The pushover analysis of the frames was performed considering a horizontal displacement-controlled loading protocol, applied to the top of the portal frame. The displacement amplitude was increased up to the achievement of the maximum value Δ_{max} , assumed equal to $\theta_{u,c} \cdot h_c$, being $\theta_{u,c}$ the expected ultimate chord rotation of the columns, computed using equation (7) provided in Eurocode 8 [35].

$$\theta_{u,c} = 0.825 \cdot 0.016 \cdot h_c \cdot (0.3^v) \left[\frac{\max(0.01; \omega') f_c}{\max(0.01; \omega)} \right]^{0.225} \left(\frac{L_v}{h_c} \right)^{0.35} 25^{\left(\alpha \rho_{sx} \frac{f_{yw}}{f_c} \right)} \quad (7)$$

In the equation (7), v is the axial load ratio, ω and ω' are the reinforcement index for tensile and compressive longitudinal rebars, f_c is the cylindrical compressive strength of the concrete, L_v is the shear span, α is the confinement coefficient, ρ_{sx} and f_{yw} are the transverse reinforcement ratio and tensile strength, respectively. The value of Δ_{max} can be reasonably assumed as an upper displacement limit, since the presence of the masonry infill walls generally reduces the displacement capacity of RC frames with respect to a bare configuration.

The lateral load-displacement response and the failure modes of the analysed frames is reported in **Figure 9** and **Figure 10**, respectively. It is worth mentioning that the shear failure of the RC frame members was not detectable by the modelling approach developed, since the mechanical model used for concrete does not account for material degradation under shear. Therefore, the occurrence of the shear failure was assessed by comparing, for each column, the maximum of shear obtained from the analysis to the analytical shear strength, V_{Rc} . The value of V_{Rc} was computed according to the variable inclination strut model [36].

Figure 9. Lateral response of the analysed portal frames.

As shown in **Figure 9**, the maximum lateral strength, F_m , was 53.4% higher in case of **FRPF** compared to **URF**. On the other hand, the contribution of the FRP layer to the elastic stiffness is neglectable. In the case of **FRPF**, retrofit debonding was observed after the attainment of F_m , at a displacement amplitude equal 17 mm. Referring to **URF**, the onset of damage in the infill wall was characterized by mortar joints cracking, followed by the generation of a strut mechanism. The maximum strength was attained for a displacement amplitude equal to 22.4 mm, while the post-peak behaviour featured mortar bed joints sliding. The strut mechanism generation, representing the compression field in the wall, leads to an uneven shear distribution among the two columns. This phenomenon is more noticeable in the case of **FRPF**, since the presence of the retrofit delays the cracking generation in mortar joints, as shown in **Figure 11**.

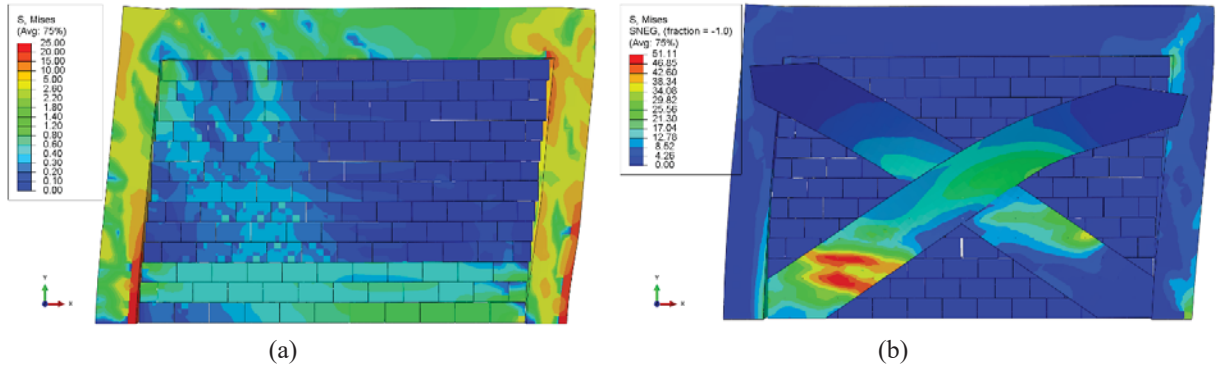

Figure 10. Failure modes in numerical simulation for (a) **URF** and (b) **FRPF**.

Figure 11. Shear-displacement response obtained for both columns (Shear_L and Shear_R) in case of (a) *URF* and (b) *FRPF*.

The maximum shear in the column in case of retrofitted infill was 67% higher than the shear strength of the column, suggesting early shear failure (**Figure 11b**). Additionally, the displacement amplitude corresponding to the attainment of the shear strength of the column was equal to 4.5 mm, namely 73% lower compared to the debonding displacement. In the case of *URF*, the value of V_{Rc} was higher than the maximum shear (**Figure 11a**), suggesting a ductile failure mode of the frame and, consequently, higher displacement and energy dissipation capacity compared to *FRPF*. The comparison of the cumulative energy dissipated up to failure (ED_{SF}), provided in **Figure 12**, evidences the high influence of the retrofit on the performance of the infilled frames analysed. The value of ED_{SF} decreases by 93.2% comparing *URF* to *FRPF* results.

Figure 12. Energy dissipation capacity up to failure of the analysed portal frames.

5 CONCLUSIONS

The influence of infill walls on the seismic performance of RC buildings has been widely demonstrated in the literature. The presence of infill walls characterized by high shear strength can significantly increase the shear demand in the columns, leading to possible premature shear failure in RC frames without adequate structural detailing. The use of FRP to avoid the out-of-plane failure of masonry infills, as well as to improve

their in-plane capacity is commonly adopted nowadays. However, this retrofit intervention is often not designed accounting for the interaction between the infill wall and the surrounding RC frame.

In this study, the response of a masonry infilled RC portal frames designed for gravity load was analysed. Two configurations were considered. The first one was characterized by unreinforced masonry infill, while in the second configuration, FRP retrofit of the of the infill was assumed. A non-linear static analysis was performed on the considered frames, aiming to assess the influence of the infill retrofit on the maximum strength, the displacement and the energy dissipation capacity.

A three-dimensional numerical model was developed, including interface interaction laws between the brick units, at the frame-infill and at the infill-retrofit interface. The interaction laws were calibrated based on diagonal compression tests on tuff stone specimens previously performed at University of Salento. The scope of the modelling approach was the accurate evaluation of the internal forces' distribution, as well as the simulation of the main mechanisms characterizing the lateral response of the analysed infilled frames.

The comparison between numerical and experimental results, referred to the diagonal compression tests, showed a high reliability of the developed finite-element models in simulating the shear response of unreinforced and retrofitted masonry walls. A satisfactory agreement was obtained in terms of maximum shear strength, elastic stiffness and failure modes. The numerical model accurately reproduced the mortar bed joints sliding and the debonding of the FRP retrofit from the wall surface.

The results of the non-linear static analyses carried out on the RC portal frames showed a significant difference in the lateral response of the considered configurations. A ductile failure mode was observed in the case of unreinforced infill, featuring flexural failure of the columns, while the introduction of the FRP reinforcement led to a severe reduction of the ductility capacity of the structure. Despite the increase of the maximum lateral strength caused by the retrofit, early brittle failure of the columns was observed.

The results of this study pointed out the importance of accounting for the interaction between RC frame and infill walls when retrofit techniques, which increase the capacity of the masonry infills, are adopted. Further studies are still required to define design prescriptions which regulate the seismic retrofit of infill walls with composite materials in existing RC buildings.

ASSESSMENT OF OUT-OF-PLANE STRENGTH OF MASONRY INFILLS ACCORDING TO EC6

Abstract

In the last decades the attention to the out-of-plane response of infills has been increasingly growing due to their influence on the global seismic behaviour of frame structures. In order to assess their out-of-plane capacity, different approaches have been proposed, such as those based on the arching effect and on the yield-line theory. Both methods are implemented in Eurocode 6 for masonry structures. The first approach is based on the observation that an arching effect develops in a wall provided that surrounding elements are able to resist thrust. The second approach consists in defining a kinematically admissible mechanism (yield-line mechanism) and calculating the limit load by equating the internal and external works. This method was implemented in Eurocode 6 (EC6) as well as in other codes by means of coefficients, which depend on the orthogonal ratio of the masonry flexural strengths, the degree of fixity at the edges of the wall and the wall aspect ratio. The suitability of the methods proposed in EC6 is investigated herein for masonry infills through comparison with experimental tests. It is found that, considering the second approach, the results are, on the average, conservative, contrary to the assumption that the method should provide an upper bound of the resistance.

Keywords: Infilled frames, Out-Of-Plane Collapse, Arching Effect, Yield-line Theory, Compressive Strength, Flexural Strength.

1 INTRODUCTION

The influence of masonry infills to the structural response of frame buildings is widely recognized. The presence of regularly distributed infills is usually beneficial, due to their capacity to reduce the displacement demand and to dissipate energy [1–5]. On the other hand, irregular distributions due to the lack of one or more panels may lead to the increase of internal forces and displacements as well as to brittle failures [6–9]. In addition, the collapse of infills, especially in the out-of-plane (OOP) direction, occurs also for moderate intensity of the ground motion [10–13], causing casualty risks and economic losses. This explains the fact that in the last years the OOP response of infills and the interaction between in-plane (IP) and OOP actions have become issues of major concern [14–19]. Different methods have been put forward for their assessment, like those based on rigid body mechanisms or on numerical and iterative solutions [20,21]. The first category includes methods derived from the yield-line theory as well as methods which take into account the arching effect.

The first approach, based on the yield-line theory, was initially proposed to determine the collapse load of reinforced concrete slab [22,23] and was subsequently applied to masonry walls [24,25]. The method allows taking into account different strengths in two orthogonal directions and the bending resistance along supports. It consists in defining a kinematically admissible mechanism in which all deformations (rotations) take place along yield lines and edges, and the single portions of the wall rotate as rigid bodies (Figure 1a). The limit load is estimated by equating the internal work, which is given by the energy dissipated along the yield lines, to the external work, i.e. the work done by the applied loads. Among the infinite number of mechanisms, the collapse mechanism is the one that occurs under the smallest load. Considering the upper bound theorem of the limit analyses, it is possible to recognise that the yield-line method provides an upper bound of the wall strength. This method was implemented in Eurocode 6 [26] (EC6 hereinafter) as well as in other codes [27] by means of coefficients, which depend on the degree of fixity at the edges of the wall, the wall aspect ratio and the orthogonal ratio of the masonry flexural strengths.

The second approach is based on the observation that the arching effect develops in a wall provided that surrounding elements are able to resist thrust. In the one-way arching model, the collapse is associated to a three-hinge mechanism (Figure 1b), which is usually activated along the shorter dimension, and the collapse load depends on the masonry compressive strength and on the wall slenderness [28]. When the infill is restrained at four edges, a two-way arching action may develop, thus increasing the OOP strength [29,30]. The one-way arching method is included in EC6 which provides an equation of the limit load that can be used when lateral deflections are small.

The suitability of the methods proposed in EC6 for masonry structures and described in § 2, is investigated herein for masonry infills through comparison with experimental tests. Specifically, a dataset of 71 experimental tests on one-storey one-bay infilled frames is compiled (§ 3) and the related experimental OOP strengths are compared with those predicted by the EC6 formulations in § 4.

Figure 1: a) example of a kinematically admissible mechanism for an infill supported on four edges for use in the yield-line method; b) one-way arching model, the collapse is associated to a three-hinge mechanism.

2 EC6 PREDICTIVE MODELS

As mentioned above, the yield-line method was included in EC6 in form of tabulated coefficients. The procedure consists in verifying that the design value of the moments applied to a masonry wall does not exceed the corresponding moments of resistance. The design moments per unit length in two orthogonal directions, M_{Ed1} and M_{Ed2} , acting on a wall subjected to the design lateral uniform pressure q_d can be calculated as:

$$M_{Ed1} = \alpha_1 q_d l_m^2 \quad (1)$$

$$M_{Ed2} = \alpha_2 q_d l_m^2 \quad (2)$$

while the moments of resistance as:

$$M_{Rd1} = f_{xd1} Z \quad (3)$$

$$M_{Rd2} = f_{xd2} Z \quad (4)$$

where: α_2 is a coefficient provided in Annex E of EC6; $\alpha_1 = \mu \alpha_2$; μ is the orthogonal ratio, i.e. the ratio between the flexural strength in the horizontal direction, f_{x1} , and in the vertical direction, f_{x2} (Figure 2); l_m is the length of the wall; Z is the elastic section modulus of unit length of the wall:

$$Z = t^2/6 \quad (5)$$

and t is the panel thickness.

The inequality between the design value of the applied moment and the design value of the moment of resistance gives:

$$\alpha_1 q_d l_m^2 \leq f_{xd1} Z \quad (6)$$

$$\alpha_2 q_d l_m^2 \leq f_{xd2} Z \quad (7)$$

thus:

$$q_d \leq \frac{f_{xd2} Z}{\alpha_2 l_m^2} \quad (8)$$

Values of α_2 , which are provided in Annex E for different boundary conditions, orthogonal ratios and aspect ratios, are given by the following equation:

$$\alpha_2 = \frac{f_{xd2} Z}{q l_m^2} \quad (9)$$

where q is the uniform load which leads to collapse, calculated through the yield-line theory. An example of calculations is reported in [31].

Figure 2: Plane of failure of masonry in bending: a) parallel to bed joints, flexural strength f_{x1} ; b) perpendicular to bed joints, flexural strength f_{x2} [26].

The other approach encompassed in EC6 is based on the assumption that an arching effect develops in unreinforced masonry walls having slenderness ratio not greater than 20 and design value of the vertical stress not less than 0.1 MPa. In these cases, a wall subjected to lateral loading may be designed by employing the following equation:

$$q_d = f_d \left(\frac{t}{l_a} \right)^2 \quad (10)$$

where: q_d is the design lateral strength per unit area; f_d is the design compressive strength of the masonry in the direction of the arch thrust; l_a is the length or the height of the wall depending on the direction along which the arching effect develops and t is the wall thickness.

Finally, it is worthwhile to mention that Eurocode 8 [32] suggests measures to avoid the OOP collapse of slender masonry panels with specific reference to panels with slenderness ratio greater than 15. Examples of measures for the improvement of both IP and OOP response include the use light wire meshes, wall ties fixed to the columns, wind-posts and concrete belts.

3 EXPERIMENTAL TESTS

Seventy-one experimental tests are employed in this study (Table 1). Both infilled reinforced concrete and steel frames are considered as well as confined masonries. The slenderness ratio, $sr = l_a/t$, and the aspect ratio, $ar = h_m/l_m$, vary in the range 7–34 and 0.5–1.0, respectively (Table 2).

The walls were made up of clay bricks having horizontal or vertical hollows, solid clay bricks and concrete blocks having vertical hollows, as specified in Table 2. The masonry

compressive strength varies between 0.5 and 28.1 MPa. However, in 80% of the cases it not greater than 15.0 MPa, higher values are related to concrete block infills.

In 39 tests the infill were loaded in the OOP direction only. Generally, the OOP loads were applied monotonically by means of airbags, in some cases they were applied at four points or at mid-height.

The interaction between IP and OOP actions was considered in 32 tests, where an IP horizontal displacement was applied at the beam level prior to the OOP load. Maximum IP interstorey drift ratios (*IDR*) are specified in Table 1.

4 ASSESSMENT OF EC6 MODELS

In order to compare the OOP strength predicted by the formulations reported in EC6 (Eq. 8 and Eq. 10) with the strength obtained in experimental test, the following assumption are made.

- The experimental flexural strength, f_{x2} , is employed in Eq. 8 instead of the design flexural strength, f_{xd2} . When the former value was not available, the flexural strength provided by EC6 for different masonry types was adopted. Such value was multiplied by 1.5 to obtain a mean value from the characteristic one.
- Similarly, when the orthogonal ratio was not available from experimental campaigns, it was derived from EC6.
- The experimental compressive strength of masonry, f_m , is used in Eq. 10 in the place of the design strength, f_d , for a consistent comparison with experimental tests.
- Eq. 10 is applied also in case of walls having slenderness ratio greater than 20 in order to investigate the influence of such parameter.

Therefore, the predicted OOP strength, q_{pred} , is determined as

$$q_{pred} = \frac{f_{x2} Z}{\alpha_2 l_m^2} \quad (11)$$

and

$$q_{pred} = f_m \left(\frac{t}{l_a} \right)^2 \quad (12)$$

according to whether the method is based on the yield-line theory (Eq. 11) or on the arching effect (Eq. 12). As mentioned in § 2, l_a is the dimension of the wall in the direction along

which the arching effect develops. Therefore, in case of infills having a top gap l_a is the wall length, whereas for infills supported along four edges, it is the height, since aspect ratios are not greater than 1.0.

The experimental strength, q_{exp} , is the maximum OOP pressure recorded during the tests. In cases where the OOP load was applied in concentrated points, an equivalent uniform pressure was estimated so as to provide the same maximum bending moment as the concentrated forces.

4.1 Results

The comparison between predicted (q_{pred}) and experimental (q_{exp}) OOP strength is shown in Figure 3 to 5, where the ratio q_{pred}/q_{exp} is plotted against the masonry compressive strength, the slenderness ratio, the aspect ratio and the IDR . The mean and the mean \pm one standard deviation of q_{pred}/q_{exp} are also shown. The expressions “yield line” and “arching action” used in the figures refer to the application of Eq. 11 and Eq. 12, which are based on the two approaches, respectively.

In Figures 3 and 4 only pure OOP tests are reported. First of all, it is noticed that the application of the arching action approach leads to a considerable overestimation of the strength when the masonry compressive strength f_m is greater than 20 MPa, while it underestimates the strength when f_m is less than 2 MPa (Figure 2a). This outcome implies that q and f_m are not linearly proportional to one another and that Eq. 12 should not be used for strong masonries. In the following comparisons, such cases (6 tests) are disregarded.

On the average, both methods underestimate the strength, being the mean ratio between predicted and experimental values equal to 0.51 and 0.86 in case of predictions obtained through the yield-line theory (Eq. 11) and the one-way arching effect method (Eq.12), respectively. However, the application of Eq. 12 leads to a significant scatter due also to the fact that it does not take into account the effect of the aspect ratio. The yield-line method gives more conservative results and a smaller scatter.

Figure 3: Ratio between predicted and experimental values of the OOP strength (for tests loaded OOP only) plotted against the masonry compressive strength. Continuous lines represent the mean values, dotted lines represent the mean \pm one standard deviation: red = yield line, grey = arching effect.

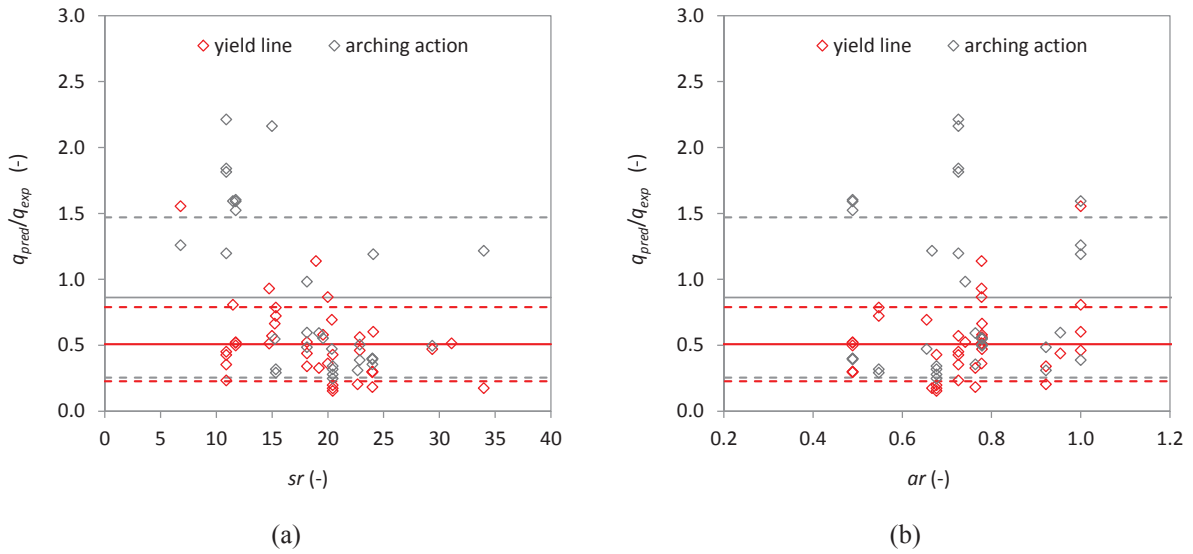

Figure 4: Ratio between predicted and experimental values of the OOP strength (for tests loaded OOP only) plotted against the slenderness ratio (a) and the aspect ratio (b). Continuous lines represent the mean values, dotted lines represent the mean \pm one standard deviation: red = yield line, grey = arching effect.

Figure 5: Ratio between predicted and experimental values of the OOP strength (for tests loaded to IP drift + OOP load) plotted against the IP interstory drift ratio (IDR). Continuous lines represent the mean values, dotted lines represent the mean \pm one standard deviation: red = yield line, grey = arching effect.

Figure 4 shows that, contrary to what expected, the predictive capacity of Eq. 12 does not worsen for slenderness ratios greater than 20. In general, the ability of the two methods in predicting the strength does not show a clear trend with varying aspect and slenderness ratios.

The predictions in case of previous IP damage are reported in Figure 5. Obviously, in this case both models overestimate, on the average, the experimental values. In fact, they do not account for previous IP damage. Also in this case, Eq. 11 gives more conservative results.

Finally, the yield-line equations provide the collapse mechanisms related to the minimum collapse pressure [31]. In Figure 6 the occurrences of predicted mechanisms is reported as a function of the infill aspect ratio. “Type 1” mechanisms (Figure 6a) refer to those cases which are most frequently observed in experimental campaigns: for infills supported along four edges the collapse mechanism is related to a first horizontal crack followed by inclined cracks

running to the corners of the panel; for infills with no support along the top, a vertical crack develops at the centre of the panel followed by inclined cracks running to the bottom corners. In “type 2” mechanisms, the first crack is vertical for panels supported along four edges, whereas in panel with a top gap only inclined cracks develop (Figure 6b). Figure 6c indicates that “type 1” mechanisms develop when ar is in the range 0.49–0.78, whereas “type 2” mechanisms occur when ar ranges between 0.64 and 1.00. The yield-line method predicts the “type 2” mechanism more frequently than “type 1”, in contrast to what observed experimentally. In fact, the method is not always able to predict the experimental collapse mechanisms, which are often a combination of different failure modes.

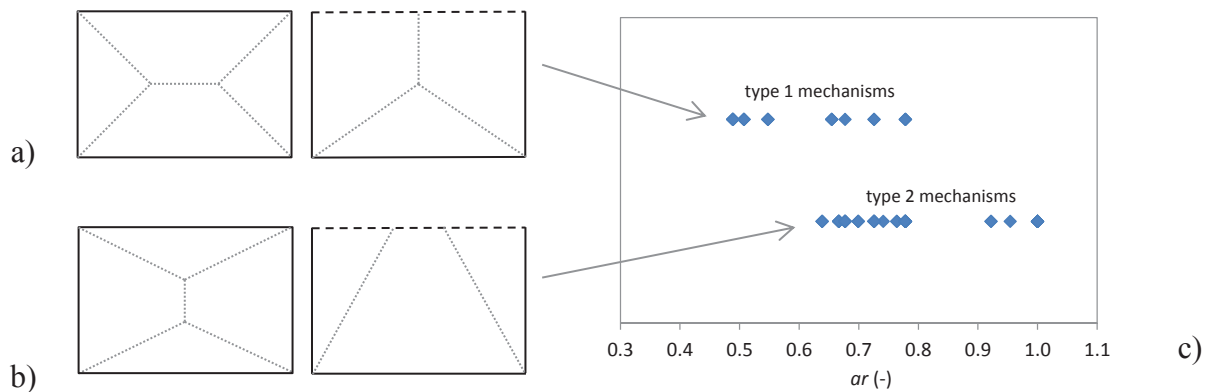

Figure 6: a) crack patterns of type 1 collapse mechanisms; b) crack patterns of type 2 collapse mechanisms; c) occurrences of predicted collapse mechanisms.

5 CONCLUSIONS

In this study the methods encompassed in EC6 to determine the OOP strength of masonry walls are investigated to evaluate their possible suitability for infills. To this aim, a dataset of 71 experimental tests available in the literature is employed. The following conclusions are inferred:

- Eq. 11, based on the yield-line theory, is, on the average, conservative. In this case, the mean value of the ratio between predicted and experimental values is equal to 0.51. This is probably due to the fact that the masonry flexural strength used to estimate the OOP resistance is derived from tests on simply supported specimen and therefore does not account for the confining effect of the frame.
- On the average, Eq. 12, which is based on the one-way arching effect, is slightly conservative, being the mean value of the ratio between predicted and experimental values equal to 0.86. However, the scatter of data is noticeable, also because the two-way arching action and the influence of the aspect ratio are not taken into account by the model.
- The effect of previous IP damage is not considered in the examined formulations and therefore, as expected, the predictions are unconservative when previous *IDR* was applied to the infilled frame. The mean value of the ratio between predicted and experimental strength is equal to 1.23 and 1.79 when using Eq. 11 and Eq. 12, respectively.
- The yield-line method is not always able to predict the experimental crack patterns related to the collapse mechanisms observed experimentally.

Abstract

Reinforced concrete frames with masonry infill walls are popular form of construction all over the world as well in seismic regions. While severe earthquakes can cause high level of damage of both reinforced concrete and masonry infills, earthquakes of lower to medium intensity sometimes can cause significant level of damage of masonry infill walls. Especially important is the level of damage of face loaded infill masonry walls (out-of-plane direction) as out-of-plane load cannot only bring high level of damage to the wall, it can also be life-threatening for the people near the wall. The response in out-of-plane direction directly depends on the prior in-plane damage, as previous investigation shown that it decreases resistance capacity of the infills. Behaviour of infill masonry walls with and without prior in-plane load is investigated in the experimental campaign and the results are presented in this paper. These results are later compared with analytical approaches for the out-of-plane resistance from the literature. Conclusions based on the experimental campaign on the influence of prior in-plane damage on the out-of-plane response of infill walls are compared with the conclusions from other authors who investigated the same problematic.

1 INTRODUCTION

Reinforced concrete frames with masonry infill walls and partition walls are popular form of construction all over the world. As infill and partition walls are not included into load-bearing system of a building, they are called *Non-structural elements*. Nevertheless, they are not included into load-bearing system of a building, they can be loaded with huge portion of in-plane or out-of-plane forces during earthquakes. They are not designed to withstand seismic forces and they depend on their own characteristics to resist these forces [1]. As a consequence, damage of non-structural elements often represents primary source of losses in seismic events [2]. Also, damage of non-structural elements during earthquakes can cause not only unacceptable economic losses, but also some serious safety concerns if the non-structural components and their supports are not properly designed for the expected seismic force [3]. Some examples of the damage of non-load bearing masonry walls during earthquakes are presented on Figure 1.

Figure 1: Left : Damage due to L'Aquila 2009 earthquake in a residential building [4,5] ; Right: Masonry wall damage of a 6-story office building in downtown area of Jiangyou City during Wenchuan earthquake in 2008 [6]

Non-structural elements can be classified either as deformation or acceleration sensitive. Deformation sensitive elements are the ones vulnerable to inter story drifts, while acceleration sensitive are the ones sensitive to the acceleration of the floors [1,7–10]. Masonry infill walls are non-structural elements which are both, deformation and acceleration sensitive elements.

Due to rigid connection of masonry infill to the surrounding concrete, as a consequence of horizontal load, compressive force is activated in the masonry wall. The paths of compressive forces in the wall mainly follow diagonal path [11–14]. Above mentioned in-plane forces can cause different failure modes of masonry infill walls, such as infill sliding shear failure, diagonal cracking failure, diagonal compression failure and corner crushing failure [12,14].

Masonry infill walls are also acceleration sensitive elements. Face load or out-of-plane loading on the masonry walls is proportional to the acceleration and the mass of the wall. Before affecting walls loaded in out-of-plane direction, ground motion is modified and filtered by two actions: by the response of in-plane loaded walls and by the response of floor diaphragm [15,16]. Furthermore, out-of-plane behaviour of masonry infill walls is highly influenced by arching effect, which introduces membrane forces into the masonry wall and increases its out-of-plane strength [17–19]. However, arching effect, as well as out-of-plane behaviour of masonry walls, is highly dependent on boundary conditions [20]. In the case of good beam-to-wall or floor-to-wall connections, and if beams / diaphragms are rigid relative to the wall, one-way bending (arching effect) can occur. This will significantly increase walls out-of-plane strength. In the case of stiff frames, properly connected on all four sides to masonry walls, those frames can guarantee two-way bending (arching effect) and in that case, walls with low tensile

strength can withstand high out-of-plane forces without losing its stability [17,20]. However, if in-plane forces are also imposed, connections of the infill wall to the surrounding frame can be damaged, and thus, it can decrease out-of-plane capacity. Out-of-plane deformation mechanism for two-sided and four-sided walls are presented on Figure 2.

Figure 2: Crack pattern of two – sided (left) and four – sided (right) masonry infill walls subjected to out-of-plane loading [19,21]

Even though highest accelerations in buildings occur at highest floors, out-of-plane failure of masonry infills often occurs at intermediate floors. The reason for this is the interaction of in-plane and out-of-plane forces during earthquakes. Effect of in-plane and out-of-plane interaction is nicely presented in the paper of Ricci et al. [22], and it is shown on Figure 3. There it can be seen, that as a consequence of in-plane damage on masonry infills at intermediate building stories, out-of-plane capacity is reduced and can be smaller than out-of-plane strength demand.

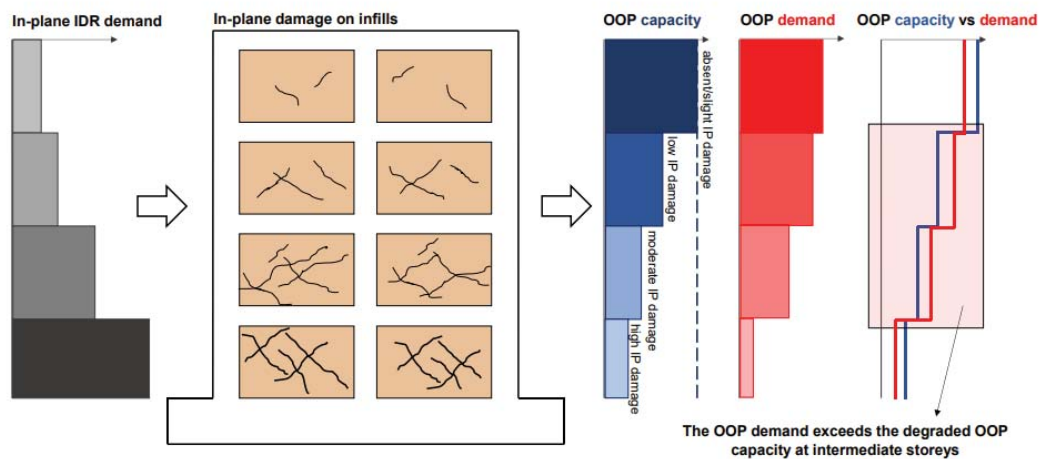

Figure 3: Influence of in-plane and out-of-plane interaction on the out-of-plane capacity at different floor levels[22]

Influence of prior in-plane damage on the out-of-plane load-capacity of masonry walls has been highlighted in few experimental campaigns. Angel and Abrams [23] stated that the slenderness (h/t) of infill wall has the highest effect on the decrease of out-of-plane capacity after prior in-plane damage. Flanagan and Bennett [24] investigated the behaviour of prior in-plane damage on the out-of-plane capacity of masonry walls made of clay bricks connected to steel frames. They stated that prior in-plane damage had minor effect on the out-of-plane capacity of the walls, but that it has induced higher out-of-plane displacements and reduction of out-of-plane stiffness.

In the experimental campaign conducted by Calvi and Bolognini [25] walls previously exposed to 0.4 % of in-plane drift had decrease of out-of-plane capacity for around 50 percent and for prior in-plane drift of 1.2 %, out-of-plane capacity decreased for the factor of 5.62. Investigating different thicknesses and in-plane drift level influence on out-of-plane capacity, Da Porto et al. [26] pointed out that in-plane drift limit of 0,5 % percent given by Italian Building Code is appropriate for thick walls, but not for the thin masonry walls. Hak et al. [27] pointed out that the specimens with prior in-plane drift of 1.0 and 1.5% for fully infilled walls had similar out-of-plane residual capacity, but that the significant stiffness degradation of approximately 40 % occurred. Specimen subjected to prior in-plane drift of 2,5% had decrease of out-of-plane capacity around 60 %, followed with stiffness degradation of 75 %. Furtado et al. [28] came to the conclusion that the walls without prior in-plane damage had 4 times higher out-of-plane capacity compared to the specimen with prior in-plane drift of 0,5 %. It was also pointed out that prior in-plane damage significantly decreased out-of-plane wall stiffness. DiDomenico [19] and Ricci et al. [29,30] stated after their experimental campaign on two different slenderness ratios of masonry infills, 15.2 and 22.9, that slenderness ratio affects in-plane and out-of-plane interaction if it is lower than 20.4 and that higher values of slenderness ratio have similar influence on the interaction as the slenderness ratio of 20.4. They pointed out the importance of “critical” in-plane drift, after which, further increase of in-plane displacement will decrease out-of-plane capacity of the wall. Akhoundi et al. [31] concluded that prior in-plane damage reduces out-of-plane stiffness and strength. They also stated the importance of the workmanship, as bad constructed top joints can significantly decrease out-of-plane strength of the wall. In their experimental campaign, Butenweg and Marinković [32] pointed out that prior in-plane drift of 1.25 % led to the 8-10 times smaller out-of-plane capacity compared with the wall without prior damage. De Risi et al. [33] investigated different length-to-height (w/h) ratios of masonry infills with the same slenderness ratios of 22.9. They stated that specimens with higher w/h ratios (1.26) showed higher level of damage after cycles of in-plane loading and higher reduction of out-of-plane strength compared to the square walls. Xie et al. [34] investigated 7 full-scaled masonry infilled one-span reinforced concrete frames for a typical classroom building in China. The investigation showed that prior in-plane drift significantly decreases out-of-plane wall capacity, when certain value of prior in-plane drift is reached. According to the authors, this limit value is between 0.1–0.3 % of in-plane drift. Da Porto et al. [35] conducted experimental campaign on thick masonry infill walls with and without openings and stated that after different levels of in-plane drifts, out-of-plane capacity of thick infills walls is satisfactory. In the experimental campaign of Di Domenico et al. [36] it was concluded that square panels are less prone to the interaction of in-plane and out-of-plane compared to the rectangular ones.

2 EXPERIMENTAL CAMPAIGN AND TEST SETUP

In order to investigate the influence of prior in-plane damage on out-of-plane behaviour of unreinforced masonry infill walls, experimental campaign was conducted on 2 wall specimens. This experimental campaign was carried out in the scope of the project “Development of an innovative approach for decoupling infills and non load-bearing masonry walls from the main structure” [37]. Walls were made of clay bricks, and the dimension of the bricks were 247 x 249 x 300 mm³. Dimensions of wall specimens and surrounding concrete frame are shown on Figure 4.

Figure 4: Front and side view of frame and wall specimens for tests T1 and T2

Characteristic values of used materials are presented in Table 1. Only bed joints were mortared, using thin layer mortar Maxit D900.

Table 1: Material property values for the materials used in experimental campaign

Tests T1 and T2					
Mortar MAXIT	Mortar type	Compressive strength f_m (N/mm ²)		Flexural tensile strength $f_{m,flex}$ (N/mm ²)	
	Thin layer mortar	12.8		2.4

Masonry	Compressive strength f_k (N/mm ²)			Modulus of elasticity E_m (N/mm ²)	
	2.68			2680	

Masonry infill walls were connected on all 4 sides to the surrounding concrete frame. Axial force of 200 kN per column was introduced by hydraulic actuator, and it was kept constant during both experiments. In-plane displacement was imposed by steel frame and hydraulic

actuators. Steel bars and plates were placed to keep self-equilibrium and to keep the force in the system. Out-of-plane loading was imposed using 4 airbags. Velocity of the applied load for the out-of-plane direction was 50 N/sec. Reaction plate was made at the back side of the wall, to keep airbags in the contact with the wall. Test setup is presented on Figure 5.

Figure 5: Test specimen with test setup for in-plane movement of the specimen

2.1 Test T1

Test T1 was pure out-of-plane test, without any prior in-plane drift imposed. Velocity of the load applied in out-of-plane direction was 50 N/sec, and it was introduced by 4 airbags, in load cycles of 90 kN. At the end of the first cycle, highest displacement of 1.6 mm was measured at the center of the wall, as it is shown on Figure 6. Wall didn't exhibit any kind of visible damage at that moment. As it can be seen from the Figure 6, based on out-of-plane displacements, two-way arching was activated.

Figure 6: Out-of-plane displacement of infill wall at the end of first cycle of test T1

At the end of the first cycle, residual displacement in out-of-plane direction was minimal and it was near 0. During the second cycle, when the force of around 136 kN was reached, first small cracks in the mortar joints occurred. Future increase of the load led to the first cracks in the bricks in the upper right part of the wall, which occurred at 154 kN. When force reached 170 kN, high intensity crack of the bricks occurred, which was followed by fast increase of out-of-plane displacement with small increase of out-of-plane force. At the force of 176 kN, brittle failure of the wall occurred. It was governed by failure of bricks in the upper right part of the wall. Rotation of the wall due to arching effect occurred through the cracked cross section of the brick, which led to brittle and fast failure of the wall in out-of-plane direction. At the moment of failure, displacement at the center of the wall was 9.86 mm. Complete force – displacement curve of the test T1 is shown on Figure 7. Outlook of the test specimen after the brittle collapse can be seen on Figure 7.

Figure 7: Look of test specimen T1 at the end of the test (left) and force – displacement curve for the out-of-plane behaviour of test specimen T1 (right)

Top rotation point for the arching effect was moved from the connection of the top beam and infill wall, to the cracked section of the bricks in the last row. This is shown on Figure 8, where it can be seen that cracks initiate through the thickness of the wall, breaking thin webs of the brick and making this weakened cross section as a plane around which the wall rotates. This type of the behaviour can be explained with yield line theory, presented for the out-of-plane behaviour of masonry infills by Dawe and Seah [21]. In their approach, mortar joints at the wall middle and at the top and bottom connection of masonry infill to surrounding concrete represent cracked cross sections. When the test specimen T1 was bricked up, mortar connection of the wall and top beam was made of high quality thin bed layer mortar, which was inserted using the pump under high pressure. Nevertheless, it is important to point out that this high quality of mortar joint connections to the surrounding concrete is difficult to have on a construction site, and it is not expected to be done in that manner, as it is time-consuming.

Figure 8: Look of test specimen T1 at the end of the test and cracks penetrating through the thickness of the wall in the plane of the rotation, cause collapse of thin brick webs

2.2 Test T2

Test specimen T2 was subjected to 1.2 % of in-plane drift prior to the out-of-plane loading. Complete hysteresis curves of force–displacement and force–drift for both directions of in-plane load are shown on Figure 9.

Figure 9: Force – displacement (left) and force – drift (right) hysteresis curve for the in – plane phase of loading of test specimen T2

For each cycle of in – plane drift, three amplitudes were reached. Time period for reaching prescribed displacement for each of the amplitudes was 15 seconds. First change of the stiffness was noticed in the fourth cycle, when in–plane drift of 0.022 % was reached. Reason for the first dropdown of the stiffness were initiations of the cracks in mortar bed joints, mainly at right part of the wall. Force that was reached at that moment was 60 kN. Surface plot of the strains is shown on Figure 10a.

Highly pronounced compressive struts, characteristic for the masonry infill walls, occurred in sixth cycle, with prescribed drift of 0.11 %. At this point, bricks were still undamaged. Only visible damages were a bit cracked mortar joints at the connection of the infill wall to the concrete columns and top beam. Surface plots of the strains are shown on Figures 10b and 10c.

Figure 10: Surface plot of the wall strains of specimen T2 at drift levels of 0.012 % (a); 0.11% when moving the wall from right to left (b); and 0.11% when moving the wall from left to right (c)

Peak force of the in–plane hysteresis curve for both directions of in–plane loading was reached at 11th cycle. Corresponding force of 280 kN was reached when the frame was pushed from left to the right. Drift reached at this cycle was 0.8 %. Surface plot of the tensile strains at drift level of 0.8 %, while moving the wall from left to right, is presented on Figure 11a. At the end of 15th cycle, last for in–plane phase of the test, drifts of 1.2 % were reached, and the forces were 225 and 196 kN, respectively. Surface plot of the tensile strains at drift level of 1.2 %, while moving the wall from left to right and right to left, are presented on Figures 11b and 11c.

Figure 11: Surface plot of the wall strains of specimen T2 at drift levels of 0.8 % (a) ; 1.2% when moving the wall from left to right (b); and 1.2 % when moving the wall from right to left (c)

At this level of in-plane drift, significant amount of the damage on infill wall was noticed. At the back side of the wall, almost along whole length of the wall, outer brick shells were cracked in rows 5 and 6. Cracks were also pronounced on the bricks at top right and left corner, and they also went through concrete columns. On the front side of the wall, outer shells of the bricks felt off from 2 bricks in the 5th row. Minor diagonal cracks were seen on the bricks close to the columns on the front side off the wall, which were following the trajectory of compressive struts.

In the second phase of the test, investigation of the out-of-plane capacity of the wall with prior in-plane damage was conducted. Out-of-plane loading was carried out in 11 cycles. In the last cycle, while reaching out-of-plane force of 87 kN, high increase of out-of-plane displacement occurred, followed by dropdown of out-of-plane force. In order to prevent brittle failure, test was stopped. Out-of-plane displacement at the end of the test was 18.42 mm, as it is shown on Figure 12. Furthermore, from the Figure 12, where the surface plot of out-of-plane displacement is shown, it can be seen that two-way arching was exhibited, as in test T1. It can be concluded that even though mortar joint at the connection of infill wall and top beam had cracks, they were insufficient to jeopardize two-way arching. Out-of-plane displacement of the wall from the laboratory is shown on Figure 13, as well as force–displacement curve for the second phase of test T2.

Figure 12: Surface plot of out-of-plane displacement at the end of the test on test specimen T2

Figure 13: Force – displacement curve of the out-of-plane loading phase of test specimen T2 (left) and lateral look of the out-of-plane displacement at the end of the test (right)

3 COMPARISON OF THE OUT-OF-PLANE BEHAVIOUR OF TEST SPECIMENS T1 AND T2

As it can be seen from Figures 6 and 12, and surface plots of out-of-plane displacements of the walls T1 and T2, both walls remained in full contact on all 4 sides to the surrounding concrete. This implicates that the walls exhibited two-way bending and arching effect. Such fact goes on contrary with the conclusions of some of the authors stated in the literature review, as it is often the case that due to prior in-plane drift, connection of the masonry infill and concrete frame is partially or completely lost. Full connection of the masonry infill and concrete frame on all 4 sides during all the phases of in-plane and out-of-plane loading in tests T1 and T2 is a consequence of unrealistically high bond strength of the mortar joints. The reason for that high bond strength of connection joints was, as it was already explained in Chapter 2, the use of high-pressure pump for placing the mortar. This construction procedure highly increased bond strength of mortar joints. Use of the pump in that manner is inapplicable in practice due to time-consuming reasons and construction difficulties on the construction site, so it can be said that this full connection of infill walls to surrounding concrete after in-plane loading cannot truly represent real behaviour in practice.

Comparison of the out-of-plane force-displacement curves for tests T1 and T2 is shown on Figure 14. It can be seen that reduction of the out-of-plane capacity was 51 %.

Figure 14: Force – displacement curves of the out-of-plane loading phase for test specimens T1 and T2

Also, it can be seen that prior in-plane damage triggered significant decrease of stiffness in out-of-plane direction. This goes in the line with the conclusions of all previous experimental campaigns from the literature, where the authors pointed out the importance of prior in-plane damage on the stiffness degradation in out-of-plane direction.

It is important to mention brittle behaviour of test specimen T1. Even though this specimen showed high level of out-of-plane capacity compared to the test specimen T2, wall T1 had small out-of-plane displacements at the failure, compared to the ones reached in test T2. Comparing the values of displacement at failure and wall thickness, out-of-plane displacement at failure of wall T1 was equal to 3.29 % of the wall thickness. This represents quite a small value for pure out-of-plane tests, as according to some theoretical approaches for out-of-plane capacity, displacement at the failure can reach around 50 % of wall thickness [18]. The reason for small out-of-plane displacement at failure for test specimen T1 can also be explained with perfect boundary conditions and connection of the infill wall with surrounding frame. This fact decreased the possibility for the rotation of the wall through the cross sections in the mortar plane. On contrary, rotation cross sections and “hinges” occurred at the first and last row of the bricks, at the moment when the bricks started to crack through the thickness of the wall. Also, this was the reason for the fast and brittle failure after appearance of the cracks. As it is already mentioned, test specimen T2, subjected to prior in-plane loading, kept the connection to the surrounding concrete for the entire duration of the test. Nevertheless, the main reason for the increase of the displacement at failure in out-of-plane direction during the second phase of test 2 was the influence of prior in-plane loading on mortar joints within the wall and next to the surrounding concrete. This prior in-plane loading decreased the level of rigidity of mortar connections and also it changed the boundary conditions at the connection of top beam and the wall. For the test T1, this connection was almost clamped and for test T2 it showed more hinged-like connection due to prior in-plane loading.

4 COMPARISON OF TEST RESULTS WITH ANALYTICAL APPROACHES

Results from the test specimens described in experimental campaign were compared with the existing analytical approaches which take into account influence of prior in – plane damage on out-of-plane capacity of masonry infill walls. The interaction of in-plane and out-of-plane loading is usually taken into account with factor R , which represents the decrease of out-of-plane capacity due to prior in-plane damage. Factor R is related to the level of in-plane drift to

which the wall had been previously exposed, so it is a kind of displacement – based and not strength – based factor. First one to propose reduction factor which takes into account prior in-plane damage to the out-of-plane capacity was Angel [23], and the reduction factor is shown in Equation 1. Reduction factor can be used if in-plane drift is higher than “critical” in-plane drift at which first brick cracking occurs. Else, $R=1$. Interstory drift ratio is denoted as IDR.

$$R = \left(1,08 - 0,015 \left(\frac{h}{t} \right) - 0,00049 \left(\frac{h}{t} \right)^2 + 0,000013 \left(\frac{h}{t} \right)^3 \right)^{\frac{IDR}{2IDR_{cr}}} \quad (1)$$

New Zealand standard NZSEE 2017 [38] proposes reduction factor which takes into account slenderness ratio of the wall. This reduction factor is shown in Equation 2.

$$R = \min \left(1,1 \left(1 - \frac{h/t}{55} \right); 1 \right) \quad (2)$$

FEMA 274 [39], FEMA 356 [40], ASCE/SEI 41-06 [41] and ASCE 41-13 [42] proposed reduction factor R equal to 0.76 for all situations of the interaction of prior in-plane damage on out-of-plane capacity.

FEMA 306 [43] suggests to use Equation 1 for the calculation of reduction factor, with further description that for moderate in-plane damage it should be taken into account that $IDR=IDR_{cr}$ and that for severe damage $IDR=2IDR_{cr}$.

ASCE/SEI 41-17 [44] suggest that reduction factor R should be equal to 0.6. It is calculated using Equation 1, for the situation when $IDR=2IDR_{cr}$ and slenderness ratios is equal to 25.

Morandi et al. [45] proposed reduction factor to be calculated using Equation 3. Their reduction factor is fitted and calibrated for slender infills.

$$R = \begin{array}{ll} 1 - 2.67IDR & IDR \leq 0.30\% \\ 0.2 & 0.30\% < IDR \leq 1.00\% \\ 0 & IDR > 1.00\% \end{array} \quad (3)$$

Based on the experimental results, Verlato et al. [46] proposed Equation 4 for the reduction factor.

$$R = \begin{array}{ll} 1 - 0.86IDR & IDR \leq 0.70\% \\ 0.4 & 0.70\% < IDR \leq 1.20\% \\ 0 & IDR > 1.20\% \end{array} \quad (4)$$

Cavaleri et al. [47] reduction factor R reported in Equation 5, has been proposed based on the experimental database.

$$R = \min(0.26IDR^{-0.37}; 1) \quad (5)$$

Ricci et al. [29] proposed reduction coefficient R using statistical regression, based on the some results from the literature. This reduction coefficient is shown in Equation 6.

$$R = \min(0.14IDR^{-1.12}; 1) \quad (6)$$

Later, Ricci et al. [30] also proposed another reduction coefficient R , after conducting experimental campaign. This reduction coefficient is based on statistical regression and it is shown in Equation 7, and it is calibrated according to Authors for thin walls ($h/t > 15.2$). For walls with lower slenderness ratio, Equation 8 is proposed. Equation 8 is calibrated based on two wall specimens from the literature with slenderness ratio equal to 8.8.

$$R = \min \left\{ 1; \left(0.98 - 0.04 * \left(\min \left(\frac{h}{t}; 20.4 \right) \right) * IDR^{-0.97} \right) \right\} \quad (7)$$

$$R = \min \left\{ 1; \left(1.21 - 0.05 * \left(\min \left(\frac{h}{t}; 20.4 \right) \right) * IDR^{-0.89} \right) \right\} \quad (8)$$

Based on their experimental campaign, Akhoundi et al. [31] proposed that reduction of out-of-plane capacity due to prior in-plane damage should be taken into account using Equation 8.

$$R = \frac{2 - IDR}{2} \quad (9)$$

Da Porto et al. [35] used data from their experimental campaign on thick infill walls to proposed reduction coefficient R , shown in Equation 9.

$$R = \frac{1}{2.1} * (1.1 * e^{-(2.6*IDR)^2} + 1) \quad (10)$$

Using statistical regression and data available from the literature, Di Domenico et al. [36] proposed reduction factor R for thin and thick walls, presented in Equations 10 and 11, respectively. Equation 10 can be used if $h/t > 15$, while Equation 11 can be used for walls with $h/t > 8$.

$$R = \min \left\{ 1; \left(1.438 - 0.245 \left(\frac{w}{h} \right) - 0.042 * \left(\min \left(\frac{h}{t}; 20.4 \right) \right) * IDR^{-0.719} \right) \right\} \quad (11)$$

$$R = \min \left\{ 1; \left(1.510 - 0.190 \left(\frac{w}{h} \right) - 0.050 * \left(\min \left(\frac{h}{t}; 20.4 \right) \right) * IDR^{-0.730} \right) \right\} \quad (12)$$

In order to use some of the above mentioned Equations for the calculation of reduction coefficient R , input data should be IDR_{cr} which represents in-plane drift at which first crack in the wall occurs. For test T2, described in this paper, drift of 0.027 % is taken as IDR_{cr} . At that drift level, first stepwise cracks through the wall occurs, as it is shown on Figure 15.

Figure 15: Surface plot of crack pattern of the specimen T2 under in – plane drift of 0.027 %

Above mentioned analytical approaches for the calculation of out-of-plane capacity due to prior in-plane damaged are compared with measured values for test specimen T2. Values of the parameters necessary for the use of Equations 1-12 are the following: $h/t= 8.4$; $w/h= 1.1$; $IDR= 1.2\%$ and $IDR_{cr}= 0.027\%$. In experimental campaign, with above mentioned values, test specimen T2 exhibited reduction of the out-of-plane capacity due to prior in-plane damage for a factor $R= 0.49$. Comparison of the experimental result with existing analytical approaches is shown on Figure 16. Values of the predicted reduction coefficients are shown in Table 2.

As it can be seen from the Figure 16 and Table 2, the closest prediction of the reduction factor for the test specimen T2 was obtained using Equation 10, proposed by da Porto et al. [35]. Reduction factor calculated using above mentioned Equation 10 is 0.476, while reduction factor calculated from the experimental campaign was 0.494. The reason for this good match is probably in the fact that Equation 9 is fitted for the walls which had same thickness as wall T2, and similar h/t ratio. Also, reduction coefficient proposed by Ricci et al. [30] showed good match with the experimental one, as it slightly overestimates walls out-of-plane capacity. This reduction coefficient is calculated using Equation 7. Among all other Equations, only the Equation 12 is fitted for the walls with smaller slenderness ratios than 15, but this Equation 12 also doesn't give satisfying match, as it is calibrated only on one experimental campaign from the literature, using statistical regression. Regarding the level of in-plane drift, presented Equations are valid for drift values until 1.2 %, which was the drift level imposed in the experimental campaign. However, it is important to mention that reduction factor of 0.494 for wall specimen T2 should be taken with reserve, having in mind that connection of masonry infill to the concrete frame is not constructed in usual manner. Regarding that, this high quality connection could potentially increase residual out-of-plane capacity and overestimate reduction factor, compared with the situation when connection joints are constructed as in practice. Nevertheless, it can be concluded that, even though there is certain amount of existing equations which take into account reduction of out-of-plane capacity due to prior in-plane loading, they are empirical – based and fitted only for some results available from the literature, or only for one existing experimental campaign. Regarding that, conclusion is that they can be used for calculation of the reduction factor if wall parameters are very similar to the ones for which these equations are calibrated, but there is a need for developing new equations which can take into account reduction of out-of-plane capacity due to in-plane damage for more general application.

5 CONCLUSIONS

In this paper, influence of prior in-plane damage on the out-of-plane capacity of masonry infills has been investigated. First, literature review of previous experimental campaigns dealing with this topic has been conducted. It has been pointed out that all the studies concluded that prior in-plane damage of masonry infill walls decreases stiffness of the wall and initiates higher displacements in out-of-plane direction.

Since experimental test on full scale specimens, investigating influence of in-plane loading on out-of-plane capacity, are rare, experimental campaign on two different wall specimens made of clay brick masonry, was conducted. Wall specimen denoted as T1 was subjected to cyclic out-of-plane loading until failure. Failure occurred at the load of 176 kN. Wall denoted as T2 was loaded in two phases. In the first phase, in-plane load was imposed on the system in 15 cycles, each containing 3 amplitudes. Highest drift level that was reached was 1.2 %, and the wall peak force occurred at drift level of 0.8 %. Afterwards, specimen was unloaded in in-plane direction, and out-of-plane cyclic load was imposed in 11 cycles. At the load of 87 kN, high increase of out-of-plane displacement followed by the decrease of the force occurred, and the test was stopped.

Analyzing the results from conducted experimental campaign it can be concluded that in-plane drift significantly decreases out-of-plane strength capacity and stiffness of masonry infills. Also, it changes the behaviour of the wall in a way that walls exhibit more ductile behaviour due to the higher deformability of mortar joints, if previously, in-plane force is introduced. Out-of-plane displacements at failure in test T1 were low due to different type of the behaviour of the wall than expected. The reason for that were boundary conditions at the connection of masonry infill to the surrounding concrete. Reason for that lies in the fact that, for the placing of mortar, high-pressure pump was used. This pump is not used so far in practice, so it can be said that above mentioned conclusions represent the situation with perfect boundary conditions and very high mortar bond strength, which is not the case in the practice. Due to this construction procedure and mortar bond strength, crack planes for the out-of-plane rotation of infill walls were moved from the top and bottom connection of masonry infills to the first and last row of the bricks. This led to fast and brittle failure of the specimen T1, when the tensile cracks penetrated through the thickness of the wall, destroying thin webs of the brick.

Wall denoted as T2 had reduction of out-of-plane capacity of 51 % compared to the wall specimen denoted as T1, as a consequence of prior in-plane damage. In-plane drift of 1.2 % damaged the wall, which had some minor and some moderate damages. Most common damage of the bricks was falling out of the outer shells of the bricks in the middle two rows of the wall. From the investigation at the site, it can be pointed out that these bricks probably had to be replaced, if the same situation happened in the building. This implies that repair would not be an option. Also, due to high compressive forces, some bricks near the columns exhibit diagonal cracks, which were also visible in the concrete columns. Mortar joints at the connection of masonry infill and concrete were cracked. This cracks in mortar joints didn't jeopardize two-way arching of the masonry infill wall, which stayed in contact with surrounding concrete until the end of the test. Also, it is important to point out that even though in-plane damage decreased out-of-plane capacity of the wall, the wall still had significant amount of out-of-plane capacity.

It can be concluded that prior in-plane damage has to be taken into account when out-of-plane capacity of the wall is discussed, and that this interaction poses an important factor and safety hazard for masonry infill walls during seismic events.

Results from test campaign for the out-of-plane capacity with prior in-plane damage were compared with analytical approaches for reduction of out-of-plane capacity from the literature. Best match was noticed with the approach proposed by da Porto et al. [35], due to similar wall parameters. Nevertheless, it has been concluded that reduction factor equations from the literature are empirical - based and that results from those equations need to be taken with reserve. Further investigations are needed and they are planned as the part of comprehensive experimental campaign within the AIF project “Development of innovative approach for decoupling infills and non-load bearing masonry walls from the main structure” [37].

ACKNOWLEDGEMENTS

The authors would like to acknowledge the support from the “Institut für Ziegelforschung Essen e.V” and express their special thanks to Dr. Matija Gams from the University of Ljubljana for the support and fruitful discussions during the execution of experimental campaign within “Development of innovative approach for decoupling infills and non-load bearing masonry walls from the main structure” project.

Abstract

Masonry infills are commonly used as exterior or interior walls in reinforced concrete (RC) frame structures and they can be encountered all over the world, including earthquake prone regions. Since the middle of the 20th century the behaviour of these non-structural elements under seismic loading has been studied in numerous experimental campaigns. However, most of the studies were carried out by means of in-plane tests, while there is a lack of out-of-plane experimental investigations. In this paper, the out-of-plane tests carried out on full scale masonry infilled frames are described. The results of the out-of-plane tests are presented in terms of force-displacement curves and measured out-of-plane displacements. Finally, the reliability of existing analytical approaches developed to estimate the out-of-plane strength of masonry infills is examined on presented experimental results.

Keywords: Seismic loading, Masonry infill, Out-of-plane load, Out-of-plane strength.

1 INTRODUCTION

The influence of infills on the seismic response of frame structures has long been recognised [1]. However, the issue of how the infills affect the seismic performance of an RC building is intricate as well as their exact role during an earthquake is complex and not yet clearly understood [2]. Regularly distributed infills may significantly contribute to withstand the seismic actions, as also proved during moderate and strong earthquakes, reducing the deformation demand and improving the energy dissipation capacity of the system [3,4]. However, regular infill distribution is not easy to be accomplished in practice. Furthermore, as the deflection of RC frame activates much stiffer infill walls that have a low drift capacity of 0.2–0.3% [5] and rather stiff and brittle in-plane response, infill panels achieve its maximum load capacity very fast which is followed by a sudden decrease of strength. Therefore, it can be concluded that infill wall increases the strength of infilled frame, but it highly decreases its ductility, which conflicts with ductile seismic design [5]. Increase of the stiffness of the overall system due to the infills leads to an increase of the natural frequencies and thus to an increase of the horizontal earthquake loads with a significantly different global vibration behaviour of the overall structure [6]. In addition to this, if the infills are irregularly arranged in plan and elevation, torsional effects can lead to additional loads with unfavourable load distributions which accelerate a failure of the infills [7,8,9]. Moreover, additional critical torsional effects may also occur over the course of the successive failure of overloaded infill elements, even if the infills are arranged in a regular manner [6]. If taking these shortcomings into account, it is not surprising that in almost every moderate to high intensity earthquake event RC frames with masonry infill walls suffered damage, in some cases even a total collapse [10]. In order to provide better understanding of the complex frame-infill interaction and its influence on overall seismic performance of structures, most experimental campaigns focused on behaviour of infilled frames under in-plane component of seismic loading.

On the other side, the performance of infilled frames under out-of-plane seismic loading component was the subject of significantly smaller number of experimental researches. In one of the first experimental investigations on out-of-plane behaviour of URM walls conducted by McDowell et al. (1956a,b) [11,12], the important arching action or arching effect was discovered. Further experimental studies on out-of-plane response of masonry infills were carried out by Dawe and Seah (1989b) [13], Angel et al. (1994) [14], Flanagan and Bennett (1999b) [15] and Di Domenico (2018) [16], among others. In the work of these authors, the parameters affecting arching action were investigated and it was concluded that infill wall built in a traditional way with a full contact to surrounding frame can achieve a several times larger out-of-plane capacity than its expected flexural capacity. In addition to this, the results showed that arching effect is mostly governed by a compressive strength of the wall, panel dimensions (slenderness), boundary conditions between the infill and the frame and stiffness of the surrounding frame. Furthermore, the development of arching or rigid body mechanism can be distinguished depending on the condition of infill-frame connections [17]. The ineffective frame-infill connections can be caused by poor quality execution as pointed out in [18] or mortar shrinkage. In more recent studies, the influence of workmanship was therefore investigated in the work of Akhoundi et al. (2020) [19]. The further investigations of out-of-plane behaviour of masonry infills appear to be inevitable after observations of damages after recent earthquake events. For instance, in the L'Aquila 2009 earthquake in Italy, out-of-plane mechanisms led to the lowest capacity of the infills, thus representing the condition of highest risk for human safety [20]. To make the matters worse, not only can the out-of-plane failure occur on upper storeys of buildings due to higher amplification of ground acceleration, but masonry infills can also suffer substantial damage due to interaction of in-plane and out-of-

plane actions in the lower storeys of buildings. The detrimental combination of in-plane and out-of-plane loading was pronounced in recent earthquakes in L'Aquila 2009, Central Italy 2016, Lorca 2011, and Albania 2019.

The available experimental results have served as a useful basis for many researchers to propose simple analytical equations based on arching theory that can be applied in engineering practice for the estimation of out-of-plane capacity of masonry infill walls. Despite the fact that most theories agree in recognizing the aforementioned out-of-plane behaviour for the infilled frames, their results are often conflicting. In most cases this may be justified by substantially different choices in the reference experimental programs [21]. In this paper results of two experimental tests carried out on masonry infills with different boundary conditions are presented. Furthermore, analytical approaches based on arching theory are summarized and their accuracy in estimation of out-of-plane capacity is examined on test results.

2 EXPERIMENTAL TESTS

For the purpose of investigating the correctness of analytical expressions for out-of-plane strength of infill walls, two out-of-plane experimental tests will be used. The first test was conducted within the experimental campaign of the European research project INSYSME (Innovative systems for earthquake resistant masonry in reinforced concrete buildings) [22], whereas the second one was carried out in the scope of the project "Development of an innovative approach for decoupling infills and non load-bearing masonry walls from the main structure" [23] and represents the continuation of the research work done within the INSYSME project [22]. In this paper, only out-of-plane tests on two masonry infills are described. Test BO was carried out in the former and test T1 in the latter experimental campaign.

2.1 Test specimens

Both infill walls were constructed in a usual way of bricklaying. Bed joints were filled with thin layer mortar while head joints were made as dry joint connection without mortar. However, it has to be pointed out that in the specimen BO, the general purpose mortar was used to fill the remaining gap at the top, while in specimen T1 the execution of the top joint was carried out by a special pump in order to completely and perfectly fill the top gap with thin layer mortar. In both specimens bottom and side connections of masonry infill to the surrounding frame were made by general purpose mortar, but in the specimen BO a gap of 5 cm between infill and RC column was left in order to consider the case of wall having door opening along its whole height. In that sense, BO specimen presents three-sided and T1 specimen four-sided wall. The dimensions and mechanical characteristics of bricks, thin layer and general purpose mortar used in specimens are summarized in Table 1 and 2.

The surrounding reinforced concrete frames were designed according to DIN EN 1992-1-1 (2011) [24] and DIN EN 1998-1 (2010) [25] considering the German national annexes for ductility class L. Columns have 25/25 cm quadratic cross section with the 1.48 % of longitudinal reinforcement. The percentage of transverse reinforcement in middle column section is 0.42 %, while there is 0.63% of transverse reinforcement in column corners. Beam was designed to have a width of 45 cm and height of 25 cm with the 1.05% of longitudinal reinforcement and 0.23% and 0.35% of transverse reinforcement in middle and corner sections, respectively. Dimensions of the frame and arrangement of reinforcement can be found in [6, 17].

Test BO

2.2 Test setup and loading protocols

The test setup for specimen BO was specifically constructed for the experimental tests within the INSYSME project [22]. Vertical force of 200 kN per column was applied with the vertical hydraulic jacks before the application of out-of-plane load and kept constant during the whole test. Air bags for out-of-plane loading were placed between the stiff supporting panel and infill wall thus allowing only the deformation of infill wall. Detailed description of the test setup for specimen BO can be found in [6, 17].

The test setup for specimen T1 was purposely designed for the experimental tests within the project “Development of an innovative approach for decoupling infills and non load-bearing masonry walls from the main structure” [23]. Vertical force of 200 kN per column was applied by one-way hydraulic actuators connected to a pressure accumulator to ensure near constant pressure during the test. A special harness is used for these actuators, which consists of two rods per column, a steel beam at the top and specially designed steel angles connected to the frame at the foundation beam. After the application of vertical load, the out-of-plane load is imposed to the infill by four airbags. The airbags are placed between the infill and a wooden reaction wall at the back of the wall.

2.3 Experimental results

2.3.1. Test BO

In test BO masonry infill wall supported on three sides with one free vertical edge was subjected to out-of-plane loading applied in four cycles. On Figure 1 load-displacement curve is presented. It shows that the specimen achieved maximum resistance of about 170 kN which corresponds to a uniformly distributed load of about 24 kN/m². In first two loading cycles the out-of-plane displacements were relatively small due to stable arching action. However, in the third load cycle at the load level of about 24 kN/m² sudden friction failure occurred in the top joint between infill and the upper beam of the frame which triggered the tilting of the wall. In addition to this, splitting and overloading of the bricks in the uppermost infill row caused the loss of boundary condition at the top. The substantial increase of displacements was observed at the infill free edge, especially at the top (Figure 2).

Figure 1. Force-displacement curve for out-of-plane loading of the test BO (Marinković, 2018) [17]

Figure 2. Side view of the out-of-plane displacements of the vertical section at the free edge of the wall in test BO (Marinković, 2018) [17]

In the final load cycle the splitting of the bricks at the wall base occurred too and thus destroyed the bottom boundary condition. As a consequence, the formation of arching effect was prevented. Right side of the wall moved as a rigid body until the occurrence of cracking through head joints in the central part of infill (Figure 3). The measured out-of-plane displacements at the end of the fourth cycle are presented in Figure 4.

Figure 3. Damage to the wall at the end of the test BO (Butenweg et al. 2019) [6]

Figure 4. Side view of the out-of-plane displacements at the end of the fourth loading cycle of the test BO (Butenweg, et al. 2019) [6]

2.3.2. Test T1

In test T1 four side supported masonry infill wall was subjected to out-of-plane loading applied in two cycles. On Figure 5 load-displacement curve is presented. The specimen was able to withstand the total out-of-plane force of 175.6 kN which corresponds to 25.2 kN/m² of uniform load. The wall deflection in the first load cycle indicated the formation of two-way arching mechanism (Figures 6 and 7). The out-of-plane displacements in this loading phase were quite small, not exceeding 2 mm. With the further application of the out-of-plane loading in the second cycle, the out-of-plane displacements increased. Central vertical and horizontal strips deflected more than the outer strips (Figure 8) thus confirming the presence of strong two-way arching action. Although there were no visible signs of any substantial

damage to the masonry infill, at the load level of about 25 kN/m^2 the part of the infill abruptly fell out. Due to strong and undamaged connections at the top and bottom of the infill wall, the rotation between topmost row of bricks and upper beam and lowermost row of bricks and bottom beam was limited at higher load levels. Due to this, compressive stresses increased faster in the compressive thrust near the arc supports. The thin and brittle webs of bricks in compression zones of arc supports crushed under excessive compressive stresses which led to the expulsion of the part of the wall and complete failure of specimen (Figure 9).

Figure 5. Force – displacement curve for out-of-plane loading of the test T1

Figure 6. Side view of the out-of-plane displacements of the central vertical section of the test T1

Figure 7. Top view of the out-of-plane displacements of the central horizontal section of the test T1

Figure 8. Deflection of vertical strips in the end of second loading cycle of test T1

Even after the collapse of the infill, thin layer mortar at the top remained intact and strongly connected to the top beam and rest of the bricks in the uppermost row of the infill. Namely, during the inspection of specimen after the test, it was noticed that vertical holes of bricks were filled with a huge amount of thin layer mortar since it had been falling into narrow voids during its application by a special pump.

Figure 9. Infill wall after the collapse (test T1)

3 SUMMARY OF ANALYTICAL APPROACHES ESTIMATING OUT-OF-PLANE CAPACITY

In the case of earthquake loading, masonry infills are subjected to out-of-plane loads due to the mass and inertia of the wall. Since the out-of-plane loads can be approximated as uniformly distributed, out-of-plane capacity of masonry infills is usually defined as the uniform lateral pressure causing the collapse of the wall. Some of the first approaches used for estimation of out-of-plane capacity were derived from Timoshenko theory (Timoshenko and Woinowsky-Krieger, 1959) [26]:

$$q = \frac{f_{mt}}{6\beta_1 \left(\frac{h}{t}\right)^2} \quad (1)$$

The governing parameter is a tensile strength f_{mt} of linearly elastic, homogeneous and isotropic material, while β_1 is a coefficient depending on the aspect ratio of the panel and its restraint conditions. In the other methods two-way action was taken into account by using yield line analysis (Hendry, 1973; Hendry and Kheir, 1976) [27,28]. In the approach proposed by Haseltine (Haseltine, 1976; Haseltine et al. 1977) [29,30] the governing parameter is flexural tensile strength f_{xk2} orthogonal to the bed joints:

$$q = \frac{f_{xk2}}{6a \left(\frac{h}{t}\right)^2 \gamma_m \gamma_f} \quad (2)$$

Panel shape and restraint conditions are taken into account by bending coefficient a , γ_m is safety coefficient related to the materials and γ_f is an importance factor.

These approaches that considered tensile or flexural strength as the governing parameter appeared to be limited in the prediction of ultimate out-of-plane capacity and only capable of estimation of masonry cracking. However, experiments [13-16] showed that membrane forces appear in the wall due to deformation of the wall after cracking, thus proving that the arching action is a predominant resisting mechanism.

McDowell et al. (1956a,b) [11,12] were the first to propose calculation of out-of-plane capacity of masonry walls considering one-way arching action. Instead of flexural or tensile strengths which were used in preceding approaches, they incorporated compressive strength of masonry into their formulation. In the researches that followed this one, two-way arching action was also considered in analytical models.

After verification of their postcracking analysis program on the results of out-of-plane tests on concrete masonry infills surrounded by steel frames, Dawe and Seah (1989b) [13] conducted an extensive parametric study in order to determine the most important parameters affecting out-of-plane capacity of masonry infills. Based on the results of this study they developed empirical relationship for the calculation of out-of-plane capacity of masonry infills:

$$q = 0.8f_m'^{0.75}t^2 \left(\frac{\alpha}{l^{2.5}} + \frac{\beta}{h^{2.5}} \right) \quad (3)$$

where f_m' is masonry compressive strength (MPa), t is the infill thickness (mm), h is the infill height (mm), l is the infill length (mm). Parameter α takes into account the relative stiffness of the bounding column, while parameter β takes into account the relative stiffness of the bounding beam. The parameters should be calculated according to the equations below, distinguishing the case of four-sided wall (eq. 4 and 5) or three-sided wall with the gap at the top (eq. 6 and 7):

$$\alpha = \frac{1}{h} (EI_c h^2 + G_c J_c t h)^{0.25} \leq 50 \quad (4)$$

$$\beta = \frac{1}{l} (EI_b l^2 + G_b J_b t l)^{0.25} \leq 50 \quad (5)$$

$$\alpha = \frac{1}{h} (EI_c h^2 + G_c J_c t h)^{0.25} \leq 75 \quad (6)$$

$$\beta = 0 \quad (7)$$

In the equations (4-7), E is the modulus of elasticity of frame material (MPa), I_c is the moment of inertia in the plane of the infill of the column (mm^4), I_b is the moment of inertia in the plane of the infill of the beam (mm^4), G is shear modulus (MPa), J_c is torsional constant of the column (mm^4), J_b is torsional constant of the beam (mm^4).

Angel et al. (1994) [14] developed analytical model based on arching action of an infill strip spanning between two rigid supports. The authors distinguished two failure modes depending on the slenderness ratio; for the infills with h/t values lower than determined critical slenderness ratio crushing at arc boundaries is expected to occur, otherwise the snap through the panel may appear. In addition to this, they considered the effects of previous in-plane damage, flexibility of the confining frame and panel slenderness ratio on the out-of-plane behaviour. Therefore, the ultimate out-of-plane strength could be estimated by the following equation:

$$q = R_1 R_2 \frac{2f_m' \lambda}{h/t} \quad (8)$$

where t is the thickness of the wall (mm), h is the height of the wall (mm), l is the length of the wall (mm), f'_m is the compressive strength of masonry infill (MPa) and λ is the dimensionless parameter that can be calculated according to equation (9) proposed by Flanagan and Bennett (1999c) [31]. Coefficient R_1 is the reduction factor that considers previous in-plane damage and coefficient R_2 accounts for the flexibility of the confining frames in the case of edge location of the infill, meaning that the panel is located in the exterior bay or the uppermost story. Coefficients R_1 and R_2 can be calculated by using the equations (10-12).

$$\lambda = 0.154 \exp\left(-0.0985 \frac{h}{t}\right) \quad (9)$$

$$R_1 = (1.08 - 0.015 \frac{h}{t} - 0.00049 \left(\frac{h}{t}\right)^2 - 0.000013 \left(\frac{h}{t}\right)^3)^{\frac{\Delta}{2\Delta_{cr}}} \quad (10)$$

for $\frac{\Delta}{2\Delta_{cr}} \geq 0.5$

$$R_2 = 0.357 + 2.49 EI \cdot 10^{-14} \text{ for } EI < 25.83 \cdot 10^{12} \quad (11)$$

$$R_2 = 1 \text{ for } EI \geq 25.83 \cdot 10^{12} \quad (12)$$

$$EI = E \min\{I_b; I_c\} \quad (13)$$

where Δ represents the maximum in-plane inter-story drift that panel has experienced and Δ_{cr} is the cracking drift, EI is the flexural stiffness corresponding to the smallest member of the confining frame at the panel edge with no continuity.

In the thorough study of Flanagan and Bennett (1999c) [31], the performance of analytical methods proposed by Dawe and Seah (1989b) [13] and Angel et al. (1994) [14] in estimating the out-of-plane strength of masonry infills was examined on 36 experimental tests carried out by Thomas (1953) [32], Anderson and Bright (1976) [33], Dawe and Seah (1989b) [13], Fricke et al. (1992) [34], Frederiksen (1992) [35], Angel et al. (1994) [14] and Flanagan and Bennett (1999b) [15]. The empirical method proposed by Dawe and Seah (1989b) [13] provided the best prediction of out-of-plane capacity, but with consistent overestimation. Therefore, Flanagan and Bennett (1999c) [31] modified the constant in (3) from 0.8 to 0.73 and proposed the following equation for the calculation of out-of-plane capacity of masonry infills:

$$q = 0.73 f'_m{}^{0.75} t^2 \left(\frac{\alpha}{l^{2.5}} + \frac{\beta}{h^{2.5}} \right) \quad (14)$$

where f'_m is masonry compressive strength (MPa), h is the height of the wall (mm), l is the length of the wall (mm). The authors recommend the application of the modified thickness of the wall $t_2 = h/8$ if the infill walls slenderness ratio is less than 8 ($h/t < 8$). Parameters α and β can be calculated according to the following equations:

$$\alpha = \frac{1}{h} (EI_c h^2)^{0.25} \leq 50 \quad (15)$$

$$\beta = \frac{1}{l} (EI_b l^2)^{0.25} \leq 50 \quad (16)$$

In the equations (15-16), E is the modulus of elasticity of frame material (MPa), I_c is the moment of inertia in the plane of the infill of the column (mm^4), I_b is the moment of inertia in the plane of the infill of the beam (mm^4). The authors neglected the influence of torsional stiffness on the out-of-plane capacity of masonry infills which was considered in the method of Dawe and Seah (1989b) [13].

In Eurocode 8 (2004) [36] it is stated that particular attention should be paid to masonry panels with a slenderness ratio greater than 15, but there are no specific design recommendations for the calculation of out-of-plane strength of masonry infills. However, in Eurocode 6 (2005) [37] one-way arching action is assumed as lateral loads resisting mechanism of URM wall and the out-of-plane capacity of URM walls can be calculated according to the equations:

$$q = f'_m (t/a)^2 \text{ for } t/a < 20 \quad (17)$$

where f'_m is compressive strength of masonry infill (MPa), t is the thickness of the wall (mm), h is the height of the wall (mm), l is the length of the wall (mm) and a is taken as:

$$a = \max\{h; l\} \quad (18)$$

Based on analytical investigation of the behaviour of masonry infills supported on two sides under transverse loading, Moghaddam and Goudarzi (2010) [38] developed semi-empirical relationship between out-of-plane capacity of masonry infills and rigidity of the bounding frame, properties of the masonry material and slenderness ratio. Two failure modes are distinguished: boundary crushing (q_{cr}), when the crushing takes place at the supports of the infill and transverse instability (q_{max}), which occurs due to the large transverse deflection of the infill. The out-of-plane capacity corresponds to the smaller of two values:

$$q = \min\{q_{cr}; q_{max}\} \quad (19)$$

$$q_{cr} = \left(\frac{0.85 f'_m}{(h/t)^2} - \left(0.12 + \frac{0.045}{\alpha} \right) \frac{f_m'^2}{E_m} \right) \quad (20)$$

$$q_{max} = \left(\frac{0.18 E_m}{\left(0.12 + \frac{0.045}{\alpha} \right) \left(\frac{h}{t} \right)^4} \right) \quad (21)$$

$$\alpha = 384 \frac{EI_b h}{E_m t l^4} \quad (22)$$

where f'_m is compressive strength of masonry infill (MPa), E is Young's modulus of frame material (MPa), E_m is Young's modulus of masonry infill wall (MPa), t is the thickness of the wall (mm), h is the height of the wall (mm), l is the length of the wall (mm).

Morandi et al. (2013) [39] proposed the equation for the calculation of ultimate out-of-plane capacity of the masonry infill based on the recommendations from Eurocode 6 (2005)

[37]. Besides the contribution of the arching mechanism to out-of-plane capacity of the infill, the presence of vertical reinforcement in the masonry infill may also be taken into account:

$$q = 0.72 \left(\frac{t}{h} \right)^2 f'_m + 7.2 \frac{t}{lh^2} A_s f_y \quad (23)$$

where, f'_m is the compressive strength of masonry infill (MPa), t is the thickness of the wall (mm), h is the height of the wall (mm), l is the length of the wall (mm), A_s is the total cross sectional area of the vertical reinforcement in tension (mm²) and f_y is the reinforcement yield strength (MPa). However, the authors stated that the equation refers to the masonry infills which did not suffer any previous in-plane damage.

Unsatisfied with the reliability of existing formulations for prediction of out-of-plane strength, first cracking load and displacement at the collapse of masonry infills, Ricci et al. (2018) [40] proposed semi-empirical approach that defines the characteristic points of a trilinear out-of-plane force-displacement curve based on geometric and mechanical properties of infills. They applied a linear least square regression in their work and defined the cracking and peak out-of-plane uniformly distributed loads q_{crack} and q_{max} , respectively:

$$q_{crack} = 0.31 f_m'^{0.05} \frac{t}{h^{2.66}} \quad (24)$$

$$q_{max} = 1.95 f_m'^{0.35} \frac{t^{1.59}}{h^{2.96}} \quad (25)$$

where t is the thickness of the wall (m), h is the height of the wall (m) and f'_m is the compressive strength of masonry infill (MPa).

4 ESTIMATION OF OUT-OF-PLANE CAPACITY

Results of described experimental tests are used to examine the precision of predicting out-of-plane capacity of masonry infills by means of simple analytical equations summarized in Chapter 3 of this paper. It has to be pointed out that only methods based on arching theory were considered. Figure 10 and Table 3 show the comparison of predicted and experimental values from test BO, whereas the comparison of analytical and experimental results for test T1 is presented in Figure 11 and Table 4.

From Figure 10 and Table 3, it could be concluded that only estimation by method of Flanagan and Bennett (1999c) [31] is in good agreement with experimental result of test BO. This could be explained with the fact that this semi-empirical analytical approach could be applied to walls with a gap at one side by setting parameter α that accounts for stiffness of columns to 0. The similar semi-empirical equation proposed by Dawe and Seah (1989b) [13] overestimates the actual capacity 34 %, although it also considers case of three-sided BO wall by neglecting columns stiffness. However, it is surprising that predictions calculated according to Angel et al. (1994) [14], Eurocode 6 (2005) [37], Moghaddam and Goudrazi (2010) [38], Morandi et al. (2013) [39] substantially overestimate the actual capacity of BO specimen as their theories are based on one-way arching which was the major resisting mechanism in test BO until the occurrence of tilting. Such a significant discrepancy between experimental result and out-of-plane strengths predicted by these analytical approaches might be due to the loss of boundary conditions at the top and bottom of the BO wall which led to the inhibition of the arching action and therefore moving of the infill out of RC frame plane. The reason for overestimation of actual capacity of specimen BO by semi-empirical approach

of Ricci et al. (2018) [40] could be that it was based on regression that produces satisfactory ratio of predicted to experimental values of masonry infills supported on four sides.

Figure 10. Comparison of calculated out-of-plane capacities with actual capacity in test BO

Author	q_{pred} [kN/m ²]	q_{pred} / q_{exp}
Dawe and Seah (1989b) [13]	32.06	1.34
Angel et al. (1994) [14]	58.29	2.43
Flanagan and Bennett (1999c) [31]	21.08	0.88
Eurocode 6 (2005) [37]	65.03	2.71
Moghaddam and Goudrazi (2010) [38]	54.54	2.27
Morandi et al. (2013) [39]	46.83	1.95
Ricci et al. (2018) [40]	37.84	1.58

Table 3. Comparison of calculated out-of-plane capacities with actual capacity in test BO

On the other side, perhaps due to the same reason explained above, in the case of masonry infill restrained on four sides analyzed in test T1 the best estimation of out-of-plane capacity is achieved by semi-empirical approach proposed by Ricci et al. (2018) [40]. Among two formulations that take into account two-way arching effects, Flanagan and Bennett (1999c) [31] appeared to be closer to actual out-of-plane strength of specimen T1 due to the lower numerical constant in their equation (14) than in the equation (3) of Dawe and Seah (1989b) [13]. The small discrepancy between out-of-plane capacities predicted by Angel et al. (1994) [14] and Morandi et al. (2013) [39] and experimentally measured out-of-plane resistance of four-sided specimen in test T1 needs to be interpreted cautiously since the contribution of horizontal arching was not considered in the approaches of these two authors, but it is pronounced in specimen in test T1. Other two approaches developed assuming one-way arching (Eurocode 6 (2005) [37] and Moghaddam and Goudrazi (2010) [38]) overestimated the actual out-of-plane strength of T1 specimen with an error of about 25 %.

Figure 11. Comparison of calculated out-of-plane capacities with actual capacity in test T1

Author	q_{pred} [kN/m ²]	q_{pred} / q_{exp}
Dawe and Seah (1989b) [13]	33.01	1.31
Angel et al. (1994) [14]	26.67	1.06
Flanagan and Bennett (1999c) [31]	29.39	1.17
Eurocode 6 (2005) [37]	31.44	1.25
Moghaddam and Goudrazi (2010) [38]	31.65	1.26
Morandi et al. (2013) [39]	27.35	1.09
Ricci et al. (2018) [40]	26.32	1.04

Table 4. Comparison of calculated out-of-plane capacities with actual capacity in test T1

This short study shows that Flanagan and Bennett (1999c) [31] can quite accurately predict the out-of-plane capacity of three-sided masonry infill in test BO since ratio of predicted to experimental value is 0.88. As expected, estimation of Dawe and Seah (1989b) [13] is less conservative than Flanagan and Bennett (1999c) [31] as predicted to experimental ratio is 1.34. The other approaches overestimate the actual strength of specimen BO more than 1.5 times. The lowest ratio of predicted to experimental out-of-plane capacity ($q_{pred}/q_{exp} = 1.04$) of four-sided masonry infill in test T1 is achieved by application of semi-empirical approach by Ricci et al. (2018) [40], while calculation according to Dawe and Seah (1989) [13] leads to the largest ratio of 1.31.

5 CONCLUSIONS

This paper deals with investigation of out-of-plane behaviour of masonry infills. Firstly, full scale out-of-plane experimental tests carried out in the scope of two related experimental campaigns are described. The out-of-plane response of masonry infills with different boundary conditions was investigated in the tests. Three side supported wall resisted the imposed out-of-plane loading by stable vertical arching action. However, due to loss of boundary conditions at the top and bottom whole wall started to move out of RC frame plane, with largest deflections at the free edge. The out-of-plane displacements of infill were relatively small until the sudden loss of top joint connection which prevented the arching action and triggered the wall tilting. On the other side, in the four side supported infill wall

pronounced two-way arching action was established. The out-of-plane displacements were relatively small until the explosion-like collapse of the wall. Unlike the first test, frame-infill connections did not suffer any damage and remained in good condition thanks to perfectly executed, but difficult and time demanding filling of the gap at the top with thin layer mortar by pump. Due to this, the rotation was shifted from top connection one joint lower. Additionally, thin brick webs crushed under high compressive stresses induced by arching action. As a consequence, part of the infill defined by head joints and crushed bricks fell out of wall plane.

It has to be pointed out that achieved out-of-plane capacities of both infills represent a significant level of seismic safety in terms of out-of-plane failure. This can be explained by favourable slenderness ratios ($h/t = 6.9$ in test BO; $h/t = 8.4$ in test T1) and relatively low weight of hollow clay bricks resulting in low mass of the considered walls (about 1.5 t in test BO; 1.3 t in test T1). However, the results show a clear dependency of out-of-plane response on the quality of execution of frame-infill joints, especially at the top.

Furthermore, the existing analytical approaches for prediction of out-of-plane strength are summarized. The importance of discovery and consideration of arching effect in the evaluation of out-of-plane strength of masonry infills is explained and various parameters affecting arching mechanism are discussed.

In the end a short study was conducted with the aim to test the reliability of analytical equations proposed in the literature on presented experimental results. The out-of-plane capacity of three-sided panel investigated in test BO was fairly well predicted by analytical equation of Flanagan and Bennett (1999c) [31], while Dawe and Seah (1989b) [13] overestimated the experimental value, but with smaller error in comparison to predictions of other approaches. The recommendation from Ricci et al. (2018) [40] was the most precise in the estimation of out-of-plane strength of four-sided panel in test T1. Out-of-plane capacities of specimen T1 calculated according to equations proposed by Angel et al. (1994) [14] and Morandi et al. (2013) [39] are also in good agreement with the experimental value, but the results need to be studied with special attention as these two approaches were not developed under consideration of two-way arching action which is pronounced in test T1. If taking average value of predicted to experimental ratio from both experimental tests into account, the method proposed by Flanagan and Bennett (1999c) [31] seems to be applicable in prediction of out-of-plane strengths of both three-sided and four-sided infills. However, the larger experimental database should be considered in order to determine the analytical equation with best fitting to experimental results. In addition to this, the important aspect of the interaction between in-plane and out-of-plane seismic actions should be investigated in the future experimental studies in order to provide more realistic evaluation of out-of-plane capacity of masonry infills. As most of the analytical approaches do not consider the influence of in-plane loading on the out-of-plane strength and thus considerably overestimate the out-of-plane resistance of masonry infills, more work on the formulation that accounts for reduction of out-of-plane capacity due to in-plane damage should be carried out.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the support from the “Institut für Ziegelforschung Essen e.V” and express their special thanks to Dr. Matija Gams from the University of Ljubljana for the support and fruitful discussions during the execution of experimental campaign within “Development of an innovative approach for decoupling infills and non load-bearing masonry walls from the main structure” project.

Abstract

Despite numerous research studies conducted in the field of masonry-infilled steel (and concrete) frames, there is still no adequate codified design method. There is, however, a consensus that masonry-infilled frames should be treated as potentially hazardous earthquake context structural solutions. While masonry infill has positive effects on steel frames, which are often neglected in design, adverse effects cannot be overlooked. Over the last decade, several structural solutions aimed to improve the overall structural behavior of these interactive composite systems were proposed and tested in laboratory conditions. It is not rare that these approaches are opposite to each other, which additionally stresses the fact that there is a need for recognition and validation of the key structural directions. Among various proposed design options, the authors are very interested in those which tend to include the beneficial effect of masonry infill, but at the same time preserve desired ductile behavior of steel frames, all by using simpler and easy to apply structural solutions. Some of them are already proposed by the authors, which are discussed in the paper, along with a summary and comparison of contemporary structural solutions in steel masonry-infilled frames, as an important step towards codification.

Keywords: steel-masonry, composite structure, earthquake design, structural solutions

1 INTRODUCTION

Masonry blocks, due to easy production, installation and accessibility are the most widespread infill type in frame structures, especially in Europe. It is known that the presence of masonry infill can significantly increase stiffness and strength, but it can also limit the ductile behavior of frames in case of higher lateral load such as an earthquake. Consequently, researchers evaluate the contribution of the masonry infill and their influence on the frame, and through this process started to develop innovative structural concepts to mitigate the negative effects of

masonry infill. Based on this, numerous structural concepts in the design of infilled frames can be found, aimed to improve the overall interaction between infill and frame. The typical solutions are application of various infill types (i.e. using soft or strong materials for infill), modification of the failure mechanisms, reinforcing of the infill etc. These methods can be generally categorized into two groups [1]:

- Strengthening of the masonry infill through which the composite structure frame+infill behaves as a monolithic construction.
- Limiting frame-infill interaction through which both monolithic and separate behavior of the frame and the infill may be observed.

The strengthening methods are mainly characteristic for concrete frames, while the limited interaction is characteristic for steel frames, although some deviations can be found in the literature review that follows.

One of the most natural types of strengthening infill was covered in the study done by Pul and Arslan [2]. They used and compared plastered, non-plastered, and wire-plastered masonry walls made from hollow clay brick. Results show that plaster and wire plaster enhance load-carrying capacity and ductility, which is good since most of the masonry application includes a plaster surface layer. Jebadurai et al. [3] focused their research on enhancing the bond strength between masonry units in RC frames by adding a different percentage of styrene-butadiene rubber latex in the mortar. Experiments showed that using modified mortar with a certain percentage of latex increased ductility by 12.90%. Binici et al. [4] investigated a well-known infill type, autoclaved aerated concrete, but with an improvement regarding infill execution - metal slider connectors in AAC blocks. Due to this slider connector, the interaction between the RC frame and infill is limited. As a result, the in-plane damage is postponed at higher drift ratios and the out-of-plane damage is limited. Ruey-Shyang Ju et al. [5] studied separation of RC infill walls from steel moment frames by making vertical slits and leaving a horizontal gap between the upper steel beam and the infill RC wall. Results of this study showed that proper design and arrangement of slits can absorb the relative deformation between the column and infill wall and it can isolate the separated wall from damage. Innovative isolation of masonry infill from steel frames is presented by Tsantilis and Triantfillou [6], as they use a cellular material (foamed polyethylene) placed in the frame-infill interface. The cellular material has high deformation capabilities which mitigate interaction between the steel frame and masonry infill in the initial phase of loading. As loads get higher the cellular material gets fully compressed and the diagonal compression strut is activated. M. Mohammadi et al. [7] investigated three different techniques to improve steel frame ductility: (i) cornerless infill, (ii) column fuse, and (iii) infill fuse (applied metal sheets in infill layer to provide horizontal sliding). The infill fuse method has shown a significant increase of ductility with no significant cracks or corner crushing up to 7.1% drift. Preti and Bolis [8], and Morandi et. al. [9], tested the steel frame by dividing infill into more subpanels with wooden boards placed in the horizontal and vertical direction. Each of those configurations has shown a serious reduction of infill stiffness and strength in comparison to the reference masonry infill. Marinkovic and Butenweg [10] developed a system named INODIS, in which an elastomeric cellular material is used around the infill frame surface. Besides reduced interaction between the frame and infill, it reduced stress and infill damage. Moreover, the INODIS system allowed higher interstory drifts (more than 3%). Silva et. al [11] developed new units with an interlocking tongue and groove configuration, with vertical reinforcement. Due to reinforcement, an increase of lateral resistance up to 40% in relation to the bare frame was observed. Aliaari and Memari [12] introduced an idea of seismic isolator subframes attached to the structural frame, which they named SIWIS - a system made of one horizontal and two vertical sandwiched light-gauge steel members with a brittle element inside. They aimed to reduce the story drift at low and moderate lateral loads through the beneficial

effect of infill (higher stiffness and strength), while at higher lateral loads the brittle element acts as a „fuse“ in which they attempt to separate infill-frame interaction. Misir et al. [13] researched a new potential infill type without layers of mortar between them - locked brick. Besides the cracks in plaster, locked bricks stay intact and are less damaged in comparison to standard infill. Markulak et. al [14] presented a newly developed masonry unit for infill with lower initial stiffness and strength with a tendency to achieve minimal detrimental influences on the frame, while at the same time acknowledging environmental aspects.

Through a brief overview of structural concepts, it can be observed that there are numerous efforts of researchers to provide adequate solutions to undesired structural behavior of masonry infilled frames. Although some of them are challenging in terms of the execution (e.g. complexity, extra work hours, overall economic costs), provided experimental results and conclusions are of significant importance. The authors of this paper also conducted various experiments on infilled-steel frames in the mentioned direction, some of them accompanied with corresponding numerical models. The main intention being to keep favorable properties of the masonry while maintaining the steel frame ductile behavior at higher lateral loads. For calibration of experimental results various numerical models are used, with more details given in [15, 16]: (i) single equivalent strut (SSM), (ii) three equivalent struts (MSM), (iii) infill panel element (SPM), (iv) micro-model (AMM).

This paper presents findings regarding the influence of the different types of infill on steel frames. This is done through a short literature overview, to correlate the purpose of different experiments. Conducted experiments will be presented along with calibrated numerical results and grouped based on infill type - hollow clay brick (strong infill), autoclave aerated block (weak infill), the combination of those two (innovative solution proposed by authors), and newly developed RBA-EP unit (new structural concept proposed by authors).

2 STEEL FRAMES INFILLED WITH CLAY HOLLOW AND SOLID UNITS

Masonry units are the most used infill in conducted experiments [6, 17, 18, 19, 20, 21]. The masonry infill can be grouped depending on the unit configuration, i.e. as hollow clay block (HC) and solid clay block (SC). Despite different configurations, both types of blocks considerably increase initial stiffness and lateral bearing capacity. In most of the infilled frames, a diagonal compression strut mechanism is developed, accompanied with horizontal sliding along the bed joints. Horizontal shear sliding is the predominant mode of cracking in most of the experiments where the mortar is of insufficient strength. Most of the cracks are developed through the bed and head joints. Diagonal cracking or corner crushing is observed as an ultimate failure mechanism. Besides corner crushing, spalling of blocks is also observed.

The experimental setup that the authors executed consisted of three specimens of a one-bay, one-story rigid steel frame infilled with hollow clay units, designated as RF-C-i, with frame dimensions of 2176x1613 mm [1, 15]. Hollow clay units' average vertical and horizontal compressive strengths were 13.10 MPa and 2.10 MPa, respectively. Cement-lime mortar was utilized, with an average compressive strength of 5.02 MPa. The average value of compressive strength and modulus of elasticity of masonry wallets made from hollow clay units was 2.0 MPa and 4613 MPa, respectively. The steel frame is constructed using HE 120 A profiles for columns and beam with steel grade S275. All the properties of the steel frame were identical for all three specimens. The loading protocol of each specimen consists of two types of loading. At the initial stage up to yielding, quasi-static and cyclic loads were applied stepwise in a series of increments of 10 kN. After yielding, the load was applied as a displacement control in which displacements were increased by increments of 1 mm until a drift of 1.0-2.0% was reached.

Table 1 presents the key parameters that were tested - initial stiffness (S_0), the load at the start of yielding (F_y), ultimate load (F_u), and corresponding maximum displacement (d_{max}) in

which (F_y) represents the onset of the first significant crack. The mean initial stiffness was determined as 31.3 kN/mm and the first significant crack was observed at loads of 59 kN, 70 kN, and 51 kN. For all three specimens, the first crack occurred in the middle of the infill with cracks through the mortar. The average maximum achieved load was 135 kN, while the average maximum displacement at a corresponding drift ratio of 1.39% was 22.46 mm. It should be noted that the steel frame on tested specimens did not exhibit significant plastic deformations. By exceeding the compression strength of infill diagonal cracking occurred with the appearance of shattering and spalling of hollow clay units. Alongside aforesaid failure, bed joint sliding shear failure was also observed. Those types of failure mechanisms are also noticed for the same infill type but with less pronounced corner crushing in [6]. An identical failure mechanism is observed with solid clay units in [19], but with permanent plastic deformation at the bottom of columns.

Table 1: Experimental and numerical results of specimens with strong infill

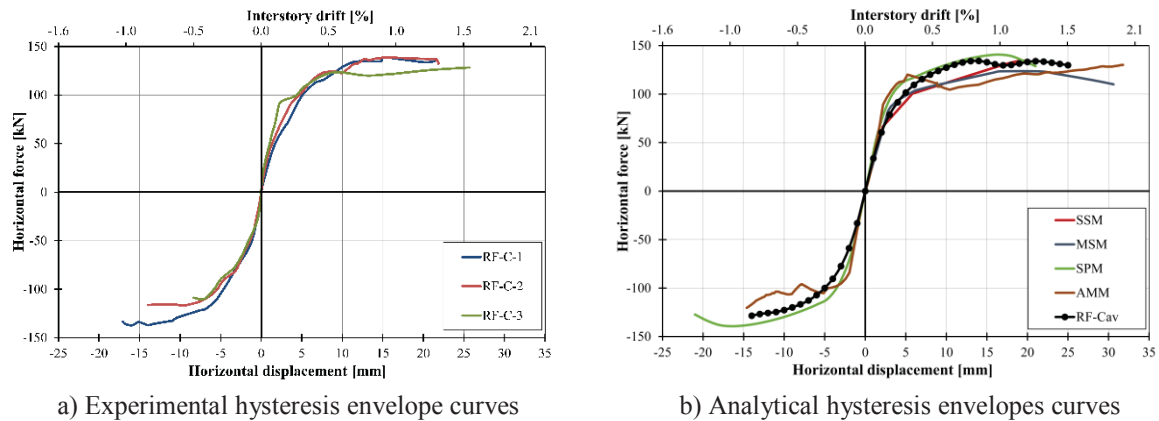

Figure 1: Comparison of experimental hysteresis envelopes (a) and analytical results for C-i series (b)

Regarding numerical models, Table 1 shows a good agreement with experimental results in terms of initial stiffness. SSM and AMM models provide the best agreement, while the SPM method overestimates the initial stiffness (19%). Considering the ultimate lateral load, SSM again provides the best agreement with only a 1% difference. MSM and AMM models underestimated the ultimate lateral load by 8% and 4%, respectively. Figure 1 presents hysteresis envelope curves for each calibrated numerical model, along with experimental results. SSM and MSM models predict a bilinear behavior, although the MSM model provides a smoother envelope. The envelope curve obtained from the AAM model matches very well with experimental initial stiffness, although lateral loads are somewhat lower. The envelope curve obtained from SPM shows a good fit for experimental results overall. It can be concluded that all calibrated models provide a good fit regarding infill made of HC units.

3 STEEL FRAMES INFILLED WITH AUTOCLAVED AERATED UNITS

Autoclaved aerated concrete block (AAC) is a light-weight unit with a significantly lower compressive strength compared to HC and SC units. Due to their small weight, they are favorable units to use as an infill, especially in terms of seismic design. Experiments based on AAC units as infill in steel frames are presented in [22-24], where it is confirmed that they increase initial stiffness and ultimate load capacity. They have lower compressive strength and infill tends to crack at very low loads, as shown in [24] where cracks developed diagonally passing through AAC units and mortar. All of the mentioned three studies report yielding of the steel frame and in [22, 23] local buckling of the flange in the base of the column was reported. Furthermore, in [23] AAC panels crushed and began to spall at similar displacement when the top flange of the column buckled. Contrary to that, in [24] AAC blocks did not fail even at the drift of 1.4% when the test was stopped due to the yielding of the steel frame, but without out-of-plane instability.

The experimental setup that the authors executed consisted of three specimens with the same experimental arrangement as described for RF-C-i specimens (Section 2), with samples designated as RF-A-i [1, 15]. Detailed results of testing individual AAC units and wallets are available in [15] - units vertical compression strength was 2.11 MPa, mortar glue compression strength 9.13 MPa, wallets vertical compressive strength and modulus of elasticity 1.21 MPa and 1174 MPa, respectively.

The experimental results are given in Table 2, from which it can be observed that RF-A-i specimens have lower initial stiffness than RF-C-i specimens (60%). The mean initial stiffness was 19.83 kN/mm. Sample RF-A-1 stands out in regards to initial stiffness (Fig 2.), which can be attributed to inaccuracies during erection [15]. Despite an earlier onset of cracking (average of 51 kN) in relation to RF-C-i specimens, the infill remained compact. The maximum achieved load is 146 kN, with a maximum displacement of 28.01 mm at a corresponding drift ratio of 1.74%. It can be noticed that maximum loads are higher than for RF-C specimens, despite lower mechanical characteristics of AAC blocks. This could be due to the higher compressive strength of bonded glue. Attained ultimate drift ratio of 1.74% signifies that there is plastic deformation at the steel column base.

Experimental results					Numerical results		
Labels	S_0 (kN/mm)	F_y (kN)	F_u (kN)	d_{max} (mm)	Model	S_0 (kN/mm)	F_u (kN)
RF-A-1	26.23	54	152	26.83	SSM	13	152
RF-A-2	15.07	51	139	30.73	MSM	15	123
RF-A-3	17.50	49	146	26.47	SPM	19	134
RF-A _{av}	19.83	51	146	28.01	AMM	23	141

Table 2: Experimental and numerical results of the specimen with weak infill

The failure mode of the RF-A-i specimens is similar to RF-C-i specimens, but with less intensity of diagonal cracking, i.e. infill was compact with more minor cracks and without extensive crushing and separation from the steel frame with horizontal sliding along the bed joints.

Initial stiffness obtained by the SSM model does not coincide with experimental results and the SPM method provides the best agreement in this regards (deviation of 10%). The AAM model slightly overestimates the value of the initial stiffness. In terms of ultimate lateral load MSM, SPM and AMM models underestimate values regarding all three specimens, while the SSM model overestimates the ultimate lateral load concerning all specimens. For a detailed

comparison of behavior between experimental and numerical results Figure 2 presents hysteresis envelope curves for each numerical model.

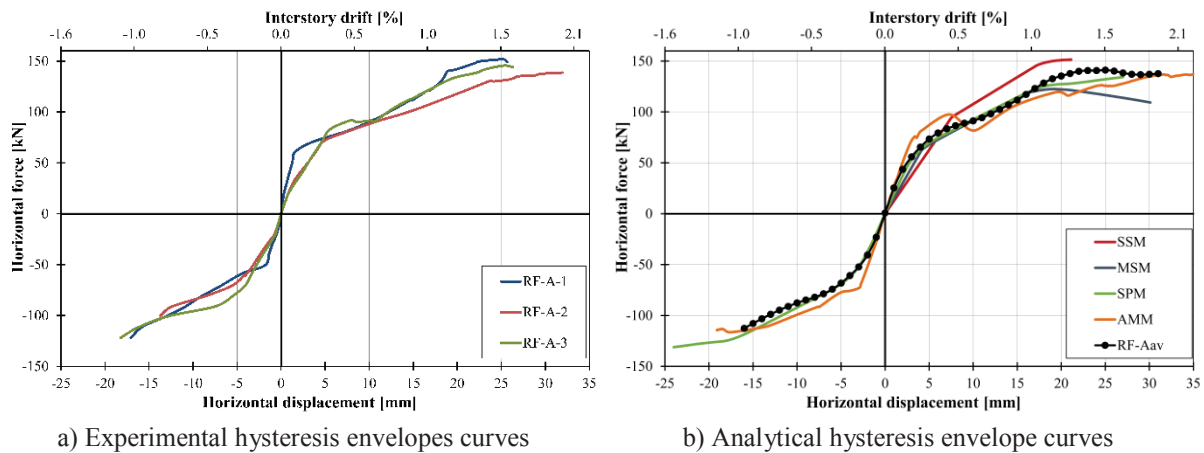

Figure 2: Comparison of experimental hysteresis envelopes (a) and analytical results for A-i series (b)

4 STEEL FRAMES WITH COMBINATION OF CLAY AND AAC UNITS INFILL

This innovative structural concept, presented in [15], is based on limiting (reducing) the interaction between the masonry infill and the steel frame. It is based on the solution of using a combination of AAC and HC units in an infill, to utilize the lower and higher compressive strengths in areas where needed. Weak infill is placed near the column-masonry interaction area are to act as a fuse. Since the AAC units have significantly lower compressive strength, the assumption was that those units will fail first and the steel frames will be preserved from further negative impacts of infill. This solution is distinct by two types of behavior: the monolithic at the initial stage of loading (higher initial stiffness and bearing capacity) and after the separation happens a steel frame dominated behavior. A similar solution can be found in [5, 6, 10, 12] where there are also two stages of behavior, but the initial stage is designed to be dominated by the steel frame, and at higher loads, the steel frame starts to interact with the masonry infill.

The executed experimental programme consisted of three specimens of steel frames infilled with combined HC and AAC units. The AAC units were additionally weakened with drilled holes of different diameters ($\varnothing 54$, $\varnothing 74$, $\varnothing 84$) to alter their compressive strength - vertical compressive strength of 2.11 MPa (for AAC= $\varnothing 54$), 2.03 MPa (for AAC= $\varnothing 74$) and 1.6 MPa (for AAC= $\varnothing 84$) are determined. The experimental setup and loading protocol were the same as for RF-C-i and RF-A-i testing (Section 2 and 3). The influence of holes is significant and it should be emphasized that three specimens of this type of infill represent three different systems.

Experimental results presented in Table 3 show that specimens RF-CA-i, in general, provide higher initial stiffness than RF-A samples, which can be attributed to the higher influence of clay blocks. Despite the higher initial stiffness, cracks were observed much earlier in all three specimens and mostly in AAC blocks. RF-CA-1 achieved the desirable behavior (higher initial stiffness and bearing capacity in the initial loading stage regarding bare frame) whereas the weakening of AAC blocks for other samples was excessive with premature separation occurring. The main difference between RF-A and RF-CA-1 was that the steel frame did not exhibit plastic deformations and the central part of masonry infill was practically undamaged in RF-CA-1. Despite the undamaged infill, proper attention should be paid to the out-of-plane restraint, which can be prevented from falling out-of-plane by construction provisions [1,15]. The maximum obtained load of RF-CA-1 was 106 kN, while the maximum measured displacement was

15.27, which corresponds to a drift ratio of 0.95%. Table 3 presents the numerical results. Concerning the initial stiffness, SSM provides the poorest fit to experimental results (deviation of 38%) and the closest fit is provided with the SPM model. Figure 3 illustrates experimental and numerically predicted behavior, from which the desired effect of pronounced bilinear behavior can be seen. The AAM calibrated envelope curve almost perfectly matches with results for RF-CA-1, which is also true regarding cracks forming in the infill [1, 15].

5 STEEL FRAMES WITH NEWLY DEVELOPED UNITS INFILL

Previous experiments indicate that achieving higher compressive strength and modulus of elasticity of the masonry units is not of great importance to improve the behavior between infill and steel frame, especially in terms of achieving higher ultimate load. Hence, the lower stiffness and strength of the masonry unit can also benefit a steel-masonry infill system. Having this in mind, a new structural solution to this composite structure is proposed by developing a masonry unit that will mitigate negative effects on the steel frame, while preserving positive aspects of an infilled system. Consequently, masonry units from self-compacting concrete (SCC) were developed at the Faculty of Civil Engineering and Architecture in Osijek.

The newly developed masonry block is presented in previous research [25], with the main idea being to manipulate the composition of the developed block. For that purpose, self-compact concrete (SCC) was selected and to reduce stiffness and strength, replacement of natural aggregate was done with recycled crushed brick (RB) and ground expanded polystyrene (GEP) – RBA-EP. The mean value of compressive strength of RBA-EP is 4.04 MPa, which is in comparison with the hollow clay bricks 70% lower and 48% higher compared with AAC block. The modulus of elasticity obtained from wallets made of RBA-EP is 2746 MPa, which is in comparison to wallets made of hollow clay brick and AAC 60% lower and 57% higher, respectively. When considering the weight, the masonry panel made of RBA-EP, AAC, and hollow clay

brick was 293.2 kg, 140.0 kg, and 264.0 kg respectively. For the testing in frames, two types of RBA-EP units are made (Figure 4) - RBA-EP-Type A as a standard unit and RBA-EP-Type B as a weakened unit without one vertical wall along the sidewall.

Figure 4: Configuration of Type A (left) and Type B (right)

Experimental testing of steel frames infilled with newly developed masonry units was done in two series, in a one-bay, one-story rigid steel frame and a pinned steel designated as RF and PF, respectively (dimensions 2332x1683 mm as in previous cases). The rigid steel frame was constructed of HE 120 A profile for columns and beam, while the pinned frame was constructed of HE 280 A profiles. Besides one bare rigid frame (RF) as a control specimen, the rest of the specimens were done as two samples per series. RF-M was infilled with RBA-EP-Type A units only whereas RF-MF was infilled with both RBA-EP-Type A and Type B units. RBA-EP-Type B units were placed at the column-masonry contact, which attempted to be used as a fuse. PF-MF was infilled with RBA-EP-Type A units in the pinned steel frame. All specimens were bonded with M5 class mortar. The loading protocol consists of a horizontal load applied by displacement control with increasing displacement by 0,5mm in each consecutive stage.

Experimental results reported in Table 4 present key parameters that were tested - initial stiffness (S_0), load at start of yielding (F_y), ultimate load (F_u), and corresponding maximum pushover displacement (d_{max}). RF-M and RF-MF have the highest initial stiffness of the tested specimens. Average values of initial stiffness for RF, RF-M, RF-MF, and PF are, respectively, 3.1 kN, 14.4 kN, 14.3 kN, and 7.6 kN. According to the highest initial stiffness, the highest ultimate loads are obtained for RF-M and RF-MF specimens, while the lowest is for PF specimen. The similarity of RF configuration is observed in the value of the horizontal load at start of yielding (the average F_y for RF, RF-M, and RF-MF was respectively, 69.4 kN, 64.9 kN, and 68.4 kN [14]). Although those values are close, the achieved horizontal displacements at the corresponding F_y were significantly different. Average horizontal displacement d_y for RF, RF-M, and RF-MF were, respectively, 23.8 mm, 7.4 mm, and 6.2 mm. Horizontal load F_y of PF-M configuration deviates from the other specimens and it is significantly lower (average F_y 21.0 kN). Average values of F_y and d_y in the comparison of RF-M and RF-MF specimens are very alike, which exposes the fact that the activation of Type B units as a fuse was not achieved. Consequently, the desired separation of infill and frame was not realized. The average ultimate drift of RF-M and RF-M is 2.5%.

Specimen label	Infill type	S_0 (kN/m)	F_y (kN)	F_u (kN)	d_{max} (mm)
RF	-	3.1	69.4	81.5	69.0
RF-M	RBA-EP Type A	14.4	64.9	128.0	48.7
RF-MF	RBA-EP Types A and B	14.3	68.3	132.3	59.9
PF-M	RBA-EP Type A	7.6	21.1	52.8	46.8

Table 4: Experimental results of the specimen with newly developed units

Figure 5 presents an even more detailed behavior of all specimens with RBA-EP units [14]. All tested specimens provide a much higher initial stiffness than the bare frame. Despite the higher initial stiffness of the pinned steel frame, the ultimate lateral load is much lower than for RF. From the PF-M envelope curve, it can be observed (especially on the positive side of the envelope) that there are frequent changes in behavior, which can illustrate the consequent redistribution of the loads in the masonry infill. Furthermore, it is obvious that the contribution of the infill in the pinned frame cannot be simply added to the bare frame to achieve the structural behavior of the infilled frames. As for rigid frame specimens (RF-M and RF-MF), the envelope is smoother and there is symmetry in the negative and positive sides of envelopes. It can be also observed that RF-M and RF-MF specimens have high ductility (maximum drift ratio 2.1%-3.7%).

Figure 5: Hysteresis envelope curves of specimens

Regarding the fracture mechanism, RF-M and RF-MF again showed similarities. Dominated fracture mechanism on the change of initial stiffness is the diagonal formation of concentrated strain, and it is in line with mortar head and bed joints. Moreover, the configuration of RF-M and RF-MF ensures the composite system behavior in the quasi-elastic area, but without significant damage to the frame [14]. The highest concentration of strain in PF-M is also observed at the diagonals, but it is also spread over the whole panel. In terms of out-of-plane stability during in-plane loading, it is noticed that perforated units are more prone to out-of-plane stability issues (e.g., hollow clay brick). Despite that, the RBA-EP unit did not present that issue. This can be associated with their low elastic modulus and thick sidewalls [25].

6 COMPARISON OF RESULTS

The experimentally obtained average values of initial stiffness, load at the start of yielding, ultimate load, and maximum drift ratio are summarized in Table 5. It can be noticed that the average values of RF-C specimens, RF-C, provides the highest initial stiffness among all tested specimens, which was expected based on the highest compression strength of the masonry units and the modulus of elasticity of the masonry wallet. The lowest initial stiffness was achieved in the specimen with RBA-EP units, as was planned, but the ultimate load does not deviate from other specimens. Consequently, the authors successfully manipulated the properties of RBA-EP in which ultimate lateral bearing capacity is not significantly reduced. This similar behavior

is presented in the values of RF-A which had the highest ultimate load. Through the ultimate drift ratio, as a measure of ductility, it can be observed that specimens with RBA-EP units are more ductile than the rest of the specimens. The average value of the ultimate drift ratio for RF-M and RF-MF is 2.5%, while for RF-A and RF-C is 1.7% and 1.39% respectively. The lowest drift ratio is observed in RF-C_{av} specimens which had the highest initial stiffness. At the cost of ductility, higher initial stiffness is not a favorable property of infill. RF-M and RF-MF specimens additionally show similarity to the RF-A values in terms of compactness of the infill panel (e.g., no falling out of blocks, redistribution of stress through the infill). Besides numerous similarities, the difference is observed in the onset cracking. in the value of RF-A indicates that it happens earlier, while in RF-M and RF-MF the value of F_y is similar to the bare frame, but with different values of displacement. This confirms that the configuration of the specimens with RBA-EP preserved the steel frame from higher detrimental effects.

Specimen label	S_0 (kN/m)	F_y (kN)	F_u (kN)	$D_{r,max}$ (%)
BF	3.1	69.4	81.5	3.25
RF-C _{av}	31.3	60.0	135	1.39
RF-A _{av}	19.83	51.3	146	1.74
RF-M	14.4	64.9	128.0	2.50
RF-MF	14.3	68.3	132.3	2.65
PF-M	7.6	21.1	52.8	2.70

Table 5: Comparison of initial stiffness and ultimate load

Figure 6: Hysteresis envelope curves of all tested specimens

Figure 6 [14] presents the hysteresis envelope curves of all tested specimens with different type of infills. It confirms a higher ultimate load in the presence of infill but with very different drifts. It can be noticed that RF-C value quickly attains the ultimate load which leads to an earlier onset of the failure mechanism. The hysteresis curve offers one more similarity between RF-M, RF-MF, and RF-A – trilinear behavior which ensures gradual redistribution of stress.

Through the experiments, it is once again confirmed that an infill panel plays an important role in the behavior of an infilled frame concerning the seismic design and that there is no adequate codified design method.

7 CONCLUSIONS OF CONDUCTED EXPERIMENTAL TESTS

A comparison of experimental programmes from previous studies is shown in this paper – rigid steel infilled frames with various types of infill, pinned steel frame, and a bare steel frame. The infill was made of hollow clay blocks, AAC blocks, and newly developed RBA-EP blocks. The experimental results show that simple construction provisions can lead to better behavior. Results can be summarized into the following conclusions:

- Infill provides a higher stiffness to the frame. Among all tested specimens, the highest initial stiffness was obtained in the RF-C configuration, which was expected because of the significantly higher compressive strength of hollow clay blocks. Despite higher initial stiffness, the ductility of these frames was lower. Lower initial stiffness did not negatively influence the ultimate strength of RF-A, RF-M, and RF-MF specimens. Consequently, the behavior of RF-A, RF-M, and RF-MF specimens is favorable.
- In terms of ductility, frames with RBA-EP units achieve higher ductility than RF-A specimens, which is manifested through ultimate drift. The average ultimate drift of RF-M and RF-MF specimens is 2.5%, which is 30% higher than RF-A.
- RBA-EP units are heavier in comparison to the AAC and hollow clay blocks, but they are environmentally favorable because they use waste products (recycled crush brick and polystyrene) in their production.
- Regarding the PF-M configuration, the results deviate in comparison to the rigid configurations, especially in terms of the ultimate load and the change of initial stiffness. Beyond that, the observed concentration of strain is spread over the whole panel and the stress state does not coincide with the infill in a rigid frame. Through this configuration, it is concluded that the bearing capacity of an infilled frame also depends on the rotation capacity of joints.
- Regarding the numerical models, it can be concluded that SSM and MSM can give good predictions in the case of C units, with a lack of accuracy for AAC units. Despite that, they still represent an acceptable method based on simplicity regarding the rest of the methods (fast calculation, the capability of producing hysteresis behavior). AMM and SPM models predict behavior much better with the included various types of failure mechanisms. Although the obtained results are better, the required time and complexity are important setbacks.

In future work, experimental tests of specimens with RBA-EP should be accompanied by numerical models to compare with C and AAC units. Furthermore, probabilistic methods should be conducted to evaluate the reliability of this type of structural concept.

Abstract

The importance of assessing the overall dynamic behavior of buildings considering the contribution of infills is nowadays widely recognized considering that they play an important role in the verifications at damageability limit states and, at ultimate limit states, they can trigger fragile mechanisms of structural members preventing the evolution of dissipative ones. In addition, in case of strategic structures, for which often high performance levels are required such as the full operativity condition (i.e. absence of damage to both structural and non-structural components) after severe earthquake, the contribution of non-structural members should be necessarily included in the seismic assessment.

The paper proposes a simplified procedure for estimating the stiffness of masonry infill walls through expeditious dynamic impact tests. Stiffness can be adopted to model infills into conventional 3-D finite element models of buildings. The procedure is validated by means of an experimental campaign carried out on a laboratory real-scale mock-up and then applied to a real infilled reinforced concrete frame building. Experimental results are compared with those obtained from refined finite element models including infills, proving the methodology reliability.

Keywords: Infill masonry wall stiffness, impact load tests, experimental modal analysis, ambient vibration tests, building finite element modelling.

1 INTRODUCTION

Infill masonry walls are very common components used worldwide in r.c. frame buildings and nowadays it is well known that the stiffness and strength, together with the mass, provided by these non-structural elements may significantly affect the global behavior of buildings, especially in earthquake prone regions [1-4]. The common practice of modelling infills within building f.e. models only in terms of masses is recognized to be not correct, particularly when the f.e. models must be representative of the real building behavior. As an example, the prediction of the real building behavior subjected to earthquake becomes crucial in case of strategic buildings (e.g. hospital, fire and police stations) that must remain in operational condition to guarantee the post-earthquake emergency management [5-6]. Moreover, reliable f.e. models of buildings, i.e. capable to represent the building operational conditions, could be very useful to develop Structural Health Monitoring (SHM) systems [7-9] and to interpret data collected during the monitoring period, in order to assess the building conditions and to detect possible damage to the structural and non-structural members.

From above considerations it is evident the importance of modelling these non-structural components in a reliable manner. Many works in the technical and scientific literature deals with infill modelling strategies, from the simple adoption of a single diagonal strut [10-11] to refined linear and non-linear models [12-13]. Anyway, modelling uncertainties always exist and could affect the modelling correctness. Many researchers investigated the infill behavior with the aim of reducing these uncertainties: most of them studied infills subjected to static lateral loads [14-15], other adopted out of plane loads, and very few used dynamic tests on infills, as, for instance, Ambient Vibration Tests (AVTs) [16-17]. It clearly emerges that a standardization of the infill properties is almost impossible to achieve, considering they are built with different construction materials and typologies all around the world.

This paper proposes a procedure to estimate the stiffness of infill masonry walls that can be used to model these non-structural components within f.e. models of buildings. The proposed approach is based on a combined experimental and numerical procedure: the former foresees the development of dynamic tests on infills through which the modal parameters of the non-structural components are identified; the latter consists in the development of a f.e. model of the structures in which the infills are modelled and investigated with the aim of estimating their stiffness, expressed in terms of elastic modulus. The proposed procedure is preliminary well described, then it is validated through the support of a real-scale laboratory mock-up, used as a case study. Finally, the methodology is applied to a real building to verify its applicability to real structures.

2 THE PROPOSED METHODOLOGY

The proposed methodology is a combined experimental and numerical procedure that foresees dynamic tests on infills and their numerical investigation through the support of f.e. models. In the sequel a summary of the methodology, is reported; for further details the reader can refer to [18].

The dynamic tests performed on infill masonry walls are Impact Load Tests (ILTs) that allow the determination of the Out Of Plane (OOP) dynamic behavior of the non-structural components. ILTs consist in exciting the wall with hammer blows and in recording input and output in the horizontal direction, orthogonal to the wall plane. The output are the time histories of the accelerations produced by the impacts. To perform tests, an instrumented hammer and one or more accelerometers can be used: the accelerometer is fixed on a specified position on the wall, while hammer blows are applied in several points, with the target to identify the panel vibration modes, possibly considering also superior modes. The use of more than one sensor (or moving

the sensor in different positions) may be useful to identify modes that present null value of modal displacement in proximity of the sensor position. The wall can be suitably divided with a regular grid whose spatial resolution depends on the accuracy and on the number of modes that have to be identified. The accelerometer is fixed in one grid point, while hammer blows are provided in all points, applying more than one impact for each of them, allowing to obtain a reliable data set. The impulse-acceleration data recorded are adopted to identify the OOP modal parameter of the panel, performing Single-Input Single-Output modal analyses. In the sequel, the Line-Fit algorithm [19] (a simple degree of freedom identification methodology working in the frequency domain) is adopted to identify the infill modal parameters.

The numerical step of the methodology consists in performing an iterative procedure with the aim of estimating the infill stiffness and, particularly, its elastic modulus. Indeed, despite masonry infills are generally characterized by an orthotropic behavior, the adopted strategy is based on the idea that the dynamics of infills subjected to low input excitations (like hammer blows) can be well captured through homogenous isotropic elastic thin plate elements. So, the stiffness of these non-structural components is mainly governed by the elastic modulus, assuming a constant Poisson's coefficient (e.g. 0.25 as suggested in [20]). At first, the investigated infill is modelled as bidimensional shell elements into the f.e. model of the bare frame structure, adopting its real thickness and with mass estimated based on the adopted construction materials, which are known in most cases. The first tentative elastic modulus E_0 of the infill can be calculated based on closed-form expressions available in the literature for clamped rectangular plates. Considering the formulation proposed in [21], the tentative elastic modulus is calculated as follows:

$$E_0 = \frac{48\rho(1-\nu^2)}{\pi^2 t^2} f_{1,exp}^2 \left[\left(\frac{1+\Delta_m}{l} \right)^2 + \left(\frac{1+\Delta_n}{h} \right)^2 \right]^{-2} \quad (1)$$

where ρ is the mass per unit area, t is the wall thickness, ν is the Poisson's coefficient, l and h are the length and height of the wall, $f_{1,exp}$ is the first OOP vibration mode frequency experimentally identified and Δ_m and Δ_n are the edge effect factors, that can be calculated as:

$$\Delta_m = \left[\left(\frac{l}{h} \right)^2 + 2 \right]^{-1} + 0.017 \quad (2a)$$

$$\Delta_n = \left[\left(\frac{h}{l} \right)^2 + 2 \right]^{-1} + 0.017 \quad (2b)$$

Then, eigenvalue analyses are performed and the numerical modal parameters relevant to the infill OOP dynamic behavior are determined. This procedure is performed several times, varying at each step the infill elastic modulus, until the numerical modal parameters fit well the experimental ones. In order to quantify the goodness of the estimated moduli, two convergence criteria are introduced, based on the comparisons of the experimental and numerical natural frequencies and mode shapes, respectively. When criteria satisfy the conditions reported in Eqs. 3a and b, the estimating procedure stops and the elastic modulus is considered as representative for the wall at hand.

$$\frac{\sum_{i=1}^N \frac{1}{i} \left| \frac{f_{i,exp} - f_{i,num}}{f_{i,exp}} \right|}{\sum_{i=1}^N 1/i} \leq \delta_f \quad (3a)$$

$$1 - \frac{\sum_{i=1}^N \frac{MAC_i}{i}}{\sum_{i=1}^N 1/i} \leq \delta_s \quad (3b)$$

In Eq.s 3a and b $f_{i,exp}$ and $f_{i,num}$ represent the i -th experimental and numerical frequency value of the total N identified OOP vibration modes, while MAC_i is the i -th Modal Assurance Criterion index [22] used to compare two mode shapes. δ_f and δ_s represent the admissible errors in the comparison between frequencies and mode shapes, respectively; in this work, values of $\delta_f = 0.05$ and $\delta_s = 0.25$ are proposed and considered in the successive case studies.

As common in practice, r.c. frame structures are usually modelled with frame elements, so the area of modelled infills is greater than the real one since physical dimensions of columns and beams are neglected. Thus, when infills are modelled with shell elements within frame structure f.e. models, their dimensions (length and height) are greater than the real ones; consequently, to consider this approximation, the mass and stiffness of the modelled panel must be suitably modified. In detail, the mass density (ρ_m) and the elastic modulus (E_m) of the modelled infill are reduced by a factor λ that represents the mean percentage increment of the panel dimensions for both sides:

$$\rho_m = \rho / \lambda^2 \quad (4a)$$

$$E_m = E / \lambda^2 \quad (4b)$$

The estimation of infill elastic modulus, assuming the geometry and mass to be known, permits the reduction of the uncertainties and the updating of parameters in sophisticated f.e. models of infilled frame structures. Obviously, the elastic modulus estimated with this procedure permits to predict the infill behavior under low level of excitation and, consequently, it is useful when building behavior under low level of excitation needs to be interpreted. Indeed, as shown in the sequel, refined f.e. models of structures, obtained modelling the infill with the proposed approach, reveal to be able to well predict the structural responses under ambient vibration excitations.

3 METHODOLOGY VALIDATION THROUGH A LABORATORY CASE STUDY

The proposed methodology is applied on a laboratory mock-up considered as case study, experimentally tested, and then numerically investigated. The aim is to validate the proposed approach through an application to a simple structure under controlled laboratory conditions with limited uncertainties. The mock-up is a steel-concrete composite structure consisting of a pair of one-story two-bay moment-resisting frames with height of 3.00 m and span length of around 4 m (Fig. 1). Columns and beams are realized with steel profiles and the composite slab is obtained with a 12 cm thick concrete layer casted on a collaborating steel sheet. Some concrete blocks are placed over the composite floor to simulate permanent and live loads on the structure. Two infill walls (W1 and W2) are built with hollow clay bricks (dimension of 25 x 25 x 6 cm) and mortar joints, filling only one of the two longitudinal bays. Successively, both sides of both walls are covered with a thin gypsum plaster layer (less than 1 cm). This infill typology can be considered representative for the light infills adopted very often to realize interior partitions in common buildings.

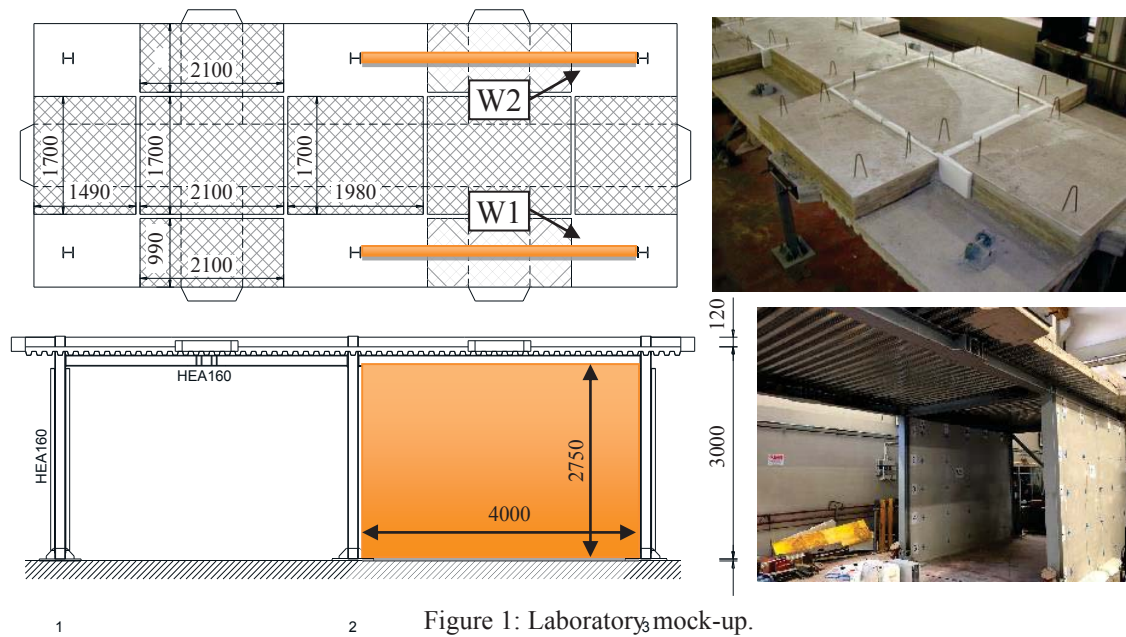

Figure 1: Laboratory mock-up.

Both infills are dynamically tested through ILTs; for each of them, a regular grid of twenty-five points is drawn on a panel face and two accelerometers are fixed on the wall in two grid points with the target to identify as many vibration modes as possible. Then, hammer blows are provided at each grid point, recording both impulses and accelerations, for a time length of 10 s per impact, considered adequate to capture the entire oscillation. It is worth noting that both panels are tested twice, before and after the plastering. Based on acceleration and impact records, the OOP modal parameters of each infill are identified; in detail, many vibration modes are found, as can be observed from Tab. 1 and Fig. 2. Each mode is named with a couple of number that represent the number of semi waves present in the mode shape along the horizontal and vertical directions. Identified natural frequencies, listed in Tab. 1, show that both walls are characterized by almost the same frequency values, even if those relevant to W2 are slightly higher than those of W1. Moreover, after the plaster, all frequency values increase, as expected. Fig. 2 provides an example of the mode shapes of W1 with plaster. Those relevant to W2 are not reported, being very similar to W1.

To validate the proposed procedure, a 3-D full-shell element f.e. model of the bare mock-up is created (Fig. 3a). Moreover, this preliminary model is calibrated with the support of the global 3-D mock-up experimental modal parameters determined through AVTs performed on the bare structure. After that, the two infills are added in the calibrated f.e. model (Fig. 3b), both with shell elements having thickness equal to the real ones. Based on the experimental fundamental frequency of each wall, a first tentative elastic modulus E_0 is calculated. Values of 2445 and 2775 MPa are calculated for W1, before and after plastering, respectively, while 2210 and 2420 MPa are calculated for W2. At this point, iterative procedures are performed by varying the elastic modulus of each wall one by one, until the convergence criteria (calculated considering all the identified OOP modal parameters) are satisfied. The obtained elastic moduli at the end of the procedures are listed in Tab. 2; it is interesting to observe that the Young's moduli of the two walls are quite similar but not equal. After the plastering, the infill elastic moduli increase, mostly for W1.

Table 1: Experimental natural frequencies for both infills without and with plaster.

Mode	Frequency [Hz]			
	W1		W2	
	No plaster	Yes plaster	No plaster	Yes plaster
<i>1,1</i>	16.80	17.30	17.90	18.10
<i>2,1</i>	27.47	31.60	29.53	32.15
<i>1,2</i>	40.10	49.00	48.00	49.97
<i>3,1</i>	46.55	49.40	45.35	50.50
<i>2,2</i>	57.54	63.88	59.20	64.50
<i>4,1</i>	63.07	66.50	66.85	68.10
<i>5,1</i>	76.85	120.71	78.93	119.90
<i>3,2</i>	79.79	85.98	76.10	82.67
<i>2,3</i>	/	105.30	/	107.13
<i>4,2</i>	104.98	113.75	104.40	127.30
<i>3,3</i>	117.77	131.19	119.40	133.20
<i>5,2</i>	132.28	143.93	139.10	155.90
<i>5,3</i>	177.60	198.85	175.24	212.50

Figure 2: Experimental mode shapes for W1 with plaster.

Figure 3: 3-D global f.e. model of the mock-up: a) bare structure, b) infilled structure.

To assess the reliability of the estimated elastic moduli, the numerical modal parameters of the whole infilled mock-up (using the infill elastic moduli reported in Tab. 2) are compared with those obtained from AVTs performed on the whole infilled structure before and after the plastering. Comparisons, in terms of natural frequencies and mode shapes (the latter obtained through the MAC indexes), are reported in Tab. 3. As can be observed, the numerical modal parameters (NUM) are in very good agreement with the experimental ones (EXP), proving the reliability of the elastic moduli estimation. It is worth noting that, in this case, the mass densities and the elastic moduli used in the global f.e. model are not reduced since the modelled infill dimensions are the same of the real ones.

Table 2: Estimated elastic moduli E for both infills without and with plaster.

Wall	Elastic modulus [MPa]	
	No plaster	Yes plaster
W1	4700	4900
W2	5340	5360

4 APPLICATION TO A REAL BUILDING CASE STUDY

The proposed methodology is applied to a real building in order to prove its usefulness and applicability to real structures. The considered case study is a r.c. frame building (Fig. 4a) with plan dimensions of around 16.50 x 11.70 m composed by two stories, for a total height of about 8.00 m. The underground level is mainly realized by r.c. retaining walls, while the upper one is realized with spatial r.c. frames. The infill masonry walls are built both along the building perimeter and inside the building, and they can be divided into three main typologies, as reported in Fig. 4b: E1 is adopted for all external infills, I1 is adopted to separate the housing units within the building at the underground and ground levels, while I2 is adopted to realize all the interior partitions. The building was investigated and tested during its construction process; in detail, AVTs were performed on the bare and on the infilled structure, whereas ILTs on infills were performed only in the phase without plaster.

As for tests on infills, three infills representative for all the infills typologies are tested (W-E1, W-I1 and W-I2). All walls are located at the ground floor and have no openings. The geometry of the tested infills is illustrated in Fig. 5. ILTs on the three infills are performed with the same instrumentation and test protocols adopted for tests on laboratory mock-up infills, and the infill OOP modal parameters are identified again using the Line-Fit algorithm. The experimental OOP modal parameters of the walls are reported in Fig. 6, both in terms of frequencies and mode shapes. As can be observed, four vibration modes are identified for each infill.

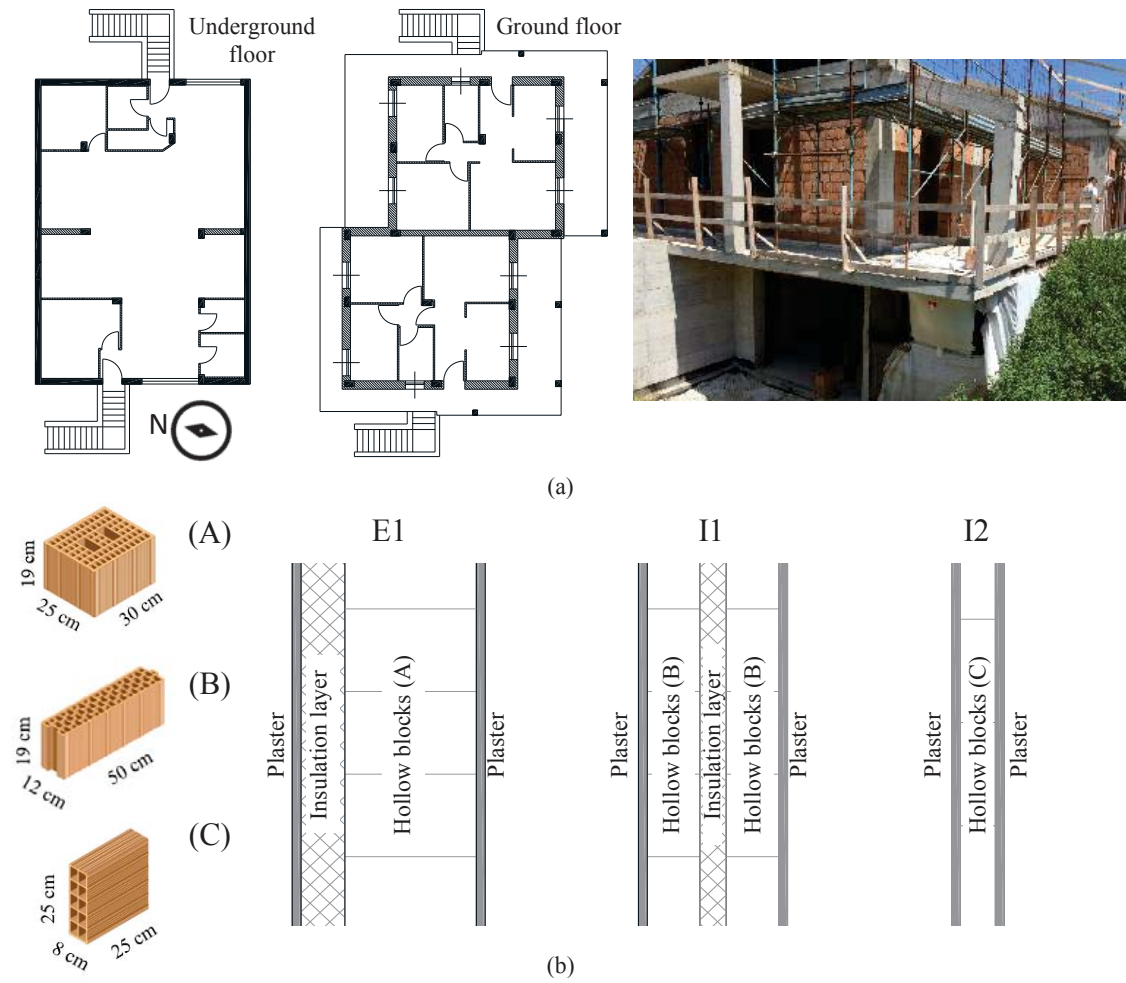

Figure 4: Real case study: a) building floor plans and picture during construction, b) infill masonry wall typologies.

Figure 5: Geometry of tested infill masonry walls of the building.

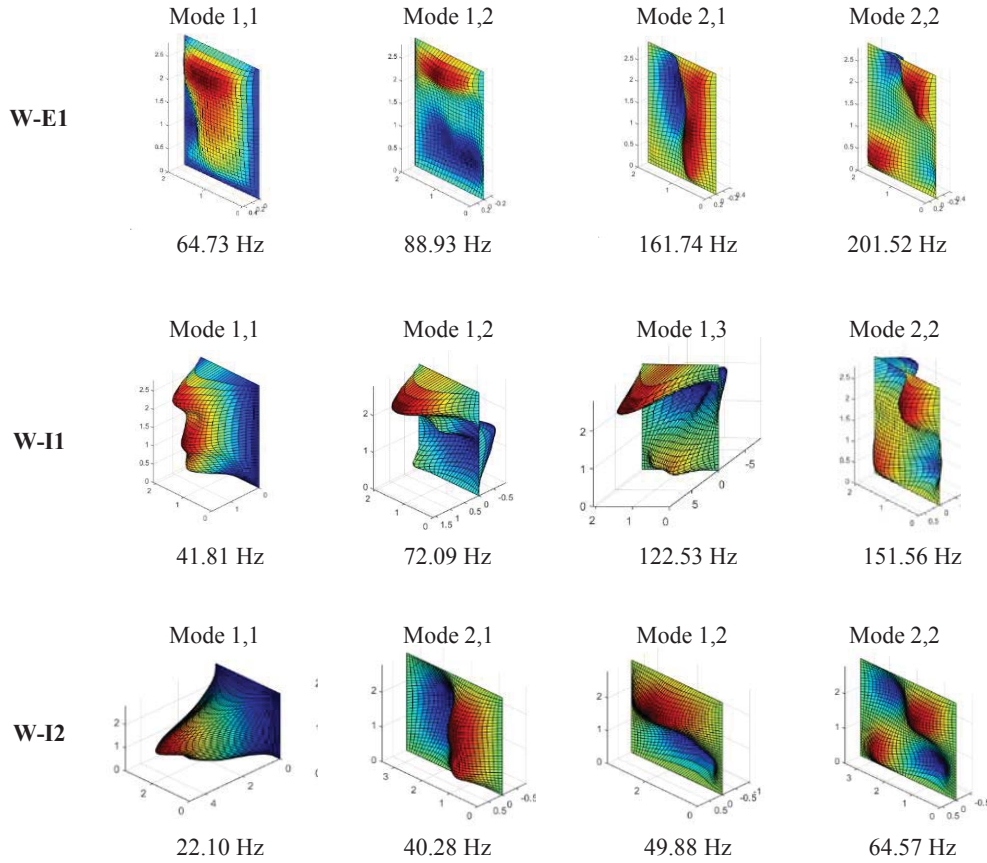

Figure 6: Experimental OOP modal parameters of tested infills.

The numerical investigation of infills is performed to estimate their elastic moduli. The f.e. model of the bare building is developed, modelling the r.c. frame with frame elements, while floors, slabs and retaining walls with shell elements. This model is preliminary calibrated based on experimental modal parameters of the whole building obtained from AVTs on the bare structure, with the aim to accurately predict the building dynamic behavior. Then, the investigated infills and the adjacent ones (to consider accurately the infill boundary conditions) are modelled with shell elements. Thus, three separated iterative procedures are performed, one for each investigated wall, and the elastic moduli are estimated once the convergence criteria (the same adopted before for the laboratory mock-up) are satisfied. In this case, four OOP modal parameters for each infill are considered in the iterative procedures to calculate the convergence criteria. Differently from the laboratory mock-up, the r.c. frame elements are modelled with beam elements, so the modelled infills have greater dimensions with respect to the real ones. Hence, the mass and elastic modulus of each infill is reduced, considering, for the sake of simplicity and with good approximation the mean percentage increment λ of the infill dimensions of each panel. The estimated elastic moduli are 3000 MPa for wall W-E1, 2550 MPa for W-I1 and 3150 MPa for wall W-I2. As before, to assess the reliability of these elastic moduli estimation, all infills are modelled within the global f.e. model of the building, considering their typology, openings and adopting the estimated elastic modulus for each infill typology. The numerical modal parameters of this infilled f.e. model are compared with the experimental ones obtained from AVTs measurements on the infilled structure, and the results are reported in Tab. 4. As can be noted, both frequencies and mode shapes are in very good agreement, proving the reliability of the proposed approach also when applied to real buildings.

Table 4: Comparison between experimental and numerical modal parameters of the infilled building.

Building mode	Frequency [Hz]		MAC
	EXP	NUM	
1 st	10.71	10.74	0.78
2 nd	13.04	13.09	0.83
3 rd	15.75	14.94	0.96

5 CONCLUSIONS

A procedure to estimate the stiffness of infill masonry walls through a combined experimental and numerical procedure has been proposed in this paper. The procedure is firstly validated through investigations on a real-scale laboratory mock-up and then applied to a real infilled r.c. frame building. In both cases, the methodology reveals capable to furnish a reliable and realistic infill stiffness estimation, leading to obtain trustworthy f.e. models of the infilled structures. The proposed approach furnishes a practical and expeditious tool that can be suitably used to reduce uncertainties in the f.e. modelling of framed buildings when infills must be included. This should be fundamental when results of ambient vibration measurements need to be interpreted with refined f.e. models of structures or when results of structural health monitoring systems must be analyzed. The procedure has the great advantage of requiring fast and non-invasive dynamic tests on infills, thus it can be executed in new or in existing buildings.

Abstract

On November 26, 2019, a magnitude $M_w = 6.4$ earthquake struck Northwestern Albania. It was the strongest to hit Albania in more than 40 years. Cities such as Thumanë, Tirana, and Durrës suffered damage, but Durrës was the hardest hit with several buildings collapsed [1,2].

A reconnaissance team under the auspices of American Concrete Institute (ACI) visited Durrës, Albania to assess the extent of damage to modern reinforced concrete (RC) buildings (i.e. built after 1990). The team^{*1} surveyed buildings during the week of January 12, 2020, with a focus on RC buildings that were infilled with clay block masonry. Over the course of seven days the team documented 55 buildings that had RC frames as their main lateral resisting system. All of the surveyed buildings had unreinforced masonry infills (hollow clay blocks). Most of the buildings had ribbed or waffle slabs. Typical damage observed in these buildings was in-

^{*1} Researchers from University of Nebraska-Lincoln, Wiss, Janney, and Elstner Associates, Inc., University of Minnesota-Twin Cities, Epoka University (Tirana, Albania), Josip Juraj Strossmayer University of Osijek (Osijek, Croatia), and Bauhaus-Universität Weimar (Weimar, Germany)

plane or out-of-plane failure (dominant) of masonry infill walls throughout the building height. More damage was observed when these masonry walls were not confined well within the RC frame i.e. acting as partitions. In many cases, these masonry walls were not connected to the RC frame at all, having only bed-joints filled with mortar.

This report focuses on the performance of masonry components (infill walls, partitions, etc.) in the buildings in Durrës that were affected by the earthquake. Examples of the damage to the masonry infill, structural details that affected the damage, and its impact on building performance are described.

The paper provides an overview of the earthquake-induced damages in several building types and their variation within different structural systems focusing on RC frames with unreinforced masonry infills in Durrës. Reasons for significant differences in observed damage will be discussed in close relation to the building code development and the preferred design concepts. Besides response phenomena and typical damage patterns which have been observed after other earthquakes worldwide, an attempt is made to investigate parameters with high damage potential according to [3].

1 INTRODUCTION

The field reconnaissance missions following natural disasters provide valuable information on the performance of buildings during such events. As part of the American Concrete Institute disaster reconnaissance committee (ACI 133) mission, a team of researchers from the US, Croatia, Albania and Germany surveyed 55 buildings affected by the M_w 6.4 earthquake in Durrës, Albania on November 26, 2019.

The earthquake struck Northwestern parts of Albania, with an epicentral distance of 17 km from Durrës and about 35 km away from the northwest of the capital city of Tirana. Fifty-one people died because of the earthquake and 100,000 were affected. The earthquake caused serious damage to more than 1,400 buildings in Tirana, and about 900 buildings in the city of Durrës and the town of Thumanë with reported cases of collapsed buildings. Besides partial to complete failure due to shaking, a few buildings in the Durrës area were tilted due to liquefaction [4,5].

Events in Albania with a magnitude ($5.0 < M < 7.0$) are considered to be rare [6]. The last large event in the region was the earthquake in Montenegro on April 15, 1979 [7]. It was suggested that the region is going to be at a low seismicity rate interval from the event in Montenegro until the end of the second decade of the 21st century based on the seismic energy release for Albanian earthquakes [8].

The most affected buildings by the earthquake damage were reinforced concrete (RC) frame buildings with infill walls in Durrës. The poor performance of unreinforced masonry infill walls dominated the damage pattern, mostly due to simultaneous in- and out-of-plane dynamic excitation [9]. Thus, the global damage grade is mostly governed by the behavior of the partition/infill walls. Further, up to two or three grades, larger damages to the infill walls could be observed which makes the assignment of the damage grade according to EMS-98 [11] difficult.

Infill/partition walls are usually treated as non-structural/secondary elements (see Eurocode 8, and EMS-98), whereas past earthquakes have shown that they mainly contribute to the horizontal stiffness and seismic resistance. The herein presented field observation highlight again the need for a proper design to avoid brittle behavior and out-of-plane failure (Eurocode 8).

In this study, the damaged buildings surveyed in Durrës are assessed and key observations are highlighted. Besides, quantitative measurements are used to assign the seismic vulnerability of buildings using the Hassan and Sozen index [10].

2 EARTHQUAKE CHARACTERISTICS AND CONSTRUCTION PRACTICE IN ALBANIA

2.1 Parameters of the earthquake

The earthquake of Nov. 26, was recorded at seven accelerometric stations of the Albanian network, in the range of epicentral distances from 15 km to 130 km as shown in Figure 1.

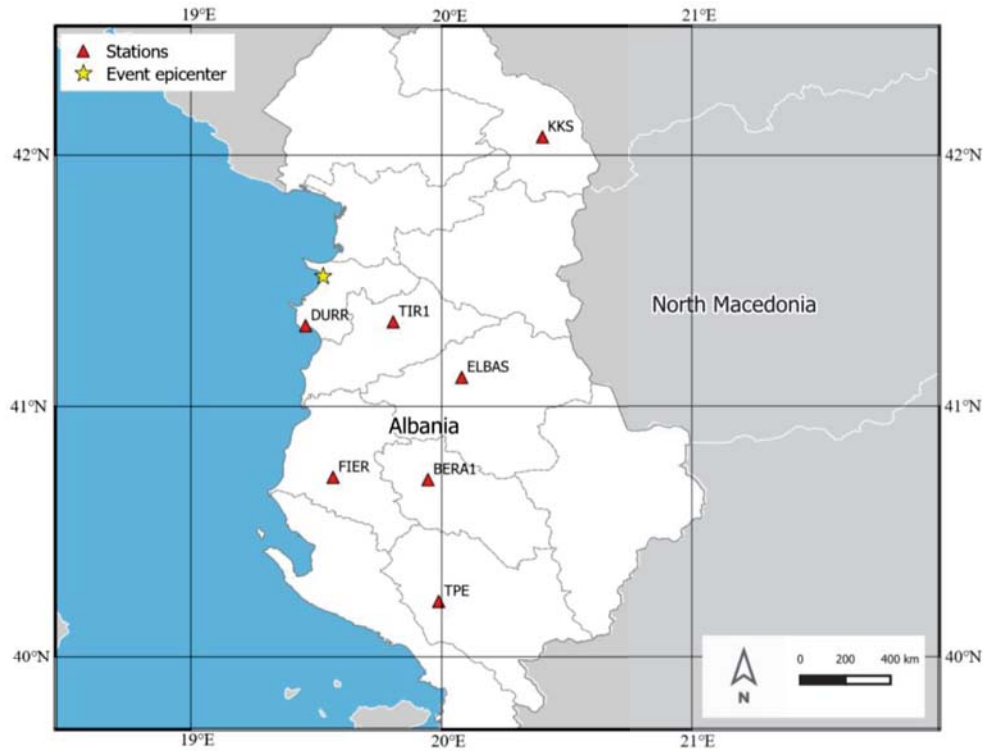

Figure 1: Strong motion stations in Albania that recorded the Nov. 26, 2019 earthquake and its epicenter [2].

The mainshock was followed by multiple aftershocks, two of which have a magnitude $M_w > 5.0$ as shown in Table 1. Figure 2 shows the shakemap of the mainshock calculated using surveyed macroseismic dataset collected through felt reports by the EMSC [11] and combined with expected intensities derived from strong-motion records using the correlation function of Faenza and Michelini, 2010 [12]. Up to intensity $I_{EMS} = VIII$ on the EMS-98 intensity scale [13] was estimated.

DURR station in Durrës, which lays on soft soil recorded only 15 s of the mainshock due to electricity pause [2]. This record has a horizontal peak ground acceleration (PGA) of 0.196g and spectral acceleration of more than 0.5g for 5% damping in a period range of 0.25s to 1s, as shown in Figure 4. This period range could be related to the fundamental period of buildings with five or more stories according to Eurocode 8 (EC8), which lays in the height range of observed damaged and collapsed buildings in the area.

Date	Time (UTC)	Lat. (°)	Long. (°)	M_w	Depth (km)	Reference name
26/11/2019	02:54:12	41.514	19.526	6.4	22	Mainshock
26/11/2019	06:08:21	41.571	19.424	5.5	10	Aftershock (1)
27/11/2019	14:45:23	41.550	19.479	5.3	10	Aftershock (2)

Table 1: Focal parameters of the Nov. 26, 2019 mainshock and following moderate aftershocks (USGS).

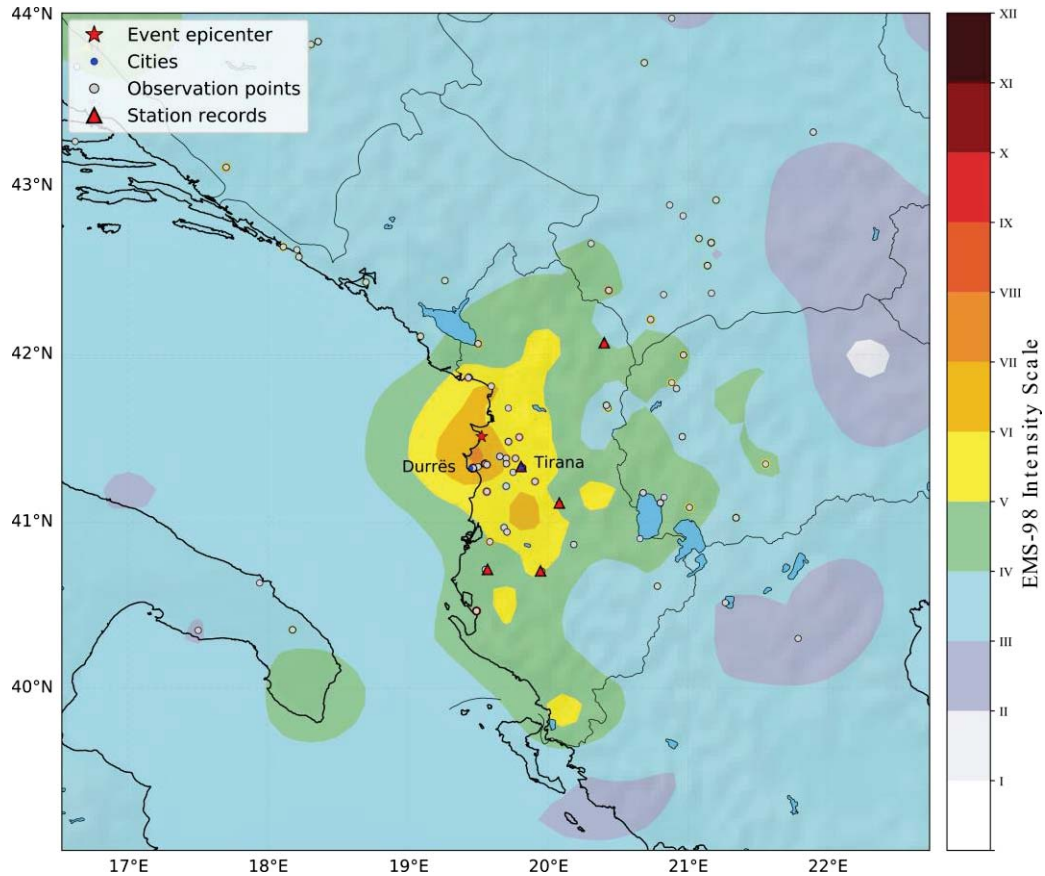

Figure 2: Macroseismic shakemap with EMS-98 intensity for the mainshock.

To evaluate the spectral acceleration obtained from the mainshock, response spectra from EC8 and the Albanian code (KTP-89) are calculated as shown in Figure 3. EC8 spectra are calculated with a PGA of 0.24g obtained from a probabilistic seismic hazard map with a 475-year return period proposed by [6] for Albania. The KTP-89 spectra are calculated based on the seismic code map with intensity $I_{MSK-64} = VIII$ for Durrës. By comparing the code spectra with the recorded mainshock spectra, the mainshock spectrum from the DURR station exceeded the KTP-89 spectra for periods higher than 0.2s for all soil types. However, the EC8 spectrum with soil type D (soft-soil) covered the recorded spectra. The aftershock records showed similar period ranges to the mainshock (0.2 to 1s) as shown in Figure 4.

It can be concluded that buildings designed according to the KTP-89 spectra were affected by higher ground motion, whereas the design forces according to EC8 and a PGA equal or greater than 0.2g covered the ground motion of the 2019 Albania EQ.

2.2 Design and construction standards

The current officially enforced earthquake design code in Albania is the 1989 KTP-89 code [14]. This code uses the seismic zoning map with expected intensities based on MSK-64 scale for the next 100 years and zones from $I_{MSK-64} = VI$ to IX developed by [15]. Multiple studies highlighted the need for increasing the seismic coefficients used in the code as they show a low return period when compared with the probabilistic assessment of seismic hazard studies [6,16]. In particular, the city of Tirana, assigned to $I_{MSK-64} = VII$ with of 0.08g seismic coefficient according to KTP-89, has a return period of approximately 50 years for a rock soil (category I) [16].

There were recent efforts to translate and implement the Eurocodes in Albania. Drafts of national annexes were prepared with updated seismic hazard maps [17]. However, the Albanian legislation still requires following the KTP-89 code and allow using Eurocodes voluntarily [18].

In addition, local engineers reported that building regulations were not properly enforced during the 1990s and early 2000s. That resulted in problems as buildings without a permit and improper addition of stories to existing buildings, which were reported in some of the collapsed buildings in Durrës [19].

Figure 3: Response spectra of mainshock (5% damping) with KTP-89 and EC8 spectra.

Figure 4: Response spectra of aftershocks (5% damping).

3 PERFORMANCE OF THE MAJOR BUILDING TYPES

3.1 Surveyed buildings

During the reconnaissance mission in Durrës city, totally 55 buildings were surveyed with a focus on modern multi-story RC buildings (i.e. built after 1990). Figure 5 shows the location of the surveyed buildings (all in the area of $I_{EMS} = VII$), in addition to 4 out of 7 reported collapsed buildings in Durrës [19]. Data was collected from the surveyed buildings in the form of building type, dimensions, structural characteristics, and damage observations if exist. Table 2 shows the damage levels description used in the survey for RC elements and masonry infill walls. The damage level is linked to the EMS-98 damage classification [13].

The team focused on mid to high-rise buildings (see Figure 6 for sampled surveyed buildings). Figure 7 (a) and (b) shows the height distribution and damage levels for the infills and structural elements respectively in the surveyed buildings.

Material	Damage level	EMS-98 damage classification	Definition
RC (Structural)	Light	Grade 2	Hairline inclined cracks and/or flexural cracks
	Moderate	Grade 3	Spalling of concrete cover
	Severe	Grade 4	Local structural failures
Masonry (Non-structural)	Light	Grade 1	Hairline cracks. Flaking of plaster
	Moderate	Grade 2	Cracks in walls and joints between panels. Flaking of large pieces of plaster
	Severe	Grade 3	Wide and through cracks in walls and joints between panels

Table 2: Definition of damage levels used in the survey forms and in compliance with [20]

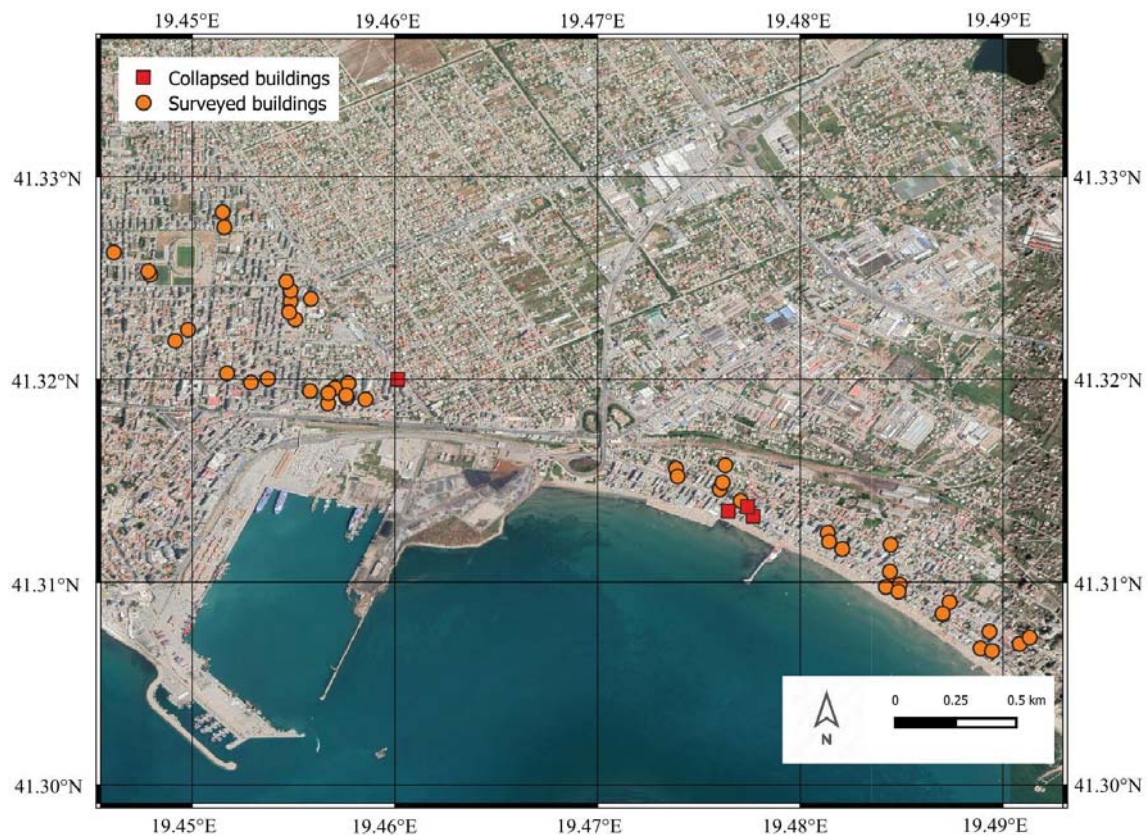

Figure 5: Locations of surveyed and collapsed buildings (Basemap: [21]).

Figure 6: Samples of the surveyed building with 8, 12, and 13 stories.

Figure 7: Distribution of the number of stories for surveyed buildings with (a) masonry infill damage levels, (b) RC element damage levels.

Figure 8: Undamaged multi-story masonry structures in Durrës.

It is worth mentioning that no significant structural damage to low-rise multi-story unreinforced masonry structures was observed in the surveyed city areas during the reconnaissance mission (see Figure 8).

3.2 Observed damage to RC buildings

The inspected buildings were scattered among the two most affected areas of the earthquake; the inner part of the city and the coastal (beach) area (see Figure 5). Those buildings were mostly built after the year 2000. Based on the field observations, the RC frame with infill walls was the dominant structural system in the inspected area. The presence of a dual system (RC frame + shear wall) was less common. Shear walls, if present, were mainly used for elevator core shafts.

The structural plans of the buildings were diverse. Buildings with soft-story and vertical irregularity were observed. Nevertheless, in most buildings, light or no structural damage was observed in the load-bearing RC elements, as it seems that the structural systems dissipated the seismic shock properly.

3.2.1 Damages on infill walls

Even though the structural safety in many of the observed buildings was met, the serviceability conditions of the observed buildings were poor. Considerable damage was observed in the infill walls, (see Figure 9 for in-plane failure samples). Usually, the damage was proportional to the number of stories. As expected, the ground floors were the most heavily damaged. The damage level was reduced with increased height. One of the most dominant characteristics of the damaged infill walls was observed to be poor workmanship and the lack of a proper connection between the masonry units. In all the cases, standard clay blocks with high volume horizontal voids were used (Group 4 in compliance with EC6).

It was observed that there was a lack of head joints in some of the inspected buildings. The brick-laying practice mainly consisted of the application of a bed joint and leaving the bricks unconnected with mortar vertically as shown in Figure 10 (a). Lack of vertical confinement at walls intersections was also observed, as in Figure 10 (b and c).

Another problem was the arrangement of the hollow bricks. In some of the observed buildings, the hollow bricks (even though horizontally perforated) were purely placed with voids horizontally (perpendicular to the direction of gravity). There is a lack of interlocking force of the bricks that is achieved through alternating their positions.

Extensively damaged infill walls are also considered to be a consequence of a ductile design of the buildings. The absence of the shear walls and RC cores has made the structure more flexible and was more susceptible to drifts. The path of load transfer of the lateral seismic loads through columns goes through the infills in the form of compression struts (only not in case of dominant bed joint sliding). The shear-force induced inside the infills (which seem to not have been designed to carry any shear load) has caused the damage of the infills. The extent of cracking is closely related to the workmanship quality, area of the infill, and opening presence. There were cases where the outer walls showed slight cracks only, but the interior walls were heavily damaged.

Another important observation related to the infill walls, was the improper connection of the wall to the frame, as well as in many cases, the lack of that connection. This phenomenon caused large pieces of the walls (sometimes the whole infill panels) to be dislocated and fall out of the plane (Figure 11). Lack of confining beams that are cast inside the infill walls was observed.

Figure 9: Infill in-plane failure.

Figure 10: Poor workmanship for infill walls (a) Lack of head-joints (b) and (c) Lack of vertical confinement at walls intersection.

Figure 11: Infill out-of-plane failure.

The summarized damage observations show the challenges in making vulnerability and damage grade assignments according to EMS-98 [13], especially with respect to the relation between structural and non-structural damage. From Figure 12, it can be observed that moderate and severe structural (RC frame) damage co-existed with severely damaged and collapsed infill walls. However, non-structurally damaged buildings experienced different levels of infill damage. Thus, the behavior of non-structural components can heavily influence the global damage grade. Therefore, the vulnerability affecting factors like the number of stories and the properties of non-structural elements should be considered as important attributes of a building typology and the corresponding vulnerability table/matrix [22]. The damage observations lead to the conclusion and confirm that the quality of construction and material of the infill walls may have a strong influence on the interaction with the primary (structural) load-bearing system [23,24].

At the same time, many out-of-plane damages could also be observed on the upper and lower floors (see also [25,26]), caused by the influence of bi-directional loading and IP damage, where the two components of a floor movement are of similar importance. The magnitude of the loads in-plane decreases at the upper floors, while the forces acting perpendicular to the plane increase due to the increase in acceleration over the height of the building.

Figure 12: Observed infill damage level linked to observed structural damage level.

3.2.2 Damaged RC frame elements

Besides the surveyed buildings, it was reported that 7 buildings collapsed in Durrës due to the earthquake [19]. Figure 13 and Figure 14 show collapsed 4-story and soft-story buildings respectively. The collapse of these buildings could be attributed to the high shaking effects, poor construction practice, and the insufficient respect of the building code requirements.

Figure 13: 4-story collapsed building in Durrës (Left photo: [27], Right photo: courtesy of C. McKenney [28]).

Figure 14: Collapsed Lubjana Hotel in Durrës (Left photo: [29], Right photo: courtesy of C. McKenney [28]).

Figure 15: Soil settlement in buildings.

3.2.3 Damage due to the ground conditions

The ground conditions in the near coastal part were susceptible to liquefaction, which was observed during the survey in few buildings as shown in Figure 15. It was reported that extensive soil liquefaction was observed along the coastal side of Durrës city [30]. This settlement caused tilting of buildings, which could be visually observed.

4 ASSESSMENT OF SURVEYED BUILDINGS

To evaluate the surveyed buildings quantitatively, the two indices method proposed by Hassan and Sozen [10] is used. This method is based on wall index (WI) and column index (CI), calculated as follows:

$$WI = (\Sigma A_w + 0.1 \Sigma A_m) / \Sigma A_f \quad (1)$$

$$CI = (0.5 \Sigma A_c) / \Sigma A_f \quad (2)$$

where ΣA_w , ΣA_m , ΣA_c and ΣA_f are the sum of: RC walls area at ground floor in the direction of smallest RC wall area, masonry walls at ground floor in the direction of smallest RC wall area, columns area at ground floor, and total floor area above the ground floor respectively. Figure 16 shows the column and wall indices for the surveyed buildings, where floor plans were sketched or obtained.

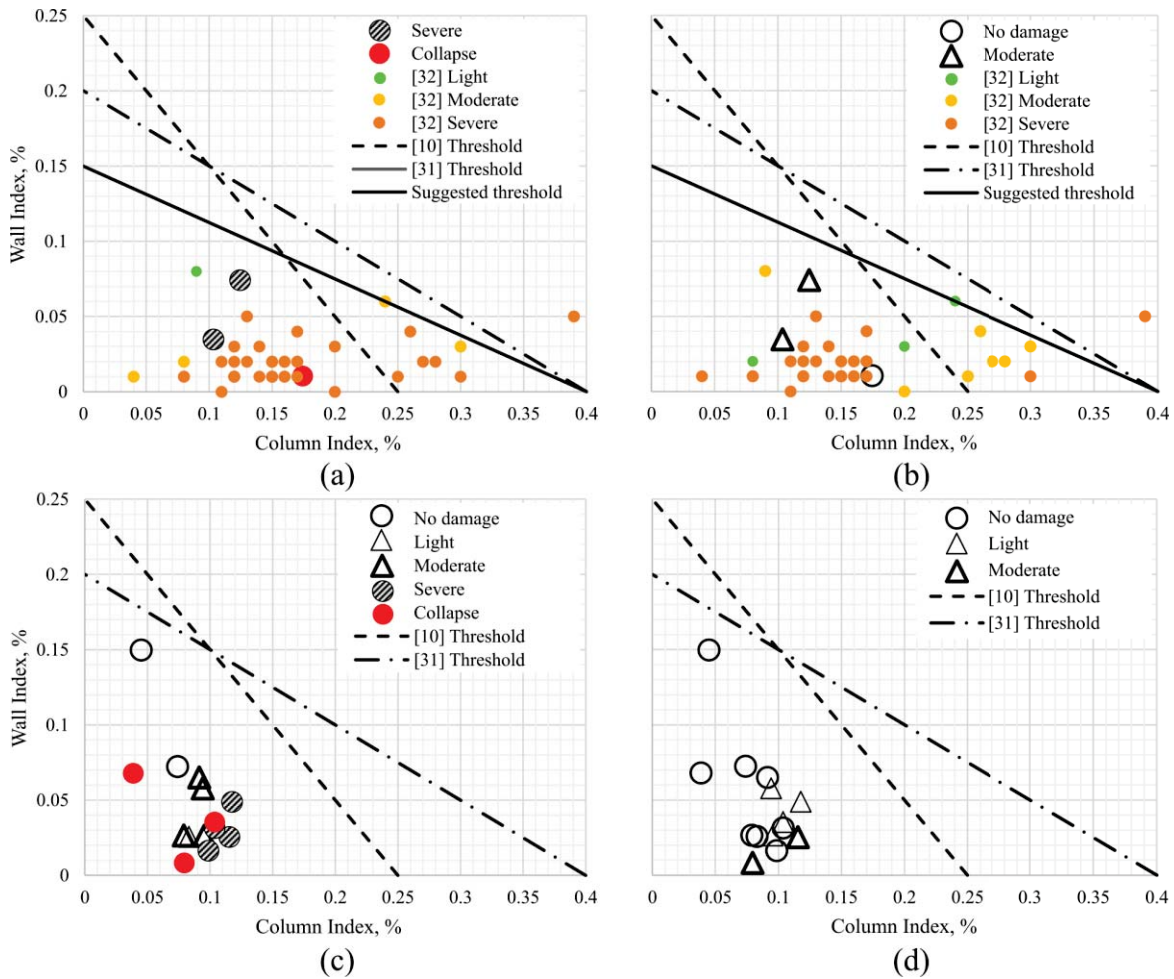

Figure 16: Calculated wall and column indices for surveyed buildings (a) Infill damage (4-6 stories) (b) Structural damage (4-6 stories) (c) Infill damage (≥ 7 stories) (d) Structural damage (≥ 7 stories).

Since more damage was observed in the infill walls, the indices are separately related to infill damage and structural damage states. In addition, the buildings were separated into two groups (mid-rise: 4-6 stories and high-rise: ≥ 7 stories). Especially, to consider that the originally proposed relation is not valid for buildings with more than 7 stories.

Figure 16 (b) and (d) show that all buildings lay beyond the thresholds suggested by [10,31]. These thresholds are suggested for low-rise [10] and low to mid-rise [31] structures to identify the most vulnerable to damage and may not be suitable for medium and high-rise buildings. A reduction in the limits by reducing the wall index limit is suggested to better fit the data with $(WI + 0.375CI = 0.15\%)$ for midrise structures similar to [31]. In addition it is suggested to further adapt the wall and column indices for high-rise structures, because of the rather large margin/distance between the derived data points and the thresholds by [10,31]. This decrease in the wall index and might be also in the column index could be related to the “nonlinear” ratio of the wall area at the ground floor and the total floor area above the ground floor. Whereas, more data need to be elaborated towards structural and non-structural damage to define an appropriate threshold for high-rise buildings.

Figure 16 (a) and (c) show the infill wall damage grades related to the wall and column indices of each building, separately. The data sets are extended by the field study of the 2016 earthquake in Ecuador [32] for further justification of the very limited Albania data set for mid-rise buildings. It highlights the need for column indices larger than 0.4 to also limit infill wall damages. Whereas, it is clear that further data need to be elaborated for justification.

5 CONCLUSION

A reconnaissance mission was conducted after the $M_w = 6.4$ earthquake that struck Albania on November 26, 2019. The damage to RC frame buildings with masonry infill walls built in compliance with contemporary building codes, i.e. after 1990's, was assessed by surveying 55 buildings. The observed performance of RC buildings in Durrës to the earthquake – less damage to RC elements (except in case of highly irregular construction); heavy in- and out-of-plane damage to the unreinforced masonry infill/partition walls – is the result of one or more of these aspects:

- 1) Improper construction practice, as the building code is not appropriately updated and enforced, especially towards the infill/partition walls.
- 2) Lack of proper shear walls in mid to high rise building to increase the stiffness and reduce drifts.
- 3) Poor workmanship of masonry infills, as they were built without head joints and confining elements, and not restrained against out-of-plane failure.

The seismic wall and column indices were calculated using the collected data and related to RC frame (or wall) and masonry infill wall damage. Thresholds for mid to high-rise RC buildings are suggested.

The survey and observation confirm that non-structurally damaged buildings (un- or slight-damaged RC elements) may experience different levels – up to grade 4 and 5 – of infill damage. Thus, the behavior of non-structural components can heavily influence the global damage grade and therefore need to be properly designed or build.

The gained experience and damage observations confirm the principle results of recent analytical and experimental studies [3,33,34]. As a next step, the previously experimentally validated models will be applied to the detailed surveyed Albanian buildings for further real-world validation by the comparison of a damage prognosis with the observation. A number of useful data sets could be collected as part of the reconnaissance mission for further analytical studies.

6 ACKNOWLEDGMENT

The writers express their appreciation to the American Concrete Institute (ACI) for supporting the reconnaissance mission. Efforts from Prof. Santiago Pujol to coordinate the mission and from Prof. Chungwook Sim to both coordinate and carry the field survey are gratefully acknowledged. The efforts from Dr. Enea Mustafaraj, Andi Gjoci, and Jurgen Mema from Epoka University in Albania in the field survey are greatly appreciated.

The kind help of Peshawa Luqman Hasan from Bauhaus-University Weimar to prepare the shakemap is highly appreciated.

Abstract

The comparison of the seismic performance of different typologies of masonry infills is usually related to the technical response according to post-seismic inspection, experimental outcomes, and numerical studies. Although the economic losses due to the achievement of some limit states could represent one of the main aspects that should be taken into account in the selection of the masonry typology to be adopted for the masonry infills, few studies have been addressed to this topic ([1]). Moreover, the economic losses related to the seismic response of masonry infills are usually dealt without a specific procedure that differentiates the masonry of the infill, the infill typology (e.g., traditional vs innovative infill systems), and other aspects which may modify the seismic performance of non-structural element. In this paper, a comparison in terms of the economic losses between different “traditional” masonry infills and an innovative solution with sliding joints [2] is presented through the adoption of a new approach ([8]) that computes the expected annual losses based on the PERR's PBEE procedure.

Keywords: Expected annual losses, infill seismic performances, innovative infill, sliding joints, performance based earthquake engineering.

1 INTRODUCTION

The seismic performance of buildings is usually evaluated through their structural response that is typically referred to their capacity to withstand earthquake action without threaten human-life and/or exceed specific levels of damage. Although it is widely recognized that the safety of the inhabitants must always be guaranteed, the need to limit the damage, also in case of minor earthquakes, and to reduce the costs of repairing or of the downtime of the activities conducted within the structure, is becoming more and more important.

Focusing the attention on reinforced concrete (RC) frame buildings with masonry infill walls, field observations after major earthquake events have highlighted the vulnerability of these structure, if specific seismic-details are not adopted (*i.e.*, [3],[4],[5]). Moreover, also in case of recently designed buildings or with low seismic actions, where the collapse of the structural members is avoided, the damage could occur in the infill walls due to their high vulnerability and the associated monetary losses could be quite relevant.

In order to improve the seismic response of the infills and to reduce the detrimental effects of the interaction between RC frame and masonry panels, typical for traditional masonry walls built in-place with no specific seismic details, the researchers of the University of Pavia have conceived an innovative infill typology, characterized by the presence of deformable mortar at the frame/infill interface and sliding joints within the masonry panel. Further information regarding the system is provided by Morandi *et al.* ([2]).

This technology proved to be promising, ensuring good seismic performance of the infill-frame system based on an extended experimental campaign, as fully described by Morandi *et al.* ([2]) about the in-plane seismic behaviour, by Milanesi *et al.* ([6]) regarding the out-of-plane seismic response and by Manzini *et al.* ([7]) for the overall building performance.

The recent studies conducted ([1],[8]), mainly developed in numerical researches on this topic (*i.e.* [9],[10]), have also demonstrated that the adoption of such an innovative infill typology could lead to a significant reduction of the costs of reparation of the building and of the elements after significant seismic events, despite an initial higher cost of construction, compared to the same RC structure with traditional infill walls.

This paper aims at presenting the results by applying a novel methodology proposed by Rossi *et al.* ([8]) and evaluate the influence of the choice of a specific infill typology in the computation of the expected annual losses for a typical RC frame building in Italy, built in compliance with current seismic codes. Moreover, the structural and monetary advantages given by the adoption of the innovative infill solution are discussed.

2 NEW METHODOLOGY FOR THE EVALUATION OF THE LOSSES IN INFILLED RC FRAMES

A novel procedure to evaluate the expected annual losses (EAL), tailored specifically for RC infilled frame, was conceived by Rossi *et al.* ([8]) within the well-known PEER's PBEE framework ([11],[12],[13],[14],[15]).

The EAL is the expected loss that should be paid every year in order to repair or even replace a specific reference structure. The novel procedure considered to evaluate the EAL of infilled frame structures has been partially adopted in early studies carried by Rossi *et al.* ([16] and [17]). Recently, Di Trapani *et al.* ([1]) presented a similar study, also based on PBEE framework, including an innovative infill solution with sliding joints studied by Preti *et al.* ([18]).

In the present work, the definition of damage in all the considered infills was inferred directly by laboratory tests and by numerical simulations on the same infill panels adopted in the analyses and the computation of losses is referred to updated official costs of repair and

replacement actually adopted in Italy. Finally, the evaluation of the seismic performance in terms of EAL of a building with specific indications on infill typologies allows a consistent comparison on the effective contribution of different infill solutions and an estimation of the economic benefits that the use of innovative infill systems could provide as respect to traditional infills.

According to Baker and Cornell ([13]), EAL is computed as a discrete summation:

$$EAL = \sum E[DV|IM=im] \cdot \Delta \lambda_{IM}(im) \quad (1)$$

where, DV is decision variable, IM is the intensity measure, im is a specific value of the IM , $E[DV|im]$ is the expected total repair/replacement cost conditioned on $IM = im$, $\lambda_{IM}(im)$ is the conventional hazard curve, being equal to the mean annual frequency (MAF) of IM exceeding a certain value of IM .

The decision variable, DV , is the metric necessary to evaluate the performance of the building and used by the stakeholders to justify their decisions.

Therefore, according to Equation (1) the EAL is the area under the curve, depicted in Figure 1.

Figure 1. Graphical representation of a generic EAL.

The methodology, in accordance with Cornell and Krawinkler ([11]), could be subdivided in four steps: facility definition, structural analysis, damage analysis and loss analysis.

The aspects of novelty introduced in the methodology proposed stay in the fact that the attention is mainly focused on the influence of infill walls in the evaluation of the structural and economic performance of the overall building. In particular, the definition of damage in all the considered infills was inferred directly by laboratory tests and by numerical simulations on the same infill panels adopted in the analyses; moreover, the computation of the losses was referred to updated official costs of repair and replacement actually adopted in Italy. The evaluation of the seismic performance in terms of EAL of a building with specific indications on infill typologies has allowed a consistent comparison on the effective contribution of different infill solutions and an estimation of the economic benefits that the use of an innovative infill system could provide as respect to traditional infills.

3 APPLICATION TO CASE STUDY

3.1 Facility definition

In order to evaluate the influence on infill walls in the seismic performance of a common newly designed 6-storeys high RC frame building in Italy, a reference model was assumed. The structure aimed to represent a typical residential building designed in high ductility class in compliance with the Italian standards ([19]) and Eurocodes ([20],[21]), therefore in accord-

ance with the “capacity design” principles. The building is regular both in plan and elevation and located on a flat ground, with soil type C, in L’Aquila (Italy). Further details on the reference structure are fully described in Hak *et al.* ([22]).

The numerical model is a 2D frame of the entire building, being representative of all the structure, as shown in Figure 2. The analyses have been conducted using Ruaumoko finite element program ([23]) and a macro-model approach was deemed to be the best compromise between reliable results and reasonable computational burden.

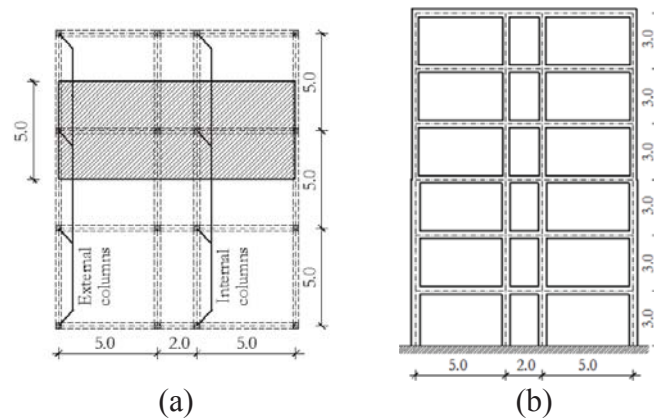

Figure 2. Geometry of the reference building: (a) plan view; (b) elevation view.

In the numerical model, only the structural elements (RC beams and columns) and the infills walls have been modelled, whereas the other non-structural components, assumed to be irrelevant to the structural response of the system, although they could be damaged, have been accounted only *a-posteriori*.

Figure 3. Portion of the structure analyzed.

The additional shear demand on the columns of the frame due to the in-plane thrust of the infill and the out-of-plane verification on the panels have been considered as reported according to Rossi *et al.* ([8]); the local interaction method is based on the specific studies ([24],[25]), meanwhile the out-of-plane verifications are referred to researches based on experimental results (*i.e.* [26],[27],[28],[29],[6]).

The foundation beam is considered to behave perfectly elastically and not damageable, except in case of global collapse of the building. In that case, also the costs of demolition and rebuilding of the foundation beam is accounted. In the central bay of the in-plane frame, a glass panel representing a door is assumed to be placed.

The arrangement of infills and of all the elements is shown in Figure 3, and a list of all damageable elements accounted in the case-study is reported in Table 1.

Typology	Element	Dimension	Quantity
Structural elements	Foundation beam	Height: 1.7 m; Width _{top} : 0.45 m; Width _{bottom} : 2.0 m; Length: 23 m	53.25 m ³ in total
	Columns	Section of elements at the 1 st , 2 nd and 3 rd floor: 45x45cm; otherwise: 35x35cm	11.70 m ³ in total
	Beams	Section: 30x45cm	23.65 m ³ in total
Non structural elements	Infill panels – in-plane, 1 st floor	2.775x4.55m each	25.25 m ² per floor
	Infill panels – in-plane, 2 nd & 3 rd floor	2.55x4.55m each	23.21 m ² per floor
	Infill panels – in-plane, 4 th , 5 th , & 6 th floor	2.55x4.65m each	23.72 m ² per floor
	Infill panels – out-of-plane, 1 st floor	2.775x4.55m each	25.25 m ² per floor
	Infill panels – out-of-plane, 2 nd & 3 rd floor	2.55x4.55m each	23.21 m ² per floor
	Infill panels – out-of-plane, 4 th , 5 th , & 6 th floor	2.55x4.65m each	23.72 m ² per floor
	Ground floor slab	60 m ² (per floor)	60.0 m ²
	Floor slab, from 1 st to 5 th floor	60 m ² (per floor)	60.0 m ² per floor
	Roof	60 m ² (per floor)	60.0
	Ceilings	60 m ² (per floor)	60.0 m ² per floor
	Piping (hot and cold water) and electrical, hydraulic and heating systems	Small diameter threaded steel pipes ($\leq 60\text{mm}$)	60.0 m per floor
	Internal glass door, 1 st floor	2.775x1.55m each	5.33 m ² per floor
	Internal glass door, 2 nd & 3 rd floor	2.55x1.55m each	5.10 m ² per floor
	Internal glass door, 4 th , 5 th , & 6 th floor	2.55x1.65m each	5.20 m ² per floor
	Sanitary, boilers and machines	Engineering judgement: 140 € / m ²	
	Partition wall	Gypsum walls, 18mm thick	25 m ² per floor
	Frames	4 windows and 4 doors	10.24 m ² per floor

Table 1. List of the damageable elements.

With the aim to represent common traditional masonry infill typologies, three different “non-ductile” solutions have been studied. The masonry panels were made of clay units and considered as built in full contact with the surrounding RC frame. Their characteristics are resumed herein and sketched in Figure 4:

- 1) Typology T2 (“medium strength/stiffness infill solution”). It is represented by double-leaf 12 cm thick walls with horizontally perforated “weak” units, with 60% void percentage. The panel has 1 cm of plaster on each external side of the leaf.
- 2) Typology T3 (“strong infill solution”). It is made of vertically perforated (50% of void) robust 30 cm thick blocks. The panel has 1 cm of plaster on each side of the wall.
- 3) Typology TA (“strong infill solution”). Similar to T3 solution, but the vertically perforated blocks are thicker (35 cm) and the tested masonry infills has provided higher deformation capacity than T3. The panel has 1 cm of plaster on each side of the wall.

The strength and stiffness of the infills adopted are different in order to account for a quite wide range of typologies.

Figure 4. Masonry infill typologies [22].

Besides the non-ductile “traditional” infills, the innovative ductile infill solution with sliding joints (“TSJ1”, [2]) was considered, with the goal to estimate if this solution improves the performance as respect to rigidly attached typologies, also terms of economic benefits. The innovative system was conceived to improve the seismic response of the infills and to control the damage and the stability of the panels, being characterized by the presence of sliding joints that divide the infill into horizontal stripes and that are designed specifically to allow the relative in-plane movement of these stripes ([2]). Moreover, at the wall-frame interface, flexible joints limit the detrimental interaction of the infill with the surrounding RC frame (Figure 5). The unreinforced masonry of the infill is constructed with 25 cm thick vertically perforated lightweight clay units and 1 cm thick general-purpose mortar bed- and head-joints. The overall thickness was equal to 29 cm due to the plaster layer of 2.0 cm which is placed on both sides of the panel. The out-of-plane stability of the infill is ensured by properly designed steel “shear keys” attached to the column and by “C-shaped” clay units placed at the edges of the masonry panel. Further details on this innovative system are described in Morandi *et al.* ([2]) and Milanesi *et al.* ([6]).

Figure 5. (a) Innovative masonry infill with sliding joints and deformable joints at the panel/frame interface; (b) Details of the innovative masonry infill with sliding joints: 1.C-shape units; 2. mortar bed-joints; 3. Sliding joints; 4. clay units; 5. interface joints; 6. shear keys; 7. plaster [2].

3.2 Seismic Hazard

In order to apply the same (scaled) ground motions to all the building models with different infill walls, there was the need to adopt an intensity measure metric capable to ensure consistency. For the purpose of the present work, the average spectral acceleration, $AvgSa$, introduced in Kohrangi *et al.* ([30],[31]), was assumed to be a good metric, defined as the mean of the log spectral accelerations (Sa) at a set of n periods of interest (Equation 2 from [31]):

$$AvgSa = [\prod_{i=1}^n Sa(T_i)]^{1/n} \quad (2)$$

This metric is considered a good predictor for both inter-story drift ratio and peak floor acceleration; moreover, its hazard can be evaluated using existing ground motion prediction equations.

Twenty ground acceleration time histories, for each of the ten levels of intensity-measure, were supposed to be sufficient for the purposes of the present study, giving sufficiently good estimation of the most probable response of the structure. Each ground motion, *GM*, had two perpendicular components (North-South and East-West); the one adopted in the analyses was the one with the highest value of spectral acceleration at $T=1$ second. Further information is reported in Rossi *et al.* ([8]).

Figure 6. Seismic hazard curve.

4 STRUCTURAL PERFORMANCE

In order to evaluate the infill influence in the overall performance of the building, both nonlinear static and nonlinear dynamics analyses have been performed. The discrete selection of *IM* level, introduced previously, was adopted to perform a MSA (Multiple Stripe Analysis) ([32]). As aforementioned, the numerical models were considering only columns, beams and infill walls. The other non-structural elements were assumed to do not influence the structural behavior of the frame also in the case of the nonlinear time-history analyses.

The overall results reported in Figure 7 have demonstrated that the structural performance of the RC frames is strictly related to the structural performance of the typology of infill walls adopted. In particular, Figure 7a, shows the force-drift envelopes of the infill contribution only to the in-plane horizontal response. The dots indicate the thresholds of the three limit states of infill walls in terms of inter-storey drift, as defined by Morandi *et al.* ([33],[2]): operational limit state (OLS), damage limitation limit state (DLS) and life safety/ultimate limit state (LSS/ULS). In Figure 7b, the pushover curves of the buildings characterized by the presence of the four same infill typologies are shown. Also in this case, the dots show when the performance-level thresholds are exceeded by the infill walls.

The main results of the MSA are represented by the fragility curves of the infilled RC frames, which are reported in Figure 8.

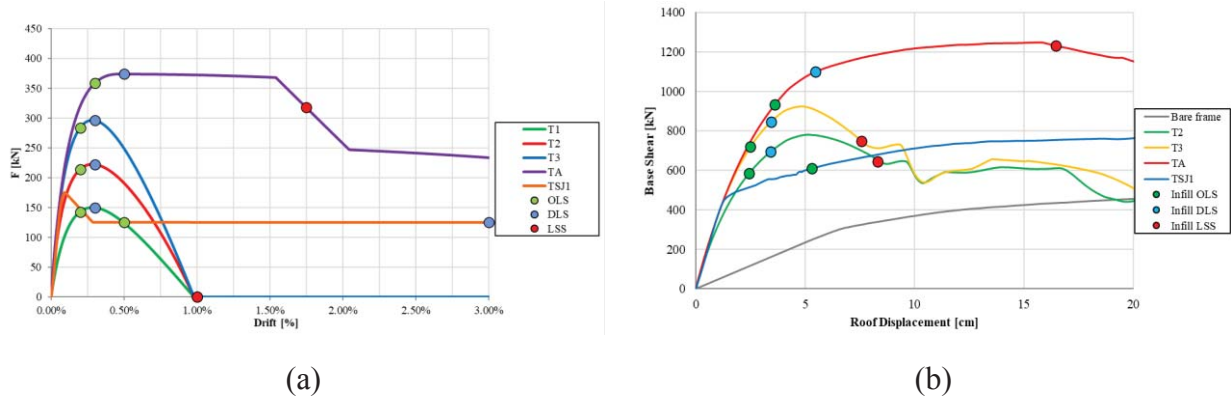

Figure 7. (a) Envelopes of the infill contributions; (b) Pushover curves.

Figure 8. Global fragility function related to the collapse of the infilled frames, (a) nonlinear dynamic analyses; (b) nonlinear static analyses.

The fragility function related to the plane-frame with the innovative ductile infill system shows very small values of probability of exceedance till a value of $AvgSa$ of about $1g$, where the slope of the curve rapidly increases. In the range of ground motions with PGA similar to the design PGA , the adoption of the innovative infill solution leads to have a probability of collapse almost equal to zero. This result is quite encouraging, because it demonstrates that the adoption of this innovative infill, conceived with the purpose of limiting the damage in the infill, has also a beneficial influence on the overall in-plane seismic response of the structure.

A peculiarity of this work is the fact that the correlation between the level of damage in the infill walls and the inter-story drift (*i.e.*, the *EDP*: engineering demand parameter) was deterministic. Actually, this fact does not represent a limitation, because the *EDP*-damage relationship was inferred from full-scale in-plane cyclic tests on the same infill panels adopted in the analysis, with the same mechanical characteristics and aspect ratio.

5 MONETARY LOSSES

The results of the structural analyses have allowed the identification of specific values of damage, which can be therefore correlated with costs of repair/reconstruction. The consequence function specifically created for each vulnerable element ([8]), both structural and non-structural, have permitted to define the costs in accordance with the Public Works Price-list of 2020 ([34]) along with an engineering judgement. Table 2 resumes all the cost of construction and demolition for each of the aforementioned elements.

		T2	T3	TA	TSJ1
Structural elements	Foundation beam	21'008 €	21'008 €	21'008 €	21'008 €
	Columns & beams	31'111 €	31'111 €	31'111 €	31'111 €
Non structural elements	Infill panels IN PLANE	16'765 €	19'620 €	21'316 €	23'309 €
	Infill panels OOP (with thermal insulation)	20'366 €	23'222 €	24'917 €	26'910 €
	Floor slabs (roof included)	89'143 €	89'143 €	89'143 €	89'143 €
	Ceilings	17'833 €	17'833 €	17'833 €	17'833 €
	Pipings (hot and cold water)	73'109 €	73'109 €	73'109 €	73'109 €
	Internal glass door	6'915 €	6'915 €	6'915 €	6'915 €
	Sanitary, boilers and machines	50'000 €	50'000 €	50'000 €	50'000 €
	Partition walls	11'982 €	11'982 €	11'982 €	11'982 €
	Windows and doors	35'741 €	35'741 €	35'741 €	35'741 €
	Complete demolition	17'463 €	17'463 €	17'463 €	17'463 €
	Demolition + Building cost	391'437 €	397'148 €	400'539 €	404'525 €
	Building cost only	373'974 €	379'685 €	383'075 €	387'062 €
	Building cost / m ²	1'039 €	1'055 €	1'064 €	1'075 €

Table 2. Costs of demolition and complete reconstruction of all damageable elements.

