under the assumptions of parapet wall, Figure 1a, and simply supported wall, Figure 1b) are given by:

$$T_{PW} = \frac{4}{p} \cosh^{-1} \left(\frac{1}{1 - \frac{\theta_0}{\alpha}} \right) \quad (2)$$

$$T_{SSP} = 1 - 2\sin^2(\alpha_1) \quad (3)$$

Where $p = \sqrt{3g/4R}$ is a *frequency parameter* of the block referring to the pendulum frequency of the block assumed hanging from its pivot point and α_1 is the slenderness ratio of simple supported wall. Observing Eqs. (2) and (3), it is worth mentioning that the natural periods of the rigid body motion depend on the rocking amplitude in addition of the geometry of the system.

Several studies have been conducted to investigate the response of a rocking rigid block, subjected to a free-vibration motion ([6], [16], [17]), harmonic oscillations ([17], [18]) and earthquake loadings ([19], [15]). One of the main purpose of these studies was the representation of the energy dissipated during the rocking motion.

According to the classic theory, the dissipation is only concentrated at the impacts, when the rotation is switched from one base vertex to the another. It is generally assumed that the impact induces an instantaneous reduction of the velocity controlled by the introduction of a restitution coefficient (e) ranging from 0 to 1. A value of $e = 0$ corresponds to a totally inelastic impact, while $e = 1$ indicates a perfectly elastic impact. By imposing the conservation of the angular moment about the centre of rotation, just before and after each impact, the classical

theory provides analytical expressions of the restitution coefficient for parapet walls, e_{PW} in Eq. (4), and simple supported walls, e_{SSW} in Eq. (5).

$$e_{PW} = 1 - \frac{3}{2} \sin^2 \alpha \quad (4)$$

$$e_{SSW} = 1 - 2 \sin^2 \alpha_1 \quad (5)$$

Some experimental observations showed different values of the restitution coefficient than those predicted by the classic theory [20] suggesting that continuum energy dissipations due to flexural masonry deformation and plastic deformations at the rocking interfaces contribute significantly to the energy dissipation process. In a recent work, Graziotti et Al. [21] found values of the coefficient of restitution ranging from 0.84 to 0.91.

In view of to this observations, continuous viscous damping models alternative to the impact dissipation have been adopted, with constant or variable damping ratios, also considering the ease mathematical formulation and software implementation of the viscous damping model [22] [23] [24].

Continuous viscous damping models are generally implemented removing the hypothesis of rigid block dynamics and describing the rocking behavior assuming a single degree of freedom (SDOF) system characterized by a one-dimensional bi-linear [25] or tri-linear [5] [26] force-displacement relationship, as depicted in Figure 2, where the backbone curve of the ideal rigid block equilibrium path is characterized by the ultimate load multiplier (F_0) and the ultimate displacement (Δ_u) while the SDOF system is characterized by the initial elastic stiffness (k_L), the yield force ($F_y = \beta F_0$) and the yield displacement ($\Delta_y = F_y/k_L$).

Figure 2: Force-displacement relationship models

Several studies have been performed to find a correlation relation between the equivalent viscous damping ratio, ξ , and the dissipation related to impacts controlled by coefficient of restitution [16] [20] [27] [28]. More recently, Tomasetti et Al. [21] proposed an energy equivalence between restitution coefficient and SDOF analytical formulation for different viscous damping models, constant damping coefficient (CDC), constant damping ratio (CDR) and stiffness-proportional damping ratio (SDR), proposing the empirical expression reported in Eq. (5) to evaluate the damping ratio ξ_{eq} to associate to the initial elastic frequency of the system ($\omega_L = \sqrt{K_L/m_{eff}}$), where m_{eff} is the effective mass of associated to the system [21]. They found $x_{CDC} = 0.667$, $x_{CDR} = 0.350$, $x_{SDR} = 0.218$ and $y_{CDC} = 0.450$, $y_{CDR} = 0.074$, $y_{SDR} = 0.195$.

$$\xi_{eq} = -x (\Delta_y/\Delta_u)^y \ln(e) \quad (6)$$

2.2 The Discrete Macro-Element Model

According to Discrete Macro-Element (DMEM) approach, the masonry is modelled through an equivalent mechanical scheme constituted by a hinged quadrilateral, whose in-plane deformability is governed by a single Lagrangian parameter, to rule the diagonal shear behavior. Each macro-element interacts with contiguous elements or constraints along its four edges by means of a discrete distribution of nonlinear springs, denoted as interfaces which govern the flexional and the sliding behavior. This approach was originally introduced for modelling the in-plane behavior of Unreinforced Masonry Structures [9], Figure 3a. The plane element possesses four degrees of freedom, a single row of transversal links and a single in-plane sliding link and is able to model the main failure mechanisms of the masonry in its own plane. Two subsequent upgrades were achieved to expand the potentialities of the approach. First, the out of plane (spatial) behavior, typical of historical constructions, was added [10] by considering additional rows of transversal links and two additional out-of-plane sliding links (able to govern the out of plane shear behavior and the torsion), thus enabling the out of plane degrees of freedom, Figure 3b. Subsequently, a further upgrade was introduced considering a shell macro-element characterized by an irregular geometry, variable thickness along the element and skew interfaces [29] to deal with curved structures, such as vaults and domes, Figure 3c.

Figure 3: Layout of the macro-element adopted for masonry at its three stages: (a) plane element, (b) spatial regular element and (c) three-dimensional element for curved structures.

The flexural (rocking) response of macro-elements is governed by the interface transversal links which are calibrated following a fibre-discretization approach of the panel cross section [10]. According to this strategy, the initial stiffness of the links is related to the axial stiffness of the corresponding masonry strips, evaluated in Eq. (8) where E_m , is the masonry Young's modulus and L_n , A_{sn} , the length and cross-section area of the masonry strip. The yielding forces in tension (F_{ytn}) and in compression (F_{ycn}) are related to the influence area and to the tensile and compressive strength respectively. Finally, the tensile and compressive yielding displacement (u_{yt} and u_{yc}) are associated with the yielding forces and the initial stiffness, Table 1.

The DMEM has been employed to simulate the seismic behavior of monumental masonry constructions by means of non-linear static (pushover) analysis. A more recent upgrade extended the DMEM approach to the dynamic field allowing the simulation of the non-linear dynamic behavior under seismic load. The mass of each macro-element is concentrated at its barycenter. According to this hypothesis, a diagonal mass matrix with, along the diagonal, the three translational inertia components and the three rotational inertia components of the volume represented by the macro-element [13]. More details on the DMEM are reported in the

referenced papers.

K_n	F_{ytn}	F_{ycn}	u_{yt}	u_{yc}

Table 1: Calibration of the interface transversal links.

3 NUMERICAL SIMULATIONS

The numerical simulations are performed considering rectangular blocks subjected to two-side rocking motion. Free vibration motion is considered in Section 3.1 whilst earthquake excitations are considered in Section 3.2.

Three models are considered. Namely, the ideal rigid block (RB) model, Figure 3a, a simplified DMEM model with the interfaces located at the base rocking section, Figure 2b, and a refined DMEM model in which the wall height is discretized by a mesh of macro-elements with height equal to the wall thickness, Figure 2c. The response of the RB model is evaluated considering the analytical solution of Eq. (1) while, the analyses on the DMEM models are performed using the software HISTRA [30] through the Newmark method considering the Newmark's parameters $\alpha=0.9$, $\beta=0.25$ and $\gamma=0.5$ and a time step of 0.005 s.

At each step, the dynamic equilibrium is imposed with reference to the initial configuration while the effects of the geometric nonlinearities are considered by updating the load vector position (P - δ effects). The wall thickness is divided in ten rows of links and characterized by the distribution of normal stiffness $k_n = K_n/\lambda$ where K_n already defined in Table 1 and λ the distance between the links along the wall thickness. Although different constitutive laws can be adopted in the DMEM, aiming at performing a consistent comparison a linear behavior in compression and zero tensile strength have been assumed. Furthermore, a viscous damping, proportional to the global stiffness matrix, has been calibrated according to Eq. (6) evaluating the ratio Δ_y/Δ_u through a pushover analysis.

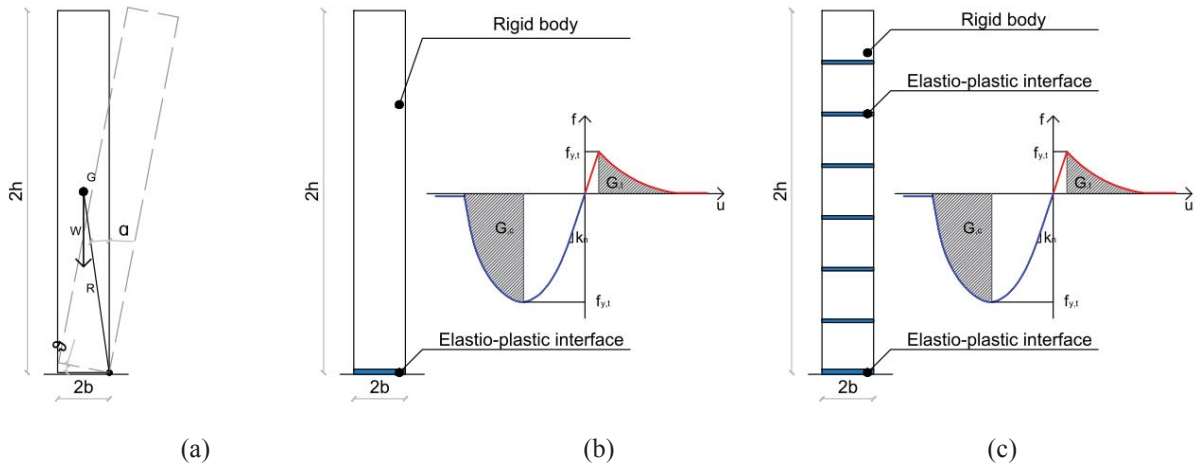

Figure 4: a) Rigid block model (RB), b) DMEM simplified model, c) DMEM refined model.

3.1 Free-vibration analyses

In this section, rectangular blocks subjected to two-side free-vibration rocking motions, activated imposing an initial displacement of the wall top section equal to the wall half-width ($b/2$), are analysed by the rigid block (RB), Figure 4a, and the DMEM model, Figure 4b and

Figure 4c. The analytical response of the RB is obtained by integrating Eq. (1) considering $\theta(0) = b/4$; $\dot{\theta}(0) = 0$. Two different parapet walls (PWs), characterized by different geometries and slenderness ratios (λ_w) and already numerically investigated in the literature [21], are considered.

For simplified DMEM models, two different values of coefficient of restitution are considered in the analyses, namely the analytical value (e_{an}) calculated by Eq. (4) and a reduced value of ($e=0.85$) consistent with experimental observations [31]. The normal stiffness of the DMEM interfaces (k_n) is evaluated by considering a reference value of masonry Young modulus $E_m=800$ MPa. The effective mass (m_{eff}) used to evaluate the lateral frequency (ω_L) is assumed equal to $4/3m$ in the case of the DMEM and equal to the mass activated at the first mode of vibration in the case of the DMEM refined model. The complete set of parameters characterising the DMEM simplified model is reported in Table 2 while, the characterisation of the DMEM refined model is reported in Table 3 where both the stiffness of the base interface ($k_{n,base}$) and inner interfaces connecting two contiguous macro-elements ($k_{n,base}$) are reported.

The time history of the top section of PW₁ and PW₂, obtained by the DMEM simplified model, are reported in Figure 5 and Figure 6, respectively. The results are compared with those obtained by RB solution. A satisfactory agreement is observed between the two models, in all the cases investigated, although the DMEM model tends to underestimate the peaks when compared to the RB model.

Table 3: Details of the walls analysed by the refined DMEM model.

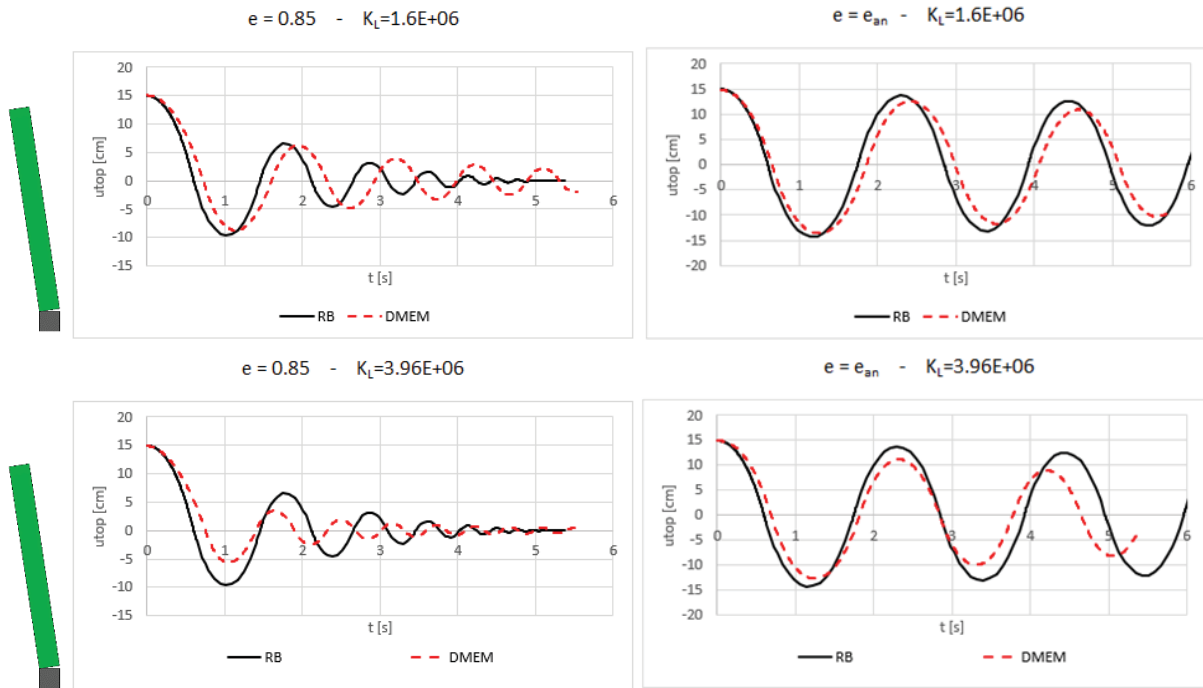

Figure 6: Free vibrations of the PW2 sample evaluated by the RB and simplified DMEM models.