Furthermore, the global vulnerability functions, related to each building with the four infill typologies, are shown in Figure 9. The costs have been evaluated through consequence functions specifically defined for each element. Further information is reported in Rossi *et al.* ([8]). The expected annual loss (EAL) of one building is the area under its vulnerability curve. In agreement with the previous results, the smallest value of EAL is the one of the RC frame with the innovative infill system (EAL=0.16%). This value is more than about 2 and 4 times smaller than the one of buildings with the TA (EAL=0.28%) and the T2-T3 (EAL=0.57%-0.63%) traditional infills, respectively. The return period of the investment has been found to be always less than 10 years (9 years for TA, 8 years for T2, and 4 years for T3). This period of time has been estimated without considering the risk of injuring and losing the life of people and without considering all the indirect costs and the downtime of the building, which would have furtherly decrease such time.

Finally, according to the Italian law DM 58 ([35]) which defines a method for a simplified classification of the seismic risk for constructions, the building with infill typologies T2 and T3 would lie in risk class A_{EAL}, whilst the building with infill typologies TA and TSJ1 in class A⁺_{EAL} (*i.e.*, the class with best performance).

Figure 9. Global vulnerability function relative to the frame structure (Rossi *et al.* ([8])).

6 CONCLUSIONS

Within the present work, a novel method to compute the annual losses has been adopted to compare the seismic performance of three different non-ductile rigidly attached masonry infills and an innovative ductile system with sliding joints [2]. The economic comparison, which has been conducted through nonlinear analyses on code-compliant RC frame structure, has demonstrated the influence of the infill typology in the computation of the expected annual loss (EAL). The choice of a particular infill typology, in a common RC frame structure, could strongly influence both the structural and economic performance of the building, despite the fact that they are assumed to be non-structural elements. The EAL has been calculated through a novel methodology presented by Rossi *et al.* ([8]) in accordance with PERR's PBEE procedure ([11],[12],[13],[14],[15]). In the computation, the influence of the non-structural elements that do not interfere with the seismic structural response has been considered *a-posteriori*.

The monetary losses relative to each building were compared. The loss analyses confirm that the adoption of an infill system conceived with the explicit intent to reduce the damage in the masonry panel, as the innovative solution proposed by researchers of Pavia ([2],[6]), should be preferred as respect to traditional infill solutions without any seismic detail. The initial investment, due to the higher cost of construction of a structure with the innovative infill solution, is paid back by the lower costs of repair in the case of seismic events.

Although the present work shows an updated picture of the situation, the ongoing research on ductile masonry infills with sliding joints (*e.g.*, about the local structure-panel interaction effects [36]), and the continuous development of new typologies of masonry infills (*e.g.*, [37],[38]), represent some of the future upgrades of the presented study.

ACKNOWLEDGEMENTS

The present study was carried out by the researchers of University of Pavia, Eucentre and IUSS, thanks to the project INSYSME "Innovative Systems for earthquake resistant Masonry Enclosures in rc buildings", grant FP7-SME-2013-2-GA606229, 2013-2016 and the Executive Project DPC-RELUIS 2013-2019. The financial support received is gratefully acknowledged. A particular acknowledgement is due to Prof. Paolo Bazzurro, who gave us precious suggestions and indicates possible future developments of this work.

LOCAL EFFECTS DUE TO THE SEISMIC INTERACTION BETWEEN INNOVATIVE DUCTILE MASONRY INFILLS AND RC ELEMENTS

Abstract

The seismic vulnerability of rigidly attached masonry infills has been repeatedly highlighted through post-event surveys, experimental and numerical studies. Although many innovative solutions have been proposed, especially in the last decades, many aspects of these systems are object of ongoing or future studies. The ductile infills with sliding joints have been currently investigated by different researchers starting from experimental tests and using the test outcomes to calibrate and create finite element models with the aim to perform parametric analysis and define the local and global interaction with the structure. Moreover, the innovative infills with sliding joints have shown a completely different in-plane behavior with respect to the non-ductile ones. Since the creation of the diagonal strut is avoided and the shear sliding mechanisms fostered in predefined sliding joints, the interaction between the masonry panel and the RC members represents novelty with respect to the “traditional” rigidly attached masonry solutions. Within the present paper the results of a numerical model calibrated according to in-plane experimental tests are presented and the local interaction between the RC structural member and the innovative ductile infill with sliding joints is discussed. The study adopts a validated finite element model approach to an experimental campaign that has never been simulated through detailed FEMs and compares the numerical results with the experimental results related to the local effects.

Keywords: Local effects, infill-frame interaction, innovative infills, ductile infills, sliding joints, fem modeling of infills.

1 INTRODUCTION

The seismic vulnerability of rigidly attached masonry infills, also called non-ductile infills, has been repeatedly highlighted through recent post-event surveys (*i.e.*, [1],[2],[3],[4]). Several problems have been observed such as the in-plane/out-of-plane interaction in the seismic response of these non-structural elements (Figure 1a), the global influence in the overall seismic behaviour of the structure and the structural damages caused by local interaction between the masonry panels and the structural members (Figure 1b). The seismic behaviour of non-ductile masonry infills has been studied also experimentally and numerically into many researches that had different goals such as, the infill/structural global interaction ([5],[6],[7]), the in-plane behaviour ([8],[9]), the out-of-plane response ([10],[11],[12]). The in-plane/out-of-plane interaction ([13],[14],[15]), the economic evaluation of the expected annual losses ([16],[17]) and the local interaction between the infill and the structural members ([18],[19],[20]) as, for example, shown in Figure 2, were investigated as well.

Figure 1: (a) Infill damage and collapse due to in-plane and out-of-plane behaviour during the Central Italy earthquake 2016 ([3]), (b) Focus on the local damages on RC members due to the infill-structure local interaction ([2]).

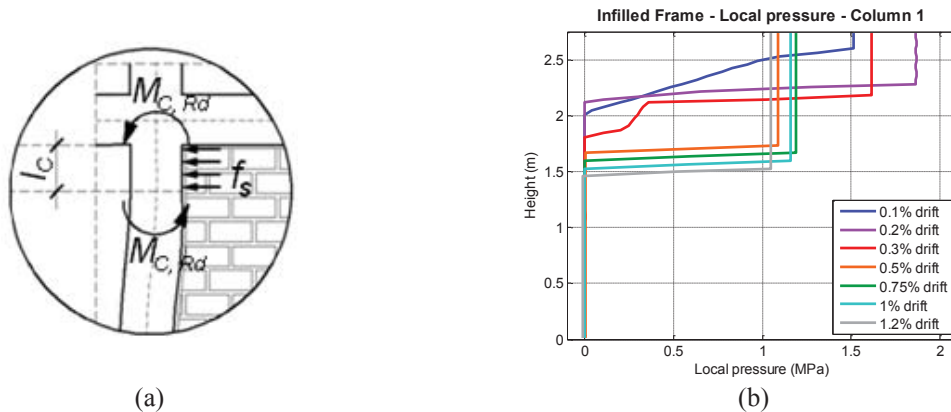

Figure 2: (a) Local effects on a non-ductile infill to the adjacent column ([20]); (b) Example of local pressure at different drift on the RC columns due to the presence of a non-ductile infill made of AAC units ([20]).

The aforementioned issues have recently encouraged the research and the industry in developing innovative infills that can be generally classified into three categories: the enhanced infills ([21],[22],[23],[24]), the panels uncoupled from the frame ([25],[26]) and the ductile infills ([27],[28],[29],[30],[31]). The latter innovative infill typology, that has been recently proposed and studied both experimentally and numerically, is object of ongoing and future studies. The infill with sliding joints, which are investigated in this work, are classified as ductile infills. The innovative infills with sliding joints have shown a completely different in-plane behaviour with

respect to the non-ductile ones [32]. Since the creation of the diagonal strut is avoided and the shear sliding mechanisms fostered in predefined sliding joints, the interaction between the masonry panel and the RC members represents a novelty with respect to the “traditional” rigidly attached masonry solutions.

Figure 3: (a) Details of the innovative masonry infill with sliding joints: 1. C-shape units; 2. mortar bed-joints; 3. sliding joints; 4. clay units; 5. interface joints; 6. shear keys; 7. plaster ([28],[29]); (b) Idealization of the compressed strut in the case of ductile infill with sliding joints ([28]).

Within the present paper the results of a numerical model calibrated according to in-plane experimental tests are presented and the local interaction between the reinforced concrete structural member and the innovative ductile infill with sliding joints is discussed. The study adopts a validated finite element model approach ([33]) extended to an experimental campaign ([28]) that has never been simulated through detailed FEMs and compares the numerical results with the experimental ones related to the local effects.

2 SPECIMEN DESCRIPTION AND INSTRUMENTATION

At the Department of Civil Engineering and Architecture and at the Eucentre Foundation, within the European FP7 “INSYSME” project, a ductile seismic resistant masonry infill with sliding-joints ([28] and [29]) with original details has been conceived, based on the conceptual design proposed in Preti *et al.* [34]. The engineered system reduces the interaction between the structure and the infill in the in-plane direction by facilitating the shear-sliding damage in specific previously designed elements corresponding to the sliding joints. The infill is subdivided into four horizontal subpanels that can mutually slide through properly conformed sliding joints. Moreover, the interface between the masonry subpanels and the reinforced concrete is filled with a deformable mortar to decrease the stress concentration. The unreinforced masonry used in the subpanels of the infill is realized with vertically perforated lightweight clay units and general-purpose 1 cm thick mortar bed- and head-joints.

The reference experimental campaign has included test on characterization on every material (concrete, reinforcement, mortar, clay units and masonry), in-plane pseudo-static cyclic tests (called IPL) on fully and partially infilled (with a central opening) full scale one-storey one-bay reinforced concrete frames. The infill without opening has been tested also at “high-velocity” (called IPH) to study the behaviour of the sliding joints subjected to dynamic actions. Subsequently, the same specimens have been tested dynamically out-of-plane on a shaking table to investigate the out-of-plane response. Finally, a dynamic test on a shaking table on a prototype 2-storeys 5-bays building has been carried out. The in-plane response is presented by Morandi

et al. [28], the out-of-plane experimental behaviour is discussed in Milanesi *et al.* [29], whereas the building test is presented in Manzini *et al.* [35].

The full infill, named TSJ1, had a length of 4.22 m and a height of 2.95 m, and the reinforced concrete members have a square section with base/height of 35 cm (Figure 4). The specimen design, that aimed to represent a part of a realistic full-scale reinforced frame structure, is detailed in other works ([9] and [28]).

The experimental displacements and deformations occurred during the in-plane tests have been measured through 45 displacement transducers (linear potentiometers) (Figure 5a). The ones numerated between 30 and 44 are located at the panel/column interface to measure the compression of the deformable mortar joint or the detachment of the subpanel with the reinforced concrete column (Figure 5b). Each subpanel has 2 potentiometers for each masonry/column interface, being one at the top and the other at the bottom of the subpanel.

Figure 4: Layout of the fully infilled specimen represented without plaster ([28]).

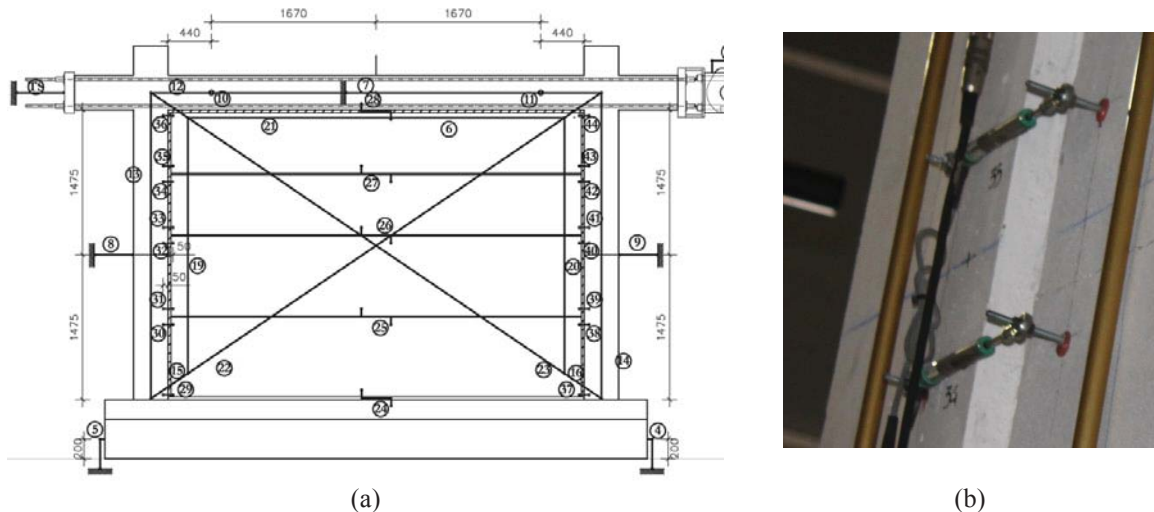

Figure 5: (a) Sketch of the linear potentiometer installed in the specimen during the in-plane cyclic test; (b) Detail of the potentiometer 34 and 35 installed to monitor the subpanel/column local interaction.

3 EXPERIMENTAL RESULTS

The force-displacement hysteretic curves and the corresponding envelopes for each cycle of the fully infilled configuration (TSJ1) are reported in Figure 6a, whereas the results of the bare frame specimen (called TNT) are shown in Figure 6b. The TNT specimen has been taken as

reference for a proper evaluation of the infill contribution and it has been tested in a previous experimental campaign ([9]).

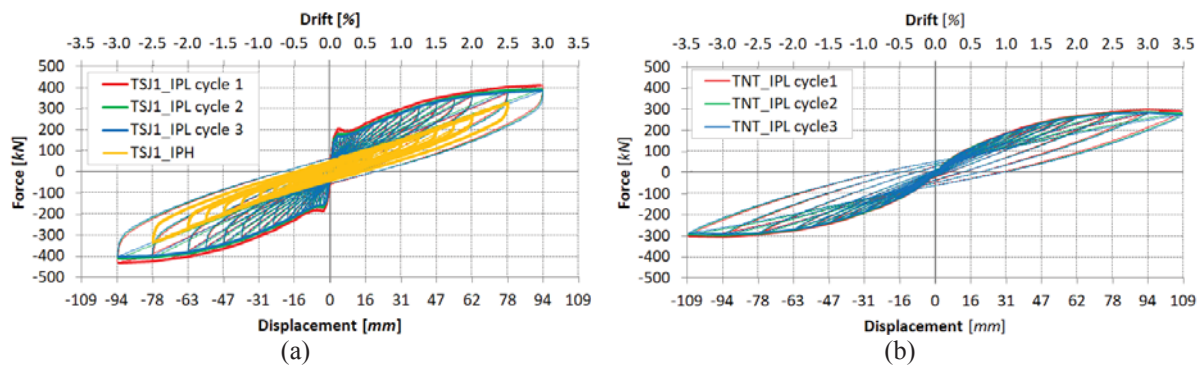

Figure 6: Experimental force-displacement cyclic and envelopes curves of (a) specimen TSJ1, fully infilled and (b) bare frame.

The damage related to the in-plane tests, which is detailed in Morandi *et al.* [28], can be summarized to horizontal cracks corresponding to the sliding mechanism of the sliding joints starting from low levels of drift (from 0.20%), sub-horizontal flexural and light diagonal cracks in the upper and bottom part of the reinforced concrete columns due to the in-plane deformation of the structural frame (at about 1.00-1.25%), detachment of small area of plaster in corner of the subpanels (2.00%) and spalling of the concrete cover at the bottom of the columns (3.00%). At the subpanel/column interface, the occurrence of the sliding mechanism in the engineered sliding joints has created a contact area and a detached portion for every subpanel due to the deformation of the reinforced concrete frame respect to the infill (Figure 7).

Figure 7: Focus of the masonry/column interface joint at the max imposed in-plane drift of 3.00%.

As aforementioned, the experimental campaign has included also a comprehensive mechanical characterization of the materials. The masonry has been therefore characterized through vertical, horizontal, and diagonal compressive strength tests, flexural pure bending tests, and tests on triplets to determine the initial shear resistance and the friction coefficient of the mortar bed-joints and the sliding joints. All tests of characterization on masonry have been conducted on specimens with and without plaster in order to evaluate its influence for each resistance. In the present work only the horizontal compressive resistance of the masonry (Figure 8a) and the shear tests on masonry triplets to characterize the cohesion and the friction coefficient of the mortar bed-joints and the sliding joints (Figure 8b) have been considered.

Figure 8c reports the results of the triplet tests on masonry for the sliding joints, for the mortar bed-joint with and without plaster. The stress-strain curve obtained from the horizontal compressive tests is reported in Figure 12b.

Furthermore, the deformable interface mortar (called “deformable mortar” in the following) placed between the masonry subpanels and the structural member has been characterized in several ways: by testing mortar prisms in compression (Figure 9a), mortar pads (Figure 9b) to investigate the influence of the dimension and by replicating the whole interface region also including the steel omega element and the C-shape clay unit (Figure 9c). The results, that are reported in Figure 13a, highlight the lack of a common curve and the necessity to make some assumption regarding the compressive behaviour of this material.

4 MODELING DESCRIPTION

The modelling technique here adopted to interpret the test response is based on the approach proposed in several studies ([36][37],[38]) and specified for sliding joint infill in Bolis *et al.* ([33]). The specific configuration of the infill with sliding joints and the layer of deformable mortar interposed at the frame to masonry interface, is modelled with interface and smeared-crack elements, respectively. For the specific specimen under consideration here, the deformable mortar is modelled assuming a simplified linear response calibrated on the mechanical characterization tests.

The model is a two-dimensional plane-stress finite element model implemented using the FEAP ([39]) environment.

The modelling scheme of reinforced concrete columns, beam members and masonry infill ([38]) are reported in Figure 10. The sliding joints are modelled using interface elements; the lateral deformable mortar joints are simulated using a smeared-crack element directly connected to the nearest reinforced concrete member on one side and through an interface element to the adjoining masonry subpanel. Unlike the model proposed in Bolis *et al.* ([33]) the base

joint is modelled like the horizontal mortar joints and the top deformable mortar joint between the masonry infill and the beam is modelled like the lateral vertical joints (Figure 11).

Figure 10: Finite element discretization reprinted from Stavridis and Shing ([38]).

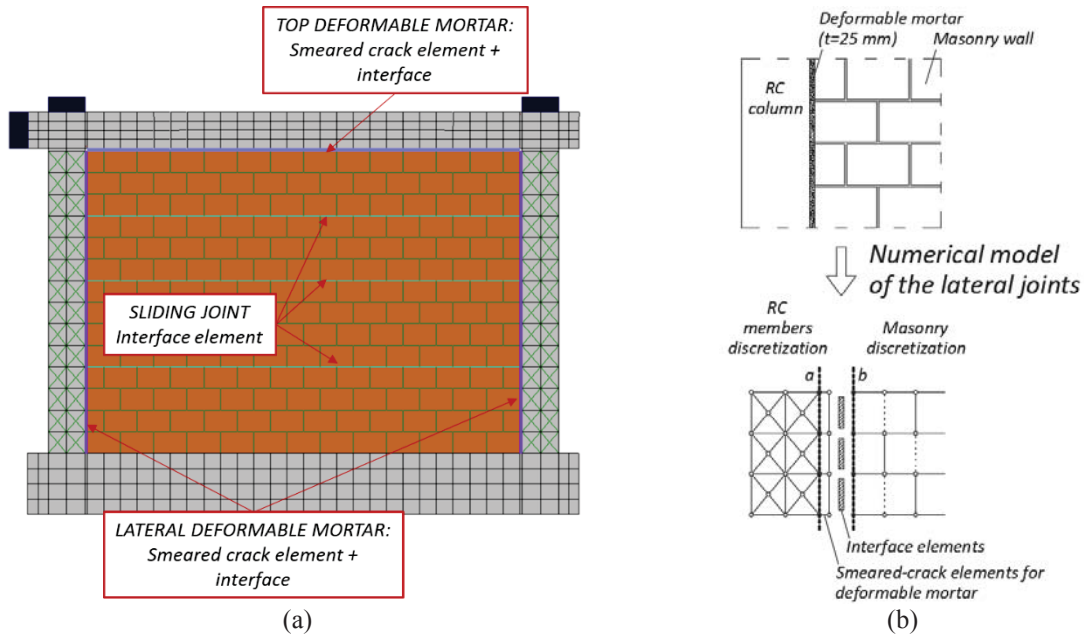

Figure 11: (a) Infill frame mesh and detail of the sliding and contact joints; (b) detail of the contact joint modeling

4.1 Parameter calibration

The model parameters are calibrated as proposed in Stavridis and Shing ([38]) and Bolis *et al.* ([33]), referring to experimental tests performed on subassembly and to literature references. The main parameters are reported in Table 1 and Table 2.

Material	SMEARED-CRACK ELEMENTS					
	E [MPa]	G [MPa]	ν [-]	t [mm]	f_c [MPa]	f_t [MPa]
Concrete	25000	10417	0.20	350	37	1
Masonry	2600	1150	0.13	250	2.9	0.6
Deformable Mortar top	5	2	0.38	100	10.0	2.0
Deformable Mortar lateral	8	2.9	0.38	250	10.0	2.0

Table 1: Main parameters adopted for the smeared-crack elements.

The comparison between the numerical and experimental results of the main calibration tests are reported in the following Figure 12 and Figure 13.

Lateral and top deformable mortar joints are modelled using smeared-crack elements calibrated to have an elastic behaviour in the range of deformation of interest. The elastic modulus of the lateral deformable mortar is calibrated to obtain a stress strain curve secant to the experimental one in the range of strain of 15-20%, which corresponds to the peak strain level measured in the experiment on the infilled frame structure at drift level of about 2.0%. In Figure 13a is reported the comparison between the assumed elastic curve and the experimental stress-strain ones obtained in the characterization tests. A similar approach is adopted for the top deformable mortar, accounting for a lower strain demand during the test.

The interface elements representing the sliding joints are calibrated fitting the residual yield surface to the experimental results. The initial yield surface is obtained by shifting upward the residual one calibrated to the test of the only sliding joint to consider the effect of the reduced plaster thickness at the sliding joint location.

Material	INTERFACE ELEMENTS					
	s_0 [MPa]	μ_0 [-]	μ_r [-]	r_0 [MPa]	r_r [MPa]	t [mm]
Bed joints	0.45	0.88	0.75	0.005	0.005	250
Brick head joints	0.70	1.00	0.80	0.28	0.21	250
Mortar vertical joints	0.90	0.862	0.75	0.005	0.005	250
Concrete joints	1.00	0.90	0.70	0.25	0.20	350
Lateral joints	0.05	0.50	0.45	0.10	0.10	250
Top joint	0.05	0.25	0.20	0.10	0.10	250
Sliding joints	0.15	0.361	0.361	0.02	0.02	250

5 NUMERICAL AND EXPERIMENTAL RESULTS COMPARISON

5.1 Global behavior

In Figure 14 the monotonical hysteresis is reported in terms of force applied at the top of the frame versus the displacement for both positive and negative in-plane loading, for experimental and numerical results. The experimental curve considered is the envelope of positive (push) and negative (pull) displacements of the cyclic tests conducted. Given the symmetry of the model the same numerical behaviour is considered for each load direction.

In both direction of loading the initial stiffness is well captured, whereas the initial peak of resistance is slightly underestimated, probably due to the uncertainties in the evaluation of the reduced thickness of the plaster over the sliding joints. As the drift increases, the horizontal joints start sliding and the behaviour exhibits a stiffness decay. The peak resistance reached in the simulation is slightly higher than the experimental ones, with an overestimation lower than 10% and more evident in the positive direction.

The quality of the numerical simulation can be better evaluated by focusing on the local response of the masonry/column deformable mortar joints shown in Figure 15.

Figure 14: Experimental and numerical hysteresis.

5.2 Local behavior

The comparison between experimental and numerical local deformation of the lateral joints along the frame height is herein presented. Given that the masonry is two order of magnitude stiffer than the deformable mortar, therefore, the local experimental deformations are estimated assuming that the displacement read by the potentiometer is localized in the deformable mortar joint only. The ratio between the displacement output and the thickness of the interface mortar joint, equal to 25 mm, has been assumed as the experimental strain of the deformable material. Since there are two potentiometers for each subpanel, the deformation profile of each of them is obtained considering the line interpolating the two values.

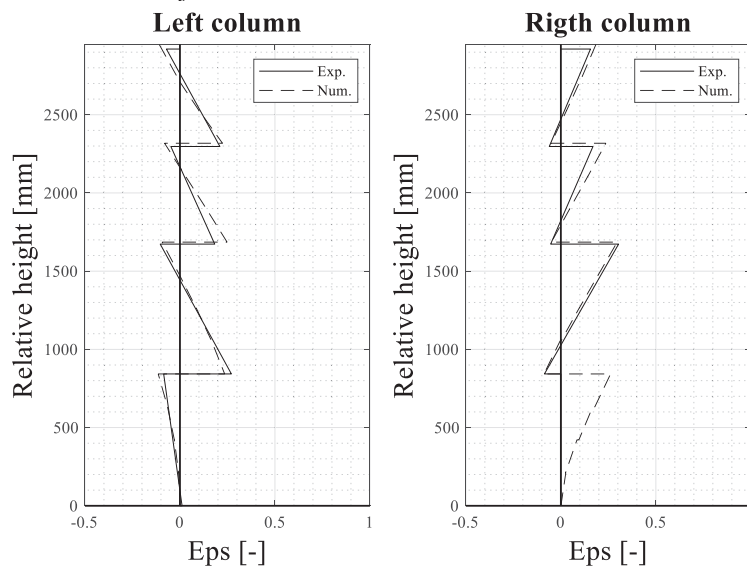

Numerically, the deformation profile is obtained directly from the difference of displacement between the masonry node and the concrete node near the lateral joints (alignment “a” and “b” in Figure 11).

It is important noting that the profile given represents the average strain in the lateral joint and it is not the specific deformation of the mortar. However, it can be assumed as an acceptable estimation of the compression strain level.

For all drift level the compression area is well captured. At 2.00% of drift the maximum compressive strain is approximately equal to 20‰, confirming the strain level considered for the deformable mortar elastic modulus calibration.

Lateral joints deformation for each column at 0.5% Drift

Lateral joints deformation for each column at 1.0% Drift

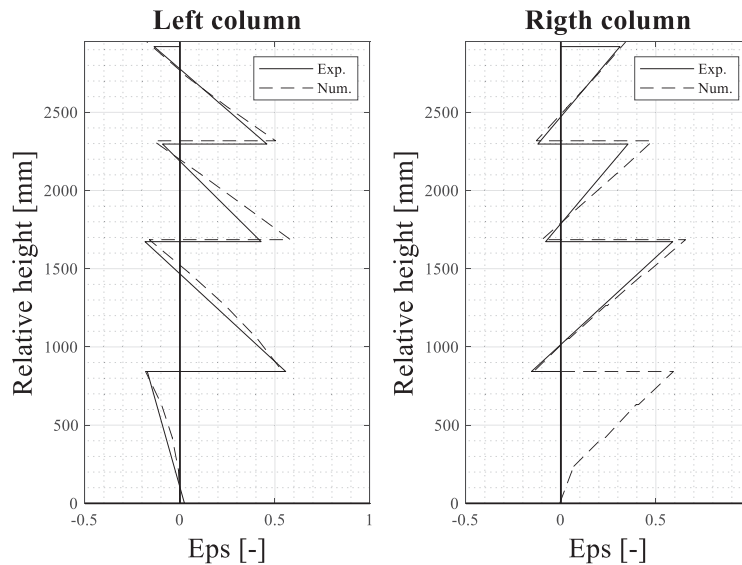

Figure 15: Lateral joint deformation for each column at different levels of drifts.

6 CONCLUSIONS

The recent outcomes from different post-seismic inspections and experimental and numerical studies on infills have identified many issues on non-ductile rigidly attached masonry infills. Three categories of innovative solutions have been proposed to improve the seismic response of these non-structural elements, being the ductile infills with sliding or deformable joints the latest respect to the others that aim to enhance the masonry and to uncouple the panel from the structure. The innovative ductile infill system with sliding joints is object of ongoing and future investigation to improve the knowledge about this new infill typology.

The experimental tests summarized in the present work ([28]) have been integrated with a detailed finite element model that has been previously adopted for a similar infill ([27],[33]). The model is a two-dimensional plane-stress finite element model implemented using the FEAP ([39]) environment. The results of the numerical simulation of the experimental in-plane test on the fully infilled solution has shown the capability of the model to capture both the overall behaviour and the local deformation located in the deformable mortar at the masonry/column interface. Moreover, one future development of the present study will be the computation of the local forces that occur in every subpanel/column contact area starting from the strain plots of the interface deformable mortar discussed herein.

Finally, the experimental evidence and the numerical results highlight the different in-plane behaviour of the infill typology and their new local interaction with the structure respect to non-ductile “traditional” systems, therefore new design provisions for the shear verification of the structural members could represent another future development of the present study.

ACKNOWLEDGEMENT

The experimental campaign presented in this work has been conducted thanks to the financial support of the European Commission within the project INSYSME “INnovative SYStems for earthquake resistant Masonry Enclosures in rc buildings”, grant FP7-SME-2013-2-GA606229, 2013-2016 is acknowledged. ANDIL and its associated companies, and RUREDIL spa are gratefully acknowledged as industrial partners of the INSYSME project, where the University of Pavia has also been partner. The contribution of Capaccioli srl for the supply of the sliding joints is acknowledged. The numerical part and the study of the local effects have been

whereas conducted within the framework of DPC/ReLUIS project 2019-2021, WP10, where both the University of Pavia and the University of Brescia are involved.

Keywords: Infilled RC frames, Hysteresis, Macro-model, Bouc-Wen, OpenSees.

Abstract. *Mechanics-based macro-models are often used to simulate the cyclic response of infilled reinforced concrete (RC) frames. However, these approaches are affected by uncertainties regarding damage and failure mechanisms. Therefore, this contribution proposes a new smooth data-driven model for the hysteresis of infilled RC frames. The infill panel is modeled through a damage-based Bouc-Wen element, which accounts for both pinching and deterioration of the mechanical characteristics. The parameters of the model are calibrated from an experimental data set of cyclic responses of RC infilled frames. Analytical correlations between parameters and geometric and mechanical characteristics of the infilled frame are derived. Blind validation tests are carried out in order to demonstrate the effectiveness of the proposed model.*

Figure 1: Scheme of the macro-model for the infilled frame: the bare frame is modeled with the software OpenSees, while the infill panel is simulated as a spring whose constitutive law is given by the Bouc-Wen model.

1 INTRODUCTION

The cyclic behavior of infilled frames has been widely investigated from both theoretical and experimental points of view [1–5]. However, the mechanical modeling of such structural systems is still an open challenge [6]. This mainly because the response of an infilled frame depends on many geometric and mechanical factors, which influence the damage mechanisms.

Many authors developed equivalent strut macro-models to predict the in-plane behavior of infilled frames [7–10]. However, predictions from different models lead to results that are often conflicting. Moreover, these modeling strategies are often complex and involve a large number of parameters that are very difficult to predict a priori. For the above reasons, recently many mechanics-based data-driven models have been developed [9, 11, 12]. In this case, the parameters governing the mechanical behavior of the structural system are estimated using regression formulas based on large data-sets. This modeling strategy has been proven to be reliable for many typologies of infilled frames.

This contribution proposes a new hysteresis data-driven macro-model based on the Bouc-Wen equation [13–15]. Deterioration of both stiffness and strength are taken into account through degrading functions for cyclic damage [16]. Pinching is introduced by adding in series a slip-lock element [17] to simulate the effect of masonry cracking. The model is governed by 11 parameters that have clear physical meanings. The regression formulas of these parameters were obtained with a data-driven approach, based on calibrations performed with experimental data of real infilled frames. The validation of the model was performed through additional blind prediction tests. The model proposed in this work is an effective tool for nonlinear dynamic analyses and probabilistic assessments [18, 19].

2 MACRO-MODELING OF THE INFILLED FRAME

The infill panel was replaced by a spring connected to the bare frame through rigid links, as shown in Figure 1. The constitutive behavior of the spring was defined by the hysteresis model proposed in this work. The bare frame was modeled on the OpenSees 2.5 software platform by using fiber-section beam-column elements with distributed plasticity.

Figure 2: The infilled frame is regarded as a simple oscillator composed of two springs in parallel, one representing the bare frame and one representing the infill panel.

As depicted in Figure 1, the rigid links constrain the frame and the spring to undergo the same horizontal displacement. Thus the infilled frame was regarded as a simple oscillator whose stiffness is given by two contributions. One is provided by the bare frame, the other by the spring representing the panel. The sum of these two contributions gives the response of the entire infilled frame (Figure 2).

In the following section, the analytical formulation of the hysteresis model for the spring (infill panel) is presented.

3 ANALYTICAL DESCRIPTION OF THE PROPOSED HYSTERESIS MODEL

The proposed hysteresis model consists in a degrading Bouc-Wen element [13, 14] integrated with a slip-lock element [17, 20]. The latter was specifically introduced to simulate the typical pinching of masonry due to cracks opening and closure.

The equation of motion for a single-degree-of-freedom system is

$$m\ddot{x} + c\dot{x} + F_s[x(t), z(t), t] = F(t) \quad (1)$$

where x is the relative displacement of the mass of the system m with respect to the ground, c is the linear viscous damping coefficient, $F_s[x(t), z(t), t]$ is the non-damping restoring force, $z(t)$ is the hysteresis displacement and $F(t)$ is the external excitation. The overdots indicate the derivative with respect to the time, thus \dot{x} and \ddot{x} represent velocity and acceleration, respectively.

The Bouc-Wen model gives the following expression for the restoring force:

$$F_s[x(t), z(t), t] = \alpha kx(t) + (1 - \alpha)kz(t) \quad (2)$$

where k is the elastic stiffness of the system and α is the ratio between the final tangent stiffness k_f and the elastic stiffness ($0 \leq \alpha \leq 1$). Eq. (2) is composed of two contributions: the linear elastic component $\alpha kx(t)$ and the hysteresis component $(1 - \alpha)kz(t)$, which depends on the past history of stresses and strains. The hysteresis displacement $z(t)$ is given by the differential equation

$$\dot{z}(t) = A\dot{x}(t) - [\beta|\dot{x}(t)||z(t)|^{n-1}z(t) + \gamma\dot{x}(t)|z(t)|^n] \quad (3)$$

with the initial condition $z(0) = 0$. The parameters β , γ , and n control the shape of the hysteresis cycles. The parameter A determines the tangent stiffness but it is set to unity to avoid redundancy [21, 22]. The hysteresis energy dissipated by the system is defined as the area under the hysteresis restoring force $F^h[z(t), t] = (1 - \alpha)kz(t)$ along the total

displacement $x(t)$. The hysteresis energy can be normalized with respect to the mass, as follows [23, 24]:

$$\varepsilon(t) = \int_{x(0)}^{x(t)} \frac{F^h[z(t), t]}{m} dx = (1 - \alpha)\omega_0^2 \int_0^t z(\tau)\dot{x}(\tau)d\tau. \quad (4)$$

According to some results in literature [25–27] a linear proportionality between β and γ was introduced

$$\gamma = \eta_0\beta. \quad (5)$$

A dimensionless damage index, involving both energy dissipated and maximum displacement reached, was considered

$$d_i(t) = \frac{\varepsilon(t)}{kx_y^2/m} + \frac{|x_{max}(t)|}{x_y} \quad (6)$$

where x_y is the yielding displacement and $x_{max}(t)$ is the maximum displacement of the system until time t . Since the degrading Bouc-Wen model is a smooth hysteresis model, there is not a standard way to compute the yielding displacement x_y . Hence, this is an unknown parameter that must be identified along with the other model parameters.

The damage index $d_i(t)$ allows to define the following stiffness and strength degrading functions [16]:

$$\begin{aligned} A(d_i) &= e^{-\delta_k d_i(t)p_k(d_i)} \\ \beta(d_i) &= \beta_0 e^{[\delta_k p_k(d_i) - n\delta_f]d_i(t)} \end{aligned} \quad (7)$$

where δ_k and δ_f are two parameters that control respectively the amount of stiffness and strength degradation. The function $p_k(t)$ controls the stiffness degradation rate

$$p_k(t) = e^{-\psi d_i(t)} \quad (8)$$

where ψ is a parameter that controls the rising of stiffness degradation.

With the introduction of the degrading functions, the differential equation defining $z(t)$ assumes the following expression:

$$\begin{aligned} \dot{z}(t) &= A(d_i)\dot{x}(t) - \beta(d_i)(|\dot{x}(t)||z(t)|^{n-1}z(t) + \eta_0\dot{x}(t)|z(t)|^n) = \\ &= e^{-\delta_k d_i(t)p_k(d_i)}\dot{x}(t) - \beta_0 e^{[\delta_k p_k(d_i) - n\delta_f]d_i(t)}(|\dot{x}(t)||z(t)|^{n-1}z(t) + \eta_0\dot{x}(t)|z(t)|^n). \end{aligned} \quad (9)$$

A slip-lock element [17] was introduced in order to properly simulate the opening and closure of cracks in the infill panel. The slip-lock element was linked in series with the Bouc-Wen element (see Figure 3). Therefore, the relationship between the two elements is the following:

$$x(t) = x_1(t) + x_2(t) \quad (10)$$

where x is the total displacement of the system. The term x_1 is the contribution of the degrading Bouc-Wen differential equation, expressed by Eq. (9). The term x_2 is the contribution of the slip-lock element, which is given by the following relation:

$$\dot{x}_2(t) = a(t)f(z)\dot{z}(t). \quad (11)$$

Figure 3: Schematization of the proposed hysteresis model, which is obtained as composition of degrading and slip-lock elements.

The function $f(z)$ defines the shape of the slip-lock phenomenon and is defined as

$$f(z) = e^{-z^2/Z_s^2} \quad (12)$$

where Z_s is the range of z in which the slip lock occurs. Parameter a is a function of the attained ductility

$$a(t) = A_s \frac{|x_{max}(t)|}{x_y} \quad (13)$$

where A_s is a parameter that controls the slip length, x_{max} is the maximum displacement reached at the prior cycle and x_y is the yielding displacement.

Combining Eqs. (9), (10) and (11), the following differential equation for the hysteresis displacement is obtained:

$$\dot{z}(t) = \dot{x}(t) \frac{A(d_i) - \beta(d_i)[\text{sgn}(\dot{x})|z(t)|^{n-1}z(t) + \eta_0|z(t)|^n]}{\{1 + a(t)f(z)[A(d_i) - \beta(d_i)(\text{sgn}(\dot{x})|z(t)|^{n-1}z(t) + \eta_0|z(t)|^n)]\}}. \quad (14)$$

4 CALIBRATION OF THE PROPOSED MODEL USING EXPERIMENTAL DATA

The model parameters were calibrated according to experimental data. The data involve 10 real specimens and were collected from the experimental campaigns by Cavaleri and Di Trapani [6], Mehrabi et al. [2], Colangelo [28], Kakaletsis and Karayannis [29] and Mansouri et al. [30]. For each specimen, the force-displacement hysteresis curve was acquired. All the campaigns considered performed displacement control tests in quasi-static loading.

For each specimen, the contribution of the infill panel was represented by the difference between the entire response of the infilled frame and the response of the bare frame modelled on OpenSees. The parameters of the proposed model for the infill panel were calibrated on the basis of this contribution. For each specimen, the calibration of the parameters was performed through a genetic algorithm implemented in a MATLAB® code. The genetic algorithm finds the set of parameters that minimizes the following objective function

$$OF(\boldsymbol{\theta}) = \frac{\int_{x_0}^{x_f} |[F_e(x) - F_s(\boldsymbol{\theta}, x)]| dx}{\int_{x_0}^{x_f} |F_e(x)| dx} \quad (15)$$

where $\boldsymbol{\theta}$ is the parameter vector, x_i and x_f are the initial and final displacement records, $F_e(x)$ is the force derived from the experimental data and $F_s(\boldsymbol{\theta}, x)$ is the one simulated by

the proposed model. Parameters α , η_0 , n and ψ assumed very similar values for different specimens. Thus their values were fixed for simplicity, since small variations did not affect the results significantly.

The calibration was performed for 10 specimens, but in this work only 2 of them are shown for the sake of brevity. The two specimens considered are S1A from [6] and specimen 4 from [2]. The parameters identified in the calibration are listed in Table 1 and the results are shown in Figure 4.

5 EMPIRICAL CORRELATION LAWS AND BLIND VALIDATION TEST

The dependence of the parameters k , x_y , β_0 , δ_k , δ_f , Z_s , A_s on the geometrical and mechanical properties of infilled frames was investigated. The most representative quantities like the elastic modulus of masonry, the compression strength of masonry or the compression strength of concrete were gathered in a functional. Considering all the specimens, the values assumed by each model parameters were put in relation with the values assumed by the functional. In this way, the correlation laws defined are able to predict the values of the model parameters in function of the geometrical and mechanical properties of a generic infilled frame.

The proposed correlation laws were validated on the basis of experimental data related to a specimen different from the one used for calibration. The specimen used for validation is specimen S1C from the experimental campaign in [6]. The geometrical and mechanical properties of specimen S1C are different from those of the specimens used for in the calibration. Therefore, this specimen was considered eligible for the blind validation test. Table 2 collects the parameters predicted by the correlation laws and Figure 5 shows the result of the validation test.

6 CONCLUSIONS

The data-driven macro-model proposed in the present contribution is able to predict the hysteresis response of infilled frames. The combination of degrading Bouc-Wen element and slip-lock element provides a model that captures hysteresis and damage of such structural systems.

The model involves 11 parameters with clear physical meanings. Four of them have less impact on the final behavior, so they were fixed. The 7 remaining parameters were

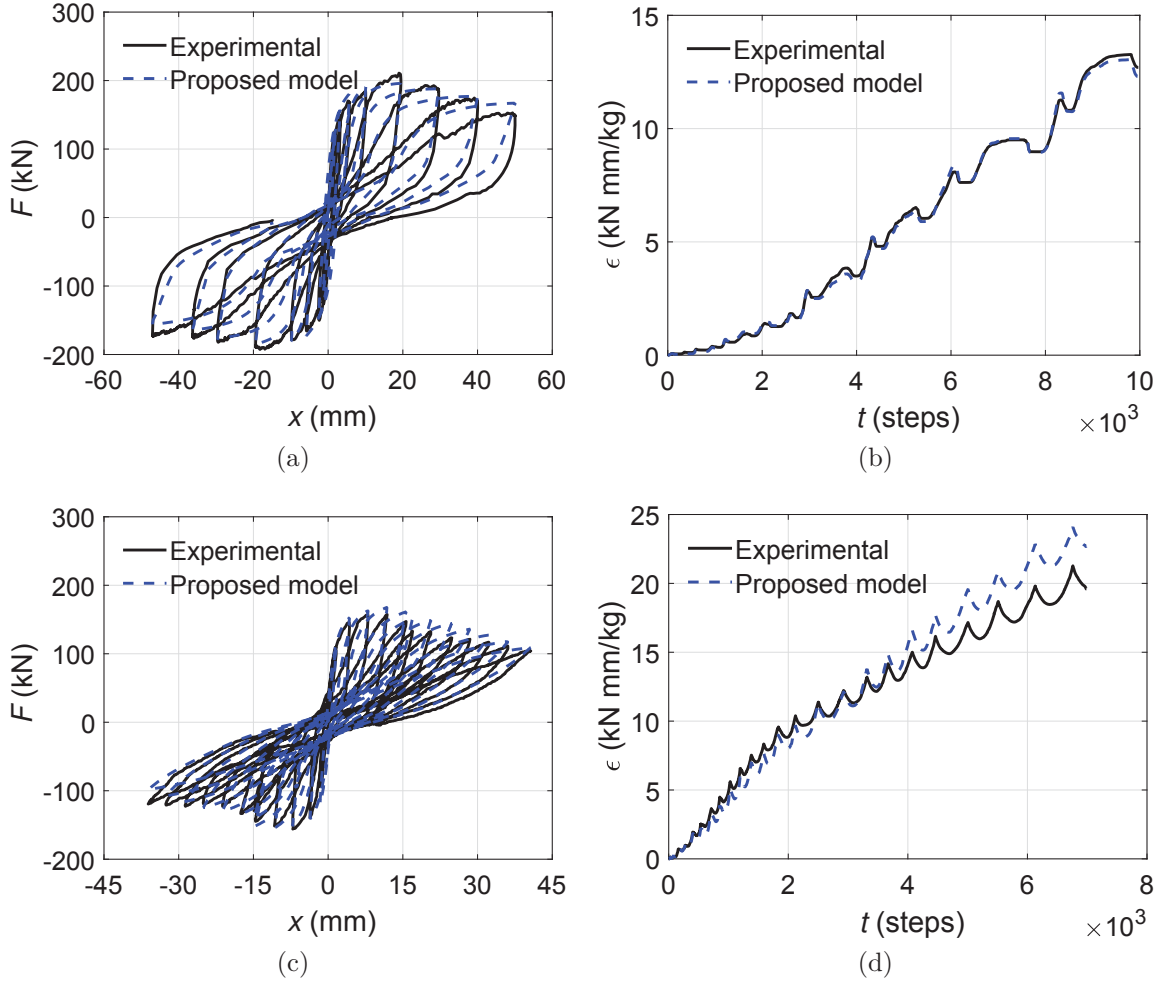

Figure 4: Results of the calibration for specimen S1A from Cavaleri and Di Trapani [6] and specimen 4 from Mehrabi et al. [2]: (a) S1A hysteresis cycles; (b) S1A dissipated energy; (c) Mehrabi 4 hysteresis cycles; (d) Mehrabi 4 dissipated energy.

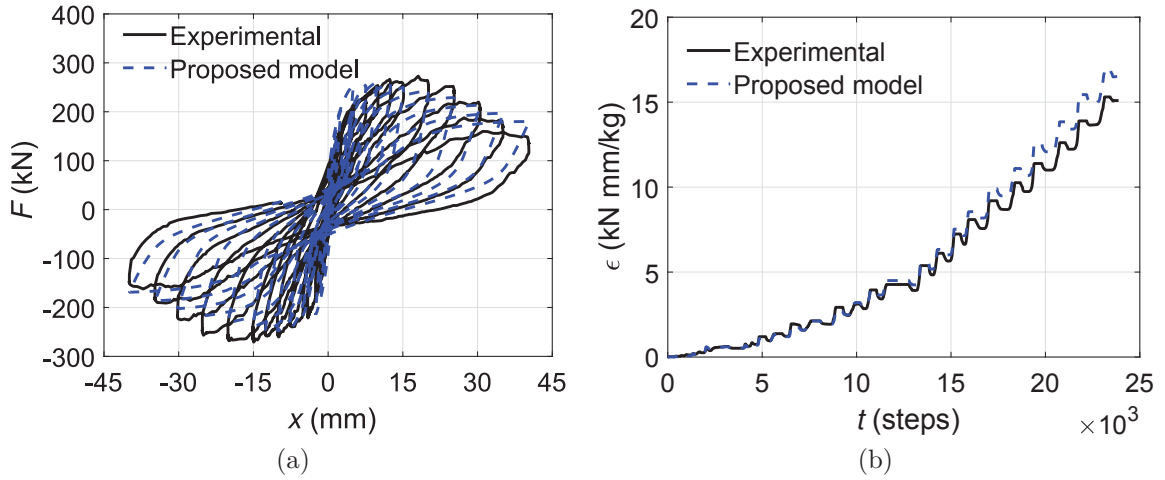

Figure 5: Blind validation test on specimen S1C from Cavaleri and Di Trapani [6]: (a) hysteresis cycles; (b) dissipated energy.

calibrated on the basis of experimental data of real infilled frames. Regression laws were estimated and final blind validation tests were performed. The results demonstrated that the model is accurate.

The simplicity and the smooth nature of the governing equations make the proposed model suitable for numerical simulations, such as nonlinear time-history and stochastic analyses.

Abstract

Infilled reinforced concrete (IRC) frames are commonly built across the world. Modern building codes address the influence of infill walls in seismic design and assessment of existing structures. Other building codes commonly consider infill walls as non-structural elements and do not require any explicit verification. One of such codes is the Pakistan Building Code (PBC), which does not foresee recommendations and guidelines for IRC frame structures, despite being a common construction typology in the Country. Records of past earthquakes show that infill types and material properties strongly affect the seismic response of buildings thus highlighting the importance of such parameters and making the topic worth investigating in detail.

This paper introduces a numerical model for infill walls, which predicts different features of the nonlinear response, such as cracking, peak force, failure and residual force. Such features are expressed as function of infill friction coefficient between mortar and brick surface and mortar strength, whose effects are commonly neglected in available numerical models. The model is applied to a comprehensive case study of a three-story IRC frame factory building, located in the city of Mirpur, Pakistan, hit by an earthquake of magnitude 5.9 on 24 September 2019. The results obtained the model show good agreement with the observed in-situ damage patterns, thus revealing the importance of correctly modeling the infill walls when seismically designing and assessing Pakistani IRC buildings.

1 INTRODUCTION

The construction typology of infilled reinforced concrete (IRC) frames is not only common in Pakistan but across the globe. The typology became more common in Pakistan especially after October 2005 Kashmir earthquake [1], [2], [3], [4], [5]. With the increasing demand for IRC frame constructions in the country, the local research community and practitioners started developing an increasing interest towards several important issues, such as, frame-infill interaction models, role of brick types, and optimal material properties of the infill wall constituents [6]. While the use of IRC frames has been growing in the Country, the Pakistan building code (PBC) has not developed any recommendation or guideline for their design and construction [1], [7]. This is also the case of many building codes around the world [8], [9], whereas some more advanced building codes, including Eurocode, already include some essential yet incomplete considerations about the role of infill walls in both design and assessment of IRC frame structures. As a matter of fact, many practitioners still consider infill walls as non-structural elements, despite being aware of their strong influence on the seismic response of IRC frame structures [10], [11]. This is also due to the fact that, although extensive studies have been dealing with the topic in the past 50 years, sound and reliable design and assessment methods including the effects of infills seem still far from being used in practice [12]. Besides, there is a lack of basic understanding regarding the infill walls contribution to the IRC frame response, whether it is beneficial or detrimental and under which circumstances. This depends on various parameters, such as: infills-frame interaction, infills-frame relative strength and stiffness, type of materials used for bricks, mortar and concrete [13][14][9]. Assessment of seismic performance of IRC frames requires proper modeling techniques and reliable analytical equations to correctly predict their response [15]. Many existing IRC frames are more vulnerable to seismic actions as a result of improper and poor understanding of such features [16].

Some usually neglected parameters, such as friction coefficient between mortar and brick surface, mortar strength, and their effects on the seismic performance of IRC frames are not reported in the literature, despite their strong influence on the failure mode of infill walls [17]. Recent earthquakes show that also newly built IRC frames designed with seismic detailing are equally vulnerable as older ones, due to the detrimental interaction with infills [18]. Moreover, IRC frames are not only vulnerable during natural seismic events, but also due to human-made hazardous events, such as blast and terrorism acts, which makes the topic worth investigating [19].

In case infill walls are uniformly distributed in plane and elevation of the building, IRC frames under seismic action are less vulnerable than the equivalent bare frames, because the infill walls interact directly with the surrounding RC frame [20]. However, brittle failures may occur in columns, beams and joints, due to local interaction. These issues should be dealt with when modeling an existing building [21].

The infill walls can be modeled by different numerical approaches, such as micro, meso, and macro modeling [22]. The former two require detailed computational efforts and are commonly used for detailed research purposes, while the latter makes use of one or more diagonal struts, which require less computational effort and are preferred in practical applications [23].

Usually, in Pakistan, common practice with IRC frames only accounts for infill walls through their dead load [2], [7]. As a consequence of such design practice, the same types of infill walls made of fire burnt clay bricks are used across the northern part, including Punjab, Khyber Pakhtunkhwa, Pakistan-administrated Kashmir, Baluchistan, capital territory Islamabad, and other seismic prone regions of the country, without the necessary variations in size and properties required by the local seismic hazard [24]. Besides, there are no variations in thickness or infill

types related to the occupancy/types of the building, i.e., hospital, school, industrial, or residential, which is not a reasonable strategy for the seismic safety of those buildings [2], [1].

2 NUMERICAL MODELLING

Satisfactory advancements in modeling infill walls have been recently achieved in terms of simplified macro modeling, in which the infill panel is replaced by equivalent diagonal single or multiple struts. The laying of bricks and the materials mechanical characteristics affect the ability of such models to predict the local response and the damage pattern. In terms of global response, it has been widely recognized that the modeling choices of infill walls affect the overall seismic performance of IRC frame structures and bring to largely different outcomes.

Generally, seismic forces affect infill walls both in-plane and out-of-plane. In-plane interaction has been the object of several experimental researches, which concluded that infill panels behave as a monolithic resisting system, until partially detached from the surrounding frame and start behaving as a compression strut, which claims for adequate modeling. The proposed model focusses on this aspect.

Considering the construction typology of IRC frames in Pakistan, the materials used, and the common design practice, is the objective of the proposed numerical model, which is a modified version of Combescure (1996) [25] model expressed as function of friction coefficient between mortar and brick surface and mortar strength. It considers a compression diagonal strut representing the infill wall in the in-plane, with a simple yet effective constitutive law shown in figure 1.

Figure 1. Adopted model for infill walls showing the main features of the response

The proposed model aims at better capturing such response at different stages, i.e., elastic, cracking, maximum force, failure, and residual force.

The relative stiffness between infill wall and column can be calculated by the dimensionless parameter first proposed by Stafford Smith (1967).

$$\lambda_h = h_c \left[\frac{E_m t_w \sin 2\theta}{4 E_c I_c h_w} \right]^{1/4} \quad (1)$$

where h_c is the height of the RC frame to the centerline of the beam, E_m , E_c are the moduli of elasticity of masonry and concrete respectively, t_w , h_w are the thickness and height of the infill wall, respectively, I_c is the moment of inertia of the column, θ is the angle of the diagonal panel strut.

Many authors proposed different formulations for the diagonal panel strut width[22]. According to Mainstone (1974), it can be calculated by the following equation:

$$\frac{w_w}{d_w} = 0.17 \lambda_h^{-0.4} \quad (2)$$

Where w_w , d_w are width and inclined length of the diagonal strut.

The four branches, i.e., cracking, maximum force, failure, and residual force shown in figure 1, are described sequentially by the following equations.

It is expedient to start from the maximum force and the corresponding displacement:

$$F_{w\theta} = f_w \cdot t_w \cdot w_w \quad (3)$$

$$\delta_{w\theta} = \frac{f_w}{E_{w\theta}} d_w \quad (4)$$

where, f_w , t_w and w_w are the compression strength of the wall along the diagonal direction, the wall thickness, and the strut width, respectively, and $E_{w\theta}$ is the elastic modulus along the diagonal direction at angle θ , given by the following equation [26]:

$$E_{w\theta} = \left[\frac{\cos^4 \theta}{E_{mh}} + \frac{\sin^4 \theta}{E_{mv}} + \cos^2 \theta \sin^2 \theta \left(\frac{1}{G} - 2 \frac{\nu}{E_{mh}} \right) \right]^{-1} \quad (5)$$

Where E_{mh} , E_{mv} are the horizontal and vertical elastic moduli of masonry walls, respectively, G is the masonry shear modulus, and ν is the Poisson ratio.

The cracking force of the infill and the corresponding displacement at the onset of the first branch of figure 1, can be found as:

$$F_{e\theta} = \frac{F_{w\theta}}{2} \quad (6)$$

$$\delta_{e\theta} = \frac{F_{e\theta}}{2K_{w\theta}} \quad (7)$$

Where $K_{w\theta}$ is the diagonal strut axial stiffness, calculated as:

$$K_{w\theta} = \frac{E_{w\theta} t_w w_w}{d_w} \cos^2 \theta \quad (8)$$

Where θ is the strut angle.

The failure force and the corresponding displacement at the end of the third branch of figure 1 can be found as:

$$F_{wu\theta} = \mu (f_m t_w w_w) \quad (9)$$

$$\delta_{wu\theta} = 0.005 \frac{h_w}{\cos \theta} \quad (10)$$

Where, μ , f_m , t_w , and w_w are friction coefficient between mortar and brick surface, mortar compressive strength, wall thickness, strut width, respectively, and h_w is the infill wall height.

Finally, the last point of residual force is proposed as:

$$F_{u\theta} = \frac{F_{w\theta}}{10} \quad (11)$$

$$\delta_{u\theta} = 18 \delta_{w\theta} \quad (12)$$

Having calibrated the strut model, in the following section it is applied in the comprehensive modeling of an infilled frame reinforced concrete building, selected as a case study.

3 CASE STUDY

The selected case study considers an IRC three-story factory building situated in Mirpur city, Pakistan, which was severely hit by the earthquake on 24 September 2019. The factory building is 17.7 km away from the epicenter. The model of the building and a satellite image are shown in figure 2. According to the acquired information, the building was designed in 1986, when the code did not enforce any seismic provisions. As per common practice in the country, infill walls were considered as non-structural components.

Figure 2. Model of the selected factory building (left) and satellite image location of the building from the epicenter (right)

According to the detailed site visits and survey reports of the building, some cracks were observed in the beams, columns and their joints whereas the infill walls are badly damaged, as shown in figures 3-6.

The overall in-plane dimensions of the building are 94.91 m \times 24.38 m and the typical inter-storey height is 3.66 m. It consists of three blocks, i.e., storage, manufacturing, and office at the back, center, and front, respectively. The infill walls are 228 mm (9 inches) thick made of solid fire burnt clay bricks. The geometry of beams and columns are rectangular with variable sizes depending on their location and ranging from 228 mm \times 457 mm to 228 mm \times 2438 mm and 305 mm \times 305 mm to a maximum of 381 mm \times 381 mm.

Figure 6. Cracks in column due to the presence of opening in infill (right) severe cracks in infill on the frame selected for analysis (left)

4 NUMERICAL MODELS

A 2-D frame is considered, pertaining to the office block where maximum damages in the infill walls were observed. Nonlinear static pushover analysis was performed considering two configurations: bare frame (BF) as reference, and infilled frame (IF). The foundation plan, the elevation of the selected frame having five equal bays of length 4.88m, equal inter-story height of 3.66m and the geometry of beams and columns are shown in figures 7-9.

Figure 7. Foundation plan of the building and, highlighted, the frame selected for analysis

Figure 8. Frame selected for analyzing the infills (left), bare frame (right)

Figure 9. Section of columns (left), first-floor beam (center), second-floor beam (right)

The frame was modeled in SAP2000 where frame elements were used for beam-column elements and nonlinear multilinear elastic link with the proposed model properties were used for the infills. Mander (1988) [27] model was used for confined and unconfined concrete within the cross sections of the structural elements. From the available drawings and design specifications of the building, the characteristic values of compressive strength of the brick unit, brick masonry, mortar, concrete, and yield strength of steel are set as 8 MPa, 4.3 MPa, 5 MPa, 20 MPa, and 400 MPa, respectively, which are commonly used properties in the country [2], [1], [24], [28], [29]. Other materials properties, such as friction coefficient between mortar and brick surface, and Poisson ratio are considered as 0.3 and 0.14, respectively. The models of IF and BF are shown in figure 10.

Figure 10. Models considering different configurations: infilled frame (left) bare frame (right)

5 RESULTS AND COMPARISON WITH IN-SITU OBSERVED DAMAGE

Detail surveys and site inspections of the building after the earthquake showed that the RC elements were not significantly damaged by the earthquake action. As shown in the figures 3-6, some beams and columns were partially damaged, however, most of the damages were observed in the infill walls. In fact, they sustained a large portion of the horizontal forces and, consequently, increased significantly the stiffness and strength of the building, thus preventing the structural components from failing. In this case, the presence of the infills was beneficial to the overall performance of the structural elements. The BF model predicted much higher damage in the structural elements, while the IF model, thanks to the inclusion of the proposed struts, showed good agreement with the observed damage in the structure.

From the quantitative standpoint, the resulting capacity curves of IF and BF can be appreciated in figure 11. It is noticed that IF has an almost 3 times larger strength than BF, provided by the presence of the infills. Also, the initial stiffness increased 11 times, which resulted in a 70% decrease of the fundamental vibration period. It was also observed that drift ratio, top story drift, and ductility of IF compared to BF decreased by 60%, 7%, and 40% respectively. Using the ATC-40 capacity spectrum method, it was possible to ascertain that the presence of the infills allowed the IF performance to increase up to 130% with respect to BF.

Figure 11. Capacity curves of the bare frame (solid line) and of the infilled RC frame (dashed line)

The IF model allowed to correctly detect the presence of the most relevant in-plane failure mechanisms in the infill walls, such as, diagonal cracking, corner crushing, bed sliding/shear failure (figures 5-6). This was highlighted by the behavior of the strut elements, which got damaged in the same locations observed in the building. It was also confirmed that the infill walls stiffen the frame and thus reduce the damage in the reinforced concrete elements. Finally, as a last remark, it was confirmed that if the infill walls are made with bricks having strength higher than the mortar strength, an additional friction-related energy dissipation develops during cyclic loading, thus reducing the overall response of the structure and thus avoiding brittle failures in the bricks. This important phenomenon, which has two-fold beneficial consequences, is naturally accounted for in the proposed model through the use of the basic parameters of friction coefficient between mortar and brick surface and mortar strength

6 CONCLUSIONS

The following conclusions can be drawn from the study presented in this paper:

- The analysis results obtained from numerical model show good agreement with the observed in-situ failure pattern on the case study building.
- The analysis results show that the seismic performance of the selected building is correctly predicted by including an appropriate model of the infilled frame.
- In-situ observation and analysis results confirm that infill walls have strong influence on the seismic performance of building. Therefore, types of infill walls, material used and mechanical characteristics of materials are important to consider when deal with IRC frame structures, especially in Pakistan where this practice is not commonly applies.
- Strength and stiffness of the selected IRC building considerably increased with infill walls while less ductile failure is observed. Therefore, effect of infill walls should be carefully accounted for in appropriate models, both in designing new structures and in assessing existing structures.
- The proposed numerical model considers the effects of commonly ignored yet important parameters such as friction coefficient between mortar and brick surface and mortar strength, which is simple to apply and requires less computation efforts as compare to more detail models, thus, helping practitioners and structural engineer to deal with IRC structures.

Abstract

Fragility assessment of unreinforced masonry (URM) infill walls under seismic loads is a current research topic for large scale risk analysis of reinforced concrete frame structures. In this paper, Out-of-Plane (OoP) fragility functions are developed by probabilistic approach based on Monte Carlo simulations employing a numerical macro-element model for the evaluation of the OoP capacity of infills. Uncertainties in the capacity were considered depending on the level of In-Plane (IP) damage and the variability in the geometrical and mechanical properties of the masonry infills. The fragility functions are therefore obtained considering the variability in the capacity instead of the seismic input as for other studies, considering also their sensitivity to the position in low rise buildings.

Keywords: Fragility, Macro-element model, URM infill, Out-of-plane, IP-OOP interaction.

1 INTRODUCTION

Seismic risk mitigation for reinforced concrete (RC) structures requires the use of reliable strategies for the evaluation of the seismic capacity in view of performing large scale analysis [1]. RC structures exhibit often significant structural and non-structural damage when subjected to medium-to-strong ground shakings. Retrofitting strategies as well as energy dissipation and isolation can be considered effective strategies for the improvement of the seismic behavior of load bearing frame elements such as beams or columns [2-12]. However, non-structural damage related to elements such as infill walls is often neglected in the evaluation of the overall structural behavior.

Damages in infills result in huge economic loss due to a significant downtime and repair cost [13]. Particularly, out-of-plane (OoP) failure can be a big threat to human life. Such infill walls resulted to be highly vulnerable to in-plane (IP) and out-of-plane (OoP) actions caused by seismic loads in past and recent earthquakes [14, 15] and it has been confirmed by a number of experimental studies that OoP capacity of the infills reduce as the IP damage increases [16-20].

Fragility functions are important tools to estimate the probability of OoP collapse of infill walls. But very few works have been done in this direction, often limited because of the computational effort in analyzing a huge number of cases due to variations in infills' properties as well as the IP-OoP interaction [21-23]. Some of the available fragility curves were developed by using macro-element models considering the IP-OOP interaction in determining the OoP strength of infill walls [24-31].

Another important aspect is that the most of the available fragility functions were derived considering the variability in the ground motions (uncertainties in the demand) without taking into account uncertainties in the capacity due to the variability of infill mechanical and geometrical properties and, at the same time, the IP-OoP interaction: this is the main aim of this study for the case of low-rise buildings.

The novel contribution of this work is therefore to consider the variability of the capacity of infills by employing a probabilistic approach based on Monte Carlo simulations including the uncertainties in the mechanical and geometrical properties instead of the variability in the seismic input. The macro-element model proposed by Pradhan and Cavaleri [28] has been used for numerical analysis. The probabilistic approach allowed to consider the uncertainty in the infills' strength and geometric features as well as the uncertainty in the IP drift (inter-storey drift ratio) during an earthquake. Fragility curves have been derived for infill walls built with two types of masonry units (hollow and solid) and interested by three different levels of IP damage: low, medium and high corresponding to three ranges of IP-drift. The fragility curves proposed in this study refer to infills positioned at different floors of low-rise RC frame buildings.

2 PROCEDURE PROPOSAL TO DERIVE FRAGILITY CURVES

2.1 Theoretical framework

For the derivation of OoP fragility curves of masonry infill walls, a probabilistic approach employing a specific range of variability for the input parameter has been implemented by using Monte Carlo simulation. The outputs are therefore affected by random assumption over a range of representative input cases.

To reproduce the physical process using a probabilistic approach, first, a cycle of IP demand randomly assigned is applied to an infilled frame with random geometrical and mechanical characteristics, and then the infill is pushed in OoP direction to determine the capacity

and consequently the Peak Ground acceleration (PGA). Monte Carlo methodology includes the following steps:

- 1) Random generation of variables such as the thickness and strength of masonry, IP displacement demand, etc.;
- 2) Calculation of OoP capacity by a macro-element model in OpenSees [32];
- 3) Determination of the equivalent OoP pseudo (spectral) acceleration;
- 4) Derivation of the PGA associated to the pseudo acceleration;
- 5) Determination of the probability of exceedance of OoP collapse and obtaining of the fragility for a given case study.

The above procedure was implemented first in Matlab code for the generation of a random input variables' matrix characterized by a certain number of cases; then, the random matrix was linked to OpenSees [32] to perform numerical analyses, getting the matrix of the results corresponding to each case of analysis. The results obtained by OpenSees were the maximum OoP forces and the corresponding displacements. Additionally, the value of forces, corresponding to one-third of the maximum ones, and the associated OoP displacements, were extracted for each analysis to derive OoP stiffness of the infills.

2.2 Range of parameters and base assumptions

Two fragility groups have been defined for URM infill walls: a) infill with solid masonry units (isotropic property), and b) infill with hollow masonry units (orthotropic property). Additionally, the fragility has been sub-grouped according to the level of IP damage as: low, medium and high (0-0.7%, 0.7-1.4% and 1.4-2% respectively) and the aspect ratios of infills (1.0, 1.25, 1.50 and 1.75). Only one damage state has been considered in the OoP direction i.e. the damage state of collapse. The masonry infill collapse in OoP direction is immediately identified by the OoP pseudo acceleration equal to the ratio between the OoP strength and mass. However, as before-mentioned, the Peak ground acceleration (PGA) has been taken as an Engineering Demand Parameter for the fragility assessment.

Infill walls are bounded by square columns of size 300 mm×300 mm and 300 mm×400 mm beams at top and bottom. Columns are provided with 8 @18 mm longitudinal rebars while the beams have 3 @16 mm rebars at top and bottom. The concrete in the frame members is confined by rectangular stirrups (@ 8 mm) kept at a spacing of 75 mm. The effect of confinement, - provided by the steel reinforcement, as suggested in [33, 34], has been taken in to account according to Mander's model [35]. The yield strength of reinforcement steel is taken as 500 MPa.

For the solid masonry, minimum thickness of infill has been kept as 100 mm while the maximum thickness is assumed to be 200 mm and for the hollow masonry, the thickness was varied from 100 mm to 300 mm. For sake of simplicity, for infill walls built with solid masonry units, the mechanical properties of masonry are assumed as isotropic. In case of masonry with hollow masonry units, orthotropic properties are considered. Elastic modulus of masonry material is assumed as 1000 times the value of compressive strength in both isotropic and orthotropic cases. The main characteristics of the random variables are shown in Table 1. An example of distribution of the compressive strength of masonry for orthotropic and isotropic masonry cases is shown in Fig. 1 a-b.

For each case of low, medium and high IP damage and for each different case of aspect ratio of infill wall, 400 different random samples were generated. Inter-storey drift ratio (IDR) imposed on the infill wall is taken as a measure of IP damage. In Fig. 2a, a sample distribution of IDR to consider three different levels of IP damage is shown while in Fig. 2b, the distribution of the masonry thickness for the case of solid and hollow unit masonry is shown.

Variable	Property	Distribution features
Strength of concrete	Uniform distribution	
	Min (MPa)	20
	Max (MPa)	30
IP damage	Uniform distribution	
	Low level (%)	IDR 0 to 0.7
	Medium level (%)	IDR 0.7 to 1.4
Thickness of solid masonry	Uniform distribution	
	Min (mm)	100
	Max (mm)	200
Thickness of hollow masonry	Uniform distribution	
	Min (mm)	100
	Max (mm)	300
Strength of solid masonry (Isotropic behavior)	Gaussian distribution	
	Min (MPa)	3.0
	Max (MPa)	7.0
	Mean (μ)	5.0
Strength of hollow masonry (Orthotropic behavior)	Gaussian distribution	
	Min (MPa)	1
	Max (MPa)	6
	Mean (μ)	3.5
	Standard deviation (σ)	1.0

2.3 Macro-element modeling of the URM infill walls

The capacity of the panels has been calculated by using macro-element model by Pradhan and Cavaleri [28]. The model consists of four struts (two diagonals, one horizontal and one vertical). The model was validated with results of different experiments [16-18, 29, 36] covering the range of infills' geometrical and mechanical characteristics. Each strut in the model is represented by two fiber-section beam-column elements connected by a node at the mid-span (Fig. 3).

Figure 3: Macro-element model (Pradhan and Cavaleri 2020)

In the model, the width of the diagonal struts w_d is defined as one-third of the diagonal length d while the widths of the horizontal strut w_h and vertical struts w_v are calculated as a function of w_d in the following ways:

$$w_d = d/3 \quad (1)$$

$$d = \sqrt{l^2 + h^2} \quad (2)$$

$$w_h = h - w_d / \cos \theta \quad (3)$$

$$w_v = l - w_d / \sin \theta \quad (4)$$

where l and h are the length and height of the infill wall respectively, while l' indicates centre to centre distance between the columns and h' indicates the height of infill plus half the height of top beam and θ is the angle defining the slope of the diagonal struts. In the model, to represent both IP and OoP resistances of the infill wall more accurately, the width and thickness of the diagonal, vertical and horizontal struts were replaced by the surrogated values. For any of the struts with width w and thickness t , surrogated width \bar{w} and surrogate thickness \bar{t} are derived in the following ways:

$$\bar{w} = \frac{f_{mo}}{f_m} \times w \quad (5)$$

$$\bar{t} = \frac{f_m}{f_{mo}} \times t \quad (6)$$

The mechanical properties of the strut fibres in compression are defined by using four stress strain parameters, namely, f_{mo} , f_{mu} , ε_{mo} and ε_{mu} as shown in Fig. 3. These numerical parameters can be calculated based on two different mechanical properties of masonry i.e. the equivalent compressive strength f_m and equivalent elastic modulus E_m , according to the equations provided in Pradhan and Cavaleri [28].

The equivalent properties of masonry, namely f_m and E_m , are derived by taking into account the directional properties following the Eqs. 7-8.

$$f_m = \sqrt{f_{mv} \times f_{mh}} \quad (7)$$

$$E_m = \sqrt{E_{mv} \times E_{mh}} \quad (8)$$

where f_{mv} and f_{mh} represent the masonry's compressive strength in vertical and horizontal directions and E_{mv} and E_{mh} indicate the masonry's elastic modulus respectively in two directions respectively. This provision facilitates the model to consider the orthotropic nature of masonry. The definition of f_m and E_m is purely conventional and this technique relates well with the equivalent strut stress-strain parameters to be used in the model.

For the current study, in case of solid masonry units, the equivalent properties of masonry are derived considering itself as isotropic ($f_{mv} = f_{mh}$ and $E_{mv} = E_{mh}$) and for the case of hollow units as orthotropic. The numerical modelling was performed in OpenSees platform. The concrete and infill materials were modelled by using Concrete02 material, while the steel reinforcement was simulated by using Steel02 material available in OpenSees. The numerical model of any infilled frame was prepared by interfacing Matlab to OpenSees, the former allowed the generation of each set of random parameters. To consider the effect of IP damage in the OoP capacity, IP load was applied to achieve randomly generated IDR demands before the application of OoP load. IP displacement demand was imposed at the top of the infilled frame while OoP load was applied to the centre of the equivalent struts. The OoP capacity of infill walls considering the effect of IP-OoP interaction was thus estimated for all cases investigated.

2.4 Evaluation of PGA from the response spectrum

For a given case, in evaluating the approximate capacity in terms of pseudo (spectral) acceleration, the OoP strength is divided by the mass of the infill wall. In calculating the mass of the infill, density of solid masonry is assumed to be 1900 kg/m^3 in average while for hollow masonry it is assumed as 900 kg/m^3 . Each pseudo (spectral) acceleration can be associated to a PGA by the demand spectra.

Demand spectra for non-structural elements like infills depend upon their position along the height of a building, the fundamental period of the infill and the fundamental period of the building [37, 38]. According to the Italian Building Code 2018 [37], the expression of the demand spectrum $S_a(T_a, T_1, Z/H)$ is given as:

$$S_a = \begin{cases} \left[PGA \left(1 + \frac{Z}{H} \right) \frac{a_p}{1 + (a_p - 1) \left(1 - \frac{T_a}{aT_1} \right)^2} \right] \geq PGA & \text{for } T_a \leq aT_1 \\ PGA \left(1 + \frac{Z}{H} \right) a_p & \text{for } aT_1 \leq T_a < bT_1 \\ \left[PGA \left(1 + \frac{Z}{H} \right) \frac{a_p}{1 + (a_p - 1) \left(1 - \frac{T_a}{bT_1} \right)^2} \right] \geq PGA & \text{for } T_a \geq bT_1 \end{cases} \quad (9)$$

In the above expression, T_a is the fundamental vibration period of the infill wall, T_1 is the fundamental vibration period of the building, H is the height of the building, and Z is the level at which the infill is located. In Eq. 9, PGA is expressed in g (gravity acceleration). In the present work, the fundamental period of the building is evaluated by means of a simplified equation as follows:

$$T_1 = c \cdot H^{3/4} \quad (10)$$

c being a coefficient depending on the type on the material (0.075 for RC structures). In Eq. 9, the parameters a , b and a_p define the interaction between the infill and the structure depending on the fundamental period T_1 according to Table 2 [39].

	a	b	a_p
$T_1 < 0.5 \text{ s}$	0.8	1.4	5.0
$0.5 \text{ s} < T_1 < 1.0 \text{ s}$	0.3	1.2	4.0
$T_1 > 1.0 \text{ s}$	0.3	1.0	2.5

Table 2: Parameters for the response spectrum interaction.

Once the period of the panel T_a and the fundamental period of the structure T_1 are obtained, by imposing the equivalence between the spectral acceleration $S_a(T_a, T_1, Z/H)$ and the pseu-

do-acceleration obtained numerically (that is the infill OoP capacity), it is possible to use Eq. (9) to derive the PGA associated to the infill OoP capacity.

2.5 Evaluation of the fundamental period of the panel

Two different approaches were made in view of calculating the fundamental period of the panel in the OOP direction:

1. By analytical approach proposed by the Italian Building Code 2018 suggestions [37]
2. From the numerical model based on the results of the analyses in terms of stiffness.

Regarding the analytical approach, the fundamental period T_a of the masonry infill in the out-of-plane direction is calculated by the expression given in Eq. (11), where m_w is the mass of the infill per unit height h , E_w is the vertical modulus of elasticity of masonry and I_w is the moment of inertia of the infill horizontal cross section with respect the line obtained as intersection of the middle plane of the infill and the horizontal cross section. Eq. (11) is:

$$T_a = \frac{2h^2}{\pi} \sqrt{\frac{m_w}{K_{red} \cdot E_w \cdot I_w}} \quad (11)$$

It is to be noted that, in evaluating the period of the panel, the reduction in the flexural stiffness due to the IP damage has been considered to obtain a more realistic prediction. To do so, the coefficient K_{red} for the OOP stiffness reduction proposed by Cavaleri et al. [40] was used, that is:

$$K_{red} = [\min(1; 0.17 IDR^{-0.67})] \quad (12)$$

being IDR the inter-storey drift in percentage experienced/assigned by/to the panel in IP direction. The above equation was validated by the authors against a range of experimental and numerical cases.

The second approach is based on the results provided by the numerical analysis depending on the effective stiffness evaluated at one-third of the OoP maximum force and the corresponding displacement. In detail, the numerical period is calculated by using the well-known formula for one degree of freedom system (the equivalent one dof system is that described by the OoP displacement in the center of an infill and the corresponding restoring force) as follows:

$$T_a^* = 2\pi \sqrt{\frac{M^*}{K_{num}}}, \quad K_{num} = \frac{F_{\max, OOP/3}}{\delta(F_{\max, OOP/3})} \quad (13)$$

In calculating the vibration period, the participating mass M^* corresponding to the first OoP mode of vibration of the infill has been taken as 50% of the total mass of the infill wall. As regard to this choice, different values have been adopted in the literature [21, 22, 23, 29, 31]. The affinity of currently used model with the study of Di Trapani et al [23] oriented such choice of assuming 50% first mode mass in this study.

2.6 Determination of the probability of exceedance of OOP collapse, and obtaining of the fragility for a given case study

Fragility curves are cumulative distribution functions that represent the probability of exceedance of a certain damage state (DS) for a given type of building/structural element over a range of an intensity measure IM (in the context of the present work, the Peak Ground Acceleration “PGA”). A log-normal distribution function can be and is here assumed for the fragility associated to the collapse state according to the following expression:

$$P[DS / IM] = \phi \left(\frac{\ln(IM) - \ln(\overline{IM})}{\beta} \right) \quad (14)$$

where ϕ is the standard normal cumulative distribution function, \overline{IM} refers to a median value and β is the log-standard deviation that accounts for the uncertainties in the capacity of the building/structural element fragilities for the collapse damage state.

In the present study, the uncertainties were assigned for i) the strength of concrete of the reinforced concrete frame surrounding an infill, ii) level of IP damage, iii) thickness of infill, and iv) compressive strength of masonry, employing different distributions of variables. It allowed the evaluation of the median and the log-standard deviation in the results.

3 RESULTS

The fragility curves were obtained in this work assuming low-rise reinforced concrete buildings i.e. 3-storey moment resisting RC frame structure with an inter-storey height of 3 m (total height of the building is 9 m) for which the fundamental period resulted 0.39 sec (Eq. 10). In this context, the fragility was evaluated considering also the influence of the position of the panel with respect to the floors of the structure, evaluating the PGA at collapse state for infill walls placed at the ground storey (first floor) and at the top storey (third floor) of the reference structure.

In the following description of the results, the analyses were labelled depending on the type of masonry (i.e. iso and ortho for solid and hollow masonry respectively), the level of IP damage (i.e. ld, md, hd for low, medium, and high IP damage respectively), the aspect ratio in terms of length-to-height (1.0, 1.25, 1.5, 1.75) and the positioning of the panel with respect to the structure (I and III for the first and the third floor respectively). As an example, the fragility curve iso_ld_1.0_I indicates the fragility for an infilled wall made with solid masonry units, with low IP damage for a panel with aspect ratio 1.0, placed at the first floor, while, the fragility curve ortho_hd_1.5_III indicates the fragility for an infilled wall made with hollow masonry units, with high IP damage for a panel with aspect ratio 1.5, placed at the third floor.. In addition, I or I* and III or III* it is used respectively to give distinction between results calculated by using the period calculated by Eq. (11) (analytical evaluation) or Eq. (13) (by numerical results).

3.1 Influence of the fundamental period in the evaluation of the PGA

The PGAs obtained by using the two different approaches before mentioned for the evaluation of the vibration period of infills in the OoP direction were compared highlighting the sensitivity to the interaction with the response spectrum. In this comparison, the infills placed at the third floor of the low rise reference structure were considered.

First, it has to be noticed that, as expected, the OoP pseudo acceleration as well as the PGA decrease with the increasing level of IP damage and the increasing of the aspect ratio. For a given level of IP damage, infill panels with aspect ratio 1.0 provided higher OoP capacity than panels with aspect ratio 1.25, 1.5 or 1.75. At the same time, for a given value of aspect ratio, infill panels experiencing low levels of IP damage (0.0-0.7%) showed higher capacity compared to that obtained by increasing the level of IP damage (medium and high – drift in the ranges 0.7-1.4% and 1.4-2.0% respectively).

Another consideration has to be done regarding the different responses obtained depending on the type of masonry walls. Overall, it was noticed that hollow masonry showed PGA values higher than solid masonry. This is due to the higher thickness coupled with a low mass of the panels that provided higher pseudo-accelerations and lower vibration periods. Table 3

shows the results for each case of analysis in terms of median values of the PGA and mean values for the vibration period for the two approaches. It is reminded that T_a and T_a^* refer to vibration period calculated by Eq. (11) and Eq. (13) respectively.

At the same time, the vibration period of the panels is affected by the IP damage and aspect ratio. The increasing of the vibration period leads to a different positioning in the response spectrum. It was noticed that with the increasing of the level of IP damage and the increasing of the aspect ratio, the vibration period of the panel increases too and in some cases, it changes from the first branch of the response spectrum ($T < aT_I$) to the second ($aT_I < T < bT_I$). This requires to use a different equation in evaluating the PGA as shown in Eq. (9). This was observed in most of the analysis cases. Having said this, by using Eq. (11), the period of vibration is not much affected by the aspect ratio but only by the level of IP damage. Conversely, by using Eq. (13), the vibration period is significantly influenced both by aspect ratio and IP damage level because the numerical model takes into account the change in stiffness directly. This causes high scatter between T_a and T_a^* that can make the former up to two times the latter. These variations are clearly highlighted in Fig. 4 and Fig. 5 for hollow and solid masonry units respectively. For the above-described reasons, in the subsequent results regarding the evaluation of the fragility curves, it was assumed to evaluate the PGA by using the vibration period calculated from the numerical data to obtain more reliable results.

3.2 OoP fragility curves

The OoP fragility curves obtained by means of the proposed procedure are shown focusing on the influence of the different assumptions during the investigation, which are:

- aspect ratio;
- level of IP damage;
- positioning of the infill panel with respect to the structure;
- type of masonry (solid and hollow units).

The results in terms of fragility curves obtained for solid and hollow units are shown for panels placed at both the first floor and the third floor, considering all the three levels of IP damage (low, medium, high), depending on the aspect ratio of the infill walls. In detail, Figs. 6-7 show the comparisons for given aspect ratio, while Figs. 8-9 show the comparisons for

given range of IP damage. The median and standard deviation values obtained for each case of analysis are shown in Table 4.

The fragility for the panels placed at the top of the reference structure (third floor) resulted to be higher compared to that at the base (first floor) for the same level of IP damage. At the same time, the fragility appeared higher when the level of IP damage and the aspect ratio increased. Overall, what above described was observed for both types of infills made with hollow and solid masonry units. In detail, for aspect ratio 1.0, the PGA (median) values at the first and the third floor resulted of 4.24 g and 2.70 g for the infills with solid units, while for the case of hollow masonry units, the PGA resulted in 7.52 g and 4.78 g respectively. By increasing the aspect ratio from 1.0 to 1.75 and by increasing the level of IP damage from low to high, it was observed that the PGA values dropped to 0.40 g and 0.32 g for the solid masonry units and 0.86 g and 0.55 g for the hollow units. This resulted to be very important in view of showing the high variability in the results depending upon different assumptions.

Based on the results, it can be stated that, in the absence of previous IP damage, the infilled frames provide a high strength and high PGA in the out-of-plane direction. Consequently, lower vulnerability is obtained. On the other hand, in the presence of previous IP damage, regardless of whether it is medium or high, the strength in the OoP direction drops to critical values, providing to the infilled frames very high vulnerability for low values of PGA especially at higher floors and for high values of aspect ratio. To clarify better what above described, the fragility curves for infilled frames with different aspect ratio at high level of IP damage, placed at the top of the reference 3-storey RC structure, are shown in Fig. 10 for both type of masonry walls (solid and hollow units).

4 CONCLUSIONS

This paper presented a procedure for the derivation of infill walls out-of-plane fragility functions for low rise RC buildings with respect to the Peak Ground Acceleration (PGA) at collapse. A probabilistic procedure was employed based on Monte Carlo simulations, generating random input variables such as geometrical and mechanical characteristics of the panels and in-plane damage, assuming significant variations. Differently from available studies dealing with infill walls OoP fragility, the novel contribution of the present work was to take into account the uncertainties the capacity instead of in the demand. In evaluating the results, different aspects were investigated such as the influence of the aspect ratio, the influence of the level of IP damage, the influence of the positioning of the infill panel with respect to the structure and the influence of the type of masonry (solid and hollow units).

The results indicated that the OoP fragility of the infill walls increases as the level of IP damage increases as well as for the increasing of the aspect ratio. In the presence of previous IP damage, regardless of whether it is medium or high, the strength in the OOP direction drops to critical values, providing very high fragility for low values of PGA. In addition, for a given level of IP damage and aspect ratio at all floor levels from bottom to the top, the probability of collapse resulted to be higher for panels placed at the top of the structure than those placed at the base of the structure, where the pseudo acceleration of the structure is higher too.

Moreover, for the ranges assumed in this study, high PGA at collapse i.e. lower fragility was observed for infill walls made with hollow masonry units in comparison to infills made with solid masonry units.

Abstract

The assessment of out-of-plane resistance of infilled frames is an issue of primary importance, in fact, post-earthquake damage observations have shown that infills subject to combined in-plane and out-of-plane inertial forces may fail out-of-plane. This collapse mode results particularly dangerous for the safety of people in the proximity area of a building subject to earthquake loads. Therefore, the possibility to perform accurate safety evaluations is fundamental to prevent this kind of failures. Available expressions for the evaluation of out-of-plane resistance of infilled frames are based on too restricted or too large datasets of experimental investigations. Because of this, such expressions are many times conflicting, showing good reliability in some cases and less in others. In order to fill this gap, this paper proposes a new data-driven empirical expression estimating OOP resistance of infilled frames. This expression is based on hybrid data-set, merging experimental data with data from numerical simulations obtained from a refined FE micro-model. The new expression has the advantage to take into account both the aspect ratio of the infilled frame, the influence of vertical loads and the mode of application of the OOP load. Validation tests are finally carried out against experimental and numerical specimens.

Keywords: ABAQUS, empirical, FEM, Masonry, Infilled Frames, Reinforced concrete, Data-driven

1 INTRODUCTION

The evaluation of out-of-plane (OOP) resistance of infilled frames is an issue of primary importance in the assessment of seismic risk of frame structures. In fact, even if infills are not primary structural elements, they strongly interact with primary structures undergoing in-plane (IP) damage and therefore becoming more vulnerable against out-of-plane forces. OOP failure of infills is quite dangerous to the safety of people who are around a building during an earthquake. Simple and at the same time reliable verification methods are therefore necessary to engineers to perform safety checks of OOP resistance of masonry infills.

Experimental and numerical studies have been carried out in recent years to investigate the behaviour of infilled frames subjected to combined in-plane and out-of-plane (IP + OOP) actions [1-8]. These studies converged in claiming that, following a seismic event, infill panels are weakened due to in-plane actions and combined IP and OOP cracks lead to different potential damage, ranging from the loss of functionality of the infill to its complete collapse. It should be also observed that infills with moderate-to-low slenderness and well restrained at the sides, can develop significant resistance and displacement capacity because of the arching mechanism and two-way bending effect which develops under out-of-plane actions. Several studies addressed specifically out-of-plane resisting mechanism [1,4,5,7,9-18], developing different formulations estimating OOP resistance to perform safety checks [1,18-24]. Although starting from similar theoretical consideration, results provided by these models are often conflicting [24], giving the impression that some of them are more reliable in some cases and less in others. The recognized difficulty of analytical models to achieve a general validity is due to three major aspects: a) large heterogeneity masonry constitutive materials and different potential combination with the boundary frames in terms of aspect ratio, slenderness, relative strength and stiffness; b) limited experimental background (e.g. with respect to in-plane tests); c) different OOP test loading condition (e.g. 4-point OOP test or airbag uniform pressure test). Because of these uncertainties, the definition of a generalized relationship providing a good estimation of the OOP resistance of masonry infill is still a needed.

Considering the aforementioned aspects, this paper proposes a new empirical expression estimating OOP resistance of infilled frames. The formulation of the new predictive model is based on a hybrid data-set collecting data from real experimental tests and numerical tests from a refined FE model realized in Abaqus environment which has been experimentally calibrated and validated. Parametric analyses on the FE model were carried out to generate additional reference numerical tests investigating the effect of the variation of mechanical, geometric and load conditions on the ultimate OOP resistance. A reliability comparison with available literature model is finally presented.

2 CONSIDERATIONS ON LITERATURE DESIGN MODELS FOR THE EVALUATION OF OUT-OF-PLANE RESISTANCE OF MASONRY INFILLS

For the sake of space a selection of only four literature models is presented. To make the different formulations comparable, they are expressed in terms of OOP force, by multiplying the ultimate pressure by the area of the infill ($w \times h$). One of the most popular expressions for the estimation of the ultimate OOP load capacity of an infilled frames (F_{OOP}) was proposed by Angel, 1994 [1] and Abrams et al., 1996 [9].

Those studies evaluated the out-of-plane resistance of masonry infills as a function of the degree of in plane damage. Results brought a formulation able to take in consideration the effect of previous in-plane damage and the effect of frame stiffness according to the following formulation:

$$F_{OOP} = \frac{2f_m}{(h/t)} \cdot \lambda \cdot R_1 \cdot R_2 \cdot w \cdot h \quad (1)$$

where f_m is the vertical compressive strength of the masonry expressed in [MPa] and h , w and t are the infill height, width and thickness respectively. The lengths are expressed in [mm]. Coefficients R_1 , R_2 and λ , are related to the degree of in-plane damage (Eq. 2), to the frame members flexural stiffness (Eq. 3) and to the infill slenderness (Eq. 4) respectively, so that:

$$R_1 = \left(1.08 + \left(\frac{h}{t} \right) \left\{ -0.015 + \left(\frac{h}{t} \right) \left[-0.00049 + 0.000013 \left(\frac{h}{t} \right) \right] \right\} \right)^{\Delta/2\Delta_{cr}} \quad (2)$$

$$R_2 = 0.357 + 2.49 \times 10^{-14} EI \leq 1.0 \quad (3)$$

$$\lambda = 0.154e^{-0.0985(h/t)} \quad (4)$$

in which Δ is the current previous in-plane relative displacement, Δ_{cr} is the same displacement associated with the formation of the first crack in the panel, EI is the flexural rigidity of the smallest element composing the concrete frame.

In the Eurocode 6 [22], the following formulation, based on the one-way arching mechanism, is provided:

$$F_{OOP} = f_m \left(\frac{t}{h} \right)^2 \cdot w \cdot h \quad (5)$$

Symbols appearing in Eq. (5) have the same meaning of those previously described. In this formula the out-of-plane resistance has inverse proportionality with the square of the infill slenderness ratio. An adjustment of the prediction models in Eq. (5) has been provided by Ricci et al. 2017 [23], who corrected the expression with the introduction of empirical coefficients. The experimental dataset included the tests by Angel 1994 [1], Flanagan e Bennet 1999 [10,11], Calvi and Bolognini 2001 [12], Hak et al. 2014 [13] and Furtado et al. 2016 [14]. The obtained final formulation was:

$$F_{OOP} = 1.95 f_m^{0.35} \frac{t^{1.59}}{h^{2.96}} \cdot w \cdot h \quad (6)$$

where the lengths are expressed in mm.

More recently, Liberatore et al. 2020 [24] provided a further updated considering also the influence of the aspect ratio (h/l) on the infill with the following expression:

$$F_{OOP} = 0.26 f_m^{0.9} \frac{h}{l} \left(\frac{h}{t} \right)^{-1.23} \cdot w \cdot h \quad (7)$$

Previous studies (e.g. Liberatore et. al 2020 [24]) have shown significant scattering of predictive results from these expressions, but two major considerations have to be done. The first is that some of these expression (e.g. Angel et al. 1994 [1]) were based on a limited experimental dataset. The second is that is it not realistic thinking that these expressions can be reliable in predicting the OOP resistance even of infills with RC of steel frames and also of

confined masonry. Considering single categories would be more proper but, of course, this would reduce the experimental database. The strategy adopted in the following of the paper aims to consider only infills with reinforced concrete frames. A selected number of very complete experimental tests was considered to form the database. The latter is expanded through the definition of a numerical database that is generated based on refined FE model of infilled RC frame, experimentally validated. Details of the model definition are provided in the following section.

3 REFINED FE MICRO-MODEL

The refined FE micro-model was realized with the Abaqus [25] software platform. Masonry blocks constituting the infill were modelled individually as well as frame and reinforcement elements. Mortar joint between blocks and between blocks and columns were modelled by frictional interface elements. The reference experimental test used for the model definition and calibration is specimen 80_OOP_4E by Ricci et al. 2018 [5]. The reference test considers a hollow clay masonry infilled RC frame infill restrained at the four sides having dimensions 2350mm x 1830 mm and thickness 80 mm (Fig. 1a). The out-of-plane load was applied by imposing an out-of-plane displacement with an actuator equipped with four point-load devices (Fig. 1b). Mechanical properties of specimen materials are shown in shown in Table 1.

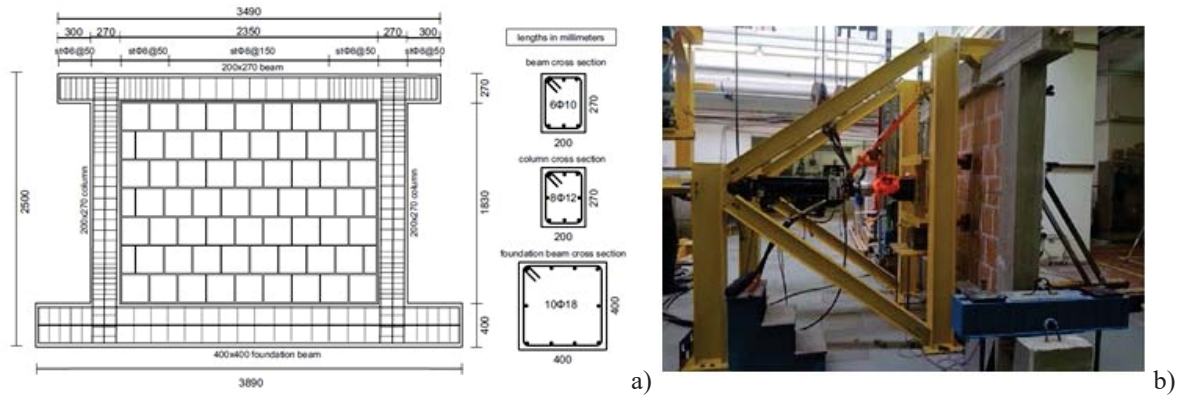

Figure 1: Specimen 80_OOP_4E by Ricci et al. 2018 [5]: a) Design details of the specimen; b) Test setup.

Mechanical properties	Symbol	Mean value (MPa)
Concrete compressive strength	f_{cm}	36.00
Steel rebars' yielding stress	f_{ym}	552
Masonry tensile strength	f_t	0.23
Bricks' compressive strength (parallel to holes)	f_{bh}	5.00
Bricks' compressive strength (perpendicular to holes)	f_{bv}	2.00
Mortar compressive strength	f_j	8.29

Table 1: Mechanical properties of the materials used in test 80_OOP_4E, Ricci et al. 2018 [5]

The concrete damaged plasticity model was used model the behaviour of brittle materials, namely concrete frame members and masonry blocks. The blocks were modelled as solid isotropic brick elements. To take into consideration the orthotropic behaviour due to the presence of hollows, a quadratic mean between the two compressive resistance in horizontal and verti-

cal direction of the block was used to define a unique reference conventional resistance value (\tilde{f}_b), so that:

$$\tilde{f}_b = \sqrt{f_{bh} \cdot f_{bv}} \quad (7)$$

where f_{bh} is the experimental horizontal compressive resistance of the unit and f_{bv} is the vertical one. The conventional elastic modulus of the blocks was estimated as a function of \tilde{f}_b , in analogy of what suggested in Eurocode 6 [22] for masonries, as:

$$\tilde{E}_b = 1000 \cdot \tilde{f}_b \quad (8)$$

The constitutive law used to define the compression behaviour of the block is of the parabolic type with a linear softening branch up to the ultimate strain ε_{cu} [26]. The model proposed by Hsu & Mo 2010 [27] was used to describe the tensile behaviour of the blocks. In Fig. 2 the constitutive laws adopted for the masonry units are shown.

Figure 2: Constitutive laws adopted for masonry blocks: a) Compressive stress- total strain response; b) Compressive stress-inelastic strain response; c) Tensile stress- cracking strain response.

The elastic and plastic parameters in Table 2 are used for the materials definition. As regards the angle of dilatancy for the concrete a value of 37° was assumed as suggested in [25], while for masonry an angle of 10° was adopted as suggested by Van der Pluijm et al. 2000 [28]. Plastic parameters regulating the eccentricity (ε), biaxial resistance domain f_{b0}/f_{co} , and viscosity were assumed as suggested in [25].

Material	Mass density ton/m ³	Elasticity parameters			Plasticity parameters			
		Young's modulus (MPa)	Poisson's ratio ν	Dilatation Angle ψ	Eccentricity ε	f_{b0}/f_{co}	K_c	Viscosity
Concrete	2.5E-09	32308	0.3	37	0.1	1.16	0.667	0.0003
Masonry bricks	1.10E-09	3160	0.2	10	0.1	1.16	0.667	0.0003

Table 2: Material properties of concrete and masonry blocks used in ABAQUS

Steel reinforcement was modelled using 1D truss elements whose mechanical response is simulated by a simple elasto-plastic with strain hardening material model. Steel rebars were modelled as embedded elements within the concrete, so that relative sliding between steel bars and concrete could not occur.

Mortar joints behaviour was modelled using elasto-plastic interfaces with friction and cohesion. The interface normal (k_{nn}) and transverse (k_{ss} , and k_{tt}) stiffnesses were obtained following a calibration process of the model. Obtained values are reported in Table 3.

Tangential	Normal	Stiffnesses (MPa)		
Friction coefficient	Hard contact	K_{nn}	K_{ss}	K_{tt}
0.6		200	88	88

Table 3: Interfaces mechanical properties.

All the model elements were modelled by solid 3D elements with 8 nodes (C3D8R) with a sufficiently refined mesh. Fig. 3 shows the scheme of the model assembly (Fig. 3a) and the mesh of the elements (Fig. 3b). A non-linear quasi-static analysis was performed to simulate the test. Out-of-plane displacements were imposed at the four loading plates.

Figure 3: Definition of the micromodel: a) Scheme of the model assembly; b) Mesh of the model,

Results of the numerical simulation of the OOP test are shown in Fig. 4 and compared with the experimental response. It can be observed that the model is able to effectively reproduce the experimental behaviour in terms of initial stiffness, peak resistance, and the post peak behaviour. The deformed shape of the model in correspondence of the peak load is also shown in Fig. 5.

Figure 4: Comparison between numerical simulation and experimental response of the OOP test 4E by Ricci et al. 2018 [5]

Figure 5: Deformed shape of the infilled frame micro-model in correspondence of the peak-load

The analysis allowed also an investigation in terms of stress distribution and damage localization. Figs. 6-7 show the compressive and tensile principal stresses on the windward and leeward sides of the specimen in correspondence of the peak load. The analysis of the stress field confirms that the model effectively reproduced the horizontal and vertical arching action and the 2-way bending response. A further comparison between tensile damage pattern resulting by the FE model at the ultimate displacement and real cracking pattern in shown in Fig. 8, confirming a certain consistency.

Figure 6: Compressive stress field at the peak load: a) windward side; b) leeward side.

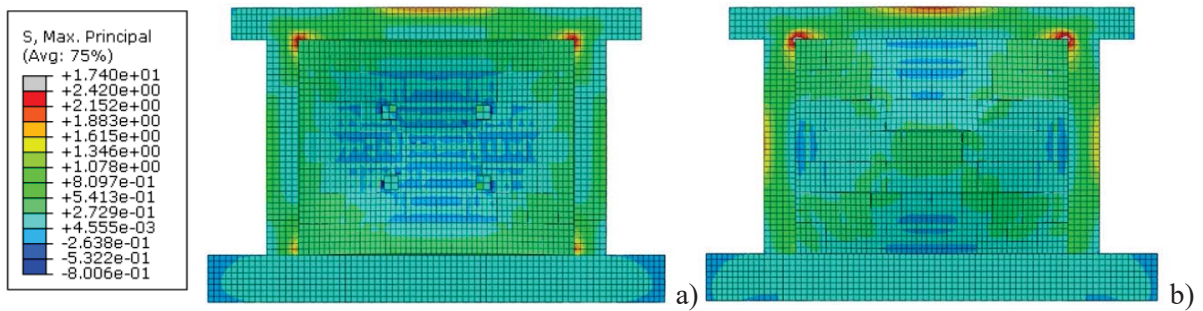

Figure 7: Tensile stress field at the peak load: a) windward side; b) leeward side.

Figure 8: Ultimate displacement damage at: a) model tensile damage pattern; b) experimental cracking pattern by Ricci et. al 2018 [5].

After the calibration, the model predictive capacity has been blind-tested against two further experimental tests. These were specimens 120_OOP_4E by Ricci et al. 2018 [5] and De Risi et al. 2019 [7]. These two specimens were modelled according to the above described procedure. Experimental / numerical comparisons are shown in Fig. 9. The latter, besides validating the model, confirmed its suitability to be used as a reliable predictive tool to generate reliable simulated tests.

Figure 9: Comparison of numerical and experimental OOP response: a) Specimen 120_OOP_4E by Ricci et al. 2018 [5]; (b) Specimen by De Risi et al. 2019 [7] OOP

4 PARAMETRIC INVESTIGATION

The additional FE tests were generated starting from the reference models and individually varying single parameters. In this way, the influence of each variation to the overall resistance was analysed. Varied parameters were the infill slenderness (h/t), the blocks conventional resistance (\tilde{f}_b), the entity of the distributed load applied on the upper beam (q).

The variation of the slenderness ratio was performed on two different models, characterized by a different aspect ratio ($w/h=1-1.28$). The slenderness was varied between 9.15 and 22.87, to cover a sufficiently wide range. Results confirmed inverse proportionality between OOP ultimate load and slenderness (Figs. 10-11).

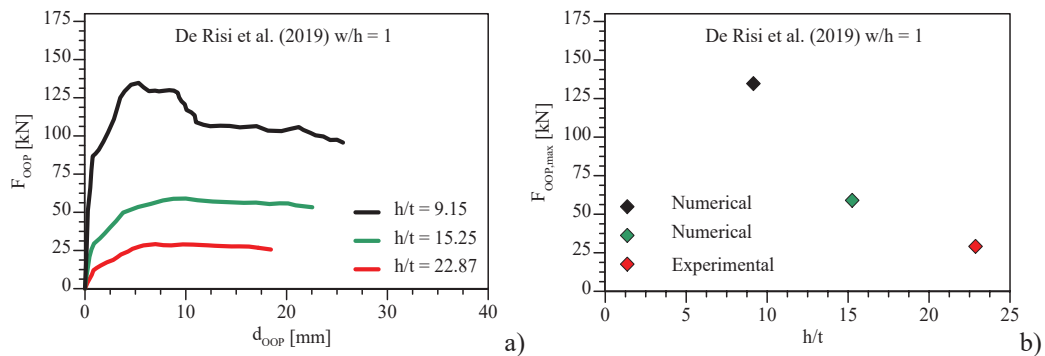

Figure 10: Effect of slenderness variation ($w/h = 1.00$): a) OOP force-displacement curves; b) Maximum OOP force vs. slenderness.

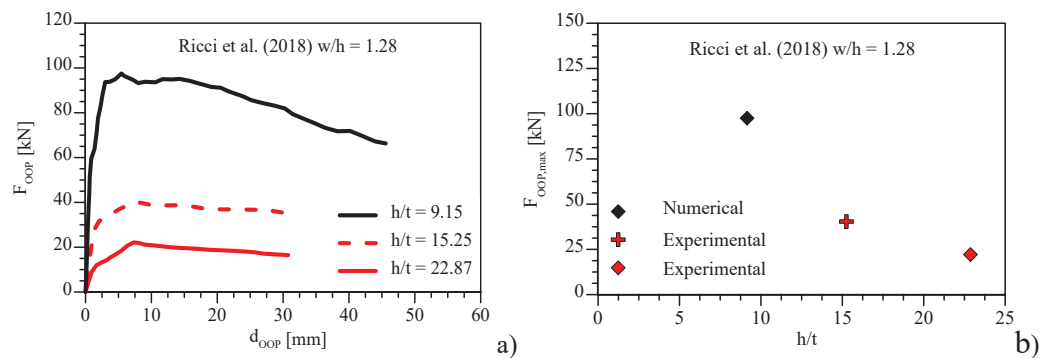

Figure 11: Effect of slenderness variation ($w/h = 1.28$): a) OOP force-displacement curves; b) Maximum OOP force vs. slenderness.

The effect of units resistance variation was evaluated on three different models, Ricci et al. 2018 [5] (infill thickness 80 and 120 mm) and De Risi et al. 2019 [7]. The latter was varied in the range 0.5-2.0 $\tilde{f}_{b,ref}$, where $\tilde{f}_{b,ref}$ is the conventional resistance originally used in the calibration and validation phases. Results show that an increment of the unit strength involves an increase of the out-of-plane resistance of the infilled frame (Figs. 12-14). This behaviour seems to be characterized by a limit, beyond which further increases of the unit strength do significantly affect the OOP resistance.

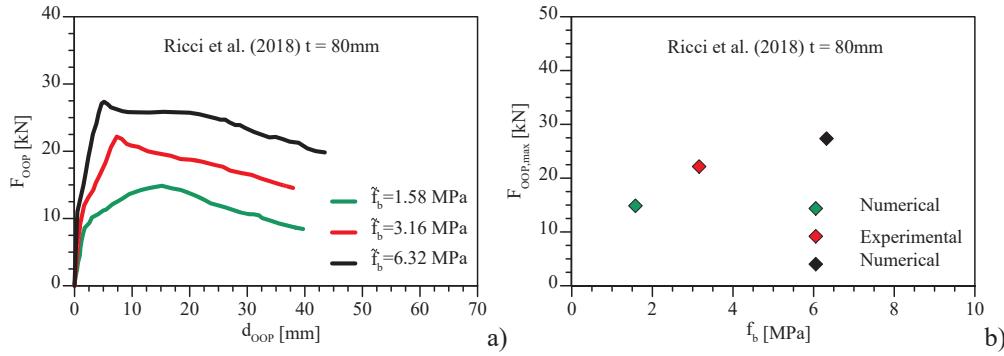

Figure 12: Effect of unit's compressive strength on the ultimate OOP capacity: a) OOP force-displacement curves; b) Maximum OOP force vs. \tilde{f}_b . Reference specimen by Ricci et al. 2018 ($t=80$ mm) [5]

Figure 13: Effect of unit's compressive strength on the ultimate OOP capacity. a) OOP force-displacement curves; b) Maximum OOP force vs. \tilde{f}_b . Reference specimen in Ricci et al. 2018($t=120$ mm) [5]

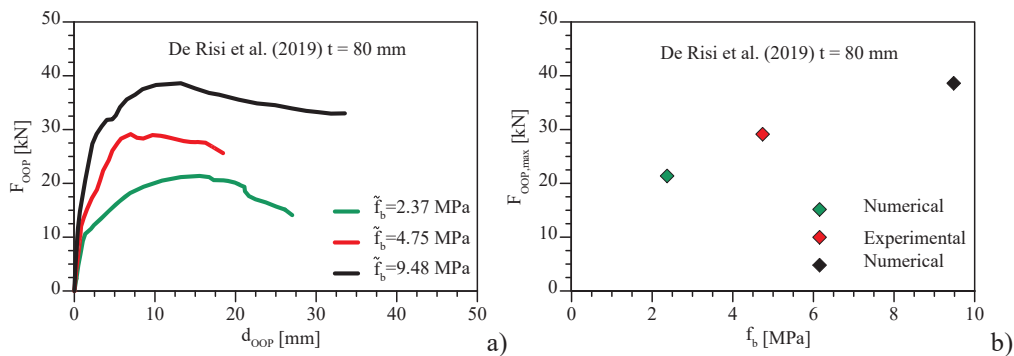

Figure 14: Effect of unit's compressive strength on the ultimate OOP capacity. a) OOP force-displacement curves; b) Maximum OOP force vs. \tilde{f}_b . Reference specimen in De Risi et al. 2019 ($t=80$ mm) [7]

The influence of a distributed load acting on the top beam was finally investigated using specimen 80_OOP_4E [5] as reference. The load was varied in the range 0-30 kN/m.

A linear increment of the OOP resistance was observed as a function of the extent of the vertical load (Fig. 15). This trend is justified by the pre-stressing action exerted on the infill by the compression load, which makes the arching mechanism more effective.

Figure 15: Effect of vertical load (q) on the ultimate OOP capacity. a) OOP force-displacement curves; b) Maximum OOP force vs. q . Reference specimen in Ricci et al. 2018 ($t=80$ mm) [5]

5 DEFINITION OF THE EMPIRICAL FORMULATION

An hybrid database composed of 9 experimental tests [1,4,5,7,12,15-17] and the 13 numerical simulations presented before was assembled to put in relation test results with the geometric and mechanical properties of the infilled frames. Data processing was performed to derive an empirical analytical relationship between the out-of-plane resistance the most relevant geometric and mechanical features of a generic infilled RC frame. The reference experimental tests and the numerical simulations are collected in Tab. 4 together with the specification of the parameters varied for each test/simulation and the modality of application of the vertical load. This latter parameter has been specifically investigated to evaluate its influence in conditioning the out-of-plane resistance. To highlight this aspect a specific test was carried out using the reference FE model 8_OOP_4E [8] and simulating its OOP response by applying a uniform load (instead of the original 4-point loading), which is more similar to the actual trend of inertial forces. Results evidenced a double OOP resistance if the infill is uniformly loaded (Fig. 16).

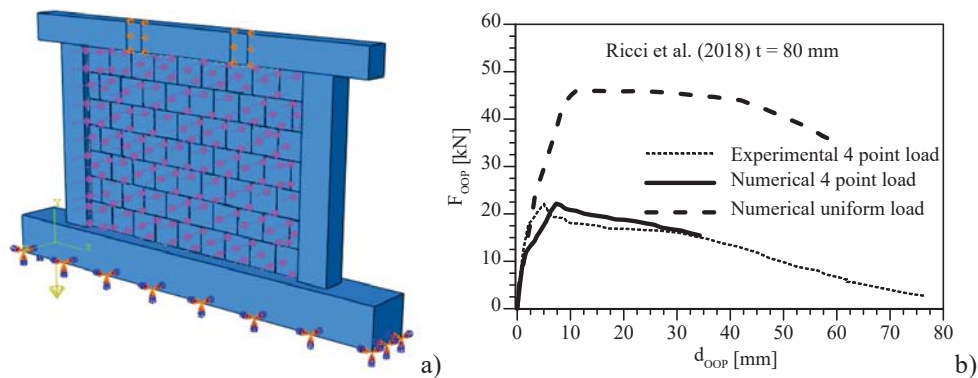

Figure 16: Effect of the way of application of the OOP load on the ultimate capacity: a) Simulation of the application of the uniform load on the FE model; b) OOP response of the FE model with 4-point and uniform load.

In consideration of results of previous numerical tests and past experimental evidence the search for a new empirical formulation considered the following major parameters: aspect ratio of the infill (w/h), slenderness of the infill (h/t), conventional resistance of the units (\tilde{f}_b),

resulting vertical load acting on the upper beam ($Q = q \cdot w$) and mode of application of the OOP load (α). The latter coefficient allows uniformizing OOP test results obtained by 4-point load tests and airbag tests (uniform loading). The proposed predictive relationships allows direct evaluation of the undamaged OOP resistance of an infilled frame. The latter has the following expression:

$$F_{OOP} = \alpha \cdot \left[\left(\frac{w \cdot h}{100} \right)^\beta \left(\frac{w}{h} \right)^{-0.41} \tilde{f}_b^{0.43} \left(\frac{h}{t} \right)^{-1.67} + 0.058 \cdot Q \right] \quad (9)$$

where β is an aspect-ratio related coefficient defined as:

$$\beta = -0.372 \cdot \left(\frac{w}{h} \right)^2 + 0.787 \frac{w}{h} + 0.3455 \quad (10)$$

and α is the conversion factor used to make experimental 4-point load test and uniform load tests comparable and assuming the following values:

$$\begin{cases} \alpha = 1 & \text{4-point load} \\ \alpha = 1.557 \left(\frac{w}{h} \right)^{1.138} & \text{uniform load} \end{cases} \quad (11)$$

A comparison between experimental and numerical OOP resistance values with the predictions by Eq. (9) is shown in Fig. 17, demonstrating very low dispersion of results by the proposed empirical model.

6 COMPARISONS WITH THE EXISTING PREDICTIVE MODELS

A comparative analysis of the proposed relationship with respect to the predictive models available in the literature is finally carried. For this comparison only experimental test results were considered. The reference experimental tests and the respective experimental and predicted OOP resistance values are shown Table 5. Results are graphically represented in Fig. 18. It can be observed how the proposed model is able to fit better than the other predictive models. The models proposed by Ricci et al. 2017 [23] and Liberatore et al. 2020 [24] provided also an adequate reliability although they seem having an overestimation tendency. On the contrary, the model by Angel 1994 [1] significantly underestimated the experimental results. The improved predictive capacity shown by the proposed model with respect to the previous ones is justified by the fact that this model enriches the formulation taking into account additional information such as the influence of vertical loads and the mode of application of the out-of-plane load. Moreover, the model is specifically calibrated using only OOP tests of in-filled RC frames, therefore it results more accurate than the other formulations base on a more heterogeneous database.

7 CONCLUSIONS

Assessment of out-of-plane capacity of infilled frames is not straightforward. Available literature models for the prediction of the out-of-plane resistance are often conflicting, being in general too conservative or, on the contrary, overestimating the capacity. The reasons of this inconsistencies are different. First of all, some of the available models (e.g. Angel et al. [1]) are calibrated based on a limited investigation. Conversely, other literature models have been defined using a too wide dataset, including also steel infilled frames or confined masonries. Finally, the way of application of the OOP load influences on the OOP capacity, therefore some formulations can result unsuitable in match experimental results of specimens loaded with different modalities (e.g. 4-point load or uniform load). In consideration of this, a hybrid database, composed of 9 experimental tests and 13 numerical simulations by a refined FE micro-model was specifically defined. FE models allowed increasing the extent of the dataset and to investigate on the influence of some parameters not taken into account by previous experimental investigations (e.g. the influence of distributed load on the upper beams or the influence of the modality of application of the OOP load).

Postprocessing of the collected data allowed defining a new empirical relationship for the direct estimation of the OOP resistance of a generic infilled frame. The proposed model showed matching better the other the experimental results. The reasons of its better capability in estimating experimental results is justified by the following major considerations:

- The model takes into account the way of application of the OOP load, which greatly influences the OOP resistance.
- The model considers the influence of vertical loads which increase the effectiveness of the arching mechanism.

- The model proposes the use of the conventional unit compressive strength (\tilde{f}_b) instead of the vertical strength of the masonry as parameter having major correlation with the OOP resistance of the infill.

Abstract

The paper proposes a new quadri-linear empirical force-displacement relationship to model the inelastic response of infill equivalent struts. The definition of the model is based on a data-driven approach rather than a mechanical one, therefore parameters defining the force-displacement curve are analytically evaluable by means of empirical correlations. The latter link the force-displacement parameters regulating the axial response to the geometrical and mechanical features of an infilled frame. The analytical correlations are obtained from an experimental data-set enlarged with data from refined finite element simulations. Blind validation tests of the proposed modelling procedure are carried out against experimental results different from those used to build the data-set. A reliability comparison between mechanics-based models and empirical models is finally presented and discussed.

1 INTRODUCTION

Infill-frame interaction has been largely investigated during last 60 years by researchers from all over the world. Despite this, the interest devoted to this topic is still noticeable. This can be easily observed, for example, by the experimental activity, which continues nowadays. In fact, besides the availability of a number of in-plane experimental tests (e.g. [1- 7]), several new ones have been performed out only recently (e.g. [8-14]). In the same period, thanks to the improvements in the efficiency of computational capacity of computers and software, in-depth numerical studies were also addressed to assess the global influence of infills in seismic response of building frames [15-23] or local interaction issues [24-28].

Comparing an overview of past and recent literature on in-plane equivalent strut modelling of infilled frames, it results that predictions from different models lead to results which are many times conflicting [16,29-32], raising doubts on the reliability of the different models. One of the possible reasons is the fact that most of the force-displacement relationships used to model the response of the equivalent struts, are based on mechanical approaches, which are typically a consequence of supposing limit equilibrium conditions. Unfortunately, this way of approaching this problem may fail in accuracy if the actual collapse mechanism is different from the one assumed. Another reason is that most of past design equations were calibrated on the experimental knowledge available in a previous period or for a specific typology of infills. Based on these premises, this paper first presents a new equivalent strut macro-model, which is defined using an empirical data-driven approach. A typical quadri-linear axial-force/axial-displacement relationship is proposed for the axial response of the struts. The force-displacement model is simply ruled by four parameters modulating the cracking strength, the post-cracking stiffness, the softening branch, and the residual strength peak strength. Analytical expressions for these parameters are derived in the paper making use of a hybrid experimental/numerical data-set, built after an iterative calibration process of the equivalent strut models on real experimental tests and additional finite element simulations. The four analytical correlation laws directly link geometrical and mechanical properties of an infilled frame to four parameters (called force-displacement parameter) regulating the force-displacement relationship. Blind validation tests of the model are carried out against eight different experimental test data, not belonging to those used to build the data-set used to derive the correlation laws. The proposed model predictive capacity is also compared to that of other six literature models making consideration about the different reliability of mechanics based and empirical based formulations.

2 PROPOSED EQUIVALENT STRUT MODEL

2.1 Computational model and formulation

The computational scheme of the proposed model refers to the classical configuration of a pair of compression-only concentric equivalent struts (**Fig. 1a**). Beam and column elements are modelled using distributed plasticity fiber-section elements. The equivalent strut elements are modelled as trusses with inelastic force-displacement behaviour, characterized by the axial force – axial displacement behaviour illustrated in **Fig. 1b**. In the current study, the *OpenSees* software platform [34] is used to perform modeling and simulations. The *Pinching 4* material is used to model the axial response of the struts. However, this modelling strategy can be easily reproduced with any structural software handling nonlinear analysis of frame structures, using multilinear plastic links as shown by [11].

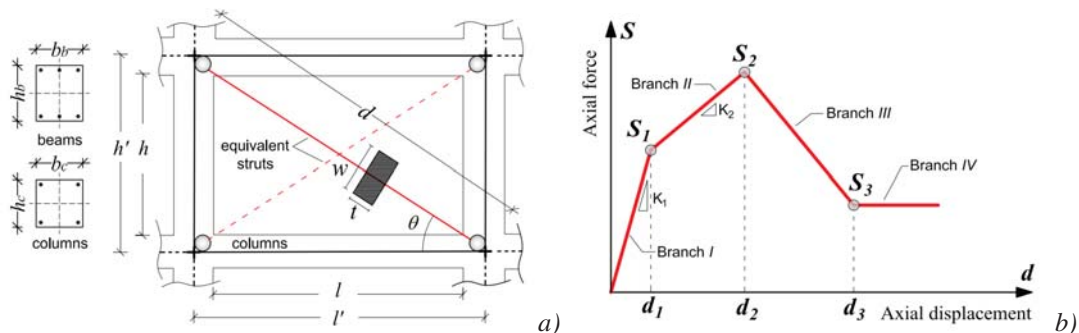

Figure 1. Equivalent strut modelling of the frame-infill system: a) Geometric configuration; b) Proposed axial force – axial displacement model for the struts.

The shape of the inelastic relationship for the strut is the same as the one proposed by other authors (e.g. [35,36]). The latter provides an initial uncracked branch up to the point S_1-d_1 , characterized by the stiffness K_1 , a second cracked stiffness branch up to the peak point S_2-d_2 , having stiffness K_2 , a third softening branch and a fourth residual strength branch starting in correspondence of the point S_2-d_3 . The latter branch can be considered having unlimited or specified deformation threshold. The force-displacement is defined as follows.

Branches 1 and 2, are evaluated similarly to what provided by [11] and [37], therefore, the initial stiffness (branch I) is defined as:

$$K_1 = \frac{\tilde{E}_m t w}{d} \quad (1)$$

where t , w and d are the thickness, the width and the length of the diagonal strut and \tilde{E}_m is the conventional elastic modulus, defined as [33]:

$$\tilde{E}_m = \sqrt{E_{m1} \cdot E_{m2}} \quad (2)$$

in which E_{m1} and E_{m2} are the Young moduli of masonry along the horizontal and vertical direction respectively. As regards the identification of the equivalent strut cross-section width (w), this is performed by following the procedure proposed by [33]. The stiffness of branch II is related to the stiffness K_1 by the parameter β (≤ 1) as:

$$K_2 = \beta K_1 \quad (3)$$

The peak strength S_2 can be considering S_2 as the product of the diagonal peak resistance of the strut (f_{md0}) and the area of its cross section, namely:

$$S_2 = f_{md0} t w \quad (4)$$

where f_{md0} can be analytically evaluated as provided by [33]. Once evaluated S_2 , the peak strength S_1 is defined through the parameter α (≤ 1) as:

$$S_1 = \alpha S_2 \quad (5)$$

The cracking and peak displacements are then defined as:

$$d_1 = \frac{S_1}{K_1}; \quad d_2 = d_1 + \frac{S_2 - S_1}{K_2} \quad (6)$$

The softening branch is obtained as a linearization of the exponential softening branch proposed by [37]. This is done connecting the point S_2-d_2 and the auxiliary point $S_3^*-d_3^*$ (**Fig. 2a**), where for S_3^* it is conventionally set $S_3^*=0.7S_2$, and d_3^* is obtained through the expression [11] (**Fig. 2b**):

$$d_3^* = \frac{1}{\zeta} \ln \left[\frac{S_2}{S_3^*} \exp(\zeta d_2) \right] \quad (7)$$

in which ζ is one of the empirical parameters to be calibrated.

Finally, the residual strength (S_3) is related to the peak strength by the parameter η (≤ 1) as:

$$S_3 = \eta S_2 \quad (8)$$

The displacement at which the constant branch starts is obtained as interception of the lines identifying the branches II and IV, which results from the following equation:

$$d_3 = d_2 + (\eta - 1) \left(\frac{d_3^* - d_2}{S_3^* - S_2} \right) S_2 \quad (9)$$

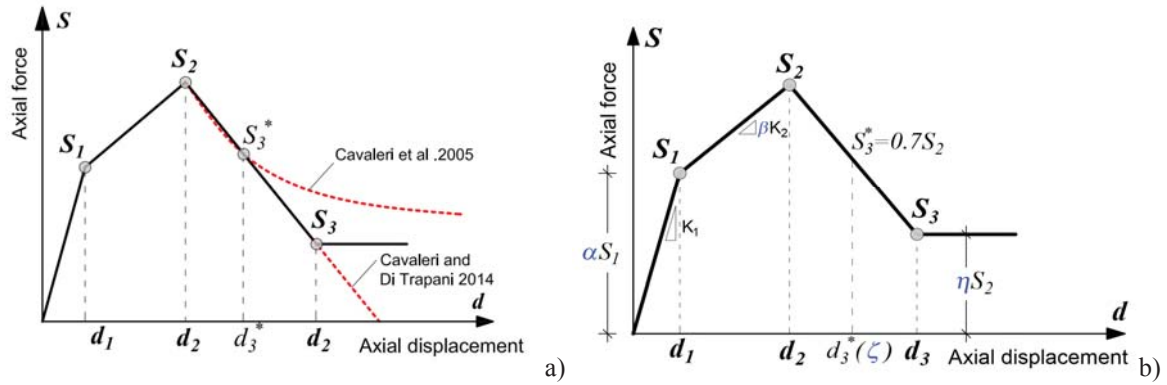

Figure 2. Force-displacement relationship for the equivalent strut: a) Comparison with **Cavaleri et al.** [38] and **Cavaleri and Di Trapani** [11] relationships; b) Calibrations parameters.

According to previous equations the force-displacement response is defined once the four parameters α , β , ζ , and η (called “force-displacement parameters”) are defined. These parameters have a strict dependence on masonry mechanical properties, but, more in general, their values depend on geometrical and mechanical features of the whole infilled frame. Their determination is possible by the empirical analytical correlations derived in the following sections.

3 CALIBRATION OF FORCE-DISPLACEMENT PARAMETERS FROM EXPERIMENTAL TESTS

The reference specimens are selected from the experimental tests by [2,5,6,7,11]. Geometric and typological details of specimens are reported in **Table 1**, while the other mechanical properties are shown in **Table 2**, together with the equivalent strut cross-section widths and the other parameters evaluated for the identification of the struts.

The simulation of the tests was carried out in OpenSees by conducting simple pushover analyses of the equivalent strut model of each specimen. The calibration process was performed by comparing the obtained monotonic force-displacement curves with the backbone curves of the cyclic experimental responses. Results are shown in **Figures 3-7**, where numerical pushover curves at the end of the calibration process, and the experimental results (positive and negative backbone curves) are overlapped.

The experimental values of masonry shear strength (f_{vm}) and compressive strength along orthogonal directions (f_{m1} and f_{m2}) are reported in **Table 3** together with the conventional compressive strength (\tilde{f}_m) defined as [33]:

$$\tilde{f}_m = \sqrt{f_{m1} \cdot f_{m2}} \quad (10)$$

and the diagonal compressive strength (f_{md0}) of the equivalent struts.

4 FORCE-DISPLACEMENT PARAMETERS CALIBRATION FROM FE MODELS

In order to enlarge the data-set, additional numerical tests were considered by taking those provided by [33]. The latter are obtained through a refined FE model experimentally validated and implemented in the ATENA 2D software platform. A view of the reference FE model is illustrated in **Fig. 8a**. The comparison between the FE model prediction and the reference experimental tests used for the validation (Specs. S1B by [11]) is also shown in **Fig. 8b**.

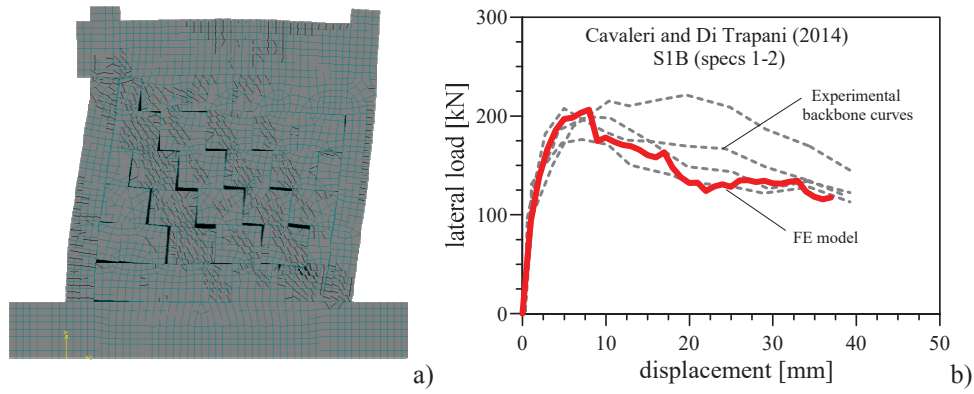

Figure 8. Reference FE model: a) View of the model during a typical pushover test; b) Comparison between FE model prediction and experimental backbone curves of specimens S1B (Cavaleri and Di Trapani [11]).

Numerical tests specimens extrapolated by the reference FE model were obtained by varying compressive and tensile strength of masonry (f_m and f_{vm}), infill thickness (t) and masonry elastic Young's modulus (E_m). The interface and concrete parameters were instead maintained fixed, as well as the geometry of the frame (spec. S1B by [11]). The geometrical and mechanical parameters which were varied to generate the numerical models are reported in **Table 5**, highlighting those each time varied. The infilled frame equivalent strut models associated with the generated FE models were then built and calibrated to derive force-displacement parameters as shown in the previous section. Force-displacement curves at the end of the calibration are depicted **Fig. 9** together with the respective force-displacement curves of the FE model simulations. Parameters evaluated at the end of the calibration and related force-displacement parameters obtained are finally reported in **Table 6** together with the resulting force-displacement values for the struts.

Figure 9. Force-displacement curves from FE models and equivalent strut models after the calibration: a) variation of masonry strength; b) variation of infill thickness; c) variation of elastic modulus.

Table 6. Identification parameters of equivalent strut, parameters α , β , ζ and η after the calibration and resulting force and displacement values for the struts.

5 DEFINITION OF THE EMPIRICAL CORRELATION LAWS

The experimental and numerical data-sets containing the calibrated parameters α , β , ζ and η together with the associated geometrical and mechanical features of the respective infilled frames were merged in to a unique hybrid data-set. Results were then analysed in order to understand the dependence of α , β , ζ and η on the parameters involved in the identification process of each model. In detail parameters λ^* , \tilde{E}_m , (l/h) , t , \tilde{f}_m , f_{md0} , f_{vm} where individuated as the most meaningful to the inelastic response of an infill frame, as these take into account the aspect ratio, the stiffness ratio and the strengths of the masonry and of the strut. The relationships with α , β , ζ and η have been found by defining four correlation parameters (A , B , Z and Y) to get the maximum determination coefficients (R^2) of the analytical interpolating functions relating α , β , ζ and η as $f(A)$, $f(B)$, $f(Z)$ and $f(Y)$. Results provided the following expressions for the correlation parameters:

$$A = \lambda^{*0.1} \left(\frac{l}{h} \right)^{-3} \left(\frac{f_{md0}}{f_{vm}^{0.4}} \right) \quad (11)$$

$$B = \lambda^{*0.7} \left(\frac{l}{h} \right)^{1.8} \left(\frac{f_{md0}^{-1.7}}{f_{vm}^{-0.7}} \right) \frac{1}{t^{0.5}} \quad (12)$$

$$Z = \left(\frac{\tilde{E}_m}{\tilde{f}_m} \right)^{0.7} \left(\frac{l}{h} \right)^{0.7} \left(\frac{f_{md0}^{0.7}}{f_{vm}^{0.35}} \right) \frac{1}{t} \quad (13)$$

$$Y = \left(\frac{\tilde{E}_m^{0.7}}{t} \right) \left(\frac{l}{h} \right)^{1.2} \left(\frac{\tilde{f}_m^{-0.5}}{f_{vm}^{0.1}} \right) \quad (14)$$

The relationships between parameters α , β , ζ and η and correlation parameters A , B , Z and Y are illustrated in **Fig. 10**, together with the obtained optimal analytical correlation laws.

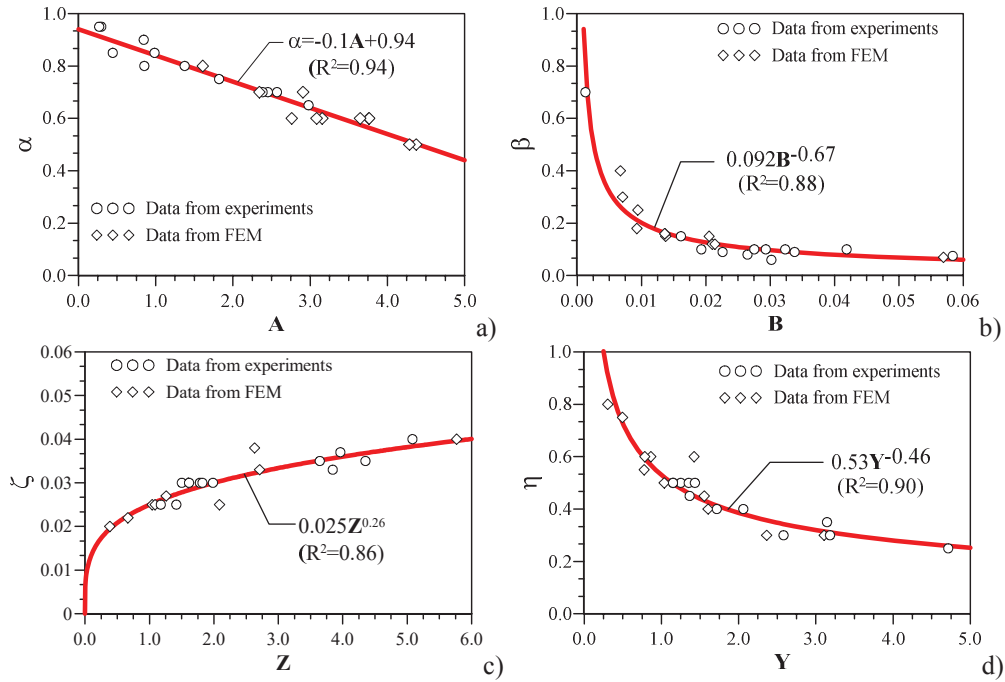

Figure 10. Relationships between parameters α , β , ζ and η and correlation parameters A , B , Z and Y and proposed analytical correlation laws.

Based on the obtained equations, the procedure for the complete identification of the equivalent strut follows the below reported steps:

1. Evaluation of the equivalent strut width w [33];
2. Evaluation of the peak strength of the strut S_2 (Eq. 4);
3. Evaluation of correlation parameters A , B , Z , Y (Eqs. 12-15);
4. Evaluation of force-displacement parameters α , β , ζ , η (Fig.10);
5. Determination of the force-displacement relationship for the strut (Eqs. 1, 3 and 5-9);

6 BLIND VALIDATION TESTS AND RELIABILITY COMPARISONS

The proposed empirical correlations have been validated with the experimental test results of eight specimens, not belonging to the set of specimens used to derive the correlations. The considered specimens were those by [14] (Spec. TA-2), [10] (Spec. URM-U), [6] (Spec. V21), [12] (Spec. FT-2), [13] (Specs. GLD and SLD), [9] (Spec Unr), [11] (Spec S1C). With regards to the experimental campaign by [6], of which some specimens have been used to build the data-set, it should be specified that experimental results used for the validation are those of Specimen V21, which has not been previously considered and presents substantially different mechanical properties of the masonry infill with respect to those included in the data-set. The same considerations may be taken for the specimen S1C of the experimental campaign by [11]. The other six specimens belong to other experimental campaigns not considered at all in the calibration phase. It should be also specified that specimens GLD and SLD by Verderame et al. [13] have the same geometric and mechanical characteristics for what concerns the frame and the infill. The differences are instead in the arrangement of the longitudinal and transverse reinforcement that is made considering gravity loads only (GLD) or seismic loads (SLD). Geometric details of the specimens are listed in Table 7. Equivalent strut models have been defined according to the procedural steps described in the previous section. Tables 7-9 collect all the fundamental geometric and mechanical data of the models and the associated parameters used for the definition of struts. The correlation and force-displacement param-

eters evaluated by means of **Eqs. (12-15)** and equation if **Fig. 10** are shown in **Tables 10-11**, together with the obtained values for the axial-force / axial-displacement relationship of the struts. The comparison between experimental force-displacement curves and numerical predictions are depicted in **Fig. 11**. It can be observed that for all the considered cases, numerical predictions resulted in a very good matching with experimental data, providing sufficient reliability despite the large heterogeneity of the blind test specimens and in consideration of the uncertainty degree affecting masonry mechanics in general and infilled frames in particular.

In order to compare the reliability of the proposed model predictive capacity with respect to that of other existing ones, the simulation of the blind tests has been conducted also implementing other six equivalent strut models available in the literature and applying them on the blind tests. The equivalent strut models are the models by Di Trapani et al.[33], Panagiotakos and Fardis [35], Dolsek and Fajfar [38], Bertoldi et al. [36], De Risi et al. [32], Sassun et al. [39]. The comparisons between the experimental test responses and those by the seven equivalent strut models are illustrated in **Fig. 11**.

Table 11. Final axial force- axial displacement data calculated for the blind test specimen equivalent struts.

It can be firstly observed that the accuracy of each model in reproducing the experimental responses is different for the different cases. For example, while for the test by da Porto et al. [10] (**Fig. 11b**), Colangelo [6] (**Fig. 11c**) and Verderame [13] (**Figs. 11e-f**), all the models performed with similar reliability, very significant differences in the predictions are recognized for the test by Morandi et al. [14] (**Fig. 11a**). However, it should be also recognized that data-driven empirical models as the proposed one and the one by Di Trapani et al. [33], performed with noticeable reliability for all the considered tests. On the other hand, the models by Panagiotakos and Fardis [35], Dolsek and Fajfar [38] and De Risi et al. [32] have shown good predictive capacity in 5 out of 8 tests, while they led to significant strength overestimation in the tests by Morandi et al. [14] (**Fig. 11a**), Bergami and Nuti [12] (**Fig. 11d**) and Sigmund & Penava [9] (**Fig. 11g**). For the model by Panagiotakos and Fardis [35] and Dolsek and Fajfar [38] this is justified by the fact that the estimation of the strength capacity by these models is obtained considering a single collapse mode, leading to incorrect evaluations in all the cases in which a different mechanism develops. A confirmation of this comes observing the performance of the model by Bertoldi et al. [36] and Sassun et al. [39], which instead, based on their mechanism-sensitive formulation, resulted more effective in general with respect to the peak-strength estimation, although they still give a peak strength overestimation in 2 out of 8 cases. Another noteworthy issue is related to the softening branch, which is in general more accentuated by Panagiotakos and Fardis [35] and Dolsek and Fajfar [38] models. But while for the former this can be calibrated by a stiffness coefficient, the assumption by Dolsek and Fajfar [38] of an ultimate displacement of 5 times the peak one is generally not acceptable for more ductile infilled frames. The forced prediction of a brittle behaviour is accentuated by the low or null residual strength provided by these models, which instead it has been found to range between 0.25 and 0.8 the peak strength, as it can be deduced from the η coefficients reported in **Tables 4, 6 and 10**. In conclusion it can be observed that data-driven empirical models, including the proposed one, resulted more reliable with respect to the mechanics-based in predicting the lateral response of an infilled frame. This can be reasonably justified by two main factors. The first is that their calibration is analytically updated in consideration of a large number of parameters characterizing both the frame and the infill. More-

over, the analytical equations used to calibrate the model are based on robust correlations considering a significant number of experimental and numerical tests. The second aspect to take into account, is that the mechanics-based models here considered, despite largely employed in the practice, have been validated on a reduced number of experimental tests with respect to those available currently, and therefore they can only reflect well the behaviour of infilled frames having similar characteristics to those at the base of their validation.

7 CONCLUSIONS

Assessment of inelastic response of infilled frames is not straightforward. Phenomenological models have to summarize a large number of variables into a relatively simple model. The flexibility of available strut models to update their force-displacement (or stress-strain) response, as a function of the different potential failure damage mechanisms occurring for infilled frame, is fundamental to get reliable predictions. The uncertainty in predicting the collapse mode, which depends on a large amount of geometric and mechanical parameters, propagates in the reliability of estimations.

In consideration of this, the paper has shown a proposal for a new single equivalent strut model based on axial-force/axial-displacement relationship of the strut. The model can be easily implemented in most of the finite element codes handling nonlinear analysis of frame structures. The major advantage of the proposed model is that the force-displacement relationship is modulated by four analytical correlation equations linking the geometrical and mechanical features of an infilled frame to the force-displacement parameters. The correlation equations are derived from a robust data-set realized including experimental data and refined numerical simulations.

Validation tests have been carried out against eight experimental test data different from those used to define the empirical data-set. Results have demonstrated the predictive reliability of the proposed model and of the empirical relationships used to define it. This suggests the proposed approach as an effective methodology when performing nonlinear static analyses for the assessment of seismic performance, and also highlights the potential use of correlation equations as design tools for the performance-based design of the infilled frames. The same tests are used to carry out a comparison with six additional equivalent-strut models available in the literature besides the proposed one. Results have shown a major reliability of data-driven models because of the flexibility of the case-by-case calibration provided. On the other hand, the lower reliability of mechanics-based model is justified by the reduced number of experimental tests available when they were validated.

Abstract

This paper describes the concept of an innovative, interdisciplinary, user-oriented earthquake warning and rapid response system coupled with a structural health monitoring system (SHM), capable to detect structural damages in real time. The novel system is based on interconnected decentralized seismic and structural health monitoring sensors. It is developed and will be exemplarily applied on critical infrastructures in Lower Rhine Region, in particular on a road bridge and within a chemical industrial facility. A communication network is responsible to exchange information between sensors and forward warnings and status reports about infrastructures' health condition to the concerned recipients (e.g., facility operators, local authorities). Safety measures such as emergency shutdowns are activated to mitigate structural damages and damage propagation. Local monitoring systems of the infrastructures are integrated in BIM models. The visualization of sensor data and the graphic representation of the detected damages provide spatial content to sensors data and serve as a useful and effective tool for the decision-making processes after an earthquake in the region under consideration.

Keywords: early warning and response system, interconnected sensor systems, seismic structural damage detection via SHM, integration SHM in BIM

1 INTRODUCTION

Germany's seismicity in general is characterized as low or moderate. However, there are seismic events of moderate to strong ground motions with damage potential (Tailfingen 1978 $M_w = 5.7$, Roermond 1992 $M_w = 5.9$). These events arouse attention because the exposed regions are densely populated, highly industrialized and have an extended network of critical infrastructures. These infrastructures were mainly designed according to currently outdated or none seismic provisions. The early warning and rapid response system combined with local health monitoring systems can act supplementary as an additional arrow in the quiver of earthquake engineering to reduce the seismic risk, especially for critical infrastructures.

This contribution describes the conception and the progress of the works, that had been performed in the framework of the German nationally funded research project "ROBUST". Fundamental element of the novel system is the automated interaction of smart seismic or structural sensors and sensor systems, which are capable not only to record motions or strains, but also to process the recordings decentral and to forward the results of the assessment. In the past decades, the breakthrough in software and hardware development of sensors and techniques for data processing enabled the extended and low-cost use of a remarkable number of seismic and monitoring sensors [1]. Reliable earthquake early warning systems (EWS) were developed all over the world and especially in seismic prone areas as Japan, California and Mexico [2]. Simultaneously, engineering diagnostics is an emerging field concerning health assessment of civil engineer's structures. Post-earthquake damage detection through sensor systems is a research topic of increasing interest. Acknowledging the developments in both directions (SHM and EWS), the examined system tries to incorporate and extend their advantages and provide a useful tool for the protection of critical infrastructures [3]. The examined system is going to be applied in Lower Rhine Region. A road bridge and a chemical industrial facility are selected as benchmark structures. The innovative system consists of four basic components: (i) the seismic sensors network, (ii) the local monitoring systems for the critical infrastructures, (iii) the communication infrastructure and (iv) the integration of the sensor data in BIM models of the monitored critical infrastructure.

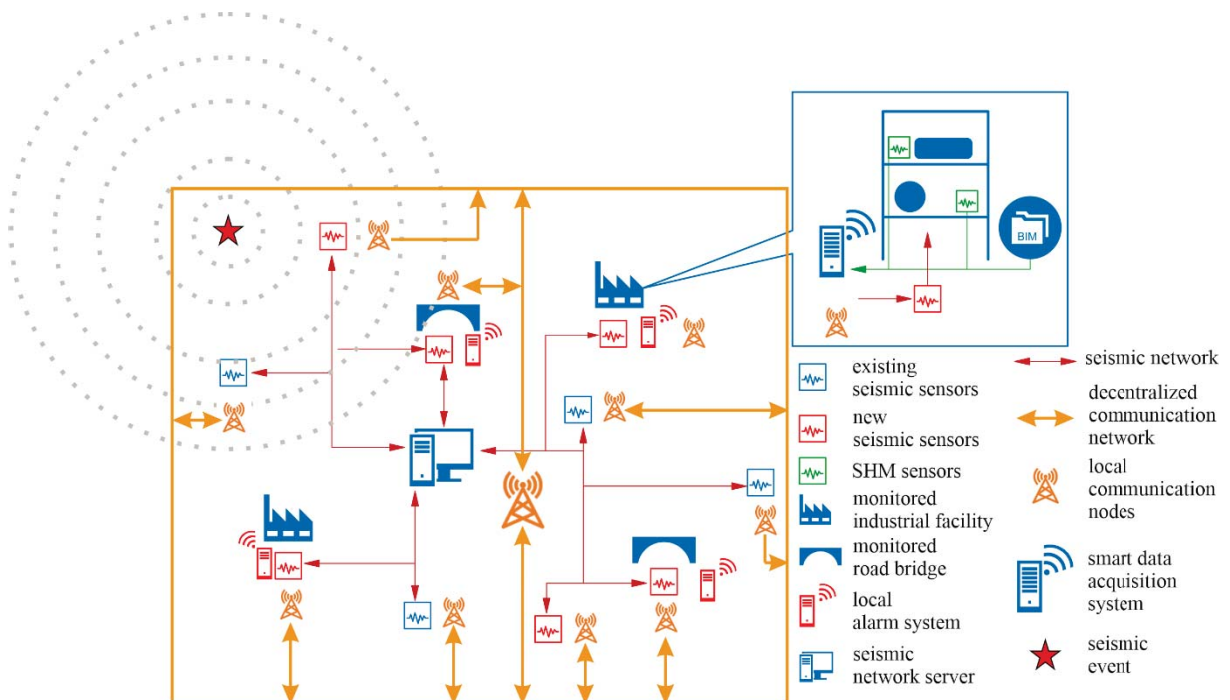

Regarding the first component, namely the seismic network, the existing sparse regional network is being extended by new smart seismic sensors. To this end, an algorithm has been developed, aiming at the optimization of the location of the new sensors such, that while accounting for the geophysical conditions, reliable information on earthquakes relevant for the infrastructures can be obtained and communicated to maximize the lead time while, at the same time, to minimize the risk of false alarms. The novel sensors, developed by the German Research Center for Geosciences (GFZ), are capable to evaluate the intensity of the ground motion in real time and to send out messages via the developed communication network to the operators of critical infrastructures or local authorities (civil protection), before the arrival of the destructive seismic waves to the structures of interest. The information on a detected earthquake triggers also the local monitoring systems.

The flow of the seismic incidence information takes place through a communication network, which consists of several decentralized nodes. Every seismic sensor and every monitored infrastructure correspond to a communication node, which is responsible to send and receive the appropriate information. Synchronously, the same communication infrastructure, under development by Fraunhofer Institute for Open Communication (FOKUS), will provide warnings regarding the expected damages to the concerned parties (local authorities, operators of critical infrastructures). This allows the recipients to trigger safety measures. The kind and the intensity of the measures depend on the expected damages of the detected ground motion and can be

updated relying on the most current measured data. After the assessment of the seismic performance of the monitored structures, health reports will be sent to interested actors.

The local health monitoring systems consist of a number of sensors (accelerators, velocity recorders, displacement transducers, strain gauges, thermometers etc.) and data acquisition devices. The sensors are placed in appropriate positions to record effectively the response of the structure or components and to detect particular damage indicators. The definition of the damage indicators depends on the geometry, dynamic properties and seismic risk of the various components of the monitored infrastructures. In “almost” real time, the measurements from the monitoring sensors are evaluated either decentral and locally by smart data acquisition systems or remotely at a central site by linked computers. The results of the damage identification are integrated in two steps in the communication platform. Right after the earthquake, very basic information is forwarded (e.g., whether a bridge is accessible or not or if parts of the facility are severely damaged). Gradually, more detailed information based on a refined interpretation of the sensors’ recordings will be communicated to the clients, including a graphical representation of the damages.

One of the fundamental objectives and an innovative part of the project is the graphic representation of the damage distribution of the monitored infrastructures right after an earthquake. This is possible because of the integration of the SHM system in 3D BIM models. Necessary precondition is the coupling of the sensor data with the graphic objects representing the real sensors in BIM models. For this purpose, the Desite MD software was selected. It provides the opportunity to link databases containing sensor measurements with an imported BIM model. Responsible for the development of the monitoring systems, the damage detection techniques and the integration of the sensor data in BIM models are the Center for Wind and Earthquake Engineering (CWE) of RWTH Aachen University and Wölfel Engineering GmbH.

2 EARTHQUAKE EARLY WARNING AND RAPID RESPONSE SYSTEM

2.1 General Information

The Lower Rhine Embayment in Western Germany is one of the most important areas of earthquake recurrence north of the Alps, facing a moderate level of seismic hazard in European context, but a significant level of risk due to a high population density and a large number of critical industrial infrastructures. As the seismic faults are directly crossing the study area, the lead time, i.e. the time between the onset of an earthquake and the arrival of the destructive seismic waves is in the order of a few seconds at most for events in the Lower Rhine Embayment. In this context, the project aims at designing a user-oriented hybrid earthquake early warning (EEW) and rapid response system where regional seismic monitoring is combined with smart, on-site sensors, resulting in the implementation of decentralized early warning procedures.

2.2 Seismic scenarios for the area of interest

One of the tasks of this project deals with finding an optimal regional seismic network arrangement given the known seismicity in the area. The optimization approach used here requires a representative sample of relevant seismic recordings. In the design of an EEW network, it is critical that all potential and known earthquake sources in the area are considered. Due to the sparsity of significant earthquake recordings in the region, stochastic simulations of scenario earthquakes were performed using the finite-source ground motion simulation code EXSIM [4] and the known seismicity in the area [5]. Overall, over 700 realistic scenario earthquakes were considered (for their location see Figure 2). This approach is ideally suited for the purposes of our study, as our emphasis is not on the simulation of the complete wavefield for given scenario earthquakes, but rather on the generation of a large set of spectra for hypothetical sources located according to a seismic catalog.

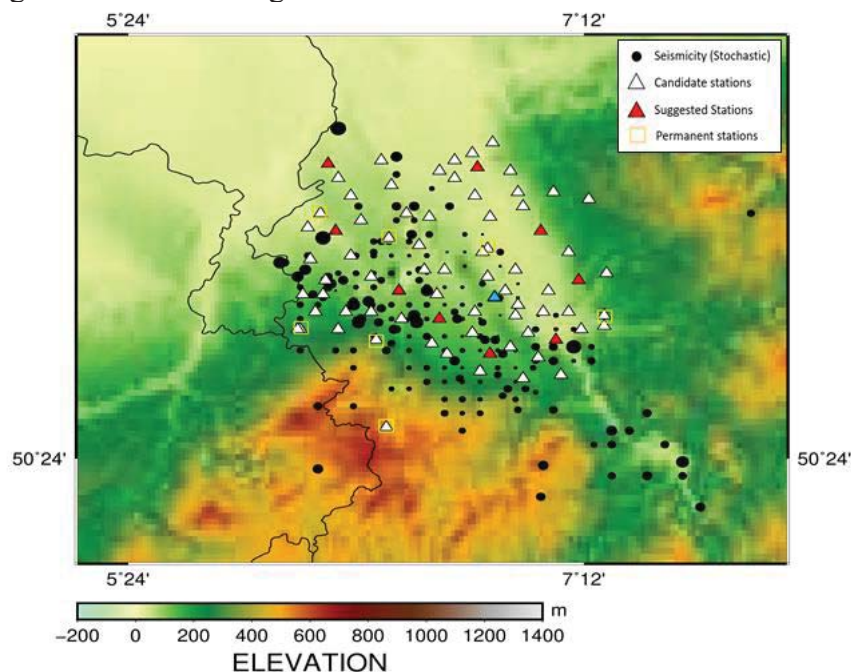

Figure 2: The Lower Rhine Embayment, Germany. The potential network is represented by candidate stations (white triangles) and suggested installations sites (red triangles) together with the existing permanent stations (yellow squares). The blue triangle represents the target site. The simulated scenario earthquakes are represented by black dots with diameter proportional to earthquake magnitude.

2.3 Optimal densification for real time assessment and early warning

The possible station locations were considered by public buildings (municipalities, schools etc) in the Lower Rhine Embayment. For each location, stochastic seismograms were computed for all scenario earthquakes resulting in a database consisting of more than 30,000 traces representing ground acceleration. An important aspect of an EEW system's performance is its ability to give not only timely, but also reliable warnings with respect to the shaking that needs to be expected at the target site. For our study site, a threshold of 0.02 g was selected, as such events can be considered as potentially damaging. The optimal network is the one that can give the correct level warning (i.e., correct level of expected ground motion at the target site) at a sufficiently long lead time for the highest number of scenario earthquakes.

To quantify this network quality, we use the cost function developed by Oth et al [6]. For finding the optimal station locations, a microgenetic algorithm was used. Such algorithms are a specific subset of genetic algorithms (GAs), which are guided search techniques based on evolutionary principles to find optimal models with respect to a given objective function (i.e., cost function). By minimizing the cost function, a comparison of the best earthquake early warning system design can be performed and the potential usefulness of existing and additional stations in the region is considered (see Figure 1). As indicated by the red triangles, by adding nine stations to the existing network, such optimal design will allow strong ground-motions with respect to the target site to be detected most quickly and most reliably.

2.4 Rapid response system

An earthquake early warning system can reduce the seismic risk on critical infrastructure more effectively, if combined with a response system. The term response system includes all automated measures that can be taken immediately after the detection of the first earthquake waves within the lead time. Structural damages are not the only threat especially for critical infrastructures. Accidents or side effects due to a seismic event such as fire or more rarely explosions or dispersion of toxic substances can have even more harmful consequences than the mechanical damages directly induced by the ground motion [7]. Possible countermeasures to limit damages and prevent domino effects that can be performed in range of seconds are emergency shutdown of gas lines, activating backups, safe stop of lifts or other equipment, interruption of medical operations, access prevention in road bridges or tunnels [7]. Within the ROBUST project, the production process of the chosen industrial facility is not interrupted automatically. The warning for a coming seismic incidence and the damage prediction is forwarded to the facility operators, who are responsible to trigger appropriate measures. Regarding the bridge, the access can be interrupted by a traffic light, in case an earthquake with damage potential is detected. Depending on “almost” real time assessment from the local monitoring system of the bridge, the access restriction will be recalled or it will remain for all or some kind of vehicles.

3 COMMUNICATION NETWORK

Essential part of the developed system is the decentralized communication network. It enables the interaction between seismic sensors and local monitoring sensor systems and is responsible to forward warning messages and structural health status reports to subscribed recipients (user oriented). Each user has access to different level and kind of information depending on his involvement. As users can be considered facility managers, local authorities, civil protection or rescue teams. From the communication infrastructure point of view, all the participants are divided into two categories: (i) sensors and (ii) actors. Sensors “produce” information and actors “consume” information. The nodes are spatially distributed and one node corresponds to

each seismic sensor. At the monitored infrastructures one node is responsible for the seismic sensor and for the controller of the local monitoring system. Predefined subscriptions specify the flow of information between the nodes. At the idle period, the platform is responsible to control, which devices are connected, their health status and the plausibility of the measurements of the sensors. The administrators of each subsystem are informed through automated messages about the health status of the whole sensor infrastructure.

When a ground motion, which exceeds a predefined threshold of acceleration, is detected by the seismic network, the communication node of the corresponding seismic sensor forwards the information to the subscribed recipients to trigger the monitoring system to measure with a higher sampling ratio, in order to obtain detailed information for the response of the structures during the seismic event. If a seismic event with damage potential is detected by the seismic network, messages, graded indicative lamp systems or smart traffic lights will inform the corresponding users about the upcoming event. No emergency shutdowns or other measures are triggered directly by the communication platform. During the seismic event, the sensor signals are continuously evaluated with regard to exceedance of values indicating damages. Right after the earthquake, the health status of the infrastructures, is evaluated based on the recording of the monitoring system and sent via the communication infrastructure to the concerned subscribers. The first report includes a rapid assessment of the performance of the structure (e.g. partial or total collapse of the infrastructure, risk for fire or explosion, operational status of a bridge). After a few minutes, a second more precise health status report is delivered. It contains information about the detection of damages and their spatial distribution. The second health status report includes information about the operability of the infrastructure and a graphic 3D representation of the structural damages.

4 STRUCTURAL HEALTH MONITORING OF CRITICAL FACILITIES

4.1 Critical Infrastructures

Critical infrastructures, according to German Federal Office for Civil Protection and Disaster Assistance, are organizations and facilities with crucial significance for the state community, the failure or impairment of which would result in lasting difficulties in supply chain, significant threats for the public security or other dramatic consequences [8]. Although buildings are considered to be the most vulnerable component of the urban built environment to seismic hazard, the resilience of complex systems like transport and utility networks, gas and electric network systems, health care system, power plants and selected industrial facilities is even more critical, as they have an extreme socio-economic impact and can affect the regional prosperity [9]. Although the seismic code provisions in Germany are constantly improving [10] and seismicity of the Lower Rhine Embayment was investigated in detail the recent years [11], an important part of the critical infrastructure was designed with lower seismic actions or without any seismic code provisions. According to [11], in this region there are 51 electricity supply substations, 108 hospitals, about 1500 industrial facilities, 4 industrial chemical parks and 8 road and railway bridges over Rhine.

Interdependencies between complex systems may result in rapid damage propagation. Therefore, there is a demand for interconnected monitoring systems, that can detect damages and provide this information to crisis management centers. Appropriate safety measures to prevent or mitigate damages can be triggered effectively, only if sufficient information is available within a short time. Awareness of the structural health status of critical nodes of the transport network, such as bridges, is beneficial for the definition the optimal routes for rescue teams and ambulances (interaction health care system – transport network). Chemical industries are an important component of the infrastructure in Lower Rhine. The main threat after an earthquake

in chemical industries with hazardous processes is the risk of accidental scenarios such as fire, explosion or dispersion of toxic substances due to loss of containment. Immediate countermeasures must be triggered to limit the consequences of such events in terms of fatalities, environment pollution and repair cost [12].

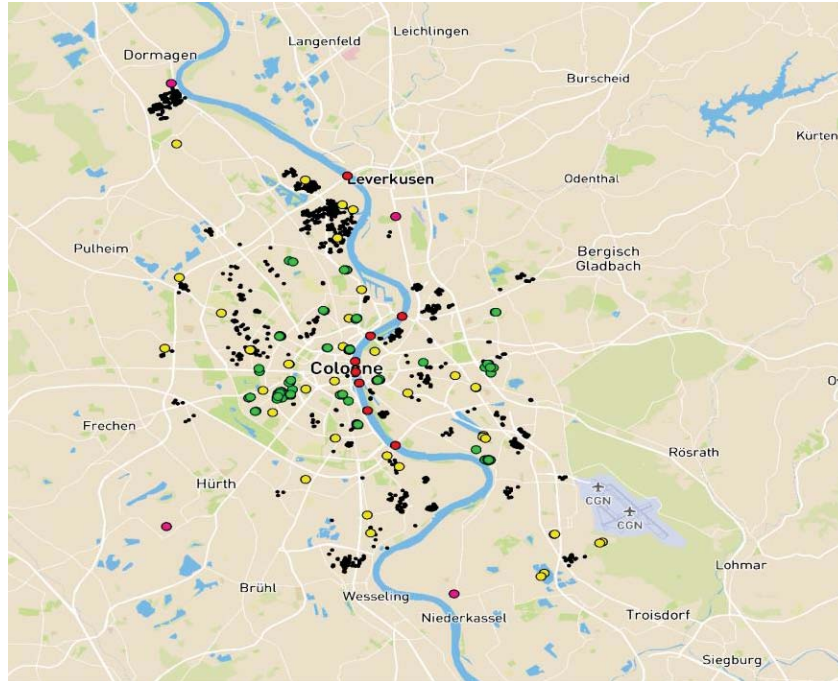

Figure 3: Distribution of critical infrastructures in Lower Rhine Region: electricity substations (yellow circles), hospitals (green circles), road & railway bridges over Rhine (red circles), industrial facilities (black circles), chemical industry parks (purple circles) [11]

4.2 Implementation of health structural monitoring system on demonstration facilities

Taking into consideration the distribution of critical infrastructures in Lower Rhine Region, an industrial facility (chemical industry) and a road bridge are selected as case studies for the installation of the local SHM systems. For both infrastructures, a probabilistic earthquake risk analysis is carried out, to define the seismic hazard. The vulnerability curves of different elements and components are defined based on the corresponding literature [13][26][27][28]. The most susceptible components are prioritized, their possible failure modes and the position of the expected damages is investigated in detail. Especially for the industrial facilities, the influence of non-structural components should be taken into account. Storage tanks, vertical and horizontal vessels, processing equipment, pumps and piping systems are connected with each other and structural damages on one process unit can generate a multiplicity of accident chains due to mutual interactions [14]. After the basic identification of the facilities, suggestions for further damage prevention or damage limitation will be provided and discussed with the facility operators [12]. The damage scenarios determined by simulations will be communicated to the operators and may be used for improving emergency actions and prevention of cascade effects. For this purpose, appropriate damage indicators and assessment methods, providing necessary information about the global performance of the structure or local failures of critical component will be implemented. Structural damages can result in a loss of stiffness, indicated by changes in natural frequency, mode shapes or modal shape curvature. For the monitored bridge, the critical indicators are aiming at the condition of the superstructure (global response, local damages) and at the bearings (critical movement of the superstructure) [29][30]. Regarding the industrial facilities, peak floor acceleration (PFA), interstorey drift ratio (SDR), residual SDR,

response of connections or strains in critical locations, for example elbow or tee connections of pipelines can be used as damage indicators [15] [16]. The number and the kind of the selected sensors (accelerators, velocity and displacement transducers, strain gauges etc.) depends on the chosen indicators and are structure specific.

Immediate damage detection and quantification, especially for critical infrastructures, is essential to minimize their operation interruption due to shut down time. Traditionally, engineering inspections and nonlinear analyses are necessary to evaluate the capacity of the structures after seismic events. This may last weeks or months, accompanied with an important economic cost due to shut down. Modern structural health systems can provide real time damage detection based on changes in dynamic properties of the monitored structures [16]. There is a variety of methods both in time and frequency domain such as autoregressive methods, stochastic subspace identification, frequency domain decomposition method, which can assess the seismic performance and health condition through different indicators [17]. The comparison of measurement data and simulation data allows a more precise prediction of damage stage and distribution within the infrastructures. Moreover, the existence of a geotechnical seismic sensor close to the monitored facilities, allows the application of either output only or input/output methods [18]. For different structural types, different types of damage indicators may be more effective [16]. The functionality of the measurement chain, selected damage indicators and assessment methods will be verified in scaled benchmark structures and substructures in laboratory in advance. In the aftermath of an earthquake, the fundamental information that should be extracted from the monitoring system concern the operational ability of the corresponding infrastructure depending on the distribution of damages. The smart data acquisition devices, which are capable to process data in real time and forward the crucial information to the communication network [19] play an important role in the integration of local monitoring system to the whole early warning and response system.

4.3 Integration health monitoring system in BIM modelling

The integration of the local monitoring systems of critical infrastructures in 3D BIM models is one of the objectives of the research project. BIM is an intelligent 3D model - based process, which promotes the interdisciplinary cooperation of different architects, engineers, constructors and facility operators [20]. The integration of SHM systems in BIM offers geospatial content to the measured and processed data and provides better control and management of the infrastructure [21]. In case of an earthquake with damage potential, the visualization of damages provides a fast and structured overview for operators of critical infrastructure and supports the decision-making processes. Another asset concerns mainly the rescue teams for whom a comprehensive graphic overview of the damages before entering a facility is important. Finally, the knowledge of the updated health status of infrastructures is a useful tool for the effective management and decision making at regional level.

The implementation is divided in two main parts: (i) the generation of a BIM Model including sensors and (ii) the coupling of the graphic objects with sensor data. For the creation of a 3D BIM model, Revit Structure 2020 [31] is selected. The principle is presented using the example of a simple steel frame structure. At first, the steel frame is designed according to the Eurocodes. The next step is the implementation of accelerometers as separate family component by means of an IFC class for the graphical representation of the sensors. The accelerometer created as a family component is imported in the main model. The IFC class names *IfcSensor* and *IfcSensorType* in Revit are classified as specialty equipment object [22]. Therefore, a subcategory "accelerometer" is manually defined in the file "exportlayers-ifc-IAI.txt". Alternatively, it is possible to use an existing object from the Revit library, such as fire alarm. However,

this may result in misunderstanding between different users. Revit gives the opportunity to provide static information like position, Id/name, manufacturer, type, cost etc. to each sensor [23].

However, the key challenge is the development of a “dynamic” BIM Model with continuous connection to the actual sensor data. For this purpose, Desite MD (Manage Data) is chosen [24]. Desite MD provides the opportunity to import BIM Models as IFC files and to interact with them through a Javascript API. The interaction is possible via an internal customized web browser, which allows the development of user-oriented applications [25]. Two main tasks have to be implemented: (i) the coupling of the IFC objects representing sensors with the corresponding measurements on the database and (ii) the representation of seismic damages in a 3D model. Concerning the first target, through the API, when a graphic sensor is selected by the user, its ID is identified and can be linked with data available in the database. The data are requested by the API from the corresponding table of the database. In general, it is possible to request either raw data or post-processed data. The sensor values are updated in time intervals appropriate for the specific application. The measurements can either be represented in tabulated views or in diagrams. The color of the sensor objects can be adapted considering the sensors operation status and the corresponding measurements. For example, an accelerometer can be: (i) grey: for sensor out of function, (ii) green: for sensor in function and maximum recorded acceleration during the last 30 sec. lower than m_1 , (iii) orange: for sensor in function and maximum measurement during the last 30 sec. between m_1 and m_2 and (iv) red: for sensor in function and maximum measurement during the last 30 sec. higher than m_2 . Threshold values (m_1 , m_2) depend on the requirements of each structure. Moreover, through the web form module, a graphical interface will be developed, where the user can request various data from sensors – namely from the database (raw or evaluated values, maximum/minimum values within a time period etc.).

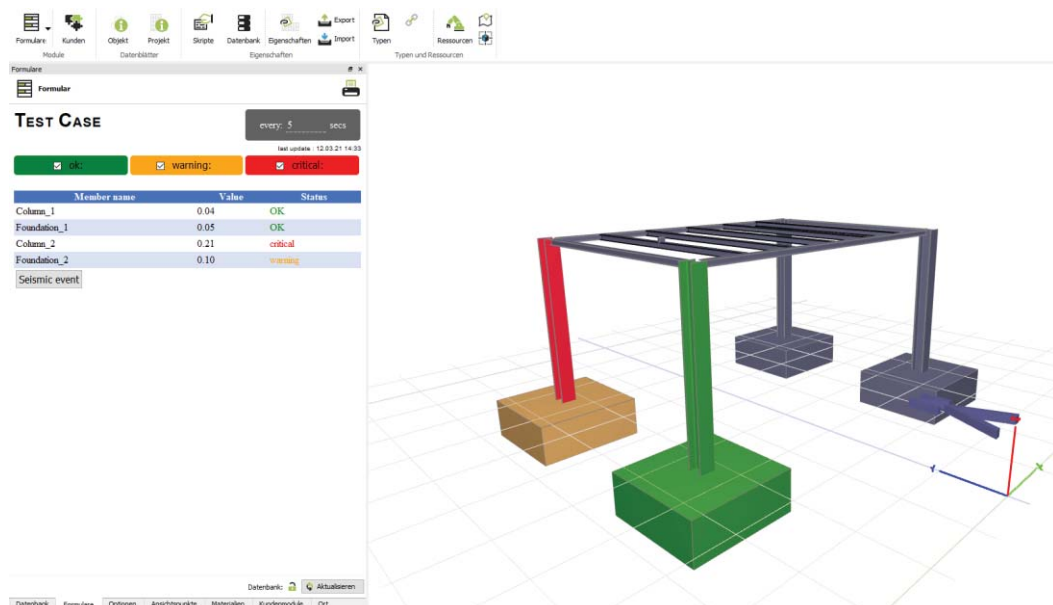

Figure 4: Visualization of damage detection after a seismic event

Regarding the damage detection, the color of monitored members/components is adapted depending on defined damage threshold values (Figure 4). The predefined threshold values (for instance interstorey drift ratio limits) are compared with post-processed sensor data, which result from one or more sensors. The updated model with the adapted colors of critical members/components and sensors is saved and compressed in a packed model after every update. After a seismic event, members and sensors maintain the most unfavorable health status-color,

even if measurements return to values below thresholds after the seismic event. The compressed file of the model including the visual distribution of damages is forwarded to the interested subscribers. Civil protection and rescue teams equipped with a BIM-Viewer will be able to open on tablets or smartphones the adapted compressed 3D model, in which the identified damages are indicated e.g., by colors and descriptive labels.

5 CONCLUSION

The presented paper describes the concept of a user-oriented earthquake early warning and rapid response system based on interconnected decentralized smart sensors and sensor systems integrated in BIM models. Aim of the project is to contribute to the mitigation of seismic risk, especially with respect to critical infrastructures. The investigated system is prototypically applied in Lower Rhine Region, which is one of the most important seismic areas north of the Alps. Although its seismicity can be categorized as moderate in European context, the seismic risk due to the population and infrastructure density is high. Exemplarily, a road bridge and a chemical industrial facility will be monitored and investigated in a holistic approach, considering their interactions with other infrastructures and networks. The essential relay between the seismic network (responsible for the early warning), the local monitoring systems (responsible for the evaluation of the seismic performance and detection of damages of critical infrastructure) and the interested parties, namely the facility operators and the local authorities, is the decentralized communication network, which enables the transfer of warning, health status and other critical information. The integration of SHM system in BIM models is a step forward in the management of infrastructures. The opportunity to visualize the detected damages in 3D models will improve the understanding and the decision-making processes for facility managers and will increase the resilience by reducing production interruptions and related economic losses. Furthermore, it is a useful tool to support rescue teams.

Abstract

The aim of this work is to improve the current structural health monitoring (SHM) methods for civil structures. A field experiment was carried out on a two-span bridge with a built-in unbonded prestressing system. The bridge is a 24-metre long concrete beam resting on three bearings. Cracks were formed subsequently when a prestressing force of 350 kN was changed to 200 kN, so that different structural states could be demonstrated. The structural assessment of this reference bridge was accomplished by the non-destructive testing using ultrasonic devices and vibration measurements. The ultrasonic velocity variations were investigated by using the coda wave interferometry method. The seismic interferometry technique was applied to the vibration recordings to reconstruct the wave propagation field in the bridge. This investigation shows that the wave velocity is sensitive to the current structural state and can be considered as the damage indicator. Overall, the implementation of coda wave interferometry and seismic interferometry technique facilitates structural health monitoring (SHM) in civil engineering.

Keywords: structural health monitoring, non-destructive testing, coda wave interferometry, seismic interferometry, ultrasonic measurement, prestress.

1 INTRODUCTION

The application of prestressing and post-tensioning techniques to civil infrastructures such as long span bridges improves the structural performance in their lifetime. Since the prestress loss can occur while the structure is in service, it is important to monitor the prestressed civil structures. However, a lot of studies lack the reference condition of large-scale test objects for comparison in the evaluation.

In our study, a large-scale concrete bridge model containing a built-in unbonded prestressing system was monitored. The variable prestressing force was a benefit to our investigation on the bridge. As the structural capacity was enhanced by the high prestressing force, the structural condition was considered as the baseline for damage detection. Thus, we could explore damage indicators of the prestressed bridge.

To achieve the research aim, both active and passive procedures were applied in the field experiment. Since damage leads to changes in the dynamic properties of the structure, vibration monitoring is useful as a non-destructive evaluation tool. However, the measured eigenfrequencies are also sensitive to environmental influences [1]. Referring to the advantage of the wave-based method, two kinds of wave propagation were considered in our study: ultrasonic wave propagation, which is widely used for non-destructive testing (NDT), and the resultant of seismic interferometry of noise recordings.

Ultrasonic waves are sensitive to variations of several parameters (stress, temperature, moisture) and to any kind of damage. Different mechanical wave propagation regimes have been investigated for concrete so far [2]. In the attenuation phenomenon, the waves scatter and induce the onset of late arrival, constituting the so-called ultrasonic coda. In seismology, the coda waves are known for its high sensitivity to small perturbations of the medium. Coda waves are defined as the part of the signal that occurs directly after the arriving phases. In a heterogeneous medium, the small change has less influence on the waves arriving first than on the diffusion waves arriving later. As coda waves travel longer distances, the sampling repeats and the influence of the small change is amplified [3]. Hence, the coda energy change is more detectable than the direct ones.

Recently, coda wave interferometry (CWI) has been used to ultrasonic coda and noise recordings in civil structures. The implementation of CWI enabled the detection of early subtle changes in reinforced concrete structures until crack formation [4]. In an earlier study [5] using ultrasound to monitor stress distribution and cracking in concrete beams, they were loaded until failure to detect cracks before visual signs appear on the surface. The application of CWI to the waveform of the cross-correlation function of two vibration records was presented in another study [6] to analyse the wave velocity variation.

This contribution introduces the background of CWI and the application of CWI to our measurement data. We studied the effect of the post-tensioning force change based on the coda wave velocity variation. The experiment result confirms the applicability of the monitoring method using CWI. This research shows the progress towards the development of a cost-effective and reliable technique for real-time monitoring in large-scale structures.

2 CODA WAVE INTERFEROMETRY

We studied the effect of the post-tensioning force change based on the coda wave velocity variation. For this, the same waveform in two different bridge states was compared using coda wave interferometry (CWI). The principle of CWI is to compare the waveform consistency of coda waves recorded in two different states. Figure 1 shows two signals recorded before and after perturbation. The first arrivals of the signals are almost the same, while the coda wave

(later arrivals) shows significant wave propagation time lags. The relative time lag ($\frac{\delta t}{t}$) between the two signals before and after the perturbation indicates the relative wave velocity change ($\frac{\delta v}{v}$). Since the prestress has a homogeneous effect on the wave propagation velocity, the linear relation is applied

$$\frac{\delta v}{v} = -\frac{\delta t}{t}. \quad (1)$$

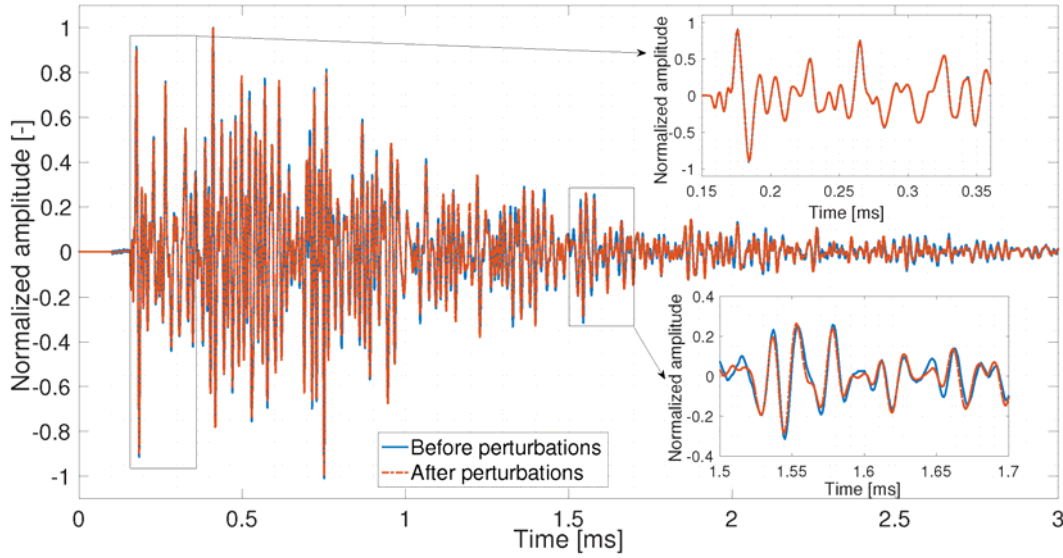

Figure 1: Repeated ultrasonic signals with difference just visible in the coda [7].

The following explains how to estimate the wave velocity variation by applying the stretching method to CWI.

2.1 The stretching method

As the relative velocity decrease is defined as the stretch factor α

$$\alpha = \frac{\delta v}{v}, \quad (2)$$

the shift time in wave propagation is represented by $t(1 + \alpha)$.

Hence:

$$u_s = u_o(t(1 + \alpha)), \quad (3)$$

where the original waveform u_o is stretched and turned into u_s .

According to this formulation, the sign of α is negative if the waveform is compressed.

The cross-correlation between the stretched and the original waveform is then shown as follows

$$CC(\alpha) = \frac{\int_{t-T}^{t+T} u_o(t')u_s(t')dt'}{\sqrt{\int_{t-T}^{t+T} u_o^2(t')dt' \int_{t-T}^{t+T} u_s^2(t')dt'}} \quad (4)$$

The cross-correlation coefficient (CC) is considered as a quality indicator. If two waveforms are identical, the cross-correlation coefficient is equal to 1. Vice versa, the cross-correlation coefficient between -1 and less than 1 indicates the difference depending on the dilation level.

2.2 Application

We investigated the impulse response in the different prestressed states using coda wave interferometry. One waveform was considered as a reference and the other was stretched by the factor α in a range $[-dv, dv]$. The best α was determined by comparing CWI in the reference waveform and the stretched waveform. Such an α maximizes the cross-correlation of two compared waveforms. At the same time, the wave velocity change is obtained in the best fit condition. As a result, we could study the relationship between the prestressing force variations, temperature change and wave propagation velocity in the concrete bridge model.

3 EXPERIMENT

3.1 Test structure BLEIB

The test structure was a prestressed concrete bridge model exposed to the nature environment at the BAM test site [8]. No traffic vibrations were induced as background noise on the bridge. The bridge model has been used for various loading and vibration tests. Thereby, vertical cracks had developed near the two midspans (Fig. 2). For our study, no additional external load was applied to the bridge, thus no significant post-cracking behavior occurred. This reduced the confusion of the external interferon.

Figure 2: The damage condition after vibration and loading tests (photographed in 2018).

We induced the natural damage by opening the already existing cracks. Initially, we increased the prestressing force up to 550 kN (level 1 in Tab. 1) and then adjusted the magnitude of the prestressing force (level 2-9 in Tab. 1) to obtain the different event extensions of the already existing cracks.

Level	Prestressing force [kN]
1	553
2	457
3	403
4	353
5	300
6	255

7	200
8	353
9	455

Table 1: Prestressing force level.

3.2 Vibration measurements

We implemented passive monitoring by vibration measurement. Geophones (Fig. 3 left) were used and the sampling rate was 600 Hz. The blue markers in Fig. 4 indicate the geophones' position. The distance between every two adjacent geophones is 3 m.

Figure 3: Sensors. Left: geophones. Right: ultrasonic transducers SO807 [9].

Figure 4: Side view of the bridge and sensor positions.

Figure 5: Impulse response in Level 2. Left: hammer impact received at the position 2. Right: seismic interferometry of the ambient noise at the position 1 and 2.

We directly obtained the real impulse response caused by the impulse source excited by the hammer impact (the position reference to the black arrow in Fig. 4). The measured impulse response lasted 20 sec. Fig. 5 on the left shows the impulse response received at the position 2. We also performed the ambient vibration measurement for 3 min. for each prestressing level. To extract the virtual impulse response, the seismic interferometry technique (the cross-

correlation method) dealing with the reconstruction of Green's functions between two receivers was used. One of these two receivers was turned into a virtual source. Finally, two virtual impulse responses extracted from 3-minute measurement data were stacked and normalized. Fig. 5 on the right shows the impulse waveform with the window size of 20 sec. between position 1 and position 2.

3.3 Ultrasonic measurements

For active monitoring, we performed the ultrasonic transmission measurement. 14 ultrasonic transducers “SO807” ([9], Fig. 3 right) were mounted inside the bridge during its construction before casting (position reference to the green markers in Fig. 4 and Fig. 6). This sensor can operate as both a transmitter and a receiver. The ultrasonic wave was generated with a central frequency of 60 kHz. The sampling rate is 1MHz. In the measurement, 10000 samples were taken.

Figure 6: The embedded SO807 sensors in a cross section.

4 RESULTS

First, we show the modal analysis results of the bridge finite element model and the evaluation of the influence of the prestressing force on the natural frequency. Then the results of the ultrasonic impulse response, the real impulse response and the virtual impulse response are presented. The influence of temperature and prestressing on the coda waves is finally discussed.

4.1 Natural frequency and structural stiffness

The opening/close of the already existing cracks caused the overall stiffness change. Consequently, the structural dynamic behaviour changed due to the superposition of two effects from the prestressing force and the cracks. The comparison of the first natural frequency in the simulation of the intact bridge model (Fig. 7) with the measured result in the Level 1 state (Fig. 8 left) showed that the current bridge condition is damaged.

Figure 7: Half span of the finite element (FE) model (left). The first mode shape corresponds to 3.9 Hz (right).

Furthermore, Fig. 8 shows the first two modal frequencies in the Level 1 and 7 states. The decrease of natural frequencies depends on the prestress loss and the event extension of the already existing cracks in the bridge. Based on this, we were able to demonstrate different structural states by adjusting the prestressing force.

Figure 8: Natural frequency spectrum. Left: Level 1. Right: Level 7.

4.2 Influence of temperature and prestress change

On the measurement day, the ambient temperature increased from 28 °C to 30 °C during the prestressing adjustment from Level 1 to Level 9. Therefore, the high prestress level coincides with the high measured concrete temperature. The increasement in concrete temperature was higher than that of the ambient temperature. The results (Fig. 9 and 10) show that in our case the velocity variation is independent from the temperature change.

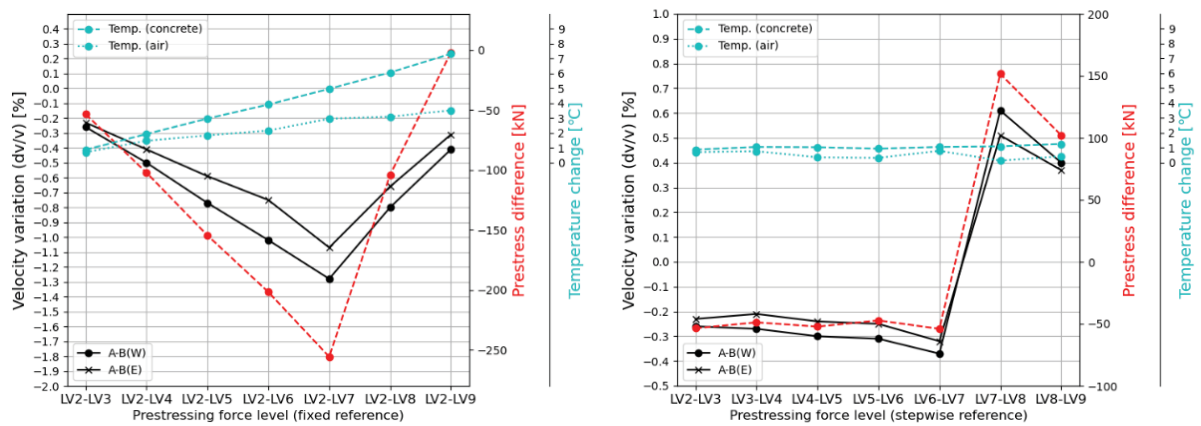

Figure 9: Ultrasonic coda velocity variation. Left: the fixed reference (Level 2). Right: the stepwise reference.

Figure 10: Impulse wave velocity variation (fixed reference: Level 2). Left: obtained from the real impulse response. Right: obtained from the virtual impulse response.

4.3 Discussion

Although Fig. 8 shows the natural frequency change due to the overall stiffness change, it is difficult to quantify the real damage condition and even more difficult to detect the structural property alteration with smaller prestress changes. Moreover, the natural frequency as a global dynamic characteristic is not sensitive to the damage location.

Fig. 9 and 10 show that the variation in velocity for both the ultrasonic coda and the impulse response coda corresponds very well with the prestress change. Particularly the velocity variation of the ultrasonic coda was greater in the west side than in the east sides (Fig. 9 left). The high sensitivity of the ultrasonic coda came as a benefit in the detection of the local damage condition. The wave velocity variations in the impulse response received at the position 1 and 2 were the same (Fig. 10 left). Thus, the hammer impact had the same influence on both receiver positions. Comparing the results shown in Fig. 10, the velocity variation in the virtual impulse response fits the prestress change better than the real impulse response. The applicability of seismic interferometry used to extract the virtual impulse response for CWI is approved. In addition, a significant drop in velocity variation was observed between Level 6 and 7. We state that this result is caused by the open cracks. This revealed the influence of the post-tensioning force on the already existing cracks.

5 SUMMARY AND OUTLOOK

Contrary to many researchers who have focused on the assessment of ultrasonic waves in concrete specimens in the laboratory, our study explored the applicability of ultrasound on a large-scale bridge model in a field experiment. The damage condition and the experiment setting made this bridge an ideal test structure to perform not only active, but also passive monitoring. Coda wave interferometry was applied to the ultrasonic coda and the vibration recordings. We investigated the effect of the prestressing force change based on the coda wave velocity variation. The monitoring schemes were verified by the good match of the coda wave velocity variation and the prestress alteration.

One drawback of our experiment is that the ultrasonic measurement duration at different prestress levels is too short to obtain the relationship between the temperature and the wave velocity. Performing a long-term measurement without prestress change will be our next step to investigate the dependence of the coda wave velocity variation on temperature.

Abstract

The determination of seismic risk is the foundation for risk mitigation decision-making and a key step in risk management. Large corporations and other enterprises (e.g., local governments) analyze their 'portfolio' of properties, to determine how to best allocate limited funds for structural strengthening of buildings, or other risk reduction measures such as emergency planning. When assessing the seismic vulnerability of buildings, it is essential to first establish the project objectives, before subsequently choosing the most appropriate strategy and tools necessary for building assessment and fulfillment of these objectives. It is also extremely important to understand the difference between the detailed approaches used for individual building assessment and those methods most efficient for larger scale analysis, pursued for city center assessment. While the latter results can be used as a general measure of seismic risk for different types of buildings, the actual seismic risk for any individual building may vary considerably and will depend upon its exact configuration and condition. In this study, some historical masonry buildings located in Alsace France are considered and the dynamic characteristics of these structures were estimated by the analysis of seismic noise recordings by sensors installed at each floor of the buildings under study. The estimated dynamic properties for small amplitude vibrations of these historical structures were used to derive fragility curves through vulnerability models with different level of complexity and accuracy. These fragility curves have been calculated using incremental dynamic analysis for the seismic demands generally imposed upon linear and slightly nonlinear models of single and multiple degrees of freedom, which is the case for the effects of induced seismicity. Considering the latter case of induced seismicity, the vulnerability assessment requires the expected damage to refer to non-structural components. The conclusions through comparison of the results of this study in terms of refinement of the verified structural models will prove useful for both local end-users and industrial stakeholders, with a clear perspective for a better understanding of the risk related to induced and triggered seismicity and its sound management.

Keywords: fragility curves, non-structural components, masonry, induced seismicity.

1 INTRODUCTION

The determination of seismic risk is the foundation for risk mitigation decision-making, a key step in risk management. Large corporations and other enterprises (e.g., local governments) analyze their 'portfolio' of properties to best allocate limited funds for structural strengthening of buildings or other risk reduction measures such as emergency planning. When assessing the seismic vulnerability of buildings, it is essential to first establish the project objectives before choosing the most appropriate strategy and tools necessary for building the assessment and fulfilment of these objectives. It is also extremely important to understand the difference between the detailed approaches used for individual building assessment and those methods most efficient for larger-scale analysis, pursued for city center assessment. While the latter results can be used as a general measure of seismic risk for different types of buildings, the actual seismic risk for any individual building may vary considerably and will depend upon its exact configuration and condition.

In this study, some historical masonry buildings located in Alsace France, are considered, and the dynamic characteristics of these structures were estimated by the analysis of seismic noise recordings by sensors installed at each floor of the buildings under study [1],[2].

In the considered test site, the analysis of the collected exposure information indicates that traditional or historical masonry structures occur in large numbers near to the mostly rural areas close to the geothermal platforms in Alsace region in France [3]. Two general classes of structures, namely unreinforced masonry (URM) and timber-framed masonry (TFM) buildings, have been considered, and the simple performance assessment models [1],[2] have been adopted in order to carry out a preliminary vulnerability assessment for these classes of structures. The objective is to rapidly identify buildings and their non-structural components that are at greater risk in the event of an induced earthquake, and to model their non-structural fragility.

The vulnerability modelling focused on buildings constructed of masonry, which may be more susceptible to the range of ground motion expected in the event of induced seismicity in the area. The measurements have been carried out using the MPwise (Multi-Parameter Wireless Sensing System) smart device [4], which has been designed to carry out rapid measurement activities by exploiting the computing and advanced networking capacities embedded in individual units. Based on environmental, seismic noise measurements, the fundamental frequency of vibration of the inspected buildings has been estimated and used to calibrate the respective fragility curves.

In collaboration with GFZ and ES-Géothermie a three-day acquisition campaign was organized, which involved installing four sets of sensors in private houses located in villages located around the Soultz and Rittershoffen geothermal sites. The fundamental period of these structures was verified by analyzing the ambient noise measured using the MPwise sensors [4], with one sensor installed outside of the buildings and the three others installed on each floor of the houses (basement, ground floor and first floor). The sensors were installed to record the ambient noise and to draw a vulnerability mode that allows the issuing of damage forecasts (Table 1, [1],[2]). Finally, the main geometry required as input for the simplified vulnerability models was taken through field inspection of these buildings.

No	Building Type	Building Latitude	Building Longitude	Fundamental ESDOF Model Period (s)	Fundamental Frequency Sensor (Hz)
1	URM	48.964946	7.881095	0.17	5.5

3	URM	48.905270	7.950266	0.11	9
4	TFM	48.914307	7.882233	0.15	6.7
5	URM	48.932865	7.874377	0.32	3.1

Table 1: Real URM and TFM buildings located near the geothermal platforms in Alsace region in France [1],[2].

2 INCREMENTAL DYNAMIC ANALYSIS OF EQUIVALENT SINGLE DEGREE OF FREEDOM SYSTEM (ESDOF)

The estimated dynamic properties for small-amplitude vibrations of these historical structures were used to derive simplified vulnerability models. While steel or concrete frames are mostly lumped systems with stiff diaphragms, URM buildings have distributed mass and stiffness commonly in combination with flexible diaphragms. This fact obstructs the adoption of the established methodologies to URM buildings. Specifically, the latter buildings' fundamental mode shape involves a low percentage of the total mass of the building below the 75% limit required for the good performance of ESDOF-based methods. In order to solve this issue, the simplified procedure of Vamvatsikos and Pantazopoulou (2015) [5] was adopted. In their procedure, the dynamic URM building response is represented. Global response indices are transformed to local deformation measures in closed-form seismic assessment solution both for demand and supply in the critical structural locations. The solution involves the definition of the fundamental vibration mode, approximated by 3D shape function consistent with the building's boundary conditions. Strength and deformation indices are adopted for the evaluation of the acceptance criteria. Typical local failures are estimated through a local shape of deformation while the model captures the global dynamic characteristics. The adopted method allows the automation of the necessary calculations through closed-form expressions.

In the case of TFM the walls are reinforced with timber elements, both horizontal and vertical, but also X-type diagonal braces. It is evident historically, since the Bronze Age, that the timber reinforcement into masonry walls is strongly related to seismic resistance in earthquake-prone areas. In TFM walls, there is also recent experimental and numerical evidence [6] that the diagonal braces' contribution is vital for walls' lateral behaviour in the nonlinear range due to early detachment of the masonry infill from the surrounding timber frame in the event of an earthquake. It is also observed that the diagonals in tension detach from the surrounding frame for very low horizontal displacement. Therefore, it is suggested [6] that the diagonals should contribute to the lateral behaviour only in compression and, moreover, the infill masonry walls of the timber frame should not be considered in the analytical model. Based on these considerations, a macro-model was proposed [6],[7] where its input can be easily determined since it involves only the key geometric characteristics of the timber panels and the timber strength. The latter model facilitates the seismic assessment of TFM walls resulting in a valuable tool for simplified seismic vulnerability and risk analyses [8]. Based on the resulting pushover curves produced by pushover analysis [9] of the TFM walls' macro-model, a shape-function is defined for the derivation of the ESDOF properties which is similar to the methodology already described for URM buildings [5].

Figure 1: Proposed analytical fragility curves for first damage state (pre-yielding damage state –DS1-0.1% drift limit for non-structural damage [14]) for Unreinforced Masonry Buildings (URM) and Timber-Framed Masonry Buildings (TFM). The buildings are located near the geothermal platforms in Alsace France and are loaded in the weak/short plan view direction of shaking. The fundamental period of these structures was verified with ambient noise measurements through applied sensors [1].

Considering these real TFM and URM building cases in Alsace France (Table 1) the corresponding fragility curves are derived in terms of Peak Ground Acceleration (PGA) with the aid of structural analysis for a gradually increasing intensity (Incremental Dynamic Analysis - IDA) [10]. The latter analysis of ESDOF of the building cases under study was performed with the MATLAB [11] toolbox FEDEAS Lab [12]. The PGA values of the recordings used in the IDA with the corresponding PGV values follow the rule that for very flexible structures (structures with very high fundamental periods) the relative velocity response spectrum of the used record tends to the peak ground velocity (PGV). The induced ground motions obtained from the PEER database were employed and applied in the transverse/short/weak building plan direction [13]. As already mentioned, the fundamental periods of these structures were verified with ambient noise vibration measurements using sensors [4] located at each floor of the buildings under study (Table 1). Moreover, the main geometry required as input for the simplified vulnerability models was taken through field inspection of these buildings. The results are shown in Fig. 1. Comparing the fragility curves for URM and TFM buildings, it can be noticed that URM buildings have approximately the same range of probability of damage while the more earthquake-resistant TFM building is less fragile for low and medium intensities.

3 INCREMENTAL DYNAMIC ANALYSIS OF THREE-DIMENSIONAL MODEL

The above fragility curves (Fig. 1) have been developed using IDA for the seismic demands generally imposed upon linear and slightly nonlinear (serviceability limit state) models of single and multiple degrees of freedom, which is the case for the effects of induced seismicity. If considering the latter case of induced seismicity, the vulnerability assessment requires the expected damage to refer to non-structural components [14]. In this section, a comparison is provided of the results of this study in terms of refinement of the verified structural model for the No.1 building in Table 1 that will prove helpful for both local end-users

and industrial stakeholders, with a clear perspective for a better understanding of the risk related to induced and triggered seismicity and its sound management.

3.1 Structural modelling process

In this work, the production of analytical fragility curves for URM buildings is demonstrated on a box-shaped unreinforced masonry structure, presented in Figure 2. Namely, this building comprises the town hall of Keffenach (URM building No.1 of Table 1) in the Alsace region in France. It can be observed in Figure 2 that the building has one storey, a roof attic and one basement. In the same Figure, the respective views of the structural model are presented.

The structural model was assessed using thick-shell elements for modelling the URM walls, thin-shell elements for the reinforced concrete floor slab, while wooden elastic frame elements with rectangular section were used for modelling the roof members. As far as it concerns material properties and the structure's dimensions, they can be found in the previous work of Megalooikonomou (2020) [2], where ESDOF analysis was performed. The ESDOF model of the URM building did not include an analytical roof model. However, it was found that the roof's bearing structure affected the period of the eigenmodes. Thus, for the analytical 3D model (Fig. 2), the roof was designed to resemble the actual building and obtain the fundamental period corresponding to 0.17 s (Table 1) obtained from the installed sensors.

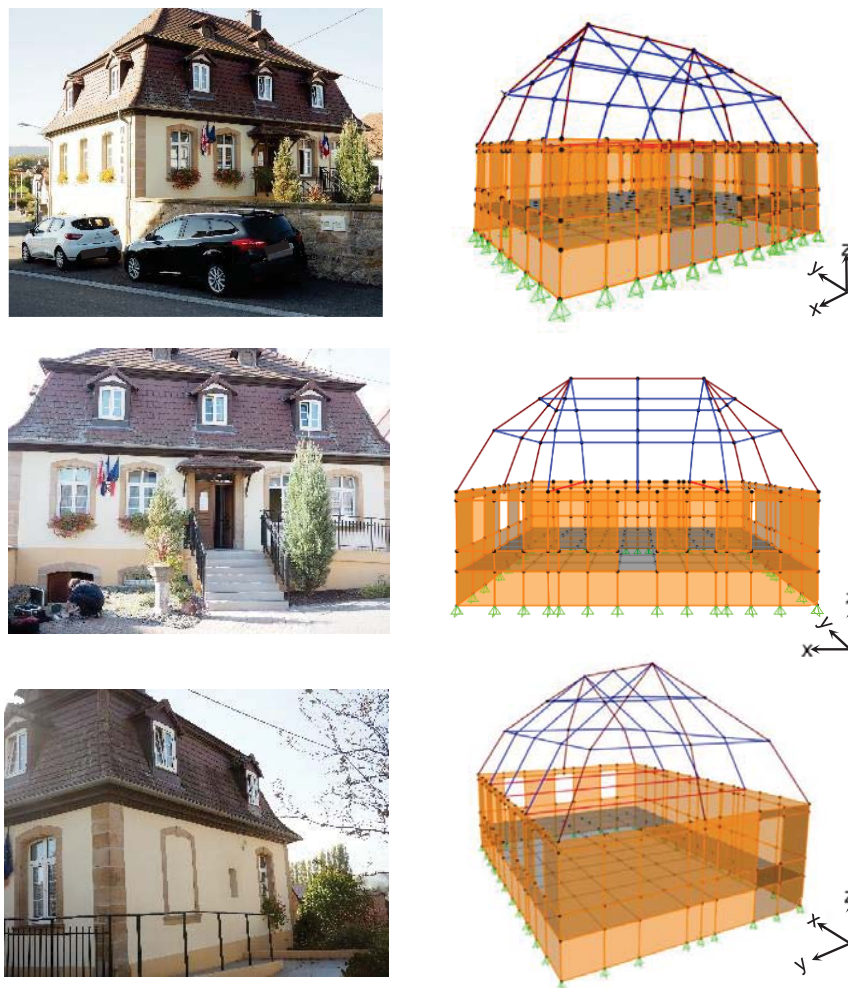

Figure 2: URM building's actual views and the generated model's respective views

3.2 Time history analysis

Producing the analytical fragility curves of the 3D model requires a number of actual induced ground motion recordings, which after scaling, were used in elastic time history analysis of the 3D model. In this work, ground motion data of 9 induced earthquakes was used [13]; more information can be found in Megalooikonomou *et al.* (2018) [1]. The ground motion data was incrementally scaled based on its Peak Ground Acceleration to obtain different shaking levels. The levels of ground acceleration used for scaling were 10 and ranged from 0.1g (9.81 m/s²) to 1g (with increments of 0.1g). Regarding the application of the scaled ground motions, 100% of the motion was applied in the primary (weak) direction (*i.e.* parallel to the y-axis in Figure 2), while 30% of the same ground motion was applied simultaneously in the secondary-strong direction (*i.e.* parallel to the x-axis in Figure 2).

After performing all 200 (20 recorded ground motions x 10 scale factors) elastic time history analyses, the ground motion that produced the largest displacements of the URM building is demonstrated for completeness of the present paper's results. This ground motion was recorded at the Luther Middle School station (Sparks, Oklahoma, USA) in 2011, and the earthquake had a moment magnitude of 5.68 at an epicentre distance of 54 km and generated a peak ground motion of 0.27g [13]. Figure 3a depicts the scaled ground motion of the earthquake rendering the largest displacements of the 3D model. Moreover, the same Figure presents the time-dependent displacements for the node of the URM walls where the maximum displacement was observed for the weak building direction of applied ground motion (Figure 3b) and the same in the strong building direction (Figure 3c).

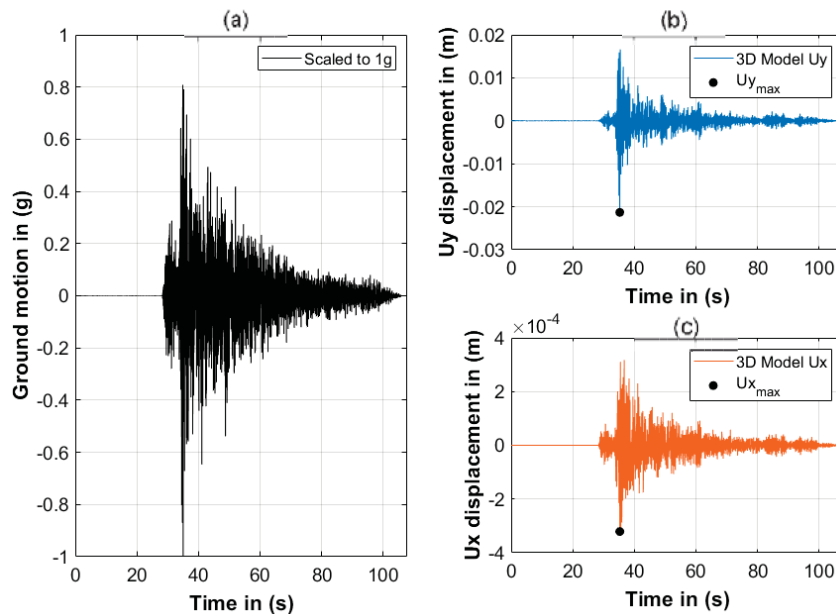

Figure 3: (a) Ground motion of earthquake producing maximum displacements; (b) node displacement for weak building direction (y-direction in Figure 2) and (c) node displacement for strong building direction (x-direction in Figure 2).

3.3 Analysis results

The results of the elastic time history analyses of the 20 ground motions and the considered scale factors for the 3D and ESDOF models were used to fit log-normal distributions for each model. Figure 4a presents the probability density functions of the 3D model and ESDOF. His-

tograms of the natural logarithm of maximum drift comprise the analysis actual results that allowed normal distributions to be fitted for both 3D and ESDOF models (Figure 4a). The fits were used to estimate the fragility curves for the different levels of Peak Ground Velocity (PGV) depicted in Figure 4b [see also Figure 1 (URM, $T=0.17s$)]. It is evident from Figure 4b that the 3D detailed analytical model results to a more vulnerable to non-structural damage historical masonry building.

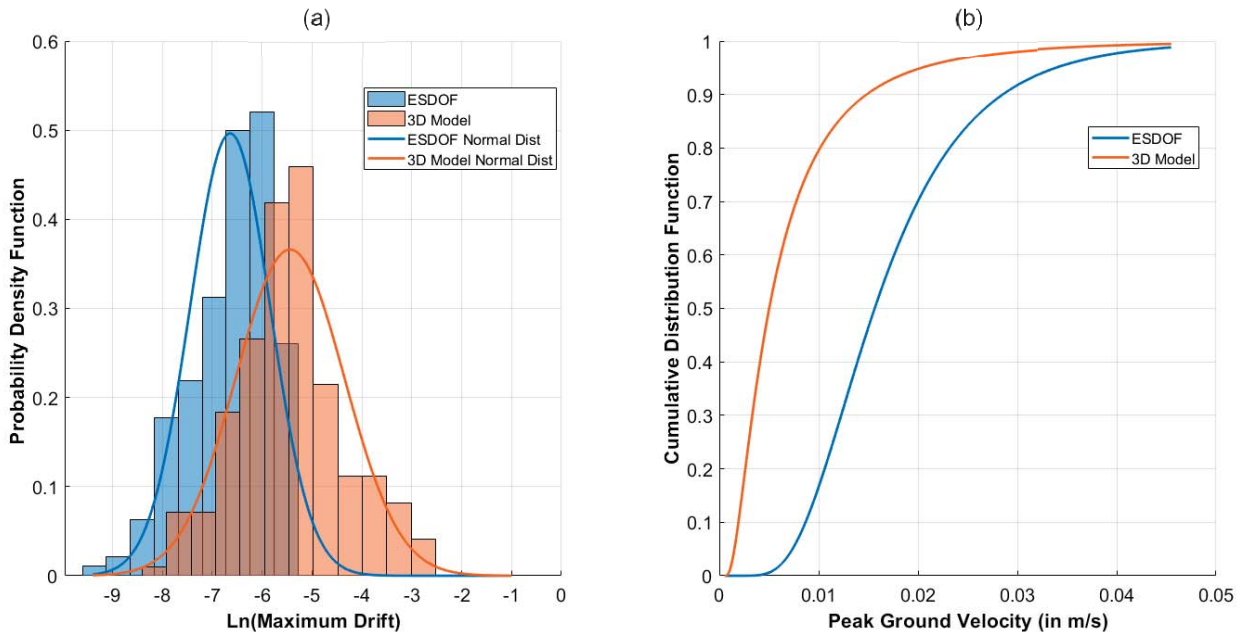

Figure 4: Analysis results for ESDOF and 3D model: (a) Relative frequency and probability density function of the natural logarithm of the maximum drift at height 3.81m and (b) Fragility curves – PGV in (m/s).

4 CONCLUSIONS

- The estimated dynamic properties for small amplitude vibrations of the historical structures near the geothermal platforms in Alsace, France considered in this work were used to derive simplified vulnerability models that were compared with a detailed 3D model for one of these masonry buildings under study.
- Moreover, Eurocode 8 defines the interstorey drift limit of a building for non-structural damage by looking at its displacement-sensitive non-structural components at the serviceability limit state. Adopting these limits and the developed vulnerability models, new non-structural fragility curves for typical historical masonry building types dominant in the region under study are proposed.
- The fragility curves have been calculated using incremental dynamic analysis for the seismic demands generally imposed upon linear and slightly nonlinear models of single and multiple degrees of freedom, which is the case for the effects of induced seismicity.
- A comparison is provided of the results of this study in terms of refinement of the verified structural model. It is evident that using simplified vulnerability models compared to detailed 3D structural models may lead to a considerable error regarding the probability of non-structural damage due to induced seismic events.
- These results will prove useful for both local end-users and industrial stakeholders, with a clear perspective for a better understanding of the risk related to induced and triggered seismicity and its sound management.

Abstract

Several scenarios can trigger bi-axial shear in reinforced concrete (RC) vertical members such as wind actions, earthquake, column loss induced by explosions and/or impacts. The majority of standard codes impose uniaxial shear verification of vertical members and neglect the interaction between shear forces and bending moments acting along the two principal directions of inertia of the transversal cross section. Moreover, bi-axial shear interaction curves proposed by codes are based on the fitting of experimental data conducted on heavily reinforced specimens. In this paper, the bi-axial shear failure envelope of existing RC columns, is investigated. A database previously published by Authors on experimental data on beams and columns tested under bi-axial loading is updated. Afterwards, the experimental shear resistances of the database's members subjected to both monotonic and cyclic loading are compared with analytical predictions. Three different formulations are adopted for the analytical calculation of the uniaxial shear resistance: (i) Model Code 2010, (ii) Eurocode 8 and (iii) the cyclic shear resistance recently proposed by Biskinis and Fardis. Such resistances are adopted to create the bi-axial shear failure envelope. Finally, the shape of the bi-axial shear failure envelope is critically analysed in order to select the formulation that provides the best fitting between experimental and analytical bi-axial shear resistances.

Keywords: Reinforced Concrete columns, Bi-axial shear, Analytical prediction.

1 INTRODUCTION

Seismic as well as wind actions can trigger bi-axial shear in reinforced column members [1]. Moreover, in the robustness assessment of structures, the bi-axial shear demand in beams and columns - associated to vertical element loss scenarios - was also highlighted, even if international codes and guidelines such as Unified Facilities Criteria [2] and Eurocodes [3], [4], are considering only the verifications in the case of uniaxial shear scenarios. Hence, even if the bi-axial shear demand covers almost all the fields of structural engineering, the bi-axial shear resistance is almost neglected in European Codes. Several experimental campaigns were carried out during years to investigate the bi-axial monotonic or cyclic shear behaviour of reinforced concrete columns. Usually, square or rectangular sections were investigated. An early study was conducted by Maruyama et al. [5] in 1979. They observed that the applied lateral loads did not significantly affect the column shear strength until the maximum lateral drift was greater than that corresponding to the maximum monotonic shear strength. Woodward et al. [6] in 1980 conducted several experimental tests on squat reinforced concrete columns with the aim to investigate the effects of both longitudinal and transversal reinforcement ratios. They did not observe a significant increase of the lateral strength with reducing the stirrups spacing. Umehara et al. [7] in 1982 investigated 20 columns with square and rectangular sections subject to unilateral and diagonal loadings. They observed that the shear capacity of squat columns under diagonal loadings could be evaluated based on the response in the two principal directions using interaction domains. In particular, for square section a circumference function can be used to represent the bi-axial shear domain, while an elliptical curve can be used for rectangular sections. In the experimental program by Joh and Shibata [8] in 1984, columns square and rectangular cross-sections were tested under lateral bi-axial loading until achievement of shear failure, using a normalized interaction domain respect to the shear strength along principal directions. Mizoguchi et al. [9] in 1990 investigated the effects of varying axial load on bi-axial loading response of squat columns, observing that columns diagonally loaded had a 5-6% lower resistance compared with counterparts loaded along principal directions. In more recent studies by Pham et al. [10] and Dang et al. [11] the shear strength mechanisms were associated to the lack of transversal reinforcement and vulnerability of low-rise structures characterized by in-plane and elevation irregularities. The mentioned experimental tests were collected from the authors in a Database [12] and used for comparisons with analytical provisions [13].

Actually, the majority of international normative and guidelines such as Model Code 2010 [14] and Eurocode 8 [15] neglect the interaction between shear and bending acting along the two principal directions of cross section. Conversely, the Japan Society of Civil Engineers (JSCE) guidelines [16] can consider bi-axial loading capacity using an interaction domain.

In this paper, three analytical formulations are considered in order to calculate the uniaxial shear resistance; in particular the formulation proposed by Eurocode 8 [15], Model code 2010 [14] and Biskinis and Fardis [17].

Afterwards, according to Japanese Code [16], the bi-axial failure criterion is evaluated. Finally, the bi-axial shear resistances are compared with the experimental results collected by Authors in their database.

2 EXPERIMENTAL DATABASE

In the following, the experimental database collected by Authors is reported in terms of member geometry, reinforcement ratios, mechanical properties and loading conditions. Columns have square or rectangular cross section. The boundary conditions are mostly fixed at the base and allow the lateral displacement at the top according to the so called “shear type” scheme,

see Figure 1a. Only in the experimental campaign conducted by Dang et al. [11], the boundary conditions allow lateral displacement and rotation at the top of the column. The loading is applied at the top of columns by applying monotonic or cyclic forces, Figure 1b. The axial load can be varied to study its influence of shear resistance and lateral drift capacity.

3 ANALYTICAL FORMULATIONS

In this paragraph, the analytical formulations provided by Eurocode 8 [15], MC 2010 [14] and Biskinis & Fardis [17] model are briefly reported.

3.1 Eurocode 8

Firstly, the formulation provided by Eurocode 8 [15] is reported. The yield chord rotation capacity is evaluated for beams and columns, Eq. (1):

$$\theta_y = \phi_y \frac{L_v}{3} + 0.0013 \left(1 + 1.5 \frac{h}{L_v} \right) + 0.13 \phi_y \frac{d_b f_y}{\sqrt{f_c}} \quad (1)$$

The ultimate chord rotation capacity is evaluated through, Eq. (2):

$$\theta_u = \frac{1}{\gamma_{el}} 0.016 \cdot (0.3^v) \left[\frac{\max(0.01; \omega')}{\max(0.01; \omega)} f_c \right]^{0.225} \left(\frac{L_v}{h} \right)^{0.35} 25^{\left(\frac{a p_s}{f_c} \right)} (1.25^{100 \rho_s}) \quad (2)$$

The strength degradation due to cyclic loading is calculated as a function of the ductility $\mu_{\Delta pl}$ which is calculated by the ratio between the plastic and the yield chord rotation, Eq. (3):

$$\mu_{\Delta pl} = \frac{\theta_u}{\theta_y} - 1 \quad (3)$$

The value of $\mu_{\Delta pl}$ may vary between 0 and 5, corresponding to null and maximum degradation, respectively. The resisting shear strength V_r under cyclic conditions can be determined using Eq. (4):

$$V_r = \frac{1}{\gamma_{el}} \left\{ \frac{h-x}{2L_v} \min(N; 0.55 A_c f_c) + [1 - 0.005 \min(5; \mu_{\Delta pl})] \left\{ 0.16 \max[0.5; 100 \rho_{tot}] \left[1 - 0.16 \min\left(5; \frac{L_v}{h}\right) \right] \sqrt{f_c} A_c \right\} + V_w \right\} \quad (4)$$

Three contributions are considered: the axial load magnitude N , steel reinforcement ratio ρ_{tot} and the plastic ductility $\mu_{\Delta pl}$.

3.2 Model Code 2010

The Model Code 2010 [14] formulation is based on in the Level of Approximation (LoA) framework for the evaluation of the shear resistance. LoA I and II are used for both members with and without transverse reinforcement while LoA III can be used only for members with shear reinforcement. Since stirrups are provided in all the analysed members, in this paper the LoA III is used for the calculation of the shear resistance. The longitudinal strain ε_x is evaluated in correspondence of the mid-depth of the effective shear depth as follows, Eq. (5):

$$\varepsilon_x = \frac{1}{2 \cdot E_s \cdot A_s} \left[\frac{M_{Ed}}{z} + V_{Ed} + N_{Ed} \left(\frac{1}{2} \mp \frac{\Delta e}{z} \right) \right] \quad (5)$$

The shear resistance V_{Rd} for elements with stirrups is calculated through Eq. (6):

$$V_{Rd} = V_{Rd,c} + V_{Rd,s} \leq V_{Rd,max}(\theta_{min}) \quad (6)$$

To consider the cyclic degradation effects, Model Code 2010 imposes the use of the following strut inclination angles (linear interpolation is allowed):

- wherever the plastic part of the chord rotation demand is more than twice the elastic part θ_y , set $\cotg(\theta) = 1$.
- for elastic flexural response, with zero plastic chord rotation, set $\cotg(\theta) = 2.5$.

3.3 New proposal by Biskinis and Fardis

The new proposal by Biskinis and Fardis [17] for the assessment of the cyclic shear resistance is based on the monotonic shear resistance of Model Code 2010. The new model allows to consider the degradation effect associated to cyclic loading, by applying the following modifications to the shear resistance formulation proposed in Model Code 2010:

- The longitudinal strain ε_x is firstly evaluated in correspondence of the section mid-depth:

$$\varepsilon_x = \frac{1}{2A_s E_s} \left(\mu \frac{M_{Ed}}{z} + \frac{N_{Ed}}{2} + V_{Ed} \right) \leq \min \left(0.02; \frac{1}{2A_s E_s} \left(\mu \frac{\max M}{z} + \frac{N}{2} \right) \right) \quad (7)$$

- The contribution due to the axial load N in columns is considered by adding the term $V_{R,N}$ given in Eq.(8) :

$$V_{R,N} = N \frac{h-x}{2L_s} \quad (8)$$

Where x is the neutral axis and L_s is the shear span.

- The contribution of transverse steel to shear resistance is:

$$V_{R,S} = (\rho_w b_w z f_{yw}) \cot(\theta) \quad (9)$$

Where the upper limit on the yield stress of shear reinforcement is set equal to $f_{yw} = \min(f_{yw}; 6 / \rho_w)$.

- The contribution of concrete to shear resistance is:

$$\begin{cases} k_V = \frac{0.4}{1 + 1500\varepsilon_x} \left(1 - \frac{V_{Ed}}{V_{Rd,max}(\theta_{min})} \right) \\ V_{Rd,c} = k_V \frac{\sqrt{f_{ck}}}{\gamma_c} z \cdot b_w \end{cases} \quad (10)$$

The shear resistance is calculated based on the selected Level of Approximation as follows:

- For LoA II: $V_R = V_{R,N} + V_{R,S} \leq V_{R,max}$
- For LoA III: $V_R = V_{R,N} + V_{R,S} + V_{R,c} \leq V_{R,max}$

In this study, the Level of Approximation III is used. Note average mechanical properties and partial safety factors equal to 1 are used to compare analytical and experimental shear resistances. The comparisons of the shear capacity in terms of resistance and ductility obtained by using the three formulations are reported in Figure 2.

Figure 2 Capacity curves for: (a) Model Code 2010 [14]; (b) Eurocode 8 [15]; (c) Biskinis and Fardis [17].

The previously explained formulations are adopted to calculate the shear resistance under monotonic or cyclic loading along the two principal directions of the transversal cross section of the column. Afterward, to account for bi-axial shear resistance, the interaction domain proposed by JSCE [16] is used, according to Eq. (11):

$$\left(\gamma_i \frac{V_{Ed,x}}{V_{Rd,x}} \right)^2 + \left(\gamma_i \frac{V_{Ed,y}}{V_{Rd,y}} \right)^2 = 1 \quad (11)$$

In Figure 3 are reported possible failure modes of RC columns, based on the intersection between bilinear flexural and shear (based on EC8 [15] approach) capacities curves. Indeed, three failure modes are possible based on the intersection between simplified bilinear flexural capacity and shear resistance provided: (i) flexural failure, without intersection with shear capacity, (ii) mixed flexural-shear failure after achievement of flexural yielding, (iii) shear failure before flexural yielding. In this study, shear and mixed flexural-shear failure modes are considered.

Figure 3 Exemplificative flexural vs shear (EC8 [15] approach) capacities and failure modes.

4 RESULTS AND DISCUSSION

In this paragraph the bi-axial domains obtained from experimental results and analytical formulations are plotted and compared. Average mechanical properties and partial safety factors equal to 1 are used for calculations. Figure 4 and Figure 5 are related to specimens without and with compressive axial load, respectively.

Figure 4 shows that the analytical provision by Biskinis & Fardis [17] tends to underestimate the shear resistance compared to Model Code 2010 and Eurocode 8 provisions. This is attributed to the reduction coefficient equal to 1.8 introduced in the k_ε formulation by Biskinis & Fardis [17] which accounts for cyclic loading. Indeed, this coefficient affects the magnitude of $V_{Rd,max}$ calculated at θ_{min} equal to 21.8° as provided for LoA III, see Eq. (12):

$$\left\{ \begin{array}{l} k_\varepsilon = \frac{1}{1.8(1.2 + 55\varepsilon_1)} \\ V_{Rd,max}(\theta_{min}) = k_\varepsilon \cdot \eta_{fc} \cdot \frac{f_{ck}}{\gamma_c} \cdot b_w \cdot z \cdot \sin(\theta_{min}) \cdot \cos(\theta_{min}) \end{array} \right. \quad (12)$$

As consequence, the coefficient k_V and the corresponding concrete shear resistance contribution $V_{Rd,c}$ reported in Eq. (10) are relatively small.

 Figure 4 Interaction domains $N = 0$: (a) Joh & Shibata specimen SSN0-; (b) Mizoguchi et al. specimen 0V-.

Figure 5 shows that in the case of compressive axial force applied to columns, the analytical approaches proposed in Eurocode 8 and by Biskinis & Fardis provide a better fitting of the experimental results. Indeed, the former approaches consider the additional beneficial term related to the compressive axial load contribution, which for Eurocode 8 is defined by Eq. (13), while for Biskinis & Fardis [17], is defined by Eq. (8):

$$V_{R,N} = \frac{h-x}{2L_s} \min(N; 0.55A_c f_c) \quad (13)$$

Conversely to the mentioned approaches, the Model Code 2010 consider the effect of the axial force only in the strains' calculation of the longitudinal reinforcement, according Eq. (5).

 Figure 5 Interaction domains $N < 0$: (a) Joh & Shibata specimen SSN2+; (b) Pham et al. specimen R.C1.7.

Moreover, by analysing the formulations in Eq. (8) and (13), it is evident the dependency on the cross-section height h , the shear span L_s and neutral axis depth x . This latter term is fundamental and can be calculated using different assumptions based in the cross-section deformability level: (i) at ultimate limit state considering tensile rebars at yield and concrete at a compressive strain of 3.5 ‰, (ii) at the elastic state, where compressive concrete strain is below 2 ‰, thus the hypothesis of linear stresses is valid. Therefore, the assumption adopted to calculate the neutral axis should be coherent with the assumed ductility level.

5 CONCLUSIONS

This paper treats the calculation of the bi-axial shear resistance of reinforced concrete columns under cyclic loading. Such shear capacity is calculated by adopting the interaction domains provided by JSCE, starting from the uniaxial resistances of columns calculated along the principal axes of the transversal cross section. Moreover, three different analytical approaches from Eurocode 8, Model Code 2010 and the new proposal by Biskinis & Fardis are compared with available experimental tests collected in a Database created by Authors. The results show that:

- In absence of axial force, the interaction domains calculated from Model Code 2010 (LoA III) provide higher resistances than Eurocode 8 and Biskinis & Fardis approaches and a better fitting of experimental evidences. This is attributed to the fact that in the new formulation by Biskinis & Fardis, a reduction coefficient equal to 1.8 - which accounts for cyclic loading - is applied to the concrete compressive strut resistance. This leads to a considerable reduction of concrete contribution to shear resistance.
- In presence of compressive axial force, the interactions domains calculated from Model Code 2010 (LoA III) provide lower resistances compared to Eurocode 8 and Biskinis & Fardis approaches. This is attributed to the additional term accounting for the beneficial contribution of compressive axial load. The new proposal from Biskinis & Fardis provide a better fitting of experimental evidences compared to the other analytical provisions considered in this paper.

Abstract

In the last years, a growing attention has been devoted to the seismic vulnerability assessment of existing Reinforced Concrete (RC) framed buildings designed only for gravitational loads. The seismic behavior of existing framed buildings with an inner RC stairwell core has been investigated much less so far, even if this structural typology has known a certain spread from the Seventies onwards, especially in the Italian largest urban areas. In this work, the seismic behavior a relevant and representative example of existing pre-code RC core medium rise building is evaluated by performing nonlinear pushover analyses. The effect of different modelling assumptions regarding the degree of collaboration between frames and RC walls on the structural response is discussed. The influence of masonry infills on the global structural response is also evaluated by running the analyses both on the bare structure and on a structural model considering a distribution of masonry panels not regular in elevation: the latter distribution corresponds to a typical situation for the considered typology.

Keywords: reinforced concrete, core systems, non-linear analysis, existing structures, infills.

1 INTRODUCTION

A significant share of the existing Italian Reinforced Concrete (RC) building stock was designed for gravity loads only (so-called pre-code buildings), or according to now outdated seismic standards. Consequently, those buildings are generally vulnerable to seismic actions, often showing a non-ductile behavior, due to the non-optimal in-plan distribution of the structural elements (with frames only in one direction and stair cores often placed in an asymmetric position), poor structural details and material properties, deterioration phenomena due to environmental exposure conditions and to a limited maintenance over time.

During the past years, a lot of efforts were devoted to assessing vulnerability of existing RC framed buildings, which represent the most widespread structural typology within the RC building stock, not only in Italy, but also in several other seismic-prone countries in the Mediterranean area. The vulnerability of these structures is typically represented in terms of fragility curves, which express the probability of exceeding a predefined damage level for a wide range of ground motion intensities [1,2]. However, from the Seventies onwards, the presence of multi-story RC frames with shear walls realizing the elevator or stairwell core, has become increasingly common, especially in larger urban areas. It is well known that a correct in-plane disposition of the walls, together with an adequate choice of their dimensions and reinforcement, guarantees a good seismic response of modern RC structural wall buildings, reducing the inter-storey drift at damage limit state and providing enough ductility and strength at collapse. Nevertheless, in pre-code RC core structural systems, the position of elevator or stairwell core often creates structural irregularities and torsional actions, whose effects, together with the poor detailing of reinforcement (both in the walls and in the frame elements) should be carefully taken into account in vulnerability assessment studies. The specific features of existing core buildings, together with the high stiffness of the walls, make their seismic response quite different from that of framed structures, and consequently a different definition of the damage states used for the construction of fragility curves, as well as of the corresponding engineering demand parameters, may be required [3].

A further complication in the vulnerability assessment of these buildings is related to the presence of masonry infills. It is well known that infills significantly alter the seismic response of RC framed buildings, by producing a remarkable increase of lateral stiffness and base shear, as well as a reduction of the period of vibration. Moreover, their spatial arrangement within the framed structure can cause irregularities in the distribution of masses and stiffnesses, both in-plan and/or in elevation, with possible detrimental effects on the seismic response, as proved by observed damage data collected in post-earthquake surveys (i.e., among others, [4-8]). If almost uniformly distributed, infills can instead reduce the dissipation energy demands in frame elements, as well as the maximum displacements of the structure. For this reason, even if infills are traditionally treated as “non-structural” elements, it would be better to include their presence in numerical analyses, to allow a more realistic representation of the global behavior of the structure. Masonry panels are commonly schematized through equivalent nonlinear inclined struts, which represent a good compromise between accuracy and simplicity (i.e. [9-12]). The most of the studies available on this topic in the literature are however mainly focused on infilled RC frames, while the effect of masonry panels in case of framed buildings with an inner RC core has been less investigated so far. In this case, an irregular distribution of infills may alter the expected damage state sequence, due to the interaction between the infills themselves and the RC walls.

In this study analyzes the seismic response of a prototype pre-code RC 6-storey building with frames aligned in the longitudinal direction and RC walls realizing an internal asymmetric stair core. Pushover analyses are performed on the finite element model of the structure, by

simulating frame components with beam elements and the shear walls with shell elements. The nonlinear behavior of RC walls is taken into account through PARC_CL_2.1 constitutive model [13], implemented into the finite element code ABAQUS [14]. The influence of different modelling choices on the global response of the building is explored, by considering the two alternative assumptions of linear elastic pendulum frames and non-linear collaborating frames. Moreover, the influence of infills and of their progressive damage on the global response is investigated, by highlighting their effects in terms of displacement capacity, global stiffness and strength.

2 CASE STUDY

The case study analyzed in this paper is a representative a typical pre-code RC 6-storey building, with frames aligned in the longitudinal direction and RC walls realizing an internal asymmetric stair core. The building has a rectangular plan, with dimensions equal to 11.7 m x 24.4 m, and a total height of 19.04 m. An interstorey height of 3.06 m is assumed, except for the ground floor, where it is set equal to 3.74 m. This lower level is partially underground. The framed structure consists of six bays in the longitudinal direction, with spans ranging between 2.8 m and 5.2 m, and two bays with the same span (equal to 5.7 m) in the transverse direction. As can be seen from the floorplan depicted in Figure 1, in transverse direction beams are present only in the external frames. The stairwell core, which is realized with 200 mm thick RC walls, has an asymmetric position in plan.

Slabs are composed with parallel RC joists, running through the transverse direction, and interposed hollow clay blocks, with a 400 mm thick RC topping. Over the last floor, an inclined roof is realized by means of masonry walls with variable height and ceramic flooring blocks. For intermediate floors, a dead load equal to 6.2 kN/m^2 is assumed, and an additional permanent load of 2.0 kN/m^2 is also applied to account for the presence of internal partitions; the live load is set equal to 2.0 kN/m^2 . For the last storey, a dead load of 7.2 kN/m^2 and a live load of 1.2 kN/m^2 (snow) are instead considered.

Figure 1: Typical floorplan of the examined case study building (dimensions in cm).

The considered case study represents a typical Gravity Load Designed (GLD) building, without specific provisions for earthquake resistance. RC elements forming the frame are designed to sustain vertical loads only. Beams are realized within the thickness of the slab forming the floor (240 mm), and have a variable width, ranging from 300 to 500 mm for the

external frames, and equal to 1200 mm for the internal one. Columns dimensions are typically equal to 300 x 300mm or 300 x 400 mm, except those belonging to the inner frame, which have a variable cross-section, ranging from 500 mm x 400 mm at the lower storey, to 300 mm x 400 mm at the top storey. The walls around the stairwell are conceived as a core system with high stiffness and are designed to sustain the wind load and a conventional horizontal action equal to 0.5% of the weights. As regards material properties, C25/30 concrete (with $f_{cd} = 14.2$ MPa) and B450 steel (with $f_y = 391$ MPa) are assumed. Further details on the considered case study structure can be found in [15, 16], to which reference is made.

Vertical closures of the buildings are realized by means of double layer brick infills, with a total masonry thickness of (120 + 60) mm. Opening distribution within infills is depicted in Figure 2. Opening dimensions are assumed equal to 1.2 x 1.3 m. As can be seen, infills are assumed to be completely missing only in the rear side of the building (both on the right-hand and left-hand sides of the RC wall belonging to the core) at the lower level, so to allow the entry to garages. This not-regular infill distribution has been chosen since it is quite common for this type of buildings.

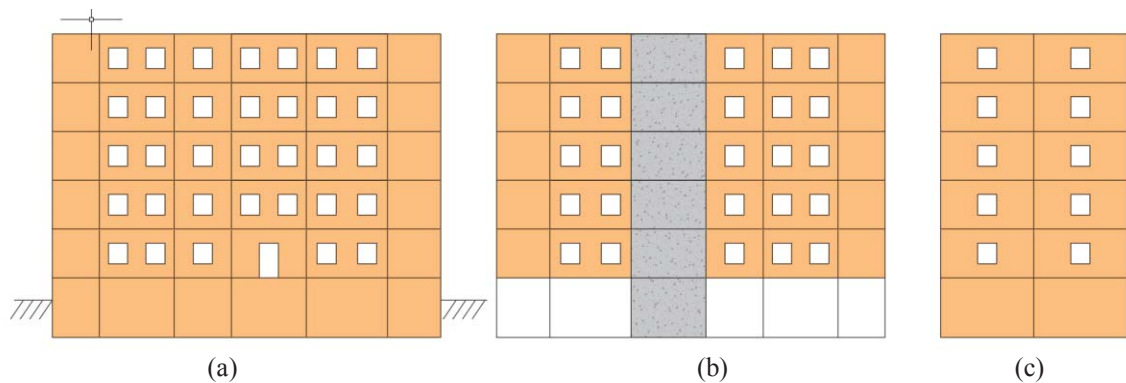

Figure 2: Sketch of the opening distribution within infill panels: (a) main façade; (b) rear side; (c) lateral side of the case study building.

3 MODELLING ASSUMPTIONS

The seismic behavior of the case study structure is studied by performing nonlinear pushover analyses, with the commercial Finite Element (FE) software ABAQUS [14].

As already highlighted, the considered building can be treated as a wall-equivalent dual system, since the elements belonging to the frame are designed for vertical loads only, while possible horizontal loads are mainly absorbed by the walls of the inner core. Taking in mind this aspect, two different models are realized, which are characterized by different complexity and different degree of interaction between the frame and the core during the earthquake. In Model#1, the collaboration of the frame in sustaining horizontal actions is completely disregarded, and all the sources of nonlinearity are simply assigned to the walls forming the core, while beams and columns are assumed as linear elastic. Regarding FE choices, pendulum frame components are modelled by using three-node beam elements with 2 integration points for columns, and 2-node truss elements with one integration point for beams.

In Model#2, the possible interaction between the frame and the core walls is explicitly taken into account (collaborating frame). In this case, beam elements are adopted for the modeling of all the frame component, with 3 nodes and 2 integration points for columns, and 2 nodes and 1 integration point for beams. The nonlinear response of beams and columns is dealt with a concentrated plasticity approach, and consequently they are modelled through elastic elements with rotational hinges at the ends. The assigned moment-curvature relation is

calculated by adopting Saenz law with ultimate strain equal to $3.5 \cdot 10^{-3}$ for concrete and an elastic-perfectly plastic law for steel.

As concerns the presence of infills, the analyses are repeated twice, by considering two different configurations (Figure 3): the limit case of the bare structure (no infills present) and the “real” distribution of infills depicted in Figure 2.

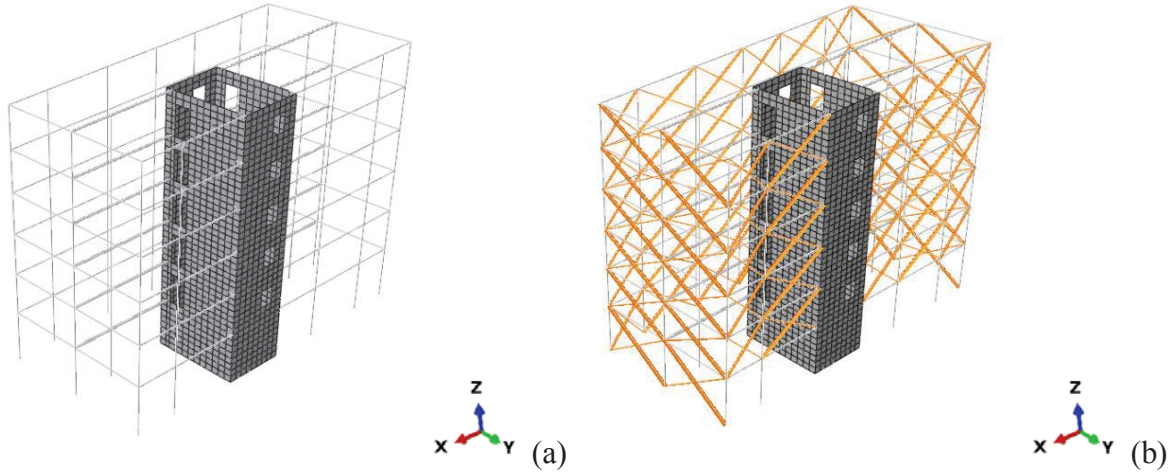

Figure 3: FE model: (a) bare structure; (b) structure with infills, according to the distribution depicted in Figure 2.

In this second case, the effect of infills on the global behaviour of the case study structure is assumed as equivalent to diagonal bracing, by adopting the single-strut model proposed in [12]. Each panel is replaced in the FE model by an equivalent pin-jointed diagonal strut, working only in compression, made with the same material of the infill and characterized by the trilinear lateral force-displacement relation shown in Figure 4a. The first branch of the curve represents the linear elastic response of the infill up to cracking, and its slope can be evaluated as:

$$K_i = \frac{G_w L_{in} t_w}{H_{in}} \quad (1)$$

as a function of the geometric dimensions of the infill (respectively being L_{in} , H_{in} and t_w the length, the clear height, and the thickness of the panel), and of the shear modulus of the masonry G_w .

The cracking force F_c is assumed equal to 0.6 the maximum strength of the infill F_m , which is in turn expressed as:

$$F_m = 0.818 \frac{L_{in} t_w f_{tp}}{C_I} \left(1 + \sqrt{C_I^2 + 1} \right) \quad (2)$$

with:

$$C_I = 1.925 \frac{L_{in}}{H_{in}} \quad (3)$$

and being f_{tp} the cracking strength of the infill (which can be determined from diagonal compression tests). It is assumed that the strength F_m is reached at a storey drift equal to 0.2% and 0.15% respectively in case of infills without and with openings. It should be noted that Equations (1-2) are referred to the horizontal direction, and consequently it is necessary to transform them in the inclined direction θ to obtain the force-displacement envelope of the

diagonal strut. The displacement at collapse is assumed equal to $5 D_m$, being D_m the displacement corresponding to the maximum force (Figure 4a, [12]).

A further reducing coefficient is introduced to represent the presence of openings within the infills and to account for their effect on the initial stiffness and strength of the struts, having the following expression:

$$\lambda_0 = 1 - \frac{1.5 L_0}{L_{in}} \geq 0 \quad (4)$$

being L_0 the horizontal length of the opening. In this work, the following values are assumed for masonry properties: $G_w = 1080$ MPa and $f_{tp} = 0.3$ MPa for the external layer; $G_w = 400$ MPa and $f_{tp} = 0.1$ MPa for the internal one.

In order to reduce computational efforts, even if the infill panels are formed by a double masonry layer, only a single strut (instead of two superimposed struts) is considered, and its force-displacement relation is evaluated as the envelope of those of the two layers. Moreover, in order to insert this relation within the adopted FE code, it is further reworked and expressed in terms of stress vs. strain curve (an example is reported in Figure 4b).

Figure 4: (a) Force-displacement relation for the diagonal struts representing the masonry infills (adapted from [12]; (b) implemented stress-strain law (referred to a strut of unit area), evaluated as the envelope of the two masonry layers.

In both Model #1 and Model #2, the RC walls of the core are modelled with 8-node, one-layered shell elements, with 4 Gauss integration point in the shell plane and 5 Simpson integration points in the thickness (element type S4R5). The nonlinear behavior of the walls under cyclic loads is considered by means of a user-defined constitutive law, named PARC_CL 2.1 [13], which is written in the form of a Fortran subroutine and implemented as a User Material (UMAT) in ABAQUS. PARC_CL 2.1 can be included in the framework of fixed smeared crack models, and it is based on a total strain formulation. The reinforcement is assumed to be smeared within the hosting concrete element through the reinforcement ratio ρ_s . PARC_CL 2.1 was developed starting from a well-validated constitutive model for membrane elements subjected to general plane stresses, named PARC [17], which was previously conceived at the University of Parma for the analysis of RC structures under static loads. For static loads only, an alternative model based on a strain decomposition approach and named 2D-PARC model is also available at the same University [18, 19].

PARC_CL 2.1 can be applied for the prediction of the cyclic and dynamic response of RC structures since it includes the effects of plastic and irreversible deformations in the unloading-reloading phase [20]. The model also allows to correctly catch other aspects which can be

very important in the analysis of existing RC structures, such as the buckling of longitudinal reinforcement [21], time-dependent effects and the corrosion of reinforcement [22], which however lie outside of the scope of this work.

Finally, the presence of rigid diaphragms is included in the FE model by applying a kinematic coupling condition, which constrains the displacements of the nodes at each floor level to those of a reference “master” node. The master node is herein assumed coincident with the bottom-left corner of the RC core.

4 NLFEA: PROCEDURE, RESULTS AND DISCUSSION

The behavior of the case study building under seismic actions is investigated by performing pushover analyses on the different FE models described in Section 3. To this aim, two lateral force distributions are considered: a uniform pattern (uniform response acceleration) and a triangular pattern (or modal pattern) proportional to the displacement shape of the first mode [23, 24]. To take into account the effect of the accidental eccentricity of loads, by limiting at the same time the number of performed analyses, the center of mass is shifted away from its original position, so to maximize its distance from the center of stiffness. This new position of the center of mass is determined by combining the two accidental eccentricities in X and Y directions, calculated according to [24]. The lateral response is described in terms of base shear vs. top displacement relationship. The top displacement is set equal to the average of the values registered at two nodes, placed at the opposite corners of the roof floorplan, i.e. the upper-right and at the lower-left ones (Figure 1).

The results obtained from pushover analyses for Model #1 and Model #2 without infills are shown in Figure 5, with reference to lateral force distributions acting along the negative X and Y directions. As can be seen, Model #2 is characterized by a higher bearing capacity with respect to Model #1 when considering lateral forces acting in $-X$ direction, thanks to the additional resisting contribution offered by the three longitudinal frames. On the contrary, the lack of internal beams connecting the columns in the transverse direction makes almost negligible the bearing contribution of frame elements for seismic loads acting along $-Y$, and the global behavior is consequently governed by the walls belonging to the core. In both models, the asymmetric position of the internal core gives rise to torsional effects, as demonstrated by the deformed shape plotted in Figure 6, which is referred to Model #2 without infills, for a uniform lateral load distribution respectively acting along $+X$ and $+Y$ direction.

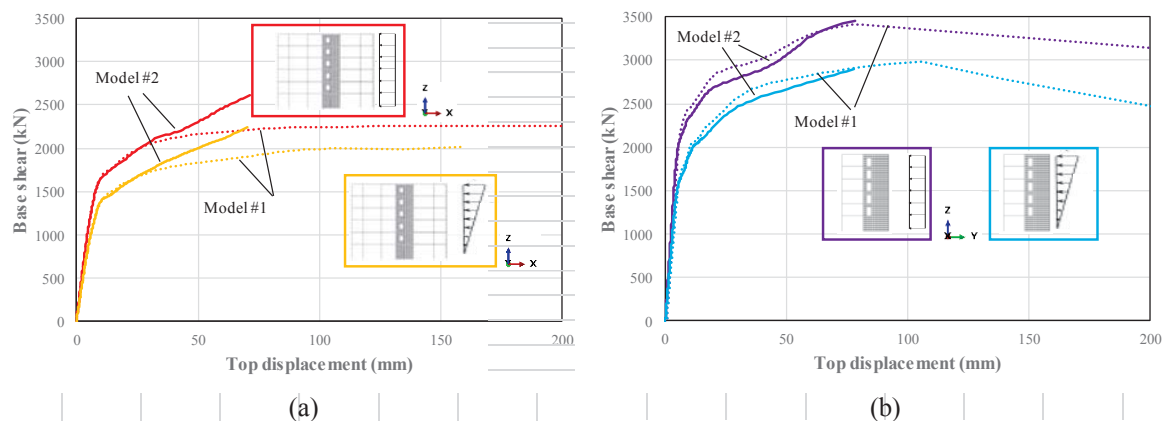

Figure 5: Base shear- top displacement curves obtained for Model #1 and Model #2 without infills from pushover analyses: (a) forces acting along $-X$ direction; (b) forces acting along $-Y$ direction.

Figure 6: Deformed shape of the case study building obtained from Model #2 without infills subjected to a uniform lateral load distribution acting along direction (a) +X and (b) +Y.

The influence of infills on the global behavior of the structure is shown in Figure 7. For the sake of brevity, only the comparisons based on Model #2 (with collaborating frames) are proposed in the case of uniform lateral load distribution acting in the $-X$ direction. To take into account the progressive damage of infills on the seismic response, the following procedure is proposed. At first, the analysis is carried out by considering the presence of infills according to the distribution depicted in Figure 2 (“Model #2 with infills” in Figure 7). The results of the model are then elaborated so to detect the progressive degradation of infills panels. More in detail, the time increment corresponding to the achievement of the degrading branch of the force-displacement curve in some of the masonry panels is found, and the analysis is restarted from that increment, by removing the damaged infills through the ABAQUS option *MODEL CHANGE, REMOVE, and re-applying the horizontal load distribution. This operation is then repeated until almost all the infills are collapsed, so obtaining a sort of “envelope” curve (“Model #2 with infills – progressive infill damage” in Figure 7). For comparison, an additional “lower-limit” curve is also plotted (“Model #2 with infills – complete infill removal” in Figure 7), which is obtained by removing all the infills together, at the time increment corresponding to the first appearance of damage in some of them. It can be seen that the presence of infills greatly increase the lateral stiffness and strength of the structure; however, with the progressive damage of the panels, the base shear-top displacement curve obviously tends to superimpose that of the bare structure.

Figure 7: Base shear-top displacement curve for Model #2 with and without infills, with indication of the progressive damage of masonry panels.

The sequence followed for the removal of damaged infills (which are marked in red) is also sketched in Figure 7. It can be observed that the damage distribution within masonry panels is strictly related to the torsional deformation of the building under seismic loads (Figure 8), with a consequent stress concentration localized in some bays of the structure. Furthermore, it can be seen that the degrading branch of the force-displacement curve is reached before in those masonry panels characterized by a greater length L_{in} , where a higher number of openings is assumed according to Figure 2.

Figure 8: Deformed shape for Model #2 with infills, corresponding to point 1 of the base shear-top displacement curve reported in Figure 7, when the first panels start to damage.

Figure 9: Displacement and inter-story drift profiles corresponding to point 1 in Figure 7.

In correspondence of point 1 in Figure 7, over 33% (almost 45% if referring only to the X-direction) of the infill panels at the second storey have reached they maximum resistance and start to degrade. It can then be assumed that this point corresponds to the reaching of the so-called “Damage Limitation” state (DL LS, see, i.e., [4]), which is defined as a first limit state characterized by quite limited damage almost localized in non-structural elements, that should be easily and economically repaired (also known as slight damage state, LS1). The average values of lateral displacement profile corresponding to point 1 in Figure 7 are shown in Figure 9. The same Figure also reports the inter-story drift ratio, evaluated as the average lateral displacement difference between two consecutive floors (inter-story drift), divided by the height of the storey. The maximum obtained ISD ratio is comparable with the threshold values (typically ranging between 0.1 and 0.25%) suggested in the literature to define the limit state corresponding to slight damage in numerical analyses on framed structures; these values are conventionally adopted when infills are not explicitly included in the FE model.

A further check on the model results reveals that when the first infills start to damage, yielding in RC elements of the frame has not been reached yet, and also the spreading of cracks in the RC walls of the core is very limited. On the contrary, yielding strain of longitudi-

dinal reinforcement is already registered in some portions of the walls (see Figure 10a; it should be noted that the condition $\varepsilon_{s, \text{long}} > \varepsilon_y$ is already reached for an average top displacement of 11 mm, corresponding to the yellow star in Figure 7). This behavior can be explained in the light of the particular distribution considered for infills, which is not-regular in elevation on the rear side of the building, so producing a stress concentration in the RC walls. Moreover, the modelling technique adopted for infills (though diagonal struts) is probably not optimal in case of RC walls, since it may lead to concentrated loads on the shell elements connected to the nodes of the strut. In this specific case study, the not-uniform infill distribution is then responsible for a change in the expected damage sequence, since the yielding of the reinforcement of the walls (which corresponds to a moderate damage, LS2) is reached before the damage of masonry infills (corresponding to slight damage LS1). However, further analyses with different infill distributions are required to draw more general observations.

In a previous work [3] focused on the same structural typology (frame + inner core) investigated herein, the Authors have suggested as a possible criterion for the definition of slight damage limit state LS1 when infills are not explicitly included in the model, the reaching of the cracking strain in the RC elements of the shear walls, by following an approach conceptually similar to that described in FEMA 356 [25]. With reference to the pushover curve reported in Figure 7 (“Model #2 – bare structure”), this criterion leads to the reaching of LS1 for an average top displacement value equal to 6.75 mm (green star in Figure 7). The ISD ratio profile corresponding to that situation is reported in Figure 10b, together with a contour showing the crack pattern in the core walls, as obtained from Model #2 without infills. As can be seen, these values are lower than those commonly associated to infill damage in framed structures.

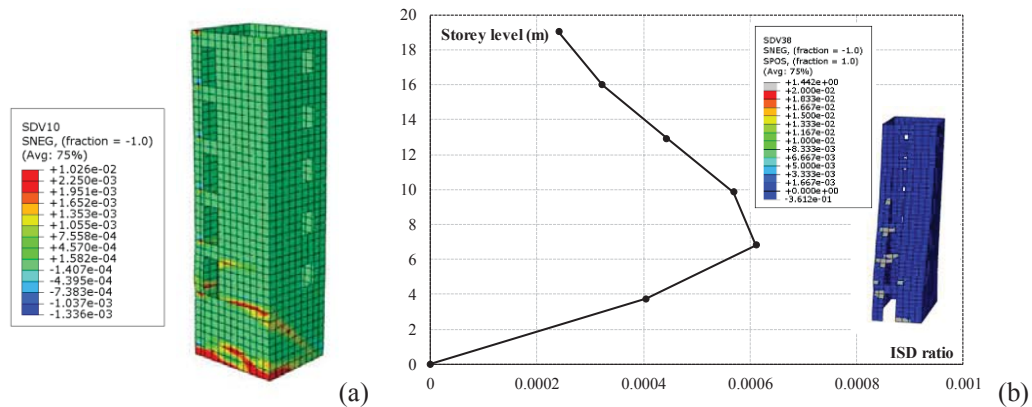

Figure 10: (a) Strain field in the longitudinal reinforcement of the walls corresponding to point 1 in Figure 7; (b) ISD ratio and crack pattern obtained from Model #2 without infills, in correspondence of the green star of Fig. 7.

5 CONCLUSIONS

The results proposed in this paper confirm that presence of an asymmetric core, which is quite typical of pre-code RC buildings realized in large urban centers in the last 40 years, significantly affects the seismic response of the structure, giving raise to torsional effects. Specifically, the following main observations can be highlighted:

- The walls belonging to the core absorb the larger part of the lateral loads; however, the resistant contribution offered by frames (which are usually aligned in one direction only) is not negligible.
- The presence of infills modifies the global response of the structure, providing a remarkable increase the lateral stiffness and strength of the structure, as observed in framed

structures. The reaching of the limit state corresponding to slight damage is often evaluated on the basis of the progressive appearance of damage in infills; when they are not explicitly included in numerical analyses, a conventional value of inter-story drift is often assumed. In case of framed structures with a RC core, alternative approaches, based on a material-level approach, can be also followed.

- Infill distribution has a great influence on the structural response and on the damage sequence taking place in structural and non-structural elements under seismic loads; further studies are required to draw general indications for the individuation of the damage states to be considered in derivation of fragility curves.

Abstract

The main part of the existing buildings in the Mediterranean area is extremely vulnerable to seismic actions. Since a complete renewal of the building heritage is not possible, the seismic assessment of existing structures has gained importance to identify the structural deficiencies and design the most appropriate retrofit interventions. Nonlinear dynamic analysis is widely recognised as the most accurate tool to predict the seismic behaviour of structures. However, it has high computational cost and is not suitable for professional purposes. To provide a tool that reliably assesses the seismic behaviour of structures, with an acceptable computational burden, nonlinear static methods of analysis have been developed.

This paper proposes a multimodal adaptive procedure named overDamped Displacement Adaptive Procedure (D-DAP) for seismic assessment of RC frames. The D-DAP is ruled by two main parameters: the value of top displacement adopted as step size and the number of modes of vibrations deemed significant for the determination of the load vector. Furthermore, the D-DAP is equipped with an equivalent damping law to consider the increase of the energy dissipation due to the cumulated damage in both structural and non-structural members.

The goal of this paper is to determine the values of the displacement step size and the number of modes of vibration necessary to achieve a suitable accuracy by means of the D-DAP. In addition, a new equivalent damping law is calibrated considering also infilled frames. In fact, nonlinear static analysis provided in literature are not optimised to estimate the nonlinear behaviour of infilled frames, despite the well known influence of infill panels on the structural response. A parametrical investigation that includes frames with and without infills is conducted. A set of 54 RC frames have been designed to be representative of existing buildings with various levels of seismic deficiencies and analysed. The adopted research methodology assumed the response obtained by Incremental nonlinear Dynamic Analysis (IDA) as target.

Keywords: nonlinear static analysis, infill walls, RC frames, seismic assessment.

1 INTRODUCTION

Recently, increasing efforts have been devoted by the scientific research to develop methods of analysis to predict the seismic behaviour of existing structures. Since real structures cannot keep an elastic behaviour under strong earthquakes, an accurate estimation of the seismic performance of existing structures requires the determination of the inelastic deformation experienced by structural members during earthquakes. To this end, the nonlinear dynamic analysis is considered the most reliable tool. However, due to its complexity and high computational cost, this type of analysis is still considered accessible only for experts in seismic engineering and is not suitable for daily professional use.

From the need of a tool that estimates the inelastic deformations of structures subjected to earthquake with relative low computational burden, the scientific research has developed the nonlinear static methods of analysis. Among the approaches available in scientific literature, the Capacity Spectrum Method (CS), proposed by Freeman [1], and the N2 Method, proposed by Fajfar [2], are the most popular. Although the results obtained by these analyses are generally deemed adequate for low-rise plane frames, common nonlinear static analyses do not take into account the contribution of higher modes of vibration to the seismic response, and do not consider the progressive reduction of the structural stiffness due to the nonlinear behaviour of the structure. To improve the level of accuracy, advanced nonlinear static methods of analysis were developed. Among others, innovative approaches are the DAP proposed by Pinho et al. [3, 4], and the Advanced N1 method proposed by Lenza et al. [5, 6]. Despite the innovative character of these two latter methods, they still suffer from some approximations: the DAP still requires the use of an equivalent SDOF system for the evaluation of the displacement demand, whilst the Advanced N1 method neglects the effect of the energy dissipation due to the inelastic behaviour of the structure.

An additional important aspect is that existing structures are generally endowed with infill panels. Usually, infills are considered nonstructural elements, and their contribution to the seismic response is “conservatively” neglected. However, frames with infill panels have a significantly larger stiffness, and their dissipative capacities and collapse mechanisms are deeply influenced by the presence and mechanical properties of infills. Despite this, neither the nonlinear static methods of analysis suggested by codes, nor the advanced nonlinear static methods were conceived to estimate accurately the nonlinear behaviour of infilled frames, which may be “unconservatively” predicted.

To overcome these issues, in a previous paper [7] the authors proposed a multimodal adaptive nonlinear static procedure named overDamped Displacement Adaptive Procedure (D-DAP). This method was developed by combining the approach by Antoniou and Pinho [3] and Pinho et al. [4] to update the load vector, with the procedure by Lenza et al. [5, 6] to associate the peak ground acceleration to the displacement demand. The D-DAP explicitly considered the increase of the energy dissipation due to the cumulated damage in the structure and, to this end, the equivalent viscous damping ratio was updated at each step of the pushover analysis. The goal of this paper is to calibrate the value of the parameters ruling the method, i.e. number of modes to be enveloped and size of the incremental step. In addition, an equivalent damping law is calibrated here on RC framed structures, with and without infills. Then, the efficiency of the calibrated method in predicting the seismic response of RC frames is investigated. To this end, a set of 54 RC frames has been designed to be representative of existing RC buildings, suffering from various types and levels of seismic deficiency. The set of case studies includes frames endowed with infill panels with negligible, medium and large stiffness and strength. The adopted research methodology assumed the response obtained by Incremental nonlinear Dynamic Analysis (IDA) as target.

2 THE OVERDAMPED DISPLACEMENT ADAPTIVE PROCEDURE

The proposed D-DAP is structured in three main steps: (1) definition, application and scaling of the load pattern, (2) association of the displacement demand to the corresponding PGA, (3) overdamping correction. The three steps are repeated until the structural collapse (or a target displacement) is achieved. Figure 1 shows the flowchart of the procedure.

The D-DAP applies a displacement load pattern, that is updated at every step of the analysis according to the modal shapes of the structure at the current step. For this reason, at the beginning of every step of D-DAP a modal response spectrum analysis is run. The modal response spectrum analysis is carried out assuming an elastic spectrum having a reference peak ground acceleration $a_{g,ref}$ and 5% equivalent viscous damping ratio. The contributions of n modes of vibration to the seismic response are considered. The displacement D_i of the load pattern (at the i -th storey) is calculated as the sum of the interstorey drifts Δ_k from storey 1 to the i -th storey, following the interstorey displacement-based scaling approach suggested in [3, 4]:

$$D_i = \sum_{k=1}^i \Delta_k \quad (1)$$

The interstorey drift Δ_k is determined at every storey as the SRSS combination of the considered modal shapes. The displacements obtained by Equation 1 are normalised to keep the maximum displacement equal to 1. Hence, the normalised modal scaling vector D' defines the shape, not the magnitude, of the load (or increment of load) vector.

At each step of the analysis, a fixed increase of the top displacement ΔD_t is imposed. The displacement load pattern obtained from the modal response spectrum analysis is scaled so that the displacement at the top storey corresponds to ΔD_t . The final load pattern $D_{i,s}$ applied at the current step s at each i -th storey is given by the summation of the displacement vector cumulated up to the previous step $D_{i,s-1}$ and the increase of the loading vector at the current step $\Delta D_{i,s}$.

In order to associate the displacement demand to the corresponding PGA, the following observation is made: as long as the increase of the load pattern is assumed small enough, it can be reasonably assumed that the structure has a linear response within the step [5, 6].

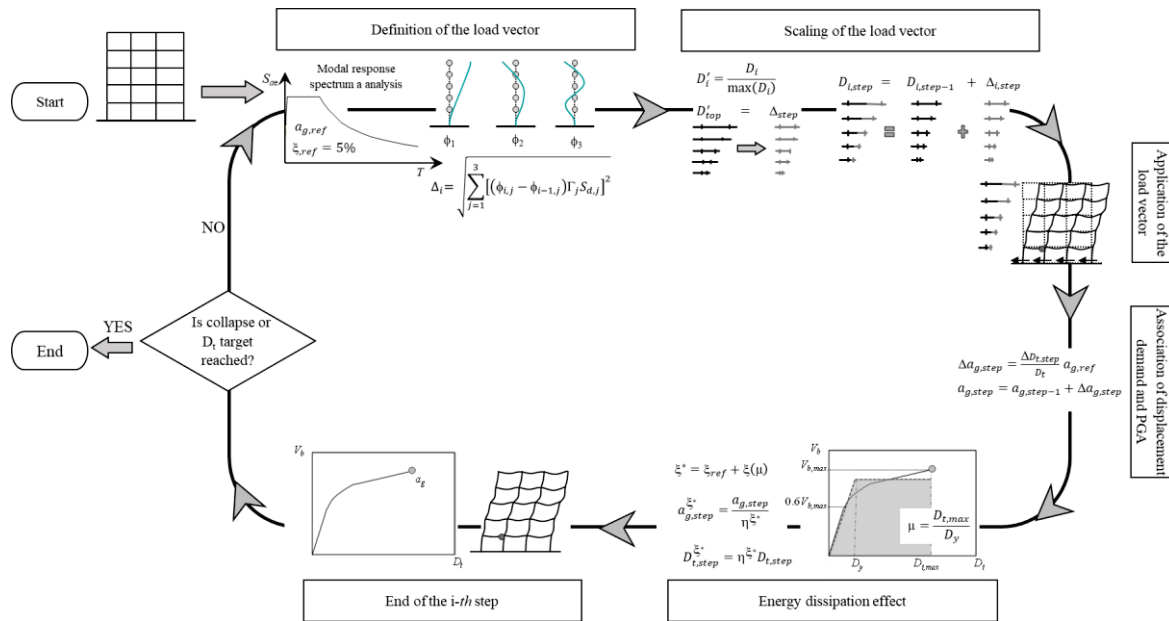

Figure 1 – Flowchart of the D-DAP procedure

Hence, the increase of PGA ($\Delta a_{g,s}$) that has caused the increase of load pattern $\Delta D_{t,s}$ at the step s is evaluated by linear interpolation (note that the increase of load pattern corresponds to the increase of the top displacement of the structure):

$$\Delta a_{g,s} = \frac{\Delta D_{t,s}}{D_t} a_{g,ref} \quad (2)$$

where D_t is the displacement at the top of the structure provided by the modal response spectrum analysis with response spectrum characterised by the reference acceleration $a_{g,ref}$. The acceleration $a_{g,s}$ corresponding to the top displacement at the end of step s is:

$$a_{g,s} = a_{g,s-1} + \Delta a_{g,s} \quad (3)$$

So far, the increase of acceleration Δa_g (Eq. 2) has been evaluated with reference to a fix value of the equivalent viscous damping ratio ξ_{ref} . However, it should be noted that, the equivalent viscous damping ratio increases at every step of the analysis along with the spread of the yielding in the structure. The value of ξ_{ref} is included in the factor η , which appears in the equation proposed by EC8 for the determination of the spectral displacement S_{de} . As ξ_{ref} is assumed equal to 5% in both Equations 5 and 6, the energy dissipated by the structure through yielding is not taken into account yet. To account for this, the PGA evaluated by Equation 6 is corrected considering higher values of ξ_{ref} . Regardless of the fundamental period T_1 or the type of soil, the ratio of a spectral displacement $S_{d,e}^{5\%}$ obtained from the response spectra scaled with 5% damping and the spectral displacement $S_{d,e}^{\xi^*}$ obtained from the response spectra scaled with a larger damping ratio $\xi_{eq} = \xi^*$ is equal to the ratio of the corresponding parameters η :

$$\frac{S_{d,e}^{5\%}}{S_{d,e}^{\xi^*}} = \frac{\eta^{5\%}}{\eta^{\xi^*}} \quad (4)$$

Since η is equal to 1 when the damping ratio is 5% [7] it follows that:

$$S_{d,e}^{\xi^*} = \eta^{\xi^*} S_{d,e}^{5\%} \quad (5)$$

Since the effect of the equivalent viscous damping is the result of the entire damage cumulated by the structure, from the beginning of the analysis until the considered step, the correction that accounts for the increase of the equivalent damping can be applied straightforwardly to the total PGA at the end of each step of the D-DAP:

$$a_{g,s} = \frac{a_{g,s}^{5\%}}{\eta(\xi^*)} \quad (6)$$

3 DESIGN OF CASE STUDIES

Two sets of RC frames have been created to simulate existing buildings with different features. The first set is composed of frames (named GL) that are drawn from buildings designed to sustain gravity loads only and are representative of typical Italian residential buildings of the seventies. The frames of the second set (named SR) are extracted from RC buildings designed for earthquake resistance in low seismicity areas according to the Italian standards for constructions and seismic resistance [10] in force in the nineties. Two different plan layouts have been considered (Figure 3): in the first plan layout, the unidirectional slab is characterised by reinforcements orientated along the y-direction (Figure 2(a) and (c)), while in the second arrangement the unidirectional slab is parallel to the x-direction (Figure 2 (b) and (d)). All the analysed frames lay along the x-direction. Each set of frames includes three types of frames: frame type 1 and 2 are the central and the outermost frames, respectively, extracted from the buildings where the slab is parallel to y-direction. In consequence of the orientation

of the deck, frame type 1 supports larger gravity loads than frame type 2. Frame type 3 is drawn from the building with the slab orientated along the x-direction and supports only the self-weight of beams, columns, infills and the weight of an additional 50 cm wide stripe of deck. Both the SR frames and the GL frames were designed with five 5.5 m wide bays and with a number of storeys equal to 3, 6 and 9. The interstorey height is equal to 3.2 m. To investigate the influence of infill panels on the seismic response of buildings, the RC case study frames have been endowed with infill panels, supposing the distribution of the infills uniform along the height of the frame. Particularly, two kinds of infill panels are considered: one with high stiffness and strength, and another having lower stiffness and strength. Furthermore, the case study frames have been considered in the bare configuration as well. These cases represent the limit case of frames having very weak infill panels. In total, 54 RC frames are analysed.

Hereinafter, each frame is identified by a label. The first two letters indicate which set the frame belongs to, the first number indicates the number of storeys and the last number the amount of gravity load. Frames with the largest gravity loads are indicated with 1, frames with the lowest gravity loads are indicated with 3 and the intermediate loaded frames are indicated with 2. The second part of the label is required in the case of infilled frames. Here, the letter I indicates the presence of infill panels and the number indicates the cracking strength of infills in MPa.

The design internal forces of structural members belonging to GL frames are evaluated considering gravity loads only [8]. The internal axial forces N on columns and the distributed loads on beams are evaluated based on the tributary area concept. The dimensions of the cross sections and the size of steel reinforcements are determined by the allowable stress method [9].

To design the seismic-resistant frames, the regulations for building structures and seismic resistance enforced in Italy in the nineties [10] are followed. The effect of the seismic forces is determined by the lateral force method of analysis supposing that, at the time of construction, the location of the building was classified as low seismicity area.

Details on the design of frames can be found in [7].

4 CALIBRATION OF PARAMETERS

In this section, first, an analysis is conducted to calibrate (1) the number of modes to be enveloped and (2) the value of the displacement step size. The goal is to select the values of the optimal ruling parameters that ensure the best accuracy together with the best efficiency of the D-DAP for the case study frames. Hence, once these optimal parameters have been determined, a new equation of the equivalent viscous damping ratio as a function of the period of the first mode of vibration is proposed. The numerical analyses are performed by OpenSees [11].

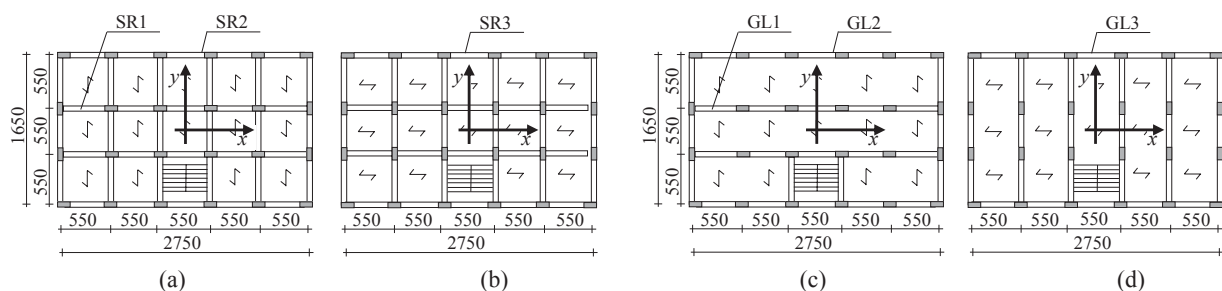

Figure 2 – Plan layout of buildings (units in cm): (a) GL building and (c) SR building with slab perpendicular to longitudinal frames; (b) GL building and (d) SR building with slab parallel to longitudinal frames

4.1 Numerical model and seismic input

The nonlinear response of the case study frames has been investigated by a 2D numerical model with masses concentrated at floor levels. The slab at each level is assumed rigid in its own plane and is simulated by a rigid diaphragm. A leaning column is added to the numerical model to account for $P-\Delta$ effects. For nonlinear dynamic analysis, a Rayleigh viscous damping is used and set at 5% for the first and the third mode of vibration.

The gravity loads assigned to beams and columns are those specified in EC8 for the seismic design situation. The floor masses are determined as a percentage of the total mass of the deck and are equal to 99.3 t for frames GL1 and GL2, 198.6 for frame GL3 and 106.1 t for frames SR. The gravity load at each level of the leaning column is equal to the seismic weight of the storey of the frame (i.e. the floor mass assigned to frame times 9.81).

Beams and columns of the RC frame are modelled as members constituted by an elastic element with plastic hinges at their ends (Beam With Hinges Element in OpenSees). The length of the plastic hinge is equal to the depth of the cross section and a fibre cross section is assigned to each plastic hinge. The concrete part of the cross section is subdivided into fibres having 5 mm depth and width equal to the width of the cross section. Single fibres enclosed in the cross section are used to model rebars.

The Mander constitutive law (“Concrete04” uniaxial material) is assigned to concrete fibres [12]. The parameters used for concrete material are summarized in Table 1. Since frames SR are expected to be endowed with dense and well detailed stirrups, the concrete compression strength of the core of the member cross sections is supposed to increase due to the confinement effect of the stirrups. The confinement effect on the core of member cross sections is neglected for frames GL, because RC structures designed without seismic provisions generally have very few stirrups. An elasto-plastic with strain kinematic hardening constitutive law (“Steel01” uniaxial material) is assigned to steel fibres and the values of the mechanical parameters are reported in Table 2.

A “ZeroLength Element” is added at one end of each beam. This element connects the end of the beam to the corresponding node restrained by the rigid deck and is characterized by a low axial stiffness and very large shear and flexural stiffnesses. This expedient allows the beams to deform axially, so as to prevent arising of axial force, which leads fibre modelled

RC beams to an artificial stiffening and strengthening [13]. In the meantime, it ensures the transfer of shear force and bending moment from the beam to the frame node.

Infill panels are modelled as a pair of diagonal trusses without tension resistance. The force-displacement relationship of the diagonal truss is calibrated to replicate the shear force-drift relationship proposed by Panagiotakos and Fardis [14] and Celarec et al. [15]. This relationship consists of four branches and the stiffness and the value of the maximum force of each branch are determined according to the equations proposed in [15]. Two types of infill panels have been considered here and both of them were supposed to be realized by ceramic bricks, with thickness equal to 20 cm, Young modulus and shear modulus equal to 4130 and 1240 MPa, respectively. The so called “strong” infills were characterized by stiffness and cracking strength (0.28 MPa) that were twice the stiffness and strength (0.14 MPa) of the “weak” type of infills. The mechanical properties were taken from the data provided in [15] according to the experimental tests conducted at the University of Pavia [16]. Further details on the adopted infill modelling may be found in [7].

4.2 Calibration of the number of modes of vibration

The load vector applied in the D-DAP is evaluated from the envelope of the modal drifts at each storey. In this regard, it is well recognized that the higher the mode of vibration, the least its contribution to the total seismic response. In order to select the number of modes actually significant for the analysed frames, the seismic response of the case study frames has been evaluated by the D-DAP including an increasing number of modes. For each frame, the number of modes of vibration ranged from 1 to the total number of participating modes, equal to the number of storeys. The final step of each analysis has been set at a target top displacement equal to the 5% of the total height of the frame.

For the sake of simplicity, Figure 3 shows the results of the analysis conducted on frame type GL-1 and SR-1, with 3 and 9 storeys, with and without infills. The seismic responses of

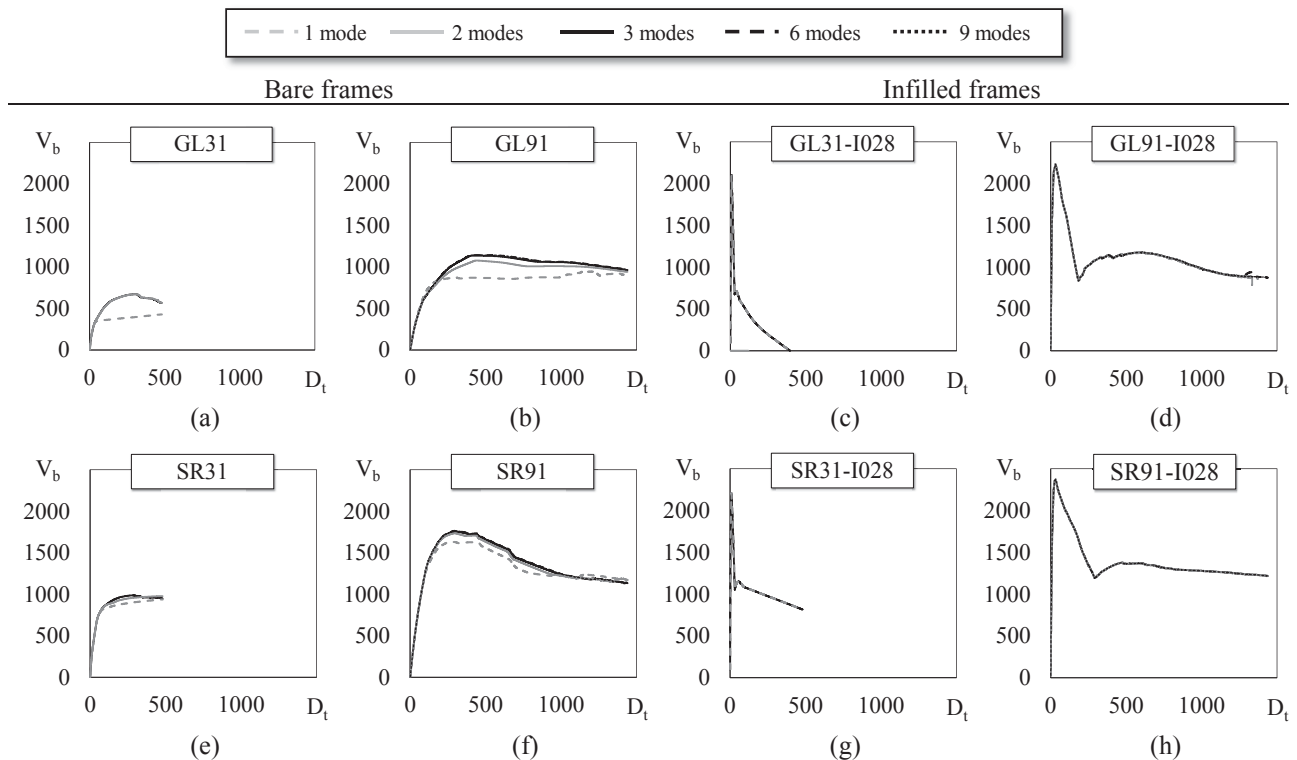

Figure 3 –Analysis of significant modes of vibration for frame (a) GL31, (b) GL91, (c) GL31-I028, (d) GL91-I028 (e) SR31, (f) SR91, (g) SR31-I028, (h) SR91-I028

the considered bare frames (Figures (a), (b), (e) and (f)) show that for a fixed value of the top displacement the influence of the higher modes of vibration leads to a larger base shear. In particular, this tendency becomes more significant when the number of storeys increases. Indeed, when the structure yields, the first mode of vibration becomes very flexible and its period increases. As a consequence, the contribution of the first mode to displacements becomes progressively more significant, while its contribution to the internal forces reduces and tends to be negligible. On the contrary, higher modes of vibration are less influenced by yielding of the structure. Thus, although the structure has already yielded, higher modes still contribute to the internal forces of the structure. This means that when the contribution of higher modes of vibration is taken into account, the base shear of the structure keeps increasing even after yielding of the structure. In particular, for the considered bare frames, the contribution of the second and third modes of vibration is actually significant, while higher modes of vibration become negligible. If infill panels are included in the frame (Figures (c), (d), (g), (h)), the first mode of vibration is predominant regardless of the number of storeys, and the contribution of higher modes of vibration becomes negligible. Based on the previous considerations, it is sufficient to include three modes of vibration when the D-DAP is applied to RC framed structures with or without infill panels

4.3 Calibration of the displacement step size

Another crucial choice is the value of the increment of displacement within the loading step Δ_{step} . In order to select the most appropriate step size, the frames have been analysed by the D-DAP with gradually reduced displacement step sizes. Three values of displacement step size have been considered: 10, 1 and 0.1 mm. Figure 4 shows the results of the analysis conducted for frames GL-1 and SR-1, with 3 and 9 storeys, with and without infill panels. When the step size is 10 mm, sometimes the analysis stops before the target displacement (5% of the total height of the frame) is reached, or fails at the very beginning. A value of $\Delta_{step} = 1$ mm

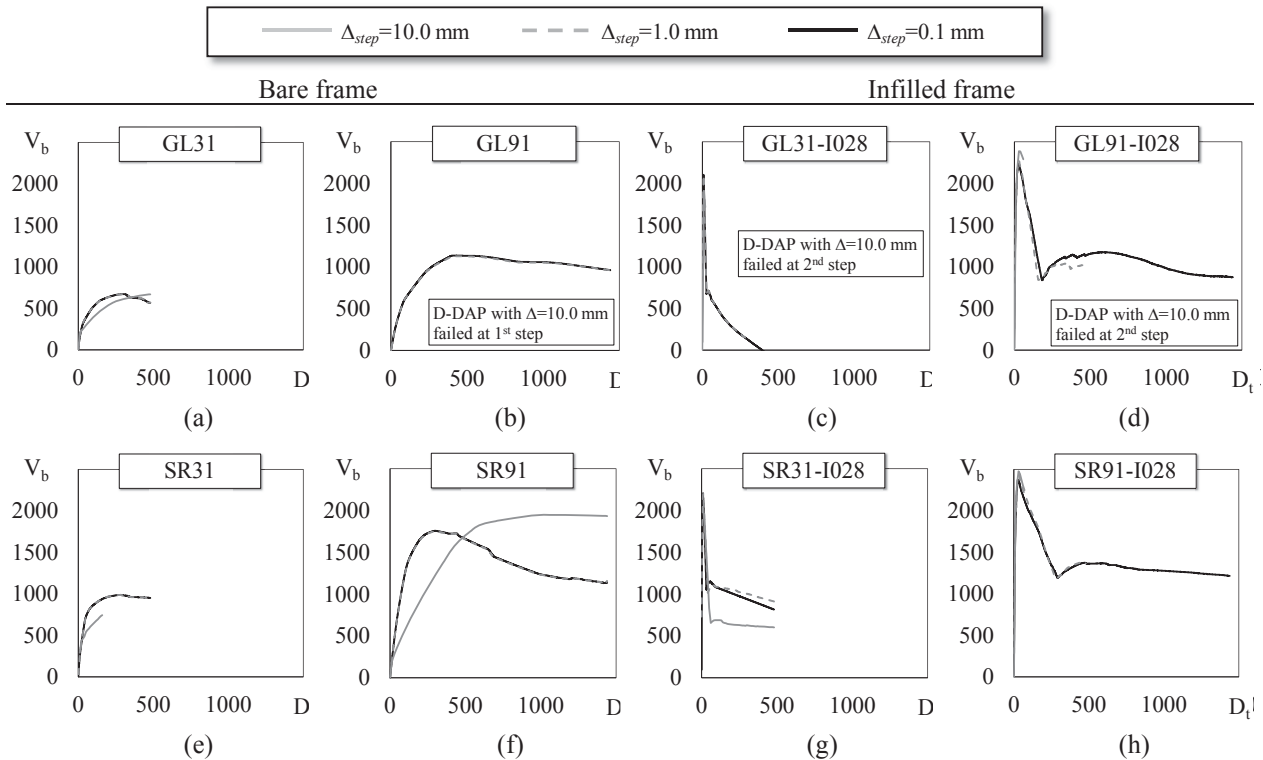

Figure 4 –Analysis of incremental step size for frame (a) GL31, (b) GL91, (c) GL31-I028, (d) GL91-I028 (e) SR31, (f) SR91, (g) SR31-I028, (h) SR91-I028

avoids the untimely failure of the analysis, especially in the case of infilled frames (Figure (c), (d), (g), (h)) whereby the analysis with larger Δ_{step} stopped right after the attainment of the maximum strength of infills. Furthermore, the prediction of the seismic response provided by the D-DAP with $\Delta_{step} = 1$ mm is significantly different from that obtained with $\Delta_{step} = 10$ mm, as showed in Figure 5 (a), (d), (e), (f), (g). No significant changes in the prediction of the seismic response were observed when the step size has been further reduced to 0.1 mm. Since the tendency noted in the shown frames has been essentially observed in all other analysed frames, a value of $\Delta_{step} = 1$ mm could be considered appropriate. However, since the D-DAP with $\Delta_{step} = 1$ mm in very few cases failed slightly before the target displacement was reached, for the sake of accuracy the displacement step size has been assumed equal to 0.1 mm.

4.4 Calibration of the equivalent damping law

The total equivalent viscous damping ratio is the summation of the inherent viscous damping in the elastic range ξ_0 , and the viscous damping ξ_{hyst} due to the hysteretic behavior [17, 18]. The damping ratio due to the hysteretic behaviour ξ_{hyst} (hysteretic damping) is generally assumed as a function of the ductility demand μ , according to the following form:

$$\xi_{hyst} = \xi_{\infty} \left(1 - \frac{1}{\mu^{\alpha_1}} \right) \quad (7)$$

whereby ξ_{∞} represents the asymptotic value that the hysteretic damping reaches for infinite values of ductility demand, and α_1 is a constant usually assumed equal to 0.5 or 1. Here α_1 is taken equal to 1.

The goal of the numerical calibration is the determination of the asymptotic damping ξ_{∞} that is appropriate for the structural types under investigation. To this end, the average drift Δ_m , defined as the summation of drifts at all storeys divided by the total number of storeys, is assumed as the reference parameter of the numerical calibration. Incremental Dynamic Analyses (IDA) are conducted for every case study frame, for PGAs increasing from 0.02 g to 2 g, in steps of 0.02 g. A set of ten artificial ground motions (EC8-Part 1 [19]), compatible with the EC8 elastic spectrum for soil type C and characterized by 5% damping ratio and reference PGA for soil type A equal to 0.35 g, is adopted as reference seismic input. The accelerograms were generated by SIMQKE computer program [20] so that the mean spectrum in terms of acceleration is compatible with the response spectrum proposed by EC8 in Appendix A. For every level of seismic excitation and for each of the 10 ground motions, the maximum value during the time history of the average drift Δ_m is calculated. Then, the mean value of the average drift Δ_m over the 10 ground motions is calculated for each PGA. The value of Δ_m is calculated also at each step of the D-DAP analysis. Thus, every average drift Δ_m corresponds to a value of peak ground acceleration PGA determined by the D-DAP with an elastic response spectrum with fixed 5% damping. Generally, for a fixed Δ_m , the D-DAP with 5% damping underestimates the values of PGA provided by the IDA. Hence, the PGA evaluated by the D-DAP has to be corrected with an appropriate damping ratio. Thus, for every relevant frame, the optimal hysteretic damping ξ_{∞} is calculated as the value that minimizes the summation of the squares of the differences between the PGAs by D-DAP and that by IDA. For every case study frame, the optimization process led to a different value of optimal ξ_{∞} .

In the second part of the calibration, the optimal values of ξ_{∞} obtained for every frame were plotted as a function of different parameters. Out of the considered parameters, the fundamental period T_1 showed the most significant influence on the value of ξ_{∞} . In particular, in the case of very stiff structures the values of ξ_{∞} tend to increase with T_1 (Figure 5a). This ten-

Figure 5 – (a) Relation between the optimized ξ_∞ and the fundamental period T for every case study frame; (b) Equivalent damping evaluated by the proposed law plotted for fixed value of T_1

endency is demonstrated by almost all the infilled case study frames, whose fundamental periods is smaller than 0.4 s (grey and black dots). This tendency is inverted for larger T_1 , and the values of ξ_∞ tend to decrease. This trend is exhibited by all the analysed bare frames (black diamonds). In fact, the lack of infill panels strongly reduces the stiffness of bare structures, which have fundamental periods ranging from 0.40 to 1.95 s. Only two infilled frames fall in this region, and they are frame GL91-I028 and GL91-I014 with T_1 equal to 0.433 and 0.548 s, respectively. Based on these results, the asymptotic damping ratio ξ_∞ can be reasonably expressed as a function of the fundamental period of the structure.

To propose an equation for the evaluation of the asymptotic damping ξ_∞ , the domain $\xi_\infty - T_1$ has been divided into two regions. For low fundamental periods, the relation between ξ_∞ and T_1 could be approximated by a linear function, whilst for larger fundamental periods it could be approximated by a hyperbolic function. The linear equation has been calibrated by minimizing the sum of the square deviations of values of ξ_∞ determined by numerical analyses and by the proposed equation for frames whose fundamental period was lower than 0.40 s. Instead, the hyperbolic function has been calibrated by minimizing the sum of the square deviations of values of ξ_∞ in the case of frames with fundamental period higher than 0.40 s. Hence, given a period T_1 , the value of ξ_∞ to be assumed is the minimum between the values provided by the linear and the hyperbolic equation, as expressed in the following function:

$$\xi_\infty = \min \left(65T_1; \frac{5.4}{T_1^{1.3}} \right) \quad (8)$$

The intersection between the two functions occurs for a period of vibration equal to 0.34 s. In Figure 5(a) Equation 8 is plotted with the continuous black line. It can be seen that the calibrated function approximates with a good accuracy the tendency of the values of ξ_∞ . Finally, the equation of the proposed equivalent viscous damping ratio is:

$$\xi_{eq} = \xi_0 + \min \left(65T_1; \frac{5.4}{T_1^{1.3}} \right) \left(1 - \frac{1}{\mu} \right) \quad (9)$$

Figure 5 (b) plots the proposed equation of ξ_{eq} as function of the ductility demand μ . Each curve displays the results obtained for a different value of T_1 . Regardless of T_1 , the equivalent viscous damping ratio increases with the ductility demand μ . However, when the ductility demand becomes larger, the rate of increase of ξ_{eq} becomes smaller, and the equivalent viscous damping tends towards the asymptotic value $\xi_0 + \xi_\infty(T_1)$.

5 ANALYSIS OF THE RESULTS

To validate the calibrated D-DAP, IDA was run to assess the seismic response of each case

study frame. To this end, the numerical model described in Section 4.1 was subjected to the set of 10 ground motions introduced in Section 4.4. The PGA in IDA was increased in step of 0.02 g until the 5% of storey drift is attained at one of the storeys. For every PGA and for each ground motions, the maximum values during the time history of the following Engineering Demand Parameters (EDP) are evaluated: maximum top displacement D_t , maximum base shear V_b , maximum drift at each i -th storey Δ_i and the maximum average drift Δ_m . The mean over the values of the 10 ground motions is calculated for each EDP and are assumed as the benchmark to evaluate the accuracy of the calibrated D-DAP.

For the evaluation of the seismic response at local level, three limit states were considered in the IDA, i.e. the attainment of a maximum storey drift equal to 1%, 2% and 4%, which correspond to the attainment of the Immediate Occupancy (IO) limit state, the Life Safety (LS)

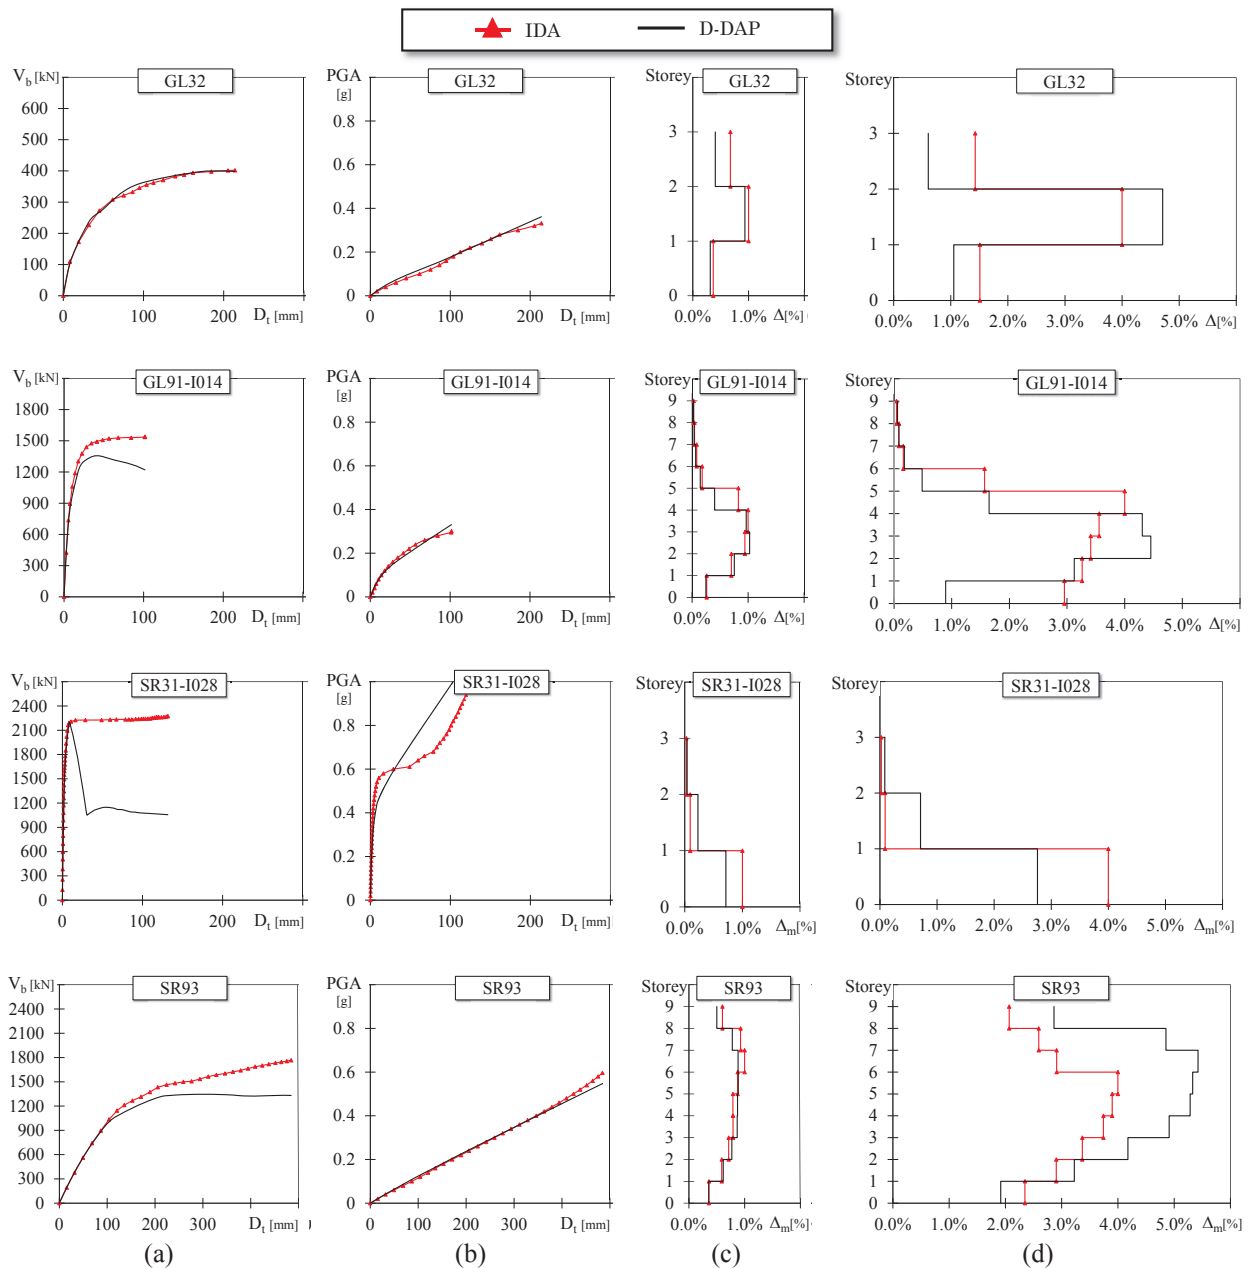

Figure 6 – Seismic performance of frames GL32, GL91-I014, SR31-I028 and SR93 in terms of (a) V_b - D_t , (b) PGA- D_t , (c) distribution of drifts corresponding to the PGA leading to 1% maximum drift in the ID, (d) distribution of drifts corresponding to the PGA leading to 4% maximum drift in the IDA.

limit state and the Near Collapse (NC) limit state, respectively. Given the PGA corresponding to the attainment of the considered limit state in the IDA, the corresponding distribution of storey drift has been evaluated by the D-DAP. For the sake of simplicity, the results are here presented for four significant frames. To cover the widest possible range of behaviour, the four selected frames included frames with 3 and 9 storeys, with large, medium and low gravity loads resting on beams, with and without infills. The frames thus picked are: GL32, GL91-014, SR31-028 and SR91.

The first column of Figure 6 shows the seismic response of the considered frames in terms of V_b-D_t . It can be observed that the D-DAP provides an accurate estimate of the seismic behaviour of the considered bare frames (plots in first and last row of Figure 6). In those cases, the maximum base shear increases with the top displacement, and the D-DAP follows the trend of the IDA, with an error lower than the 18%. In the case of infilled frames, an almost constant branch is observed in the V_b-D_t curve determined by the IDA. This upper value of the base shear is due to the fact that for every PGA the maximum base shear is recorded in the IDA. Thus, once the infills have cracked, the displacement keeps increasing while the maximum base shear maintains almost the same value. This constant branch represents an upper limit for the base shear and is here interpreted as the ultimate lateral strength of the frame. The D-DAP estimates accurately the elastic behaviour predicted by the IDA and provides an abrupt reduction of the base shear force right after the cracking of the infills. Indeed, for such degrading structures, the D-DAP evaluates the maximum resistance with an error lower than 15%. In the second columns of Figure 6, the PGAs associated to the displacement demands by the D-DAP are compared to the values predicted by the IDA. It can be observed that the D-DAP leads to an accurate prediction of the displacement demand regardless of the presence of infill panels.

Eventually, Figure 6 shows the distribution of storey drifts along the height for two of the considered limit cases, i.e. 1% storey drift (column c) and 4% storey drift (column d), respectively. At 1% limit state, the D-DAP estimates the maximum storey drift with an error lower than 5% for GL91-I014 and 35% for SR31-I028. For medium and large storey drifts (i.e. 2% and 4% limit state), the prediction of storey drifts of the IDA obtained by the proposed D-DAP still has an acceptable level of accuracy for the bare frames. Particularly, in the case of infilled frames, the error committed by the D-DAP in evaluating the maximum drift is lower than 12% and 31% for frame GL91-I014 and SR31-I028, respectively.

Even though it is not shown in figure, given the PGA corresponding to the 4% limit state in the IDA, the D-DAP predicted the average drift Δ_m with less than 10% of error for frame GL32. For frame SR93 the error reached a value around 35%. In the case of infilled frames, the error committed by the D-DAP is lower than 14% and 20% for frame SR31-I028 and GL91-I014, respectively. The tendency showed by those cases study can be found generally in all the other case study frames.

6 CONCLUSIONS

The research developed in three steps. First, the parameters ruling the operations of the D-DAP, i.e. The number of modes to be enveloped in the loading vector and the size of the displacement increment, were calibrated. To this end, two analyses were conducted and for the considered frames it was found that (i) the contribution of the modes of vibration higher than the third one is negligible and (ii) a displacement increment of 0.1 mm has to be assigned at each step to get accurate results for all the considered frames at reasonable computational cost. Afterwards, a new damping law was formulated by an optimization process that minimizes the differences between the results provided by the D-DAP and those obtained by the IDA.

The new equivalent damping law is a function of both the ductility demand and the fundamental period of vibration. According to the proposed equation, for very stiff structures, the value of ξ_{eq}

is linearly dependent from T_1 . Instead, for more flexible structures, the relation between ξ_{eq} and T_1 is hyperbolic. The effectiveness of the proposed D-DAP with the proposed damping law is investigated and the following conclusions can be drawn:

- As for the seismic response in terms of V_b-D_t , the D-DAP with the proposed damping law predicted the maximum base shear with an error on average equal to 20% for bare frames, and 15% for infilled frames. The seismic response in terms of a_g-D_t was predicted accurately by proposed D-DAP, as well.
- The proposed D-DAP predicted the average drift at 4% limit state of infilled frames with an error lower than 20%.

Abstract

Time history analysis is considered as the state-of-the-art in modeling of the seismic response of RC structures. Its validation involves predicting the response of an RC structure tested on a shaking table. However, blind prediction contests show that most contestants fail to predict the seismic response of the tested specimens. Given that numerical models are able to accurately capture the behavior of RC members at a component level, we can conclude that a large part of the error sources from the assumptions made to pass from component level to system level, i.e. assumptions related to damping formulation, component interaction, boundary conditions etc. In parallel, the prediction of the response of a structure subjected to a single ground motion has been proven to be too strict of a validation procedure. Oftentimes, a statistical approach involving many specimens and ground motions is necessary. Such an approach is clearly only feasible at a very small scale. At such scales, the reinforcement fabrication and positioning become major issues. We propose to use additive manufacturing technology to digitally fabricate the reinforcement cage necessary for the micro RC element.

This paper presents the results from cyclic tests on 1:40 scale RC cantilever columns. The reinforcing cages were manufactured using a Selective Laser Melting 3D printer that was able to print rebars with submillimeter diameter and yield strength 378MPa. Two different micro-concrete mixtures were used based on cement and gypsum. Each sample was reinforced with 18 longitudinal rebars of 0.6mm diameter, and 0.35mm stirrups with 2.5mm of spacing. The cyclic behavior of the columns closely resembles the behavior of full-scale columns indicating that such small-scale specimens can be used of the statistical validation of global level assumptions that numerical models make.

1 INTRODUCTION

Non-linear time history analysis is considered to be the state-of-the-art of structural modeling in earthquake engineering. Its most widespread validation procedure consists of predicting the response of an RC structure tested on a shaking table. However, blind prediction contests show that the contestants fail to predict the response of the tested specimens with reasonable accuracy, even for structures much simpler than the ones constructed in practice, and even when the structural properties and measured excitation are given to the contestants [1-4].

In order to better understand where the error sources from, one can break down the problem into 3 levels: Material, Component, and System Level. In fact, given the behavior at each level, the engineer makes certain assumptions to level-up. For instance, for given material properties the engineer uses a set of assumption, such as beam theory, the interaction of rebars, concrete etc., to reach the component level cyclic behavior. Then, using another set of assumptions (boundary conditions, interaction of components, damping model, numerical integration scheme) we reach system-level dynamic behavior. Blind prediction contests on component level cyclic behavior prove that structural models perform relatively well at this level [5, 6]. It is the system level behavior that they fail to predict. Therefore, it is reasonable to assume that one main source of error in the structural models at system-level lies in the assumptions made to scale up from component-level cyclic to system-level dynamic behavior. Hence, these need to be improved and, to this end, more system-level tests are needed.

In parallel, it has been claimed that the appropriate way to validate models in earthquake engineering is to perform multiple tests of virgin specimens under the different ground motions that represent the hazard in a given site and to demand that the structural models predict the Cumulative Distribution Function (CDF) of the maxima of the response quantity of interest. This approach has been investigated by Bachmann et al. [7, 8] who have used this statistical validation procedure on the 1963 Housner dynamic response model of an uplifting structure. They performed 600 shaking table tests as well as 600 numerical simulations and they compared both individual test responses and the statistical aggregates of these responses (empirical CDF of the maximum tilt angle). They showed that the 1963 Housner passed the statistical validation test even though it failed the one-to-one validation test. This statistical approach, is not a “good to have”, but often a necessity given the often not discussed non-repeatability of many tests.

Extending the statistical validation to validate the system-level assumptions of RC structures is not trivial since it would require multiple virgin specimens to be tested on a shaking table. This is cost- and time- wise not viable in full scale. To address this problem we suggest performing the statistical validation carrying out multiple tests with small-scale (1:40) specimens in a geotechnical centrifuge. The validation concerns only the system-level assumptions for given and experimentally determined component level behavior. We have also suggested the same method for masonry structures [9].

Reduced scale models of piles and walls are often used in geotechnical engineering to study soil structure interaction, although using different materials. Knappett et al. 2011 [10] and Loli et al. 2014 [11] developed a micro reinforced concrete to study a rocking isolated RC bridge pier at 1:40 scale. Although their results are encouraging, the manufacturing of the RC elements showed three limitations: the construction time, the accuracy in positioning the reinforcement, and the size limitation of the steel rebars and stirrups. These limitations can be overcome by using a metal 3D printer to manufacture the reinforcement [12]. The use of a metal 3D printer allows manufacturing of the entire reinforcement cage (longitudinal and horizontal reinforcement) with the desired layout. Moreover, these machines can print rebars as small as 200 μ m, which in scale 1:40 correspond to 8mm.

This paper aims at characterizing the flexural behavior of 1:40 scale RC columns by means of full-reversed quasi-static cyclic tests. Two cantilever specimens were constructed using two different types of micro-concrete. One sample was manufactured with cement-based micro-concrete (named HSC), and another with a gypsum based micro-concrete (HSG). The tests were designed according to FEMA-461 [13] and a 3D digital image correlation system was used to analyze the strain field during the tests.

2 MATERIALS AND METHODS

The flexural behavior of micro RC components is investigated performing quasi-static cyclic tests on two small-scale (1:40) micro RC columns. The specimens consist of 2 cantilever elements of 15x15mm cross section and 52.5mm span, with a 65x65x20mm base that functions as a footing (Figure 1). Both samples have the same reinforcement, i.e. 18 rebars of 0.6mm diameter with 0.35mm stirrups with 2.5mm spacing, and a concrete cover of 1.64mm. They differ from each other in terms of the type of micro-concrete used. The HSC Sample (“C” stands for cement) was manufactured using cement based micro-concrete, whereas sample HSG (“G” stands for gypsum) was manufactured with gypsum based micro-concrete. The experiments were performed with a setup that was installed in a Universal Testing Machine (UTM). The measurement system consisted of LVDTs and a 3D-DIC (Digital Image Correlation) system. The latter allowed for the analysis of the displacement and the strain field during the tests.

2.1 Experimental Setup

A fully reversed cyclic loading was applied at the top of the samples. The elements were placed horizontally and fixed on a steel support designed to fit in the UTM and to align the samples to the center of the machine (Figure 2).

The base of specimens was fixed to the lateral support with 4 M6 bolts. A 2mm steel plate was placed between the bolts and the face of the base to avoid local crushing of the concrete due to compressive force applied by the screws. The load is applied at the centerline of the element by two loading pins, which are connected to the double-hinged fork (Figure 2). The latter transfers the vertical load applied by the UTM. The measuring devices consist of 2 LVTD and a 3D-DIC system. The first LVDT measures the vertical displacement at the application point of the load, namely the loading pins shown in Figure 2, the second LVDT measures the vertical displacement of the base of the element (to measure any possible sliding of the base). The DIC was used to measure the displacements and the strain field at the surface. By measuring the strain distribution, we are able to identify any cracks and micro-cracks formed during the tests as well as to locate the plastic hinges that formed at the base on the element.

Figure 1. Specimen geometry and dimensions.

Figure 2. Experimental setup and detail of the loading apparatus.

2.2 Loading Protocol

The load is applied by displacement control, applying a displacement Δ at the top of the elements. Nonetheless, the kinematic parameter that is used to define the loading protocol is the drift ratio φ , which is defined as the ratio between the top displacement and the element length $l_v = 52.5\text{mm}$ (in this case it also represents the shear length).

The test program is defined based on FEMA-461, in which the amplitude increase is defined as $\varphi_{n+1} = 1.4 * \varphi_n$. However, to capture the behavior of the element in the elastic range, the first amplitude was set equal to $0.5 * \varphi_y$ and the second one was set to the yield drift, φ_y (Figure 3). The yield drift was calculated for specimen HSC and HSG using a fiber model in Opensees [14]. The micro-concrete was modelled with a Concrete02 constitutive model whereas the 3D printed steel was modeled using Steel02 model. Both material models were calibrated on uniaxial test results that we performed.

The velocity of application of the load was selected considering two principles. First, the displacement needs to be as slow as possible to neglect any inertia effect and to minimize any strain rate effect. Second, the loading rate needs to be reasonably fast to avoid creep and to make the test feasible time-wise. On these premises we started by defining a strain-rate range $\dot{\epsilon} = 10^{-5} - 10^{-4} \text{sec}^{-1}$. This strain refers to the outermost fiber of the cross section of the column that lies closer to the foundation. The lower end of the strain-rate range corresponds to a displacement rate of the top of the column equal to 0.075mm/min , which was used for the first three amplitudes of the loading protocol. For the subsequent four amplitudes, the displacement rate was set to 0.413mm/min , which corresponds to a strain rate of $5.6 \times 10^{-5} \text{sec}^{-1}$. Finally, the last cycles were applied with a displacement rate of 0.75mm/min , corresponding to the upper limit of the aforementioned strain rate range.

2.3 3D Printed Reinforcement

The use of a 3D printer allows manufacturing of the entire reinforcement cage, namely the longitudinal and shear reinforcement, with the designed layout. The rebars size is not constrained by the manufacturing method. Depending on the 3D printer, we can print rebars as small as 0.20mm ($200\mu\text{m}$), which in the prototype scale (1:40) represent $\Phi 8$ rebars.

In our study, we used a ConceptLaser M2 Laser Powder Bed Fusion (LPBF) printer. It is able to manufacture various types of metal. For our study, we used gas-atomized stainless steel 316L powder with a grain size $15-45 \mu\text{m}$.

Figure 3. Loading protocol in terms of drift ratio φ .

We tested specimens with a longitudinal reinforcement ratio $\rho_l = 3.7\%$ and a shear reinforcement ratio $\rho_w = 0.9\%$. The reinforcement layout consists of 18 bars of 0.6mm, and 0.35mm diameter stirrups with a 2.5mm of spacing. In addition, the longitudinal bars were linked with shear ties as shown in Figure 4.

All rebars were printed with ribs on the surface to increase bonding with concrete. In addition, the 3D printed steel has a roughness R_a value of 15-20 μm , hence it has an inherent roughness that is beneficial for the steel-concrete bonding.

The mechanical properties of the 3D printed steel were characterized with a series on uniaxial tension tests performed on 0.6mm diameter bars identical to the ones used as reinforcement in the micro RC samples. Due to the small cross-section, we used a sensor arm extensometer, instead of strain gauges, with a gauge length on 30mm to measure the strains during the tests. The resulting average yield strength f_y was 378MPa, the average maximum strength $f_{s,max}$ was 430MPa, and the average Young's Modulus E_s was equal to 180GPa. These values are in line with those reported by Casati et al. 2018 [15] for 3D printed Stainless steel 316L.

Figure 6. Passing distribution of the sand used for the micro-concrete.

2.4 Micro Concrete

Due to the small scale of the specimens, it is necessary to scale the inert component of the concrete so that the ratio inert size / rebars / cross section is about the same as in the real scale. We used Perth silica sand with a $d_{50} = 0.23\text{mm}$. Its grain distribution compares very well to the typical aggregate size when scaled 40 times (see Figure 6). Moreover, a different binding agent was studied, alongside the more common cement, i.e. gypsum. The use of gypsum to manufacture micro concrete models is not new, in fact, both Knappett et al. 2011 [10], and Harris et al. 1999 [16] suggest using gypsum to accelerate the curing time and consequently speeding up the specimen manufacturing. Gypsum takes around 48 hours to reach the full strength compared to the usual 28 days for concrete, hence the manufacturing of several specimens for the statistical validation would become considerably faster.

The concrete based micro-concrete used in sample HSC comprises a mixture of cement Normo52.5R, Perth sand, and water. The other mixture, i.e. gypsum based micro-concrete used in HSG, was made of alpha-formed gypsum based plaster (Saint-Gobain Hartform 1) instead on cement. The ratio binding component / sand / water was $1 / 1 / 0.5$ and $1 / 1 / 0.6$ for cement and gypsum based mix respectively. The mix designs were chosen to minimize the water percentage while preserving a good workability and flowability of mixture.

The mechanical properties of both types of micro-concrete were investigated through a series of uniaxial compression tests on cylindrical specimens of 20mm diameter and 50 mm height, and several 4 point bending tests performed on prisms specimens with cross section 15 by 15mm and length of 80mm. Table 1 presents the mean values of the compressive strength f_c , the strain at the maximum load ε_1 , the Young's modulus E_c , and the modulus of rupture f_{ct} .

Micro Concrete	f_c [MPa]	ε_1 [%]	f_{ct} [MPa]	E_c [MPa]
Cement	34.5	1.2	3.40	2089.0
Gypsum	18.5	0.9	7.20	1109.9

Table 1. Mechanical properties of micro-concrete.

3 RESULTS

3.1 Cyclic Tests

The lateral force-displacement loops (P- Δ) for specimens HSC and HSG are shown in Figures 7 and 8, respectively. The failure load is conventionally defined as a strength degradation up to 85% of the peak load.

Specimen HSC exhibits a maximum shear load $F_{max} = 172.80\text{N}$ at a drift ratio $\varphi_{F_{max}} = 1.47\%$ and an ultimate strength $F_{0.85} = 146.80\text{N}$ at a drift ratio $\varphi_{0.85} = 3.0\%$. Yielding occurred at a shear load $F_y = 115.60\text{N}$ at a yield drift ratio $\varphi_y = 0.82\%$. Visual inspection of the sample did not show diffuse cracking on any of the surfaces. Nonetheless, the horizontal strain distribution at peak load, measured with 3D-DIC system, shows tensile strains along the span of the elements HSC (Figure 7, right) that suggest that micro cracks formed during the tests. Regardless of the micro cracks, a localized crack at the base of the element followed by the fracture of the outer longitudinal rebars are to be considered as the causes of failure; no other failure mechanisms could be observed, i.e. concrete spalling.

Specimen HSG reached a maximum load $F_{max} = 184.20\text{N}$ at a drift $\varphi_{F_{max}} = 4.76\%$ and ultimate strength $F_{0.85} = 156.57\text{N}$ at a drift ratio $\varphi_{0.85} = 7.65\%$. The load at yielding F_y was equal to 157.40N at a yield drift ratio φ_y of 1.58% . The hysteresis loop in Figure 8 shows a clear pinching behavior, unlike the loop of the HSG sample. The strain distribution at peak load did not show concentrated tensile strains anywhere along the specimen unlike what was observed in specimen HSC. The tensile strains concentrated at the base of the element. This confirms what was observed visually, namely that the failure was caused by a localized crack at the base. Similarly to HSC, in specimen HSG no concrete spalling was observed. Comparing the two results, the sample with cement based micro-concrete resulted in a stiffer and less ductile behavior than the sample with gypsum based micro-concrete. Moreover, cracks are more diffused in the HSC micro RC specimen.

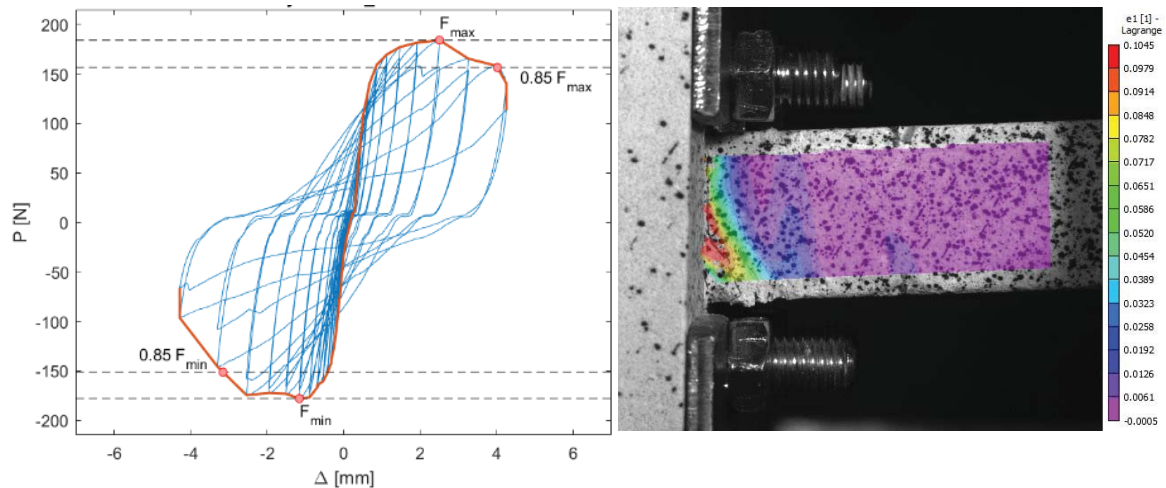

Figure 8. Left: HSG Hysteresis loop and backbone curve. Right: Horizontal strain field at maximum load.

Parameter	Value
f_y	378 [MPa]
E_s	180 [GPa]
b_s	0.004
ϵ_{lim}	0.09

Table 2. Steel02 parameters used in the Opensees model.

Specimen	f_c [MPa]	ϵ_1	f_{cc} [MPa]	ϵ_{cc}	f_{ccu} [MPa]
HSC	34.5	0.012	43.16	0.027	42.64
HSG	185	0.009	26.81	0.029	21.24

Table 3. Concrete02 parameters used in the Opensees model. The properties f_{cc} , ϵ_{cc} , and f_{ccu} refer to the confined concrete of the section core.

3.2 Numerical Model

Numerical models of the cyclic tests were implemented in Opensees, and the results were compared against the experimental curves. The specimens were modelled as cantilever beams with a fixed support. This assumption was confirmed by the DIC measurements that showed no rotation at the connection of the elements with their footings. The reinforcement was modeled using the OpenseesnSteel02 model, and the strain at failure ϵ_{lim} was modeled using the MinMax model. The parameters used are summarized in Table 2.

The Opensees model used for concrete is Concrete 02 with different parameter values for the core and the cover material. The latter was calibrated based on the material level tests on the small-scale specimens, whereas the core concrete properties were calculated using Mander's model [16]. The model parameters are summarized in Table 3.

Figure 9 (left) shows the comparison between the experimental and numerical results of the HSC specimen. The numerical simulation is able to capture the maximum load measured during the test, as well as the strength degradation of the post elastic behavior. The stiffness degradation in the numerical curve is also remarkably similar to the experimental curve. On the other end, the numerical simulation of specimen HSG (see Figure 9, right) fails to capture key values, such as the peak load, the strength degradation, and most of all the stiffness degradation. In fact, the simulation does not show any pinching behavior unlike the experimental curve of HSG.

Figure 9. Comparison between experimental curves and Opensees models.

4 CONCLUSION

Additively manufactured reinforcement allows the production on multiple small-scale reinforced concrete specimens. The tested elements show a flexural behavior, which is similar to full size prototype RC structural members. Cement based micro-concrete has a compressive and tensile strength similar to concrete, unlike gypsum based micro-concrete that has a tensile strength substantially higher than concrete. Moreover, the numerical simulations in the case of specimen HSC (cement base micro-concrete) are able to accurately capture the experimental behavior. The numerical model of specimen HSG does not match the behavior observed experimentally, as it could not capture neither the peak strength nor the pinching behavior of the tested specimen. Further component level tests are required to fully characterize the flexural behavior of micro RC specimens. Nonetheless, it seems feasible to produce small-scale models of a full structure to perform dynamic tests in a geotechnical centrifuge. The shake table tests could provide a dataset to statistically validate the assumptions that are usually made to scale up from component-level cyclic to system-level dynamic behavior.

Abstract

Many times, either the research engineer or the design engineer needs to model reinforced concrete (R/C) structural elements in order to study their behavior. In the present research work, an attempt is made to study the correct way of modeling a reinforced concrete column using the finite element ANSYS software. Three-dimensional finite elements are used to model the column. The results of the column modeling and analysis using ANSYS software are compared with the corresponding experimental results of a column with the same geometric characteristics and the same material and load properties as those of the analytical modeling. The only difference between the analytical column modeling and the experimental specimen is the difference in the loading rate. The analytical and experimental results are compared with each other. The influence of the loading rate as well as the mesh method is examined. Useful conclusions are drawn regarding the influence of the loading rate and the mesh method on the behavior and results of reinforced concrete components.

1 INTRODUCTION

The rapid growth of technology and the development of the computer, favored the development of theories and computational methods adapted to the capabilities of the computer, in order to solve, yet, unsolved problems in the field of engineering. The most common arithmetic method developed is the Finite Element Method, a numerical approximation method that has the ability to solve complex problems, expressed in the form of differential equations [1]. The basic concept of the Finite Element Method is the ability to represent an area as a set of distinct subareas [2].

As mentioned by Daryl [3], the idea of the Finite Element Method was first presented in the publications of Turner, Clough, Martin and Topp (1956), taking data from research by Courant (1943) [4], Hrenikoff (1941) [5] and McHenry (1943) [6], however, due to the complexity of the arithmetic operations they contained and the lack of computational power of the time, they did not prosper. The official presentation of the Finite Element Method with its current form, took place in the period 1954-60 in the publication of J. Argiris et.al. [7, 8], while the term "Finite Element" was used for the first time in the late 1960s by Clough [9].

In recent years, with the rise of supercomputers and the creation of finite element software run in Windows OS environment, the method has become widely known and accessible, even to the average user, enabling the numerical solution of complex problems while minimizing the need for extensive experimental testing, due to the increased reliability of the method. The most important advantage of the method is that it allows the engineer to see how the product will behave and to point out any mistakes that have been made so far, before proceeding to time-consuming and expensive processes of manufacturing and testing physical prototypes, achieving the early optimization of the product and at the same time, reducing both the time and the cost of studying the experimental process [3].

ANSYS is a general-purpose finite element software, which from the beginning of its creation, has been a pioneering program, with its use in various fields of Engineering [10]. Its analysis process includes the construction of the simplified simulation model, the generation of the finite element grid, the imposition of loads on the model and the solution process using differential equations [10]. The results are exported from the program in a legible way through graphs, tables and / or animations [10].

To investigate the reliability of ANSYS finite element software, the study and comparison of the behavior of a reinforced concrete column, which is subjected to uniaxial compressive load, in relation to the column of the experimental process conducted by Chrysanidis [11]. Chrysanidis in his experiment [11], deals with the study of parameters that affect the stability of seismic reinforced concrete walls, when they are subjected to cyclic loading. For the purposes of the experiment, 10 identical specimens were constructed, on a scale of 1:3, which simulated the edges of a wall, the only difference between the specimens being the increasing degree of elongation and the ratio of longitudinal reinforcement. The fabricated specimens are subjected to two loading cycles, with the first cycle subjecting the specimens to uniaxial tensile loading, with a low loading rate of 4 mm / min, and then, in the second loading cycle, the specimens being gradually subjected to uniaxial compressive loading with a low loading rate of 1 mm / min, until their failure. Based on the experimental process, useful conclusions were drawn about the factors that affect the lateral buckling of the specimens. It has to be noted the fact that other experiments have taken place in the international bibliography concerning the behavior of reinforced concrete columns from various researchers [12]–[23].

In the present research work, a comparison is made between the experimental results of the specimen L-0 and the results of the specimens L-0-A and L-0-B, which are obtained through simulations using ANSYS software. It must be noted that the specimen L-0 characterized as a

‘virgin specimen’ having a degree of elongation equal to 0‰ and a longitudinal reinforcement ratio equal to 1.79%. Also, the experimental specimen has the same geometric characteristics, material and load properties as those of the analytical simulation. It is important to note that the experimental specimen was subjected to uniaxial compressive load with a low loading rate of 1 mm / min. The influence of the soil and its parameters have been neglected [24]–[31].

2 SIMULATION DESCRIPTION IN ANSYS

2.1 Specimens’ characteristics

Therefore, in order to compare the analytical with the experimental results of the L-0 test, as mentioned above, the simulation behavior of two specimens, which are called L-0-A and L-0-B, were studied. The noticeable difference between the two specimens is that the specimen L-0-A, consists only of the active region of the experimental specimen L-0. The active area of the specimen L-0 is the area of the specimen between the two steel blades (Figure 1). As a result, the dimensions of the specimen L-0-A were equal to 15 x 7.5 x 64 cm. Inside the specimen L-0-A are placed the transverse and longitudinal reinforcement, with the longitudinal reinforcement containing 4 reinforcing bars with a diameter of 8.0 mm and, at the same time, the transverse reinforcement contained ties with a diameter of 4.2 mm, which are placed with the distance between them being equal to 33 mm.

The specimen L-0-B consists of the integrated specimen L-0 with dimensions 15 x 7.5 x 76 cm, which at its ends has steel blades. It must be noted that the steel blades penetrate inside of the, so-called, “Shoe”. The “Shoe” is solid, in the form of a cube, in which the dimension of each side is equal to 20 cm and inside of it is placed a spiral with a diameter of 5.0 mm. Specifically, the total height of column of the specimen L-0-B is equal to 90 cm, although, its net height is equal to 76 cm, which is equal to the distance between the two cubes which are called as “Shoes”. Inside the specimen L-0-B are placed the transverse and longitudinal reinforcement, with the longitudinal reinforcement containing 4 reinforcing bars with a diameter of 8.0 mm and, at the same time, the transverse reinforcement contained ties with a diameter of 4.2 mm which are placed at distances equal to 33 mm.

Figure 1 shows the geometry of the experimental specimen L-0 [11] which forms the base of the simulations of specimens L-0-A and L-0-B. Table 1 shows the specimens’ characteristics which are required for the construction of the geometry of the specimens L-0-A and L-0-B. The geometry of the steel blades is not contained at Table 1, due to its complexity and as a result is presented in Figure 2. Table 2 shows the material properties for concrete which is used to make the “Shoe” and the column. Also, Table 3 shows the measured material properties for steel which is used for the longitudinal and transverse reinforcement, the spiral reinforcement and the steel blades [11].

2.1.1. Loading of specimens

The specimens L-0-A and L-0-B were strained under a uniaxial compressive load applied on the upper “Shoe” of each specimen vertically. The load application took place gradually till the resistance of each specimen reduced and the specimens failed. Despite of the experimental procedure, during which the specimen L-0 was strained at a low monotonic loading rate of 1 mm / min, at the analytical simulation, the compressive stress of the specimens is carried out at a high loading rate of 1 mm / sec. Based on that fact, conclusions are drawn, concerning the significant influence of the loading rate on the behavior of reinforced concrete structures. Table 4 shows the load values per time until the resistance of each specimen is greatly reduced and the specimen becomes unstable.

2.2 Simulation of specimens

2.2.1. General

The analytical simulation took place in the educational version of the finite element software ANSYS 20.0. It is important to note that the educational version of ANSYS 20.0 is subject to restrictions. Firstly, the discretization of the specimens requires reducing the numerical number of finite elements until the numerical limit being equal to 32,000, even if the constructed grid is not considered appropriate by the general rules of technical metrics [32]. Furthermore, in the solution stage, the loading time is in seconds versus minutes of the experiment and, as a result, the loading being carried out at a high rate on the specimen. Finally, at the design stage is required to reduce the complexity of the specimen's geometry, which is achieved by making use of the symmetry of the specimen. It is noteworthy that the final restriction took place only during the simulation of the specimen L-0-B.

2.2.2. Specimen L-0-A

The specimen L-0-A is simulated via ANSYS 20.0 software and the Workbench subroutine. The first stage of the simulation was the construction of the geometry of the specimen L-0-A which is designed into the software via the SpaceClaim tab. The design process is started from the inside to the outside part of the geometry of the specimen L-0-A. The definition of materials and their properties are defined through the software library. It is noteworthy that the default library values for each of the materials used are modified only when they have been redefined, as shown in Tables 2 and 3, otherwise they remain the same. Figure 3 shows the specimen L-0-A.

Figure 3: The specimen L-0-A.

The model is discretized via the Multizone Mesh Method by using a set of hexagonal finite elements to construct the grid, with the size of the finite elements being 14 mm. The suitability of the mesh is studied in terms of orthogonal quality, skewness, aspect ratio and element quality parameter, which according to the basic general guidelines for the construction of the mesh [32], the orthogonal quality and skewness parameter provided values within the desired limits even though the aspect ratio parameter did not. In particular, for the skewness parameter, its maximum value is equal to 0.39, while at the same time, the minimum value of the or-

thogonal quality parameter is maintained above 0.72. Nevertheless, the maximum value of the aspect ratio parameter is equal to 4.67.

Regarding the element quality parameter, all possible mesh methods are investigated for the specimen L-0-A, with the Multizone Mesh Method being preferred, which provided for the element quality parameter a minimum value equal to 0.32. On the other hand, the mesh, which is made via Automatic mesh method comprises a combination of hexahedral and tetrahedral elements, with the lowest value for the element quality parameter being 0.01. Moreover, the mesh, which is made via Tetrahedron Mesh Method using a set of tetrahedral elements provides for element quality parameter a minimum value equal to 0.02. It is recalled that, according to the general guidelines for the constructions of the mesh, the element quality parameter has a value range of 0-1, with the value 1 being the best [32].

Figure 4 shows the discretization of the specimen L-0-A via Multizone mesh method. Figure 5 shows the element quality parameter for the possible mesh methods. It is noteworthy that the Sweep and Hex Dominant mesh methods could not model the specimen L-0-A. As a result, the software exported the messages shown in Table 5. For simulation of the loads which the specimen L-0-A is subjected to, the categories of Support and Load are used. Therefore, the Fixed Support command is used by the Support category to define that the specimen is connected at the bottom to a rigid body [10]. At the same time, the loading of the specimen is defined using the Force command via the Load category. Thus, the force was applied vertically at the top of the specimen.

The current research work investigates the results of the stress, the deformation and the strain of the specimen L-0-A. It is noteworthy that for the investigation of the deformation is studied either the total deformation of the specimen L-0-A or the deformation to the horizontal and vertical axis.

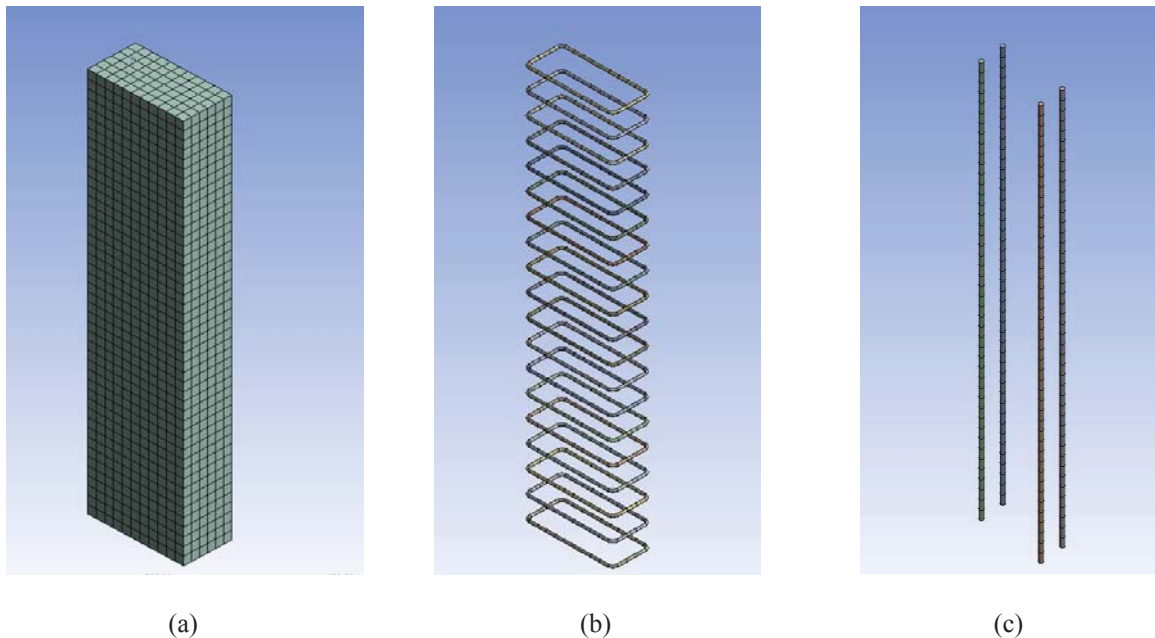

Figure 4: The mesh of the: (a) Concrete, (b) tie, (c) rebar.

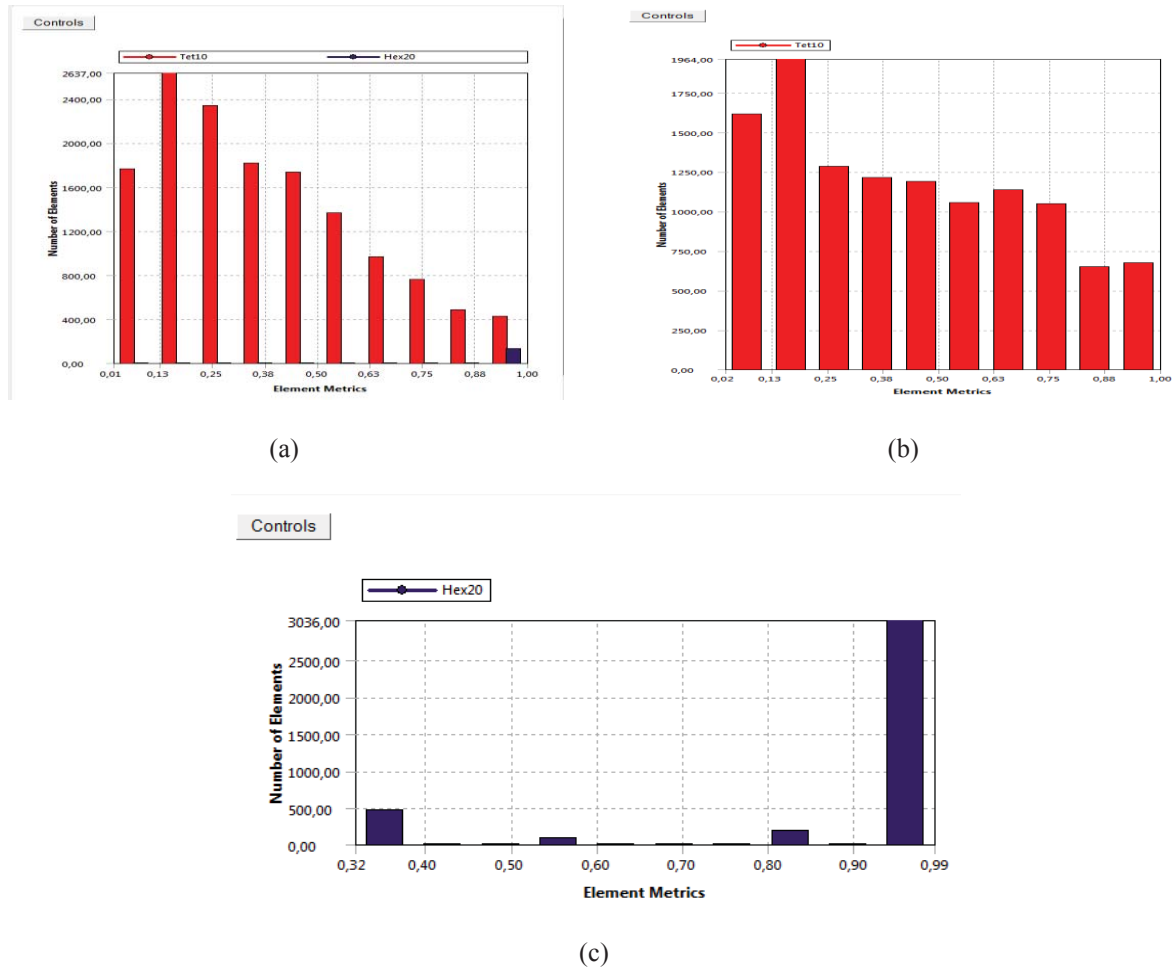

Figure 5: The element quality parameter for: (a) Automatic, (b) Tetrahedron, (c) Multizone Mesh Method.

Mesh Method	Simulation's messages of the specimen L-0-A
Sweep	1. Mesher failed to initialize.
	2. One or more non-sweepable bodies have sweep method controls and cannot be swept.
	3. The mesh generation did not complete due to poor quality elements or incorrect input. Please try meshing with another mesh method or different mesh options.
Hex Dominant	1. Mesher has failed to generate hex dominant mesh for one or more bodies. Try using a different mesh method.
	2. A mesh could not be generated using the current meshing options and settings.
	3. At least one body selected for hex dominant meshing has a small normalized volume to surface area ratio. The result may be a low percentage of hexs or poorly shaped elements.

Table 5: Non-completion messages about simulation of the specimen L-0-A.

2.2.3. Specimen L-0-B

The specimen L-0-B is simulated using ANSYS 20.0 finite element software and the Workbench subroutine. The first stage of modeling was the construction of the geometry of the specimen L-0-A like before, which is designed into the software through four stages via the SpaceClaim tab. The first stage involves the design of the geometry of the column, with the design process being similar to that of the specimen L-0-A, starting from the inside to the outside part of the geometry of the specimen L-0-B.

The second stage is the design process of the geometry of the “Shoe”, which is the same design sequence followed as in the first stage, including the design from the inside to the outside part of the geometry of the “Shoe”. Specifically, first of all, the geometry of the spiral reinforcement is designed, which is placed inside the “Shoe” and then, the “Shoe” cube that surrounds it. The third design stage includes the creation of the steel blades. As a fourth and final design step, the above steps are assembled to produce the specimen L-0-B.

It is noteworthy that due to the limitations of the educational version of ANSYS, which concern the complexity of the geometry of the specimen L-0-B, it is necessary to use the symmetry of the specimen L-0-B. Otherwise, the ties would probably have to be removed, which would not correspond to the geometric features of the specimen L-0. Figure 6 shows the specimen L-0-B.

Figure 6: The specimen L-0-B.

The definition of L-0-B test materials and their properties are defined through the software library. It is noteworthy that the default library values for each of the materials used are modified only when redefined, as shown in Tables 2 and 3, otherwise they remain the same. The model is discretized using the Multizone Mesh Method, using a set of hexagonal finite elements to construct the mesh with the finite element size being equal to 18 mm.

The suitability of the mesh is studied in terms of orthogonal quality, skewness, aspect ratio and element quality parameters, which according to the basic general guidelines for the construction of the mesh [32], the orthogonal quality and skewness parameters provided values within the desired limits, even though the aspect ratio parameter did not. In particular, for the skewness parameter, its maximum value is equal to 0.39, while at the same time, the minimum value of the orthogonal quality parameter is maintained above 0.70. However, the maximum value of the aspect ratio parameter is equal to 5.60.

As far as the element quality category is concerned, all possible mesh methods for the L-0-B specimen are being investigated, with the Multizone method being deemed necessary, as no

other mesh method was possible due to the complexity of the model geometry and the small numerical limit on the number of finite elements of the mesh. Therefore, for the Multizone Mesh Method, the minimum value in the element quality parameter is 0.17. It is recalled that, according to the general guidelines for the creation of the grid, the element quality parameter has a value range from 0-1, with the value 1 indicating the perfect quality [32].

Figure 7 shows the discretization of the specimen L-0-B using Multizone mesh method. Figure 8 shows the element quality parameter for the Multizone mesh method. Table 6 shows the messages exported of the impossible discretization with the other mesh methods. Even if, for the Tetrahedron Mesh Method the software does not output any message, however, the specimen L-0-B could not be discretized according to the constraints, even when the finite element size is equal to 200 mm. For simulation of the forces which the specimen L-0-B is subjected to, the categories of Support and Load are used. Therefore, the Fixed Support command is used by the Support category to define that the specimen is connected at the bottom to a rigid body [10]. At the same time, the loading of the specimen is defined using the Force command via the Load category, thus, the force was applied vertically at the top of the specimen.

The current research work investigates also the results of the stress, the deformation and the strain of the specimen L-0-B. It is noteworthy that for the investigation of the deformation is studied either the total deformation of the specimen L-0-B or the deformation to the horizontal and vertical axis.

3.2 Analytical results of mesh methods

For investigation of the influence of mesh methods on the reliability of the analytical results, the specimens L-0-A and L-0-B are discretized using all the available mesh methods of

the ANSYS software. It is noteworthy that the geometrical characteristics, the properties of the materials and the loading rate remained the same for each simulation, as mentioned earlier. Table 10 shows the stress results according to the mesh method and Table 11 shows the strain results according to the mesh method.

4 ANALYTICAL INVESTIGATION

4.1 Investigation of analytical results

Therefore, the analytical research of the two simulations in the present research has led to the following common results to between the two simulations:

- The rate of loading, in the case of reinforced concrete structures, affects the deformation results, by increasing the resistance of the specimen.

- The rate of loading of vertical and horizontal deformation remains completely constant throughout the load, which is not observed in the experimental results.
- The rate of loading of stress remains perfectly constant throughout the loading duration, just as in the experimental results.
- The values of the transverse deformation remain below zero throughout the loading duration, without observing the behavior of the two stages of deformation, which are described in the research of Chrysanidis [11].
- Increase of the resistance of the specimen L-0-A and L-0-B in relation to the resistance of the experimental specimen L-0.
- The average value of the percentage error for the simulation of specimen L-0-A is of the order of 395.2%, while for the simulation of specimen L-0-B is of the order of 598.8%.

With the percentage error values far from the permissible limits, it becomes obvious that neither the analytical results of the specimen L-0-A nor of the specimen L-0-B converge with the experimental results of Chrysanidis [11] and as a result the two simulations cannot be characterized as reliable in terms of the coherence of the results.

4.2 Investigation of mesh method's results

Based on the element quality diagrams and the tables of the mesh method results, it appears that:

A. For the simulation of specimen L-0-A

- The rate of loading, in the case of reinforced concrete structures, affects the deformation results, increasing the strength of the specimen.
- The mesh is performed only by Automatic, Tetrahedron and the Multizone mesh methods, due to the geometry of the simulation which contained bodies that Sweep and Hex Dominant mesh methods could not mesh.
- Due to the limitation of the educational version for the number of finite elements used, the mesh of the Automatic, Tetrahedron and Multizone mesh methods do not meet the requirements of a suitable grid, according to the general rules for the element quality measurement technique. However, from the above methods, the Multizone mesh method is preferred.
- A mesh made only of hexahedron finite elements provides more reliable results than a mesh made of tetrahedron finite elements.
- The type and the number of finite elements do not affect the behavior of the specimen during the loading period.

B. For the simulation of specimen L-0-B

- The mesh is generated using only the Multizone mesh method.
- Due to the complexity of the geometry, the method of the Automatic and Patch Confirming Tet, cannot distinguish the model with a number of finite elements less than 32,000.

- The Sweep method and the Hex Dominant method do not produce a mesh, due to the geometry of the specimen containing bodies, in which the methods cannot work.
- Due to the limitation of the educational version for the number of finite elements used, the mesh of the Multizone method does not meet the requirements of a suitable grid, according to the general rules for the technique of measurement of the element quality category. However, the choice of mesh made with the Multizone mesh method is considered necessary.
- The type and the number of finite elements do not affect the behavior of the specimen during the loading period.

5 INFLUENCE OF LOADING RATE

According to the detailed results, there are two stages during the duration of the loading. The first stage includes the time from the imposition of the load at 0 kN to the loading with a load equal to 430 kN. Then, the second stage includes the unloading process of the model. In particular, in the first stage there is an increase in the deformation and stress at a constant rate, until the stress reaches its maximum value, in contrast to the experimental results where the rate of deformation follows a different flow. Then, in the second stage, the deformation and the stress are reduced at a constant rate until the values are 0, returning the specimen to its original state. It is noteworthy that during the experimental procedure, there is a deformation with the higher value being calculated at 10% of the height of the L-0 specimen, measured by its base. In addition, it is observed that the number and type of finite elements do not affect the behavior of the specimen during the loading process, despite of the mesh method used.

Therefore, it turns out that the universal load in the behavior of the specimen L-0-A and L-0-B in relation to the experiment by Chrysanidis [11], is due solely to the high loading rate of the two simulations, with which concludes that, in reinforced concrete structures, the loading rate affects the results of deformation increasing the strength of the structure.

6 INFLUENCE OF MESH METHOD

The type and number of finite elements used greatly influence the reliability of the results. In particular, the influence of the type of finite elements on the suitability of the mesh and consequently on the reliability of the results is observed. More specifically, a grid made of hexadecimal elements, such as the mesh of Multizone mesh method, is more suitable, according to the general technical metrics rules, and at the same time more reliable than a grid made of tetrahedral elements, such as the mesh of Tetrahedron mesh method. On the other hand, the number of finite elements depends on the complexity of the geometry of the model that it is called upon to mesh. A grid with a small number of elements in a complex geometry, is quite difficult to be characterized as suitable and at the same time, its results cannot be considered as being reliable.

The large numerical differences between the simulation results are due to both the chosen mesh method and the size of the finite elements of the grid. However, it is impossible to create a more appropriate grid than that in section 2, due to the limitations of the ANSYS educational version.

7 CONCLUSIONS

By comparing the analytical results of the L-0-A and L-0-B specimens with the experimental results of the L-0 specimen [7], the reliability of the ANSYS software and the factors

which might influence it are investigated. The resulting conclusions can be summarized as follows:

- The rate of loading, in the case of reinforced concrete structures, affects the deformation results, increasing the strength of the specimen.
- The number and the size of the finite elements of a simulation affect the accuracy and reliability of the results.
- The number and type of finite elements do not affect the behavior of the model during loading period.
- The number and type of finite elements of a simulation affect the accuracy and reliability of the results, whether or not the grid is suitable.
- The number of finite elements depends on the complexity of the model geometry.
- The type of finite elements affects the reliability of the simulation results, with hexahedron elements providing more accurate results.

ABSTRACT

Damage reports after recent earthquakes prove that the structural deficiencies of non-ductile Reinforced Concrete (RC) buildings often lead to structural element local damage and collapse of the entire structure. The structural weakness of the Beam-Column joints, due to the absence of seismic detailing and capacity design principles, plays a key role in the seismic vulnerability of European building stock designed before the 1970's, thus before the introduction of modern seismic codes. In RC buildings subjected to reversed cyclic earthquake loads, high stress concentration occurs at the Beam-Column joints, making these regions prone to the occurrence of severe damage and brittle mechanisms. Yet, a common engineering practice consists in modeling the Beam-Column joints as rigid elements in concrete frames, neglecting the joint's deformability and, more importantly, their actual local mechanism. Consequently, the predicted stiffness and the collapse mechanisms of the structure can, unconservatively, change significantly from the actual one. Starting from the experimental results available in literature, this work aims at calibrating the key parameters that characterize the equivalent joint moment-rotation hysteresis behavior of existing substandard Beam-Column joints, by using a simple while reliable lumped plasticity modeling approach. The numerical model was developed in OpenSees and validated on many experimental results collected from the literature. The global joints response relationships under cyclic loads, defined as a function of the joint structural detailing and the axial load, satisfactorily reproduce the experimental findings in terms of first cracking point, yielding point, overall hysteretic behavior, pinching effect, and strength degradation. Moreover, the initial and post-yielding stiffness values of the joint's backbone curve were further improved when compared to those recently proposed by the NZSEE2017 Seismic Assessment Guidelines.

1 INTRODUCTION

Several studies on the seismic behavior of reinforced concrete joints within existing frames in seismic areas have been carried out in the last few decades. The brittle failure of joint panels has been recorded more frequently, following the most recent seismic events [1], which, in addition to extensive structural damages, have caused great economic losses [2-5] and highlighted the strong vulnerability of pre-70's buildings [6-9].

In RC frame structures stressed only by gravity loads, joint panel regions are rarely subjected to significant stresses, but the situation is rather different when considering seismic actions. Therefore, a very high stress state is generated in the joint region, where specific transverse/shear reinforcement should be adopted to reduce the stress variation. Instead, older frame buildings are typically characterized by poor reinforcement detailing, poor bond properties, inadequate confinement, and more importantly, lack of capacity design principles.

As shown in many experimental programs, the joint panels of pre-70's were characterized by insufficient tensile strength due to the absence or lack of horizontal and vertical reinforcement. This weakness appears clearly with the joint failure induced usually by shear or bond flaws [9-11]. The flexural and shear forces, generated into the joint panel by the cyclic tests, create a stress distribution transferred through the joint, producing a wide diagonal crack pattern along the principal compressive directions. This pattern leads to either a tensile failure or to a compression/crushing failure of the diagonal strut, and thus to a strength and stiffness deterioration within the joint. In other cases, the joint failure occurred with the instability of the vertical column bars, devoid of horizontal reinforcements, i.e., stirrups or wall beam bars.

Therefore, growing attention in the literature has been focused on the analytical/numerical modeling of gravity load designed RC beam-column, considering the joint panel zone's deformability and capacity [12-14]. In the last decades, many numerical models have been developed and proposed either based on Finite Elements (FE) modeling, or on simplified macro-models or lumped plasticity (e.g. [15-19]) and analytical approaches (e.g. [20]).

The present work analyzes experimental tests conducted on the external joints with the aim to verify the accuracy of the proposed constitutive laws. In particular, the response prediction obtained by a simple moment-rotation backbone, whose parameters are defined a priori based on current knowledge on the topic, with respect to a more complex backbone calibrated ad-hoc from the experimental results. Taking one of these nodes as a case study, a numerical model was built in OpenSees based on a lumped plasticity approach and relying upon a joint rotational spring. Two different relations have been defined: a bi-linear relationship based on the NZSEE2017 Seismic Assessment Guidelines and associated literature [15, 21] and a more refined tri-linear relationship that better approximates the first cracking point, the elastic and softening branches. The hysteresis behavior was modeled through the use of a "uniaxial hysteretic material" already present in OpenSees library. Regarding the other tests analyzed, only the parameters useful for defining their backbone curve are reported.

2 EXPERIMENTAL STUDIES ON RC JOINT SUBSYSTEMS

In literature, several experimental studies on beam-column joints with non-ductile detailing have been carried out to understand the as-built parameters that would influence the seismic performance of these structural connections.

In the last decades many exterior beam-column joints, representatives of pre-1970s construction and/or gravity-only design buildings, characterized by inadequate joint shear reinforcements, inadequate bond resistance, and non-ductile beam anchorage details by modern standards, were tested with the aim to assess the seismic behavior of these connections (e.g. [9-11]), several

design methodologies were developed (e.g. [15-19]) and nowadays suitable types of reinforcement interventions were investigated (e.g. [22-27]). In general terms, depending on the structural detailing adopted and on the axial load variation assumed, the failure modes of beam-column connections can be significantly different, so they need to be checked on a case-by-case basis. To this aim, the moment – axial load performance domain and the hierarchy of strength approach can be used to evaluate the sequence of the collapse events between beam, column, and joint panel zone [28].

Considering the typical structural weaknesses of existing RC buildings, in the late 1990s and early 2000s, Pampanin et al. carried out quasi-static tests on existing RC beam-column joint subsystems considering plain-round reinforcements with end-hook anchorages, under quasi-static cyclic loading and varying column axial load according to the European construction practice of the 1950-1970s period [7-9]. Further comprehensive experimental and numerical testing campaigns on beam-column joint subassemblies have been carried out at the University of Canterbury (2002-2010) [29-31]. Test results [30] and numerical simulations [32] revealed extensive shear damage in the joint panel zone, which would lead to a severe and critical reduction of lateral and gravity load capacity of the overall frame system. The implication of joint damage and collapse within the frame system collapse mechanism become up a crucial issue in recent days.

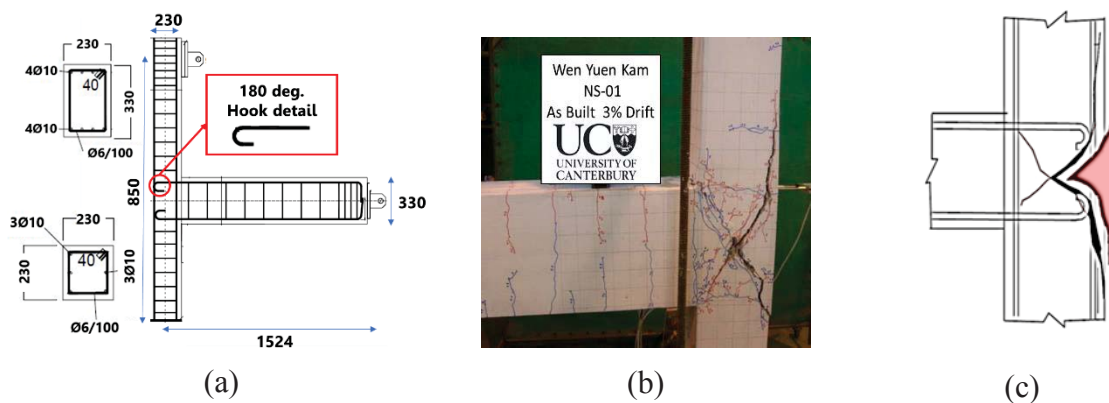

Figure 1: (a) Reinforcing and geometry details for test unit NS-O1 [30], (b) cracks pattern at top drift equal to 3% [30], (c) “concrete wedge” mechanism formation [15].

In this paper, the 2/3-scaled exterior beam-column joint unit NS-01, belonging to the experimental tests carried out by University of Canterbury UC research team [31], shown in Figure 1, was selected to begin the direct calibration of the moment–rotation relationship key parameters, starting from the values suggested by NZSEE Seismic Assessment Guidelines and associated literature [15, 21]. The chosen specimen is characterized by plain-round reinforcements with end-hook anchorages and tested under a unidirectional quasi-static cyclic lateral loading. The geometry of the trial specimen was chosen to be close to the pre-1970s non-ductile RC beam-column joint benchmark, see Figure 1 (a). Deformed mild steel reinforcements and commercial pre-mix concrete compression strength of 30MPa were used. The lateral loading protocol used in this test consisted of two displacement-controlled cycles at increasing amplitudes: 0.1%, 0.2%, 0.5%, 1.0%, 1.5%, 2.0%, 2.5%, 3.0% and 4.0% inter-story drift. The lateral load was coupled with a varying axial loading, N , as suggested since [9], to simulate the actual frame sway action, as per the experimental test, considering N as a function of the lateral load F_C : $N = 110kN \pm 4.63F_C$. Most previous literature experiments on beam-column joint subassemblies (for both existing capacity and retrofit solution evaluations) have used either constant or

zero column axial loads, so the chosen test represent an interesting case- study. The specimen NS-01 showed a crack pattern that develops along the main principal compressive direction at a top drift value equal to 3% (end of the test), as represented in Figure 1 (b). In addition, the punching action from the smooth bars with end up develops the so called “concrete wedge” mechanism [9, 7, 15], due to the development of stresses in the only portion of the joint panel unconfined (no stirrups, no convergent beam), see Figure 1 (c).

In the next sections, the numerical lumped plastic model approach used to evaluate the global force-top drift curve of the proposed experimental test is described along with the various parameters used for evaluating pinching behavior, unloading, and reloading stiffness degradation, strength degradation, and energy dissipation.

3 NUMERICAL MODELING APPROACH

The numerical model adopted to reproduce the experimental test was implemented in OpenSees. For the overall system, a finite element lumped plasticity approach was used, considering for the converging elements a linear-elastic region in the middle and the inelasticity concentrated at the ends. The plastic hinge length was evaluated by using the Priestley formulation [12]. Regarding the joint panel strength-deformation capacity and its non-linear behavior, a simplified macro-model approach was adopted [7, 9, 15]. Thus, joints behavior both in linear and non-linear range was considered through a single rotational spring placed in its core region.

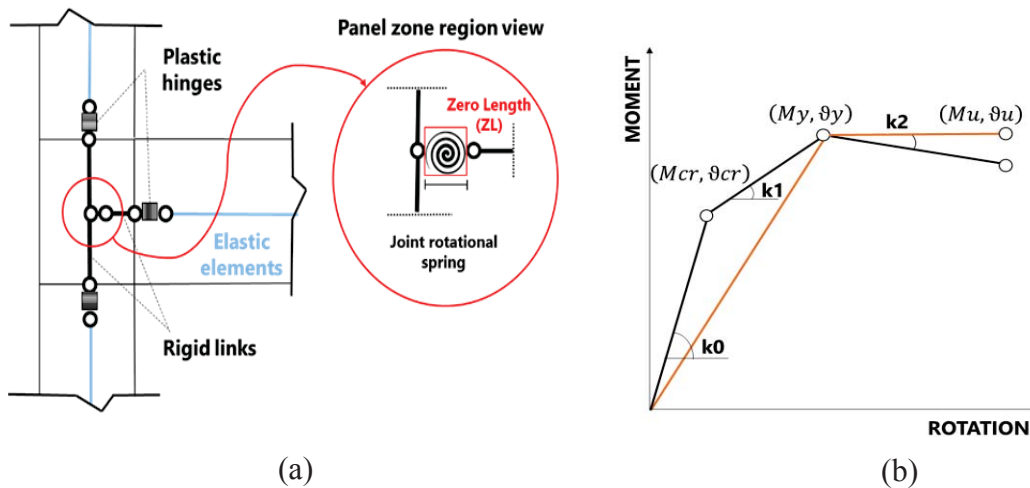

Figure 2: (a) Numerical model performed in OpenSees, (b) bi-linear and tri-linear Backbones.

The rotational spring was linked to beam and column interfaces with rigid links. All plastic hinges non-linearities were included through Zero Length (ZL) elements at the end of the members and in the joint panel, see Figure 2 (a). Once the numerical model has been defined, two backbone types have been used to reproduce the experimental test. The simplest envelope curve, orange line of Figure 2 (b), represents a bi-linear constitutive relationship defined according to the parameters from the NZSEE2017 Seismic Assessment Guidelines [21]; while a more refined version, black line of Figure 2 (b), considers, through a trilinear constitutive relationship, the pre-cracking stage and the softening behavior after the peak. In both curves, the pairs of points (M, ϑ) with the subscript “y” and “u” define the yielding condition and the ultimate condition, respectively. Notably, while the yielding point is the same for both curves, the ultimate points are different. Only for the tri-linear backbone curve, the first cracking condition has been defined and indicated with the subscript “cr” in the black curves of Figure 2 (b), thus forming a knee that anticipates the yielding point. The next section will discuss the parameters

governing the capacity and the hysteretic uniaxial material used for both the bi/tri-linear backbone.

3.1 JOINT MOMENT-ROTATION HYSTERESIS BACKBONE

The joint spring capacity in terms of bending moment can be derived from the principal tensile or compressive stresses, where they consider the axial load acting on the top of the column.

For a joint with no horizontal confinement provided by the stirrups ($\sigma_h = 0$), its capacity, expresses in terms of moment resistance M_{joint} , both in pull and push directions, has been determined by using the following equations:

$$M_{joint} = \frac{v_{jh}/A_c}{\phi} = \frac{V_{jh}}{\phi} \quad (1)$$

$$v_{jh} = \sqrt{p_{t,c}^2 \pm p_{t,c} \left(\frac{N_v}{A_c} \right)} \quad (2)$$

$$\phi = \frac{2L'_b L_c - 1.8dL_b}{L_b 0.9dA_c(L_c - L_b)} \quad (3)$$

In (1) v_{jh} is the horizontal shear stress, A_c represents the column cross section area, and V_{jh} is the horizontal shear force acting at the mid-depth of the joint core. In (2) $p_{t,c}$ are the principal tensile or compressive stresses, evaluated by using the Mohr circle while N_v represents the axial load acting on the top of the column. In (3) ϕ is a geometric term which depends on the joint subsystem dimensions and on the lever arm d . All the terms reported in Equations (1), (2), (3) are represented in Figure 3, while push direction implicates beams upper fibers in compression state and pull direction the tension one. For the complete procedure, refer to NZSEE2017 Seismic Assessment Guidelines and associated literature [15, 21, 23]. For the analyzed test, the bending moment capacity results equal to 35.5 kNm in push-direction and 27.5 kNm in pull direction. Concerning the rotation corresponding to the maximum bending moment, actually no formulations are available and the proposed value by the NZSEE2017 Seismic Assessment Guidelines [21] are independent from the construction details and geometry parameters.

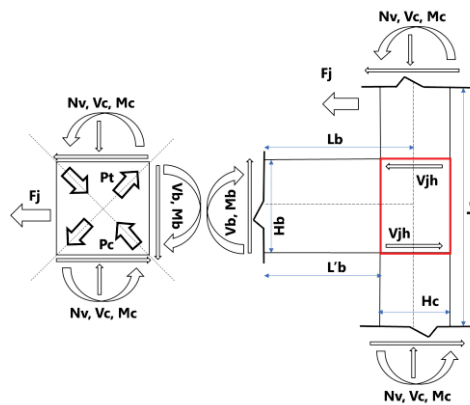

Figure 3: Moment, shear, and stresses at joint region and, Free-body diagram of a beam-column joint subassembly (push direction).

Moreover, no indication on the pre-cracking stage is available, because on the safe side the NZSEE2017 neglects the pre-cracking stage.

Therefore, in the present work a preliminary calibration of the parameters governing the pre-cracking stage is performed based on the analyzed experimental test.

To model the cyclic behavior of the joint panel (e.g. [15, 33]), a hysteretic uniaxial material was adopted in OpenSees library. In addition to the envelope parameters, the initial elastic stiffness K_0 and the pairs of points of the envelope (M, ϑ) , the cyclic model, represented in Figure 4, requires the definition of several inputs parameters such as Pinch- x/y pinching factor for rotation/moment during the reloading branches, Damage 1 due to ductility (μ), Damage 2 due to energy dissipation, and finally the power unloading stiffness (β), which governs the cycles stiffness degradation; they are all schematized in Tab. 1. The calibrated parameters used in the numerical model are: $Pinch_x = 0.3$, $Pinch_y = 0.05$, $Damage_1 = 0.02$, $Damage_2 = 0$, $\beta = 0.5$.

Figure 4: (a) Hysteretic material backbone, (b) Hysteretic material input parameters

The adopted hysteretic model shows the advantage to manage independently the positives (first quadrant) and negatives (third quadrant) notable points of the envelope, with subscripts “p” and “n” in Figure 4. This opportunity allows to account the non-symmetric response of the subsystem in the two directions, push and pull directions, of the seismic action as shown by many experimental tests

4 EXTERIOR JOINT MODEL CALIBRATION AND RESULTS

The bi-linear backbone (BB) and tri-linear backbone (TB) are both adopted to reproduce the experimental response of NS-O1 joint panel. The first simplest backbone is an elastic perfect plastic one and its parameters are defined thanks to the actual guidelines (blind prediction), instead the parameters of the second one is calibrated ad-hoc to match the experimental response on the basis of the analyzed experimental test. As will be shown, both the models capture the experimental test with a slight, and expected difference in the level of accuracy.

In Table 1, all the parameters that characterize the envelope curves are reported, both for bi-linear backbone (BB) and tri-linear backbone (TB). For both the backbones, the parameters governing loading and reloading branches are set equal to $Pinch_x=0.3$, $Pinch_y=0.05$, $D_1=0.02$, $\beta=0.5$, and the maximum bending moment M_y was calculated according to eq. (1) for push

direction, while it was reduced of about 22% in pull direction. Concerning the rotations at yielding and ultimate condition, for the elastic perfectly plastic backbone they are set equal to those proposed by NZSEE2017 Seismic Assessment Guidelines [21] in both directions, while for the trilinear backbone based on the experimental test, they result slightly higher in both the directions.

Proposed envelope curves for specimen NS-01

Model	M_{cr} (kNm)	M_y (kNm)	M_u (kNm)	K_0 (kN/m)	K_1 (kN/m)	K_2 (kN/m)	ϑ_{cr} (rad)	ϑ_y (rad)	ϑ_u (rad)
BB	-	+27.5 -35.5	+27.5 -35.5	+1364 - 1618	-	0	-	± 0.005	± 0.01
TB	+16 -20.5	+27.5 -35.5	+22 -28.4	+3142 +2150	+474 +658	-19 -106	+0.00085 -0.001	± 0.0075	+0.015 -0.012

Table 1: Backbone values used in NS-O1 numerical model.

The axial load protocol used in the numerical analysis was back calculated from the experimental data, where the axial load was imposed during the test. The cyclic analyses in terms of lateral force vs top drift results for NS-O1 are compared with the test results, as shown in Figure 5 (a), (b).

Figure 5 (a) shows the comparison between the experimental test and numerical model with elasto-plastic backbone, while Figure 5 (b) shows the same comparison using a tri-linear backbone curve. Looking at the numerical bi-linear backbone of Figure 5 (a), the stiffness K_0 is equal to 1364 kN/m for the pull and 1618 kN/m for push loading, respectively. This value was 50% and 16% lower than the experimental one equal to 2730 kN/m in the pull direction and 1926 kN/m in the push direction, respectively. The stiffness K_0 under-estimation observed in the cyclic analyses is due to the fact that the elastic perfectly plastic backbone neglecting the pre-cracking stage.

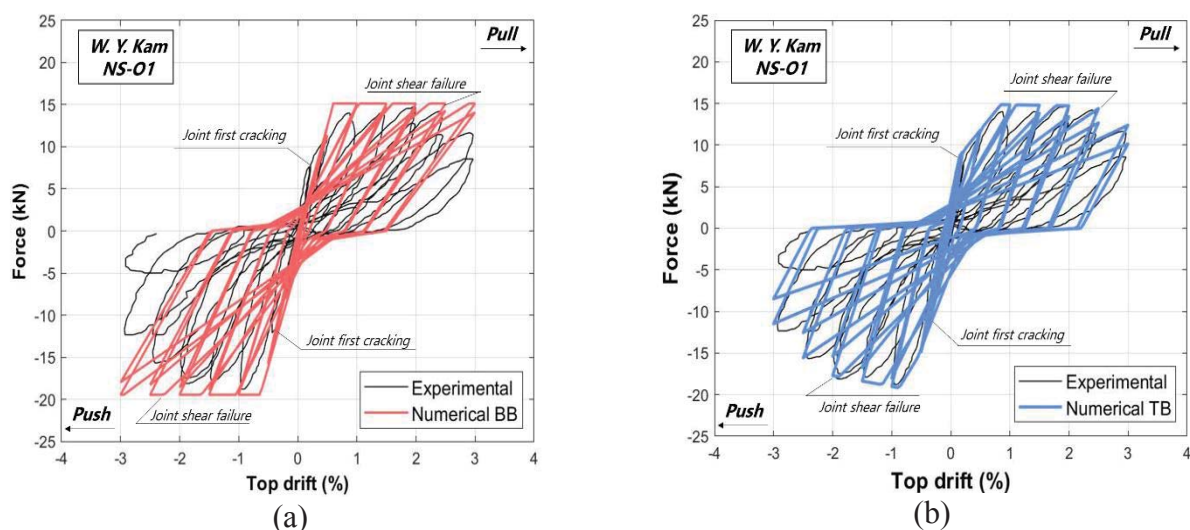

Figure 5: Horizontal Force – Top drift for specimen NS-O1, comparison between experimental and numerical results. (a) bi-linear backbone, (b) tri-linear backbone.

The bi-linear backbone could not fully reproduce the post-peak behavior of the force-top drift hysteresis, especially in the pull direction, where the higher axial loads were both beneficial

(confining the cracked joint core) and harmful (additional compressive force that accelerates bar buckling and concrete spalling) to the joint post-cracking behavior. On the other hand, the monotonic envelope matched well in capturing the peak point as maximum of resistance achieved, in the push direction.

The proposed trilinear backbone model, reported in Figure 5 (b), simulates the response of specimen NS-O1 successfully. However, it slightly overestimates the initial branch slope where the K_0 initial stiffness intends to capture joints first cracking peak.

The tri-linear hysteresis curve is capable, when compared to the simplified bilinear curve, one in capturing the strength degradation, especially the rapid degradation due to the joint concrete spalled occurred for cumulative damage. In the cyclic analysis, the damage accumulation improved the prediction of the post-peak behavior and was computed by using factors damage 1 and β , to govern the strength and stiffness degradation reached at the same displacement-imposed level and the progressive stiffness degradation as the displacement itself increases. These aspects related to the decay system evaluation were considered in both numerical simulations from the pinching re-loading curve after one complete pull-push loading cycle.

Indeed, the bi-linear backbone, given its simplicity, can still remain a valuable tool, yet rather advanced, for professional practice, where there is the need to consider the joint deformability. Furthermore, the experienced practitioner can consider for simplicity, a symmetrical resistance peak in the push-pull directions, taking as a reference one the lower of them, being in safety condition. As further developments, for more detailed studies, a trilinear curve might offer a more accurate representation of the initial stiffness and cracking point.

Worth noting that the strength degradation part of the post-peak region can either be modeled as an additional relationship to the bilinear curve model (e.g., Ruaumoko [33]) or be directly integrated in the trilinear curve as herein demonstrated. In both cases, issues associated with the numerical convergence of a pinched and strength degrading hysteresis loop, particularly when running fully dynamic non-linear time-history analysis can be anticipated and should be carefully considered.

5 PROPOSED BACKBONE VALUES FOR EXTERIOR JOINTS MODEL

Following the numerical calibration of the backbone curve on the experimental results of specimen NS-O1, similar approach was extended to various experimental tests on external joints specimens available in the literature (e.g. [9-11] and [29-32]).

The intent is to report in a simple way the main parameters that allow the user (be it a researcher or an experienced practitioner) to effectively describe the external joints backbone, selecting the appropriate level of targeted accuracy. It is worth noting that, when evaluating the equivalent joint moment capacity, expressed in terms of: M_{cr} , M_y , M_u , as previously described, it is preferable to evaluate the peak moment M_y following Equations (1), (2), (3) as it closely depends on joints geometry, structural details, and axial load variation.

As it can be noted from the calibrations carried out on the proposed experimental tests, the ratio M_{cr}/M_y varies in the range 0.4-0.7 while the ratio M_u/M_y varies between 0.7-1.

As for the rotations, building on the values suggested by NZSEE2017 Seismic Assessment Guidelines and associated literature [15, 21], calibrated values are herein proposed on the basis of the tests shown in Table 2.

Based on these calibrations, it is possible to define ranges for ϑ_{cr} , ϑ_y , ϑ_u to be used as simple and practical references for the joints rotations to be adopted in the numerical models, without going through the full p_t - γ formulation, see Table 3.

Calibrated values for the proposed numerical models

Joint rotations ranges			
Joint's type	ϑ_{cr} (rad)	ϑ_y (rad)	ϑ_u (rad)
External	$0.0006 \leq \vartheta \leq 0.0015$	$0.003 \leq \vartheta \leq 0.0075$	$0.01 \leq \vartheta \leq 0.02$

Table 3: Proposed ranges for external joints rotations.

Figure 6 shows the envelopes obtained for the experimental tests on external joints analyzed in terms of joint rotation (ϑ) vs normalized moment (M/M_y). By observing the shape of the proposed curves, it can be seen that on the basis of the case study, the most appropriate backbone was chosen to describe the joints behavior (bi-linear or tri-linear).

Figure 6: Envelope curves of numerical tests on literature specimens reported in Table 2.

6 CONCLUSIONS

In this paper, an experimental test on an exterior beam-column joint designed for gravity loads has been numerically modelled by a lumped plasticity approach. The joint non-linear deformation capacity represented through a single non-linear rotational spring placed at beam-column intersection. For what concerns the numerical settings, it was necessary to define an efficient moment-rotation relationship allowing to obtain a reliable prediction of the selected exterior joint specimen NS-O1. Moreover, the parameters to be defined were the elastic stiffness, pre- and post-cracking slopes, as well as the pinching behavior, as a function of the type of joints (exterior), joint dimensions, axial load ratio, longitudinal reinforcement type, anchorage details.

Finally, two different backbones were chosen to simulate the experimental test in terms of top force-global drift response. The first one consists of a simple bi-linear relationship, useful for the experienced practitioner, which should adopt the most convenient approach to consider joint deformation capacity, according to NZSEE2017 Seismic Assessment Guidelines [21].

The second one consists of a tri-linear relationship, useful in the research field when the goal is to capture detailed aspects of the experimental test to be reproduced, or in general of the overall joint behavior, depending on the required degree of accuracy and scope of work. In this case, the tri-linear backbone can capture and better model the point of first cracking, the elastic and softening branches.

All the parameters that characterize the backbone curves and their hysteretic behavior are reported, highlighting how the values provided by NZSEE2017 Seismic Assessment Guidelines [21] are intentionally and reasonably providing average behavior, while, for a case-by-case specific analysis, more appropriate parameters can be identified to better describe the joints performances. This work represents a small part of a more extensive numerical simulation campaign on existing joints currently under development.

ASSESSMENT OF THE RESPONSE ENVELOPE OF REINFORCED CONCRETE MEMBERS WITH DIFFERENT FAILURE MODES

Abstract

The expected lateral response of reinforced concrete (RC) elements strongly depends on their failure mode. Code-conforming RC members are supposed to exhibit a flexural (F) ductile failure, with complete exploitation of their post-peak displacement/deformation capacity. However, substandard RC elements, which are typical of existing structures, may undergo a shear failure after yielding (FS) or even before yielding (S) of longitudinal reinforcement. In this case, the element is classified as “shear-sensitive” and may be characterized by an abrupt collapse after the attainment of the peak load-capacity, with a fast loss of lateral load-bearing capacity up to the onset of the progressive reduction of the axial load-bearing capacity. This condition may trigger structural collapse, as also shown from surveys of damages due to strong earthquakes in past and recent times. So, the determination of the failure mode of RC members is paramount for a reliable assessment of the seismic safety of structures.

In general, static criteria are applied to pre-classify the expected failure mode of RC members and their response backbone is defined dependently on the determined failure mode. However, a comprehensive approach for modelling, with a unique set of predictive equations, the response envelope of RC members without pre-determining with a deterministic approach their failure mode is missing.

In this paper membership functions are defined to determine for RC columns the possibility that they exhibit an F, an FS, or an S failure. A set of basic predictive equations are defined, based on experimental data, to define a multilinear response envelope. The proposed equations may be combined with membership functions to use a unique set of equation able to reproduce the behaviour of RC columns with different expected failure modes.

Keywords: RC element, existing, seismic assessment, failure mode, response envelope, model.

1 INTRODUCTION

In the last decades, one of the trends of research in the structural engineering field is aimed at providing robust and reliable tools for nonlinear modelling of structural members. This is an essential step towards a complete implementation of a performance-based approach for the seismic design and assessment of structures in technical codes and current practice.

In Reinforced Concrete (RC) structures, primary elements may have a different lateral nonlinear response dependently on their failure mode. If, under lateral loads, the element can first yield and then exploit its entire ductility capacity (as shown in Figure 1), its failure mode is ductile and flexure-controlled. Such a kind of element is defined flexure-critical, the name of its failure mode is usually abbreviated with an “F”, the element itself can be defined as an “F element”. If, under lateral loads, the element cannot exploit its entire ductility capacity (as shown in Fig. 1), the element is defined shear-critical, since the ductile response of the element is prematurely interrupted by the occurrence of a shear failure. Two conditions may occur: if the element is anyhow able to yield, the failure mode is defined “FS”, since it is first governed by flexure (the element can yield), then by shear (the element cannot attain its ductility capacity since a shear failure occurs first); if the element is not able even to yield, since the shear failure occurs before yielding, the failure mode is defined “S”, since it is governed by shear. Also in this case, elements experiencing an FS failure mode are called “FS elements”, while elements experiencing an S failure mode are called “S elements”.

Also from Figure 1, it is clear that RC members with different failure modes have different lateral response. For this reason, the assessment of the expected failure mode (or “classification of the failure mode”) is essential to correctly model the nonlinear response of each member and, so, to obtain a reliable prediction of the structural performance. This is of paramount importance especially when dealing with nonlinear modelling and seismic capacity assessment of existing RC buildings.

In the literature, different approaches have been proposed for the classification of the failure mode of structural members. Some of them have been also introduced in building codes. The first approach to the classification of failure mode was described by Priestley et al. [1] based on ATC-6 [2] provisions. First, it is stated that the shear strength of a RC structural members is maximum when the element is in the elastic field; such a strength decreases at increasing ductility demand due to the damage of the element, up to a minimum (or “residual”) value. Similarly to what is represented in Figure 1, the failure mode is F if the shear force corresponding to flexural strength is less than the residual shear strength; the failure mode is S if the shear force corresponding to flexural strength is more than the initial shear strength; otherwise, the expected failure mode is FS. This approach for the classification of structural members’ failure mode, with consistent nonlinear modelling of the lateral response of these structural members, has been adopted for nonlinear time-history analyses on case-study existing RC buildings in [3]. However, different authors, based on experimental evidences, highlighted that the ratio between the shear strength of a member and the shear demand in equilibrium with its flexural strength cannot completely explain the observed failure mode of RC elements.

For example, Zhu et al. [4] proposed, based on experimental data, a classification method distinguishing F and S elements; FS elements are mostly included among S elements. According to this method, first the transverse reinforcement ratio should be calculated. If this ratio is lower than 0.002, the element is classified as S. Otherwise, the shear span-to-dept of the cross section ratio and the ratio between the plastic shear demand and the shear strength by Sezen and Moehle [5] are calculated. If the first ratio is lower than 2 or the second ratio is higher than 1.05, the element is classified as S. Otherwise, it is classified as F.

Ghannoum and Matamoros [6] and Ghannoum [7] proposed a modification to the method of classification of the failure modes of columns due to splice deficiency reported in ASCE/SEI 41-13 [8]. The proposal has been implemented in ASCE/SEI 41-17 [9] together with a proposal for the definition of the significant points of the lateral response of RC columns depending on the potential failure due to splice deficiency.

Based on experimental data, Hua et al. [10] proposed a classification method of the failure mode of RC members based on the concept of likelihood of shear failure. The probability of shear failure is calculated based on a demand-to-capacity ratio in which the capacity is evaluated through a proposed shear strength model.

Based on experimental data, Ma and Gong [11] proposed the calculation of a factor ω depending on geometric and mechanical characteristics of the RC columns. Based on the value assumed by the factor ω , it is possible to establish the expected failure mode of the element. One of the most significant advantages of this approach is that, differently from other methods, the prediction of the failure mode is independent on the specific shear strength model adopted. A similar approach will be introduced also in this study.

Figure 1: Illustrative sketch of the expected lateral response of F, FS, and S members.

One of the shortcomings of most of these approaches is their deterministic outcome. In this work, an empirical approach based on fuzzy theory is proposed for the assessment of the failure mode of RC members. In other words, the proposed approach aims at assigning to each generic RC structural element the “possibility” (expressed through a scalar between 0 and 1) of being “member” of the sets of F, of FS and of S elements. This scalar is calculated via membership functions which are defined for each of the three sets/failure modes. The definition of a “continuous” classification of the failure mode of structural elements is a preliminary step towards the assessment of the lateral response of RC members without an explicit pre-classification, but by means of an implicit modification of the expected ductile response backbone of the element by using the proposed membership functions. Based on the same experimental database, empirical equations are proposed for the assessment of the expected response envelope of ductile elements.

2 EXPERIMENTAL DATABASE

The definition of the proposed approach for the direct assessment of RC elements’ failure mode is based on the experimental data collected in the ACI 369 Rectangular Column Database [12], which will be briefly named “ACI database” in the following.

The ACI database is constituted by 326 cyclic tests of rectangular RC columns. In this work, only cyclic tests of rectangular-reinforced columns are considered. All specimens are characterized by the presence of deformed (i.e., ribbed) longitudinal rebars, while transverse reinforcement may be realized with deformed or plain bars. For each specimen, the following data are reported:

- Material properties (for concrete, longitudinal and transverse reinforcement);
- Column geometry (for the overall column, longitudinal and transverse reinforcement);
- Confinement details (i.e., the configuration of transverse reinforcement);
- Test configuration details (i.e., how the lateral load was applied on the specimen);
- Test results in terms of observed failure mode, significant values of force and displacement, force-displacement loops (if available).

Since the assessment of the failure mode is the core issue of this work, it is worth mentioning how the definition of the failure mode was performed by the Authors of the database. Two approaches are considered for failure mode classification: the first one is consistent with the approach adopted by PEER in [13] and is more based on the “observed” response of the specimens; the second, which is more “practice-oriented”, is based on the assessment of transverse reinforcement detailing and on the ratio between the plastic shear demand and the expected shear capacity. The discussion presented in this paper is based on the first classification approach, i.e., the one consistent with PEER [13], since it is independent of the assessment of shear strength by means of a specific shear capacity model. In fact, consistently with the PEER approach, a first distinction is made between shear-sensitive and non-shear-sensitive members. If the Authors of each experimental test reports the occurrence of shear damage for a certain specimen, the element is classified as “shear critical”. Otherwise, it is classified as “flexure critical” and the assigned failure mode is F.

Among Shear Critical elements, a mixed analytical/empirical approach is adopted to distinguish FS and S elements. First, for each specimen, the maximum lateral force attained (F_{eff}) is evaluated. Then, the theoretical maximum force corresponding to the attainment of a maximum strain in concrete equal to 0.4% ($F_{0.004}$) is calculated. In addition, based on the experimental response of the specimen, the ductility capacity μ_{fail} is calculated by assuming as failure displacement the one associated with a force capacity equal to 0.80 times F_{eff} on the softening branch of the force-displacement response. If F_{eff} is lower than 0.95 times $F_{0.004}$ or μ_{fail} is equal or lower than 2, the Shear Critical element is classified as S. Otherwise, it is classified as FS.

Among the 326 tests collected in the database, only those for which all the significant geometric, mechanical and response parameters were available have been used for this study. In addition, only “completely cyclic” tests were considered: in other words, test with monotonic loading before and/or after yielding were excluded. In addition, columns with spliced reinforcement were excluded since they can undergo a premature failure due to insufficient anchorage length, as shown, for example, for the specimens by Melek and Wallace [14] that are included in the original ACI dataset but are not considered for this study. Hence, a subset of the ACI database constituted by 260 tests is considered in this work. In this reference subset, hereinafter named “collected database”, 156 tests are classified as F (60% of the database), 69 tests are classified as FS (26% of the database), 35 tests are classified as S (14% of the database). Despite other databases considering shear-sensitive RC members have been collected including a larger amount of S tests (e.g., [15, 16, 17]), it was preferred to adopt ACI database since it includes also F elements, which is fundamental for the scope of this study; on the other hand, “merging” F elements from ACI and FS/S elements from other databases was excluded, in order to use

data associated with RC columns whose failure mode has been classified with a unique and consistent approach.

The tests collected in the reference subset are characterized by $0 \leq v$ (axial load ratio) ≤ 0.90 , $13 \leq f_c$ (compressive strength of concrete) ≤ 118 MPa, $318 \leq f_{yl}$ (yielding stress of longitudinal rebars) ≤ 587 MPa, $249 \leq f_{yw}$ (yielding stress of transverse rebars) ≤ 1424 MPa, $0.0068 \leq \rho_l$ (longitudinal reinforcement ratio) ≤ 0.0694 , $0.0006 \leq \rho_w$ (transverse reinforcement ratio) ≤ 0.0321 , $0.11 \leq h/L_s$ (cross section height-to-shear span aspect ratio) ≤ 0.87 , $0.11 \leq s/d$ (transverse reinforcement spacing-to-effective depth of the cross section ratio) ≤ 1.27 . In addition, the experimental response loops of specimens were corrected, if necessary, in order to remove the spurious effect given by geometric non-linearity (i.e., P- Δ effects) and, so, consider only mechanical sources triggering the post-peak softening. The correction has been performed in order to lead back the experimental response of the selected specimens to “Case I” according to [13].

The database is described more in details in [12].

3 ASSESSMENT OF FAILURE MODE VIA MEMBERSHIP FUNCTIONS

In this work, the collected database is considered as the union of fuzzy sets [18]. A fuzzy set is a collection of objects with a certain membership. More specifically, each specimen can be member of the “F elements” fuzzy set, of the “FS elements” fuzzy set and of the “S elements” fuzzy set. In other words, it is possible to define, for each specimen, if it is certainly F, certainly FS or certainly S.

However, when dealing with a generic structural member belonging to a structure, it is not always possible to define with certainty if it will behave as an F element, or as an FS element or as an S element. In this case, a membership function allows expressing the possibility [19] of that element of behaving as an F element, as an FS element and as an S element. In other words, the membership function for F elements, μ_F , expresses with a number ranging from 0 to 1, the possibility that a certain structural member belongs to the set of F elements; the same applies for the membership function for FS elements, μ_{FS} , and for the membership function for S elements, μ_S . Of course, it is certain that a member will be part of one of the three sets. So, the sum of the values assumed by the three membership functions for a certain structural element should always be equal to 1.

The membership function can express the possibility of a certain structural member of being part of a certain set as a function of a predictive parameter (or of more predictive parameters) that represents the structural member characteristics. Of course, the significant characteristics of the structural member (i.e., those that can define a potential domain – also called support – for the membership function) depend on the nature of the membership function itself. For example, since the membership functions that are defined in this work are related to the concept of failure mode, it is expected that parameters like the axial load ratio or the amount of longitudinal and transverse reinforcement may be appropriate as predictors. Section 3.2 is dedicated to the definition of the most appropriate predictive parameter(s).

Consider now to have defined a certain predictive parameter x . Hence, the membership functions are expressed as $\mu_F(x)$, $\mu_{FS}(x)$, $\mu_S(x)$. The values assumed by the membership functions are set based on the experimental data reported in the collected database. The procedure adopted to define the shape of the membership functions is reported below, with reference to the illustrative sketch reported in Figure 2.

Figure 2: Illustrative sketch of the adopted membership functions.

1. Membership functions are assumed as piecewise linear;
2. The value x_{00} of the predictor parameter is set. It is defined in order to have $\mu_F(x \leq x_{00}) = 1$. In other words, if the predictor x is lower than or equal to x_{00} , it is assumed that certainly the structural member will exhibit an F failure mode. The value of x_{00} is obtained from the collected database as the maximum value of x below which no FS or S failure is observed;
3. The value x_0 of the predictor parameter is set. It is defined in order to have $\mu_S(x \leq x_0) = 0$. In other words, if the predictor x is lower than or equal to x_0 , it is assumed that certainly the structural member will not exhibit an S failure mode. The value of x_0 is obtained from the collected database as the maximum value of x below which no S failure is observed;
4. The value x_2 of the predictor parameter is set. It is defined in order to have $\mu_S(x \geq x_2) = 1$. In other words, if the predictor x is higher than or equal to x_2 , it is assumed that certainly the structural member will exhibit an S failure mode. The value of x_2 is obtained from the collected database as the maximum value of x above which no F or FS failure is observed;
5. The membership function for FS failure mode $\mu_{FS}(x)$ is assumed equal to $1 - \mu_F(x) - \mu_S(x)$;
6. Being $f_1 = \mu_F(x_1)$ and $s_1 = \mu_S(x_1)$, the values of x_1 (which is between x_0 and x_2), f_1 and s_1 are set after an iterative procedure aimed at obtaining the “best performance” for the membership functions, i.e., the set of x_1 , f_1 , and s_1 values for which the adopted membership functions are able to correctly predict the failure mode of the specimens of the collected database in the highest number of cases.

In a previous work [20], different potential predictors were already evaluated, namely the axial load ratio, the aspect ratio and the ratio between the mechanical ratio of longitudinal and transverse reinforcement. In general, as also reported in section 1, the distinction between shear critical and flexural critical structural members can be performed via a “static” approach by comparing shear demand at yielding V_y (i.e., the one in equilibrium with the yielding moment acting at the base of column) and the shear demand at maximum V_{max} (i.e., the one in equilibrium with the maximum moment acting at the base of column), with the shear resistance of the column, V_R . A member is flexure critical if V_{max} is lower than the minimum value of V_R ; otherwise, it is shear-critical. It should be considered that at increasing axial load ratio, both the maximum moment (i.e., V_{max}) and the shear resistance V_R , first increase and then decrease. So,

a specific trend for the frequency of each failure mode at increasing v is not expected. In fact, in [20], it was observed that the axial load ratio alone is not a good predictor of the failure mode. A better performance is obtained by considering as predictor the aspect ratio and the ratio between longitudinal and transverse reinforcement mechanical ratios. However, it was observed that the best performance was obtained by adopting as predictor a combination of these two parameters, as shown in Equation 1.

$$x = \frac{h}{L_s} \frac{\omega_l}{\omega_w} = \frac{h}{L_s} \frac{s}{d} \frac{A_{sl} f_{yl}}{A_{sw} f_{yw}} \quad (1)$$

Since the predictive parameter x has been chosen, it is possible to define the membership functions. Based on the collected database, it is observed that:

1. For x lower than or equal to 0.75, only F failures are observed. Hence, x_{00} (see Figure 2) is assumed equal to 1;
2. No S failure is observed for x lower than or equal to 1.50. Hence, x_0 (see Figure 2) is assumed equal to 1.50;
3. Only S failures are observed for x higher than or equal to 13. Hence, x_2 (see Fig. 2) is assumed equal to 13.

The best performance set of membership functions is obtained if x_1 (see Figure 2) is assumed equal to 3.1, if f_1 (see Figure 2) is assumed equal to 0.07 and if s_1 (see Figure 2) is assumed equal to 0.09. With these assumptions, in fact, a correct prediction of the failure mode (i.e., the more possible failure mode corresponds with the actual failure mode) is obtained in 84% of cases. Note that the values of x_{00} , x_0 , x_2 , x_1 , f_1 , and s_1 are different with respect to those shown in [20] since they were evaluated with respect to a smaller database.

The obtained membership functions are shown in Figure 3 and compared with the experimental failure modes. Experimental failure modes are reported as filled circles if they are predicted as the most possible failure mode by the adopted membership functions; otherwise, they are reported as blank circles.

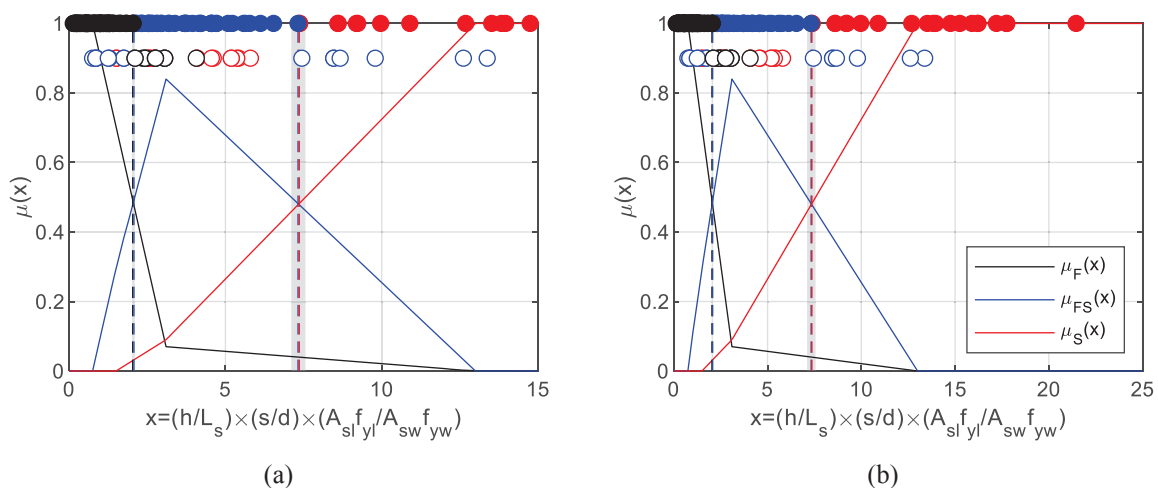

Figure 3: Adopted membership functions. Graph with x between 0 and 15 (a) and graph with x between 0 and 25 (b).

It is possible to observe that for x lower than 2 the most possible failure mode is F; for x between 2 and 7.3 the most possible failure mode is FS; for x higher than 7.3, the most possible failure mode is S. It is worth recalling that for x lower than 0.75 the only possible failure mode is F, while for x higher than 13 the only possible failure mode is S. It is also worth mentioning that for x between 2 and 2.1 and for x between 7.1 and 7.6 there is no failure mode with possibility of occurrence higher than 50%: special caution should be adopted when dealing with structural members belonging to these “transition zones” (grey-filled areas in Figure 3).

4 BASIC RESPONSE ENVELOPE

In this section, the basic bending moment M – chord rotation θ response envelope is determined for ductile members, i.e., for RC columns with x lower than or equal to 0.75.

4.1 Response envelope and methodology

Based on the response envelope of the experimental response of ductile members included in the database, the following characteristic points/conditions were defined.

- The first point of the proposed envelope is yielding point. First, a theoretical prediction of M_y was obtained by means of a fibre section analysis and indicated as $M_{y,fiber}$. Then, the experimental maximum moment M_{max} was determined. If M_{max} resulted higher than $1.07M_{y,fiber}$, the yielding point was identified on the experimental envelope at the attainment of M equal to $M_{y,fiber}$; otherwise, according to [21], the yielding point was identified on the experimental envelope at the attainment of M equal to $0.80M_{max}$;
- The second point of the envelope is the peak load point. It was simply determined at the attainment of a moment equal to the maximum moment M_{max} .
- The third point of the envelope was determined on the descending branch of the experimental response envelope at the attainment of a moment equal to $0.80M_{max}$. This point corresponds to the attainment of a conventional “ultimate” condition.
- The fourth and last point of the envelope is the one corresponding to the complete loss of lateral load capacity of the column. It was determined, on the experimental envelope, by linear extrapolation up to zero moment resistance of the extreme points of the imposed displacement cycles defining the descending branch of the experimental envelope beginning from the experimental point at conventional “ultimate”, as defined at the previous point. Note that, to limit the use of unreliable extrapolated data, only tests for which at least a 50% strength decrease after peak load point attainment were considered for the assessment of this point.

A consistent approach was adopted to define an equivalent set of predictive equations for the assessment of the response envelope of rectangular RC column with plain bars in [22].

The following parameters were adopted to identify the abovementioned characteristic points of the response envelope, as shown in Figure 4.

- The ratio between the flexural secant stiffness at yielding of the member cross-section (also called “effective stiffness”), EI_y , and the flexural stiffness of the gross section EI_g . This ratio allows defining, together with the yielding moment M_y previously defined, the chord rotation at yielding, θ_y ;
- The maximum moment M_{max} together with the corresponding post-yielding plastic chord rotation, θ_{max}^{pl} ;

- The post-capping plastic chord rotation at conventional “ultimate” condition, θ_{ult}^{pc} ;
- The post-ultimate plastic chord rotation at the attainment of zero lateral load capacity, θ_0^{pu} , together with the softening stiffness toward zero lateral load capacity, K_θ .

Figure 4: Characteristic points and assumed parameters of the base moment (M) - chord rotation (θ) response envelope.

In order to define empirical formulations for the prediction of the abovementioned response parameters, some potential predictors were selected. The candidate predictors were chosen by considering the outcomes of past studies (e.g., [23]), as well as their expected mechanical influence. In addition to those listed for the description of the experimental database (see section 2), some combinations of them were assumed as potential predictive parameters, namely:

- the ratio between the spacing of transverse reinforcement, s , and the cross-section depth, d ;
- the ratio between the spacing of transverse reinforcement, s , and the diameter of longitudinal rebars, d_b ;
- a factor related to the proneness to buckling of longitudinal bars, $s_b = (s/d_b) \cdot (f_y/100)^{0.5}$;
- the area/mechanical ratio of longitudinal rebars ρ_l and ω_l ;
- the area/mechanical ratio of transverse reinforcement ρ_w and ω_w ;
- the longitudinal reinforcement area/mechanical ratio calculated by separating the contribution of reinforcement in compression (ρ_2 and ω_2 , respectively) from the contribution of reinforcement in tension + web reinforcement (ρ_1 and ω_1 , respectively);
- the ratio between the area/mechanical longitudinal reinforcement ratio for rebars in compression and the mechanical longitudinal reinforcement ratio for rebars in tension.

The statistical procedure adopted for defining the predictive equations below listed is described in detail in [24]. More specifically, linear least squares regressions were performed relating the output variables (expressed in terms of natural logarithm) and the potential predictors (expressed in their natural form, in terms of natural logarithm, or absent). The final equations proposed were selected among the ones with the minimum number of input variables but deemed as “statistically equivalent” – based on F-tests – to the basic predictive equations including all the potential predictors. For the assessment of predictive equations, T-tests were performed to remove outliers from the experimental database [25].