The time history responses and the maximum deformation obtained by the DMEM refined model are reported in Figure 7 compared to the analytical solution of the rigid block model. The two models provide comparable results demonstrating that the equivalent viscous damping model adopted in the DMEM model is energetic consistent to the impact dissipation mechanism characterising the RB model. Finally, Figure 8 shows the hysteretic cycles of the DMEM models, expressed in terms of top displacement versus the wall base shear, superposed to the corresponding push-over curve. It can be observed that the dynamic responses show a significant deviation from the static curve due to the presence of the inertia and damping forces.

3.2 Earthquake analyses

In this section, non-linear dynamic analysis under earthquake excitations are performed on a Vertical Spanning Walls (SPW) already experimentally and numerically investigated in the literature [32] [33]. The tested specimen was composed of regular tuff blocks, with self-weight 12.3 kN/m^3 , and lime-cementitious mortar. The wall was 3.48m height, 1.53m width and 0.25m thick. On the top section of the wall it was located a reinforced brick-work beam 0.27m height and 0.25m thick, characterised by a self-weight of 18 kN/m^3 . The beam was connected to the underlying masonry with 600 mm long connectors in steel reinforced grout (SRG). The horizontal displacements of the beam were constrained by a steel IPE200 beams, placed on top of lateral stiffened steel frames. Rubber cylinders were placed between the IPE200 and the specimen to permit the upward displacement and rotations of the top section of the wall.

The test layout comprised an additional load of 6 kN placed on the top of the reinforced-brick beam. The characteristics of the input signals are reported in Table 4. The specimen was numerical investigated by means of a 2D DEM model using the software UDEC (Itasca 2010) using different scale factors for the signals [32].

Earthquake information			Horizontal component			Vertical component

Table 4: Input signal

The DMEM model is developed using 78 macro-elements corresponding to 546 DoFs. The boundary conditions on the top of the wall are simulated by inserting elastic stiff macro-elements whose mass density is evaluated to simulate the mass of the brick-wall beam plus the external load and restrained against the horizontal displacements. The analysis is performed in two stages, first a static analysis is conducted applying the gravity loads, then the dynamic analysis is performed assuming as initial condition the final configuration of the vertical analysis. The complete set of parameters characterising the DMEM models are reported in Table 5.

h [m]	b [m]	e_{an} [-]	k_n [N/mm ³]	K_L [N/m]	E [N/mm ²]	σ_t [N/mm ²]	G_t [N/mm]	m_{eff} [Ns ² /m]	ω_L [1/s]	Δ_y/Δ_u [-]	$\xi_{SDR}(e)$ [-]
3.48	1.53	0.85	4.9E+08	1.05E+06	294	0.001	0.01	1112.64	30.69	0.064	0.060

Table 5: Parameters characterizing the DMEM model

The results of the analyses are reported in Figure 9 in terms of time history of the point subject to maximum displacement which is located approximately at a height of 2.15m. The Different amplification factors are considered to scale the signal ($SF=1.25$; 1.5; 2.0). In Figure 9a the response of the wall to the signal scaled by 1.25 scale factor is shown. In the graph, the maximum displacement registered during the test are also reported. A very good agreement can be observed between the peak displacement predicted by the DMEM model and that observed experimentally. In Figure 9b the numerical responses to the different levels of amplification of the signal are reported. It is evident how the DMEM model is able to catch the period elongation of the system due to the opening of the tensile cracks and the activation of the rocking mechanism.

4 CONCLUSIONS

This paper applies the DMEM model to simulate the rocking behaviour of unreinforced masonry walls. The results of the DMEM model are compared with the exact solution consistent to the rigid block theory as well as to an experimental campaign for which other numerical strategies have already been applied. The effects of the energy dissipation and masonry deformability are investigated in the analysis. A stiffness-proportional viscous damping model to be employed in the DMEM analyses has been calibrated and validated. The results demonstrate that the DMEM can be adopted to accurately predict the dynamic response of monumental structures with a limited computational burden showing the capability of the method to be employed for the simulation of large historical masonry monumental structures, being able to simulate both the in-plane and out-of-plane response of masonry walls.

Abstract

This paper presents a Grasshopper (GH) plugin to evaluate the admissible out-of-plane mechanisms in multi-storey masonry buildings and visually display the possible locations for each admissible mechanism at which the failure can happen. Adopting the macro-block modelling approach, GH components are developed considering a limited number of geometric and construction parameters as inputs that allow the possible mechanisms. These include the quality of the connections between the building walls, applied strengthening devices, and the examined building location within an urban block. Modelling the building, all the potential mechanisms and their possible locations are demonstrated in a user-friendly and readable way. The plugin can finally compute the actual mechanism and its optimised geometry as well as the actual building out-of-plane capacity adopting the limit analysis method.

Keywords: 3D Macro-Block Model, Out-of-Plane Behaviour, Limit Analysis, Visual Programming, Grasshopper Plugin.

1. INTRODUCTION

Out-of-plane (OOP) mechanisms can take place in masonry buildings without a box-type behaviour, especially in the peripheral walls of existing buildings, even when they are under low intensities of ground motion [1]. The most recurrent ones are related to simple and complex rocking mechanisms, as well as to flexure mechanisms, as identified and classified by systematic surveys of the typical seismic damages and crack patterns in masonry buildings [2-5]. Post-seismic surveys [2, 6] and experimental tests [7] have also identified particular conditions governing the classified OOP mechanisms, including: the quality of the connections between the orthogonal walls as well as the walls and horizontal diaphragms, the roof typology, the positions of the openings and of the building within an urban block. The seismic assessment of historical masonry buildings with respect to OOP mechanisms cannot disregard these aspects, especially when non-linear static and dynamic analysis are employed [8-10] and strengthening interventions [11-13] or dissipative devices are to be designed [14].

Within the simplified approaches to investigate the OOP failure modes in masonry buildings, the kinematic method of limit analysis is one of the most popular and reliable in the literature [15, 16]. According to it, local mechanisms can be considered as kinematic chains of masonry portions, regarded as rigid macro or micro-block assemblages, interacting through interface elements. In particular, the macro-block model assumes that the general failure involves a number of cracks, which separate the structure into a few rigid macro-blocks, and all the possible relative motions among units (rocking and/or sliding) are concentrated along these cracks [5, 17].

However, despite several advantages of the macro-block modelling approach, like being computationally efficient, it normally faces a considerable level of uncertainties, since the given input data for the analysis are simplified into a limited number of parameters. These aspects are well addressed in [2], where the FaMIVE (Failure Mechanism Identification and Vulnerability Evaluation) procedure is introduced to evaluate the most recurrent failure modes in aggregate buildings and to find the optimal option among them. When the advanced macro-block model developed in [5] is adopted, the admissibility of possible mechanisms in aggregate buildings also depends on the involved portions of walls at each storey and on the height ratios between the main building and the adjacent ones, in addition to the position of strengthening devices and the wall connections quality considered by FaMIVE.

Determining the admissible and inadmissible mechanisms for each storey/side of a building is though not very handy and readable using the text-based representations proposed in [2] and [5]. Instead, their graphical visualization would help the evaluator to better assess the reliability of the final solution as well as the other possible alternatives.

To this aim, taking advantage of the 3D visualization [18, 19], this paper presents a novel graphical approach based on the development of a Rhino Grasshopper (GH) plugin. This allows to parametrically model multi-storey masonry buildings and visually check all the potential OOP failure modes and their positions in real time, evaluated according to the work of Casapulla et al. [5]. Using the powerful optimization toolbox, the plugin can also compute the collapse load factors related to each possible mechanism at each storey and visualize the crack pattern of the related OOP mechanism and specifically performs the most likely collapse mechanism configuration and its related (optimal) load factor.

Adopting the concept of visual programming, the developed plugin provides a fast and user-friendly tool for: 1) parametric modelling; 2) visual analysis of all the possible mechanisms in a multi-storey masonry building; 3) computing the minimum load factor among all the possible mechanisms and visualize the related crack pattern; 4) easily linking the modelled building and mechanisms to other analytical software implementations, e.g.,

macro or micro-model finite element [20] and discrete element [21] approaches for further analyses.

In the following, an overview on the typical OOP failure mechanisms and the evaluation process to find the admissible mechanisms at each storey of a building is presented, with an application to the corner failure as an example. Then, the computational implementation of the GH plugin is presented to visually check the admissible and optimized mechanisms in real time.

2. MODELLING THE OOP FAILURE MODES

The adopted macro-block model [5] is a 3D portion of walls in a multi-storey masonry building that remains undamaged under the seismic motion and is based on the assumption that the constituent micro-blocks (units) have infinite compressive, tensile and shear strengths. Walls are considered to be single-leaf with the modular masonry units at each storey arranged with the running bond pattern. The contact interfaces between the units have no tensile and finite frictional resistance governed by the Coulomb failure criterion. A horizontal static action as a percentage of dead loads (by means of a load factor) is applied to the centre of mass of each moving macro-block, in addition to all the other external loadings.

Figure 1 shows some of the most recurrent OOP mechanisms for a façade wall of a multi-storey building, that are the rocking (M_A , M_B and M_C) and flexural (M_D and M_E) failures. The onset of each mechanism is represented by advanced formulations considering frictional resistances, which are obtained by the linear kinematic approach of limit analysis, as elaborated in [5].

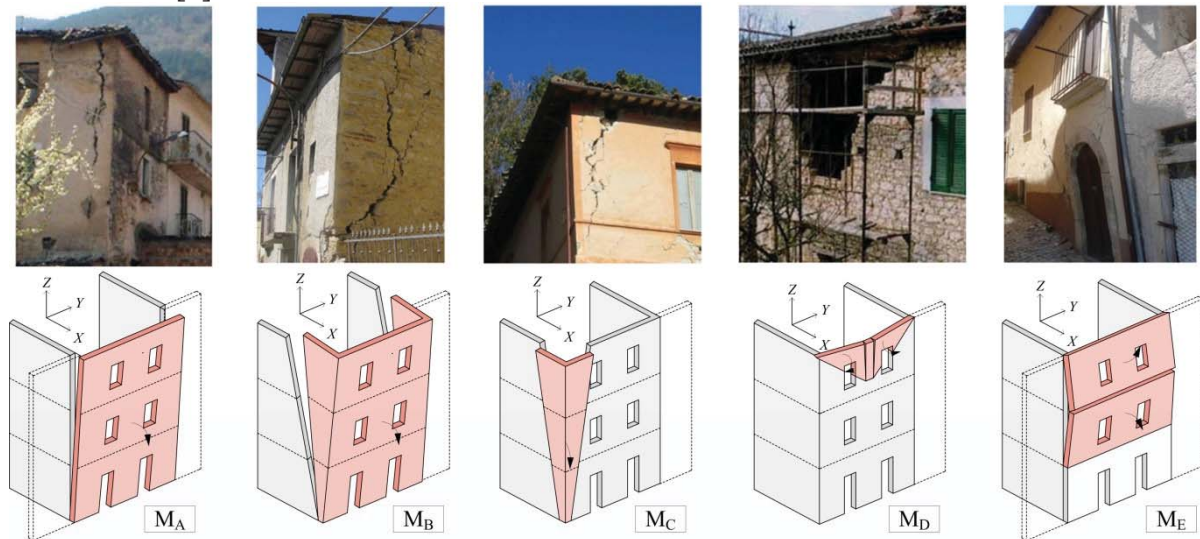

Figure 1: Simple (M_A) and compound (M_B) rocking walls, rocking corner (M_C). Horizontal (M_D) and vertical (M_E) flexural OOP mechanisms.

2.1 Parameters governing the admissibility of OOP failure mechanisms

The admissibility of the failure mechanisms shown in Figure 1 is strictly related to the specific features of the aggregate buildings under study, as highlighted by previous works [2, 3]. The main geometric and construction parameters herein considered are the following ones:

1. Quality of the connection between the façade and sidewalls: this structural feature strongly affects the mechanical integrity of the main building. Poor connection quality between these orthogonal walls usually results in generating the failure modes M_A and

M_E . On the other hand, mechanisms M_B and M_C can occur in the presence of strong connections, while failure mode M_D is not affected by this feature.

2. Position of the building within the urban block (Figure 2): it is herein assumed that the position of the building can influence the failure mechanisms M_C and M_D . Besides, the height of the main building with respect to the adjacent buildings is another important aspect, which has not been taken into account in [2] and [3]. In fact, when, e.g., the building is located in a middle position (P_M and P_S cases), mechanism M_C can only occur if the main building is higher than the adjacent ones, while the horizontal arch failure (mechanism M_D) cannot be triggered because the lateral restraints exerted by the adjacent buildings would prevent any lateral displacements.
3. Strengthening devices: Figure 3 shows six configurations of strengthening devices including ring beams and tie-rods. The presence of strengthening devices influences the feasibility of all the mechanisms considered in Figure 1. In fact, all mechanisms can occur in the absence of strengthening devices, except the failure mode M_E that requires their presence to onset. Since the corner failure in the walls below the tie-rods locations are usually prevented, in the cases of implementing S_{RB} , S_{T3} , and S_{T2} , no mechanism is possible beneath them.

Figure 2: Position of the building within an urban block.

Figure 3: Simple layouts of different configurations of strengthening devices.

Each of these three parameters is linked to each mechanism that may occur at a generic storey of a multi-storey building, as displayed in Table 1. If a mechanism is feasible, it will be identified as an admissible mechanism (A), while inadmissible (I) in the opposite case. In some cases, the admissibility of a mechanism depends on the conditions that vary from storey

to storey, e.g., in the case of different heights of the adjacent buildings it is related to the number of free storeys (D1), while in the presence of strengthening devices (D2) it depends on the highest storey where they are placed.

Obviously, for a given building, the table should be made explicit for each storey, with the admissibility of each possible mechanism depending on the storey properties. Also, to have a more comprehensive evaluation, the table must be extended to each side of the façade wall when, e.g., the storeys number of the adjacent buildings on the right and left sides are different or in the case of having asymmetric strengthening devices (S_{T1} and S_{TM}) applications. These aspects would make the table relatively complex and reduce its readability.

To shed more light on this evaluation process, mechanism M_C (corner failure) is herein chosen as a reference example and how its admissibility is evaluated for a given building is elaborated in the next section.

Mechanism	Connection with sidewalls		Position of the building within the urban block		Strengthening devices			
	Strong	Weak/Absent	$P_I - P_E - P_C$	$P_M - P_S$	NO	$S_{RB} - S_{T3} - S_{TM}$	$S_{T1} - S_{T2}$	S_M
M_A	I	A	A	A	A	D2	D2	D2
M_B	A	I	A	A	A	D2	D2	D2
M_C	A	I	A	D1	A	D2	D2	A
M_D	A	A	A	D1	A	D2	A	D2
M_E	I	A	A	A	I	D2	D2	D2

A: admissible possible mechanism

D1: mechanism occurrence depending on the number of stories of the adjacent buildings

D2: mechanism occurrence depending on the highest storey with the strengthening devices

Table 1: Relation between the construction parameters of a building and the feasibility of the mechanisms.

2.2 Conditions governing the corner failure

The failure mechanism of a free corner (Mechanism M_C in Figure 1) is quite common in masonry buildings isolated, positioned at the end of an urban block, or in their free higher storeys. It is characterised by the rocking-sliding of a rigid wedge-shaped macro-block around a hinge point. The corner failure in a masonry building generally involves well-connected masonry walls under orthogonal forces, whose geometry is not known a priori.

Figure 4 shows a 4-storey façade between two adjacent buildings (case P_S) with two and one stories on the left and right sides, respectively, having the S_{T1} configuration of strengthening devices at the first floor (Storey no. 4 on the right side of the building). Table 2 shows the possibility of occurrence of mechanism M_C at the top-most (Storey no. 1) to the lowest level (Storey no. 4).

As shown in the table, the admissibility of each mechanism is checked (A for being admissible and I for being inadmissible) regarding the connection quality, building position, and the applied strengthening devices separately and, finally, the overall admissibility check is executed for each storey. First of all, according to the first column of the table, mechanism M_C is a possible failure mode for all storeys since the connections are considered strong enough in both right and left sides of the façade wall. On the other hand, since the adjacent buildings on both sides are shorter than the main building, the corner failure is possible on both sides, at the free storeys only. However, since the adjacent buildings have different heights, the corner failure may have different configurations in either the left or right sides of the building. Similar conditions can occur regarding the applied strengthening device, which

is also asymmetric. The last column of the table shows the overall admissibility check for the corner failures at each storey of the building.

Figure 4: Example of the main building position within an urban block.

Storey	Connection with sidewalls = Strong		Position of the building within the block = P_S		Strengthening devices Devices = S_{T1} (right side-storey 1)		Final assessment	
	Left side	Right side	Left side	Right side	Left side	Right side	Left side	Right side
1	A	A	A	A	A	A	A	A
2	A	A	A	A	A	A	A	A
3	A	A	I	A	A	A	I	A
4	A	A	I	I	A	I	I	I

A: admissible mechanism
I: inadmissible mechanism

Table 2: The possibility of occurrence of mechanism M_C for the 4-storey building.

To achieve a comprehensive admissibility evaluation, the same procedure should be developed for all the other mechanisms and the admissibility results gathered all together, which would provide very large tables, even difficult to read. Adding a visual approach would, instead, overcome these difficulties and allow a more user-friendly evaluation.

The following section presents the GH plugin that has been developed to firstly visualise all the possible OOP mechanisms and their locations for a multi-storey building and then to find the actual load factor and the related geometry of the corner failure, used as the reference example.

3. COMPUTATIONAL IMPLEMENTATION

A GH plugin has been developed to visually and parametrically demonstrate the potential mechanisms by which a multi-storey masonry building surrounded by adjacent buildings might fail and to compute the actual (optimal) failure mechanism for the building.

The GH plugin has three main functions:

- It enables the user to model the main and adjacent buildings by assigning the number of storeys and the related height. The main building is modelled assigning the length, height, and thickness of the façade and sidewalls, as well as choosing the configuration

and position of the strengthening devices. The user can parametrically change the input values and observe the updated model in real time.

- Given these geometric inputs, the plugin displays all the potential failure modes (among the selected six mechanisms) that are possible for the model and demonstrates all the possible locations at which the model might fail.
- Given a set of mechanical and external load information, the plugin computes and demonstrates the optimal geometry of the actual failure mechanism and the related load factor.

In the following, these three functionalities are described in detail.

3.1 Modelling

The plugin extends the GH environment, a visual programming add-on for Rhinoceros 3D. To develop the plugin, C# language has been used. The first developed component of the plugin enables the user to visualize the examined buildings and, through parametric change of the inputs, simply observe the updated model in real time. Figure 5 demonstrates all the inputs necessary to construct the main and adjacent buildings. The inputs can be parametrically changed by the user.

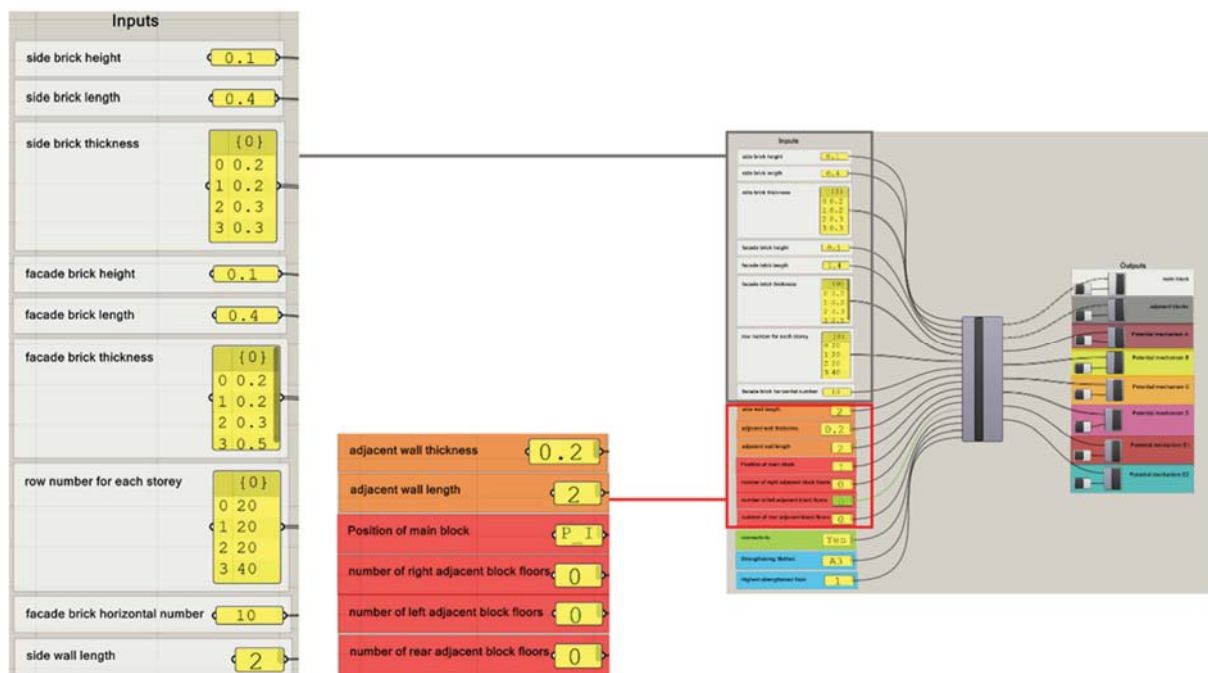

Figure 5. Masonry building modelling component and its inputs.

As examples, Figure 6 illustrates different models developed by different inputs, regarding different storey numbers and heights for the main building as well as different façades, sidewalls lengths and thicknesses. Besides, Figure 7 displays different storey numbers and lengths of the adjacent buildings.

Figure 6. Parametric change of the geometric inputs of the main building.

Figure 7. Parametric change of the geometric inputs of the adjacent buildings.

3.2 Potential mechanism visualization

Taking advantage of the 3D visualization in GH, the approach elaborated in Section 2 has been adopted to develop a GH component to demonstrate all the possible mechanisms and the locations at which a specific potential failure can occur. Figure 8 shows all the feasible mechanisms and locations among those gathered in Figure 1 and related to the example in Figure 4.

Figure 8. Different types of potential mechanisms along with all the locations at which the failure is possible.

In particular for the corner failure, Figure 9 visually represents the data reported in Table 2, i.e., all the potential mechanisms that can occur for the main façade presented in Figure 4 and all the possible locations to form a hinge (blue dots) as well as all the possible crack inclinations are visually presented. It is worth highlighting that the crack lines in dry-joint masonry walls have the maximum inclination given by the staggering ratio of the masonry

units [9]. As can be observed, the readability of the potential failure mechanisms is considerably improved if compared to the data in Table 2.

Figure 9. Visualizing all the possible locations for the hinges (blue dots) and crack inclination of mechanism M_C .

3.3. Actual mechanism visualization

The plugin can also compute the actual load factor and find the related mechanism shape through managing specific geometric parameters by which the mechanism can be modelled. For example, mechanism M_C can simply be modelled only by finding the hinge position and the crack inclinations on the façade and sidewalls. The optimization formulations, developed in [5] using Eqs. (10) and (11) of that paper, have been adopted in this work for the assessment of the corner failure. In particular, the geometric variables of the mechanism are the inclinations of the two crack lines for the façade and sidewalls, defining the wedge at each storey where the hinge is placed.

The optimization is executed using MATLAB as the back end. Given the geometric inputs as well as the external loads and the mechanical properties, the developed GH component computes the actual load factor and demonstrates the optimised failure mechanism. For example, Figure 10 demonstrates the actual mechanism M_C for the building of Figure 4 with its detailed dimensions. As shown in the figure, the expected load factors for the left and right sides of the wall are 0.295 and 0.282, respectively, while the hinges are formed respectively at the second and first storeys (from the bottom to the top). However, the crack inclinations on the façade wall in both mechanisms are both equal to 26° and similarly the crack inclinations on both sidewalls are 25° .

Figure 10. Crack pattern of the corner failures on both sides of the main building.

4. CONCLUSIONS

This work deals with the graphic visualization of the seismic vulnerability of historical masonry buildings, isolated or in aggregate, with respect to local failure mechanisms. The mechanical model is based on the kinematic approach of limit analysis developed in [5]. A GH plugin has been developed to parametrically model the main building and visualise all the possible OOP mechanisms and their potential locations, based on the adopted macro-block modelling approach. The plugin has been developed using C# language.

The visual output data for the potential mechanisms have been compared to similar tables existing in the literature, showing the readability improvements of the visual outcomes comparing to the tables. The plugin can also compute the optimised mechanism and visualize its actual geometry. MATLAB has been used to perform the optimization tasks.

In future works other types of collapse mechanisms will be introduced together with strengthening devices, whether made of traditional or innovative materials. The final goal is to develop a digital framework able to forecast and verify the seismic capacity of the most recurrent local mechanisms, both on the urban scale and building scale.

Abstract

The assessment of the effectiveness of strengthening interventions against the out-of-plane failure mechanisms of masonry walls requires developing a proper modelling approach. In this paper, the attention is focused on strengthening systems based on injected anchors made of carbon fibre reinforced polymer (CFRP) tubes. The resistance to corrosion and the possibility of using traditional grouts make such systems a promising alternative to steel bars in interventions on masonry structures aimed at improving poor connections between orthogonal walls. The paper introduces a modelling approach to assess the anchors contribution in the out-of-plane response of T-shaped masonry walls under horizontal actions. The approach adopts a rigid macro-block model of masonry based on the kinematic method of limit analysis. The contribution of the anchors is evaluated at the onset of the out-of-plane response of the strengthened system, defining its horizontal capacity and the crack inclination of the expected mechanism. The results obtained with the proposed model are firstly validated through the comparison with literature experimental findings. Then, parametric analyses are developed accounting for geometric and loading parameters characterizing T-shaped wall connections, and the performance of different layouts of anchors is assessed. Preliminary design indications are also provided to address the optimal balance between effectiveness, low invasiveness, and costs of such strengthening interventions.

Keywords: Masonry T-shaped walls, injected anchors, CFRP, macro-block model, limit analysis, out-of-plane mechanisms.