4.2 Predictive equations

The equations derived to define the response envelope of ductile rectangular RC columns with deformed bars are reported below, together with, for each proposed equation, the statistics – mean, median and Coefficient of Variation (CoV) – associated with the set of the observed value-to-predicted value ratios for the entire experimental database. In the proposed equations, forces must be expressed in Newtons and lengths in millimetres.

The ratio between secant-to-yielding and gross section stiffness, EI_y/EI_g can be calculated as reported in Equation 2 (observed-to-predicted ratio: mean=1.09, median=1.00, CoV=0.42).

$$EI_y/EI_g = 0.0318 \cdot 6.11^\nu \cdot (L_s/d)^{1.21} \quad (2)$$

Alternatively, the ratio between secant-to-40% of yielding moment and gross section stiffness, EI_{40}/EI_g can be calculated as reported in Equation 3 (observed-to-predicted ratio: mean=1.13, median=0.99, CoV=0.49).

$$EI_{40}/EI_g = 0.100 \cdot 3.20^\nu \cdot (L_s/d)^{0.871} \quad (3)$$

Note that both Equations 2 and 3 were obtained by considering not only F, but also FS specimens included in the database.

The post-yielding plastic chord rotation, θ_{\max}^{pl} can be calculated as reported in Equation 4 (observed-to-predicted ratio: mean=1.15, median=0.97, CoV=0.54). Note that for the assessment of θ_{\max}^{pl} some tests were not considered since their response envelope was provided with a branch at pseudo-constant moment demand roughly equal to the maximum moment. In these cases, the value of the chord rotation at peak load was not determinable in a unique and not ambiguous way.

$$\theta_{\max}^{pl} = 0.0073 \cdot 0.436^\nu \cdot (s/d)^{-0.261} \cdot 1.05^{100\omega_2} \quad (4)$$

For the calculation of the peak resistance, M_{\max} , a simple mean value is proposed attempting to predict the M_{\max}/M_y ratio, i.e., $M_{\max}/M_y = 1.31$ (observed-to-predicted ratio: CoV=0.15), with M_y calculated by means of a section fibre analysis.

The post-capping “ultimate” plastic chord rotation, θ_{ult}^{pc} can be calculated as reported in Equation 5 (observed-to-predicted ratio: mean=1.16, median=0.99, CoV=0.58).

$$\theta_{ult}^{pc} = 0.0126 \cdot 0.161^\nu \cdot 5.66^{\omega_l} \cdot 1.88^{100\rho_w} \quad (5)$$

The post-ultimate plastic chord rotation towards zero resistance, θ_0^{pu} can be calculated as reported in Equation 6 (observed-to-predicted ratio: mean=1.11, median=1.16, CoV=0.42). It is limited to the maximum value of θ_0^{pu} observed in the database.

$$\theta_0^{pu} = \min(0.065; 0.0193 \cdot 0.061^\nu \cdot 1.19^{100\omega_w}) \quad (6)$$

To avoid modelling issues, namely to avoid that the bilinear softening branch of the response envelope is characterized by decreasing (in absolute value) softening stiffness, the post-ultimate plastic chord rotation resulting from Equation 6 must be further limited according to Equation 7.

$$\theta_0^{pu} \leq 4\theta_{ult}^{pc} \quad (7)$$

4.3 Application

The comparison of the outcomes of proposed model for ductile RC members with six experimental responses included in the experimental database (the three specimens with the “best” performance of the proposed model and the three specimens with the “worst” performance of

the proposed model) is shown in Figure 5, together with the cyclic envelope calculated by applying the model by [23]. The best performance of the proposed model is obtained for specimens C5-00N tested in [26], C1-1 tested in [27] and Test1 tested in [28] while the worst performance is observed for specimens No.7 tested in [29], 214-08 tested in [30], and HC4-8L19-T10-0.1P tested in [31].

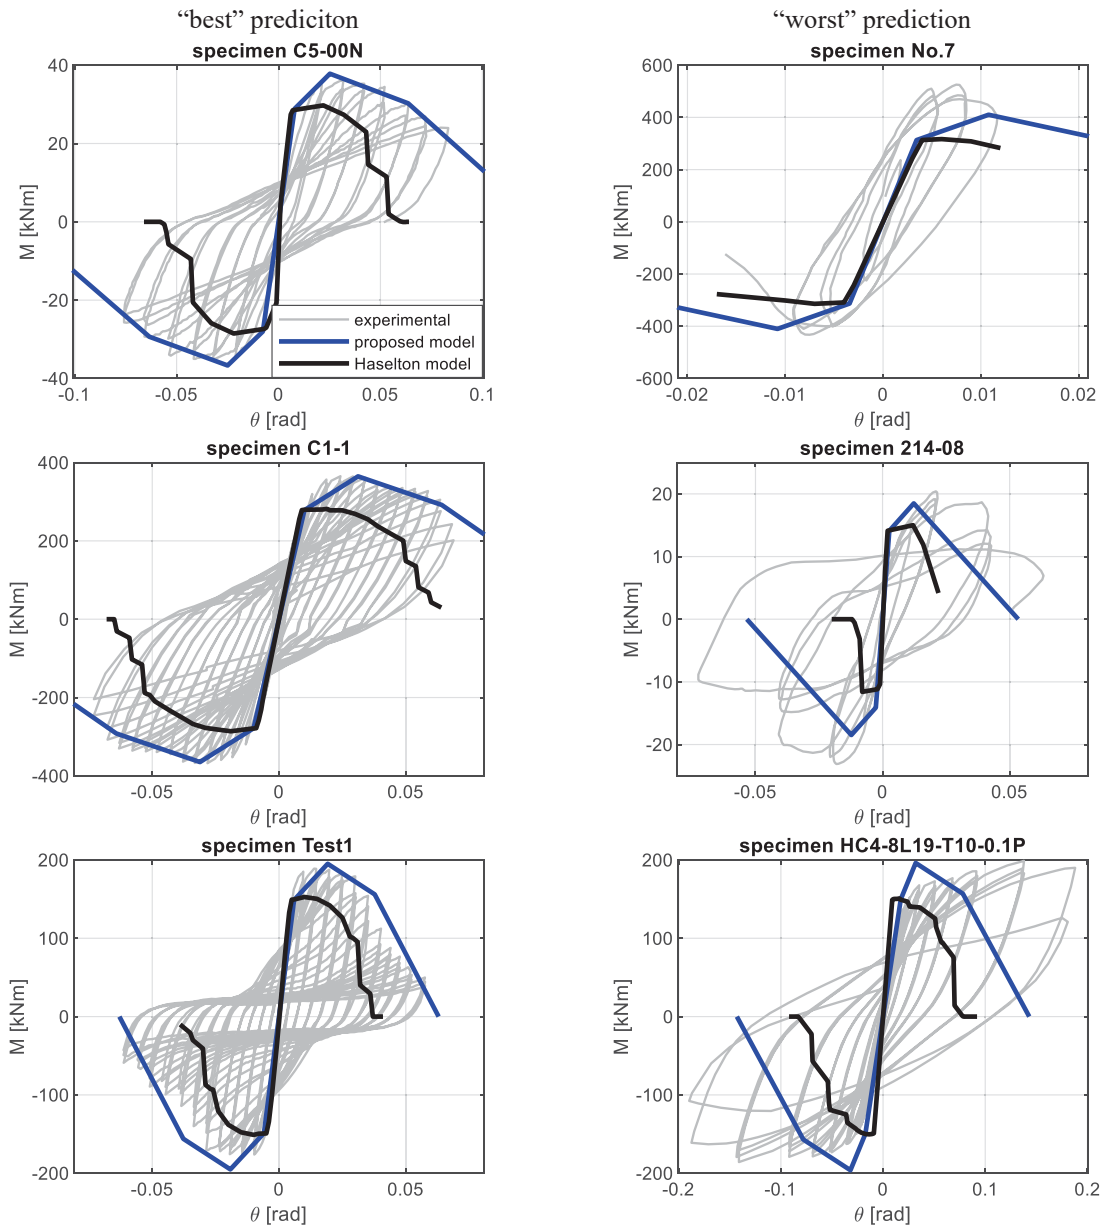

Figure 5: “Best” (left column) and “worst” (right column) predictions of the proposed model compared with the experimental response of the selected specimens and with the cyclic envelope predicted by applying the model proposed by Haselton et al. [23].

Since it was determined based only on cyclic tests, the proposed model already includes in its envelope the sources of strength degradation typical of members under cyclic (such as seismic) loading. On the contrary, the response envelope proposed by Haselton et al. [23] is monotonic, as it is based on the results of monotonic tests and on the expected monotonic envelope derived from a back-analysis of the results of cyclic tests. The cyclic envelope shown in Figure 5 as a

result of the application of the model by Haselton et al. is obtained by modelling the specimen in OpenSees [32] by adopting ModIMKPeakOriented Material model and by applying to it the real imposed displacement path. In general, it was observed that the model by Haselton et al. can show a fast decay of strength capacity, both in terms of maximum moment capacity and in terms of steepness of the softening branch when the imposed displacement path is characterized by a significant number of loading-unloading cycles. On the other hand, the proposed model seems to not predict well the cyclic response envelope when the maximum moment capacity is significantly higher than yielding moment and, in tune, the chord rotation at maximum is significantly higher than the chord rotation at yielding.

5 CONCLUSIONS AND FUTURE DEVELOPMENTS

- A subset of ACI 369 database of experimental tests on rectangular RC columns with deformed longitudinal rebars [12] has been selected. The selected tests were cyclic and realized on columns without lap-sliced anchorage of longitudinal rebars. In addition, they are characterized by different failure modes assessed independently on a specific shear strength model: namely, 156 tests are classified as F (60% of the database), 69 tests are classified as FS (26% of the database), 35 tests are classified as S (14% of the database).
- Based on the experimental database collected, a “continuous” approach for the assessment of the expected failure mode has been proposed. In fact, a single predictor parameter has been identified depending only on geometric and mechanical properties of the RC element. Based on this predictor, named x , membership functions are proposed to calculate the possibility (a number between 0 and 1) that the considered member exhibits an F, and FS or an S failure. RC members with x lower than or equal to 0.75 are expected to exhibit only an F failure mode, while members with x greater than 13 are expected to exhibit only an S failure mode. The proposed approach can correctly predict as most possible the actual failure mode of the specimens included in the database in 84% of cases.
- For RC members with x lower than or equal to 0.75, i.e., for expected ductile RC members, a set of predictive equations have been proposed to assess their cyclic moment – chord rotation response envelope up to the complete loss of lateral load resistance. This set of equations can be useful for modelling RC members, within a lumped plasticity approach, for collapse risk assessment of RC structures via nonlinear analyses.
- In the literature, a similar model with the same aims was already proposed by Haselton et al. [23]. However, it was observed that the cyclic response envelope predicted by applying this model may be affected by premature decay of strength capacity when the RC element is subjected by a significant number of loading-unloading cycles. In addition, the equations proposed by Haselton et al. [23] can predict only the expected monotonic envelope of the RC element, while the cyclic envelope including strength and stiffness degradation effects typical of seismic action can be determined only by applying to the RC member the real imposed displacement path. This makes the model by Haselton et al. [23] unfit for the assessment of RC structures via nonlinear static analysis, which is still a useful tool adopted by practitioners and researchers, especially for the assessment of existing buildings.
- In future works, the proposed equations for the assessment of the cyclic response envelope will be combined with the proposed membership functions in order to make them applicable for the evaluation of the expected response envelope for RC members with whichever

failure mode and, above all, without the necessity of pre-determining the expected failure mode. In addition, the parameters for modelling the cyclic degradation of unloading and reloading stiffness, as well as the so-called “pinching” effect will be calibrated.

Abstract

The seismic assessment of reinforced concrete (RC) structures is commonly carried out neglecting previous damage, eventually induced by other phenomena, although different forms of hazard can affect a structure during its existence. The coexistence of many hazard sources is very common, i.e., in countries affected by landslides, also characterized by high seismicity, like Italy. The aim of this work is both to demonstrate the potential utility of satellite data derived from the Differential Synthetic Aperture Radar Interferometry (DInSAR) to support the structural health monitoring of a RC infilled building within a landslide-affected area and to assess its safety conditions after experiencing two different hazards, that are landslide and earthquake. A 3D model of the case study building, including also infills, is created based on the information available from a geometrical survey, obtaining the missing parameters from literature. The seismic assessment of the building structural elements, caused by the design seismic action, is initially shown. Then, the seismic assessment is repeated, considering the building to be in a state of known landslide-induced stress-strain condition. Finally, an interesting comparison is proposed between the safety condition of the building expected in both cases, with or without the consideration of the precedent landslide-induced displacements.

Keywords: Multi-Hazard Assessment, Existing RC Buildings, Remote sensing, Earthquake, Landslide, Damage Assessment

1 INTRODUCTION

Different forms of hazard can affect structures throughout their existence; this is very common, for example, in countries affected both by landslides and high seismicity.

The effects of the single hazard source on existing reinforced concrete (RC) buildings have been a widely discussed research topic worldwide, in the last decades. For the seismic assessment, the international literature includes many methodologies and applications related to specific investigation issues [1-4]. Many studies can also be found regarding the evaluation of the structural damage as consequence of phenomena inducing slow displacements, monitored through satellite data for consistent periods [5-7], in particular for landslides [8-12]. The research in terms of landslide-earthquake multi-risk analysis, indeed, is very limited [13].

In this work, a RC infilled building, constructed in the 60s, located in Moio della Civitella, South of Italy, having typical structural deficiencies of pre-seismic designed structures, is used as case study. A structural 3D model of the building, including infills, is created based on the information available from original documents and an in-situ survey, while the missing parameters are obtained from literature. A modeling approach specifically elaborated for RC members with plain bars [14] is implemented for the non-linear flexural behavior of RC members, concentrating it at the ends of the beams and columns. Couples of diagonal struts are used for infills modeling, which behavior is defined as illustrated by Panagiotakos and Fardis [15].

The effect of the landslide phenomenon on the structure is monitored through the Differential Synthetic Aperture Radar Interferometry (DInSAR) technique [16]. The processing of ascending and descending COSMO-SkyMed images allows to obtain DInSAR deformation data, as a result of detected displacements of targets on the ground (buildings, rocks, infrastructures, etc.), with accuracy of the millimeter, carrying out maps of mean displacement rates and time series of deformations [17-19]. The surface ground movements, detected in the period 2012-2019, and extended to the 2020, have been applied to building foundations.

Then, non-linear static (pushover) analysis procedure is implemented twice: the first time in a condition of integer structure (earthquake [EQ] scenario) and the second time considering the structure already affected by the monitored slow-moving landslide (landslide plus earthquake [LAN+EQ] scenario). In both situations, the analysis results allow to carry out code-based [20, 21] seismic safety assessments, and the calculation of the “seismic safety index” (called for brevity “safety index”) [22, 23] with reference to the Italian Life-Safety (LS) *limit state* (*ls*) [20].

This paper aims to demonstrate the potential utility of DInSAR technique at a small scale, to support the structural health monitoring of an RC building, and to demonstrate the importance of a multi-risk seismic safety assessment, cumulating the actions coming from the two different hazards, that are landslide and earthquake.

2 METHODOLOGY

The fundamental input for the multi-risk analysis, in this work, is the landslide advanced monitoring, for a quite wide period of time, obtained from the DInSAR technique. Then, the aims of the work is pursued by performing pushover analysis and, therefore, the seismic safety local checks for RC members and the global safety index assessment for the whole structure. The theoretical basis of the previous approaches are explained, respectively, in Section 2.1 and Section 2.2. The territorial frame of the case study, its information and the modeling aspects are reported in Section 3. Moreover, Section 4.1 and Section 4.2 present the DInSAR analysis and displacements application, and the seismic structural assessment for the case

study building, in the EQ and LAN+EQ scenario. In conclusion, the results obtained by the multi-risk analysis are compared with the results of the traditional one.

2.1 Differential SAR Interferometry technique

DInSAR approach is based on time series of radar images [24] acquired by sensors installed on satellite platforms, travelling along semi-polar orbits. The acquisition is ensured when the observation of radar targets, namely Permanent Scatterers (PS) [25], is possible. PSs are typically parts of buildings, metallic structures, rocks or other elements already present on the ground, with electromagnetic characteristics more or less constant over time. Having a stack of images on the same area, in which specific PSs can be identified, DInSAR approach allows to create maps of mean displacement rates and time series of the deformations measured along the LoS, with an accuracy of the millimeter. The mentioned type of maps can also be obtained for more significative directions with respect to the phenomena developing on Earth surface. This is possible considering that, because of the Earth rotational movement, an area can be enlightened by a Synthetic Aperture Radar (SAR) sensor, either from East or from West, along descending (from North to South) or ascending orbits (from South to North), respectively. Descending and Ascending acquisitions can be combined, after the definition of a x, y, z Cartesian coordinate system, in which the three directions coincide with the horizontal E-W and N-S and vertical, respectively, thus obtaining the displacement vector. It is important to underline that, due to the geometrical characteristics of the acquisition system the N-S direction is considered negligible [17]. This is a DInSAR technique limit, that, consequently, furnishes deformation components only in the horizontal E-W and vertical directions.

2.2 Seismic assessment framework

The pushover analysis is implemented, through a step-by-step procedure, by subjecting the structure to two monotonically increasing pattern of lateral forces, as recommended in NTC (2018) [20]. The lateral forces, one proportional to the fundamental mode of vibration (Mode X and Mode Y), one proportional to the mass distribution (Mass X and Mass Y), are applied in the model at the centers of floor mass (X and Y directions are assumed accordingly to Fig. 2 (a)). Then, the so-called “inelastic demand point”, D_{inel} is determined, through method A of the standard [26], based on [27], in the Acceleration Displacement Response Spectrum space (ADRS, [28, 29]).

Once the results of the pushover analysis are obtained, the seismic safety checks are reported in this work for the LS- ls [20], equivalent to the Limit State of Significant Damage (SD) defined in EC8-3 [21]. The structural checks in the inelastic demand point D_{inel} at LS- ls are performed with regards to ductile and brittle mechanisms. The structural capacity of beams and columns in ductile terms, θ_u , is evaluated according to the capacity model suggested by [26] and [21], in terms of chord rotation capacity. The brittle failures for beams, columns and beam-column joints are checked according to capacity models suggested by the codes [21, 26, 30].

The seismic structural assessment allows the determination of the inelastic “performance point” of the structure, C_{inel} , at the considered ls , as that point in which the very first structural element experiences a failure mechanism. From C_{inel} it is possible to individuate its elastic correspondent point, C_{el} , necessary to find the “capacity spectrum” of the structure, in the ADRS space. The latter, defined as the elastic spectrum that pushes the structure in crisis, is a fundamental element to quantify the structural safety condition. In fact, the safety index, ζ_E [22, 23], is defined as the ratio between the demand PGA, based on the design seismic action prescribed by the code for the LS- ls , and the capacity PGA of the building, represented by the

anchor acceleration of the capacity spectrum. The structure can be considered safety against seismic actions when ζ_E assumes values greater than one.

3 CASE STUDY AND MODEL DESCRIPTION

3.1 Case study description

The case study RC building is located in the town of Moio della Civitella (Campania Region, Southern Italy), composed of two urban centres, Moio and Pellare. According to the Hydro-geomorphological Setting Plan of Hydrographic District of the Southern Apennines (HDSA)[32], building is affected by significant foundation displacements as a consequence of an intermittent landslide phenomenon with slow kinematics, (*Fig. 1*), as also presented in [33-35].

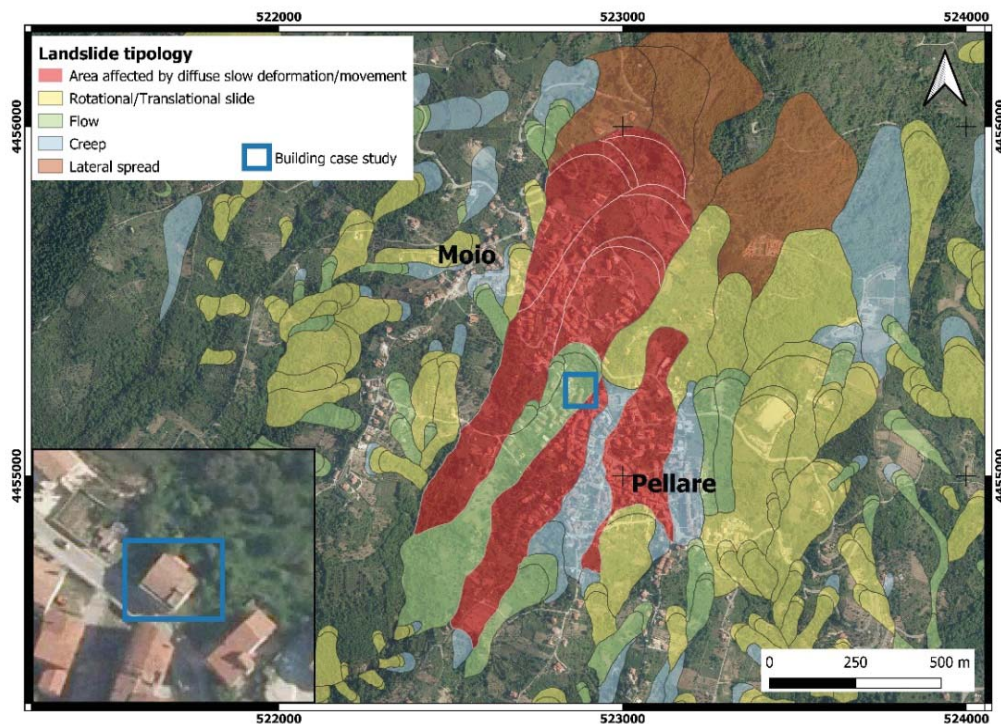

Fig. 1. Landslide inventory map (2012) with location of considered building.

The RC building was constructed in 1960s, and designed for gravitational loads only, with a plane parallel frames structural system; it is independent, with a rectangular plan of 11,90 m by 11,95 m, terraces excluded, built on three levels, with a pitched roof (*Fig. 2(a-c)*).

The most recent of many visual surveys conducted in the last decade, refers to December 2020. From the in situ-inspections, it has been possible to determine the following information. Columns have rectangular cross sections of dimensions 40x55 cm or 40x40 cm, except the stair columns, that are 55x50 cm, 60x35 cm and 55x40 cm. They are reinforced with smooth bars, 4 longitudinal ones, $\phi 16$, and stirrups $\phi 6/20$ " *Fig. 2(d)*. The primary beams, belonging to plane frames, and the secondary beams, that orthogonally link the four frames at the ends, have 35x60 cm and 20x50 cm rectangular cross sections, respectively.

The missing information about the beams reinforcement have been obtained by a simulated design, following the Italian standard R.D.L. [36], according to which the structure has been designed, then combining its results with evidence of local engineers about the construction procedures of the building period. Therefore, longitudinal bars $\phi 16$ have been adopted: 9+3

for the primary beams, while 3+2 for the secondary beams. Moreover, a transversal reinforcement of $\phi 6/15''$ has been utilized.

Regarding the mechanical materials properties, literature references have been employed. For the reinforcement bars, it is assumed the presence of Aq.42 steel, with an average yield strength f_{ym} of 328,6 Mpa, from the work of Verderame et al. [37], and an elastic modulus E of 200000 MPa. For the concrete, a cylindric mean compressive strength f_{cm} , of 21,3 MPa, according to Verderame et al. [38], and an elastic modulus, E , of 27607 MPa have been used.

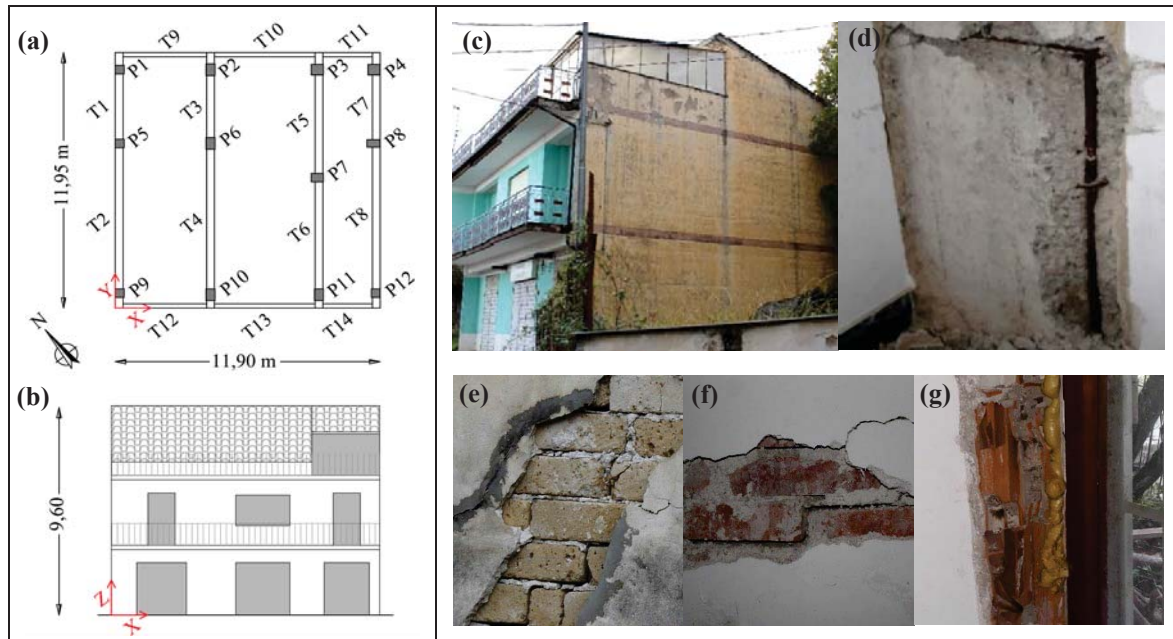

Fig. 2. Schematic geometrical plan (a) and front view of the S-W façade (b). In situ survey (December 2020): external picture (c); vertical smooth bars found at the column base (d); infills details – tuff (e); solid clay bricks (f); hollow clay bricks (g).

Different types of infills have been found during the in-situ inspection, as shown in *Fig. 2* (e-g): double-leaf vertical hollow clay bricks with a thickness of 8+12 cm, then 12+12 cm solid clay bricks and finally regular tuff with a thickness of 25 cm. A clear schematization of the different infills types distribution, with a labelling of the building fields, can be found in *Fig. 3*. In particular, hollow clay bricks, solid clay bricks and tuff are indicated with blue, orange and green lines, respectively. Moreover, it can be noted that AB, BC, A'B' and B'C' are the fields including only infills without openings (solid lines), while CD, DE, EF, C'D', D'E' and E'F' are the fields including also infills with openings (dashed lines).

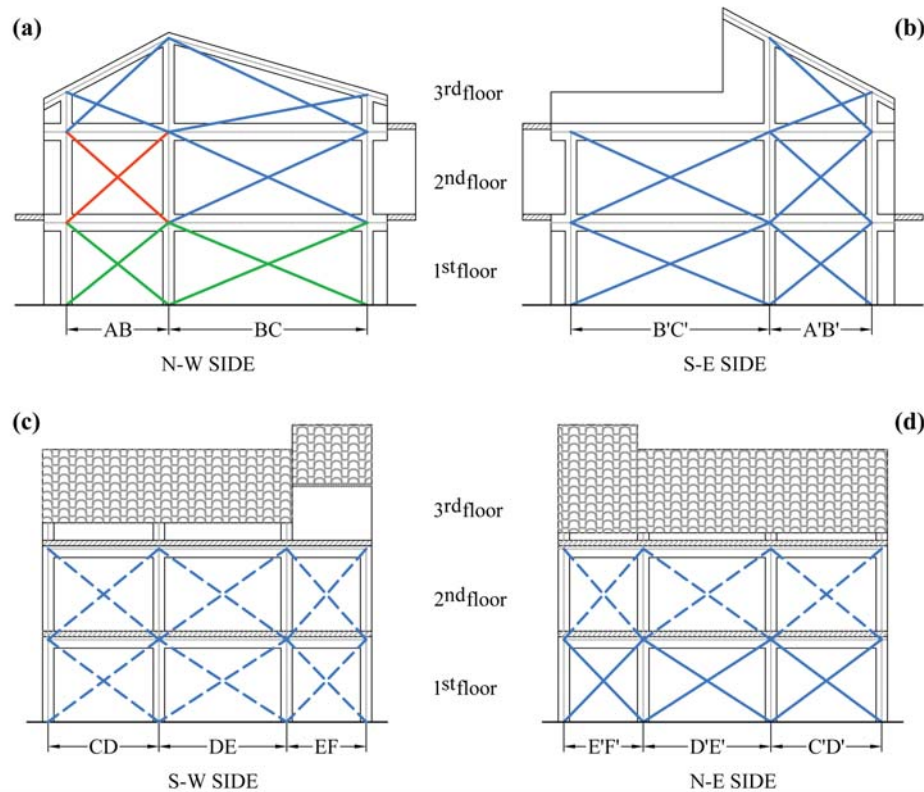

Fig. 3. Building prospects with identification of the different infills types of the building (hollow clay bricks, blue lines; solid clay bricks, orange lines; tuff bricks, green lines) differentiated in: without openings (continuous lines, (a-b)) and with openings (dashed line, (c- d)).

Mechanical properties for tuff and solid clay bricks have been derived from Italian NTC (2018) [20]; for hollow clay bricks, they have been assumed from [39] (see *Tab. 1*).

Mechanical Property	Tuff	Hollow clay bricks	Solid clay bricks
Elastic modulus E_{mh} [N/mm ²]	1410	1255	1500
Shear modulus G_{mh} [N/mm ²]	450	315	500
Tensile strength τ_0 [N/mm ²]	0,060	0,215	0,09

Tab. 1. Mean values of infills mechanical properties.

3.2 Modeling description

As regards the non-linear flexural behavior of RC members, a fourth-linear moment-chord rotation modeling approach, specifically elaborated for plain bars [14], has been adopted. The non-linear flexural behavior has been assigned as a plastic hinge at each end cross section of beams and columns. It has been verified that bending failures precede the shear for the RC members. However, these elements have been verified with respect to shear mechanisms in post processing, using code formulations as suggested in Section 2.2. Moreover, each infill has been modeled with a couple of equivalent diagonal struts resistant to compression, according to Al-Chaar [40] and Fardis [41], with a lateral response modeled following the equivalent single strut model proposed by Panagiotakos and Fardis [15]. The three-linear moment-chord rotation bond has been assigned at the middle cross section of each diagonal strut as axial hinges. More details about the evaluation of the geometric characteristics of these infills can be found in [12].

Based on the acquired geometrical and mechanical information, a 3D FEM structural model has been created using SAP2000 (v. 21.0.2, [42]). 2-D elements have been used for modeling beams, columns and the couple of diagonal struts representing the infills. The base columns have been fixed to consider the presence of foundations. The last floor has been modeled such that its height creates an equivalence of areas of the infills between the second and third order beams. The infills of the third floor, with openings, have been considered only as line masses and as line loads, because of the significant difference in shape from the panels used in the model proposed by Panagiotakos and Fardis [15]. The ones in the fields AB, BC and A'B' have been modelled; finally, there is a parapet in the B'C' field, and in the EF field there is no infill because of the presence of a veranda.

The elastic vibration periods of the 3D model, for the first two vibration modes, are $T_1=0,47$ s and $T_2=0,39$ s, in the direction with and without openings, respectively.

4 SEISMIC ASSESSMENT WITHOUT AND WITH CONSIDERATION OF THE PRECEDENT LANDSLIDE-INDUCED DISPLACEMENTS

4.1 DInSAR analysis and displacements application for the case study building

Cosmo-SkyMed images, obtained in the framework of MapItaly Project [43], were processed by means of DInSAR technique. In detail, X-band stripmap in ascending and descending mode images, characterized by a ground resolution of 3 x 3 m, were processed using SUBSIDENCE software. Coherent Pixel Technique–Temporal Phase Coherence (CPT-TPC) approach [44, 45] has been used to obtain ground displacements from satellite radar images. A detailed description of the whole algorithm can be consulted in [44, 45]. A phase quality value equal to 0,7 has been set in order to obtain an acceptable displacement error, lower than 1,5 mm, and to select an adequate number of points. *Fig. 4 (a, b)* shows mean displacement rates maps for ascending and descending acquisitions.

Starting from the discrete maps, vertical and horizontal E–W displacement components, with millimeter accuracy, have been obtained at the end of each year in the period 2012–2018 and for the first three months of 2019, by a combination process. In this way, the profiles of cumulated vertical and horizontal (in the direction parallel to the building sides) displacements, occurred to building foundations, have been provided. Moreover, to obtain the cumulated displacement components at the end of 2019 and 2020, an extrapolation has been done, based on the hypothesis that the landslide phenomenon keeps evolving linearly in time, as observed in the monitored period. The cumulate displacement profiles are shown in *Fig. 4 (c, d)*. The monitoring of the landslide that caused ever-increasing displacements of the foundation soil over the years can be also considered as base to carefully hypothesize the condition of the future years in order to program typical retrofit operation on the RC building [46] or to make prediction loss assessment evaluation for structures/infrastructures portfolio [47].

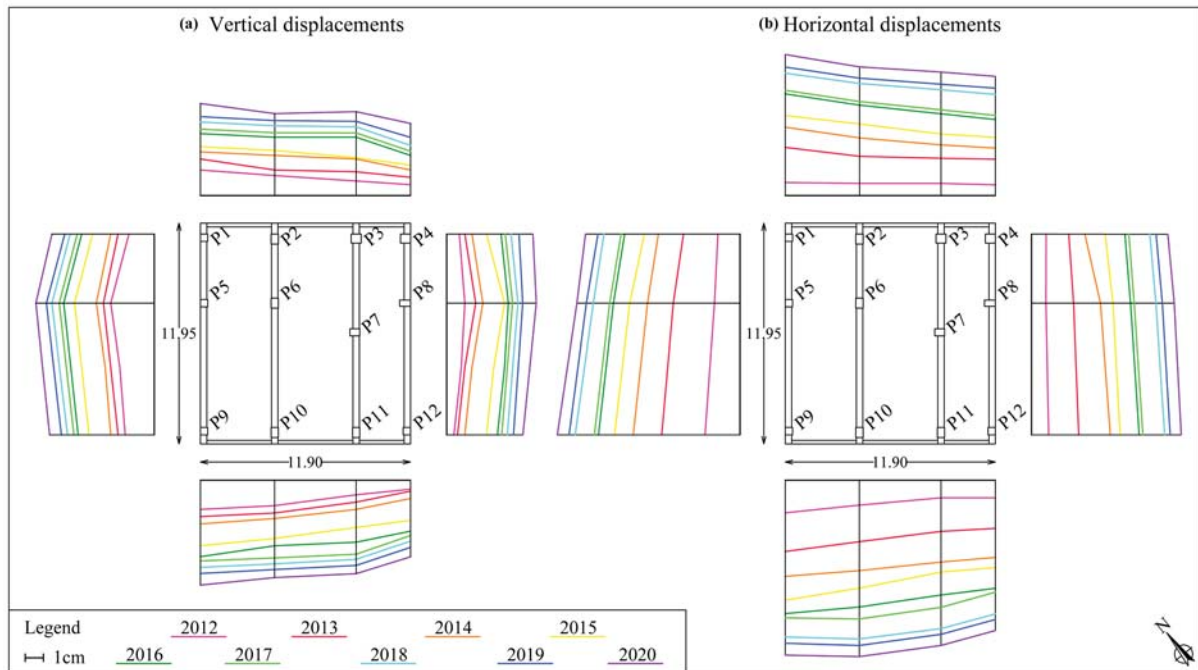

Fig. 4. Foundation displacement profiles the end of each year in the period 2012–2020: vertical (a) and horizontal (b).

4.2 EQ and LAN+EQ results and comparisons

As mentioned in Section 2.2 as first step of the proposed methodology, the seismic capacity of the RC elements at the LS-*ls* has been evaluated, after the definition of the seismic action according to Italian NTC (2018) [20].

The first case investigated is the EQ scenario, in which the building is in a deformed condition only for gravity loads before the application of the seismic action. Then, in the LAN+EQ scenario, the seismic assessment procedure is implemented on the structure, already deformed because of the differential slow-moving landslide-induced displacements, applied at the base of the first-floor columns.

Following what illustrated in Section 2.2, pushover analysis has been implemented, by applying two monotonically increasing pattern of lateral forces to the structure, as recommended in NTC (2018) [20]. The resultant pushover curves are represented in Fig. 5. It can be observed that LAN+EQ scenario's curves (black dotted lines) start from a significant displacement value of the control point induced by the landslide effect, while EQ scenario's curves (grey continuous lines) start from quite null values of roof displacement.

The seismic verifications in terms of ductile and fragile mechanisms in the step corresponding to the inelastic demand point D_{inel} , for the LS-*ls*, have been carried out once obtained the results of the pushover analysis. In Fig. 5, also the evolutions of the failure sequences found for both scenarios are compared. In both cases, the first failure mechanism attained is the tensile-shear failure in beam-columns unconfined joints (represented with red triangles), followed by brittle shear failures in the beams (orange squares) and in the columns (yellow circles). For each load case, ductile failures are never achieved at LS-*ls*, up to D_{inel} (indicated with a green pentagram).

The application of the differential landslide-induced displacements provokes an aggravation of the stress state in the structural elements. In fact, they enter in crisis for lower steps with respect to those attained in the EQ scenario; moreover, the number of elements in crisis at the LS-*ls*, until the corresponding D_{inel} , increases. In particular, in the LAN+EQ scenario,

the first joint failures happen at the step zero of the pushover, meaning that they are caused by the action of the landslide, before the application of the seismic action.

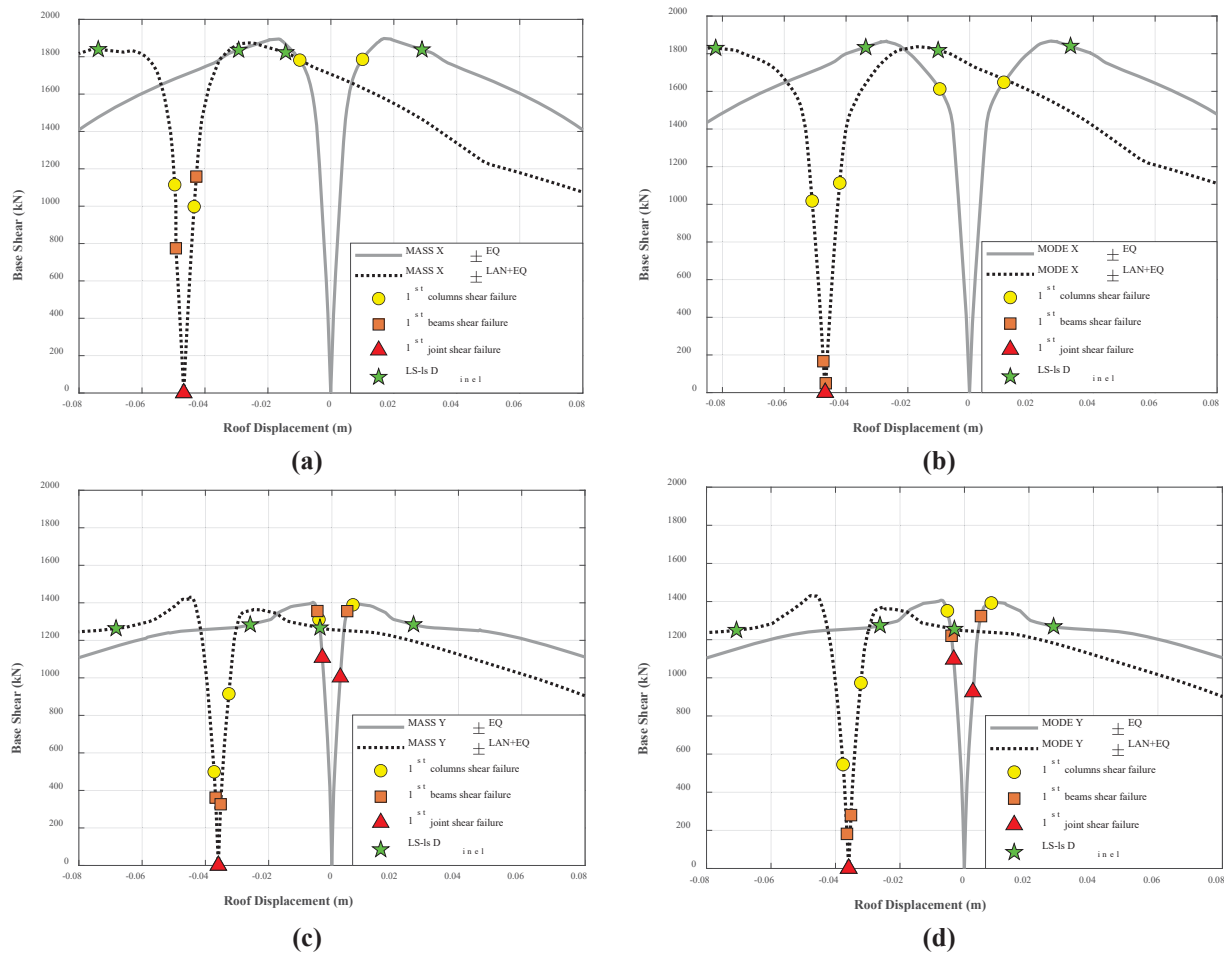

Fig. 5. Comparison of the pushover curves and relative failure mechanism progress of structural elements, until the demand point, in the EQ and LAN+EQ scenarios: Mass X (a), Mode X (b), Mass Y (c) and Mode Y (d).

It can be observed that, from EQ scenario to LAN+EQ scenario, the number of elements experiencing brittle crises at LS-*ls* passes from 11 to 19 for joints, from 7 to 17 for columns and from 2 to 8 for beams. This increase of the number of elements exceeding the *ls* can be attributed to the action of the landslide, which is active independently from the earthquake.

Moreover, an overall comparison of the global structural condition between the two scenarios has been done in terms of safety index, ζ_E as suggested in Section 2.2. In the EQ scenario, the safety index at LS-*ls* is equal to 0,27. Taking into account the previous landslide phenomenon with the first failure at the step zero of the curves, according to Sisma-Bonus Guidelines [48], the spectrum referred to the Beginning of Damage-*ls* (10 years return period) has been considered as a lower limit for the determination of $PGA_{capacity}$. The result is that in LAN+EQ scenario, a ζ_E of 0,11 has been obtained. In both cases the structure shows a lack of seismic capacity, meaning that it is able to withstand only a little percentage of the total design seismic action.

5 CONCLUSIONS

This study presented the seismic safety assessments of an existing RC infilled building, constructed in the 60s, located in a landslide-affected area. The work has a dual purpose.

From one side, it shows how the DInSAR satellite data can be used to support the structural health monitoring of RC buildings affected by slow-moving landslides. In general, the presented methodology can be applied also to phenomena with a different origin, if slowly evolving in time. On the other side, the aim is to highlight the importance of the seismic safety assessment in a multi-risk analysis, cumulating the action coming from the two different hazards, that in the specific case are the landslide and the seismic action.

The DinSAR remote sensing technique has been used for the detection of the landslide-induced displacements, confirming to be an extremely effective tool not only for the monitoring of phenomena at a territorial scale, but also with refers to the detail scale. A structural 3D model of the building, considering infills, has been implemented, to carry out the seismic assessment in two phases. Initially, a traditional seismic assessment, based on non-linear static analysis, has been done. Then, the landslide-induced displacements obtained by DInSAR monitoring technique, affecting the base of the structure, have been applied to the model, allowing to carry out a new pushover analysis in a multi-risk perspective.

In the two cases, the evolution of the stress-strain condition in the members has a different evolution. Since the landslide-induced displacements vary among all the columns bases, the phenomenon causes the born of a heterogeneous stresses path in the structural elements, that becomes the starting condition for the application of the design seismic action. For this reason, in the LAN+EQ scenario, the number of elements exceeding the $LS-ls$ increases.

Moreover, the illustrated results remark that by neglecting the effects of the existing differential displacements landslide-induced, the safety index overestimates the threshold of the seismic safety. It is important to underline that an overestimation of ζ_E can conduct to an underestimation in the definition of the structural retrofit procedures and of their costs.

Abstract

Conservation and protection of art works is a primary goal of each community, since artifacts represent a fundamental cultural and economic asset. In most cases, art goods are exhibited in Museums, which are appointed for their protection. Some of them, however, are exhibited outdoor, since they are conceived and made to enrich the public areas. In these cases, the art goods result to be even more vulnerable, since they are subjected both to natural hazard (i.e. earthquakes and floods) and to vandalic attacks. Art works have an intrinsic vulnerability, due to their irregular shape, slenderness, fragility and to their oldness. This paper is focused on the dynamic response of statues to blast explosion; a valuable case-study, i.e. the Fountain of Neptune, located in “Piazza della Signoria”, in Florence. The Fountain of Neptune is a marble and bronze opus made by Bartolomeo Ammannati between 1560 and 1565. The main character of the Fountain, Neptune, is a marble statue 5.7 meters tall, with a weight equal to 11.5 ton. A preliminary laser scanner survey has been made to achieve the geometrical representation of the statue. The geometrical model has been arranged, in order to be used for structural analyses. A numerical analysis has been performed to find the dynamic response of the statue to the loading resulting from a blast explosion. Such response has been found by assuming the explosion of assigned amounts of TNT. Some different cases have been considered, and a limit loading condition has been found for the blast, as a function of its amount.

Keywords: Blast loading; artifacts preservation; art works reliability; seismic vulnerability; multi-hazard analysis

1 INTRODUCTION

Artifacts are the focus of the artistic and cultural identity of a country. Despite their fundamental importance, their safety, usually, is not adequately pursued. Different hazard, both natural and human-induced, can threaten the art goods [1]. Furthermore, they are usually very vulnerable, due to their geometrical features (in-plan and in-elevation irregularity, slenderness) their age, and the possible fragility of their material.

Marble sculptures result to be very vulnerable to overturning, due to their high mass and the fragility of the material. Furthermore, the marble sculptures can be very tall, to take advantage of the strength of the material, with a consequent high slenderness. For this reason, many studies have been made on their vulnerability to overturning, with a special attention to the seismic excitations [2-4].

The analysis has been performed on a case-study, i.e. the main sculpture of the Fountain of Neptune, in Florence. It is a marble and bronze opus made by *Bartolomeo Ammannati* between 1560 and 1565 [5]. The main sculpture of the Fountain, Neptune, is 5.7 meters tall, and it has a weight equal to 11.5 ton.

The explosion has been assumed to be caused by the blast of fixed amounts of TNT, compatible to a vandalic or terroristic attack. The response of the statue to the assumed blast has been checked through Finite Element analysis.

The FE methods have been largely developed in these last years [6,7], even thanks to the outstanding developments occurred in the digital survey, with the consequent improvement of the artifact modelling [8,9], and the increasing availability of computational resources.

In this study, the FE model used for the analysis has been arranged on the basis of a very detailed geometrical model defined after a laser-scanner survey, which provided a points-cloud of the Fountain. The geometrical model described the lateral surface of the manufact; it has been arranged in order to represent the volume of the manufact, and simplified, in order to limit the number of tetragons constituting the model, and the main geometrical irregularities.

The analysis has been performed along the “weakest” direction of the sculpture, i.e. the direction with its lowest lateral stiffness. Different amounts of TNT have been considered to find the limit capacity of the sculpture to blast attacks.

2 THE CASE-STUDY

2.1 The Neptune Fountain

The Fountain of Neptune, placed in Florence in *Piazza della Signoria*, was made by *Bartolomeo Ammannati* between 1560 and 1565 [5,10] after the commitment of *Cosimo I de' Medici*.

The Fountain, shown in Figure 1a, consists of many different parts, made in marble and bronze; the main sculpture, representing Neptune, is placed on a central pedestal representing a horse-drawn cart placed in an octagonal basin, a space further decorated with statues of Scylla and Charybdis; all around, some minor marble and bronze sculptures were added, representing river gods, satyrs and sea-horses. Some of the sculptures currently constituting the Fountain are copies made the XIX century, to preserve the original artifacts from vandalism. Indeed, from its construction, the Fountain experienced many vandalic actions. The first documented damage dates back to 1580, and many other damaged were made along the centuries; the last event occurred in 2005, when three vandals climbed Neptune, damaging one hand and the trident of the sculpture.

a. The Fountain of Neptune

b. Neptune

Figure 1. The Fountain of Neptune

2.2 The statue of Neptune

The main character of the Fountain, Neptune, is a marble statue 5.7 meters tall (see Figure 1b), with a weight equal to 11.5 ton. The marble used for the sculpture has been taken by a Carrara quarry. The mechanical properties assumed in the work, listed in Table 1, have been found through an experimental survey made on samples of marble similar to the one used for the statue [11,12]. A special attention has been paid to the value to assume for the friction coefficient [13,14], which plays an important role in the prediction of the collapse mode of the sculptures under horizontal excitations.

Table 1. Mechanical properties of the marble

Density	[kg/m ³]	2700
Young Modulus	[MPa]	50000
Poisson coefficient	[MPa]	0.2
Compressive strength	[MPa]	50
Tensile strength	[MPa]	5
Friction coefficient	-	0.8

2.3 The structural model

The structural model of Neptune has been made on the basis of a geometrical survey made on the Fountain of Neptune, made through laser-scanner. The geometrical survey provided a points-cloud, which has been used to find the geometrical model consisting of a detailed lateral surface described through 1234492 polygons [15]. Such geometrical model has been deeply simplified to obtain the structural model to use for the dynamic analysis, made of a lower number of polygons. Besides being simplified (the number of polygons of the lateral surface of the model has been reduced to 29000), the model has been changed by a “surface”

to a solid one; finally, a model made of 152000 tetragons has been obtained. Figure 2 shows the various steps of the modeling procedure.

a. Points-cloud	b. Geometrical model	c. Structural model	d. Main information
			<p>Height 5.68 m</p> <p>Volume 4.27 mc</p> <p>Weight 11.5 ton</p> <p>Footprint 100 x 134 cm</p>

Figure 2. Geometrical and structural models.

3 THE BLAST ACTION

The loading acting to the sculpture as an effect of the blast has been assumed equal to the reflecting pressure, which has been determined according to the empirical approach [16,17] based on the Kingery and Bulmash [18] contribution.

The pressure applied to the statue surface has been quantified as a function of the normal reflected pressure peak, P_{r0} , defined as a function of the Hopkinson-Cranz scaled distance Z , as provided by Karlos and Solomos [19]:

$$Z = \frac{R}{W^{1/3}} \quad (1)$$

where W is the assumed charge mass (expressed in metric tons) and R is the distance (expressed in meters) of the target surface from the center of the blast. The quantity has been found through the equation (2), according to [16].

$$P_{r0}(Z) = \left(1 + \frac{1}{2e^{10Z}}\right) \exp[2.0304 - 1.8036 \ln Z - 0.09293 \ln^2 Z - 0.8779 \sin(\ln Z) - 0.3603 \sin^2(\ln Z)] \quad (2)$$

After the peak, the pressure wave presents a degrading wave phase [16] of duration t_0 , which ends with the zeroing of the pressure (positive phase), and a further phase characterized by the negative sign of the overpressure (negative phase). There are various expressions to describe the reflected pressure, such as has the *modified Friendlander equation* [20], based on the Heaviside function. In this work, however, a simplified approach has been adopted, and the trend of the pressure in the positive phase has been assumed as triangular, with an effective positive duration, t_0 , quantified through the expressions proposed by Vannucci *et al.* [21]:

$$t_0(Z) = t_{0w} W^{1/3} \quad (3)$$

as a function of the scaled positive duration, t_{0w} , quantified through the equation (4).

$$t_{0w}(Z, W) = \exp\{0.592 + 2.913\ln Z - 1.287\ln^2 Z - 1.788\ln^3 Z + 1.151\ln^4 Z + 0.325\ln^5 Z - 0.383\ln^6 Z + 0.090\ln^7 Z - 0.004\ln^8 Z - 0.0004\ln^9 Z + 0.537\cos^7[1.032(\ln Z - 0.059)] \sin[1.088(\ln Z - 2.023)]\} \quad (4)$$

In this work, two different cases of analysis have been made, differing from each other for the assumed amount of TNT, respectively equal to 10 kg and to 50 kg; both cases are compatible to the quantities compatible to vandalism actions [22]. The placement of the explosive has been assumed equal to 8.8m from the statue, i.e. along the external fence. In Table 2 the main data describing the blast loading have been listed.

Table 2. Main data regarding the blast loading.

Quantity	[unit]	case #1	case #2
Mass of TNT, W	[kg]	10	50
Distance, R	[m]	8.8	8.8
Scaled distance, Z	[m][kg ^{-1/3}]	4.08	2.39
normal reflected pressure peak, P_{r0} ,	[MPa]	0.1676	0.6029
Scaled positive duration (t_0)	[ms][kg ^{-1/3}]	3.53	2.25
Effective positive duration (t_{0w})	[ms]	7.62	8.30

4 THE ANALYSIS

4.1 The preliminary investigations

Some preliminary investigations have been made before performing the dynamic analysis. The analyses have been made by assuming the TNT placed along the direction with the minimum inertia of the statue, as shown in Figure 3; furthermore, the pedestal of the statue has not been included in the analysis. Indeed, due the position of the statue within the Fountain, the pedestal is not fully involved by the pressure wave induced by the explosion (see Figure 4).

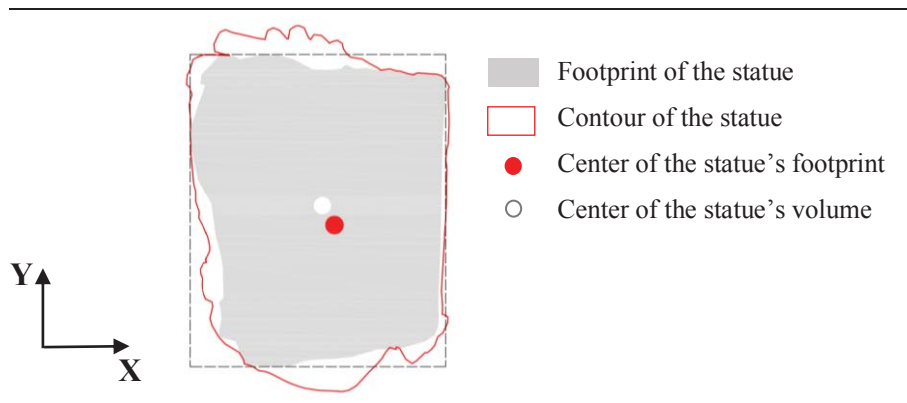

Figure 3. Direction of analysis of the sculpture

First of all, a modal analysis has been made through the software Marc & Mentat [23] to check the dynamic properties of the statue. The results of the modal analysis, in terms of frequencies and correspondent shapes, have been shown in Figure 5. The Fundamental period found for the sculpture is equal to 0.081 sec, compatibly to the ones found for similar statues [3]. As can be seen, the first mode is mostly translational, along the X direction, whilst the following ones have a relevant rotational response.

Figure 4. Position of the sculpture within the Fountain

Figure 5. Modal shapes of Neptune.

The level of stress in the material as an effect of the gravitational loads has been checked by performing a linear elastic analysis; the maximum stress achieved in the sculpture at its base (see Figure 6) is equal to about 1.35 MPa, well below the limit value of the material.

Furthermore, the limit conditions in terms of top displacement ($d_{lim} = 1.38$ m) for the overturning (see Figure 7) have been found. The limit top displacement has been found by imposing the gravitational load of the sculpture center at the limit of the inertial core of the sculpture print.

Figure 6. Maximum stress (Pa) under gravitational loads

Figure 7. Top displacement at the overturning

The horizontal force corresponding to the overturning, instead, has been found by equalizing the capacity moment to the moment of demand. The moment of capacity is defined as the product of the gravitational load, supposed to be applied to the centroid of the volume and the distance between the centroid and the turning point of the basement; the moment of demand, instead, is defined as the product of the horizontal force - supposed to be applied to the statue centroid - and its distance to the turning point, i.e. the height of the statue centroid, h . This simplified analysis has been made by representing the sculpture as a rigid body simply supported on the pedestal.

4.2 The dynamic analysis

The response of the case-study to the considered blast excitation has been found by performing a dynamic analysis through the Finite Element model described in § 2.3 through the software Marc & Mentat [23]. The duration of the positive pressure wave is very short, so that the blast can be assumed as instantaneous loading. In the numerical simulation, the blast occurs at the time $t = 1$ sec, after the application of the static (gravitational) load. The response of the system to the blast loading has been checked for further 9 seconds, as shown in Figure 8.

Figure 8. Duration of the analysis and loads timing.

The base restraint has been assumed to be as a simple support, with a friction coefficient between the contact surfaces equal to 0.8, to account for probable roughness of the surfaces and the presence of mortar. The top displacement of the sculpture, i.e. the displacement at the top of the head of the sculpture, has been compared to the displacement experienced by the two extremes (front and back) of its base. Figures 9 and 10 show the displacement histories found for the two assumed quantities of explosive.

Figure 9. Displacements histories for the case # 1 ($W = 10$ kg)

As can be noted, for the blast induced by 10 kg of TNT (Figure 9), the maximum top displacement, recorded along the X -direction, is around 3 cm, much lower than the overturning limit of the statue. The sculpture exhibits a rocking response, with a different period in the two directions. The dynamic response sculpture of the sculpture is almost symmetric in the X -direction, whilst it is strongly non-symmetric along the Y -direction. In both cases, after the rocking the sculpture settles in a different equilibrium asset.

Figure 10. Displacements histories for the case # 2 ($W = 50$ kg)

When the higher loading condition is considered (Figure 10), the maximum displacement achieved by the sculpture head overcomes 1 meter, resulting close to the overturning limit found according to the simplified static analysis. Even in this case, the sculpture exhibits a symmetric response along the X -direction, differently from the Y -direction. The rocking has a period much larger than in the other cases (around 2 seconds), similar for the two directions.

In this case, the system does not achieve a different equilibrium within the duration of the analysis; it should be underlined, however, that no damping has been introduced in the analysis.

5 CONCLUSIONS

In this paper the capacity of the main sculpture of the Fountain of Neptune in Florence has been checked with reference to an explosion due different amounts of TNT, respectively equal to 10 kg and to 50 kg. Before performing the dynamic analysis of the statue under the assumed blast conditions, some preliminary analyses have been carried, to check the dynamic properties of the sculpture, its limit condition to overturning and the static response under gravitational loads only.

The dynamic response of the statue under the assumed blast cases has been found by performing a nonlinear dynamic analysis on a very detailed FE model. The structural model has been set on the basis of a detailed laser-scanner survey, by arranging the geometrical model, starting from the points-cloud.

The analysis evidenced a rocking response of the statue along the *X*-direction, accordantly to results provided by the modal analysis. The dynamic response of the statue shows even a torsional behavior, which can be noted by observing the displacement histories of its base points along the *Y*-direction. The torsional response of the system becomes even more evident at the increasing of the assumed loading intensity. The blast due to the higher amount (50 kg) induces on the system a dynamic response close to its capacity; the maximum top displacement overcomes 1 meter along the *X*-direction, whilst along the *Y*-direction the system does not find a new static equilibrium within the analysis duration.

Further analyses should be made to check the role of the blast position on the statue response, and to assess the best possible restraint condition to minimize the vulnerability of the sculpture.

Abstract

The historical art works represent a priceless asset of communities. Despite their importance, such artifacts are often subjected to many hazards; in Italy, the seismic risk represents one of the most serious dangers which affect the art works, especially those more exposed to overturning. In these years, many studies have been made on the seismic response of artifacts, which evidenced the possible vulnerability of statues to seismic excitations. This paper is focused on the safety assessment of one of the masterpieces of the XVI century art: the marble statue “Oceanus”, made by Giambologna in 1570. The sculpture, currently exhibited at the courtyard of the Museo del Bargello in Florence, has a mass of almost 2 tons, and a height of over three meters, and it is the only giant statue made by Giambologna. In the work, a simplified assessment of the seismic response of the sculpture, and of the consequent seismic safety, has been made, by performing a non-linear static analysis. The role played by the base restraint and by the pedestal of the sculpture have been checked and discussed. The assessment proposed in the paper is aimed at providing a general comprehension of the dynamic response of the case-study under seismic excitations, and to suggest a proper criterion to set a more detailed model for further analyses.

Keywords: Seismic performance of artifacts; artifacts preservation; art works reliability; seismic vulnerability; marble sculptures.

1 INTRODUCTION

Artifacts, at each scale, represent the core of the artistic and cultural identity of communities, and they must be protected against all hazard sources [1-3]. Within artifacts, human-form statues result to be even more vulnerable than others. Beside being subjected to time injuries, they are slender, with an irregular shape and usually made by brittle materials [4]; therefore, they can easily overturn due to horizontal actions. For this reason, the statues result to be very sensitive to the seismic actions, and their capacity to contrast seismic accelerations before overturning has to be carefully checked.

In these last years, many studies have been devoted to the assessment of the vulnerability of statues to horizontal actions. The first contribution to this issue was made by Housner in 1963 [5], with its rigid block analysis, which has been widely developed [6-9]. With the development of the modern techniques of geometrical survey and the consequent possibility to set proper 3D structural models, even the Finite Elements (FE) analysis has been largely adopted for investigating the dynamic response of sculpture to horizontal loading [10-13].

The most suitable method to adopt for predicting the structural behavior of sculptures depends on the contact behavior between them and their supports, and on the expected collapse mechanism. In most cases, marble masterpieces of the Renaissance stand over their pedestal without any specific fixing devices, and therefore their response to horizontal actions are a function of the friction coefficient of the material [14-16]. The proper description of the effective friction at the base of the sculptures requires to adopt proper models and software, able to describe the interface behavior of the object. Furthermore, the effective connection between the artifact and its support is not always known; in many cases, a preliminary study of the quality of the response of the artifact, i.e. the assessment of the most probable collapse mechanism, is essential to correctly drive the choice of the analysis to perform.

In this work, a simplified analysis has been performed to make a quick assessment of the seismic safety of an artifact. Such simplified approach leads to understand if the assessment of the artifact safety is reliable enough; if more comprehensive investigations are needed, it can provide useful information about the choice of the model to use and its setting.

The proposed simplified analysis has been performed on two different models, both defined on the basis of a detailed laser scanner survey. The first model represents the statue as a rigid block, and it leads to investigate its capacity at the overturning. The horizontal action at the overturning has been related to the expected seismic hazard, described through the Technical Code provisions for the area and the foundation soil of the Museum of Bargello, where the statue is placed.

The second model, instead, consists of a FE representation, and provides the amount of stress arising in the case-study under the same assumed seismic excitation. The results provided by the performed analyses have been used to find the Safety Index (SI) of the statue, which has been expressed in term of acceleration, displacement and stress. The SI has been referred to the dynamic response of the sole statue, and of the system made of the statue and its pedestal. The comparison of the obtained results led to have a first assessment of the safety level of the case-study under the expected seismic excitation, and to have useful information to perform further analyses.

2 THE CASE-STUDY

Oceanus is a giant statue made by *Giambologna* between 1572 and 1576 for a Fountain placed in the “Boboli Gardens”, next to *Palazzo Pitti*. The Fountain represented the myth of controlling the waters, as an allegory for good government, and it comprehended even a huge granite basin, roughed out by sculptor and architect *Niccolò Tribolo*. The Fountain was

moved in another position within the Boboli Garden, where it is still now; the sculpture of Oceanus was moved to the National Museum of Bargello in 1911, and it was replaced it in the original location by a copy. At the current time, therefore, Oceanus is placed in the Courtyard of the Museum of Bargello, as can be seen in Figure 1.

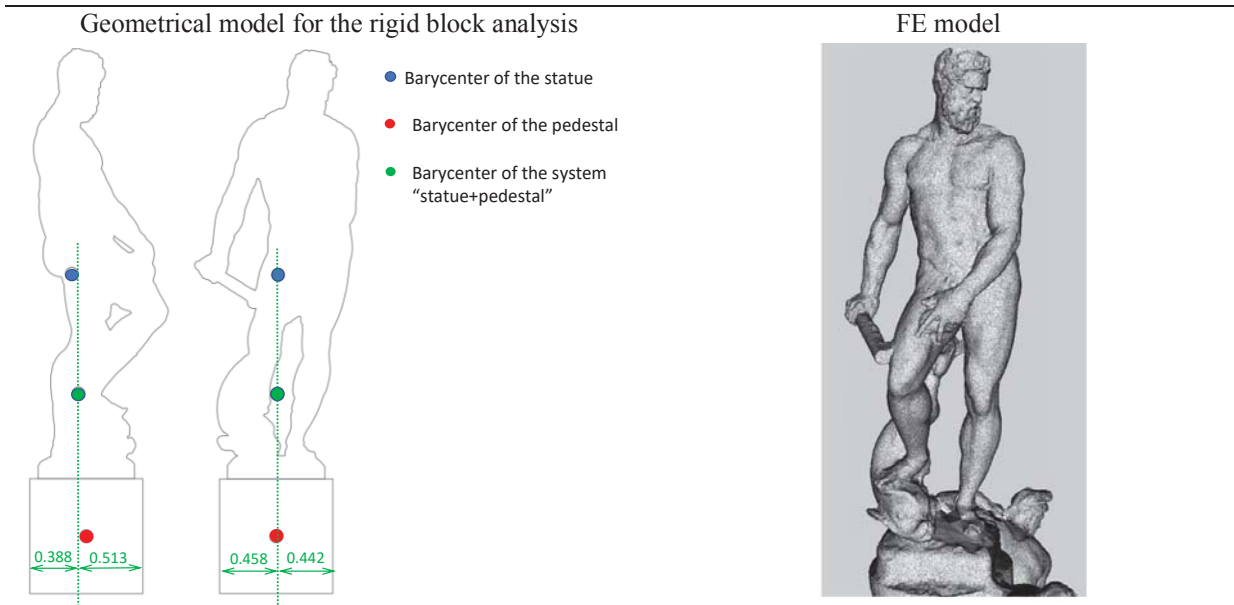

Figure 1. The statue of *Oceanus* at the Museum of Bargello in Florence

Oceanus (see Figure 2) has an height equal to 3.31 m, and a weight of about 2 tons, and it is made of Carrara's marble.

Main data assumed for the analysis

Geometrical model		Mechanical properties of the marble	
Mass of the statue (kg)	1966	Module of Young	50000 MPa
Height of the statue (cm)	331	Compressive strength	50 MPa
Pedestal sides (cmxcmxcm)	90 x 90 x 91	Tensile strength	5 MPa
Pedestal material	concrete	Coefficient of friction	0.8

Figure 2. The statue of *Oceanus*: geometrical and structural models and main data.

The geometry of the statue has been defined after a detailed laser-scanner survey, which led to define both the equivalent rigid block and the FE model. This latter model has been found from the geometric one through some proper arrangements. The first change consisted in a reduction of the polygons from 2000000 to 103259, in order to obtain a simpler model, suitable to be used for the structural analysis. Successively, the “surface” model has been changed in “solid” one, by including the area inscribed in its lateral surface. Figure 2 shows the geometry of the sculpture, together with the main information on the geometry. The barycenter has been found with reference to the statue only and to the system made of the statue and the pedestal together. In the same figure, some information regarding the mechanical properties assumed for the material has been shown. Oceanus is made of Carrara’s marble; the mechanical properties of the marble have been found after proper experimental investigation [17,18] made on marble samples taken from the Carrara’s quarries. A special attention has been paid to the assessment of the friction coefficient (CF). The pedestal of the statue is made of concrete; there is not information regarding the fixing between the statue and the pedestal. In this work, therefore, a CF equal to 0.8 has been assumed, in the hypothesis of lack of specific fixing devices, but assuming a layer of mortar between the statue and the pedestal.

3 THE SAFETY ASSESSMENT

3.1 The preliminary analyses

Two preliminary analyses have been performed to check the dynamic properties of the statue and the amount of stress arising under gravitational loads only. In both cases, a FE model has been adopted, and a fixed base restraint has been assumed. In Figure 3 the first five Periods of the case-study have been listed, together with the corresponding participating mass and modal shape, and the first two modal shapes are shown.

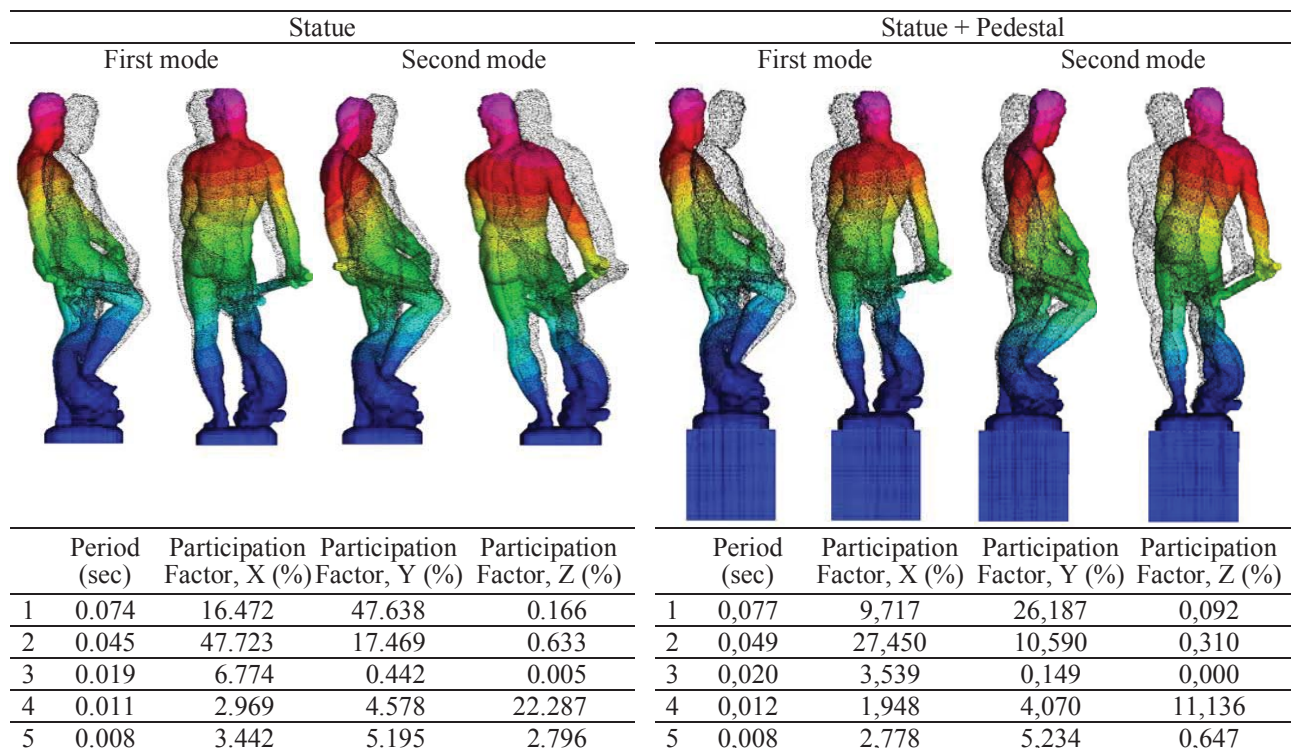

Figure 3. Main vibrational periods and modal shapes of the case-study.

As can be noted, the first mode refers to the Y (front-back of the statue) direction, while the second mode refers to the X (left-right) one. The statue evidences a torsional response even in the first modes. When the pedestal is included in the analysis, the quality of the vibrational modes does not change, but the participation mass of the first modes decreases a lot.

In Figure 4 the distribution of stress experienced by the material under gravitational loads only is shown. As can be observed, the highest stress is gathered in the ankles of Oceanus, which are the narrowest cross sections of the statue. The amount of stress, however, is about 20 times below the elastic limit of the material.

Figure 4. Stress distribution under gravitational loads only.

3.2 The seismic assessment

The assessment of the seismic safety of a statue is related to its collapse mechanism. Previous studies made on similar artifacts [13,19,20] found out the overturning to be the most probable collapse mechanism; such prediction, however, cannot be made regardless of the assumed base restraint and of the mass distribution.

When the base-restraint is a simple support, the amount of stress in the material is quite low, and the collapse is related to the displacement experienced by the object. About Oceanus, the type of the base restraint is not known; the simply supported restraint, however, is the most likely to have been adopted. In this work the simplified seismic safety assessment has been made with reference to both the possible base-restraint hypotheses. In both cases, the seismic response of the case-study has been studied both by considering the statue by itself, and integral with its pedestal.

The limit values of the displacement at the overturning have been determined by imposing the equilibrium of the rigid body. The simplified approach proposed by Parisi and Augenti [21] has been applied, and the overturning of the statue has been represented by equalizing the moment demand, defined as the product of the horizontal force applied to the statue centroid and its distance to the turning point, and the corresponding capacity, defined as the product of the sculpture weight and the distance between its centroid the basement side.

Figure 5 shows the top displacement (TD) at the overturning found for the case-study in the two directions, respectively neglecting the pedestal or taking it into account.

The limit horizontal accelerations corresponding to the system overturning have been found by considering the seismic hazard of the area. A soil class B has been assumed for the foundation, according to previous investigations made on the Museum of Bargello [22].

The seismic ground acceleration, A_g , has been assumed equal to $0.1659g$, corresponding to the *Life Safety* limit state for a class of use $c_u=2$, a nominal life equal to 50 years and a Return Period equal to 949 years (Probability of Occurrence of 10%). The Fundamental Period of the system has been assumed equal to 0 sec, i.e. the sculpture has been assumed as perfectly rigid. The amplification factor (f_a), has been found according to the current Code (NTC 2018, [23]):

$$f_a = \frac{a_0 \times q_a}{A_g \times S \times CF} \quad (1)$$

where a_0 is the acceleration corresponding to the overturning mechanism, q_a is the behavior factor, assumed equal to 2, CF is the confidence factor, assumed equal to 1, and S , assumed as 1.2, is the product of the stratigraphic amplification factor and the topographic amplification factor.

Figure 5. Overturning rotations and Tod Displacements of the case-study.

In Table 1 the values of the overturning acceleration and the amplification factor are listed for the two directions, together with the corresponding Acceleration Safety Index, SI_ACC , defined as $1/f_a$. It is worth noting that the system is safe for SI_ACC values below the unity, and that the safety factor of the system is the highest of those provided by the considered cases of analysis.

Table 1. Parameters assumed for defining the seismic demand.

	Statue		Statue + Pedestal	
	X-direction	Y-direction	X-direction	Y-direction
Overturning acceleration, a_0	0,229	0,166	0,279	0,245
Amplification Factor, f_a	2.30	1.67	2.80	2.46
Safety Index, SI_ACC	0.43	0.60	0.36	0.41

The safety of the case-study has been assessed even in terms of displacements. Figure 6 shows the main quantities involved in the spectral assessment of the Safety Index expressed in terms of displacement, SI_DISPL , which is defined as the ratio between the displacement demand, of the center of mass, D_d , and the corresponding ultimate displacement, D_u^* .

The quantity D_u^* , in turn, is defined as the 40% of D_{max}^* , that is the value of the displacement of the barycenter at the overturning. The displacement demand is found as the intersection of the spectral seismic demand (line in green in Figure 6) and the secant Period of the

system, T^*_S , which has been determined according to the expression provided by the current Technical Code (Circ. n. 7, Section C8.7.1.2.1.8, [24]).

As can be noted, the values found for the spectral demand respectively accounting and not for the statue's pedestal are almost coincident; the corresponding ultimate displacements, though, differ significantly from each other; when the performance of the statue is considered without the contribution of its pedestal, its ultimate displacement reduces a lot. In Table 2 the values found for the SI_DISPL have been listed together with the main quantities found for their determination.

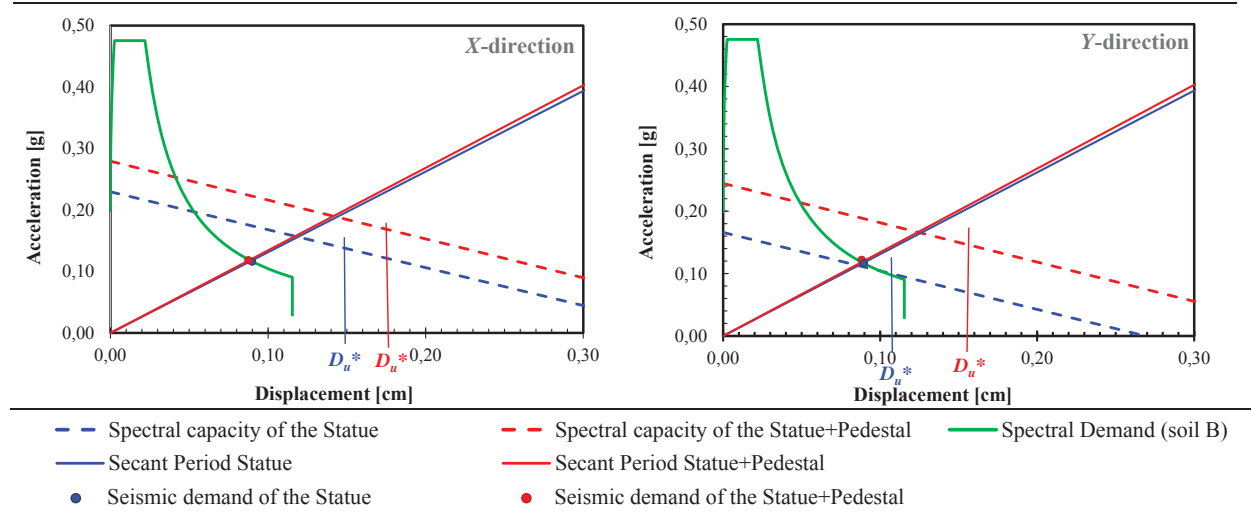

Figure 6. Capacity domains of the case-study along the two main directions.

Table 2. Main quantities used for the safety assessment.

	D_{max}^* (cm)	D_u^* (cm)	T^*_S (sec)	D_d (cm)	SI_DISPL
Statue, X-direction	37.2	14.8	1.73	8.91	0.599
Statue, Y-direction	26.9	10.8	1.73	8.91	0.828
Statue + pedestal, X direction	44.2	17.7	1.75	8.80	0.498
Statue + pedestal, Y direction	38.8	15.5	1.75	8.80	0.567

Finally, the seismic safety has been assessed in terms of stress amount. In this case the statue has been assumed to be fixed at the base, since the amount of stress is larger in fixed, i.e. stiffer, systems. Figure 7 shows the stress distribution within the statue found by performing a modal analysis based on the Code spectrum, by using the same seismic input already described in this Session. As can be observed, the larger tensile stress is placed in the back side of the ankles and at the top of the dolphin. The maximum amount of tensile stress is equal to 2.57 MPa and 3.63 MPa, respectively, for the sole statue and the statue with the pedestal; since the maximum tensile stress of the marble has been assumed equal to 5 MPa, the Safety Index can be expressed in terms of stress (SI_STRESS) as the ratio of the tensile peak and the corresponding capacity.

It is interesting to note that when the pedestal is considered as integral part of the system, the maximum tensile stress is achieved in the front part of the ankles, whilst, when the sole statue is considered, the most tensile points are in the ankles front.

The values of the Safety Index found in terms of acceleration, displacement and stress respectively, have been compared. Figure 8 shows obtained values of SI ; as can be observed, all the SI are well below the unit, even if they differ very much from each other.

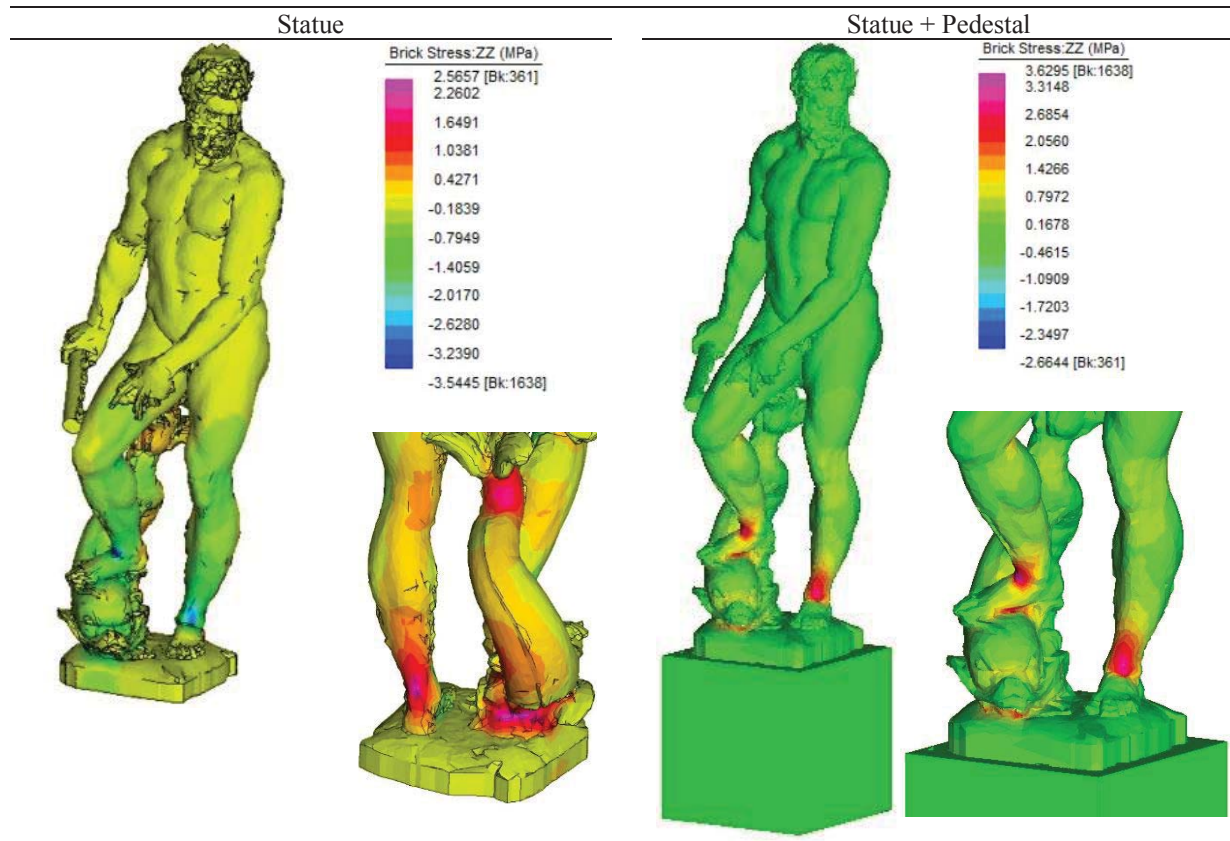

Figure 7. Stress distribution found by performing the modal analysis.

By comparing the values found for the Safety Index, some considerations can be made. First of all, the parameter which is closer to the safety threshold is the displacement; the collapse mechanism to assume for a more comprehensive analysis, therefore, should be the overturning, associated to a simply supported base restraint and a proper mechanical description of the interaction between statue and pedestal. As regards the overturning, when the pedestal is considered as integral to the statue, its contribution improves the performance of the system. The SI_DISPL found for the statue only, however, could not represent the most dangerous seismic response of the system, since it neglects the contribution of the pedestal in the transmission of the seismic action, and/or in the contribution to the total displacement experienced by the statue.

Figure 8. SI values obtained from acceleration, displacement and stress.

4 CONCLUSIONS

In this paper a simplified assessment of the seismic safety of Oceanus, the Renaissance masterpiece made by Giambologna, has been made, applying the simple spectral nonlinear static method. The analyses have been performed by using both a rigid block and a Finite Element models; a special attention has been paid to the role of the pedestal on the seismic response of the case-study and on the restraint condition to assume at the base of the sculpture with reference to the assumed collapse mechanism. Three different Safety Indexes have been found, expressed, respectively, in terms of acceleration, displacement and stress. The analysis states a satisfactory safety level of the statue; however, the differences found between the various Safety Indexes, and the higher value of the *SI* expressed in terms of displacement comparing to the others, suggest to perform further analyses, checking the nonlinear dynamic response of the statue to seismic excitations, and accounting for the contact behavior between the statue and the pedestal, and between the pedestal and the soil.

Abstract

Strategies for the protection of the Cultural Heritage priceless value are highly demanded, being both earthquake and support movement (and a combination of the two of them) severe threats for their safety and integrity. To this scope, computer-based numerical formulations have been representing a powerful tool for the simulation of expected loss in terms of pieces of art damages, with the scope to save them as much as possible. In this framework, the conference paper is devoted to the vulnerability assessment of monumental artworks using dynamic analysis in a rigid block modelling environment.

The numerical formulation adopts a discrete rigid block-based model, where the mortar joints contribution is accounted for by frictional, no-tension interfaces between the masonry units. The procedure adopted to solve the formulation is based on a dual variational problem where equilibrium, kinematic and failure conditions equations are involved at the same time, and which is solved via mathematical programming.

An application to a system of two blocks vertically stacked, one representing the support and one representing the artefact, subjected to free rocking motion will be proposed in the paper. The main scope is to investigate the seismic response of such a system, which is typical for most of museum's collections (e.g., statues). The computational efficiency and accuracy of the proposed numerical strategy will be discussed.

Keywords: Masonry block structures; Non-linear time history analysis, Free rocking motion, Mathematical programming.

1 INTRODUCTION

The possibility to develop computational strategy for the investigation of museum collections behaviour against seismic-induced dynamic actions represents a challenging task, playing a crucial role in the artworks integrity protection. The response of blocky structures, such as monumental statues made of stone blocks, against lateral forces is typically characterized by rocking behaviour [1–3].

The development and use of analytical and numerical tools for the investigation of blocky structures and historical masonry monuments subjected to different loading conditions by using both static and dynamic approaches is a widespread topic in literature [4–33]. Various numerical approaches are available in literature for the investigation of the dynamic response of multi-block structures and types undergoing rocking. Among those, the interest in the use of Non-Smooth Contact Dynamics (NSCD) methods has been growing in the recent years, essentially due to the advantageous possibility to account for the blocks interactions through a system made of both equilibrium and complementary conditions. In this framework, NSCD approach represent a valid alternative to common modeling approaches such as finite element method (FEM) and discrete element method (DEM) [34–37].

The use of NSCD technique has been increasing especially in the analysis of the structural response of masonry structures [38]–[40], where fast and accurate algorithms are available in the literature for the numerical solution of the formulations proposed for the mathematical programming problem arising from the conditions governing the contact dynamics [41–44].

In this paper we adopt a simple formulation for dynamic analysis of blocky structures aiming to investigate the rocking behaviour of a system of two blocks, comparable to the configuration of a monumental statue typical of museum's collections standing on its base. The aim of this research is to assess the computational efficiency of the in-house numerical procedure and to investigate to which extent it can be properly adopted in the prediction of the rocking behaviour of museum's artefacts to save them against any possible loss or damage. It is worth noting that the modelling approach for contact interfaces can be regarded as the extension to the dynamic field of a contact point formulation developed for limit analysis of collections of polyhedral rigid blocks.

The paper is organized as follows: the dynamic formulation is described in section 2 in terms of static and kinematic variables as well as the problem formulated to govern the behaviour of the rigid block model. Section 3 deals with the numerical application of the adopted procedure to the case study of a two blocks system subjected to free rocking motion already considered in literature.

2 THE RIGID BLOCK DYNAMIC MODEL

The proposed numerical model is composed by a collection of quadrangular rigid blocks i interacting by means of contact points k located at the vertexes of contact surfaces j (Figure 1a). The behaviour of contact interfaces is governed by a no-tension and associative frictional model under the assumption of infinite compressive strength. The dynamic model is formulated according to the approach proposed in [45, 46] for granular materials.

The contact variables are represented by the internal forces located at contact point k , which are essentially the shear and normal force (Figure 1b), collected in the vector \mathbf{c}_k .

The relative displacement rates, both tangential Δu_{tk} and normal Δu_{nk} , represent the kinematic variables associated to the contact forces in a virtual work sense. They are finally collected in the vector $\Delta \mathbf{u}$ (Figure 1c).

The centroid of the rigid block i is attached by the external loads and the position of the block centroid is collected in the vector \mathbf{x}_i as described in equation (1) and Figure 1b.

$$\mathbf{x}_i = [x_i \quad z_i \quad \omega_i]^T \quad (1)$$

θ -method is used to discretize the equations of motions, as described in equations (2) and (3) with regard to time $t = t_0 + \Delta t$.

$$\alpha(t) = \frac{v - v_0}{\Delta t} \quad (2)$$

$$v(t) = \frac{1}{\theta} \left[\frac{\Delta \mathbf{x}}{\Delta t} - (1 - \theta)v_0 \right] \quad (3)$$

being $\Delta \mathbf{x} = \mathbf{x} - \mathbf{x}_0$ the displacement vector, x_0 the known position and v_0 the known velocity at t_0 and $0.5 < \theta \leq 0.5$.

The incremental equation (2) allows to formulate the equation of motion of the collection of rigid blocks using a contact point model as described in the next equation (4):

$$\bar{\mathbf{M}}\Delta \mathbf{x} + \mathbf{A}_0 \mathbf{c} = \bar{\mathbf{f}}_0 \quad (4)$$

where \mathbf{A}_0 is the contact equilibrium matrix, $\bar{\mathbf{M}} = \frac{1}{\theta \Delta t^2} \mathbf{M}$ is related to the mass matrix \mathbf{M} which collects the mass and the inertia moment of each block and $\bar{\mathbf{f}}_0 = \mathbf{f} + \bar{\mathbf{M}}v_0\Delta t$.

Ad-hoc expression are formulated to account for non-penetration condition at potential contact point, by using the so-called Signorini unilateral contact condition.

Finally, sliding failure condition at contact interfaces is governed by a Coulomb friction law, expressed by the following equation (5).

$$\pm t_k - \mu n_k \leq 0 \quad (5)$$

being μ the value of friction coefficient.

Figure 1. Rigid block dynamic model: (a) Rigid block i , interface j and contact point k ; (b) contact forces and (c) kinematic variables at block centroid i , and contact point k .

2.1 Formulation of the mathematical programming problem

The dynamic problem can be expressed by an equations system which collect the equilibrium equations, the kinematic and the failure conditions in a typical linear complementarity problem (LCP). In this framework, the contact dynamics problem can be posed as described in equation (6), where \mathbf{Y}^T is the matrix of failure condition, λ is the vector of flow multipliers and \mathbf{g}_0 is the vector collecting initial gaps at each contact point.

The problem expressed in equation (6) is uncoupled in two dual quadratic programming problems, a force-based and a displacement-based problem, respectively. In this way, the

computational costs significantly decrease thanks to the possibility to use efficient solution algorithms.

$$\begin{bmatrix} \bar{\mathbf{M}} & \cdot & \mathbf{A}_0 \\ \cdot & \cdot & -\mathbf{Y}^T \\ -\mathbf{A}_0^T & \mathbf{Y} & \cdot \end{bmatrix}_{n \times n} \begin{bmatrix} \Delta \mathbf{x} \\ \lambda \\ \mathbf{c} \end{bmatrix}_{n \times 1} + \begin{bmatrix} \cdot \\ \cdot \\ \cdot \end{bmatrix} \mathbf{y} = \begin{bmatrix} \bar{\mathbf{f}}_0 \\ \cdot \\ -\mathbf{g}_0 \end{bmatrix} \quad (6)$$

$$s.t. \quad -\mathbf{y} \geq 0 \quad \lambda \geq 0 \quad \mathbf{y}^T \lambda = 0$$

It is worth noting that the dynamic problem formulated in the equation (6) is formally equivalent to a classic limit equilibrium problem when the dynamic forces and contact gaps tend to zero. An incremental procedure was implemented to solve the optimization problem assuming kinematic variables derived by Lagrange multipliers and updating the block position and gaps values per each step.

The analyses were carried out a 3.50 GHz Intel Xeon Processor E5-1650 with 16.0 GB of RAM. The value of algorithm parameter θ for time discretization was set equal to 0.7 and time increment was set in the range 0.001-0.002 s.

3 NUMERICAL APPLICATION TO A TWO-BLOCK SYSTEM SUBJECTED TO FREE ROCKING MOTION

The dynamic numerical procedure described in the previous section is here applied to the case study of a two-block system undergoing to free rocking. This case study was previously investigated in [47]. The geometrical properties of the two blocks are showed in Figure 2a, being equivalent to the example performed in [47]. The first block has a slenderness ratio H_1/B_1 equal to 1 whereas the second one has a slenderness ratio H_2/B_2 equal to 2.5. The base widths are $B_1 = 1.25$ m and $B_2 = 1.0$ m respectively. As for the material properties, the two blocks are considered homogeneous, with a weight for unit volume $\rho_1 = \rho_2 = 2500$ kg/m³. The investigated case study is characterized by a value of the starting rotation angles $\theta_1 = \theta_2 = 0.15$ rad and zero starting angular velocities for both the considered blocks.

Figure 2. Two-block system: (a) geometrical properties and (b) example of configuration during free rocking motion.

The outcomes of the simulation are reported in Figure 3. According to [47], starting from the initial configuration, the angles of rotation of the two blocks, θ_1 and θ_2 , tend to decrease due to the oscillation movement, and this occurs with a faster rate for the block at the base. In the first part of the motion, the two blocks move as one-single block rocking about the point O_1 , until the occurrence of an impact at the foundation. After the impact, the two blocks start to independently rock and other impacts occur up to the rest. As for the outcomes obtained with the proposed rigid block dynamic model, the curve showed in Figure 3 deals with the rotation angle θ_2 of the upper block around the point O_2 . The results are in a very good agreement with those obtained in [47] until the first impact of the upper block. After this initial stage, the second rotation is somewhat different with respect to the rotation predicted in [47]. Nevertheless, the two curves are very close, and so are the maximum oscillations obtained by the two models. The comparison is, therefore, very satisfying. With regard to the final stage, i.e. after the second impact of the upper block, the results obtained with the proposed rigid block dynamic model tends to predict a faster rocking performance compared with the results obtained in [47]: a higher number of impacts (i.e. change of rotation) is exhibited by the upper blocks. Finally, the two models come to a rest step at about 3.5 seconds analysis.

Figure 3. Free vibration response of a two-block system. Comparison with the results obtained in [47].

4 CONCLUSIONS

In this paper an in-house rigid block model for contact time-history analysis was described. The computational strategy is particularly suitable to investigate the response of stacked-blocks objects subjected to ground excitation. From this point of view, the dynamic model could represent a useful numerical tool for the vulnerability assessment of museum's collections affected by seismic-induced action, aiming to the protection of such artworks against earthquakes events. The capabilities of the proposed formulation were tested on a case study of a two-block system experiencing free rocking motion, already investigated in literature. The outcomes showed high potentialities of the adopted strategy in the prediction of the rocking behaviour of blocky objects.

Abstract

The Tarantola Etruscan pediment comes from a single-chamber tomb located in the Tarquinia area, dating back to 520-530 B.C.; it was found in 1904, during some agricultural works, close to Villa la Tarantola, from where the name. It consists of a trapezoidal tympanum 3.5 m long and 1 m high with a painting banquet with four diners (men) recumbent on a mattress placed at ground level. Fabrizio Lucarini detached it on behalf of the Royal Archaeological Museum of Florence, now National Archaeological Museum, where it is still conserved. The Tarquinia tombs were carved into the local Quaternary calcarenite named "Macco". The pictorial decoration was removed as solid-wall that was reinforced at the back with a layer of concrete. In the last years, the Tarantola pediment had been restored by the Opificio delle Pietre Dure (OPD). In the frame of a cooperation agreement between OPD and the Department of Earth Science (DST), it has been the subject of NDT analysis and survey for the reconstruction of a 3D model content. According to the MIBACT guideline (2011), the NDT surveys consisted into georadar, sonic and thermographic investigations. The location of the NDT data in their real space in the 3D model allowed their correct interpretation for a multi-disciplinary evaluation about the structures of the pediment. The NDT survey also allowed identifying and locating minor and micro fissures and gypsum integrations below previous painting restorations. In conclusion, the 3D modelling and NDT brought positive improvements for the structural and conservation knowledge of the Tarantola Etruscan pediment allowing better well-addressed restoration works.

Keywords: HBIM, 3D model, NDT investigations, Etruscan tomb, Cultural Heritage.

1. INTRODUCTION

This paper investigates the potential of BIM (Building Information Modelling) methodology applied to cultural heritage. The methodology, used in architecture and engineering, allows to create a three-dimensional model of a project, inserting also the properties and information of any single object. This makes BIM a good way to manage cultural heritage projects, from historic buildings to artworks, in all phase of the restoration work.

The management of a cultural heritage object through an "informative model" presents difficulties related for example, to the modeling of non-standard forms and this is truer in the case of unique and particularly complex objects such as artworks.

The Tarantola pediment is an example of a mural painting detached as a solid-wall from its architectural context and therefore today it can be classified as a mobile artwork exhibited in a museum. Therefore, the pediment represents a case study halfway between wall paintings and artworks, and constitutes an opportunity for experimenting the application of the BIM methodology to objects such as artworks that are particular both for their uniqueness and for the complexity of the shapes.

This paper provides how this tool can be suitable for reconstructing the complex shapes of the cultural asset and at the same time constituting a repository of all the data for a correct 3D placing of all the information supporting the conservation and restoration activities.

A modeling based on a photogrammetric survey and the results of extensive NDT surveying campaigns formed the starting point for the case study represented by the Etruscan pediment of the Tarantola at the National Archaeological Museum of Florence (Italy).

The research has allowed a better address for the restoration of this mural painting that took place in 2019-2020 by the Opificio delle Pietre Dure.

To achieve this objective, the investigations followed the 2011 MIBACT Guidelines (point 4.1.6) [1] and were conducted by DST (Department of Earth Science), in full collaboration with the Museum and the Opificio delle Pietre Dure. The investigations carried out concerned the type and characteristics of the substrate for the Tarantola mural painting. The history of the pediment and its current assembly was studied and a series of non-destructive tests (NDT): GPR, sonic and ultrasonic and thermography.

2. BIM APPLIED TO HISTORIC BUILDINGS AND ARTWORKS

The preservation of the Italian historical and artistic heritage requires an in-depth diagnostic knowledge that is preparatory for every type of intervention and that expresses into non-destructive or slightly destructive investigations campaigns.

The MIBACT 2011 Guidelines [1], dedicated to historical-monumental buildings, draw attention to the historical and constructive knowledge of the asset.

This knowledge can be achieved by means of surveys and investigations that allow the acquisition of often hidden information (under plaster, behind false ceilings, etc.).

In this sense, the Guidelines consents for indirect non-destructive investigation techniques (thermography, georadar, sonic tomography, etc.) or weakly destructive direct inspections (endoscopies, peeling of plaster, essays, small burglaries, etc.).

The management of the knowledge deriving from the diagnostic campaign is always quite complex: there is a lack of coordination between the different disciplines, the multimedia supports are different with the risk of losing information and making difficult for future users to consult them.

In this section will be exposed a brief state of the art of BIM applied to cultural heritage.

2.1 State of art and normative references

The use of digital models in restoration is a topic already investigated by several researchers in order to create a model as a single "container" (2D or 3D) to store geometric information and information relating to the intervention and maintenance phases on the artefact.

In this sense, we can cite examples of 2D Gis models such as Sicar (Information System developed by Liberologico and by the Superintendence of Fine Arts and Landscape for the provinces of Pisa and Livorno, in a working group that involved the National Research Council (CNR), Ministry for Cultural Heritage and Activities (MIBACT) and Small and Medium Enterprises), created to manage documents and analyzes collected during the restoration, or the applications of 3D-GIS by Barattin et al. [2].

In recent years, international studies have multiplied for the application of the BIM process to the historical architecture, the aim being a tool for classification, management and analysis of information. This process is called HBIM.

The first use of BIM applied to existing buildings is represented by the researches of Arayici [3] and Murphy et al. [4,5] who develop Historic Building Information Modeling (HBIM) by experimenting with libraries of parametric objects built from historical data with intelligent data integration and a system to map the parametric object on a point cloud.

Despite the difficulties encountered by these early authors, especially in the modeling phase, contributions on HBIM have multiplied to solve problems by simplifying the workflow of the restoration project and opening new ways for experimentation.

Among the topics covered are the modeling of objects starting from a point cloud [6,7], the enrichment of the model through the insertion of information or the reconstruction of the evolutionary phases of the building with the contributions of Apollonio et al., [8] and Brumana, et al., [9], the integration between BIM and GIS in the research of Dore and Murphy [10].

The methods of consulting the database through web platforms and augmented reality were also studied [11] and the construction of databases for building maintenance [12].

As part of the research activity carried out by the DST, various types of diagnostic investigations are performed on historical buildings and artworks: georadar investigations, sonic and ultrasonic investigations, video inspections, laboratory investigations on stones and mortars, micro-perforations, thermographic investigations, etc.

In order to organize the data collected during the research, 3D models of the cases studies are realized to highlight the geometric characteristics, as well as the location of the surveys in their real 3D location and the results in a unified framework.

This workflow was applied to case studies such as the Resurrection Christ by Piero della Francesca in Sansepolcro [13], the Garden of the Camelie and the Bona Hall in Palazzo Pitti [14].

Finally, a brief mention of the BIM legislation in Europe which has as its reference the "Directive on public procurement of the European Union" 2014/24 of 26 February 2014 [15] that invites EU Member States to encourage the use of BIM for projects, while Italy has adopted UNI 11337 [16] (divided into 10 parts), opening the discussion on the use of the BIM methodology to cultural heritage.

3. THE ETRUSCAN PEDIMENT OF THE TARANTOLA

The Tarantola pediment is a mural painting taken away as a solid-wall from a tomb in the necropolis of Tarquinia. The necropolis was excavated in the local soft calcarenite, called "Macco", which represents the support of the mural paintings that decorate the walls.

Since October 2018 the Pediment of the Tarantola is being restored at the Opificio delle Pietre Dure, as subject of a thesis by SAFS/PFP1 [17].

3.1 Finding and conservative history

The work, known in scientific literature as “Frontone della Tarantola” (Figure 1), was part of the mural decoration of an Etruscan tomb with a single chamber, it was originally located in the Tarquinia area within a property called the Tarantola fund, belonging to the Etruscan necropolis of Monterozzi. Dated around 520-530 B.C., it was found in 1904, during some agricultural works. The pictorial decoration located in the tympanum of the back wall inside the tomb was detached by Fabrizio Lucarini (a well-known restorer), on behalf of the Royal Archaeological Museum of Florence who bought the work from the owner of the land [18].

Figure 1: The pediment before the restoration.

The painting represents a banquet with four diners [19] (all men) recumbent on a mattress placed at ground level and a fair probably a lion, a panther or a particular species of dog. Below there are a continuous frieze of 13 bands in alternating colors, red, white, black and gray.

There are many reasons of interest: from the historical/artistic point of view, as a testimony of high value of Etruscan painting of the Archaic period (end of the 6th century B.C.) [20]; from the point of view of the history of the restoration, it represents a rare testimony of solid-wall detachment framed in wood for strength and transport [21] and, very important, the wooden elements used to detach it still contribute to the conservation of the property, as the diagnostic investigations have confirmed. For the detachment of the painting from the buried tomb at a depth of 4.5 meters, a solid transport was carried out which involved the removal of both the pictorial decoration and the support: in fact, together with the pictorial surface, about 15-18 cm of stone were removed. In order to strength the removed Macco slab, Lucarini applied on the back first a layer of mortar (Malta Lucarini, made with Macco sand) and then a thin layer of concrete. Lucarini enclosed the fragment within a cusped wooden frame. For this reason, it can be assimilated to a pediment.

Since then, with the name of “pediment” (Frontone), due to its triangular shape, it has become part of the exhibition of the National Archaeological Museum of Florence [22]. After the flood of 1966, when it had suffered no particular damage [23], it was first transferred to the warehouses and then to the premises of the archaeological restoration laboratories and exhibited only during exhibitions, often abroad.

4. THE INVESTIGATIONS CAMPAING FOR THE DEFINITION OF THE COGNITIVE FRAMEWORK

The following section describes the research and analysis carried out to understand the materials and the state of conservation of the pediment. In the next paragraphs will analyze the types of NDT investigations carried out and will be showed the results obtained.

The information deriving from the cognitive framework out-lined has been included in the BIM model as described in section 5.

4.1 GPR survey

The Ground Penetrating Radar (GPR) is a Non-Destructive investigation technique that was developed for investigating subsoil objects [24]; subsequently it was used for defining lithological contacts [25, 26], faults [27] and fractures in rock-mass [28, 29] and for defining soil units [30, 31] and the water table level too [32, 33, 34].

GPR has been also applied in investigating the competence of concrete in bridges and tunnels and for the bond durability. Recently GPR has been used for investigate masonry structure and assemblage [35, 36, 37].

The GPR principle uses the two-way travel time between a high-frequency electromagnetic input in the radar range 100 MHz-100 GHz and its return (Figure 2). The radar input travels in the material at a velocity mainly related to the magnetic conductivity and permeability of the medium [38, 39].

Figure 2: GPR operating on Tarantola pediment and principle: an antenna inputs a radar signal in the medium, the boundary between materials with different electromagnetic properties backscatters the signal to the receiver determining the two-way travel time.

The boundary between materials with different electromagnetic properties partially backscatter the signal to the antenna. The entity of penetration of the signal into the material is a function of the material properties and the signal frequency: lower is the frequency and higher is the penetration, but less are the details of the investigation because they are function of the wavelength.

The knowledge of the wave velocity in the medium or that of a distance of a sure signal are compulsory for fixing the scale of the investigation and therefore for correctly placed in the surveyed body the material interfaces, voids included.

In investigating a manifold, a good practice is measuring the thickness of the wall plus placing a still/iron plate as reference to the opposite side of investigation for having a sure end-signal of the masonry, in order to fix the scale of resulting radargram.

The Georadar campaign was carried out on the Tarantola pediment in collaboration with IDS Georadar S.R.L. (Hexagon Group), under the supervision of Dr. David Morandi, using the IDS C-Thru system, with a 2GHz antenna (Figure 2). The acquisition campaign consisted into 4 horizontal scan-lines, spaced of 7-10 cm, all along the entire length of the painted surface. Tomography analysis was made for having information relating to the material setting inside the pediment.

In order to avoid damaging the painting with the wheels of the instrument, the surface was temporarily consolidated in the most delicate areas. The GPR surveys, both the single horizontal surveys and the tomographic survey, were implemented in the 3D model (Figures 3 and 4).

Figure 3: 3D mounting of GPR linear survey on the 3D model

The tomography results outline the Macco be affected by several discontinuities. On the right side of the pediment of concave shape up to a depth of approximately 5 cm is clearly visible, that is referred to a previous integration made by gypsum.

Figure 4: Georadar tomography in a section at 0.5 cm from the front surface, mounted on the 3D model.

Georadar analysis does not recognize the interface between Macco and Lucarini mortar because the composition of the mortar is very similar to that of the Macco, but well defines the interface with the concrete at the back.

4.2 Sonic test

The sonic test is based on the generation of elastic waves in the frequency range of sound (20 Hz - 20 kHz), by means of mechanical impulses generate by a hammer and recorded by a receiver.

The data acquisition system used was a Novasonic U5200 CSD module of IMG. The processing signal consisted of measuring waves travel times, a specific software allows the visualization of the transmitted and received signals on time domain [40]. The first arrival of the wave is obtained using an automatic algorithm that may be checked and corrected by the operator through visual access and manual operation.

Sonic pulse velocity tests were carried out on the Tarantola pediment following two configurations: direct and indirect [41] (Figure 5).

In the first hammer and accelerometer are placed on opposite faces and the longitudinal waves are measured, in the second hammer and accelerometer are placed on the same face this method is more used to access to surface waves.

The pulse velocity represents the qualitative characteristics of the investigated object, influenced by composition, the contact between different materials, as well as by the presence of inhomogeneities, voids, cracks presence and deteriorated areas [42, 43, 44].

Figure 5: Sonic velocity test configurations, a) direct and b) indirect.

The direct acquisition was carried out considering 111 impact positions located on the back of Tarantola pediment along vertical alignments, while the receive was located in the front (Figure 5a). For each point, 3 travel times were recorded, and considering the thickness of Tarantola pediment as distance between the hammer and the receiver, the sound velocity was computed.

The indirect acquisition was carried out considering 16 impactions on the highest points of the vertical alignments and 100 receptions. For each point, 3 travel times were recorded, and considering the progressive distance between the hammer and the accelerometer, the sound velocity was computed (Figure 5b).

The punctual measurements were elaborated using ESRI® ArcGIS software, in particular the Natural Neighbor interpolation tool [45], to compute a sonic velocity distribution map, the results, both direct and indirect, were reported on the 3D model (Figures 6 and 7) of the Tarantola pediment.

The average velocity of the two configurations is the same of about 600 m/s, this can be explained with the fact that the Tarantola pediment is constituted by a calcarenite (Macco) with a high porosity (20-30%), in addition some restoration supports as mortars and concrete in the back side and gypsum in front right side are present.

Figure 6: Sonic velocity from indirect acquisition mounted on the 3D model.

Figure 7: Sonic velocity from direct acquisition mounted on the 3D model.

All these materials lead to a general slowing down of the sound waves, indeed the indirect test shows an average velocity distribution on whole surface, this is the result of superficial velocity on the backside concrete and mortar layers, which is well distributed over the entire pediment.

Of particular interest are the result of direct test, on the back left side a higher speed area is present, this corresponds in the front of an area with the gypsum integration. The gypsum, in this case, is more homogeneous and compact and here the Macco is thinner and two different porous materials such as mortar and gypsum are in contact.

4.3 Thermography campaign

The use of thermography on the cultural heritage on masonry buildings allows, with specific conditions, the view of the internal layers hidden by the plaster; in particular, its use is still helpful to detect the structural part in the slabs and to check the texture of vaults and masonry walls.

Thermography on mural or panel paintings has some examples of use to detect various types of defects in the painting layer [46] or sublayer composition evaluation with the help of adapted image and signal processing algorithms to detect small discontinuities inside structures or extract material characteristic information [47].

Thermography is a no-contact test and can cover large areas. Thermography sums on the external surface the response from the whole masonry, therefore it is difficult to detect the in-

ternal anomalies in the artifact and results can be influenced by conditions and by non-homogeneous heating.

In the case of the pediment, the experimental campaign has been made using a FLIR T460 thermal camera and was carried out in both passive and active conditions, heating the room evenly. The results of the thermographic campaign were subsequently inserted on the 3D model (Figure 8).

Figure 8: Visualization of the thermographic map inside the model.

In both cases, differences in temperature were detected due to the presence of different materials such as plaster repairs on the front, while no interesting anomalies were found on the back.

5. THE DEFINITION OF THE INFORMATIVE MODEL

In order to organize the data collected during the campaigns, a 3D model of the pediment was realized to highlight the structure, as well as the location of the surveys and their results in a unified framework.

In section 5.1 will describe the phase of the metric survey of the pediment by means of photogrammetry.

In sections 5.2 and 5.3 will describe the operational phase consisting of modeling the pediment and creating customized families for entering the data of the surveys carried out. It will also be presented how to enter data and query the database using specific methods.

5.1 The photogrammetric survey

The starting data for the geometry reconstruction of the pediment come from a photogrammetric survey. It was decided to use photogrammetry due to the speed of data collection and obtaining the results.

Photogrammetry is a technology that allows, starting from the acquisition of high-definition images, the reconstruction of a textured 3D model.

It is already used for architectural, cartographic, topographical survey, and now it is also applied to artistic artefacts. It allows arriving at a detailed knowledge of the surfaces of the artwork in order to obtain information for conservation and valorization.

Using a 24 Mpx camera, 1000 photographic shots were taken, taking care to maintain an adequate overlap between different frames and keeping the machine settings unchanged. The

images were aligned and processed using photogrammetric software in order to obtain a point cloud (Figure 9) and a textured model (Figure 10).

Figure 9: The point cloud deriving from the photogrammetric survey.

The point cloud of the pediment was imported into Autodesk Revit (®Autodesk academic license) for modeling in the BIM environment, while the orthophoto and textures for mapping the BIM model were obtained from the textured model.

The dense point cloud obtained consists of approximately 49.700.000 points, which, during the processing of the mesh, give rise to approximately 9.900.000 triangular faces. The high density of the point cloud and the definition of the mesh made it possible to obtain an extremely detailed model.

Figure 10: The textured model deriving from the photogrammetric survey.

5.2 The modeling phase

The difficulties of modeling cultural heritage objects in BIM environment are several, first of all the very irregular shapes. However, in this case, the choice to operate using BIM software is aimed at testing the potential for managing information related to cultural heritage.

It's useful to refer to the LOD achieved in the realization of model. The LOD provides the degree of reliability of the geometry detail level and information level. According to the BIM Forum Level of Development Specification [48] the model of the pediment can be framed in a

LOD 300. If this level is accurate, geometric data can be measured directly on the model and any type of information (materials, decay, historical data, etc.) can be added via external references. Therefore, the three-dimensional model were made with attention to the modelling of the structure and archiving the results of the diagnostic campaign.

The pediment was modeled trying to be true to its shape and features using Autodesk Revit software. The greatest difficulty is due to the not perfectly planar conformation of the wooden frame and the pediment. Starting from a reference level, the Revit wall system families were used to model the layers that make up the artwork, in particular the Macco.

Figure 11: A general view of the BIM model.

Wall-objects were created with customized stratigraphy and materials that had suitable textures to guarantee the recognizability of the different structures (Figures 11 and 12). Instead, the wooden frame was modeled using parametric beam elements.

We have tried to use *in place* modeling as little as possible, which is often not recommended as it is a traditional methodology that goes beyond the rules of BIM, creating non-reusable objects that weigh down the file. Therefore, every object that could not be modeled with a system family, such as the beams of the frame, was inserted starting from a parameterized and customized family that can be further enriched with information.

Figure 12: Exploded view of the BIM model.

The inclusion of the surveys in the model was addressed through the creation of specific families to which the parameters described in section 5.3 are linked. The geometry of the objects that represent the surveys has been studied according to its characteristics (Figures 5-8).

For example, the georadar survey was modelled on a panel of variable dimensions. This mode allows a faster and more efficient visualization and understanding of the model.

All this led to create a family library that allowed a rapid modelling of the case study and can be reused in future works.

The BIM model was designed to facilitate the understanding of the wall structure of the painting, to store information found during the diagnostic campaign and during restoration, and to allow easy viewing and consultation.

5.3 The implementation of the informative model

This work phase illustrates how the data were entered into the model and how it was assigned to each object.

For each element modeled in 3D, it is possible to connect data relating to the general characteristics of the element, to the dimensions, the results of the investigations, the materials and the monitoring data, etc. It is also possible to associate links to external files such as images, videos, documents.

Each object was created within an appropriate category, and preferably associated with instance parameters. All parameters are shared and subsequently converted into project parameters, linking them to the relevant category.

The families of the surveys have been associated with parameters that allow inserting information such as the date of execution, the description, the instrument used and the results. It was possible to create parameters to insert links to photos, documents and videos.

Parameters such as dimensions, wood essence, dating were associated to the beams of the frame, while the characteristics of the materials were associated with the layers constituting the support. Each object has been provided with an ID that identifies it and which can be viewed using the appropriate label. The creation of abacus allowed the classification of the objects by category and the interrogation of the model (Figure 13).

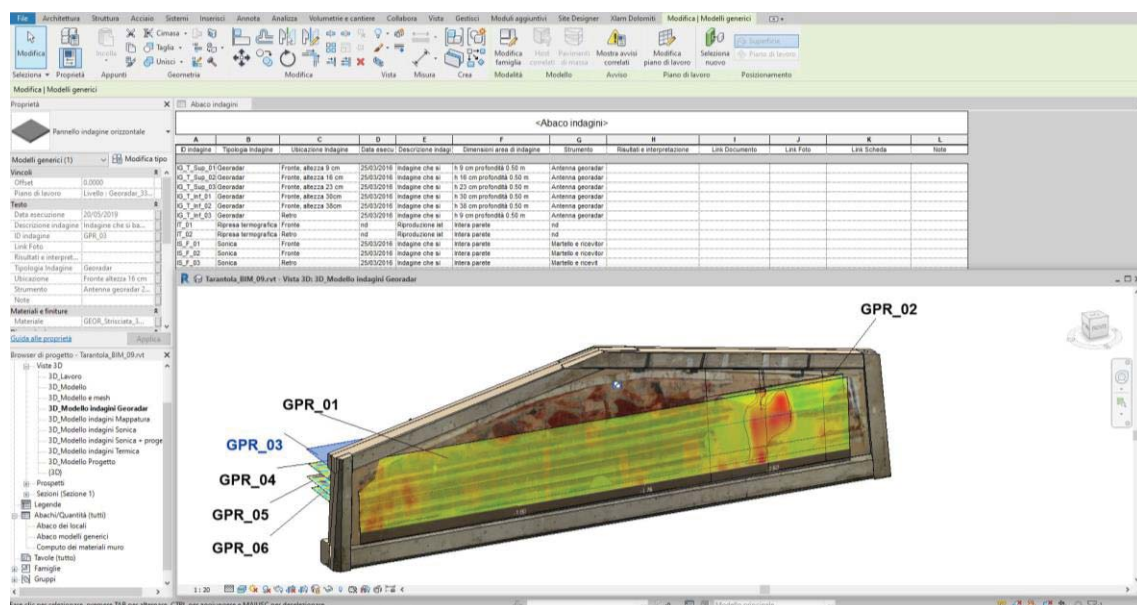

Figure 13: The identification of the surveys by label, the visualization of the parameters connected to the object, and an example of abacus that allow managing all the surveys.

By selecting an element inside the abacus, Revit allows to view it within the model. Furthermore, the objects inside the schedules can be filtered and sorted according to the parameters created, making it easy to interrogate even very complex models.

Revit software also allows managing the visualization of the model through customized views and in the 3D environment through dynamic sections and exploded view that facilitate in the modeling phase and in the public presentation phase of the research results.

The creation of specific abacus allowed the interrogation the model. The model was subsequently organized through specific views aimed at displaying the different types of information to be highlighted.

The result obtained is a digital twin of the artwork, which makes it possible to analyze the results of the investigations in close relation with the areas investigated and to locate and measure any anomalies.

6. CONCLUSIONS AND FUTURE DEVELOPMENT

The workflow presented made it possible to test the possibilities of digitization and archiving using the BIM methodology applied to a very particular case study of cultural heritage.

The result is a model that describes with a good level of detail the current state of the pediment and its wall support, while the information was stored in a simple and easily accessible way.

Even in this particular case study, BIM is a valid tool for management and storage for the speed of modeling thanks to parameterization.

Among the problems encountered are the difficulty of modeling complex elements with non-standard forms, the lack of categories related to the restoration and diagnostic process, the absence of information classification procedures and the lack of a single system that allows consultation and implementation of the model without using BIM software.

This last aspect can be partially solved using an online viewer or an IFC viewer, which however remain limited and allow consulting the information but do not always allow the visualization of the textures and many others problem.

The next steps of the DST research aim to study a way to consult the model also on mobile devices and without having to choose a BIM Authoring software.

Future developments foresee a double aspect: on the one hand, the creation of centralized models with multidisciplinary information that can be used in the field of conservation and enhancement of the single building or artwork, on the other hand complex databases will be created for management of museums as containers of artworks or, more generally, for the cultural heritage of entire cities.

Abstract. *A museum, an art collection and a heritage architecture all in one the former Church of San Bevignate is a 39.5m long masonry building that overlooks the countryside of the Umbria Region in Italy. Part of a Templar complex of the 13th century located in Perugia, it holds within a precious series of frescoes, depicting the heroic deeds of the temple's knights across crossings and borders. The safeguard of historical buildings in seismic hazard-prone Regions, as in this case, needs specific measures due, amongst other reasons, to the presence of artistic assets unmovable precisely as frescoes, valuable plasters/stuccoes or in general wall decorations. Therefore, to define a correlation of the seismic risks between masonry structural systems and artworks is a mandatory condition in order to perform safety evaluation and to identify the proper conditions for possible interventions. The efforts made to increase the level of knowledge concerning such buildings mainly through Non-Destructive Testing (NDT) are also important for such purposes. In this context, a non-invasive and contactless method was devised, which integrates the use of the thermal imaging camera with post-processing techniques and calculation algorithms, aimed at revealing the peculiarities inherent in the walls decorated with frescoes: a little-known possibility to bring out important factors for the conservation of the frescoes and also information on the seismic vulnerability of such historical masonry architectures in order to preserve the artefact from being damaged.*

1 INTRODUCTION

The protection of several types of museum collections against seismic phenomena is increasingly gaining interest among a range of stakeholders: the arts and culture sector, scientists, people working in local authorities and governments. Such approach takes into account the observation that in many cases damages to heritage buildings and art goods are irreparable and parietal art pieces e.g. frescoes, decorations and stuccos, are the example by antonomasia of such scenario. Indeed, the aftermath of the recent Italian earthquakes (L'Aquila, Amatrice etc.) in terms of destruction and harms to the historical collections and works was not secondary. Special programs of earthquake preparedness must be conducted in order to mitigate the expected hazard, especially for earthquake-prone countries, such as the Mediterranean countries and besides to avoid cultural losses that may have consequences on entire communities [1, 2, 3]. This contribution presents a contemporary approach to the theme of experimental investigations relating to the protection of heritage masonry buildings and the parietal art goods associated with it. The article constitutes the last phase of a research path started with laboratory tests [4, 5, 6] and, with the collaboration of the Municipality of Perugia, applied subsequently to a case study of value [7] and within the present contribution is examined more closely: the Italian Templar church of San Bevignate, part of an architectural complex from the 13th century located in the city of Perugia. Especially, this heritage building was selected because pose special challenges for damage detection and conservation, due to the presence of large parts of frescoed masonry surfaces. So, this heritage building represents a museum of itself, of its values and its precious original contents. The diagnostic methodology applied in this work is the passive thermography by means of an Infra-Red (IR) thermal camera that acquires the frescoes' painted surface without the emission of artificial thermal loads to the frescoes themselves backed up by the implementation of digital imaging processes. The surveys allowed identifying the main masonry damages like fissures, damages in stone elements, putlog holes, with a peculiar focus on the masonries' quality and texture. By means the data acquired it has been possible to obtain, starting from the processing of thermographic data on the wall texture and by means of a homogenization technique, an estimate of the fundamental mechanical properties of the load-bearing structures. Indeed, an adequate knowledge of the masonries' peculiarities assumes great importance for the estimation, through homogenization techniques, of the mechanical characteristics [8] and collapse conditions [9] of the heritage buildings both in the static and dynamic field [10, 11]. Besides, the in-situ measurement permitted to carry out an evaluation of the actual state of frescoes concerning other risks connected to their survivals like detachments, delamination or moist areas. So, without harming the wall frescoes, e.g. by taking the traditional essays or samples, valuable information were obtained concerning the frescoes conservation and at the same time the seismic safety of this historical former church, now a full-fledged museum site.

2 THERMOGRAPHIC ANALYSIS

An infrared camera is able to record the amount of radiated heat from a body.

The equation of Stefan–Boltzmann provides the relation between emitted radiation and surface temperature:

$$E = \varepsilon \sigma T^4 \quad (1)$$

where ε is the radiation (W/m^2), T is the absolute temperature (K), σ is the Stefan–Boltzmann constant ($5.67 \times 10^{-8} \text{ Wm}^{-2}\text{K}^{-4}$) and ϵ is the emissivity.

It is also necessary to introduce the relation between the wavelength of the maximum radia-

tion intensity λ (μm) and the temperature

$$\lambda = \frac{b}{T} \quad (2)$$

where b is the Wien displacement constant ($2897 \mu\text{mK}$).

The heat transfer in any material is affected by the presence of subsurface flaws or any other inconsistency in the material thermal properties. Localized energy gradients on the surface of a test object are due to the changes in the heat flow and can be measured using an infrared sensor.

For temperatures close to room temperature, the energy is in the infrared domain of the electromagnetic spectrum. In particular, the infrared radiation is the region of the electromagnetic spectrum located between visible light and microwaves, containing radiation characterized by wavelengths ranging from 0.75 to $10 \mu\text{m}$.

Temperature distributions are obtained by data processing from the measured infrared radiation and then recorded in the form of isotherm plots or thermograms. The electronic sensor of the instrument acquires the value of energy stored by every single pixel and generate an image, in greyscale represented by black and white shades or in a combination of levels of false colours, of the observed object. To experiment the efficiency to evaluate, by means of thermographic images, the texture of masonry walls covered with plaster or frescoes, a research program was started [4, 5, 6].

In particular, three masonry samples, which differed for the textures (periodic, quasi-periodic and random) were built. Using UNI solid bricks of dimensions $250 \times 120 \times 55 \text{ mm}$, either used as a whole or split in two or four, the periodic texture was constructed with the running bond scheme and using bricks with the same widths and heights. For the quasi-periodic texture, bricks with different widths but equal heights were used, avoiding the correspondence of the vertical mortar joints. In the last case, a random texture, made using bricks with different widths and heights, was created. The masonry walls, before applying 10 mm -thick plaster, are shown in Figure 1.

In that research, as well as for the present contribution, the thermographic camera model 885-2 manufactured by the Testo company has been used. This has a sensor of dimension 320×240 pixels. All the samples have been exposed to direct sunlight in order to improve the heat flux through the body.

To derive the masonry texture from thermographic images, the following procedure was proposed.

Assuming a T_t threshold temperature, that field is converted to a binary function, which is a “black and white image” or material binary image, by

$$b_i = b_i(x, y) = \begin{cases} 0 & \text{if } T_i \leq T_t \\ 1 & \text{if } T_i > T_t \end{cases} \quad (3)$$

where the value 1 (black) is associated with mortar pixels, the value 0 (white) with brick/stone pixels, and

$$T_i = T_i(x, y) \quad x = 1, 2, \dots, N \quad y = 1, 2, \dots, N \quad (4)$$

are the temperature data, relating to each thermographic image pixel, that can be reported as a scalar field where N is the image width in pixels (it is assumed that the image has equal width and height).

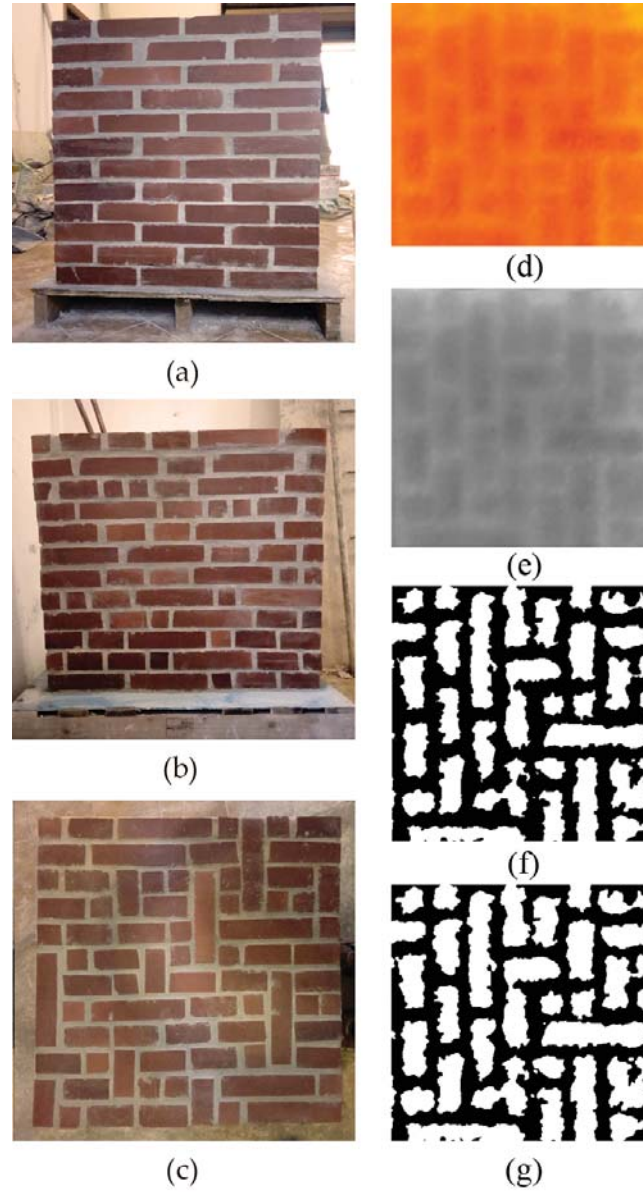

Figure 1: Samples with different masonry texture: (a) periodic, (b) quasi-periodic and (c) random. In the right column identified texture on random masonry sample: (d) thermographic image, (e) surface temperature as greyscale values $T_i(x, y)$, (f) black and white image after thresholding $b_i(x, y)$, (g) identified texture after the application of erosion and dilation factors, $b_d(x, y)$.

However, the final obtained binary image requires specific treatments in order to improve its quality. At first, mortar (black) region of pixels which are surrounded by bricks' pixels (white) are removed. Then the usage of morphological operators is required. In particular, erosion and dilation operator, in this sequence, must be used, in order to smooth the contour of the inclusions which otherwise would be very fragmented, due to the noise which belongs to the image acquisition phase.

Moreover, it was highlighted that the use of sampling Kantorovich algorithm allows to enhance remarkably the quality of the thermographic images. Furthermore, a sensitivity analysis was performed considering two sources of uncertainties: the first tied to the parameters of the morphological operator, the second related to the effects of the environmental conditions highlighting the robustness of the proposed procedure.

Applying the described process, the outcomes shown in Figure 1 were obtained; the comparison with a digital image highlights the robustness of the procedure. In fact, the resultant black and white image has a consistent separation of phases, i.e. each stone is surrounded by mortar joints and unrealistic conjunction of inclusions is obliterated as much as possible.

Nevertheless, these results were obtained in laboratory. In order to check the reliability of the proposed procedure on real cases and underline the effective importance of this tool in the historical buildings' analysis, a peculiar study on the Templar architecture of San Bevignate has been started, a former church from the 13th century, whose internal masonry walls are almost entirely covered with precious frescoes.

3 THE TEMPLAR ARCHITECTURAL COMPLEX OF SAN BEVIGNATE

3.1 History of the Church

In the countryside of the city of Perugia, and more precisely near the monumental cemetery of Monteluca, stands out for archaeological and architectural relevance the Heritage Templar asset of San Bevignate. The church, sober and austere in its external appearance with stone facades (Figure 2), is marked inside by decorations and in particular the pictorial cycles made to remind the inhabitants of the mission carried out in the Holy Ground by the Militia Templi, a.k.a. the Templars, the religious-chivalric order created in Jerusalem around 1119 on the initiative of the French knight Hugues de Payns. This exceptional artefact testifies the presence of the order in Perugia, indeed in 1256 the city's Municipality granted the authorization at the Templar diplomat friar Bonvicino to erect the religious building in place of a small church dedicated to San Girolamo. Even though the Templars, at the time, were already present in the Umbria region at the abbey of San Giustino d'Arna, since such seat was decentralized with respect to the prosperous Perugia they requested a new one. For the inhabitants of Perugia - and for the Templars - devoting the church to the figure of San Bevignate, whose history is still shrouded in mystery to this day, was important considering the popularity of its local cult back then [12]. Actually, he was not proclaimed a saint by the church of Rome but it was "laically" canonized only in 1453 by means of a decree of the Municipality of Perugia. The Templars could not see the cult of San Bevignate approved as the Congregation of Rites approved the Sanctification only in 1605, despite this they considered him already the first Templars' Saint.

In 1262 the building of the Church was finished and also that of the Romanesque bell tower with square plan. The construction of the former monastery - now used as a private residence - is coeval to the one of the octagonal well, still visible in the garden to present day. In 1312, with the suppression of the Templar Order, the monastery passed to the knights of San Giovanni of Jerusalem and in 1324 Ricco di Corbolo, a merchant of Perugia, bought the architectural complex and established a female monastic community there, likewise placed under the rule of the Order of San Giovanni. In 1517, due to economic problems, the nuns who had dwelt there were forced to leave the monastery which returned to the full possession of the Order of San Giovanni [13]. Since then, the church gradually lost its importance and in 1860, with the suppression of various religious bodies, became the property of the Municipality of Perugia and was deconsecrated. In the last century had various uses, a wood storage, a kennel and even a fire station and such peculiar events permitted to preserve - strikingly - the frescoes because they have been covered by plaster for decades. After a long and rather complex plan of consolidation and restoration in response to the 1997 earthquake, in 2009 the monumental site reopened to the public and the original decorative apparatus have also secured; result of an agreement between the municipality and the superintendence of fine arts of Perugia. In addition, in 2020 another

restoration plan concerning the frescoes of the counter-façade and part of the side walls was also performed, with particular attention to the original tones to the valuable paintings.

3.2 Architectural feature of the Church

The church of San Bevignate is located near the ancient route Spargente that was one of the five royal access road axis to Perugia. Such a distinguished monument of Gothic architecture appears as a architecture of considerable size made of sandstone and with a double sloping façade decorated with a oculus and a single round-arched portal, adorned with a marble frame with symbols typical of the Templars, while another small entrance door crowned with an ogive arch is observable on a side. At the extremity of the façade two mighty buttresses are clearly visible and recall the others located on the perimeter walls. The building ends with a quadrangular apse interrupted by a mullioned window made in travertine. The interior of the single-nave church is divided by two large spans with an ogival cross-vaulted roof and a ribbed cruise that covers the apsidal area, raised above the level of the nave. It is one of the most important documented Templar church in the world, since there is no such cycle of frescoes not even in the Chapelle des templiers de Cressac, a Templar chapel located in southwestern France that shows a valuable cycle of frescoes of reference on this theme. In addition, it is important to stress that the presence in the church of the thirteenth-century frescoes constitute the first iconographic documentation of the motion of the flagellants, also known as the disciplined, founded in Perugia in 1260 by the friar Raniero Fasani. In this same year Bonvicino became interested in the Roman Curia, under the Pope Alessandro IV, for the canonization of San Bevignate, and thus indirectly his name was linked to homonymous mysterious hermit protagonist of the “Lezenda” of Raniero Fasani itself. During the experimental campaign, the thermographic acquisitions, in conjunction with digital photography, were executed on the south wall of the nave since the opposite wall and the apse are in aggregate with other parts of the complex of San Bevignate (not the ideal environmental conditions under which passive thermal imaging must be performed), Figure 3. Furthermore, at the time of the surveys, the entrance wall and other areas were covered by scaffoldings, because there was a restoration. Among the aforementioned valuable mural paintings, the only certainly contemporaneous with the Templar period are actually those of the counter-façade and those above the apse, all the others belong therefore to other Orders. More specifically speaking, the series of the Apostles stands out on the side walls superimposed on the previous decorations, Figure 4. With reference to the counter-façade above the main entrance, is observable an unusual iconographic choice arranged in two registers inherent the efforts of the Templars in defence of the holy sepulchre. Referring to the apse, articulated decorative themes are observable portraying Biblical scenes and representations of Templar symbology and of local religious life (e.g., some flagellants can be seen and two effigies of San Bevignate), Figure 5. Concerning the apse and the decorations of the adjacent spans, geometric bands with the cornflower sign refer to the French origin of the Templar order and the presence of the nine stars surrounding the Templar cross in the fresco above the apse itself describes the nine Templars who founded the Order. At the top of the main wall of the apse the Virgin and Child are represented enthroned surrounded by angels; under the windows, there are the symbols of the four Evangelists and in the centre, immediately behind the altar, the Crucifixion is painted. On the left wall of the Last Supper is represented and on the right wall, which has no openings interruptions, the Universal Judgment is portrayed. In these portions, some flagellants can be seen and this testifies the fact that the monks of San Bevignate did not limit themselves to administering the Templar assets, but they also carried out functions of assistance and apostolate among the local inhabitants. At the end of the nave that leads to the apse, above a pointed arch

and within a complex decorative theme, fragments of the story of a miracle attributed to San Bevignate can be glimpsed, in particular the event in which he revives a child torn to pieces by a wolf. Behind the altar, a portrait of San Bevignate with a halo merits special mention and in this scene, as previously described, he receives the blessing of a bishop who seems to grant him the place in which to erect his church. In conclusion of this section, it behoves to bring up that at the same time as the restoration works following the '97 earthquake, valuable Roman ruins were discovered under the church's floorings. The finds extend for almost the entire width of the nave above and consist in an ancient fullonica characterized by the presence of five basins. The fragment of a mosaic with black and white tesserae, on the other hand, is attributable to a previous Roman domus dating back to around the second half of 1st century BC. To date, this archaeological site which also includes the crypt where was probably buried the Saint, apart from the church, is completely open to the public in a single museum itinerary.

Figure 4: Inner view of the church of San Bevignate (see cone of vision 1 in Figure 3).

Figure 5: Picture of the altar, in background the lower register of the apse's frescoes (see cone of vision 2 in Figure 3).

4 INFLUENCE OF PLASTER THICKNESS

One of the key factors in assessing the correct texture of the masonry is the plaster thickness. In particular, since the plaster is made of a material which is very similar to the one the joints are made of, and it has usually a greater thermal conductivity than the stone, the plaster diffuses the thermal flux as it crosses the plaster, therefore the thermographic image, which measures the temperature differences on the surface of the wall, may not represent in detail the actual texture but could overestimate the presence of the mortar. In order to clarify this aspect, which is crucial in estimating the mechanical properties of the masonry since usually the mortar is the weaker phase, a preliminary study based on a numerical procedure using thermal finite element analysis has been developed. A masonry wall was realized with bricks having width 250 mm and height 55 mm, the thickness of the wall was 120 mm. A running bond texture was used, with mortar joints having thickness 10 mm. Several thickness of plaster were considered, from 5 mm to 15 mm. In Figure 6 the surface temperature read in the outdoor surface of the wall in steady state when the indoor temperature was 20°C and the outdoor temperature was 0°C is shown. The plaster covers only the outdoor surface of the wall.

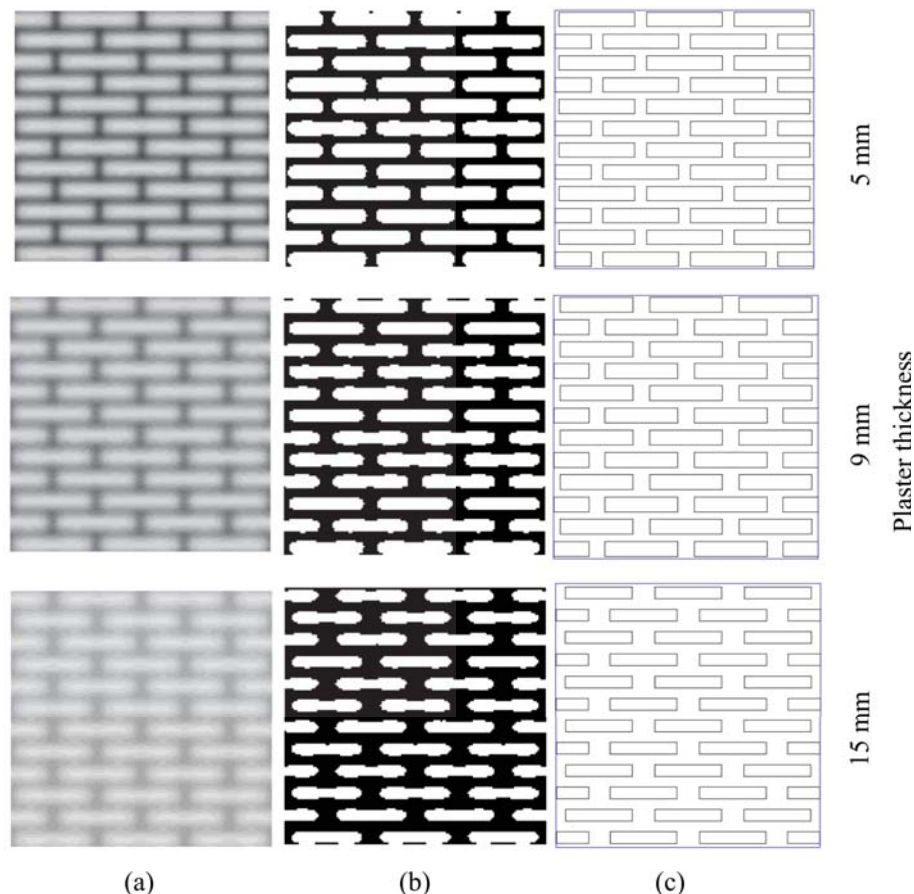

Figure 6: (a) Simulation of thermal image, (b) binary image, (c) equivalent rectangular blocks.

In the same figure, the black and white binary images obtained are shown. In order to simplify the interpretation of the results, the stones were transformed to equivalent rectangular blocks, as shown in the previous figure.

In Figure 7 the concentration ratio of the stone, which is the strong phase, is shown and compared with the reference value.

Figure 7: Concentration ratio of strong phase for various plaster thicknesses.

As can be appreciated, it seems that even small values of plaster thickness lead to a quite large decrement of the percentage estimated for the stones, and therefore further studies are necessary in order to fully assess the influence of plaster thickness when estimating the mechanical characteristics of the wall.

5 EXECUTION OF THE EXPERIMENTAL CAMPAIGN AND DIGITAL IMAGING

New technologies allow to conduct experimental investigations without harming the architectural quality of constructions, such innovations are exactly fitting with the disciplines inherent the heritage architectures [14, 15]. Among the important factors influencing the seismic response of Heritage buildings, the masonry quality and the knowledge of its processes of stratification are certainly enclosed. The acquisition of information about the non-visible masonry texture is the subject of such contribution, under the assumption that the masonry quality is the basic element to analyse and eventually improve, e.g. regarding the preferable monolithic behaviour, before to add any reinforcement intervention (metal tie-rods, mortar injections etc.).

During the actual experimental campaign, the experimental measurements were focused on the north frescoed wall of the nave and the thermographic “pictures” were taken under passive conditions: the inner wall’s surfaces were analysed without heating them, by exploiting direct sunlight and observing the thermal transient on them. This results in different responses from the elements with different thermal capacity, in particular by identifying - as mentioned earlier - with black pixels the mortar and with the white ones the stone elements.

Referring to the frescoes that decorate the examined wall, rows of overlapping ashlar are reproduced to imitate an austere wall face made of stone, this is a typical decoration of the Templar churches aimed to recall the poverty of the holy land. Moreover, the series of the twelve apostles stand out, distributed also on the other side wall, on the façade and the back walls of the apse; such pictorial cycles were superimposed on the original decoration during a second phase between 1283 and 1285. In particular, a first tranche of thermographic surveys covered the mural paintings concerning the apostle’s cycle, Figure 6.

Furthermore, dealing with a real architecture, it was necessary to add to the procedure a new

phase in order to enhance the quality of the final binary image, which is strictly connected to the sharpness of the starting thermographic image. Indeed, compared to what has been above described, an adjust contrast tool has been used aiming to improve the black-to-white mapping of the thermographic greyscale image. In visual perception, the contrast is the difference in luminance of colours that makes the elements of an image clearly distinguishable within the same field of view. In the light of the above, the thermal images recorded during the surveys were preliminarily modified by adjusting contrast so that the differences between black and white were sharp and the highlights looks brighter and the shadows looks darker, with intensity values that fill the entire range of intensities $[0, 255]$. Then, the procedure above described in Section 2, was applied.

6 MASONRY WALL TEXTURE AND PECULIAR CHARACTERISTICS OF THE FRESCOES

The approach was to have first an overview of the masonry texture and its quality and then to proceed gradually more and more closely to the wall's faces. Along with the thermographic images ordinary digital photos have been taken; in addition, reference thermal reflective elements have been placed in front of the frescoes, made by two parallel rigid meter-sticks, in order to be able to overlay subsequently the photos with the corresponding thermographic images in the next phase. Considering that in this first case the meter-sticks were separated by 2.70 m, by means of the procedure and its final binary images, elaborated by straightening photographic and measurements digital techniques, it was possible not only to seize the quality of the masonry texture but also its dimensional features, Figures 9 and 10.

Figure 8: One of the frescoes under investigation, in particular one belonging to the apostle's cycle. 3.

A quasi-periodic texture made of stone blocks with different widths, ranging from 25 to 60 cm, but similar heights, of about 20 cm, has been observed; such results matches with what was surveyed in the apse, concerning the areas where the fresco peeled off (see Figure 5) and on the external façades.

The benefits offered by the thermal imaging methods, regarding the safeguard of frescoes, mural paintings and valuable architectonic elements, have been addressed by numerous authors [17, 18, 19, 20, 16]. In addition, it was possible to contextually ascertain that there are no detachments or infiltration phenomena in place that can afflict the health of the frescoes. Moreover, recalling the historical researches from which emerged that the frescoes of the Apostles was superimposed to the pre-existing ones, the mortar distribution (in those areas) suggests a trace of the ancient techniques of fresco-makers: the surface of the previous fresco had been probably “excavated” by the masons, allowing the new fresh plaster to cling to the ancient mortar below, a less smooth and slippery surface than the one of the wall. Then, the presence of few fragments of mortar out of the joints may show that in order to seat the new murals some holes were made by hands in the previous frescoes and so their orientation does not follow an exact pattern [17]. This, therefore, testifies that the proposed thermographic method, thanks to the possibility to improve the parameters described Section 2, allows to gain information, which must be critically analysed, even about masonries subjected to various superimposed layers of frescoes.

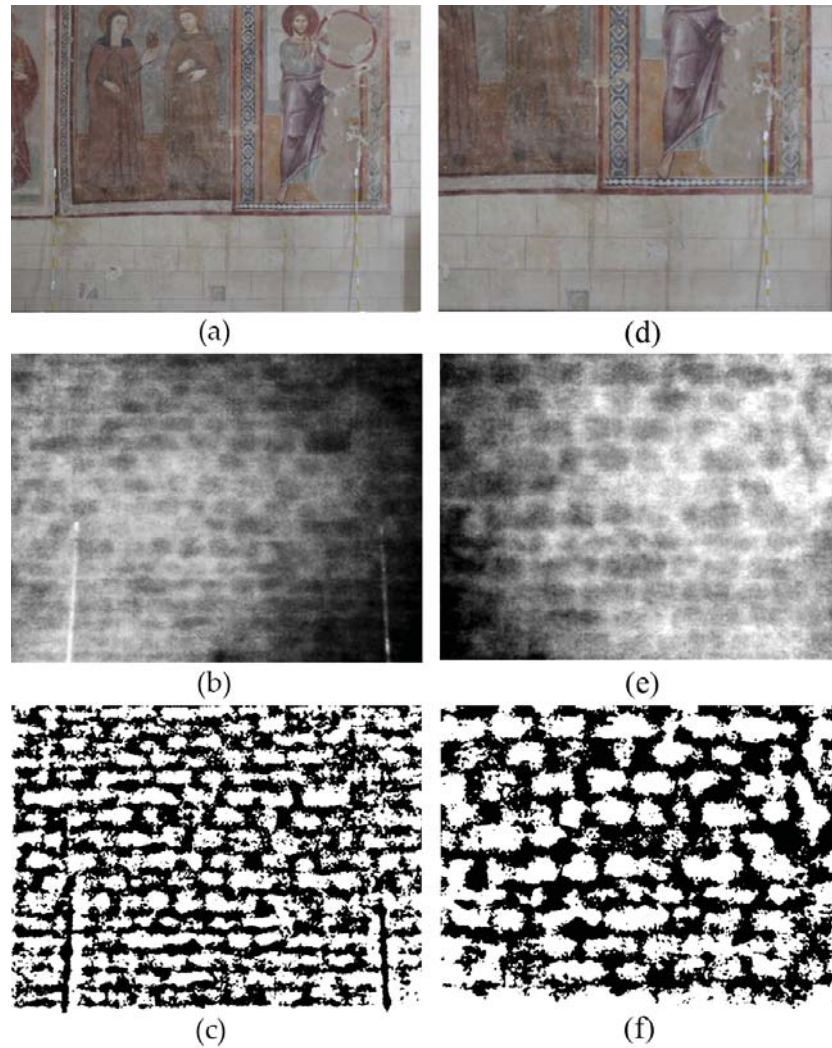

Figure 9: (a) Fresco under investigation. (b) Thermal image with improved contrast. (c) Final binary image (see the cone of vision A in Figure 3). In the right column, a thermal analysis closer to the masonry surface than the previous one: (d) Portion of the fresco under investigation. (e) Thermal image with improved contrast. (f) Final binary image (see the cone of vision B in Figure 3).

7 IDENTIFICATION OF DEFICIENCIES AND DISCONTINUITIES

The role of the latter approach in detection and qualification of deficiencies/discontinuities in the stonework is an important aspect [21, 22, 23, 24]. Through the analysis of another part of the same wall, located near the apse and in the proximity of a window, it was possible to discover the presence of a blind opening in the original masonry, which now is totally bricked up (Figure 10). In this second case the meter-sticks were placed at a distance of about 1.40 m leading to deduce a size of 65×75 cm for the part walled up with a masonry typology different from sandstone. Additionally, there was pointed out the different emissivity and the presence of an architrave made of another material (possibly wood) of about 15 cm thick. Moreover, about the constructive phases and criteria, the peculiar workmanship, and the different material were also observable on the abutments of the window.

Figure 10: (a) Picture of a fresco near the apse. In the pictures, the reflective meter-sticks located as reference points for the subsequent post-processing are visible. (b) Thermal image with improved contrast in which are visible the structural peculiarities of the masonry wall, in the right corner is observable the former recess (see the cones of vision 5 and B in Figure 3). (c) Particular of the fresco under investigation, are observable colours of different gradation. (d) Thermal image with improved contrast. (e) Final binary image (see the cones of visions 6 and C in Figure 3).

Indeed, a toothing masonry has been realized, characterized by the process of leaving alternate stone "teeths" for a better adjoining block or brick wall to be started from. Even nowadays, such technique is used when windows or door openings must be made from an existing wall, by demolition and cutting of masonry, allowing the adjoining wall to develop without having to adjust or cut bricks. It is also noteworthy to notice how, already with the naked eye - can be seen in Figure 10 - portions of the fresco with colours of different gradation are observable, probably due to varied breathability of the materials making up the masonry. This scenario is also confirmed by what emerged from a closer thermographic picture: assuming a stratigraphic interpretation of the wall, arise the construction phases of the ancient site executed by different bricklayers, made by lower rows of a type of stone (which appears darker) probably of superior quality compared to that of the band between the recess and the window where instead the masonry is composed of smaller elements thus making the presence of mortar predominant. Moreover, it is interesting to remark that the filling of the recess does not present any masonry texture as if it had been filled entirely with a concretion material. Finally, a thermographic investigation involved a part of the apse wall. This portion of the church was chosen because here can be found the coexistence of portions of plaster with parts of the masonry emerging, because of the detachments of the fresco that in past centuries were witnessed by the restorers. From the

thermographic images, one of them can be seen in Figure 11, it appears that to date there are no infiltrative nor detachment or disruptive phenomena of interest undermining the safeguard of the decorations under examination.

However, such item will be taken up in the future developments of the research campaign considering also other portions of the church and to a large extent, with reference to the ongoing works of consolidation, profiting from the opportunity to deepen the knowledge about the architecture and frescoes' manufacturing techniques. Moreover, non-destructive testing (NDT) techniques can be used in regard to both evaluation of mechanical properties and for characterization of microstructural features such as grain size, texture, nucleation, defects, deformations, or damages in various contexts, also concerning historical masonries [25, 26, 27]. In particular, the pictures obtained from thermographic surveys can be used to estimate the elastic characteristics of masonry texture, by means of the method of the test-windows [28]; preliminary results are reported in [7].

Figure 11: (a) Portion of the fresco under investigation, (b) thermal image where are highlighted in blue the edges of what remains of the frescoes, (c) thermal image with improved contrast, (d) final binary image (see the cones of vision 7 and D in Figure 3).

8 CONCLUSIONS

- A method to identify and interpret the differences of temperature in wall surfaces was proposed and applied to a heritage architecture of great value; enabling the evaluation of the historical masonry texture covered by rare frescoes;
- The outcomes highlighted the reliability of the devised procedures to identify masonry texture, a necessary information to estimate the masonry mechanical characteristics;
- A preliminary study on the influence of plaster thickness has been made;

- Moreover, the thermographic images have been very useful to detect deficiencies and discontinuities in the wall, besides to find characteristics of the frescoes in terms of realization criteria and actual conservation conditions;
- Without damaging the decorations by taking essays or samples, it was possible to obtain information not only on the risk factors concerning the frescoes conservation but also inherent to the seismic prevention, closely tied to the peculiarities and stratifications of masonry;
- From a future perspective, considering that the results are promising, the thermographic analysis will be extended to other portions of the Church.

Abstract

The majority of the RC building stock in large cities consist of old buildings where most of them were designed with codes without any seismic provisions, thus leading, most likely, to important seismic vulnerabilities. Good knowledge about the building properties and vulnerabilities and, more importantly, on how to model the behaviour of the most relevant components, is fundamental to help analysts and practitioners in the assessment and strengthening of existing RC buildings.

This paper focuses on the numerical modelling of strengthening solutions for RC buildings, with the objective of defining a modelling approach that accurately captures the behaviour of retrofitted elements. To achieve this goal, retrofitted elements are simulated through distributed plasticity models and their seismic performance compared with the most recent experimental data available on this topic.

As a case study, an existing reinforced concrete building with typical properties of non-ductile buildings in Portugal is modelled and analysed through nonlinear static analysis to determine the building structural weaknesses. The retrofitting interventions were designed based on code recommendations.

Keywords: RC structures retrofitting, carbon fibre-reinforced polymer (CFRP), numerical modelling of strengthening solutions, seismic performance improvement.

1 INTRODUCTION

A significant number of existing reinforced concrete (RC) buildings in earthquake-prone locations require seismic retrofitting since the majority of these buildings do not meet the current seismic assessment code requirements. Several deficiencies are commonly found in this type of buildings, such as poor reinforcement details, lack of adequate transverse reinforcement and insufficient confinement reinforcement at potential plastic hinges areas. These characteristics decrease the RC members' strength to shear forces, thus leading to premature brittle failures, as have been observed on field surveys performed in areas affected by earthquakes [1]–[4].

Among the different strengthening techniques, the use of fibre-reinforced polymer (FRP) composites has become progressively suitable due to the fast installation, minimal modification to the existing architecture and satisfactory mechanical properties. Moreover, as a lightweight material, FRP does not modify the cross sectional properties of elements or the structure mass [5]. Accordingly, the seismic performance of RC elements retrofitted with FRP has been the subject of extensive investigation [6]–[13]. The majority of the studies focused on experimental campaigns carried out on RC elements retrofitted with FRP. Nonetheless, the present study will give emphasis to the modelling aspects of such type of intervention.

Since it is acknowledged that vulnerable RC buildings require retrofit, it is crucial for practitioners to have the means for modelling, with accuracy, the behaviour of the existing structures, and, more importantly, to have the tools to correctly model the response of the existing retrofitted structural elements. Therefore, the first part of this paper focuses on the numerical simulation of a RC column using the *OpenSees* [14] software, with the aim of validating the modelling approach with experimental data.

The second part of the study consists of the numerical modelling of a structure representative of the Portuguese building stock in the 1950s, also using *OpenSees*, before and after the retrofitting intervention. The structure's capacity is estimated with nonlinear static analysis and its seismic performance is evaluated through the calculation of the demand/capacity ratios recommended by Part 3 of Eurocode 8 (EC8-3) [15]. The initial assessment indicates brittle and ductile failure modes in some structural elements (columns and walls). A strengthened solution employing CFRP is designed and numerically implemented in the structural model. Afterwards, a new seismic evaluation is carried out and the structure's safety assessed once more. The results demonstrate the feasibility and effectiveness of the CFRP as a strengthening solution to eliminate brittle and ductile mechanisms.

2 MODELLING APPROACH

This section introduces a numerical modelling approach to simulate the behaviour of FRP in RC elements using *OpenSees*, which will be validated through comparison of numerical with experimental data.

2.1 Experimental data

In order to fulfil the goal of accurately representing the real behaviour of retrofitted RC elements with FRP, first it was necessary to select a RC element tested experimentally from the literature. The specimen used in this paper is available in a study performed by Del Zoppo et al. [16] and consists of a RC column tested under axial load and cyclic lateral loading. The column was designed to old construction practice in order to be representative of real existing structures. As such, the specimen is characterized by poor quality concrete, no longitudinal

reinforcement in the cross-section secondary direction and the transverse reinforcement details are not compliant with current standards.

The test specimen has a square cross-section $300 \times 300 \text{ mm}^2$ with six $\phi 18 \text{ mm}$ longitudinal steel rebars and $\phi 8 \text{ mm}$ ties spaced 150 mm apart. In the zone of the load application, the spacing between ties was reduced to avoid localized damages. The column height is 1800 mm , and the lateral load was applied at a distance of 1500 mm from the foundation block. The average concrete compressive strength for the retrofitted specimen is $f_c = 14.9 \text{ MPa}$, whilst the average yielding strength of the steel bars in both longitudinal and transverse reinforcement is $f_y = 531 \text{ MPa}$.

To what concerns the retrofit solution adopted, the column was wrapped with uniaxial carbon fibre reinforced polymers (CFRP) along 500 mm from the column base, which corresponds to the location of the plastic hinge development. The geometric properties and the reinforcement details are illustrated in Figure 1. In addition, **Erro! A origem da referência não foi encontrada.** shows the mechanical properties of the CFRP.

Figure 1: Specimen geometry and strengthening configuration (adapted from [16]).

Material	Number of plies	Thickness (mm)	Elastic modulus (GPa)	Ultimate strain (%)
CFRP	1	0.33	230	1.3

Table 1: Carbon fibres material properties[in Del Zoppo et al. [16]].

Regarding the axial load applied, the specimen was subjected to a constant axial load ratio of 0.1, such that $\nu = N / A_c f_c$, where N is the axial load, A_c is the concrete gross area and f_c is the mean cylindrical concrete strength.

2.2 OpenSees modelling

As mentioned before, the modelling of the specimen was conducted using *OpenSees*, an open-source software framework developed to simulate the behaviour of structures subjected seismic actions. There are two models that can be employed in *OpenSees* to simulate the inelastic response of RC elements: distributed or concentrated plasticity approaches. In this study, the column was modelled through a distributed plasticity approach, using the *nonlinear-BeamColumn* command and considering a force-based formulation with four elements, each with five integrations points.

The element's cross-section was represented by a fibre section, which in turn was subdivided into smaller fibre sections. These fibre objects are associated with uniaxial materials that express the stress-strain relationship of concrete, steel and CFRP. The behaviour of both the cover and core concrete fibres was simulated adopting the model suggested by Popovics [17], (*Concrete04* material in *OpenSees*) whilst the steel was modelled through a uniaxial bilinear hysteretic material object, translated by the command *uniaxialMaterial Hysteretic*. The stress and strain values of the steel rebars were input into this command, which also allows for the consideration of the pinching effect. Finally, the contribution of the CFRP was achieved by adding the effect of the confinement provided by the retrofit intervention.

The effect of the confinement provided by the transverse reinforcement and the CFRP acting simultaneously was determined through the confinement model proposed in Part 3 of Eurocode 8 (EC8-3) [15]. The strength of confined concrete, f_{cc} , the strain at which the strength takes place, ε_{cc} , and the ultimate strain of the extreme fibre of the compression zone, ε_{cu} , are given by the expressions (1), (2) and (3), respectively.

$$f_{cc} = f_c \left[1 + 3.7 \left(\frac{\alpha \rho_{sx} f_{yw}}{f_c} \right)^{0.86} \right] \quad (1)$$

$$\varepsilon_{cc} = \varepsilon_{c2} \left[1 + 5 \left(\frac{f_{cc}}{f_c} - 1 \right) \right] \quad (2)$$

$$\varepsilon_{cu} = 0.004 + 0.5 \frac{\alpha \rho_{sx} f_{yw}}{f_{cc}} \quad (3)$$

In the expressions above, f_c is the concrete compressive strength, f_{yw} is the transverse reinforcement yield strength, α is the confinement effectiveness factor, ρ_{sx} is the ratio of transverse reinforcement and ε_{c2} is the strain at which f_c takes place of unconfined concrete, taken as 0.002. The mechanical properties adopted for all materials are shown in **Erro! A origem da referência não foi encontrada.** The concrete tensile strength was taken as 10% of the compressive strength.

Material		f_c (MPa)	ε_c (%)	ε_{cu} (%)
Concrete (core)	ϕ 8//150	16.7	0.32	1.21
Concrete (core)	ϕ 8//50	21.8	0.67	3.5
		f_y (MPa)	f_u (MPa)	E_s (GPa)
Steel		531	627	210
		f_c (MPa)	ε_c (%)	ε_{cu} (%)
CFRP		24.6	8.4	4.41

Table 2: Mechanical properties of the materials used in the modelling.

The adequacy of this modelling approach was evaluated through comparison of the results from cyclic pushover analysis with the experimental test data. The results obtained are illustrated in Figure 2, where the black dashed line corresponds to the experimental data and the grey cyclic curves refers to the *OpenSees* results. As it can be seen, a good agreement between the experimental data and numerical modelling was achieved, not just in terms global strength but also in what concerns the ability of the model in simulating the pinching effects. These results indicate that this type of approach is adequate to model FRP interventions in existing RC buildings.

Figure 2: Comparison between experimental results and OpenSees.

An example of this FRP modelling approach application into a real existing building is described in the following sections of this paper.

3 CASE STUDY APPLICATION

3.1 Description of the building and structural modelling

The RC building selected is a five-storey wall-frame RC building, built in the 1950s. The building has a total height of 15.4m with a typical floor height of 3.0 m, except for the ground floor, for which the height is equal to 3.4 m. It has three and five frames in X and Y directions, respectively. A shear wall is positioned at the middle of the building, oriented in the X direction, on the first three storeys. The plan and elevation views of the building are shown in Figure 3.

The information about the section geometric properties and reinforcement ratios variation of the building structural elements is presented in **Erro! A origem da referência não foi encontrada.**

Figure 3: Elevation and plan of the selected building.

Element	Columns	Beams	Walls
Dimensions(cm)	23×25–25×87	13×31–25×68	250×25
Cross Section(cm ²)	575–2175	403–1700	6250
Longitudinal rebar (cm ²)	0.63–7.29	T: 2.26–29.76 B: 3.93–33.58	15.78
Transversal rebar (cm ²)	0.18–0.71	1.48	3.15
Spacing of stirrups(cm)	5-19	20–50	15

Table 3: Sectional geometrical properties and minimum/maximum reinforcement ratios of the structural elements (*T* and *B* refer to top and bottom beam reinforcements, respectively).

The building was modelled and analysed with *OpenSees*. All the structural elements were modelled using the *nonlinearBeamColumn* command and considering a force-based formulation considering one element per beam, column and wall. The concrete and steel stress-strain relationships adopted at the fibre level were the ones mentioned in the previous section. The mean values of the material properties used in the model are listed in Table 4. The behaviour of the smooth rebars was modelled by modifying the steel constitutive law, reducing the Young's Modulus and maximum strength of the reinforcing steel to simulate the increase in member flexibility due to strain penetration effects [18].

The torsional stiffness was incorporated in the model by computing the elements torsional stiffness and assigning it through the section aggregator program command, while the rigid in-plane stiffness of the floor slab was modelled considering a rigid diaphragm multi-point constraint, through the program command *rigid diaphragm*. Second-order effects were accounted for in the model by adopting a P-Delta geometric transformation for the columns and wall. The infill panels were also modelled by assuming the two-diagonal truss approach established in [19]. The mass, which was obtained through the conversion of dead and live loads, was lumped at the centre of mass at each floor level. The dead loads include the self-weight of the RC elements, masonry infills and coatings, i.e., 8 kN/m², while the live loads have been defined according to Part-1 of Eurocode 8 [20]. The fundamental periods of vibration of the building are 0.31s and 0.41s in X and Y directions, respectively.

Concrete	f_c (MPa)	ϵ_c (‰)	ϵ_{cu} (‰)	E_c (GPa)
Cover	28	2	4	30
Core	28	2	200	30
Steel	f_y (MPa)	f_u (MPa)	ϵ_{su} (‰)	E_s (GPa)
Ribbed rebar	370	360	240	210
Smooth rebar	222	216	168	126
Masonry	G_w (GPa)	α	τ_{cr}	E_w (GPa)
Infills	1240	0.05	280	4092

f_c -compressive maximum strength; ϵ_c -strain at maximum strength, ϵ_{cu} - concrete ultimate strain, E_c - modulus of elasticity of the concrete; f_y -yielding strength; f_u - ultimate strength; ϵ_{su} - steel ultimate strain; E_s - modulus of elasticity of steel; G_w - elastic shear modulus; α - post- capping degrading branch coefficient; τ_{cr} – shear cracking stress; E_w -modulus of elasticity of the masonry.

Table 4: Material properties

A nonlinear static analysis was performed to evaluate the lateral capacity of the structure. The analysis was performed in both the X and Y directions, with positive and negative signs and, despite the slight asymmetry in the Y direction of the building, no significant differences were observed between the positive and the negative orientations. Two load patterns were considered: i) a modal load pattern, proportional to the fundamental mode of vibration, and ii) a uniform load pattern, proportional to the masses of the floors. Only the results corresponding to the modal pattern were considered since they correspond to a capacity curve with lower resistance and, consequently, more restrictive in terms of performance.

3.2 Seismic assessment

The seismic safety of the buildings was evaluated in terms of the demand/capacity ratio (DCR) for each vertical structural element (columns and walls) following the procedure recommended in EC8-3, which consists of comparing the chord rotation and shear demand with the capacity values of ultimate chord rotation and shear strength. The target displacement was determined with the N2 method, also as prescribed in EC8-3.

As established in EC8-3, the return periods to consider in the assessment of the existing buildings are: 73, 308 and 975 years for the damage limitation (DL), the significant damage (SD) and the near-collapse (NC) limit states, respectively. According to each of the limit states, the reference ground acceleration (a_{gR}) is then multiplied by a coefficient. Only the response spectrum for the Type 1 seismic action (far-field earthquake) was considered, therefore, the a_{gR} is 0.15g (Lisbon, Zone 1.3). The Portuguese Annex of EC8-3 [21] recommends that, for existing residential buildings, the assessment should be performed considering only the significant damage (SD) limit state.

Figure 4 shows the pushover curves obtained for the X and Y directions with the indication of the target displacement attainment at the SD limit state. It can be observed that, in the X direction, brittle and ductile failures occur almost simultaneously before target displacement is reached. In the Y direction, the structure exhibits lower capacity, due to the absence of RC walls oriented in this direction, and also experiences a brittle failure before the target displacement is reached. In conclusion, the brittle failure was the conditioning mechanism for both directions,

corresponding to a displacement of 0.0036 m and 0.0079 m for the X and Y direction, respectively. The occurrence of this type of mechanism at early stages of lateral deformation is common in old RC buildings designed to resist gravity loads, as verified by [22].

Figure 4: Pushover curves for the (a) X and (b) Y direction with the indication of the target displacement and failure mechanisms.

Figure 5 illustrates the location and type of damage experienced by the vertical RC elements when the displacement that corresponds to SD limit state is reached. As it can be seen, in direction X, some elements (columns and wall) are simultaneously affected by brittle and ductile failures on the first two storeys, while Y direction, the elements are only affected by a brittle mechanism on the ground storey.

Figure 5: Location and indication of the type of damage on the vertical RC elements.

The columns C5 and C2, located in level 1, were also included in Figure 5 as “Reaching Brittle Failure” because the value of the demand/capacity ratio (DCR) associated shear failure assessment was remarkably close to the unit, which means these elements were near to develop a brittle mechanism.

4 RETROFITTED BUILDING

4.1 Design and modelling of the retrofitting solution

The initial seismic assessment performed on the case study building indicated the need for improvement of some elements flexural and shear capacities. As stated before, FRP-wrapping is widely recognised as an effective strategy for increasing the deformation and shear capacity of RC elements, without modifying the structure's stiffness [5], [23].

Following the advantages of this strengthening technique, a CFRP retrofitting strategy was developed and applied to the case study building to overcome its poor seismic performance.

The design of the CFRP solution was based on the attainment of the target displacement, for SD limit state, without failure of any vertical member. This means that chord rotation and shear capacities of the elements identified in Figure 5 need to be enhanced. **Erro! A origem da referência não foi encontrada.** shows the actual and required capacity values of chord rotation and shear of those elements.

The determination of the right amount of FRP to comply with the required values of capacity followed an iterative procedure: i) knowing the required capacity that each element needs to reach, an initial strengthening solution is adopted and the new chord rotation and shear capacity of each element is computed; ii) if the capacity values obtained are higher than the values indicated in **Erro! A origem da referência não foi encontrada.**, a solution was achieved and applied to the structural model; iii) a new assessment is carried out. Otherwise, a new tentative strengthening solution needs to be considered and the procedure repeated. The new strengthening solution can be achieved by increasing the thickness of the CFRP sheet, the number of layers or upgrading the chosen FRP material.

Direc- tion	Vertical element	Failure mecha- nism	Actual θ_{SD} [%]	Required θ_{SD} [%]	Actual V_{RD} [kN]	Required V_{RD} [Kn]
X	C ₃ L0_X	Brittle	-	-	33.41	38.1
	C ₃ L1_X	Brittle	-	-	33.0	35.8
	C ₆ L1_X	Brittle	-	-	28.31	30.05
	C ₈ L1_X	Brittle	-	-	88.5	90.2
	W ₁ L1_X	Ductile	1.26	1.33	-	-
Y	C ₂ L0_Y	Brittle	-	-	111.7	128.3
	C ₃ L0_Y	Brittle	-	-	111.7	128.6
	W ₁ L0_Y	Brittle	-	-	78.4	90.7

Table 5: Actual and required capacity values of chord rotation and shear for the damaged elements

From the iterative procedure depicted above, one layer of CFRP (with the properties described in **Erro! A origem da referência não foi encontrada.**) was found to be enough to provide the desired capacity to retrofit the identified structural elements. Since these elements are subjected to a constant shear demand, the CFRP sheets were modelled as uniformly applied through the height of the element [24]. However, due to architectural constraints, the U-shaped or side bonded striped FRPs are, in some cases, the only possible solution. To avoid the fibres premature rupture, the corners of the elements were assumed to be rounded, with a radius of 4 cm and, to improve the shear capacity of the elements, the CFRP sheets were considered to be applied with the fibres aligned along the direction in which enhancement of shear strength is pursued (i.e. horizontal) [25], [26].

Fiber thickness t_f [mm]	Tensile Strength $f_{u,f}$ [MPa]	Tensile Modulus E_f [MPa]	Elongation [%]	Ultimate strain $\varepsilon_{u,f}$
0.128	3450	230000	1.5	0.0015

Table 6: Properties of the CFRP [27]

Regarding the modelling of the retrofitted solution, the contribution of the CFRP was considered through the increase of the confinement of the retrofitted elements. The core and cover materials of these elements were replaced with an equivalent material with the properties calculated by means of Equations (1) and (3). The model of the building remains the same, except for the retrofitted elements.

4.2 Assessment of the retrofitted building

Finished the design and modelling of the retrofitting solution, a new assessment was performed to the structure to evaluate the effectiveness of the adopted solution. A pushover analysis was again carried out to evaluate the lateral capacity of the structure. Figure 6 shows a comparison between the pushover curves obtained before (pre-retrofit) and after (post-retrofit) applying the CFRP. As it can be seen, the application of the CFRP contributed to an increase of the lateral strength of the structure, in both the X and Y directions, without modifying its initial stiffness. However, the structure's capacity improvement is significantly higher in the X direction in comparison with the Y direction. This is due to fact the RC walls, which were strengthened at the first and second storey levels, are oriented in the X direction.

Figure 6: Pushover curves obtained pre and post retrofitting for the (a) X and (b) Y direction.

A safety assessment was also carried out in terms of demand/capacity ratio evaluation (DCR) for each vertical structural element, as established in EC8-3. Figure 7 shows the pushover curves obtained for the X and Y directions with the indication of the target displacement that corresponds to the attainment of the SD limit state. In the X direction, the development of a mechanism, either brittle or ductile, still occurs but only after the target displacement is reached. On the other hand, in the Y direction, the columns' brittle failure is not expected to develop,

and the ductile mechanism occurs for a top displacement much higher than the target displacement. These results confirm the efficiency of the CFRP and its effect in the improvement of the structure's seismic performance.

Figure 7: Pushover curves of the retrofitted structure for the (a) X and (b) Y direction with the indication of the target displacement and failure mechanisms.

5 CONCLUSIONS

This paper focused on the modelling of retrofitting solutions with carbon fibre-reinforced polymers (CFRP) to improve the seismic performance of RC structures. The first part of this research consisted of a proposal of a modelling approach to retrofit RC elements with CFRP. The CFRP was included in the model through the increase of the element's cross-section confinement.

The core and cover materials of retrofitted element were replaced with an equivalent material, whose properties were determined using the confinement model proposed in EC8-3. Afterwards, the modelling approach was validated against experimental data. The results showed a good agreement between the numerical and experimental data, indicating that the modelling approach is adequate to model FRP interventions in existing RC buildings.

The second part of this investigation focused on the application of the proposed modelling approach to an existing RC building. The selected structure corresponds to a residential building built before the introduction of modern codes without appropriate seismic resistance and characterized by (i) low confinement and tie reinforcement in vertical structural elements; (ii) insufficient longitudinal reinforcement in all structural elements; (iii) smooth longitudinal reinforcement rebars; (iv) variation in height of the vertical structural elements section and v) absence of masonry infills at the ground level. Non-linear static analyses were carried out and a seismic evaluation was performed in terms of the demand/capacity ratio (DCR), following the procedure recommended in EC8-3. This assessment exposed brittle and ductile failures in some structural elements. A retrofitting solution employing CFRP was designed and implemented numerically in the structure's model. The comparison between the pre- and post-retrofit pushover curves showed a clear improvement on the buildings' lateral strength, mainly on the X direction due to the retrofitting of the RC walls which control the behaviour of the structure in this direction. Additionally, the seismic safety of the structure, represented by the attainment of the target displacement at SD limit state without the occurrence of any failure mechanism,

highlights the effectiveness not only of the modelling approach but also of the adopted retrofitting solution.

Abstract

The most of the reinforced concrete frame structures of the European building stock have been built without attention to the seismic action or according to obsolete code. Before the 1970's, in all the Mediterranean area, plain rebars were employed for the longitudinal reinforcement of structural members. Due to their smooth surface, they are characterized by poor bond capacity; this results in a significant slip of the loaded bar from the surrounding concrete, which strongly increases the structural deformation capacity compared to modern ribbed rebars. Whereas the cyclic response of non-conforming reinforced concrete members and structural sub-assemblies is deeply investigated in literature, a scarce knowledge about anchored plain bar cyclic behaviour is noticed. In the recent years, detailed non-linear modelling of gravity load designed structures is widely used for the seismic vulnerability assessment; a deep investigation on full scale anchorage detailing is then fundamental for the correct modelling of such structures..

In the present paper an experimental investigation on different anchorage solution of plain rebar embedded in concrete is presented; straight, hook-ended and 45° bent rebar were analysed, monitoring their axial stress versus slip behaviour. A non-linear stress-slip behaviour was observed for all the anchorage solutions since the lower loading level. Stiffness degradation due to cyclic loading was observed; on the other hand, strength decay was visible only for straight anchorage length. Hook-end device and bar bent resulted effective in providing a good anchorage performance, on the other hand their response showed a progressive plasticization.

Keywords: Existing RC Buildings, Plain reinforcement, Bar Slip, Experimental Test, Cyclic behaviour, rebar anchorage.

1 INTRODUCTION

The Reinforced Concrete (RC) structures built from the World War II to the 1970's are significantly vulnerable against the seismic action [1]–[3]. Lack in the structural organization and in the seismic detailing, design according to obsolete codes, and interaction with structural or non-structural stiff elements are the main reasons of not adequate structural response. Moreover, smooth bars were used until the seventies as reinforcement in RC frame members.

The poor bond capacities of plain reinforcement influence the structural response since they are related to significant bar slip from the concrete embedment [4]–[8]. The main mechanisms governing the bond strength are: i) the chemical adhesion between the smooth rebar and the surrounding concrete and ii) the micro-interlocking due to concrete small particles wedging action [9]. These contributions bring to a peak bond strength value, after which the slip triggering causes a progressive degradation of the bond capacity [10]. Micro-interlocking and frictional resource reduce also under cyclic loading, like clearly shown by experimental tests on a short anchorage length [11]. Moreover, beyond the reinforcement yielding, a gradual reduction of the rebar transversal section (due to Poisson effect) causes a further loss of strength [9], [12]. Rebar straight length cannot be enough to guarantee an effective anchorage; end hooked and/or bent bar are so employed to improve the anchorage performance. In this case the bar slip depends also on the plastic deformation related its straightening, which is required for the slip development. Pull-out tests on straight smooth rebars of short anchorage length are available in the literature [11], [13], [14]; however, only one of them [11] investigates the effect of a cyclic loading. A 80cm hollow square cross section bar was also tested under pull-out force [14], showing that bond stress profile significantly varies along the bar length; more in detail, the peak bond strength is shifted inward under the increase of the axial stress.

In the present work an experimental campaign is described, aimed at clarifying some of the cited aspects. Straight long length anchorage, hook-end and bent rebars are considered. Their axial stress-slip behaviour was analysed, both before and beyond the bar yielding. In the following, the experimental campaign is described, with reference to the different specimen geometry and to the adopted loading protocol. The experimental results are then presented and discussed, paying attention to the different performances related to the investigated anchorage arrangement. The analysis of the stress-slip behaviour of smooth rebar is fundamental for the assessment of the deformation capacities of existing RC member in presence of seismic loading. Indeed, previous experimental tests on columns [11], [15]–[17], beams [18], and beam-column joints [4], [5], [8], [19] showed the great influence of plain reinforcement slip in the definition of the crack pattern and in ensuring a significant flexural deformation capacity. The same results can be also useful for the definition and the validation of analytical or numerical modelling which explicitly account for the bar slip phenomenon.

2 DESCRIPTION OF THE SPECIMENS

The reference specimens are schematized in Figure 1. For testing convenience, they are organized so as one or two anchored rebars are embedded in a concrete block; when two bars are placed in the same block, they were tested separately and they were casted at sufficient distance to avoid interference between the two tests. The same choice also allows to investigate different bond conditions effects; indeed, it is possible to qualitatively consider the lower and the upper bar as being in good and bad bond condition, respectively. No transversal reinforcement is provided since possible brittle failures were not expected, due to the adopted geometry.

A straight rebar, with no end specific detailing, characterizes the so-called SL specimens. They are designed to allow the investigation of the bond performance over a significant rebar length, on which it is expected a non-constant bond stress distribution. A total number of four

specimens were casted; two of them are instrumented with three couples of strain-gauge, with the aim of measuring the axial stress on the embedded length. A reduced adherent length is thus guaranteed in this case, due to the introduction of a local cage to protect the strain gauges around the bar at the gauge location. The specific anchorage type is representative of the bar embedment into column or beam lengths. The hook-end specimens (H type) are representative of the T-column-beam joint reinforcement anchorage and of columns rebar anchorage at any cold joint. Four out of six hook-ended bar specimens are characterized by adherent straight length (prior to the hook device); in the other two, bond in the same length is prevented a plastic pipe surrounding the bar. Finally, 45° bent rebars (B type) were tested; they were frequently used in construction practice for the beam reinforcement over the supports. To monitor the axial stress along the rebar length, two bent bars (casted in the same concrete block) are instrumented with two couple of strain gauges, respectively placed at mid-way of the inclined length and in the last straight length; a steel plate is welded on the bar end, to allow the stress reading by the end gauges couple.

2.1 Geometry

12mm diameter reinforcing bars are considered; a minimum concrete cover of 100mm and a bar distance of 250mm or 450mm are guaranteed (respectively for the H and B types). SL samples are made by a concrete block with 200mm square cross section and a length of 1000mm, in which a single bar is embedded; two out of four specimens (called SL3 and SL4 in the following) are characterized by a lower 760mm embedded length, due to strain gauges application along the rebar length (Figure 3). The H sample bar geometry is referred to the Italian Code indications [20]. A 40 diameter (480mm) straight length precedes the hook device, which is characterized by an inner bending of 5 diameters (60mm) amplitude and a 3 diameters (36mm) final straight length. The four bars with embedded straight length are called H1 and H2, the other two H3. The B specimens are characterized by a 120mm long embedded straight lengths at the bar ends; their axes distance 450mm in the vertical direction, the 45° inclined length is thus 537mm long. The inner radius of the bending is equal to 10 diameters (120mm). The two instrumented rebars are called B2.

2.2 Load frame

The self-balanced steel frame schematized in Figure 2 is used to impose the bar slip. A 3.5mm thread loading screw of 32mm diameter allows a continuous refined control of the displacement imposition. Both tensile and compressive load can be applied to the rebar, thanks to the reaction guaranteed by two steel pates; one is in contact with the concrete block head, the other one on the opposite concrete block end. These reaction plates are connected by four threaded bars, lightly prestressed to avoid relative movements.

The smooth rebar sample is anchored to the frame by means of a mechanical joint made of an hollow cylinder in which three high hardness steel screws punch the rebar surface. The rebar head-joint is fixed to a load cell; the latter is then connected by a torsion-free joint to the loading screw. The frame weight and loading torque are transmitted by the steel plates on external supports.

Figure 1 Geometry of the tested specimens.

2.3 Materials

Hot rolled reinforcing steel of grade S275 JR is considered [21]. Yielding, f_y , and failure, f_u , stress were investigated by a tensile test according to [22]; they were significantly different for the straight length (SL samples) bars and for the shaped (H and B samples) ones. Also the total elongation on a 10-diameter reference length across the failure section ΔL is defined.

The reference concrete mix design was the same for all the samples. Since they were casted in different times, the average compressive strength, f_c , and the elastic modulus, E_c , are defined

for each specimen type. The results are reported in Table 1 in terms of mean values; they are representative of the properties of the material employed in the reference RC frame construction.

Sample type	Steel			Concrete	
	f_y [MPa]	f_u [MPa]	ΔL	f_c [MPa]	E_c [MPa]
SL	442	535	13.70	24.71	25490
H	361	519	20.16	19.53	22810
B	363	520	18.98	22.52	25175

Table 1 Mean values of the mechanical properties of the employed materials.

3 INSTRUMENTATION AND LOADING PROTOCOL

3.1 Instrumentation

Load and displacement transducers are used to measure the bar axial stress-slip behaviour. Three different LVDTs are concentrically placed around the rebar head; they measure the displacement between the load frame head joint and the concrete block. A supplemental LVDT monitored the slip of the bar tail in SL specimens. The load cell is placed in the load frame, as it is schematized in Figure 2.

Strain-gauges are used to measure the axial strain along the rebar embedded length. An 80mm length is deactivated around the extensometer, to protect the gauges and avoid bond interference; the simplified representation of the arrangement is shown in Figure 3. On straight bars (SL3 and SL4) they are placed with a spacing of 250mm, therefore three different cross section are monitored. On bent rebars they are placed at midway of the inclined length and in the straight tail end. In this case, a mechanical anchorage is guaranteed after the last gauges, to allow a stress reading; indeed, no embedded length is present beyond the gauge deactivated length.

Figure 3 Detailing of the strain gauge isolation from the surrounding concrete.

3.2 Loading protocol

The straight rebars are tested in slip control during all the test. On the other hand, the shaped bars are load-controlled below the yielding point and slip-controlled beyond it. A summary of the reference loading protocol is visible in Figure 4.

The unloading phase was always characterized by the recovering of all the imposed slip; thus, also compressive loads were imposed to the rebar. For the H specimens in which the straight length was not adherent to the concrete, the unloading is stopped at the null force point since the application of compression to the rebar triggered its buckling.

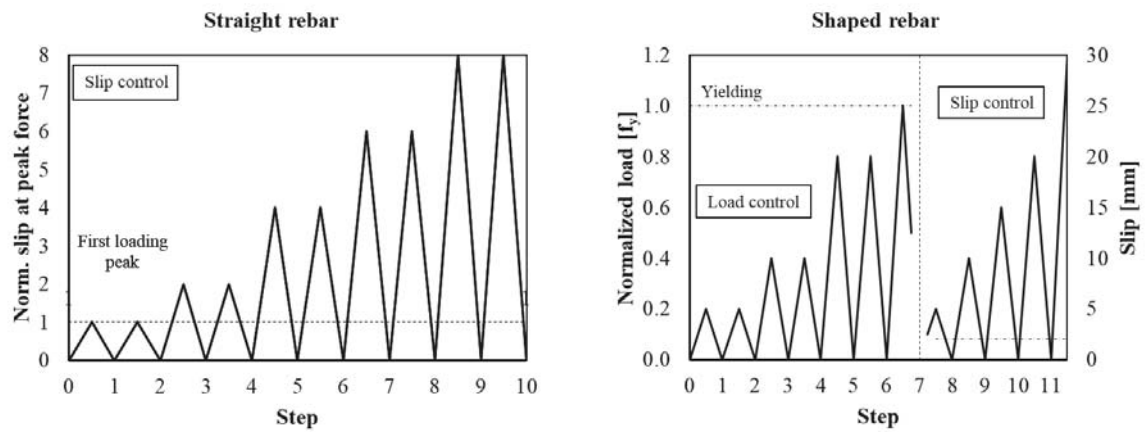

Figure 4 Loading protocol schematization for straight and shaped rebars.

4 EXPERIMENTAL RESULTS

4.1 Straight bar

The experimental results of the four tested rebars are divided according to the total embedded length (Figure 5). SL1 and SL2 samples are adherent to concrete along all the specimen length (1000mm); on the other hand, SL3 and SL4 samples are embedded for 760mm, due to strain gauge application along their length. The former showed the capacity in anchoring the bar yielding, whereas the latter showed a strength decay at a force lower than yielding. Nevertheless, the strength degradation is observed after the triggering of the bar tail slip in both the case. After the reach of the peak force, the cyclic behaviour is controlled by a lower strength. A reloading force can be observed exploring new slip of larger amplitude; cycling at a target deformation level, a residual lower strength is instead noticed. Subsequent cycles and slip amplitude within the range previously explored seemed not to influence the reference strength capacities.

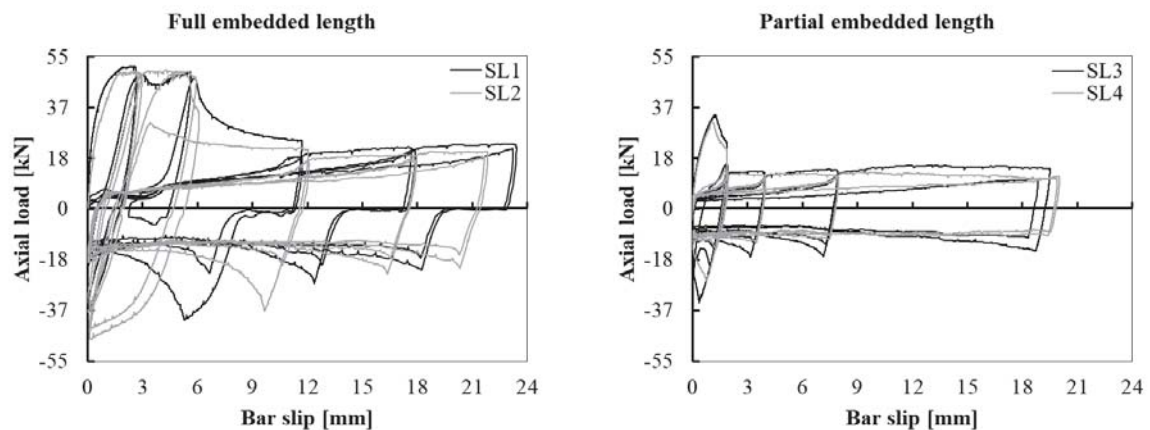

Figure 5 Stress-slip behaviour of the SL-type specimens: full and partial embedded length samples response.

4.2 Hook-end bar

In the following the bottom bars of the H specimens are qualitatively identified as being in good bond condition, whereas the top ones are considered in bad bond conditions. In Figure 6 the response of two different concrete specimens (H1 and H2) is represented up to the reach of

the bar yielding. A non-linear elastic loading branch was followed by a plastic plateau. The cyclic behaviour was characterized by a linear force-slip relationship, stiffer for the unloading and secant during the reloading (oriented to the maximum explored slip point at the previous cycle). Significant difference in the elastic stiffness is noticed with respect to the identified bond conditions. The unloading stiffness is not influenced in subsequent cycles and by the explored drift level; it is higher than the secant value at the yielding point. Good anchoring performance was observed also in presence of compressive loads; moreover, a less stiff behaviour is noticed at the load reversal.

In presence of unbonded straight length (H3 specimens), the behaviour was similar (Figure 7); however, a less stiff loading can be observed. In this case the bond conditions seemed not to affect the force-slip relationship. It is possible to conclude that the hook device alone can provide the bar anchorage; it is effective also in ensuring the bar overstrength (hardening behaviour). This is clearly visible in Figure 7, where the complete response of the upper bar of the concrete block H3 is represented up to a slip magnitude of 45mm.

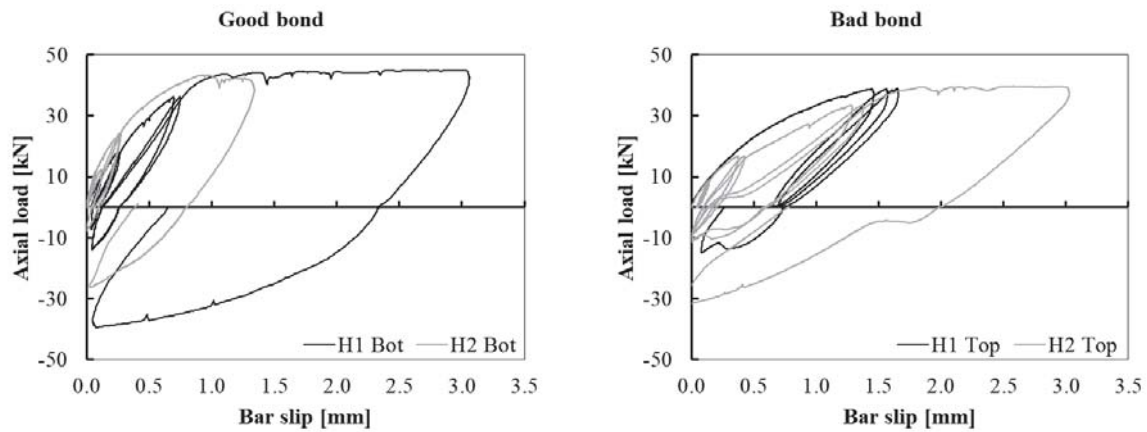

Figure 6 Experimental response of H1 and H2 samples: lower (good bond) and upper (bad bond) tested rebar responses.

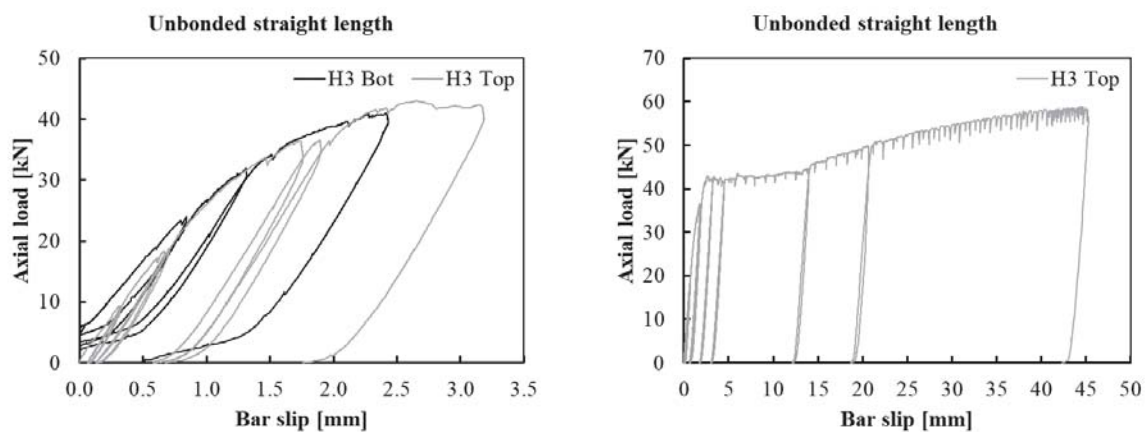

Figure 7 Cyclic response of H3 sample rebars: focus on the elastic cycles and complete response of the upper bar.

4.3 Bent rebar

Since the B type rebars cross the concrete block from top to bottom, and vice versa, in the following good or bad bond conditions refer to the bar head position (end on which the load was applied). The response of the bent rebars (Figure 8) was very close to the one of the hook-ended bars, especially in good bond conditions. The cycles in the range of the elastic stress were enveloped by a non-linear stress-slip relationship, after which a plastic plateau took place. The bending of the rebar ensures the anchorage of the bar up to yielding stress, and more, including overstrength (the graphs of Figure 8 are cut at the cycles of yielding). Only the instrumented bar (B2 sample) showed difference stress-slip response before yielding (bad bond condition); indeed it was more deformable.

The bars in bad bond conditions showed an increasing stiffness gradient (concave stress-slip curve) before yielding. This behaviour was associated with an initial sliding of the rebar, which was confirmed by a strain reading in both the strain gauge placed on the instrumented rebar in bad bond condition.

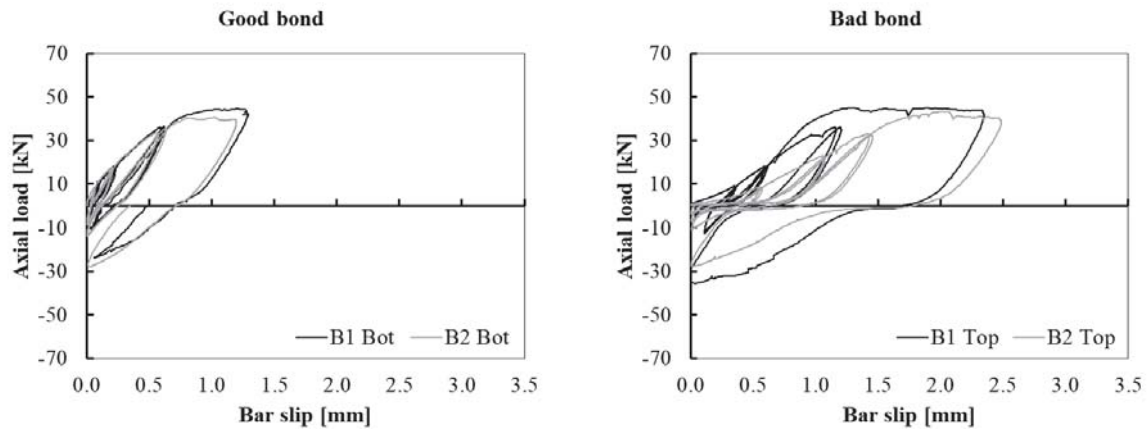

Figure 8 Stress-slip behaviour of bent rebars under cyclic loading up to the yielding point.