1 INTRODUCTION

Poor connections between orthogonal walls represent one of the primary sources of vulnerability for existing masonry buildings under seismic actions [1], together with weak connections between walls and horizontal diaphragms [2]. Indeed, they frequently cause the onset of out-of-plane failure mechanisms involving entire walls or portions of them, which can collapse for loss of equilibrium. Strengthening interventions based on injected anchors have been used since the first decades of the last century in buildings with masonry made of traditional and innovative aggregates [3]. Traditional injected anchors consist of tensile steel elements grouted in boreholes, crossing the wall connection; they can provide horizontal resistance either by bond or anchor plates, improving masonry wall connections [4].

Despite the widespread use of such a typology of anchors, their long-term durability has proved unsatisfactory due to corrosion phenomena and grout powdering. Such an aspect implies high economic and environmental impact during the building life cycle [5]. Thus, innovative typologies have recently been used in masonry structures as an alternative to steel devices [6]. They deal with anchors made of stainless steel or fibre reinforced polymer (FRP) materials, like glass or carbon fibres; they overcome the critical issues mentioned above and achieve better compatibility with the masonry substrate when used together with traditional no-cement grouts.

Many research works have investigated the behaviour of injected anchors: typical local failure modes have been identified, involving both the bond failure at the interface grout-masonry or grout-anchors, and the cone masonry detachment [7-9]; experimental campaigns have investigated the influence of geometrical and mechanical parameters on the pull-out strength [10-12], and analytical formulations have been proposed to evaluate the pull-out strength based on experimental data [13]. However, the definition of a proper modelling approach to assess the effectiveness of injected anchors on the out-of-plane response of masonry walls is still an open issue together with the formulation of design provisions [9] to achieve the best balance of effectiveness, low invasiveness and costs.

The present paper aims to address these issues, providing a modelling strategy to assess the horizontal load capacity and the expected failure mechanism of T-shaped walls, strengthened with CFRP injected anchors. An extended rigid macro-block model is first developed and applied to a literature case study [14] to verify its reliability against experimental results. Then, parametric analyses are carried out to investigate the influence of geometric and loading parameters on the performance of two different layouts of the strengthening system. The results of these analyses are used to derive preliminary design indications.

2 A MODELLING STRATEGY FOR ROCKING-SLIDING MECHANISMS IN T-SHAPED MASONRY WALLS STRENGTHENED WITH CFRP INJECTED ANCHORS

2.1 The rigid macro-block model

This section presents a modelling approach to assess the horizontal load capacity of T-shaped masonry walls strengthened with CFRP injected anchors. The approach is developed as an extension of the rigid macro-block model proposed by Casapulla et al. [15, 16] to assess the out-of-plane behaviour of unreinforced stone masonry structures. It is based on the non-linear kinematic method of limit analysis and accounts for frictional resistances. Both force and displacement-based assessments are possible.

The adopted model assumes that the relative displacements among the masonry units involved in out-of-plane failure mechanisms are concentrated along a few main cracks, separating

the structure into a number of rigid macro-blocks. Moreover, the macro-blocks and the constituent units have infinite strength in compression, tension and shear, while no-tension and frictional behaviour characterise the contact interfaces along the cracks (Coulomb failure criterion).

When the onset of a failure mechanism is investigated, the horizontal capacity of unreinforced stone masonry structures can be found as the minimum horizontal force verifying the limit equilibrium condition of the involved macro-blocks. The equilibrium refers to the rest position of the macro-blocks since their rotation is null at the onset of the mechanism. In particular, for a T-shaped wall (Figure 1a), the geometry of the macro-block involved in a rocking-sliding is defined by two parameters: the height, H_o , of the rotational hinge from the base, and the inclination angle of the main crack, α_c , affecting the spine wall (Figure 1b,c). Such parameters represent the geometric variables used in the minimization procedure and characterise the possible failure modes (Figure 1b-d).

Figure 1. Rocking-sliding failure modes of a T-shaped wall: (a) geometrical configuration, (b) simple and (c) compound rocking of part of the front wall, (d) rocking of the whole T-shaped wall.

Once identified the geometry of the macro-block at the onset, a displacement-based approach allows following the evolution of the mechanism up to collapse. To this aim, the equilibrium of the macro-block defines the horizontal capacity related to each value of the rotation angle θ , representing the kinematic configuration of the system.

The macro-block model also accounts for the frictional resistance; in particular, for combined rocking-sliding mechanisms, the criterion proposed and validated by Casapulla et al. [15] evaluates the actual frictional force F_i acting on the i^{th} bed joint as a rate of the maximum value \bar{F}_i through a coefficient ω , which depends on α_c . Hence, it can be expressed as:

$$F_i = \omega \bar{F}_i = \left(1 - \frac{\alpha_c}{\alpha_b}\right) \bar{F}_i \quad (1)$$

where α_b is the inclination angle corresponding to the units staggering ratio, i.e., $\alpha_b = \tan^{-1}(v/h)$ (Figure 2a). It is worth noting that, according to the proposed criterion, the frictional forces are taken into account only if $\alpha_c < \alpha_b$; otherwise, a simple rocking mechanism occurs without frictional resistances.

The frictional forces achieve the maximum value, \bar{F}_i when the bed joints along the crack are involved in a simple sliding mechanism, i.e., in the case of a vertical crack with inclination angle $\alpha_c = 0$ (Figure 2b). \bar{F}_i can, indeed, be expressed as the sum of two components due to the self-weight and the overload affecting the spine wall (see Figure 2a):

$$\bar{F}_i = [i \cdot (\gamma \cdot t_s \cdot h \cdot v) + q_s \cdot v] \cdot f \quad (i = 1, \dots, n_c) \quad (2)$$

being γ the unit weight of masonry, t_s the thickness of the spine wall, h the height of the units, v their overlapping length, q_s the overload per unit length, uniformly distributed on the spine

wall, f the friction coefficient, n_c the number of involved courses ($n_c \leq n$, being n the total number of courses along with the height). It is worth noting that Eqs. (1) and (2) refer to single leaf walls arranged in a running bond pattern; such an idealised regular arrangement of unit blocks assures the monolithic behaviour of the transversal section of the wall. Non-regular bond patterns can also be implemented if an average size of the unit blocks can be identified, as in [16].

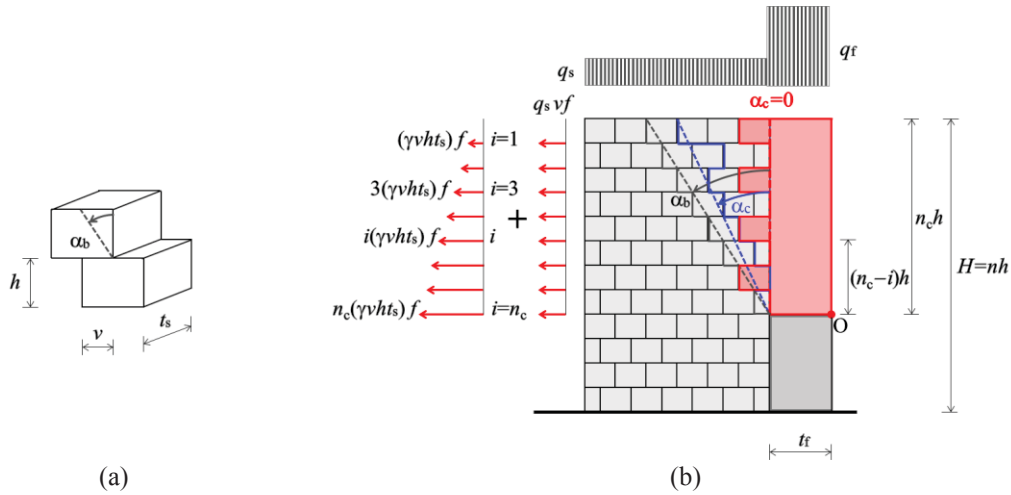

Figure 2. (a) Stone masonry unit dimensions; (b) maximum frictional forces, acting on each bed joint.

2.2 A modelling approach for strengthened T-shaped walls

The macro-block modelling approach is herein extended to the analysis of T-shaped masonry walls strengthened with CFRP injected anchors. The contribution of such a strengthening system can be taken into account on the basis of some assumptions described in the following.

First of all, it is assumed that the tensile behaviour of CFRP injected anchors can be described in a simplified way through a bi-linear load-slip relationship, T - s , as:

$$T = K_1 s \quad \text{if } s \leq s_1 \quad T = T^* - K_2 (s - s_1) \quad \text{if } s > s_1 \quad (3)$$

As an example, Figure 3a represents a bi-linear curve overlaid on experimental curves derived from literature pull-out tests [13]. It refers to CFRP tubes wrapped with a stainless-steel fabric (Figure 3b, c) and will be used in the numerical analyses developed in the following.

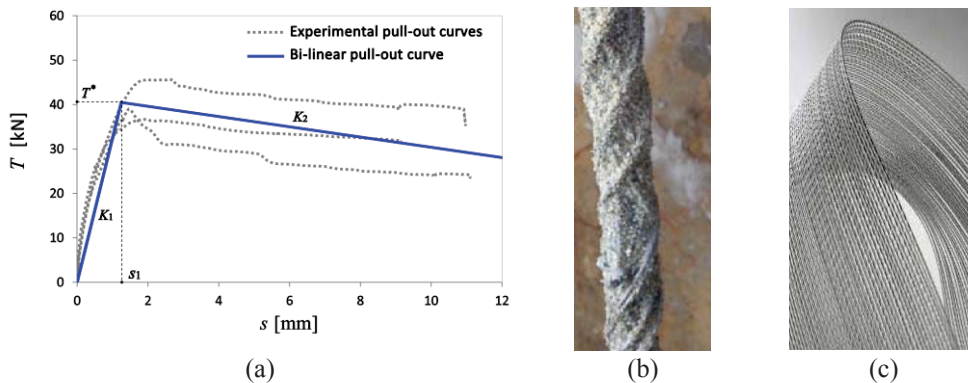

Figure 3. (a) Simplified bi-linear curve overlaid on experimental pull-out curves related to wrapped CFRP tubes [13]; (b) wrapped CRFP tubes; (c) stainless steel fabric.

The parameters defining such a bi-linear curve can be derived from the experimental data as average values; they are $K_1 = 32.4$ kN/mm, $K_2 = -1.2$ kN/mm, $T^* = 40.5$ kN, $s_1 = 1.25$ mm.

It is also assumed that the anchors are only tensioned by the relative horizontal displacements occurring along the crack line; thus, a generic row of anchors contributes to the global resistance if it crosses the main crack, and the embedded length in the resting portion of the wall is higher than that required to achieve the maximum strength. For the wrapped CFRP tubes considered in this paper, the minimum embedded length l_0 is 250 mm, based on literature pull-out tests [13]. Such a value allows exploiting the maximum strength T^* (Figure 3a).

Lastly, the resultant contribution of the active anchors at the onset of a failure mechanism is not calculated on the initial position ($\theta = 0$) of the macro-block but on the kinematic configuration ($\theta > 0$) that provides the maximum value of such contribution. The approximation can reasonably be accepted considering that CFRP anchors have very high elastic modulus and achieve the maximum tensile strength T^* for very small displacements, as fully verified in [17]. However, it is pointed out that the maximum contribution of the whole system of active anchors does not imply that they all achieve the maximum strength, T^* . This, because the forces provided by the anchors depend on the horizontal displacements that, in the rigid model, increase with the distance from the rotational hinge; consequently, the lowest rows of anchors may not reach T^* .

Based on these assumptions, it is possible to consider the limit equilibrium condition of the strengthened macro-block involved in a rocking-sliding failure mechanism. The related forces (Figure 4a) are the horizontal force F_h applied to the control point C, the resultant W of all the gravitational loads (self-weight of the macro-block and overloads), the tensile forces T_{Aj} provided by m rows of injected anchors ($j = 1, \dots, m$ from the top) and the frictional forces F_i acting on the bed joint i ($i = 1, 2, \dots, n$, from the top). It is easy to verify that the values of W and F_i strictly depend on the unknown crack inclination angle, α_c , as well as on H_0 (see Eq. (1)).

In a generic varied kinematic configuration, identified by the finite rotation angle θ (Figure 4b), the position of the forces is defined by their polar coordinates with respect to the hinge O, i.e., by their position radius R and its inclination angle, $\alpha + \theta$, on the horizontal axis.

Figure 4. (a) Forces acting on the rocking-sliding macro-block with (b) their polar coordinates related to a generic rotation angle θ .

Hence, the horizontal force F_h related to the generic rotation angle θ can be obtained as the sum of the contributions $F_{h,m}$ and $F_{h,T}$ due to masonry and injected anchors, respectively:

$$F_h = F_{h,m} + F_{h,T} = \frac{Wx'_G + \sum_{i=1}^n F_i z'_{Fi}}{z'_G} + \frac{\sum_{j=1}^m T_{Aj} z'_{Aj}}{z'_G} \quad (4)$$

where the parameters with the superscript are the lever arms of the forces in the varied configurations [16, 17]:

Assuming $\theta = 0$, Eq. (4) provides the lever arms of the forces at the onset of the mechanism. Under such an assumption, for the as-built configuration ($T_{Aj} = 0$), the expected geometry of the moving macro-block is obtained by minimising the horizontal force F_h in Eq. (4), with respect to the position of the hinge, H_0 , and the inclination of the crack, $\tan\alpha_c$, assuming $H_0 \leq H$.

For the reinforced configuration, on the other hand, F_h in Eq. (4) is not a continuous function of $\tan\alpha_c$, since the contribution T_{Aj} of the j^{th} row of anchors at the height h_j becomes null for the angle:

$$\alpha_{cj} = \tan^{-1}(L_s - l_0)/h_j \quad (5)$$

being L_s the length of the spine wall crossed by the anchors and l_0 the minimum embedded length (Figure 5); note that α_{cj} depends on the length l_0 , which is a function of both the axial stiffness of the anchors and the mechanical properties of masonry and grout [10].

Hence, the pursuit of the crack inclination providing the minimum value of F_h has to be carried out in a discrete form by comparing a set of values, F_{hj} , representing the minimum related to all the possible configurations of active rows of anchors. As an example, for the strengthening system with three rows of anchors in Figure 5, the values F_{hj} have to be calculated in the following ranges of α_c :

$$0 \leq \alpha_c < \alpha_{c1}, \quad \alpha_{c1} \leq \alpha_c < \alpha_{c2}, \quad \alpha_{c2} \leq \alpha_c < \alpha_{c3}, \quad \alpha_{c3} \leq \alpha_c < 90^\circ \quad (6)$$

Indeed, the values F_{hj} correspond to a progressive reduction of the rows of active anchors starting from the upper one.

Figure 5. Crack inclination angle α_{cj} excluding the j^{th} row of anchors.

3 EXPERIMENTAL VALIDATION OF THE ANALYTICAL APPROACH

In this section, the proposed modelling approach is applied to a literature case study to illustrate the methodology and verify its reliability. The case study deals with the full-scale T-shaped wall experimentally investigated by Maddaloni et al. [14]; it was strengthened with anchors made of CFRP tubes wrapped with a stainless-steel fabric (Figure 3b) and injected with pozzolana-based grout. The geometric features of the T-shaped wall are represented in Figure 6, together with the layout of the strengthening system. The anchors had a length of 1200 mm and were placed in 30 mm diameter holes, alternatively along two vertical lines at a distance of

250 mm. Since the experimental pull-out curves in Figure 3a refer to the same typology of anchors, the bi-linear schematization represented in the same figure has been used in the numerical analyses.

Figure 6. T-shaped wall tested by Maddaloni et al. [14]: (a) overall dimensions and arrangement of the unit blocks (b) layout of the strengthening system made of CFRP injected anchors.

3.1 Assessing the case study with the proposed approach

In applying the frictional macro-block model to the case study, a schematization of the arrangement of the stone masonry units is introduced, considering average values for both the overlapping length v and the height h of the units (Figure 2a), based on the actual ones. The friction coefficient is taken as $f = 0.6$, based on experimental data for dry-jointed tuff blocks [15]. The adopted values are reported in Table 3, with the related ones, i.e., n and $\tan\alpha_b$.

v	h [mm]	$n = H/h$	$\tan\alpha_b = v/h$	f
100	158	12	0.63	0.6

Table 2. Values of the parameters used to schematize the arrangement of the unit blocks.

The validation of the proposed approach concerns the pursuit of the crack inclination angle α_c^* providing the expected failure mechanism for the strengthened system and the minimum value F_h^* of the horizontal capacity F_h . To this aim, F_h and its components, $F_{h,m}$ and $F_{h,CFRP}$, are displayed in Figure 7a as functions of the crack inclination angle, α_c . For each α_c , the maximum values of both components are reported, assuming they occur at the onset, as previously explained. It is worth noting that F_h is applied at the control point used in the experimental test, placed at 1600 mm from the base (point C in Figure 4).

Figure 7a first shows that $F_{h,m}$ increases with α_c , with different trends due to the contribution of the frictional forces, which become null for $\alpha_c = \alpha_b = 32^\circ$ (see Eq. (1)). Its minimum value (about 49 kN) corresponds to the activation of the most likely mechanism for the unreinforced wall system, which occurs for $\alpha_{c0} = 5^\circ$, in good agreement with the experimental results related to the as-built specimen [14]. On the other hand, $F_{h,CFRP}$ exhibits a stepwise decreasing trend, where the shift from a step to the next one represents the progressive reduction of the active rows of anchors, starting from the top. For each step, the sum of the two contributions $F_{h,m}$ and $F_{h,CFRP}$ achieves a minimum value F_{hj} , which is highlighted on the red curve by a star marker. It represents the horizontal load capacity related to the failure mechanism with the crack inclination α_{cj} ($j = 0, \dots, m$, being m the rows of anchors), which excludes the first j rows of anchors, starting from the top. The crack inclinations α_{cj} associated with the possible failure mechanisms

are summarised in Figure 7b.

Thus, the horizontal load capacity of the strengthened T-shaped wall coincides with the minimum among the values F_{hj} , i.e., $F_h^* = F_{h8} = 71$ kN. Such a value corresponds to the crack inclination $\alpha_c^* = \alpha_{c8} = 82^\circ$ that excludes all the eight rows of anchors and identifies the expected failure mechanism for the strengthened T-shaped wall.

Figure 7. (a) Horizontal load capacity as the sum of masonry and CFRP anchors contributions vs. crack inclination angle; (b) crack inclination angles characterizing the possible failure mechanisms.

By concluding, it can be asserted that the proposed approach allows defining with good approximation both the failure mechanism and the horizontal load capacity of the experimental case study; this latter, in fact, after the strengthening intervention, exhibited a failure mechanism of global rocking with a cylindrical hinge at the base ($\alpha_c = 90^\circ$), with a triggering horizontal load of about 71 kN.

4 PARAMETRIC ANALYSES

This section analyses the influence of geometric and loading parameters on the horizontal load capacity of a T-shaped wall. The system is strengthened with injected anchors made of wrapped CFRP tubes, as the case study previously presented. Two layouts of the reinforcement are taken into account: Layout A, with eight rows of anchors as the experimental case study, and Layout B, with only three rows (Figure 8). For both of them, the length of the anchors is 1200 mm and the bi-linear relation presented in Figure 3a is used to describe their tensile behaviour.

Figure 8. Layouts of CFRP injected anchors adopted in the parametric analyses.

The analyses account for the independent non-dimensional parameters reported in Table 3

with their reference and limit values; in the same table, the dependent dimensional parameters and the fixed ones are also reported. Most of them are displayed in Figure 2.

The reference values of the parameters and the global dimensions of the analysed T-shaped wall are similar to those of the case study, but a non-limited length is assumed for the spine wall to exclude the failure mechanism of global rotation, which actually does not occur in a real T-shaped wall connection. Moreover, to generalize the procedure, the horizontal force F_h is applied to the gravity centre of the moving macro-block.

It is worth noting that the variable parameter ρ refers to the overload due to upper masonry levels and affects both the façade and the spine wall; the parameter η , instead, refers to the overload due to floor slabs and is fixed. In the first set of parametric analyses, η only affects the façade wall, with $\eta = \eta_f$ in the expression of q_f (Table 3); then, in a further set of parametric analyses, it affects the overload on the spine wall, with $\eta = \eta_s$. In the latter case, the expressions of the overloads reported in Table 3 change as follows: $q_f = \rho \gamma_m H$ (with $0.05 \leq q_f \leq 0.15 \text{ N/mm}^2$) and $q_s = \eta_s \rho \gamma_m H$ (with $0.15 \leq q_s \leq 0.45 \text{ N/mm}^2$).

According to the proposed approach, the horizontal capacity, F_h^* , of a strengthened T-shaped wall, at the onset of the failure mechanism, coincides with the minimum among the horizontal forces F_{hj} related to the possible failure mechanisms with crack inclination angles α_{cj} ($j = 0, \dots, m$, being m the rows of anchors). On the other hand, among the angles α_{cj} , α_c^* provides the minimum F_{hj} , i.e. F_h^* , and identifies the expected failure mechanism.

Hence, F_{hj} and the related α_{cj} are evaluated for different values of the accounted parameter and each layout. Figure 9 reports the results related to $\eta = \eta_f$, for all the investigated parameters ($\tan\alpha_b$, ρ , f , n). The results related to $\eta = \eta_s$ are reported in Figure 10 only for the most significant parameters, i.e., ρ and $\tan\alpha_b$. In both figures, the values of the horizontal capacity (i.e., the minimum F_{hj}) are highlighted by red circles, and the values of the related inclination angle α_c^* are reported.

The analyses show that the parameters ρ and $\tan\alpha_b$ are the most relevant ones for both layouts. Their increasing values imply increasing horizontal capacity of T-shaped walls. Moreover, such a trend is enhanced when the spine wall is loaded more than the façade, i.e., in the case of $\eta = \eta_s$ (Figure 10). As an example, for $\tan\alpha_b = 1.5$, Table 4 compares the values of the horizontal capacity F_h^* provided by Layouts A and B for $\eta = \eta_f$ (Figure 9a,b) and $\eta = \eta_s$ (Figure 10a,b).

	Parameters	ID	Reference values	Range of variation
Variable, independent non-dimensional parameters	Staggering ratio	$\tan\alpha_b$	0.63	0.5 - 1.5
	Size ratio	n	12	8 - 19
	Overload parameter	ρ	3.63	1.67 - 5
	Friction coefficient	f	0.6	0.35 - 0.75
Variable, dependent dimensional parameters	Overlapping	$v = h \tan\alpha_b$	100 mm	
	Height of masonry units	$h = H/n$	158 mm	100 - 238 N/mm ²
	Façade wall overload	$q_f = \eta_f \rho \gamma_m H$	0.3 N/mm ²	0.15 - 0.45 N/mm ²
	Spine wall overload	$q_s = \rho \gamma_m H$	0.1 N/mm ²	0.05 - 0.15
Fixed parameters	Masonry unit weight	γ_m	14.5 kN/m ³	
	T-wall height	$H = n h$	1900 mm	
	Compressive stress	$\sigma = \gamma_m H$	0.03 N/mm ²	
	Overload	η	3	

Table 3: Ranges of variation of parameters considered in the analyses.