5 RESULTS COMPARISON

5.1 Straight length anchorage

To evaluate the anchorage performance of a straight bar, an average constant bond stress distribution along the rebar embedded length is considered, as suggested in literature. With reference to experimental measure of i) peak, ii) reloading, and iii) residual forces, the calculated bond capacities are reported in Table 2.

To help the comparison of the experimental evidences with literature available models, a normalization of the bond strength τ_b over the concrete compressive strength is taken:

$$\tau_b = C\sqrt{f_c} \quad (1)$$

with C non dimensional coefficient and f_c mean cylindrical concrete compressive strength. The values reported in Table 2 are lower with respect to the literature available model in term of peak force [11]–[13], [15]. On the other hand, the reloading and residual capacities well match with the available indications [11], [15].

Sample	Peak strength		Reloading strength		Residual strength	
	Force [kN]	Bond [MPa]	Force [kN]	Bond [MPa]	Force [kN]	Bond [MPa]
SL1	51	1.36	22	0.58	12	0.32
SL2	50	1.33	19	0.50	12	0.32
SL3	34	1.18	15	0.52	6	0.28
SL4	31	1.09	12	0.42	8	0.21
Mean	Bond [kN]	1.24	Bond [kN]	0.51	Bond [kN]	0.28
	C	0.25	C	0.10	C	0.06

Table 2 Estimation of the anchorage capacity along a straight rebar in hypothesis of constant bond stress.

5.2 Shaped anchorage

The difference in stiffness between the response of bars anchored in good or bad bond conditions is clearly visible by the observation of the graphs in Figure 9. The cyclic response below the yielding point is plot for all the shaped anchored rebars tested; it makes exception the H3 block bars, whose response was not affected by bond conditions. The stiffer behaviour showed the reach of the bar yielding at a slip level lower than 0.75mm; on the other hand, the less stiff response showed the yielding reach at a slip magnitude of about 1.50mm. Therefore, two different values of the secant stiffness at yielding can be attributed to the bars in good bond conditions. Moreover, the response in good bond conditions is very similar both for hooked or bent shape. On the other hand, in bad bond conditions the stress-slip relationships of the different anchorage solutions is strong; nevertheless, the secant stiffness at yielding is similar.

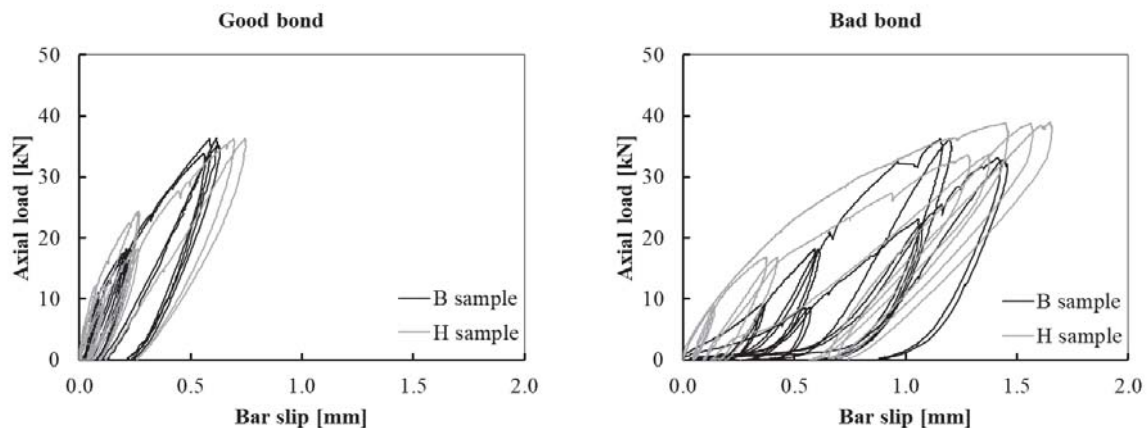

Figure 9 Focus on the elastic response of hooked (grey lines) and bent (black lines) rebars.

6 CONCLUSIONS

The experimental cyclic response of different anchorage solutions for smooth rebar is herein investigated. Long straight anchorage length, hook-end device, and bar bent were tested in presence of both tensile and compressive loads. The response, in term of force versus slip relationship, was monitored and it is herein discussed.

The straight length anchorage gave equilibrium to different applied force values, depending on its overall embedded length; in presence of the lower anchorage length (760mm) a peak strength about the 60% of the bar yielding stress was reached. In all the cases, at the triggering of the last embedded section slip, a force degradation was observed. Exploring higher slip level, a reloading bond strength can be defined, while cycling in the same slip range (of previously explored cycles) a lower residual strength was observed. Hook-end device and bar bent were

effective in ensuring the bar yielding and overstrength force. No force degradation was observed, and the response was stable, also at the highest slip imposition. The position of the shaped rebar with respect to the concrete block sample significantly influenced the stiffness of the response; the lower (good bond condition) bars reached the yielding point at slip level lower than 0.75mm, the top ones (bad bond condition) at a value of deformation twice. The unloading of the shaped anchorages showed a residual plastic deformation, also cycling at stress values lower than the yielding one. Since a straightening is required for the bar pullout under tensile force, plastic deformations are expected in the hook (or bending) length; moreover, the same straightening causes high local stress in the surrounding concrete. The different concrete porosity can affect the anchorage slip development, justifying the difference herein presented between the anchorage response in good or bad bond conditions. This aspect will be considered in future studies.

ACKNOWLEDGEMENT

The experimental campaign presented in this work has been supported within the framework of DPC/ReLUI project 2019-2021, WP5.

Abstract

The masonry infill walls are widely spread over the reinforced concrete buildings due to different demands. The buildings' thermal energy efficiency is a top priority nowadays since many of the existing building stock comprises buildings with low energy performance. The buildings' external envelope is suffering a transformation with the appearance of the vertical hollow concrete blocks with high thermal and acoustic demands. However, recent evidence from a strong earthquake shows that the masonry infill walls are vulnerable to out-of-plane loadings and were responsible for many casualties, injuries, and economic losses. Based on that, this work's main objective is to study the out-of-plane (OOP) behaviour of masonry infills made with vertical hollow concrete blocks. The experimental campaign comprises the OOP testing of three full-scale infill walls made up of these masonry units. One of them was as-built without previous damage, one with previous damage due to an earlier in-plane test and the third one retrofitted. All the tests consisted of applying the loading-unloading-reloading history of imposed displacements in the OOP direction through a uniformly distributed load. The results will be presented in terms of OOP force-displacement responses, deformed shapes, damage evolution, energy dissipation capacity and damping. Finally, the test results are compared to each other to assess the previous damage and the retrofit technique's effectiveness.

Keywords: Masonry infill walls, Out-of-plane behaviour, lightweight concrete blocks, Experimental testing.

1 INTRODUCTION

Masonry infill walls are widely spread over the reinforced concrete (RC) building structures. Different masonry units were developed over the years to be used to construct the RC buildings envelopes. Their geometric, thermal and acoustic characteristics followed the building code demands, neglecting the vulnerability's assessment under out-of-plane (OOP) seismic loadings. At the beginning of 1950, hollow clay horizontal bricks with different thicknesses (70mm, 110mm, 150mm and 220mm) and at the 2000 decade, clay and concrete vertical thermal blocks were developed. Their acoustic and thermal characteristics were improved to be used in the buildings façade. However, experimental studies on the seismic behaviour of lightweight concrete blocks are very scarce.

Different investigations were carried out concerning the OOP behaviour of masonry infill walls [1, 2], from which it was concluded that the OOP strength reduces with the increasing of the panel slenderness [3, 4]. Ricci, et al. [4] performed a series of OOP tests assessing the effect of the walls slenderness in their OOP behaviour. Before the OOP tests, the walls were subjected to different IP damage levels (Low – 0.30%; Medium – 0.60% and High – 1%). Hollow clay horizontal units were used to construct the scaled walls with slenderness equal to 22.9 and 15.2. It was observed during the tests a more significant decrease of the OOP maximum strength and initial stiffness for the thinner panels.

De Risi, et al. [5] carried out a testing campaign to study the effect of the panel aspect ratio (1.28 and 1) in their OOP response. The authors found that square and rectangular infills have very different damage states. For examples, the rectangular walls showed more damage than square ones. For panels previously subjected to low IP drift (0.30%), the square panel exhibited a strength reduction of 24%, while the rectangular panel reduced by about 52%.

Based on this motivation, this research work's primary goal was to study the OOP behaviour of full-scale masonry infill walls made with lightweight concrete blocks. An experimental campaign was carried out comprising three full-scale specimens. The first specimen was tested without previous damage and without strengthening. The second specimen was tested with prior damage caused by a previous IP test with a maximum drift of 0.3% without strengthening. The third wall was tested without previous damage, but it was strengthened with a TRM based solution. All the tests have been performed by imposing a half-cyclic (loading-unloading-reloading) history of displacements in the OOP direction employing a uniform distributed load provided by small pneumatic jacks. The results will be presented in terms of damage evolution and OOP force-displacement responses.

2 DESCRIPTION OF THE TESTING CAMPAIGN

2.1 Specimens characteristics

A full-scale RC frame was built in a laboratory 4.80m long and 3.30m high and was designed according to Eurocode 8 – Part 1 [6] for medium ductility class. The columns dimensions are 0.30x0.30m² with longitudinal reinforcement 4ø16+2ø12 and transversal reinforcement equal ø8//0.05m along the plastic hinge regions and ø8//0.15m in the remaining extension of the column. Regarding the beam cross-section detailing, it was defined to be 0.30x0.50m² with symmetrical longitudinal reinforcement of 5ø16+5ø16 and transversal reinforcement of ø8//0.10m along the plastic hinge length and ø8//0.20m in the remaining beam extension. The dimensions and detailing of the frame are presented in Figure 1.

Figure 1 – RC frame dimensions and detailing.

The masonry infill walls were constructed with vertical hollow concrete blocks. These light lightweight concrete blocks (Figure 2) of expanded clay aggregates have the nominal dimensions of $400 \times 190 \times 315 \text{ mm}^3$. The thermal transmission coefficient (U) is $0.51 \text{ W/m}^2\text{°C}$ and were specially designed for simple exterior walls or in contact with unheated areas. It can also be used in partitions between fires, stairwells and elevators. Vertical compressive strength tests were carried out in masonry units according to the standard EN 772-1 [7].

Figure 2 – Detail of the masonry unit: a) general overview; and b) geometric details (units in millimetres).

All the panels have the same geometrical dimensions, boundary conditions and materials. The construction of each wall started with the placement of a continuous layer of mortar over the entire width of the previously humidified frame. The blocks were then placed and positioned. The masonry infill walls were aligned with the external surface of the RC frame. Due to that, a short portion of the masonry infill walls remained 15 mm from the frame's back face (the thickness of the block is 315mm, and the beam width is 300mm). Discontinuous bed joints

approximately 15 mm thick were placed using a mortar box provided by the supplier. This procedure was repeated until it was impossible to fit another row of blocks, leaving about 130 mm between the panel and the lower face of the RC frame's upper beam to be filled. It was decided to close the masonry panel two or three days after its construction to guarantee stabilization in the deformation of the wall during the mortar curing, ensuring the sealing between the upper face of the masonry and the upper beam of the frame. An M5 class mortar was used to build the masonry infill walls. Vertical bed joints with 10mm thickness were assumed between the concrete masonry units.

As mentioned before, the specimens LWC_Ref and LWC_IPOOP were built with the same characteristics. The third wall LWC_S was strengthened with TRM. The reinforcing mesh was applied only on one side of the wall. The strengthening consisted of using a glass fibre textile mesh with a matrix of 4x4cm and a tensile strength equal to 70kN/m². The construction process started with the first layer of plaster (0.5cm thick) over the whole panel and 12cm in length and the RC elements. For this plaster, it was used an M10 mortar. After that, the textile mesh was placed and fixed to the panel using plastic connectors. These connectors were set all over the wall with a geometry defined in Figure 6. Also, the mesh was anchored to the RC elements using thin steel plates and steel connectors M8. According to the supplier recommendations, a textile mesh overlapping with a total length of 100mm was used. The interface wall-RC frame was used to layers of stripes with a full extension in the columns and beams of 170mm and the panel of 400mm, in agreement with the standard ACI 549 4R recommendations. After applying the textile mesh, a second layer of mortar (1cm) was applied. The schematic layout of the LWC_S strengthening is presented in Figure 3

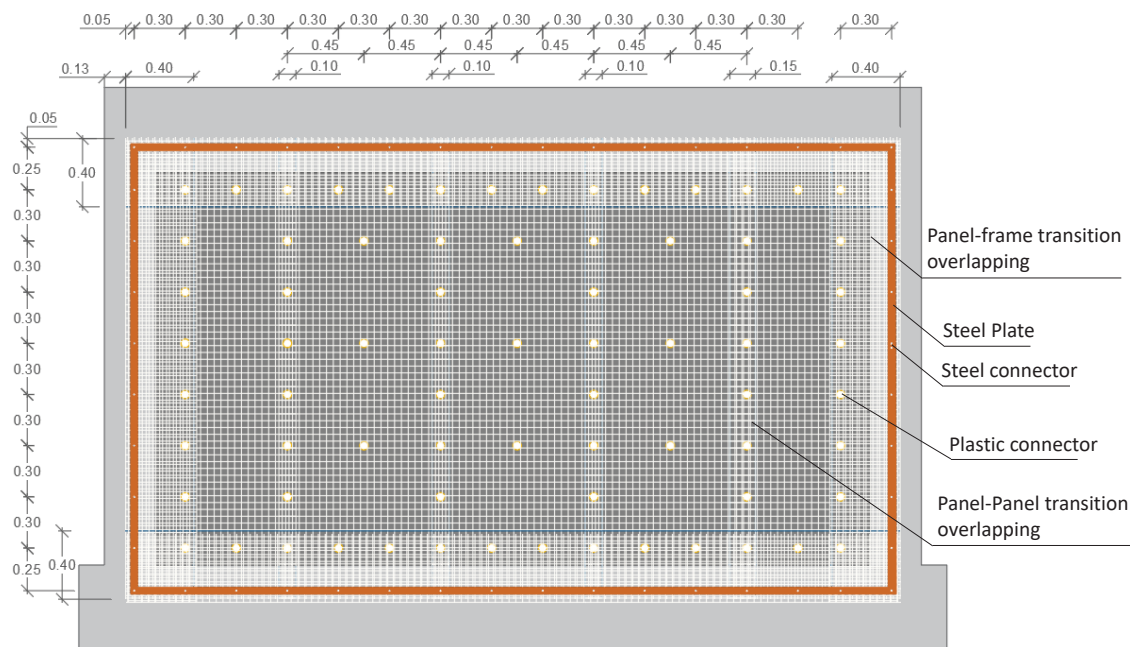

Figure 3 – Schematic layout of the strengthening solution of the wall LWC_S.

2.2 Description of the in-plane and out-of-plane test setup

The quasi-static IP cyclic test consisted of applying a horizontal force at half the height of the RC frame's upper beam through a hydraulic actuator with a capacity of approximately 500 kN and +/-150 mm travel. The hydraulic actuator is connected to a steel reaction structure. The

horizontal force transmission to ensure full-cycle tests were performed using two steel profiles positioned on the top beam's extremities linked together through four dywidag pre-stressed bars ($\phi 27$ mm), resulting in a beam compression of about 170 kN. The quasi-static cyclic test schematic layout is shown in Figure 4. A steel structure was used at the back of the RC frame, linked in two points of the frame top beam. The primary goal was to avoid OOP displacement or rotation of the structure during the test. The frame's base IP and OOP displacement were restricted using a steel profile attached to the strong slab.

The IP drift ratio was computed using the displacement of the top beam-column joint divided by the distance between the bottom and top beam-column joints. The IP displacement of the bottom beam-column joint is subtracted from the displacement of the top beam-column joint to avoid possible frame sliding effect.

The quasi-static IP cyclic loading consisted of applying a horizontal load at half-height of the RC frame upper beam, in the form of target displacements until a drift of 0.3%. Each cycle started with an increase in loading until reaching the target displacement and after unloading the inverse target, displacement was applied, ending after unloading. Three target displacements 2.8, 5.6 and 8.4 mm were imposed, corresponding to 0.1%, 0.2% and 0.3% drift, respectively, with three repetition cycles for each target displacement, totalling nine complete cycles.

Figure 4 – Schematic layout of the IP test setup.

The OOP test consisted of applying a distributed OOP loading through twenty-eight pneumatic actuators that mobilize the entire infill panel surface resorting to wood plates (one per actuator) placed between the actuators and the panel. The maximum strength capacity of each pneumatic actuator is 20kN and a total displacement amplitude of 185mm. The system has a full-strength ability to apply a distributed load of 560kN. This testing platform can test infill panels with openings (with different configurations and dimensions). This test setup also allowed placing the instrumentation in the back of the reaction structure, which helps to perform OOP tests until the panel collapse without damaging any equipment. Identifying the panels' cracking throughout the OOP tests becomes easier as the quality of the pictures and films recording of each test improved significantly. A self-equilibrated system was used, which balances the transmission of the OOP loadings to the reaction frame attached to the RC frame. Thus, this test setup uses pneumatic jacks linked to four horizontal alignments performed by HEB140 steel profiles, which react against five vertical alignments made of

HEB200 steel profiles. The horizontal alignments are coupled with hinged devices that allow lateral sliding. The steel structure is attached to the RC frame in twelve points (5 in the bottom beam, 5 in the top beam, and 2 in middle-height columns) with steel bars coupled with load cells to monitor the OOP loadings. Figure 5a and Figure 5b present the schematic layout and the general view of the test setup. The pneumatic actuators applied the OOP loading, and the test control is ensured by monitoring their internal pressure and the imposed OOP displacements in a selected control point.

Figure 5 – Layout of the OOP test setup using pneumatic actuators: a) front and b) near view.

The loading protocol is based on the protocol used in the previous tests [8] and consisted of the application of several half-cyclic OOP displacements (loading-unloading-reloading) that were imposed with steadily increasing displacement levels, targeting the following nominal peak displacements at the control node located in the centre of the panel: 0.5, 1, 1.5, 2, 2.5, 3.5; 5; 7.5; 10 mm; and then 5 by 5 mm up to a maximum OOP displacement of 120 mm (largest capacity of the pneumatic actuators). Two half-cycles were repeated for each lateral deformation demand level. No axial load was applied on the top of the adjacent RC columns.

3 DISCUSSION OF THE EXPERIMENTAL RESULTS

3.1 Individual results

3.1.1. Specimen LWC_Ref

The undamaged and no-strengthened specimen LWC_Ref was tested under OOP loadings and reached the first cracking for a $DR_{OOP,crack}$ of 0.29% and a corresponding force equal to 76.75kN. The cracking was located at the panel centre and is horizontal with a full-length extension of 2m. The initial stiffness was estimated at 24024kN/m. After that, diagonal cracking emerged from the horizontal first one to both bottom corners of the panel. A vertical crack was also visible at the panel middle length, from the horizontal first crack to the panel's top. This cracking configuration is similar to trilinear cracking, which typically corresponds to a wall with three borders constrained, and the top boundary is unrestricted or less restricted. This phenomenon is justified by the quality and type of construction of the wall last row (top beam-panel interface), which was mortared. Similar observations were reported in the literature by other authors [8, 9].

At this stage, the specimen reached the maximum peak load of about 229.6kN for a $DR_{OOP,max}$ equal to 4.19%. When compared with the first cracking stage, it is possible to observe that the peak load and the OOP drift are 3 and 14.4 times higher, respectively. Afterwards, the panel reduced its OOP strength slightly until reaching the OOP drift of 6% in which occurred a large detachment of the panel from the top beam and a slight separation from the bottom

beam. New oblique cracks appeared. Horizontal and vertical cracks became thicker and crack developed at the bottom panel-frame interface, presenting a crack pattern maintained until the end of the test. Upon reaching the $DR_{OOP,ult}$ of 7.63% with a residual strength of 149.2kN. The panel exhibited an increase of detachment concerning the upper and lower beams of the frame and presented new vertical cracks in the panel's centre. Based on the measurements made by the vertical displacement located at the top of the frame structure and based on this cracking pattern, it can be concluded that the arching mechanism controlled the response of the wall. Two-way bending occurred similarly to a panel three borders constrained. The top panel-frame interface was not fully mortared due to difficulties in the wall constructions, which is quite common in constructing infill walls, as observed in previous research works [5, 8, 10]. Finally, it can be stated that the conventional rupture occurred for an OOP drift of 6.94%. The force-displacement curve is presented in Figure 6a. The damages observed at the end of the test are shown in Figure 6b.

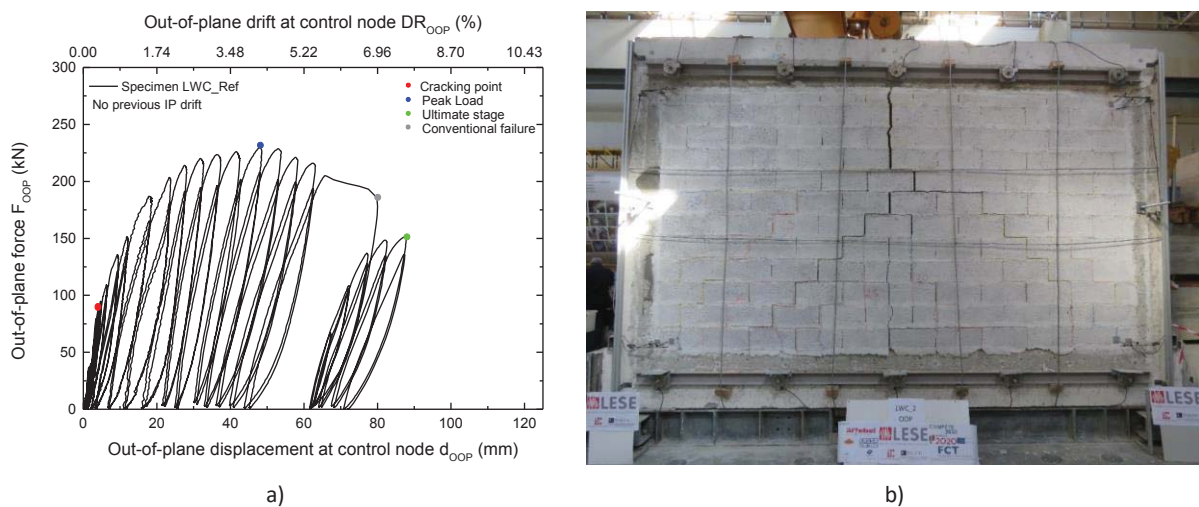

Figure 6 – Specimen LWC_Ref: a) Force-displacement curve; Damages observed at the end of test and b) Front view.

3.1.2. Specimen LWC_IPOOP

The out-of-plane load was applied after the in-plane test, in agreement with the protocol described before. From the test, it was observed that the first crack occurred for a $DR_{OOP,crack}$ equal to 0.71% and a corresponding force of 204.4kN. The first crack appeared horizontally, followed by two oblique cracks up to the panel's lower corners. The initial panel stiffness was 60427kN/m. After that, the peak load was reached for a value equal to 246.06kN and a corresponding drift of 1.39%. A vertical crack appeared at the top of the panel, and horizontal cracks develop in this stage. The OOP strength remains almost constant until 2.3%, when it started to reduce progressively. The conventional rupture was reached for an OOP drift equal to 3.87%.

After that, the panel rupture occurred through the vertical sliding and cracking of the concrete blocks from the panel upper part. The separation of the panel into two pieces resulting from the arching mechanism development becomes more evident. The trilinear cracking pattern was observed at the test end for a $DR_{OOP,ult}$ equal to 4.77% and a residual force of 155.9kN. Based on the measurements made by the vertical displacement located at the top of the frame structure and based on this cracking pattern, it can be concluded that the arching mechanism controlled the response of the wall. Again, two-way bending occurred similarly to a panel three borders constrained, as observed in previous research works [5, 8, 10]. Figure 7a shows

the force-displacement curve. The damages observed after the end of the test are shown in Figure 7b.

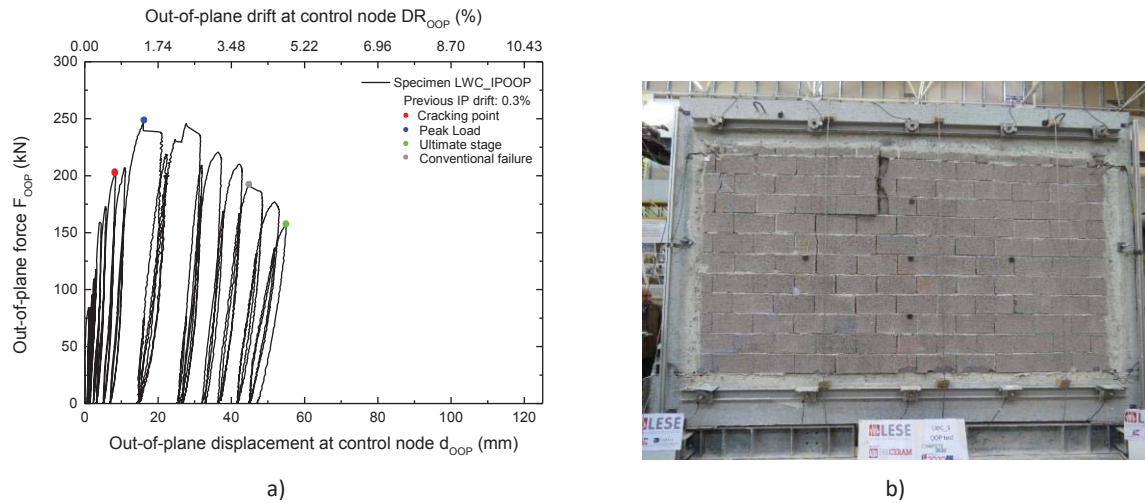

Figure 7 – Specimen LWC_IPOOP: OOP test a) Force-displacement curve; Damages observed at the end of test b) front view.

3.1.3. Specimen LWC_S

The strengthened panel LWC_S was subjected to a pure OOP test and presented an initial stiffness equal to 69250kN/m. The development of the first visible horizontal cracks occurred for a $DR_{OOP,crack}$ equal to 0.30% for a corresponding force of 171.3kN. The OOP force increased to values around 280kN and remained almost constant until reaching the maximum value of 281.28kN for a drift of 2.76%. The panel detached from the upper beam during this period and developed a vertical crack in the panel's upper part. The first diagonal cracks appear. The vertical crack is more evident at the peak stage, and new vertical cracks occur at the panel's top and bottom. Horizontal cracks become thicker, and cracks develop at the interface between the panel and the frame. After that, there is a sudden reduction of the OOP force of about 25% for a drift of 3.1%. The degradation of the OOP strength was then slow until reaching the conventional collapse for the drift of 6.17%. At this moment, it occurred again, a reduction of the panel strength of about 20% for a 6.82% of drift. After that, the panel strength was continuously reducing until the last stage, where it was observed the sliding of the glass fibers of the reinforcement mesh from the steel plate. The residual panel strength was 103.57kN for a drift of 8.21%. Based on the measurements made by the vertical displacement located at the top of the frame structure and based on this cracking pattern, it can be concluded that the arching mechanism controlled the response of the wall. Again, two-way bending occurred similarly to a panel three borders constrained. The force-displacement curve is plotted in Figure 8a. The damages observed after the end of the test are shown in Figure 8b.

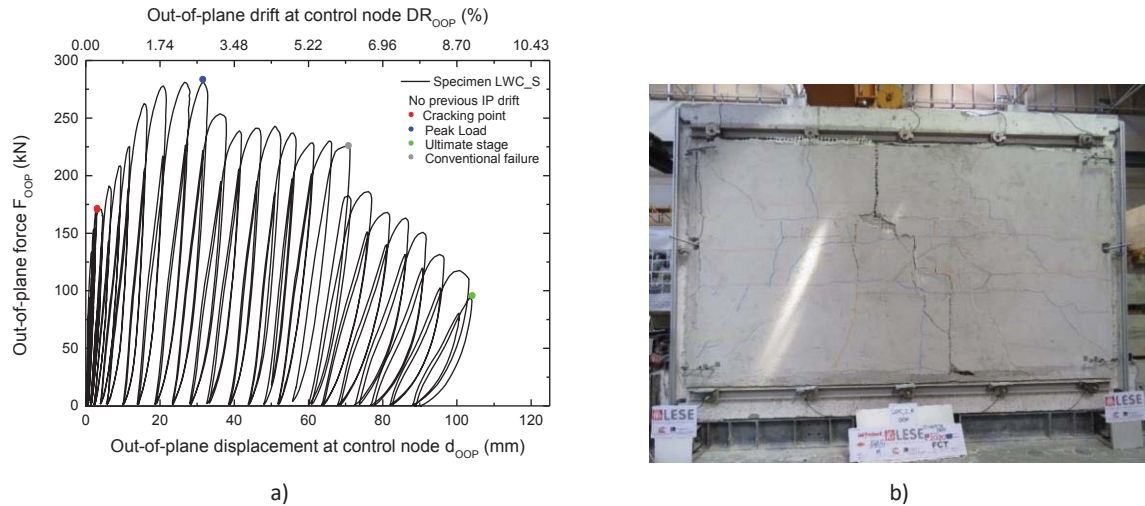

Figure 8 – Specimen LWC_S: a) Force-displacement curve; Damages observed at the end of the test; b) Front view.

3.2 Global results comparison

The initial secant stiffness, $k_{OOP,sec,ini}$, was calculated for each specimen by dividing the peak load of the first half-cycle by the respective OOP displacement. It can be observed that the LWC_S reached, as expected, the highest one. The initial stiffness of the panel LWC_S is 2.88 times higher than LWC_Ref and 14% than LWC_IPOOP. Surprisingly, LWC_IPOOP got an initial stiffness 2.52 times higher than LWC_Ref. Since this panel was damaged before the OOP test due to the IP test, it was expected that the initial stiffness would be lower than LWC_Ref. Based on this, and since no other experimental evidence can justify this result, this higher initial stiffness of LWC_IPOOP can only be attributed to experimental variability.

Regarding the first cracking development, the lowest $DR_{oop,crack}$ was 0.29%, and LWC_Ref reached it. The highest $DR_{oop,crack}$ was 0.71% achieved by the LWC_IPOOP, 2.44 times higher than LWC_Ref. The previous damage was the reason that justifies this significant variation. The cracks developed in the IP test widened and the other ones only emerged for a larger OOP drift demand. The TRM strengthening increased the $DR_{oop,crack}$ by about 3.4%. Concerning the $F_{oop,crack}$, LWC_IPOOP and LWC_Ref again reached the highest and lowest result with 204.4kN and 76.8kN, respectively. Experimental variability can justify that LWC_IPOOP $DR_{oop,crack}$ was 2.66 times higher than LWC_Ref. The strengthening increased the $F_{oop,crack}$ about 2.23 times.

The maximum peak load was reached by the strengthened specimen LWC_S with 281.3kN, proving the technique's efficiency to increase the wall strength capacity. LWC_Ref achieved the lowest peak load with 229.6kN. The TRM strengthening increased the strength capacity about 23%, but it occurred for a $DR_{oop,max}$ 35% lower. The previously damaged LWC_IPOOP reached a $F_{oop,max}$ 7% higher than the reference one due to variability often observed in experimental tests [4]. The $DR_{oop,max}$ of the specimen LWC_IPOOP was 77% lower than the reference specimen.

The conventional rupture occurred first for the specimen LWC_IPOOP ($d_{oop,conv}$ equal to 3.87%), highlighting the importance of previous damage in reducing the OOP capacity. The $DR_{oop,conv}$ of the specimen LWC_REF was two times higher than LWC_IPOOP. The strengthening solution did not contribute to the increase of the $DR_{oop,conv}$, since the panel LWC_S reached the conventional rupture at 6.17%, 11% lower than the reference specimen. However, the residual strength capacity was 22% higher.

No reliable conclusions can be extracted from the ultimate stage since the tests were interrupted for different OOP displacement demands depending on the level of damage.

Table 1 - Global results comparison.

Parameters	LWC_Ref	LWC_IPOOP	LWC_S
$k_{OOP,sec,ini}$ (kN/mm)	24024	60427	69250
$F_{OOP,crack}$ (kN)	76.75	204.41	171.3
$F_{OOP,max}$ (kN)	229.6	246.06	281.3
$F_{OOP,conv}$ (kN)	183.7	196.3	225
$F_{OOP,ult}$ (kN)	149.2	155.92	103.6
$DR_{OOP,crack}$ (%)	0.29	0.71	0.30
$DR_{OOP,max}$ (%)	4.19	1.39	2.76
$DR_{OOP,conv}$ (%)	6.94	3.87	6.17
$DR_{OOP,ult}$ (%)	7.63	4.77	8.21

CONCLUSIONS

This manuscript's primary goal was to study the OOP behaviour of full-scale masonry infill walls made with lightweight concrete blocks. An experimental campaign was carried out comprising three nominally identical full-scale specimens were built. One of them without previous damage and without strengthening. The second specimen was tested with prior damage caused by a prior IP test with a maximum drift of 0.3% without strengthening. The third wall was tested without previous damage, but it was strengthened with a TRM based solution. All the tests have been performed by imposing a half-cyclic (loading-unloading-reloading) history of displacements in the out of plane (OOP) direction employing a uniform distributed load provided by small pneumatic jacks. From the testing campaign, the following conclusions can be drawn:

- The previous damage increased the displacement corresponding to the first crack development. On the other hand, the strengthening reduced this cracking displacement. The same phenomenon was observed at the peak load, and conventional rupture stages. It should be taken into account the variability often observed in experimental tests;
- The OOP strength capacity was not affected by the previous damage, which can be associated with experimental variability. A minor increase of the panel peak load was also observed when strengthened with TRM compared with the reference specimen. Globally, it can be stated that the IP damage and strengthening affect the ductility in negative and positive manners. Only three tests were carried out to assess both effects, which are not enough to draw solid conclusions. Additional tests need be carried out to validate the findings herein extracted;
- The TRM strengthening provided no significant improvement in all the response parameters. Besides the use of a textile mesh with high tensile strength, the strength capacity was not improved. Even the strength degradation was similar to the reference specimen.

Abstract

The poor performance of school buildings in Italy during past seismic events has underlined their high vulnerability to earthquakes. To improve their seismic performance, retrofitting interventions are commonly designed and then evaluated against a range of key decision criteria. However, more than one intervention may be found to reduce the seismic risk of the structure but it may not be clear which scheme is the most effective given the diverse evaluation criteria. In such cases, multi-criteria decision-making procedures are practical tools that can help to solve this issue, especially when multiple evaluation parameters are considered. This study conducts a full seismic assessment of two existing RC school buildings located in different regions of Italy. For both buildings, similar retrofitting interventions are proposed and designed according to the requirements specified by the Italian building code, NTC 2018. The retrofitting interventions are assessed through non-linear dynamic analyses to thoroughly estimate their overall performance and expected losses. The retrofitting interventions are then comparatively evaluated considering parameters that integrate economic, social, environmental and technical aspects that have a significant role in the decision-making process. The preferential rankings of the retrofit alternatives obtained for both buildings are used to identify the optimal retrofitting solutions for each case and are compared to determine what parameters influence such optimal solutions according to the different buildings' characteristics. The outcomes of this study can assist engineers, or general decision-makers, throughout the evaluation and subsequent selection of retrofit options for existing school buildings.

Keywords: RC school buildings, MCDM, retrofitting interventions, NTC 2018, evaluation parameters.

1 INTRODUCTION

The seismic risk of existing school buildings is an important topic that has been addressed in recent years. For instance, Perrone et al. [1] conducted an extensive performance assessment for three school building typologies adapted from the Progetto Scuole developed by the European Centre for Training and Research in Earthquake Engineering (EUCENTRE). Building upon such work, Carofilis et al. [2] proposed and assessed different retrofitting techniques to reduce the seismic risk of the same school buildings. Besides evaluating the seismic performance, Carofilis et al. [2] determined the economic feasibility of these alternatives through a cost-benefit analysis [3]. However, as further explored by Carofilis et al. [4], the consideration of a diverse set of decision variables (DV) for a set of retrofitting strategies may result in a distinct retrofitting preference, when compared to traditional economic assessments. Therefore, Carofilis et al. [4] suggested that multi-criteria decision making (MCDM) analysis is more suitable than other methodologies, which tends to focus only a few decision variables, for selecting the most advantageous option from a set of retrofitting strategies. Similarly, MCDM has been adopted in other studies focusing on the retrofitting alternatives for residential buildings (Caterino et al. [5]) and school buildings (Gentile and Galasso [6]), where technical, social, and economic aspects were evaluated.

With the current focus on reducing impact that humans have on the environment, a body of recent research has also focused on assessing the environmental impacts associated with the seismic damage of existing buildings. Recently, Caruso et al. [7] proposed a methodology for considering the life cycle costs and environmental impacts (EIs) associated with the seismic and energy efficiency retrofitting of existing buildings. Additionally, Caruso et al. [7] investigated how this methodology could be used for the selection of retrofitting alternatives.

Subsequently, Clemett et al. [8] carried out a detailed and comprehensive review of five different metrics that can be used to account for the EI of retrofitting strategies within an MCDM framework. They found that incorporating the EI into the MCDM analysis influenced the identification of the ideal retrofitting solution, as the selection of an appropriate EI DV affected the preference ranking of the retrofitting solutions. Therefore, in the selection of the most convenient retrofitting strategy for an existing school building not only traditional aspects (i.e. technical, economic and social views), but also environmental impacts should be considered. With the above aspects in mind, this paper looks at the retrofitting of two case study existing buildings in Italy, where several retrofitting alternatives are examined and the choice via an MCDM framework, considering economic, social, environmental and technical aspects, is carried out.

2 MULTI-CRITERIA DECISION MAKING (MCDM)

The MCDM framework is advantageous when considering a number of different DVs, complemented by an analytical hierarchy process (AHP) [9]. Additionally, the “technique for order preference by similarity to ideal solution” (TOPSIS) [10] can be applied to rank the assessed options according to their relative closeness to an ideal alternative, which comprises all of the most convenient characteristics (e.g. best performance, lowest cost, lowest losses, etc.). Nevertheless, the closeness to an ideal solution depends on the importance given to each DV by the analyst, as well as to their specific values.

2.1 Description of the method

At the start of an MCDM analysis, it is necessary to define the evaluation parameters or DVs. Then, the importance given to each DV is assigned. This importance is represented

through a weight vector (w), which can be defined according to a preference matrix as implemented by Caterino et al. [5] or through a survey, as performed by Carofilis et al. [11] and Gentile and Galasso [6]. The values of each retrofitting alternative associated with each DV create the decision matrix (D), which along with the weight vector (w) represent the input variables. Figure 1 summarizes the process to develop the MCDM analysis. The decision matrix is normalized since each DV may be expressed in different units. The normalized decision matrix R is determined by applying Equation 1 to the elements of the decision matrix (D). Then, the weight normalized decision matrix V is calculated through Equation 2, where r_{ij} represents the components of matrix R and w_j the elements of the weight vector (w). From the matrix V the most ideal solution A^* and negative-ideal solution A^- are determined, representing the most and least convenient values for each column of matrix V . These parameters are used to calculate the distances S_i^* and S_i^- as indicated by Equation 3. As illustrated in Figure 1, these distances represent the proximity of each alternative to a fictitious ideal and negative-ideal alternative. Finally, the relative closeness (Equation 4) is used to rank the alternatives and determine the most convenient one, i.e. the alternative with the largest relative closeness. For example, in Figure 1, it is observed that A_2 is closer to the ideal fictitious alternative in comparison with A_1 and A_3 . Consequently, A_2 will be assumed the most favourable alternative since its relative closeness would be much larger than that of the other alternatives. Further details of this method can be found in [5] and [4, 11].

$$r_{ij} = \frac{d_{ij}}{\sqrt{\sum_{k=1}^m d_{kj}^2}} \quad (1)$$

$$v_{ij} = r_{ij} * w_j \quad (2)$$

$$S_{i*} = \sqrt{\sum_{j=1}^n (v_{ij} - v_{j*})^2}; \quad S_{i-} = \sqrt{\sum_{j=1}^n (v_{ij} - v_{j-})^2} \quad (\text{Distances } S_{i*} \text{ and } S_{i-}) \quad (3)$$

$$C_{i*} = \frac{s_{i-}}{s_{i*}+s_{i-}} C_{i*} = \frac{s_{i-}}{s_{i*}+s_{i-}} (\text{Relative closeness}) \quad (4)$$

2.2 Evaluation parameters

The DVs selected for this study were in part characterised through an ad-hoc survey devised by Carofilis et al. [11], which collected information on which evaluation parameters are considered important in the assessment of retrofitting options for school buildings. These variables are reported in Table 1, where it is indicated to which aspect they are related and how they are estimated for each retrofitting configuration. Some of these variables have also been investigated in past studies [5, 6].

Label	Decision Variable	Aspect	How this DV is determined
C1	Installation Costs	Economic	Total cost of installation comprising removal, demolition, application of retrofitting technique and all other cost associated with applying the intervention
C2	Maintenance Costs	Economic	Cost of maintenance over the lifetime of the structure.
C3	Duration of Works	Economic/ Technical	Number of days needed to fully complete the intervention and start the normal operation of the building
C4	Architectural Impact	Social	Qualitative evaluated through AHP [9]
C5	Need for Specialized Labor	Technical	Qualitative evaluated through AHP [9]
C6	Foundation Intervention	Technical	Estimates of the maximum axial load ratio between the retrofitting intervention to the as-built configuration
C7	Expected Annual Losses	Technical	Evaluated as the expected annual loss obtained from the loss assessment using PACT [12].
C8	Expected Annual EI	Technical/ Social	Refer to Section 2.3

Table 1: Evaluation parameters.

2.3 Environmental impact

Clemett et al. [8] highlighted how an EI metric that captures the entire life cycle impacts can be incorporated into the MCDM. The EI of a building can be estimated in several ways. For instance, through a Process Life Cycle Assessment (PLCA) inventory, containing a list of all the processes that contribute to the life cycle of a building. PLCA is generally considered a meticulous approach for estimating the life cycle EI of a structure, however, it is particularly time-consuming to develop a full inventory accounting for all sources of EI. Therefore, PLCA is susceptible to truncation bias (i.e. 30-50% of the total life cycle impacts [13]). An alternative to PLCA is the Environmentally Extended Input-Output Life Cycle Assessment (EEIOLCA), which, unlike PLCA, is a top-down method based on economic input-output (IO) models [14]. These IO models capture the monetary transactions that occur between the different sectors of the economy and are generally represented as matrices [15] (Figure 2, point 3). If rows and columns are included for the various EI metrics of interest, these tables can be used to assess

the EI of each industrial sector. The values for each impact category are generally presented in EIs/\$ [16]. The EI of a building can be calculated by disaggregating the total cost estimate of the structure into each of the available industrial sectors and then multiplying the dollars spent in each sector by sector- unique EI/\$ value.

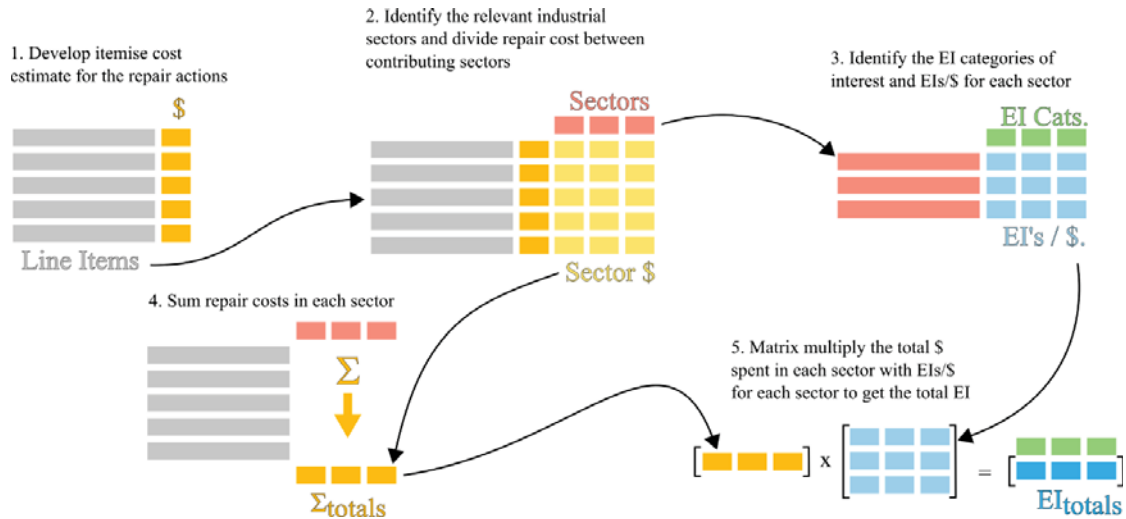

Figure 2: EEIOLCA impact assessment procedure adapted from Huang and Simonen [16].

Nevertheless, it is important to note that EEIOLCA has three primary sources of error: aggregation error (i.e. values represent a weighted average of several smaller economic sectors); the homogeneity assumption (i.e. all products produced within a specific sector have the same average EI), and; the linearity assumption (i.e. EIs are linearly correlated with the market price, meaning that a higher price leads to higher emissions) [8]. Additionally, EEIOLCA might present other limitations and potential sources of uncertainty. For example, the USEEIO [17] inventory has been developed using US economic data so that EIs derived from its use are applicable only within the United States. The application of this inventory to case studies outside of the US will likely increase the error of the impact estimate unless it can be demonstrated that the economy of interest has the same structure as the US economy. In this study, the use of the USEEIO inventory for a case-study building in Italy can be justified by the fact that the assessments performed are for comparative purposes and any error resulting from the use of a US inventory will likely have an equal effect on all of the retrofitted structures. Additionally, the USEEIO database [17] does not consider any sort of uncertainty in the EI estimates for each sector, however, uncertainty in these values is accounted for in the PACT software (version 3.1.2) [12] by assuming that the uncertainty of the EIs is related to the uncertainty of the cost estimate (refer to Equation 1 of Clemett et al. [8]).

For this study, the EI, denoted C8, was estimated using EEIOLCA which represents the ongoing cost associated with the retrofit alternatives, and is impacted by the seismic performance (i.e. the effectiveness) of the retrofit alternatives [8]. The reconstruction EI was coarsely approximated by first converting the reconstruction cost, in 2020 € to 2013 \$, then multiplying the reconstruction cost by the EIs/€ factor for “schools and vocational buildings” from the USEEIO database [17]. An additional 15% of the reconstruction EI was added to

account for the impacts associated with the demolition and disposal of the damaged structure [8].

3 CASE-STUDY BUILDINGS

Two existing reinforced concrete (RC) school buildings located in different regions of Italy with medium-high seismicity are used as case-study. These structures share the same modelling techniques (Figure 3a), as well as structural deficiencies. The first building is referred to as Building 1 (Figure 3b) and is located in central Italy, at Isola del Gran Sasso, Parozzani. This school building consists of two storeys and one underground portion (staircase section), the construction period is estimated at around 1960–1970. The area of the underground level is 133m^2 and for the subsequent levels is 631m^2 . Likewise, the inter-storey heights are 3.75, 3.75 and 4.75m, respectively for each level. The second building is denoted as Building 2 (Figure 3b) and is located on Italy's Adriatic coast, in Ancona. It is estimated that the construction period of this building dated back to the 60s. The structure is composed of three storeys including an underground level. The floor area is about 690m^2 , and inter-storey height of 3.83m for the underground level and first storey, and 3.77m for the second storey.

3.1 Structural modelling

These buildings share similarities in their configuration, size, material and year of construction. Therefore, the same assumptions were adopted for the numerical modelling of both buildings with the software OpenSees [18] as illustrated in Figure 3. The modelling techniques suggested by O'Reilly and Sullivan [19] for old RC Italian frames were implemented. For example, beams and columns were created through force-based beam-column elements with a modified Radau plastic hinge integration scheme with lumped plasticity (Scott and Fenves [20]). Even though the shear behaviour was assumed elastic, a post-processing analysis was carried out to compare the shear forces of these flexural elements to their maximum shear capacity determined through NTC -2018 [21]. On the other hand, the beam-column joints were modelled using a zero-length rotational spring to capture any potential shear failure for joints. Furthermore, the buildings also incorporate a rigid floor slab and consider second-order geometry effects ($P-\Delta$). Regarding damping, a 5% tangent-stiffness-proportional Rayleigh damping model for the periods of the fundamental modes was adopted. Additionally, the effects of the exterior masonry infills were incorporated into the model through a system of equivalent diagonal struts that represent the behaviour of the infills, following the recommendations of Sassun et al. [22]. To account for the influence of openings, the stiffness and strength of the struts were affected by a reduction factor proposed by Decanini et al. [23]. The strut models used in these analyses are only capable of modelling the in-plane behaviour of the infills and do not consider out-of-plane failure. Further details about the building configuration and modelling can be found in [8] and [1, 2] for Building 1 and 2, respectively.

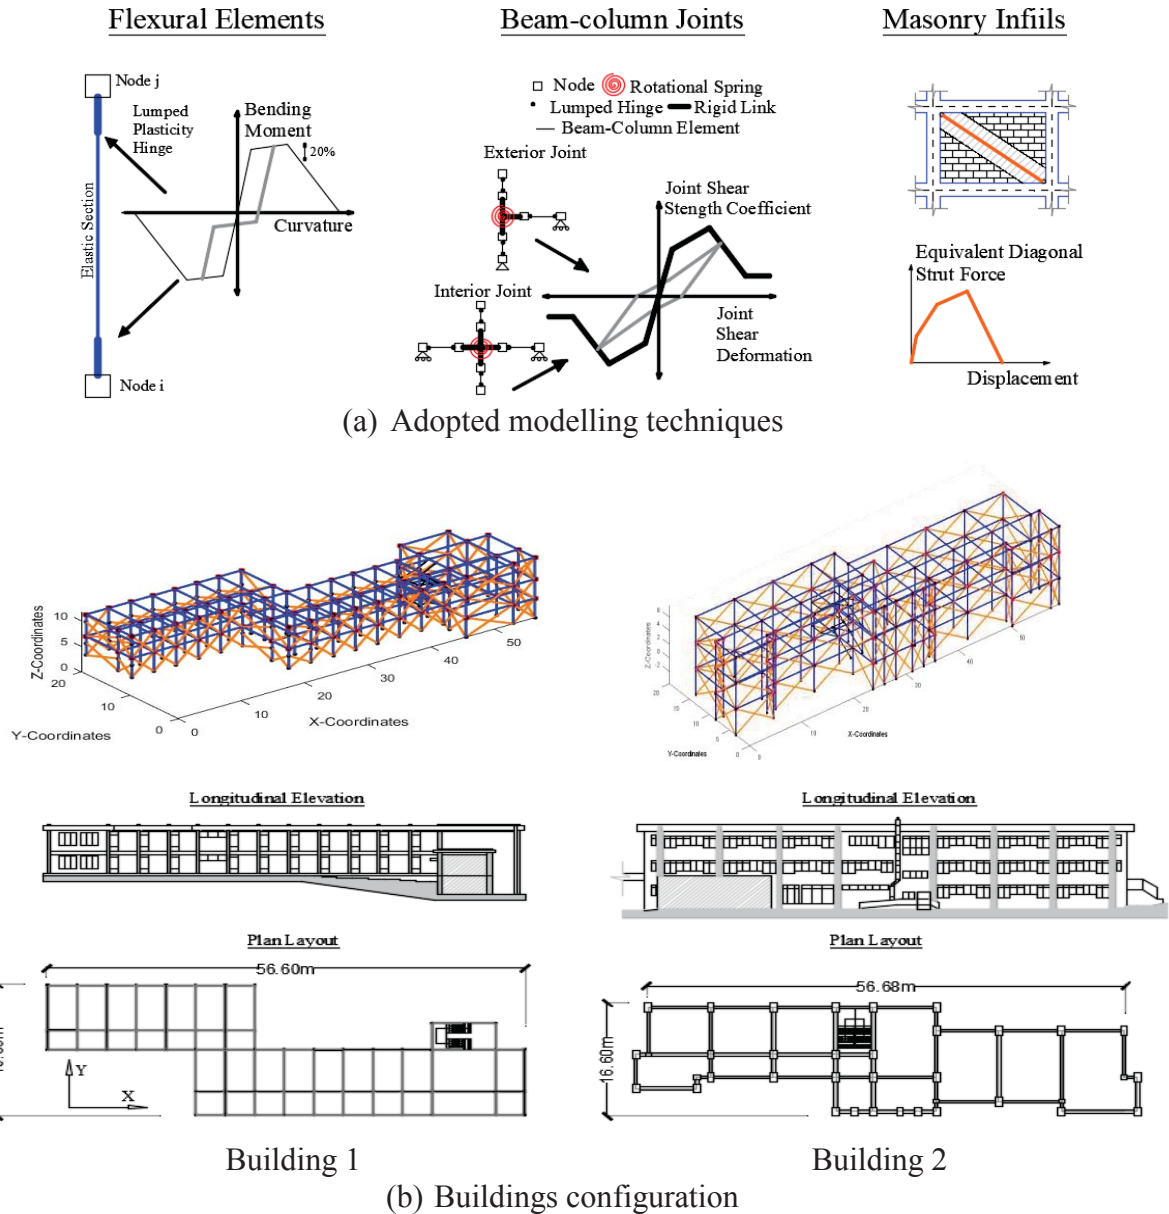

Figure 3: Schemes of case-study school buildings.

3.2 Performance assessment

A performance assessment was developed for both buildings, carrying out verifications of deformation and strength capacity for the seismic demands imposed by NTC 2018 [21] according to the site location of each building. For a school building, the NTC 2018 [21] specifies a design life of 75 years (occupancy class III) and return periods associated with four limit states: Operational limit state (SLO) 45 years; Damage limitation limit state (SLD) 75 years; Life safety limit state (SLV) 712 years, and; Collapse prevention limit state (SLC) 1463 years. For the serviceability limit states, the code imposes two drift limits 0.17% and 0.5% for SLO and SLD, respectively. For a building of occupancy class III, it is only necessary to verify the limit at SLO, however, in this study, both limits were checked.

The results of the preliminary performance assessment are illustrated in Figure 4. They are expressed in terms of the base shear coefficient (i.e. lateral capacity divided by the seismic weight of the building), building roof drift (i.e. roof displacement divided by the total height of the building) and drift profiles related to the different limit states. On the one hand, it is observed

that the capacity of both buildings is controlled by the premature failure of joints, and thereby controlling the other limit states as well. In the case of the drift profile, Building 1 meets the drift limit for both serviceability limit states in both directions. On the other hand, Building 2 exceeds these limits, especially for the Y direction. For the limit states associated with the ultimate capacity (i.e. SLV and SLC), both buildings present a soft-storey mechanism which is denoted by the drift concentration in one of their storeys, namely second storey for Building 1 and third storey for Building 2.

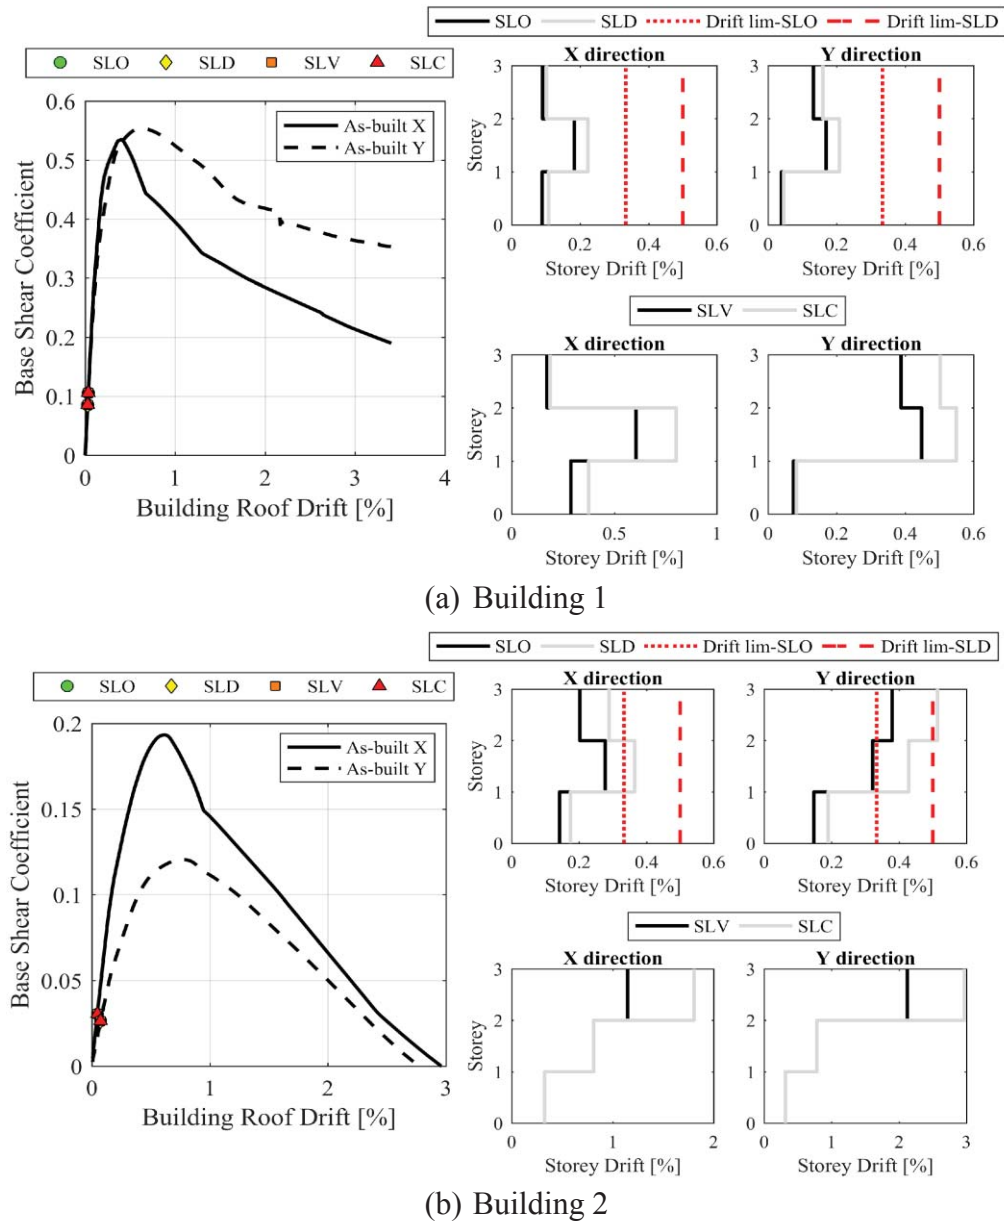

Figure 4: School buildings structural performance.

4 RETROFITTING INTERVENTIONS

Four retrofitting strategies were proposed for both school buildings. As illustrated in Figure 5, these strategies are the same for both buildings and consist of: A1 involves carbon fiber reinforced polymer (CFRP) wrapping of columns along with CFRP bars, as well as CFRP strips placed on beam-column joints; A2 implements exterior cross-steel braces in some strategic locations of the building; A3 combines the two previous interventions (i.e. CFRP and steel

braces) and, lastly; A4 combines CFRP and viscous dampers placed strategically in the building. Moreover, the infill-strut elements were removed from the models in response to the seismic separation of the infills and the frames. To accommodate this assumption, additional checks were carried out during the non-linear analyses to ensure that the estimated drifts did not exceed the 50mm seismic gap provided. Further details of the original and retrofitted configurations, as well as their design, can be found in [4, 8].

Figure 5: Proposed retrofitting configurations.

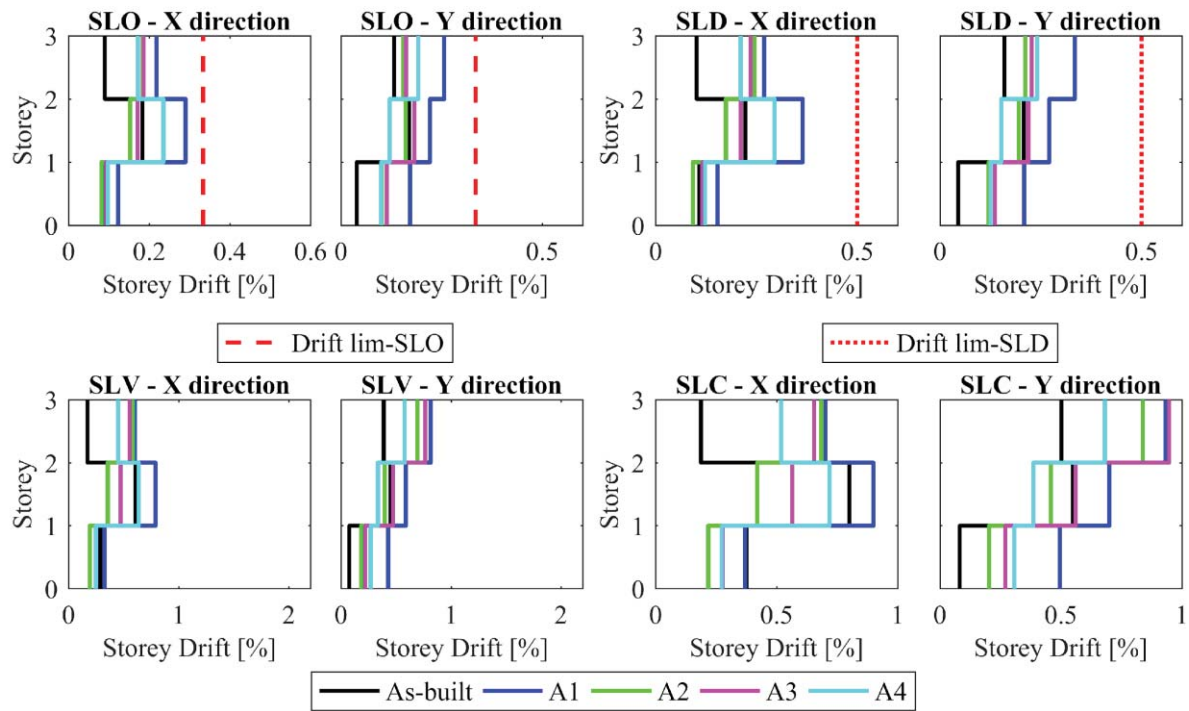

4.1 Performance assessment of retrofitting strategies

The performance assessment was applied to the retrofitting configuration, again this assessment is reported as drift profiles (Figure 6) and lateral capacity (Figure 7). For Building 1 all retrofitting interventions meet the drift limit for SLO and SLD whereas they reduce the drift concentration for SLV and SLC. In the case of Building 2, all strategies improve the drift distribution, especially for the Y direction. However, strategy A1 is slightly exceeding the drift limit at SLO and at SLD the maximum storey drift coincides with the drift limit.

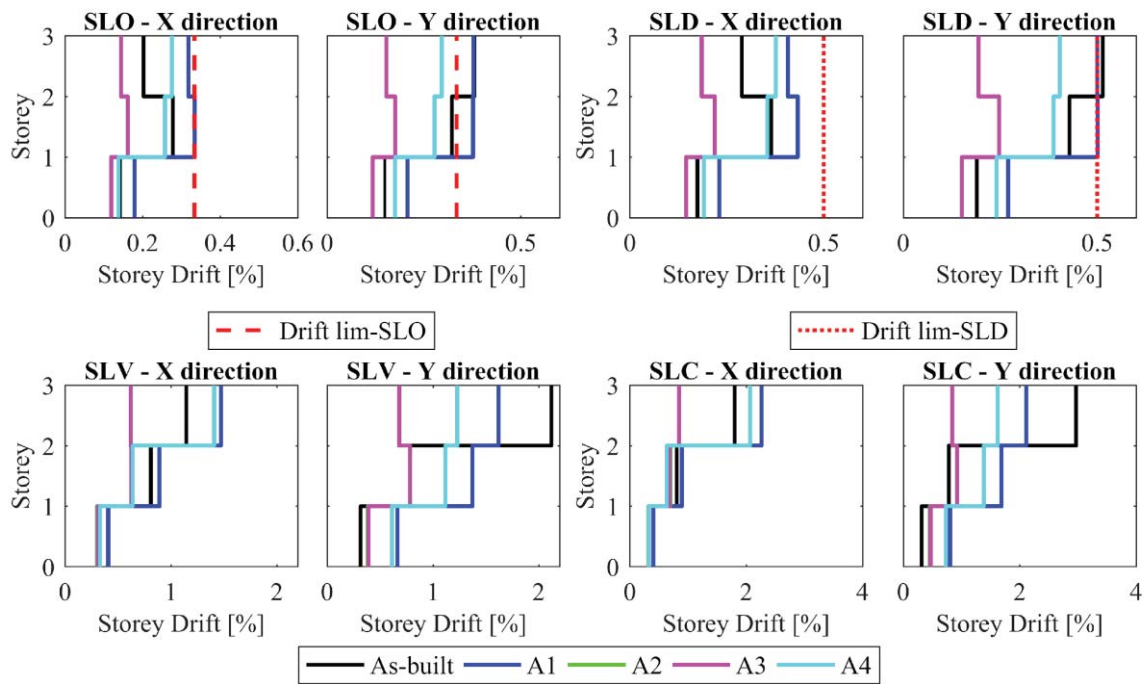

The strategies involving steel braces (A2 and A3) prove to be more effective in reducing the storey drift in both building configurations. The strategy with viscous dampers (A4) reduces the drift concentration, and the option with CFRP (A1) also reduces the drift profiles but its effect is not as substantial as the other strategies.

Moreover, the lateral capacity, as well as performance capacity points, are improved for all strategies except for A2 (steel braces). Even though this strategy boosts considerably the lateral

capacity of the buildings, in terms of local strength does not account for an improvement since the strength capacity remains unchanged and thereby the premature failure of joints still persists. Strategy A3 also boosts the lateral capacity of the buildings, the action of the CFRP increases the local capacity of the structural elements so that the capacity points are shifted to the right (i.e. a zone of better performance). The same effect is observed for A1 and A4, which also incorporate CFRP. Furthermore, a particular difference of the steel bracing options (A2 and A3) is noted in the lateral capacity of the case-study buildings (Figure 7a). The contribution of the bare frame (due to seismic separation of infills) and steel braces present a lower initial stiffness than that of the as-built configuration for Building 1. On the other hand, in Building 2, this same combination results in a stiffer building, meaning that the steel bracing system surpasses the stiffness of the infilled configuration (as-built).

4.2 Collapse vulnerability and loss estimation

The next stage in the performance assessment was to conduct refined nonlinear time history analysis (NLHA). Therefore, the fundamentals periods of all models were determined (they are reported in Table 2 and Table 1 for Building 1 and 2, respectively). Due to the period variability of the different models, the average spectral acceleration (AvgSa) was considered as intensity measure to carry out a ground motion record selection, since it is a more efficient and unbiased quantifier of response in these structural typologies, as shown by O'Reilly [24]. The software

OpenQuake [25] was used to carry out the probabilistic seismic hazard analysis (PSHA) and disaggregation analyses for the site locations defined in Section 3. The Italian seismic source model MPSO4 (Meletti et al. [26]) and the ground motion model by Akkar, Sandikkaya, and Bommer [27] and Sandikkaya, Akkar, and Bard [28] were adopted. The geometrical period (T_{gm}) was determined as the square root of the product between the two fundamental periods. The period range of $0.2T_g - 1.5T_g$ was used to perform the AvgSa-based selection, as suggested by Kohrangi et al. [29]. The period range of 0.05s to 1.0s was adopted for Building 1 whereas a range of 0.10s to 1.60s was used for Building 2. A set of 20 pairs of ground motion records in two horizontal components were selected for ten return periods: 30, 45, 75, 100, 200, 475, 712, 975, 1463 and 2475 years. Figure 8 illustrates the hazard curves for the two sites locations, expressed in terms of the mean annual frequency of exceedance (MAFE) and AvgSa, as well as a scheme of the ground motion selection at a specified intensity.

Model	$T_x[2]$	$T_y[s]$	$T_g[s]$	$0.2T_g[s]$	$1.5T_g[s]$
As-built	0.27	0.24	0.25	0.04	0.38
A1	0.60	0.37	0.47	0.09	0.71
A2	0.41	0.37	0.39	0.07	0.58
A3	0.40	0.35	0.37	0.08	0.56
A4	0.75	0.35	0.51	0.10	0.77

Table 2: Fundamental periods, geometric period, and period range for the models of Building 1.

Model	$T_x[2]$	$T_y[s]$	$T_g[s]$	$0.2T_g[s]$	$1.5T_g[s]$

Table 3: Fundamental periods, geometric period, and period range for the models of Building 2.

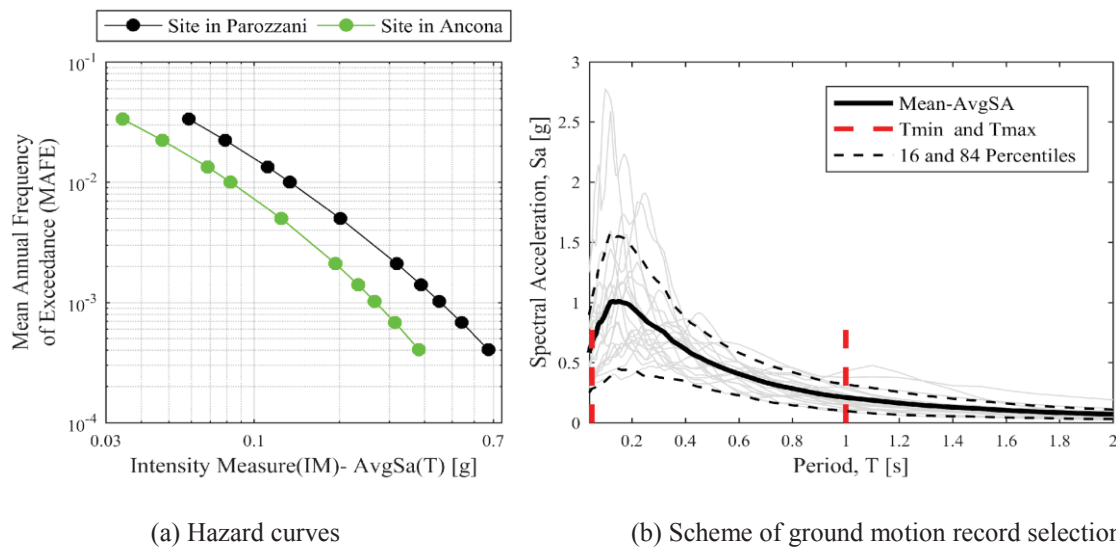

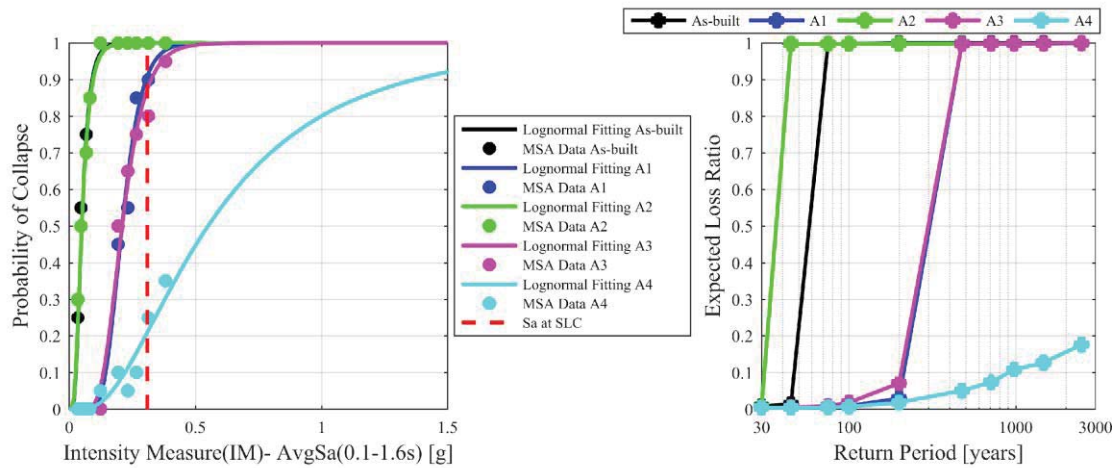

Figure 8: Hazard curves and ground motions selected using AvgSa for the site locations.

Multiple-stripe analysis (MSA) [30] was conducted to characterize the response of the structures using the records selected. The results from the MSA were used to develop collapse fragility curves, for all models for both buildings, by recording at each intensity level, the number of collapses observed. The collapse criteria adopted here was based as the first of: the shear force demand exceeds the shear resistance of one or more of the flexural elements; the rotation of one or more flexural elements exceeds the SLC deformation limits; the shear deformation in one or more of the beam-column joints exceeds 0.02 rad [19]. The curves were fitted from the MSA collapse data using a lognormal distribution and maximum-likelihood estimation [31]. The fragility curves obtained from the fitting procedure account for the record-to-record variability of the selected ground motions (Figure 9). To account for the modelling uncertainty, the median and dispersion values from the fitting procedure were modified following the recommendations of O'Reilly and Sullivan [19]. Moreover, Figure 9 also illustrates the expected economic losses, which were determined through the software PACT (version 3.1.2) [12].

The retrofitting alternatives A3 and A4 substantially reduce the collapse vulnerability and expected economic losses, especially for Building 1. A1 improves the collapse capacity of Building 1 and expected losses but this improvement is not as prominent as the one given by A3 and A4. On the other hand, A2 achieves a slight enhancement of both aspects. In case of Building 2, A4 has a considerably better performance in terms of collapse vulnerability and expected economic losses. On the other hand, A1 and A3 reach a similar reduction for both aspects, and lastly, A2 does not seem to improve these two parameters. Indeed, A2 has a worse performance compared to the as-built configuration of Building 2. Furthermore, from Figure 7b, it can be predicted that A2 would generate higher floor accelerations, as well as higher losses associated with this demand parameter. Likewise, the period shortening observed in Table 2 indicates that this strategy will be conditioned to larger inertial forces. As a result, the structural elements will be subjected to higher internal forces, which leads to more local failures. These same effects are expected for A3, however, the contribution of CFRP increases the local strength and thereby decreases the number of element failures (i.e. collapse cases).

(a) Building 1

(a) Building 2

Figure 9: Collapse vulnerability and expected economic losses.

Tables 5 and 6 report the expected annual losses (EAL) and expected annual environmental impacts (EAEI) for all configurations of both buildings. These calculations were based on the total replacement cost of the buildings. The average costs of building demolition and reconstruction were assumed as 95.50€/m² and 1805.75€/m², respectively [32]. Given an approximate floor area of 1395m², the demolition and reconstruction costs were estimated to be 133,223€ and 2,519,021€ respectively (total replacement cost of 2,652,244€) for Building 1. On the other hand, for Building 2 with an approximate floor area of 2067m² the demolition and reconstruction cost resulted in 197,427€ and 3,733,027€, respectively (total replacement cost of 3,930,454€). Furthermore, replacement EI for Building 1 is 1,830,000kg-CO₂e and 2,713,000kg-CO₂e for Building 2. For simplicity, the total replacement cost and EIs were considered to be the same for all of the alternatives in each building case.

Model	EAL [%]	Rep. Cost[€]	EAEI [%]	Rep. EI [kgCO ₂ e]
As-built	0.50	2,652,244	0.51	1,830,000
A1	0.20		0.18	
A2	0.43		0.39	
A3	0.16		0.11	
A4	0.06		0.04

5 APPLICATION OF MCDM

5.1 Input variables

The input variables (i.e. weight vector w and decision matrix D) are reported in Table 7 and 8 for Building 1 and 2, respectively. The values assigned to the decision matrix (D) were determined as described in Section 2.2 whereas the weight vector (w) was adopted from Carofilis et al. [11].

DV [units]	C1 [€]	C2 [€]	C3 [days]	C4	C5	C6	C7 [%]	C8 [%]
A1	850,458	1,520,883	36	0.07	0.25	1.40	0.20	0.18
A2	43,120	229,829	8	0.17	0.04	14.70	0.43	0.39
A3	389,477	794,218	28	0.28	0.25	14.80	0.16	0.11
A4	679,445	810,781	29	0.49	0.45	1.20	0.06	0.04
w	6.83	7.04	6.17	5.38	5.54	6.50	6.87	6.08

Table 7: Input variables for MCDM, Building 1.

DV [units]	C1 [€]	C2 [€]	C3 [days]	C4	C5	C6	C7 [%]	C8 [%]
A1	1,792,080	2,915,946	92	0.07	0.25	1.33	0.33	0.33
A2	41,528	43,487	16	0.17	0.04	2.90	1.77	1.77

A4	224,661	186,082	28	0.49	0.45	1.24	0.13	0.12
w	6.83	7.04	6.17	5.38	5.54	6.50	6.87	6.08

Table 8: Input variables for MCDM, Building 2.

5.2 Ranking of retrofitting interventions

The rank of each retrofitting alternative is listed in Table 9 (Building 1) and Table 10 (Building 2). To evaluate the influence of EI, two analyses were carried out, i.e. one including EIs (all DVs of Table 1) and other without considering EIs (excluding C8). For Building 1, it is observed that when EI is integrated into the MCDM, A4 results as the most convenient retrofit alternative. The relative closeness among A4, A3 and A2 is very similar, especially between A3 and A2. On the other hand, when EI is excluded from the analysis, A2 is ranked as the first option. In this scenario, the relative closeness of A2 is larger than A3 and A4, but for A3 and A4 this parameter is close to one another.

Moreover, for Building 2, the influence of EIs does not affect the rank preferences of the retrofitting options. For both analysis scenarios, A3 is selected as the most ideal solution with a considerably larger relative closeness compared to the other strategies. Indeed, the rank remains unchanged (i.e. A3-A4-A2-A1). However, it is observed that the relative closeness decreases when EIs are not considered in the MCDM analysis. A possible reason for this same pattern is that the values associated with EI (C8) for Building 2 are very similar to EAL (C7). Therefore, this similarity does not affect considerably the rank preference, especially since C8

is considered sixth in the order of preference of the weight vector w (i.e. sixth larger weight 6.08).

One could argue that A2 should not be considered within the set of retrofitting alternatives for both buildings, given that, even though the resulting lateral capacity is considerably larger than that of the as-built configuration and the storey drifts are reduced, the performance capacity (controlled by joint failure) remains unchanged. Additionally, the nonlinear dynamic analysis showed that the collapse vulnerability and expected losses were only slightly improved or even worsened with respect to the original building. However, this depends on the analysis and/or conditions of the project. Additionally, integration of refined methods or conservative assessment approaches that are more consistent with reality may not be possible, especially for regions where prompt solutions are needed. Therefore, the MCDM may be applied to select the most appropriate solution in conjunction with simplified methods, as long as they include relevant evaluation parameters for a particular case study.

Consideration	Alternatives	A1	A2	A3	A4
With EI	Relative closeness	0.472	0.522	0.523	0.539
	Rank	IV	III	II	I
No EI	Relative closeness	0.459	0.573	0.484	0.494
	Rank	IV	I	III	II

Table 9: Rank of alternatives for Building 1.

Consideration	Alternatives	A1	A2	A3	A4
With EI	Relative closeness	0.444	0.577	0.756	0.697
	Rank	IV	III	I	II
No EI	Relative closeness	0.400	0.638	0.745	0.676
	Rank	IV	III	I	II

Table 10: Rank of alternatives for Building 2.

6 CONCLUSIONS

This paper looked at the seismic retrofitting of two case-study existing buildings in Italy. Several retrofitting alternatives were examined and the choice via a multi-criteria decision making (MCDM) framework considering economic, social, environmental and technical aspects was evaluated. Based on the results obtained, the following observations can be made:

- The influence of environmental impacts greatly affects the preference of a retrofitting strategy and can alter the rank of the options in a multi-criteria decision making analysis, highlighting the importance of also considering the environmental impacts for evaluating retrofitting options;
- The retrofitting strategy based solely on CFRP was ranked as the least convenient solution in both buildings. Even though this strategy has the lowest architectural impact, the high

values associated with installation cost, maintenance and duration of works, diminish its attractiveness;

- The strategy with steel braces and CFRP is considered as the most convenient strategy for Building 2 and second-best for Building 1; this strategy achieves a balance among all the evaluation parameters that make it stand out among the other strategies;
- The strategy involving CFRP and viscous dampers achieved the best structural performance and was selected as the most beneficial strategy for Building 1. However, this option was ranked as the second most favourable solution for Building 2;
- The retrofitting scheme composed only of exterior steel braces had an insignificant performance improvement, but its lowest implementation costs made it stand out as the most convenient strategy for Building 1 when environmental impacts were not considered. This strategy is however not practical for Building 2 since its performance resulted to be worse than that of the as-built configuration.

Lastly, MCDM can be adopted in large scale scenarios or in cases where there are limited resources (e.g. developing countries) where retrofitting options are evaluated for many buildings. In such cases, simplified methods [33] can be practical for selecting the most appropriate retrofitting strategy, as an alternative to refined nonlinear dynamics analysis.

Abstract

The substantial damage to Reinforced Concrete (RC) structural walls observed from post-earthquake reconnaissance has prompted the attention on the need for improved code-based design provisions for these structural elements as well as for detailed investigations on their residual capacity, typically neglected in the retrofit/repair evaluation. Although several research works and international guidelines focusing on the seismic performance of damaged structural walls are available from a state-of-the-art review, a specific methodology to evaluate the earthquake-related damage to structural walls is still missing in literature. Therefore, this research work investigates the seismic residual capacity of RC walls through parametric numerical analyses, aiming to provide indications on the assessment methodology to be used in practical applications. The numerical investigation is initially carried out by implementing Finite Element Modelling of RC walls with different mechanical properties and expected failure mechanisms. This allows to evaluate and collect stiffness/strength reduction coefficients to be adopted for different post-earthquake damage conditions. Then, the influence of residual capacity on the economic seismic losses of wall structures is investigated and discussed. Specifically, a multi-story case-study RC building is selected, and pre- and post-earthquake loss assessments are carried out considering alternative wall typologies and damage levels. Analytical-based nonlinear analyses highlight that the loss of stiffness and strength can lead to increasingly higher economic losses depending on the damage level of the structural wall. Moreover, substantial economic losses can be estimated if residual capacity is taken into account even at low-intensity seismic levels. Therefore, such methodology could provide valuable information to support decisions on the post-earthquake repair/retrofit/demolition.

Keywords: Residual Capacity, Seismic Assessment, Reinforced Concrete, Wall Structures, Repair Costs.

1 INTRODUCTION

The recent seismic events in seismic-prone countries have further highlighted the controversial issues related to the rehabilitation of earthquake-damaged buildings. On one hand, rapid post-earthquake surveys are needed for the evaluation of the safety level of damaged buildings and their possible re-occupancy [1]. On the other hand, a detailed assessment of the seismic residual capacity of damaged buildings, including loss investigations, is critical to support the decision-making process of repair vs. demolition and guide in the selection/design and implementation of appropriate techniques able to ‘restore’ the building to its undamaged conditions. Moreover, the crucial need to gain a better understanding of the residual capacity of earthquake-damaged buildings refers to both existing and new structures. In fact, according to the “Capacity Design” philosophy, even modern buildings are often affected by extensive structural damage after a major earthquake, as observed in *Kam et al.* [2] during the Canterbury Earthquake Sequence 2010-2011.

Focusing on Reinforced Concrete (RC) structural walls, widely used as primary lateral-force resisting systems in earthquake-resistant structures, the substantial damage to these components observed from post-earthquake reconnaissance (2010 Darfield and 2011 Lyttleton in New Zealand [2]; 2010 Chile [3]; Figure 1) has prompted the attention on the need for improved code-based design provisions for these structural elements as well as for detailed investigations on their residual capacity, typically neglected in the retrofit/repair evaluation.

Figure 1: Observed damage to RC structural walls in a) the 2010 Chile earthquake [3] and b) the 2011 Lyttleton earthquake, New Zealand [2].

Despite research works and international guidelines focusing on the seismic performance of damaged structural walls are available in literature (e.g. FEMA 306 [4]; JBDPA Guideline [5]), a specific methodology to evaluate the earthquake-related damage to structural walls as well as the consequent loss of stiffness/strength affecting the component capacity is still missing. Following this goal, this paper aims to investigate the seismic residual capacity of RC walls through numerical modelling, providing indications on both the methodology and the stiffness/strength reduction coefficients to be adopted for different post-earthquake damage levels. A parametric analysis is thus developed to study the residual capacity of RC walls with different mechanical properties and expected failure mechanisms (flexural, flexure-shear, shear). The structural walls are analyzed adopting a refined FEM modelling approach, based on the modified compression field theory, using the structural software VecTor2 (*Vecchio* [6]). Firstly, the seismic behavior of the RC walls under reversed-cyclic loads is investigated to simulate the achievement of specific damage states, assessing residual cracks and residual

displacements at each damage level. Then, a unidirectional monotonic lateral load is applied to the damaged wall to evaluate the force-displacement capacity curve for each configuration. Hence, according to the FEMA 306 approach, stiffness and strength reduction coefficients, namely λ_k and λ_Q respectively (as shown in Figure 2), are derived by comparing the pre- and post- earthquake force-displacement curves for each damage state and wall configuration. Lastly, the influence of residual capacity on the estimation of the economic seismic losses of wall structures is also investigated and discussed. Specifically, a RC case-study building is selected, and loss assessments are implemented considering different wall typologies and damage levels. For each configuration, the economic losses are computed in terms of both Expected Annual Losses (EAL) and Probable Maximum Losses (PML) to highlight the importance of including residual capacity considerations when implementing economic analyses.

2 EVALUATION OF RESIDUAL CAPACITY

In the past decades, a substantial research effort has been dedicated at international level to gain a better understanding of the post-earthquake residual capacity of buildings. In 1994 *Holmes* [7] discussed the critical need for improved seismic assessment accounting for the actual lateral load of buildings and considering different damaged levels. Following this research line, two main guidelines were developed: 1) FEMA 306 [4] in the United States, and 2) JBDPA Guideline [5] in Japan (described in English in *Nakano et al.* [8]; overview available in *Maeda et al.* [1]). Both documents propose a conceptually similar approach, based on the definition of capacity reduction factors for structural members to simulate the achievement of a specific damage state. In FEMA 306 a modification of plastic hinges' response is proposed for damaged elements, based on stiffness, strength and ductility reduction coefficients, namely λ_k , λ_Q and λ_D (Figure 2a). In the JBDPA Guideline a single capacity reduction factor for structural members, i.e. η , defined as the ratio between residual energy dissipation capacity and original energy dissipation capacity is adopted (Figure 2b).

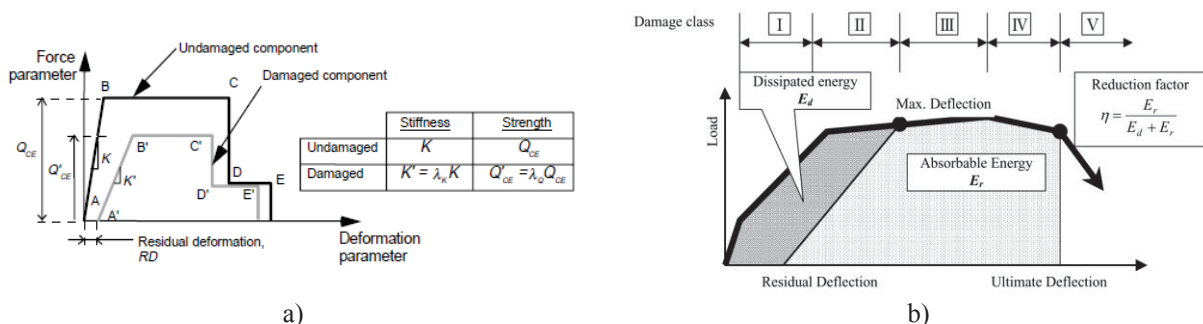

Figure 2: a) Stiffness, strength and residual displacement reduction coefficients in FEMA 306 [4]; b) capacity reduction factor for structural members in JBDPA Guideline [5].

Furthermore, FEMA 307 [9] reports background and theoretical information as well as an example of application of the FEMA 306 procedure. According to FEMA 306 (whose procedure is adopted within this research work), the most reliable approach to determine λ reduction factors would consist of performing experimental investigations on two identical specimens for each structural component. One specimen would represent the component in its pre-earthquake condition, while the other specimen would represent the component in its post-earthquake condition (i.e., earthquake-damaged). Therefore, the reduction factor values would be derived by comparing the force-displacement capacity curves of the two specimens. However, FEMA 307 highlights that at the date of the document, no such test campaigns on RC walls were available in literature to calculate the λ factors. In the absence of this type of

tests, an alternative approach was adopted, based on individual cyclic-static tests. According to this approach, the change in force-displacement response from cycle to cycle is examined as the displacement increases. As reported in FEMA 307, firstly the component type and behavior mode (e.g., flexural, shear, etc.) are defined according to the selected test. The critical damage states (e.g., spalling, cracking, etc.) are observed during the load-displacement history of the test and are correlated with the displacement ductility achieved by the component. Then, by comparing the initial and subsequent cycles, λ factors are derived. Finally, both the critical damage indicators and the associated reduction factors are discretized into six damage severity levels (from “None” to “Extreme”). An example of FEMA 306 component damage classification is reported in Figure 3a for an isolated wall with ductile flexural behavior and “Insignificant” damage level. It is worth noting that, even for “Insignificant” damage level, stiffness reduction occurs, since the component stiffness is most sensitive to damage, as shown in Figure 3b.

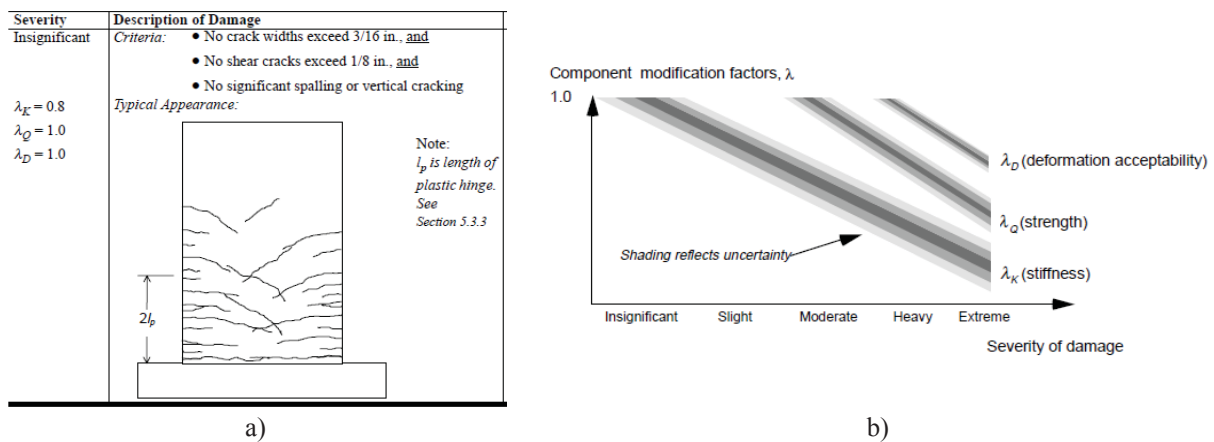

Figure 3: a) Example of component damage classification for an isolated wall with ductile flexural behavior; b) general relationship between damage severity and modification factors [4].

Following the FEMA 306/307 approach, significant research effort has been dedicated in order to derive coefficient reduction factors for damaged structural elements as well as to define a detailed general framework for the evaluation of the residual capacity of RC buildings (e.g., [10, 11]). Nevertheless, these investigations mainly focused on frame systems (e.g., [12–14]). Looking at structural walls, several experimental and numerical studies can be found in literature, however these research works focused at improving the understanding on the seismic response and performance of RC walls. *Dashti et al.* [15] developed a finite element model based on curved shell element formulation to predict the nonlinear behavior of planar RC structural walls with specific focus on out-of-plane instability mechanisms. Moreover, the same authors carried out a detailed experimental investigation on the out-of-plane instability in rectangular RC walls [16]. *Shegay et al.* [17] performed experimental testing on four flexural walls with rectangular cross sections in order to investigate the impact of the imposed axial load ratio as well as the transverse reinforcement detailing on their seismic performance. *Niroomandi et al.* [18] experimentally investigated the effects of the bi-directional loading on the seismic behavior of slender rectangular RC walls. An overview of comprehensive research programs, developed in New Zealand, following the 2010/2011 Canterbury earthquakes, and including practical recommendations for the design and assessment of RC walls, is available in *Shegay et al.* [19]. *Li and Xiang* [20] suggested a formulation for assessing the effective stiffness of RC squat structural walls by performing a comprehensive parametric study. A similar study was discussed in *Sharifi and Shafieian* [21], who proposed a formulation to de-

termine the effective stiffness of slender and squat walls, based on statistical analyses of 154 existing experiments available in literature. *Kolozvari et al.* [22] developed an analytical model able to capture the interaction between axial/flexural and shear responses for RC walls subjected to reversed-cyclic, based on a two-dimensional fiber-based macroscopic model, and the experimental calibration and validation of this analytical wall model was also carried out [23]. Finally, a special collection of 10 papers presenting recent advances in seismic design of Reinforced Concrete walls can be found in *Sritharan and Beyer* [24]. However, as mentioned above, further investigations and research efforts are required to study and better understand the post-earthquake residual capacity of structural wall systems.

3 PARAMETRIC INVESTIGATIONS ON RC WALLS

A parametric analysis is carried out to investigate the seismic residual capacity of RC walls. After the collection of experimental literature data on structural walls, refined FEM models are implemented and calibrated by comparing numerical and experimental results. Then, additional case-study walls are defined by modifying the geometrical and structural details of the selected RC walls. Non-linear static analyses are thus performed to assess the seismic performance of the walls in their undamaged and damaged configurations. Different damage conditions as well as assessment methods are indeed considered. Finally, for each case-study wall system, strength and stiffness reduction factors are derived. Detailed information about the implemented methodology and the analysis results are reported within this section.

3.1 RC wall configurations and modelling approach

The case-study structural walls are selected from experimental tests available in literature and taking into account alternative collapse modes (i.e., flexural, flexural/shear and shear). Specifically, six experimental tests on structural walls are selected. Geometrical details and material properties of these RC walls are reported in Table 1. More details about the specimens can be found in the cited papers.

Note: A.R. = Aspect Ratio; H_w = wall height; t_w = wall thickness; S.S.R. = Shear Span Ratio, ν = axial load ratio; f'_c = concrete compression strength; f_y = steel yield stress; $\rho_{l, BE}$ = boundary element longitudinal reinforcement ratio, $\rho_{h, web}$ = web horizontal reinforcement ratio.

Table 1: Geometrical details and material properties of the selected structural walls.

The structural walls are analyzed adopting a refined Finite Element Modelling approach based on the Modified Compression Field Theory (MCFT, *Vecchio and Collins* [30]). The MCFT is an analytical model for predicting the load-deformation response of reinforced concrete membrane elements subjected to shear and normal stresses. It is based on three sets of relationships: 1) compatibility relationships for concrete and reinforcement average strains; 2) equilibrium relationships involving average stresses in concrete and reinforcement; 3) constitutive relationships for cracked concrete and reinforcement [31].

The numerical analyses are performed using the structural software VecTor2 [6]. The reinforced concrete wall is modelled by plane stress rectangular elements. Steel transversal bars are modelled as smeared reinforcement in concrete elements, while steel longitudinal bars are represented by mono-dimensional “truss” elements. The *Popovics* [32] stress-strain relationship is adopted to model the (unconfined) concrete cover, while the *Mander et al.* [33] behavior is used for the (confined) concrete core. The steel stress-strain relationship is modeled according to *Seckin* [34], allowing to include the so-called Bauschinger effect. Figure 4 shows an example of structural wall numerical model in VecTor2 and the results obtained in terms of crack patterns (numerical vs. experimental).

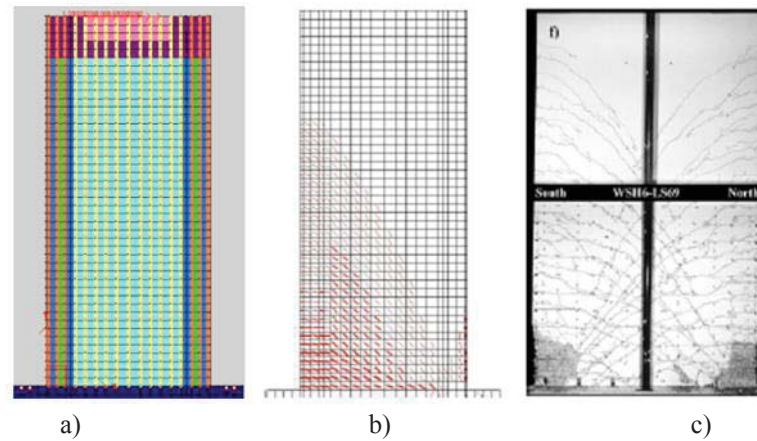

Figure 4: Example of: a) numerical model in VecTor2; b) crack patterns obtained by VecTor2 vs c) crack patterns observed during the experimental tests performed by *Dazio et al.* [26].

For all the selected walls, numerical vs. experimental comparisons in terms of cyclic response and crack patterns are carried out. Results highlight a good agreement between numerical and experimental behavior, confirming the reliability of the adopted modelling approach. In Figure 5 an example of comparison in terms of cyclic response is presented for two flexural-dominated walls (for the walls affected by shear collapse mechanisms, only monotonic experimental curves are available).

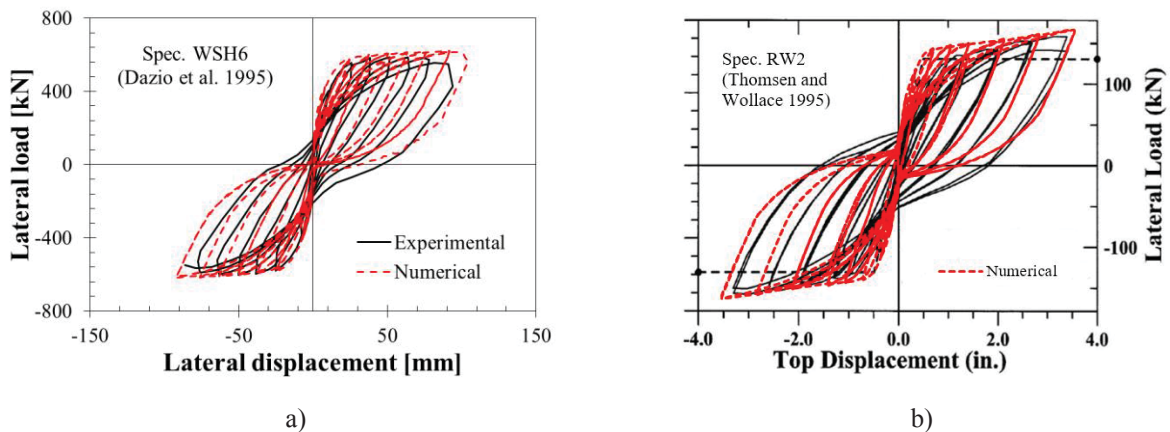

Figure 5: Example of comparison in terms of cyclic response: a) Experimental data from *Dazio et al.* [26]; b) original graph from the experimental tests by *Thomsen and Wallace* [25].

In order to increase the dataset, parametric configurations of the RC walls listed in the previous Table 1 are identified and numerical analyses are simulated for each additional case-

study adopting the same modelling approach previously described. Specifically, the walls are parameterized in terms of geometrical details (i.e., aspect ratio), applied axial load (v) and material properties. It is worth noting that the expected behavior/collapse mode of the wall (flexural or shear or flexural/shear) can thus change, especially when the aspect ratio is modified. Table 2 summarizes the main properties of each structural wall considered to develop the parametric analysis. In total 39 RC walls are involved (13 for each collapse mode).

Collapse mode	ID Case-study	A.R. [-]	H_w/t_w [-]	S.S.R. [-]	v [-]	f'_c [MPa]	f_y [MPa]	$\rho_{l, BE}$ [%]	$\rho_{h, web}$ [%]

Table 2: Selected case-study walls.

3.2 Non-linear static analyses

Non-linear static analyses are performed to assess the seismic performance of all the case-study structural walls in their pre- (undamaged) and post- earthquake (damaged) conditions. In particular, three post-earthquake damage levels are considered, namely: DS1 (limited damage), DS2 (moderate damage) and DS3 (severe damage). Nevertheless, in the international codes/guidelines practical and specific methods to identify these damage states are still under development, while only a qualitative damage description is often reported. Therefore, in this paper three alternative methods are considered and compared to identify the three damage levels for each wall configuration:

- The first method (M1) refers to the FEMA 307 [9] approach. Damage severity levels are correlated with the achievement of displacement ductility levels. More details about the FEMA 307 evaluation procedure are reported in the previous section.
- The second method (M2) refers to the fragility database of FEMA P-58 [35]. The existing repository of fragility data allows to identify the damage states by the achievement of specific drift levels and damage conditions (e.g. dimensions of cracking in concrete).
- The third method (M3) refers to the damage classification of FEMA 306 [4]. Specifically, as mentioned above, FEMA 306 provides crack pattern information associated with different damage severity levels and this description can be used to identify different damage levels.

A unidirectional monotonic lateral load is initially applied to each wall in order to evaluate the force-displacement capacity curve in its undamaged configuration. Then, a two-step procedure is adopted: 1) first, reversed-cyclic loads are applied to simulate the achievement of specific damage states (i.e., DS1, DS2, DS3) considering the identification methods described above (i.e., M1 vs. M2 vs. M3); 2) then, a unidirectional monotonic lateral load is applied to the damaged walls to evaluate the force-displacement capacity curve for each damaged configuration. This allows to derive stiffness and strength reduction coefficients (i.e., λ_K and λ_Q) by comparing the pre- and post- earthquake force-displacement curves. It is worth noting that a bilinearization of the capacity curves is needed to compute these reduction factors. In this work, two different bilinearization methods are considered, according to the procedure proposed by *Paulay and Priestley* [36] and FEMA 273 [37] (referred to as B1 and B2 respectively), and compared. The first approach provides the secant stiffness intersecting the pushover curve at $0.75 V_u$, where V_u is the average of the maximum shear values at the base of the wall, while for the second method the intersection point is identified at $0.6 V_y$, where V_y is now the wall yielding shear.

Figure 6 shows an example of load history adopted in the two-step non-linear static analysis of damaged wall configurations as well as an example of assessment of reduction factors through the capacity curves of both the undamaged and damaged wall (B2 bilinearization, DS3 level). In summary, three different damaged states are considered for each case-study wall by adopting three different damage identification methods (M1, M2, M3). Moreover, reduction factors are derived according to two alternative bilinearization methods (B1, B2). This leads to a total number of 702 values for both strength and stiffness reduction factors.

Figure 6: a) Load history for the non-linear static analysis of damaged walls; b) assessment of reduction factors by comparing the capacity curves of the undamaged and damaged wall (e.g., B2 bilinearization, DS3 level).

3.3 Reduction coefficients

Results in terms of strength and stiffness reduction factors (as percentage values [%]) are summarized in Table 3. The structural walls are classified according to their collapse mechanism mode and for each damaged state (DS1, DS2, DS3) and identification method (M1, M2, M3), as well as bilinearization procedure (B1, B2), average and dispersion (standard deviation) values of reduction factors are reported.

Table 3: Reduction coefficients obtained for the case-study walls.

Results highlight that stiffness is more sensitive to damage when compared to strength, and this is in agreement with FEMA 306. Moreover, the obtained mean reduction values are lower (especially in case of λ_K) when compared to DS1/DS2/DS3 reduction coefficients of 80/60/50 and 100/100/80 for λ_K and λ_Q , respectively, provided by FEMA 306 for flexural walls. Referring to the severe damage state (DS3), the strength loss obtained for flexural-dominated walls is less than 5%, while is around 10-15% for flexural/shear walls and almost 20-25% for walls affected by shear collapse. On the other hand, referring to the same damage level, higher stiffness losses can be observed for all the wall typologies, even more than 70% at DS3. The previous table also shows that walls with shear collapse mechanism have higher dispersion in the results, as highlighted in Figure 7a for the case of Method M1-Bilinearization B2. Furthermore, differences (less than 10% for M1, while less than 20% for M2, M3) can be highlighted when the two bilinearization methods (B1 vs. B2) are compared (Figure 7). Finally, it is worth noting that the damage assessment methods strongly affect the results. In fact, adopting the M1 method the lowest dispersion is found, while the M3 method leads to the highest dispersion values. This result is in agreement with the expectation, since referring to crack patterns (M3 method) can lead to higher uncertainty in the identification of damage states than using a direct indicator as the displacement ductility (M1 method).

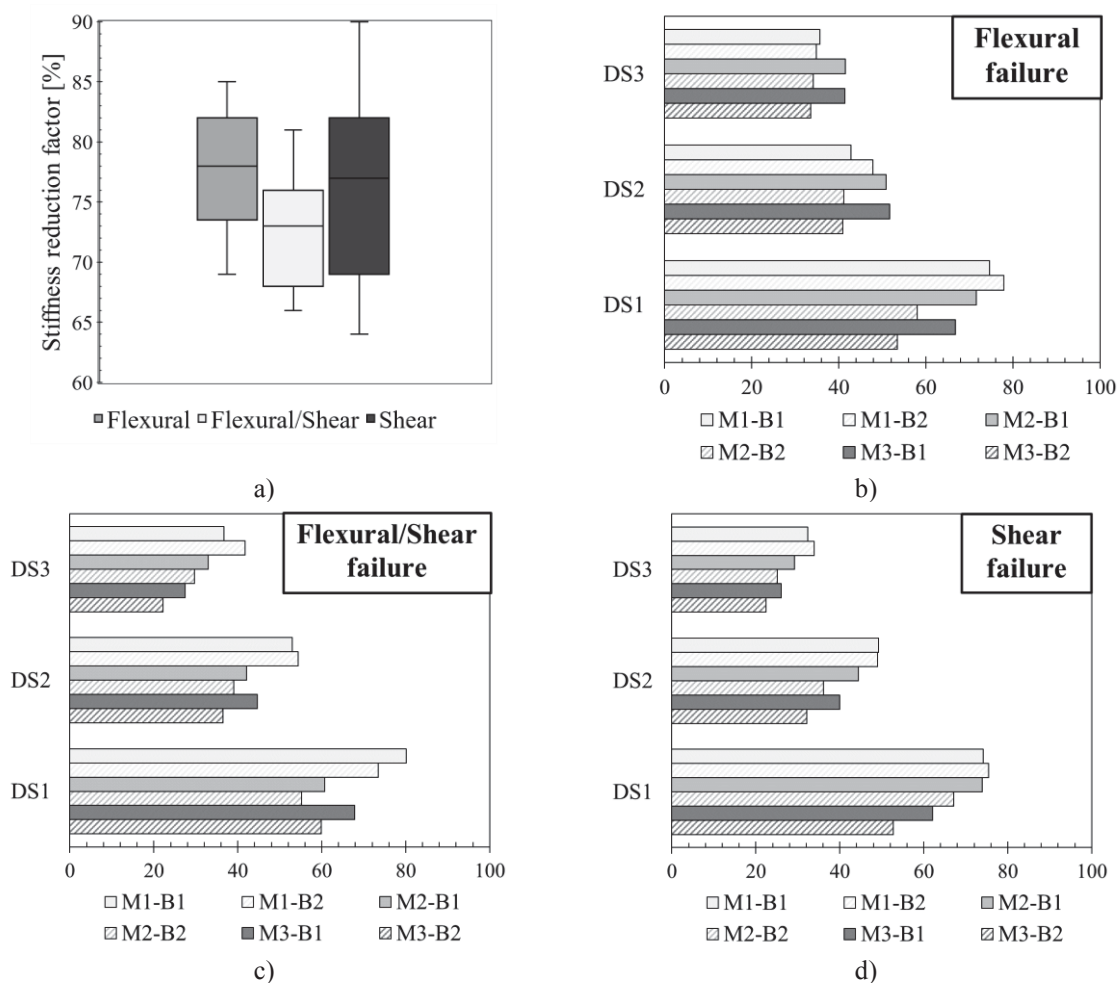

Figure 7: a) Mean and dispersion values of stiffness reduction factors λ_K (for Method M1 and Bilinearization B2); comparison between the λ_K values obtained from all the implemented approaches, in case of: b) flexural failure; c) flexural/shear failure; d) shear failure.

4 NUMERICAL ANALYSIS ON A MULTI-STORY RC BUILDING

4.1 Description of the case-study

The case-study building is a 5-story reinforced concrete structure with global dimensions and plan geometry as presented in Figure 8. This structure is selected from a previous research work developed by *Bianchi et al.* [38]. The structural skeleton consists of seismic-resistant four-bay frames in one direction and seismic-resistant walls in the orthogonal direction. The building has commercial and residential use and is located in a high-seismicity Italian zone (PGA of 0.353 g). Focusing on the wall direction, alternative typologies of structural systems are designed to provide the same Overturning Moment (OTM of 35000 kNm) of the initial reference multi-story building, namely: 1) a first case-study comprising four earthquake-resistant ductile walls, characterized by a flexural collapse mechanism (Case 1); 2) a second case-study consisting of the same geometrical configuration, but the RC walls are now affected by a brittle shear failure, i.e. no hierarchy of strengths principles is applied (Case 2). Although the reference building is a new structure, the shear-dominant walls are designed for the purpose of this study only.

Figure 8: a) Global view of the reference building (Bianchi et al. [38]; b) new geometrical configuration designed in the wall direction (Case 1: flexural collapse; Case 2: shear collapse)

4.2 Numerical analysis

Non-linear static (pushover) analyses are performed following an analytical-based approach, the so-called Simple Lateral Mechanism Analysis (SLaMA) described in the NZSEE guidelines [39-41]. This practical methodology allows to determine the base shear-displacement (capacity) curves of the two case-study wall systems by simple analytical calculations accounting for the collapse mechanism (flexure, shear, flexure/shear) developing within the structural system. Then, following the pushover-based Capacity Spectrum Method [42, 43], the building performance points are computed at different seismic intensity levels (namely SLO, SLD, SLV, SLC, or, Immediate Operational, Damage Control, Life Safety and Collapse Prevention, respectively, as indicated in the NTC 2018 [44]).

Figure 9 (a, c) shows the demand vs. capacity results obtained in the Acceleration-Displacement Response Spectrum (ADRS) domain. This figure highlights the better behavior of the ductile flexural walls, even allowing for a greater dissipation and consequently a reduced seismic demand (response spectra at Ultimate Limit States are in fact reduced considering the building equivalent viscous damping). Instead, the shear-dominated walls are

characterized by a brittle behavior leading to a ultimate capacity point not even achieving the Life-Safety design spectrum. Finally, the damaged configurations for the two case-studies (Case 1, Case 2) are determined applying the reduction strength/stiffness coefficients already computed in the previous section (Figure 9 b, d).

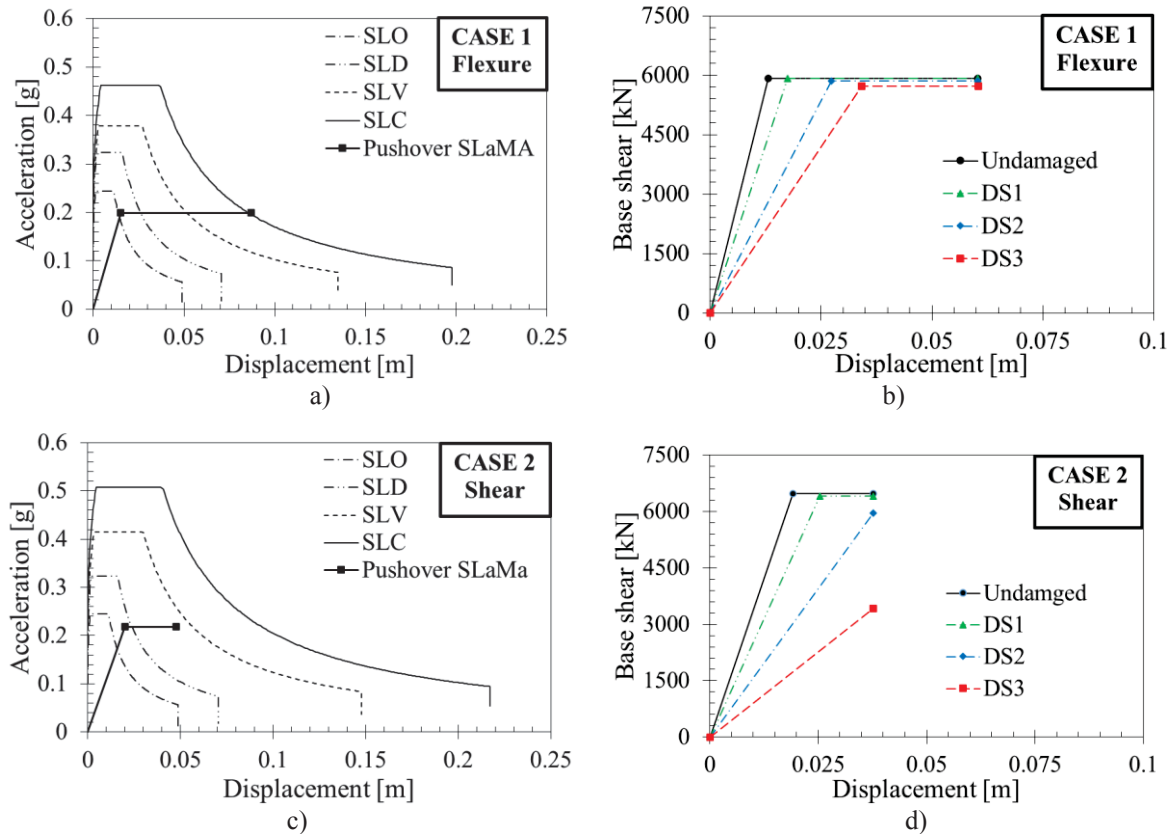

Figure 9: Capacity curves of the undamaged structure in the Acceleration-Displacement Response Spectrum (ADRS) domain and for all the damaged wall configurations (DS1, DS2, DS3): a) b) Case 1 - flexural failure mode; c) d) Case 2 - shear failure mode.

4.3 Loss assessment investigations

Loss assessment analyses are finally implemented considering as input data the floor accelerations and inter-story drift ratios (from the performance points) obtained at the various seismic intensities. Two alternative loss assessment procedures are involved: 1) the simplified approach described in the D.M. 65 [45], the “Seismic-Bonus” guidelines; 2) the rigorous probabilistic-based procedure defined in FEMA P-58 [35].

Focusing on the simplified methodology, results in terms of Expected Annual Losses (EAL) curves and values (expressed as percentage of the Replacement Cost - RC) are summarized in Figure 10 (referring to M1 damage assessment method and B1 bilinearization method) for both undamaged and damaged wall systems. The comparison highlights that the structural system comprising brittle RC walls (Case 2) leads to higher losses when compared to the structural configuration consisting of ductile walls (Case 1). Furthermore, for Case 1 and looking at DS1 damage level (and DS2 in some cases), lower economic losses are found when compared to the undamaged structure. This is due to the structural system yielding before the expulsion of the external infill walls (expected to be achieved at 0.5% drift level as per Italian NTC 2018 code [44]). Thus, the cost/frequency point at SLD is now represented by the yield-

ing of the steel rebars, causing reduced repair costs instead of the pre-fixed value imposed by D.M. 65 [45] at SLD, i.e. 15% RC (this value has been derived from the reconstruction/repair costs after L'Aquila earthquake - *White Book, Dolce and Manfredi* [46] - already including the contribution of non-structural damage, especially masonry infill walls).

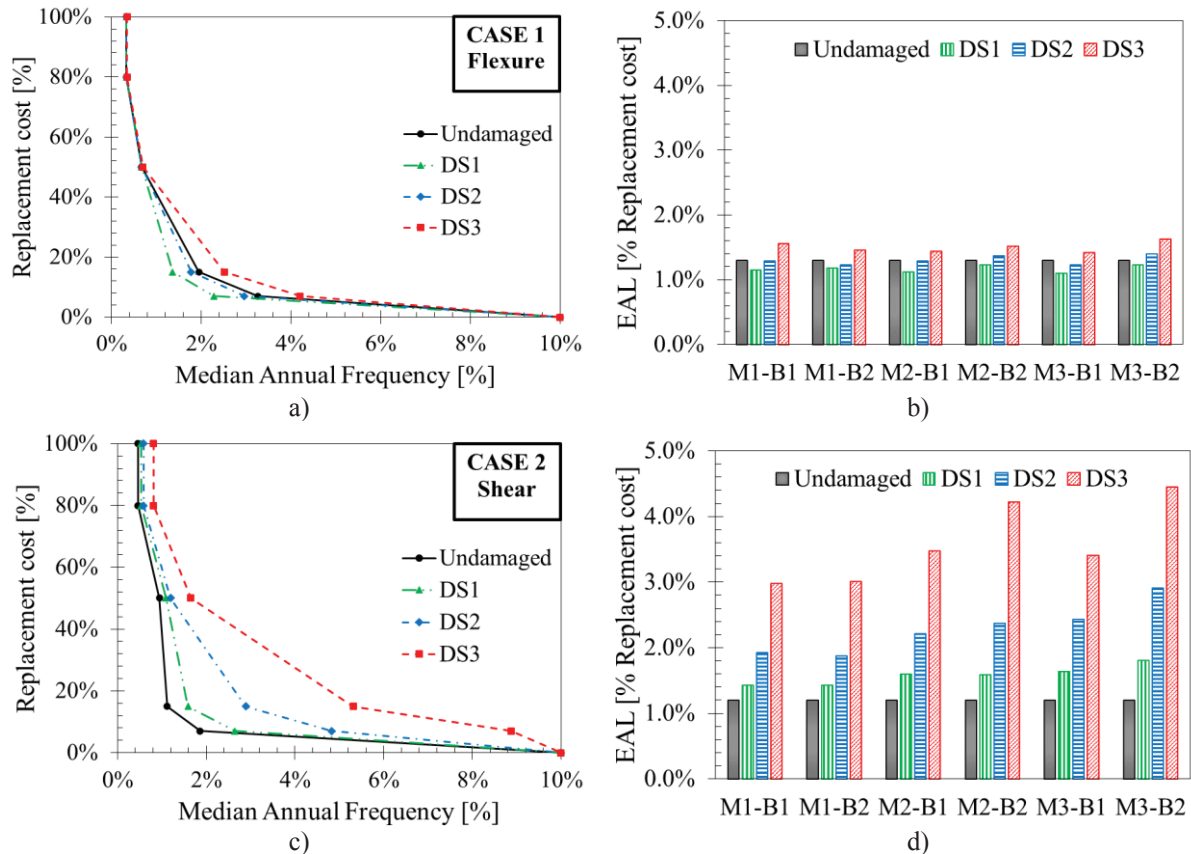

Figure 10: EAL curves and values for the undamaged and damaged wall systems: a) b) Case 1 (flexural collapse mode); c) d) Case 2 (shear collapse mode).

Consequently, looking at the yielding point as damage limit for SLD and following the analytical-based codified loss assessment approach, the lower elastic stiffness of the structure in case of DS1 (or DS2) inherently brings to lower losses (Figure 11). Therefore, losses are not properly evaluated for the flexural-dominated wall configurations at SLD (and consequently at SLO). In general, this outcome highlights the limits of the current code-compliant procedure, not accounting for the possibility of adjusting the repair cost/frequency values when a specific damage condition is achieved. In this case, the very stiff structural walls begin to damage at drift levels lower than the 0.5% (or greater) value, representing the displacement check/verification at low seismic intensity levels within the Italian Code [44]. Nevertheless, referring to international codes (as SEAOC Vision 2000 [47], NZS 1170.5 [48]), useful indications can be found to evaluate proper drift limiting values at Damage Control level for the case of wall structural typology.

Figure 11: Comparison between undamaged and damaged (DS1) response for Case 1 (flexural collapse).

In order to obtain a more accurate evaluation of the EAL values, loss assessment analyses are also implemented using the PACT (Performance Assessment Calculation Tool) provided by the FEMA P-58[35]. This tool allows to include all the component fragilities of the building under consideration, thus the issue previously highlighted for the simplified procedure is automatically solved. In fact, the methodology is flexible and opened to the possibility of including new fragility functions, as well as consequence functions, describing the behavior of specific building structural and non-structural elements. In this case, due to the absence of fragility curves representing the Italian clay-brick masonry infill walls within the available fragility database, these functions are added by referring to the data reported in *Cardone et al.* [49]. Table 4 summarizes the EAL values obtained from both loss assessment methodology for both (undamaged) case-studies. It can be highlighted that the probabilistic procedure leads to reduced repair cost values and, consequently, an improved risk class for the building, as observed for the case of flexural collapse mechanism.

Case-study	Collapse mode	EAL [%RC]		Risk class	
		D.M. 65	FEMA P-58	D.M. 65	FEMA P-58
Case 1	Flexural	1.30	0.84	B	A
Case 2	Shear	1.20	1.04	B	B

Table 4: EAL values for D.M. 65 and FEMA P-58 loss assessment methodology for undamaged case-studies

Ultimately, another decision variable useful to provide indications on the seismic performance of a building system (as well as addressing the design of new and/or retrofitted buildings, as described in the research work by *Nuzzo et al.* [50]) is represented by the expected Probable Maximum Loss (PML). This parameter provides the maximum probable building repair cost associated with a specific intensity level. Figure 12 presents the PML curves obtained from PACT tool for both case-study structures. This graph highlights how losses can be high even at low-intensity seismic levels and that higher values are obtained for the structural walls affected by shear collapse mechanism (40% more than the flexural case when looking at the maximum expected loss of Figure 12a).

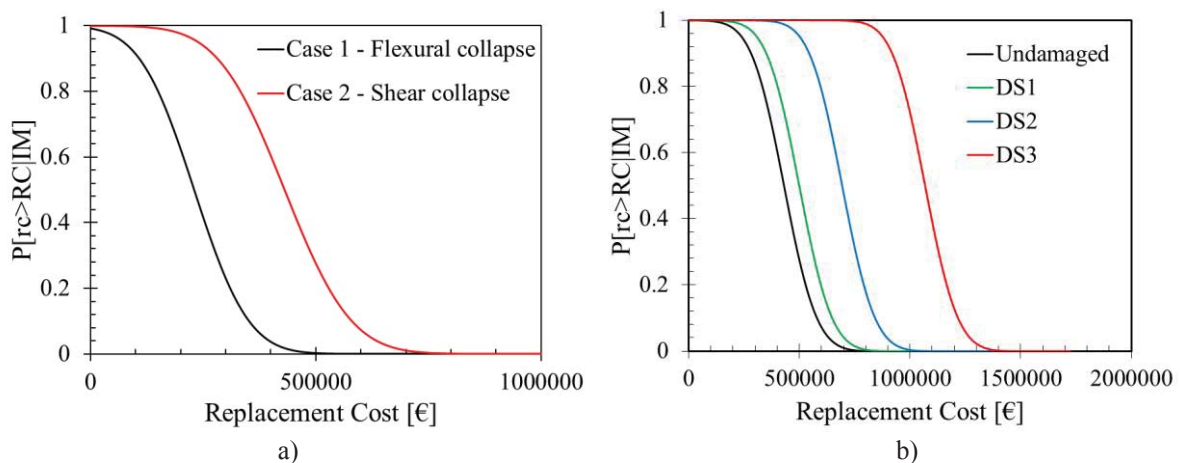

Figure 12: PML curves obtained through the FEMA P-58 methodology: a) comparison between Case 1 (flexural collapse mode) and Case 2 (shear collapse mode); b) at various damage levels for Case 2 (shear collapse mode).

The FEMA-based loss assessment results in terms of EAL/PML values are presented for the undamaged structural configurations (Case 1 vs. Case 2), with the aim of defining more reliable loss values through a more accurate prediction of the repair costs. When considering the damaged cases (DS1, DS2, DS3), the probabilistic-based procedure as developed within the PACT tool does not allow (yet) to properly consider the cumulative damage associated with the wall systems, i.e. to evaluate PML/EAL results for the damage wall configurations. In fact, modifications of the probabilistic formulations (conditional probability) as well as cumulative-based fragility/consequence functions should be considered. Therefore, in order to highlight the possible effect of the damage state into the loss assessment results (from a conceptual point of view), Figure 12b presents the PML curves obtained for the damaged structural cases when the same relative difference in losses obtained from the simplified assessment is adopted.

5 CONCLUSIONS

This paper investigated the seismic residual capacity of RC structural walls through numerical (non-linear cyclic/static, FEM/macro-modelling) analyses and loss assessment studies. The research work aimed at providing indications on the methodology to be followed in order to include residual capacity considerations in practical applications. Therefore, alternative damage assessment methods were used (or proposed) and compared to define specific damage limit states (DS1: light, DS2: moderate, DS3: severe) and the related stiffness/strength reduction coefficients for RC walls affected by either a flexural and/or shear collapse mechanism. Moreover, loss investigations on a multi-story case-study building were developed to study the effect of the damage level and type of collapse mechanism into the repair costs of structural wall systems.

The main results from the developed study are herein discussed:

- FEMA 306/307 (1998) guidelines do not provide a standardized procedure to identify the different damage states levels (DS1, DS2, DS3) in RC structural walls (e.g. in case of experimental testing, indications on the specific load history to be adopted are missing). Comparing alternative damage assessment methods, less dispersion in the results in terms of stiffness/strength reduction coefficients is related to the adoption of the

FEMA 307 procedure (describing the damage states by the achievement of specific ductility levels);

- Loss assessment results in terms of EAL highlight the importance of including residual capacity considerations in the analysis. This could provide valuable information to support decisions on the post-earthquake repair/retrofit/demolition. In fact, results highlight that greater losses are obtained even at low-intensity levels when the response of the damaged wall is considered, when compared to the undamaged wall. Moreover, when repair/rehabilitation actions need to be implemented for existing wall systems, higher attention should be paid in case of walls with brittle (shear-dominated) behavior, leading to substantial economic losses at increased damage levels.
- The simplified procedure reported in the “Sesmic-Bonus” is not able to consider realistic repair costs at low seismic intensity levels in case of stiff RC wall systems. This is due to the codified analytical procedure based on economic losses from L’Aquila 2009 earthquake accounting for alternative structural typologies and non-structural damage (especially unreinforced masonry walls). This issue could be solved by referring to post-earthquake reports and extrapolating the data related to the RC buildings only, as well as modifying the definition of the low-intensity (SLD) cost/frequency points following international codes/guidelines indications (drift limits in case of wall systems).

Nevertheless, this research work represents a preliminary parametric analysis and investigation on the residual capacity for RC walls. Further studies are needed to provide general indications on the reduction strength/stiffness coefficients to be used in practical applications, for specific wall typologies/structural response. Moreover, additional and more refined investigations (numerical modelling, time-history analysis) are needed to study the residual capacity of multi-story wall structures as well as to determine the consequent socio-economic losses - even by the implementation of a more refined procedure taking into account the cumulative damage within the building elements.

Abstract

In this study a dedicated framework for seismic losses estimation in Reinforced Concrete buildings is presented, taking advantage of a simplified analytical structural analysis, a dedicated drift-based fragility curves and a specific repair cost analysis. To this aim, the mechanically based “Pushover on Shear Type model” (POST)-method, already known in the literature [1] for simplified structural analysis, has been integrated herein to obtain expected losses due to earthquakes for infilled RC buildings. On the other hand, the thoroughly cost analysis dedicated to only masonry infill panels and services (electric and plumbing system, sanitary equipment, floors, etc.) restoration presented in [2] has been used to develop an integrated formulation for loss estimation in Reinforced Concrete buildings.

The application to a wide dataset of buildings struck by L'Aquila (Italy) 2009-earthquake is used as testbed for large-scale applications. In fact, the comparison with actual damage distribution and repair cost provides a useful validation of the whole framework, from structural analysis to loss prediction.

Keywords: Seismic risk, infilled RC buildings, mechanical methodology, loss prediction, validation.

1 INTRODUCTION

The unfavorable combination of high exposure of artistic, monumental and residential assets, together with the high seismic hazard and the high vulnerability of the major part of building stock makes seismic risk in Italy and, generally in the Mediterranean area, a pivotal issue. Thus, several methodologies for losses assessment of built inventory have been developed in Italy since the end of '80 ([3]; [4]; [5]; [6]; [7]), belonging to the first generation of approaches making use of empirical Damage Probability Matrix (DPMs) and damage factor (DF) to

determine repair cost as a function of the complete replacement cost. The second generation of methods ([8]; [9]; [10]) makes use of fragility curves for different building classes ([11]; [12]; [13]; [14]; [15]; [16]) to evaluate seismic risk maps of Italy. The last generation of methods ([17]; [18]; [19]; [20]; [21]; [22]) estimates seismic losses through a component level approaches, thus requiring the use of specific component fragility functions and consequence data.

In this study, a mechanical method for regional loss estimation is presented, taking advantage of structural analyses performed through the simplified mechanical method POST ([1]) (Push-Over on Shear Type models). POST method originally developed for fragility analysis of building portfolio ([23]; [24]; [25]; [26]), has been slightly adapted to properly determine damage distribution and resultant losses within a component-based approach for economic (direct) loss estimation.

To this aim, specific drift-based fragility curves and repair cost analysis have been defined and used for three damage states (light cracking - DS1, extensive damage - DS2, severe damage - DS3), describing the evolution of damage to the masonry infills and partitions in a RC building.

The application to a wide dataset of buildings (5095 RC buildings) struck by L'Aquila (Italy) 2009-earthquake is used as testbed for large-scale applications. In fact, the comparison with actual damage distribution and repair cost provides a useful validation of the whole framework, from structural analysis to loss prediction.

2 A REGIONAL LOSS ESTIMATION FRAMEWORK VIA POST METHOD

A novel methodology for regional loss estimation at the component-level is presented herein based on structural analyses performed through the simplified mechanical method "POST" ([1]; [23]; [24]; [25]; [26]) (Push-Over on Shear Type models).

POST method is a simplified mechanical methodology for vulnerability and fragility assessment at regional scale of RC buildings, which can be applied both at single building level ([1]; [23]; [24]; [26]) or at building class level ([25]).

The mechanical framework stated above is used to evaluate repair cost for a given building considering the contribution of all its N-components:

$$E[L|IM = im] = \sum_{j=1}^N a_j \cdot E[L_j|IM = im] \quad (1)$$

The conceptual derivation of the adopted procedure is briefly recalled in Figure 1, which shows: (i) the evaluation of IM value from ground motion characterization; (ii) the assessment of spectral displacement and resultant roof displacement through IDA curves; (iii) the consequent interstorey drift ratio (IDR) profile assessment throughout the height of building by means of pushover analysis results; and (iv) lastly the definition of damage and resultant cost through their comparison with capacity values related to specific damage levels.

The seismic hazard phase can be done both with results of Probabilistic Seismic Hazard Analysis (PSHA) or from the results of ShakeMap scenario earthquakes, depending on the objective to be pursued, namely if an unconditional risk analysis (considering the seismic events could occur in a given area and in a given time interval and their mean annual frequency of exceedance) or a conditional risk analysis (referred to a specific scenario) should be performed.

The structural response phase is accomplished with the aid of POST method, which allows to relate an engineering demand parameters (edp), i.e. roof displacement, and a resultant displacement profile, given an intensity measure (IM) value, through the use of simplified Incremental Dynamic Analysis (IDA) curves within the SPO2IDA framework ([27]). The Static Pushover (SPO) analysis is carried out in closed form based on a software package on Matlab code thanks to the simplified assumption of shear-type behaviour for RC frames. In fact, the

POST method starts generating geometrical and mechanical models of buildings based on a simulated design procedure, accounting for the technical codes in force at the age of construction and the relevant seismic classification of the site. Then, the nonlinear behaviour of RC structural components is reproduced by means of a tri-linear response, with two linear ascending branches up to yielding (defined in agreement with [28]) and perfectly plastic thereafter. Note that eventual shear critical elements are not explicitly modelled (with modified plastic hinges or explicit shear springs), but their damage due to seismic loading can be detected as reported in [24].

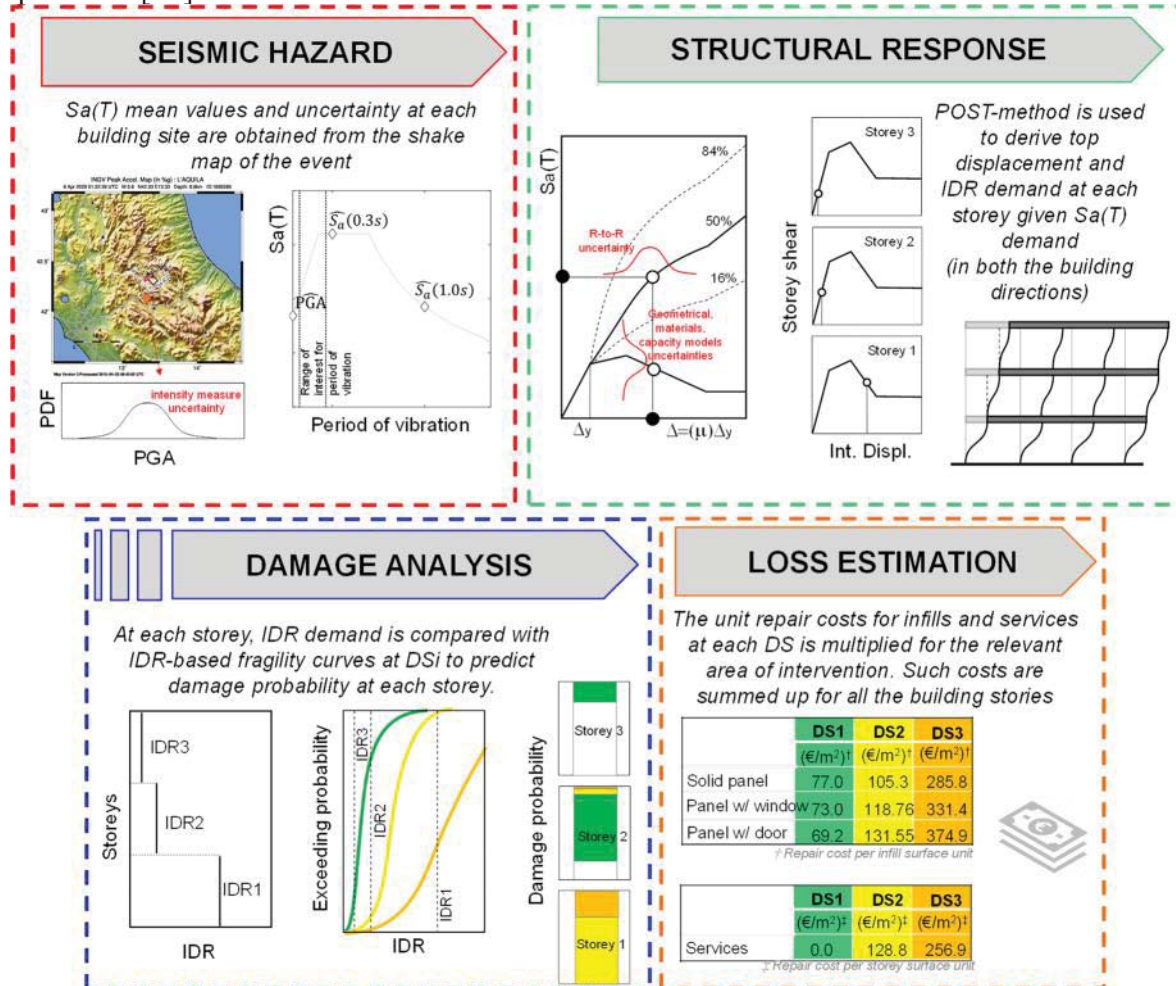

Figure 1: Flow-chart of the procedure applied in this study for loss assessment

Infills have been explicitly included in the structural models, by means of a four-branch force-displacement curve ([29]). The influence of the openings on infills' lateral force-displacement relationship is also considered, by means of the modifying behaviour parameters based on [30].

The simplified assumption of shear-type behaviour for RC frames allows obtaining a multi-linear storey shear -vs- interstorey displacement relationship at each storey by simply adding up the lateral shear-displacement relationships of all the RC columns and infill panels along longitudinal and transverse direction, separately. In such a way, seismic response via a static push-over curve is obtained in a closed-form procedure, which is force-controlled up to peak response and displacement-controlled thereafter, once the distribution of lateral forces has been set.

Therefore, the structural response estimation is entirely evaluated via POST method, which returns the evolution of the lateral displacement profile increasing the IM value through the

results of static SPO analysis for each main direction of the building. The relation between IM values and EDPs is given by the IDA curves related to the quadri-linear simplification of SPO curve.

The damage estimation phase is performed by means of specific component fragility curve, returning the probability of exceeding a discrete Damage State, DS, given the EDP.

It has to be noted, that due to the peculiarity of the building dataset considere in this work (see later), resulting to be “lightly damaged” to infills only after the 2009 Abruzzi earthquake, vertical structures will be neglected from damage and loss computation. Moreover, IDR thresholds and resultant uncertainties for infills/partitions and services have been assumed in this study from [31]’s proposal, which finds its background in [32]. In fact, the construction practices in Mediterranean region for residential RC buildings entail that services are generally allocated within building enclosure, the latter typically made up of hollow clay bricks. In this case, cascading effects could occur, such that damage to one, i.e. infills, could cause the fracture of the other one, i.e. a water or electric distribution pipes or a sanitary equipment. Thus, damage for both infill panels and services is strictly related to each other due to their firm interaction, as it will be better shown in the following application.

The comparison between IDR demand and fragility curves allows determining DS for the considered component. In such a way, the number of components suffering a given DS_i can be determined, thus evaluating its relative extension also considering the possibility of experiencing different co-existing DSs along the building height (namely at different stories).

Finally, the loss estimation phase is fulfilled taking advantage of proper repair cost analysis reproducing detailed quantity surveying considering a list of elementary actions to be performed for an area of intervention given $DM = dm$, through the use of specific unit costs from a price list (e.g., that for Public Works in Abruzzi Region - [33], as applied in the following section). Thus, the values of repair costs for infills and services per square meters of storey surface for 3 DSs reported in [2] and [22] (briefly reported in table 1 and table 2) are used.

	\bar{C}^{IP}_{DS1} (€/m ²)	\bar{C}^{IP}_{DS2} (€/m ²)	\bar{C}^{IP}_{DS3} (€/m ²)
solid panel (w/o openings)	77.0	105.3	285.8
panel with window	73.0	118.76	331.4
panel with door	69.2	131.55	374.9
interior partition	51.3	73.5	199.9

Table 1. Repair costs for double leaf hollow clay bricks for infills/partitions (IP) at each DS per infill panel unit (from [2] and [22])

	$C^{Services}_{DS1}$ (€/m ²)	$C^{Services}_{DS2}$ (€/m ²)	$C^{Services}_{DS3}$ (€/m ²)
All Services	0.0	128.8 ± 28.2*	258.9 ± 32.8*

(*) mean ± standard deviation

Table 2. Repair costs for services at each DS per plan surface unit (from [2] and [22])

Obviously, the damage and loss estimation steps have to be repeatedly calculated for all building components and for all DSs. Nonetheless, a realistic definition of losses should consider the fact that some activities should be carried out simultaneously for all the components of a given portion of the building (“minimum area of intervention”) higher than that strictly necessary for practical or aesthetic reasons which is assumed in this study as the whole storey. In other words, it is assumed that all the (structural and non-structural) components located in

a given storey are characterized by the maximum damage therein experienced, thus resultant losses are consequently evaluated, favoring an intervention that meets practical and aesthetic criteria.

3 APPLICATION OF REGIONAL LOSS ESTIMATION METHOD TO SLIGHTLY DAMAGED RC BUILDINGS AFTER L'AQUILA EARTHQUAKE

A large-scale application of the mechanical method for regional loss estimation via POST method is performed in this section, considering a building stock struck by the L'Aquila (Italy) earthquake (April 6th, 2009) and damaged to only infills, which incidence represented, for RC buildings, almost the entirety of actual losses after the most recent earthquakes occurred in Italy [34].

The main features of the event and of the analysed building stock are completely treated in previous works and briefly recalled in what follows. For further analysis the reader is referred to [2].

The seismic event investigated for this application struck the Abruzzi region, with a magnitude M_w equal to 6.3, resulting in IX-X grade of the Mercalli-Cancani-Sieberg scale.

For this application, the IM characterization is fulfilled by means of the shake map of the seismic event which struck the Abruzzi region on 6th April 2009, with a magnitude M_w equal to 6.3, resulting in IX-X grade of the Mercalli-Cancani-Sieberg scale. The latter is derived following the procedure reported in [35].

3.1 Building stock description

Building stock characterization is made available from post-earthquake reconnaissance filed trips carried out in the aftermath of L'Aquila earthquake with the supervision and coordination of Department of Civil Protection (DPC), and recently made available on the Da.D.O platform ([36]). These inspections collected data for each building about location, typology, geometry, age of construction, and suffered damage for structural components (including vertical structures, horizontal structures, stairs, roofs and infills) and non-structural components, by means of the so-called AeDES forms ([37]). Additionally, for each component damage, its severity and its extent have been recorded.

Overall, out of a total of about 7500 residential RC buildings listed in the Da.D.O. platform, only a subset of 5095 buildings have been selected, hereinafter defined as "lightly damaged buildings", since they are characterized to be damaged only to infills.

Their main geometrical properties (number of stories, N_s , and average plan surface, A), are thoroughly analyzed in ([2]), where it has been shown that a major part of considered building stock is characterized by three or four stories (about 75% of the whole database), that 92% of the building stock has been built after 1972 and that the most common average plan surfaces range between 70 and 230m² (about 80% of the building stock).

3.2 Building class definition for loss analysis via POST-method

The case study (large-scale) application is performed through a class-oriented approach to reduce the computational burden required by the derivation of structural analysis for an extensive (5095 units) building stock. In particular, 15 building classes have been considered herein as a function of number of storeys, N_s , and average plan area, A , such that their statistical characterization well reproduces data collected from post-earthquake AeDES survey forms. Thus, for each class of storey (from 1 to 5), three further sub-classes (low, medium and high) of plan area are defined.

Moreover, in order to explicitly consider the uncertainties related to seismic risk estimation, different kind of uncertainties are considered within a Monte Carlo simulation procedure approach, dealing with:

- (i) **geometrical-typological parameters**, i.e. building plan ratio, infills thickness, the type of opening (no opening; window opening; door opening).
- (ii) **material properties**, i.e. compressive strength of concrete (f_c), steel yield strength (f_y), mechanical characteristics of infill panels (shear strength - τ_{cr} , shear modulus - G_w).
- (iii) **capacity models**, both for the non-linear behaviour of both RC columns and infill panels.
- (iv) **intensity measure**, from INGV ShakeMap in terms of PGA (mean and logarithmic standard deviation values at each site);
- (v) **record to record variability**.

A summary of all the considered random variables (RV) and the parameters for their characterization are briefly reported in Table 3.

Type of R.V.	R.V.	Reference	Distribution	Median value	CoV [-]
Geometry	Building area	survey data	uniform	from survey	-
	Building plan ratio	[1]; [24]	uniform	median([1.0-2.5])	-

4 EVALUATION OF PREDICTED DAMAGE AND LOSSES FROM STRUCTURAL ANALYSIS

Maximum damage (DS_{max}) can be easily determined from results of structural analysis as the most severe DS_i suffered in all stories and in both directions. Contrarily, mean damage gathers information on both severity and damage extension – DE_i related to DS_i . To this aim, DE_i is evaluated from results of POST method as:

$$DE_i = \frac{\sum_{j=1}^{n_s} 1_i \cdot (\sum_{s=1}^{n_b} {}^x A_{j,s}^{II} + \sum_{k=1}^{n_b} {}^y A_{j,k}^{II})}{\sum_{j=1}^{n_s} (\sum_{s=1}^{n_b} {}^x A_{j,s}^{II} + \sum_{k=1}^{n_b} {}^y A_{j,k}^{II})} \quad (2)$$

where 1_i is the indicator function which is 1 if infill panels at that storey are characterized by DS_i at least in one (longitudinal or transversal) direction and 0 vice-versa. Previous equation is derived referring to the minimum area of intervention (the whole storey surface), thus

assuming that all the (structural and non-structural) components located in a given storey are characterized by the maximum damage therein (i.e. at that storey) experienced in both (longitudinal and transversal) directions. In Eq.2 A_j^{ii} is the area of j^{th} infill panel in s^{th} - or k^{th} -direction.

Obviously, since the damage distribution of infills can be characterized by the attainment of different DSs along the height of building, a synthetic information about the co-existing DS_i and its extent is represented by the “mean damage” level (hereinafter referred to as \overline{DS}), calculated as follows:

$$\overline{DS} = \sum_{i=0}^3 i \cdot DE_i \quad (3)$$

Therefore \overline{DS} is always lower than or equal to DS_{max} , and it can range between 0 and 3, since the maximum possible average damage is achieved when the maximum possible damage state (DS3) is reached in the whole building ($DE_3=1$).

Finally, the total repair cost for unit surface area (trc) is evaluated for each building as a function of specific repair costs for infills and services reported in Tables 1 and 2:

$$trc = \sum_{i=1}^3 \left\{ \sum_{j=1}^{N_s} 1_i \cdot \left[\overline{C}_{DS_i}^{IP} \left(\sum_{s=1}^{n_b} A_{j,s}^{ii} + \sum_{k=1}^{n_b} A_{j,k}^{ii} \right) / A + C_D^S \right] \right\} \quad (4)$$

The trc is evaluated by summing up the relative repair costs for each storey. The latter is determined given the maximum DS (DS_{max}) suffered by at least one infill panel in one of the two directions and extended to all the remaining one, in addition to services (plumbing systems, radiators, electrical system, floor/wall tiles), too. This circumstance is given in Eq. (6) through the indicator function (1_i) which is equal to 1 when at least one infill panel suffers DS_i at that storey and 0 vice-versa. Obviously, the repair costs of infills are first multiplied by the panel area (A^{ii}) and then divided by the floor area (A) to obtain the total repair cost for unit surface area.

5 PREDICTED-TO-OBSERVED COMPARISON OF DAMAGE AND LOSSES

Predicted damage and loss estimation presented in the section 4 are here compared with damage actually observed for the investigated buildings population (section 5.1) and with repair costs directly obtained from this damage (section 5.2) (hereinafter referred to as “observed damage” and “observed losses”, respectively). Note that all details about “observed damage” and “observed losses” can be found in [2] and [22].

5.1 Comparison between Observed and Predicted damage

The actual data about damage suffered by the collected building stock (“observed damage”) represents the anchorage to reality against which predicted data should be compared. Such a comparison will be shown in this section to “validate” the mechanical based procedure presented in this work.

The observed-versus-predicted agreement in terms of maximum achieved DS, reported in Figure 2, results very satisfying, considering the simplification of the method and its large-scale application. A slight underestimation of no-damaged ($DS_{max}=DS_0$) buildings can be noted, along with an overestimation of DS3-buildings.

“Predicted” damage well reproduces the “observed” damage, independently on the number of stories, as shown in Figure 3, where “predicted” and “observed” DS_{max} scenarios are reported depending on the number of stories, N_s , for the most frequent classes of N_s , namely from 1 to 5 stories.

Figure 2. Comparison between observed and predicted damage scenario in terms of DS_{max}

Figure 3. Comparison between observed and predicted damage scenario in terms of DS_{max} depending on the number of stories (N_s)

Figure 4 reports the comparison between observed and predicted mean damage given the maximum achieved DS, where the 16th, the 50th and the 84th percentiles are also reported. A quite good agreement between mean “predicted” and “observed” mean damage can be generally observed.

Additionally, when median values of “observed” mean damage are considered, a clear trend exists depending on the number of stories, as in Figure 5, where buildings are grouped depending on the maximum achieved DS. When DS_{max} is equal to DS1 or DS2, the average damage tends to decrease when N_s increases from 1 to 3 stories, then keeping a pseudo-constant value for taller buildings. At DS3, such a decreasing trend is observed from 1 to 5 stories. The predicted damage successes in reproducing such a trend.

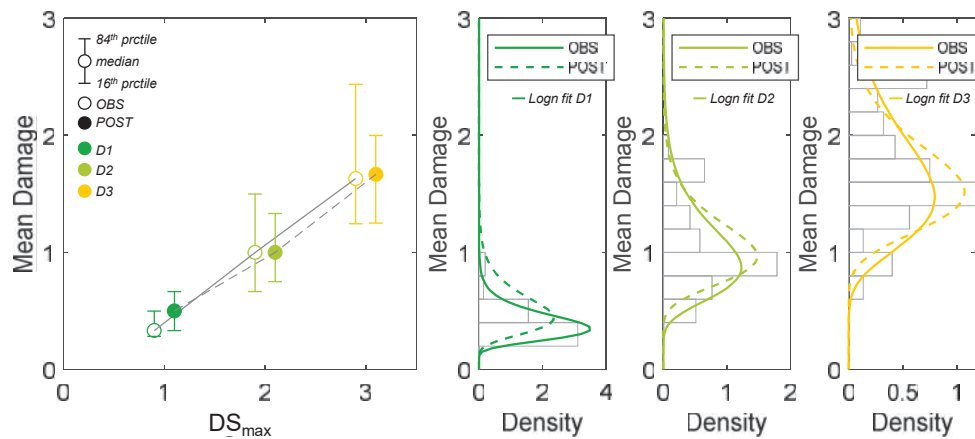

Figure 4. Predicted (POST)-versus-observed (OBS) comparison: mean damage-versus-maximum achieved DS (DS_{max}); 16th, 50th and 84th percentiles.

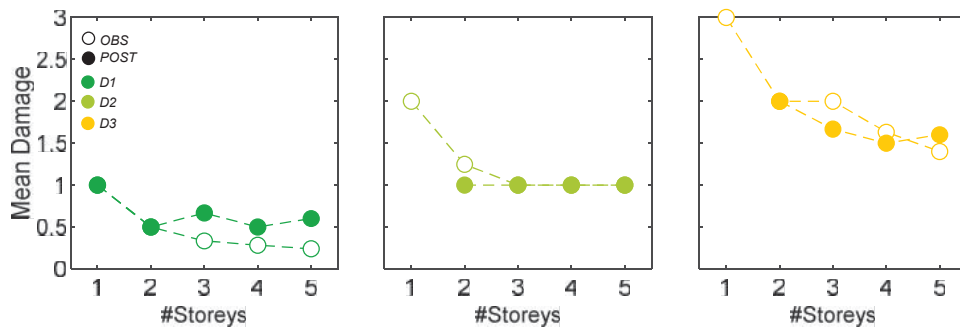

Figure 5. Predicted (POST)-versus-observed (OBS) comparison, given DS_{max} : trend of mean damage depending on the number of stories.

5.2 Comparison between Observed and Predicted losses

In this section, the comparison between observed and predicted losses (in terms of trc) is shown. In Figure 6, the 16th, 50th and 84th percentiles of observed and predicted trc are reported, showing a very good agreement, on average, especially when DS_{max} is equal to DS2 (-11%) or DS3 (-3%). A slight overestimation of the “observed” losses is obtained at DS1.

In Figure 7, the trends between the trc and N_s , given DS_{max} , are reported. It can be noted that both “observed” and “predicted” trc decrease, on average, when N_s varies from 1 to 3 when the maximum achieved damage is DS1 or DS2, then keeping an almost constant value for higher N_s . At DS3, a decreasing trend of trc is observed, on average, for N_s varying from 1 to 5, for both “observed” and “predicted” trc .

As for the “predicted” trc , “observed” trc can be also shown as a function of mean damage (Figure 8). A clear linear trend exists between the average mean damage and trc , with an increasing slope for increasing maximum damage severity. Obviously, when the average damage is exactly equal to a given maximum DS_i (with $i=1,2,3$), trc can be very easily computed as the sum of the repair costs per floor unit related to infills and services at that DS_i , equal to respectively: 142.1 €/m² for DS1; 352.9 €/m² for DS2 and 744.4 €/m² for DS3. It can be easily verified that the ratio between trc and average mean damage (= DS_i) is very close to the slope of the linear fitting plotted in Figure 8, for the “observed” trc .

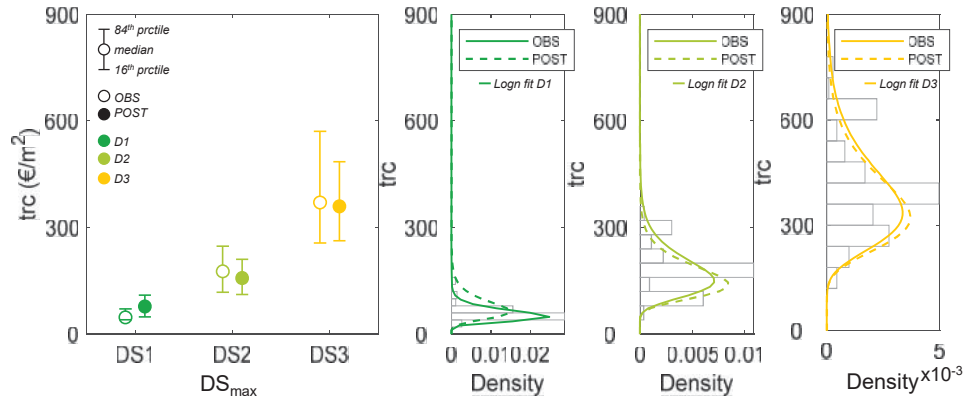

Figure 6. *trc* percentiles depending on DS_{max} : predicted (POST)-versus-observed (OBS) comparison.

Figure 7. Predicted (POST)-versus-observed (OBS) comparison, given DS_{max} : trend of *trc* depending on the number of storeys.

Figure 8. Predicted-versus-experimental comparison: *trc* depending on average damage level. Along x- and y-axis the distributions of mean damage and *trc* are reported.

6 CONCLUSIONS

In this work provides a regional loss estimation framework via the “Pushover on Shear Type model” (POST)-method ([1]) for residential Reinforced Concrete (RC) buildings has been shown. The proposed component-based procedure accounts for the contribution of infills/partitions and services to the buildings seismic repair costs, using dedicated drift-based fragility curves and specific repair cost analysis for masonry infills and partitions and for three damage states (DSs) proposed in [31].

The methodology has been applied to a wide dataset of real buildings, struck by L'Aquila (Italy) 2009-earthquake and resulted damaged to infills or partitions only, as testbed for its reliability and robustness.

A generally satisfying agreement between observed and predicted results was shown. In fact, predicted damage successes in well reproducing the general observed trend in terms of maximum achieved DS, also catching their trend with the number of stories, namely, the higher the number of stories, the higher the percentage of buildings with more severe damage. The mechanical method allowed to well reproduce the damage distribution observed over the buildings, beyond their maximum value; in fact, the predicted mean damage index – combining damage severity and its extent – well replicates the “observed” outcomes, along with their trends depending on the number of storeys and on maximum achieved DS. Finally, a good agreement can be found also between predicted and observed total repair costs, capable of also capturing the observed trend of loss as a function of number of storeys and mean damage values.

In conclusion, the comparison between numerically predicted and actually observed damage scenario and seismic losses allowed the validation of the implemented procedure, showing its potential for large-scale applications.

Abstract

The seismic assessment and retrofit of non-conforming Reinforced Concrete (RC) buildings still represent a challenge for researchers and practitioners worldwide due to several aspects. On one hand, low standards RC buildings typically present some failure typologies very different from newly designed buildings, and such failure modes should be properly modelled for a reliable seismic performance assessment. On the other hand, retrofitting strategies should be chosen carefully looking both at safety at collapse and at seismic capacity at less severe performance levels, considering non-structural components as well. Masonry infills, typically defined as non-structural components despite their structural role, significantly affect the seismic behavior of existing RC buildings, especially at low-medium intensity measures. Therefore, when the seismic performance of as-built or retrofitted RC buildings is assessed, their contribution should be considered. In this work, a preliminary analysis of two 4-storey low-standard RC buildings, different for design typology, is presented, based on static nonlinear analyses. First, case-study buildings, representative of Italian pre-70 residential buildings, have been assessed in their “bare” configuration (without infills), as common in design practice, in a code-based approach (according to Italian code). Based on the as-built assessment outcomes, their retrofit has been designed by means of two main strategies: (1) the complete resolution of all the shear failures (in columns or joints), if any; (2) the reduction of the displacement demand by means of RC column jacketing, when necessary, along with the resolution of shear failures (as for the previous strategy). Then, both the as-built and retrofitted building configurations have been modelled and analysed explicitly considering the presence of infills and shear-critical elements. Fragility curves have been obtained at different Damage States according to European Macroseismic Scale EMS-98, considering record-to-record variability, and compared to each other. Remarks about the choice among strengthening strategies are carried out, based on these outcomes and on a preliminary estimation of the expected mean annual losses for the investigated buildings.

Keywords: RC buildings; damage states; masonry infills; strengthening; fragility curves; losses.

1. INTRODUCTION

The seismic assessment and retrofit of non-conforming Reinforced Concrete (RC) buildings still represent a challenge for researchers and practitioners worldwide, due to several aspects.

On one hand, low standards RC buildings typically present some failure typologies very different from newly designed buildings [1]-[2], and such failure modes should be properly modelled for a reliable seismic performance assessment. In existing buildings, columns can likely suffer shear damage under seismic actions, due to the very poor concrete quality or the insufficient stirrups mechanical percentage, leading to reduced lateral displacement capacity, especially if shear failures are expected to occur before the member yielding ([1], [3]-[6]). Additionally, beam-column joints typically in low-standard buildings have been not designed at all and totally lack of stirrups. This means that shear failures in those connections could occur before the yielding of the adjacent members, thus limiting the overall ductility capacity of the whole building [7].

On the other hand, retrofit strategies should be chosen carefully to comply with current codes, preventing the structural collapses (e.g. [1]). Nevertheless, in addition, a proper retrofit should also guarantee an reduction in expected annual seismic losses (e.g. [8]-[11]). To this end, the retrofit design should look at collapse safety and at seismic capacity at less severe performance levels as well. Especially at less severe performance levels, i.e. at more frequent seismic events, non-structural components must be considered. Among them, masonry infills, typically defined as non-structural components despite their structural role, significantly affect seismic performance and relevant losses in existing RC buildings, both as-built and retrofitted, as recently demonstrated by ([12]-[14]). Therefore, when seismic performance of retrofitted RC buildings is assessed, their contribution should be properly considered in numerical modelling and in damage and loss assessment.

In this work, a preliminary analysis of two case-study low-standard RC buildings, different for design typology, is presented, based on static nonlinear analyses. The investigated case-study structures are 4-storey buildings representative of Italian pre-70 residential buildings, designed for gravity loads only (GLD) or according to obsolete seismic design (OSD).

First, they have been assessed in their “bare” configuration (without infills), as typical in design practice. In such a first-step-assessment only nonlinear flexural response of beams and columns has been modelled, whereas columns/joints shear failures have been detected in post-processing, based on the current Italian code [15].

Then, based on the as-built assessment outcomes, the retrofit phase has been designed by means of two alternative strategies:

1. *Strategy “A”*: the complete resolution of all the shear failures (in columns or joints), if any (by means, for example, of localised steel cages, pre-stressed steel strips or wrapping with Fiber Reinforced Polymers (FRP) fabrics);
2. *Strategy “B”*: the reduction of the displacement demand by means of RC column jacketings, when necessary, along with the resolution of shear failures (as for the previous strategy).

These two strategies represent two boundary conditions for the retrofitted buildings since in strategy “A” no modification in the lateral stiffness is produced, whereas strategy “B”, the most invasive one, necessarily leads to a higher lateral stiffness of the building.

Lastly, both the as-built and retrofitted building configurations have been modelled and re-analysed explicitly considering the presence of infills, and, in the case of as-built configurations, potential shear failures in columns/beams and joints. SPO analyses has been carried out and Incremental Dynamic Analyses (IDAs) curves have been derived by means of SPO2IDA tool [16]. Fragility curves have been finally obtained at different Damage States (DSs) according to European Macroseismic Scale EMS-98 [17], considering record-to-record variability, and compared to each other. Remarks about the choice of the strengthening strategies are carried out, based on these outcomes and on a preliminar estimation of the expected mean annual losses for the investigated buildings.

2. CASE-STUDY BUILDINGS

In this work, two residential RC buildings are investigated as case-study structures. They have the same floorplan (see Figure 1a), symmetric in both directions. 4 meters length bays are present in both directions, except than the central bay, which has a length equal to 3 meters. The interstory height is 3 m. In both cases, in the transverse direction, only two (external) frames are present, as typical for pre-70 existing buildings in Italy.

Figure 1: Plan view of the case-study buildings and column labels (a) (measures in centimetres); 3D view (b)

The two buildings differ to each other for the design typology. One building has been designed to sustain gravity loads only, as typical in Italy before '70 in most of the country. It will be referred to as Gravity Loads Designed (GLD) buildings. The other building has been designed according to an Obsolete Seismic Design (OSD) in force in Italy until the beginning of '70 and adopted for the (few) sites classified as seismic zone in that time period, as described later. Therefore, the investigated buildings are representative of the Italian building stock related to the same time period (between '50 and the very beginning of '70) but located in different sites (with different seismic hazard at the year of construction), as explained in section 2.1.

2.1 Location and seismic hazard

Both the considered buildings are in medium-high seismic hazard sites in Italy. The GLD building is located at Morra de Sanctis, in the Southern of Italy. Such location has been classified as a seismic-prone site only after the well-known Irpinia earthquake (1980) and, therefore, all the buildings realized before '80 have been designed to sustain gravity loads only.

The OSD building is assumed to be located in L'Aquila city (Abruzzi region, Italy), which has been classified as seismic-prone starting from the very beginning of the last century, and, thus, the major part of its existing RC buildings has been designed to take into account seismic actions, according to seismic prescriptions as obsolete as their age of construction.

Figure 2a shows the location of these two sites on the current seismic Italian hazard map by the National Institute of Geophysics and Vulcanology (INGV) in terms of expected ground acceleration with a 10% probability of exceedance in 50 years. Additionally, Figure 2b reports a comparison between the pseudo-accelerations ($S_a(T)$) of the two selected sites at different return period (T_R) corresponding to four limit states according to Eurocode 8-part 1 [18] and Italian code [15]

(Immediate Occupancy, $T_R=30y$; Damage Limitation, $T_R=50y$; Life-Safety, $T_R=475y$; Near Collapse, $T_R=975y$).

In both cases, it is assumed soil type “C” and soil topography “T2” [18] for the definition of the local seismic amplification effects.

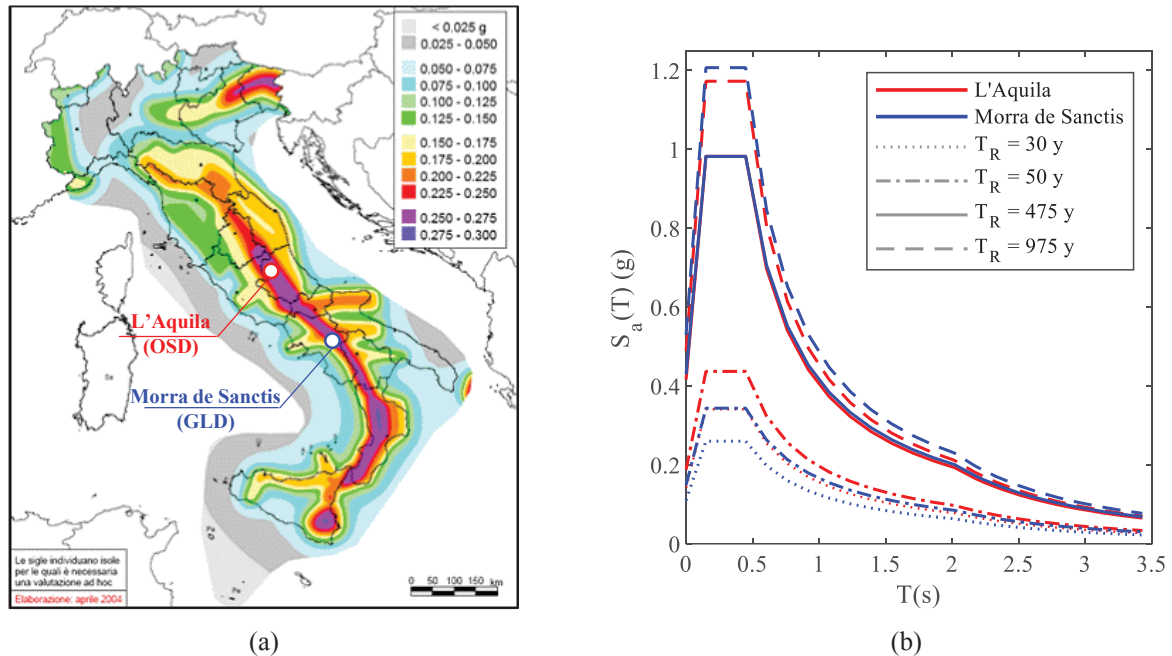

Figure 2: Buildings locations on the current hazard map by the National Institute of Geophysics and Vulcanology (INGV) (a); comparisons among pseudo-acceleration ($S_a(T)$) spectra at different return periods (T_R) (b)

2.2 Simulated design

The moment resisting frames (MRFs) system for both the buildings is characterized by 2D resisting frames in the longitudinal (X) direction, whereas, in the transverse (Z) direction, MRFs are present only along the exterior perimeter. Floors are 20 cm thick, with 4 cm RC slab. As shown in Figure 1a, the floor weight is sustained by the longitudinal frames only. Infills differ between the two directions for the openings presence: the opening percentage ranges from 0 to 15% of the infill total area, as qualitative shown in Figure 1b. An infill weight (per panel unit surface) equal to 2.00 kN/m² and 2.36 kN/m² for longitudinal and transverse direction, respectively, is assumed for exterior frames. “Maximum allowable stress method” is adopted for the “simulated design” of these buildings [19]. Since all the buildings were “located” in the same time period, the design mechanical properties of reinforcing steel and concrete are identical for all the buildings. Maximum allowable concrete strength was assumed equal to 5 MPa or 6 MPa, for purely compressive loads or bending actions, respectively (according to [21]). A maximum allowable strength equal to 140 MPa has been adopted for reinforcing bars [21] in the hypothesis that steel typology “AQ42” was used, as typical in the reference time period in Italy [20]. It is worth noting that plain bars were used as reinforcement typology, as typical in pre-‘70 RC buildings in Italy ([20], [22]). Additionally, infill panels are supposed to be identical for both the analysed buildings, and in particular made up of hollow clay bricks assembled with mortar: the presence of two coupled leaves is assumed, with 120 mm and 80 mm thickness, respectively, as typical in Italian and Mediterranean area in the reference time period [23].

GLD buildings have been designed to sustain gravity loads only and to comply code prescriptions about minimum amount of longitudinal and transverse reinforcement as defined by the Italian R.D.

[21]. On the contrary, OSD buildings are designed to sustain horizontal loads, too, the latter defined according to obsolete seismic codes in force in the reference time period ([24]-[25]), which allowed modelling the seismic actions as horizontal equivalent forces constant along the building height. The design horizontal acceleration was equal to 0.07 times the gravity acceleration ([24]-[25]). Additionally, the total design base shear is divided among resisting frames proportionally to the vertical loads supported by each of them, as typical for the reference time period. This means that transverse frames should support very low lateral actions, whereas longitudinal interior frames should sustain the highest horizontal loads. As a result, transverse frames are almost identical between GLD and OSD buildings; whereas, longitudinal frames generally result in a higher reinforcement amount, especially at the lowest stories (where columns have the highest longitudinal reinforcement percentage). The reinforcement percentage values of the first-floor columns significantly decrease at the upper stories (varying around about 0.7%). Stirrups with 250 mm maximum spacing and 8 mm diameter have been used in the beams; stirrups with 140 mm spacing and 6 mm diameter have been used in the columns (in agreement with prescriptions by [21]). All the beams resulted in a $30 \times 50 \text{ cm}^2$ cross-section, whereas column sections vary from a minimum of $30 \times 30 \text{ cm}^2$ (for most of the columns) to a maximum of $30 \times 40 \text{ cm}^2$ (for central columns). Rectangular columns are always oriented in the longitudinal direction. Further details can be found in [26].

2.3 Material properties

Lastly, a key issue for the complete assessment and modelling of the case-study structures is the definition of the strength values used for concrete, steel and infills.

As far as the as-built buildings is concerned, mean values of concrete compressive strength (f_c) and reinforcing yielding strength (f_y) have been assumed equal to 20.0 MPa and 322.4 MPa, respectively, according to suggestions by [27] and [20] for the adopted steel typology and the reference time period. Infill panels are characterized by a diagonal compressive strength (τ_{cr}) equal to 0.27 MPa and a Young modulus (parallel to the holes) of 3000 MPa. Such values are based on a subset of data collected in [28] on weak Italian infills characterised by horizontally placed hollow clay bricks with a void percentage of about 60%, as typical of the investigated case-study buildings. It is worth noting that the definition of infill mechanical properties is a complex issue, since they are characterised by a very high variability and they significantly depend on brick typology and strength, mortar mechanical properties, bricks void percentage, bricks compressive strength. Therefore, a further extension of the present work should explicitly consider the possible variability of the key infill mechanical properties and their effect on structural response (e.g. [29]).

3. CODE-BASED ASSESSMENT AND DESIGN OF RETROFIT

This section shows the first-step seismic assessment of the two case-study buildings, performed according to the current Italian code [15]. A “Normal Knowledge Level” (KL2) ([15], [30]) has been assumed; therefore, according to [15], the mean values of the mechanical properties of existing materials used in the capacity calculation have been divided by a confidence factor equal to 1.20. Two performance levels have been analysed for this code-based assessment: “Damage Limitation” (DL) and “Life Safety” (LS) limit states, corresponding to seismic actions with a return period of 50 and 475 years, respectively ([15], [30]). The building’s capacity at DL limit state is assumed to be achieved when for the first time an inter-story drift ratio (IDR) equal to 0.5% is achieved. The LS limit state is reached when for the first time a member achieves a chord-rotation equal to 3/4 of the ultimate rotation (θ_u) (flexural failure) or when a shear failure arises (in beams, columns, or joints), as explained in this section. Demand-to-capacity peak ground acceleration (PGA) ratio for each considered limit state represents the building’s safety index (SI) at that limit state. Thus, the design of retrofit has been carried out based on this index, as explained in detail in the next sub-sections.

3.1 Modelling assumptions

The seismic response of the investigated case-study buildings has been numerically reproduced in OpenSees platform [31] and analysed by means of nonlinear static pushover (SPO) analyses in N2 framework [32], according to the modelling assumptions explained herein. In particular, a lumped plasticity approach has been used for RC members by means of *zero-length elements* in OpenSees located at the ends of each beam/column element in series with *elastic BeamColumn elements* (see Figure 3).

First of all, for this code-based assessment and the relevant design of retrofit intervention, the buildings have been modelled as “bare frames”, namely, infills are not included in the numerical models, unless in the definition of masses and loads, as usual in common practice approaches. Additionally, the “code-based” numerical models only reproduce the nonlinear flexural response of the RC members; therefore, static pushover curves are derived in the hypothesis that all the elements are “ductile” members.

For elements with plain bars, the flexural (bending moment, M – versus – chord rotation, θ) response of beams and columns has been modelled by means of the (quadri-linear) proposal by [22], calibrated for RC elements reinforced with plain bars, and implemented in the adopted software with a *Zero-Length Elements* (Figure 3) characterised by the *Pinching4 uniaxial material* (F-elements). The four-point envelope represents: the yielding point (“y”), the capping point (“cap”), the softening branches’ intersection (“int”), the zero-strength condition (“0”). Such material has been slightly modified by adding an additional point corresponding to the first cracking (“cr”) point (Figure 3).

Lastly, floors are assumed to be stiff in their own plane.

Figure 3: Schematic view of the modelling adopted for each bay in a code-based approach

In this code-based assessment phase, ductile members reach their capacity at the LS Limit State [18] when their chord rotation demand reaches $\frac{3}{4}$ of the ultimate chord rotation capacity (θ_u), the latter assessed according to the proposal by [33], as suggested by the Eurocode 8 [18] and the Italian prescriptions [34].

Nevertheless only the flexural response is modelled, as explained before, eventual shear failures in columns/beams or joints have been detected by means of a post-processing of the static pushover results, as common in practice. To this end, the Italian code-prescriptions have been adopted, so that:

- joint shear failure occurs when its principal compressive stress, p_c , overcomes 0.5 times the concrete compressive strength, f_c , or if the principal tensile stress, p_t , overcomes 0.3 times the square root of f_c [34], based on suggestions by [35] and limiting the joint failure to its shear cracking (each further strength mechanism beyond the shear cracking is neglected by this code);

- columns/beams shear failure occurs when the demand shear load overcomes the shear strength, the latter evaluated according to the model by [36] as suggested by the Eurocode 8 [18] and [34], and thus depending on the inelastic displacement demand.

3.2 As-built assessment according to Italian (D.M. 2018) code

SPO analyses have been performed separately in longitudinal (X) and transverse (Z) directions. Two lateral load patterns have been used: (i) (pseudo-)“Uniform” pattern, proportional to the storey mass distribution, and (ii) “Modal” pattern, proportional to the first-mode deformed shape in the considered direction, according to Italian prescriptions [15].

Figure 4 shows the resulting SPO curves in terms of top displacement (Δ_{top}) - versus - base shear, along with the achievement of the first joint cracking, the first shear failure in RC members, the first “ductile” failure (chord rotation demand reaches $3/4 \theta_u$), and the capacity point at the DL limit state, for GLD and OSD case-study buildings. SPO curves of OSD building generally present in the longitudinal direction higher base shear values and displacement capacity with respect to GLD building; conversely, SPO curves in the transverse direction are quite similar to each other, mainly due to the very low difference in geometry and reinforcement amount in that direction (as a consequence of the simulated design, as explained in section 2). A global collapse mechanism is observed in the transverse direction for both the case-study buildings and for both the lateral load patterns; whereas local mechanisms are observed in the longitudinal direction. In particular, for the GLD building local first- and second-floor mechanisms are observed applying respectively the “Uniform” and the “Modal” distributions; for OSD building a second- and third-floor mechanism are observed.

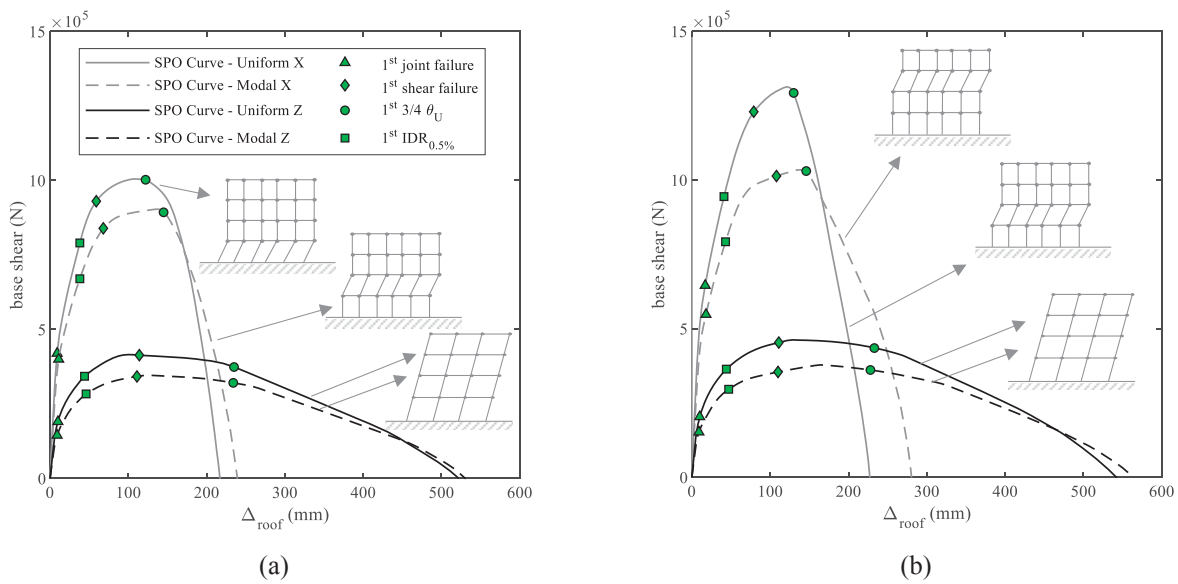

Figure 4: Static Pushover curves for (a) GLD and (b) OSD case-study buildings

Starting from each SPO curve (SPC), the capacity curve (CC) of the equivalent single-degree-of-freedom (SDOF) system [32] can be obtained dividing the abscissa and ordinates of SPO curve by the first modal participation factor in the considered direction (see Figure 5a). The CC has been bi-linearized using an equal-energy approach (according to [15]) thus obtaining an Elastic-Perfectly-Plastic (EPP) curve (whose first elastic branch is characterised by an “effective” period, T_{eff}). The EPP curve is, then, represented in the Acceleration-Displacement Response Spectrum (ADRS)

domain, where also the demand spectrum at the considered limit state can be reported (see Figure 5b).

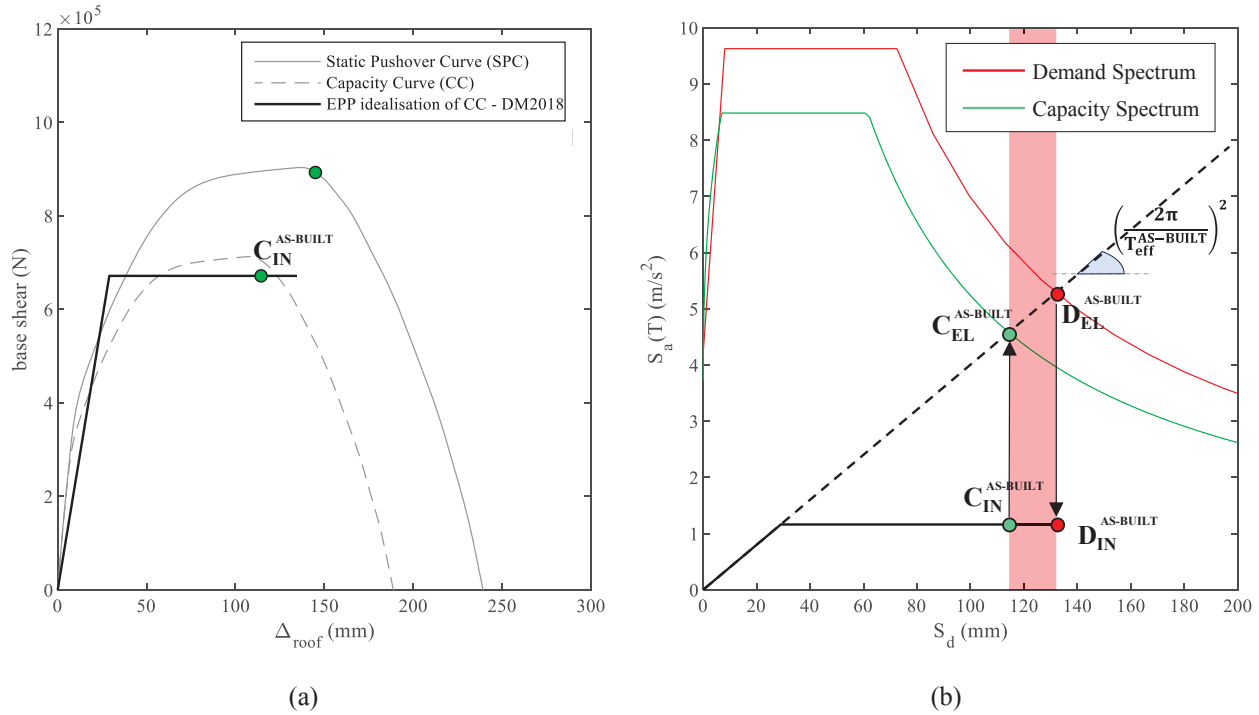

Figure 5: Example of the seismic assessment procedure: from the SPO curve to EPP capacity curve (a); from the EPP capacity curve to the capacity spectrum (b)

In order to obtain the “capacity spectrum” for a given capacity point, the elastic capacity point (i.e., $C_{\text{EL}}^{\text{AS-built}}$ for the as-built configuration) should be detected starting from the corresponding inelastic capacity point ($C_{\text{IN}}^{\text{AS-built}}$), using the equal displacement rule, modified for short period systems by [37]. In particular, in case of long or intermediate effective period of the equivalent SDOF ($T_{\text{eff}} \geq T_c$), the elastic and the inelastic displacements (i.e., the abscissas of $C_{\text{EL}}^{\text{AS-built}}$ and $C_{\text{IN}}^{\text{AS-built}}$ points) match each other, whereas the ordinate of $C_{\text{EL}}^{\text{AS-built}}$ point can be graphically obtained by intersecting the vertical line through $C_{\text{IN}}^{\text{AS-built}}$ with the elastic branch of the bi-linearization. The resulting spectrum passing by $C_{\text{EL}}^{\text{AS-built}}$ is the capacity spectrum at the considered limit state, to be compared with the demand spectrum at the analysed limit state. In particular, the demand-to-capacity ratio in terms of PGA is defined herein as the building’s safety index (SI), based on which the design of retrofit has been carried out.

In Figure 6 the above-explained seismic assessment procedure is shown for the (i) DL limit state, and the (ii) LS limit states (at the achievement of the first ductile failure (DF)), for GLD and OSD case-study buildings, separately in longitudinal (X) and transverse (Z) directions.

Quite low SI values have been obtained at DL limit state, especially in the Z direction, being SI_{DLLS} equal to 0.63 and 0.50, for GLD and OSLD buildings, respectively.

For both the buildings and in both directions, the safety index at LS limit state ($SI_{\text{LSLS,DF}}$) is quite high, if only ductile failures are considered (especially for the OSLD case-study building). Nevertheless, when shear failures are considered, too, at LS limit state, the SIs values significantly decrease, as reported in Table 1, which shows also the resulting SIs in terms of PGA at the first joint cracking and at the first shear failure in RC beams/columns for each direction and for both case-study buildings. Note that, for the first joint failure, in both directions the same SI is observed, being the corresponding capacity return periods less than 30 years for both the main directions. Thus, for both directions, the same “minimum” code-based [15] spectrum has been considered as capacity spectrum

($T_R=30y$). Based on these outcomes, the retrofit of the two case-study buildings has been designed by means of two main strategies, as explained in the next sub-section.

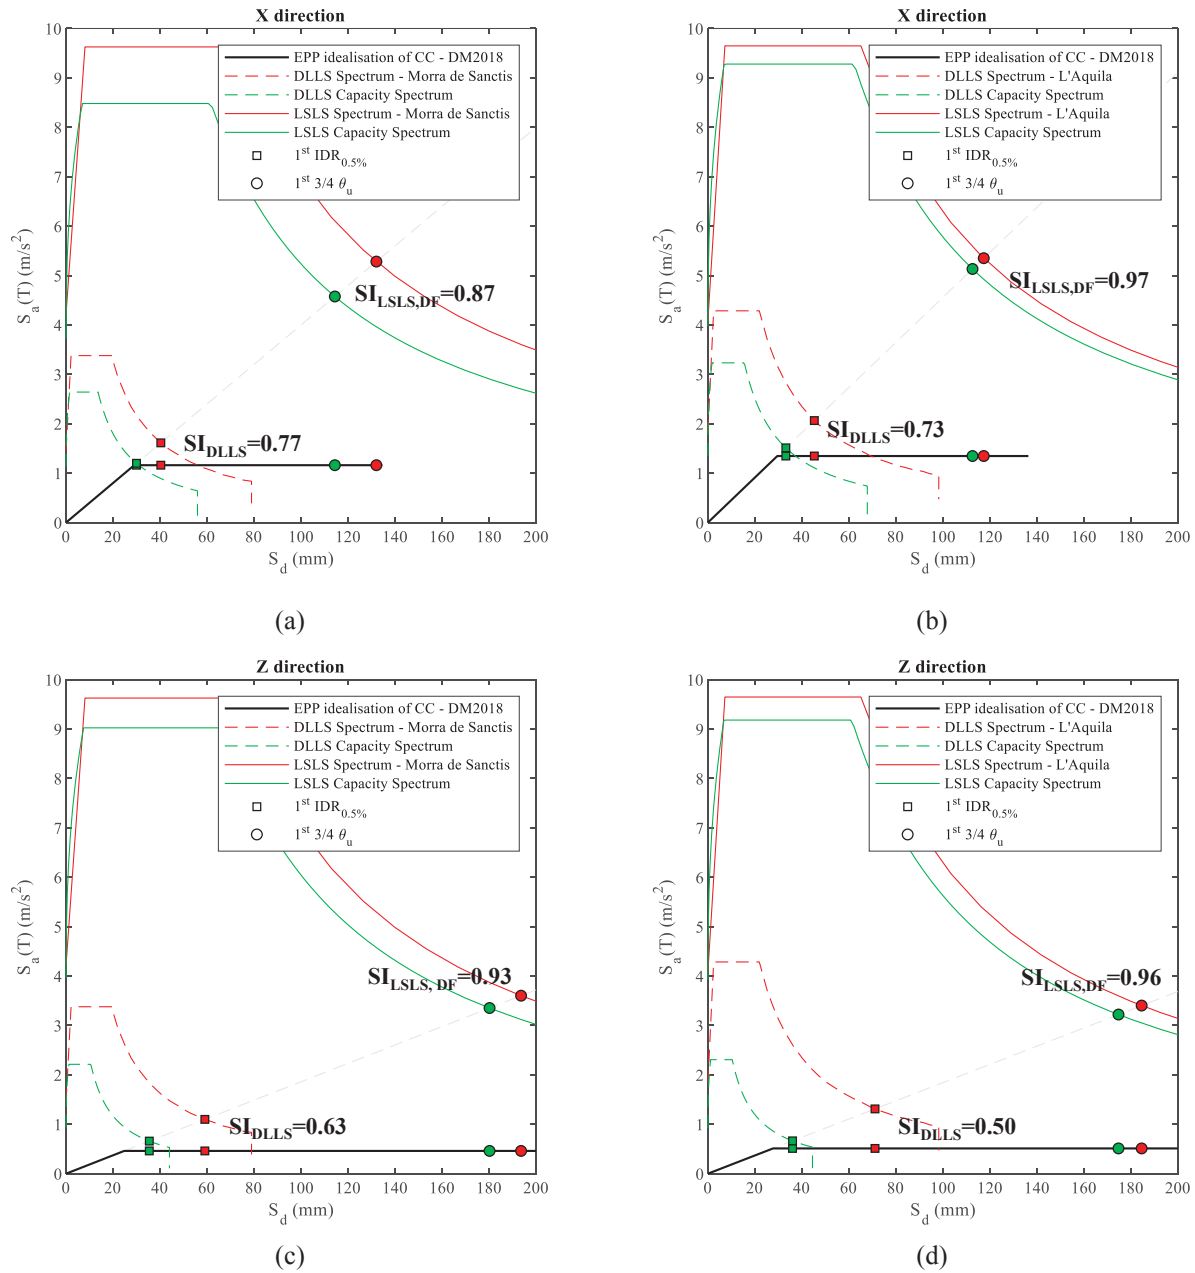

Figure 6: Seismic assessment with reference to Damage Limitation (DL) and Life Safety (LS) limit states for (a; c) GLD and (b; d) OSD case-study buildings

	GLD		OSD	
	X direction	Z direction	X direction	Z direction
1 st IDR=0.5%	0.77	0.63	0.73	0.50
1 st joint failure	0.34	0.34	0.19	0.19
1 st shear failure	0.62	0.52	0.43	0.47
1 st ductile failure	0.87	0.93	0.93	0.96

Table 1: SIs summary

3.3 Design of retrofit

The main aim of the design of the retrofit strategies is to increase the SI towards/beyond the unity, by adopting one of the available retrofitting techniques or also combining them. Mainly, these techniques are based on strategies which involve the reduction of the seismic demand or/and the increase of the building's capacity. In this work, two main strategies for the retrofit's design have been considered:

- (A) the complete resolution of all the shear failures (in columns or joints) only, by means, for example, of localised wrapping with Fiber Reinforced Polymers strips, steel cages, or pre-stressed steel strips;
- (B) the reduction of the displacement demand at DL limit state by means of RC column jacketings, when necessary, along with the resolution of shear failures (as for the strategy A).

Strategy "A" aims at the resolution of all the shear failures, both in joints and shear-critical columns, by means localised interventions. According to this strategy (see Figure 7a), any shear failure in the post-retrofit phase is solved, so that the seismic capacity moves from the first shear failure of joint - the minimum one in the as-built configuration - (at $J^{As-built}$ in Figure 7a) to the first ductile failure (at $C_{IN}^{As-built}$). This strategy does not reduce the seismic displacement demand (being $T_{eff}^{As-built} = T_{eff}^{Retrofit}$), but only increases the shear capacity and, in tune, the deformation capacity of the retrofitted members. As a result, the final SI of the building is not higher or equal to the unity, but it corresponds to the first ductile failure capacity (which in these cases is always beyond the 80%, namely already "acceptable" according to current codes [15]). Such strategy could be pursued by means of FRP fabrics, steel cages or pre-stressed steel strips. However, note that the exact definition of the technique and the material properties to be used to apply this strategy is beyond the scope of this work.

Conversely, strategy "B" is based on the decrease of the seismic demand of the entire structure by means of the increase of building's stiffness. In Figure 7b, the retrofit strategy "B" is graphically shown, starting from the elastic demand point in the as-built condition ($D_{EL}^{As-built}$). This point belongs to the demand spectrum at the considered limit state and can be detected considering the effective period of the equivalent SDOF ($T_{eff}^{As-built}$). The corresponding inelastic demand ($D_{IN}^{As-built}$) can be found through the equal displacement rule. Therefore, to achieve SI equal to one, the retrofit intervention should be able to move the inelastic demand from $D_{IN}^{As-built}$ to $C_{IN}^{As-built}$, reducing the effective period of the equivalent SDOF. This strategy may be implemented by using the RC jacketing, making an additional concrete layer outside the perimeter of the existing members, and introducing additional longitudinal and transversal reinforcements. For both the buildings, RC column jacketing are designed by assuming as $C_{IN}^{As-built}$ the capacity at DL limit state, instead than the first ductile failure at LS limit state. It is worth noting that in a code-based approach, the safety check at DL limit state is not mandatory [15], but in this study it has been analysed to create an upper bound for the lateral stiffness that can be reached for these buildings. For both the buildings, the retrofit's designed involved the columns belong to the MRFs along the exterior perimeter in Z direction (see Figure 8). The concrete overlay of the four-sided jacket is at least 100 mm, to guarantee a sufficient cover for the new reinforcement. In particular, all the jacketed columns resulted in a 50x60 cm² cross-section (starting from the original 30x30 cm²) for GLD building and in a 50x70 cm² cross-section (starting from 30x30 cm for the corner's columns and 40x30 cm for the remaining ones) for OSD building. The jacket's concrete class and the reinforcement steel type is C25/30 ($f_{ck}=25$ MPa; $f_{cm}=33$ MPa), and B450C ($f_{yk}=450$, $f_{ym}=500$ MPa) respectively [18]. The longitudinal reinforcement is 12Φ18 and 12Φ20 (i.e., about 1% of the new cross-section area) for GLD and OSD buildings, respectively. Additionally, stirrups with 140 mm spacing and 8 mm diameter have been used in both buildings; they were designed to guarantee a ductile behaviour for these new columns.

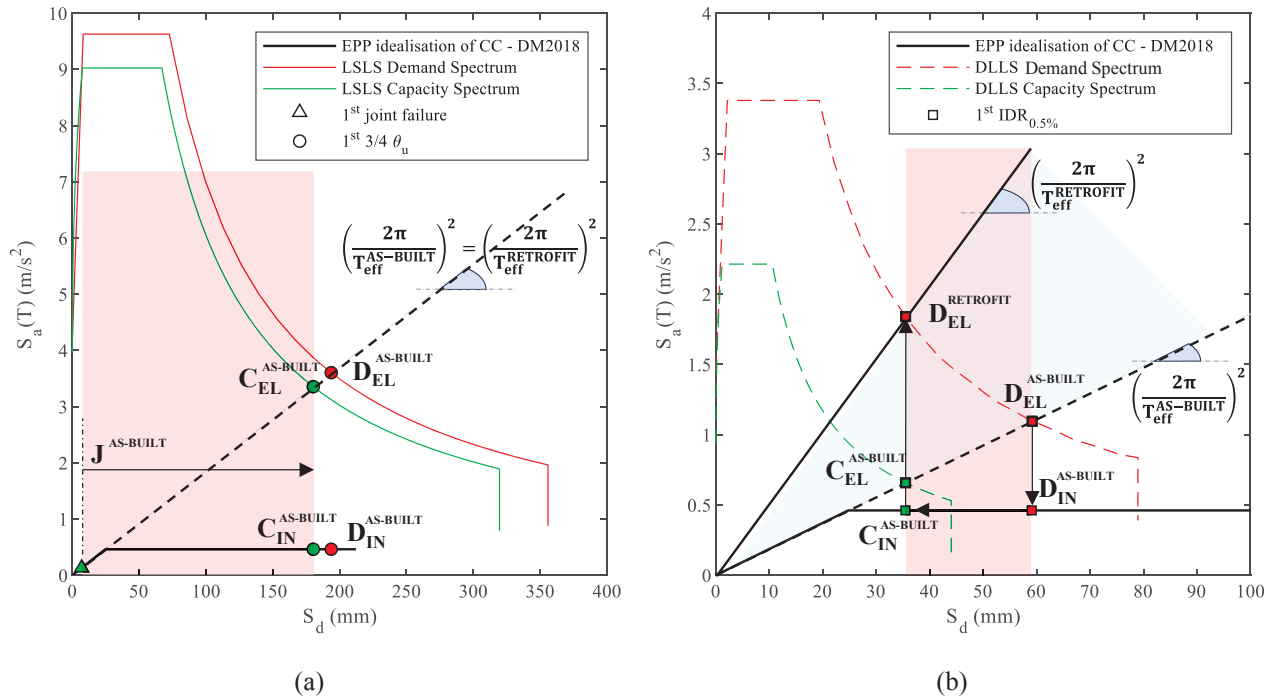

Figure 7: Strategies “A” (a) and “B” (b) for buildings’ retrofit in the ADRS domain.

These retrofit solutions allow to increase the safety indexes.

If Strategy “A” is applied, SI at LS limit state increases from 0.34 to 0.87 for the GLD building, and from 0.19 to 0.93 for the OSD building (see Table 1); the re-analysis of the retrofit buildings is not necessary since no modification in mass and stiffness are expected to occur if this strategy is applied [38]. Additionally, DL limit state safety check does not change at all, obviously.