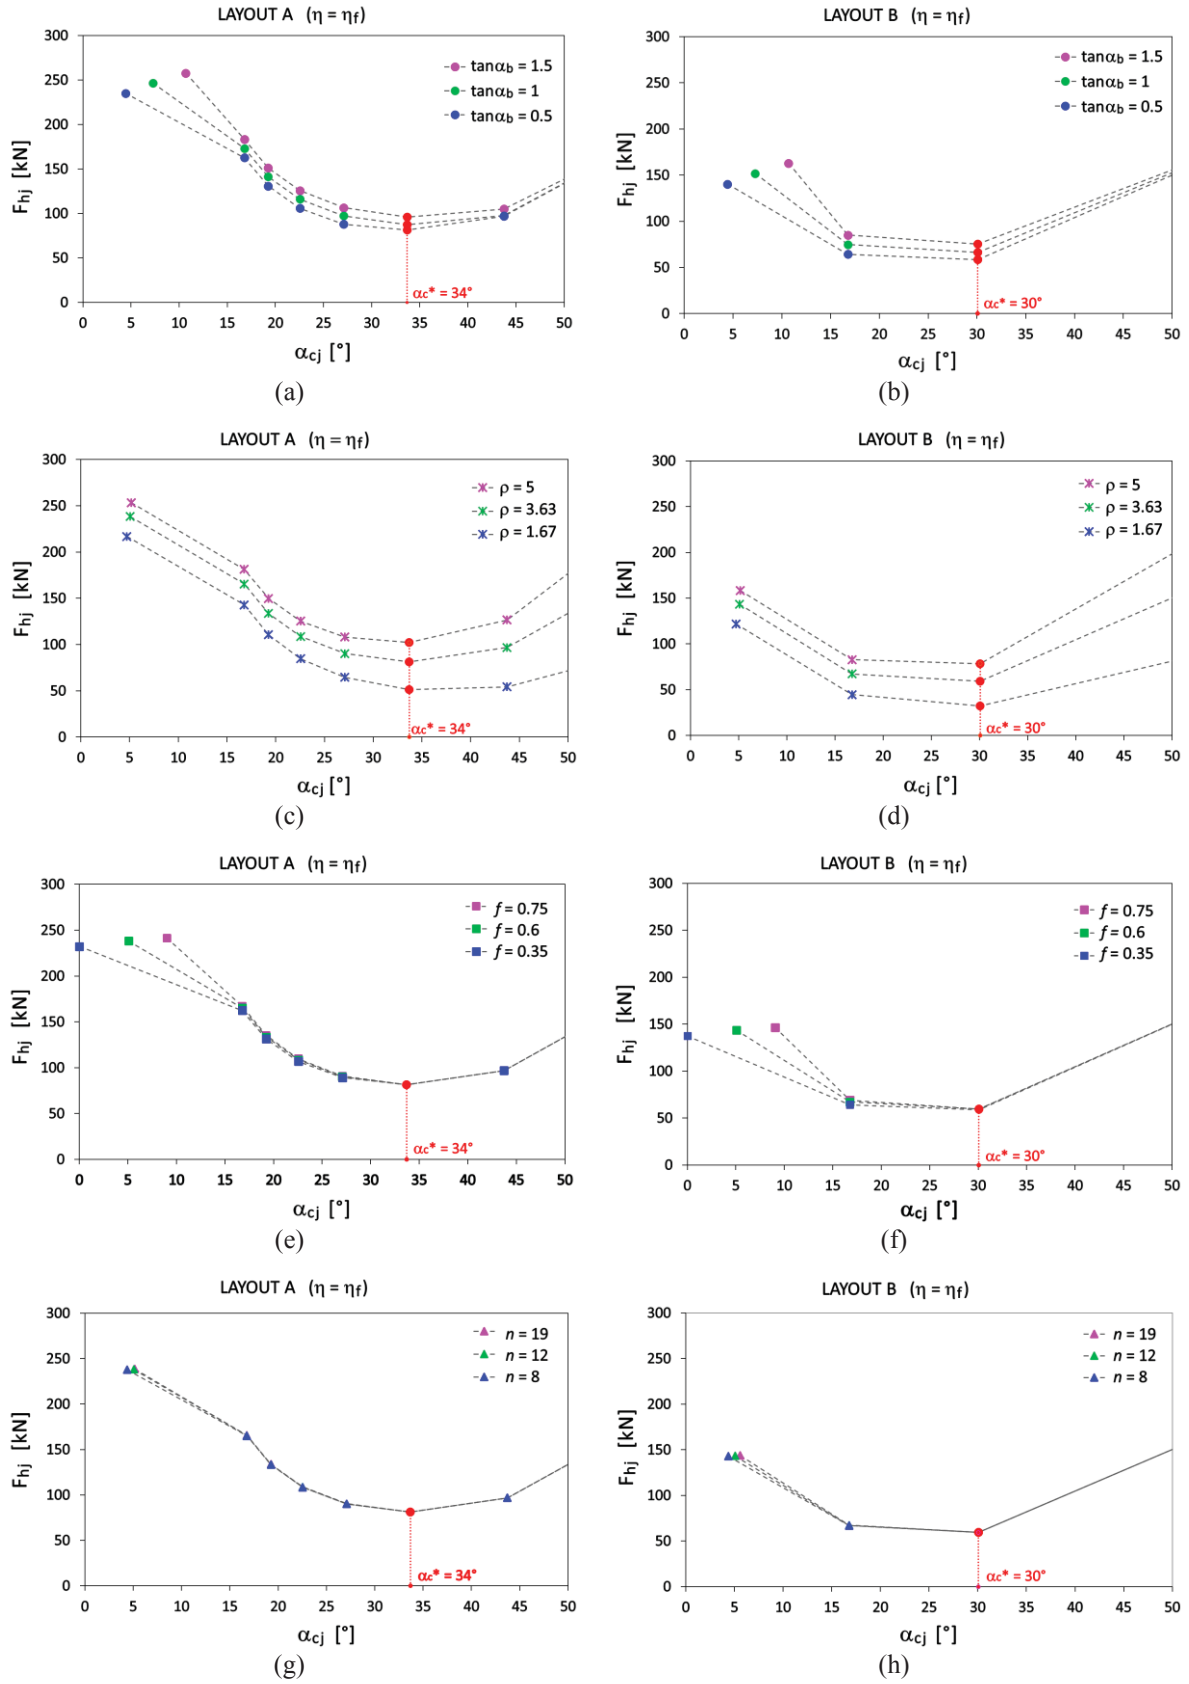

Figure 9. Results of the parametric analyses based on $\eta = \eta_f$, for (a, c, e, g) Layout A and (b, d, f, h) Layout B.

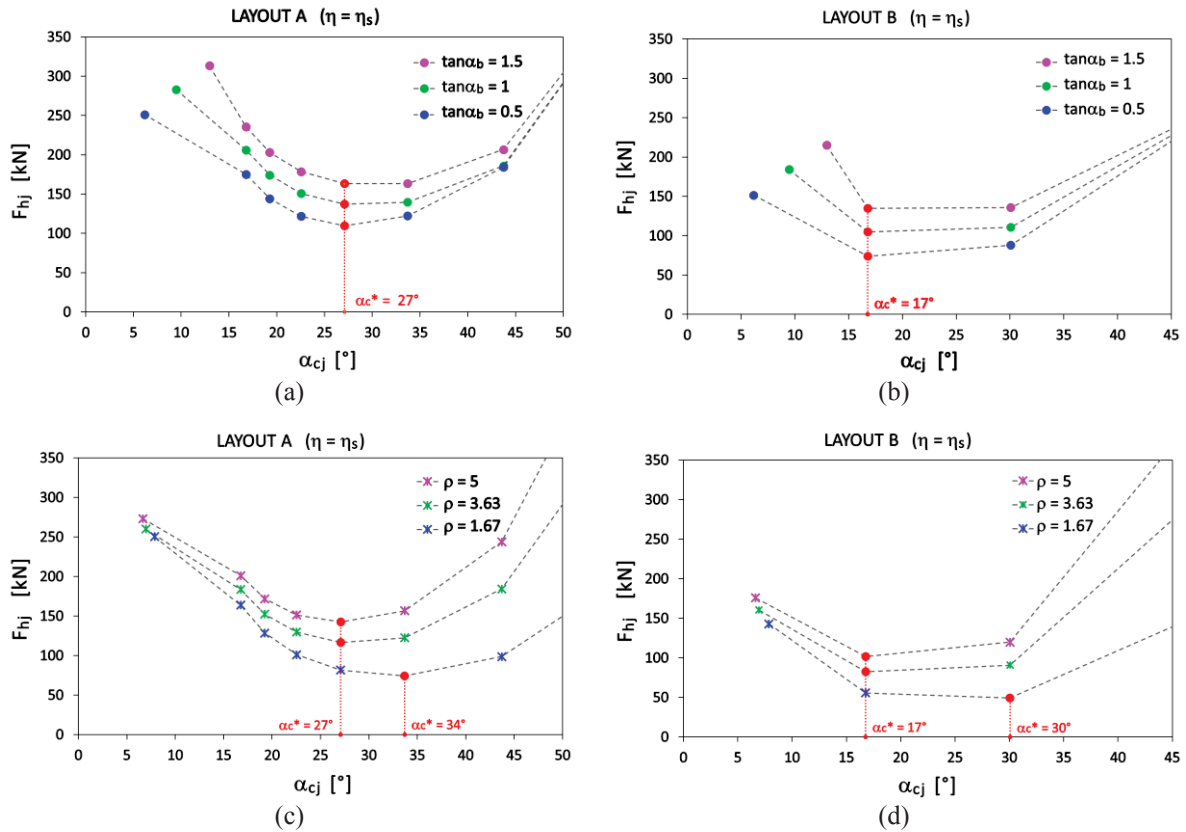

Figure 10. Results of the parametric analyses based on $\eta = \eta_s$, for (a, c) Layout A and (b, d) Layout B.

Layout	F_h^*		ΔF_h^*	%
	$\eta = \eta_f$	$\eta = \eta_s$		
A	96 kN	163 kN	67 kN	70%
B	75 kN	135 kN	60 kN	80%

Table 4. Comparison of the horizontal capacities provided by Layouts A and B related the cases $\eta = \eta_f$ and $\eta = \eta_s$, being $\tan \alpha_b = 1.5$, $\rho = 3.63$, $f = 0.6$, $n = 12$.

Figure 9e-h, related to $\eta = \eta_f$, also shows that the friction coefficient, f , and the size ratio, n , are not very significant. On the other hand, the crack inclination angle α_c^* characterizing the expected failure mechanisms ranges in 30° - 34° , being quite close to $\alpha_b = 32^\circ$, which implies that the frictional forces are close to zero according to Eq. (1). The influence of the parameter η also concerns the crack inclination angle α_c^* . In particular, when $\eta = \eta_f$ (Figure 9), α_c^* keeps constant with all the variable parameters ($\tan \alpha_b$, ρ , f , n), being $\alpha_c^* = \alpha_{c,j=5} = 34^\circ$ for Layout A and $\alpha_c^* = \alpha_{c,j=2} = 30^\circ$ for Layout B. It means that the number of active rows of anchors (five for Layout A and two for Layout B) and their contribution to the resistance do not vary with the accounted parameters. Consequently, the increase of the horizontal capacity is only due to masonry, whose contribution instead increases with such parameters.

When $\eta = \eta_s$, α_c^* is still constant with $\tan \alpha_b$ (Figure 10a,b), being $\alpha_c^* = 27^\circ$ for Layout A and $\alpha_c^* = 17^\circ$ for Layout B. Both values, however, are lower than those related to $\eta = \eta_f$ (Figure 9a,b), implying a higher number of active rows of anchors and consequently an improved contribution of the strengthening system. On the other hand, α_c^* can vary with the parameter ρ (Figure 10c,d). In particular, for both layouts, the lowest values of α_c^* occur when $\rho \geq 3.36$; it

confirms that when the overload on the spine wall is higher enough, the strengthened system exhibits a better performance. The parameters f and n when $\eta = \eta_s$ still have a negligible effect on the horizontal capacity as in the case $\eta = \eta_f$, although lower values of the angle α_c^* have been obtained; thus, the related analyses are not represented in Figure 10.

Finally, it is interesting to note that the values of α_c^* provided by all the parametric analyses are always lower than 90° , highlighting that the global rocking mechanism obtained both experimentally and analytically for the T-shaped wall case study never occurs. This result can be explained considering that in the parametric analyses, the length of the spine wall is not limited to 1600 mm, as for the case study, but has a realistic value; thus, for $\alpha_{cj} > \alpha_c^*$, the sewing action of the active anchors allows increasing the involved portion of the spine wall, preventing from the potential failure mechanisms with the crack inclination angles higher than α_c^* . It is worth noting that a length of only two meters is required to obtain such a result with all the accounted parameters.

5 DESIGN INDICATIONS

The performance of Layouts A and B resulting from the previous parametric analyses is herein discussed to derive preliminary design indications. For this purpose, only the most significant parameters are considered, i.e., $\tan\alpha_b$ and ρ , for both cases of $\eta = \eta_f$ and $\eta = \eta_s$.

Firstly, Table 5 summarises the better performance of the accounted layouts in terms of the percentage increase of the horizontal capacity against the as-built configuration. Such a performance is achieved for the lowest considered values of $\tan\alpha_b$ and ρ , i.e., $\tan\alpha_b = 0.5$ and $\rho = 1.67$, keeping fixed the other parameters to their reference values (Table 3).

Layout	$\tan\alpha_b = 0.5$; $\rho = 3.63$		$\rho = 1.67$; $\tan\alpha_b = 0.63$	
	$\eta = \eta_f$	$\eta = \eta_s$	$\eta = \eta_f$	$\eta = \eta_s$
A	101%	136%	133%	148%
B	44%	59%	46%	64%

Table 5. Percentage increase of the horizontal capacity against the as-built configuration.

Then, the performances of the two layouts are compared with reference to a fixed value of the required capacity, F_{hD} . It might represent the seismic demand related to a definite limit state, and for only illustration purpose, it is assumed $F_{hD} = 70$ kN, which is close to the horizontal capacity of the case study at the onset of the global rocking mechanism. The comparison capacity-demand is displayed in Figure 11, where the horizontal line representing F_{hD} is overlaid on the curves representing the horizontal load capacity of Layout A and B versus $\tan\alpha_b$ and ρ , for $\eta = \eta_f$ and $\eta = \eta_s$. The capacity related to the as-built configuration is also represented as a reference.

Hence, Figure 11a shows that, for $\eta = \eta_f$, Layout B is not adequate for the seismic demand of 70 kN until $\tan\alpha_b < 1.25$, while for $\tan\alpha_b > 1.25$, it is suitable and preferable to A for the lower number of anchors. On the other hand, for $\eta = \eta_s$ (Figure 11c), the strengthening intervention is not required until $\tan\alpha_b > 0.85$, while, when $\tan\alpha_b < 0.85$, Layout B is satisfactory. Similar considerations can be done when the parameter ρ is taken into account in Figure 11b and 11d, identifying the preferable layout.

Moreover, when the non-dimensional parameters assume the reference values ($\tan\alpha_b = 0.63$ and $\rho = 3.63$) identified in Figure 11 by a dotted vertical line, Layout B is not adequate for the seismic demand of 70 kN if $\eta = \eta_f$, while it is satisfactory if $\eta = \eta_s$.

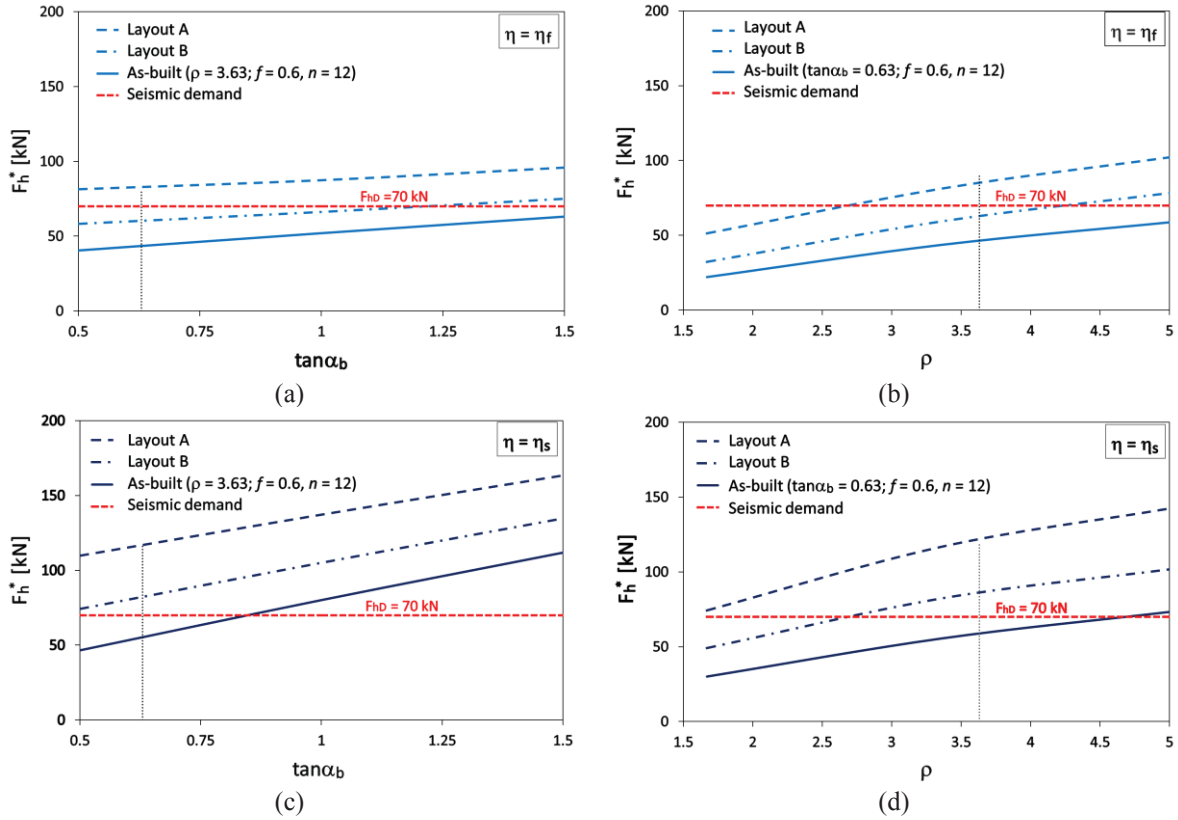

Figure 11. Performance of Layouts A and B and as-built specimen depending on $\tan \alpha_b$ and ρ , for (a, b) $\eta = \eta_f$ and (c, d) $\eta = \eta_s$.

Finally, a higher length of the anchors could be adopted to improve the performance of Layout B, especially when $\eta = \eta_f$. Thus, to generalise the issue, the effect of the variable length of the anchors, L_a , is analysed in Figure 12 for $\eta = \eta_f$ and $\eta = \eta_s$ and for both the layouts, A and B. The values of the parameters characterising the T-shaped connection are the reference ones listed in Table 3 (i.e., $\tan \alpha_b = 0.63$, $\rho = 3.63$, $f = 0.6$, $n = 12$).

Figure 12 shows that the horizontal load capacity of the strengthened system increases with the length of the anchors, as expected. However, a threshold length can be recognised, after which a further increase is irrelevant since the horizontal load capacity keeps constant. Such a threshold length is the same for Layouts A and B, i.e., 3000 mm when $\eta = \eta_f$ and 2200 mm when $\eta = \eta_s$. The horizontal load capacity of Layout A is clearly always higher than Layout B because of the higher number of anchors, but, when $\eta = \eta_f$, an increased length of 1500 mm makes Layout B adequate to sustain the seismic demand $F_{hD} = 70$ kN. Generalising, from Figure 12, it is possible to identify the length of the anchors required for a given performance and compare the different layouts.

Such considerations represent a first approach to the design issues that will be addressed comprehensively in the ongoing research.

Figure 12. Horizontal load capacity vs. length of the anchors for $\eta = \eta_f$ and $\eta = \eta_s$ provided by (a) Layout A and (b) Layout B, being $\tan\alpha_b = 0.63$, $\rho = 3.63$, $f = 0.6$, $n = 12$.

6 CONCLUSIONS

In this paper, a modelling approach has been presented to assess the onset of the out-of-plane response of T-shaped masonry walls, strengthened with CFRP injected anchors. The approach has been developed using a rigid macro-block model already validated for unreinforced stone masonry structures; it is based on the kinematic method of limit analysis and accounts for the frictional resistances. The attention has been focused on identifying the horizontal load capacity corresponding to the onset of the expected failure mechanism for the strengthened T-wall.

Assumptions have been made to account for the contribution of CFRP anchors in the rigid model adopted for masonry. These assumptions have been validated by applying the model to a literature experimental case study, and a good match has been found between experimental outcomes and analytical predictions in terms of both horizontal load capacity and expected failure mechanism.

After validating the model, parametric analyses have been carried out, based on some geometric and loading parameters affecting T-shaped masonry walls, and the most significant ones influencing the horizontal capacity have been identified. Moreover, the performance of two strengthening layouts, characterised by a different number of injected anchors with a fixed length, has been compared. The results of the parametric analyses have been used to derive preliminary design indications aimed at identifying the adequate layout for a given value of the seismic demand. Finally, the effect of a variable length of the anchors on the horizontal capacity has also been investigated, and a threshold length has been recognised, after which a further increment is irrelevant since the horizontal load capacity keeps constant.

The results of the proposed modelling approach allow deriving preliminary indications to optimise the design of strengthening interventions with injected anchors. Such a crucial topic, however, will more comprehensively be addressed in the ongoing research.

Abstract

Several research outcomes have ascertained the need of considering the infill walls in the dynamic response evaluation of reinforced concrete framed buildings. In the case of buildings designed prior the introduction of modern seismic codes, the presence of strong infill might highly influence the failure mode in case of earthquake. Furthermore, considering the increasingly adoption of retrofit techniques aimed at enhancing the in-plane and out-of-plane capacity of the infill walls, its influence on the seismic performance of the structure should be investigated at global and local level. In this study, a numerical model to simulate the response to lateral loads of reinforced concrete frames with retrofitted masonry infill walls is developed. Particularly, since the use of composites is widespread due to the well-known benefits of these materials, the work is focused on the in-plane infill retrofit by fibre-reinforced polymer (FRP). The proposed model for the retrofitted infill is validated by numerical simulation of diagonal compression tests on masonry panels previously conducted at university of Salento. Aiming to analyse the influence of the retrofit on the seismic performance of the frame, the retrofitted infill and unreinforced infill performances are compared. Depending on the infill type considered, the failure modes of the frame members, the energy dissipated under lateral loading and the displacement capacity are analysed.

Keywords: Meso-modelling, Infilled frames, retrofitted infill, seismic vulnerability, RC frames.

1 INTRODUCTION

The in-plane or out-of-plane collapse of infill walls caused by earthquakes can represent a major threat for life safety, particularly during seismic emergency. Moreover, the seismic damage on infills might cause in-direct losses which affect the serviceability of the building, such as failure of piping lines or electrical wiring embedded in the walls. The severe damage on masonry infill walls, documented in several post-seismic on-site recognitions [1–3], led to recent investigations through laboratory tests [4–6] and numerical studies [7,8], with the scope of characterizing their seismic response. Aiming to avoid infill's damage due to earthquake, state-of-art retrofit solutions are increasingly employed on existing buildings. Textile-Reinforced Mortar (TRM), Composite-Reinforced-Mortar (CRM) or Steel-Reinforced-Grout (SRG) jacketing significantly increase the lateral load capacity of masonry panels [9–11], even though such techniques are not always applicable due to the mass and thickness increase. On the other hand, the use of fibre-reinforced polymers (FRP) retrofit prevents out-of-plane failure and increases the in-plane tensile strength of the wall without majorly modifying its thickness [12,13].

The increasingly number of studies on strengthened masonry walls allowed to comprehensively define their in-plane and out-of-plane response, as well as the failure modes in case of lateral loading. Several analytical models were calibrated based on experimental findings, contributing to the development of guidelines for retrofit techniques [14,15], which provide instruction for their design, installation and maintenance. Most of the studies on strengthened panels are addressed to load-bearing walls in masonry structures, which are widespread in Mediterranean regions and represent a building category with high seismic vulnerability. On the other hand, the research outcome also applies to non-structural masonry panels in RC framed structures. To this regard, despite the strengthening techniques adopted for infill walls are generally identical to those used in masonry structures, additional considerations are required in the former case to account for the frame-infill interaction.

The influence of the infills on the dynamic performance of RC framed structures is well-known in earthquake engineering. Several studies provided simplified formulations to simulate the lateral behaviour of infilled frames and to predict the seismic demand depending on the properties of the masonry walls [16,17]. Additionally, the analysis of the effect of the infills on the seismic behaviour of RC frames is addressed in recent building codes [18–20]. In the case of buildings built before the introduction of modern seismic design codes, the presence of strong infill walls not only provides a significant contribution to the lateral stiffness, but can also influence the failure mode of the frame members [21–23]. The additional shear demand in columns with poor shear reinforcement caused by the infill-frame interaction can lead to early brittle failure and, consequently, reduce the displacement and ductility capacity of the RC structures [24].

Since the retrofit techniques currently used to prevent non-structural walls collapse significantly increase their lateral strength, an accurate evaluation of the consequences of the retrofit on the structural performance is strictly required when dealing with gravity load designed RC frames. In fact, a shear strengthening of the columns might be also required, in order to avoid brittle failure caused by the interaction with the retrofitted infill walls [25]. Recent studies have shown the reliability of the available numerical models in predicting the shear demand in frame members caused by the interaction with the infill, both employing macro or micro modelling approaches [26–29]. On the other hand, the complex behaviour of retrofitted infill walls might require more advanced numerical modelling approaches, which allow to account for all the possible failure modes. For instance, the simulation of the interface interaction between masonry substrate and retrofit layer is required to account for cohesive failure, which is a common failure mode in case of FRP retrofit [30].

A numerical model for the simulation of the in-plane response to lateral loads of an infilled RC portal frame is developed in this study. Two infill types are considered, namely an unreinforced masonry wall and a masonry wall retrofitted with fibre-reinforced-polymer layers. The cross section and the reinforcement of

the RC frame members were defined according to a simulated gravity load design, assuming the considered frame as part of the first floor in a four-storey building. This approach allowed to reproduce the configuration of existing buildings, characterized by low performance under seismic actions. Aiming to accurately simulate the failure modes of the analysed frames, a meso-modelling approach is adopted, explicitly defining the brick units in the wall, as well as the interface interaction with the RC frame and the retrofit. The model developed for the masonry wall is firstly validated by simulating diagonal compression tests previously performed at university of Salento [31]. The lateral behaviour of the case study RC portal frames was investigated by mean of non-linear static analyses, to evaluate the failure modes, the energy dissipation and the displacement capacity depending on the infill properties.

2 DESCRIPTION OF THE CASE STUDY PORTAL FRAMES

The portal frame considered in this study replicates the first floor in a 4-storey and 4-bay RC building designed for gravity loads, with bay length, L , equal to 5.4 m in both directions and floor height, h , equal to 3 m. The dead and live loads on the slab were assumed equal to 5.8 kN/m² and to 2.0 kN/m², respectively. The cross section of the columns was designed computing the axial load through to the tributary area method, while the beam's cross-section was assumed equal to $L/10$. The longitudinal and transverse reinforcement was defined according to the gravity load design provisions of the Italian building code [32]. The mechanical properties assumed for concrete and reinforcing steel are provided in **Table 1**.

Concrete	
Compressive strength f_c [MPa]	27.0
Young's modulus E_c [MPa]	32306.0
Tensile strength f_{ct} [MPa]	2.7
Reinforcing steel	
Yielding strength f_{ys} [MPa]	450.0
Young's modulus E_s [MPa]	210000.0

Table 1. Mechanical properties of concrete and steel rebars assumed for the numerical model.

In **Table 2**, a description of the analyzed frames is provided. An identification code is assigned to each frame depending on the considered configuration (URF = Frame with UnReinforced infill; FRPF = Frame with Fiber-Reinforced-Polymer infill). The portal frame in its two configurations considered in this study is illustrated in **Figure 1**. The infill wall was composed of tuff stone bricks typical of southern Italy, whose properties were defined based on laboratory tests previously conducted at University of Salento [31]. The compressive strength, f_{cw} , and the elastic modulus, E_w , were equal to 13.9 MPa and 7796 MPa, respectively. The bed joints were characterized by cementitious mortar with low mechanical properties, to simulate the behaviour of infill walls in existing old buildings.

ID	Column cross section [mm]	Beam cross section [mm]	Infill thickness [mm]	Infill retrofit type
URF	400x400	400x500	200	none
FRPF	400x400	400x500	200	FRP Layer

Table 2. ID of the case study frames.

Figure 1. Configuration of the case study frames: (a) *URF* and (b) *FRPF*.

2.1 Simulated design of the retrofit

The FRP retrofit of the infill wall is composed of diagonal basalt-fibre composite sheets with thickness, t_{FRP} , and width, b_{FRP} , equal to 0.14 mm and 650 mm, respectively. The tensile strength, f_{FRP} , and the elastic modulus, E_{FRP} , were equal to 2326 MPa and 75.98 GPa, respectively. The wall retrofit was designed by replicating a realistic scenario in which a lateral strengthening of the infill is required to avoid severe in-plane cracking in case of earthquake. A target lateral shear strength of the wall, F_{hw} , was computed based on the seismic base shear demand, F_h , defined according to the equivalent static approach described in the Italian building code [32]:

$$F_h = \frac{S_a(T_1) \cdot \lambda \cdot W_b}{q_b} \quad (1)$$

In equation (1), W_b is the total weight of the building, q_b is the behaviour factor, λ is the participating mass coefficient and $S_a(T_1)$ is the spectral acceleration corresponding to the first period of the structure.

The behaviour factor was assumed equal to 1.5 to assume a low ductility of the frame, in consistency with the gravity load design. The value of $S_a(T_1)$ was defined based on a high seismic hazard zone in Italy and considering a design return period equal to 475 years, as prescribed in the Italian building code for residential buildings [32].

The value of F_{hw} was calculated as $F_{hw} = \alpha_w \cdot F_h / [n_w \cdot (\alpha_w + 1)]$, being α_w the infill-to-frame relative elastic stiffness (equation (2)) and n_w the number of infill walls in the considered direction. This approach assumes that the total base shear in the building is distributed among the RC columns and the infill walls along the perimeter, proportionally to the lateral stiffness of each element.

$$\alpha_w = \frac{n_w G_w t_w l_w h_c^3}{n_c 12 E_c I_c h_w} \quad (2)$$

In equation (2), l_w and h_w are the length and the height of the infill wall, respectively; E_c , I_c and h_c are the elastic modulus of the concrete (computed according to Italian building design code [32]), the moment of inertia of the cross section and the height of the columns, while n_c is the number of columns oriented in the considered direction. It is worth mentioning that the approach adopted for the evaluation of F_{hw} assumes the masonry infill walls as part of the lateral loads resisting system.