On the contrary, if Strategy “B” is applied, the retrofitted buildings should be re-modelled and re-analysed to prove its effectiveness. In this case, for member with deformed bars, namely only for columns interested by RC jacketing in the retrofitted buildings, the nonlinear flexural response has been modelled by means of the proposal by [39]. Note that, for sake of simplicity, and according to Italian code [15], it is assumed that the “new” jacketed” sections are made up of the new steel and concrete only, and that the whole new section will sustain the total axial load (including gravity loads already present in the as-built phase). The “shape” of the moment-rotation relationship of the nonlinear response used for these elements is similar to that already described for members with plain bars, except than for the softening phase, as shown in Figure 3. It is worth noting, however, that an important difference exists between the models used herein for members with plain bars and with deformed bars: the model by [22] proposes a monotonic backbone that already reproduces the envelope of the cyclic response of columns subjected to cyclic lateral loading; on the contrary, the monotonic curve provided by [39]’s model does not account for any cyclic degradation, and some degrading rules have been suggested explicitly depending on the case-specific loading history. Such a discrepancy should be necessarily solved in future works, if a comparison based on static pushover curves has to be performed. With these modelling hypotheses, Figure 9 (a,b) shows the SIs in Z direction (the direction that conditioned the design of retrofit) for the buildings retrofitted by means of the Strategy “B”, highlighting a great reduction in the effective period of the equivalent SDOF, and resulting in SI_{DLLS} very close to the unity for both the buildings.

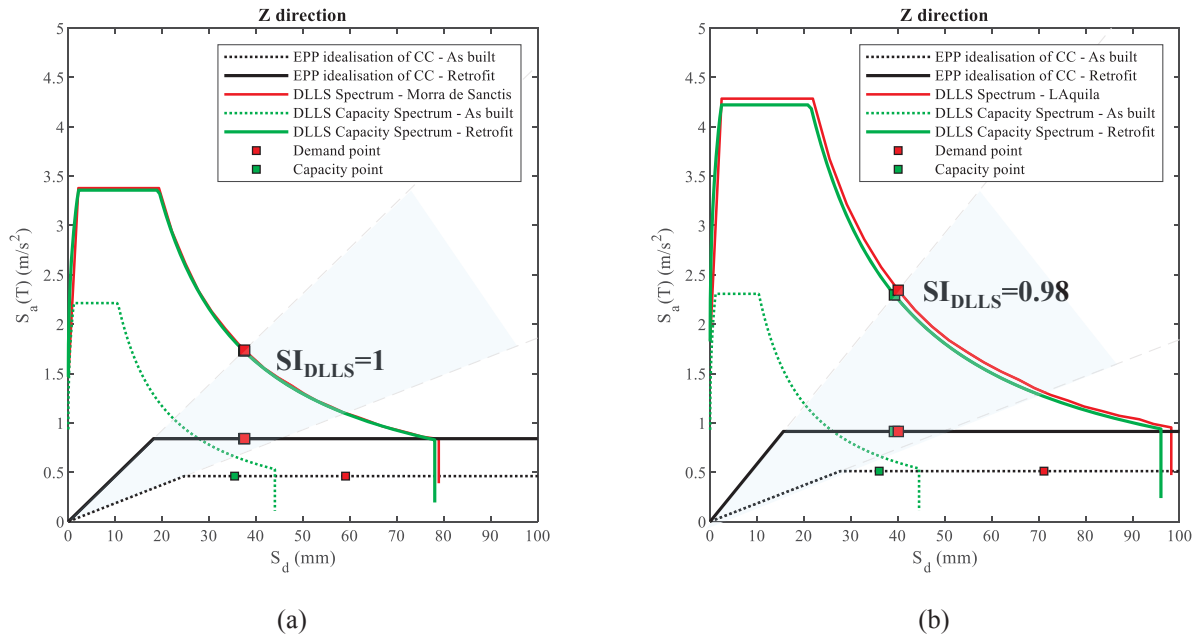

Figure 9: Seismic assessment with reference to Damage Limitation (DL) limit state for as-built and retrofitted (a) GLD and (b) OSD buildings

4. RE-ASSESSMENT OF AS-BUILT AND RETROFITTED BUILDINGS: ASSUMPTIONS

After the code-based assessment of the as-built buildings and the design of their retrofit, a re-assessment of these buildings has been performed, as explained in this section. This further phase of

assessment is aimed at the evaluation of the “real” seismic capacity of the as-built and retrofitted buildings, explicitly considering the infills contribution, the beam-column joints nonlinear behaviour, and the limited displacement capacity of columns potentially subjected to shear failures (see section 4.1). To this end, damage states definition according to EMS-98 macro-seismic scale [17] has been adopted instead than code-conforming limit states (see section 4.2).

4.1 Modelling assumption

A lumped plasticity approach has been used for RC members by means of *zero-length elements* in OpenSees located at the ends of each beam/column element in series with *elastic BeamColumn elements* (see Figure 10), as for the “code-based assessment” phase.

For member with plain bars, the flexural (bending moment, M – versus – chord rotation, θ) response of beams and columns has been modelled by means of the (quadri-linear) proposal by [22], as already explained in section 3.1. In addition, for the as-built buildings, a pre-classification of each RC member has been performed to a-priori identify its failure mode (i.e., flexural element, F; flexure-shear element, FS; purely-shear element, S), by comparing plastic shear load and shear strength, the latter calculated according to [5]’s shear strength model. When FS or S elements were detected, the relevant flexural moment-chord rotation relationship shown in Figure 10 has been modified, according to [2], by limiting the element deformation capacity according to [6]’s proposal for shear critical RC columns. For the GLD-building, only some interior columns at lower stories resulted to be FS-elements. In the case of OSD-building, almost all columns at the first floor (except than column belonging to the exterior transverse frames) resulted FS-elements. In the retrofitted buildings for both the adopted possible strategies (“A” and “B”), it is assumed that the shear failures of these elements have been solved, with a proper technique (e.g., by mean of localized steel cages or FRP fabrics), so that the shear strength of each element becomes higher than its plastic shear load. In such a hypothesis, all the elements in the retrofitted buildings have been assumed as “ductile” (“F” failure mode) with their relevant displacement capacity.

For members with deformed bars, namely for columns interested by RC jacketing (in the case of Strategy “B”), the nonlinear flexural response is modelled by means of the proposal by [39], as commented in section 3.1. Since model by [39] is used only for RC jacketed members, no further modifications are needed to account for any eventual shear failures. In fact, for each jacketed element, a proper number of stirrups can be used to prevent shear failures and ensure its ductile behavior.

Nonlinear response of beam-column joints has been modelled, too (see Figure 10). A zero-length rotational spring has been introduced in the numerical modelling at each beam-column centreline and rigid offset spreading within the joint panel have been modelled at the ends of the beams/columns. The joint moment (M_j)- shear strain (γ_j) response depends on the joint typology. The model proposed by [7] is adopted for exterior joints. For interior joints, the joint shear strain values proposed by [40] and the joint shear strength proposed by [41] have been used. For further details, see [7]. As for shear failures in columns, also for joints, it is assumed that, in the retrofitted buildings, the potential shear failure of these elements will be completely solved by means of proper strategies (e.g., by means of pre-stressed steel strips or FRP fabric in the joint core) in both the possible strategies (“A” and “B”), so that the beam-column joints become simple elastic elements.

About infill panels, two diagonal (concentric) compressive-only resisting struts (one per loading direction, as shown in Figure 10) have been implemented in each bay (with *truss element* of OpenSees library). [28]’s (tri-linear) model has been adopted herein: the corresponding axial load-axial strain (N_w - ε_w) response have been implemented with a *Hysteretic uniaxial material* (see Figure 10) for each truss element. Additionally, [42]’s reduction coefficients of infill lateral strength and stiffness have been used when openings are present.

Lastly, P-Delta effect are considered.

Figure 10: Schematic view of the modelling strategy adopted for each bay for the “real” assessment approach

4.2 Damage States definitions

A key issue for the assessment of the “real” seismic capacity is the definition of Damage States (DSs) for the investigated buildings. Two aspects should be considered for these buildings, in agreement with [17]’s definition Table 2), namely:

- the damage to infill panels, generally significantly affecting the relevant repair costs in the aftermath of seismic events ([12]-[14]);
- the damage to RC components (beams/columns and joints).

Therefore, each DS can be achieved due to the achievement of a certain damage level in RC members or in infill panels. The achievement of DS1, DS2, and DS3 due to infills is defined herein according to [43], namely when the interstory drift ratio (IDR) reaches the median IDR capacity at each DS (see Figure 11). In this study, the achievement of DS1, DS2, and DS3 is also associated to the achievement of the first cracking, the first yielding and the first peak load, respectively, in one element among beams, columns and beam-column joints. However, damage to infills, from light cracking to severe damage, generally condition the achievement of DS1 to DS3 in infilled RC buildings [44], as in the present applications.

DS	EMS-98 [17]	Adopted in this study
DS1	Negligible to slight damage	$\min \left\{ \begin{array}{l} \text{IDR}_{\text{infills,DS1}} \\ \text{RC beam/column/joint cracking} \end{array} \right.$
DS2	Moderate damage	$\min \left\{ \begin{array}{l} \text{IDR}_{\text{infills,DS2}} \\ \text{RC beam/column/joint yielding/pre – peak} \end{array} \right.$
DS3	Substantially to heavy damage	$\min \left\{ \begin{array}{l} \text{IDR}_{\text{infills,DS3}} \\ \text{RC beam/column/joint peak} \end{array} \right.$
DS4	Very heavy damage	RC beam/column zero-load or beam-column joint residual strenght
DS5	Collapse	RC beam/column zero-load (if “FS”) or $V_{\text{base}}=0$

Table 2. Adopted DSs definition for infills and RC members and comparison with EMS-98 macro-seismic scale

DS4 and DS5 are achieved due to damage to RC members only, since, at those DSs, infill panels should be already totally damaged. In this study, in agreement with [44], it is assumed that DS4 is achieved when a beam or a column completely losses its lateral load capacity or a beam-column joint

reaches its residual capacity. When this condition occurs in FS-elements, it is assumed that DS5 also occurs (contemporary to DS4), since, when a shear-critical element loses its lateral load capacity, it is also characterized by the onset of its axial-load failure, which reasonably leads to the collapse of, at least, a part of the building. DS5 is anyway reached when the building base shear becomes null. It is worth noting that the definition of DS4 and DS5 still deserves further investigations in future research efforts.

Figure 11: Example of damage state evolution for a masonry infilled frame for the experimental test “DIST Unina” performed at the University of Naples Federico II, adapted by [43].

5. RE-ASSESSMENT OF AS-BUILT AND RETROFITTED BUILDINGS: RESULTS

Based on the assumptions explained in section 4, in this section, the SPO curves of the as-built and retrofitted buildings are shown (section 5.1), along with the simplified Incremental Dynamic Analysis (IDA) curves obtained by means of SPO2IDA tool [16] in terms of spectral pseudo-acceleration $S_a(T)$ (section 5.2). Starting from $S_a(T)$, and assuming the spectral shape suggested by [15] for the Italian country, the corresponding PGA capacity values are obtained and fragility curves in PGA at each DS are finally shown in section 5.3. A preliminary comparison among the as-built and the retrofitted buildings is also performed in terms of Expected Annual Losses (EAL) (section 5.4).

5.1 SPO curves

SPO analyses have been performed for each case-study building separately in longitudinal (X) and transverse (Z) direction. Two lateral load distributions have been applied, as already explained in section 3. Resulting SPO curves – in terms of base shear versus Δ_{top} - and their comparison are shown in Figure 12, grouped depending on the design typology and loading direction, for the as-built and the retrofitted buildings.

It can be noted that SPO curves related to the two as-built buildings are quite similar to each other, even if, as expected, OSD presents higher base shear values and displacement capacity of GLD in the longitudinal direction, as already highlighted in section 3. It can be noted that the “Uniform” distribution leads to higher base shear values. Additionally, the most important comparison can be performed by analysing the SPO curves related to the as-built conditions and Strategy “A” case. It can be observed that the SPO curves do not significantly change when Strategy “A” is adopted, except than (slightly) in the softening branch, since FS-elements in the as-built buildings (when involved in the collapse mechanism) present a stiffer softening branch and a lower displacement capacity than the “corresponding” F-elements in Strategy “A”. On the contrary, when RC jacketing are used, obviously, the SPO curves significantly change, incrementing their base shear values and displacement capacity. A very important increment in ductility capacity is also due to the global collapse mechanisms that generally characterise these buildings when the Strategy “B” is adopted.

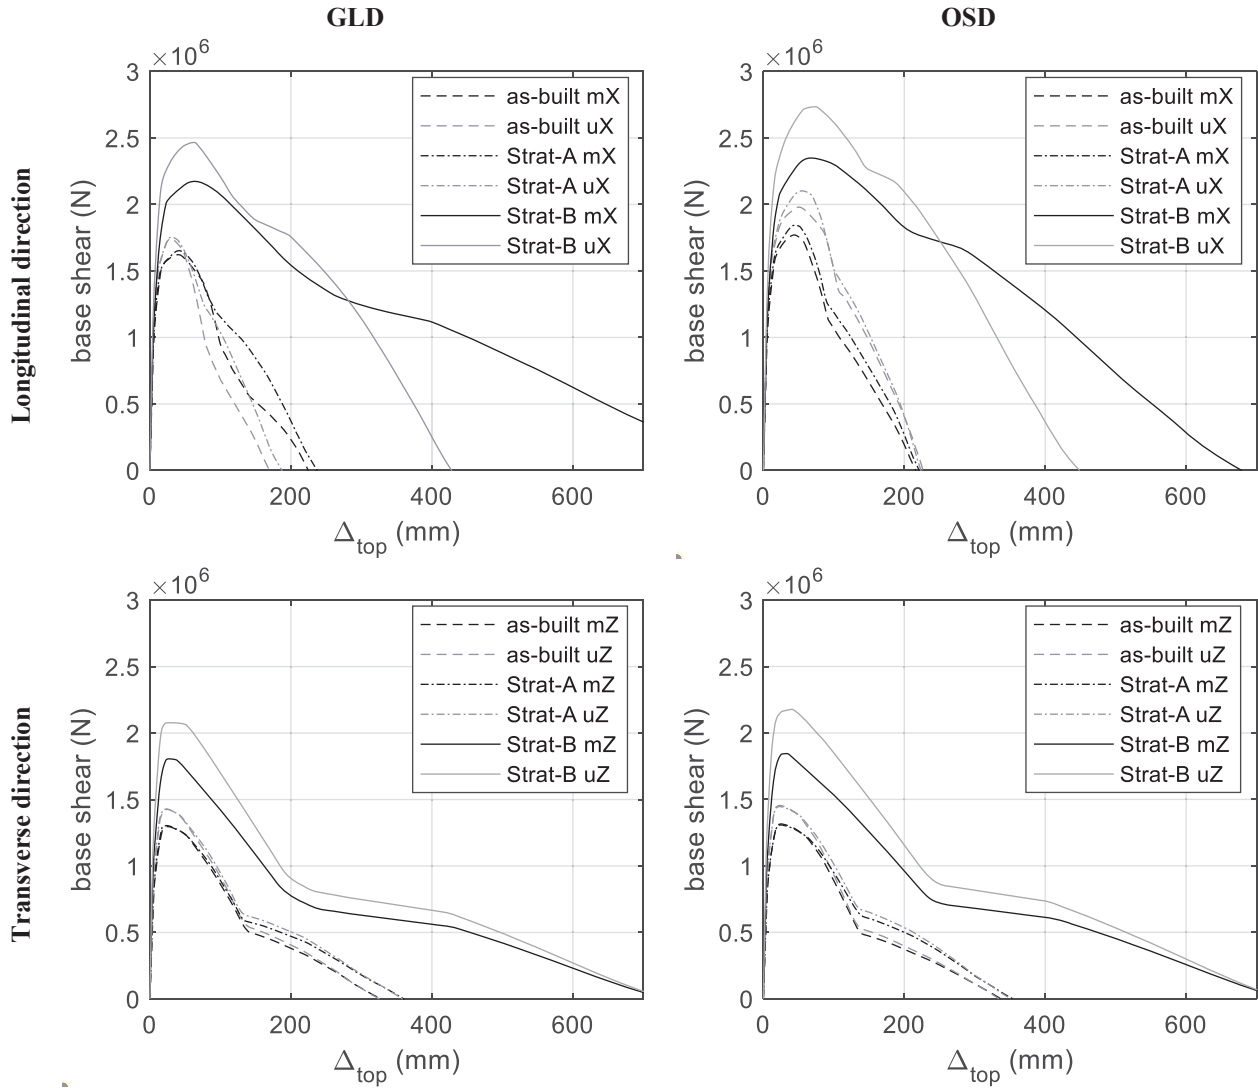

Figure 12: Comparison of SPO curves

5.2 Simplified IDA curves

SPO curves are obviously related to a multi-degree-of-freedom (MDOF) system. SPO curve' abscissa and ordinates can be divided by the first mode participation factor (Γ) of the building, in each considered direction, to obtain the capacity curve (CC) of the equivalent SDOF system [32]. Then, each CC is multi-linearized to take in due account the strength and stiffness contribution of infill panels. Nevertheless, a zero-strength residual branch is introduced, whereas the softening branch is defined based on an energy-equivalent approach between the peak load and the zero-lateral load point on the pushover curve. As a result, four-branch capacity curves are obtained for each analysed building.

Starting from each quadri-linear CC, the related Incremental Dynamic Analysis (IDA) curve have been derived thanks to the well-known SPO2IDA tool by [16], which provides the relationship between the selected engineering demand parameter (*edp*) and the seismic hazard intensity measure (*IM*). To apply the SPO2IDA tool, the CC should be first expressed in terms of ductility (μ) – strength reduction factor (*R*). The ductility μ is derived as the ratio between CC abscissas and yielding displacement. The factor *R* is the ratio between CC ordinates and yielding acceleration. SPO2IDA tool finally provides the IDA in terms of *edp* (spectral displacement) versus *IM* (spectral acceleration). Therefore, given a certain capacity *edp*, the corresponding 16th-, 50th-, and 84th- percentiles of

capacity IM can be obtained; alternatively, given a certain IM demand, the corresponding 16th-, 50th-, and 84th- percentiles of demand edp can be derived. 50th-, 16th- and 84th- percentile IDA curves also allow quantifying the record-to-record variability, which will be used later for the definition of the fragility curves “slope”.

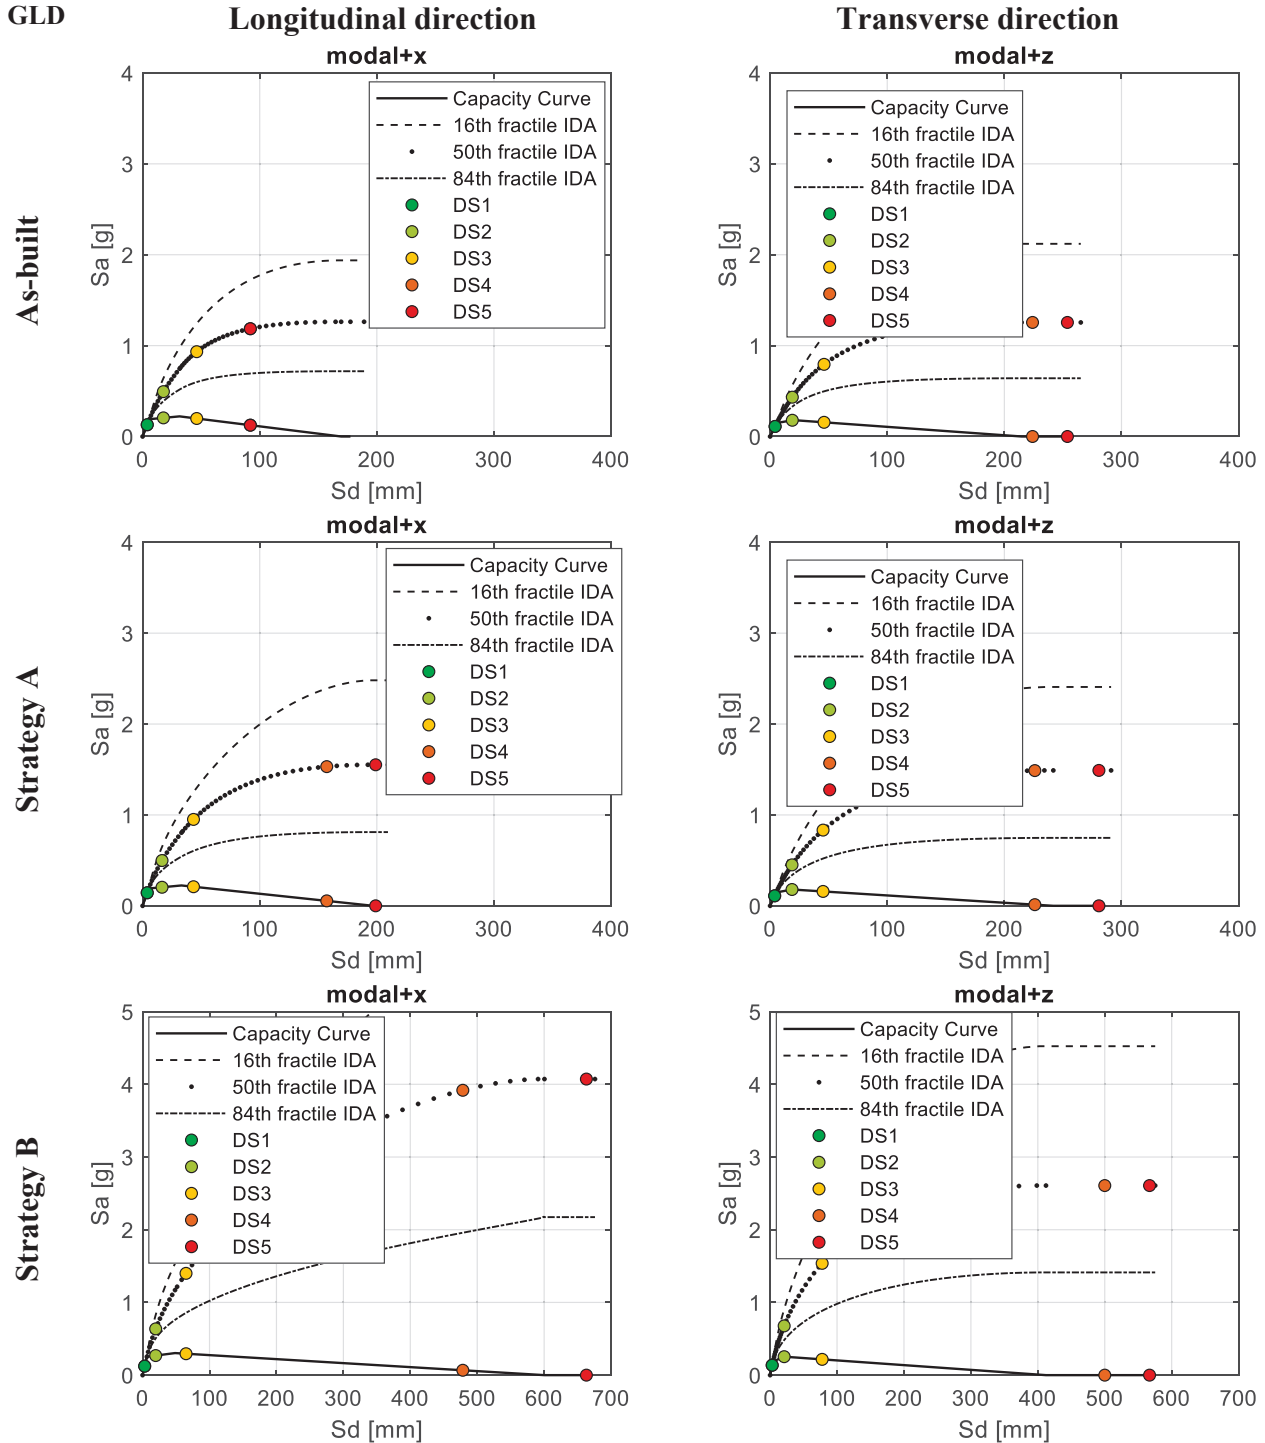

Figure 13: GLD-buildings: Multi-linearized CC, simplified IDA curves and capacity at each DS (only results for “Modal” distribution are reported, for sake of brevity)

Figure 13 and Figure 14 shows the multi-linearized CCs (reported as spectral displacement, S_d , versus spectral pseudo-acceleration, S_a , relationships) and the related (median, 16th and 84th percentiles) IDA

curves for the case-study buildings, along with the performance points related to the achievement, for the first time, of DS1 to DS5 (as defined in section 4).

OSD

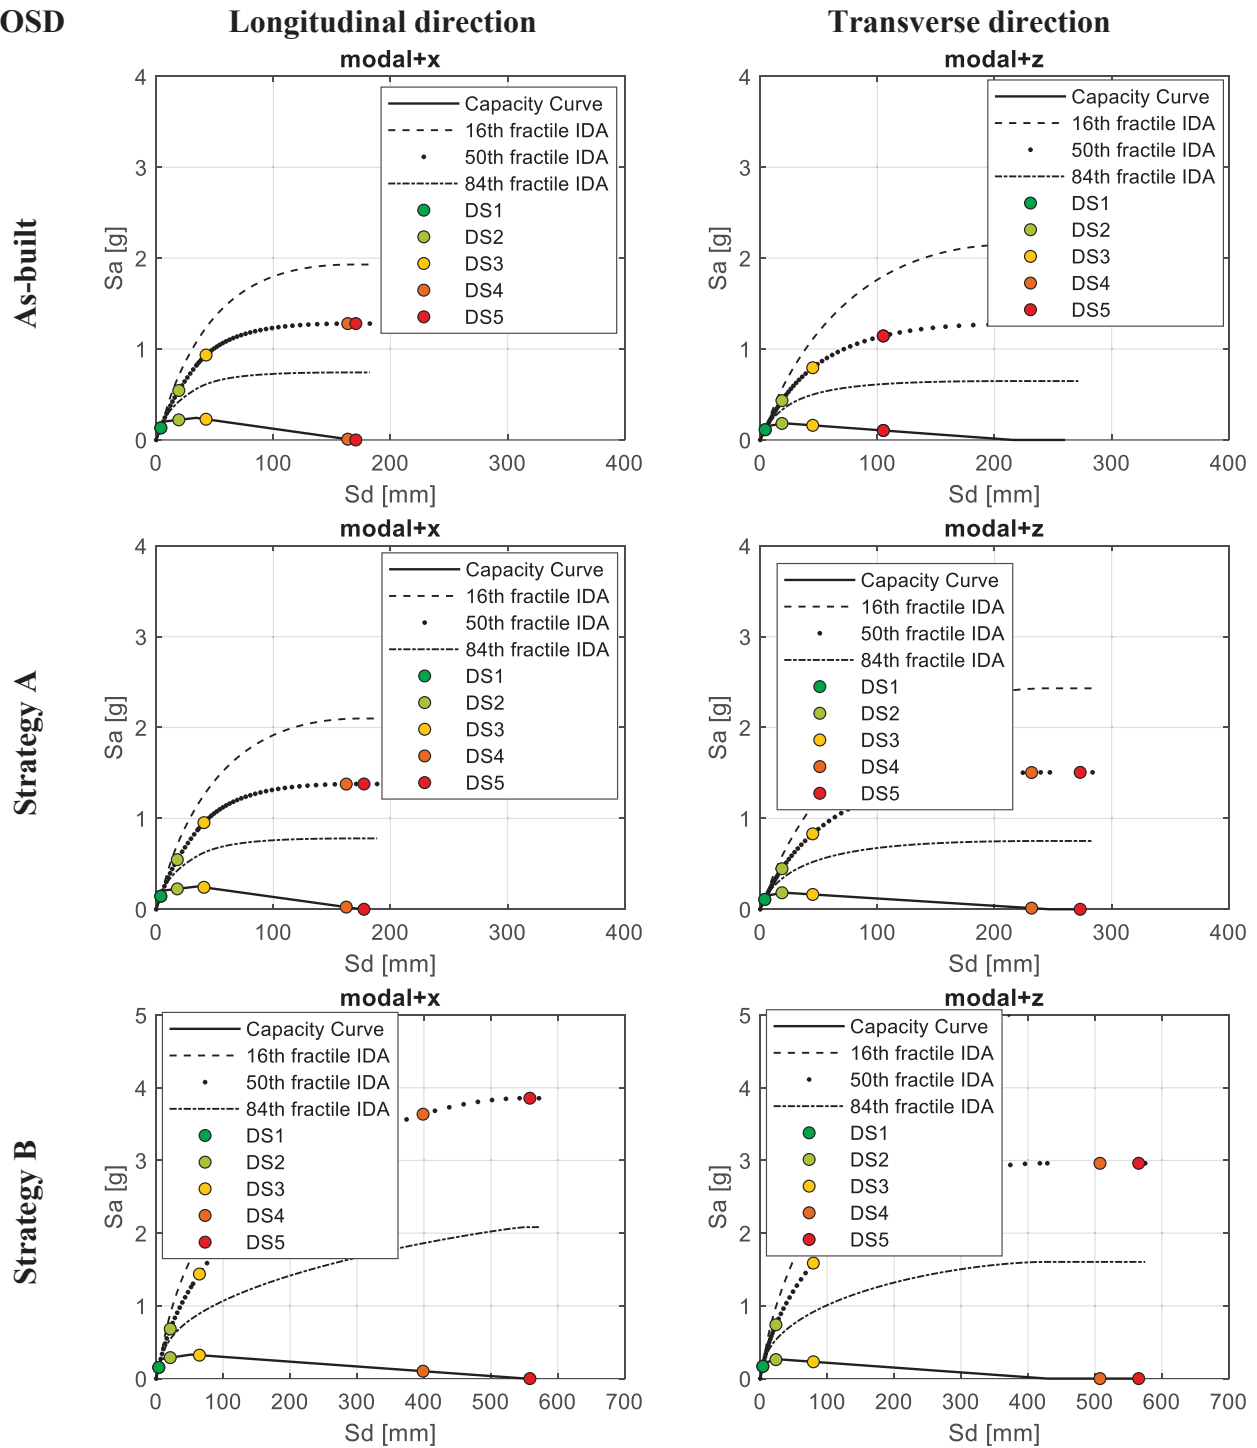

Figure 14: OSD-buildings: Multi-linearized CC, simplified IDA curves and capacity at each DS (only results from “Modal” distribution are reported, for sake of brevity)

It is worth noting that the achievement of DSi (with $i=1, 2, 3$) for infill panels is assumed to occur when the IDR demand in a panel reaches its median capacity value at that DSi. Additionally, due to the structural regularity of the case-study buildings and the same adopted capacity thresholds for all

the panels (for sake of simplicity), the achievement of DS_i “contemporary” (namely, at the same top displacement level) occurs in all the panels in a storey, in a given direction.

It can be noted that, when Strategy “A” is applied, DS1-to-DS3 remain almost unchanged, whereas displacement capacity at DS4 and DS5 can more significantly increase, especially when their achievement in the as-built buildings was strongly conditioned by the achievement of a null lateral load in shear-critical columns involved in the collapse mechanism.

On the contrary, when Strategy “B” is adopted, seismic capacity at all the DSs improves, above all at DS4 and DS5, but also at less severe DSs. This is mainly due to the increment of lateral stiffness induced by the RC jacketing and to the design approach chosen for this strategy (since it was designed to satisfy the DL limit state).

It is so clear that Strategy “A” and Strategy “B” create a range of minimum and maximum variation of the seismic capacity for these buildings, especially for what concerns the first three DSs, strongly influenced by the infill panels capacity.

5.3 Fragility curves

In this section, preliminary fragility curves have been obtained in terms of peak ground acceleration (PGA). To this end, the seismic capacity in terms of S_a has been used for each case-study, along with the spectral shape defined according to Italian code [[15]] for the sites of interest. A single fragility curve (for each DS) has been reported here for each case-study since it represents the minimum capacity between the two main directions and the two selected lateral load distributions (Uniform or Modal). Minimum values of PGA capacities for each case-study are first shown in Table 3. Fragility curves are finally shown and compared to each other in Figure 15. Only record-to-record (RtoR) variability is considered in this study. This is the reason why DS1 fragility curve is a “Z-shaped” function, since DS1 generally belongs to the first (elastic) branch of the multi-linearized CC, and no RtoR variability exists in this range of behavior. Further sources of variability should be introduced in future works.

GLD	As-built		Strategy “A”			Strategy “B”		
	β_{RtoR}	PGA (g)	β_{R2R}	PGA (g)	Retrofitted/As-built	β_{RtoR}	PGA (g)	Retrofitted/As-built
DS1	0	0.05	0	0.04	0.90	0	0.05	1.07
DS2	0.24	0.18	0.24	0.18	1.01	0.23	0.28	1.51
DS3	0.47	0.35	0.47	0.36	1.05	0.45	0.59	1.72
DS4	0.48	0.43	0.58	0.55	1.26	0.62	1.05	2.41
DS5	0.48	0.43	0.58	0.55	1.26	0.62	1.05	2.41

OSD	As-built		Strategy “A”			Strategy “B”		
	β_{RtoR}	PGA (g)	β_{RtoR}	PGA (g)	Retrofitted/As-built	β_{RtoR}	PGA (g)	Retrofitted/As-built
DS1	0	0.04	0	0.04	0.95	0	0.06	1.41
DS2	0.27	0.19	0.28	0.19	1.03	0.23	0.30	1.60
DS3	0.46	0.34	0.47	0.36	1.04	0.48	0.58	1.70
DS4	0.62	0.48	0.57	0.56	1.17	0.63	1.13	2.37
DS5	0.62	0.48	0.57	0.56	1.17	0.63	1.13	2.37

Table 3: Summary of median PGA capacity and logarithmic standard deviation due to record-to-record variability (β_{RtoR}) of fragility curves

Figure 15: Comparisons among fragility curves: GLD (a,b) and OSD (c,d) buildings

The main outcomes from Table 3 and Figure 15 can be summarized as follows:

- When Strategy “A” is applied, the seismic capacity at DS1, DS2, and DS3 changes in terms PGA capacity only slightly (generally very below the 10%);
- When Strategy “A” is applied, slight changes at DS1 can be ascribable to the small differences in the very first branch of the multi-linearized CC; on the contrary, variation in PGA capacity at DS3 are generally due to some difference in the softening branches of the multi-linearized CC;
- When Strategy “A” is applied, only PGA capacity at DS4 and DS5 is more significantly affected; it can increase from +17% (OSD) to +26% (GLD), mostly due to the capability to switch off column shear failures (when they resulted shear-critical elements in the as-built buildings);

- When Strategy “B” is applied, the maximum increment in PGA capacity at DS1 to DS3 can be observed, due to the higher lateral stiffness produced by the columns RC jacketing and the way these jacketings have been designed (namely, to satisfy the DL limit state, see section 3);
- When Strategy “B” is applied, the PGA capacity at DS4 and DS5 increases significantly (more than 100%) also thanks to the global collapse mechanism they produce.

A final comment is about the difference in terms of capacity increment assessment obtained in this section and that obtained in a code-based approach (section 3). When safety check and retrofit design are performed in code-based approach, the first joint failure significantly influences the seismic capacity of the as-built building, limiting it to the first shear cracking in the joint panel in a force-based approach. When shear-critical elements, like joints as well as columns, are analyzed in a displacement-based approach, contrary to what the code prescribes, the assessment results are very different, even in the as-built configurations. Additionally, infill panels are not accounted for in typically code-conforming practice-oriented analyses. As a result, even if Strategy “A” leads to a PGA capacity increment higher than 150% for GLD and 350% for OSD (from the first joint shear failure to the first ductile failure) in a code-based approach (section 3), such a high increment cannot be found when a displacement-based safety assessment is performed; in this latter case, the capacity increment ascribable to Strategy “A” is more limited (around +20%), at least for the buildings analysed in this work.

5.4 Preliminary estimation of EAL

A final comparison among the as-built and the retrofitted buildings is performed here in terms of mean Expected Annual Losses (EAL), to emphasize the importance of the less severe damage states – and thus of masonry infills which condition the achievement of those DSs - to the seismic loss estimation. It is worth remembering that EAL represents the average amount of money (generally expressed as a percentage of the total reconstruction cost) to be spent per year to repair damage due to seismic events during the building lifetime.

First, for each DS, the expected seismic losses, expressed as a percentage of the total reconstruction cost (%CR), should be defined. A clear association between %CR and limit states defined according to Italian [15] and Eurocode 8 [18] can be found in [44] and in [46]. In this work, such an association is preliminary based on a previous study by the Authors ([13]-[14]), which considered damage to infills/partitions and services only for the same DSs adopted herein (in particular from DS1 to DS3). Therefore, 4%, 15%, and 31% of the building reconstruction cost has been assumed here at DS1, DS2, and DS3, respectively, only accounting for seismic losses due to infills/partitions and services allocated in within. DS5 is instead a physical collapse for the building and, therefore, it is associated herein to 100% of the reconstruction cost.

Additionally, the mean annual frequency of exceeding a certain DS (λ) can be obtained (as the inverse of the capacity return period at that DS), thus obtaining all the information required to calculate the EAL, as the area underneath the λ -%CR curves (Figure 16). A maximum threshold for λ (10%) has been preserved in agreement with [46].

Resulting EAL values are finally reported in Table 4. It can be noted that the EAL related to the as-built buildings and that related to the adoption of “Strategy A” are technically identical (about 3% of reduction). This means that, when seismic capacity increment affects the most severe DSs only, no benefits can be gained in terms of seismic losses. On the contrary, the increment in lateral stiffness (produced by Strategy “B”) can reduce the EAL of about 20% for both the case-study buildings.

Figure 16: Percentage of the Reconstruction Cost (%CR) depending on the mean annual frequency of exceedance each DS (λ)

EAL (%)	GLD	OSD
As-built	1.33	1.41
Strategy “A”	1.28 (-3%)	1.36 (-3%)
Strategy “B”	1.06 (-20%)	1.08 (-21%)

Table 4: Expected annual losses, EAL (in grey, its percentage variation with respect to the relevant as-built building).

6. CONCLUSIONS

A preliminary seismic analysis of two case-study low-standard RC buildings has been presented, based on static nonlinear analyses. The investigated case-study structures are 4-storey buildings representative of Italian pre-70 residential buildings, designed for gravity loads only (GLD) or according to obsolete seismic design (OSD). First, they have been assessed in a code-based approach according to the current Italian code [15], namely without infills (as typical in practice) and modelling nonlinear flexural response of beams and columns only, whereas columns/joints shear failures have been detected in post-processing (in a force-based safety check). Then, based on the as-built assessment outcomes, the retrofit phase has been designed by means of two alternative strategies, representing two boundary conditions for the lateral stiffness modification of the buildings:

1. Strategy “A”: the complete resolution of all the shear failures (in columns or joints), if any, at Life Safety limit state;
2. Strategy “B”: the reduction of the displacement demand by means of RC column jacketings, designed at the Damage Limitation limit state, along with the resolution of shear failures at LS limit state.

Then, both the as-built and retrofitted building configurations have been modelled and analysed explicitly considering the presence of infills and shear-critical elements, including beam-column joints. Fragility curves have been obtained at different Damage States (DSs) according to European Macroseismic Scale EMS-98, from DS1 to DS5, considering record-to-record variability, and compared to each other. DSs from 1 to 3 were significantly affected by the infill presence; they were always achieved due to the achievement of the relevant drift capacity in infill panels.

The following conclusions can be drawn:

- when Strategy “A” is applied, the seismic capacity at DS1, DS2, and DS3 changes only slightly (generally very below the 10% in terms PGA capacity);
- when Strategy “A” is applied, only seismic capacity at DS4-5 is more significantly affected; PGA capacity at DS4 and DS5 it can increase from +17% (OSD) to +26% (GLD), mostly due to the capability to switch off column shear failures (when they resulted shear-critical elements in the as-built buildings);
- when Strategy “B” is applied, the maximum increment in PGA capacity at DS1 to DS3 can be observed, due to the higher lateral stiffness produced by the columns RC jacketing and the way these jacketings have been designed (namely, to satisfy the DL limit state);
- when Strategy “B” is applied, the PGA capacity at DS4 and DS5 increases significantly (more than 100%) also thanks to the global collapse mechanism they produce;
- if mean Expected Annual Losses (EAL) are evaluated, it can be noted that, when seismic capacity increment affects the most severe DSs only (as for Strategy “A”), no benefits can be gained in terms of economic losses (only 3% reduction); on the contrary, the increment in lateral stiffness produced by Strategy “B” can reduce the EAL of about 20% for both the case-study buildings.

It is worth noting that the present study analyses only two case-studies in a static nonlinear analyses approach and only considering record-to-record variability to obtain fragility curves. Other case-studies and sources of variability should be considered in future works, also in the context of nonlinear dynamic analyses. Additionally, the modelling strategies and DSs definition adopted herein will be deeper investigated, both about a more detailed definition of DS4 and DS5 (a topic still controversial in the literature), and about the modelling of further key shear-critical phenomena (above all involving beam-column joints), such as the joint axial load failure in as-built buildings (herein neglected). Lastly, in this study, infill panels have been considered to be identical in the as-built and in retrofitted buildings. Nevertheless, such an aspect could be modified in future works to consider the possibility of a change in infill typology to address energy-efficiency requirements, at least when invasive strategies (like Strategy “B”) are implemented.

ACKNOWLEDGEMENTS

This work was developed under the support of ReLUIIS-DPC 2019-2021 funded by the Italian Department of Civil Protection (DPC), and PON-AIM Ricerca e Innovazione 2014-2020 – Fondo Sociale Europeo, Azione I.2, “Smart, Secure and Inclusive Communities. These supports are gratefully acknowledged.

Abstract

This study investigates the improvement in the seismic performance of an archetype reinforced concrete (RC) frame due to varying structural retrofit levels. Specifically, the study attempts to map the increase of the displacement-based global ratio between capacity and life-safety demand (CDR_{LS}) to the reduction of seismic fragility. Such a reduction is characterized by the shift of the median fragility for different structure-specific damage states (DSs). The considered structure does not conform to modern seismic design requirements, and it is retrofitted using various techniques. Advanced nonlinear models are developed for the archetype frame, accounting for potential failure mechanisms, including flexural, joint, and shear failure. Three common retrofitting techniques are investigated, namely RC jacketing, steel jacketing, and fiber-reinforced polymers (FRP) wrapping of columns and joints. Each technique is specifically designed and proportioned to achieve predefined performance objectives (i.e., performance-targeted retrofitting), thus generating many retrofit alternatives. The improvement in seismic performance for the retrofitted frames is first characterized by computing the global CDR_{LS} , which can be obtained using nonlinear pushover analysis combined with the Capacity Spectrum Method. Subsequently, cloud-based nonlinear time-history analyses are performed to derive fragility relationships for the as-built and retrofitted configurations, monitoring the variation in the median fragility for all DSs. Finally, the global CDR_{LS} increase due to retrofitting is correlated with the corresponding shift in the median fragility. A linear trend is found, and it is used accordingly to develop simple models that engineers can implement to provide reasonable estimates for such shift once the global CDR_{LS} is known.

Keywords: Retrofitting strategies, fragility relationships, nonlinear analysis, reinforced-concrete frames, performance-based assessment.

1 INTRODUCTION

Many existing reinforced concrete (RC) buildings in earthquake-prone regions do not conform to modern seismic codes as they were mainly designed to resist gravity loads only. These buildings are vulnerable to severe damage or even collapse under moderate-to-high ground-shaking intensity levels [1]. This has led to significant economic and life losses, as demonstrated by numerous past earthquakes (*e.g.* [2], [3]).

To mitigate the consequences of earthquake events on such buildings and improve their seismic performance, structural retrofitting is often necessary. Such an approach has become very popular lately due to the ease of construction and cost-effectiveness compared to other drastic solutions like demolition and complete replacement.

Generally, retrofitting strategies aim to modify key structural parameters such as strength, ductility, and stiffness or reduce seismic demand. Several techniques (systems) are widely used to implement one or more strategies. For instance, adding RC shear walls (*e.g.* [4], [5]) or bracing (*e.g.* [6], [7]) to existing buildings improves both stiffness and lateral strength significantly. On the other hand, base isolation can be implemented to reduce seismic demands by simply decoupling the horizontal motion of the structure and that of the ground [8].

Many challenges may arise in adopting the above techniques, which are related to the architectural compatibility of the intervention, its invasiveness, the need to modify existing foundations or adding new ones, in addition to the high implementation costs and long duration of the work. Therefore, less-invasive retrofitting techniques, which represent the main focus of the current study, are more common and popular. Examples include wrapping structural elements with fiber-reinforced polymers (FRP), and jacketing columns using either RC or steel jackets. These local techniques are fundamentally less expensive, and they pose a minimal degree of invasiveness/business interruption compared to RC shear walls or bracing.

Most of the past research focused on the experimental investigation of different retrofitting techniques and developing analytical and numerical models to simulate their effect on existing structural elements and/or systems. For instance, some studies investigated the effects of steel jackets on RC columns experimentally and developed design procedures (*e.g.* [9]–[12]), while others explored FRP retrofitting (*e.g.* [12]–[15]) and RC jacketing for columns (*e.g.* [16], [17]).

Retrofitted buildings are expected to perform better against earthquake-induced ground shaking. However, field observations for those buildings under actual seismic events are still scarce, indicating the lack of sufficient empirical fragility and vulnerability models in the literature. This demonstrates the need for numerically developing such models considering different retrofitting techniques and geometric layouts, which are essential for applications related to seismic risk reduction and increasing resilience of earthquake-prone communities around the world. This has indeed attracted many research efforts in the past few decades, but a limited number of studies is available. A detailed review of such studies is outside of the current paper's scope, but a few are briefly discussed to provide the reader with some background.

Some studies developed fragility relationships considering FRP, RC jacketing, base isolation, and adding shear walls (*e.g.* [18], [19]). However, the fragility models accounted for collapse only, without considering other damage states (DSs). Moreover, retrofitting was either applied based on engineering judgment, *i.e.* without properly accounting for structure-specific seismic deficiencies or predefined performance objectives [18], or considering only one, rather than multiple, performance objectives (*e.g.* [19], [20]). Other studies considered applying different retrofitting techniques with varying intervention levels to achieve different performance objectives (*e.g.* [21], [22]), but only collapse fragility relationships were evaluated.

The current study investigates the improvement in seismic performance of an archetype RC frame located in a high-seismicity zone considering varying levels of retrofitting intervention

This frame does not satisfy the main seismic design provisions such as those for capacity design and strong-column-weak-beam. Beams and columns are poorly confined, and the latter elements have a very low amount of longitudinal reinforcement (*i.e.* less than 1%). Moreover, the joints lack transverse reinforcement, use smooth bars, and improper anchorage [24]–[26]. This makes the frame susceptible to developing brittle failure mechanisms such as joint failure, soft-storey, and shear failure. Typical average values for the material properties are used, which are representative of that era. Specifically, the average compressive strength of the concrete (f_{cm}) is 16.5 MPa, in compliance with other studies (*e.g.* [27], [28]). The average yield strength (f_{ym}) of reinforcing steel is 330 MPa [29]–[31].

2.2 Selected retrofitting techniques

Three different retrofitting techniques are investigated in this study: FRP wrapping, steel jacketing, and RC jacketing. Typical cross-sections for columns retrofitted using these techniques are illustrated in Figure 2.

Figure 2: Typical cross-sections of a column retrofitted using (a) FRP; (b) steel jacketing; and (c) RC jacketing

FRP wrapping is mainly used for joints and columns to prevent brittle shear failure mechanisms. It also provides a high level of confinement for columns, thus improving their ductility under extreme loading conditions (*e.g.* [13], [14]). The contribution of FRP wrapping to the stiffness and flexural strength is minimal as the unidirectional fibers are placed perpendicular to the longitudinal axis of columns.

Rectangular and elliptical steel jackets are another popular option to prevent shear failure of columns. They are also able to increase lateral stiffness due to the isotropic properties of steel [12]. However, only elliptical (or circular) steel jackets are used in the current study because they are very effective in improving confinement and ductility due to the continuous confining pressure they provide [9]. This technique also offers some enhancement of flexural strength. Conversely, experiments demonstrated that rectangular steel jackets lose much of their confinement efficiency (*e.g.* [9], [16]). A gap of 50 mm is deliberately left between the edges of the steel jacket and foundations/beams to prevent excessive flexural strength enhancement, which transfers forces to adjacent members [9].

RC jacketing is the most traditional and common technique in practice as it is characterized by a low cost and does not require specialized labor. It comprises encasing existing columns with a cast-in-place RC jacket to improve confinement, ductility, and both shear and flexural strengths. Continuous column jacketing in two consecutive floors also enhances joint behavior. The thickness of an RC jacket is controlled by the size of longitudinal and transverse reinforcement to be used, in addition to the minimum cover requirement (*e.g.* [16], [32]). Compared to the other two techniques, RC jacketing poses the highest level of invasiveness. It can notably increase the size of existing columns and might require extending reinforcement through slabs, foundations, and joints.

2.3 Design of retrofitting techniques

A trial-and-error design procedure is adopted for the three retrofitting techniques, aiming to achieve a predefined set of performance objectives, as explained later. For each technique, design iterations might vary with respect to detailing, geometric characteristics, and the number of retrofitted elements to ensure incremental improvements in seismic performance.

For the FRP technique, laminated pre-cured sheets with high-strength carbon fibers (CFRP) are wrapped around the full height of existing columns. The elasticity modulus (E_f) is equal to 140 GPa, ultimate tensile strength (F_{fu}) is 2000 MPa, and rupture strain (ϵ_{fu}) is 1.2% [33], assuming that each layer has a thickness of 0.5 mm. It is considered that the maximum number of FRP layers is five to ensure confinement efficiency [34]. It should be noted that the FRP is also used for joint retrofit in cases where joint failure is observed (mainly external ones).

On the other hand, full-height elliptical/circular steel jackets are used. The space between the steel jacket and retrofitted column can be filled with either grout material or plain concrete [9], [12]. The jackets are made of structural steel grade S235 with an average yield strength (f_{yj}) of 235 MPa and a minimum thickness of 1.5 mm, which is increased during the iterative design process. As mentioned earlier, a gap of 50 mm is left between the edges of steel jackets and column ends to prevent transferring forces to adjacent members [9].

In the case of RC jacketing, a full-height encasement of existing columns is made using cast-in-situ concrete, with the possibility of extending longitudinal reinforcement through foundations and slabs. RC jackets with a minimum thickness of 50 mm are adopted, with at least 4 Φ 14 mm for external columns and 4 Φ 16 mm for internal ones (Φ refers to the diameter). Hoops with Φ 8 mm are used with a spacing not exceeding 150 mm. The reinforcement and/or jacket thickness are increased gradually during the iterative design, as stated earlier. The concrete material is characterized by f_{cm} of 33 MPa, while f_{ym} for the reinforcement is equal to 490 MPa.

2.4 Nonlinear modeling strategies

The nonlinear response of the case-study building is simulated by developing 2D numerical models using OpenSees [35]. Structural components are modeled as beam-column elements with finite-length plastic hinges to simulate the nonlinear flexural response, which is defined by performing moment-curvature analysis following the rules defined by [36] and [37]. The post-capping degrading response for the moment-curvature and the hysteretic parameters are assigned according to [38]. Additional shear springs are added in series to the beam-column element to account for potential shear failure modes, as illustrated in Figure 3. The backbone curve parameters for the shear response are calculated in accordance with [39]–[41].

Figure 3: Modelling strategy for structural components

As mentioned earlier, joints in older Italian RC frames are characterized by the lack of transverse reinforcement and the use of smooth bars with end-hooks, particularly in external joints [24]–[26]. Therefore, the early failure of such joints leads the building to develop a brittle failure mechanism. Therefore, an additional spring is added in each beam-column joint zone. The parameters of the nonlinear material of joints are defined according to [38], which is a mechanics-based approach introduced in many other studies (*e.g.* [42], [43]).

To account for the effects of FRP on columns, the moment-curvature relationship is modified considering the confinement provided by this technique. This is achieved by first assuming that the entire column cross-section is confined rather than the core only since the FRP layers are wrapped around the external perimeter of the column. Next, the confinement pressure (f_l) due to FRP wrapping is calculated based on [13] and then the compressive strength and ultimate strain of the confined concrete (f_{cc} and ϵ_{ccu}) can be estimated based on [44] and [13], respectively. It should be noted that FRP wrapping around rectangular columns is less effective than circular ones because only inward corner forces provide the confinement in the former case instead of continuous pressure around the perimeter. Thus, a confinement effectiveness factor is used to reduce the value of f_l as per [33]. Moreover, the additional shear strength due to FRP is calculated and added to the shear strength of the as-built column in accordance with [13].

It should be noted that the unique failure modes pertaining to FRP, such as debonding and fracture mechanisms, are not explicitly modeled, assuming the FRP retrofitting is designed and installed appropriately so that the concrete and reinforcement will govern the softening behavior of the retrofitted elements at high levels of deformation (*e.g.* [22], [45]).

Steel jacketing is treated in a similar manner to FRP. The value of f_l is estimated as per [9], whilst f_{cc} and ϵ_{ccu} are found based on [44] and [16], respectively. These new values are adopted to modify the moment-curvature relationship. The additional shear strength due to the steel jacket is estimated according to [9].

Finally, columns retrofitted with RC jackets are treated as equivalent monolithic members. This assumption is deemed valid as long as the jackets are well constructed and the surface of existing columns is adequately treated (*e.g.* [45], [46]). However, to address the possibility of a poor bond between the new RC jackets and existing columns, it is recommended to use the as-built value of f_c for the entire cross-section and to assume that lateral confinement is provided solely by the hoops of the new RC jacket [16].

2.5 Damage state definition and thresholds mapping

Three structure-specific DSs are adopted in order to characterize different damage conditions, which reflect the performance level (PL) of the building. Each DS occurs when the structure attains a specific threshold defined with respect to an engineering demand parameter (EDP). This study adopts the maximum interstorey drift ratio (MIDR) as an EDP, which is a reliable and widely-used proxy to quantify global structural and nonstructural damage (at least in the case of drift-sensitive nonstructural components).

The MIDR thresholds are calibrated by assessing multiple measurable criteria during non-linear static (*i.e.* pushover) analysis using a modal-pattern incremental load. These criteria are adopted from [47] and are also summarized in Table 1. The parameters θ_y and θ_u in Table 1 represent the yield and ultimate chord rotations, respectively. The latter parameter is evaluated according to [48]. It should be noted that the MIDR threshold for each DS is based on the first occurrence of any criterion among those shown in Table 1 (*e.g.* [47]).

The three DSs are described as follows: DS1, which accounts for moderate damage levels, is characterized by moderate structural and nonstructural damages with no significant yielding. The building here maintains the limited occupancy PL, but minor repairs may be required. DS2,

which corresponds to significant damage (SD), incorporates severe damages in both structural and nonstructural components, but buildings still retain some residual strength and stiffness. The building in DS2 meets the PL of life safety (LS), in which significant repairs are needed, which might not always be feasible. Finally, DS3 represents here the collapse-prevention PL, characterized by the full exploitation of strength and ductility. Minimal residual strength and stiffness remain in DS3, and the building is in a near-collapse condition [49].

Level/DS	DS1	DS2	DS3
Section Level	Reaching yield bending in a supporting column	Max. bending strength of a column is reached	Reaching shear failure in any element
Component Level	Reaching θ_y in any supporting column	Reaching 75% of the θ_u in any component	Reaching the θ_u in any component
Global Level	Reaching the global yield point of the structure	Reaching the maximum strength	About 20% drop in the maximum strength
General description	Moderate structural and nonstructural damage. No significant yielding of members	Severe structural and nonstructural damage. Some residual strength and stiffness retained	Full exploitation of strength and ductility. Low residual strength and stiffness

Table 1: Criteria used for mapping of DSs; adopted from [47]

The analytical formulation for θ_u requires inputting the amount of transverse reinforcement. This is directly applicable for the existing structural components and those retrofitted using RC jackets. In the case of FRP or steel jacketing, the concept of equivalent transverse reinforcement is implemented (*e.g.* [12], [22], [45]). In this approach, the FRP or steel jacketing can be simply converted to standard transverse reinforcement that mimics their effect by generating a lateral confining pressure equal to that produced by either of them.

2.6 Performance-targeted retrofitting

As indicated earlier, varying retrofitting levels are designed and applied to the case-study structure to meet some predefined performance objectives (*i.e.* performance-targeted retrofitting). These objectives represent achieving specific PLs (or DSs), either fully or partially, under a selected level of seismic hazard (*e.g.* [50]). The selected hazard level in all performance objectives is the one associated with life safety, *i.e.* corresponding to a mean return period of 475 years (*e.g.* [48], [50], [51]), as it is the most relevant and widely-used hazard level for the design and assessment of buildings – and for which hazard maps/curves are readily available.

To investigate whether a retrofitting intervention achieves a particular performance objective, the displacement-based global ratio between capacity and LS seismic demand, *i.e.* CDR_{LS} is considered. The LS displacement demand is calculated by transforming the force-deformation relationship (*i.e.* capacity curve) derived from pushover analysis to a capacity spectrum of an equivalent single-degree-of-freedom (SDoF) system plotted in the acceleration-displacement response spectra (ADRS) space. Subsequently, the capacity spectrum method (CSM) is applied in order to obtain a graphical representation of the performance [52]. A summary of the selected performance objectives is provided in Table 2.

It should be highlighted that the seismic demand used to design and assess different retrofitting cases is characterized by a Type 1 response spectrum according to [53], with a peak ground acceleration (PGA) of 0.30g and ground type C to account for high-seismicity conditions.

Performance objective	Description
No-collapse performance	Achieve the collapse-prevention PL (DS3) against the LS seismic demand
Limited performance	Partially achieve significant damage PL (DS2) against LS demand ($CDR_{LS} \approx 75\%$)
Basic performance	Achieve the significant-damage PL (DS2) against LS demand (100% of CDR_{LS})
Advanced performance	Achieve moderate damage (DS1; limited occupancy) against LS seismic demand

Table 2: Selected performance objectives for seismic retrofitting

2.7 Fragility relationships and selection of ground-motion records

Retrofitting of structures can result in a significant improvement in their seismic fragility. Fragility relationships characterize the conditional probability of exceeding different building-level, structure-specific DSs given a ground-shaking intensity level (IM), *i.e.* $P(DS \geq dsi|IM)$. It is possible to derive fragility relationships by performing nonlinear time-history analysis (NLTHA) using a set of unscaled (as-recorded) ground-motion records, *i.e.* by performing cloud analysis [54], among other alternative approaches. Hence, clouds of IM vs. EDP are developed and appropriate probabilistic seismic demand models (PSDMs) are fitted via power-law regression, which allows deriving fragility relationships using a closed-form solution [55] as shown in Eq. (1)-(2).

$$EDP = aIM^b \quad (1)$$

$$P(DS \geq dsi|IM) = \Phi\left(\frac{\ln(IM/\mu)}{\beta}\right) \quad (2)$$

where a and b are the regression parameters, μ is the median IM, and β is the dispersion. The records used for the NLTHA are adopted from the SIMBAD (Selected Input Motions for displacement-Based Assessment and Design) database developed by [56], which incorporates 467 three-component records related to shallow crustal earthquakes with magnitudes between 5.0 and 7.3 and epicentral distances less than 30 km [56]. To reduce the computational effort yet maintaining the engineering significance of the analysis, only 150 records are selected following the same criteria defined in [20], [57]. Specifically, the ground motions are ranked with respect to their PGA, obtained as the geometric mean of the two horizontal components. For each ground motion, the horizontal component with the highest PGA is kept, and then the 150 records with the highest ranking are selected. Such procedure is compatible with cloud analysis, and therefore it does not require a site-specific record selection. Moreover, this approach is deemed appropriate for regional-scale seismic risk assessment of building portfolios, especially when coupled with optimal IMs.

The IM implemented in this study is the geometric mean of the 5%-damped spectral acceleration over a specific range of vibration periods (avgSa). Such an IM accounts indirectly for the effects of higher modes, in addition to the period elongation due to the strength and stiffness degradation as well as the damage of different components (*e.g.* [58]–[60]). This IM, compared to other conventional ones like the spectral acceleration at the fundamental period $Sa(T_1)$, minimizes response variability, and it has a higher relative sufficiency [61].

The avgSa in this study is calculated considering 10 equally-spaced periods ranging within $0.2T_1$ and $1.5T_1$ (e.g. [62]). However, to allow for fragility comparison between the as-built and the retrofitted case-studies, the same period range is adopted for all of them, which is based on T_1 of the as-built case. This assumption is deemed appropriate as the change in T_1 for the majority of retrofitted cases is not very significant.

3 RESULTS AND DISCUSSION

3.1 Initial assessment for the as-built structure

To understand the response and failure mechanism of the as-built case-study structure, an initial assessment is carried out using pushover analysis to identify DS thresholds and then apply the CSM to evaluate the CDR_{LS} before any intervention through retrofitting.

Figure 4(a) shows the pushover curve with the horizontal axis representing the MIDR among all stories and the vertical axis showing the base shear. The first occurrence of some damage observations are also illustrated in Figure 4(a), such as first yield for beams and columns, SD for columns and joints (θ_{SD} and γ_{SD}), and joint failure (γ_u); mainly external ones. The MIDR thresholds for all DSs are also summarized in Table 3.

It can be observed in Figure 4(a) that both DS2 and DS3 are controlled by the limit states of the joints, which take place before those pertaining to the columns. It is also noticed that the beams do not reach their θ_{SD} and θ_u despite their yielding. This demonstrates that the nonlinear deformation is concentrated in the columns and joints, which depicts a non-ductile joint and column-sway mechanism. Accordingly, retrofitting efforts must be directed towards improving the key properties (*i.e.* strength, ductility, stiffness) of these structural components in particular, which will eventually improve the overall plastic mechanism of the building towards a beam-sway one (mainly characterized by beam hinging).

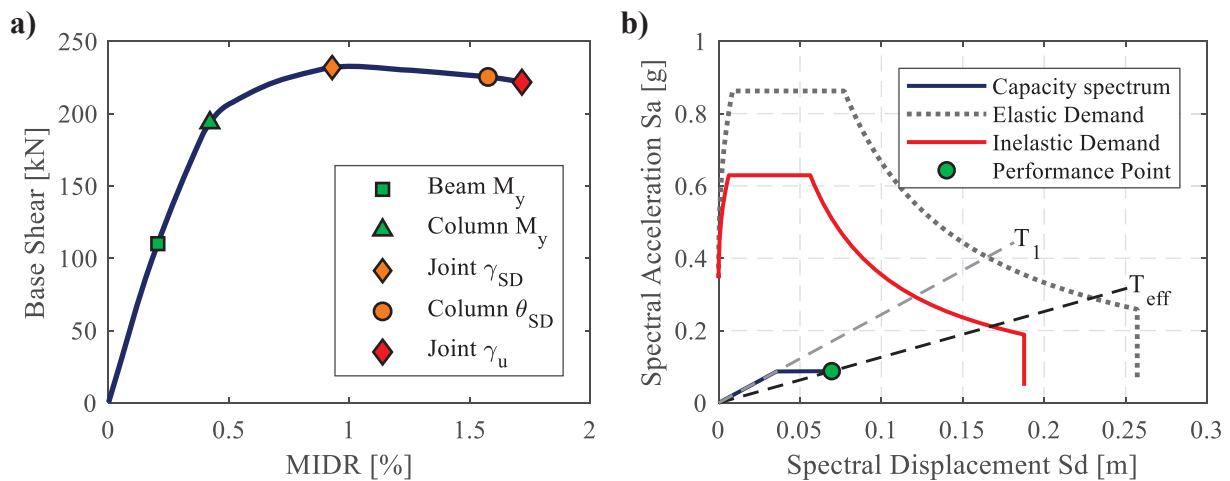

Figure 4: (a) Assessment for the as-built structure using pushover analysis and damage observations; (b) Graphical illustration for the capacity and demand spectra using the CSM

Damage state (DS)	DS1	DS2	DS3
MIDR threshold [%]	0.41	0.93	1.71

Table 3: MIDR thresholds for different DSs derived from pushover analysis

Figure 4(b) illustrates the idealized capacity spectrum of the equivalent SDoF system and the demand spectrum, both elastic and inelastic, plotted in the ADRS space. Applying the CSM, it is found that the inelastic demand spectrum significantly exceeds the capacity of the as-built structure. In other words, the performance point (PP) cannot intersect the inelastic demand spectrum, thus indicating a CDR_{LS} less than 1.0. According to Figure 4(b), the maximum capacity corresponds to a spectral displacement (S_d) of 0.07 m only. However, the expected demand displacement identified through the intersection between the secant stiffness line and the inelastic demand spectrum is nearly 0.167 m. Therefore, the CDR_{LS} of the as-built structure is very low, *i.e.* 42%, demonstrating the need for structural retrofitting.

3.2 Designed retrofitting solutions

As mentioned in section 2.3, the as-built structure is retrofitted with varying intervention levels to achieve the selected performance objectives (see Table 2). This process resulted in 13 retrofitted case studies using FRP wrapping of columns and joints, 15 cases for steel jacketing, and 18 for RC jacketing. The details, layout, and amount of retrofitted elements using FRP for all performance objective are listed in Table 4. For the sake of brevity, only one retrofitted case-study is described for each performance objective; particularly the one that satisfies the objective with the minimum possible amount of intervention.

Performance objective	Achieved CDR_{LS}	Description of FRP retrofitting	Graphical illustration
No-collapse performance	65.4%	1 layer for external columns and joints in the 1 st to 3 rd floor and 1 layer for internal columns in the 1 st and 3 rd floors	
Limited performance	75.5%	Same joint retrofitting as above. 2 layers for the 3 rd floor columns and internal columns of the 1 st floor. 1 layer for external columns in 1 st to 2 nd floor.	
Basic performance	105.0%	Same joint retrofitting as above. 1 layer for the 2 nd floor columns. 4 layers for the 1 st floor and internal columns in 3 rd floor and 5 layers for the 3 rd floor external columns.	
Advanced performance	N.A.	N.A.	N.A.

Table 4: Description of FRP retrofitting alternatives for different performance objectives

Table 4 demonstrates that the advanced performance objective could not be achieved using FRP retrofitting. This is because FRP wrapping improves ductility through confinement and increases shear strength while its contribution to the lateral strength and stiffness is minimal (less than 10% in the current study). In fact, enhancing these parameters (*i.e.* stiffness and lateral strength) is essential with respect to moderate damage PL (or DS1) as the columns will not yield quickly, especially at low IM levels. It should be noted that the maximum value of CDR_{LS}

that could be achieved is around 110% since the number of FRP layers that could be applied for the columns cannot exceed five layers (see section 2.3).

Table 5 provides similar information about the retrofitted case studies using steel jacketing. It was possible to generate many cases of retrofitted buildings with large values of CDR_{LS} , particularly up to 147%. This is related to the high effectiveness of circular/elliptical jackets with respect to the high and continuous (radial) confinement they provide. This, in turn, significantly improves the ductility of the columns, thus making them capable of sustaining large levels of inelastic deformation. This also improved the (near) collapse situation, allowing beams to undergo failure prior to columns. Like the FRP case, all these advantages are insufficient to make the structure experience moderate damage (DS1) only against the LS demand (*i.e.* the advanced performance level) for the same reasons explained previously regarding the FRP.

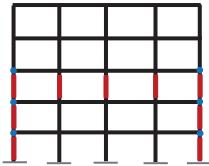

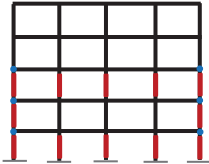

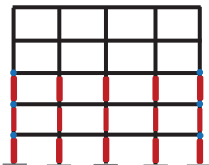

Performance objective	Achieved CDR_{LS}	Description of steel jacketing retrofitting	Graphical illustration
No-collapse performance	61%	1.5 mm thick jacket mm for the external columns in 1 st to 3 rd floor and internal ones in the 3 rd floor. Also retrofit external joints in 1 st to 3 rd floors using FRP.	
Limited performance	80%	Same joint retrofitting as above. Use 1.5 mm thick jacket for the external columns in the 1 st to 3 rd floor and internal ones in the 1 st and 3 rd floor	
Basic performance	106%	Same joint retrofitting as above. 1.5 mm thick jacket for the columns of 2 nd floor. 2.5 mm thick jackets for the 3 rd floor and external columns of 1 st floor. 3 mm jacket for the internal columns in 1 st floor	
Advanced performance	N.A.	N.A.	N.A.

Table 5: Description of steel jacketing retrofitting alternatives for different performance objectives

Finally, a summary for the case studies with RC jacketing is provided in Table 6, which shows that unlike FRP and steel jacketing, the advanced performance objective is achieved. This is because the RC jacketing provides a significant overall enhancement for the stiffness and strength, both shear and flexural, and improves the ductility through confinement. These features can also shift the building mechanism from local (*e.g.* soft-storey) to global, *i.e.* beam-sway. Therefore, the (frame-level) MIDR threshold of DS1 becomes much higher, and the retrofitted structure will not be easily subjected to yielding and moderate damages, especially at low IM levels. Nevertheless, as illustrated in Table 6, achieving the advanced performance level requires retrofitting the entire columns in the frame, thus making a global intervention to the frame rather than local, which might be expensive and technically challenging.

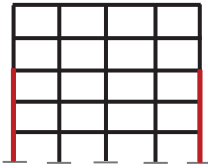

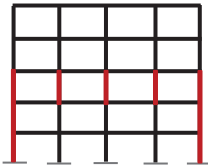

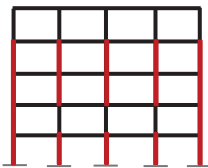

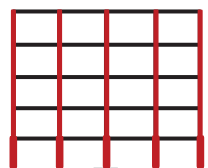

Performance objective	Achieved CDR_{LS}	Description of RC jacketing retrofitting	Graphical illustration
No-collapse performance	65%	Retrofit external columns in the 1 st to 3 rd floor with 50 mm jacket with 4 Φ 14 mm bars and 1 Φ 8/150 mm hoops.	
Limited performance	78%	50 mm jackets for the external columns in the 1 st to 3 rd floor with 4 Φ 14 mm bars and 1 Φ 8/150 mm hoops. 50 mm jackets for the internal columns of the 3 rd floor with 4 Φ 16 mm bars and 1 Φ 8/150 mm hoops	
Basic performance	105%	50 mm jackets for the external columns in the 1 st to 4 th floor with 4 Φ 14 mm bars and 1 Φ 8/150 mm hoops. 50 mm jackets for the internal columns in 1 st , 3 rd , 4 th floors with 4 Φ 16 mm bars and 1 Φ 8/150 mm hoops	
Advanced performance	181%	100 mm jackets with 8 Φ 16 mm bars and 1 Φ 8/100 mm hoops for external, and with 12 Φ 22 mm bars and 1 Φ 10/80 mm hoops for the internal columns of 1 st floor. 50 mm jackets with 8 Φ 20 mm bars and 1 Φ 8/150 mm hoops for external and with 8 Φ 22 mm bars and 1 Φ 8/150 for the internal columns of 2 nd floor. 50 mm jackets with 8 Φ 14 mm bars and 1 Φ 8/150 mm hoops for the 3 rd , 5 th and external columns of 4 th floor. Similar jackets but with 8 Φ 16 mm bars for internal columns of the 4 th floor	

Table 6: Description of RC jacketing retrofitting alternatives for different performance objectives

3.3 Fragility assessment

Upon developing all the case studies, including both the as-built and retrofitted structures, NLTHA is performed using the selected set of ground-motion records to assess the performance and derive the corresponding fragility relationships. Figure 5 shows both the IM vs. EDP cloud along with the fitted PSDM and the derived fragility relationships for the as-built structure. As demonstrated by Figure 5(a), the following points must be highlighted:

- The as-built structure remained undamaged only in 19.3% of the analysis cases.
- Moderate damage (DS1) was experienced by the frame in 23.3% of the cases.
- The frame was subjected to DS2 in a considerable portion of cases, particularly 21.3%.

- The near-collapse condition characterized by DS3 was experienced by the as-built frame in a significant number of analysis cases, which represents 36%.

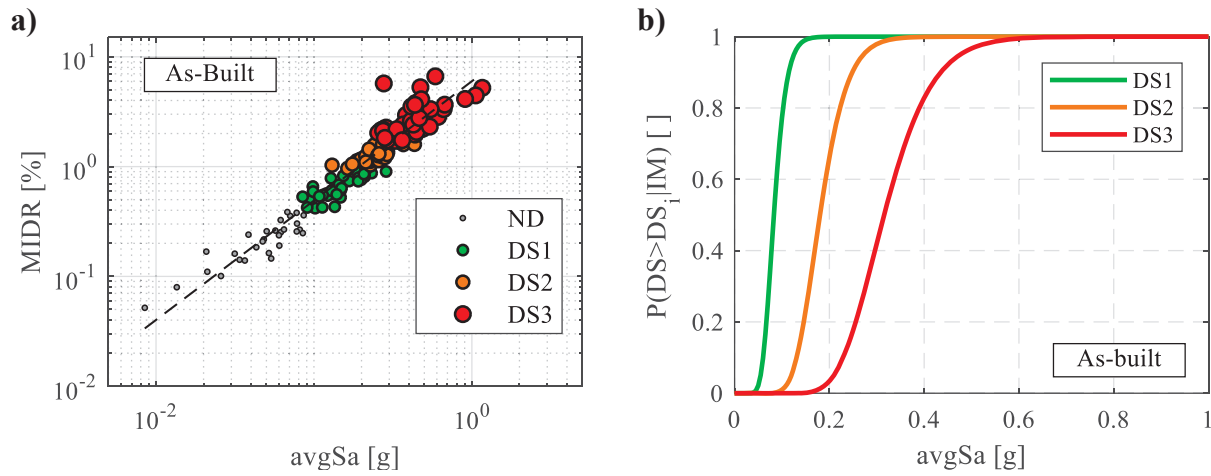

Figure 5: (a) IM vs EDP cloud; and (b) fragility relationships for the as-built structure

The poor performance of the as-built structure is reflected in the fragility relationships in Figure 5(b), which shows that the building is expected to experience high DSs, even at low IM levels. The fragility parameters including median (μ_{DS}) and dispersion (β) are given in Table 7.

DS	μ_{DS} [g]	β
DS1	0.083	
DS2	0.180	0.2504
DS3	0.316	

Table 7: Fragility parameters for the as-built structure

Fragility assessment is then carried out considering the retrofitted case studies defined previously. To illustrate the substantial impact of retrofitting, the fragility relationships for the as-built structure and the retrofitted cases are depicted in Figure 6. For each retrofitting technique, the fragility relationships for one retrofitted case only are plotted per performance objective, particularly the one that satisfied that objective with minimal intervention.

As per Figure 6, a significant improvement can be observed in the fragility relationships of DS2 and DS3 when the frames are retrofitted until satisfying the basic performance objective ($CDR_{LS} \approx 100\%$), which is represented by the rightward shift. This improvement is very similar for the three different retrofitting techniques but slightly higher for both steel and RC jacketing.

Figure 6(a),(b) demonstrate that the improvement in the fragility relationships of DS1, unlike DS2 and DS3, is relatively low when the frames are retrofitted using either FRP wrapping or steel jacketing. This can be explained by the fact that both techniques are mainly enhancing the ductility through confinement, in addition to prevention of shear failure, which is beneficial for DS2 and DS3 as they are associated with the performance of the building under high levels of inelastic deformation. On the other hand, improving DS1 fragility requires the enhancement of both lateral strength and stiffness to control the sway mechanism of the building and make it more difficult to develop moderate damages due to early yielding. However, the contribution of steel jacketing to the lateral strength and stiffness is minor compared to RC jacketing, whereas the contribution of FRP is approximately negligible.

In contrast, RC jacketing can change the mechanism of the building to a full beam-sway one. It also provides a significant overall improvement for all the aforementioned parameters, which resulted in a considerable shift in DS1 fragility relationship shown in Figure 6(c). Furthermore, the advanced performance objective could also be achieved using RC jacketing, which caused a considerable shift in the fragility relationships of the three DSs.

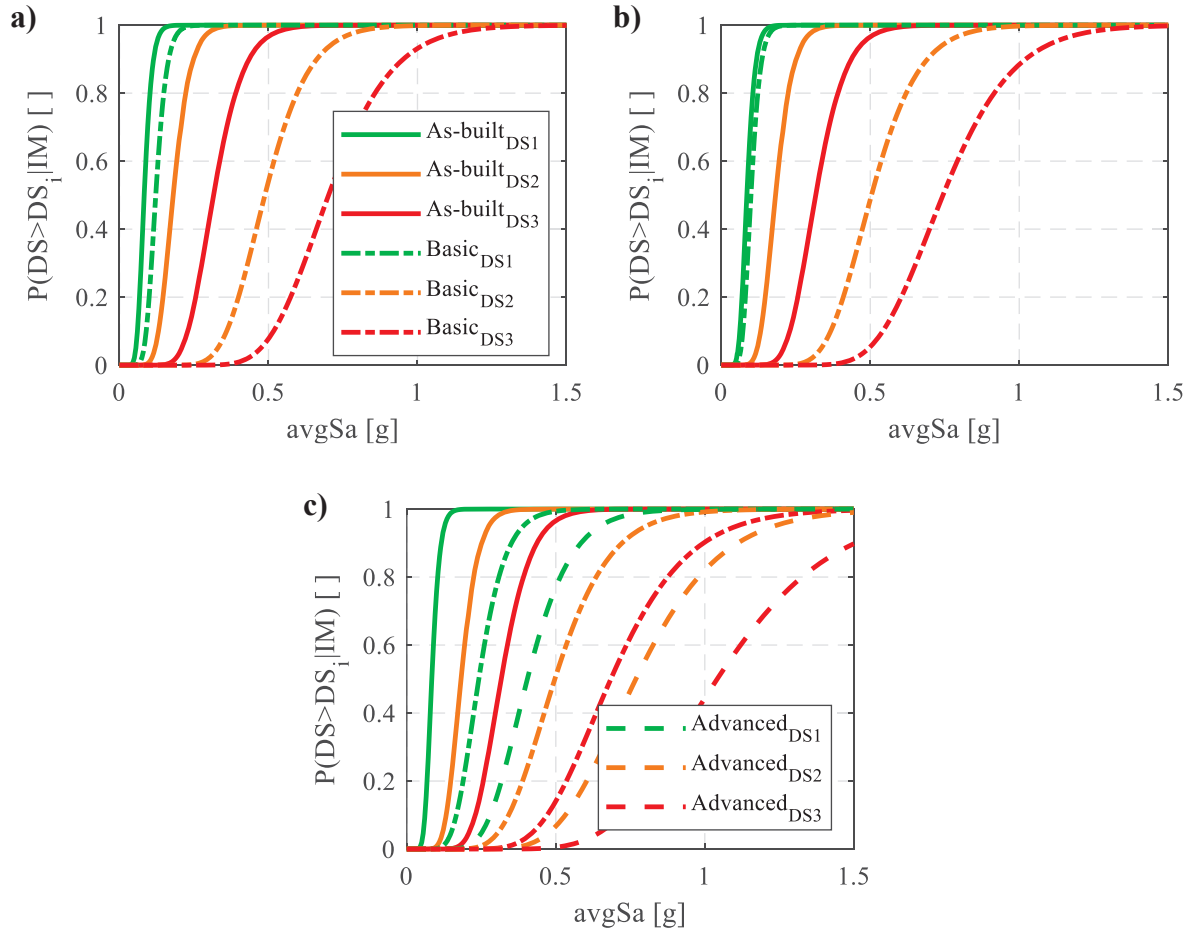

Figure 6: Fragility relationships for different performance objectives considering (a) FRP wrapping; (b) steel jacketing; and (c) RC jacketing

Overall, the previous analysis shows that the three techniques are similar with respect to improving the fragility relationships for the significant damage (DS2) and near collapse (DS3) conditions. In contrast, the improvement in DS1 fragility relationships is trivial if the FRP or steel jacketing are used. This indicates that structures retrofitted using these two techniques will remain highly susceptible to moderate damages, even at low ground-shaking levels.

4 CORRELATION BETWEEN CDR AND FRAGILITY PARAMETERS

The current study also attempts to map the improvement in the seismic performance of the case-study frame due to the varying retrofitting levels to the corresponding reduction in fragility. A reasonable approach to address this task is by correlating a simplified performance metric, which is the CDR_{LS} in this study, to the median of all fragility relationships, *i.e.* μ_{DS} . This is shown in Figure 7. A gradual increase in the values of μ_{DS} for DS2 and DS3 is observed for all the retrofitting techniques, which results from the performance improvement characterized by the CDR_{LS} . A sudden jump in the values of μ_{DS} can be also noticed in Figure 7(c) for the RC

jacketing, particularly at a CDR_{LS} close to 90%. This jump represents the case in which the RC jacketing becomes very effective due to the shift of the failure mechanism to beam sway.

In contrast, the overall increase in μ_{DS} of DS1 is trivial for both FRP wrapping and steel jacketing, as demonstrated by Figure 7(a),(b), even at very high levels of CDR_{LS} (see Section 3.3 for the discussion on this result). In fact, only the RC jacketing, with reference to Figure 7(c), is capable of significantly improving the μ_{DS} values for DS1, indicating that the structure becomes less susceptible to moderate damage, especially at low IM levels.

It should also be noticed that large values of CDR_{LS} could be reached using either steel or RC jacketing. After these levels, the retrofitting might become ineffective because the failure becomes associated with the beams rather than the columns and/or joints. However, the extent of CDR_{LS} increase in the case of the FRP technique is notably lower since a limited number of layers can be wrapped around to ensure confinement efficiency, as stated earlier.

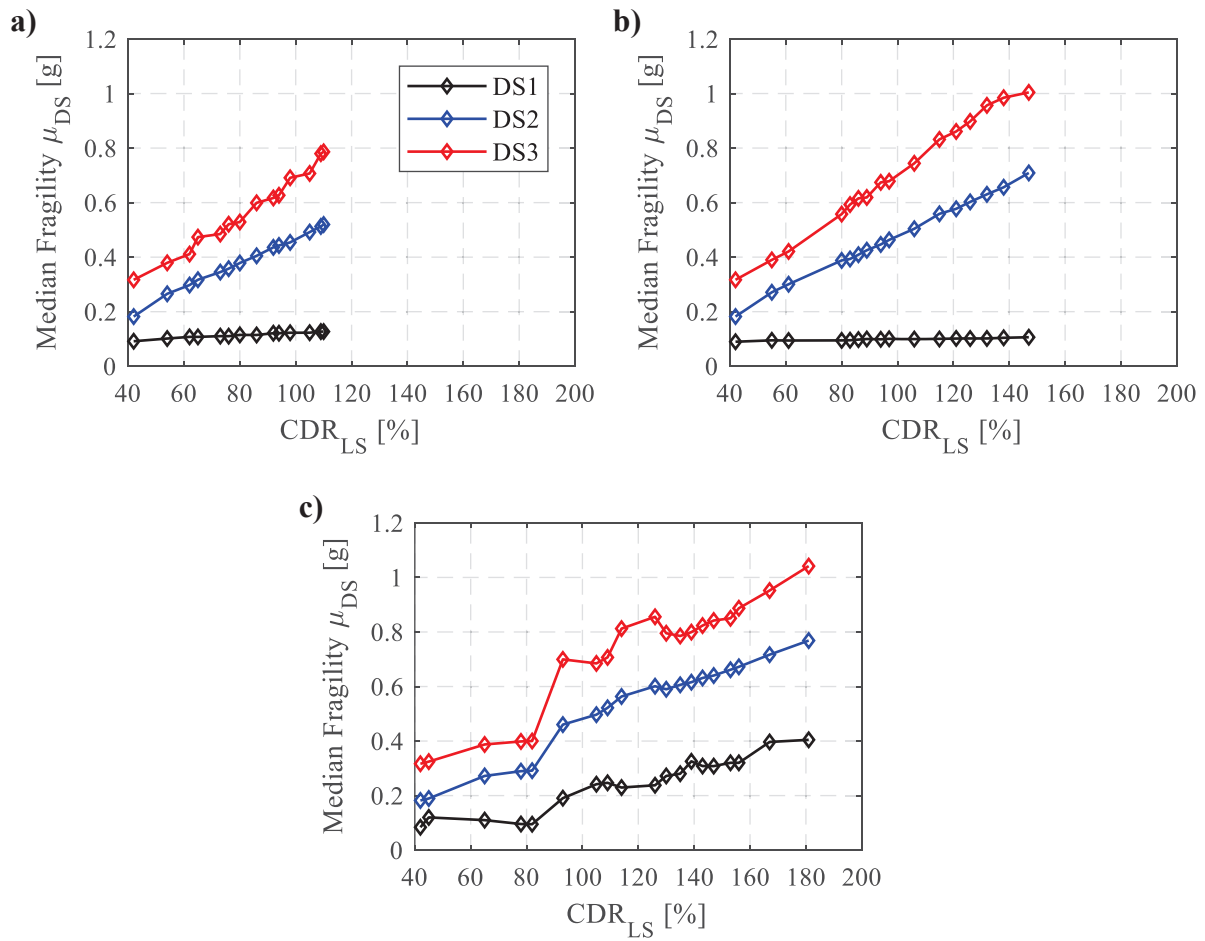

Figure 7: Variation of μ_{DS} against CDR_{LS} for (a) FRP wrapping; (b) steel jacketing; and (c) RC jacketing

A simplified model expressing the variation in μ_{DS} as a function of CDR_{LS} is defined by the best-fit line that minimizes the sum of squares of residuals (*i.e.* least-square approach). It should be noted that the variation of μ_{DS} is treated in a normalized fashion, which means that the developed expressions consider the variation in μ_{DS} resulting from retrofitting as a percentage of μ_{DS} of the as-built structure ($\Delta\mu_{DS}$). Figure 8 illustrates the fitted simplified models on the CDR_{LS} vs. $\Delta\mu_{DS}$ space, taking into account all the investigated DSs and retrofitting techniques. The coefficient of determination values (R^2) are also shown, which depict a clear linear trend between the two parameters. It must be noted that the initial CDR_{LS} is assumed equal to 42%.

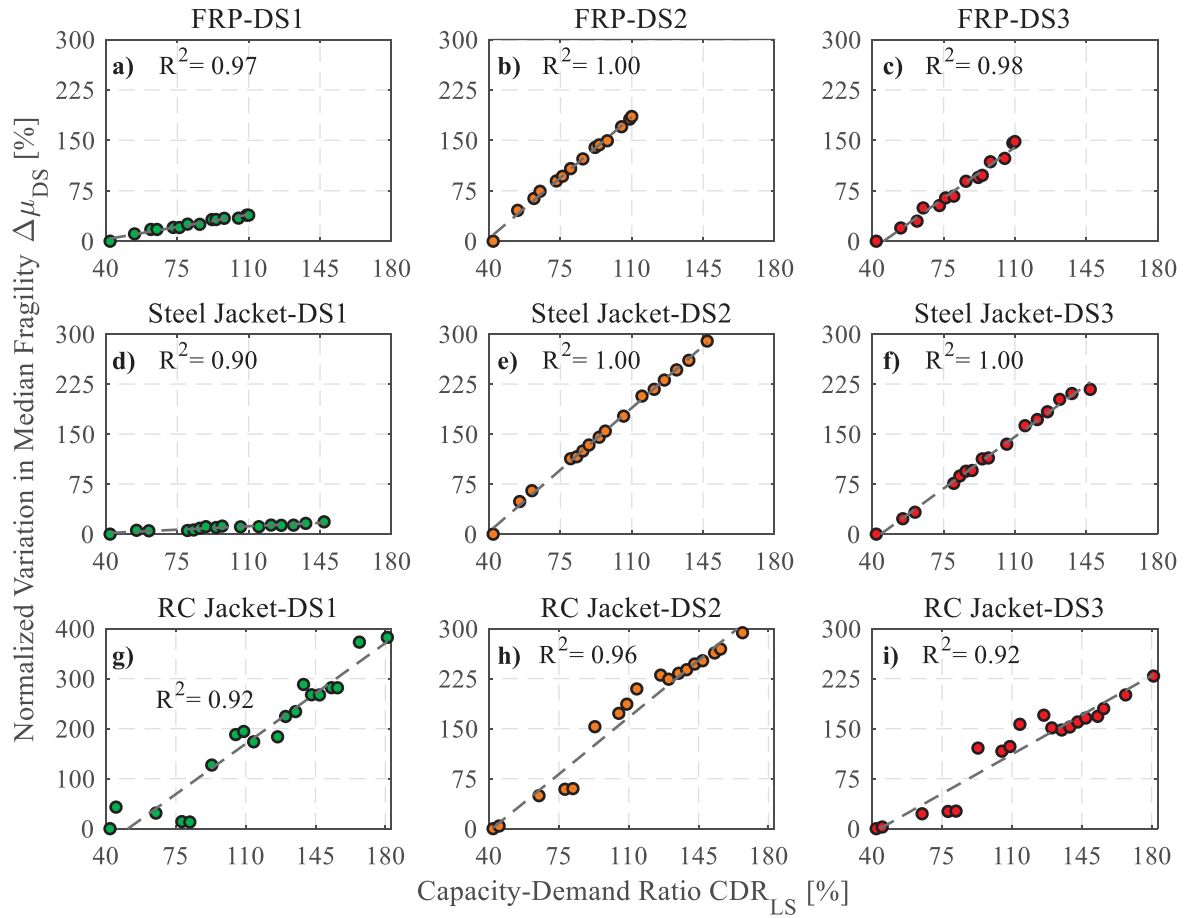

Figure 8: Correlation between the normalized variation of μ_{DS} against the CDR_{LS} for all DSs and techniques

The proposed simplified models can be easily used to provide reasonable estimates for the shift in fragility relationships of an as-built structure due to retrofitting once the CDR_{LS} is determined by just performing a pushover analysis. The outcome of these simplified models is directly used to modify the median values of the original fragility relationships to achieve the desired shift. Such an approach is deemed a quick and reasonable approximation in lieu of performing computationally expensive NLTHAs to derive new fragility relationships.

Nevertheless, it is important to highlight that the results obtained by the proposed models are limited by the uncertainties associated with the adopted modeling assumptions, material properties, geometry, layout, etc. Accordingly, additional research effort is needed to improve the accuracy of these expressions through incorporating additional case-study structures with different failure mechanisms, geometric/material properties, and layouts.

5 CONCLUSIONS

This study investigated the mapping between the improvement in seismic performance of a case-study RC frame and the seismic fragility reduction, which was achieved by designing and implementing varying structural retrofit levels. This is specifically characterized by correlating the increase in the CDR_{LS} values resulting from retrofitting to the shift of median parameters of fragility curves expressed by $\Delta\mu_{DS}$. The considered case study is an older non-ductile RC bare frame, which is designed to resist gravity loads only.

Three common and widely-used retrofitting techniques were adopted: FRP; steel jacketing, and RC jacketing. These techniques were designed via trial and error to achieve multiple

predefined performance objectives and thus generate numerous retrofitted case studies. The improvement in the seismic performance is initially quantified by applying pushover analysis in conjunction with the CSM in order to estimate CDR_{LS} for each case study.

The analysis of the as-built structure demonstrated a very poor seismic performance due to its susceptibility to high DSs, even at low IM levels. In contrast, a substantial improvement could be achieved through retrofitting. For example, fragility analysis showed that the μ_{DS} of DS2 and DS3 increased by at least 125% using any of the three techniques by just achieving the basic performance objective through retrofitting. However, only the RC jacketing was very effective in improving the DS1 fragility curves compared to FRP and steel jacketing. This is attributed to the fact that the latter two techniques improve ductility only, which is necessary for the DSs associated with high levels of nonlinear deformation, *i.e.* DS2 and DS3. Conversely, improving DS1 fragility curve requires enhancing both stiffness and lateral strength in addition to controlling lateral-sway mechanisms in order to make it difficult to develop early yielding and experience moderate damages, especially at low IM levels. This was possible to accomplish only by using the RC jacketing technique.

Finally, simple mathematical models were developed to relate the CDR_{LS} achieved by retrofitting to the $\Delta\mu_{DS}$ estimated using fragility analysis accounting for all DSs and retrofitting techniques. It is worth mentioning that these models are limited to the implemented case-study structure, modeling choices, and material properties. Therefore, additional research efforts are required in order to produce more generic models and reduce the uncertainty. After appropriate generalization, those expressions can be adopted to provide reasonable and quick quantification of the shift in median fragility parameters by just plugging in the value of CDR_{LS} , which can be calculated using simple pushover analyses. Such a simplified method can be used to analyze and/or design scenario-based retrofit implementation plans at a portfolio level, drastically reducing implementation efforts in a regional seismic risk model.

ACKNOWLEDGEMENTS

This study has received funding from project “Dipartimenti di Eccellenza”, funded by the Italian Ministry of Education, University and Research at IUSS Pavia. RG received additional funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement No. 843794. (Marie Skłodowska-Curie Research Grants Scheme MSCA-IF-2018: MULTIRES, MULTI-level framework to enhance seismic RESilience of RC buildings).

Abstract

Seismic strengthening of existing adobe masonry (AM) buildings has been recognized as a critical issue due to the dramatic consequences of recent seismic events occurred especially in developing countries, where a great part of the population lives in those constructions. Previous studies investigated the effectiveness of different retrofitting techniques by means of experimental programs consisting of either dynamic or static tests on reduced- or full-scale specimens, representing partial or complete AM dwellings. In this study, the output of diagonal compression tests on adobe masonry panels before and after external strengthening are presented. Three series of specimens were tested, namely, unreinforced and strengthened wallets with textile reinforced matrix (TRM) systems made of either hemp or glass meshes. Those tests benefitted from the characterization of the mud mortar that was used for both masonry joints and matrix, representing typical characteristics of existing Italian AM buildings. Main testing outcomes obtained for the AM wallets, particularly in terms of observed damage and response curves, are presented and discussed. In the end, the effectiveness of the applied TRM systems in the improvement of shear strength and ductility capacity is assessed.

Keywords: Adobe masonry; Experimental tests; Textile reinforced matrix; Shear strength; Ductility; Hemp fibres; Glass fibres; Mud mortar.

1 INTRODUCTION

Since ancient times, a large part of civil and historical buildings were realized in adobe masonry (AM), representing nowadays one of the most widespread structural typology in the world, especially in developing countries [1-4]. Furthermore, such constructions are not engineered and the recent seismic events showed their vulnerability with dramatic consequences for residents [5, 6].

In the recent past, seismic strengthening of existing AM buildings has been recognized as a paramount issue. Indeed, a number of researchers investigated the effectiveness of different retrofitting techniques via experimental testing. Several studies dealt with dynamic testing on reduced-scale specimens representative of AM dwellings, strengthened by means of mesh-reinforcement embedded in mud-mortar [5, 7-10], horizontal low-cost post-tensioning straps [11-13], systems of internal/external interconnected grids [14], combined mud-grout injection of cracks and external mesh-reinforcement [15-16]. Such techniques proved to be very promising in reducing seismic vulnerability of AM constructions, even though more detailed and comprehensive assessments should be carried out.

Few experimental studies focused on the external strengthening of real-scale AM wallets, most of which based on mesh-reinforced plasters. Specifically, cyclic tests on real-scale AM walls were described in [17]. The specimens were firstly tested in the as-built configuration, then, hydraulic lime grout was injected in the cracks and synthetic mesh incorporated in the plaster was applied. The strengthening system restored the initial stiffness and improved both lateral strength and ductility. Similar findings were presented in [18]. Finally, Turanli and Saritas [19] performed diagonal compression tests on AM specimens externally strengthened with plaster reinforcement mesh placed along mortar bed joints. Despite the increased strength and energy absorption capacity, such solution appeared to be unfeasible for strengthening existing AM buildings.

Earthen dwellings can also be found in Italy, especially in Sardinia island, where such structural typology was largely adopted until mid-last century and, currently, represents a considerable part of existing buildings [20]. Sardinian AM constructions were generally realized with adobe blocks reinforced with straw fibres, according to practice rules without any seismic design [21]. Within the framework of a comprehensive research program on seismic assessment and retrofitting of existing Sardinian AM dwellings [6, 21-24], the present study deals with the results of diagonal compression tests on AM wallets. Specifically, three series of specimens were tested, namely: unreinforced and strengthened with two different textile reinforced matrix (TRM) systems, made of hemp and glass meshes, respectively. The hemp-based TRM system (HTRM hereinafter) was composed of natural and sustainable hemp fibres, which however were characterized by considerable variability in mechanical properties due to production process. Conversely, the glass-based TRM system (GTRM) was produced using a commercial glass-fibre mesh, which is usually adopted for strengthening of other traditional masonry structures. Both hemp and glass textiles were embedded in the same mud mortar detected in masonry joints of existing Italian AM buildings.

The following sections describe the experimental campaign, presenting its main outcomes in terms of observed damage, response curves, and effectiveness of the applied TRM systems in the improvement of shear strength and ductility capacity for the AM wallets.

2 EXPERIMENTAL CAMPAIGN

Diagonal compression tests were performed on 21 specimens equally divided into three series: unreinforced AM wallets (URM series); HTRM-strengthened AM wallets (HTRM series); and G-TRM-strengthened AM wallets (GTRM series). The adopted on-site

experimental set-up typology, suggested by relevant technical codes for existing masonry [25-27], allowed avoiding the handling of specimens with reduced disturbance before testing.

2.1 Materials and specimens

AM blocks used for specimens' construction were obtained by pressing a mixture of soil, water and straw fibres into moulds with grooved internal surfaces, whereas mud mortar with same composition of AM blocks (except straw fibres) was used for both masonry joints and TRM matrix, according to traditional Sardinian practice [20]. The experimental characterization of masonry was carried out in [21, 23].

The adopted hemp textile was a bidirectional grid with mesh of $20 \times 20 \text{ mm}^2$ and thickness equal to 4 mm, which was made of three twisted yarns impregnated through epoxy resin according to 70% fraction by volume, in order to preserve its durability. Tensile strength per unit length of reinforcement was obtained by testing and Young's modulus was deducted given the value of volumetric resin fraction. More details can be found in [28]. A commercial glass fibre reinforced biaxial grid was used for strengthening of GTRM specimens. The mesh was equal to $25 \times 25 \text{ mm}^2$, with yarns of thickness equal to 3 mm and 2 mm along weft and warp directions, respectively. The grid was coated with an acrylic polymer mixture. Material properties were provided by the supplier.

Main mechanical properties of the materials used for test specimens are summarized in Table 1. In detail, the mean value and coefficient of variation (*CoV*) are provided for compressive strength (f_c), tensile strength (f_t) and Young's modulus (E). It is noticed that *CoV* is not reported for material properties of glass fibre grid, given the lack of data by the supplier, and tensile strength of the hemp grid is given as force per unit length, due to diameter variability of the cord.

Property	AM block	Mortar	Hemp grid	Glass grid
$f_c \text{ (N/mm}^2\text{)}$	1.08	0.50	-	-
<i>CoV</i>	36%	14%	-	-
$f_t \text{ (N/mm}^2\text{)}$	0.56	0.45	20*	1276
<i>CoV</i>	36%	20%	15%	n.a.
$E \text{ (N/mm}^2\text{)}$	143	49	6500 - 7000	72000
<i>CoV</i>	40%	47%	n.a.	n.a.

* Tensile strength in terms of kN/mm

n.a.: not available data

Table 1: Mechanical properties of the adopted materials.

Adobe blocks used for construction of AM wallets were approximately $200 \times 400 \times 100 \text{ mm}^3$ in size. Mud mortar joints were 10 mm thick. Two-leave AM specimens were fabricated with running bond configuration, reaching a size of $410 \times 1230 \times 1230 \text{ mm}^3$. For both HTRM and GTRM series, the TRM was applied on both sides of the wallets. First, the wallet was externally hydrated. Then, a 10-mm-thick layer of mud mortar was applied. When mortar was still fresh, the textile was installed. Finally, a covering layer of mortar was applied until a total 25 mm thickness was reached. Special attention was paid to hemp-fibre grids for which an ad-hoc, on-site fabrication process was implemented. Hemp meshes were realized by means of a proper wooden frame on which nails were placed with 20 mm spacing. Yarns were arranged along both warp and weft directions by using the nails as guide, then were impregnated of res-

in. Finally, square textiles with same specimens' dimensions were obtained by cutting. Figures 1 and 2 show a schematic view of specimens and details on fabrication of hemp mesh.

Figure 1: Layout of reinforced specimen.

Figure 2: Detail of the on-site fabrication of hemp mesh.

2.2 Testing setup and procedure

In order to reduce disturbance on specimens, the diagonal compression tests were performed directly in the manufacturing site by means of the movable system depicted in Figure 3. Specifically, the diagonal load was applied by reaction of a closed system with respect to the elongation of a hydraulic jack. Steel shoes were installed at both specimen's corners in order to distribute compressive stresses. Between such shoes and the specimen, a proper filling with shrinkage-free mortar was realized. All specimens were erected on rigid blocks. Foam sheets with low density were interposed between AM wallets and support-block, with the aim to avoid potential friction. After the installation, the loading system was self-supporting.

Diagonal compression load was applied with displacement control at 0.01 mm/s rate until failure was observed. The installed monitoring system was able to record diagonal displacements and load. In addition, four linear variable differential transformers (LVDTs) were arranged on both external surfaces of the wallet according to the typical X configuration, as shown in Figure 3. The gauge length was equal to 400 mm.

The average shear stress (τ) was derived from recorded load (F) by applying the formulation suggested by the ASTM E519-15 [29] standard (ASTM hereinafter), which is based on pure shear assumption as given in Eq. (1) in which A represents the cross-section area of the specimen (i.e., length \times thickness). The average shear strain (γ) on each side of the specimen

was obtained as the sum of the axial strains derived from LVDT displacement recordings along and perpendicular to the loading direction, respectively, as reported in Eq. (2).

$$\tau = 0.707 \frac{F}{A} \quad (1)$$

$$\gamma = \varepsilon_x + \varepsilon_y \quad (2)$$

Figure 3: Picture of the experimental set-up.

3 MECHANICAL RESPONSE AND FAILURE MODE

Shear stress versus shear strain (τ - γ) curves for series URM, HTRM and GTRM, along with crack patterns at failure, are depicted in Figure 4. In order to discuss the obtained results, for each test main mechanical parameters of the wallet were defined: the peak shear stress (τ_p), the elastic limit shear strain (γ_{cr}) corresponding to a shear stress equal to $0.7 \tau_p$, the shear strain at failure (γ_u), the latter assumed as associated to a strength drop of $0.2 \tau_p$ beyond the peak. Accordingly, the ductility capacity (μ) of the wallet was the ratio of ultimate to elastic shear strain values, as reported in Eq. (3). Such parameters are summarized in Table 2 in terms of mean and CoV for each specimen series.

$$\mu = \frac{\gamma_u}{\gamma_{cr}} \quad (3)$$

By observing Figure 4, all the specimens presented a mechanical response characterized by a first linear elastic branch up to first cracking, then a nonlinear curve up to peak stress and finally a softening until failure was observed. The recorded response was globally affected by high dispersion in displacement and force, especially in the post-peak range.

URM specimens were characterized by shear strength (τ_p) equal to 0.107 MPa on average with small dispersion (CoV = 7%). Conversely, ductility capacity (μ) resulted highly dispersed, with CoV = 41% and a mean value of 17.1. Unreinforced wallets showed similar damage patterns at failure. Large stair-stepping diagonal cracks were observed on the specimens, partially developed in joints and bricks. Shear failure occurred, resulting in quasi-brittle post-peak response.

Property	URM	GTRM	HTRM
τ_p (N/mm ²)	0.107	0.120	0.134
CoV	7%	14%	13%
γ_{cr} (-)	0.08	0.06	0.13
CoV	15%	20%	23%
γ_u (-)	1.37	2.38	7.57
CoV	52%	23%	13%
μ (-)	17.1	38.2	61.4
CoV	41%	19%	22%

Table 2: Experimental results of diagonal compression tests.

As expected, a higher shear strength was found for GTRM specimens, namely $\tau_p = 0.120$ MPa on average, in spite of a larger scatter (CoV = 14%). Generally, a more gradual post-peak softening was observed with respect to the unreinforced specimens, resulting in considerably increased ductility capacity, the mean value of which was 38.2. Failure modes were characterized by debonding of reinforcing grids after diagonal cracking onset, due to reduced mechanical compatibility of glass grid with respect to mud matrix.

Figure 4: Experimental τ - γ curves and observed damage at the end of tests: (a) URM specimens; (b) HTRM specimens; (c) GTRM specimens.

No premature debonding occurred in the case of HTRM-strengthened wallets. The observed diagonal cracks followed the same profile of the inner unreinforced specimen; therefore, the imposed deformation was transferred to the TRM system up to global failure was

reached. HTRM-strengthened specimens showed a distinct hardening behaviour due to TRM up to peak strength, followed by a gradual strength degradation up to failure. The peak stress (τ_p) was equal to 0.134 MPa. Also in this case, significant scatter was recorded. Very high ductility capacity was obtained on average ($\mu = 61.4$) with $\text{CoV} = 22\%$.

4 STATISTICAL CONSTITUTIVE CURVES

Experimental testing confirmed a significant dispersion in the mechanical response of AM specimens. Specifically, high scattered values were recorded in terms of shear strain over all specimen series (i.e., URM, GTRM, HTRM). Regarding shear strength, considerably lower dispersion was observed with respect to strain, particularly in the case of URM specimens. With the aim of assessing the influence of such variability on TRM strengthening efficiency, a statistical analysis of the experimental results was carried out. Based on the assumption of normal distribution of the shear stress (considered as random variable) conditioned upon shear strain, τ - γ curves of the 16th, 50th (median) and 84th percentiles of conditional shear stresses were derived for each specimen series. Such curves are compared to each other in Figure 5. It is noted that diagrams are plotted up to 20% post-peak strength drop, which was assumed as ultimate limit state.

Figure 5: Statistical response curves corresponding to 16th, 50th and 84th percentiles of shear stresses.

Given the shear strain, the stress scatter (S) was computed as ratio of the difference between 84th and 16th values to the median value. Accordingly, similar scatter values were derived for URM and GTRM specimens, equal to 26% and 25%, on average, respectively. Conversely, a larger S -value was obtained for wallets strengthened by means of HTRM system ($S = 39\%$). Such result was partially expected because of the higher variability in hemp grid production process, as opposed to commercial glass-grid for which stringent quality-control protocols are implemented during manufacturing [30]. By observing the statistical τ - γ curves, some general trend can be extrapolated regarding the efficiency of the two considered TRM strengthening systems. Response curves of URM specimens were characterized by negligible hardening, with peak strength reached in the elastic phase and a subsequent sudden drop in strength, resulting in a fragile failure mode. On the contrary, τ - γ diagrams of HTRM and TTRM series show a large hardening phase with gradual softening, representative of a more ductile failure. Therefore, in general, both TRM ensured considerable improvement of shear capacity, although the HTRM solution appeared more effective. In fact, on average, the increase of shear strength (e_τ , computed as ratio of the strengthened to unstrengthened peak

stress) in this latter case was equal to 1.31, whereas the mean increasing ductility factor (e_μ , defined as ratio of the strengthened to unstrengthened ductility capacities) was 3.60. By contrast, in the case of GTRM system, mean values of e_τ and e_μ were equal to 1.12 and 2.20, respectively. Average values of stress scatter (S) and efficiency factors (e_τ and e_μ) are summarized in Table 3.

Property	URM	GTRM	HTRM
S (%)	26	25	39
e_τ (-)	-	1.12	2.20
e_μ (-)	-	1.30	3.60

Table 3: Stress scatter and efficiency factors.

5 CONCLUSIONS

In this study, the critical issue of the retrofitting of AM buildings has been experimentally investigated. Specifically, the efficiency of two TRM systems made of glass- and hemp-fibre meshes, respectively (both embedded in mud-mortar matrix) was assessed by means of diagonal compression tests on AM wallets. Overall, twenty-one specimens were tested and were equally divided into three groups: unreinforced specimens (URM), specimens strengthened with glass-based TRM (GTRM), and specimens strengthened with hemp-based TRM (HTRM).

Experimental shear stress-strain curves derived according to the ASTM E519-15 standard [29] and observed failure modes allow the following conclusions to be drawn:

- URM specimens failed in diagonal tension with wide cracks along joints and blocks, evidencing negligible pre-peak hardening and a quasi-brittle post-peak behaviour.
- The GTRM strengthening system considerably improved the mechanical behaviour of AM wallets, producing significant hardening until peak stress was reached and post-peak softening. Nevertheless, the failure mode was generally detected by the debonding of the reinforcing glass-fibre grid from the mud-mortar matrix, which limited the ductility capacity. Resulting strength increase with respect to as-built configuration was equal to 10%, on average, whereas the improved ductility was twice.
- Neither debonding nor local failure of the hemp-matrix system was observed on HTRM-strengthened specimens. Their shear behaviour was generally characterized by large hardening after cracking onset and very gradual softening in the post-peak response. Indeed, the observed diagonal cracks gradually developed until failure, the latter being caused by tensile fracture of hemp grid. Accordingly, the HTRM system ensured high efficiency, increasing the unreinforced shear strength by about 30% and resulting into a ductility capacity 3.6 times that of URM wallets.

Definitely, the feasibility of using TRM with the aim to obtain a crucial reduction of the seismic vulnerability of existing AM structures has been illustrated in this study. Both the considered TRM strengthening systems ensured considerable retrofitting efficiency with highly improved energy dissipation of AM wallets. The HTRM solution proved to be preferable due to its major mechanical compatibility with poor mud mortar and adobe blocks. Nevertheless, due to large dispersion of mechanical properties and response, great emphasis should be given on the improvement of the manufacturing process.

Abstract

The increasing development of computational power in modern digital devices has spread the use of structural optimization in design applications of different fields of engineering problems. This approach exposes engineers to challenging design procedures aimed to optimize all variables to satisfy the imposed requirements, finding the “optimal” solution. Despite this wide use, the application of optimization algorithms for the design of seismic retrofitting strategies becomes tougher, due to the difficulties in finding a mathematical expression which includes and combines all the key variables (i.e., cost, safety, sustainability, design) and the nonlinearity of the analysis. In this paper, the Genetic Algorithm search method (GA) has been used to optimize the retrofitting, using Buckling-Restrained Braces (BRBs), of a three-storeys RC structure designed to resist only gravity loads. The optimization aims to ensure the safety level required, minimizing intervention costs and use of materials, particularly finding the best topology solution for BRB positioning. To this purpose, an objective function has been applied to the model to minimize retrofit costs intervention using GA. The procedure has been implemented in Python Programming Language. In particular non-linear static analysis has been run using OpenSeesPy framework to evaluate the seismic required safety level at each simulation, while GA has been carried out with a custom design code to provide the best topology position of BRBs to minimize costs and consequently the use of materials. The method brought out the real possibility to ensure the required seismic safety level while reducing intervention cost and use of materials with an optimized and structured BRB positioning.

Keywords: Structural optimization, Genetic Algorithm, Retrofitting, BRB.

1 INTRODUCTION

Soft-computing techniques are becoming increasingly common in the field of civil engineering for structural optimization. These methods are widely used for sizing, topology optimization, and form-finding of new structures and infrastructures [1], but structural optimization is less commonly used for structural retrofitting of existing structures. Despite the growing interest in retrofit of existing framed RC structures, it is difficult to find procedures to define the optimal parameters for intervention design. It is also important to note that the displacement demand on existing structures depends on the stiffness, the mass of the structure and the dynamic characteristics of the system. The introduction of new lateral-resisting components, such as braces, shear walls, or stiffening frames, alters the force-displacement demands, and the design of the retrofit cannot be achieved in a closed-form. As a result, retrofitting applications are often designed without an "engineered process", and often lead to an overestimated retrofit solution. The scientific community has only recently begun to address this issue, and some innovative applications using soft-computing techniques and artificial intelligence have recently been proposed [2]. In this field, Genetic Algorithms (GAs) have shown to be especially useful for optimizing design processes. GA is a meta-heuristic algorithm built on Darwin's "evolution of species" [3], that has been commonly used for optimization problems [4, 5], but only a few recent applications are available for structural retrofitting. Di Trapani et al. [6] presented a GA model for designing steel jacket confinement of columns in 3D structures with a typical gravity load configuration. In the present paper a GA implementation, for structural optimization of seismic retrofitting interventions in 2D RC frames with BRBs, is presented. The aim is to use the GA approach to design BRB configurations that provide the necessary level of safety while minimizing costs. The RC frames are modeled using fiber section beam elements with force formulation and plastic hinge regions at the extremities, implemented using OpenSeesPy framework [7]. The GA was implemented using a custom code written in Python programming language [8], where a boolean integer design vector is used to assign the position of the BRB and its orientation. For each configuration, the algorithm performs a modal and a non-linear static analysis to check the safety level of the frame according to N2 verification [9]. The fitness of the solution is evaluated at each iteration combining the retrofit cost and a penalty factor, implemented to penalize infeasible solutions in terms of seismic safety. The opensource environment here proposed (Python-OpenSeesPy) allows finding the optimum BRB configuration for the frame to retrofit, ensuring seismic safety and minimizing the retrofit cost.

2 CASE OF STUDY AND NUMERICAL MODELLING

A case of study of 2D RC frame retrofitted with BRB elements is here presented, Figure 1. The chosen case of study replicates a typical situation of framed structures designed in the early 1980s in Europe. The frame has 5 storeys and 4 bays with a rectangular section for all elements, in particular, some columns are disposed to be stressed on their weak inertia axis and others are oriented on their principal strong inertia axis.

The design of reinforcing steel of the section was evaluated using elastic calculations, as usually assumed in old designs approaches, particularly a set of static lateral load was assumed as a fraction of the axial forces in the columns for each storey. The latter was a usual assumption in design process according to old codes in Italy during the 1970s.

A process of calculation of uniformly distributed load was done before the implementation of the model in the algorithm, as result the assumed load on the beams was 33.64 kN/m at first storey, 32.89 kN/m at intermediate storeys and 15.79 kN/m at last storey. The load value here assumed are calculated as a combination of seismic loads-i.e. as the sum of dead gravity loads and a fraction of the live load.

Figure 1: Studied frame geometry and sections.

The materials properties, Figure 2, of the concrete and the reinforcing steel used for the model design are reported in Table 1. The steel model used, take into account isotropic hardening of the material and needs the tangent at initial strain hardening (E_{sh}) as parameters. As regards the concrete material, it was modeled without taking into account the tensile strength. The depth of the concrete cover was set for all the sections to 25mm.

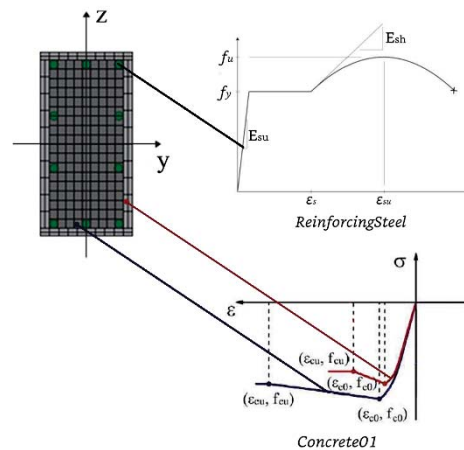

Figure 2: Fiber section discretization and materials behavior.

Steel	Unconf. Concrete	Conf. Concrete
$f_y = 319 \text{ MPa}$	$f_c = 18.4 \text{ MPa}$	$f_c = 18.4 \text{ MPa}$
$f_{su} = 365 \text{ MPa}$	$f_{cu} = 18.4 \text{ MPa}$	$f_{cu} = 20.26 \text{ MPa}$
$E_{su} = 210000 \text{ MPa}$	$E_c = 29444 \text{ MPa}$	$E_c = 32544 \text{ MPa}$
$E_{sh} = 31500 \text{ MPa}$	$\epsilon_o = 0.002$	$\epsilon_o = 0.0035$
$\epsilon_{su} = 0.06$	$\epsilon_u = 0.0035$	$\epsilon_u = 0.005$

Table 1: Materials properties.

With regards to the elements section indicated in Figure 1, the geometry details are reported in the following Table 2.

Section	Dimensions	Top reinf.	Bottom reinf.
A	600x300 mm	3 ϕ 16	2 ϕ 16
B	600x300 mm	4 ϕ 16	2 ϕ 16
C	600x300 mm	6 ϕ 16	2 ϕ 16
D	300x600 mm	3 ϕ 16	3 ϕ 16
E	600x300 mm	4 ϕ 16	4 ϕ 16
F	300x500 mm	3 ϕ 16	3 ϕ 16

A50	500x300 mm	3 ϕ 16	2 ϕ 16
B50	500x300 mm	4 ϕ 16	2 ϕ 16
C50	500x300 mm	6 ϕ 16	6 ϕ 16

Table 2: Sections and reinforcement adopted.

2.1 Modelling

As mentioned before, the numerical implementation of the considered frame was done using OpenSeesPy framework, in particular using for RC beams and columns the force-based elements with flexibility formulation. A “BeamWithHinge” element, based on plastic hinge integration [10], was used for the implementation of the beams and columns with a plastic hinge length equal to half the depth of the section for the columns and the depth of the section for the beams. The element state is determined using a total of six integration points (two for each hinge and two for the interior). Two different fiber sections are assigned for each element, one for the two plastic hinge regions and one for the remaining region of the element. The confined and unconfined concrete were modeled using Concrete01 uniaxial material, while the constitutive law for the bars was implemented using the ReinforcingSteel uniaxial material (Fig. 2).

As regards the BRB, it is well known that it usually exhibits good capacity in tension and compression. During compression phase the core plate starts to buckle, but the phenomena is prevented by the reinforcing case (usually filled with concrete). The constitutive law of the element was implemented following the model suggested by Upadhyay et al. [11]. The model adopted used Steel02 material for the steel core and in order to take into account tension and compression a Pinching4 material is added in parallel to Steel02. At this point, the material model adopted was calibrated by comparing the results achieved with the experimental data available in Xu and Pantelides [12], the calibration results are presented in Figure 3. A corotational element truss formulation is used to implement the BRB in the structural model.

The design of BRB features was executed before the implementation in the nonlinear models of the frame. The dissipative length (L_c) and the elastic end length were calculated following Gelfi et al. [13] relationship:

$$L_c = \frac{\Delta_{bm}}{\varepsilon_{cu}} = L_b \left(\frac{d_r}{h} \sin\beta \cos\beta \right) \quad (1)$$

Where Δ_{bm} is the elongation of BRB, ε_{cu} is the plastic strain, d_r is the storey displacement, L_b is the overall diagonal length of the BRB, β is the inclination of the brace and h is the height of the considered storey. Two area parameters are set for the BRB and they are fixed in all the elements: $A_c = 5000 \text{ mm}^2$ for the core area, while in the elastic zone the section area is equal to $A_e = 64500 \text{ mm}^2$.

The design length core, length end, diagonal length, inclination of the brace and the elastic modulus of the BRB vary on the basis of the considered bay.

Figure 3: Calibration of BRB constitutive model.

2.2 Analyses and structural safety

The implemented environment provides a modal dynamic and a static non-linear analysis for each analyzed configuration. Modal analysis was performed to identify the lateral load profile to be applied to the structural nodes, while the NL analysis was performed to evaluate the capacity curve (force-displacement) of the analyzed configuration. The latter analysis was performed under displacement control with incremental steps of 0.05mm and load profile proportional to the first modal shape. The maximum displacement of 200mm was imposed on all analyses and the Newton-Raphson algorithm was used with a norm displacement increment check with tolerance equal to 10^{-6} .

The required seismic action was estimated based on the elastic response spectrum reported in Figure 4, assuming a high seismicity zone (type 1) and design spectral parameters ground acceleration on rock soil $a_g = 0.286g$, soil factor $S=1.332$ and damping correction factor $\eta=1$ (corresponding to 5% damping).

Figure 4: Pseudo acceleration response spectrum.

The safety of the structure was checked in compliance with Eurocode 8 [14] by comparing the required displacement demand with the capacity of the equivalent Single Degree of Freedom (SDOF) system, as expected in N2 method [15]. The SDOF capacity curve was linearized

with elastoplastic behavior, by the equivalent energy rule, and the seismic safety was evaluated by comparing the linearized SDOF response with the Acceleration-Displacement format (ADRS). Finally, structural safety index was evaluated as the ratio between the displacement capacity and the required displacement $\zeta = d_u^*/d_{r,max}^*$.

3 IMPLEMENTATION OF THE GA FRAMEWORK

The Genetic Algorithm is a meta-heuristic search method for optimization, based on evolutionary processes in which the algorithm simulates biological mechanisms. The aim of the GA is to find the optimal solution of a predefined objective function using the solution's fitness value. In the present work, the fitness of a solution depends on retrofit cost and structural safety, in particular, retrofit cost has to be minimized.

As mentioned before the environment was implemented on custom code written in Python programming language, while for the analysis the OpenSeesPy library has been used, so that all the processes were implemented in one code using *opensource* tools only.

The first step of the procedure begins generating an initial random population of individuals ($p_{size} = 5$ in the present work), where an individual defines the location and orientation of the BRB across the frame. Each individual of the population is identified by a design vector V_d , Figure 5, with 1 row and a number of columns depending on the number of the bays of the frame. An integer encoding type is used to enable BRB retrofit using boolean parameters from 0 to 2, where 0 means bare frame, 1 means bay retrofitted with a BRB in the tensile direction and 2 means bays retrofitted with BRB in compression.

$$V_d = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 2 & 0 & 0 & 0 \end{bmatrix}_{1 \times 9}$$

0 1 2 3 4 5 6 7 8

Figure 5: Example of design vector.

Each design vector is decoded in a retrofit BRB topology configuration for the structural analysis to be executed. At the end of population analysis, the safety index (ζ), retrofit cost and fitness of individuals are calculated. The retrofit cost is obtained through the objective function, while the fitness value of the configuration is calculated as follows:

$$f = \frac{C + \delta}{100} \quad (2)$$

Where C represents the retrofit cost, while δ is a contribute that penalizes the solution if the safety index is less than 1. In particular, the latter coefficient is implemented as follows:

$$\delta(\zeta) = \begin{cases} 0, & \zeta \geq 1 \\ C_{max} + C \cdot e^{\zeta}, & \zeta < 1 \end{cases} \quad (3)$$

Where C_{max} is the maximum retrofit cost if all the bays of the frame were reinforced using BRB. The cost function, hence the objective function to minimize, is calculated as the sum of two main contributions:

$$C = C_m + C_s \quad (4)$$

C_m is the manpower and safety cost for each BRB (increased with the BRB number), while C_s is the cost that takes into account the scaffolding cost, demolition and rebuilding cost of infill walls and the cost of BRB. Is important to notice that C_s not only depends on the BRB geometrical properties but it is strictly related also to the geometrical parameters of the bay's walls.

For each population, that identify a generation, a *Tournament selection* (Fig. 6) is applied to selects 2 parents individuals used to generate a new possible solution (offspring). This selection method runs a series of tournaments inside the population pool, where individuals are randomly selected and the winner is chosen by its fitness value; in the present work lower the fitness and better is the solution.

Figure 6: Example of tournament selection implemented.

The selected parents are then coupled using the *Crossover operator*, which is used to generate new offspring that will improve the exploration of the search space. In particular, *Single-point crossover* is implemented, where a random point is evaluated to cut in half the two parents and the offspring are generated cross-merging the pieces of the two individuals. At this point, the new offspring could be modified using the *Mutation operator*, which will randomly change an integer inside the design vector. In particular, if the chosen position has a value equal to 1, it can be changed in a random value inside the list (0, 2), and so on for the other cases. The mutation will happen depending on a mutation rate parameter ($m_r = 0.2$ in this work) defined by the user.

Is important to notice that the number of offspring is generally higher than population size (p_{size}), hence before the process could proceed a *Survival selection* is applied to resize the offspring individuals to the population size. The survival selection will select the first p_{size} individuals with the best fitness to move forward to the next generation and repeat the process, but before that, a convergence check is executed to evaluate if the optimal solution has been reached. In this work the convergence is reached when there is no difference between old and new populations for a certain number of generations, depending on the number of bays and storeys of the frame.

4 RESULTS AND DISCUSSION

Figure 7 shows the optimal retrofit configuration achieved by the Genetic Algorithm. Four BRB are needed to secure the frame, one per storey disposed along the tensile direction at the three bottom storeys and along the compressive direction for the fourth storey.

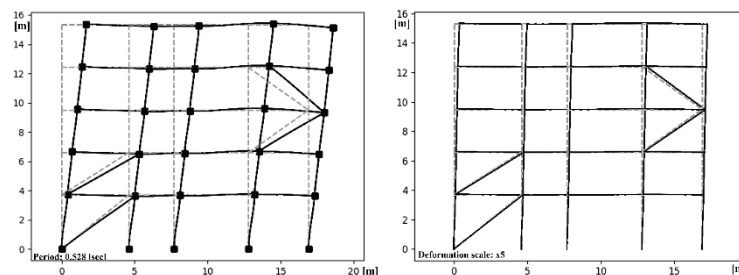

Figure 7: First modal shape and last step of static non-linear analysis of the retrofitted frame.

The optimal solution is achieved by the algorithm with a safety index $\zeta = 1.17$ and a retrofit cost of 28753€, while the total retrofit cost for all the bays of the frame with BRB is estimated to be 136597€, this means a saving cost of about 79%.

Finally, Figure 8 and 9 shows the verification of the displacement demand on the considered frame for both the bare (Fig. 8) and retrofitted (Fig. 9) configuration.

Figure 8: N2 verification of bare frame.

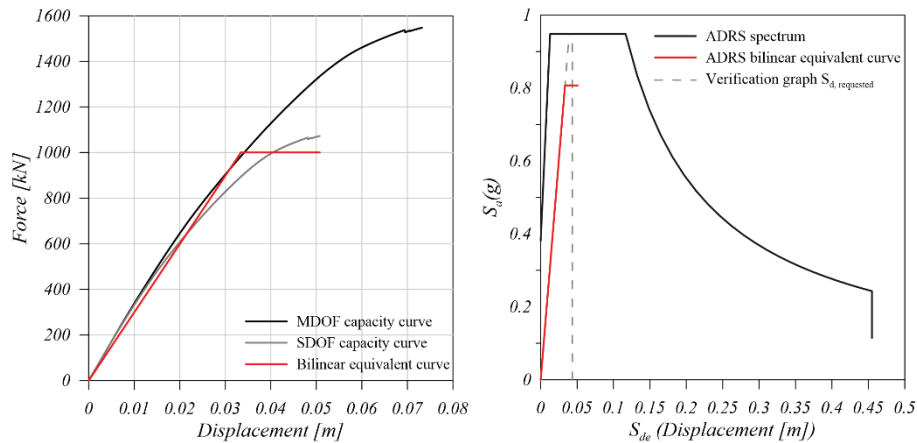

Figure 9: N2 verification of retrofitted frame.

As regards the implemented GA, the best fitness values of each generation are plotted in Figure 10(b), or for each analyzed individual in Figure 10(c), while the color of the points depends on the value of the safety index. It is observed that the solution comes after 50 generations of 5 individuals and a stable convergence is achieved with a constant value of fitness.

It is also worth noting that the solution cannot be improved, meaning that the number and disposal of braces is the minimum for ensuring the safety level. Figure 10(d) shows the best individual fitness of each generation.

Furthermore, the number of unfeasible solutions is a limited part of all the generated configurations (Fig. 10(c)), which confirms that the GA tends to select only possible solutions within the search space. The convergence of the procedure is reached after 20 generations with 5 individuals, meaning that 100 modal and pushover analyses are needing, as shown in Figure 10(d).

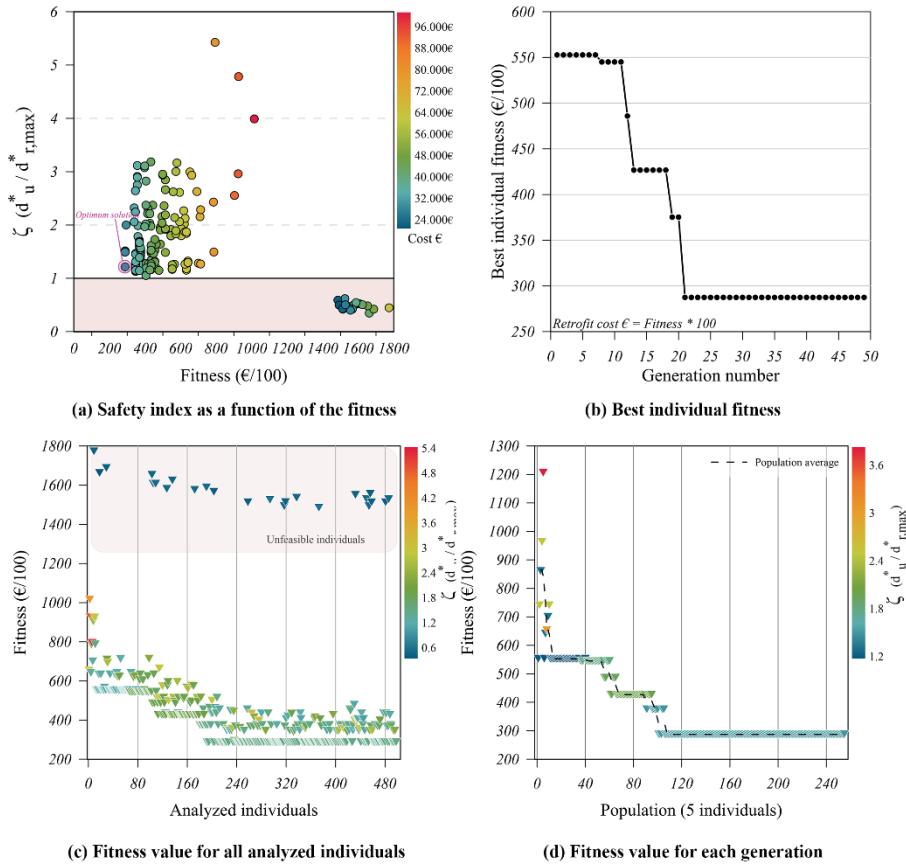

Figure 10: Results of the proposed procedure for the studied frame.

The efficacy and the stability of the proposed algorithm were assessed by comparing the results with those of multiple simulations carried out with a Monte Carlo (MC) approach. A comparison between GA retrofitted configuration, MC configuration and the bare frame is reported in Table 3.

Configuration	Period T[s]	ζ	Cost [€]	d_u^* [m]	$d_{r,max}^*$ [m]
Bare frame	1.002	0.585	-	0.09	0.146
Retrofitted (GA)	0.53	1.168	28753	0.05	0.043
Retrofitted (MC)	0.44	1.294	40439	0.04	0.0287

Table 3: Results comparison between the bare frame, retrofitted (GA) and retrofitted (MC) analysis.

The same number of analyses as GA individuals number was performed on frames with randomly disposed BRBs. In particular, the design vector was composed by generating a pseudorandom integer number in the range 0 to 2 for each bay with equal probability. The number of generated configurations was selected to keep the same computational effort in comparison with the GA and having the same number of overall structural analyses (500 simulations).

Figure 11 shows the comparison between the results obtained through the MC simulation with those achieved with the proposed GA approach. The graphs show the cost (Figures 11(a) and 11(b)) and the safety index (Figures 11(c) and 11(d)) associated with each generated configuration, while the red line indicates the moving average for each 5 individuals. It is evident that the GA quickly converges down to a minimum value of the cost of about 29000€, while

the distribution of the cost for the MC approach follows the "white noise" distribution, keeping the average cost on the starting value.

A similar consideration can be made in terms of safety index, which is almost kept constant by the GA, searching smartly the best configuration on a limited range around 1. It is also observed as the Coefficient of Variation associated with the distributions of the GA is significantly lower concerning that of the MC analysis, due to the capability of the algorithm in improving the solution progressively.

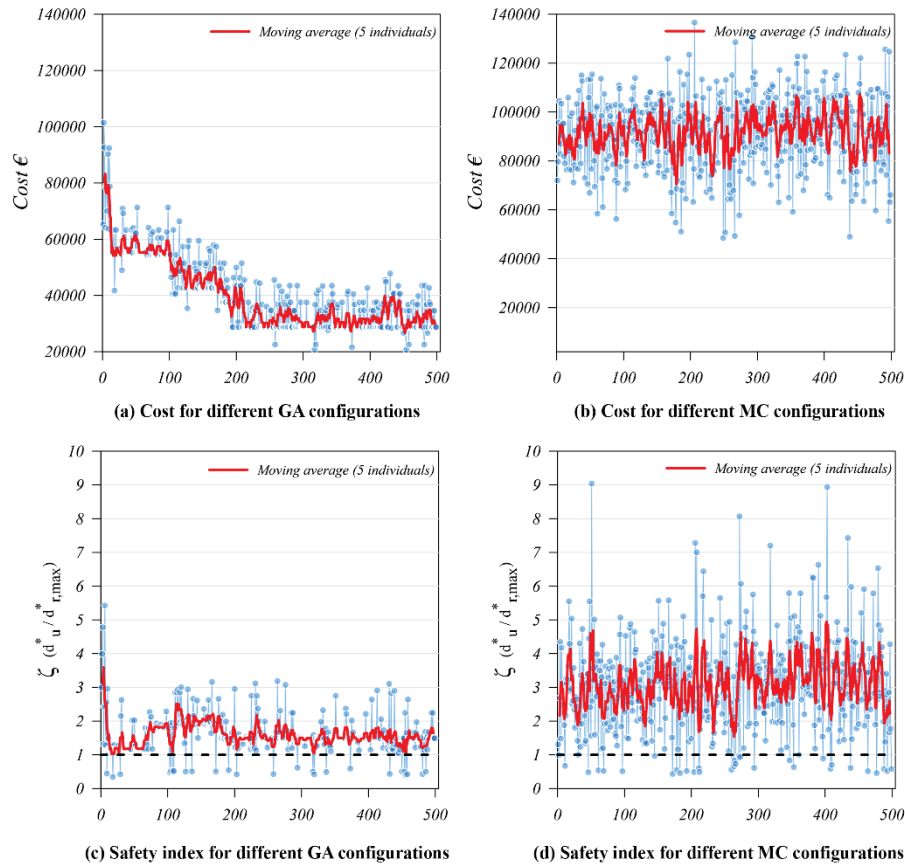

Figure 11: Comparisons between GA and Monte Carlo simulations.

It is evident that the GA allows achieving safe results with the cheapest solution. It is also to note that with the same number of analyses, hence the same computational time, the best solution of the MC simulation is more expensive than the solution found by GA of approximately 40.64% with an almost equal safety index.

5 CONCLUSIONS

This paper presented the proposal of a GA framework for designing the optimal configuration of BRBs for the seismic upgrading of plane RC frames. The algorithm allows varying the position and the direction of the braces, while the mutation and generation operations search for the most suitable configuration of the retrofitted frame. The GA was implemented in a Python environment while the OpenSeesPy library was adopted for modelling and analyzing the frames, making up a unique open-source framework for analysis and optimization.

Based on the obtained results and for the range of analyzed variables, the following conclusions can be drawn:

- the algorithm proved to be stable, finding the optimal configuration after a number of generations depending on the deformability of the structure;
- the solutions achieved for all the cases ensured the required safety level and proved to minimize the cost, on the basis of the selected features of the BRB;
- the penalty function implemented ensured the safety of the structure while the algorithm minimizes the cost;
- comparison with Monte Carlo simulations has shown the intelligence of the Genetic Algorithm in using previous information data to improve the search inside the solution space;

Further analysis has to be done to assess the algorithm behavior of the algorithm implementing 3D structural analysis and taking into account the possible shear increment at beam-column nodes.

Abstract

Shear failure of RC beams strengthened with composite textiles is often affected by the different failure modes characterizing the FRP reinforcement. The most relevant analytical models for evaluating the shear capacity of RC beams strengthened with FRP take into account these failure modes by introducing an effectiveness factor “R”, which reduces the ultimate FRP tensile stress. Moreover, the interaction between stirrups and FRP reinforcement leads to a reduced efficiency of the transverse steel reinforcement due to the brittle failure of composite textile which hinders the yielding of all the stirrups involved by critical crack. In this regard, some analytical models introduce an effectiveness factor “r”, aiming at reducing the yielding stress of stirrups. The procedures to calculate the above two parameters represent the main differences characterizing most of analytical models, significantly influencing their results. For this reason, the present paper focuses on the comparison of the different procedures to assess the effectiveness factors, proposing a new procedure for each effectiveness factor by modification of already existing formulations. Influence of the arrangement of composite reinforcement on the efficacy of stirrups, affected by brittle failure of FRP, is considered by means of the ratio between effective strain of composite to yielding strain of steel. The proposed procedures are employed in a design-oriented analytical model able to calculate the shear strength of RC beams retrofitted with FRP reinforcement arranged in any direction. The model is formulated aiming at representing an extension of EN1992 shear model to beams strengthened with FRP. The efficacy of the proposed procedures is assessed by comparing the experimental results against the predictions obtained via the design-oriented model and the above-mentioned analytical models.

1 INTRODUCTION

Over the last years, several research groups have made significant efforts to develop innovative structures, able to significantly reduce structural damage caused by destructive earthquakes [1-6]. Nevertheless, due to different factors (e.g. costs, business disruption, design limitations), a considerable share of construction market is still devoted to retrofit existing RC structures, especially those built between 1950s and 1970s, whose seismic performances are unsatisfactory if compared to recently built structures. To this aim, among the different techniques used, externally bonded Fiber-Reinforced Polymer (EB-FRP) is one of the most employed, thanks to its excellent mechanical performance to density ratio.

During the last two decades, several mechanical models have been developed to assess flexural capacity and confinement effect of RC members retrofitted with externally wrapped composite reinforcement (e.g. [7, 8]). On the contrary, it is challenging to develop analytical models able to accurately account for all the resisting mechanisms influencing shear behavior of RC members (e.g. aggregate interlock, shear span to depth ratio, size effect, dowel effect, ductility demand), and the topic is still widely debated in the literature [9-11]. Some shear capacity models (such as [12, 13]) were developed on the basis of the strut-and-tie resisting scheme, by using an additive approach. However, these models assume that there is no interaction between shear contributions provided by concrete, steel stirrups and FRP reinforcement, and each contribution is achieved at shear failure. Nevertheless, experimental results showed that this interaction occurs, and may lead to both a reduced shear contribution provided by steel stirrups due to brittle failure of FRP which can be achieved before that all stirrups passing through shear critical crack yield, and a reduced shear contribution provided by FRP due to possible limitation of the ultimate strain [14-16].

Differently from the American codes, those developed in Europe (e.g. [17-20]) evaluate shear capacity of retrofitted RC members by means of truss mechanism with variable inclination of concrete strut, consistently with that used by [21] for ordinary RC members. However, uncertainty arises when assessing shear capacity provided by concrete strut, being no common solution in the selection of the angle of reinforcement to be used in the case of simultaneous presence of steel stirrups and FRP reinforcement arranged with different inclinations.

In this framework, the present paper focuses on the comparison of the different procedures to assess the effectiveness factors, proposing new procedures for the effectiveness factors dedicated to FRP and steel stirrups, by modification of already existing formulations. Influence of the arrangement of composite reinforcement on the efficacy of stirrups, affected by brittle failure of FRP, is considered by means of the ratio between effective strain of composite to yielding strain of steel. The proposed procedures are employed in a design-oriented analytical model able to calculate the shear strength of RC beams retrofitted with FRP reinforcement arranged in any direction. The model is formulated aiming at representing an extension of EN1992-1-1 shear model to beams strengthened with FRP. The main advantage of this model is the capability of simultaneously taking into account the presence, and their mutual influence, of steel stirrups, FRP reinforcement and concrete strut, in assessing shear capacity of retrofitted members. Closed-form equations are provided, for any amount and arrangement of shear reinforcement, able to calculate stress acting at failure on steel stirrups, FRP reinforcement and concrete strut, as well as angle of inclination of concrete stress field with respect to member axis. The accuracy of the proposed procedures is assessed by comparing the experimental results against the predictions obtained via the design-oriented model and the above-mentioned analytical models.

Moreover, a modified version of the model suggested by CNR is proposed and validated, aimed at overcoming the inaccuracy of the original model when assessing shear capacity of

concrete strut. In fact, in this case CNR model considers the angle of inclination of FRP reinforcement only, neglecting the presence of stirrups. The modified version of CNR, named CNRm, proposes to calculate an equivalent angle of shear reinforcement included in the evaluation of shear strength of concrete strut, obtained as a weighted average between shear capacity provided by steel stirrups and FRP reinforcement.

2 DESIGN-ORIENTED MODEL

Colajanni et al. [22] proposed a model based on the stress field approach, able to assess the shear capacity of RC members having transverse reinforcement arranged with two different inclinations. Here, that model is modified to be applied in the case of RC beams retrofitted with FRP reinforcement inclined in any direction. The proposed model also represents the extension of a model based on the stress field approach, able to assess shear strength of retrofitted RC beams with vertically-oriented FRP reinforcement only [23]. On the basis of the same assumption of the models proposed in [22, 24], shear capacity of a strengthened RC beam can be assessed by means of three different equations, obtained by calculating the vertical equilibrium of beam segments, identified via three different sections parallel to stress field directions of concrete strut, steel stirrups, and FRP reinforcement, respectively (Figure 1).

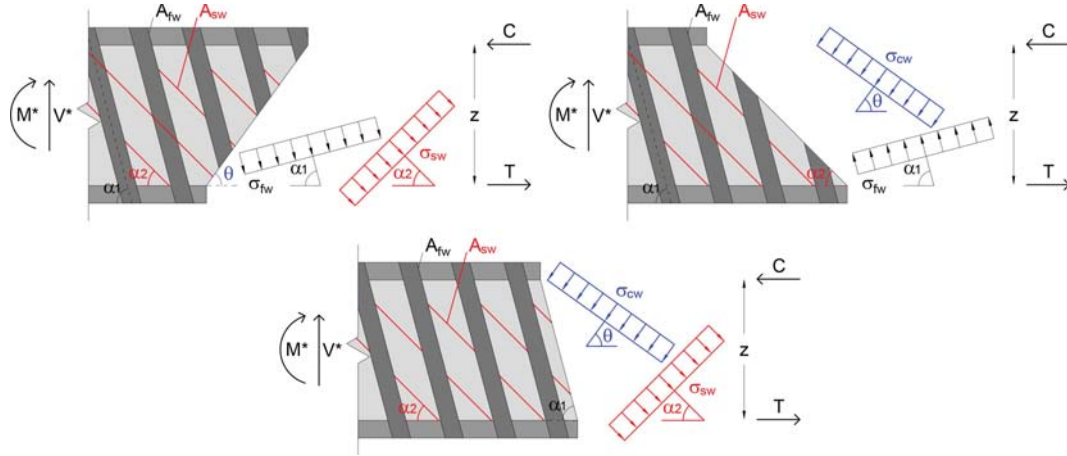

Figure 1: Different beam segments identified through three sections parallel to stress field direction of: concrete strut (a); steel stirrups (b); FRP reinforcement (c).

By doing so, each of the three equilibrium equations, which are given below, depends only on two stress fields, and can be easily solved:

$$v = R \tilde{\sigma}_{fw} \omega_{fw} (\cot \theta + \cot \alpha_1) \sin^2 \alpha_1 + r \tilde{\sigma}_{sw} \omega_{sw} (\cot \theta + \cot \alpha_2) \sin^2 \alpha_2 \quad (1)$$

$$v = \tilde{\sigma}_{cw} (\cot \theta + \cot \alpha_2) \sin^2 \theta + R \tilde{\sigma}_{fw} \omega_{fw} (\cot \alpha_1 - \cot \alpha_2) \sin^2 \alpha_1 \quad (2)$$

$$v = \tilde{\sigma}_{cw} (\cot \theta + \cot \alpha_1) \sin^2 \theta + r \tilde{\sigma}_{sw} \omega_{sw} (\cot \alpha_2 - \cot \alpha_1) \sin^2 \alpha_2 \quad (3)$$

In the above equations v is the shear strength made non-dimensional with respect to $b_w z f'_{cm}$ (b_w section width), $\tilde{\sigma}_{fw} = \sigma_{fw} / f_{fu}$, $\tilde{\sigma}_{sw} = \sigma_{sw} / f_{syw}$, $\omega_{fw} = (2 b_f t_f f_{fu}) / (b_w s_f \sin \alpha_1 f'_{cm})$, and $\omega_{sw} = (A_{sw} f_{syw}) / (b_w s_w \sin \alpha_2 f'_{cm})$ are the non-dimensional stresses and the mechanical ratios of FRP reinforcement and steel stirrups, respectively, f_{fu} is the nominal rupture stress of the fiber, R the strain and stress “effective” coefficient (effective strain $\varepsilon_{fe} = \varepsilon_{fu} R$, effective stress $f_{fe} = f_{fu} R = E_f \varepsilon_{fe}$), and r is the reduction factor

of the efficiency of the steel stirrups. The values of these efficiency coefficients will be investigated and assessed in the following sections.

The shear capacity of an RC beam is computed via the static theorem of theory of plasticity, which gives an assessment of the shear capacity as the maximum value among the possible solutions satisfying both the equilibrium condition (1)-(3) and the following inequalities of plastic admissibility:

$$0 \leq \tilde{\sigma}_{cw}, \tilde{\sigma}_{fw} \leq 1 \quad -1 \leq \tilde{\sigma}_{sw} \leq 1 \quad (4)$$

A plastic admissible condition is obtained by combining (1), (2) and (4), as follows:

$$0 \leq \tilde{\sigma}_{cw} = \left(R \tilde{\sigma}_{fw} \omega_{fw} \sin^2 \alpha_1 + r \tilde{\sigma}_{sw} \omega_{sw} \sin^2 \alpha_2 \right) (1 + \cot^2 \theta) \leq 1 \quad (5)$$

The above inequalities clarify the relation between the stress fields of the web concrete, steel stirrups and FRP reinforcement.

In this paper, only the case of major practical interest is considered, namely α_1 and $\alpha_2 \leq 90^\circ$. According to Colajanni et al. (2020), to evaluate the shear strength and $\cot\theta$ initially it is supposed that, at failure, the stress limit is reached simultaneously in the three stress fields (i.e. $\tilde{\sigma}_{cw} = \tilde{\sigma}_{fw} = \tilde{\sigma}_{sw} = 1$). Thus, on the basis of the upper limit imposed by Eq. (5), the first tentative value of the inclination of the web concrete stress field is obtained as follows:

$$\cot \theta = \sqrt{\left(R \omega_{fw} \sin^2 \alpha_1 + r \omega_{sw} \sin^2 \alpha_2 \right)^{-1} - 1} \quad (6)$$

Based on the results of the above equation, assuming $\cot\theta_{lim} = 2.5$, three cases are defined:

- $1 \leq \cot\theta \leq 2.5$: the stress limit is reached simultaneously in the three stress fields, and shear resistance can be calculated by using Eq.(1) assuming $\tilde{\sigma}_{cw} = \tilde{\sigma}_{fw} = \tilde{\sigma}_{sw} = 1$;
- $\cot\theta > 2.5$: the amount of FRP reinforcement and steel stirrups is not sufficient to induce attainment of the maximum resistance in the web concrete stress field. Thus, $\cot\theta = 2.5$ is assumed, and the shear capacity is computed through Eq. (1), assuming $\tilde{\sigma}_{fw} = \tilde{\sigma}_{sw} = 1$. The stress value in the web concrete field can be calculated by using Eq. (5), in which $\cot\theta = 2.5$;
- $\cot\theta < 1$: shear failure is due to attainment of the stress limit in the web concrete stress field and in one of the two shear reinforcements. Therefore, the other shear reinforcement is in the elastic range at beam failure. Now it is assumed that $\alpha_1 < \alpha_2$. With the aim of determining if the maximum shear is given by Eq. (2) with the FRP reinforcement reaching the effective strain in tension ($\tilde{\sigma}_{fw} = 1$) or (unlikely event) by Eq. (3) with the steel stirrups yielding in compression ($\tilde{\sigma}_{sw} = -1$), the following inequality is employed:

$$R \omega_{fw} \sin^2 \alpha_1 \leq 0.5 + r \omega_{sw} \sin^2 \alpha_2 \quad (7)$$

If the inequality is true, then the FRP reinforcement attains its stress limit, and the stress acting on the steel stirrups is computed as follows:

$$\tilde{\sigma}_{sw} = \left(0.5 - R \omega_{fw} \sin^2 \alpha_1 \right) / \left(r \omega_{sw} \sin^2 \alpha_2 \right) \quad (8)$$

Conversely, if the inequality is false, then the steel stirrups yield in compression, and the stress acting on the FRP reinforcement is calculated as follows:

$$\tilde{\sigma}_{fw} = \left(0.5 + r \omega_{sw} \sin^2 \alpha_2 \right) / \left(R \omega_{fw} \sin^2 \alpha_1 \right) \quad (9)$$

3 FRP EFFECTIVENESS FACTOR

Several experimental observations have shown that the failure of shear-strengthened RC beams with bonded FRP is often associated with achievement of a specific failure mode involving the textile material. The most common FRP failure modes reported in the literature [25, 26] are the following: failure of the FRP; debonding at the FRP-concrete interface; excessive width of the shear cracks and consequent loss of aggregate interlock; separation of the concrete cover along a vertical plane (peeling off) (e.g. [27]). To take these effects into account a reduced effective FRP design strength $f_{fe} = E_f \times \varepsilon_{fe}$, smaller than its nominal design strength $f_{fu} = E_f \times \varepsilon_{fu}$, was assumed. It was assessed by applying the effectiveness coefficient R to the nominal ultimate fiber strain. Over the last two decades, several formulations have been developed in order to estimate the above coefficient. In the proposed model, six different approaches to assessing the reduced effective FRP design strength are considered, with the aim of comparing their efficiency when introduced in the proposed model. Two of these six approaches are reported below, being assembled by using different equations reported in several papers, while the other four approaches are those suggested by ACI [12], CNR [17], fib [20], and Mofidi and Chaallal [30].

3.1 First approach: Khalifa and Nanni [28, 29] and Pellegrino and Modena [27]

According to the first approach, already used in [23], the value of R is the minimum among the three effectiveness coefficients R_i ($i=1,2,3$) proposed in [28, 29] and the fourth R_4 reported in [27], i.e. $R = \min\{R_1, R_2, R_3, R_4\}$.

The equations selected to describe the four modes of failure are reported below. The efficiency coefficient R_1 , which takes into account the tensile failure of the FRP, is computed by means of the following equation:

$$R_1 = 0.56(\rho_{fw} E_f)^2 - 1.22(\rho_{fw} E_f) + 0.78 \quad (10)$$

where E_f is the elastic modulus of the fibers. The coefficient R_2 , representing the debonding phenomenon, is calculated using the following equation:

$$R_2 = \frac{(f_{ck})^{\frac{2}{3}} (d_{ft} - \eta L_e) [738.93 - 4.06(E_f t_f)]}{\varepsilon_{fu} d_{ft} 10^6} \quad (11)$$

where L_e is the effective length, which is evaluated using the expression provided by ACI and CSA:

$$L_e = 23300 / (E_f t_f)^{0.58} \quad (12)$$

η is a parameter that takes into account the anchorage conditions, equal to 1 or 2 if the shear strengthening is U-shaped or side-only, respectively. The range of validity of Eq. (12) is $20 \leq E_f t_f \leq 90$. In case of complete wrapping or U-shaped strengthening with anchorages able to prevent a debonding effect, the coefficient R_2 is not taken into account. The coefficient R_3 , limiting the shear crack width, is set equal to:

$$R_3 = 6 \cdot 10^{-3} / \varepsilon_{fu} \quad (13)$$

In the case of side-bonding and U-jacketing reinforcement, FRP failure often involves the separation of the concrete cover along a vertical plane (peeling off). Hence, the coefficient

proposed in [27] is assumed equal to:

$$R_4 = \frac{2f_{ct}A_c \cos^2 \beta b_{c,v}}{n_f t_f L_f E_f \left[(h_f - L_e) / (h_f) \right] b_f \varepsilon_{fu}} \quad (14)$$

Further details about the parameters involved by Eq. (14) can be found in the above-mentioned paper.

3.2 Second approach: Chen and Teng [25, 26]

According to [25, 26] the coefficient of effectiveness is the minimum between two effectiveness coefficients, namely $R = \min\{R_5, R_6\}$. The effectiveness factor R_5 takes into account the tensile rupture of FRP, which usually occurs across the critical crack, correlating it with non-uniform strain distribution in the FRP along a shear crack. The authors, assuming proportionality of the fiber strain to the width of the shear crack, supposed an approximate strain linear distribution, where the FRP strain increases linearly from a minimum at the crack tip to a maximum at the lower end. Thus, R_5 can be expressed as:

$$R_5 = \frac{1 + (h_w - d_f) / z}{2} \quad (15)$$

where d_f = height of the FRP. Since experimental observations show that this kind of failure mode usually occurs in fully wrapped or U-wrapped RC beams, this coefficient must be considered only for these arrangements. Instead, the coefficient R_6 takes into account failure through debonding of FRP, which may occur when the bond length is not sufficient. According to [25] the stress in the FRP is variable along the bond length, and its maximum stress ($\sigma_{f,max}$) can be evaluated as:

$$\sigma_{f,max} = 0.427 \beta_w \beta_L \sqrt{\frac{E_f \sqrt{f'_c}}{t_f}} \leq E_f \varepsilon_{fu} \quad (16)$$

where β_w = coefficient of the FRP-to-concrete width ratio; β_L = bond length coefficient. These values can be calculated by using the following equations:

$$\beta_w = \sqrt{\frac{2 - w_f / s_f \sin \beta}{1 + w_f / s_f \sin \beta}} \quad (17)$$

$$\beta_L = \begin{cases} 1 & \text{if } \lambda \geq 1 \\ \sin \frac{\pi \lambda}{2} & \text{if } \lambda < 1 \end{cases} \quad (18)$$

where $\lambda = L_{max}/L_e$ = normalized maximum bond length; in which the maximum (L_{max}) and the effective bond length (L_e) are respectively:

$$L_{max} = \begin{cases} \frac{h_{frp,e}}{\sin \beta} & \text{for U - wrap} \\ \frac{h_{frp,e}}{2 \sin \beta} & \text{for side bonded} \end{cases} \quad (19)$$

$$L_e = \sqrt{E_f t_f / \sqrt{f'_c}} \quad (20)$$

where $h_{frp,e}$ is the effective height of the FRP (further details can be found in [25]). Thus, the effectiveness reduction factor R_6 can be expressed as:

$$R_6 = \frac{\sigma_{f,max}}{E_f \varepsilon_{fu}} \begin{cases} \frac{2}{\pi \lambda} \frac{1 - \cos \frac{\pi \lambda}{2}}{\sin \frac{\pi \lambda}{2}} & \text{for } \lambda < 1 \\ 1 - \frac{\pi - 2}{\pi \lambda} & \text{for } \lambda \geq 1 \end{cases} \quad (21)$$

4 STEEL STIRRUPS EFFECTIVENESS FACTOR

As recognized in several studies [14-16] the simultaneous presence of steel stirrups and FRP reinforcement leads to a reduction in the peak resistance provided by each shear reinforcement. The interaction between the two materials is expressed both in the decrease of the FRP shear contribution with the increase of the axial rigidity ratio between the internal steel and the external FRP [27] and in the inability of some or all of the steel stirrups, affected by critical fracture, to reach the yield strength due to FRP brittle rupture [14-16]. To overcome these drawbacks many models have been developed, connecting the interaction between the two reinforcement systems to their rigidities [30], or the shear crack width [31] or simply assuming a fixed reductive coefficient $\alpha = 0.75$ [15].

On the basis of the parameter proposed by [15], in this paper the r reduction parameter is defined by means of a bi-linear expression that relates the reduction of the contribution to the shear strength given by the steel reinforcement to the ratio between the component of FRP effective strain in the direction of the internal steel reinforcement $\varepsilon_{fe,sd}$ and the internal steel reinforcement yield strain ε_{syw} :

$$r = \begin{cases} 0.75 \frac{\varepsilon_{fe,sd}}{\varepsilon_{syw}} & \text{if } \varepsilon_{fe,sd} / \varepsilon_{syw} \leq 1.33 \\ 1 & \text{if } \varepsilon_{fe,sd} / \varepsilon_{syw} > 1.33 \end{cases} \quad (22)$$

where $\varepsilon_{fe,sd} = \varepsilon_{fe} \cos \varphi$ with φ equal to the angle between FRP reinforcement direction and steel stirrups. The reduction coefficient thus defined is able to take into account both that the strain of the most elongated steel stirrup, at beam failure, can be limited by the effective strain of the fiber, and that not all the stirrups along the critical crack are able to reach the yield strain. In particular, when $\varepsilon_{fe,sd}/\varepsilon_{sy} = 1$, only the most elongated stirrup, which intercepts the shear crack at the point of maximum width, can reach the yield strain (assuming perfect adhesion with concrete). It is also noted that r can take on a value less than 1 even if the ratio $\varepsilon_{fe,sd}/\varepsilon_{sy}$ is greater than 1. This makes it possible to take into account the second effect mentioned above, i.e. the non-uniform distribution of tension in the steel stirrups intercepted by the shear crack.

As will be seen in the following sections, the modulation of the reduction coefficient $\alpha = 0.75$ proposed in [15], through the ratio between the deformations of the interacting materials, makes it possible to minimize the inaccuracy of the proposed models due to overestimation of the steel resistance contribution.

The above effectiveness factor for steel stirrups is used in conjunction with effectiveness factors reported in sections 3.1 and 3.2 only. This is due to the fact that the effectiveness fac-

tor proposed by Mofidi and Chaallal [30] already considers reduction of contribution provided by steel stirrups, while models proposed by investigated codes do not suggest any effectiveness factor and are used in their original formulation.

5 MODIFIED VERSION OF CNR-DT 200 R1/2013 [17]

Shear capacity model suggested by CNR is developed with the purpose of representing a direct extension of the model proposed by EN1992-1-1 to evaluate shear capacity of ordinary RC members. Shear capacity of each element constituting the truss mechanism can be written in non-dimensional form, as well as shear capacity of retrofitted members, as given below:

$$\begin{aligned} v_s &= \omega_{sw} (\cot \theta + \cot \alpha) \sin^2 \alpha \\ v_f &= \omega_{fw} (\cot \theta + \cot \beta) \sin^2 \beta \\ v_c &= (\cot \theta + \cot \psi) / (1 + \cot^2 \theta) \\ v &= \min(v_s + v_f, v_c) \end{aligned} \quad (23)$$

In the third of (23), the angle α provided by CNR model is substituted with the to-be-determined angle ψ . In fact, considering the angle α would consequently neglect the presence, and its influence, of the other shear reinforcement when assessing shear strength of concrete strut. For this reason, a simple iterative procedure is proposed below to calculate angle ψ .

According to the suggestion of CNR code, in the original version of CNR model the angle ψ is set equal to angle β , while the inclination of concrete strut is assessed aiming at maximizing shear capacity of retrofitted RC member. Therefore, the sum of the first and second equation of (23) is equated to the third of (23), yielding:

$$\begin{aligned} &\cot^3 \theta (\omega_{sw} \sin^2 \alpha + \omega_{fw} \sin^2 \beta) + \cot^2 \theta (\omega_{sw} \sin^2 \alpha \cot \alpha + \omega_{fw} \sin^2 \beta \cot \beta) + \\ &+ \cot \theta (\omega_{sw} \sin^2 \alpha + \omega_{fw} \sin^2 \beta - 1) = \cot \psi - \omega_{sw} \sin^2 \alpha \cot \alpha - \omega_{fw} \sin^2 \beta \cot \beta \end{aligned} \quad (24)$$

In the proposed version of CNR model, angle ψ contained in (24) is calculated by means of the following iterative procedure:

- A tentative $\cot \theta$ value is assumed, based on the sum of the mechanical ratios of each shear reinforcement $\omega_{sw} + \omega_{fw}$ (alternatively a value of 1.75 can be used, being the average value of the range of variation of $\cot \theta$ suggested by CNR);
- By means of the first and second equation of (23) are computed shear capacities v'_s and v'_f provided by steel stirrups and FRP reinforcement, respectively. These values are employed to calculate a weighted angle ψ' as $\psi' = (\alpha v'_s + \beta v'_f) / (v'_s + v'_f)$;
- The angle ψ' obtained is inserted in (24), yielding a new $\cot \theta$ value.

This procedure can be used iteratively until the difference between two consecutive values of $\cot \theta$ is negligible. However, numerical analysis performed by means of the above procedure showed that one iteration is sufficient to obtain accurate values of $\cot \theta$.

6 DATABASE DESCRIPTION

With the aim of comparing the accuracy of the model described above, a database containing 158 specimens of RC beams having rectangular or T-shaped cross-sections, strengthened in shear by means of FRP strips or sheets was collected [14-16, 27, 32-51]. The specimen

characteristics and the test results are reported in in Table 1. The database contains beams strengthened with U-jacketing or complete wrapping schemes using carbon or glass fibers. The effective depth of the cross-section of the beams ranges between 155 and 831 mm, while the shear span is between 2.3 and 3.8. The transverse internal reinforcement is constituted by vertical steel stirrups whose maximum geometrical ratio is 0.48%. As regards FRP reinforcement, the ultimate tensile strength ranges between 106 and 4361 MPa, while the elastic modulus is comprised between 8 and 640 GPa. Lastly, the FRP geometrical ratio ranges between 0.04% and 3.00%.

The database was divided into two partial databases: DTB1, consisting of 138 specimens, in which the FRP reinforcement is arranged at right angles to the longitudinal axis of the member; DTB2, consisting of 20 specimens, in which the FRP reinforcement is arranged at an angle β different from 90° .

7 INFLUENCE OF EFFECTIVENESS FACTORS

The effectiveness factors described in previous sections are used to assess accuracy of the proposed design-oriented model, which is evaluated by means of the ratio between experimental shear capacity v_{exp} and theoretical prediction v_{the} of tests reported in Table 1. The parameters used to quantify the accuracy and reliability of the model are the average ratio between experimental and analytical values of shear capacity (Avg) and the Coefficient of Variation (CoV).

Generally speaking, all the approaches used to calculate effectiveness factor provide satisfactory results, as showed in Figure 2. Nevertheless, significant differences in the average and scatter values given by the analyzed approaches can be observed, highlighting the paramount influence of effectiveness factors in assessing shear capacity of RC beams. In fact, effectiveness factor suggested by ACI provides the best average value (0.99), while that of fib gives the worst one (0.83), overestimating significantly, in average, the shear capacity of beams. On the contrary, effectiveness factor provided by Mofidi & Chaallal leads to an overall underestimation of the shear capacity, with an average value of 1.12. With regard to effectiveness factors described in sections 3.1 and 3.2, and that suggested by CNR, they provide similar average values, showing an overall slight overestimation of shear capacity. Concerning CoV values, it can be observed that FRP effectiveness factor proposed by Chen & Teng combined with that for steel stirrups proposed in this paper provides the lowest scatter (0.20). Even if ACI effectiveness factor gives the best average value, it leads to the highest scatter (0.31), similar to that obtained by using Mofidi & Chaallal equations (0.29). As for effectiveness factor named as “first approach”, as well as those proposed by CNR and fib, scatter values range between 0.24 and 0.27. All that said, it can be stated that the procedure to calculate effectiveness factors which combines the best average accuracy (Avg value close to 1) and the highest reliability (low CoV value) is the one named “second approach”, which uses the equations proposed by Chen & Teng to evaluate effectiveness factor for FRP, and the equations proposed in section 4 to assess effectiveness factor for steel stirrups.

To provide an insight into the above-described differences, in Figure 3 are plotted the effectiveness factor values provided by the above-mentioned procedures for each specimens of the database. Moreover, power regression in the form $y = Ax^B$, as well as coefficient of determination R^2 , are given for each group of effectiveness factors in the case of U-shaped strengthening configuration. The results showed in Figure 3 help to explain the average and scatter values plotted in Figure 2. As a matter of fact, fib and Mofidi & Chaallal procedures, which averagely overestimates and underestimates the shear capacity of beams, respectively, are characterized by parameters A of power regression equal to 0.20 and 0.08, respectively.

Moreover, the high scatter in shear capacity assessment provided by ACI procedure is

Figure 2: Experimental vs. theoretical shear capacity by using the proposed design-oriented model calculating effectiveness factors as suggested by: ACI (a); CNR (b); fib (c); Chen & Teng (second approach, sections 3.2 and 4) (d); Khalifa & Nanni, Pellegrino & Modena (first approach, sections 3.1 and 4) (e); Mofidi & Chaallal (f).

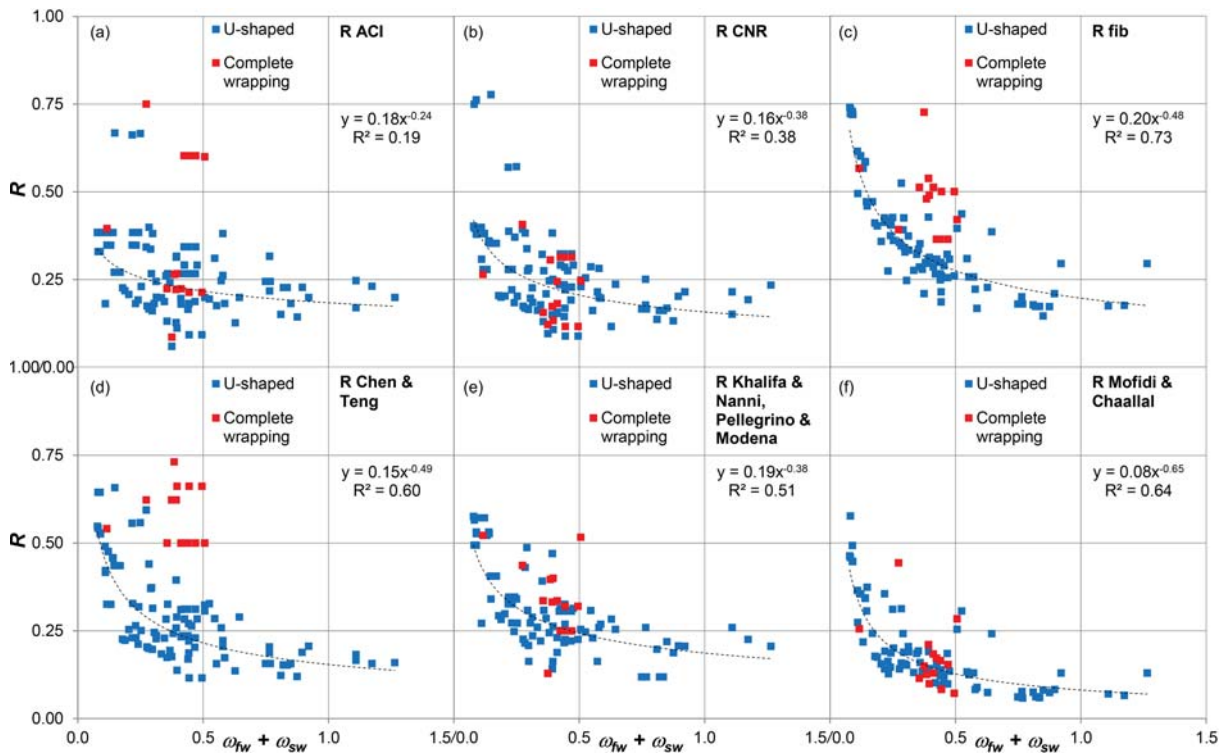

Figure 3: Effectiveness factors for FRP calculated as suggested by: ACI (a); CNR (b); fib (c); Chen & Teng (section 3.2) (d); Khalifa & Nanni, Pellegrino & Modena (section 3.1) (e); Mofidi & Chaallal (f).

confirmed by R^2 value, which is the lowest among those given by the analyzed procedures. With reference to complete wrapping configuration, it can be observed substantial differences

among the procedures. In fact, equations proposed by fib and Chen & Teng tend to provide R values higher than those given in the case of U-shaped configuration. On the contrary, equations proposed by CNR, Mofidi & Challal, and those listed in section 3.1, give R values similar to those for U-shaped strengthening scheme. With regard to ACI procedure, no trend can be noted, the R values being highly scattered.

Once the procedure to calculate effectiveness factors was selected, the proposed design-oriented model is validated against analytical results provided by code models suggested by ACI and CNR, as well as the proposed modified version of CNR, named CNRm.

In Figure 4 and Figure 5 are showed the results of the ratio between the experimental shear capacity and the theoretical prediction for each specimen belonging to the database and for each of the above-mentioned models, considering the two partial databases. Regarding results reported in Figure 4, all the models provide reliable results, even if some substantial difference can be observed. In fact, CNR model provides the best average value (1.00), to which correspond, however, the worst CoV value (0.24). With reference to the proposed model and ACI one, they provide similar values, characterized by low scatter and with a slight average overestimation of shear strength of beams. It is worth recalling that, in the case of FRP reinforcement and steel stirrups arranged with the same inclination, CNRm model gives the same results of the original CNR one.

Concerning beams having FRP reinforcement arranged with different inclination with respect to that of steel stirrups, the proposed model gives the best results. Although all the models overestimate in average shear capacity of beams, the proposed model gives the closest average to 1 and the lowest scatter. These results prove the accuracy and reliability of the proposed design-oriented model, and its superior performance in the case for which it was formulated, namely when FRP reinforcement and steel stirrups are oriented with different inclinations. It should be stressed that, in this latter case, the proposed model is the only one derived from a consistent physical model.

The results obtained in the two partial databases confirm that the use of an effectiveness factor that takes into account the strain experienced by FRP reinforcement oriented in any direction, leads to superior performance of the proposed model, which is thus able to account for the main interactions characterizing the shear resistance of a strengthened RC beam. On the contrary, model codes consider the brittle failure of FRP reinforcement, but neglect the interaction of the retrofitting system with both steel stirrups and concrete strut.

With regard to the results provided by CNR model and its modified version, CNRm, in Figure 5 it can be observed that the proposed calibration of ψ angle, which is the angle used in the evaluation of shear strength of concrete strut, slightly improves the performance of CNR model, reducing the scatter from 0.19 to 0.17. However, the proposed version of CNR model still significantly overestimates shear capacity beams, with an average value of 0.73.

To shed light on how the calibration of ψ angle influences the assessment of concrete strut inclination, in Figure 6 are illustrated $\cot\theta$ values for specimens having FRP reinforcement and steel stirrups oriented with different inclinations. It can be noted that, for high amount of mechanical ratios of shear reinforcements, $\cot\theta$ values are lower when ψ angle is computed by means of the simple procedure proposed. This contributes to reduce the overestimation of shear capacity affecting CNR model, increasing its reliability. It is worth noting that the proposed design-oriented model provides $\cot\theta$ values which are equal to 2.5 in most of the analyzed cases. This is due to the different formulation used to calculate effectiveness factor for FRP, and to the presence of the effectiveness factor for steel stirrups, which reduces the denominator value of Eq. (6).

8 PARAMETRIC ANALYSIS

Once the accuracy and reliability of the proposed design-oriented model were proved, in this section a parametric analysis is carried out, by varying inclination of FRP reinforcement, with the aim of evaluating its influence on shear capacity of retrofitted RC beams, calculated by means of the above-mentioned models based on variable inclination of concrete strut.

Among the several parameters influencing evaluation of shear capacity, mechanical ratios of shear reinforcements (ω_{fw} and ω_{sw}), as well as inclination of steel stirrups ($\alpha = 90^\circ$), are assumed, while inclination of FRP reinforcement can vary in the range $45^\circ \leq \beta \leq 90^\circ$. To highlight some peculiar aspects of the proposed model, CNR one and its modified version CNRm, four different arrangements of shear reinforcement are assumed, considered representative of real applications: the first two, $\omega_{fw} = 0.15$; $\omega_{sw} = 0.05$ and $\omega_{fw} = 0.15$; $\omega_{sw} = 0.15$, are selected to compare the influence of the increment of steel shear reinforcement having low amount of FRP shear reinforcement; the other two, $\omega_{fw} = 0.20$; $\omega_{sw} = 0.40$ and $\omega_{fw} = 0.40$; $\omega_{sw} = 0.20$, are selected to compare shear strength in the case of high amount of steel/FRP shear reinforcement. In Figure 7 are showed curves of theoretical prediction of shear capacity obtained by means of the above models, calculated by varying angle of inclination of FRP reinforcement.

Generally speaking, the proposed model provides shear capacity values which are in most cases lower than those given by the two versions of CNR model, confirming the findings of Figure 5 against experimental results. Moreover, the proposed version of CNR model provides shear capacity values which are close to that of original CNR models for low amount of steel stirrups, while approach to those of the proposed design-oriented model when increasing amount of steel stirrups. With the exception of the case with very low amount of steel shear reinforcement (i.e. $\omega_{fw} = 0.15$; $\omega_{sw} = 0.05$), the difference between shear capacity values given by CNR and CNRm increases when angle of inclination of FRP approaches to 45° . As already stated above, this difference is due to the inability of CNR model to properly take into account the inclination of both steel stirrups and FRP reinforcement when assessing shear strength of concrete strut. This difference is magnified when contribution to shear capacity provided by steel stirrups is significant. More precisely, considering only the angle of inclination of FRP in evaluating shear capacity of concrete strut, CNR model provides shear capacity values of retrofitted beams closer to those of the other models when contribution given by FRP reinforcement prevails ($\omega_{fw} = 0.40$; $\omega_{sw} = 0.20$), while substantial differences can be noted when mechanical ratio of steel stirrups is considerably greater than that of FRP ($\omega_{fw} = 0.20$; $\omega_{sw} = 0.40$).

Figure 7: Shear capacity curves obtained with the proposed design-oriented model (black dotted line), CNR model (red dashed line), and CNRm model (green dash-dotted line), by varying angle of inclination of FRP reinforcement.

Focusing the attention on the variation of shear capacity by changing angle of inclination of FRP reinforcement, it can be observed that the optimal angle to obtain maximum shear strength varies on the basis of mechanical ratios of steel stirrups and FRP reinforcement assumed. For low amount of shear reinforcement, maximum shear strength is obtained for angle between 65° and 90° , while in the case of high amount of shear reinforcement, shear strength is maximized when FRP reinforcement is arranged with an angle less than 55° .

9 CONCLUSIONS

In the present paper was carried out a comparison between different procedures able to assess the effectiveness factors used to reduce shear contribution provided by FRP reinforcement when calculating shear capacity of retrofitted RC beams. In this regard, new procedures, by modification of already existing formulations, were proposed both for FRP reinforcement and steel stirrups. Concerning the latter, the proposed effectiveness factor aims to limit the strain of stirrups on the basis of the effective strain of FRP arranged in any direction. The above procedures were compared, together with those suggested by ACI, CNR, fib, and Mofidi and Chaallal [30], by calculating theoretical shear capacity of a group of 158 experimental tests, by using a proposed design-oriented model based on stress fields with variable inclination of concrete strut. This model has the advantage to simultaneously take into account the presence, and their mutual influence, of FRP reinforcement, steel stirrups, and concrete strut, when assessing the shear capacity, as well as the concrete stress field inclination. The model was formulated in order to accurately take into account FRP reinforcement and steel stirrups arranged with different inclinations in evaluating shear strength of concrete strut. In this latter case, other models based on truss mechanism, such as that proposed by CNR, fail to consider the presence of both FRP reinforcement and steel stirrups when evaluating shear capacity of concrete strut. For this reason, a new simple formulation developed for CNR model was proposed, aimed at obtaining an equivalent angle of inclination to be used in evaluation of shear capacity of concrete strut, weighted on the basis of shear contributions provided by FRP reinforcement and steel stirrups. To highlight the improvement given by the

proposed modification to CNR model, a parametric analysis was carried out, by varying inclination of FRP reinforcement, with the aim of evaluating its influence on shear capacity of retrofitted RC beams, calculated by means of the above-mentioned models based on variable inclination of concrete strut.

Once the effectiveness factors providing the best results were selected, the proposed model was compared against models proposed by ACI and CNR, as well as the proposed modified version of CNR, named CNRm. The main findings are summarized below:

- The procedure to calculate effectiveness factors which combines the best average accuracy (Avg value close to 1) and the highest reliability (low CoV value) is the one named “second approach”, which uses the equations proposed by Chen & Teng to evaluate effectiveness factor for FRP, and the equations proposed in section 4 to assess effectiveness factor for steel stirrups.
- Concerning beams having FRP reinforcement arranged with different inclination with respect to that of steel stirrups, the proposed model gives the best results. Although all the models overestimate in average shear capacity of beams, the proposed model gives the closest average to 1 and the lowest scatter. These results prove the accuracy and reliability of the proposed design-oriented model, and its superior performance in the case for which it was formulated, namely when FRP reinforcement and steel stirrups are oriented with different inclinations.
- With regard to the results provided by CNR model and its modified version, CNRm, results showed that the proposed calibration of ψ angle, which is the angle used in the evaluation of shear strength of concrete strut, slightly improves the performance of CNR model. However, the proposed version of CNR model still significantly overestimates shear capacity of RC beams.
- Regarding the parametric analysis, the proposed version of CNR model provides shear capacity values which are close to those of original CNR models for low amount of steel stirrups, while approach to that of the proposed design-oriented model when increasing the amount of steel stirrups.
- Focusing the attention on the variation of shear capacity by changing angle of inclination of FRP reinforcement, it can be observed that the optimal angle to obtain maximum shear strength varies on the basis of mechanical ratios of steel stirrups and FRP reinforcement assumed. For low amount of shear reinforcement, maximum shear strength is obtained for angle between 65° and 90° , while in the case of high amount of shear reinforcement, shear strength is maximized when FRP reinforcement is arranged with an angle less than 55° .

Abstract

The paper presents a new specific optimization framework that is directed at minimizing seismic retrofitting intervention costs of reinforced concrete (RC) frame structures. A genetic algorithm routine is developed to provide as outputs the individuation of the retrofitted columns (topological optimization) and amount of steel-jacketing reinforcement. The major novelty regards the framework's capacity to perform retrofitting optimization both for RC structures with ductility-critical and shear-critical RC columns, also considering the additional shear demand due to infill-frame interaction. Modified genetic operators (population generator, elitism, and mutation) are defined and calibrated to be effective and computationally sustainable. The feasibility of each tentative solution is controlled by a static pushover analysis in the framework of the N2 method, accomplished by a 3D fiber-section model implemented in OpenSees. It is shown that the proposed procedure is sufficiently general and robust to handle structural configurations having different structural deficiencies, significantly reducing invasiveness, downtime, and costs.

Keywords: genetic algorithm, structural optimization, seismic retrofitting, existing structures

1 INTRODUCTION

Steel-jacketing (SJ) is one of the extensively used technique for retrofitting existing reinforced concrete (RC) structure designed prior to the entry into force of seismic guidelines. The arrangement of a cage made of steel angles and battens provides additional confinement and transverse reinforcement to the RC elements, also increasing the shear strength.

Even though steel-jacketing is quite effective as a seismic retrofitting technique, its application is invasive because it also involves several related operations, including the demolition and reconstruction of column-side masonries and plasters. This significantly affects the costs and the downtime associated with the intervention.

In this context, one of the major issues that structural engineers face in the design of this kind of interventions regard the determination of the optimal position and arrangement of the retrofitting system. Nowadays the design of this kind of interventions is mainly based on engineer's intuition and experience that needs several trial-and-error attempts, requiring noticeable time consumption.

In the last years, the scientific interest on the structural optimization was mainly focused on sizing and shape optimization of new structures. On the contrary, the issue of the optimization of seismic retrofitting of existing structures has not been investigated many times in the past, while noticeable interest is emerging in the last years. Available studies have been addressed to the optimization of carbon fibre reinforcement of concrete slabs (**Chaves and Cunha 2014 [1]**) or FRP jackets (**Chisari and Bedon 2016 [2]**, **Seo et al. 2018 [3]**). Other applications of seismic engineering optimization are related to fluid viscous dampers (**Pollini et al. 2017 [4]**), dissipative bracings (**Braga et al. 2019 [5]**) or both (**Lavan and Dargush 2009 [6]**) as seismic retrofitting devices for frame buildings.

More recent studies addressed the issue of pushover-based optimization of seismic retrofitting. Among these, **Falcone et al. 2019 [7]** proposed a framework implementing the optimization of FRP jacketing and steel X-bracings as possible reinforcements for existing RC structures. **Papavasileiou et al. 2020 [8]** faced seismic retrofit optimization of encased steel-concrete composite columns comparing three different retrofitting methods: concrete jacketing, steel jacketing and steel bracing.

Regarding steel-jacketing of standard RC columns, a recent study by **Di Trapani et al. 2020 [9]** proposed an innovative framework aimed at minimizing seismic retrofitting costs through genetic algorithm optimization. The framework provided both the optimization of the position of the reinforced columns and the amount of reinforcement for RC structures presenting ductility deficiencies as major vulnerability, while having adequate capacity against local shear failures. The current paper provides a significant step forward to the methodology proposed by **Di Trapani et al. 2020 [9]**.

An updated optimization framework with general validity is proposed and tested. Besides the ductility issues, the new optimization framework can deal with steel-jacketing optimization of potentially shear-critical RC columns, including also shear-induced mechanisms due to frame-infill interaction. The optimization is carried with a genetic algorithm-based algorithm. Novel genetic operators (population generator, elitism, and mutation) are defined by modifying the standard MATLAB® GA tool. The optimization framework provides as output the cheapest seismic retrofitting intervention among the feasible ones, defining the optimal configuration of the steel jacketing reinforcement of columns in terms of reinforcement location (topological optimization) and spacing between steel battens (sizing optimization). The feasibility of each solution is verified by the results of static pushover analyses in the framework of the N2 method from the results carried out a 3D fibre-section model, developed in the *OpenSees* software (**McKenna et al. 2000 [10]**).

2 DESIGN OPTIMIZATION FRAMEWORK

2.1 Problem statement and general operating principles

The proposed optimization framework works by connecting the MATLAB® genetic algorithm (GA) tool with a FE structural model developed with the *OpenSees* software platform. The framework aims at minimizing an objective function that computes the steel-jacketing retrofitting costs as a function of the design variables which define the retrofitting arrangement. These are the position of the retrofitted columns (topological optimization) and the battens spacing (sizing optimization). The feasibility of each tentative solution is assessed by evaluating the ductility capacity and demand ratio ($\xi_\mu = \mu_c / \mu_d$) after performing pushover analysis of the structure in the framework of N2 method (Fajfar 2000 [11]). An adaptive penalty function applied in the cases of unfeasible solutions.

The overall structure of the framework reflects the one proposed by Di Trapani et al. 2020 [9], for the optimization of the steel-jacketing retrofitting in case of structures with flexural ductility-related lacks. However, a strong review of the algorithm has been provided to redefine the genetic operators to generalize the framework for both flexural ductility-critical and shear-critical RC structures. The reason behind the need to update the framework is that, differently from RC structures with flexural ductility lacks, for shear-critical structures, a significant number of columns may need to be retrofitted. This is typical when the base shear demand exceeds the shear capacity of a storey. If the number of columns needing retrofitting is a high percentage of those included in the design space, a standard random selection of the individuals defining the population may have reduced probability to find feasible solutions. This condition may lead a GA to stall or to find a local minimum solution even in the unfeasible space (Fig. 1). The first remedy that could be thought to avoid this drawback is the expansion of the population of individuals (P) belonging to the design space to have a major chance to include feasible individuals. However, increasing the individuals means increasing the number on nonlinear static analyses and this very easily brings to a huge computational effort. Therefore, keeping a reduced population and a possibly restricted design space is fundamental to get an effective and affordable optimization through a genetic algorithm associated with nonlinear structural analyses.

Figure 1: Possible optimization outcomes in case of: (a) design space with prevalence of feasible solutions; (b) design space with prevalence of unfeasible solutions.

2.2 Encoding of the design vector

As mentioned in the previous sections, the design optimization variables are the position of the retrofitted columns and the battens spacing (s_b), assuming that:

- i) The angles are constituted by L-shaped steel profiles having fixed lateral length (l_a) and thickness (t_a) for all the retrofitted columns.
- ii) The battens are constituted by rectangular plates having fixed thickness (t_b) and width (w_b) for all the retrofitted columns.
- iii) Battens spacing is the same for all the retrofitted columns.
- iv) The design space can be restricted to a reduced number of columns (e.g. those belonging to the lower storeys).

A schematic representation of the design variables is illustrated in **Fig. 2**.

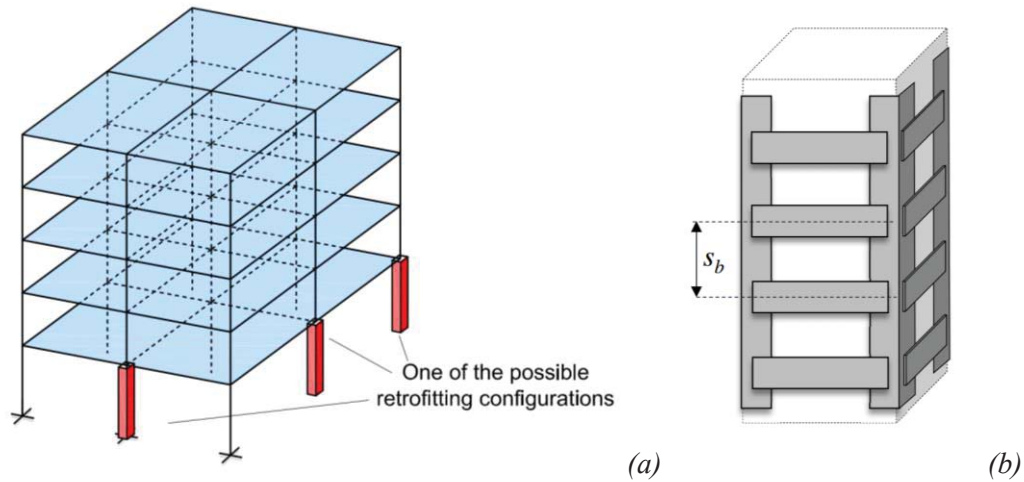

Figure 2: Representation of the optimization variables: (a) Generic column retrofitting configuration for an RC structure; (b) Typical retrofitting arrangement for a column with generic batten spacing (s_b).

The design vector collecting the design variable is formalized as follows:

$$\mathbf{b} = \begin{pmatrix} s_b \\ \mathbf{p} \end{pmatrix} \quad (1)$$

where s_b is a natural discrete number that represent the battens spacing (Fig. 4b), belonging to the interval:

$$s_b \in S = [s_{b,\min} \quad s_{b,\max}] \quad (2)$$

where $s_{b,\min}$ and $s_{b,\max}$ are the respectively the minimum and maximum battens spacing allowed. The element \mathbf{p} is the vector so defined:

$$\mathbf{p} = [\dots \quad \dots \quad c_{ij} \quad \dots]^T \quad (3)$$

in which the generic element c_{ij} , is a binary number assuming the value 1 if a column is retrofitted and 0 if not. The subscript i denotes the position of a column in plan and j the storey. In this way, each individual (namely a model) generated by the GA is univocally defined by the \mathbf{b} vector, which characterizes position and battens spacing of the retrofitted columns.

2.3 Definition of objective function and penalty function

The objective function evaluates retrofitting cost intended as the material cost and the manpower cost to realize columns steel jacketing (C_{SJ}) and necessary works for demolition and reconstruction of plasters and masonry (C_M). The general expression of the objective function is therefore:

$$C = C_M + C_{SJ} \quad (4)$$

The cost C_M is estimated considering a fixed amount (c_m) of 2000€ per column. Assuming n_c as the number of retrofitted columns and all the potentially retrofitted columns have the same cross-section dimension, one obtains:

$$\begin{cases} C_M = n_c \cdot c_m \\ C_{SJ} = n_c W_s c_s \end{cases} \quad (5)$$

where $W_{s,i}$ is the total weight of steel used to arrange a steel jacketing cage, c_s is the manpower and material cost per unit weight, which is estimated as 4.5€/kg and W_s is the weight of each steel jacketing cage. The latter can be computed as:

$$W_s = \gamma_s \cdot (V_A + V_B) \quad (6)$$

in which γ_s is the specific weight of steel ($78.5 \text{ kN} / \text{m}^3$), V_A is the total weight of the steel angles applied at the corners of a columns and V_B is the total volume of the battens belonging to a cage (on the assumption of column of square cross section), that are:

$$\begin{cases} V_A = 8 \cdot l_a \cdot t_a \cdot l_c \\ V_B = 2 \cdot t_b \cdot l_b \cdot ((b+h) - 2 \cdot l_a) \cdot \left(\frac{l_c}{s_b} \right) \end{cases} \quad (7)$$

where l_a , t_a are the width and the thickness of an angle, l_b , t_b are the width and the thickness of the batten, b , h are the dimension of the cross section of the column and l_c is the length of a column.

The feasibility of a solution is known by the evaluation of the capacity/demand ratio (ξ_μ). To effectively manage unfeasible cases a dynamic penalty approach is developed by summing to the objective function (C) above defined the penalty function (Π) into the new objective function (F) so defined:

$$F = C + \Pi \quad (8)$$

where Π is defined as:

$$\Pi = \begin{cases} 0 & \text{if } \xi_\mu \geq 1 \\ C_{\max} \cdot \left(\frac{1}{\xi_\mu} \right)^3 & \text{if } \xi_\mu < 1 \end{cases} \quad (9)$$

in which C_{\max} is the maximum possible retrofitting cost evaluated by considering retrofitting all the columns included in the design space with the minimum battens spacing. In this way, if

a solution is not feasible, the current cost is fictitiously increased by C_{\max} multiplied by the factor $(1/\xi_{\mu}^3)$ which takes into account the distance of the current solution from the feasibility condition ($\xi_{\mu} = 1$).

3 DEFINITION OF THE GENETIC OPERATORS

3.1 Population generator and elitism

The control of the population in terms of the selection of individuals is essential to the optimization effectiveness. As defined in **Eq. 1**, the genotype of each individual is a vector composed of one natural number representing the battens spacing s_b , and a sub-vector (**p**) collecting a number of binary variables which represent the retrofitted columns. In the selection phase, the parameter s_b is randomly selected by the S interval, which includes all possible spacing values as a multiple of a fixed minimum spacing variation Δs_b .

As mentioned in previous sections, and depicted in **Fig. 1**, in case of structures having shear-related deficiencies, the number of unfeasible solutions belonging to the design space can be relevant. In order to avoid algorithm stall into unfeasible design subspace, the population generator operator has been modified by introducing two subspaces in the definition of initial population (**Fig. 3**). The first subspace (p_{rand} space) collects randomly created individual. The second subspace (p_{Pr} space) is defined by a specified percentage (p_{Pr}) of individuals having an assigned probability of retrofitting (P_r). The percentage of randomly selected individuals (p_{rand}) is the complement to 100%. The probability P_r is typically high (e.g. 90%), this means that an individual included the p_{Pr} space is an individual with a high number of retrofitted column. The introduction of the p_{Pr} space within the initial population increases from the beginning the number of feasible solutions. This allows reducing population dimension and increasing the exploration efficiency of the algorithm.

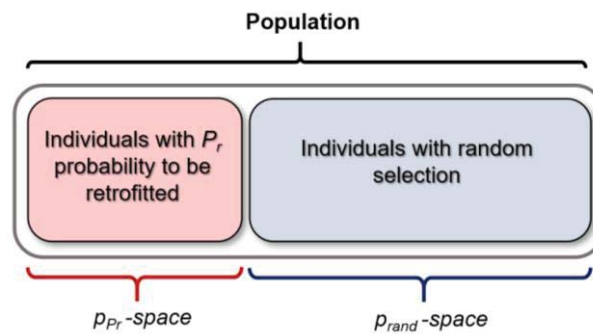

Figure 3: Definition of the population (population generator).

To further improve the algorithm performance, the *elitism* function is used. This genetic operator involves copying a small number of the fittest candidates, unchanged, into the next generation. In fact, the fittest individuals of a population can be lost during the crossover operations of consecutive generation analysis. Then, the use of the elitism function allows not losing good genetic heritage and consequently speeds up convergence.

3.2 Mutation and crossover

The crossover operator is employed to improve the genes of the individuals at the end of each generation. This is done by mixing chromosomes from parent better individuals. A uniform scatter crossover function is used in the proposed framework. The operating principle provides randomly selection of pairs of parent individuals from the previous generation. Their genomes are mixed with the generation of a random binary string of the same dimension of the parents. Base on the binary value (0 or 1) associated with each position, the gene is transferred to the child from the parent 1 or 2 (**Fig. 4a**).

The crossover function here used has a standard form, while modifications are made in the *mutation* operator. Mutation is used to bring about random changes in the population.

The standard MATLAB® mutation operator cannot handle heterogeneous vectors (e.g. vectors made of natural numbers and binaries as the vector **b**), and this made necessary the definition of a new mutation function. The latter works by fixing first a suitable mutation ratio (P_m). Then a real number u ($u \in [0,1] \subseteq \mathcal{R}$) is randomly selected for each gene. If $u \geq P_m$ the gene is maintained unchanged, otherwise if $u < P_m$ the gene is mutated. For the Boolean variables included in the design vector, the mutation of a gene is simply a switch from 0 to 1 or vice-versa. For the natural variables (the battens spacing s_b) the same procedure is applied, but in the cases in which a gene has to change ($u < P_m$) a further random number v ($v \in [0,1] \subseteq \mathcal{R}$) is chosen in order to decide if mutation will increase or decrease the battens spacing.

The new random temporary parameter v leads the mutation toward an increase or decrease of s_b if $v < 0.5$ or $v \geq 0.5$ respectively. Increases and decreases of s_b have the magnitude of the minimum spacing variation (Δs_b). A flow-chart example of the proposed mutation function is illustrated in **Fig. 4b**.

The application to the current case, in which a limited dimension of the population is used, require to increase the mutation to values which are larger than 1%. The relatively high value of mutation ratio helps in avoiding the stall of the analysis into local optimal solution.

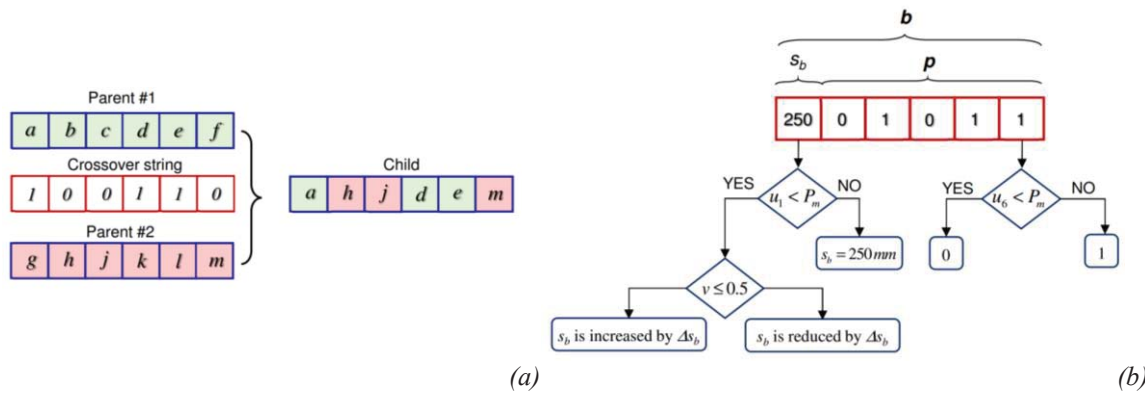

Figure 4: Example flow-charts of the: (a) uniform scatter crossover function; (b) proposed mutation function.

4 REFERENCE STRUCTURAL MODEL

The proposed optimization framework can work with any finite element program handling nonlinear static analysis. Tests and application presented in the current study are carried out using the *OpenSees* software platform and the structural modelling assumptions below described.

4.1 Modelling of RC elements with and without steel-jacketing

Frame elements are modelled adopting distributed plasticity force-based elements with five Gauss-Lobatto integration points available in OpenSees (**Fig. 5**). Fiber-section elements are modelled using a *Concrete02* uniaxial material model for the cross-section fibers. It is assumed that the effect of confinement is extended to the whole cross-section (**Fig. 5**) both for the cases of columns with and without steel jacketing reinforcement. This simplified assumption allows a formal consistency with the confinement model in the case of concrete confined by stirrups and steel jacketing (**Campione et al. 2017 [12]**) which provides uniform confinement over the cross-section. In order to simulate the crushing of the cross-section fibers, *Concrete02* material is combined with *MinMax* material. For the current case, it is assumed that crushing of fibers occurs in correspondence of the compressive strain (ϵ_{cr}) attained at a 30% reduction of the peak strength (**Fig. 8**).

Figure 5: Definition of the frame fiber-section elements with and without steel-jacketing reinforcement.

Confined concrete for RC elements confined only by stirrups will be characterized by parameters f_{c0} , f_{cu} , ϵ_{c0} , ϵ_{cu} (**Fig. 5**), while these parameters are changed into f_{cc0} , f_{ccu} , ϵ_{cc0} , ϵ_{ccu} for RC elements confined by stirrups and steel jacketing (**Fig. 5**). Confined concrete parameters for the RC elements confined only by stirrups are evaluated using the stress-strain model by **Razvi and Saatcioglu 1992 [13]**. As for the columns with steel jacketing retrofitting, confined concrete parameters are obtained using the procedure already presented by **Di Trapani et al. 2020 [9]**, which is based on the model by **Campione et al. 2017 [12]**.

Steel rebars are modelled using the *Steel02* (Giuffrè-Menegotto-Pinto) material model (elasto-plastic with linear strain hardening). Finally, rigid diaphragm behaviour is imposed at the floor nodes.

4.2 Modelling of masonry infills

Masonry infills (if any) are modelled as equivalent diagonal struts resisting only in compression. The equivalent strut model by **Di Trapani et al. 2018 [14]** is used for the fiber-section struts. The model provides a concrete-type compression-only stress-strain relationship defined by the four parameters, peak stress (f_{md0}), ultimate stress (f_{mdu}), peak strain (ϵ_{md0}) and ultimate strain (ϵ_{mdu}) obtained by empirical equations. The infill is supposed to collapse in correspondence of the axial strain $\epsilon_{mdc} = 2 \cdot \epsilon_{mdu}$.

5 STRUCTURAL ANALYSIS AND POSTPROCESSING

5.1 Pushover curve post-processing for feasibility assessment

The feasibility of each solution is assessment by a pushover analysis of the individual. Pushover analysis is carried out in the framework of the N2 method (**Fajfar 2000 [11]**), also provided by **Eurocode 8 [15]**. The feasibility of each solution is assessed by evaluating the ductility capacity / demand ratios defined by:

$$\xi_\mu = \frac{\mu_c}{\mu_d} \quad (10)$$

Where the ductility capacity (μ_c) is obtained as the ratio between the ultimate displacement capacity (d_u^*) and the yielding displacement (d_y^*) of the single degree of freedom bilinear equivalent curve (**Fig. 6**), while the ductility demand (μ_d) of an inelastic SDOF system is evaluated as:

$$\begin{cases} \mu_d = (q^* - 1) \frac{T_c}{T^*} + 1 & \text{if } T^* \leq T_c \\ \mu_d = q^* & \text{if } T^* > T_c \end{cases} \quad (11)$$

where T^* is the period of the equivalent SDOF system having mass m^* , and stiffness k^* and reduction factor q^* evaluated as:

$$T^* = 2\pi \sqrt{\frac{m^*}{k^*}}; \quad k^* = \frac{F_y^*}{d_y^*}; \quad q^* = \frac{S_{ae}(T^*)m^*}{F_y^*} \quad (12)$$

The coefficient ξ_μ is the final output of the processing of pushover curves and is used as a discriminating factor in the optimization process in order to establish the feasibility of each a single individual ($\xi_\mu \geq 1$).

Figure 6: Typical equivalent SDOF capacity curve and bilinear equivalent curve for: (a) shear-resistant structure; (b) shear-critical structure.

5.2 Shear verification of RC elements with and without steel-jacketing

Shear verification of columns is carried out in the post-processing phase in terms of strength. The ultimate displacement capacity of assumed for the SDOF system is the one associated with the first shear failure of a column. Therefore, if shear failure of a column occurs, the capacity curve is cut in correspondence of that event (**Fig. 6b**). Shear verifications are carried out according to the model by **Biskinis et al. 2004 [16]**, also included in **Eurocode 8 [15]** and in the **Italian Technical Code [17]** for the evaluation of shear strength of element

subjected to seismic loads. Still according to **Italian Technical Code [17]**, the contribution of the steel-jacketing to the shear strength is evaluated.

5.3 Additional shear demand caused by infill-frame interaction

Masonry infills induce significant increase of shear in adjacent columns. In case of single concentric strut, the additional shear demand due to infills ($V_{C,inf}$) can be estimated as (**Di Trapani and Malavisi 2019 [18]**):

$$V_{C,inf} = P_{str} \cdot \cos \alpha - \mu \cdot P_{str} \cdot \sin \alpha \quad (13)$$

where, referring to the **Fig. 9**, P_{str} is the current value of the axial force acting on the equivalent strut, α is the angle of inclination of the strut with respect to horizontal direction, and μ the friction coefficient associated with the infill-mortar-frame interface and assumed as 0.7 in absence of more detailed evaluations. The total shear demand on a column of the frame adjacent to and infill (V_D) will be the evaluated as the sum of shear force currently acting on the column ($V_{C,fr}$) and the additional shear demand ($V_{C,inf}$) so that:

$$V_D = V_{C,fr} + V_{C,inf} \quad (14)$$

6 TEST OF THE PROPOSED FRAMEWORK

As illustrated in previous sections, modified genetic operators have been introduced in the optimization framework. Their effectiveness is here tested in comparison with the standard ones, also providing some remarks on the most suitable calibration of parameters. The tests are carried out on a reference reinforced concrete frame case study structure having column with shear deficiencies in a high seismic hazard zone.

6.1 Details of the reference structure

The case study building consists of a five-storey reinforced concrete structure designed to resist only gravity loads. The building is supposed being located in Cosenza (Italy), soil type C. The reference nominal life (V_N) is of 100 years. The resulting return period is $T_R=975$ years. The structure (**Fig. 7**) has double symmetry in plan and is regular in elevation. Modeling assumptions are those illustrated in Section 4. Reinforced concrete elements are supposed to be made of concrete having average unconfined strength $f_{c0} = 20$ MPa and steel rebars with nominal average yielding strength $f_y = 455$ MPa. Reinforcement details of beams and columns are shown in **Fig. 12b** and **Table 1**.

RC members	$b \times h$ (mm)	Longitudinal reinforcement	Transverse reinforcement
Beams	400 x 500	4+4 $\phi 18$	$\phi 6$ / 200 mm
Columns	500 x 500	12 $\phi 18$	$\phi 6$ / 200 mm

Table 1: Reinforcement details of beams and columns.

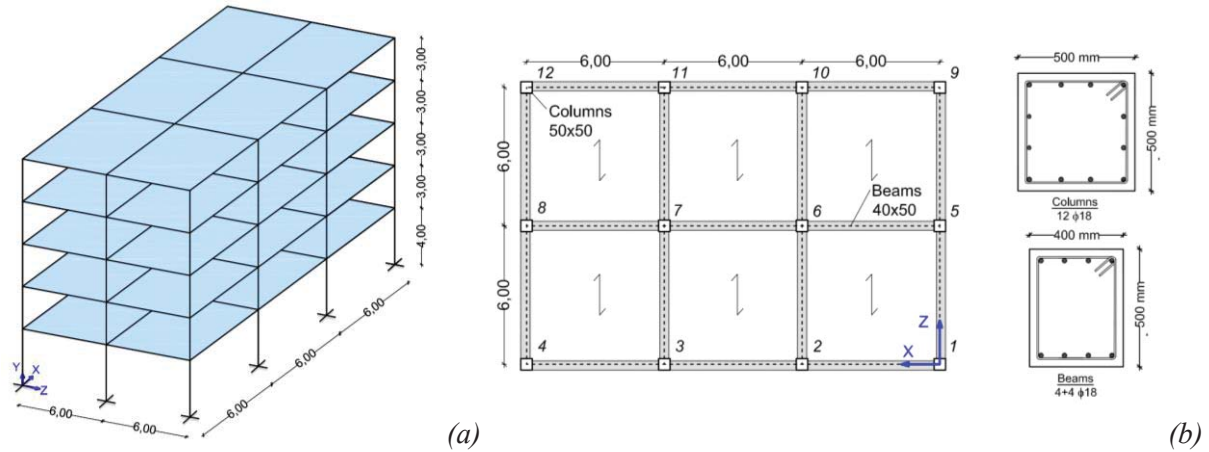

Figure 7: Geometrical dimensions of the case study structure: (a) 3D frame view; (b) dimensions in plan.

Vertical loads are modelled as point loads applied to the top node of each column as function of the respective tributary areas in plan. Pushover analyses are carried out by considering only a uniform profile for lateral loads acting along the softer direction of the structure.

A regards steel-jacketing retrofitting, it is supposed that angles and battens are made of steel having nominal yielding strength $f_{yb} = 275$ MPa and the same dimension for angles and battens (**Table 2**), while the battens spacing (s_b) range of optimization is 150-400 mm.

Angles		Battens		
Lateral length l_a (mm)	Thickness w_a (mm)	Width w_b (mm)	Thickness t_b (mm)	Spacing s_b (mm)
Columns	5	50	5	150–400

Table 2: Steel-jacketing arrangement details.

Moreover, to reduce the computational effort the following restriction have been applied to the design space:

- Retrofitted columns can be only located within the first the second floor.
- Battens spacing optimization can vary with a minimum step size Δs_b of 50 mm

6.2 Case study structural configurations description

An application of the proposed framework is carried out for a case study structure supposing two different configurations of the infills. The reference reinforced concrete frame structure is the same as the one described in the previous section. Infills are supposed made clay hollow masonry having thickness $t = 250$ mm, elastic modulus $E_m = 6400$ MPa compressive strength $f_m = 8.6$ MPa and shear strength $f_{vm} = 1.07$ MPa. Equivalent strut properties defined according to the model by **Di Trapani et al. 2018 [14]** are reported in **Table 3**.

t (mm)	w (mm)	f_{md0} (MPa)	f_{md0} (MPa)	ϵ_{md0} (-)	ϵ_{mdu} (-)
250	1053	1.88	0.86	0.010	0.073

Table 3: Geometric and mechanical details of the equivalent struts.

In the first infilled frame configuration (IFC-1), infills are located on the side frames with symmetric arrangement (**Fig. 8a**). In this configuration, infills are not provided on the ground floor. In the second configuration (IFC-2), infills are provided only in one of the external side frames and extended to the ground floor (**Fig. 8b**). The reason for the choice of these two infills configurations is related to the fact that they tend to induce a significantly different seismic demand to structures in terms of shear and ductility. Furthermore, the optimization of the two structures is carried out supposing the RC frame columns being shear-critical (SC) or shear-resistant (SR). In the first case, shear reinforcement of columns is supposed to be as described in **Table 1**. In the second case, columns are supposed to have adequate shear resistance to carry seismic loads. This further test allows examining the general efficacy of the proposed algorithm to work with both the typologies of structures.

Moreover, to reduce the computational burden, the design space of retrofitted columns is limited to the first two floors (24 columns), where the maximum seismic demand is expected in terms of shear and ductility. Optimization tests are carried out considering a pushover analysis with a uniform distribution of lateral forces along z direction.

The adopted settings for the GA optimization framework are summarized in **Table 4**.

Figure 8: Case study structures: (a) IFC 1: symmetric positioning of infills with pilotis storey; (b) IFC2: asymmetric positioning of infills.

Dimension of the design vector $\text{dim}(b)$	Population size P	Dimension of the p_{Pr} space p_{Pr}	Prob. of retrofitting of an element in the p_{Pr} space P_r	Probability of mutation P_m	No. of indiv. subject to Elitism per gen. E
25	80	50%	90%	10	5%

Table 4: GA framework settings used for the case studies.

6.3 Optimization results and discussion

As previously mentioned, four optimization tests have been carried out with the aim of assessing first the responsiveness of the proposed framework in finding optimal retrofitting solution under different potential damage scenarios (IFC-1 and IFC-2 configurations). Secondly, the general validity of the framework, and in particular of the modified genetic operators, has been tested by considering both shear-critical (SC) and shear resistant (SR) configurations for the columns. This allows understanding the algorithm performance as a function of the variety of the population.

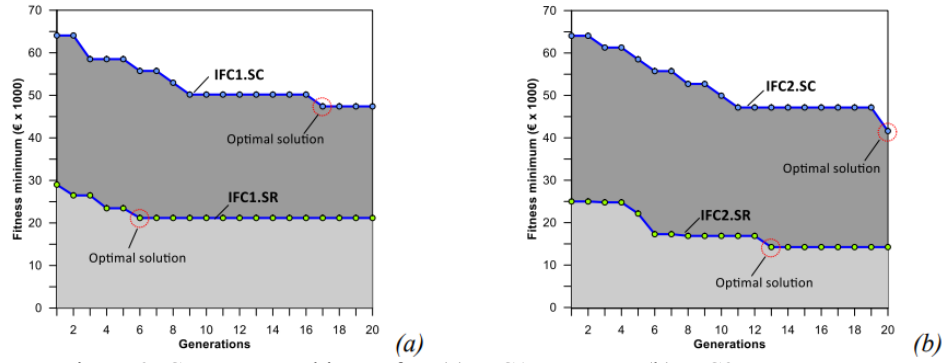

Figure 9: Convergence history for: (a) IFC1 structure; (b) IFC2 structure.

The convergence histories of the tests are depicted in **Figs. 9**. As it can be observed, the proposed framework is able to pinpoint an optimal solution for each examined cases efficiently. The performances of the optimal retrofitting configurations in terms of capacity curves are displayed in **Figs. 10**.

The consistency of the optimal retrofitting arrangements with the expected structural deficiencies is very clear from **Figs. 11**, showing the structural deformed shapes under $z+$ pushover loads and depicting in red the retrofitted columns. In fact, for both IFC-1 and IFC-2 shear resistant structures, retrofitting was provided for central columns that have reduced ductility because of the significant axial force, and leeward columns subjected to axial force increases because of the base moment. The significant amount of retrofitted columns for the IFC-1.SR configuration is related to the more severe damage mechanism (soft storey) induced by lateral loads. For what concerns shear-critical configurations IFC-1.SC and IFC-2.SC, more retrofitted columns were found. The shear deficiency of columns and the associated retrofitting demand is more evident observing **Figs. 11b, 11d**. This highlights that the additional shear demand due to the pushing action of infills plays a relevant role. In fact, retrofitting was requested to every leeward column adjoined to the equivalent struts.

For all the retrofitting configurations low battens spacing was found ($s_b=150\div 200$ mm). This can be justified considering that fixed costs influenced more than steel cage related costs. Therefore, the framework tends to prefer solutions providing the minimum possible number of columns even with reducing the spacing of battens.

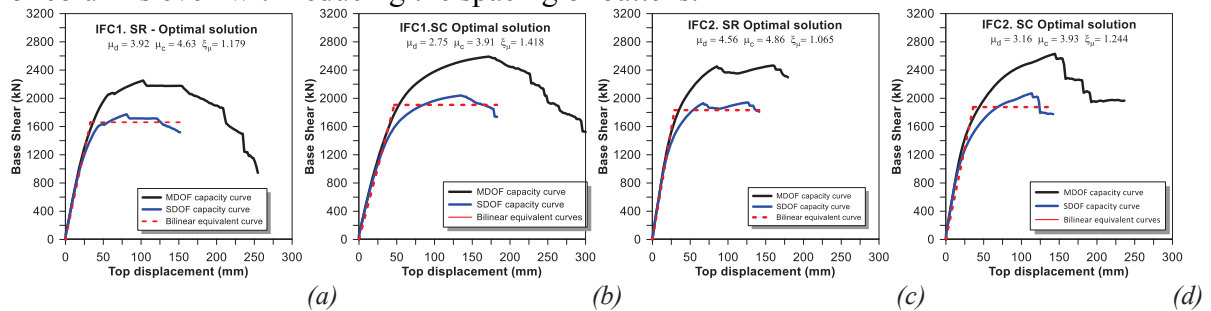

Figure 10: Optimal solutions capacity curves for: (a) IFC1.SR; (b) IFC1.SC; (c) IFC2.SR; (d) IFC2.SC

Figure 11: Optimal retrofitting arrangements for: (a) IFC1.SR; (b) IFC1.SC; (c) IFC2.SR; (d) IFC2.SC

Results of the optimization test in terms of cost, performance and arrangement are summarized in **Table 5**. Based on the previously discussed results the proposed framework has demonstrated to be sufficiently robust against the heterogeneity of the populations.

The advantages in terms of economical cost savings can certainly justify the application of a retrofitting optimization framework in the current practice. Of course, this is even more true for larger reinforced concrete frames structures, where retrofitting and downtime costs become a crucial issue.

Structural configuration	s_b (mm)	n_c (-)	C (€)	μ_d (-)	μ_c (-)	ξ_μ (-)
IFC1.SR	150	7	21 171	3.92	4.63	1.179
IFC1.SC	150	16	47 402	2.75	3.90	1.419
IFC2.SR	200	5	14 239	4.56	4.86	1.065
IFC2.SC	150	13	38 823	3.15	3.93	1.244

Table 5: Results of the optimization.

7 CONCLUSIONS

The paper presented a new genetic algorithm-based framework aimed at the optimization of steel-jacketing retrofitting interventions costs in reinforced concrete frame structures subjected to seismic loads. The proposed optimization framework can effectively handle both in the cases of shear resistance and flexural ductility lacks, providing as output the retrofitted columns' position and the amount of reinforcement associated with the minimum cost.

The development of the optimization framework was based on the MATLAB® GA tool, addressing special effort in revising the standard genetic operators (population generator, elitism, and mutation) to effectively handle retrofitting optimization of RC frame structures in the cases of lacks in ductility, shear or combined shear and ductility.

The proposed framework has been tested with a reference structure with different infills configurations and assuming the columns to be shear-critical or shear-resistant. Results have shown that the optimization algorithm is sufficiently general and robust both for the cases of shear-deficient or ductility-deficient structures. Economic and downtime gains are not clearly evident for structures with reduced size (as the ones examined in the paper); however substantial savings can be expected for larger RC structures with a noticeable number of columns.

Abstract

The paper proposes a new genetic algorithm-based framework aimed at efficiently design multiple seismic retrofitting interventions for reinforced concrete (RC) frame structures minimizing the costs of intervention. The feasibility of each tentative solution is assessed by considering in indirect way the expected annual loss (EAL). EAL evaluation is performed referring to different limit states whose repairing costs are expressed as a percentage of reconstruction costs and evaluating the respective mean annual frequency of exceedance. To effectively engage both serviceability and ultimate limit states, the compresence of two different retrofitting systems is considered. Steel bracings are used to increase the global stiffness of the structure and improve operational and damage limit states performance. FRP wrapping of columns is used to manage the life safety and collapse limit state demands. The optimization carried out by the novel AI-based framework implementing a genetic algorithm (GA). For both the retrofitting systems, their position within the structure (topological optimization) and their sizing are provided as output. Results will show that seismic retrofitting can be effectively optimized to minimize costs controlling the expected annual loss.

Keywords: structural optimization, genetic algorithm, seismic retrofitting, expected annual loss, FRP, bracing

1 INTRODUCTION

The pressing necessity of reducing the seismic vulnerability of existing structures located in earthquake-prone regions has motivated the last decade of research activities to address the seismic retrofitting techniques. Despite the large availability of retrofitting solutions with different materials and arrangement techniques, nowadays, there are no formal methods for designing this kind of interventions simultaneously controlling the resulting overall seismic performance. Therefore, in most cases, the choice of retrofitting position and amount are

exclusively entrusted to the experience and intuition of the designer. A first consequence of this empirical approach is that several trial-and-error attempts are required to find a feasible retrofitting solution. This also requires considerable time consumption to get a sufficient compromise between safety and costs. Secondly, results so obtained are not controlled in cost or in performance, therefore, obtained retrofitting solutions are feasible do not ensure maximum exploitation or the retrofitting with a consequent increase of intervention costs, invasiveness, and downtime.

In the last years, the scientific interest in structural optimization was mainly focused on sizing and shape optimization of new structures. On the contrary, the optimization of seismic retrofitting of existing structures has not been investigated many times, while noticeable interest is emerging in the last years. Few researchers have addressed the problem of the optimization of FRP jackets (Chisari and Bedon 2016 [1], Seo et al. 2018 [2]) or other applications of seismic retrofitting devices for RC buildings by using fluid viscous dampers (Pollini et al. 2017 [3]), dissipative bracings (Braga et al. 2019 [4]) or both (Lavan and Dargush 2009 [5]). More recent studies addressed the issue of optimization of seismic retrofitting costs. Among these, Falcone et al. 2019 [6] proposed a framework for optimizing the realization costs of FRP jacketing and steel bracings for existing RC frame structures through genetic algorithm optimization. Papavasileiou et al. 2020 [7] faced retrofitting optimization of encased steel-concrete composite columns comparing three different retrofitting methods: concrete jacketing, steel jacketing and steel bracing. A similar approach was followed by Di Trapani et al. 2020 [8] who proposed an innovative framework based on genetic algorithm aimed at minimizing steel jacketing seismic retrofitting costs for ductility deficient RC structures. These very recent research activities addressed their efforts in defining new effective algorithms focused on the optimization of the retrofitting interventions to minimize their cost. This provided an answer to the issue raised above, that is getting the control of the design to achieve an output goal. A more generalized view of this problem is faced in this paper, whose purpose is the development of a new optimization framework aimed at optimizing service-life costs of structures subject to retrofitting interventions, with special regard to RC frame structures. The expected annual loss (EAL) has been proved as valid tool to compare structure seismic performance during their service life Calvi (2013) [9]. It estimates the overall behaviour of the construction in terms of expected economic annual losses associated with seismic events that could take place during the reference service life.

The goal of the proposed framework is to determine, for a non-seismically conforming RC building, the best retrofitting configuration in terms of position (topological optimization) and amount of reinforcement (sizing optimization). Optimization focuses on the minimization of retrofitting costs considering in an indirect way the resulting EAL value.

Since EAL assessment involves different limit states satisfaction, the proposed framework considers multiple retrofitting interventions. In particular, the case study of a 3D multistorey RC building is considered supposing FRP jacketing of RC columns (to increase ductility) and steel bracings (to reduce lateral deformability) as retrofitting interventions to optimize.

The optimization process is carried out by a genetic algorithm (GA) developed in MatLab®. The structural performance of each solution is assessed from the results of static pushover analyses in the framework of the N2 method. The validity and efficiency of the proposed method is proved by implementing it on a case study structure. Eventually, the results are compared with the outcomes of a cost optimization that does not consider EAL control. The presented methodology is still under development, but it constitutes a novel contribution towards the use of artificial intelligence techniques to improve design effectiveness and sustainability.

2 OPTIMIZATION FRAMEWORK

The optimization framework herein proposed is based on a genetic algorithm (GA) optimization routine developed in MatLab®. The optimization algorithm relates a structural model developed with the *OpenSees* software platform (McKenna et al. 2000 [10]) with the GA process. The genetic algorithm is an evolutionary algorithm inspired by the evolution theory, therefore, it generates a *population* of *individuals* representing different tentative retrofitting arrangements. Each individual handled by algorithm is characterized by a *design vector* collecting all the decision variable to be optimized. Each design vector is associated with a potential retrofitting configuration. The optimization involves the definition of a proper *objective function*, taking into account both the feasibility of a solution (namely the passing safety checks) and cost associated to the retrofitting intervention. A schematic flowchart of the proposed framework is depicted in Fig. 1, which structure is discussed in detail in the following sections.

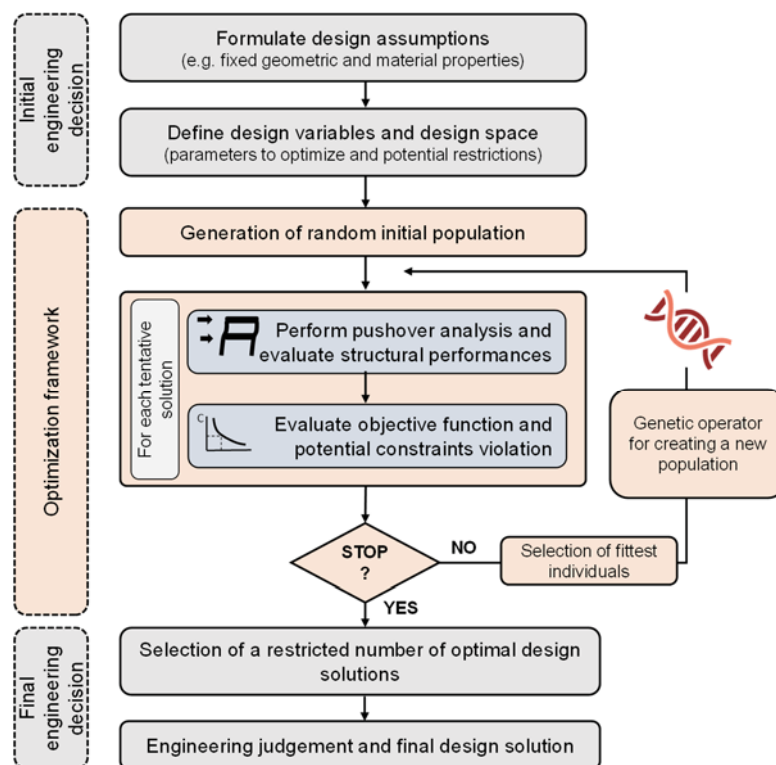

Figure 1: Flowchart of the optimization framework.

2.1 Definition of the EAL

The expected annual loss represents percentage annual loss of economic value of a structure in its reference life taking into account the associated seismic risk, which basically depends on the site hazard and on the structure seismic vulnerability. The determination of the EAL requires therefore the assessment of the performance of the structure to different limit states, associated with the respective return periods $T_{r,LS}$ and annual rates of failure, expressed as the inverse of the return periods ($\lambda_{LS} = 1/T_{r,LS}$). The achievement of a limit state is associated with a specific repair cost. The EAL curve connects the annual rate of failure of each limit state with the respective repairing cost. A simplified method to compute EAL has been proposed by Cosenza et al. (2018) [11]. According to this approach repair costs are expressed as percentages of the

repair costs (%RC) with respect to the reconstruction cost (reconstruction limit state (RLS)) and are fixed for each limit state (Fig. 2a).

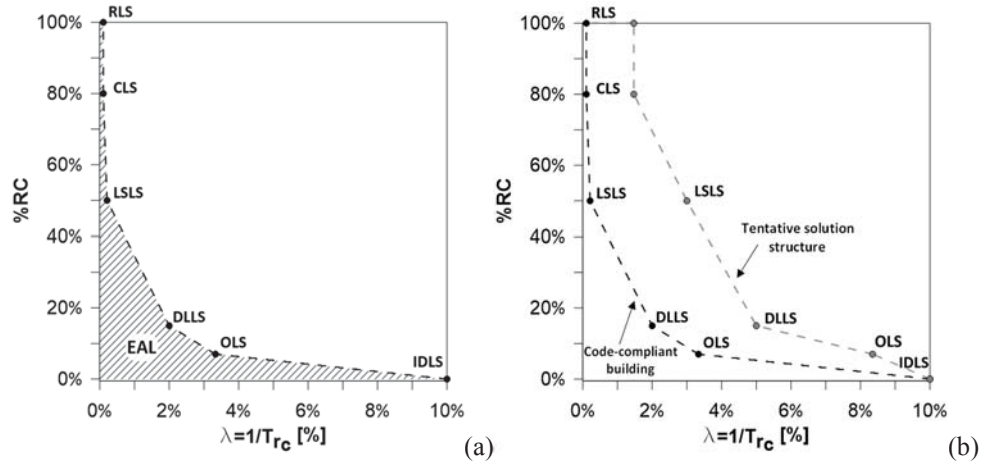

Figure 2: Expected Annual Loss curve: (a) formal EAL determination; (b) code compliant building EAL curve and generic EAL curve for a building.

According to Cosenza et al. (2018) [11], eight limit states are identified by reconstruction limit state (RLS) and collapse limit state (CLS) which are associated with repair cost (%RC) equal to 100% and 80%, respectively. Moreover, the %RC for the life safety limit state (LSLS) is set to 50%. Service limit states are the damage limitation limit state (DLLS) and the operational limit state (OLS). These two former limit states have a %RC of 15% and 7% respectively. The initial damage limit state (IDLS) is characterized by repair costs equal to zero and a mean annual frequency of exceedance that is conventionally assumed as $\lambda_{IDLS} = 10\%$. For a code-compliant structure, namely a structure having for each limit state a capacity that is exactly equivalent to the demand, the annual rates of exceedance of each limit states for the associated (fixed) reconstruction costs and are those reported in Table 1. Considering values in Table 1, the EAL of the code compliant building is 1.13%.

Limit state	%RC	$T_{r,LS}$ [years]	$\lambda_{LS}=1/T_{r,LS}$ [%]	EAL _{cc}
RLS	100	∞	0.00	1.13%
CLS	80	975	0.10	
LSLS	50	475	0.21	
DLLS	15	50	2.00	
OLS	7	30	3.33	
IDLS	0	10	10.0	

Table 1: Mean annual frequency of exceedance (λ) and repair costs (%RC) associated with each LS for a code-compliant building.

Formally the EAL is evaluated as the area under the curve that connect the points (λ , %RC) for each limit state (Fig. 1a), so that:

$$EAL = \sum_{i=2}^5 \left[\lambda_{LS(i-1)} = \lambda_{LS(i)} \right] \cdot \left[\%RC_{LS(i)} = \%RC_{LS(i-1)} \right] / 2 + \lambda_{CLS} \cdot \%RC_{RLS} \quad (1)$$

For the code-compliant building Eq. 1 results in EAL=1.13%. The evaluation of the EAL for a generic structure can be carried out performing a pushover results to determine return period associated with occurrence of each limit state ($T_{rc,LS}$). A simplified expression [11], based on the determination of the safety factor ($\zeta_{E,LS}$) can be used to evaluate capacity return period for each limit state as follows:

$$T_{rC,LS} = T_{rD,LS} \cdot (\zeta_{E,LS})^\eta \quad (2)$$

where the parameter η can be approximated to $\eta = 1 / 0.41$ and the safety factors can be calculated for the damage limitation limit state (DLLS) and life safety limit state (LSLS) as:

$$\begin{cases} \zeta_{E,LSLS} = \frac{PGA_{c,LSLS}}{PGA_{d,LSLS}} \\ \zeta_{E,DLLS} = \frac{d_{max,DLLS}^*}{S_{de,DLLS}(T^*)} \end{cases} \quad (3)$$

where $PGA_{d,LSLS}$ is the peak ground acceleration demand and $PGA_{c,LSLS}$ is the peak ground acceleration capacity, that is the one associated with the earthquake inducing LS limit state. The latter can be evaluated from the results of a pushover analysis in the framework of the N2 method (Fajfar 2000 [12]). In Eq. 3, $S_{de,DLLS}(T^*)$ is the displacement demand associated with elastic DLLS spectrum, and $d_{max,DLLS}^*$ is the top displacement associated with the achievement of the DLLS condition. This can be assessed by evaluating the maximum interstory drift. For instance, the value of $d_{max,DLLS}^*$ can be evaluated as the top displacement of the structure at which the larger interstory drift exceeds a limit drift $\delta_{i,max}$.

The corresponding annual rates of failure are then obtained as $\lambda_{LS} = 1/T_{rC,LS}$. According to [11], the annual rates of failure for the operational and collapse limit states are obtained as a function of those evaluated for DL and LS limit state, so that:

$$\begin{cases} \lambda_{OLS} = 1.67 \cdot \lambda_{DLLS} \\ \lambda_{CLS} = 0.49 \cdot \lambda_{LSLS} \end{cases} \quad (4)$$

Therefore, EAL is known once obtained λ_{DLLS} and λ_{LSLS} .

2.2 Definition of the design vector

The framework aims at optimizing the intervention cost of two different retrofitting systems: FRP wrappings of columns and concentric steel bracings. The decision variables that encode the position and sizing of both retrofit are collected together into a so-called design vector. With reference to Fig. 3, the selected design variables are the number of braced frame fields (n_{br}), the diameter of braces (ϕ_{br}), the number of layers of FRP (n_{FRP}), and the position of the columns retrofitted by the FRP. Design variables are gathered in the design vector \mathbf{b} so defined:

$$\mathbf{b} = (n_{br} \quad \phi_{br} \quad n_{FRP} \quad \mathbf{p})^T \quad (5)$$

in which the term \mathbf{p} is an array of binary numbers representing the position of the FRP retrofitted columns defined as:

$$\mathbf{p} = [\dots \quad \dots \quad c_{ij} \quad \dots]^T \quad (6)$$

in which the generic element c_{ij} , is a Boolean number assuming the value 1 if a column is retrofitted and 0 if not. The subscript i indicates the position of a column in plan and j the storey. The term n_{FRP} , instead, is a natural value that represents the number of overlapping layers of FRP on each column belonging to the interval:

$$n_{FRP} \in [1, n_{FRP,max}] \quad (7)$$

where $n_{FRP,max}$ is the maximum number of FRP layers allowed.

Figure 3: Representation of the design variables: (a) Generic FRP and bracing retrofitting configuration for a RC frame structure; (b) Usual circular steel bracings installation with generic diameter (ϕ_{br}); (c) Typical FRP arrangement for ductility reasons with a generic number of fabric layers (n_{FRP}).

To prevent premature collapse of columns that are adjoining to the bracing systems due to the additional shear demand, it is provided that they are reinforced with at least one layer of FRP. To introduce this local reinforcement into the design vector (if not already present in the retrofitting configuration) a heuristic repair technique is employed. By controlling the position of the bracings, the algorithm adjusts the vector \mathbf{p} so that the columns adjacent to the bracings are reinforced with FRP.

To reduce the computational effort, the following simplifying hypotheses are introduced for the retrofitting system:

- i) FRP fabrics have fixed height (h_f) and thickness ($t_{f,i}$).
- ii) Confinement of columns is realised by applying the FRP for a length (l_f) at both terminal part of the column where the maximum ductility demand is expected.
- iii) The number of FRP layers is constant for all the retrofitted columns.
- iv) Bracings are realised with circular cross-section steel elements. Their characteristics are constant for every frame.

2.3 Definition of the objective function

The objective function is aimed at the minimization the retrofitting intervention considering the realization of the two retrofitting systems as:

$$F = C_{br} + C_{FRP} \quad (8)$$

where C_{br} is the cost related to the arrangement of bracings and C_{FRP} is the one for the realization of the FRP wrapping of the columns. Both terms consider the material and manpower costs and the necessary works for the demolition and restoration of adjoining plaster and masonry. The first one can be evaluated as:

$$C_{br} = \sum_{i=1}^{n_{br}} (W_{br,i} \cdot c_{br}) + n_{br} \cdot c_{br,m} \quad (9)$$

where c_{br} is the manpower and material cost per unit weight (estimated in $c_{br} = 6 \text{ €/kg}$), $c_{br,m}$ is the fixed cost related to the demolition and reconstruction of masonry (2000€ every braced frame fields), and $W_{br,i}$ is the weight of the bracings in the i -th frame field that can be evaluated as:

$$W_{br} = 2 \cdot L_{br} \cdot \left(\frac{\phi_{br}}{2} \right)^2 \cdot \pi \cdot \gamma_s \quad (10)$$

in which L_{br} is the length of one bracing and γ_s is the specific weight of the steel (78.5 kN/m^3).

As regards FRP retrofitting the cost is computed as follows: C_{FRP} is computed as:

$$C_{FRP} = \sum_{i=1}^{n_c} (A_{FRP,i} \cdot c_{FRP}) + n_c \cdot c_{FRP,m} \quad (11)$$

where n_c is the number of retrofitted columns taking into account also the local reinforcement of the columns adjoining the steel bracings systems as presented in the previous section, c_{FRP} is the unit cost of the FRP (estimated in $c_{FRP} = 300 \text{ €/m}^2$), $c_{FRP,m}$ is the cost per column for the demolition and reconstruction of adjacent masonries and plasters and A_{FRP} is the area of the FRP fabric used to retrofit the generic column. The latter can be computed starting from the geometric dimensions of each column cross-section (b and h); supposing that the edges of the columns are rounded with a r_c radius, and the fabrics are applied for a length l_f at both end of the columns:

$$A_{FRP} = [2 \cdot (b + h) - (4 - \pi) \cdot r_c^2] \cdot 2l_f \quad (12)$$

As presented in the previous section, the EAL assessment is ruled only by the evaluation of λ_{DLLS} and λ_{LSLS} , thus the feasibility of each solution is restrained by the simultaneous verification that:

$$\lambda_{t_{DLLS}} \leq \lambda_{ccb_{DLLS}} \quad \& \quad \lambda_{t_{LSLS}} \leq \lambda_{ccb_{LSLS}} \quad (13)$$

which implies:

$$EAL \leq EAL_{cc} \quad (14)$$

A non-penalty approach is developed to take into account the feasibility (or not) of each tentative solution as explained in the following section.

2.4 Optimization algorithm subroutines

The search for the optimal solution through the use of GA algorithms proceeds generating a first population by randomly creating a series of individuals encoded by design vectors as

presented in the previous section. Analysing each of the population's tentative solutions, the value of fitness and the number of violated constraints is estimated.

Two different genetic operators are employed to improve the genes of the individuals at the end of each generation, the crossover, which mixes the genomes of the best individuals and the mutation, preventing local optima stuck by introducing random slight changes. The framework proceeds until one of the stopping criteria is achieved. For the current cases, only two stopping criteria on maximum number of generations and stall are imposed. In the ensuing Figure 4 a schematic flowchart of the subroutines is depicted.

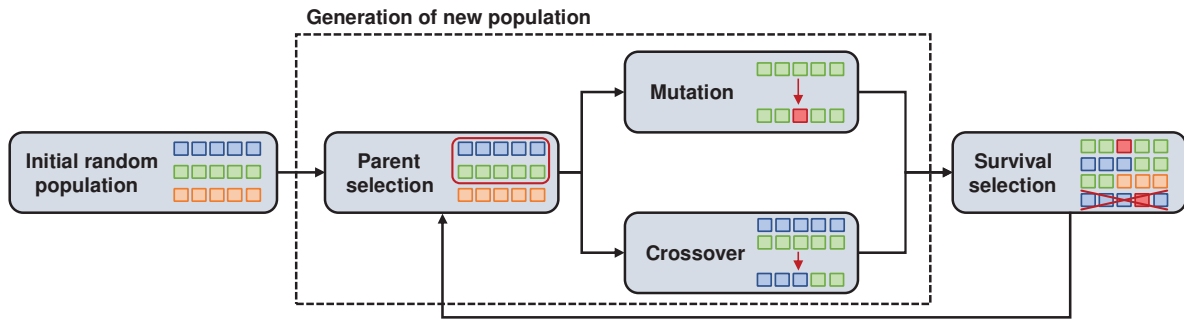

Figure 4: Schematic flowchart of the genetic algorithm process.

2.4.1. Parent selection

Parent selection is the subroutine entrusted with selecting individuals that have to be handled by other genetic operators (mutation and crossover). For the current application, random tournament selection is employed. It is based on a direct comparison of individual's performance. Within the individuals of the generation, k individuals are randomly selected (where k is called *tournament size*), among them the best individual is chosen as parent for the ensuing mating process. The comparison is carried out firstly by checking the number of violated constraints and then with respect to the fitness value. In this way, individuals with the lowest number of constraints violated are preferred. If the individuals have the same number of constraint violations the individual with the best fitness is chosen.

2.4.2. Crossover and mutation

Crossover and mutation operators are employed to improve the chromosomes at each generation. While the former works by mixing chromosomes selected by the parent selection, the latter is the genetic operator who is mainly entrusted with introducing the random component in creating offspring.

A single point mutation function is employed in the proposed GA framework. It works by selecting one random position along the design vector and changing the value of that design variable. For Boolean variables included in the \mathbf{p} sub-vector (Eq. 10) the mutation of a gene is simply a switch from 0 to 1 or vice-versa. In case the mutation has

to be achieved on the discrete values of the design vector, a new random number among the possible ones is chosen.

For the crossover subroutine, a new specific procedure has been defined to correctly handle heterogeneous genomes such as those of the proposed framework. For the binary string \mathbf{p} , a single point crossover is employed (Fig. 5). The operating principle provides the random selection of a locus along the string called crossover point. The child individual is constructed by

picking from the beginning of the chromosome to the crossover point from one parent; the rest is copied from the second one.

The crossover of the natural decision variables is conducted by randomly choosing a new value among the corresponding values of the parents. This new crossover function, which can be called *random intermediate value crossover*, is implemented to smoothly mix the parents chromosomes. An example of the proposed crossover procedure is depicted in Fig. 5.

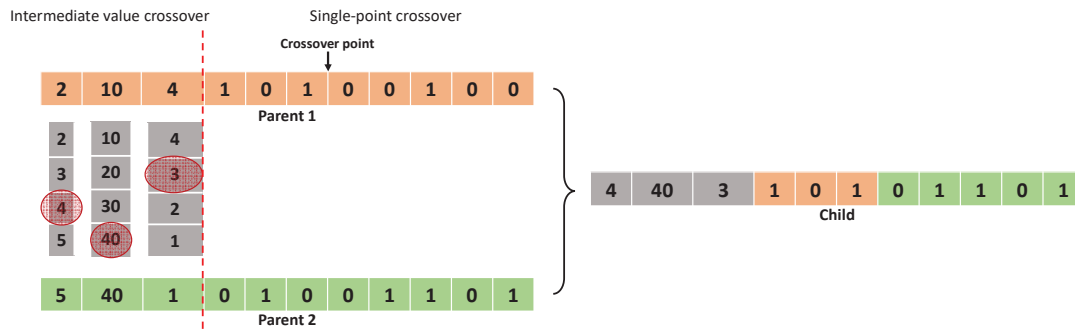

Figure 5: Example of the proposed crossover procedure.

2.4.3. Survival selection

The selection of the best individuals at the end of each generation is a fundamental step for optimization process success. The function entrusted with this task has to reject the individuals with low fitness to allow the best individuals to spread their genome. Moreover, as defined in Eq.5, the fitness evaluation does not consider the feasibility of tentative solutions; hence the selection function is responsible for managing the two constraints (Eq. 7).

A new survival selection function is developed to handle both individual's fitness and feasibility constraints efficaciously. The operating principle provides a double sorting process, first ordering the individuals with respect to the number of violated constraints and then among the individuals with the same number of constraint violation for the fitness value.

Eventually, only the best individuals are taken for the next generation. This new function that can be called *sorting and truncation selection*, has proved a valid operator to manage constrained optimization problems without requiring penalty approaches.

3 REFERENCE STRUCTURAL MODEL

The proposed framework is interfaced with a FE software to execute structural analysis. For the current application the *OpenSees* software platform. Modelling assumptions are described in detail in this section.

3.1 Modelling of reinforced concrete elements with and without FRP and of steel braces

Frame elements are modelled adopting distributed plasticity force-based elements with five Gauss-Lobatto integration points present in OpenSees (Fig. 6).

Concrete elements are modelled using a *Concrete01* uniaxial material model for the cross-section fibers. In order to simulate the crushing of the cross-section fibers, *Concrete01* material is combined with *MinMax* material, which removes the contribution of a fiber when a specified strain threshold is achieved. Steel rebars are modelled using the *Steel02* Giuffrè-Menegotto-Pinto material model (elasto-plastic with linear strain hardening).

The confined concrete model adopted for RC elements with and without retrofitting is the standard confined parabola-rectangle. According to the Italian Technical Code [13] and

Eurocode 8 [14] this model can be adopted for concrete elements confined by stirrups only or stirrups and FRP wrapping.

Figure 6: Definition of the fiber-section elements in OpenSees, concrete elements with and without FRP wrapping and steel bracings.

For the sake of brevity, the formulation of the model is here briefly recalled only for the RC elements wrapped by FRP. In detail, the confined peak stress is obtained as:

$$f_{ccd} = f_{cd} \cdot \left(1 + 2.6 \cdot \left(\frac{f_{l,eff}}{f_{cd}} \right) \right) \quad (15)$$

where f_{cd} is the peak stress of the concrete confined by stirrups and $f_{l,eff}$ is the effective lateral confinement pressure that can be evaluated as:

$$f_{l,eff} = k_{eff} \cdot f_l \quad (16)$$

where f_l is the confinement pressure exerted by the FRP that can be calculated as:

$$f_l = \frac{1}{2} \cdot \rho_f \cdot E_f \cdot \varepsilon_{fd,red} \quad (17)$$

in which E_f is the elastic modulus of the FRP (along the fiber direction), $\varepsilon_{fd,red}$ is the reduced FRP peak strain that, in case of ductility evaluations, can be obtained as:

$$\varepsilon_{fd,red} = \eta_a \cdot \frac{\varepsilon_{fk}}{\gamma_f} \leq 0.6 \cdot \varepsilon_{fk} \quad (18)$$

where ε_{fk} is the design rupture strain of FRP reinforcement, η_a is the environmental reduction factor, and γ_f is the partial factor of FRP materials. In Eq. 15, ρ_f is the geometric reinforcement percentage that, in case of rectangular cross-section and continuous confinement (FRP is not applied in strips), can be calculated as:

$$\rho_f = \frac{2 \cdot t_f \cdot (b + h)}{(b + h)} \quad (19)$$

where b and h are the cross-section dimensions, and t_f is the thickness of FRP wrapping. The latter is calculated as the number of layers (n_{FRP}) encoded into the design vector (Eq. 5) that multiple the thickness of the FRP fabric ($t_f = n_{\text{FRP}} \cdot t_{f,1}$).

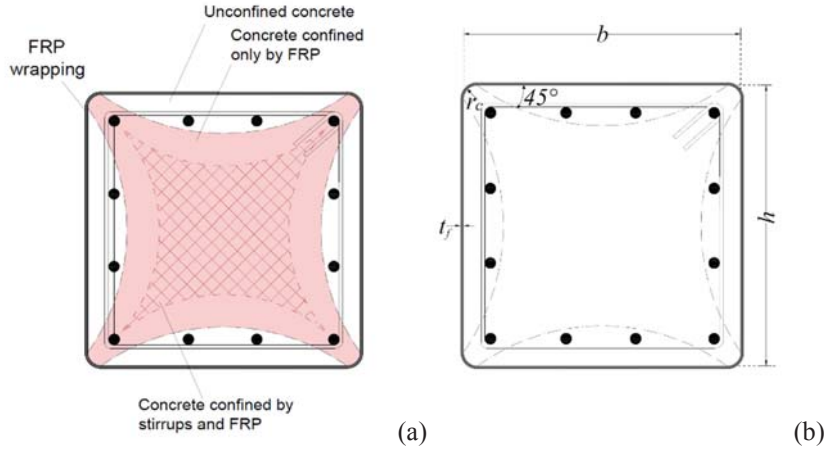

Figure 7: Configuration of the cross-section of columns retrofitted by FRP wrapping: (a) effectively confined area by stirrups and FRP; (b) geometric dimensions.

In Eq. 14 the coefficient k_{eff} represents the confining efficiency that can be calculated as the product of three different factors:

$$k_{\text{eff}} = k_v \cdot k_\alpha \cdot k_h \quad (20)$$

where k_v is the vertical confining efficiency, k_α is related to the fabric tilt, and k_h is the coefficient that represent the confining effect on the cross-section. They can be calculated in accordance with Eurocode [14], for a rectangular cross-section as:

$$k_v = \left(1 - \frac{p'_f}{2 \cdot \min\{b, h\}} \right)^2; \quad k_\alpha = \frac{1}{1 + (\tan \alpha_f)^2}; \quad k_h = 1 - \frac{(b - 2r_c)^2 + (h - 2r_c)^2}{3 \cdot b \cdot h} \quad (21)$$

In the previous equations p'_f is the distance between FRP strips, α_f is the tilt angle with respect the horizontal axis, r_c is the radius of the rounded corner.

The confined peak strain ε_{cc} and the confined ultimate strain ε_{ccu} can be evaluated as:

$$\varepsilon_{\text{cc}} = \varepsilon_{c0} \cdot \left(\frac{f_{\text{ccd}}}{f_{\text{cd}}} \right)^2; \quad \varepsilon_{\text{ccu}} = 0.0035 + 0.015 \cdot \sqrt{\frac{f_{\text{l,eff}}}{f_{\text{cd}}}} \quad (22)$$

where ε_{c0} is the peak strain of the concrete confined by the stirrups. The FRP reinforcement is supposed to be applied at both end of the columns for a length l_f (Fig. 8a). This arrangement is aimed at concentrating the confinement effect of retrofitting system in the portion of element where the major ductility is required.

The effect of FRP retrofitting is introduced into reinforced concrete elements by simply modifying the constitutive model of concrete fibers. For sake of simplicity, given that the confining effect exerted by the FRP wrapping is prevailing, the model considers only one single concrete constitutive law for the whole section.

Moreover, it is assumed that the effect of confinement is extended to the entire cross-section both for the cases of columns with and without steel jacketing reinforcement. Samples of the resulting stress–strain response in compression for a reference column cross-section fiber are reported in Fig. 8b considering different FRP layers.

Figure 8: Details of FRP reinforcement of concrete elements: (a) Typical FRP arrangement for a column with generic confined height (l_a); (b) Samples of confined concrete stress–strain responses by varying the number of FRP layers.

3.2 Modelling of steel braces

Steel bracings are modelled using truss elements available in OpenSees. The steel is modelled adopting *Steel02* elastic-plastic with isotropic strain hardening (Giuffrè-Menegotto-Pinto material model). The model provides elastic linear behaviour and strain hardening defined by the yielding stress and strain (respectively f_{yb} and ϵ_{yb}), strain hardening factor (k), and ultimate strain (ϵ_{ub}). Steel elements are assumed to have a circular cross-section whose diameter is defined by the decision variable ϕ_{br} .

Figure 9: Typical arrangement of the concentric steel bracings.

Given that the constitutive law used provides strain hardening, so in order to limit the strain value of elements, *Steel02* is combined with *MinMax* material. The bracings elements are modelled using the OpenSees *trussSection* command. In Figure 9 the typical arrangement of bracing is reported together with the representation of the constitutive law of the material.

4 CASE-STUDY TEST OF THE OPTIMIZATION FRAMEWORK

4.1 Details of the reference structural and performance of the as-built structure

The effectiveness of the proposed framework is tested by performing the retrofitting optimization for a RC structure having structural configuration typical of buildings designed prior to the entry into force of seismic guidelines. In detail, the building consists of a five-storey reinforced concrete frames structure presenting uni-directional frames (Fig. 10). Reinforcement details of beams and columns are reported in Table 2.

RC mem- bers	<i>b</i> (mm)	<i>h</i> (mm)	Longitudinal reinforcement	Transverse reinforcement
Beams	800	300	4+4 Ø18	Ø6 / 200 mm
Columns	450	450	12 Ø18	Ø6 / 200 mm

Table 2: Geometrical dimensions and reinforcement details of RC elements.

Reinforced concrete elements are assumed to be made of poor resistance concrete having average unconfined strength $f_{c0} = 20$ MPa and steel rebars with nominal average yielding strength $f_y = 455$ MPa and strain hardening ratio is assumed equal to $\eta = 0.01$.

As regards seismic hazards, the building is supposed to be located in Cosenza (Italy), soil type C, the nominal life (V_N) is 100 years. The resulting return period is $T_R = 975$ years. The structure has double symmetry in plan and it is regular in elevation. Vertical loads are modelled as point loads applied to the top node of each column as function of the respective tributary areas in plan. Rigid diaphragm behaviour is imposed at every floor.

The maximum interstory drift ratio, at which the DLLS condition is achieved, is set to $\delta_{i,max} = 0.005$. Interstory drifts are monitored at each step of pushover analysis so that the damage limitation limit state is associated with top displacement of the structure which corresponds to the first exceeding of $\delta_{i,max}$.

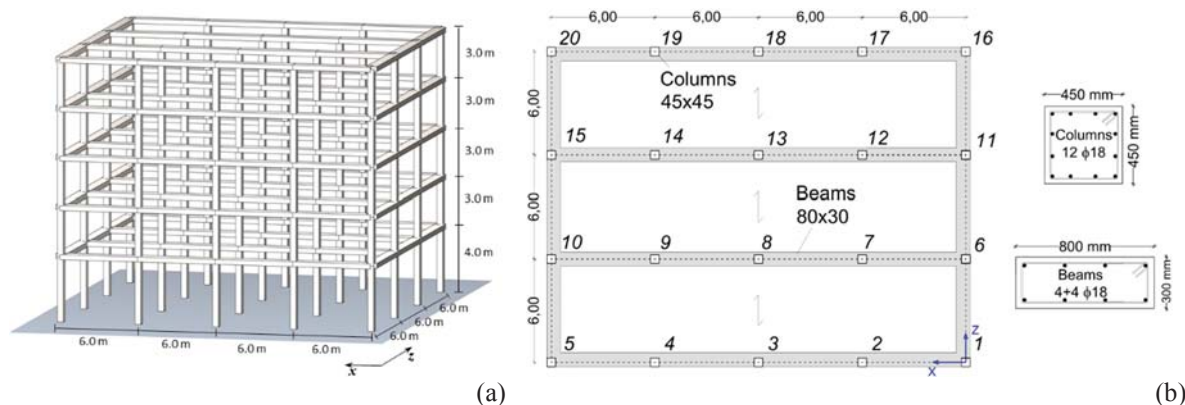

Figure 10: Geometrical dimension of the reference structural model: (a) 3D frame view; (b) in plane dimensions.

A preliminary assessment of the as-built structure has been carried out to test its performance against the reference earthquake loads. For the sake of simplicity, pushover analysis is carried out by considering only a uniform profile for lateral loads acting along the z direction of the structure, which is supposed being the most vulnerable to seismic actions. As can be seen from Fig. 11, depicting the pushover curve in the ADRS plane together with and EAL curve compared to the one associated to code compliant building, the structure shows both reduced ductility and propension to be vulnerable against damage limit states.

$\zeta_{E,DLLS}$	$\zeta_{E,LSLS}$	λ_{DLLS}	λ_{LSLS}	EAL
0.906	0.812	0.0263	0.0027	1.381

Table 3: GA analysis parameters set up for the case study.

Results are also shown in the Table 3, showing the as-built configuration safety factors related to DLLS and LSLS smaller than unity ($\zeta_{E,DLLS} = 0.9$ and $\zeta_{E,DLLS} = 0.8$). This leads to a EAL value that is equal to 1.381. Seismic retrofitting interventions are therefore needed.

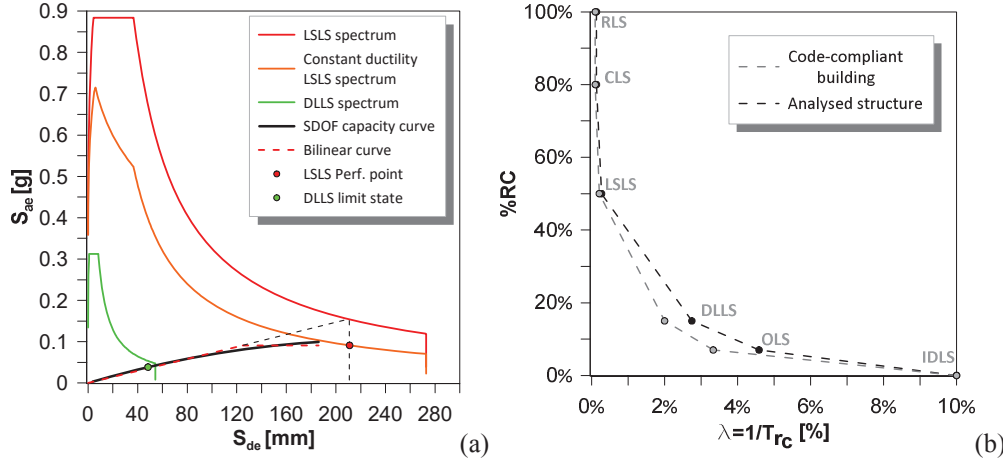

Figure 11: As-built preliminary test: (a) pushover curve in ADRS plane; (b) EAL curve compared with the curve related to code-compliant building.

4.2 Retrofitting system and hypotheses on the design space

The retrofitting system is composed of FRP wrapping of columns and concentric steel bracings. In order to reduce the computational effort of the analysis, the following restrictions are applied. Since the structure has a double symmetry in plane, the bracings are defined symmetrically on the two external transversal frames. In this way the n_{br} is the number of floors where the bracing systems are defined, starting from the ground floor, and ϕ_{br} is the diameter of the bracing, so that:

$$\begin{cases} n_{br} \in [0, n_{floor,max}] \\ \phi_{br} \in [\phi_{min}, \phi_{max}] \end{cases} \quad (23)$$

where $n_{floor,max}$ is the maximum number of floors of the structure to be potentially retrofitted (for the current case $n_{floor,max} = 5$), ϕ_{min} and ϕ_{max} are the minimum and maximum bracing diameters allowed respectively.

The FRP sheets have a thickness of $t_{f,1} = 0.337 \text{ mm}$ per layer, elastic modulus $E_f = 230 \text{ GPa}$, ultimate stress referred to net area of the fibers $f_{fib,k} = 3250 \text{ MPa}$ and ultimate strain $\epsilon_{fib} = 1.3\%$. For the implementation of FRP wrapping, it is assumed that a rounding of the column edges with a radius equal to $r_c = 25 \text{ mm}$ is carried out. The bracings are supposed to be made of S275 structural steel with $f_{yb} = 275 \text{ MPa}$, and elastic modulus $E_{sb} = 210 \text{ GPa}$.

To decrease the design space dimension, the analysis has been constrained to a limited number of columns for the confinement systems and to a restricted number of frames for the bracings. The following hypotheses are being placed:

- i) The optimization space for retrofitted columns by FRP jacketing is limited to the first two floors (red area Fig. 12).
- ii) The maximum number of FRP layers is 4.
- iii) The design space for the bracings is restricted to the central transversal frames (blue area Fig. 12).
- iv) Bracing diameter range of optimization is 20-100 mm and it vary with a minimum step size $\Delta\phi_{br}$ of 10 mm.

The resulting size of the design space is then of 6 integers that encode the number of floors where the bracings are defined (n_{br}), 9 discrete natural variables for the bracings diameter (ϕ_{br}), 4 naturals encoding the number of FRP layers (n_{FRP}), and 40 Boolean variables for the FRP position (\mathbf{p}). Therefore, the research space consists of 2×10^{14} different solutions.

Figure 12: Design space representation on the case study structure.

4.3 Optimization results

The analysis was carried out starting from a first generation of 100 randomly generated. Individuals. The algorithm proceeds by creating 100 new child every generation selecting the parents from a tournament selection on three randomly selected parents. In the following Table 4 a summary of the GA framework parameter settings is reported.

Generation dimension	Number of off-spring	Tournament size \mathbf{k}	Max generations	Max stall
100	100	3	20	5

Table 4: GA analysis parameters set up for the case study.

The convergence history of the optimization is also shown in Fig. 13, where the optimal solution is found in correspondence of the eighteenth generation with a stagnation equal to two. As shown in the convergence Fig. 13a, the proper definition of the genetic operators allows a gradual transition between the exploration and exploitation phases.

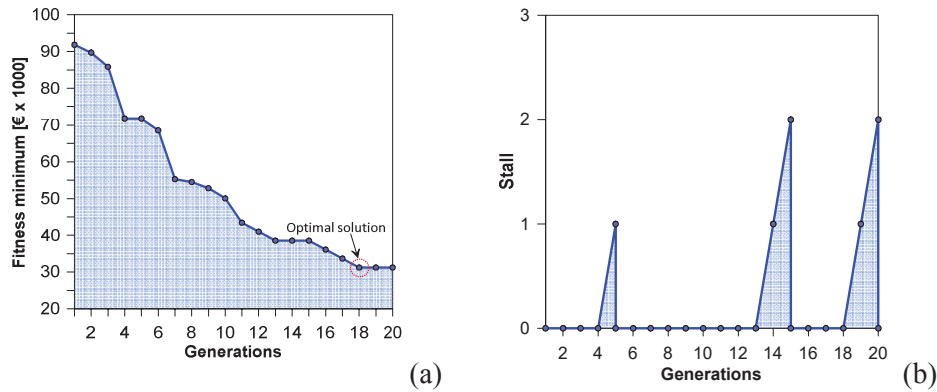

Figure 13: GA analysis performance results: (a) Convergence history; (b) Progressive optimal results stall.

The optimal solution obtained is represented in Fig. 14. It can be observed that the latter is characterized by only steel bracing retrofitting on the external frames for the first two floors, while no specific FRP interventions were required except from local reinforcement of braced frame columns. The optimal configuration bracings had a diameter $\varnothing_{br} = 50$ mm, which is equivalent to a cross-section area of $A_{br} = 19.6 \text{ cm}^2$. The overall cost of this intervention was 31299€.

Bracings were basically introduced to reduce lateral deformability of the frames, especially in along z direction, and prevent DLLS. However, bracings also provide additional strength and deformation capacity, so their contribution is also reflected on the LSLS. This double effect, combined with the overall lower cost of bracings with respect to FRP wrapping, has led the algorithm to individuate only steel bracings (as in Fig. 14) as the minimum cost solution.

Figure 14: Retrofitting configuration of the optimal solution (deformed shape).

The performance of the optimal solution is shown in Figure 15 in terms of pushover and EAL curves. The increase in stiffness due to the retrofitting system led to a reduced displacement demand, which combined with the additional resistance and ductility provided by the steel bracing allowed satisfying both LS and DL limit states. As reported in Table 5, safety factor related to damage limit state is barely close to the unity ($\zeta_{E,DLLS} = 1.025$) whereas the safety factor related to LSLS is $\zeta_{E,LSLS} = 1.585$.

The EAL curve displayed in Fig. 15b shows a noteworthy reduction with respect to as-built configuration EAL, resulting in $EAL = 1.01\%$. Given that the objective function does not directly consider the value of the EAL associated with each tentative solution (only the cost is minimized), the optimal configuration does not lead to EAL value that is optimized with respect

to the code compliant building. However, the proposed framework improves the quality of the retrofitting design by providing a cost-optimized intervention with a control on the EAL.

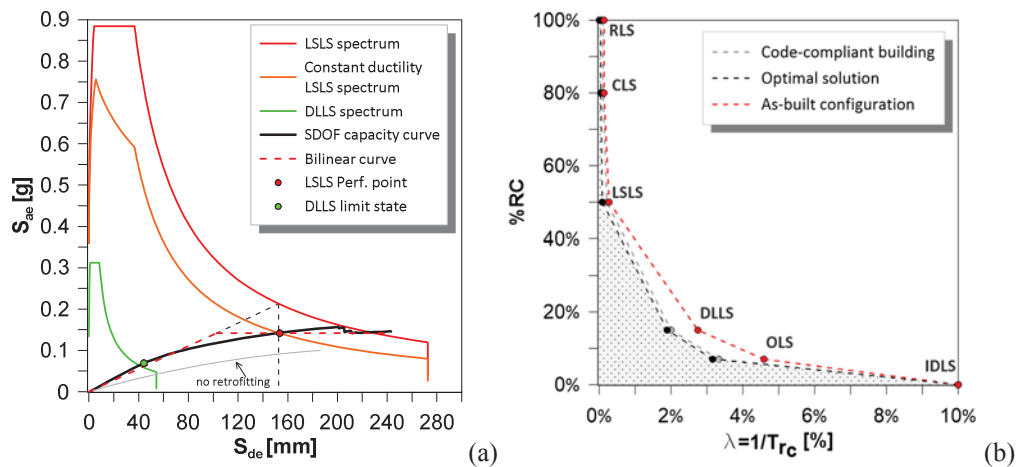

Figure 14: Optimal solution: (a) pushover curve in ADRS plane; (b) EAL curve.

n_{FRP}	n_{br}	ϕ_{br} (mm)	$\zeta_{E,DLLS}$	$\zeta_{E,LSLS}$	EAL (%RC)	Cost (€)
1	2	50	1.025	1.585	1.009	31229

Table 5: Optimization analysis results

5 CONCLUSIONS

The paper has presented a novel optimization framework aims to minimize costs related to retrofitting intervention on RC frame structures. The framework is based on genetic algorithm developed in MatLab® which interfaces with a 3D fiber-section model realized in OpenSEES. Two different typology of retrofitting system are considered: FRP jacketing of columns and steel bracings.

The main target of the algorithm is to seek the retrofitting configuration that optimize the intervention costs taking into account in indirect way of the expected annual loss value referring to that requested by the reference technical code. The performance of each tentative solution is evaluated starting from the results of non-linear static analysis in the framework of N2 method. Through a case study implementation, it has been shown that the proposed framework can pinpoint optimal retrofitting arrangement in efficient way. Eventually, the results obtained have been compared with the outcomes of an optimization procedure that neglect the EAL assessment.

An extensively usage of the framework will allow improving the management of the funds allocated to seismic retrofitting of existing structures enhancing the overall structural safety of building heritage.

THE ROLE OF THE SUSTAINED LOADS ON THE BEARING CAPACITY OF REINFORCED CONCRETE COLUMNS RETROFITTED BY STEEL JACKETS

Marco Filippo Ferrotto, Bharat Pradhan and Liborio Cavaleri

Abstract

Strengthening of reinforced concrete structures by steel jackets is a common retrofitting technique widely used in engineering practice. In most cases, reinforced concrete columns are strengthened under service loads while the columns are subjected to a certain amount of compressive stress caused by gravitational loads. In such cases, the bearing capacity for strengthened columns can be different from that obtained without existing stresses. In this paper, the effect of sustained loads in the prediction of the bearing capacity for strengthened columns is assessed by experimental, numerical, and analytical approaches. The results of the investigation revealed that the level of sustained loads at the moment of strengthening reduces the bearing capacity of columns, influencing the overall performances of retrofitted structures.

Keywords: Steel Jacketing, Confined Concrete, Sustained Loads, Preloading, Retrofitting.

1 INTRODUCTION

Retrofitting of existing RC frame structures by strengthening members such as beams and columns is among the commonly adopted strategies to improve the seismic capacity of existing buildings subjected to seismic actions [1-3]. Different approaches are available nowadays and each method provides different capacity improvement depending on the mechanical behavior of the confining device [3]. For example, Fiber Reinforced Polymers (FRP) sheets provide to the columns passive confining mechanism [4-9], and steel jackets provide semi-active or active confinement [8-15]. Other techniques can be used to increase the cross-section of the existing columns i.e. reinforced concrete jackets [18,19].

Most of the available analytical and mechanical models are provided without considering the effect of existing sustained loads on the members during the strengthening, that is a common situation for reinforced concrete structures. The consequence is that, when these formulations are used for the assessment of buildings, it is not possible to consider whether the elements are already in a stressed/strained state able to change the effectiveness of the adding reinforcement [8,17].

In the last years, few studies dealt with the modification of the capacity of strengthened members while loaded. In the case of FRP jacketing, the findings do not always lead to the same conclusions. Some authors state that there is no significant capacity modification [7], other authors state that there is a capacity reduction depending on the level of stress/strain acting on the columns at the moment of strengthening [20]. In the case of steel jackets, it was demonstrated that there is a reduction of the capacity depending on the level of sustained loads in the columns when the reinforcement is applied [17]. An important role belongs also to the time-dependent effects to consider the modification of the compressive strength of the concrete.

This paper focuses on the evaluation of the compressive behavior of columns strengthened by means of external steel cages considering the effect of the presence of service loads, and how this effect can change the compressive capacity with respect to the commonly known compressive behavior of confined members without preload.

A numerical model is assessed by the finite element software Abaqus CAE to realistically reproduce the physical process. Results by a recent experimental investigation are used for the calibration and the validation of the FE model, demonstrating the reliability of the proposed procedure.

2 THEORETICAL FRAMEWORK

Retrofitting by strengthening on existing structures is usually performed under serviceability loads (gravitational loads from beams and slabs with no live loads): the consequence is that the concrete columns are subjected to a certain stress-strain level when become strengthened. The ratio between the acting stress $\sigma(\varepsilon)$ and the compressive concrete strength f_{c0} can identify the preloading level as follows [6,17]:

$$n_p = \frac{P}{P_{\max}} = \frac{\sigma(\varepsilon)}{f_{c0}} \quad \text{for } 0 \leq n_p \leq 1 \quad (1)$$

After the strengthening, the column became confined only if further increasing of loads are applied, changing the behavior from plain concrete to confined concrete. This differs from the case of columns strengthened without preload and different results in terms of load-carrying capacity were found to be depending on the preloading level acting while the columns are strengthened.

In the following sections, the physical problem is faced by means of the finite element modeling software package *Simulia* Abaqus CAE, reproducing the pre-loading, the confinement, and the failure compressive tests. The plasticity parameters for the concrete as well as the constitutive material modeling of steel and concrete are discussed also considering the influence of the time-dependent effects due to the concrete subjected to sustained stresses. The finite element model was calibrated on the basis of a previous experimental investigation carried out by the authors. A further validation has been made with further new experimental tests presented in the second part of the paper, demonstrating the reliability of the findings and the suitability of the realistic prediction of the process carried out by numerical approach.

It is worth stating that the authors assessed this numerical procedure in the case of FRP-confined concrete cylinders subjected to preload [6].

3 NUMERICAL MODEL

The finite element software ABAQUS CAE version 6.13 [21] was used to build a FE model of reinforced concrete columns externally confined with steel angles and plates according to the study of Ferrotto et al. [16].

The column and the steel cage were modeled with C3D8-R elements (8-node linear brick, reduced integration, hourglass control). Mesh convergence studies were carried out to observe the influence of the aspect ratio of the C3D8-R elements on the global response and to determine optimal FE mesh that provides a relatively accurate solution with low computational efforts. Elements with aspect ratio not higher than 1.5 resulted to be optimal for the numerical simulations.

Concrete prismatic specimen having dimensions of 200x200x750 mm and compressive strength of 25 MPa was used. The steel cage was composed by steel angles and strips with yielding stress of 275 MPa, having dimensions of 50/50/5 (mm) and 40/4 (mm) respectively. Details of the specimen are shown in Fig. 1.

Figure 1: Geometrical configuration of the strengthened specimen.

3.1 Boundary conditions and interactions

Two rigid bodies at the top and the bottom of the specimen with the translational degrees of freedom restrained for the ends except for the vertical displacement (direction of loading) were defined. “Tie-constrain” interactions were used to define the contact properties between the steel battens and the steel angles to simulate the welding of the steel so that there was no relative motion between them. The same interactions were defined also between the concrete column and the steel angles. The latter assumption allows to define a perfect contact between steel angles and concrete (avoiding potential convergence problems due to other types of contact modeling) provided that an adequate material constitutive law is defined for the steel angles.

3.2 Material modeling of steel

According to Ferrotto et al. [16], during compression tests, RC Steel Jacketed columns can be loaded in two different ways, that are applying the load both to the steel angles and the concrete (angles fully-loaded) or to the concrete column only (angles indirectly-loaded). Buckling or frictional effects need to be considered in the constitutive modeling of the steel if tie-constrain interaction is used.

To take into account tangential stresses along the contact surfaces between steel angles and concrete (in the case of angles indirectly-loaded), Mohr-Coulomb criterion was adopted according to Campione et al. [15] and Ferrotto et. al. [16, 17]. If 0.5 is used as a friction coefficient μ , the equivalent normal stress in the angles (fictitious yielding stress corresponding to the concrete-angles sliding) can be expressed as follows:

$$f_y^* = \frac{2 \cdot n_a \cdot l_1 \cdot l_0 \cdot (\mu \cdot f_{l_{\max}})}{n_a \cdot t_1 \cdot (L_1 + t_1)} = \frac{l_1 \cdot l_0 \cdot f_{l_{\max}}}{t_1 \cdot (L_1 + t_1)} \quad (2)$$

in which n_a is the number of the angles, L_1 and l_1 are the external and the internal sides of the angles in contact with the concrete column respectively, l_0 is the overall vertical length along the columns and t_1 is the thickness of the angles. For more details, please refer to the original treatment of the authors.

In the case of angles fully loaded, the model allows the evaluation of the critical stress taking into account possible buckling by the following equations:

$$\sigma_c = \frac{1}{s_b \cdot l_t \cdot t} \cdot \frac{1}{\sqrt{2\varepsilon_s - \varepsilon_s^2}} \cdot \left\{ 2 \left[\frac{l_t^2 \cdot t \cdot f_{yb}}{4} - \frac{(N_u^*)^2}{16 f_{yb} \cdot t} \right] - \sqrt{2} f_{le} \cdot l_t \frac{s_b^2}{4} \right\} \quad (3)$$

$$N_u^* = \varepsilon_s \cdot 2 \cdot l_t \cdot t \cdot E_s \leq 2 \cdot l_t \cdot t \cdot f_{yb} \quad (4)$$

with s_b being the spacing of the horizontal steel battens, l_t the transversal width of the angles, t the thickness of the angles, and ε_s the axial strain in the angle.

3.3 Material modeling of concrete

Material modeling of concrete has been performed according to Ferrotto et. al. [16] by using Concrete Damaged Plasticity (CDP) model available in the software package, by considering modifications for the plasticity parameters to overcome problems related to the triaxial stress state of concrete under high confining stresses. In detail, modification to the yield criterion, the hardening/softening rule and the flow rule are provided by adequate laws for:

- the dilation angle ψ that defines the plastic flow potential;

- the ratio between the compressive strength under biaxial loading and uni-axial compressive strength f_{b0}/f_{c0} ;
- the ratio Kc between the second stress invariant on the tensile meridian and that on the compressive meridian for the yield function.

In the present work, CDP model was used to perform simulation in the case of confinement under monotonic loads only, therefore the damage variables were not defined.

The parameter Kc is evaluated according to Ozbakkaloglu et al. [22] depending on the ratio f_{b0}/f_{c0} as follows:

$$\frac{f_{b0}}{f_{c0}} = 1.57 \cdot f_{c0}^{-0.09} \quad (5)$$

$$Kc = 0.71 \cdot f_{c0}^{-0.025} \quad (6)$$

The dilation angle is evaluated depending on the external transverse mechanical confinement ratio ω_{st} .

$$\omega_{st} = \omega_{st,x} + \omega_{st,y} = \left(\frac{A_{st,x}}{h \cdot s_b} + \frac{A_{st,y}}{b \cdot s_b} \right) \frac{f_{yb}}{f_{c0}} \quad (7)$$

$$\psi = 56.3e^{-0.594 \cdot \omega_{st}} \quad (8)$$

In Eqs. (7) $A_{st,x}$ and $A_{st,y}$ are the area of the transverse steel bars along x and y direction respectively, b and h are the dimensions of the concrete cross-section, s_b and f_{yb} are the spacing of the horizontal steel battens and the yielding stress, f_{c0} is the unconfined concrete strength.

A three-stage stress-strain relationship for the plain concrete is therefore used to take into account the modification proposal by Ferrotto et al. [16] depending on the external transverse mechanical confinement ratio ω_{st} as well as the dilation angle.

$$\frac{f_c(\varepsilon)}{f_{c0}} = \begin{cases} \frac{x_1 \cdot \gamma_1}{\gamma_1 - 1 + x_1^{\gamma_1}} & 0 \leq \varepsilon \leq \varepsilon_{c0} \\ 1 & \varepsilon_{c0} \leq \varepsilon \leq \varepsilon_{c1} \\ \frac{x_2 \cdot \gamma_2}{\gamma_2 - 1 + x_2^{\gamma_2}} & \varepsilon \geq \varepsilon_{c1} \end{cases} \quad (9)$$

$$\gamma_1 = \frac{E_c}{E_c - \frac{f_{c0}}{\varepsilon_{c0}}}, \gamma_2 = \frac{E_c}{E_c - \frac{f_{c0}}{\varepsilon_{c1}}}, x_1 = \frac{\varepsilon}{\varepsilon_{c0}}, x_2 = \frac{\varepsilon}{\varepsilon_{c1}} \quad (10)$$

$$\frac{\varepsilon_{c1}}{\varepsilon_{c0}} = 0.2107 \cdot \ln(\omega_{st}) + 1.6455 \quad (11)$$

In the above equations, ε_{c0} is the unconfined concrete peak strain, ε_{c1} is the increasing peak strain affected by the confinement, and E_c is the modulus of elasticity of the plain concrete.

3.4 Simulation of the preloading

Differently to the case of strengthening of columns without preload, in the presence of loads (a situation that reflects several cases of reinforcement of existing buildings), the con-

fining element gives its contribution starting from a certain stress/strain level. The external reinforcement should be modeled/activated as soon as the concrete reaches the state of stress at the moment of the application of the reinforcement.

The problem is solved by using the deactivation/reactivation elements technique identified in the software by the “model change interactions”. It is thus possible to define the assembled system in such a way to activate the wrapping contribution only when desired.

The simulation of the preload conditions is obtained by articulating the analysis into two steps: i) force applied to the top section of the specimen according to the fixed preload level, ii) the external steel cage is activated and the load test continues until the failure of element.

Specifically, simulations under preload conditions require that in the first step a force/displacement is applied to the non-confined element (with the reinforcement device deactivated) and the stress/strain state at the end of the analysis corresponds to the tensional state relative to the preload level. In the second step, the confinement device becomes active in deformed conditions, characterized by the congruence of the nodal displacements of the concrete meshes, but with zero stress/strain state.

Axial stresses, lateral stresses and axial total strains corresponding to the middle section were recorded during the analysis.

The time analysis-stress and the stress-strain response are plotted in Fig. 2 for the case of compression test with no preload and with two different levels of preloading i.e. np 0.7 and 0.9. It is possible to see that, coupled with the strain lag activation of the steel cage (and therefore the providing of the lateral confinement pressure), the strength decreases as the imposed preload level increases (Fig. 2).

In Fig. 3 the stress and strain distributions in the specimen confined with steel jackets are shown for three significant steps of the numerical process:

- The end of the first step (Fig. 3 a-b) in which the unconfined concrete reached the preload without any contribution of the jacket;
- The beginning of the second step at increment 0 (Fig. 3 c-d) in which the concrete keeps the same stress/strain configuration of the previous step and the jacket becomes “active” in a virgin stress/strain state but having the same shape of the column;
- A certain increment of the second step (Fig. 3 e-f) in which the steel jackets contribute to the global response. In this phase, the strain compatibility is still given by “tie constrains interaction” and the strains in the jackets are lower than the cylinders because they are computed in the analysis before the preloading step.

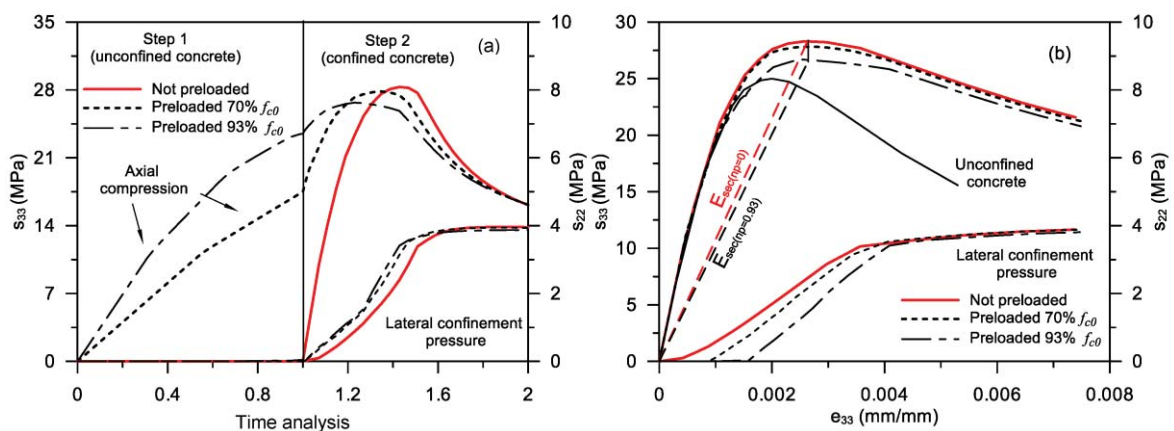

Figure 2: FE computational process (a) and Axial stress-strain behavior and lateral pressure evolution (b).

Figure 3: Stresses and strains distribution in the model (case 2) during: end of first step (a and b); second step at increment 0 (c and d) and increment 7 (e and f)

4 EXPERIMENTAL TESTING

In the following, a brief description of an experimental investigation previously carried out by the authors is provided. For more details, please refer to the original paper by Ferrotto et al. [17]. It has to be pointed out that, in the frame of the present paper, additional tests carried out for different concrete age specimens are presented to improve the number of data and the reliability of the findings.

The experimental program consisted of compression tests on columns strengthened by means of steel cages under different load conditions. Tests on unreinforced, reinforced before any loading and reinforced after axial loading at a fixed rate of the capacity were performed for low, medium and high level of the preload.

Fifteen compressive tests were performed. Among the total number of tests, ten columns were tested with an average concrete age of 146 days, while five additional columns were tested with an average concrete age of 530 days. The reason was to observe the effect of the aging of the concrete on the compressive capacity including sustained loads.

The external steel cages used for the strengthening were defined according to Fig. 1, connecting angles and battens by welding. For both angles and battens, no mortar was used at the contact surfaces with the concrete columns.

The steps of the tests of the preloaded specimens are listed hereinafter:

- Preloading: during this stage, the measuring of the shortening in the middle height of the specimens allowed to identify the stress-strain behavior of the unconfined concrete. Once the target preload was reached, stabilization of the load and acquisition of creep strains were performed;
- Strengthening: After preloading, digital transducers were removed from the concrete specimens and steel jackets were applied by welding;
- Unloading: specimens were unloaded and transferred to the load testing machine, strain gauges were applied to the steel cages and the digital transducers to the concrete specimens as in the case of the preload tests. Moreover, long digital transducers were assembled at the four corners of the specimens;
- Collapse test: the specimens were loaded up to collapse, recording axial strains of the columns and axial and lateral strains on the steel jackets.

Preloading was applied in a three-dimensional steel testing frame system composed by three rigid steel beams and four steel bars (diameter of 80 mm) fixed to the lower floor structure. Hydraulic jack and a load cell were placed between the central steel beam and the concrete specimen to apply the compressive force monitored by a digital data acquisition system.

The welding of the steel cages was done while specimens were under a certain assigned stress/strain state. The apparatus for the preloading is shown in Fig. 4 coupled with a picture of a specimen reinforced under sustained loads.

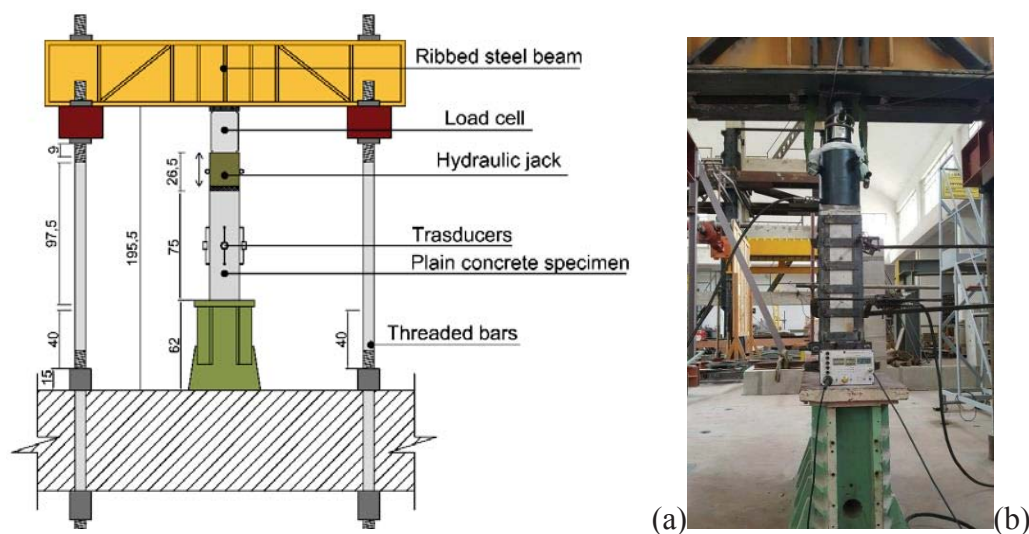

Figure 4: Preloading frame device (a); Strengthening of a specimen under sustained load.

Axial strains on the column specimens were measured by using two systems of digital transducers. Four of these had a gauge length equal to the internal length of the specimen (750 mm) and were placed at the corners. Four other transducers were placed on the lateral faces of the column at the middle height, with a gauge length of 220 mm. The double system of transducers allowed the recognition of strain concentration in the middle of the specimens. Strains on the steel cages were also recorded by means of “linear type” strain gauges with a gauge length of 13 mm. Horizontal and vertical strain gauges were bonded to the steel battens in correspondence of the middle height of the column and on the external surface of the steel angles at the top, middle and bottom respectively. This measurement layout allowed to obtain average strains and stresses of the battens (controlling, therefore, the evolution of the lateral pres-

sure) and average strains and stresses of the angles (obtaining the axial load carried out by the angles). Details of the measurement setup are reported in Fig. 5.

Figure 5: Arrangement of the measurement system.

4.1 Testing under sustained loads

The target strength for the concrete was 20 MPa. Concrete mixture was composed by CEM I 32.5 R, water, sand and aggregate with size varying from 0 to 20 mm, having proportion in weight 1:1.51:0.384:0.353. Concrete cubes having size of 150 mm were made during the concrete casting, for testing the compression strength after 28 days. The tests were performed according to UNI EN 12390 Standards. Test results provided for the plain concrete a cubic compressive strength of 19.99 MPa (and therefore, a cylinder compressive strength of 16.59 MPa), while the target strength f_{c0} was considered equal to 16.75 MPa based on the average from cubes and two full-scale plain concrete specimens (633.94 kN and 715.27 kN with average max load and stress of 674.58 kN and 16.86 MPa respectively).

Specimens were labeled depending on the type of preload (P#), the type of reinforcement (S) and the number of the specimen #. For example, specimen P0S1 referred to 0 preload force, specimen strengthened with steel jackets (S), specimen n1, while P60S2 refers to a preload force nominally equal to the 60% of the strength, specimen strengthened with steel jackets, specimen n 2. Table 1 lists the details of each test.

Specimen	Type of test	Preload level (%) and force (kN)	Average concrete age (days)
NC1-2	Plain concrete	/	146
P0S1-2	Confined	/	146
P0S3		/	146
P40S1	Preloaded and confined	40 / 270	146
P60S1-2	Preloaded and confined	60 / 402	146
P60S3			530
P70S1	Preloaded and confined	70 / 483	146
P70S2			530
P80S1-2	Preloaded and confined	80 / 530	146
P80S3			530
P90S1	Preloaded and confined	90 / 603	530

Table 1: Type of tests.

Preload tests had variable duration depending on the evolution of creep strains after the maximum load was reached. The time of preloading for each specimen was: specimen P40S1, 10 hours, P60S1-3, 11, 10 and 12 hours respectively, P70S1-2 6.5 and 8 hours respectively, P80S1-3 7.5, 5 and 8 hours respectively, and P90S1 7 hours.

In the case of low preload levels, i.e. for preloaded specimens at 40% and 60% of the strength, creep strains evolution was restricted and stable. Otherwise, for high preload forces (i.e. 70-90%), higher creep strains evolution was observed followed by smeared cracking of the specimens.

During the last stage of the preloading, specimens were strengthened by the steel jackets; then, after the unloading and the transferring to the load testing machine, specimens were equipped with digital transducers and strain gauges before the final collapse tests. For more details, please refer to the original treatment of the authors [17].

4.2 Failure compressive tests

Compressive load-strain response of the strengthened specimens was characterized by load increasing behavior up to the maximum load capacity, followed by a strain-softening behavior. Compression tests were terminated in correspondence to a reduction of 85% of the maximum load. In some cases, a premature failure of the confinement device occurred by the failure of the welding between steel angle and strip causing a high loss of load (as for specimen P0S2). Some pictures of strengthened specimens at failure are shown in Fig. 6.

The results showed a significant increase in load and deformational capacity compared to the compression response of unconfined specimens. It is important to note that this increase in the load capacity was due to the global contribution provided by the response of the confined concrete and the angles.

Compression tests of preloaded specimens showed differences with respect to the non-preloaded ones. Load-strain curves were affected by a reduction of the maximum load-bearing capacity and a significant reduction in the secant stiffness. This effect was caused by the strain-lag (lower confinement lateral pressure for a given value of axial strain with respect to the non-preloaded specimens) directly proportional to the applied preload level as for the load carried out by the angles. These reductions can be observed in Table 2 that summarizes the experimental results (and subsequently the comparisons with the FE predictions).

Figure 6: Strengthened specimens at failure.

5 COMPARISONS BETWEEN EXPERIMENTAL RESULTS AND FE PREDICTIONS

The comparisons between experimental results and FE predictions are presented hereinafter. The plasticity parameters of the concrete for the numerical model were calculated by using Eqs. (5-9), while the steel angles equivalent yielding stress was calculated by using Eq. (2). An equivalent elasticity modulus has been assigned to the steel angles to consider indirectly the sliding between the steel and concrete contact surfaces according to Ferrotto et al. [17].

The effect of the sustained loads on the compressive strength of concrete need to be considered for the modification of the compressive response of the plain concrete depending on:

- i) the level of sustained load applied before strengthening (preloading): this aspect modifies, according to the statements presented in section 3.4, the load-strain response of the confined concrete because of the strain-lag effects;
- ii) the modification of the plain concrete strength due to high sustained stresses: this aspect was considered according to the findings of Rüsç [23] and Tasevski et al. [24].

The first aspect was assessed by a modification of the hardening/softening function to consider the reduction of the confinement effects due to the strain-lag. This causes a lower equivalent compressive peak strain compared to confined concrete without preload. Besides, this effect resulted in much higher strain as the preload level increases. Differently from Eq. (11), in the frame of this study, a new equation (Eq. 12) is proposed based on non-linear regression of the numerical results depending on the mechanical confinement ratio and the preloading level. The proposed equation considers the increasing of the concrete peak strain due to the confinement and, at the same time, the reduction of the latter due to the preloading effects by the parameter $k_{(np)}$. It is remarked that, by using Eq. (12), in the case of columns without any external reinforcement and no preload, the behavior of the plain concrete is obtained.

$$\frac{\varepsilon_{c1}}{\varepsilon_{c0}} = k_{(np)} \cdot (1 + 1.6877 \cdot \omega_{st}) \quad (12)$$

$$k_{(np)} = 1 + 0.0785 \cdot n_p - 0.4695 \cdot n_p^2$$

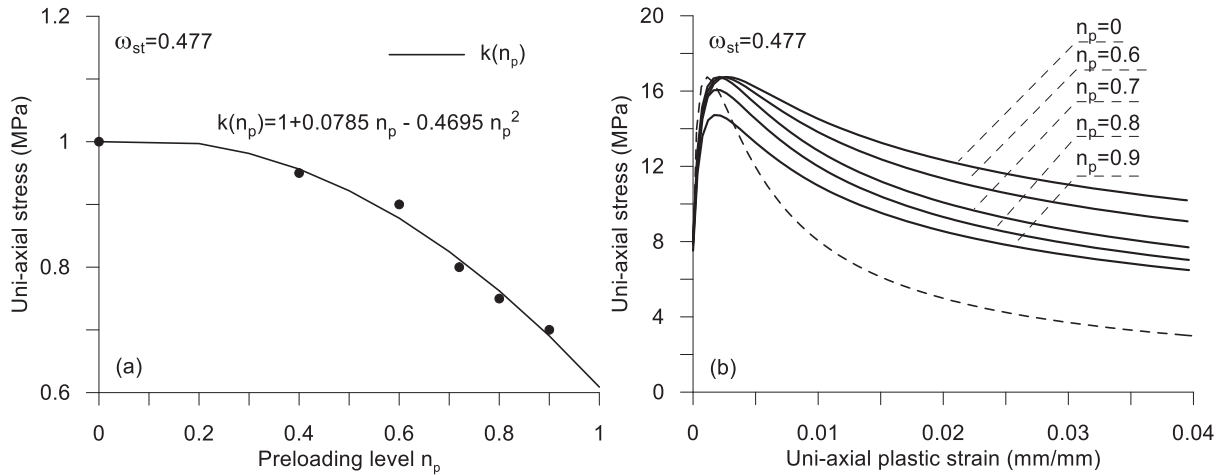

The second aspect is assessed by a simplified analytical equation to predict the compressive strength of concrete influenced by high sustained loads according to Tasevski et al. [24]. The proposed equation is selected in the present study to be used for the assessment of the numerical model.

$$\begin{aligned} f_c(np) &= 1 \cdot f_{c0} & \text{if } n_p &\leq 0.75 \\ f_c(np) &= (1.6 - 0.8 \cdot n_p) \cdot f_{c0} & \text{if } n_p &\geq 0.75 \end{aligned} \quad (13)$$

As a result, in Fig. 7 a-b, the reduction parameter $k_{(np)}$ and the uni-axial stress-plastic strain laws used for the analyses are shown for the different preloading levels according to the experimental tests. The others plasticity parameters as well as the plain concrete strengths used for the numerical analyses are shown in Table 3. Finally, the experimental-numerical comparisons in terms of load-strain response are shown in Fig. 8, highlighting the suitability of the FE model to reproduce the compressive behavior of the strengthened columns under the different levels of preload.

Specimen	P_{\max} -Exp (kN)	FE (kN)	FE/ P_{\max} -Exp
P0S1	1364.80		0.97

6 CONCLUSIONS

In this paper, the evaluation of the compressive behavior of columns strengthened by means of external steel cages considering the effect of the preload at the moment of strengthening was investigated by experimental and numerical approaches. Compared to the load-bearing capacity of columns strengthened without preload, it was observed that there is a reduction of the capacity because of the preload depending on:

- A reduction of the compressive strength of the concrete induced by high sustained loading;
- The strain-lag effects of the confining device due to the preload.

Moreover, the above-mentioned effects are more significant with the increasing of the levels of preload.

A numerical FE model was assessed and used for the experimental-numerical comparisons, showing its reliability on the realistic prediction of the physical process and the results. The FE model can be used for subsequent accurate predictive scenarios including different mechanical properties for the concrete and the steel cages.

Keywords: Digital Twins, Operational Platform, 6-DOF Excitations, Environmental Testing

Abstract. *One of the main usages for a digital twin is the centralization and utilization of numerical, physics, and experimental based data. While there has been a large amount of research in the definition and utilization of computer simulations, there exists a gap in research in the interaction between experimental setups and digital twins. This work focuses on an example of how an experimental setup can interact with a digital twin via an operational platform. The experimental setup for this work is a scaled 3 storey building excited with a 6-DOF ground shaker under various controlled environmental conditions. For the digital twin, a server-based operational platform is used to allow for interactions with the digital twin from any remote operation site. The work in this paper gives an example of how the digital twin and experimental setup interacts and explores the added benefits of using a digital twin in experimental research.*

1 Introduction

In the current state-of-the-art, digital twins are typically comprised of purely experimental (pre-digital twins), or physics (numerical twins) based models [1]. It is currently rare for digital twins to incorporate both types of models in a meaningful capacity. This has led to a greater desire in research to incorporate both experimental results and physics based simulations into a single digital twin to be useful for an analyst. The research presented in this paper is a case study for the centralization of experimental and numerical models into a digital twin.

The concept of “twinning”, the art of using a one-to-one surrogate for generating diagnostic/predictive information, dates back to the NASA Apollo missions used for training astronauts and diagnostic testing [2]. However, recently there has been a greater focus on the development of digital twins that allows easy access to both accurate physics based simulations and experimental data performed. This will lead to the utilization for decision making, such as determining a maintenance schedule [3].

Some initial work has been done in the combination of experimental data and numerical simulations, such as the work done in [3, 4, 5]. The majority of this work is focused on what is termed “grey-box modelling” that uses a combination of physics based models and experimental data to create a surrogate model. While this work is important for the use in digital twins, the work presented in this paper focuses on how the information is passed between the experimental data, physics based models, and the analyst via an operational platform.

The Digital Twin Operational Platform (DTOP) is the interface that an analyst uses to create models, investigates numerical and experimental results, and create predictions based on the available information. There are multiple methods researchers and companies have used to develop operational platforms. Currently, a majority of available digital twins are operated via an executable that can interact with a database or live sensor data. This, although designed as such, limits both the number of people and whom can interact with the digital twin. Using an executable is useful if only a small number of analysts are expected to use it, for example in a power generating facility, however researchers tend to have a larger number of analysts at various locations. In order to aide researchers in using a digital twin, this work focuses on a web based platform that is accessible to any approved analyst with internet access.

With a web based platform, there is greater access to the DTOP, even at remote locations such as test sites. However, there are connectivity issues between local hardware and the DTOP. This work will demonstrate a case study for one method to combine the local hardware used in experimental testing with the web based DTOP. Section 2 will describe the hardware setup and testing conditions tested on the demonstration system discussed in Section 2.1. To discuss the web based DTOP, Section 3 shows the generated digital twin for the demonstration system and discusses some of the selected options used for the demonstration system and alternatives for each option. Section 4 discusses the interactions between the DTOP and experimental setup and demonstrates some of the added benefits to using a digital twin with experimental systems in Section 4.1. Some concluding remarks are presented in Section 5.

2 Experimental Setup

The main purpose of these experiments are to characterize the combined effects of environmental temperature and added masses on a civil structure. More information about this system is given in Section 2.1. To test this combined effects, the advanced facilities at the Laboratory for Verification and Validation (LVV) at the University of Sheffield. The LVV is equipped with multiple environmental chambers with one specifically designed for shaker based vibration test-

ing. This specific chamber is able to operate from -50 to 50°C with a shaker able to exert a maximum acceleration of $3g$.

To study the combined effects on this structure, a suite of tests are performed at multiple temperatures with various added masses. For each temperature, the four values of added mass are $0.0, 5.72, 11.44$, and 18.2 Kg. Relative to the structure mass, this is $0\%, 4.0\%, 8.0\%$, and 12.7% respectively. These proportions are thought of as a high percentage, but still realistic for civil structures. The temperature range of interest is based on yearly range in a seismically active region. Specifically, northern Japan is used that has a typical range between -10 and 30°C , so the testing is performed on a slightly expanded range of -15 to 35°C .

For each combinations of temperature and added mass, a swept sine excitation is applied via the 6 degree of freedom shaker. This excitation was applied in a single direction with frequencies ranging from 3 to 30 Hz with a linear rate of 0.1 Hz/s and an amplitude of 0.8 m/s^2 . This range is based on the first three bending modes obtained by preliminary tap tests where the third natural frequency is near 25 Hz. Although this paper focuses on the connectivity between the experiment and DTOP, these tests are also used for other work that focuses more on the grey-box modelling.

2.1 Demonstration System

The experimental system tested in this work is a scaled 3 storey building. This is constructed using extruded T-slot aluminium that is mounted to the shaker table. The general dimensions of this building are 2.42 m tall with a cross-section of 930×820 mm. A photo of the test system mounted to the shaker table within the environmental chamber is seen in Figure 1.

Figure 1: 3 storey building

One aspect of the experimental system is the sensor layout. For these tests, there are two single-axis accelerometers for each pillar on each floor with a total of 24 accelerometers. In

addition to these 24, there is also a baseline accelerometer on the shaker table to measure the input and additional sensors on a single pillar at the half floors to identify if there are any local modes in the support pillars experienced for this system in the range of interest. As a validation for this system, a calibrated beam model is generated. This model has an adjusted Young's modulus because the exact heat treatment of the aluminium is unknown, to match the first three bending frequencies that was obtained through some preliminary impact hammer testing. The accuracy of the calibrated model for the first three natural frequencies are within 1.5%.

3 Digital Twin Operational Platform

The most import aspect of communication between a user of the digital twin, the stored information, and the experimental system is the Digital Twin Operational Platform (DTOP). Using a DTOP is a useful method to inspecting information for the digital twin, with an emphasis on the ease-of-use. The main goals of a DTOP is to perform six main operations.

1. Access the collection of simulation, experimental, and historical results to aid in decision making
2. Provide access to approved users
3. Maintain data security and redundancy
4. Schedule/perform novel simulations for the digital twin
5. Access real-time data from live sensors
6. Interact directly with the physical twin

These six goals of a DTOP represent all the needs expressed for the operational platform aspect of the digital twin. While there is currently a large amount of work being done in order to ensure that the digital and physical twins perfectly correlate, this work focuses on the access to information and the user experience (the so-called human-computer interaction). For this particular work, a large focus is placed on the first two operations listed above.

While discussing the access to digital twins via a DTOP, it is import to denote some of the different frameworks available. One of the most important frameworks is the accessibility of the DTOP to users. To discuss how a user can access a digital twin, Figure 2 shows the 3 main methods to access a digital twin via a DTOP. There are both advantages and disadvantages for each method.

The first method to access a DTOP is based on being stand-alone. This method is where a local version of the digital twin is accessed, typically through an executable. All the information from experiments, simulations, and sensors are all stored on a single machine. This provides maximum information security, however, it greatly limits the amount of work that can be performed. A common use for a stand-alone DTOP is in an energy producing plant. This example is more focused on the daily operation and predicting the needed controls under various circumstances. These types of use-cases require extremely high security and doesn't have a large number of simultaneous users.

The second method to access a DTOP is through a Local Area Network (LAN). This method is an expansion of the stand-alone by allowing access to the DTOP for multiple users on the same network. In addition to having multiple users, the LAN method also allows the utilization of distributed computing. If the site has a local high performance computer, this method can

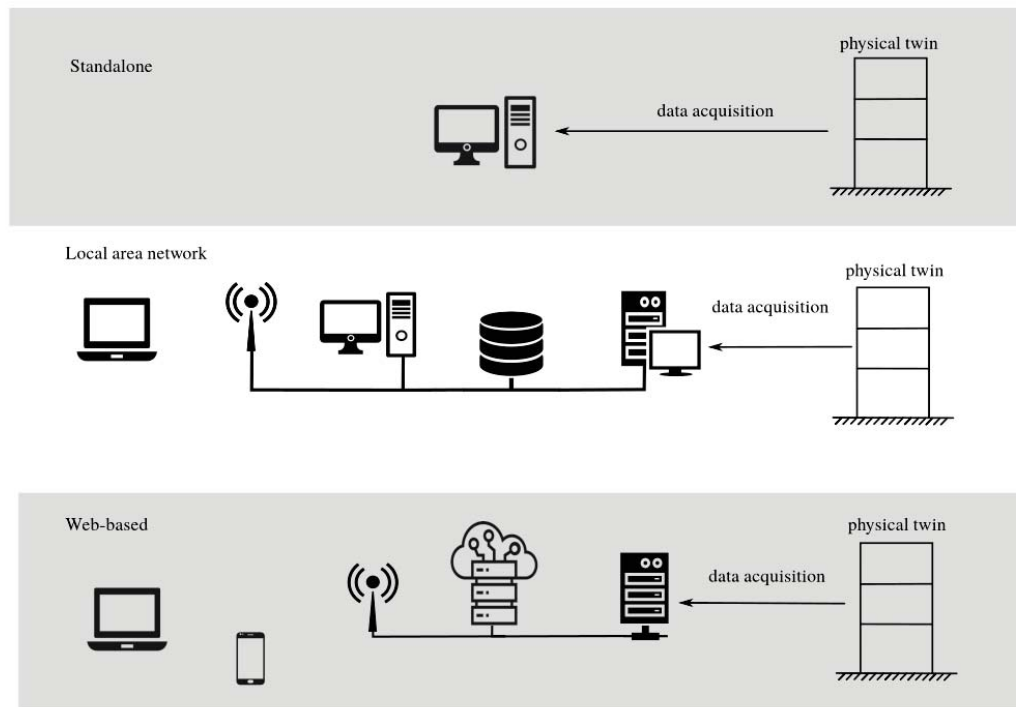

Figure 2: Different methods to access digital twins via a DTOP

utilise it in making predictions and other calculations. This method is an expected use case for the design and operation of complex systems. One example would be an aircraft, where there are multiple aspects being evaluated simultaneously, such as structural and electrical design/repair. While there is the ability for multiple users, this method also has high data security by only allowing people physically on the network to access this information.

The final method is the web-based DTOP. This greatly expands the number of possible users to anyone allowed access and internet access. Having this large accessibility encourages collaborative work and greatly expands the possibilities available. One such possibility is the ability to easily have remote sensors and monitoring a system after deployment. This method is particularly of interest for research systems, civil structures such as bridges, and large scale designs to incorporate multiple facilities at various locations.

4 Connectivity Example of Digital Twin and Experimental System

In order to demonstrate the connectivity aspects of a DTOP, an example DTOP is created using the demonstration system. This DTOP utilizes the web-based method since the testing and analysis are performed at separate locations due to social distancing requirements. To structure the web-based framework, two actions are performed. The first action is the utilization of the python code FLASK to create a webpage template to act as the user interface. FLASK uses python as a programming framework and HTML/CSS for visualization and navigation. This framework using FLASK can be used for any of the previously mentioned access methods (stand-alone, LAN, or web-based).

It is simple to utilise FLASK for a stand-alone or LAN version, but to use it as a web-based DTOP, a hosting service is required. This hosting can be done through a supporting organization, such as an University, or via a private host. For the second action of this example DTOP, a

service called Heroku is used to host the DTOP. Heroku was chosen for a few reasons including a free tier of hosting for demonstration purposes, virtual computations, and database hosting, but there are many other possible hosting services available that may fit other applications better.

There are two main simulations currently implemented in this DTOP, the first being a parametric beam finite element model. This simulation produces an ABAQUS run script then calls ABAQUS to run the simulation. The other simulation, and the main focus of this paper, is for post-processing the raw experimental data. A PostgreSQL database is utilized to store the raw experimental data and is implemented using the Heroku service.

To demonstrate this example DTOP, the main navigation page is displayed in Figure 3. This contains two main sections; The first section on the left side is a selection of the implemented simulations. This section allows the user to select which simulation they wish to perform. The other section on the right is an interactive visualization for the system of interest. This gives an “as-designed” geometric understanding of the system. One interesting aspect is that the extruded aluminium portions of the system are given directly from the manufacturer.

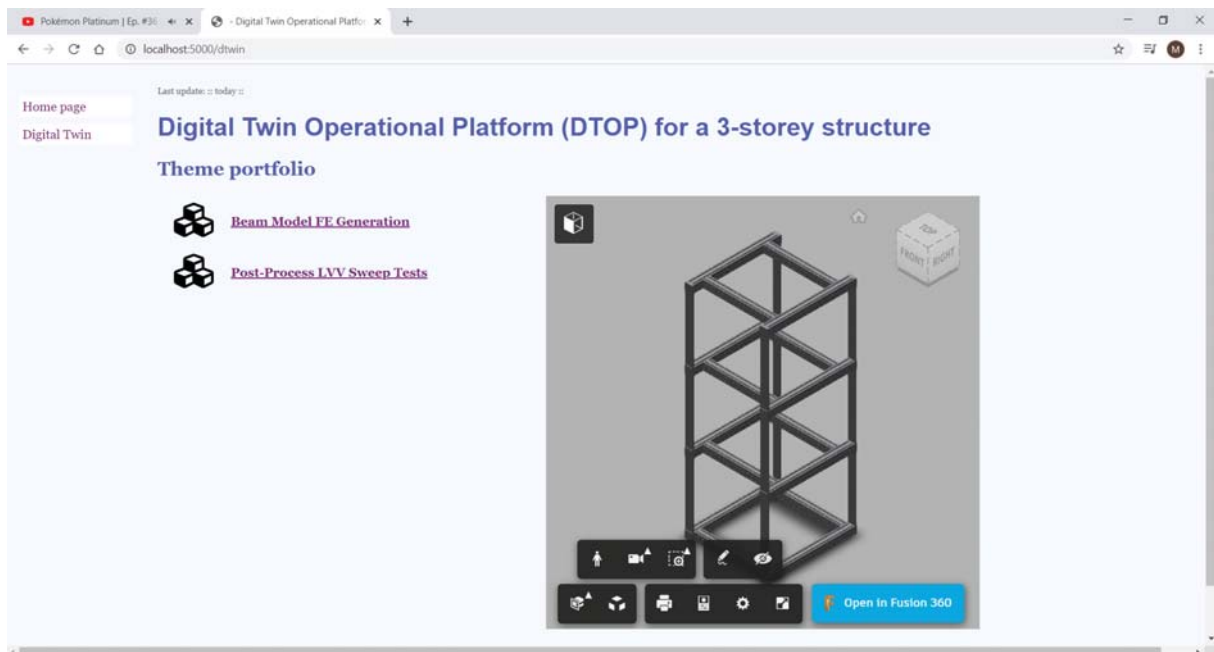

Figure 3: Main Navigation Page of DTOP

In the current implementation, there is no live streaming of the sensor information. This is primarily due to some of the proprietary software associated with controlling the environmental chamber and shaker. A prototype of streaming the sensor information is currently in development but is not the focus of this work. Instead, the data from the sensors is recorded then uploaded to the digital twin database. This upload is possible to implement within the DTOP, but currently is not to ensure a consistent data-structure. Currently, a separate python script is run that gathers the correct meta-data and stores that information and sensor data to the database.

For the post-processing aspect of the DTOP, there are two steps to perform this analysis. The first step is the selection of what experimental data to process. To aid the user with this selection, the DTOP queries the database to produce a list of available experimental tests that the user can select via a drop-down menu option. Once a test is selected, the next step is performing the

post-processing and visualization. This visualization is displayed to the user with an example shown in Figure 4. The results shown are for a test at 25°C with no added mass.

Figure 4: Post-processing page of DTOP

There are five main parts to the screen in Figure 4. The first part is an expression of the meta-data. This part gives users the testing parameters such as temperature and added mass, along with the testing date and name. Part 2 gives the scalar post-processing values. These values are the natural frequency and damping ratio for each of the three bending modes. The natural frequency is calculated via a peak picking routine and the damping is determined by a half-power method. Part 2 shows the values for these quantities by averaging all the excitation direction sensor results for the 3 repeated tests per configuration. Both of these are shown in greater details in Figure 5.

Part 4 allows for downloading the database entry onto the local drive, and can be seen in more detail in Figure 5c. This saves 6 pieces of information in a dictionary that is saved via a .npy file. These are lists containing the sensor names, time history, and PSDs. Additionally, it also saves the meta-data and vectors containing the time and frequency for the time history and PSD information. Part 3 of Figure 4, with a closer view in Figure 6, shows the auto Power Spectral Density (PSD) for a number of the sensors to denote some of the differences between sensors and tests. Since there are a large amount of sensors, this part is categorized based on the sensor location. In the current implementation, these sensors are categorized based on which floor they measure. The user can select which floor to visualize via the drop-down menu.

The final part is a measure of the variability for the calculated scalar post-processing values, specifically the natural frequencies. This shows a histogram of the calculated frequencies used in part 2 and a fitted Gaussian distribution to the same data. The first natural frequency is shown in Figure 7 with the histogram in blue and the fitted Gaussian distribution in red. This plot takes a total of 54 sensor readings to create this histogram.

Testing Parameters:

4.1 Added Benefits

Using a DTOP with an experimental system provides several benefits to both the testing engineer and the analyst. One of the greatest benefits is the data storage and access. In a traditional approach, the data is stored locally in a variety of formats depending on the software used and engineering preference. After the data is collected, it is then transferred to the analyst either via email or physical transfer such as with an USB removable drive. This requires the analyst to understand the format used by the test engineer and be able to transform it into a usable format for the analysis.

For a large amount of cases, the data is too large to send via email and the analyst is typically not at the testing location. In some cases, the analyst might be in a different country where the delivering of a physical transfer would introduce large amount of wasted time. Using a DTOP centralizes the data and allows access to an analyst at any location in an easy to understand format. This only requires the testing engineer to submit the test results to the database, and the analyst can investigate the results via the DTOP. After investigating the results, the analyst can ensure the accuracy of the tests, suggest additional testing configurations, and perform advanced calculations/predictions in a timely manner.

In addition to the efficiency increase, using a DTOP also greatly increases the collaborative nature of projects and increases visibility of the project for marketing purposes. Because the data is stored virtually, access can be granted to any collaborators regardless of physical location. In the same sense, the DTOP can be used for demonstrating the project potential, show preliminary results without the need to transfer information, and to give a live demonstration of the digital twin.

5 Conclusions/Remarks

This work demonstrates a case study of how an operational platform can benefit experimental operations through increased connectivity to analysts and simulations. The connectivity is based on the use of a web-based digital twin operational platform. This allows the experimentalist to upload experimental results and for an analyst to access this information via an easy to use interface with high time efficiency due to the reduced data transfer time.

This paper presents an example operational platform that gathers the experimental data from the database and performs post-processing on it from any device that has an internet connection. These calculations are performed virtually so there are no hardware requirements to view the data. This is particularly useful for demonstration purposes to present results without the need to ensure correct data transfer.

The operational platform also highly encourages collaborative works where researchers from different universities or companies are able to access and supplement all the collected simulation and experimental data. With all of these benefits, an operational platform, particularly for digital twin purposes, provides a useful user-interface for the collected data, perform additional simulations, directly interact with the physical system, and promote collaboration and efficiency

with both local and global partners.

Keywords: Performance-based Earthquake Engineering, Inelastic Systems, Structural Dynamics.

Abstract. *Performance-based earthquake engineering is becoming ever-more popular due to its capability to deliver structures that rationally meet society's need for a safe built environment. An important barrier to the application of this approach is the high computational demand required for providing detailed and accurate response characterization through nonlinear time history analysis. In this paper, an efficient adaptive fast nonlinear analysis (AFNA) algorithm is proposed to address this issue. This novel step-by-step integration scheme adaptively updates all solver configurations in real-time, including number of pseudo modes considered in the analysis, time step size, and potential nonlinear elements, in order to efficiently evaluate the nonlinear dynamic responses. In particular, in modeling potential inelasticity, a distributed plasticity model is considered to allow inelasticity to distribute along the length and height of the elements. The practicality and potential of the proposed algorithm are illustrated on a full scale archetype building subject to stochastic seismic excitations. The proposed algorithm is shown to be around an order of magnitude faster than traditional direct integration schemes while achieving a remarkable accuracy in both global response time histories and local hysteretic responses, therefore enabling efficient application of probabilistic performance-based design frameworks that often require repeated evaluation of nonlinear dynamic systems.*

1 INTRODUCTION

Performance-based earthquake engineering (PBEE) has gained immense interest in the past decades [1, 2, 3, 4, 5], and has recently been extended to wind engineering[6, 7, 8, 9, 10, 11, 12, 13, 14]. The popularity of PBEE can be traced back to its ability to meet society's desire for a safe built environment at reasonable economic cost. One of the key difficulties in the applications of PBEE in practice is the potentially significant computational demand associated with evaluating nonlinear responses of structural systems subject to extreme seismic events through nonlinear analysis. This computational demand can become intractable in the case of probabilistic PBEE based on stochastic simulation as such approaches generally require the repeated evaluation of the system. The most straightforward solution for this issue is to improve analysis efficiency by replacing traditional time consuming nonlinear time history analysis with computationally tractable alternatives. While approaches such as pushover analysis can meet the efficiency requirement, these approaches are generally incapable of capturing cumulative damage mechanisms or effects of higher modes [15, 16, 11], nor are they able to provide full time history responses.

Fast nonlinear analysis (FNA) [17] is a promising nonlinear time history analysis approach to overcome the aforementioned limitations. This approach keeps the concept of modal coordinate transformation and truncation, as in linear elastic analysis, which not only allows the equations of motion to be partially decoupled, such that more accurate and efficient piece-wise exact solutions can be used, but also enables the possibility to exclude unnecessary modes to lower the dimensionality of the problem for better efficiency. Based on a pre-designated set of elements that are expected to be nonlinear, this approach only considers these elements during the solution process, and thus enjoys significant gains in computational efficiency. However, the need to pre-designate elements that will experience inelasticity greatly reduces the general applicability of the FNA approach. In this work, an adaptive FNA (AFNA) is developed to address this limitation, while preserving almost all the advantages of the FNA approach. The resulting approach provides remarkably accurate full time history results at a fraction of the computational demand required by state-of-the-art direct integration schemes. The proposed approach adjusts the solver configurations, e.g. number of pseudo modes, time step size, and potential nonlinear elements, in real-time based on the state of the system, such that unnecessary computations and the need of a pre-designated set of potential nonlinear elements are eliminated. In modeling inelasticity, a distributed plasticity model is considered in this work, allowing inelasticity to distribute along the length and depth of the elements. A full scale archetype building subject to stochastic seismic excitations is presented to illustrate the efficiency and potential of the proposed approach.

2 PROBLEM SETUP

A structural system subject to dynamic load effects can in general be modeled as a multi-degree-of-freedom (MDOF) system subject to stochastic excitations:

$$M\ddot{\mathbf{u}}(t) + C\dot{\mathbf{u}}(t) + \mathbf{f}_{nl}(t) = \mathbf{F}(t) \quad (1)$$

where M , C are respectively the structural mass and damping matrices; $\mathbf{u}(t)$ is the displacement vector while $\dot{\mathbf{u}}(t)$ and $\ddot{\mathbf{u}}(t)$ are its first and second derivatives with respect to time, i.e. the velocity and acceleration vectors; $\mathbf{F}(t)$ is the external force vector while, considering a fiber-based discretization, $\mathbf{f}_{nl}(t)$ is the following nonlinear force vector:

$$\mathbf{f}_{nl}(t) = \mathbf{B}^T \mathbf{W} \boldsymbol{\sigma}(t) \quad (2)$$

where \mathbf{B} is the compatibility matrix transforming responses at global degree of freedoms (DOF) to fiber responses; \mathbf{W} is a diagonal matrix collecting multiplication factors to perform numerical integration for each of the fiber stress, typically obtained from the integration weights, fiber areas, as well as element lengths; and $\boldsymbol{\sigma}(t)$ is the vector that collects the fiber stress at all integration points of finite element discretization.

3 The adaptive fast nonlinear analysis method

In this section, the AFNA method is developed by making the solver configurations, including time step size, number of pseudo modes, and set of potential nonlinear elements, of the FNA approach adaptive in time. This eliminates the requirement of a pre-designated set of potential nonlinear elements. Methods are outlined to this end that do not compromise the original merits of the FNA approach.

3.1 The fast nonlinear analysis method

By moving the nonlinear force vector $\mathbf{f}_{\text{nl}}(t)$ to the right hand side, and introducing an pseudo positive definite stiffness matrix \mathbf{K}_e to prevent singularity, Equation (1) can be rewritten as:

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}_e\mathbf{u}(t) = \mathbf{F}(t) + \mathbf{K}_e\mathbf{u}(t) - \mathbf{f}_{\text{nl}}(t) \quad (3)$$

It should be noted that, despite how the pseudo stiffness matrix \mathbf{K}_e can be any arbitrary positive definite matrix, it is recommended to be taken as the initial elastic stiffness matrix of the structural system. The P-Delta effect can be further taken into account by considering a reduced stiffness matrix [17, 18].

By denoting $\mathbf{f}_{\text{nlc}}(t) = \mathbf{K}_e\mathbf{u}(t) - \mathbf{f}_{\text{nl}}(t)$ as the nonlinear correction force, Equation (3) can be decoupled on the left hand side using the modal approach, as follows:

$$\boldsymbol{\Theta}\ddot{\mathbf{q}}(t) + \boldsymbol{\Lambda}\dot{\mathbf{q}}(t) + \boldsymbol{\Omega}\mathbf{q}(t) = \hat{\mathbf{F}}(t) + \hat{\mathbf{f}}_{\text{nlc}}(t) \quad (4)$$

where $\mathbf{q}(t)$ is the modal displacements while $\dot{\mathbf{q}}(t)$ and $\ddot{\mathbf{q}}(t)$ are its first and second derivatives with respect to time; $\boldsymbol{\Theta} = \boldsymbol{\Phi}^T \mathbf{M} \boldsymbol{\Phi}$, $\boldsymbol{\Lambda} = \boldsymbol{\Phi}^T \mathbf{C} \boldsymbol{\Phi}$, and $\boldsymbol{\Omega} = \boldsymbol{\Phi}^T \mathbf{K}_e \boldsymbol{\Phi}$ are respectively the diagonal generalized mass, damping and stiffness matrices; $\boldsymbol{\Phi}$ is the pseudo mode matrix consisting of the generalized eigenvectors of \mathbf{M} and \mathbf{K}_e . It is worth noting that the generalized masses representing inertial effects can be non-zero or zero, which correspond to dynamic or static modes respectively. In practice, higher order dynamic modes can be considered as static modes by ignoring their inertial effects in order to enhance both the efficiency and stability of dynamic solvers. In Equation (3), $\hat{\mathbf{F}}(t) = \boldsymbol{\Phi}^T \mathbf{F}(t)$ is the generalized force vector; $\hat{\mathbf{f}}_{\text{nlc}}(t) = \boldsymbol{\Phi}^T \mathbf{f}_{\text{nlc}}(t)$ is the generalized nonlinear correction force vector, which can be evaluated as:

$$\hat{\mathbf{f}}_{\text{nlc}}(t) = \boldsymbol{\Psi}^T \mathbf{W} [\boldsymbol{\sigma}_e(t) - \boldsymbol{\sigma}(t)] \quad (5)$$

where $\boldsymbol{\Psi} = \mathbf{B} \boldsymbol{\Phi}$ is the modal strain matrix; $\boldsymbol{\sigma}_e(t)$ is the fiber stress elastic predictor for all fibers evaluated with the elastic modulus and fiber strains $\boldsymbol{\epsilon}(t)$ as:

$$\boldsymbol{\epsilon}(t) = \boldsymbol{\Psi} \mathbf{q}(t) \quad (6)$$

It can be noted that when a fiber stress is in the linear elastic range, it does not contribute to $\hat{\mathbf{f}}_{\text{nlc}}(t)$, and thus can be ignored. In practice, the FNA only considers a pre-designated set of potential nonlinear elements, such that Equation (5) can be evaluated with much higher efficiency if only a portion of the elements are potentially nonlinear.

The FNA solves Equation (3) in a step by step manner, with a step size of Δt , and starts with an initial guess solution at each of the time step through the Taylor expansion:

$$\begin{aligned} \mathbf{q}^{(0)}(t + \Delta t) &= \mathbf{q}(t) + \Delta t \dot{\mathbf{q}}(t) + \frac{\Delta t^2}{2} \ddot{\mathbf{q}}(t) \\ \dot{\mathbf{q}}^{(0)}(t + \Delta t) &= \dot{\mathbf{q}}(t) + \Delta t \ddot{\mathbf{q}}(t) \end{aligned} \quad (7)$$

where the superscripts on the left hand side indicates the number of iterations. At the k th iteration, $\mathbf{q}^{(k)}(t + \Delta t)$ and $\dot{\mathbf{q}}^{(k)}(t + \Delta t)$ will be used to determine fiber strains and subsequently fiber stresses $\sigma_e(t)$ and $\sigma(t)$ through the fiber material constitutive law. Finally, $\hat{\mathbf{f}}_{\text{nle}}^{(k)}(t)$ can be estimated through integration. The solution at the next iteration, i.e. $\mathbf{q}^{(k+1)}(t + \Delta t)$ and $\dot{\mathbf{q}}^{(k+1)}(t + \Delta t)$, is obtained by the piece-wise exact solution [19] with the external loads considered as $\hat{\mathbf{F}}(t) + \hat{\mathbf{f}}_{\text{nle}}^{(k)}(t)$. This iterative process continues until convergence is reached. The algorithm performs the process described above for each time step over the time range of interest to provide response time histories.

3.2 The adaptive solution procedure

The main limitation of the FNA approach is the requirement of a pre-designated set of potential nonlinear elements. The AFNA presented in this section addresses this issue by determining the potential nonlinear elements during analyses in real-time. This feature allows AFNA to detect the existence of nonlinear elements, and further enables AFNA to shift between linear elastic and nonlinear solvers with different time steps and number of pseudo modes.

In the implementation, modes with natural frequencies greater than a threshold of interest, f_{st} , will be considered as static by ignoring their generalized mass or inertial effect, while the remaining modes are considered as dynamic. In solving the response time histories, the algorithm first assumes that the structural system is linear elastic and moves ahead with a relatively large time step $\Delta^L t$ while considering only the dynamic modes. At the end of each time step $\Delta^L t$, fiber strains and stresses are determined based on the estimated solutions $\mathbf{q}(t + \Delta^L t)$ and $\dot{\mathbf{q}}(t + \Delta^L t)$ for the assumed linear elastic step. The algorithm will proceed to the next time step if all fibers remain in their linear elastic loading/unloading/reloading range. Otherwise, the algorithm moves back to the previous time step t and solves until reaching the time $t + \Delta^L t$ using a smaller time step $\Delta^S t = \Delta^L t / \eta$, in which η is an integer such that the $\Delta^S t$ is not greater than half the natural period of the highest dynamic mode T_{\min} , i.e. $\Delta^S t \leq T_{\min} / 2$, to ensure stability of the approach. In general, the choice of $\eta = 4$ will provide a good balance between accuracy and efficiency. Within each small time step $\Delta^S t$ the algorithm first forms a list of potential nonlinear elements by checking the fiber strains or stresses based on the predicted solutions of Equation (7). The solution process then enters the iterative scheme as in the FNA with all modes considered, if the list of potential nonlinear elements is not empty. Otherwise, it proceeds to the next small time step using the piece-wise exact solution considering the dynamic modes of the larger time step phase without iteration. Within this context, when the algorithm reaches $t + \Delta^L t$, the solution process then proceeds to the next time step considering the initial step size $\Delta^L t$ and starts another adaptive process if necessary. The entire process is then terminated when reaching the end of the time sequence, providing a full range of inelastic response histories for structures subject to dynamic external loads. The overall solution process is illustrated in the flow chart of Figure 1.

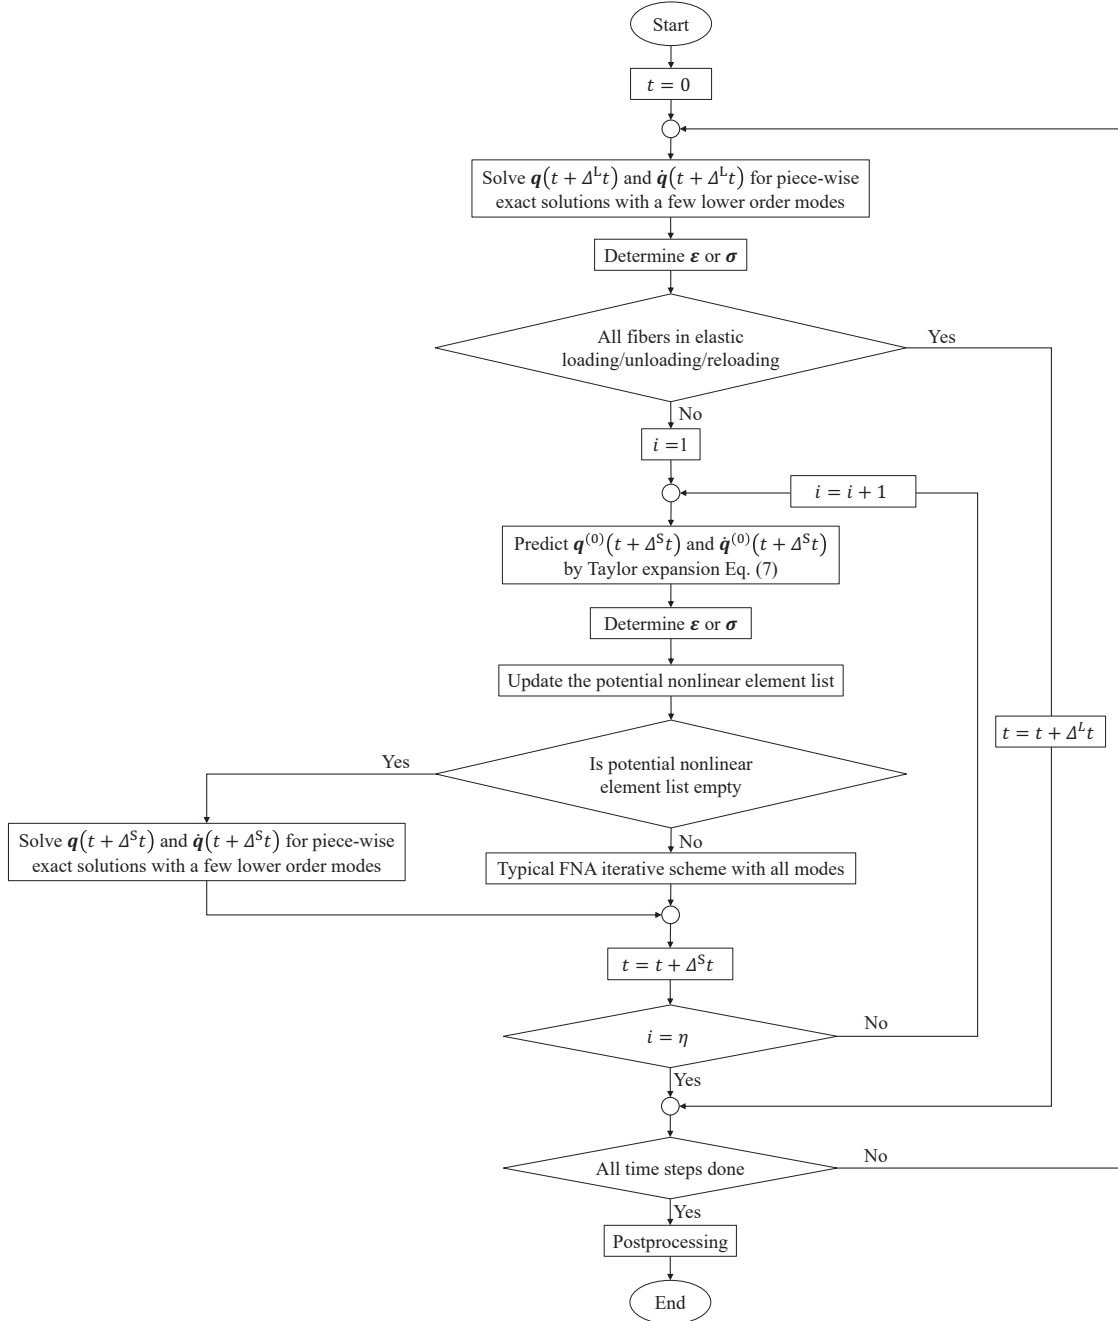

Figure 1: Flowchart illustrating the steps of the AFNA algorithm.

4 CASE STUDY

A 37-story 6 span steel moment resisting frame assumed to be located in downtown San Francisco is considered in this case study. The width of each span is 5 m while the story height is 6 m for the first floor and 4 m for the remaining floors, leading to a total height of 150 m. Box sections and W24 sections are considered respectively for columns and beams, with section sizes summarized in Table 1. The elastic modulus and the yield stress are respectively taken as $E_s = 200$ GPa and $\sigma_y = 355$ MPa. The structural mass is modeled to be lumped at each floor considering combined self and carried mass of 100 kg/m^3 , and super dead load of 23.5 kN/m .

Floor	Beams	Columns*
1-20	W 24 \times 192	50 ² \times 2.5
21-30	W 24 \times 103	40 ² \times 2.0
31-40	W 24 \times 103	35 ² \times 1.8

*(outer side size)² \times (wall thickness)

Table 1: Sections with dimensions in (cm).

Figure 2: The two synthetic ground motion samples used in the case study: (a) GM1 (b) GM2.

The structure is assumed to be subjected to a 10% exceedance probability in 50-year seismic hazard. Synthetic ground motions are generated via the model proposed by Rezaeian and Der kiureghian [20], with the filter frequency and damping optimized to fit the target spectrum constructed from the USGS unified hazard tool [21] for the building site, with the rest of the parameters chosen to be consistent with Loma Prieta records (Moment magnitude = 6.93, Rupture distance = 18.3 km). The two representative synthetic ground motion (GM) samples used in this work are shown in Figure 2. For comparison, nonlinear time history analyses based on the GM samples was carried out by direct integration in OpenSees. Elements experiencing inelasticity subject to the two GM samples are marked in red in Figure 3. It can be seen that for the two cases (GM1 and GM2) the structure experiences, respectively, moderate and significant nonlinearity.

Figure 3: Elements experiencing nonlinearity (in red): (a) GM1 (b) GM2.

All results were estimated using a machine with Intel(R) Core(TM) i7-8750H CPU @ 2.20GHz processor and 16 GB RAM. The comparison in terms of computational times is reported in Table 2. It is seen that the AFNA is around an order of magnitude faster than the state-of-the-art nonlinear analysis approach used in OpenSees for GM1, i.e. for moderate nonlinearity. Despite how a lower gain in efficiency is achieved for GM2 (significant nonlinearity), the AFNA is still notably faster. It should also be noted that the AFNA approach was programmed in Matlab and, unlike the OpenSees solvers, was not fully optimized for computational efficiency. Thus, based on the results, the AFNA algorithm is expected to be around an order of magnitude faster than the direct integration even in the case of significant nonlinearity.

The comparison between the displacements under GM1 and GM2 at the 10th, 20th, and 37th floor obtained from direct integration and the AFNA approaches are reported in Figure 4. A perfect correspondence can be observed over the entire time history. In addition, Figure 5 reports the comparison between the fiber strain and stress time histories and hysteretic curves for an extreme fiber of the exterior first floor column for the two ground motions. It is seen that the AFNA approach still achieves remarkable accuracy, even for highly localized responses, e.g. nonlinear fiber strains or stresses, which are generally challenging to compute accurately and efficiently due to the potentially large number of modes involved. Lastly, it is worth noting that, despite how an elastic perfectly plastic (EPP) material was considered in the case study,

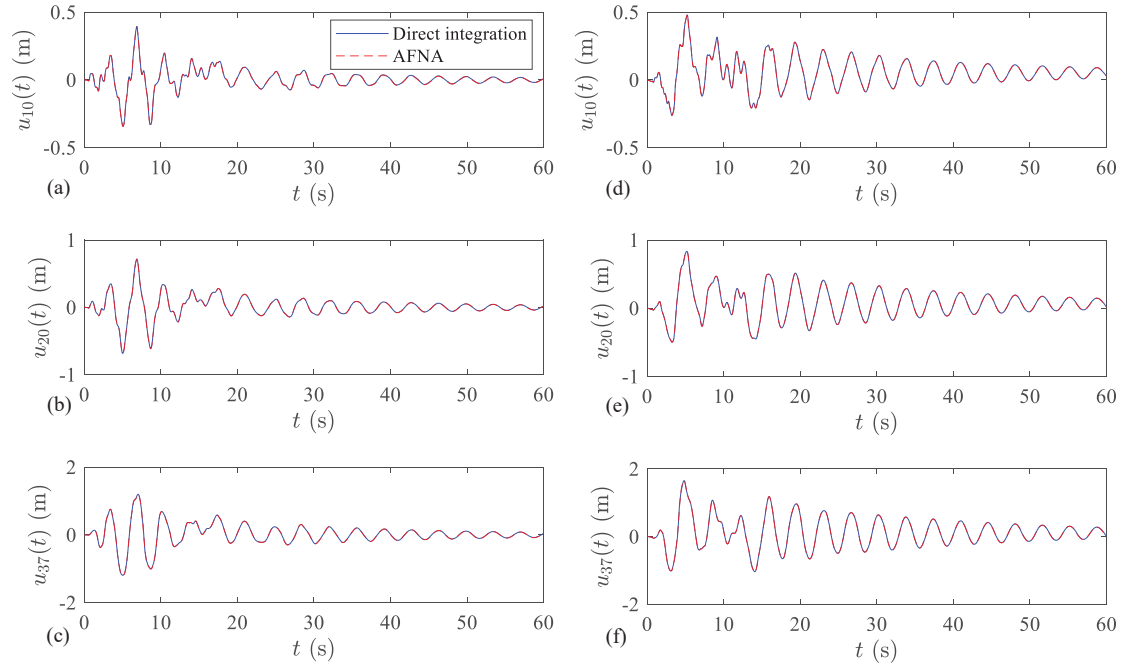

Figure 4: Comparison of displacements obtained by direct integration and AFNA for: GM1 at (a) the 10th floor, (b) the 20th floor (c), the 37th floor; and for GM2 at (d) the 10th floor, (e) the 20th floor, (f) and the 37th floor.

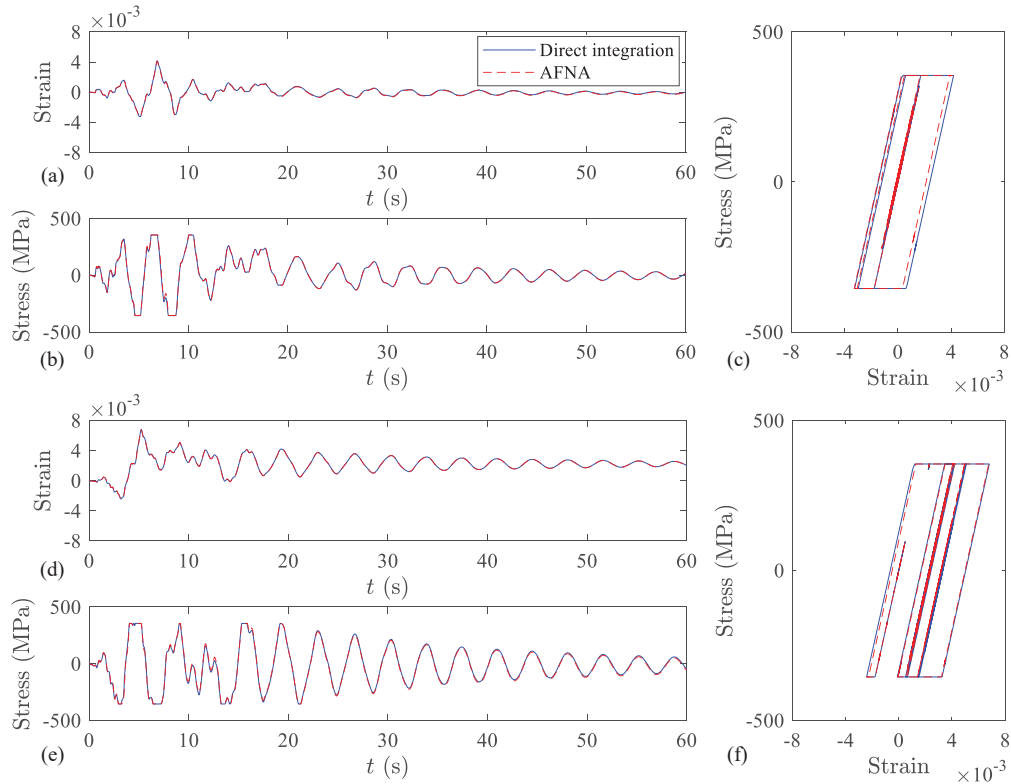

Figure 5: Extreme fiber responses for the exterior first floor column. Comparison between direct integration and AFNA: (a) strain time history for GM1; (b) stress time history for GM1; (c) hysteric curve for GM1; (d) strain time history for GM2; (e) stress time history for GM2; (f) hysteric curve for GM2.

Ground motions	GM1	GM2
Computational time: Direct integration (s)	64.58	63.90

the proposed algorithm can be used for materials with general constitutive relations.

5 CONCLUSION

In this work, a highly efficient adaptive fast nonlinear analysis (AFNA) algorithm was developed, as a computational efficient alternative to the direct integration approach to provide full time history responses for computationally intensive engineering applications, e.g. performance-based earthquake engineering. The algorithm implements the modal analysis concept that partially decouples the equation of motions, such that piece-wise linear solutions are applicable. Meanwhile, the algorithm updates the potential nonlinear elements, time step size, as well as the number of pseudo modes to be considered in real-time during the solution process. In particular, in defining the structural model, fiber-based distributed plasticity models were considered. The results show that the AFNA algorithm is capable of accurately estimating both the global response time histories and local hysteretic behaviors with around an order of magnitude less computational time as compared to state-of-the-art direct integration approaches. Finally, it is worth noting that even though only seismic input was considered in the case study, the proposed algorithm can also be directly applied to cases subject to stochastic wind loads. In this case, the algorithm is expected to provide even greater time savings, as typically less nonlinearity is experienced by structures subject to winds. Overall, the notable efficiency and accuracy of the proposed AFNA approach illustrates its potential in computationally intensive applications, such as probabilistic performance-based design frameworks, that require repeated evaluation of nonlinear dynamic systems.

Abstract

The increasing availability of strong motion records makes the use of real accelerograms an attractive option for a proper definition of the input motions in the dynamic analysis of structural and geotechnical systems. Despite different real accelerograms selection procedures have been proposed in the literature, there are situations in which it may be impossible to select a suitable code-required number of accelerograms without applying large scale factors which distort the actual characteristics of selected motions leading to unrealistic input. In these situations, the use of artificial accelerograms could represent a possible alternative.

A novel procedure for generating fully non-stationary spectrum compatible artificial accelerograms, is presented in this paper.

Depending on the aim to be achieved, it is possible to obtain the spectrum-compatibility between the generated samples and the target action in terms of response spectrum or Fourier spectrum, using two different corrective Power Spectral density function terms.

A numerical application shows the validity of the generation procedure and the accuracy of the model in reproducing realizations with statistical characteristics similar to those of the target motion.

Keywords: Artificial accelerograms, Fully non-stationary stochastic process, Real ground motion records, Spectrum-Compatibility.

1 INTRODUCTION

The worldwide increasing availability of strong motion records makes the use of actual acceleration time-histories an attractive option to properly define the input motions for dynamic analysis of both structural and geotechnical (*S&G*) systems [1,2].

The characteristics of the expected ground motion at a given site are strongly affected by the possible coupling between the frequency content of the input ground motion and the frequencies of vibration of the soil deposit which, in turn, depend on the non-linear behaviour exhibited by soils when subjected to cyclic and dynamic loadings. Consequently, soil mechanical properties considerably influence the site response to the motion imposed by an earthquake at the bedrock level and, thus, should be properly accounted for in the definition of the interval of periods of interest for the accelerogram selection [3].

In this vein and with reference to one dimensional site response analysis problems, a method for the selection of proper sets of input ground motions accounting for most of these relevant issues has been proposed in Ref. [4]; Refs[5] and [6] showed that the soil heterogeneity in terms of shear wave velocity profile and the soil non-linear behaviour under cyclic loading significantly affect: *i*) the interval of vibration periods relevant for the accelerogram selection; *ii*) the characteristics of the selected input motions. However, despite the availability of earthquake records, frequently it is not possible to find sets of time histories that satisfy the compatibility criteria between the selected records and a target code-prescribed response spectrum, without applying large scale factors to each record of the set [7]. For this reason, different numerical procedures capable to generate artificial accelerograms with energy and frequency content consistent with those of actual acceleration records have been proposed in literature.

In [8], the authors proposed a deterministic modification method based on the harmonic wavelet transform, aimed at matching the elastic response spectrum of a given accelerogram to a target code-prescribed elastic response spectrum, while in [9], a novel formulation based on the wavelet transform has been used for the stochastic generation of fully non-stationary spectrum-compatible accelerograms. In [10] the evolutionary power spectra of seismic accelerograms, estimated using the method of separation, have been used to produce artificial accelerograms compatible with given recordings while, an iterative procedure based on the spectral representation of stochastic processes in which the ground motion is constituted by two waveforms, a real record and an artificial accelerogram, has been proposed in [11].

A new method for generating fully non-stationary spectrum compatible artificial accelerograms, that requires only the knowledge of the numbers of peaks, zero level up-crossings and the value of the total energy of the target signal, is presented in this paper.

Depending on the aim to be achieved, it is possible to obtain the spectrum-compatibility between the generated samples and the target action in terms of response spectrum or Fourier spectrum, using two different corrective Power Spectral density function (*PSD*) terms.

The proposed procedure requires the following steps: *i*) subdivide a selected target accelerogram in many contiguous time intervals in which appropriate unimodal Power Spectral density functions and polynomial form of modulating function have been chosen to obtain the same energy and frequency content of real accelerograms expected at the site of interest, applying the stochastic generation method recently proposed in [12]; *ii*) evaluate the mean elastic response spectrum and the Fourier spectrum of a set of generated fully non-stationary accelerograms samples; *iii*) satisfy the compatibility of so determined spectra to target ones by means of an iterative procedure.

A numerical application shows the validity of the spectrum-compatible generation procedure and the accuracy of the proposed model in reproducing realizations with statistical characteristics similar to those of the target motion both in time and frequency domain.

2 EVOLUTIONARY POWER SPECTRAL DENSITY FUNCTION METHOD FOR MODELLING SEISMIC ACTION

The procedure for generating a set of *fully non-stationary* artificial accelerograms compatible with a target spectrum and having the same characteristics of an earthquake induced ground motion \ddot{U}_g , consist of the following four steps:

1) divide the time duration $0 \div T_D$ of the analysed accelerogram \ddot{U}_g , in n contiguous time intervals of amplitude $\Delta T_k = t_k - t_{k-1}$ ($k=1, 2, \dots, n$), in each of which a uniformly modulated process is introduced as the product of a deterministic modulating function, $a(t)$, times a stationary zero-mean Gaussian sub-process $X_k(t)$, whose power spectral density (PSD) function $G_{X_k}(\omega)$ is filtered by two Butterworth filters:

$$G_{X_k}(\omega) = \beta_k \left(\frac{\omega^2}{\omega^2 + \omega_{H,k}^2} \right) \left(\frac{\omega_{L,k}^4}{\omega^4 + \omega_{L,k}^4} \right) \frac{\rho_k}{\pi} \left(\frac{1}{\rho_k^2 + (\omega + \Omega_k)^2} + \frac{1}{\rho_k^2 + (\omega - \Omega_k)^2} \right); \quad k=1, \dots, n \quad (1)$$

where β_k is a coefficient, given in closed form solution in [12], that makes unitary the variance of each sub-process $X_k(t)$ while the predominant circular frequency Ω_k and the frequency bandwidth ρ_k can be evaluated by the following expressions:

$$\Omega_k \cong \frac{2\pi N_{0,k}^+}{\Delta T_k}; \quad \rho_k \cong \frac{\pi N_{0,k}^+}{2\Delta T_k} \left[\pi - 2 \frac{N_{0,k}^+}{P_k} \right] \quad (2)$$

being P_k and $N_{0,k}^+$ respectively the number of *maxima* and of *zero-level up-crossings* of each k -th part in which the target accelerogram is subdivided;

2) evaluate the modulating function $a(t)$ by least-square fitting the *cumulative expected energy function* of the stochastic process to the cumulative energy function $E_{\ddot{U}_g}(t)$ of the target accelerogram subdivided in three-time intervals, according to [12]:

$$a(t) = \sum_{j=1}^2 \bar{a}_j(t) \mathbb{W}(t_{j-1}, t_j) + a(t_2) \exp \left[\frac{t - t_2}{T_D - t_2} \ln \left(\frac{|\ddot{U}_g(T_D)|}{a(t_2)} \right) \right] \mathbb{W}(t_2, t_3). \quad (3)$$

being $\mathbb{W}(t_{j-1}, t_j) = \mathbb{U}(t - t_j) - \mathbb{U}(t - t_{j-1})$ the window function and $\mathbb{U}(t)$ the unit step function;

3) generate the i^{th} *fully non-stationary* sample of the stochastic process $F_0^{(i)}(t)$ via the formula:

$$F_0^{(i)}(t) = a(t) \sqrt{2\Delta\omega} \left[\sum_{k=1}^n \sum_{r=1}^{m_N} \mathbb{W}(t_{k-1}, t_k) \sin \left(r \Delta\omega t + \theta_r^{(i)} \right) \sqrt{G_{X_k}(r \Delta\omega)} \right] \quad (4)$$

$\theta_r^{(i)}$ being the random phase angles, uniformly distributed over the interval $[0, 2\pi]$ and m_N being the number of parts in which the k -th PSD function $G_{X_k}(\omega)$ is discretized with a $\Delta\omega$ frequency sampling interval;

4) obtain the spectrum-compatibility reducing the gap between the mean spectrum of the generated samples $\bar{S}^{(j-1)}(\omega, \zeta_0)$ and the target one $S^{(T)}(\omega, \zeta_0)$, through the introduction of a corrective iterative *PSD* function $\bar{G}_{X_k}^{(j)}(\omega)$:

$$\bar{G}_{X_k}^{(j)}(\omega) = \bar{G}_{X_k}^{(j-1)}(\omega) \frac{S^{(T)}(\omega, \zeta_0)^2}{\bar{S}^{(j-1)}(\omega, \zeta_0)^2} \quad (5)$$

being $\bar{G}_{X_k}^{(0)}(\omega) = 1$ [14] and ζ_0 the viscous damping.

According to the formulation described in [13], the generic spectrum-compatible sample can be generated as:

$$\bar{F}_0^{(i)}(t) = a(t) \sqrt{2\Delta\omega} \left[\sum_{k=1}^n \sum_{r=1}^{m_N} \mathbb{W}(t_{k-1}, t_k) \sin(r \Delta\omega t + \theta_r^{(i)}) \sqrt{\bar{G}_{X_k}^{(j)}(r \Delta\omega) G_{X_k}(r \Delta\omega)} \right]. \quad (6)$$

2.1 Spectrum-compatibility

Depending on the purposes of the accelerogram generation procedure, the spectrum compatibility can be checked against the following targets:

- i) the pseudo acceleration response spectrum $S_R^{(T)}(\omega, \zeta_0)$ of the target accelerogram;
- ii) the Fourier spectrum $S_F^{(T)}(\omega)$ of the target accelerogram;
- iii) the code-prescribed elastic response spectrum $S_C^{(T)}(\omega, \zeta_0)$.

To achieve the Fourier-spectrum compatibility $S^{(T)}(\omega, \zeta_0) = S_F^{(T)}(\omega)$, the corrective iterative *PSD* function $\bar{G}_{X_k}^{(j)}(\omega)$ term can be particularized as follows:

$$\bar{G}_{X_k}^{(j)}(\omega) = \bar{G}_{X_k}^{(j-1)}(\omega) \frac{S_V^{(T)}(\omega, 0)^2}{\bar{S}_V^{(j-1)}(\omega, 0)^2} \quad (7)$$

being $S_V^{(T)}(\omega, 0)$ and $\bar{S}_V^{(j-1)}(\omega, 0)$ the velocity response spectra for $\zeta_0 = 0$.

3 NUMERICAL APPLICATION

In this section, in order to verify the accuracy of the proposed method, two different sets of one hundred artificial accelerograms spectrum-compatible with the pseudo acceleration response spectrum and the Fourier spectrum of the target accelerogram, have been generated.

3.1 Target accelerogram

The North-South component of the time history recorded at Vasquez Rocks Park ($R_{JB} = 23.1$ km [15]) during the $M_w = 6.7$ 1994 Northridge earthquake has been used as target accelerogram.

The selected accelerogram, having an overall duration $T_D = 36.6$ s and a sampling interval $\Delta t = 0.02$ s, has been recorded by a station with an average shear wave velocity in the upper 30 m equal to $V_{s,30} = 996$ m/s.

The target ground motion is characterized by a peak ground acceleration $PGA = 0.132$ g, a total intensity equal to $I_0 = 1.9$ m²/s³, a significant strong motion duration (i.e. interval of time elapsed between the 5% and 95% of I_0) $SMD = 7.3$ s and a total number of zero-level up-crossings and of peaks equal to $N_0^+ = 196$ and $P_0 = 212$, respectively.

As highlighted in [12], to obtain accurate results, the analysed accelerogram must be subdivided into n time intervals, each of which containing a number of *zero level up crossings* at least equal to one; consequently, in this application, the target accelerogram is subdivided in 73-time intervals with a constant time step of 0.5 s.

Further details about the parameters used to characterize the modulating function $a(t)$ and the *PSD* function $G_{X_k}(\omega)$ associated with each time interval, have been detailed in [13].

3.2 Spectrum compatibility

According to the procedure described in Section 2, a set of one hundred artificial accelerograms has been generated by using Eq. (4).

Then, to satisfy the spectrum compatibility in terms of pseudo acceleration response spectrum (*RSC*) or Fourier Spectrum (*FSC*), the iterative procedure has been applied four times and two different sets of one hundred accelerograms, have been obtained by Eq. (6).

Figure 1 shows a comparison between the time history of the target accelerogram and the i -th generated sample $\bar{F}_0^{(i)}(t)$, after 4 iterations, using the pseudo acceleration response spectrum compatibility (*RSC*) model (a) and the Fourier spectrum-compatibility (*FSC*) model (b). In both cases the variation in amplitude of the generated samples appears to be preserved in the time domain.

In Figure 2, the mean value of the cumulative energy function $I_0(t)$ and the cumulative *zero level up crossing* function $N_0^+(t)$ of the generated samples applying the pseudo acceleration response spectrum compatibility (*RSC*) model or the Fourier spectrum compatibility (*FSC*) model, after 4-th iterations, have been compared with the trend of the target functions.

In Figure 3 and 4 the average acceleration response spectrum $Sa(T)$ and the average Fourier spectrum module $|\mathcal{F}[\ddot{U}_g(t)]|$ of the two sets of artificial accelerograms, generated after 4 iterations by the *RSC* and *FSC* model, are compared with the corresponding target spectrum, respectively.

Figure 1: Comparison among the selected accelerogram (black line) and the corresponding i -th generated sample by the proposed fully non-stationary spectrum-compatible model, after 4 iterations: a) pseudo acceleration response spectrum-compatibility (*RSC*) model, b) Fourier spectrum-compatibility (*FSC*) model.

Figure 2: Comparison among the cumulative energy function (a) or cumulative zero level up crossing function (b) between the *target* accelerogram and the corresponding mean cumulative functions of the 100 samples, evaluated using *RSC* model and the *FSC* model, after 4-th iterations.

Figure 3: Comparison between the pseudo acceleration response spectrum and the mean response spectra of the 100 samples, evaluated using the *RSC* model and *FSC* model after 4-th iterations.

Figure 4: Comparison among the Fourier spectrum module of the selected accelerogram and the mean Fourier spectrum module of the generated sample, evaluated after 4 iterations by the: a) *RSC* model, b) *FSC* model.

From the observation of the numerical results obtained in the time and frequency domain, it emerges that:

- the use of the pseudo acceleration response spectrum-compatibility (*RSC*) model leads to outcomes statistically closer to those of the target one in terms of cumulative energy function $I_0(t)$ and pseudo-acceleration response spectrum $Sa(T)$ respect to the trends obtained by the application of the *FSC* model;
- the application of the Fourier-compatibility (*FSC*) model allows to obtain samples having an average *zero level up crossing function* $N_0^+(t)$ and Fourier spectrum closer to target one trend respect to those evaluated though the *RSC* model.

4 CONCLUSIONS

In this paper, a new procedure for generating fully non-stationary artificial spectrum-compatible artificial accelerograms, has been presented.

Firstly, the target accelerogram is subdivided in many contiguous time intervals in which the modulating and the unimodal Power Spectral density functions have been evaluated to obtain an average trend of the cumulative energy function $I_0(t)$ and *zero-level up crossing function* $N_0^+(t)$ very close to the ones of the target accelerogram.

Then, depending on the type of spectrum compatibility to be achieved (response spectrum compatibility or Fourier spectrum compatibility), an iterative procedure based on the use of different corrective iterative *PSD* function terms, has been implemented.

The numerical results show that using the acceleration response spectrum compatible (*RSC*) model, the generated samples have been characterized by an average cumulative energy function and pseudo-acceleration response spectrum very close to those of the target one, while the use of the Fourier spectrum model (*FRC*) leads to samples having an average *zero level up crossing function* and Fourier spectrum in good agreement with the target one.

Abstract

This paper presents an extension of the Proper Orthogonal Decomposition method (POD) to nonlinear dynamic analysis of reinforced concrete multistory frame structure where the material nonlinearity is modeled by the multi-fiber section. To test the effectiveness of this approach, we first perform a nonlinear dynamic analysis under a seismic excitation using a direct implicit time integration scheme. Then, based on structural response observations, POD modes were extracted and used to reduce the structural system subjected to different earthquakes. A comparison was made between full model and reduced model analysis in order to assess the effectiveness of this technique.

Keywords: Reinforced concrete beam, Material nonlinearity, Multi-fiber section, Dynamic analysis, Reduced model, Proper Orthogonal Decomposition.

1 INTRODUCTION

This paper presents an extension of the Proper Orthogonal Decomposition method (POD) to nonlinear dynamic analysis of reinforced concrete multistory frame structure where the material nonlinearity is modeled by the multi-fiber section.

The multi-fiber section model consists in dividing the structural element cross section into a set of longitudinal fibers. Each fiber is made up of a single material and has the potential to undergo nonlinear inelastic longitudinal deformation according to the uniaxial stress-strain behavior of its corresponding material [1-4]. The layered shell element consists in dividing the 2D structural element into layers along its thickness. Each layer is made up of a single material and can behave nonlinearly in 2D [5-7]. When dealing with nonlinearities, nonlinear solving techniques should be adopted. The classical and most used nonlinear solvers are the Newton-Raphson method and its derivatives, displacement control approach and the arc length technique.

Dynamic excitations in structures are usually studied using direct integration time history analysis. In this approach, temporal discretization is considered and the direct time integration is conducted using implicit methods like Newmark- β [8], Wilson θ [9], HHT- α [10] or explicit methods like central difference and Runge-Kutta. The main concern in using the direct time integration analysis for linear and nonlinear models is its high computational cost especially when applied in structural seismic analysis. In fact for seismic analysis, the structure is subjected to dynamic excitations at its base. These excitations are generally based on the accelerograms of previously recorded quakes in the region. In order to cover all probable scenarios, the structure should be subjected to multiple accelerograms vibrating in all different directions which greatly increases the time cost of this analysis technique.

Due to this setback, several model reduction techniques have been proposed to decrease the time cost of the dynamic time history analysis. For linear systems, modal truncation can be used to define the most influential mode shapes of the structure and then this truncated modal base is used to reduce the dynamic equation of the structural system [11-12]. For nonlinear structures, research based on the work of [13] has been conducted to determine an analogy between nonlinear normal modes and linear ones. However, this nonlinear modal analysis is not widely used due to the limitation when non-smooth nonlinearities are present in the structure [14].

The Proper Orthogonal Decomposition (POD) is a data driven method based on the statistical Principal Component Analysis (PCA) of observations dataset. In other words, data obtained from observations at different time intervals (snapshots) are analyzed to determine the optimal subspace that can be used to recreate the entire dataset with minimum errors. This subspace is later used to reduce the model under consideration in calculation. The POD method dates back to the 1930's and today is applied in fluid mechanics for model reduction of turbulent flow, model reduction of structural dynamics, damage detection, reduction of dynamic models for microelectromechanical systems and in lots of other domains.

Seismic analysis considering nonlinear material behavior of reinforced concrete structures is classically conducted by two approaches. The first one is the pushover analysis which is a static nonlinear approach that tries mimicking the dynamic behavior of the structure by considering it to respond dynamically according to its fundamental mode shape only. Horizontal loads are distributed on the structure proportionally to this fundamental mode shape vector and are increased progressively while nonlinear material behavior is taken into account. This approach is limited to structures where the fundamental mode shape is the dominant mode of vibration and thus limiting it to regular low-rise buildings where no response in function of

time is required (only maximum values are provided). For other cases, the previously mentioned direct integration nonlinear time history analysis is used.

According to the authors' knowledge, the POD method was never used for reducing the direct integration nonlinear time history analysis of a Reinforced Concrete (RC) structure where material nonlinearity is modelled by the multi-fiber section approach. This paper presents a nonlinear multi-fiber RC multistory frame structure subjected to seismic excitations at its base and the POD is used to reduce the direct integration time history analysis cost. Section 2 presents the modeling of material nonlinear behavior for a RC beam element using the multi-fiber section approach. Section 3 is dedicated to the dynamic analysis of a RC element with material nonlinearities using classical and reduced POD procedures. Section 4 presents an application of the POD reduction method to the multistory frame structure under consideration while comparing the results with full model analysis. Section 5 summarizes the conclusions and future perspectives.

2 MULTI-FIBER BEAM MODEL

The concentrated (lumped) plasticity is the simplest and most popular approach to model material nonlinearity in structural elements. However, this technique is based on the assumption that nonlinear material behavior occurs only at specified concentrated points of the structural member (which is a major simplification). In addition, interaction between bending moments and varying axial forces at the plastic hinge is not taken into account. Moreover, the plastic hinges behavior is defined by characteristic curves (Moment versus Rotation or Force versus Displacement) provided by the seismic codes. These curves are based on rough estimations and assumptions which reduce their accuracy. On the other hand and as we will detail in this section, the multi-fiber beam model assures the distribution of nonlinear material behavior all along the structural element length and all over its cross section (distributed plasticity approach). In addition, this technique takes into account the interaction between bending moments and axial loads and can be applied to elements having non-typical cross sections. The fiber model approach is more computationally demanding than the concentrated plastic hinge technique however it remains efficient and very beneficial especially for wall elements modeled by the equivalent beam approach.

Since 2D finite elements are not addressed in this paper, the multi-fiber beam approach is adopted in this work to model the nonlinear material in 1D finite elements (beams, columns, equivalent beam model for walls) while considering the Euler-Bernoulli hypothesis (planar sections before deformation remain planar and perpendicular to the element's center line after deformation).

As already mentioned, the multi-fiber beam approach consists in dividing the structural element cross section into a set of longitudinal fibers. As a consequence, using this modeling technique requires a 3-level analysis.

Fibers are the fundamental level of analysis. Each fiber is made up of only one single material: for reinforced concrete members, the fibers can be made of steel reinforcements, confined or unconfined concrete. The fiber axial stress σ_{fiber} and the longitudinal tangent Young modulus $E_{T fiber}$ are determined as a function of the longitudinal fiber axial strain ϵ_{fiber} .

Figure 1. Multi-fiber reinforced concrete section

The element's cross section is the second level of analysis. Applying the Euler-Bernoulli hypothesis will result in perfect bond conditions between fibers (no sliding of a fiber with respect to another is allowed). In 2D structural analysis, for a fiber having its centroid located at the ordinate y in the section reference, the axial longitudinal strain in the fiber $\varepsilon(y)$ can be determined as a function of the section's uniform axial strain along x axis ε_x and the section's curvature along z axis ϕ_z

$$\varepsilon(y) = \varepsilon_x - y\phi_z = \begin{Bmatrix} 1 & -y \end{Bmatrix} \begin{Bmatrix} \varepsilon_x \\ \phi_z \end{Bmatrix} \quad (1)$$

since in nonlinear analysis the calculation is done by increments, we get:

$$\Delta\varepsilon(y) = \Delta\varepsilon_x - y\Delta\phi_z = \begin{Bmatrix} 1 & -y \end{Bmatrix} \begin{Bmatrix} \Delta\varepsilon_x \\ \Delta\phi_z \end{Bmatrix} \quad (2)$$

this axial strain increment of the fiber $\Delta\varepsilon(y)$ causes an increment in the section's internal axial force ΔN and bending moment along z axis ΔM_z .

$$\Delta N = E_{T \text{ fiber}} A_{\text{fiber}} \Delta\varepsilon(y) \quad (3.a)$$

$$\Delta M_z = -y\Delta N = -yE_{T \text{ fiber}} A_{\text{fiber}} \Delta\varepsilon(y) \quad (3.b)$$

for a single fiber, the resulting increment of internal forces in the section is

$$\{\Delta F_{\text{Section}}\} = \begin{Bmatrix} \Delta N \\ \Delta M_z \end{Bmatrix} = E_{T \text{ fiber}} A_{\text{fiber}} \begin{bmatrix} 1 & -y \\ -y & y^2 \end{bmatrix} \begin{Bmatrix} \Delta\varepsilon_x \\ \Delta\phi_z \end{Bmatrix} \quad (4)$$

for all the fibers, the entire resulting increment of internal forces in the section is

$$\{\Delta F_{\text{Section}}\} = \begin{Bmatrix} \Delta N \\ \Delta M_z \end{Bmatrix} = \underbrace{\sum_{i=1}^{n_{\text{fiber}}} E_{T \text{ fiber } i} A_{\text{fiber } i}}_{[K_T]} \begin{bmatrix} 1 & -y_i \\ -y_i & y_i^2 \end{bmatrix} \begin{Bmatrix} \Delta\varepsilon_x \\ \Delta\phi_z \end{Bmatrix} \quad (5)$$

where n_{fiber} is the total number of fibers in the section and $[K_T]$ is the section's tangent stiffness matrix.

The entire element is the third level of analysis. Linear shape functions are considered for longitudinal translation and Hermite cubic shape functions are used for bending. Applying the principle of virtual work we get

$$\{F_{\text{int}}\} = \int [B(x)]^T \begin{Bmatrix} 1 \\ -y \end{Bmatrix} \sigma_{\text{fiber}}(x, y) dV \quad (5)$$

$$[K_T] = \int [B(x)]^T \begin{Bmatrix} 1 \\ -y \end{Bmatrix} E_{T \text{ fiber}}(x, y) \{1 \quad -y\} [B(x)] dV \quad (6)$$

where $\{F_{int}\}$ is the internal nodal force vector of the element, $[K_T]$ is the element's tangent stiffness matrix and $[B(x)]$ is the gradient operator containing the derivatives of shape functions.

The volume integral required for the calculation of $\{F_{int}\}$ and $[K_T]$ is split into a surface integral on the cross section and a 1D integral along the longitudinal axis of the element. Since the element's cross section is already divided into fibers, we substitute the surface integration by the summation of fiber areas. Next, the longitudinal 1D integration is done by Gauss points.

3 FULL AND REDUCED DYNAMIC MODELS

As already mentioned, the classical time costly approach for capturing the nonlinear seismic response of a structure in function of time is the full model implicit direct integration nonlinear time history analysis. The Newmark- β method [8] is one of the famous implicit direct integration techniques used for linear and nonlinear time history analysis. For this method, knowing the structural system state at instant t_i (displacement, velocity and acceleration vectors) and assuming a variation pattern for acceleration between instants t_i and t_{i+1} (i.e. constant average acceleration) makes it possible to express the dynamic equation of the structural system at instant t_{i+1} with only one unknown (the displacement vector at instant t_{i+1}) and thus solving easily the system.

The proper orthogonal decomposition POD also known as the Principal Component Analysis PCA and the Karhunen-Loève Decomposition KLD is a statistical analysis of observation data. Let's consider a data matrix $[X]$ containing n observation vectors $[X] = [\{X_1\} \quad \dots \quad \{X_n\}]$ and each observation vector is made of m dimension

$$[X] = [\{X_1\} \quad \dots \quad \{X_n\}] = \begin{bmatrix} x_{11} & \dots & x_{1n} \\ \vdots & \ddots & \vdots \\ x_{m1} & \dots & x_{mn} \end{bmatrix} \quad (7)$$

$\{S_i\} = \{x_{i1} \quad \dots \quad x_{in}\}$ is row i in matrix $[X]$ and represents all the data collected on dimension i . If data set $\{S_i\} \forall i$ has a zero mean, the variance of $\{S_i\}$ becomes

$$\sigma^2(\{S_i\}) = \frac{1}{n-1} \times \sum_{k=1}^n (x_{ik} - \text{mean}(\{S_i\}))^2 = \frac{1}{n-1} \times \sum_{k=1}^n (x_{ik})^2 = \frac{1}{n-1} \{S_i\} \{S_i\}^T \quad (8)$$

and the covariance of $\{S_i\}$ and $\{S_j\}$ becomes

$$\text{COV}(\{S_i\}, \{S_j\}) = \frac{1}{n-1} \times \sum_{k=1}^n (x_{ik} - \text{mean}(\{S_i\})) (x_{jk} - \text{mean}(\{S_j\})) \quad (9.a)$$

$$\text{COV}(\{S_i\}, \{S_j\}) = \frac{1}{n-1} \times \sum_{k=1}^n (x_{ik})(x_{jk}) = \frac{1}{n-1} \{S_i\} \{S_j\}^T \quad (9.b)$$

High value of $\sigma^2(\{S_i\})$ indicates high action on dimension i and vice versa. High value of $\text{COV}(\{S_i\}, \{S_j\})$ indicates high similarity between the actions on dimension i and dimension j . On the other hand, $\text{COV}(\{S_i\}, \{S_j\}) = 0$ indicates zero resemblance (total independence) between the actions on dimension i and dimension j .

If data set $\{S_i\} \forall i$ has a zero mean, the covariance of matrix $[X]$ becomes

$$\text{COV}([X]) = \frac{1}{n-1} [X][X]^T \quad (10.a)$$

$$COV([X]) = \begin{bmatrix} \sigma^2(\{S_1\}) & COV(\{S_1\}, \{S_2\}) & \cdots & COV(\{S_1\}, \{S_n\}) \\ COV(\{S_2\}, \{S_1\}) & \sigma^2(\{S_2\}) & \cdots & COV(\{S_2\}, \{S_n\}) \\ \vdots & \vdots & \ddots & \vdots \\ COV(\{S_n\}, \{S_1\}) & COV(\{S_n\}, \{S_2\}) & \cdots & \sigma^2(\{S_n\}) \end{bmatrix} \quad (10.b)$$

Determining the principal components of data matrix $[X]$ starts by finding a new orthonormal reference $[N]$. The initial data matrix $[X]$ is expressed in this new reference as $[X'] = [N]^T [X]$. For $[N]$ to be containing the principal components of the data observation, $COV([X'])$ should be a diagonal matrix. In other words, we have zero similarity between actions on different new dimensions in reference $[N]$ ($COV(\{S'_i\}, \{S'_j\}) = 0$ for $i \neq j$).

Since $COV([X])$ is made up of $[X][X]^T$ it is a symmetrical matrix and thus has real eigenvalues.

$$[X][X]^T [\emptyset] = [\emptyset][\lambda] \quad (11)$$

where $[\emptyset]$ is the eigenvectors matrix and $[\lambda]$ is the diagonal matrix containing the eigenvalues. Eigenvectors are orthonormal vectors and we can demonstrate that the new reference $[N]$ we were talking about in the previous paragraph is in fact the eigenvectors matrix ($[N] = [\emptyset]$) of $[X][X]^T$. In fact for $[X'] = [\emptyset]^T [X]$ we get

$$COV([X']) = \frac{1}{n-1} [X'] [X']^T = \frac{1}{n-1} [\emptyset]^T \underbrace{[X][X]^T [\emptyset]}_{[\emptyset][\lambda]} = [\lambda] \quad (12)$$

$COV([X'])$ is a diagonal matrix and $\sigma^2(\{S'_i\}) = \lambda_i$. We notice that the higher λ_i is the more we have actions on dimension i in the eigenvectors reference. As a conclusion, principal components of the data set $[X]$ are the eigenvectors of $[X][X]^T$ and modes with high eigenvalues are the most influential in representing $[X]$.

The orthogonal eigenvectors obtained are called POD modes and the corresponding eigenvalues are called proper orthogonal values. The POD modes can be used to reconstruct the initial data matrix $[X]$. The higher the eigenvalue of a POD mode is, the more essential this mode is in recreating $[X]$.

By considering the most important s POD modes ($s < m$) and placing them in $[T] \in \mathbb{R}^{m \times s}$, the $\{X_t\}$ snapshot vector previously expressed in m dimensions can now be approximated in the lower s dimensions

$$\underbrace{\{X_t\}}_{\in \mathbb{R}^{m \times 1}} \cong \underbrace{[T]}_{\in \mathbb{R}^{m \times s}} \underbrace{\{Q_t\}}_{\in \mathbb{R}^{s \times 1}} \quad (13)$$

where $\{Q_t\}$ contains the coordinates of the snapshot vector in the new reference $[T]$. The choice of the number s of POD modes to consider in the reduced new reference should satisfy 2 conditions:

- 1- The representation in the new reference should be accurate so the error should be minimal. The higher s is, the more accurate the approximation is.

$$error = \sum_{t=1}^n \|\{X_{t_i}\} - [T]\{Q_{t_i}\}\| \quad (14)$$

- 2- For the dimensions reduction to be efficient, the number of chosen POD modes s should be relatively small.

In order to balance between accuracy and efficiency, an energy criterion is considered to determine the optimal value of s . The Proper Orthogonal Value of a mode gives an indication on the energy carried by this mode. Generally, the first s POD modes carrying at least 99% of the total system energy are considered for the new reduced reference.

$$\frac{\sum_{i=1}^s \lambda_i}{\sum_{j=1}^m \lambda_j} \geq 99\% \quad (15)$$

In structural dynamics, the POD reduction can be applied to the direct integration time history analysis for linear or nonlinear structures. In order to get the observation data required for the POD, we initially do a classical implicit direct integration time history analysis of the full structural finite element model subjected to a specific base excitation. Let's consider a nonlinear structural system with m degrees of freedom and n snapshots were taken. We calculate the POD modes and proper orthogonal values of the data matrix $[X]$ and then choose the subspace $[T] \in \mathbb{R}^{m \times s}$ containing the first s POD modes satisfying the 99% energy criterion. The dynamic equation of the system is

$$[M]\{\ddot{X}(t)\} + [C]\{\dot{X}(t)\} + R(\{X(t)\}) = \{F(t)\} \quad (16)$$

By replacing $\{X(t)\}$ and its derivatives by $[T]\{Q(t)\}$ and multiplying both sides of the dynamic equation by $[T]^T$ we get

$$\underbrace{[T]^T [M] [T]}_{[M_r] \in \mathbb{R}^{s \times s}} \{\ddot{Q}(t)\} + \underbrace{[T]^T [C] [T]}_{[C_r] \in \mathbb{R}^{s \times s}} \{\dot{Q}(t)\} + \underbrace{[T]^T R([T]\{Q(t)\})}_{R_r([T]\{Q(t)\}) \in \mathbb{R}^{s \times 1}} = \underbrace{[T]^T \{F(t)\}}_{\{F_r(t)\} \in \mathbb{R}^{s \times 1}} \quad (17)$$

The previously m degrees of freedom dynamic system is reduced to s degrees of freedom. However, the nonlinear restoring force $R([T]\{Q(t)\})$ cannot be reduced and always needs to be calculated in the full coordinate model which makes this step the most time consuming part of the entire process. In this case, the most effective direct time integration technique to adopt will be the one with the least recurrence for the expensive nonlinear restoring force calculation.

Implicit direct time integration techniques are usually used in conjunction with the Newton-Raphson approach for solving nonlinear systems. In order to reach convergence with this approach, multiple iterations are required at each time step and for every iteration we need to calculate the tangent stiffness matrix, its inverse and the nonlinear restoring force which are all time costly. Using the constant stiffness Newton-Raphson approach will save us the need for the tangent stiffness calculation and its inverse but will increase the number of iterations required for convergence.

On the other hand and for explicit direct time integration techniques, the popular central difference method requires only one iteration per time step and no expensive calculation of the tangent stiffness matrix and its inverse are needed (only the nonlinear restoring force is required). However, the central difference approach is conditionally stable and needs to satisfy the following stability condition

$$\Delta t < \frac{2}{\omega_{max}} \quad (18)$$

where Δt is the time step and ω_{max} is the largest natural pulsation of the system. Generally, the full model of the structure has a relatively large number of degrees of freedom and will result in high natural pulsations (for high modes) hence requiring small time steps to maintain calculation stability and consequently increasing the computational cost. Nevertheless, when working with a reduced structural model, significantly fewer number of degrees of freedom are considered and thus the reduced system will have smaller natural pulsations which makes it possible to use larger time steps while maintaining numerical stability. For this reason, in this work the central difference method is considered to be the most effective direct time integration technique for reduced models.

Various applications of this POD nonlinear dynamic model reduction are possible. As already mentioned for the dynamic seismic analysis, the structure is studied for a range of possible earthquakes and is analyzed and checked for each excitation (earthquake record)

separately. Since we need to conduct an analysis for each excitation, we start with the classic full model implicit direct integration nonlinear time history analysis for the first excitation. By collecting snapshots from this initial analysis, we can determine the essential POD modes and use them to reduce the dynamic model in the analysis of the remaining excitations. [15] proposed this approach and applied it on a small scale steel frame in addition to using it for studying seismic base isolators. In the current article, we will use this approach and extend it on a reinforced concrete multistory frame structure while the material nonlinearity is modeled by the multi-fiber section technique.

4 APPLICATION

At first we need to consider the base vibrations to use. The following 4 earthquake recordings obtained from the Center of Engineering for Strong Motion Data CESMD (www.strongmotioncenter.org) were considered (refer to Table 1).

Earthquake	Location	Date	Magnitude	Measurement station	Vibration direction	Total duration	Time step
Northridge	Los Angeles, USA	01/17/1994	6.4 ML	Newhall LA county fire station	0°	60s	20ms
Elcentro	California, USA	05/18/1940	6.9 Mw	Elcentro	0°	53.74s	20ms
L'Aquila	L'Aquila, Italy	04/06/2009	6.3 Mw	L'Aquila V.Aterno Centro Valle	90°	60s	20ms
Chile	Off the coast of central Chile	02/27/2010	8.8 Mw	Constitution city	90°	120s	20ms

Table 1: Considered earthquakes.

Figure 2. Earthquakes accelerograms

The structure is a 2D Reinforced Concrete (RC) multistory frame made up of 10 stories and 5 spans with a 3 m story height, a 5 m span length, a 4 t/m linear load is considered on beams and the structural self-weight is neglected (refer to Figure 3). All concrete columns and beams are divided into 1 m length finite elements and considered to have the same square cross section 40x40 cm with four 20 mm High Bond HB reinforcing bars at both top and bottom sides (refer to Figure 5). The cross section is divided into 4 concrete fibers and 2 steel fibers. Rayleigh damping was used to get a 5% damping ratio for the first two eigenmodes (more than 90% of the total mass is participating in the first two eigenmodes). The energy criteria for POD modes selection is set to 99.9% (higher than 99% due to the complexity of reinforced concrete elements).

Material nonlinearity is considered to occur in the elements near the beam column connections at the first 5 stories (refer to Figure 4). The steel rebar is considered to have a bilinear backbone curve (initially linear elastic then plastic with strain hardening) with a yielding stress of 400 MPa, a yielding strain of 2‰, an elastic Young modulus of 200 GPa, an ultimate stress of 420 MPa and an ultimate strain of 2.5‰. Under cyclic loading, if nonlinearity is reached, the steel material will undergo a kinematic hysteresis behavior (refer to Figure 6). Concrete is considered to be unconfined and modeled according to a simplified version of Mander model [16] that takes into account the damaging phenomena. The maximum concrete compressive strength is 25 MPa at a corresponding strain of 2‰, the ultimate compressive strain is 4‰, the maximum tensile strength is considered 2.5 MPa (10% of the compressive strength) at a corresponding strain of 0.1‰ and the elastic Young modulus is 25 GPa (refer to Figure 7).

Figure 3. RC frame geometry and loading

Figure 4. Position of nonlinear elements in RC frame

Figure 5. RC element multi-fiber section

Figure 6. Steel reinforcement axial stress-strain curve

Figure 7. concrete axial stress-strain curve

Northridge earthquake is considered as the initial vibration. Full Model (FM) implicit nonlinear time history analysis with a 20 ms time step was carried out for this earthquake. 50 snapshots were taken for the resulting displacement vector during the first 15 seconds of the vibration (where most of the powerful excitation occurs) and at equally spaced time intervals. POD modes were extracted from the snapshot matrix and the dynamic system was reduced based on Northridge earthquake results. Then, Reduced Model (RM) explicit nonlinear time history analysis with a 20 ms time step was carried out for the remaining earthquakes (Elcentro, L'Aquila and Chile).

It should be noted that for comparison purpose, FM implicit nonlinear time history analysis was conducted separately for Elcentro, L'Aquila and Chile earthquakes in order to have a base reference. Also RM analysis was performed for the Northridge earthquake for comparison with the initially calculated full dynamic model.

For this structure, the reduced base is made of the first 4 POD modes since they represent more than 99.9% of the system's energy. As a result, this structure with initially 1140 degrees of freedom is reduced to only 4.

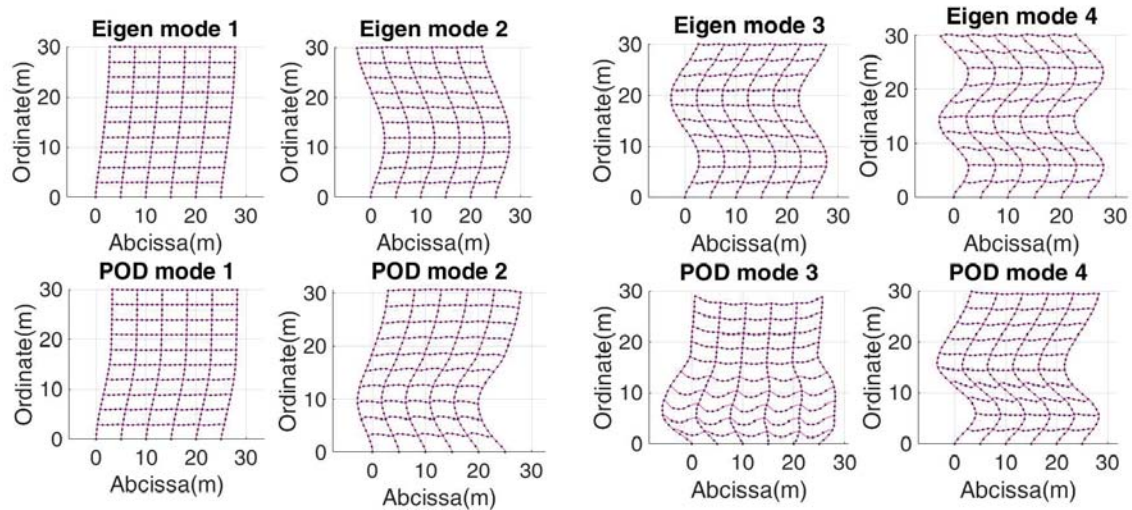

Figure 8. Classic structural eigenmodes Vs POD modes

By comparing the POD modes with the classical eigenmodes of the structure, we can clearly see the nonlinearity effect in the POD modes at the first 5 stories of the structure especially for modes 2 and 3.

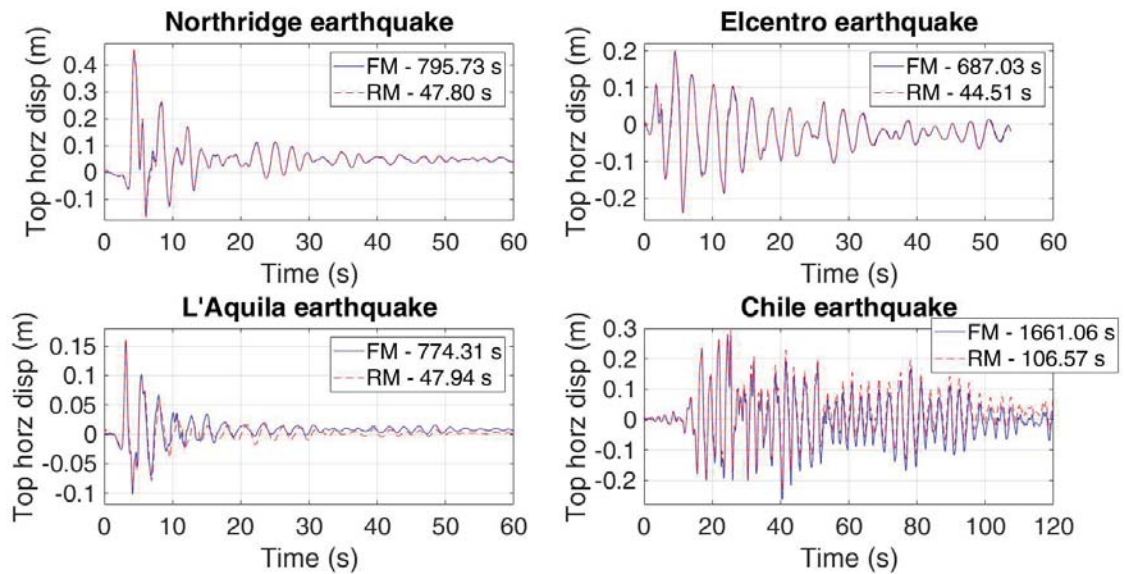

Figure 9. Structural top left corner horizontal displacement in function of time for Full Models (FM) and Reduced Models (RM)

As we can see in Figure 9 the reduced models results are very close to the full models and at a fraction of the time cost, for further details refer to the following table 2.

Earthquake	FM time	RM time	Time saving	Speedup	Average error	Max horiz displacement
Northridge	795.73 s	47.80 s	93.99%	16.6	0.28 cm	45.06 cm
Elcentro	687.03 s	44.51 s	93.52%	15.4	0.36 cm	23.96 cm
L'Aquila	774.31 s	47.94 s	93.81%	16.2	0.79 cm	15.85 cm
Chile	1661.06 s	106.57 s	93.58%	15.6	2.71 cm	27.24 cm

Table 2: Accuracy and time saving of the Reduced Model (RM) with respect to the Full Model (FM).

We can clearly see the time saving benefits of the POD modes in reducing the nonlinear structural system. In addition, the POD modes extracted from the Full Model (FM) analysis of Northridge earthquake are working well in the reduction of the structural model subjected to other excitations (Elcentro, L'Aquila and Chile Earthquake).

5 CONCLUSIONS AND PERSPECTIVES

In this paper we extended the application of the Proper Orthogonal Decomposition to reduce nonlinear dynamic analysis of reinforced concrete multistory frame structure where the material nonlinearity was modeled by the multifiber section approach. We succeeded in reducing a 1140 degrees of freedom system to only 4 degrees while achieving a speedup of around 16 (the reduced model calculation is 16 times faster than the full model) and maintaining an acceptable accuracy level. It was also shown that POD modes obtained from the analysis of a full structural model subjected to a certain base vibration were also convenient for reducing the same model when subjected to different base excitations. The key point here is having a well representative snapshot matrix of the dynamic system.

As perspectives for future work, we are looking forward for increasing the time saving, results accuracy and applying this approach on 2D reinforced concrete structural elements (plates, shells and membranes) by using the layered 2D element model.

Keywords: Daubechies wavelets, Multi-resolution analysis, Wavelet-based elements, Composite structures, Guided waves.

Abstract

A Multi-resolution wavelet-based numerical method is developed for the fast prediction of transient response in elastic homogeneous and heterogeneous rods and beams. The method takes advantage of the remarkable mathematical properties of Daubechies wavelet and scaling functions as basis functions for the spatial approximation of state variables. The Multi-resolution capability of the Daubechies wavelet family, provides the hierarchical computational framework that incorporates both scaling and wavelet functions. An uncoupled solution system between each resolution is formulated, using an explicit time integration scheme. The first level of analysis provides the coarse solution, while finer approximations are sequentially calculated and superimposed on the coarse solution, until the desired level of accuracy is achieved, without discarding the previous results obtained at coarser resolutions. Additionally, due to the orthogonality and compact support of Daubechies wavelet family, the decoupled mass matrices of each resolution are diagonal, or block diagonal and the stiffness matrices are banded. The proposed method uses a uniform grid which remains practically unchanged when increasing the order of interpolation (p-method), owing to its meshless character. Numerical results for the simulation of high-frequency wave propagation in isotropic and orthotropic rods and beams are presented and compared against confirmed models, demonstrating substantial reduction in computational effort. Furthermore, additional benefits of the proposed method are shown, such as the localization capabilities of the fine solutions, which exhibit high sensitivity in detecting discontinuities resulted from material inhomogeneity.

1 INTRODUCTION

The transient dynamic response of isotropic and composite materials and structures is attracting intensive research over the last decade, as it is central to classical problems and applications. For instance, the design of passive and active Structural Health Monitoring (SHM) systems based on linear guided waves is an emerging technology, which requires rapid and robust simulation tools for ultrasonic wave propagation in healthy and damaged structures. However, the modeling of wave propagation in light-weight structures is computationally demanding, because of the high frequencies and wavenumbers involved in SHM applications. In addition, the anisotropy and inhomogeneity of composite light-weight structures, adds further complexity and makes the analysis of such problems even more challenging. Traditional methods, such as the Finite Element (FE) and Finite Difference Method, require very fine spatial and temporal discretization, mandated by the small wavelengths and the high frequencies. Remeshing techniques are implemented for the increase of the results accuracy, but using the h- or p-refinement method requires the introduction of intermediate nodes which render the simulation of Lamb or guided waves practically intractable in terms of required computation time. Computational efficiency is further deteriorated in damage detection applications, where most of the widely used detection methods have been developed independently, without sharing common features and synergies with numerical methods.

A powerful and multifunctional mathematical tool, which is mainly used in signal processing, pattern recognition and data compression, is wavelet analysis. During the past three decades, various researchers have studied the use of wavelets to solve partial differential equations (PDEs) [1]. Also, numerous works have investigated the application of several wavelets in computational mechanics and structural analysis. Patton and Marks [2] created a wavelet-based rod element for static and free vibration problems. Ma et al. [3] constructed a beam element based on Daubechies scaling functions, that exhibited great results in static analyses. Diaz et al. [4] have also developed a Daubechies wavelet-based Euler-Bernoulli beam element and a Mindlin-Reisner plate element for static problems. Except from Daubechies wavelets, Deslauries-Dubuc interpolating wavelets, known as interpolets, have been employed for the construction of beam elements for static [5] and wave propagation analysis [6]. Ko, Kurdila and Pilant [7] have developed a class of finite elements based on orthonormal compactly supported wavelets, and used Daubechies wavelets to solve a second order Neumann problem. In a different direction, wavelets have been used in dynamic problems for the reduction of PDEs to ODEs [8],[9] and for the development of wavelet-based time integration schemes [10]. Furthermore, B-spline wavelets have been studied for the construction of rod, beam, and plate elements for static and dynamic problems [11],[12],[13],[14],[15]. Moreover, Hermitian interpolation wavelets have been exploited for the simulation of wave propagation in isotropic structures [16]. Nastos et al. have implemented the Daubechies scaling functions and introduced the Finite Wavelet Domain (FWD) method for the simulation of wave propagation problems in rods, beams, membranes and plates [17],[18],[19]. Due to the orthogonality of Daubechies scaling functions, diagonal or block diagonal consistent mass matrices are created, and the equivalent wavelet domain algebraic system is rapidly solved using explicit time integration, evincing high accuracy and convergence rates. The FWD method incorporated first order shear and higher order layerwise theories either for beam or for plate structures, to achieve rapid and efficient simulation of symmetric and antisymmetric guided waves in thin and thick laminated composites.

All the forenamed wavelet-based methods are confined to the utilization of the scaling functions of each wavelet family; hence they can be termed as single-resolution (SR) approaches. However, the most distinct property of many wavelet families is the Multi-

resolution (MR) property. This property has mainly been investigated by numerous scientists in the fields of image and signal processing, feature extraction, data compression and denoising, et cetera [20],[21]. During the last decade, many researchers implemented the MR approximation in the field of computational mechanics. Quraishi and Sandeep [22] have created customized second generation wavelets that lead to a scale-decoupled system for the hierarchical static analysis of beams and plates, because of the stiffness decoupling. Jang et al. [23] used hat interpolation wavelets to solve Neumann and Dirichlet boundary value problems. Liu et al. [24] have developed a wavelet MR interpolation Galerkin method for the targeted enrichment of the solution of plane elastic problems. Also, several research works in the field of fracture mechanics using wavelet MR approaches have also been reported [25],[26],[27]. Additionally, Shen, Li and Ou [28] have studied the wave dispersion characteristics of 2D elastic waves using multiscale B-spline wavelets on interval (BSWI) method.

The present work takes advantage of the MR property of Daubechies wavelet family, to develop a hierarchical computational method as an expansion of the FWD method. The proposed method is termed as Multi-resolution Finite Wavelet Domain method (MR-FWD) and employs both Daubechies wavelet and scaling functions as basis functions for the generalized displacement field approximation. Due to the orthogonality and the MR property of Daubechies wavelet family, the solution system is uncoupled for each resolution in the wavelet space. In the present paper, the concept of the MR-FWD method is introduced for 1D cases, and its performance and functionalities are evaluated towards the simulation of longitudinal and guided waves in rods and beams.

In the following sections, the concept of the MR analysis and the mathematical properties of Daubechies scaling functions (SF) and wavelet functions (WF) are introduced. Then, the development of the MR-FWD approximation for rods and beams is described and the hierarchical solution scheme is formulated using explicit time integration. The final physical solution consists of the coarse resolution component and the superposition of sequential finer resolution components that incrementally improve the accuracy of the analysis. Finally, numerical results for transient dynamic analysis in homogeneous and inhomogeneous rod and beam structures are presented and evaluated.

2 MATHEMATICAL PROPERTIES OF DAUBECHIES WAVELET FAMILY

Daubechies scaling functions have been employed as basis functions for the FWD and other methods, owing to their remarkable mathematical properties [21],[29]. The Daubechies wavelet family consists of compactly supported orthogonal scaling functions $\varphi(x)$ and wavelet functions $\psi(x)$. Both SF (also called father wavelet) and WF (also called mother wavelet) are needed to form the Multi-resolution approximation. Also, both SF, WF and their derivatives are algorithmically constructed and do not have analytical expressions [30]. Many researchers have studied the computation of wavelet integrals, also termed as connection coefficients, which is a challenging task because of the highly oscillatory and noisy nature of many SF and WF [7],[31],[32]. The basic mathematical properties of Daubechies SF and WF are summarized below.