Based on the target shear strength, the retrofit was designed adopting simplified formulations provided in the literature. The shear strength of the retrofitted infill, F_{FRP} , was computed according to CNR-DT 200/2013 [14]:

$$F_{hw} \leq F_{FRP} = \tau_w \cdot A_w + F_{f,FRP} \quad (3)$$

In equation (3), τ_w and A_w are the shear strength and the cross sectional area of the infill wall, respectively, $F_{f,FRP}$ is the shear strength contribution provided by the composite, defined through equation (4), depending on the elastic modulus (E_f) the thickness (t_f) and the fracture energy (Γ_f) of the FRP layer.

$$F_{f,FRP} = 0.48 \cdot l_w \cdot 2t_f \cdot \sqrt{\frac{2 \cdot E_f \cdot \Gamma_f}{t_f}} \quad (4)$$

3 NUMERICAL MODEL DESCRIPTION

A three-dimensional model was developed in ABAQUS [33] for the simulation of the lateral behaviour of the infilled portal frames (**Figure 2**). The RC frame members were modelled using eight-node linear elements (C3D8R) with embedded trusses (T3D2), representing concrete and reinforcement rebars, respectively. A simplified elastic-perfectly plastic behaviour in compression was assumed for concrete, where the elastic stress limit was equal to the compressive strength, f_c , and the ultimate strain, ϵ_{cu} , was computed according to Italian building code [32]. The tensile behaviour featured a linear elastic branch up to the tensile strength, f_{ct} , followed by tension stiffening. Referring to reinforcing steel, an elastic-perfectly plastic behaviour was assumed both in compression and tension, assuming strain at failure, ϵ_{su} , equal to 0.075.

A discrete meso-modelling approach was adopted for the masonry infill wall, explicitly defining the brick units in the geometry. The mesh of the bricks was characterized by eight-node linear elements

(C3D8R), with linear elastic mechanical behaviour, since their high compressive strength suggested the unlikely occurrence of crushing failure. To validate this statement, the maximum stress in the brick was checked at the end of each simulation performed.

A cohesive law was adopted at the brick-to-brick interface, to simulate the presence of mortar joints (**Figure 2**). The interface behaviour in tension and in the two shear directions was characterized by a linear elastic response up to maximum strength, followed by linear softening, simulating cracking evolution. The damage initiation is ruled by the maximum stress criterion provided in equation (5):

$$\max \left\{ \frac{t_n}{t_{nL}}, \frac{t_{s1}}{t_{s1L}}, \frac{t_{s2}}{t_{s2L}} \right\} = 1 \quad (5)$$

where t_n , t_{s1} and t_{s2} are the stress values in the three principal directions and t_{nL} , t_{s1L} and t_{s2L} are the limit values when the separation is either purely normal to the interface or purely in the first or the second shear direction, respectively. The tensile limit, t_{nL} , was assumed equal to 0.26 MPa, based on the results of three-point-bending tests on mortar specimens. The values of t_{s1L} and t_{s2L} correspond to the shear strength of mortar joints, τ_w , which was calibrated based on diagonal compression tests performed at university of Salento, as described in the following section. The elastic slope of the cohesive behaviour in pure tension and pure shear are equal to $k_{ss} = G_{mj}/h_{mj}$ and $k_{nn} = E_{mj}/h_{mj}$, respectively, being E_{mj} and G_{mj} the Young's and shear modulus of mortar and h_{mj} the mortar joints thickness.

Figure 2. Description of the numerical model.

The damage evolution was defined based on the mixed-mode criterion, representing cohesive failure by equation (6):

$$\frac{G_n}{G_{nL}} + \frac{G_{s1}}{G_{s1L}} + \frac{G_{s2}}{G_{s2L}} = 1 \quad (6)$$

where G_n , G_{s1} and G_{s2} are the energy values in the three principal directions and G_{nL} , G_{s1L} and G_{s2L} are fracture energy values when the separation is either purely normal to the interface or purely in the first or the second shear direction, respectively. As for the shear strength of mortar joints, the fracture energy values were calibrated based on the results of diagonal compression tests described in the following section. In **Figure 2**, the curve representing the cohesive response in pure shear is provided. The same cohesive law was used to simulate the interaction at the wall-frame interface.

The FRP retrofit was modelled through plane surfaces meshed using three-node shell elements (S3). The mechanical stress-strain behaviour of the FRP sheets was composed of a linear elastic branch up to the attainment of the tensile strength, f_{FRP} , followed by tensile failure. Aiming to simulate debonding, a cohesive law was defined at the wall-FRP interface (**Figure 2**). A rigid response was assumed up to failure, followed by linear softening. Since lateral loading mainly produces in-plane internal forces at the interface, no tensile damage was assumed. The shear stress limit, $f_{b,FRP}$, and the fracture energy value were defined based on provisions in CNR-DT 200 R1/2013 [14].

3.1 Calibration of the model adopted for the infill

The model used for the unreinforced and the retrofitted infill was firstly calibrated by simulating diagonal compression tests on masonry specimens. Two tests previously performed at university of Salento on tuff stone masonry walls were selected [31]. The tests setup and the details of the specimens are provided in **Figure 3** and **Table 3**, respectively.

ID	Dimensions [mm]	Masonry type	f_{cw} [MPa]	E_w [MPa]	t_{FRP} [mm]	b_{FRP} [mm]	f_{FRP} [MPa]	E_{FRP} [MPa]
URW	650x650	Tuff stone	13.9	7796.0	-	-	-	-
FRPW	650x650	Tuff stone	13.9	7796.0	0.14	90.0	2326.0	75980.0

Table 3. Specimens' details in diagonal compression tests.

The tests were conducted according to the ASTM E 519-02 standard [34] and were aimed at characterizing the in-plane strength of tuff stone masonry walls typical of Southern Italy. The specimens were composed of 11 layers of masonry bricks with dimensions equal to 100x50x100 mm and cementitious mortar joints of about 10 mm thickness. It is worth noting that the mechanical properties of the masonry wall and the FRP retrofit are the same described in section 2.1.

A monotonic force-controlled loading protocol was applied along the diagonal direction of the specimens through a manually-operated hydraulic jack. The restrained corners of the wall were cut to uniformly distribute the applied load on a plane surface. The diagonal deformations of the specimens were monitored

through linear variable displacement transducers (LVDT), placed at both sides along the two diagonals of the walls. An additional LVDT was also placed at each side to detect possible out-of-plane displacements.

Figure 3. Test setup for (a) *URW* and (b) *FRPW*.

The response of *URW* specimen to diagonal compression was characterized by a brittle failure caused by shear cracking of mortar joints. An off-diagonal cracking path was observed (**Figure 4a**), starting from the corner of the loaded surface. Additionally, geometry imperfections in the specimen caused a minor out-of-plane failure mode. This aspect is evidenced by the significant difference between the displacement measurements provided the vertical LVDTs at the two sides of the wall (LVDT s_x and LVDT d_x , respectively). The Load-displacement curve is provided in **Figure 5a**. The maximum strength, $F_{m,test}$, and the corresponding displacement, $D_{m,test}$, were equal to 21.5 kN and 0.32 mm, respectively.

Figure 4. Failure in case of (a) *URW* and (b) *FRPW*.

In the case of *FRPW* specimen, the failure mode was characterized by cohesive debonding of the FRP layer at both sides of the wall, followed by collapse (**Figure 4b**). The presence of retrofit significantly enhanced both the maximum strength and the displacement capacity with respect to the unreinforced

configuration. The values of $F_{m,test}$ and $D_{m,test}$ were equal to 53.1 kN (+146% with respect to *URW*) and 0.71 mm (+ 296% with respect to *URW*), respectively. Consequently, a significant increase of the cumulative energy dissipated, ED , was obtained in the case of retrofitted wall, as shown in **Table 4**.

Figure 5. Load-displacement curves obtained for (a) *URW* and (b) *FRPW*.

In the numerical model, the boundary conditions were simulated by including translational restraints in the three-principal directions and a displacement-controlled vertical load at the bottom and the top surface of the wall, respectively (**Figure 6**). The fracture energy and the shear limit values in the cohesive laws employed for the brick-to-brick and the wall-to-FRP interaction were adjusted to obtain a satisfactory matching of the experimental Load-displacement curves. The comparison between the numerical and the experimental results is provided in **Figure 7**, while the failure modes obtained in the numerical simulations are shown in **Figure 8**. In the case of *URW*, a satisfactory matching of the linear elastic slope of the experimental curve was obtained, up to a load value equal to 12 kN. Nevertheless, the progressive slope reduction observed in the test, caused by out-of-plane failure, was not simulated by the numerical model. It is worth reminding the unsymmetric vertical displacement measurements provided by the LVDTs placed at opposite sides of the wall, which suggest a significant influence of the specimen's imperfections on the test results. Being this feature not replicated in the numerical model, an accurate match of the post-elastic phase of the curve was not possible.

ID	$F_{m,test}$ [kN]	$D_{m,test}$ [mm]	ED_{test} [kNmm]
URW	21.5	0.18	2.76
FRPW	53.1	0.71	51.93

Table 4. Diagonal compression tests results.

On the other hand, a satisfactory agreement was obtained in terms of maximum strength, displacement capacity and, consequently, cumulative energy dissipated. The difference between the experimental and numerical maximum strength ($F_{m,test}$ and $F_{m,FEM}$, respectively) was equal to 4.8%. The displacement corresponding to the maximum strength in the numerical simulation ($D_{m,FEM}$) was equal to 0.17 mm, that is 5.5% lower compared to $D_{m,test}$. The failure mode in numerical simulation was characterized by minor diagonal cracking followed by bed joint sliding (**Figure 8a**). The difference between numerical and experimental results can be related to the specimen imperfections. Furthermore, it is worth evidencing that

the actual mortar joint thickness was not explicitly included in the numerical model, possibly causing a different path of internal forces comparing to the test.

Figure 6. Numerical model for the simulation of the diagonal compression tests: (a) *URW* and (b) *FRPW*.

In the case of *FRPW*, both elastic and post-cracking response were precisely simulated by the numerical model, resulting in a satisfactory matching of the energy dissipation capacity up to the maximum strength. The curve obtained from the numerical simulation is characterized by a first, minor debonding of the FRP layer, followed by a redistribution of the internal forces at the wall-FRP interface and stiffness restoration up to failure (**Figure 8b**). Despite the neglectable difference between the numerical and the experimental value of F_m (+1.0%), the numerical model was unable to simulate the post-peak response and the displacement capacity of the specimen. The value of $D_{m,FEM}$ was 23.7% higher than $D_{m,test}$, while the difference between numerical and experimental ED at failure was equal to 23.65%. This result is probably due to the high complexity of the failure mode of FRP-retrofitted wall, which can be highly influenced by imperfections, such as uneven adhesion of the FRP layer on the wall surface.

Figure 7. Comparison between numerical and experimental Load-displacement curves for (a) *URW* and (b) *FRPW*.

The calibrated values of the fracture energy and the shear limit in the cohesive laws employed for the brick-to-brick and the wall-to-FRP interaction were used in the finite element model developed for the simulation of the lateral behaviour of the infilled frames. The same properties as the diagonal compression tests specimens were assumed for masonry brick units and FRP retrofit. The wall thickness was modified from 100 mm to 200 mm, in order to reproduce the configuration of infill walls in full-scaled portals.

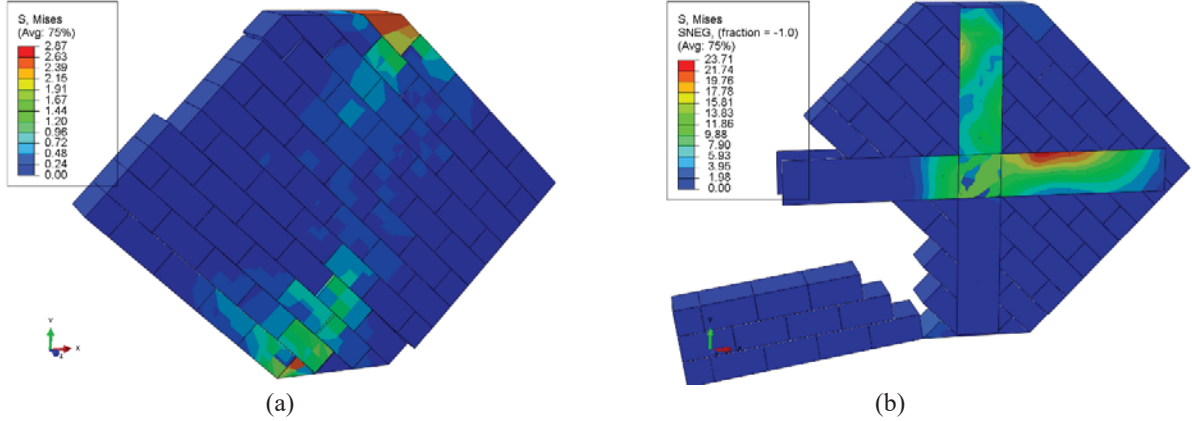

Figure 8. Failure modes in numerical simulation for (a) *URW* and (b) *FRPW*.

4 PUSHOVER ANALYSIS OF THE FRAMES