Compact Support. Both SF and WF are bounded within an interval, which spans over a compact support domain of grid points $[0, 2L - 1]$, where L is the order of the SF/WF. For the sake of conciseness, Daubechies WF/SF of order L are termed as DBL. This can be visualized in Figure 1. The values of SF and WF beyond their support are zero by definition. So, the influence of each SF/WF is limited within their support domain, that depends on the order L . Also, SF/WF of order L can be defined in the wavelet domain, either by translating the parent

SF/WF at other integer points j , thus creating new SF/WF $\phi(x-j)$, $\psi(x-j)$, or by shrinking/dilating the parent functions to form new ones $\phi(2^j x)$, $\psi(2^j x)$.

Orthogonality. The integer translates of the SF/WF are orthogonal to each other, hence, they form an orthogonal basis in the functional space,

$$\int_{-\infty}^{\infty} \phi(x-i)\phi(x-j)dx = \delta_{ij} \quad (1)$$

$$\int_{-\infty}^{\infty} \psi(x-i)\psi(x-j)dx = \delta_{ij} \quad (2)$$

$$\int_{-\infty}^{\infty} \phi(x-i)\psi(x-j)dx = 0 \quad (3)$$

Vanishing moments. The number of vanishing moments signifies the maximum degree of polynomial that can be exactly approximated by SF/WF. Daubechies SF/WF of order L have L vanishing moments, which are the highest amongst first generation wavelets. It should be noted, that a SF/WF with L vanishing moments can exactly represent polynomials up to $L-1$ order.

Two scale relation/ Dilation property. Provided by the dilation equations,

$$\phi(2^j x) = \sqrt{2} \cdot \sum_{k=0}^{2L-1} h_k \cdot \phi(2^{j+1} x - k) \quad (4)$$

$$\psi(2^j x) = \sqrt{2} \sum_{k=0}^{2L-1} (-1)^k h_{2L-k-1} \cdot \phi(2^{j+1} x - k) \quad (5)$$

where h_k is the set of $2L$ filter coefficients, and j is the resolution or scale. The dilation property constitutes the basis for the MR analysis since it mathematically connects the scaling and the wavelet function. Also, SF and WF can be calculated at dyadic points from the dilation equations.

Figure 1: Example of Daubechies scaling $\phi(x)$ and wavelet $\psi(x)$ functions of order $L=6$ (DB6).

3 THE 1D MULTI-RESOLUTION FINITE WAVELET DOMAIN METHOD

In the present section, the basic concepts of the MR-FWD method for 1D problems and the construction of MR wavelet-based elements for rods and beams are presented. Besides that, the MR hierarchical procedure using explicit time integration scheme and the achievement of effective resolution decoupling are described.

3.1 Generalized approximation of field variables

For a generalized 1D problem, Figure 2 depicts a rod or beam structure that is subdivided into 2 segments, using a uniform grid of 3 grid points. Additional $2L-2$ nodes (where L is the order of the SF/WF) are introduced at the left side of the physical domain, and so the wavelet domain is formed. The case of DB3 discretization is shown in Figure 2, so the additional nodes are 4. The approximation of the generalized displacements $u(x, t)$ in the segment between 2 grid points, also called a wavelet-based element, for R resolutions can be expressed as:

$$u(x, t) = \sum_{n=-(2L-2)}^0 \hat{u}_{Cn}^0(t) \varphi(\xi - n) + \sum_{n=-(2L-2)}^0 \left\{ \sum_{S=0}^R \hat{u}_{Fn}^S(t) \psi(2^S \xi - n) \right\} \quad (6)$$

where L is the order of Daubechies SF/WF, \hat{u}_{Cn}^0 are the coarse wavelet coefficients of generalized displacements at resolution 0, and \hat{u}_{Fn}^S are the fine wavelet coefficients of generalized displacements at resolution S . Also, apart from the global coordinate system, a normalized local coordinate system is associated with each element, as shown in Figure 2. The local dimensionless coordinate variable ξ is given in terms of the global coordinate variable x as:

$$\xi = \frac{x - x_i}{x_{i+1} - x_i} = \frac{x - x_i}{l_e} \quad (7)$$

so, in Equation (6) the spatial variables x and ξ are limited to the ranges $0 \leq x \leq l_e$ and $0 \leq \xi \leq 1$, respectively. Also, l_e is the elemental length.

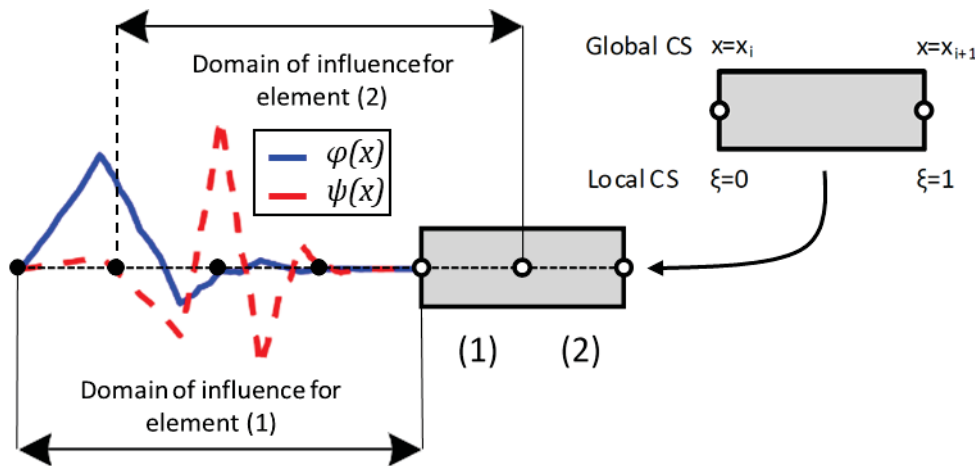

Figure 2: Discretization of the wavelet domain for 2 DB3 MR wavelet-based elements.

3.2 MR-FWD Rod-Beam element

The aforementioned MR approximation is implemented for the construction of Timoshenko beam elements. It should be noted, that the rod element is basically included in the beam element, since the rod kinematics are comprehended in the first shear deformation theory

(FSDT). Specifically, the proposed wavelet-based shear beam element encompasses transverse displacement and rotational degrees of freedom, except from axial displacement. According to the FSDT, the axial and transverse displacement, u and w respectively are expressed by the following equations:

$$u(x, z, t) = u^0(x, t) + \beta_x(x, t) \cdot z \quad (8)$$

$$w(x, z, t) = w^0(x, t) \quad (9)$$

where u^0 and w^0 are the axial and transverse displacement at the beam midplane, respectively, and β_x is the rotation of the neutral line. The axial and shear strain, ε_x and ε_{xz} , respectively, are calculated as:

$$\varepsilon_x(x, z, t) = \varepsilon_x^0(x, t) + k_x(x, t) \cdot z \quad (10)$$

$$\varepsilon_{xz}(x, z, t) = \varepsilon_{xz}^0(x, t) \quad (11)$$

in which $\varepsilon_x^0 = u_{,x}^0$, $k_x = \beta_{x,x}$ and $\varepsilon_{xz}^0 = \beta_x + w_{,x}^0$. The generalized Hooke's law takes the form:

$$\begin{Bmatrix} N_x \\ N_{xz} \\ M_x \end{Bmatrix} = \begin{bmatrix} A_{11} & B_{11} & 0 \\ B_{11} & A_{55} & 0 \\ 0 & 0 & D_{11} \end{bmatrix} \begin{Bmatrix} \varepsilon_x^0 \\ \varepsilon_{xz}^0 \\ k_x \end{Bmatrix} \Leftrightarrow \sigma_{gen} = [ABD] \varepsilon_{gen} \quad (12)$$

where N_x , N_{xz} and M_x are the axial force, shear force and bending moment, and A_{11} , A_{55} , B_{11} and D_{11} are the extensional, shear, coupling and flexural stiffness terms, respectively. As shown in Eq. (12) the generalized Hooke's law can take compact form, introducing the generalized stress $\sigma_{gen} = [N_x, N_{xz}, M_x]^T$, the generalized strain $\varepsilon_{gen} = [\varepsilon_x^0, \varepsilon_{xz}^0, k_x]^T$ and the well-known $[ABD]$ matrix of the beam. The Principle of Virtual Work provides the variational form of the equation of motion for the FSDT beam:

$$-\int_0^l \delta \varepsilon_{gen}^T \cdot \sigma_{gen} dx + \int_0^l \delta u_{gen}^T \cdot \rho_{total} \cdot \ddot{u}_{gen} dx + \int_S \delta \bar{u}_{gen}^T \cdot \bar{\tau} dS = 0 \quad (13)$$

where $u_{gen} = [u^0, w^0, \beta_x]^T$ are the generalized displacements, $\rho_{total} = \text{diag}[\rho^A, \rho^A, \rho^D]$ is the diagonal total density matrix of the beam, in which ρ^A is the linear density and ρ^D is the rotational inertia, and overbar variables are tractions and displacement on the boundary S . The approximation of generalized displacements of a MR-FWD shear beam element for R resolutions is:

$$\begin{Bmatrix} u^0 \\ w^0 \\ \beta_x \end{Bmatrix} = \sum_{n=-(2L-2)}^0 \begin{Bmatrix} \hat{u}_{Cn}^0 \\ \hat{w}_{Cn}^0 \\ \hat{\beta}_{xCn} \end{Bmatrix} \cdot \varphi(\xi - n) + \sum_{S=0}^R \sum_{n=-(2L-2)}^0 \begin{Bmatrix} \hat{u}_{Fn}^{0,S} \\ \hat{w}_{Fn}^{0,S} \\ \hat{\beta}_{xFn}^{0,S} \end{Bmatrix} \cdot \psi(2^S \xi - n) \quad (14)$$

and the generalized strains for resolution R , are expressed as:

$$\begin{Bmatrix} \varepsilon_x^0 \\ \varepsilon_{xz}^0 \\ k_x \end{Bmatrix} = \sum_{n=-(2L-2)}^0 [\Phi_{,x}] \cdot \begin{Bmatrix} \hat{u}_{Cn}^0 \\ \hat{w}_{Cn}^0 \\ \hat{\beta}_{xCn} \end{Bmatrix} + \sum_{S=0}^R \sum_{n=-(2L-2)}^0 [\Psi_{,x}] \cdot \begin{Bmatrix} \hat{u}_{Fn}^0 \\ \hat{w}_{Fn}^0 \\ \hat{\beta}_{xFn} \end{Bmatrix} \quad (15)$$

where matrix $\Phi_{,x}$ is the coarse strain shape function matrix:

$$[\Phi_{,x}] = \frac{1}{l_e} \begin{bmatrix} \varphi_{,\xi}(\xi - n) & 0 & 0 \\ 0 & \varphi_{,\xi}(\xi - n) & l_e \cdot \varphi(\xi - n) \\ 0 & 0 & \varphi_{,\xi}(\xi - n) \end{bmatrix} \quad (16)$$

and matrix $\Psi_{,x}$ is the fine strain shape function matrix for resolution R:

$$[\Psi_{,x}] = \frac{1}{l_e} \begin{bmatrix} \psi_{,\xi}(2^S \xi - n) & 0 & 0 \\ 0 & \psi_{,\xi}(2^S \xi - n) & l_e \cdot \psi(2^S \xi - n) \\ 0 & 0 & \psi_{,\xi}(2^S \xi - n) \end{bmatrix} \quad (17)$$

The implementation of Eqs. (14), (15), (16) and (17) to Eq. (13) yields the MR stiffness and mass matrices of the shear beam element. For simplicity, the hierarchical MR process for resolution 1 will be presented, considering that the generalized displacement field is termed as u in the physical space.

Resolution 1 ($C^0 + F^0$). Following the hierarchical MR scheme, the fine approximation at resolution 0 (F^0) needs to be calculated and added to the coarse solution at resolution 0 (C^0) in order to obtain C^1 solution. The MR discretized solution system is:

$$\begin{bmatrix} M_{CC} & 0 \\ 0 & M_{FF} \end{bmatrix} \begin{Bmatrix} \ddot{\hat{u}}_C(t) \\ \ddot{\hat{u}}_F(t) \end{Bmatrix} + \begin{bmatrix} K_{CC} & K_{CF} \\ K_{FC} & K_{FF} \end{bmatrix} \begin{Bmatrix} \hat{u}_C(t) \\ \hat{u}_F(t) \end{Bmatrix} = \begin{Bmatrix} F_C(t) \\ F_F(t) \end{Bmatrix} \quad (18)$$

where \hat{u}_F are the generalized fine wavelet coefficients and \hat{u}_C are the generalized coarse wavelet coefficients of the coupled equations of motion for resolution 1. The coarse solution at resolution 0 (C^0) is obtained assuming that $\hat{u}_F = 0$. In that way, this single-resolution coarse solution, termed as \hat{u}_{CC} , is basically the same solution that the FWD method provides, employing only the Daubechies SF $\varphi(x)$. It is important to point out that \hat{u}_C is not equal to \hat{u}_{CC} , because of the coupling between the coarse and fine equations of motion. That coupling emanates from the coupling stiffness matrices $[K_{CF}]$ and $[K_{FC}]$ that are nonzero in opposition to $[M_{CF}]$ and $[M_{FC}]$ that are equal to zero because of the orthogonality between $\varphi(x)$ and $\psi(x)$. Also, $[K_{FF}]$ and $[M_{FF}]$ are the fine resolution stiffness and mass matrices, respectively, and F_F is the fine resolution load vector. More specifically, all the aforementioned MR stiffness and mass matrices are calculated as:

$$[K_{CC}^e] = \begin{bmatrix} \frac{A_{11}}{l_e} \Gamma_{kl}^{11} & \frac{B_{11}}{l_e} \Gamma_{kl}^{11} & 0 \\ & \frac{A_{55}}{l_e} \Gamma_{kl}^{11} & A_{55} \Gamma_{kl}^{01} \\ (S) & & A_{55} l_e \Gamma_{kl}^{00} + \frac{D_{11}}{l_e} \Gamma_{kl}^{11} \end{bmatrix} \quad (19)$$

$$[K_{CF}^e] = \begin{bmatrix} \frac{A_{11}}{l_e} \Gamma 1_{kl}^{11} & \frac{B_{11}}{l_e} \Gamma 1_{kl}^{11} & 0 \\ & \frac{A_{55}}{l_e} \Gamma 1_{kl}^{11} & A_{55} \Gamma 1_{kl}^{01} \\ (S) & & A_{55} l_e \Gamma 1_{kl}^{00} + \frac{D_{11}}{l_e} \Gamma 1_{kl}^{11} \end{bmatrix} \quad (20)$$

$$[K_{FC}^e] = [K_{CF}^e]^T \quad (21)$$

$$[K_{FF}^e] = \begin{bmatrix} \frac{A_{11}}{l_e} \Gamma 2_{kl}^{11} & \frac{B_{11}}{l_e} \Gamma 2_{kl}^{11} & 0 \\ & \frac{A_{55}}{l_e} \Gamma 2_{kl}^{11} & A_{55} \Gamma 2_{kl}^{01} \\ (S) & & A_{55} l_e \Gamma 2_{kl}^{00} + \frac{D_{11}}{l_e} \Gamma 2_{kl}^{11} \end{bmatrix} \quad (22)$$

$$[M_{CC}^e] = \rho_{total} \cdot l_e \cdot \Gamma_{kl}^{00} \quad (23)$$

$$[M_{FF}^e] = \rho_{total} \cdot l_e \cdot \Gamma 2_{kl}^{00} \quad (24)$$

where $\Gamma_{kl}^{ij}, \Gamma 1_{kl}^{ij}, \Gamma 2_{kl}^{ij}$ in which $i, j = 1, 2$, determine the order of the derivation of the SF and WF, are the so called connection coefficients [17]. The computation of the connection coefficients is a challenging numerical procedure that is rigorously explained on [31],[32],[7]. Considering the previous equations, the wavelet integrals are given as:

$$\begin{aligned} \int_0^1 \varphi^{(i)}(\xi - k) \varphi^{(j)}(\xi - l) d\xi &= \Gamma_{kl}^{ij} \\ \int_0^1 \varphi^{(i)}(\xi - k) \psi^{(j)}(\xi - l) d\xi &= \Gamma 1_{kl}^{ij} \\ \int_0^1 \psi^{(i)}(\xi - k) \psi^{(j)}(\xi - l) d\xi &= \Gamma 2_{kl}^{ij} \end{aligned} \quad (25)$$

Due to the orthogonality of SF and WF, there are no coupling mass matrices because:

$$[M_{CF}^e] = [M_{FC}^e]^T = \rho_{total} l_e \int_0^1 \varphi(\xi - k) \cdot \psi(\xi - l) d\xi = 0 \quad (26)$$

The mass decoupling and the fact that the mass matrices are consistent and diagonal, leads to crucial computational benefits in the transient dynamic structural analysis. The mass decoupling feature is further discussed in section 3.3 for the hierarchical MR procedure using explicit time integration.

Another important feature of the novel MR-FWD method, is that when the traditional p-refinement method is utilized, the mesh remains practically unchanged [17]. Due to the meshless character of the proposed method, increasing the order of Daubechies SF/WF only leads to an increase in the additional grid points to the left side of the physical domain (Figure 2) and the rest of the mesh remains intact.

Moreover, the hierarchical MR solution system that is shown in Eq. (18) can be generalized for $S+I$ resolutions. The $S+I$ resolution stiffness matrices, mass matrices, generalized displacement vectors and load vectors are formed as:

$$\begin{bmatrix} K_{CC}^{s+1} \end{bmatrix} = \begin{bmatrix} K_{CC}^s & K_{CF}^s \\ K_{FC}^s & K_{FF}^s \end{bmatrix}, \begin{bmatrix} M_{CC}^{s+1} \end{bmatrix} = \begin{bmatrix} M_{CC}^s & 0 \\ 0 & M_{FF}^s \end{bmatrix}, \begin{bmatrix} F_C^{s+1} \end{bmatrix} = \begin{bmatrix} F_C^s \\ F_F^s \end{bmatrix}, \begin{bmatrix} \hat{u}_{CC}^{s+1} \end{bmatrix} = \begin{bmatrix} \hat{u}_C^s \\ \hat{u}_F^s \end{bmatrix} \quad (27)$$

It should be noted, that the MR procedure that is presented for the FSDT beam case in Eq. (18) is the same for the rod case, and so is the generalized form of the MR matrices and vectors in Eq. (27).

3.3 Hierarchical MR process using Explicit time integration scheme

The hierarchical MR process is shown in Eq. (18) for resolution 1. Essentially, the solution at resolution $S+1$ is the superposition of two different solutions (coarse and fine) at resolution S , that are obtained in two independent steps. The first step is always the SR solution that provides the coarse component approximation. For generality, the MR procedure will be described for resolution $S+1$. Considering Eq. (27), the following mass uncoupled MR solution system, that involves both coarse and fine approximation is obtained at resolution $S+1$:

$$\begin{bmatrix} M_{CC}^s & 0 \\ 0 & M_{FF}^s \end{bmatrix} \begin{Bmatrix} \ddot{\hat{u}}_C^{s,t} \\ \ddot{\hat{u}}_F^{s,t} \end{Bmatrix} + \begin{bmatrix} K_{CC}^s & K_{CF}^s \\ K_{FC}^s & K_{FF}^s \end{bmatrix} \begin{Bmatrix} \hat{u}_C^{s,t} \\ \hat{u}_F^{s,t} \end{Bmatrix} = \begin{bmatrix} F_C^{s,t} \\ F_F^{s,t} \end{bmatrix} \quad (28)$$

The component \hat{u}_C^s is set as:

$$\hat{u}_C^s = \Delta \hat{u}^s + \hat{u}_{CC}^s \quad (29)$$

where \hat{u}_{CC}^s is the already calculated single-resolution coarse approximation, and $\Delta \hat{u}^s$ is the residual between \hat{u}_C^s and \hat{u}_{CC}^s , called correction component. It is already mentioned that the multi-resolution coarse component \hat{u}_C^s is not equal to the single-resolution coarse component \hat{u}_{CC}^s because of the stiffness coupling terms. Combining Eqs. (28) and (29), leads to:

$$\begin{bmatrix} M_{CC}^s & 0 \\ 0 & M_{FF}^s \end{bmatrix} \begin{Bmatrix} \Delta \ddot{\hat{u}}^{s,t} \\ \ddot{\hat{u}}_F^{s,t} \end{Bmatrix} + \begin{bmatrix} K_{CC}^s & K_{CF}^s \\ K_{FC}^s & K_{FF}^s \end{bmatrix} \begin{Bmatrix} \Delta \hat{u}^{s,t} \\ \hat{u}_F^{s,t} \end{Bmatrix} = \begin{bmatrix} 0 \\ F_F^{s,t} - K_{FC}^s \hat{u}_{CC}^{s,t} \end{bmatrix} \quad (30)$$

The diagonality of the total MR mass matrix of Eq. (30) results in two uncoupled equations for the prediction of $\Delta \hat{u}^s$ and \hat{u}_F^s , using the central differences explicit time integration scheme. Those are calculated as:

$$\Delta \hat{u}^{s,t+1} = \frac{\begin{bmatrix} M_{CC}^s \end{bmatrix} (a_2 \Delta \hat{u}^{s,t} - a_0 \Delta \hat{u}^{s,t-1}) - \begin{bmatrix} K_{CC}^s \end{bmatrix} \Delta \hat{u}^{s,t} - \begin{bmatrix} K_{CF}^s \end{bmatrix} \hat{u}_F^{s,t}}{a_0 \begin{bmatrix} M_{CC}^s \end{bmatrix}} \quad (31)$$

$$\hat{u}_F^{s,t+1} = \frac{F_F^{s,t} + \begin{bmatrix} M_{FF}^s \end{bmatrix} (a_2 \hat{u}_F^{s,t} - a_0 \hat{u}_F^{s,t-1}) - \begin{bmatrix} K_{FC}^s \end{bmatrix} (\hat{u}_{CC}^{s,t} + \Delta \hat{u}^{s,t}) - \begin{bmatrix} K_{FF}^s \end{bmatrix} \hat{u}_F^{s,t}}{a_0 \begin{bmatrix} M_{FF}^s \end{bmatrix}} \quad (32)$$

where $a_0 = 1/\Delta t^2$ and $a_2 = 2/\Delta t^2$, in which Δt is the time step for the explicit dynamic solver. The superposition of the three components \hat{u}_{CC}^s , $\Delta \hat{u}^s$ and \hat{u}_F^s at resolution S , forms the coarse approximation of the next resolution $S+1$, as:

$$\hat{u}_{CC}^{s+1,t+1} = \hat{u}_{CC}^{s,t+1} + \Delta \hat{u}^{s,t+1} + \hat{u}_F^{s,t+1} \quad (33)$$

4 NUMERICAL RESULTS

The efficiency and the functionalities of the MR-FWD method are evaluated towards the simulation of longitudinal and guided waves in homogeneous and heterogeneous aluminum rods and laminated carbon/epoxy beams. The mechanical properties of the involved materials are shown in Table 1.

	E_{11} (GPa)	$E_{22}=E_{33}$ (GPa)	$G_{12}=G_{23}=G_{13}$ (GPa)	$\nu_{12}=\nu_{13}=\nu_{23}$	ρ (kg/m ³)
Aluminum	70	70	26.923	0.3	2700
Damaged Aluminum	7	7	2.6923	0.3	2700
Carbon/Epoxy	120	7.9	5.5	0.3	1580
Damaged Carbon/Epoxy	114	7.505	5.225	0.3	1580

Table 1: Material properties.

4.1 Homogeneous Aluminum Rod

An aluminum rod with length $l=4m$, cross section $A=10^{-4}m^2$ and mechanical properties that are shown in Table 1, is modeled. The rod is clamped at its left edge and it is excited at its center ($x=2m$), by a 5-cycle tone burst with 25 kHz central frequency. The analysis duration is 0.3 milliseconds (ms). The effectiveness of the MR hierarchical procedure is investigated for resolution up to 2, for DB3 wavelet-based elements. A converged 3-node FE analysis with 401 nodes is considered the reference solution. It is worth mentioning that both the 3-node FE and the DB3 wavelet-based elements, are quadratic approximation elements. The hierarchical process is shown in Figure 3, following top-down sequence.

The first step of the analysis is the SR approximation (C^0) that involves 54 grid points. It is obvious that this coarse solution \hat{u}_{CC}^0 diverges a lot from the reference solution. Moving to resolution 1, the components $\Delta\hat{u}^0$ and \hat{u}_F^0 are calculated and superimposed to \hat{u}_{CC}^0 , using the same grid points. In that way, the coarse solution at resolution 1 (C^1) is obtained, and it is shown that crucial correction is provided by $\Delta\hat{u}^0$ and \hat{u}_F^0 . The same procedure is repeated for resolution 2, but the shrinking of the DB3 WF requires the use of 104 grid points, for the calculation of $\Delta\hat{u}^1$ and \hat{u}_F^1 . The total summation of the above 5 components ($\hat{u}_{CC}^0, \Delta\hat{u}^0, \hat{u}_F^0, \Delta\hat{u}^1, \hat{u}_F^1$) provides the overall solution at resolution 2 (C^2), which has converged to the reference solution. It can be concluded, that the components $\Delta\hat{u}^s$ mainly improve the frequency and the time of flight of the wave packets, whereas the components \hat{u}_F^s provide a small correction on the amplitude of the wave packets. The functionalities of the fine components will be extensively assessed at the inhomogeneous cases.

Figure 3: Predicted axial displacement field of the aluminum rod. The MR hierarchical procedure is shown from resolution 0 to resolution 2 (top-down sequence).

The MR hierarchical process demonstrates substantial reduction in the computational effort, because not only the required grid points for a converged solution are much fewer compared to the 3-node FE, but also the mass diagonality permits the initial $2N \times 2N$ algebraic system (Eq. (28)) to be solved as two $N \times N$ algebraic systems (Eq. (31) and (32)), using explicit time integration. Considering the computational cost in terms of floating-point operations (flops), a matrix inversion using LU decomposition requires approximately $2n^3/3$ flops. So, inverting two $N \times N$ matrices requires approximately 75% less flops in comparison with inverting a $2N \times 2N$ matrix. In that way, additional computational benefits arise from the hierarchical MR procedure, apart from the exploitation of the already calculated coarse solution.

4.2 Laminated Composite Beam

A 1m long unidirectional $[0]_8$ carbon/epoxy beam with cross section $A=10^{-4}m^2$ and mechanical properties shown in Table 1, is modeled. The beam is clamped at its left edge and it is transversely excited at its center ($x=0.5m$), by a 5-cycle tone burst with 50 kHz central frequency. The analysis duration is 0.15 ms. The simulation of antisymmetric guided waves is more challenging than the simulation of pressure waves, owing to the smaller wavelengths and the dispersive nature of the antisymmetric mode. In this case, the effectiveness of the p-method for resolution 1 solutions (C^1) is demonstrated. As shown in Figure 4, MR-FWD models with DB3, DB6, DB8 and DB11 wavelet-based elements are used to predict the transverse displacement field of the composite beam. The reference solution is a converged and validated FWD analysis (C^0) that employs DB3 elements with 434 grid points.

Figure 4: Predicted transverse displacement of the right half of the laminated beam. Minimum number of nodes required for a converged solution are illustrated for each discretization case inside the parentheses.

The superiority of the high order MR DB elements is depicted in Figure 4, where it is obvious that higher order MR models require substantially fewer nodes to obtain an accurate solution. Moreover, observing the case of DB3 discretization, the MR hierarchical method demonstrates remarkable precision and critically decreases the already decreased computational effort required by the single-resolution FWD method. Considering the grid points needed for a converged solution, there is a reduction of almost 50% for the C^I DB3 case and up to 82% for the C^I DB11 case, compared to the C^0 DB3 analysis. Finally, it should be noted that the wavelet-based FSDT beam elements do not exhibit shear locking effects, which is another significant advantage compared to traditional shear beam FE [17].

4.3 Inhomogeneous Aluminum Rod

An inhomogeneous aluminum rod with length $l=4m$ and cross section $A=10^{-4}m^2$ is modeled. The rod consists of two different materials, aluminum, and damaged aluminum, and their mechanical properties are shown in Table 1. The damaged area spans from $2m \leq x \leq 2.2m$, as depicted with dark grey in Figure 5a. The rod is clamped at the left edge and it is excited at its right free end ($x=4m$), by a 5-cycle tone burst with 25 kHz central frequency. The duration of the simulation is 0.8 ms. The reference solution is a converged SR analysis of 800 DB3 elements. Figure 5b depicts the axial displacement of the MR process, for 200 DB3 elements and resolutions from 0 to 2.

It is obvious that the initial scale of analysis (C^0) exhibits substantial error compared to the reference solution. Moving up to the C^I there is crucial correction of the predicted displacement field, but there is still divergence from the reference solution. Finally, the C^2 solution shows excellent agreement with the reference solution. The examination of the fine components introduces certain critical results and reveals some of their extraordinary benefits.

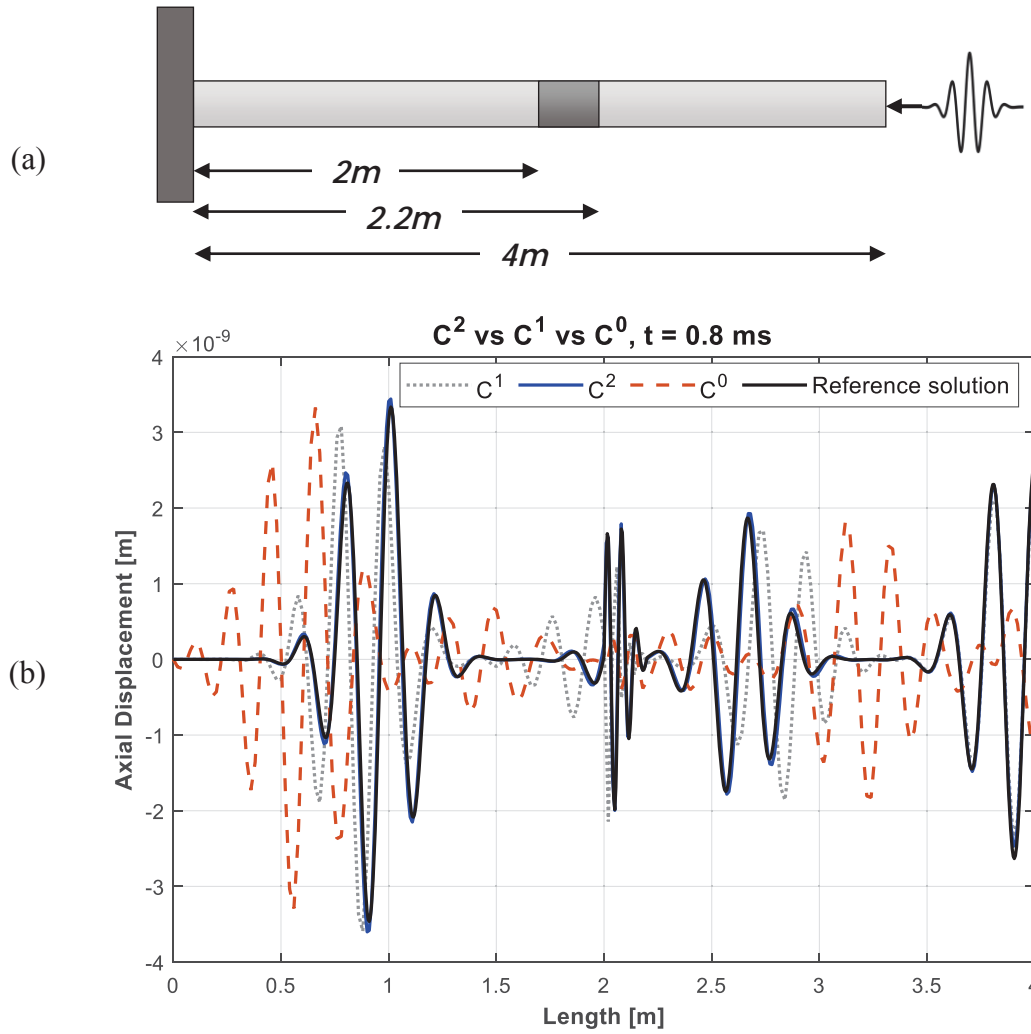

Figure 5: (a) Wave propagation in damaged rod structure. (b) Axial displacement field of the inhomogeneous rod for resolutions 0, 1 and 2.

Figure 6: Contribution of the fine components of resolutions 0 (left) and 1 (right), in which the inhomogeneity is precisely detected and also the higher wavenumber inside the damaged area is accurately predicted.

As shown in Figure 6, the fine components \hat{u}_F^0, \hat{u}_F^1 exactly localize the span of the damage and capture the higher wavenumbers inside the inhomogeneity due to the high frequency nature of Daubechies WF. In particular, the \hat{u}_F^0 component uses the same nodes as the \hat{u}_{CC}^0 , but efficiently approaches the smaller wavelengths that arise from the lower Young modulus of the damaged region. Apparently, the \hat{u}_F^1 component that uses double nodes in comparison with the \hat{u}_{CC}^0 solution, precisely predicts the higher wavenumbers inside the inhomogeneity. Thus, besides the critical benefits of the MR-FWD method in terms of accuracy and computational effectiveness, there are additional gains concerning the fine components, which are extremely sensitive in detecting discontinuities and can numerically simulate steep gradients, even at coarse discretization cases.

4.4 Damaged Composite Beam

A 1m long cross-ply [0/90/0/90]_s carbon/epoxy beam with cross section $A=10^{-4}m^2$ is modeled. The beam consists of two different regions, the pristine carbon/epoxy, and the damaged carbon/epoxy region. The mechanical properties of those materials are shown in Table 1. The damage is assumed to induce 5% degradation to all the elastic moduli. The damaged area ranges from $0.75m \leq x \leq 0.8m$, as illustrated with dark grey in Figure 7a. The beam is clamped at its left edge and it is excited at its center ($x=0.5m$), by a 5-cycle tone burst with 50 kHz central frequency. The analysis duration is 0.2 ms. The efficiency of the MR hierarchical scheme is highlighted in the previous sections. In this section, the sensitivity of the fine components is exhibited. A converged discretization of 314 grid points of DB8 elements is used for resolution up to 1.

Figure 7b depicts the predicted deflection of the beam for the converged solutions C^0, C^I and the fine component w_F^0 . The objective of this analysis is not to emphasize the computational gains of the MR-FWD method in terms of the required grid points, since C^0 and C^I approximations are in excellent agreement. Hence, moving up to resolution 1 does not offer any correction at the C^0 solution. Nevertheless, the existence of the damaged area is not perceptible at C^0 or C^I solution, even though the right wave packet passes through the heterogeneity at $t=2ms$. The fine component w_F^0 provides precise detection of the interfaces between the damaged and the pristine composite beam despite the small degradation of its mechanical properties by 5%. In this case, the fine component does not capture a dissimilar wavenumber inside the heterogeneity, because of the insignificant difference among the material properties of the damaged and the pristine carbon/epoxy. Also, w_F^0 does not practically participate in the total solution in quantitative terms, since the C^0 solution is meticulous due to the dense discretization. However, the fine solution can exactly localize the boundaries between the two materials, introducing a pioneering additional property of the proposed numerical method.

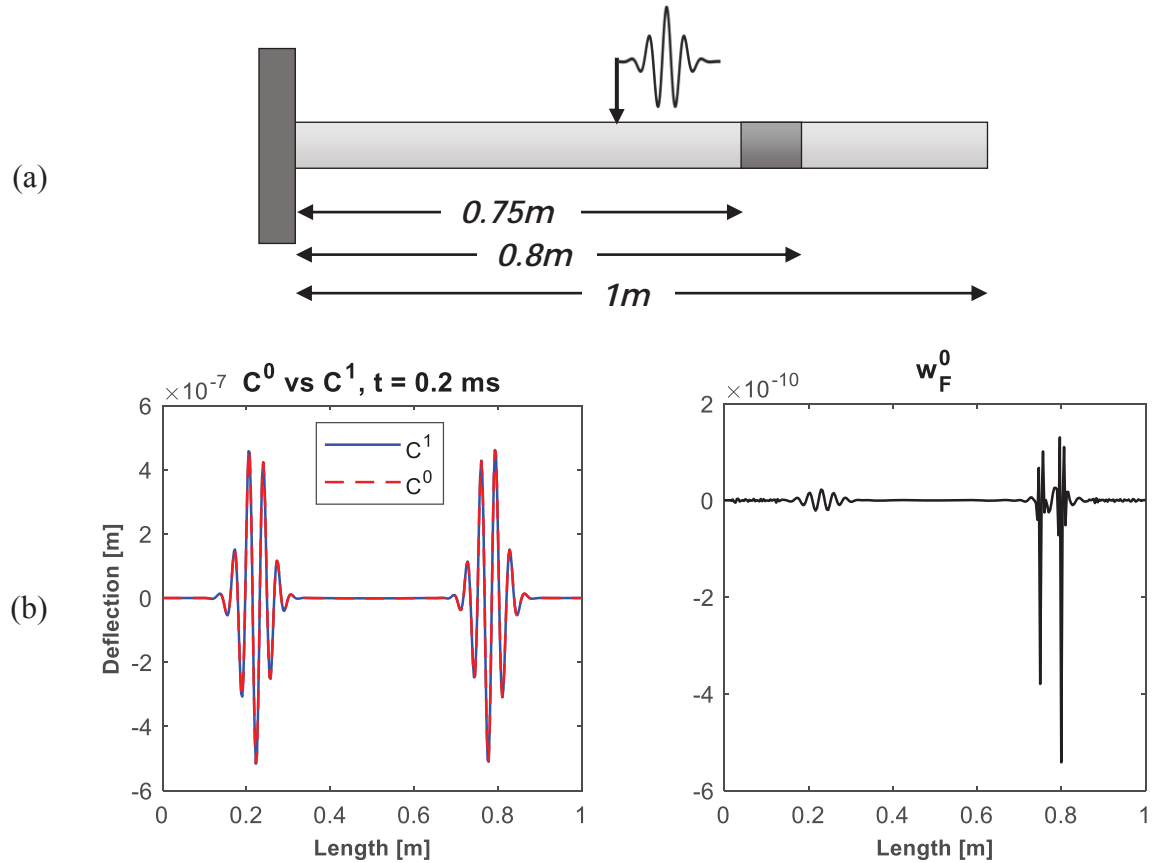

Figure 7: (a) Wave propagation in damaged composite beam. (b) C^0 and C^1 solutions are converged (left) but the inhomogeneity is not visible. The fine component accurately delimits the damage span (right).

5 CONCLUSIONS

A novel Multi-resolution hierarchical wavelet-based method for the efficient simulation of transient dynamic response of rods and beams, is presented. Taking advantage of the remarkable mathematical properties and the unique MR capability of Daubechies wavelet and scaling functions, the proposed 1D MR-FWD method has been developed, as an expansion of the single-resolution FWD method. The MR approximation includes two types of variables, the coarse and fine wavelet coefficients of each resolution. The implementation of the MR approximation at the equations of motion, yields a MR solution system that involves both coarse and fine resolution degrees of freedom. The hierarchical process starts with the coarse solution (C^0), which basically is the FWD method, and then a fine approximation (F^0) is calculated and superimposed on the coarse solution, forming the 1st improved solution (C^1). This procedure can be continued until the desired level of accuracy is achieved. Therefore, the proposed MR-FWD method exploits the non-converged solutions that are obtained at coarser resolutions, compared to traditional numerical methods that discard them. Due to the orthogonality of the Daubechies wavelet and scaling functions, the consistent mass matrices of each resolution are diagonal or at least block diagonal. Also, the mass diagonality results in decoupling of the discretized dynamic equations with the use of explicit time integration scheme. It should be emphasized, that the approximation C^1 provides a much more accurate prediction than C^0 , using the same grid points as the approximation C^0 . Additionally, it should be noted, that performing p-refinement to the proposed method, leaves the mesh practically unaffected. The precision and computational efficiency of the developed method were evaluated by com-

paring the predicted longitudinal and guided wave responses of homogeneous and heterogeneous rods and beams, with validated FE and single-resolution FWD models.

The numerical results demonstrated 4 key advantages of the MR-FWD method: (1) the MR property of Daubechies wavelets leads to a hierarchical MR set of dynamic equations, that introduce a new type of refinement which utilizes the solution of an already obtained coarser analysis; (2) the hierarchical MR procedure in synergy with the advantageous use of the classical p-method, enables the exact solution of demanding transient dynamic problems, using smaller size algebraic systems compared to the single-resolution FWD method; (3) the consistent diagonal mass matrices of each resolution in conjunction with the mass decoupling, lead to faster analyses with the use of explicit time integration; and (4) the fine components of the MR analysis introduce additional benefits to the MR-FWD method, such as the efficient capture of the higher wavenumbers and the exact localization of inhomogeneities and interfaces. Future work may focus on the inclusion of a higher order layerwise theory to the proposed MR-FWD method, for the accurate simulation of both symmetric and antisymmetric modes in thick composites and sandwich structures.

Abstract

Time history analysis using a time integration method is a powerful broadly accepted tool for structural dynamic analysis. In practical areas, such as earthquake engineering, computations based on time history analysis might be computationally very expensive. In 2008, a technique was proposed to considerably reduce the computational effort by reducing the data in the earthquake record. This technique, which is recently named as a SEB THAAT, is reviewed in this paper. After a brief review on the formulation and implementation, the positive points, the limitations, and the challenges facing versatile implementation of the SEB THAAT are addressed, and a future perspective is presented.

Keywords: Time History Analysis, Earthquake Engineering, Computational Effort, SEB THAAT, Existing Challenges, Future Perspective.

1 INTRODUCTION

The true behavior of structural systems is nonlinear and dynamic. Time history analysis using a time integration method is a versatile tool to study structures' nonlinear dynamic behavior. The analysis process is briefly reviewed in Fig. 1. Evidently, the analysis leads to approximate responses and is computationally expensive. Specifically, the run-time may be considerable in many real analyses. The significance of these features highlights in earthquake engineering, where seismic codes require structures' time history analysis considering several ground acceleration records. Also there exist advanced seismic computations such as IDA

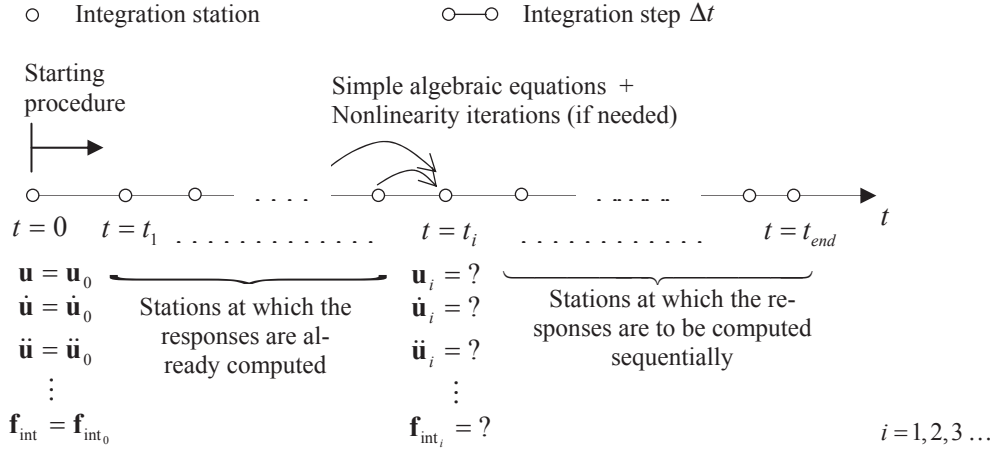

Figure 1: Brief description of the process of time history analysis using a time integration method [1].

(Incremental Dynamic Analysis) [2], for which many time history analyses are essential and the computational effort can be very high. Some main approaches to lessen the computational effort are: (1) reducing the structural systems by replacing the structures finite element models with models with less degrees of freedom [3, 4], (2) reducing the number of essential earthquake records, e.g. see [5-7], (3) reducing the number of oscillatory modes [8, 9], and (4) using higher order time integration methods [10-12]. Meanwhile, in the last two decades, approaches are developed to reduce the computational effort by reducing the earthquake records' data [13-15].

The semi-discretized equation of motion can be expressed as [1, 11, 16-19]:

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{f}_{\text{int}}(t) = \mathbf{f}(t) \quad 0 \leq t \leq t_{\text{end}}$$

$$\text{Initial Conditions : } \begin{cases} \mathbf{u}(t=0) = \mathbf{u}_0 \\ \dot{\mathbf{u}}(t=0) = \dot{\mathbf{u}}_0 \\ \mathbf{f}_{\text{int}}(t=0) = \mathbf{f}_{\text{int}_0} \end{cases} \quad (1)$$

Additional Constraints : \mathbf{Q}

where, t and t_{end} imply the time and the duration of the dynamic behavior; \mathbf{M} is the mass matrix; \mathbf{f}_{int} and $\mathbf{f}(t)$ stand for the vectors of internal force and excitation; $\mathbf{u}(t)$, $\dot{\mathbf{u}}(t)$, and $\ddot{\mathbf{u}}(t)$, denote the vectors of displacement, velocity, and acceleration; \mathbf{u}_0 , $\dot{\mathbf{u}}_0$, and $\mathbf{f}_{\text{int}_0}$, define the initial status of the model ($\mathbf{f}_{\text{int}_0}$ is essential in presence of material nonlinearity; see [20]); and finally, \mathbf{Q} represents restricting conditions, e.g., additional constraints in problems involved in impact or elastic-plastic behavior [21, 22].

For time history analysis of Eq. (1), using a time integration method, the broadly recommended integration-step [1, 23-26] is as follows:

$$\Delta t = \text{Min} \left(\frac{T}{\chi}, \Delta t_{cr}, f \Delta t \right) \quad (2)$$

where, T is the smallest oscillatory period with worthwhile contribution in the response [26], Δt_{cr} stands for the largest integration step leading to numerically stable responses [10, 11, 23], $f \Delta t$ is the step by which the excitation is digitized [13, 25], and as addressed in [1, 23-26],

$$\chi = \begin{cases} 10 & \text{when the behavior is linear} \\ 100 & \text{when the behavior is nonlinear and there is no impact} \\ 1000 & \text{when the behavior is nonlinear and there is impact} \end{cases} \quad (3)$$

In view of Eqs. (1)-(3), there are techniques [14] that replace the earthquake digitized record and specifically replace t_{end} with $(t_{end})_{new}$, such that: (1) after an ordinary time integration analysis, the main features of the response remain almost unchanged, and (2)

$$(t_{end})_{new} < t_{end} \quad (4)$$

There are also techniques [13, 15] that replace the excitation record, such that: (1) the main features of the response, e.g. peak response and frequency content, are almost preserved, and (2) the integration-step Δt , can be replaced with $(\Delta t)_{new}$, satisfying

$$(\Delta t)_{new} > \Delta t \quad (5)$$

The purpose of both of these groups of techniques is to reduce the number of integration steps, and accordingly, lessen the computational run-time and effort; also see [1].

With attention to the following features of a technique in the second group, i.e. the SEB THAAT (Step-Enlargement-Based Time History Analysis Acceleration Technique) [13, 27]:

1. Significant reduction in computational effort; see Table 1,
2. Simple implementation; see [1, 13, 28]
3. Good accuracy for the time history of the response [28]
4. Versatility (see Table 1) [1, 28, 31-34],
5. Having a mathematical basis [13].

the objective of this paper is to review the SEB THAAT, address the existing challenges, and present a perspective of the future.

2 THE SEB THAAT AND ITS PAST

The SEB THAAT is developed, based on two mathematical statements, a broadly accepted convention, and a realistic assumption, such that to preserve convergence and its order, for responses obtained from time integration. The two statements are:

1. Consider analysis of Eq. (1) by a time integration method of order q . Consider an approximation of the $\mathbf{f}(t)$ in Eq. (1), i.e. $\mathbf{f}_{new}(t)$, which converges to $\mathbf{f}(t)$ with respect to the integration step, with an order q' satisfying $q' \geq q$. Analysis of Eq. (1) by that integration method, after replacing $\mathbf{f}(t)$ with $\mathbf{f}_{new}(t)$, would lead to responses converging with order q (see [13, 35]).

System	Effort reduced in the price of negligible change in accuracy (%)	Details
Shear frames	60-80	A few linear shear frames subjected to different excitations
Residential buildings	50-90	More than 200 buildings structures with linear and nonlinear behavior and regularity and irregularity in plan or height subjected to different excitations
A thirty-storey building	50	A thirty-storey steel three-dimensional frame subjected to two different excitations
Bridges	30-80	About 20 real bridges with linear and nonlinear behaviors, some with pre-stressed elements, subjected to different excitations
Power station, Cooling tower, Space structure, Silo	>50	One or two of each special structure, considering linear and nonlinear behavior and different near-field and far-field excitations and different integration schemes
Earth dams	<80	Several earth dams each subjected to many earthquake records

Structural systems damped non-classically	30-90	Considering linear and nonlinear behavior, and different integration schemes

Table 1: A summary of the tests carried out on the SEB THAAT [1, 27-30].

2. In view of the Taylor series expansion [36], for an arbitrary continuous function of x , i.e. $H(x)$,

$$H(x + \Delta x) + H(x - \Delta x) = 2H(x) + O(\Delta x^2) \quad (6)$$

The convention is the second order of accuracy of majority of time integration methods [1, 10, 11]. An extension of the SEB THAAT disregarding this convention is addressed in [13], the numerical tests are however few; see [37]. And finally, the realistic assumption is:

The $\mathbf{f}(t)$ in the right hand side of Eq. (1), though is available in digitized format, can be considered originally continuous with respect to time.

Provided these considerations, implementation of the SEB THAAT means ordinary time integration analysis after replacing the $\mathbf{f}(t)$ in Eq. (1), digitized in step ${}_f\Delta t$, with a new excitation $\mathbf{f}_{new}(t)$, digitized in step $({}_f\Delta t)_{new}$,

$$({}_f\Delta t)_{new} = n {}_f\Delta t \quad (7.1)$$

$$n = 2, 3, 4, \dots \quad (7.2)$$

where, n stands for the enlargement scale of the digitization-step (see also Fig. 2), and

Figure 2: Typical changes in the $\mathbf{f}(t)$ in Eq. (1) because of implementation of the SEB THAAT:
 (a) Digitization stations, (b) Digitized data.

$$\mathbf{f}_{new}(t) = 0, \quad \text{unless when } t = t_0, t_1, t_2, \dots (\text{the digitization stations}) \quad (8.1)$$

$$\mathbf{f}_{new}(t = t_i) = \begin{cases} \mathbf{g}(t_i) & \text{when } t_i = t_0 = 0 \\ a\mathbf{g}(t_i) + (1-a) \sum_{k=1}^{n'} b_k [\mathbf{g}(t_i + k_f \Delta t) + \mathbf{g}(t_i - k_f \Delta t)] & \text{when } 0 < t_i < t'_{end} \\ \mathbf{g}(t_i) & \text{when } t_i = t'_{end} \end{cases} \quad (8.2)$$

$i = 0, 1, 2, \dots$

$$t_i = i(n_f \Delta t) = 0, n_f \Delta t, 2n_f \Delta t, 3n_f \Delta t, \dots t'_{end} \quad (9)$$

$$\mathbf{g}(t_i) = \begin{cases} \mathbf{f}(t_i) & \text{when } 0 \leq t_i \leq t_{end} \\ \mathbf{0} & \text{when } t_{end} < t_i \leq t'_{end} \end{cases} \quad (10)$$

$$a = \frac{1}{2} \quad (11.1)$$

$$b_k = \frac{1}{2n'} \quad (11.2)$$

$$n' = \begin{cases} n-1 & \text{when } t_i = t_1 = n_f \Delta t \text{ or } t_i = t'_{end} - n_f \Delta t \\ \left\{ \begin{array}{l} \frac{n}{2} \text{ (even values of } n) \\ \frac{n-1}{2} \text{ (odd values of } n) \end{array} \right. & \text{when } n_f \Delta t < t_i < t'_{end} - n_f \Delta t \end{cases} \quad (12)$$

$$t'_{end} = \begin{cases} t_{end} & \text{when } \frac{t_{end}}{n_f \Delta t} \in Z^+ \text{ (} Z^+ \text{ implies the set of positive integers)} \\ l(n_f \Delta t) & \text{when } \frac{t_{end}}{n_f \Delta t} \notin Z^+, \exists l \in Z^+, t_{end} < l(n_f \Delta t) < t_{end} + n_f \Delta t \end{cases} \quad (13)$$

and extension of Eqs. (8-13) to fractional/real values of n (see Eq. (7.2)), is discussed in [1, 38, 39]. Evidently, in view of Eq. (2), the SEB THAAT is effective and may reduce the run-time, only when

$$_f \Delta t < \text{Min} \left(\frac{T}{\chi}, \Delta t_{cr} \right) \quad (14)$$

and more, in view of Eqs. (8-13), the effort needed for computing $\mathbf{f}_{new}(t)$ is negligible compared to that of the time history analysis. Accordingly, the enlargement scale n implies reduction in run-time for linear analyses, where no additional computation is needed to model the nonlinearities. Furthermore, in view of Fig. 1 and notion of computational effort [40, 41], the reductions in run-time and computational effort because of the SEB THAAT are identical, for linear analyses.

There is no guarantee about sufficiency of the accuracy of the results of the SEB THAAT when using arbitrary value of n . The reason is that convergence (and its rate) is the only accuracy-related basis of the SEB THAAT. Furthermore, when the SEB THAAT is successful for some value of n , upper-bounds will exist on n . Considering this and some different theoretical questions, research on the SEB THAAT has been followed in two directions. In one direction, to study the performance of the SEB THAAT, many cases are studied, considering changes of structural system, time integration method, digitized excitation (e.g. far- and near-field earthquakes), etc.. For each case, responses are investigated for the following three questions:

- (1) Does $_f \Delta t$ governs Eq. (2), for the case under study (see Eq. (14))?
- (2) For cases with $_f \Delta t$ as the governing term of Eq. (2), can, for some value of n , implementation of the SEB THAAT cause no notable loss of accuracy, i.e. is the following statement correct?

$$\exists n > 1: \mathbf{R}_{new} \cong \mathbf{R} \quad (15)$$

where, \mathbf{R}_{new} and \mathbf{R} are the responses obtained from time integration with and without implementation of the SEB THAAT, respectively.

- (3) For cases, where $_f \Delta t$ governs Eq. (2), is the largest value of n satisfying Eq. (15) (n_{max}) consistent with Eq. (2), i.e. is the following statement correct?

$$\forall n \quad \mathbf{R}_{new} \cong \mathbf{R}: \exists n_{max} \cong \frac{1}{_f \Delta t} \text{Min} \left(\frac{T}{\chi}, \Delta t_{cr} \right): 1 < n \leq n_{max} \quad (16)$$

The consequence was positive responses in almost all cases [1, 27-30, 37-39, 42-56]. Specifically, a very interesting numerical observation, for two cases reported in [42, 43], was the more accuracy after implementation of the SEB THAAT (compared to that of the ordinary analysis). This leads to the fact that the inaccuracy because of the SEB THAAT can be added or subtracted from the inaccuracy originated in the approximate time integration, and accordingly,

$$\exists \text{ Cases : } \|\mathbf{R}_{new} - \mathbf{R}_{exact}\| < \|\mathbf{R} - \mathbf{R}_{exact}\| \quad (17)$$

where, \mathbf{R}_{exact} stands for the exact response and $\|\cdot\|$ represents arbitrary norm [57]. Finally, it is worth noting that the reduction in run-time because of the SEB THAAT is generally considerable, as addressed in Table 1 and Fig. 3. And, as already stated, for linear analyses, the reduction in run-time is equal to the reduction in computational effort.

Figure 3: Reduction in the run-time with respect to the enlargement scale n , for linear analyses accelerated by the SEB THAAT.

In the other direction, some theoretical studies were carried out. First, enlarging the digitization step, without changing the record at the non-eliminated time stations (see Fig. 4), which is implemented as a simple approach for faster analysis since decades e.g. [58], was studied. It was demonstrated that though in some cases the simple approach leads to good accuracy and reduced computational effort compared to the ordinary analysis, the efficiency is in all cases better, when using the SEB THAAT [59]. Specially, cases were observed, where the result of the simple approach was totally erroneous, while the corresponding result of the SEB THAAT was satisfactory [59].

Figure 4: Typical comparison between excitation records in implementation of the SEB THAAT and the traditional simple step enlargement approach considering $n = 2$.

It is then studied whether the inaccuracy because of the SEB THAAT can lead to instability, or in other words, whether the SEB THAAT may negatively affect the responses stability. The response was negative [1, 60], i.e. when Eq. (2) is satisfied the responses are numerically stable regardless of implementation of the SEB THAAT. The main reasons are the convergence basis of the SEB THAAT and the relation between convergence and numerical stability in time integration analyses [61-63]. In the next step, selecting values for a and b in Eq. (8.2), different from those stated in Eqs. (11), and subjected to (see [13]):

$$\sum_{k=1}^{n'} b_k = \frac{1}{2} \quad (18)$$

was studied [64]. As the result, though in some examples Eqs. (11) did not present the best alternative, the overall best selection can be considered as stated in Eqs. (11). Another question was on how to consider non-integer values as the enlargement scale n . This is essential especially with attention to Fig. 3 and when the n_{\max} available from Eq. (16) satisfies:

$$1 < n_{\max} < 2 \quad (19)$$

Two simple approaches to extend the SEB THAAT to:

$$n, n_{\max} = \frac{p}{q} \quad , \quad p, q \in \mathbb{Z}^+ \quad (20)$$

and

$$n, n_{\max} \in \mathbb{R}^+ \quad (\mathbb{R}^+ \text{ stands for the set of positive real numbers}) \quad (21)$$

can be found in [38, 39].

The effect of nonlinear behavior on the performance of the SEB THAAT was another area for theoretical study. The carried out brief study led to the good performance of the SEB THAAT, when adequate values are assigned to the nonlinearity parameters [49, 65]. Further study seems essential.

Meanwhile, in response to a question, after a conference presentation, it was demonstrated that the T in Eq. (2) should be related to the response, the accuracy of which, is under study [66]. Some initial study was also carried out on the frequency content of the inaccuracies because of the SEB THAAT [67].

And finally, the most recent study was on the performance of the SEB THAAT when the structural viscous damping is non-classical. The study had a numerical/theoretical nature. As the consequence, for majority of integration methods, the performances of the SEB THAAT in application to classically and non-classically damped analyses are conceptually similar [27]. For other integration methods, the case may be the same as well, though can not be guaranteed before the analysis [27].

3 THE EXISTING CHALLENGES

As implied in the previous sections and specifically in Table 1 and Fig. 3, the reduction in computational effort because of implementation of the SEB THAAT can be considerable. Considering this, the simplicity and versatility of the SEB THAAT, the comparisons made between the SEB THAAT and other analysis acceleration methods [1, 68], the importance of computational effort in practical structural analyses, and the fact that structural systems become larger and more complicated every new day, the SEB THAAT can be considered a successful analysis acceleration technique in need of further research for broad practical

implementation. Accordingly, special attention should be paid to the challenges facing the SEB THAAT. Some of the most important challenges are as follows:

The first challenge relates to the T in Eqs. (2), (14) and (16). The T is not only vague, because of the expression “worthwhile contribution” in its definition (see the definition just after Eq. (2)), but also is not computable prior to the analysis. The consequence is a serious problem in determination of n_{\max} and n ; see Eq. (16). Practical implementation of the SEB THAAT will hence be significantly affected and indeed becomes complicated, the least; i.e. what is the value to be assigned to step enlargement scale n resulting in the determination of the $(\int \Delta t)_{\text{new}}$ and $\mathbf{f}_{\text{new}}(t)$? Recently, efforts for overcoming this problem are reported (see [31]). These efforts make use of a convergence-based conventional error-control method [23, 69, 70] and the practical suggestions stated in seismic standards [25, 71]. According to these efforts, the analysis is carried out via sequential time history analyses, each throughout $[0 \ t'_{\text{end}}]$ using a special enlargement scale. The repetitive analyses are continued, till two sequential responses are sufficiently close. The resulting analysis seems powerful and versatile, in the limits of structural dynamics problems, but not restricted to satisfaction of Eq. (14). More study on this effort and analyzing problems in real need of run-time reduction are essential.

The second challenge relates to the true nature of many oscillatory behaviors, which is a combination of inertial (structural dynamics) behavior and wave propagation. As implied in Eqs. (1) and (2) and Table 1, the SEB THAAT is mostly applied to analysis of structural dynamic problems. Study on application of the SEB THAAT in analysis of wave propagation problems is complicated, especially because of the CFL condition [72] (this condition upper-bounds the time integration step by a coefficient of the element sizes in spatial discretization by finite elements). Despite, successful numerical efforts presented in this regard [29, 30, 48], further detailed study is essential, both in theory, as well as in application. The relaxation method recently proposed for the CFL condition [73, 74] seems a good starting point.

The third challenge returns to the purpose of the SEB THAAT, i.e. reduction of the computational effort in time integration analysis of structural systems against digitized excitations. As implied in Eqs. (2) and (14), the SEB THAAT cannot reduce the analysis computational effort, when the excitation digitization step $\int \Delta t$ does not dominate Eq. (2), i.e.

$$\text{Min}\left(\frac{T}{\chi}, \Delta t_{cr}\right) \leq \int \Delta t \quad (22)$$

Overcoming this restriction is a main challenge facing the SEB THAAT for highly oscillatory and highly nonlinear problems, for which T can be sufficiently small to satisfy Eq. (22). Though the ongoing efforts on the first challenge seem effective in easing this challenge, direct efforts to cancel this restriction would be instructive and reasonable. No such effort is reported yet. Enhancement in the accuracy or order of accuracy of the integration scheme and/or the SEB THAAT seems an appropriate solution.

A fourth challenge is implementation of the SEB THAAT in analysis of structural systems subjected simultaneously to several excitations digitized in completely different step-sizes. Considering that many important structural systems, e.g. offshore or super-tall structures, are in this group, overcoming this challenge is of high practical importance. No special effort is reported yet.

And finally, for practical implementation of the SEB THAAT, besides clear determination of the enlargement scale (n) discussed as the first challenge, it is important to have an idea about the resulting reduction in computational effort. Figure 3 clarifies this ambiguity for lin-

ear analyses. The case is however different for nonlinear analyses, and even there is yet no theoretical guarantee for the reduction of the run-time and computational effort. Especially the method of nonlinearity iteration and the related parameters can significantly affect the reductions. Though in many nonlinear analyses, the reduction in run-time is less than that reported in Fig. 3, the opposite can be correct, as well; see [42, 43, 75]. Considering that nowadays structural dynamic analyses are generally nonlinear, without overcoming this challenge, implementation of the SEB THAAT would hardly be accepted in practice. Yet, no effort is reported.

4 A LOOK AT THE FUTURE

In view of the discussions presented in Sections 1-3, the SEB THAAT can be considered as a successful analysis acceleration technique in need of further research. Nevertheless, especially to manage and access the research resources, it is important to have a perspective of the future of the SEB THAAT and the probable needs to this technique.

With attention to Section 3, the SEB THAAT seems in progress in both numerical experiments' direction, as well as the theoretical aspects' direction. The growing sizes of structural models, and complicatedness of analysis requirements from different points of view, e.g. material and excitation, highlight the significance of analysis acceleration. In addition, the seismic recording instrumentation is in progress towards smaller digitization step $f_s \Delta t$ [76]. Besides, because of the everyday advancement in structural design optimization and the growing popularity of the optimization, the T in Eq. (2) will likely become larger in future. These lead to more chance for $f_s \Delta t$ to be the governing term in Eq. (2). The consequence is more need to the SEB THAAT, in near- and mid-future. Accordingly, it is reasonable to anticipate efforts to overcome the first challenge addressed in Section 3, i.e. clear determination of the enlargement scale n , in near future. The study reported in [31] implies an initial step that should be established, after which extending the SEB THAAT to wave propagation problems can be anticipated for future studies. The next step can be plugging the SEB THAAT in a commercial soft ware, e.g. seismo-struct [77]. With an analysis soft ware equipped with the SEB THAAT, many different numerical tests, considering different structural materials, such as wood, aluminum, epoxy glass composites, different nonlinear behaviors, interaction with completely different behaviors, subjected to different earthquake records, temperature changes, soil-structure-interaction, etc. can be simply carried out. Specifically, efforts on the fourth challenge addressed in Section 3 can be carried out much simpler. In mid- and far-future, it will be reasonable to try for improving the SEB THAAT, especially to overcome the third challenge addressed in Section 3. This seems possible, either directly with attention to the very details of the technique [1], the integration methods, or even by combining the SEB THAAT with other techniques, such as those proposed in [5-7, 14].

Furthermore, and in view of the mathematical basis of the SEB THAAT [1, 13], this technique can be tested in non-seismic problems, where the excitation is not originated in earthquakes. First steps in this area are already taken; see [32, 78]. Even more, the digitization might be limited to some part or some components of the $\mathbf{f}(t)$ in Eq. (1), or more, to terms of Eq. (1) other than the excitation. Some related studies are already reported [33, 34]. In far future, the SEB THAAT seems having the potential to be accepted as a general tool for data simplification for arbitrary numerical computation. The most important pre-requisite is however to overcome the first challenge addressed in Section 3.

Meanwhile, no anticipation is possible for the future of the fifth challenge, addressed in Section 3. The reason is the same ambiguity for ordinary time history analysis, persisting since decades. A unique solution can however be anticipated for both ambiguities.

5 CONCLUDING REMARKS

As a technique for accelerating time history analysis, by enlarging the excitation records' digitization steps ($\int \Delta t$),

1. The SEB THAAT can be considered a successful analysis acceleration technique, in need of further research.
2. For practical implementation in real problems, there are still challenges to be overcome; the most important challenges can be summarized as:
 - (a) clear determination of the enlargement scale (n),
 - (b) providing the capability to successfully implement the SEB THAAT in analysis of wave propagation problems,
 - (c) providing the capability to successfully implement the SEB THAAT in analysis of highly oscillatory/nonlinear problems,
 - (d) providing the capability to successfully implement the SEB THAAT in analysis of problems with several excitations completely different in digitization step and time length,
 - (e) clarifying the amount of run-time and computational effort reduction in nonlinear analyses prior to the analyses.
3. The future of the SEB THAAT is promising, especially considering the improvements in the recording instrumentation.
4. Besides, the challenges addressed in the Point 2 above, some areas for further research are:
 - (a) Combination of the SEB THAAT, with other analysis acceleration techniques.
 - (b) Plugging the SEB THAAT in commercial structural analysis soft ware, and application of the SEB THAAT to different time history analyses.
 - (c) Applying the SEB THAAT to computations other than those in structural and earthquake engineering.
 - (d) Study on the details of the SEB THAAT, to improve the results accuracies.

Finally, the author anticipates that the SEB THAAT will eventually be extended to a data simplification technique.

Abstract

In recent years, the numerous seismic events occurred have pointed out the need for a prompt classification of the built heritage in terms of seismic vulnerability. the concept of vulnerability is closely linked to the definition of the capacity curve, requiring sophisticated numerical procedures to be performed, such as the inelastic incremental analysis.

Therefore, the simplified method herein proposed requires use of only analytically simple analyses such as the elastic analysis and the rigid-plastic analysis. For this reason, this method can be used in the immediate aftermath of an earthquake and also for a large-scale classification of the buildings. The proposed methodology has been set up by a wide parametric analysis, carried out on 420 frames designed according to 3 different approaches: the first one is linked to the Theory of Plastic Mechanism Control (TPMC), assuring the design of structures showing global collapse mechanism (GMRFs), the second is based on the Eurocode 8 requirements (SMRFs) while the third is a non-seismic design, based on vertical loads (OMRFs).

Keywords: Pushovers, Capacity, Performances, Vulnerability, Simplified methods.

1 INTRODUCTION

The evaluation of seismic performances of existing buildings has gained, in recent years, an increasingly interest in seismic and structural engineering [1]-[11]. In particular, the setting up of design rules based on the so-called hierarchy criteria has changed the designer approach to let building able to withstand seismic events with an adequate level of reliability [12]-[22]. In the safeguard of the built heritage the knowledge of the seismic response of the structures plays a fundamental role [24]-[25]. Therefore, any seismic retrofitting or improvement of an existing building should be preceded by a strength evaluation phase before the intervention. The evolution of codes, numerical methods and calculation tools has provided designers the access to advanced methodologies of seismic assessment [26]. The seismic performances of buildings are evaluated by comparing the capacity of dissipating incoming seismic energy with the seismic demand. The main difficulties that arise from developing a performance checking procedure, are linked to the definition of damage levels corresponding to predetermined performance levels, in a methodology that can be applied in everyday practice [27]-[30]. Resorting to non-linear static analysis, through a structural analysis programme, is conditioned by the precision of the structural model, having to be adequately accurate to catch the non-linear behaviour. The whole process is not easy to standardise and for this reason a simplified methodology, able to define the capacity curve analytically, has been defined. This model shows a full inclination to code liability not requiring complicated analyses and being uniquely defined. To this scope, several parametric analyses, in terms of pushover, on 420 frames, designed according to three different approaches, were made and their results in terms of capacity curves were analysed. In particular, each capacity curve has been simplified by defining 3 branches: the elastic response curve, the maximum horizontal forces multiplier curve and the mechanism equilibrium curve. In this evaluation, the role of the beam-to-column joints has not been considered considering that the beam ends are equipped with full strength-full stiff joints [31]-[38].

2 TRILINEAR MODEL OF THE CAPACITY CURVE

2.1 Definition of the three branches

One of the most common tools adopted to assess the capacity of a structure is the pushover analysis. The simplified method herein proposed only requires use of common analyses such as the elastic structural analysis and the rigid-plastic analysis. For this reason, it lends itself well to be used in the immediate aftermath of an earthquake, not requiring any static or dynamic non-linear analyses. Therefore, the user can quickly obtain the capacity curve through the intersection of three linear branches (Fig. 1), computed by means of simple equations reported in the following. The shape of the capacity curve, for a given structure, is affected by the occurring collapse mechanism. The first branch is affected by the elastic behavior of the structure. The knee depends on the plastic capacity distribution, appearing sharper as more as the plastic hinges develop simultaneously while the slope of softening branch is linked to the second-order effects.

Referring to the trilinear model proposed, the first branch of the curve can be approximated by the elastic response curve; the horizontal one is provided by the maximum load bearing capacity, while, the softening branch is given by the collapse mechanism equilibrium curve of the structure, influenced by the second order effects. The definition of the third branch, is linked to the concept of mechanism equilibrium curve [40], [41]. Therefore, the mechanism equilibrium curve is a straight line, expressed in the following form:

$$\alpha = \alpha_0 - \gamma_s \delta \quad (1)$$

Figure 1: Trilinear model of the capacity curve.

where α_0 is the kinematically admissible multiplier of horizontal forces due to first-order rigid-plastic analysis and γ_s is the slope of the mechanism equilibrium curve [42]-[51]. Providing input data about mechanical and geometric properties of structural members, acting forces [52]-[54] and the potential collapse configurations, both α_0 and γ_s can be computed for each type of possible collapse mechanism. According to the extension of the kinematic theorem of plastic collapse to the concept of mechanism equilibrium curve, the triggering mechanism will be the one characterized by the curve located below the others into a given displacement range compatible with the local ductility supply.

2.2 Parametric analysis

The definition of the horizontal branch of the trilinear curve and the plastic rotation demand corresponding to the collapse condition was achieved through a wide parametric analysis on moment resisting steel frames (MRFs) and calibrated by regression analysis according to the results obtained by the pushovers performed on MRFs.

The parametric analysis has been carried out with reference to three categories of frames:

- GMRFs (Global moment resisting frames) designed according to TPMC procedure (showing global collapse mechanisms);
- SMRFs (Special moment resisting frames) designed according to hierarchy criterion as suggested by Eurocode 8 [53], able to avoid “soft storey” collapse mechanisms;
- OMRFs (Ordinary moment resisting frames) designed without any requirement aimed at the control of the collapse mechanism and usually showing “soft storey” collapse mechanism.

The parametric analysis regarded 140 geometrical schemes of low-rise frames by varying the *number of bays*, n_b from 2 to 6, the *number of storeys*, n_s from 2 to 8, the *bay span*, equal to 3,00 m, 4.50 m, 6.00 m, 7.50m and the three different design approaches for a total number of

420 designed structures. All the combinations were analysed considering dead loads (G_k) equal to $3.5kN/m^2$, live loads (Q_k) equal to $3kN/m^2$ and interstorey height of 3.5m [54].

2.3 Calibration of maximum multiplier formula

To define the horizontal branch of the trilinear curve and the point corresponding to the collapse condition, wide parametric and regression analyses on moment resisting steel frames (MRFs) have been carried out. In particular, MRFs are analysed through pushover analyses - [56] in order to check the correspondence between their results and the aforementioned trilinear model. The maximum multiplier corresponding to the maximum bearing capacity is derived by the Merchant-Rankine formula [57] as a combination of the collapse multiplier obtained by the rigid-plastic analysis α_0 and the critical collapse multiplier for vertical loads. Introducing a calibration factor, useful to ensure a large application of the method, the relation has been rearranged as:

$$\alpha = \alpha_0 - \gamma_s \delta \quad (2)$$

where:

$$\alpha = \alpha_0 - \gamma_s \delta \quad (3)$$

$$\alpha = \alpha_0 - \gamma_s \delta \quad (4)$$

I_b and L_b are the inertia and the length of the beam, respectively; I_c e L_c are the inertia and the height of the column; E is the elastic modulus; a and b are the regression coefficients. The parameter ξ is calculated with reference to the first storey members.

The coefficient Ψ can be computed according to the following relation, which guarantees an accurate evaluation of the α_{max} as Figure 2 testifies:

$$\alpha = \alpha_0 - \gamma_s \delta \quad (5)$$

Figure 2: Regression analysis for the maximum multiplier formula.

2.4 Characteristic points of the trilinear model

Starting from the trilinear approximation model, four characteristic points of the simplified capacity curve (points A, B, C, D of Fig. (3)) have been identified. These points are associated to limit states with the meaning of identifying a target performance [58]-[61].

Figure 3: Characteristic points of the trilinear capacity curve

▪ Point A

This point corresponds to the minimum value between the maximum storey displacement under serviceability conditions and the multiplier of the horizontal forces corresponding to the formation of the first plastic hinge. It is associated with the "Fully Operational" limit state.

The multiplier corresponding to point A, will be calculated as follows:

$$\alpha = \alpha_0 - \gamma_s \delta \quad (6)$$

▪ Point B

Point B corresponds to the development of the maximum bearing capacity of the structure and to the elastic limit of the structure and is associated with the "Operational" limit state. To locate point B, the maximum multiplier ($\alpha_{max} = \alpha_B$) has to be computed, by means of the Merchant-Rankine formula (Eq. (2)).

Therefore, it can be stated that:

$$\alpha_{max} = \alpha_B = \frac{1}{\delta_1} \delta_B \quad (7)$$

where the unknown is the top sway displacement δ_B

▪ Point C

Point C corresponds to the development of the collapse mechanism and is associated with the "Life Safety" limit state.

The corresponding top sway displacement δ_C can be derived as follows:

$$\delta_C = \delta_{mecc} = \frac{\alpha_0 - \alpha_{max}}{\gamma_s} + \delta_y \quad (8)$$

▪ Point D

Point D corresponds to the overcoming, at least in one member, of the local ductility supplies and is associated with the "Near Collapse" limit state. This is the case of very rare seismic events in which considerable local ductility is required.

The corresponding top sway displacement $\delta_D = \delta_u$, is calculated as follows:

$$\delta_D = \delta_C + (\vartheta_{p.u} - \vartheta_{p.mecc})H_0 \quad (9)$$

where $\vartheta_{p.u}$ is the plastic hinge rotation assumed equal to $8.0 \vartheta_y$ according to Eurocode 8 [60], $\vartheta_{p.mecc}$ is the plastic hinge rotation corresponding to the formation of the collapse mechanism, H_0 is the total height of storeys involved into the collapse mechanism.

For the evaluation of plastic rotations occurring in the critical members, an analytical formulation is proposed, based on a simplified Grinter's (shear type) single storey portal in which it is assumed that the plastic moments are different at the top and at the base of the columns, to represent the plastic redistribution capacity characterizing frames with more storeys and bays. The relationships for the evaluation of the plastic rotation corresponding to the development of the collapse mechanism are proposed as follows:

$$\frac{\theta_{p.mec} H_0}{n_s \delta_y} = \frac{\Psi_1}{\Psi_2} \Psi_3 \left(\frac{\alpha_{max}}{\alpha_y} - 1 \right)^{\Psi_4} \frac{1 - \Psi_5 \gamma_s}{1 - \Psi_6 \gamma_s} \quad (10)$$

$$\frac{\theta_{p.mec} H_0}{n_s \delta_y} = \frac{\Psi'_1}{\Psi'_2} \Psi'_3 \left(\frac{\alpha_{max}}{\alpha_y} - 1 \right)^{\Psi'_4} \frac{1 - \Psi'_5 \gamma_s}{1 - \Psi'_6 \gamma_s} \quad (11)$$

where H_0 is the total height of storeys involved into the collapse mechanism, n_s is the number of storeys, α_y is the multiplier of the horizontal forces corresponding to the formation of the first plastic hinge, δ_y is the displacement corresponding to the formation of the first plastic hinge. The Ψ_i coefficients, determined by regression analyses, are given by:

$$\Psi_1 = a_1 + b_1 n_b \quad \Psi'_1 = a'_1 + b'_1 n_b \quad (12)$$

$$\Psi_2 = a_2 + b_2 n_s \quad \Psi'_2 = a'_2 + b'_2 n_s \quad (13)$$

$$\Psi_i = a_i + b_i \xi \quad i = 3, \dots, 6 \quad \Psi'_i = a'_i + b'_i \xi \quad i = 3, \dots, 6 \quad (14)$$

The results of linear regression on GMRFs and SMRFs, are reported in Figs. (4-7).

Figure 4: Regression analysis GMRFs - $\theta_{p.mec}$, 1st yielded element.

Figure 5: Regression analysis GMRFs - $\theta_{p.mec}$, critical column.

Figure 6: Regression analysis SMRFs - $\theta_{p.mec}$, 1st yielded element.

Figure 7: Regression analysis SMRFs - $\theta_{p.mec}$, critical column.

3 ASSESSMENT PROCEDURES IN TERMS OF SPECTRAL ACCELERATIONS

3.1 ADRS spectrum approach

According to the ADRS spectrum approach, for each limit state, the spectrum $S_a - S_{De}$ will be defined by means of the relationship $S_{De}(T) = S_a(T)(T/2\pi)^2$. For the definition of the capacity it is necessary to represent the characteristic points of the trilinear curve of the structure, in the ADRS plane through the abscissa, that is the displacement $d_{LS}^* = d_{LS}/\Gamma$.

It is necessary to distinguish between the cases $T^* > T_C$ e $T^* < T_C$. If $T^* > T_C$. The capacity in terms of spectral acceleration, for a specific limit state, can be obtained through the following relationship:

$$S_{aSL} = d_{LS}^* \omega_0^{*2} \quad (15)$$

The demand is represented by the spectral acceleration provided by the code, for the specific limit state, considering the equivalent period of vibration T^* .

For the assessment procedure, the inequality $S_{als} \geq S_a(T^*)$ has to be satisfied.

If $T^* < T_C$ and $q > 1$, according to equality of energy criteria, there is a different procedure to evaluate the capacity that leads to the anelastic spectrum:

$$F_{ls}^* = \frac{m^* S_a(T^*)}{q_{ls}} \quad (16)$$

$$q_{ls} = 1 + (\mu_{ls} - 1) \frac{T^*}{T_C} \quad (17)$$

$$S_{aSL} = q_{ls} \frac{F_{ls}^*}{m^*} \quad (18)$$

3.2 Nassar & Krawinkler approach

The proposed approach overcomes the limits of the verification methodology proposed by the current seismic codes. In addition, it accounts for second-order effects, occurring when the collapse mechanism is fully developed.

In the framework of capacity-demand checking procedure, the MDOF actual system is replaced by an equivalent SDOF system an equivalent SDOF system introducing the modal participation factor Γ . Multiplying the multiplier of horizontal forces α with the design base shear the capacity curve is reported in a $F_b - d_c$ plane (base shear force-top-sway displacement).

The capacity curve must be reduced through the modal participation factor and represented in a $F^* - d^*$ plane through the relations $F^* = F_b/\Gamma$, $d^* = d_c/\Gamma$.

The demand can be estimated through the period T^* and the equivalent mass m^* . In the following, the verification procedure for each characteristic point of the capacity curve approximated with trilinear model is reported.

- Point A (Fully operational)

The capacity in terms of spectral acceleration for the point A is given as follows:

$$F_{FO}^* = m^* S_{aFO}(T^*) \quad (19)$$

- Point B (Operational)

The capacity in terms of spectral acceleration for the point B is given as follows:

$$S_{aO}(T^*) = \frac{F_O^*}{m^*} \quad (20)$$

▪ Point C (Life Safe)

The capacity in terms of spectral acceleration for the point C is given as follows:

$$S_{aLS}(T^*) = \frac{F_{LS}^*}{m^*} q_{LS} \quad (21)$$

$$q_{LS} = q_0(\mu, T, \gamma=0) = [c(\mu_{LS} - 1) + 1]^{1/c} \quad (22)$$

where $c = \frac{T^*}{1+T^*} + \frac{0.42}{T^*}$ and $\mu_{LS} = \frac{d_{LS}^*}{d_O^*}$.

In the case of point C (and point D), the structure draws on its own plastic resources to dissipate incoming seismic energy. Consequently, the q structure factor comes into play, expressed according to the formulation of Nassar and Krawinkler [30], as a function of the ductility μ_{LS} .

▪ Point D (Near Collapse)

The capacity in terms of spectral acceleration for the point D is given as follows:

$$S_{aNC}(T^*) = \frac{F_{NC}^*}{m^*} q_{NC} \quad (23)$$

$$q_{NC} = \frac{q_0}{\varphi} \quad (24)$$

To take these into account, the coefficient φ which is a function of the ductility μ and the slope of the equilibrium curve γ (expressing the sensitivity of the structure to second-order effects), has been introduced:

$$q_0(\mu, T, \gamma=0) = [c(\mu_{NC} - 1) + 1]^{1/c} \quad (25)$$

where $c = \frac{T^*}{1+T^*} + \frac{0.42}{T^*}$ and $\mu_{NC} = \frac{d_{NC}^*}{d_O^*}$

$$\varphi = \frac{1+0.62(\mu_{NC}-1)^{1.45}\gamma}{(1-\gamma)} \quad (26)$$

4 CONCLUSIONS

In conclusion, the proposed methodology opens-up new scenarios regarding the seismic classification of the built heritage. An analytical methodology allows to evaluate uniquely the seismic vulnerability of buildings without passing through complex analyses not manageable by means of codes and prescriptions. The trilinear model seems to be the right compromise between accuracy in analysis and computational speed and fits well in all the major seismic codes. The assessment of structure performances, in terms of comparison capacity-demand, has been performed by means of the Nassar & Krawinkler approach, characterized by a wide generality because it does not discriminate between high and low periods of vibration and accounts for second-order effects by means of the stability coefficient φ . Finally, it is important to note that discretization in characteristic points of the capacity curve makes easy the comparison capacity-demand and already shows inclination towards the generality of the application of the method, being associated with behavioural characteristics of structures that are independent of the structural type.

Abstract

Existing steel moment-resisting frames in several seismic regions worldwide are often characterised by high vulnerability to earthquakes due to insufficient local and/or global ductility. Nowadays, it is of paramount importance to assess their response under strong motions and provide cost-effective retrofitting strategies. Amongst others, the seismic behaviour of these frames is often strongly affected by the presence of masonry infills which, from one side, if adequately distributed, beneficially contribute to the seismic resistance of the structure providing stiffness and strength to the frame, from the other side often experience a brittle behaviour and are very vulnerable to seismic actions. To this end, the H2020-INFRAIA-SERA project HITFRAMES (i.e., Hybrid Testing of an Existing Steel Frame with Infills under Multiple EarthquakeS) experimentally evaluated a case study building representative of non-seismically designed European steel frames with masonry infills and investigated a possible retrofit strategy. This paper takes advantage of the experimental results of the HITFRAMES project to calibrate numerical models in OpenSees of a case study building which is analysed as bare, infilled and retrofitted frame with buckling-restrained braces (BRBs). The impact of masonry infills and BRB-retrofit is investigated by comparing the response of models with different configurations.

The numerical results provide some insights on the ability of BRB-retrofit option in protecting not only the steel frames from experiencing critical damage during earthquakes but also the masonry infills and on the importance of using appropriate models for the masonry infills in the assessment procedures.

Keywords: Existing steel frames, Retrofitting, Buckling-restrained braces, Masonry infills, Seismic response, Numerical Simulations.

1 INTRODUCTION

Many existing steel structures worldwide were built before the introduction of modern seismic design provisions and may exhibit high seismic vulnerability due to lack of proper lateral resisting systems and detailing, as well as inadequate energy dissipation capacity [1,2]. Among others, Di Sarno *et al.* [3] investigated the failure patterns of an existing steel moment resisting frames (MRFs) located in Amatrice and damaged by the 2016 Central Italy earthquakes. The case study structure was characterised by large residual lateral drifts with significant yielding at beam-column connections and soft storey mechanisms. Severe damage was also noted in non-structural components, including in-plane and out-of-plane failure of masonry infill walls. This damage is consistent with damage reported in previous earthquakes (*e.g.*, [4–6]). Although masonry infills can significantly contribute to the overall strength and stiffness of a steel MRF [7–9], their structural properties easily degrade with strong or long ground motions (GMs), as well as with cumulative demands, such as foreshock-mainshock-aftershock sequences, as in the case of the 2016 Central Italy Earthquake [10–13].

In this context, the H2020-SERA project HITFRAMES (Hybrid Testing of an Existing Steel Frame with Infills under Multiple Earthquakes) is aimed on assessing the seismic performance of existing steel frames with masonry infills under multiple earthquakes and the feasibility of retrofitting with buckling restrained braces (BRBs) [14–18]. Among others, the objectives of the HITFRAMES project include: (1) to experimentally assess the seismic performance of non-seismically designed steel frames with masonry infills under earthquake sequences, including the effects of cumulative damage; (2) to evaluate the existing masonry infill models and to develop new calibrated models aimed at describing the behaviour of masonry panels within infilled steel MRFs; and (3) to experimentally evaluate the contribution and effectiveness of BRB-based retrofitting strategies in steel MRFs.

Figure 1 shows the set-up of the experimental test carried out as part of the HITFRAMES project. It consists of a 75% scaled, two-storey steel MRF, designed primarily for gravity loads with insufficient seismic detailing [19,20]. The test was conducted at the Structures Laboratory (STRULAB) of the University of Patras, Greece, and it included a pseudo-dynamic (PsD) testing procedure. The prototype building was designed to be a representative of non-seismically designed steel frames based on the characteristics observed in the Amatrice building [3]. The specimen was subjected to GM sequences, based on GMs recorded at Norcia (NRC) station, in Central Italy, and summarised in Table 1.

The present paper proposes a preliminary numerical study of the seismic response of the steel building tested during the HITFRAMES experimental campaign. First, a preliminary calibrated masonry strut model is developed, based on the observations of the HITFRAMES experiment. This model is compared with three widely used single strut masonry models available in literature, through time history analysis and by considering GM1. Then, the numerical model is retrofitted by means of BRBs, in order to evaluate the effectiveness of the devices when interacting with the masonry panels. Finally, conclusions are drawn highlighting the relevance of accurately modelling the masonry infills while assessing the performance of the retrofitted structure.

Event	Date & time	Mw	R _{epi} [km]	PGA [g]
GM1	24/08/2016 1:36	6.0	15.3	0.35
GM2	30/10/2016 6:40	6.5	4.6	0.48
GM3	26/10/2016 17:10	5.4	9.4	0.3

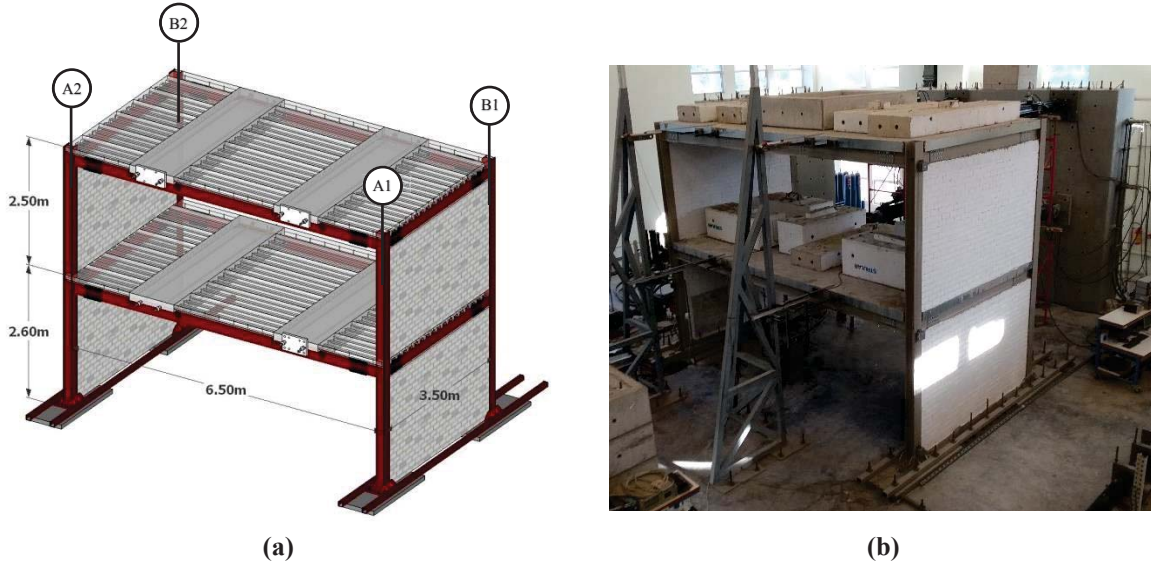

Figure 1: Experiment set-up: (a) 3D model of lab specimen; (b) constructed lab specimen.

2 EVALUATION OF EXISTING MASONRY INFILL MODELS

For the present paper, a non-linear OpenSees numerical model [21] is developed. Columns are modelled with a distributed plasticity approach (*Steel01*), while the beams are modelled by considering a lumped plasticity approach. In the latter approach, plastic hinges are modelled by considering the formulation by Lignos and Krawinkler [22] and modified according to Zareian and Medina [23]. Material properties are consistent with the characterisation tests performed on the steel members after the experiments.

Masonry panels are included by considering a macro-modelling approach, which consists of one simple compression-only diagonal strut on each direction (*i.e.* in X shape). The behaviour of the masonry infills is represented by using a *pinching4* OpenSees material.

2.1 Calibration of masonry infill struts based on experimental results

The calibration of masonry struts is carried out by reproducing the deformation history imposed during the PsD testing in an OpenSees numerical model. The full GM sequence comprises six records in the following order: GM1, GM1, GM2, GM3, GM1 and GM2, with the last two upscaled to 300% in the acceleration axis. As the 75% scaling rules followed for the lab specimen consider constant stress, the time axis in the accelerogram is also multiplied by $0.75^{1/2} = 0.87$ in all GMs.

The masonry strut displacement values (δ_n) are directly obtained from the horizontal floor deformation (Δ_n), assuming negligible vertical deformation and by considering a simple geometric transformation, as follows

$$\delta_n = d_n - d_0 = \sqrt{d_0^2 + 2L\Delta_n + \Delta_n^2} - d_0 \quad (1)$$

where d_0 is the undeformed diagonal length, d_n is the deformed diagonal length at step n , and L is the span length of the frame. Forces are estimated under the assumption that the MRF system works in parallel with the masonry strut, which effectively creates a truss-like mechanism with the steel frame (*i.e.*, the infill-frame interaction does not modify the frame deformation pattern), therefore, the forces assigned to the masonry strut in the numerical model are simply a subtraction of the total storey shear minus the storey shear exhibited by the bare frame at the same level of storey drift.

For this purpose, the elastic and modal properties of the bare frame OpenSees model are validated by comparing the results of the lab characterisation tests (*i.e.*, material testing, snap-back test) [13] with the numerical model. The validated numerical model of the bare frame is then subjected to the storey displacement history observed during the PsD testing in a displacement-controlled manner, with the resulting storey shear values (V_n) recorded. The resulting horizontal shear values at each storey (V_n) are approximated to diagonal equivalent forces (F_n), as follows

$$F_n = \frac{V_n \sqrt{h^2 + (\Delta_n + L)^2}}{\Delta_n + L} \quad (2)$$

where h is the inter storey height.

Figure 2 shows the forces and deformations attributed to one masonry panel (*i.e.*, one compression-only strut on each direction) in comparison with the calibrated model. Four masonry panels per storey are considered in the numerical model (*i.e.*, two double layer walls), therefore, the struts shown in Figure 2 only withstand one quarter of the total load. The masonry struts are calibrated on the *pinching4* material in OpenSees, and their properties are summarised in Table 2.

Figure 2: Hysteretic behaviour of the masonry struts during the HITFRAMES experiments, in comparison with the calibrated model. The calibrated pinching parameters are $rDisp = 0.5$, $rForce = 0.2$, $uForce = 0.05$. The calibrated degradation parameters are $gK1 = 0.15$, $gD1 = 0.15$, while all the others keep their default values.

2.2 Comparison of existing masonry infill models with experimental results

Several masonry strut models have been proposed in literature, nonetheless, most of them have been calibrated for reinforced concrete (RC) frames and their application to steel frames is not yet validated. Some of these models comprise complex strut configurations (*e.g.*, multiple struts, additional shear springs, etc.), nonetheless, the most common ones are based on a single strut approach.

Panagiotakos and Fardis (PF) [7,24] proposed a single-strut constitutive model to represent the behaviour of solid (*i.e.*, with no openings) masonry infills in RC frames. This model is characterised by four stress states: (1) initial elastic behaviour of the uncracked masonry infill; (2) post-elastic linear response, characterised by a reduced stiffness; (3) softening of the masonry panel after the maximum force; and, (4) residual axial strength region. The strut resistance is calculated based on the area of the masonry strut, which is the product of the wall thickness and the theoretical width of the strut. This measure depends not only on the properties of the masonry wall, but also on the surrounding frame. Dolšek and Fajfar (DF) [8] proposed a similar model whose main difference is to have a strut resistance implicitly calculated in the capacity formulations. In addition, this model considers that the masonry strut possesses no residual capacity. Decanini and Fantin [25] proposed a model, successively updated by Liberatore and

Decanini (LD) [26], for the evaluation of the seismic response of high-rise RC buildings designed as bare frames but with significant infill contribution. This model considers empirical relationships to define the horizontal capacity and stiffness of the struts.

A comparison of the calibrated masonry strut model is made with the aforementioned models proposed in literature and is shown in Figure 3. The basic material properties of the masonry were obtained from material characterisation tests: compressive strength, $\sigma_{w0} = 2.85$ MPa; shear strength, $\tau_{w0} = 0.653$ MPa. The elastic modulus was estimated by using the relationship proposed by FEMA 356 [27], $E_{w0} = 550\sigma_{w0}$, while the shear modulus is considered to be $G_{w0} = 0.4E_{w0}$. The following observations can be made from the comparison with the calibrated masonry struts: (1) the calibrated model for the bottom storey seems to have more similarities in terms of forces with the PF model and the DF model; (2) the LD model tends to underestimate the force capacity and to overestimate the deformation capacity; regardless of the similar inter-storey heights, the top masonry strut exhibits lower capacity; and (4) the calibrated model exhibits lower initial and post-yielding stiffness than any of the models available in literature. A comparison of the backbone properties for each model is detailed in Table 2.

Figure 4 shows a comparison of the storey shear response obtained during the GM1 of the displacement-based test, by considering the LD and the calibrated models. As observed, the LD shows larger force at low values of displacement, in comparison with the calibrated model. On the other hand, forces are larger in the calibrated model at large displacement values. These observations are consistent with the larger initial stiffness and lower maximum force capacity of the LD model.

3 ASSESSMENT OF THE RETROFITTED STRUCTURE

The frame with calibrated masonry struts is retrofitted by including diagonal steel braces equipped with BRBs. The sizing of the device is carried out by a simplified code-based design approach. For this matter, the structure is considered to be located in Central Italy and the design of the retrofitting was done in accordance with the recommendations of the Eurocode 8 Part 1 (EC8-1) [28] and Eurocode 3 Part 1-1 (EC3-1-1) [29]. The design is performed for the Ultimate Limit State (*i.e.*, probability of exceedance of 10% in 50 years), considering a Type 1 spectrum, with soil Type B, and Peak Ground Acceleration (PGA) equal to 0.25g. The structure is designed by considering a basic behaviour factor $q_0 = 3$. The design requirements are paired with a commercial catalogue of BRB devices, and result on a device with an initial yielding force $F_{y0-BRB} = 143$ kN. The device is included in the numerical model by using the *SteelBRB* model [30] in OpenSees. The monotonic and hysteretic properties of the device are validated with a characterisation test made by the manufacturer. The hysteretic behaviour of the BRB model is shown in Figure 5. The length of the BRB is 1.535m, therefore, the device is connected in series to a steel tubular section ($\varnothing = 0.16$ m, $t = 0.01$ m) which completes the diagonal length. The full BRB and elastic brace system is pinned at the ends.

Figure 5. BRB model in OpenSees by using the *SteelBRB* material. $F_{y0-BRB} = 143$ kN; $F_{1-BRB-C} = 178$ kN; $F_{1-BRB-T} = 151$ kN.

Time history analyses based on GM1 were performed on the unretrofitted and retrofitted structures, by considering the calibrated masonry strut model and the LD model. Figure 6 shows the spectrum of GM1 and the comparison of the spectral accelerations (S_a) corresponding to the fundamental period of each structure. The period of the unretrofitted calibrated structure matches the observed fundamental period during the characterisation test of the lab specimen. The addition of the BRBs further reduces its fundamental period to 0.11 s. While considering the LD model, the fundamental period is shorter in the unretrofitted structure due to the higher initial stiffness of the struts and reaches a value of 0.09 s with the addition of BRBs. As observed in Figure 6, for the considered GM, the retrofitted structures benefit from a slight reduction on the demand due to the increased stiffness.

Figure 7, Figure 8, Figure 9 show the inter-storey deformation and storey shear demands during the time history analysis of GM1, for the calibrated and LD masonry strut models, considering the unretrofitted and retrofitted conditions. The deformation in the struts is compared with their own cracking deformation (δ_y), as suggested by the ASCE 41-17 [31] as a limit for the Immediate Occupancy Performance Level. When comparing the unretrofitted cases, the LD model exhibits lower deformation and force values than the calibrated model, as it avoids the strut deformation to reach significant levels of cracking. Nonetheless, the calibrated model (as

well as the lab specimen during the testing) exhibited extensive cracking in the struts. When comparing the retrofitted models, the addition of BRBs significantly reduce the demands on the masonry infills of the calibrated model. Nonetheless, the improvement is not as noticeable in the case of the LD model.

These observations highlight the sensitivity of considering higher values of initial stiffness in the masonry strut model. On one side, the larger stiffness underestimates the damage that the masonry panel could experience in the unretrofitted case. On the other side, it underestimates the capacity of the BRBs in protecting the masonry infills from damage in moderate intensity earthquakes.

Therefore, when the masonry strut properties are properly accounted for, the BRBs can protect the case-study structure from damage at lower and moderate intensity earthquakes, while they simultaneously increase the energy dissipation capacity of the structure at higher levels of demands.

4 CONCLUSIONS

The present paper investigates the interaction of masonry infills and buckling restrained braces (BRBs) when these are used as a retrofit measure in existing steel moment resisting frames (MRFs). The study takes advantage of the experimental results of the HITFRAMES project to calibrate numerical models in OpenSees for a case study steel MRF which has been analysed as bare, infilled and retrofitted frame with BRBs. The impact of masonry infills and BRB-retrofit is investigated by comparing the response of different infills models. The numerical results provide some insights on the ability of BRB-retrofit option in protecting not only the steel frames from experiencing critical damage during earthquakes but also the masonry infills and on the importance of using appropriate modelling strategies for the masonry infills during the assessment procedures. The following conclusions can be drawn:

- All of the considered masonry strut models exhibited larger values of initial stiffness, in comparison with the calibrated model. The Panagiotakos and Fardis (PF) model, and the Dolšek and Fajfar (DF) model, exhibited larger force capacity but lower deformation capacity than the calibrated model. The Liberatore and Decanini (LD) model exhibited lower force capacity but higher deformation capacity than the calibrated model.
- Large values of initial stiffness were translated in an underestimation of the seismic demands (for GM1) and an overestimation of the capacity. This could lead to larger than expected levels of damage in masonry panels. The calibrated model is able to capture the cracking observed during GM1 in the pseudo-dynamic testing carried out on the lab specimen.
- The addition of BRBs as a retrofit measure for masonry infilled steel MRFs can reduce the damage in the masonry infills at low and moderate seismic demands. Nonetheless, it is necessary to consider a more accurate masonry strut model in the numerical analysis, as the relative stiffness between the masonry and BRB system will dictate the capacity of the BRB to protect the infills.

Abstract

It is now widely recognised that masonry infill plays an essential role in the seismic behaviour of existing steel buildings; however, there is still a lack of clear guidance on the modelling of masonry infill in the current Eurocode 8-Part 3. Several methods for the numerical modelling of masonry infills have been proposed in literature over the past few decades, which either adopt a detailed approach (micro-model) or a simplified approach (macro-model). In the former case, bricks are individually modelled, taking into account the brick-mortar cohesive interface, which is able to provide detailed insights of the behaviour of masonry infills and the frame-wall interaction but usually at a high computational cost. On the other hand, a simplified model can be easily built within finite element software, most of which replace the infill wall panel with one or more equivalent struts in the diagonal direction. It has been demonstrated that the strut models can simulate RC infilled structures’ global response with acceptable accuracy; however, there are still no adequate recommendations for their modelling within steel frames. Besides, these models are generally incapable of capturing the interactions between the infills and the frame members. To this end, the present paper numerically investigates an Abaqus macro-model of the infilled steel frame, which was experimentally tested as part of the recent SERA HITFRAMES project. The preliminary re-

sults shows that the different detailing of steel frames could lead to different damage patterns in the infill walls when compared to RC frames. In particular, instead of a single diagonal strut, at most three struts were observed in this study. The results also suggested that the number and geometry of struts could change with increasing displacement demands, hence it might not be appropriate to use the same strut model for infill walls on different floors.

1 INTRODUCTION

Masonry infill walls were widely used in existing steel frame structures as exterior walls mainly for insulation and aesthetic purposes; hence in the code-based assessment procedures of existing buildings, *e.g.*, Eurocode 8-Part 3 [1], they are typically considered as non-structural components. As a consequence, only the self-weight of infill walls is usually considered during the assessment, while their effects on the structural behaviour under lateral load are often neglected. However, it has been widely recognised that masonry infill can significantly affect the seismic response of structures, as they considerably influence the lateral stiffness and strength of structures (and their distribution), as well as the energy dissipation capacity under seismic loading [2-8]. In addition, the strut action of infill wall panels may also exert concentrated force to beams, columns and beam-column joints, increasing local seismic demands. Besides, in the case of infill walls not uniformly distributed, *e.g.*, non-infilled ground floor, severe soft-storey mechanisms can also be triggered [9-11], leading to complete failure of the non-infilled storey.

Currently, a considerable number of studies focused on the behaviour of masonry infills within reinforced concrete (RC) frames, while the current knowledge level on the behaviour of infilled steel frames is still inadequate. Although the masonry infill confined by RC and steel frames share some commons in their seismic response, the different characteristics of steel frames may significantly alter masonry infill response. Steel frames are usually more flexible and more ductile and have different features and detailing compared to RC members, such as the aspect ratio of the frames and the geometries of steel beams and columns. Moreover, when involved in the infill-frame interactions, some local details typical of steel structures, *e.g.*, stiffener plates and connections, may cause local stress concentration in the wall and, consequently, lead to a different response and failure mode of the masonry infills. Despite some experimental tests investigated the behaviour of infilled steel frame over the past few decades [*e.g.*, 6, 12, 13], and a few simplified models have been proposed [*e.g.*, 14, 15], further research is still of great necessity for the development of simplified models that can be used in practice for the assessment of infilled steel buildings. In addition, within the European context, there is an urgent need for additional and detailed rules and recommendations for the assessment of existing steel structures [*e.g.*, 16] to be implemented within an updated version of the Eurocode 8-Part 3. These should include and consider the interaction with the masonry infills, thus promoting reliable assessment procedures.

Finite element modelling of masonry infill can be classified into two groups, namely *micro-* and *macro-modelling*. Detailed micro-modelling approaches usually include a detailed description of brick units and mortar as continuum elements and the brick-mortar interfaces to simulate the cohesive behaviour between brick units and mortar. Such models are able to reproduce the basic mechanisms of the masonry unit, hence are more likely to capture the complex damage patterns of masonry infill accurately. However, the high computational cost of detailed micro-models usually constrains their application to small structures. To this end, simplified micro-models were proposed as an alternative to detailed micro-models, which usually neglect the geometry of mortar and utilise expanded brick units to account for the thickness of mortar [17-19]. Subsequently, the material properties are often defined based on masonry samples, and the interactions between expanded brick units are simulated through cohesive elements or surface-based cohesive behaviour. The simplified micro-modelling can effectively reduce the computational cost but may lead to less accurate results. On the other hand, macro-modelling approaches consider the masonry infill as homogeneous isotropic material, whose mechanical properties can be defined based on various material tests of masonry triplets [11, 20, 21]. As a cost-effective computational strategy, macro-models are usually

adopted while investigating the global response of infilled frames and/or to perform preliminary analyses of the stress distribution in the infill wall panel.

The present paper investigates the behaviour of infilled steel moment frames through the macro-modelling approach. The finite element models are validated based on the results of large-scale experimental tests conducted on a one-bay two-storey infilled steel frame as part of the HITFRAMES SERA project. The steel frame was designed to be representative of typical existing steel frames with inadequate seismic detailing at joints. A pushover analysis is carried out, providing insights into the response of masonry infills. In particular, the change of number and geometry of struts formed in the infill walls were investigated considering increasing displacement demands.

2 EXPERIMENTAL TEST

2.1 Description of the steel frame

A two-storey single-bay 3:4 scaled steel frame was experimentally tested to investigate the behaviour of masonry infill confined by steel members. The test frame had a storey height of 2.5 m, and span of 3.5 and 6.5 m in the transverse (X) and longitudinal (Y) direction, respectively. A sketch of the steel frame is shown in Figure 1. The columns, primary and secondary beams profiles were HE 180A, IPE 200 and IPE 140, respectively. The test was performed in the X-direction with the columns placed along with their weak axis; beam-to-column joints were made through full penetration welds with stiffeners installed to increase joints’ rigidity, while beam-to-beam connections, for the primary beams, were placed at a distance of 400 mm with respect to the column axis. Besides, the columns’ bases were welded to 30 mm-thick steel plates with stiffeners to ensure their rigidity. The stiffened beam-column joints, the beam-to-beam connection and column bases are shown in Figure 2.

Figure 1: Plan and side view of the steel frame experimentally tested in the laboratory.

Figure 2: Detailing at the beam-column joints (left) and column base (right) of the test frame.

The test frame included a composite slab at both storeys, consisting of 150 mm-thick concrete slabs poured on a 1.25 mm-thick corrugated steel sheet. Shear studs were implemented on both external and internal beams to ensure the transfer of applied horizontal loads to the steel frame through the slab. However, shear studs were omitted in the 0.5-m-wide regions around the columns to avoid the development of composite actions in the joints. Finally, only the masonry infill in the transverse direction of the steel frame were included in the experimental test, each consisting of two layers of 58 mm-thick perforated bricks of size $58 \times 83 \times 190$ mm.

2.2 Experimental setup

The test frame is shown in Figure 3 and was built in the laboratory, according to standard European constructional practice. The steel members were prepared in the workshop and fully assembled in the lab. Two parallel tubular beams were placed on top of each steel base plates and anchored to the strong floor in order to increase the rigidity of the base restraints of the test frame. Besides, the composite slab was built following the assembly of the bare steel frame, where the corrugated steel sheets were installed on the beams and fixed with the shear connectors, with the concrete slab subsequently cast and poured on-site.

Figure 3: Experimental setup and positions of the actuators.

As shown in Figure 3, two actuators were placed at each storey of the test frame and connected to the reaction wall. Additionally, pre-cast concrete blocks were placed on the slab of each storey to simulate the gravity loads imposed on the structure, which would influence beams and columns' behaviour. It is noteworthy that additional concrete blocks were used to represent the mass of infill walls in the preliminary dynamic characterisation tests and were successively removed upon the installation of infill walls.

2.3 Experimental test scheme

A snap-back test was performed to capture the frame's modal properties for both the bare and infilled configurations. The initial displacement imposed on the frame also allowed the definition of the test frame's lateral stiffness. Both stiffness and modal properties were used for the numerical models' calibration.

After the modal characterisation test, pseudo-dynamic (PsD) displacements' control tests were performed to investigate the infilled frame's behaviour subjected to an earthquake sequence. Three ground motions, recorded during the 2016 Central Italy earthquakes, were selected to define the earthquake sequence used in the PsD tests. The time-history of accelerations of the earthquake sequence is shown in Figure 4. Two scaling factors (SF) of the earthquake sequence, $SF = 1.0$ and 3.0 , were used during the PsD tests. The scaling factors were decided based on comparisons of the response spectra of selected ground motions with

the code-based elastic response spectrum, where the use of unit scaling factor was to investigate the behaviour of the test frame subjected to real earthquakes, while the scaling factor of 3.0 was adopted to ensure the failure of the test frame, *i.e.*, the collapse of infill walls and severe yielding of steel members.

Figure 4: Accelerogram of the selected earthquake sequence.

2.4 Experimental results

The response of the infilled steel frame recorded during the entire PsD test, *i.e.*, top storey displacement against base shear, is shown in Figure 5(a). Aside from the response curve, envelopes are also presented individually for the positive and negative direction. Subsequently, the corresponding backbone curve could also be derived based on the envelopes, which was assumed to be symmetric in the positive and negative direction.

Figure 5: Response of the infilled steel frame with backbone curves: a) global response; b) first storey displacement against base shear.

As shown in Figure 5(a), the first significant change of the frame's lateral stiffness corresponds to a 10 mm top storey displacement. Then the steel frame reached the maximum base shear of around 650 kN when the lateral displacement at the top storey was approximately 25 mm. This also marked the onset of negative stiffness in the backbone curve of the steel frame. In addition, degradation of strength was also noticed at 100 mm of top floor displacement, where the capacity of base shear dropped by about 8% to 600 kN. Lastly, the largest top storey displacement experienced during the PsD test corresponds to 140 mm, when the collapse of infill occurred, and the test was terminated.

The pushover numerical analysis requires the knowledge of the forces and displacements' distribution at both storeys. To this end, the response history at the first storey was determined and is shown in Figure 5(b). This also included the envelopes for the definition of the corre-

sponding backbone curve. The comparison of the backbone curves for both storeys is shown in Figure 6, and six points were selected for the determination of displacement ratios of the top storey to the first storey, as also summarised in Table 1. It can be concluded that initially the displacement ratio was around 1.5, however, when the displacements were increased, the ratio was slightly reduced to 1.34 at point D and 1.20 at point E, which was attributed to the concentrated damage at the first storey. Consequently, it can be anticipated that soft storey mechanism might be triggered at some point beyond 140 mm top floor displacement.

Figure 6: Comparison of backbone curves for the first and top storey of the steel frame (symmetric in the positive and negative directions). See Table 1 for more details.

3 NUMERICAL STUDY

3.1 Finite element modelling of masonry infill and steel frame

Finite element models of the bare and infilled steel frame were built in Abaqus [22]. Only half of the 3D steel frame was modelled due to symmetry conditions and to reduce the computational cost. Meanwhile, all the internal secondary beams were excluded from the model as their contribution to the lateral resistance of the steel frame were considered negligible. All steel and masonry components were modelled using the solid element C3D8R. Figure 7 shows an overview of the Abaqus model.

The material properties were defined based on the results of material tests when possible. For parameters that could not be obtained from the tests conducted, typical values recommended in literature were adopted. The yield and ultimate strength of steel were defined to be 433 and 575 MPa, respectively, while the Young's modulus was assumed to be 210,000 MPa. On the other hand, as the masonry infill walls were modelled using macro-modelling approaches, the Young's modulus of masonry was manually adjusted to be about 3,000 MPa based on model calibration.

The concrete damaged plasticity model was used to simulate the inelastic behaviour of masonry. This model is characterised by five parameters: 1) dilation angle (ψ); 2) the flow potential eccentricity (ϵ); 3) the ratio between initial equibiaxial compressive yield stress to initial

uniaxial compressive yield stress (f_{b0}/f_{c0}); 4) the ratio between second stress invariant on the tensile meridian to that on the compressive meridian at initial yield (K), and 5) the viscosity parameter (μ). Values recommended by D’Altri *et al.* [19], reported in Table 2 were adopted in this study as typical assumptions for masonry infill. Besides, the compressive and tensile strength of masonry were defined to be 5.70 and 1.30 MPa, respectively. Furthermore, the composite slabs were modelled as rigid bodies to simulate the rigid diaphragm behaviour and ensure a smooth transfer of load to the steel frame. Lastly, a 75 mm-thick concrete block was included in the model as the base of ground floor masonry infill. Since no damage was observed on this concrete base during the experimental test, it was assumed to behave in the elastic range with a Young’s modulus of 35,000 MPa.

Figure 7: Numerical models of the steel frame in Abaqus using macro-model of masonry infill.

ψ	ε	f_{b0}/f_{c0}	K	μ
10°	0.1	1.16	0.667	0.0005

Table 2: Parameter to define the inelastic behaviour of masonry infill using concrete damaged plasticity model in Abaqus [21].

Beam-to-column joints, stiffeners, and cover plates of the beam-to-beam connections were modelled through tie constraint. Appropriate boundary conditions were applied at the end of the transverse beams to simulate the structure’s symmetric condition. Besides, in the region with shear connectors, a tie constraint was used to simulate the slab-beam interaction. Conversely, for the region without shear studs, a surface-to-surface contact interaction was defined between the slab and the beam with ‘Hard’ normal behaviour and a friction coefficient of 0.7 for the tangential behaviour. Lastly, a surface-to-surface contact (with the same properties as above) was also introduced to simulate the masonry infill and steel frame interaction.

3.2 Model validation

The numerical models’ validation was performed with respect to the stiffness and dynamic properties observed during the snap-back tests. During this test, lateral loads of 13 and 31 kN were imposed on the top storey of the bare and infilled frame, respectively. The comparisons of the numerical and experimental lateral displacement profiles are shown in Figure 8 and reported in Table 3.

As shown in Figure 8, both the bare and infilled frame models achieved a ‘good’ match of lateral displacements with the test mockup, and the discrepancies were all within 10%. In both cases, the comparison of the numerical and experimental results show a nearly identical initial lateral stiffness at the first storey. Conversely, the top storey’s lateral stiffness was slightly underestimated in the bare frame and slightly overestimated when the masonry infills were present.

Figure 8: Comparisons of lateral displacement profile of the bare frame (left) and the infilled frame (right) during the modal characterisation test.

	Test		Abaqus			
	First floor	Top floor	First floor		Top floor	
Bare	5.25	13.97	5.28	+0.57%	14.78	+5.80%
Infilled	0.34	0.75	0.34	0.00%	0.70	-6.67%

Table 3: Comparisons of the lateral displacements of the steel frame obtained numerically and experimentally.

3.3 Pushover analysis

The results of the pushover analysis is presented hereafter. The numerical model was pushed up to 140 mm at the top storey, which was the maximum lateral displacement measured during the test. The pushover analysis was done assuming three displacement ratios of top storey to first storey (d_2/d_1). When the top storey displacement was less than 30 mm, the ratio d_2/d_1 was assumed to be 1.5. Then when the top storey displacement was between 30 and 100 mm, the ratio d_2/d_1 reduced linearly from 1.5 to 1.2. Eventually, when the top storey displacement was larger than 100, the ratio d_2/d_1 was equal to 1.2. Figure 9 presents the comparison between the pushover curve, *i.e.*, the top storey displacement-base shear relation, and the structural response of the steel frame measured during the experimental test, while Figure 10 shows the evolution of stress distribution in the infill walls during the pushover analysis.

It can be seen that in general the numerical model were in good agreement with the test results when the displacement was smaller than 30 mm. However, the numerical model failed to capture the deterioration of strength which took place beyond 30 mm top storey displacement.

This is because that firstly a bi-linear relation was assumed for the mechanical property of masonry, which did not account for the strength degradation. Besides, the simplified modelling approach adopted was unable to simulate the falling of crushed bricks at the top corners. Consequently, the base shear of the numerical model continued to increase beyond the actual point of the onset of strength and stiffness degradation.

Figure 9: Pushover curve of infilled steel frame.

Figure 10: Stress contour of the masonry infill walls during the pushover analysis (See Figure 9): a) Point 1; b) Point 2; c) Point 3; d) Point 4; e) Point 5; f) Point 6.

As can be seen in Figure 10(a), initially when the model was within the elastic range, stress concentration was noticed at both storeys surrounding the beam splice connections before any struts were formed in the infill walls. This illustrated the occurrence of cracks at the top corners of each infill wall, which were due to the interlock between the bolts of beam splice connections and the top layer of bricks. When the displacement demand was increased, an inclined strut was formed within the lower storey infill wall, as can be seen in Figure 10(b). Successively, when the top floor displacement was approaching 30 mm (Point 3 in Figure 9), the previous strut was split into a diagonal strut and an off-diagonal strut, as shown in Figure 10(c), and the diagonal strut appeared to be wider than the off-diagonal strut. In the meantime, an inclined strut started to form in the top floor infill wall as well, which had a similar shape

to the one previously formed in the lower storey infill wall. When the displacements at both storeys of the infilled steel frame were further increased, as shown in Figure 10(d) to (f), the contact length between the infill and the surrounding steel members remained almost unchanged, and the diagonal strut in the lower storey infill wall was further split into two smaller struts. It is clear that the upper strut connected the top corner and the end of contact length over the other column, while the middle strut connected the bottom corner and the mid-point of the contact length over the other column. Figure 10(f) also shows the tendency that with increasing lateral displacement, the upper strut would become wider, and the middle and lower struts might eventually become one single strut that has approximately the same width as the upper strut. It was also noticed that despite the infill wall on the top floor exhibited the same behaviour as that on the lower floor, the two infill walls contained different numbers and geometries of struts at the same step of pushover, which indicated that it might not be appropriate to use the same simplified strut model to represent the infill walls on different floors.

4 CONCLUSIONS

This paper presented numerical modelling of infilled steel frame using a macro-model of masonry infill. It was concluded that the steel joints that were in contact with masonry infill caused local stress concentration in the part of infill wall adjacent to the joints. Besides, a single inclined strut was noticed at small displacement, when the overall structural was within the elastic range. Subsequently, when the displacements at both storeys became larger, the single strut was firstly split into two struts and eventually became three struts. The width of struts was also found to be changing during the pushover analysis. Moreover, the contact length over beams and columns were also observed, which initially increased with increasing displacement and then remained approximately constant. Lastly, it was also concluded that the masonry infill on different floors could form different numbers of struts with varying geometries, which should be taken into consideration when developing simplified strut models.

Future studies should be conducted using a more detailed micro-model of masonry infill to investigate the development of cracks in the infill walls and achieve more accurate observation of infill-frame interactions.

Abstract

In recent years, modular construction has been used in low-to medium rise multi-story and even high-rise buildings. Pre-fabrication by off-site manufacture leads to faster and safer construction, improved quality, reduced resources and waste.

The research activity summarized in this paper is carried out within the European project INNO3DJOINTS and it aims at developing innovative plug-and-play joints which enable modularity, faster construction and deconstruction. The developed modular construction system is hybrid, whereby tubular columns are combined with cold-formed lightweight steel profiles using plug-and-play connections to provide an efficient structural system.

The influence of the type of floor system, the horizontal and vertical load-bearing systems and the type of truss on the structural performance are investigated. The results obtained from numerical analyses allowed optimizing the geometry of the examined hybrid modular system. To highlight its effectiveness and versatility, a case study building was used to compare the proposed hybrid system with other conventional structural solutions.

Keywords: Plug-and-play joints, Steel Construction, Cold-formed steel, Hybrid system, Modular construction, Eurocode 3.

1 INTRODUCTION

Sustainability is a key driver in the construction sector requiring innovative solutions to face the existing challenges in terms of consumption of natural resources (responsible for the consumption of 40% of the global materials) and construction waste management and treatment. Prefabricated modular construction system can greatly contribute to minimizing waste, improving the overall quality, with shorter construction times, lower resources, and on-site labour costs [1], promoting the development of structural solutions that are suitable for deconstruction and possible reuse of the entire structure or part of the structure in multiple life cycles.

The level of prefabrication may refer to components, subframes or even the whole building [2], [3]. Recently prefabricated modular solutions have been presented for high-rise and multi-storey buildings [4], but its applicability is still limited [5]. It is recognized that one of the biggest challenges is related to inter and intra module connections, ensuring that adequate performance requirements are attained [6]. The competitiveness of these innovative modular systems relies on several parameters, such as span, span, floor height and type, number of floors, resistance to lateral loads and connections, which are a critical part of the overall structural stability and robustness of the building.

Light gauge cold-formed steel (CFS) structural solutions, due to its versatility, are very efficient systems that lead to relevant weight savings of up to 35% when compared to an equivalent hot-rolled solution [7]. Light Steel Framing (LSF) systems comprising CFS members are panelised construction systems using close spaced studs and different types of sheathing (OSB, gypsum, lightweight concrete panels) providing adequate in-plate stiffness. Typically, standard CFS construction is very efficient for low-rise buildings and spans in the 4 m range. Several panelised modular systems using CFS are available, which are delivered on-site and easily erected. At the European level, several research projects were devoted to this topic. In the scope of the research project, DRYCONDIS the capabilities of light-weight steel dry construction system [8] was assessed. Others were devoted to the study of light-weight steel systems for prefabricated steel buildings and their integration with the steel skeletal system (e.g. ETHICS; InFaSo; FrameUp; PRECASTEEL, [9]-[12]). However, few have considered the erection stage and ease of assembly and disassembly as critical parameters in the development and optimization of the system.

The extension of the light-weight steel solutions to medium rise construction brings new challenges due to the higher demands in terms of lateral load strength and stiffness. For CFS multistorey buildings, reinforced concrete cores may also be considered as a lateral force resisting system, ensuring that the CFS modular part only carries gravity loading [3]. Other solutions have been developed and investigated. Hong et al. [13] developed a modular building solution using double skin steel panels as the lateral force-resisting system and concluded that the steel panel system greatly increases the initial lateral stiffness of the system. More recently, the performance of light steel framing wall panels with Oriented Strand-Boards (OSB) [14] was assessed through experimental tests. It was observed that OSB can be considered as an effective sheathing solution to enhance the lateral stability of CFS structures. Lightweight steel frames with OSB panels are also effective systems to resist seismic actions by means of energy dissipation in the OSB sheathing-to-frame connections as shown by experimental tests formerly carried out at the University of Naples Federico II [15], [16].

New buildings using CFS construction often require larger free spans and the possibility of large openings (of the order of the span length) within the alignments of the load bearing panelised walls. In these cases, tightly spaced CFS trusses [16]. The use of CFS trusses is attractive but their generalized application in the same structure may lead to a reduction of the lateral

stiffness of the structure. This can be a critical issue if no auxiliary lateral load resisting systems are not used.

In the scope of the European research project INNO3DJOINTS [18], a new hybrid, prefabricated structural system was developed, aiming to address existing challenges related to modular construction. The modular hybrid system consists of cold-formed steel trusses combined with tubular columns using innovative plug-and-play joints. The investigation reported in this paper aims to characterize the innovative hybrid system, assessing the use of such system in multi-storey buildings. The innovative hybrid structural system was developed to address the following objectives:

- To allow the specification of architectural plans with 4 m to 6 m free spans and similar sized openings in the load-bearing wall alignments.
- To provide adequate lateral stiffness through a combination of cold-formed trusses and tubular sections for the column positions at the intersection of the main grid axes and load-bearing light steel framing walls with diagonal steel straps as cross-bracings. Tubular sections have some advantages over “I” or “H” sections, such as higher torsional rigidity, possible replication of the configuration of the joints in both plan directions, availability in high-strength steel and better aesthetic quality [18];
- Developing innovative hybrid plug-and-play joints between the truss and the tubular column, easy to assemble and disassemble using simple tools and erection equipment.

2 THE INNO3DJOINTS HYBRID MODULAR CONSTRUCTION SYSTEM

The main components of the developed structural system (Figure 1) are:

- Tubular columns: cold-formed circular, rectangular, or square hollow profiles, as the main vertical structural elements.
- Truss-girders: span up to 6 m, light-gauge CFS profiles, as the main horizontal structural elements. For spans without openings, the LSF walls are stiffened by OSB panels.
- Plug-and-play joints: devices connecting the columns and the truss-girders that guarantee a fast and safe on-site execution.
- CLT slab: the floor is constructed using CLT panels, providing the necessary gravity load-bearing capacity and in plane diaphragm effect.

Figure 1: INNO3DJOINTS system a) Global view with the prescribed floor system. b) Detailed view of the plug-and-play joint.

The plug-and-play joint is composed by parts that connect the columns and the truss-girders: a socket, which is welded to the column, and a T-plug with a Y-fork (plug), where the T-plug

is bolted to the socket and Y-fork is connected to the truss by a bolted simple lap joint. The socket comprises a set of two cold bent plates welded to the tubular column with a spacing equal to the thickness of the T-plug plus the necessary tolerances. The spacing between the two pieces allows the positioning of the T-plug. Stiffeners can be added to the socket and/or to the Y-fork depending on the performance requirements. During fabrication of the structure in a steel workshop, the T-plug with Y-fork are assembled to the truss girder and the socket is welded to column.

3 INFLUENCE OF THE GEOMETRICAL AND MECHANICAL FEATURES ON THE DESIGN OF THE BASIC MODULE OF THE INNO3DJOINTS SYSTEM

The development of the structural system comprised the analysis of several aspects, such as: the configuration of the trusses; the floor system; and the layout of the lateral force resisting system.

3.1 Description of the numerical model and design verifications

The assessment of the structural behaviour was based on numerical linear elastic analyses developed using SAP2000 [19]. Beam elements were used for the modelling of the 2D and 3D structures. The 2D frame models were implemented according to the scheme illustrated in Figure 2. The chords were modelled with releases at their extremities, to impose pinned members (in plane rotations are free).

The joints between the trusses and the columns are modelled using a rigid link that prevents relative translations between the column and the truss-girder. Pinned boundary conditions were considered at the column bases.

Figure 2: Schematic representation of the 2D FEM models

The 3D FEM models were implemented using the same modelling assumptions. The floor system and the sheathing panels were modelled using orthotropic shell elements. The connection between the sheathing panels and the framing was modelled using linear links.

3.2 The influence of the type of truss girder

Different types of truss-girder arrangements were tested: the cross-diagonal truss with flat plates as diagonals and the Howe, Pratt Warren trusses, with C profiles as diagonals, all shown in Figure 3.

Figure 3: Selected types of truss girder.

The truss elements were designed according to EN 1993-1 parts 1 and 3, satisfying strength and serviceability limits and corresponding to similar utilization ratios and the solutions were compared based on their performance and weight.

Figure 4: Horizontal and vertical displacements for the selected truss configurations

The displacements at the middle of the top chord were used to compare the deformability of the frames (Figure 4), confirming that smaller vertical displacements occurred for the Howe truss and Warren truss types, followed by the Pratt truss, while the cross-diagonal truss deforms the most.

The weight comparison of the tested typologies showed that the cross-diagonal truss is slightly lighter, yet it is characterized by the greater deformability.

3.3 The influence of the floor system

A regular building with three spans and 3 floors was used to analyse the type of floor system to be employed with the proposed structural system. This was exploited on the basis of three examples – MRF (moment resisting frame) or conventional hot-rolled solution, HF (hybrid frame) or the proposed solution using tubular column and CFS truss and HF+CT (Hybrid frame + column truss). The structural systems were considered together with three types of floor structure:

cold-formed steel joist with OSB sheathing; composite reinforced concrete-steel deck slab; cross laminated timber slab (CLT).

The structures were subjected to the same actions (varying only their self-weight) and the utilization ratios were used as comparison parameters. The steel and total weights of the structures are shown in Figure 5. Based on the results obtained, the CLT solution was considered the best since it is light solution, which can be easily erected on site and it can provide sufficient diaphragm effect [27, 28].

Figure 5: Weight comparison (tonnes)

3.4 The influence of lateral force resisting system

Within the development of the structural system, it was important to define the lateral force resisting system. In this case it was sought to understand if the solution using column truss (CT) can be viable and on a second step the use of structural walls with OSB panels was addressed.

For these analyses: the steel classes for hot-rolled and for CFS are S355 and S350GD, respectively; the height of the storey is 3 m; the new plug-and-play joints are simulated by Rigid Links; and the supports of the columns are assumed as pinned. Only the horizontal displacement, lateral stiffness and weight were considered for the assessment of the performance of the systems.

Regarding the solution using CT four options were considered: (i) no column truss (no CT); (ii) no interaction between the column truss and the truss-girder (CT 1); (iii) full-interaction (CT 2); and (iv) full-interaction with battened profiles (CT 3), (Figure 6). The analysis was based on these four main reference frames with column cross-section SHS150x6.3. These solutions were compared to the configuration no CT but changing the column dimension in order to find the same stiffness as if one of the column truss configurations were used..

Figure 6: Summary of the reference frame layouts (dimensions in centimetres).

The analyses were conducted for frames with 4, 5 and 6-meter spans, where the span length was not found as influencing parameters. A summary of the results for the 6 m frames is shown in Figure 7.

Figure 7: Lateral stiffness and weight for the frames 6m

The results showed that the SHS180x8 section matches the lateral stiffness given by the utilization of SHS150x6.3 with the CT1, the sections SHS300x12 and SHS300x12.5 reach similar lateral stiffness values as the SHS150x6.3 with the CT2 and the SHS300x16 and SHS350x10 sections are comparable to the SHS150x6.3 with the CT3 solution. Even though the CT2 and CT3 configuration result in much higher stiffness, they were not considered practical from construction point of view, hence these configurations were disregarded.

A possibility of using LSF wall with OSB panel was also exploited. In this assessment, the solution CT1 was compared with the configuration without CT and also with the solution using OSB panel.

The span length varied between 4, 5 and 6 m and single, double, and triple-span frames were considered (Figure 8)

Figure 8: Reference cases – 6-meter span

Figure 9 summarizes the obtained weight and stiffness for each of the studied cases. As expected, the adoption of the wall with OSB panel led to significant increase in the lateral stiffness. In addition, the consideration of CT1 type was not considered economical since it does not bring significant increase in lateral stiffness and it is harder to produce.

Figure 9: Lateral Stiffness and weight (2nd Set)

4 CASE STUDY

After defining the main structural components, a real building was used to analyse the performance of the system. For the assessment, three structural configurations were used: SC 1 – tubular columns with cold-formed truss beams; SC 2 – tubular columns with envelope walls with OSB panels; and MRF (moment resisting frame) – hot rolled structure using IPE and HE profiles.

The building was adapted from a real residential case built in Angola, but it was designed as if it was located in Coimbra (Portugal). The structure is 3-meter four-storey building with an area of 456 m². The structure is shown in Figure 10.

Figure 10: Plan, 3D view and cross-sections for SC1 and SC2

The building was designed in accordance with the Structural Eurocodes [22-25]; its fire performance was verified using a prescriptive approach EC3-1-2 [26]; and its seismic performance was considered for low seismicity conditions according EC8-1 [21]. For fire safety, gypsum boards 12.5 mm thick were chosen, providing fire resistance periods longer than 60 minutes. In

this case, the critical temperature is 662.5°C, reached after 69.08 minutes. For the floor system, CLT, the fire resistance is provided by the manufacturer, and an appropriate fire-resistant solution was chosen for the loads [23] and spans considered (max. 6 m), resulting a 160mm-thick panel. A fire resistance of at least EI 60 minutes is achieved.

A seismic action is considered [21], assuming a low seismicity zone and a $q > 1.5$, for low ductility structures. The reference PGA for this site is $a_g = 0.12g$, and a type C ground and Type I spectrum were adopted.

The performance of the three structural solutions was evaluated on the basis of their stiffness and weight. Table 3 summarizes the result obtained.

The MRF was used as a reference solution, where it is concluded that SC1 is lighter (78% of the MRF) while SC2 resulted in a similar weight of steel (96%). When the lateral stiffness of the three configurations for the x and y directions is compared, SC1 is 1.5 / 1.62 times stiffer and SC2 is 2.78 / 2.18 stiffer.

Structural System	Weight		Stiffness y-y					Stiffness x-x				
	Steel	Total	$k_{y,1}$	$k_{y,2}$	$k_{y,3}$	$k_{y,4}$	K_y	$k_{x,1}$	$k_{x,2}$	$k_{x,3}$	$k_{x,4}$	K_x
MRF	92.93	356.3	58	37	33	26	13	73	50	44	35	17
SC 1	62.42	167.9	46	120	126	122	26	45	117	128	121	27
SC 2	75.26	193.9	143	221	218	202	62	98	212	219	196	51

Table 1: Weight and lateral stiffness (kN/mm).

5 CONCLUSIONS

A new hybrid modular structural system comprising lightweight cold-formed steel trusses and tubular columns connected using innovative plug-and-play joints was presented. To assess the global structural performance of the innovative structural building, a parametric study was undertaken, examining the following parameters: the type of truss, different spans, the lateral force-resisting system and the type of floor system.

The truss-girders with better performance in terms of deformability, when subjected to horizontal and vertical loading, are the Howe truss and Warren truss.

From the conducted analysis the solutions incorporating the column truss connected to the tubular column and truss-girder (CT2 and CT3), were discarded due to assembly difficulties and possible localized problems. Meanwhile, the adoption of OSB panels significantly increases the stiffness of the frames

Considering the selected case study, it was found that the highest lateral stiffness was attained for the solution with the envelope walls and OSB sheathing (SC2 solution). Also, the innovative structural systems (SC1 and SC2) provide the lightest solutions in terms of steel consumption.

Abstract

As widely investigated in literature, the local behavior of the joints strongly influences the whole performance of the steel structures; thus, both in the design and assessment of the moment resisting frame (MRF) the joint performance should be properly accounted for. The present work is focused on local assessment and retrofit the beam-to-column joints of an existing non-conforming steel building. Therefore, the monotonic and cyclic behaviors of internal beam-to-column joints are investigated by means of finite element analyses (FEAs). The main peculiarities of these joints are the continuity of beams and hollow square columns interrupted at each level and connected both by bolts and fillet welds to the tapered flanges of the beams. On-site surveys allowed fully characterizing the geometry of the joints. The joint assemblies were sub-structured from the moment resisting frames and analyzed against both the vertical loads and seismic actions. The results showed that these types of joints exhibit very poor seismic behavior, concentrating most of the damage within the welds. Therefore, different local strengthening interventions were designed and numerically checked. The comparison between the response of the unreinforced and the various strengthening joints is described, and the best solutions in terms of both cyclic behavior and technological feasibility are subsequently identified.

Keywords: Existing structures, Beam-to-column joints, Seismic retrofit, ductile behavior, finite element model.

1 INTRODUCTION

Nowadays many studies investigated the behavior of the steel structures in seismic areas [1-12], with the aim to obtain ductile structures that could resist to the earthquake action without showing any brittle behavior; however, in many cases, these studies and innovative solutions could be applied not only to the new structures but could represent a viable solution also for the existing structures.

The existing steel buildings are characterized by a great variability in terms of structural conception, typology and distribution of resisting systems, and details adopted for the connections. Moreover, old steel buildings were often designed without considering any seismic action or, even when some lateral loads were considered, no hierarchy criteria between structural members were adopted. Thus, in the assessment of the existing steel building particular attention should be given to the joint's details; indeed, as deeply investigated in literature for the new structures [13-22], also in the analyses of the existing buildings the joint could influence the global structural behavior.

In this framework, an existing steel multi-storey building located in Naples has been selected as a case study due to its structural peculiarities. The design was carried out in accordance to the Italian provisions that were in force during the 1960 as reported in [23]; therefore, only gravity and wind loads were considered at that time. The P-Delta effects were also completely neglected despite of the height of the building (22.5 m). The structure was conceived and manufactured not in conformity with the majority of similar contemporary buildings.

The main aim of this research is to investigate the local behavior of the moment resisting joints and to investigate the efficiency of some local intervention to strengthen and improve the joint behavior. The paper is divided in four main parts; initially the structural feature of the building is described; then the main aspects of the finite element model (FEM) are presented. The third part is mainly focused on the results of beam-to-column joints under both vertical and horizontal action. Finally, the efficiency of four possible retrofitting solutions is presented.

2 DESCRIPTION OF THE STRUCTURE

2.1 History and general features

The multi-storey building serves for offices and depository of documents. The structure was built between 1960 and 1961 to replace a former two-storeys masonry construction used as public office. The V-shape of the original plan of the building was preserved (see Figure 1), with a footprint of about 1400 m². The design was carried out in accordance to the Italian provisions that were in force during the 1960; therefore, only gravity and wind loads were considered. MRFs were adopted on the longitudinal axes of the construction, while various types of concentric braces (X and Y shaped) were located in the transverse direction.

2.2 History and general features

The columns of the MRF systems have a hollow squared tubes cross section, with a constant external size along the height of the building (140x140 mm), but the thickness of the tubes varies from 18 to 6 mm from the bottom to the top. The main beams are made with IPN 320 profiles at all storeys. Floors were made using corrugated steel sheets filled with concrete for a total height of 55 mm. Geometrical features of MRF joints are summarised in Fig. 2.

According to the design report [23], all members are made with Aq 42 Steel, with an allowable stress of 1600 kg/cm², with the only exception of the tubes, which are manufactured with Aq 55 Steel, with an allowable stress of 2000 kg/cm². High-strength bolts (8.8) has been considered.

A total of six beam-to-column joints (one for each floor) have been investigated under both vertical and horizontal actions. Therefore, a specified nomenclature was introduced to identify each investigated joint in function of the floor ("Fx") and the load scenario (vertical or seismic).

3 MODELING ASSUMPTIONS

The finite element models (FEMs) were developed using ABAQUS 6.14 [24]. The modelling assumptions are the same as described by the Authors in previous publications [25-26]. Therefore, only the main features of the models are summarized in the following for the sake of brevity.

The beam-to-column joints were modelled considering a sub-assembly of the whole structure, which is obtained by extracting both the columns and the beams at the inflection points of the bending moment diagram induced by gravity and horizontal loads on the MRF. All elements were discretized using C3D8R solid element type. The characteristic dimension of mesh was set equal to 5 mm for bolts, welds and plates, and 20 mm for the beams and the columns.

According to the design report, a yield stress of 240 MPa was assigned to all the existing members, with the only exception of the columns, for which the yield stress was set to 300 MPa.

Figure 2: Detail of investigated MRF beam-to-column joints.

Steel yielding was modelled using the Von Mises criterion. The kinematic and isotropic hardening were implemented. The constitutive law for high-strength bolts (class 8.8) was modelled according to D'Aniello et al. [27]. The weld steel was modelled with the Ramberg-Osgood constitutive law; in absence of more detailed information from the design report, the yielding strength of existing welds was assumed to be equal to the highest between the existing members (300 MPa). Finally, an European S355 steel grade was used for all strengthening elements.

Displacement histories were applied at the tip of the beams in the sub-assemblages, reaching a maximum chord rotation of 0.06 rad. AISC 341 [28] protocol was adopted for cyclic analyses.

4 RESULTS FROM FINITE ELEMENT ANALYSES

4.1 Behavior of MRF beam-to column joints under vertical loads

The behaviour of MRF beam-to-column joints under vertical loads was investigated imposing maximum vertical displacements at the beam tips equal to 120 mm.

As expected, the internal beam-to column joints showed a good overall response, with the activation of plastic hinges at the extremity of the beams with basically no involvement of the column that remains in elastic range (see Fig. 3). Plastic hinges start to develop nearby the continuity restraint, while increasing the vertical displacements also the activation other two plastic hinges at the beam extremity can be observed. Moreover, since the beam profiles do not change among the different floors, the response in terms of bending resistance is almost the same for all the investigated joints, as shown in Fig. 3a.

However, a very small difference in terms of elastic stiffness can be observed owing to the variation of the column bending stiffness at each floor.

Figure 3: Results of MRF joints at 3rd floor under vertical loads in terms of moment-rotation curve (a) and PEEQ distribution of joint (b).

Figure 4: Results of MRF joints at 3rd floor under seismic loads in terms of moment-rotation curve (a) and PEEQ distribution of joint (b).

4.2 Seismic behavior of MRF beam-to column joints

The seismic behaviour of MRF beam-to-column joints is depicted in Fig. 4 in terms of moment-rotation curves and distribution of equivalent plastic strains (PEEQ); in Fig. 4b it can be notice that all plastic deformations are concentrated in the columns and in the fillet welds. The beams always remain in an elastic range; the same type of failure mode can be observed at each floor of the building. The maximum bending resistance is showed by the joint at the first floor, as shown in Fig. 4a; indeed, due to the variation of the column thickness a reduction of the resistance along the structural height can be observed.

In Table 2 results from each scenario are reported in terms of maximum bending moments.

Figure 5: Different retrofitting solutions for the beam-to-column joint: weld collar (a), 65 mm high ribs (b), 150 mm high ribs (c)

Floor	Vertical [kNm]	Seismic [kNm]
Floor 1	356.1	102.8
Floor 2	355.4	101.4
Floor 3	355.0	94.8
Floor 4	354.3	85.2
Floor 5	353.9	72.2
Floor 6	351.9	56.5

Table 2: Results from numerical analyses in terms of maximum bending moments.

4.3 Strengthening solutions

The results of the numerical analyses showed that MRF joints have a good behaviour under gravity loads while exhibit a poor ductile response, with a large plastic concentration in the column's tip and in the adjacent fillet welds (see Fig. 4b). Therefore, three different strengthening interventions have been designed and numerically tested to improve the seismic performance of the joints by preventing welds brittle failure. For sake of brevity only results of the joint at the third floor (with the medium value of column thickness) are reported hereinafter.

The main geometrical features of the interventions (see Fig. 5) are summarised as follows:

1. Complete replacement of the fillet welds with a continuous weld collar made with stronger material (e.g. yielding stress equal to 450 MPa), see Fig. 5a (RS1).
2. Replacement of the welds and introduction of four 65x10 mm rib stiffeners made with steel S355, two on each side of the column, shaped with an angle of 40°, see Fig. 5b (RS2).
3. Replacement of the welds and introduction of four 150x10 mm rib stiffeners made with steel S355, two on each side of the column, see Fig. 5c (RS3).

The results of monotonic analysis for each RS scenario are depicted in Fig. 6. Maximum bending moments and the relative increment with respect to unreinforced joint response are also reported in Table 3. As it can be observed, the retrofitting solutions provide a large variation of both resistance and elastic stiffness; indeed, with the only exception of RS1, that only implies the change of the welds, the introduction of the rib stiffeners increases the assembly stiffness and the resistance. The maximum increase of the bending capacity is not very high (RS3, 17% with respect to the unreinforced joint) but the real benefit of the presence of the ribs is to obtain a more ductile mechanism moving the failure from the weld to the column allowing a larger rotational capacity. This aspect can be better observed in case of cyclic analyses (see Fig. 7).

Thus, comparing the unreinforced solution with the RS3 (the one with two ribs) it can be observed that the first case a large concentration of plastic deformation appears in the welds and at the column tip. Contrariwise, the reinforced solution provides a slightly larger resistance and a more stable energy dissipation without pinching. In this case plastic strains are concentrated in the columns, leaving the welds in elastic range.

Figure 6: Moment – rotation curves for all different strengthening solutions.

Intervention	$M_{i,Max}$ [kNm]	Resistance increment [%]
RS0 (Unreinforced)	94.8	-
RS1 (Replaced Welds)	99.2	+5%
RS2 (Ribs 65 mm)	104.5	+10%
RS3 (Ribs 150 mm)	110.2	+16%

Table 3: Comparison between different scenarios in terms of bending moments.

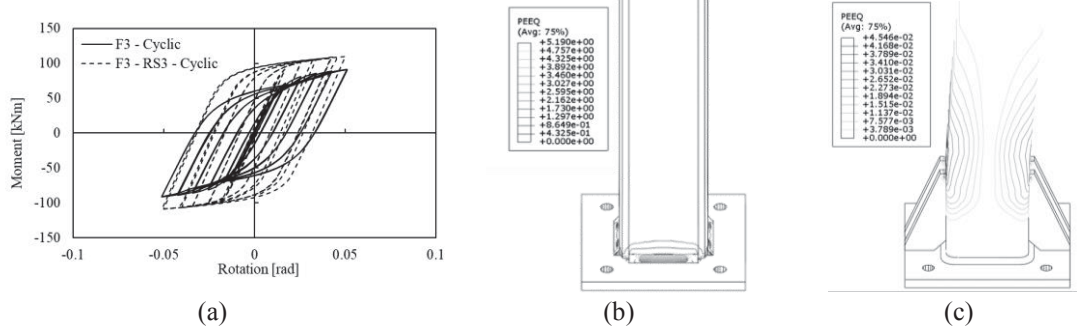

Figure 7: Moment-rotation curves for the unreinforced column and the RS3 proposal (a) and distribution of equivalent plastic strains under cyclical horizontal actions for the same cases (b-c).

5 CONCLUSIONS

An existing non-code conforming six-storey steel building has been investigated. Particular attention was paid on both vertical and lateral behaviour of the MRF beam-to-column joints. From the results of FEAs the following observations can be pointed out:

- Moment resisting joints are able to support the vertical loads showing only the activation of the plastic hinges at very large value of chord rotation.
- Lateral loads induce stress concentration in the welds around the columns, which represent a brittle component. Therefore, local interventions have been designed to retrofit joints.
- The first retrofitting intervention (RS1) involves the replacement of the original welds; results show that the increment of weld resistance is not enough to change the failure mode.
- The second (RS2) and third (RS3) interventions consist in the use of rib stiffeners to increase the resistance of the connection. The numerical results show that both under monotonic and cyclic action the introduction of rib stiffeners allows to reduce the plastic demand within the welds. Therefore, the local ductility of the joints is preserved despite additional consideration should be done from a global point of view.

Abstract. *In this contribution, the dynamic response of two railway bridges, represented by a viscoelastically supported Euler-Bernoulli model, subjected to high-speed trains is analyzed and discussed. Different types of high-speed trains are considered, which are modeled as moving mass-spring-damper (MSD) system. The structural response is determined by a dynamic substructuring approach, in which the equation of motion of the beam bridge model and the equations of motion of the MSD system, both written in state space, are coupled using a generalized corresponding assumption. The coupled set of equations of motion representing the dynamic soil-structure-vehicle interaction model are solved by time history analysis. The utilized approach captures all essential features of dynamic soil-structure-vehicle interaction and allows for a numerically efficient evaluation of the dynamic responses of the structure. Particular attention is paid to the influence of the MSD system on the beam bridge during approach and after departure. The structural response of the considered beam bridges is compared and discussed for the different types of high-speed trains and different subsoil conditions.*

1 INTRODUCTION

The increasing operational speed along train lines involves new challenges on the design of railway bridges and on the assessment of existing bridges. At certain train speeds, especially short-to-medium span railway bridges are excited to resonance, which leads to a significant structural acceleration response at the deck level [1]. Resonance effects can lead to destabilization of the ballast, to increased wearing of the rails which is associated with increased maintenance costs of the line, and in extreme cases even to the hazard of train derailment. These aspects demand a detailed dynamic analysis of the response behavior within the framework of a reliability assessment of bridge structures for trains with high-speed. In common computational models the subsoil of the bridge is assumed to be rigid and only a few studies deal with the influence of SSI on the dynamic response behavior of the bridge (e.g. [2, 3, 4, 5]). However, dynamic soil-structure interaction (SSI) effects may have a significant influence on the structural response of high-speed railway bridges and therefore should to be taken into account when performing a reliability analysis.

The most general modeling approach for the prediction of the structural response including SSI is provided by three-dimensional (3D) finite element (FE) models [4, 6, 7]. A 3D FE bridge model offers the possibility of taking the full coupling between the track and the soil into account, the geometry of the bridge can be modeled in detail, and in a time domain formulation nonlinear constitutive behavior can be implemented [3]. In a numerically more efficient but more elaborate approach, an FE model of the bridge is coupled with a boundary element (BE) model of the subsoil [3, 5, 8]. For instance, [5] investigated the influence of SSI on the structural responses of a single-span railway bridge subjected to moving trains at different speeds. In this study, a mass-spring-damper (MSD) train model is coupled with a 3D FE track and bridge model in combination with the BE soil model. The prediction of the structural bridge response using FE or BE-FE formulations involves a significant computational effort, and in the context of reliability assessment, where many limit state function evaluations are required, it is not feasible to use such complex and computationally expensive models. For this reason, the authors of this paper have recently developed a numerically efficient dynamic soil-structure and bridge-train interaction model [9] that allows for a large number of computations in the context of a reliability analysis.

In this contribution, this model is utilized to determine the structural response of beam bridges subjected to moving high-speed trains. The trains are modeled as a planar MSD system, and the bridges as an Euler-Bernoulli beam resting at both ends on spring-damper elements that capture the effect of the subsoil. A dynamic substructuring approach is used to determine the system response, in which the equation of motion of the beam bridge model and the equations of motion of the MSD system are written separately in state space and then coupled via a generalized corresponding assumption. Particular emphasis is paid to the influence of the MSD system on the bridge response during approach and after departure of the bridge. In two application examples, the structural response of two existing bridge structures subjected to three different German high-speed InterCity Express (ICE) trains is assessed.

2 DYNAMIC SOIL-BRIDGE-TRAIN INTERACTION MODEL

2.1 Dynamic substructuring approach

The response of the coupled bridge-MSD system is found by a dynamic substructuring technique [9]. In this approach, the equations of motion of the two subsystems (i.e., the bridge and the MSD system) are derived separately and then coupled utilizing a coupling condition at the interfaces of the subsystems. The beam bridge is subjected to a planar viscoelastic

MSD system representing the moving train at constant speed v (see Figure 1). To account for soil-structure interaction effects, the bridge is modeled as an Euler-Bernoulli beam with spring-dashpot elements at both ends, which is thus non-classically damped. In addition, the rotational springs consider the bending stiffness of the rails and the lumped masses account for the mass of the foundation (see Figure 1).

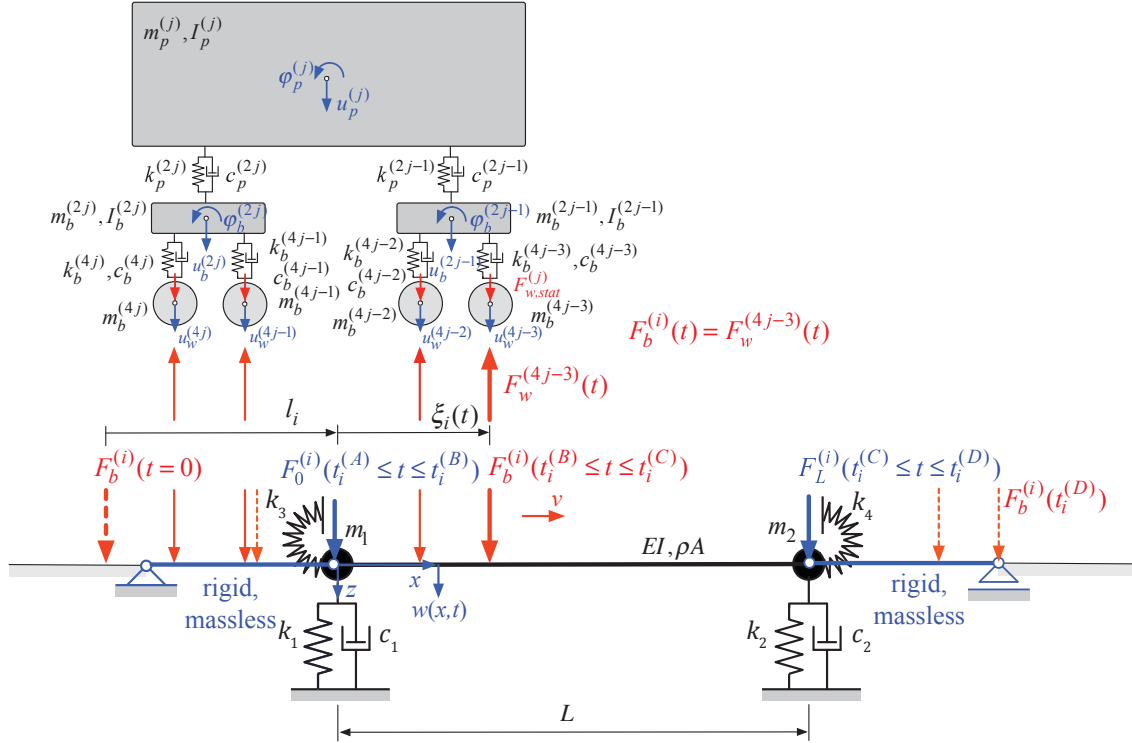

Figure 1: Viscoelastically supported Euler-Bernoulli beam model and planar MSD model, modified from [9]

The procedure described in [9] is based on a complex modal series representation of the beam bridge displacement $w(x, t)$ and the acceleration $\ddot{w}(x, t)$,

$$w(x, t) \approx 2\mathcal{R} \left\{ \sum_{r=1}^{N_\Phi} \Phi_r(x) y_r(t) \right\}, \quad \ddot{w}(x, t) \approx 2\mathcal{R} \left\{ \sum_{r=1}^{N_\Phi} \Phi_r(x) s_r \dot{y}_r(t) \right\} \quad (1)$$

with $\Phi_r(x)$ denoting the r -th complex eigenfunction of the non-classically damped beam and s_r is the corresponding complex natural frequency. The modal equations of motion in state space for the first N_Φ modes of the Euler-Bernoulli beam read [9]

$$\mathbf{A}_b \dot{\mathbf{y}} + \mathbf{B}_b \mathbf{y} = \mathbf{f}_b \quad (2)$$

where \mathbf{y} is the vector of the complex modal coordinates y_r , $r = 1, \dots, N_\Phi$, and their conjugate complex counterparts \bar{y}_r , matrix \mathbf{A}_b contains the coefficients of the decoupled first order differential equations related with $\dot{\mathbf{y}}$, matrix \mathbf{B}_b the coefficients related with \mathbf{y} , and \mathbf{f}_b denotes the vector of the modal interaction forces f_r and \bar{f}_r , $r = 1, \dots, N_\Phi$, between the bridge and the train model,

$$\begin{aligned} \mathbf{y} &= [y_1, \dots, y_r, \dots, y_{N_\Phi}, \bar{y}_1, \dots, \bar{y}_r, \dots, \bar{y}_{N_\Phi}]^T, \\ \mathbf{A}_b &= \text{diag}[a_1, \dots, a_r, \dots, a_{N_\Phi}, \bar{a}_1, \dots, \bar{a}_r, \dots, \bar{a}_{N_\Phi}], \\ \mathbf{B}_b &= \text{diag}[b_1, \dots, b_r, \dots, b_{N_\Phi}, \bar{b}_1, \dots, \bar{b}_r, \dots, \bar{b}_{N_\Phi}], \\ \mathbf{f}_b &= [f_1, \dots, f_r, \dots, f_{N_\Phi}, \bar{f}_1, \dots, \bar{f}_r, \dots, \bar{f}_{N_\Phi}]^T \end{aligned} \quad (3)$$

The MSD train system is composed of rigid bodies with mass representing the passenger stage, two bogies, and four wheel pairs connected with spring-dashpot elements, as shown in Figure 1 [10, 11]. The equations of motion of this MSD system with 10 degrees of freedom (DOFs) in state space representation are given as [11, 12],

$$\mathbf{A}_c \dot{\mathbf{d}}_c(t) + \mathbf{B}_c \mathbf{d}_c(t) = \mathbf{f}_c(t) \quad (4)$$

with the matrices \mathbf{A}_c , \mathbf{B}_c , and vector \mathbf{f}_c

$$\mathbf{A}_c = \begin{bmatrix} \mathbf{C}_c & \mathbf{M}_c \\ \mathbf{I}_c & \mathbf{0} \end{bmatrix}, \quad \mathbf{B}_c = \begin{bmatrix} \mathbf{K}_c & \mathbf{0} \\ \mathbf{0} & -\mathbf{I}_c \end{bmatrix}, \quad \mathbf{f}_c = \begin{bmatrix} \mathbf{F}_c \\ \mathbf{0} \end{bmatrix} \quad (5)$$

composed of the mass matrix \mathbf{M}_c , the damping matrix \mathbf{C}_c , the stiffness matrix \mathbf{K}_c , the vector \mathbf{F}_c comprising the axle forces, and the identity matrix \mathbf{I}_c . The vector $\mathbf{d}_c = \{\mathbf{u}_c^{(1)}, \dots, \mathbf{u}_c^{(j)}, \dots, \mathbf{u}_c^{(N_c)}, \dot{\mathbf{u}}_c^{(1)}, \dots, \dot{\mathbf{u}}_c^{(j)}, \dots, \dot{\mathbf{u}}_c^{(N_c)}\}^T$ contains all DOFs of the MSD system and their first derivative in time of the DOFs.

The equation of motions of beam and MSD system are coupled with the so-called generalized corresponding assumption [9, 13], where it is assumed that the displacement in the vertical direction of the beam and the MSD system at the contact point are equal. Consequently, lift-off of the wheels is not possible, see Figure 2. The generalized corresponding assumption yields the following expression for the vertical displacement $u_w^{(i)}$ of the i -th wheel, which is at time t at position $\xi_i(t)$, together with Eq. (1) [9],

$$u_w^{(i)}(\xi_i) = w(\xi_i, t) \approx \sum_{r=1}^{N_\Phi} \Phi_r(\xi_i) y_r(t) + \sum_{r=1}^{N_\Phi} \bar{\Phi}_r(\xi_i) \bar{y}_r(t) \quad (6)$$

Figure 2: Generalized corresponding assumption for beam and wheel contact at position $\xi_i(t)$ [9]

Finally, the resulting coupled set of equations of motion in state space reads as [9, 13]

$$\mathbf{A}^*(t) \dot{\mathbf{x}}^*(t) + \mathbf{B}^*(t) \mathbf{x}^*(t) = \mathbf{f}^*(t) \quad (7)$$

with the time-dependent system matrices

$$\begin{aligned} \mathbf{A}^*(t) &= \mathbf{\Gamma}_1^T(t) \left[\mathbf{A} \mathbf{\Gamma}_1(t) + \mathbf{A} \dot{\mathbf{\Gamma}}_2(t) + \mathbf{A} \mathbf{\Gamma}_2(t) \mathbf{S} + \mathbf{B} \mathbf{\Gamma}_2(t) \right], \\ \mathbf{B}^*(t) &= \mathbf{\Gamma}_1^T(t) \left[\mathbf{A} \dot{\mathbf{\Gamma}}_1(t) + \mathbf{B} \mathbf{\Gamma}_1(t) \right] \end{aligned} \quad (8)$$

and

$$\mathbf{f}^*(t) = \mathbf{\Gamma}_1^T(t) \left[\mathbf{f}(t) - \mathbf{A} \dot{\mathbf{\Upsilon}}(t) - \mathbf{B} \mathbf{\Upsilon}(t) \right] \quad (9)$$

The time-dependent transformation matrices $\Gamma_1(t)$, $\Gamma_2(t)$ include terms that consider the interaction between the subsystems. This system of equations is solved for the vector \mathbf{x}^* utilizing the 4-th order numerical Runge-Kutta time-step integration scheme of the explicit form of Eq. (7), i.e. $\dot{\mathbf{x}}^*(t) = \mathbf{A}^*(t)^{-1} (\mathbf{f}^*(t) - \mathbf{B}^*(t)\mathbf{x}^*(t))$. A detailed derivation of the equations of motions of the beam bridge model and the MSD system can be found in [9, 13].

2.2 Modeling of the approach and departure phase of the train

When the train approaches the bridge, the bridge is lowered slightly due to the flexibility of the subsoil. This lowering must be taken into account in the mechanical model to avoid a physically unreasonable acceleration jump in the calculation. The same applies accordingly after the train has left the bridge. As described in [14], in the mechanical model the lowering of the bridge in the approach and departure phases is achieved by two fictitious massless rigid beams placed before and after the bridge, respectively, as shown in Figure 1. The effect of N_w axle loads of the MSD system in the approach phase on the first massless beam and in further consequence on the bridge model can be simply described by a force on the left support $F_0(t)$ (at $x = 0$) that increases linearly in this phase [14],

$$F_0(t) = \sum_{i=1}^{N_w} F_b^{(i)}(t) \left(1 + \frac{vt - l_i}{L_a} \right) \delta(x) \Pi(t, t_i^{(A)}, t_i^{(B)}) \quad (10)$$

where the Dirac delta function $\delta(x)$ indicates the position of $F_0(t)$ at $x = 0$, i.e. at the left beam support. The i -th force $F_b^{(i)}$ is activated at time $t_i^{(A)} = (l_i - L_a)/v$ by the Heaviside function $H(t - t_i^{(A)})$ when it enters the fictitious rigid beam, and at time $t_i^{(B)} = l_i/v$ deactivated by the Heaviside function $H(t - t_i^{(B)})$ when $F_b^{(i)}$ runs onto the flexible support, i.e., $\Pi(t, t_i^{(A)}, t_i^{(B)}) = H(t - t_i^{(A)}) - H(t - t_i^{(B)})$. Accordingly, a single force $F_L(t)$ on the right support (at $x = L$) captures the movement of the train away from the bridge [9],

$$F_L(t) = \sum_{i=1}^{N_w} F_b^{(i)}(t) \left(1 - \frac{vt - l_i - L}{L_d} \right) \delta(x - L) \Pi(t, t_i^{(C)}, t_i^{(D)}) \quad (11)$$

At time $t_i^{(C)} = (l_i + L)/v$ the i -th force of the MSD system leaves the beam bridge, and at time $t_i^{(D)} = (l_i + L + L_d)/v$ it leaves the fictitious rigid beam of length L_d , consequently, $\Pi(t, t_i^{(C)}, t_i^{(D)}) = H(t - t_i^{(C)}) - H(t - t_i^{(D)})$.

The r -th modal form of these forces read as [9]

$$\begin{aligned} f_0^{(r)}(t) &= \int_L \sum_{i=1}^{N_w} F_b^{(i)} \left(1 + \frac{vt - l_i}{L_a} \right) \delta(x) \Pi(t, t_i^{(A)}, t_i^{(B)}) \Phi_r(x) dx = \\ &= \sum_{i=1}^{N_w} F_b^{(i)} \left(1 + \frac{vt - l_i}{L_a} \right) \Pi(t, t_i^{(A)}, t_i^{(B)}) \Phi_r(0) \\ f_L^{(r)}(t) &= \int_L \sum_{i=1}^{N_w} F_b^{(i)} \left(1 - \frac{vt - l_i - L}{L_d} \right) \delta(x - L) \Pi(t, t_i^{(C)}, t_i^{(D)}) \Phi_r(x) dx = \\ &= \sum_{i=1}^{N_w} F_b^{(i)} \left(1 - \frac{vt - l_i - L}{L_d} \right) \Pi(t, t_i^{(C)}, t_i^{(D)}) \Phi_r(L) \end{aligned} \quad (12)$$

Consequently, the r -th modal load in Eq. (3) is given as $f_r = f_0^{(r)} + f_b^{(r)} + f_L^{(r)}$, where $f_b^{(r)}(t) = \int_L \sum_{i=1}^{N_w} F_b^{(i)}(t) \delta(x - \xi_i) \Pi(t, t_i^{(B)}, t_i^{(C)}) \Phi_r(x) dx = \sum_{i=1}^{N_w} F_b^{(i)}(t) \Pi(t, t_i^{(B)}, t_i^{(C)}) \Phi_r(\xi_i)$ accounts for the modal form of the series of N_w moving single forces crossing the beam bridge. During the approach and departure phase of the MSD system the dynamic interaction between the beam and the MSD system is explicitly considered in the transformation matrices $\Gamma_1(t)$, $\Gamma_2(t)$, see [9, 13].

3 Application

This dynamic substructuring approach is used to efficiently evaluate the acceleration response of two example bridges subjected to the German InterCity Express trains ICE 2, ICE 3, and ICE 4. In the considered configuration, the ICE 2 train with a maximum train speed of $v_{\max} = 77.8$ m/s (280 km/h) and a total length of $L_{\text{train}} = 205.4$ m is composed of one power car followed by seven passenger cars. The UIC axle classification [15] of this train with in total 32 axles thus reads $\text{Bo}'\text{Bo}' + 2'2' + 2'2' + 2'2' + 2'2' + 2'2' + 2'2' + 2'2'$, with Bo' representing one pair of axles of the power car and $2'$ representing one pair of axles of the passenger car. The considered ICE 3 train contains four power cars and four passenger cars with an UIC axle classification of $\text{Bo}'\text{Bo}' + 2'2' + \text{Bo}'\text{Bo}' + 2'2' + 2'2' + \text{Bo}'\text{Bo}' + 2'2' + \text{Bo}'\text{Bo}'$. The length of this train with 32 axles and a maximum speed of $v_{\max} = 91.4$ m/s (330 km/h) is $L_{\text{train}} = 200.8$ m. The considered ICE 4 train with a maximum speed of $v_{\max} = 69.4$ m/s (250 km/h) has 3 power cars and 4 passenger cars, which add up to 28 axles and a total length of $L_{\text{train}} = 202$ m. The corresponding UIC axle classification is $2'2' + \text{Bo}'\text{Bo}' + 2'2' + \text{Bo}'\text{Bo}' + \text{Bo}'\text{Bo}' + 2'2' + 2'2'$. The parameters of the MSD model of the ICE 2 and ICE 3 can be found in [16, 17], and of the ICE 4 train in [18].

In general, the maximum acceleration of the bridge deck is decisive for the assessment of the reliability of the railway bridge exposed to high-speed trains [19]. Therefore, the acceleration response of the two beam bridges subjected to the MSD system representing the considered trains is computed for five different subsoil conditions. In this study, the time history of the beam bridge response at closely spaced beam locations x is analyzed for a given speed v of the train models in the observation period $T = (l_1 + L_{\text{train}} + L_a + L + L_d)/v$, and subsequently the absolute value of the peak response is recorded, i.e. the peak acceleration $a(v) = \max \{ |\ddot{w}(x, t, v)| : 0 \leq x \leq L, 0 \leq t \leq T \}$. The modal expansions are approximated by seven modes, i.e. $N_\Phi = 7$. Structural modal damping of $\tilde{\zeta}_r = 0.25\%$ ($r = 1, \dots, N_\Phi$) is taken into account and the surface of the beam is assumed to be perfectly smooth.

The properties of the soil under the bridge foundation are varied, representing a range from moderately soft to stiff soils. Five homogeneous soils with different stiffness are considered, whose soil parameters (constrained modulus E_s , Poisson's ratio ν , mass density ρ) are summarized in Table 1 [13, 20]. Soil 1 with the lowest stiffness corresponds to a medium stiff soil and soil 5 to a stiff soil (rock). Since the required contact area A_0 of the foundations depends on the soil stiffness (i.e. the stiffer the soil the smaller the required area), the product of the base area of the foundation A_0 and the root of the constrained modulus of the soil E_s is kept constant when determining k and c , i.e., $A_0 \sqrt{E_s} = 2.289 \cdot 10^4 \sqrt{\text{Nm}}$ [14]. It is assumed that the foundation has the same mass for all soils considered: $m = 1.5 \cdot 10^5$ kg.

	E_s [MN/m ²]	ν [-]	ρ [kg/m ³]	k [N/m]	c [kg/s]
1	200	0,30	2263	$5,895 \cdot 10^8$	$1,089 \cdot 10^6$
2	250	0,28	2300	$7,662 \cdot 10^8$	$1,098 \cdot 10^6$
3	300	0,26	2333	$9,495 \cdot 10^8$	$1,106 \cdot 10^6$
4	400	0,25	2367	$1,284 \cdot 10^9$	$1,114 \cdot 10^6$
5	500	0,25	2400	$1,605 \cdot 10^9$	$1,121 \cdot 10^6$

Table 1: Soil parameters and corresponding parameters of the spring-dashpot elements [13]

3.1 Example bridge 1

Example bridge 1 models an existing single-span ballasted steel railway bridge located in Austria with a span length of $L = 16.8$ m. Its bending stiffness is $EI = 3.262 \cdot 10^{10}$ Nm² and its mass per unit length $\rho A = 1.220 \cdot 10^4$ kg/m. Table 2 presents the first four natural frequencies $f_r (= \mathcal{I}(s_r)/2\pi = \Omega_r/2\pi)$, $r = 1, \dots, 4$, and equivalent damping coefficients $\zeta_r + \tilde{\zeta}_r$ for the beam model on viscoelastic supports representing various subsoil conditions, and for the simply supported beam bridge model (i.e., in this case the subsoil is rigid). In this context, it should be noted that higher modes, associated with higher frequencies, are less critical for bridge failure [13].

Table 2: First four natural frequencies and damping coefficients of bridge model 1 resting on soils 1 to 5 and on rigid soil

	soil no. 1	soil no. 2	soil no. 3	soil no. 4	soil no. 5	simply supported beam
f_1 [Hz]	6.59	7.12	7.49	7.94	8.19	9.10
f_2 [Hz]	8.96	10.19	11.34	13.16	14.68	36.39
f_3 [Hz]	12.96	13.68	14.45	15.87	17.19	81.90
f_4 [Hz]	38.80	38.85	38.89	38.99	39.08	145.60
$\zeta_1 + \tilde{\zeta}_1$ [%]	2.71	1.96	1.46	0.94	0.69	0.25
$\zeta_2 + \tilde{\zeta}_2$ [%]	5.41	4.79	4.35	3.77	3.39	0.25
$\zeta_3 + \tilde{\zeta}_3$ [%]	2.94	3.17	3.20	3.18	3.08	0.25
$\zeta_4 + \tilde{\zeta}_4$ [%]	0.42	0.43	0.44	0.45	0.46	0.25

Figure 3 shows the maximum acceleration response $a(v)$ of example bridge 1 subjected (a) to the ICE 2 train and (b) to the ICE 3 train as a function of the train speed v . The local response peaks of these so-called response spectra are referred to as resonance peaks, and the associated train speeds are known as critical speeds or resonance speeds. At such a critical train speed, defined as $v_j^{(r)} = df_r/dj$, $j = 1, 2, 3, \dots$, the r -th natural bridge frequency is excited to a state of resonance due to the repetitive axle loads with constant distance d [21].

When the beam is rigidly supported, the ICE 2 train induces a maximum bridge deck acceleration $a = 6.6$ m/s² at speed $v = 79.5$ m/s (which is close to the resonance speed $v_3^{(1)} = 80.1$ m/s, based on the wagon length of the ICE 2 train $d = 26.4$ m). For the beam resting on soil 5, the maximum acceleration $a = 3.6$ m/s² occurs at the train speed $v = 71$ m/s, which is close to the resonance speed $v_3^{(1)} = 72.1$ m/s. Soil 4 and soil 3 lead to the acceleration maxima $a = 2.9$ m/s² and $a = 1.9$ m/s² at the train speeds $v = 68.8$ m/s, $v = 66.7$ m/s, respectively. Due to the considerable geometric damping at soil 1 and soil 2, no pronounced resonance peak is visible in these cases. These results show that SSI reduces the peak accelerations at resonance compared to the rigidly supported beam bridge model. Simultaneously, the corresponding critical train speeds

also decrease, which could be of concern because these speeds are below the maximum train speed (cf. Figure 3(a)).

The overall response behavior of this example bridge is very similar when subjected to the ICE 3 train, see Figure 3. In the rigidly supported beam bridge model, the global acceleration maximum at $v = 74.6$ m/s is $a = 10.3$ m/s², which is close to the resonance speed $v_3^{(1)} = 75.2$ m/s, based on the ICE 3 wagon length $d = 24.8$ m. The global resonance peak of the bridge resting on soil 5 is $a = 5.7$ m/s² at $v = 66.7$ m/s (close to resonance speed $v_3^{(1)} = 67.6$ m/s). The structure in combination with soil 4 yields the maximum acceleration $a = 4.1$ m/s² at $v = 64.7$ m/s, and in combination with soil 3 $a = 2.6$ m/s² at $v = 60.4$ m/s. As in the case of the ICE 2 train, no distinct acceleration peaks can be observed for the structure resting on soil 1 and soil 2.

Figure 3: Maximum bridge acceleration of example bridge 1 subjected (a) to the ICE 2 train and (b) to the ICE 3 train as a function of the train speed for different soil conditions.

Figure 4 presents the maximum acceleration response of example bridge 1 subjected to the MSD system of the ICE 4 train. As before, the rigidly supported beam bridge model exhibits the largest bridge deck acceleration $a = 12.6$ m/s² at $v = 86.4$ m/s (close to the resonance speed $v_3^{(1)} = 87.7$ m/s; wagon length $d = 28.9$ m). Likewise, the maximum bridge acceleration and the associated resonant speed decrease with decreasing base stiffness (soil 5: $a = 7.9$ m/s² at $v = 77.7$ m/s; soil 4: $a = 6.7$ m/s² at $v = 74.5$ m/s; soil 3: $a = 4.9$ m/s² at $v = 70.7$ m/s; soils 1 and 2: no pronounced response peaks).

Comparison of Figures 3 and 4 reveals that at bridge 1 on rigid soil the ICE 3 train leads to the dominant resonance peak at the lowest speed, while the ICE 2 train induces the lowest bridge accelerations. On the other hand, the ICE 4 train excites the bridge to the largest accelerations, however, at the largest resonance speed compared to the other train models.

Figure 4: Maximum bridge acceleration of example bridge 1 subjected to the ICE 4 as a function of the train speed for different soil conditions.

3.2 Example bridge 2

With $L = 21$ m, the span length of example bridge 2, which is also the model of an existing single-span ballasted steel railway bridge, is larger than that of bridge 1. The flexural stiffness is $EI = 2.6 \cdot 10^{10}$ Nm² and the mass per unit length $\rho A = 7083 \cdot 10^4$ kg/m. The first four natural frequencies of example bridge 2 f_r , $r = 1, \dots, 4$, and corresponding equivalent damping coefficients $\zeta_r + \tilde{\zeta}_r$ depending on the subsoil conditions are compiled in Table 3.

Table 3: First four natural frequencies and damping coefficients of bridge model 2 resting on soils 1 to 5 and on rigid soil

	soil no. 1	soil no. 2	soil no. 3	soil no. 4	soil no. 5	simply supported beam
f_1 [Hz]	5.96	6.19	6.33	6.47	6.55	6.80
f_2 [Hz]	9.18	10.45	11.61	13.44	14.96	27.20
f_3 [Hz]	10.88	11.95	13.01	14.79	16.35	61.20
f_4 [Hz]	28.62	28.67	28.73	28.85	28.99	108.80
$\zeta_1 + \tilde{\zeta}_1$ [%]	1.40	0.91	0.67	0.46	0.38	0.25
$\zeta_2 + \tilde{\zeta}_2$ [%]	5.52	4.88	4.4	3.79	3.37	0.25
$\zeta_3 + \tilde{\zeta}_3$ [%]	4.46	4.34	4.15	3.79	3.50	0.25
$\zeta_4 + \tilde{\zeta}_4$ [%]	0.45	0.47	0.49	0.52	0.56	0.25

Figures 5(a),(b) and 6 show the peak acceleration response of this structure subjected to the ICE 2, ICE 3 and ICE 4 train models. In all cases, the maximum peak acceleration occurs at the rigidly supported beam. The ICE 2 train induces large responses of the bridge resting on soil 1 (smallest stiffness) compared to structure on the stiffer soils 5, 4, 3, and 2, as can be seen from Figure 5(a). However, in general the ICE 2 train does not cause significant acceleration responses of this structure. Another observation is that the peak acceleration of bridge 2 on soil 3 induced by the ICE 3 train is larger than for the bridge on soils 5 and 4, cf. Figure 5(b). Clearly, the ICE 4 train yields the largest bridge accelerations, as can be seen from Figure 6. For instance, the rigidly supported beam bridge model exhibits the largest acceleration $a = 17.4$ m/s² at $v = 64.7$ m/s, which is close to the resonance speed $v_3^{(1)} = 65.5$ m/s. The peak acceleration and the corresponding resonance speed for the bridge on flexible soil decrease with decreasing soil stiffness. Soil 5: $a = 13.2$ m/s² at $v = 62$ m/s (close to $v_3^{(1)} = 63.1$ m/s); soil 4: $a = 12.2$ m/s²

at $v = 61.3$ m/s; soil 3: $a = 10.1$ m/s² at $v = 59.8$ m/s; soil 2: $a = 8.2$ m/s² at $v = 58.5$ m/s; soil 1: $a = 5.9$ m/s² at $v = 56.4$ m/s.

Figure 5: Maximum bridge acceleration of example bridge 2 subjected (a) to the ICE 2 train and (b) to the ICE 3 train as a function of the train speed for different soil conditions.

Figure 6: Maximum bridge acceleration of example bridge 2 subjected to the ICE 4 as a function of the train speed for different soil conditions.

4 CONCLUSIONS

In this study, a soil-bridge-train interaction model recently developed by the authors was used to efficiently evaluate the structural response of two example bridges subjected to the German high-speed trains ICE 2, ICE 3 and ICE 4. This model is based on a dynamic substructuring approach in which the bridge is modeled as a beam and the train as a mass-spring-damper system. To obtain physically meaningful results, the arrival and departure phases of the train were considered. Train-bridge interaction was explicitly considered in the approach and departure phases.

The influence of the soil-structure interaction and the bridge-train interaction on the response of the example bridges subjected to the three different train types was shown. When the soil-structure interaction is considered, the maximum acceleration at resonance is reduced due to the additional damping of the system, but simultaneously also the resonance peaks are shifted to lower train speeds. This trend is visible for the two example bridges and all three train types considered.

ACKNOWLEDGEMENTS

The computational results presented have been achieved (in part) using the HPC infrastructure LEO of the University of Innsbruck.

Abstract

Based on past earthquake events, bridges are the most critical and usually the most vulnerable component of road and rail transport systems, while bridge damage is related to substantial direct and indirect losses. For the case of railway bridges, the estimation of seismic fragility is a rather complex and computationally demanding procedure due to the real-time interaction of the train movement and the bridge and the different failure modes of subsystems. Several methodologies are available in the literature to estimate train-bridge systems' seismic fragility, ignoring the nonlinear behavior of the bridge during earthquake loading and the different failure modes of critical components. The scope of this research paper is to propose a component-based methodology for the estimation of bridge fragility curves, considering all critical components and failure modes of subsystems. The coupled VBI (vehicle bridge interaction) is solved in a software platform using the co-simulation approach, based on a force-displacement coupling technique and a Gauss-Seidel communication pattern. The co-simulation implementation, i.e., the orchestrator and the functional mockup units (FMUs), were developed in the environment of PyFMI. The vehicle-rail system is solved using a C++ tailor-made code based on a novel mathematical formulation of constrained dynamical systems with a set of pure ordinary differential equations and is wrapped in an independent FMU. The inelastic bridge model is developed and solved using OpenSees.py, which is wrapped in an independent FMU. Also, an ad-hoc software for implementing the probabilistic framework and the derivation of fragility curves is developed in Python. The methodology and the software developed are described and applied to a case study bridge of the Greek railway network, and the fragility curves are provided and discussed.

Keywords: Railway bridges, vehicle-bridge interaction (VBI), Co-simulation, fragility curves

1 INTRODUCTION

Roadway and railway bridges are considered the most critical infrastructure of relevant networks exposed to multiple hazards, while damage at their critical components is related to substantial direct and indirect losses. Furthermore, decision-making for upgrade and expansion of existing roadway and railway networks should be based on detailed technical studies accounting for various social and economic parameters, infrastructure robustness and reliability data. In this context, a robust and reliable assessment of railway bridges is a valuable tool for both retrofit prioritization and investment planning. Several methodologies for seismic fragility assessment of railway bridges are available, however a detailed framework considering both the vehicle bridge-interaction and the coupled system's limit states incorporated within a fully parameterized, tailor-made software for the derivation of fragility curves has not yet been proposed.

The dynamic behavior of a train-bridge system is a coupled and complex model consisting of two main subsystems, the train, and the bridge. The train subsystem can be described as a multibody assembly and the bridge subsystem can be modeled using classical structural finite element formulations. The subsystems interact through forces between the vehicle wheels and the rail on the bridge deck. Several researchers worldwide have worked on train-bridge interaction problems integrating the train, track and bridge as a single system [1,2]. Vehicle-rail-bridge (VRBI) models have been introduced to analyze dynamic interaction between moving trains and railway bridges, based on the dynamic integration methods [3,4,5,6,7]. Due to the nonlinear interaction of subsystems, it is widely accepted that the dynamic analysis of train-bridge system during earthquakes cannot be a simple combination of bridge seismic design and train-bridge interaction calculation. Therefore, several studies have investigated the response of coupled systems under dynamic (earthquake) loading [8] as well as the seismic performance for different levels of earthquake intensity (fragility analysis) [9].

Based on the above, the scope of this paper is to propose and develop a novel methodology for the modeling and analysis of the coupled train-railway bridge system, considering an appropriate numerical discretization scheme and a solution strategy based on a co-simulation approach. Efficient modeling of the vehicle multibody assembly is proposed using a tailor-made C++ code, while the nonlinear bridge model is developed and analyzed using open-source software. Interaction between the vehicle and the bridge is proposed via an integrated approach that employs co-simulation techniques and FMI (functional mockup interface) for the communication and joint solution of subsystems in the time domain considering different time steps for analysis and selecting Gauss Seidel communication pattern. All the above are incorporated into a holistic methodology proposed herein for seismic fragility analysis of the coupled train-bridge system considering VBI, multiple critical components, and appropriate limit states that account for the running safety of high-speed trains along with the possibility for derailment. The novel methodology for fragility analysis and the relevant software developed are applied to a representative bridge of the Greek railway network, providing the subsystems' and coupled systems' fragility curves. The results are discussed and assessed, providing insight regarding seismic fragility analysis of coupled train-bridge systems and the computational framework required for their estimation.

2 VEHICLE-BRIDGE SYSTEM INTERACTION (VBI)

2.1 Description of vehicle modeling

A typical railway vehicle consists of car bodies, bogies, wheelsets and spring-damper primary and secondary suspensions. A car body is connected to the bogie frame through the sec-

ondary suspension system, whereas the bogie is connected to the wheelsets through the primary suspension system [10]. The vehicle system can be seen as an assembly of rigid and flexible parts subjected to a set of kinematic constraints and connected through springs and dampers. This assembly constitutes a multibody system with bodies that can undergo large rotations, move at high speed, and interact with each other inducing large forces and moments. The target is to study the dynamical synergy between a moving train and a rail when the latter is attached to the bridge and may be subjected to seismic loads (and/or high lateral winds). Realistic modeling of derailment constitutes a crucial step for evaluating train running safety and should be accordingly considered.

Each vehicle of the high-speed train consists of two bogie sub-systems, connected to the car-body via an inline joint and spring-damper elements (SPDP). The latter constitutes the vertical and lateral secondary suspension system. At the lower part of each bogie, two wheelsets are placed, connected to the bogie via the axle boxes. The axle boxes are connected to the bogie with vertical and lateral spring-damper elements, forming the primary suspension system. There is a revolute joint linking the two axle boxes to the wheelset at both ends of the wheelset. The revolute joints allow the wheelsets to rotate freely to the axle boxes and vice versa. The direction of rotation is the wheelset's centerline and the wheelset-axle boxes system has eight degrees of freedom. Six of those DOFs include its rigid body motion, while the last two leave the relative rotation free between the axle boxes and the bogie, bringing the functionality of the primary suspension system. Therefore, each vehicle consists of 15 rigid bodies. The geometric cubic splines of the wheel and rail profiles and that of the track centerline generate the wheel and rail surfaces. To form the entire high-speed train a specific number of vehicles are considered, placed at a predefined distance from each other, connected through a selected type of constraint joint. A practical selection is that of the spherical joint leaving all three rotational degrees of freedom free, while the remaining three translational are unconstrained. Finally, the front vehicle has the constraint of constant linear velocity along the direction of the train movement, simulating the driving motion of the entire train assembly. The resultant contact force between the wheel and the rail can be decomposed in two component forces. The first is the normal contact force which is always perpendicular to the common tangent plane of the two surfaces at the contact point. The second component is the friction force acting in the tangent plane. This friction force is described by Kalker's linear theory.

The analysis described above is based on the assumption that the normal direction \underline{n} is known. Knowing the position and orientation of the wheelset along with the analytical forms of the surfaces for the wheel and rail, a minimization problem can be formulated to determine \underline{n} . The minimization function is defined in the form of the square of the Euclidian distance between a point on the wheel and a point on the rail. The local minimum determines the points on the two surfaces with the shortest distance. The unit vector along the line connecting these two points provides the contact normal direction. This is the direction used to calculate the value of the contact constraint needed for the numerical integration of the equations of motion.

A dully tailored software in C++ is developed to apply the methodology described above for the vehicle analysis. The numerical algorithm for the solution of the constrained multibody system is based on the methodology developed in [11] and [12]. The software is wrapped in an FMU and is used within the proposed co-simulation framework for the analysis of the coupled vehicle and bridge system for earthquake loading.

2.2 Description of bridge modeling

The bridge structure is modeled using an open-source FEM program, OpenSees.py [13]. The detailed inelastic model of the bridge system is developed, considering all critical parameters and boundary conditions. The deck is commonly prestressed and intended to remain elastic during earthquake loading; therefore, it is modeled using elastic beam elements with the relevant properties. Bridge piers are modeled using inelastic beam-column elements considering concentrated plastic hinges at pier bottom for the case of cantilever piers and at pier top and bottom for multicolumn piers or piers with monolithic pier-to-deck connection. Based on the results of moment-curvature analysis the secant stiffness of the fully cracked section at yield ($EI_{\text{eff}} = M_y / \phi_y$) is estimated and used for the consideration of cracked elastic pier section. Regarding bearings of railway bridges, it is noted that elastomeric bearings are commonly used for the support of bridge deck on piers and seat-type abutments, while the use of pot bearings and stoppers, lead rubber bearings (with increased damping) and isolation devices are also common. For the modeling of bearings, either the linear effective stiffness or the non-linear hysteretic behavior may be considered with the parameters calculated based on literature recommendations [14], [15], etc. Regarding pier shallow or pile foundation, linear or nonlinear springs are used for the modeling of soil-structure-interaction (SSI), playing an important role in both component and system seismic performance and fragility, as mentioned in [16]. Piles are modeled using elastic beam-column elements, while vertical (friction) and horizontal (p-y) springs are calculated considering SSI. Modeling of boundary conditions at abutment location is crucial; therefore both the gap in the longitudinal direction and the inelastic abutment-embankment system behavior (described in detail in [17]) are modeled. It should be highlighted that for the case of railway bridges there is no gap in the transverse direction, in order to prevent derailment phenomena. Response history analysis of the inelastic bridge model is performed using OpenSees.py, in order to calculate inelastic bridge responses and bridge fragility.

3 EARTHQUAKE ANALYSIS CONSIDERING VBI PROPOSING A CO-SIMULATION APPROACH

Coupled simulation or co-simulation has been proposed as a solution to overcome the challenges emerging in complex, coupled engineering systems. The holistic problem is being broken down into two or more individual subsystems and the coupling variables between the subsystems could be either in force terms (applied-force coupling), or in force-kinematic terms (displacement-displacement (X-X) and displacement-force (X-T) respectively) [18]. The co-simulation process is being carried out by a third simulator, named orchestrator, that is responsible for the integration, coupling, and communication between subsystems. The orchestrator leads each co-simulation step (communication interval), exchanges variables with the subsystems simulators, and checks the coupling conditions (convergence).

Regarding the communication scheme, the Gauss-Seidel (serial) communication scheme is proposed for the solution of the vehicle(train)-bridge system in the time domain. Applying an iterative Gauss-Seidel approach, the vehicle subdomain is first solved for the communication interval H (starting point $T_N = t_{0, \text{tr}}$), assuming a known solution for the bridge subdomain. The vehicle subdomain is integrated until the next communication step, i.e. $T_{N+1} = t_{1, \text{tr}}$. At this time point, the output variables of the vehicle subdomain are being used by the orchestrator in order to calculate new inputs for the bridge subdomain. The bridge subdomain is solved until $T_{N+1} = t_{1, \text{br}}$ (starting point $T_N = t_{0, \text{tr}}$). The process described above is repeated until the coupling conditions are satisfied (convergence) and the co-simulation can proceed to the next communication point. The vehicle subdomain is solved using a multibody dynamics method devel-

oped at the Laboratory of Machine Dynamics (AUTH), whereas the bridge subdomain is solved via OpenSees, a general FEM open-source code. The coupled vehicle-bridge systems' analysis procedure is described in Figure 1, explaining the analysis of every subsystem at every distinct step and the communication pattern.

Figure 1: Outline of the methodology for dynamic high-speed train -bridge interaction

4 SEISMIC FRAGILITY ANALYSIS OF COUPLED RAILWAY BRIDGE SYSTEMS CONSIDERING VBI

The framework proposed for seismic fragility analysis of bridges is based on analysis results of the coupled vehicle-bridge system for different levels of earthquake intensity, estimating the probability of damage of critical bridge components and the vehicle for various limit states (minor damage to collapse) [10]. The methodology proposed is outlined in Figure 2.

For the estimation of *vehicle subsystem* fragility, serviceability and ultimate limit state thresholds are defined, based on the recommendations of EN1990-prANNEX A2, (2001) and BS EN 14363: (2016), as described in Table 1. The vehicle limit states proposed consider vehicle stability (LS1), the dynamic performance of the bridge (LS2) and vehicle safety (derailment LS3 &4) (Table 1). The *vehicle subsystem* properties (i.e., number of boogies), speed, and time step that the vehicle enters the bridge are initially defined, and analysis of the subsystem is performed considering real-time vehicle-bridge interaction via co-simulation techniques. The threshold values are compared to the ones monitored at the vehicle during the coupled system analysis for the selected earthquake ground motions to estimate the probability of exceedance and plot the relevant fragility curves (Figure 2).

Regarding the *railway bridge subsystem* fragility estimation, the engineering demand parameters and their threshold values are initially defined at component level for different limit states, as described in detail in [17]. The structural type of the railway bridge is selected, along with varying properties (random variables selection), for probabilistic treatment and

derivation of bridge samples using Latin Hypercube Sampling (LHS). The bridge samples are analysed considering real-time train-bridge interaction for accelerograms of varying intensity (0.1~1.0g), selected applying Multiple Stripe Analysis (details for Multiple Stripe Analysis and accelerogram selection are available in [16]). The engineering demand parameters values at component control points are monitored to estimate the probability of limit state threshold exceedance and plot fragility curves at component and system level. Based on the above, fragility curves for the subsystems and the coupled system are proposed accounting for series connection and complete correlation of critical components.

	Criteria for train running stability			Criteria for bridge dynamic performance		Criteria for train running safety		
	Lateral accel. (boogie)	Lateral accel. (veh.body)	Vertical accel. (veh.body)	Accel-eration	Transverse deformation & vibration of deck	Overturn Coefficient	Overturn Criterion	
Parameter	Accel. (m/s ²)	Accel. (m/s ²)	Accel. (m/s ²)	Accel-eration (m/s ²)	Curvature (1/m) [<i>r</i> = <i>l</i> ² /8· <i>δ_h</i>]	<i>D</i> = <i>P_d</i> / <i>P_{st}</i>	$\kappa = \frac{\sum_{boogie} Q_{JA} - \sum_{boogie} Q_{JB}}{\sum_{boogie} Q_{JA} + \sum_{boogie} Q_{JB}}$	
Limit Values	12.0 m/s ² – (m ⁺ /5t) = 11.392 m/s ²	3.0	5.0	0.35g (3.5m/s ²) for ballasted track	<i>Speed range (km h⁻¹)</i>	<i>Limits</i>	0.80 (for all wheels at the same time)	1.0
					V≤120	1700		
					120≤V≤200	6000		
					V>200	14000		

Table 1: Limit values for vehicle and fragility analysis of the coupled train-bridge system

For the estimation of the coupled systems' fragility curves, seismic analysis of the coupled system is performed considering earthquake loading of varying intensity (0.1~1g). The analysis results are recorded at the vehicle and the bridge control points for the all the coupled (train-bridge) system samples. The values are compared to the limit state thresholds of each subsystem (and component) and statistical analysis of the results is performed estimating the mean and standard deviation of capacity over demand exceedance and, eventually, the seismic fragility curves of the vehicle and bridge subsystem. For the estimation of uncertainty in capacity and demand the methodology described in [17] is followed. The fragility curves of the coupled system are calculated assuming series connection between subsystems (vehicle and bridge) according to Eq. 1 (upper and lower bound, Zhang &Huo, (2009)):

$$\max_{i=1}^n [P(F_i)] \leq P(F_{system}) \leq 1 - \prod_{i=1}^n [1 - P(F_i)] \quad (1)$$

The lower bound corresponds to completely correlated components, while the upper bound assumes no correlation between components. Therefore, the coupled system's fragility lies within these two bounds and the exact value is dependent on the correlation of the component response.

5 APPLICATION TO A CASE STUDY RAILWAY BRIDGE FOR THE ESTIMATION OF SEISMIC FRAGILITY OF THE COUPLED SYSTEM

The methodology presented above is applied to a representative bridge of the Greek railway network with simply supported deck, using the software developed for real-time bridge-vehicle analysis. A five boogies Vehicle is considered to cross the bridge during the earthquake. The vehicle is entering the bridge about 3[sec] before the earthquake peak. Based on the coupled system analysis results, fragility analysis is performed, and fragility curves are provided for all the critical bridge components, the bridge subsystem, the vehicle subsystem and the coupled system. The effect of VBI consideration on seismic fragility of critical bridge

components (piers and abutments since pot bearings are used in combination with stoppers, rendering the bearings a non-critical component) is evaluated providing relevant fragility curves for the cases of earthquake only analysis and earthquake analysis accounting for VBI. Moreover, the seismic fragility curves of the bridge subsystem with and without VBI consideration are provided for both longitudinal and transverse direction, highlighting the effect of VBI on the subsystem's fragility. The seismic fragility of the vehicle subsystem is also provided for both directions along with the fragility curves of the coupled (vehicle and bridge) system based on series connection assumption. The effect of the consideration or ignorance of vehicle subsystem limit states and fragility, i.e. the consideration of the coupled system instead of the bridge system solely, is evaluated and discussed.

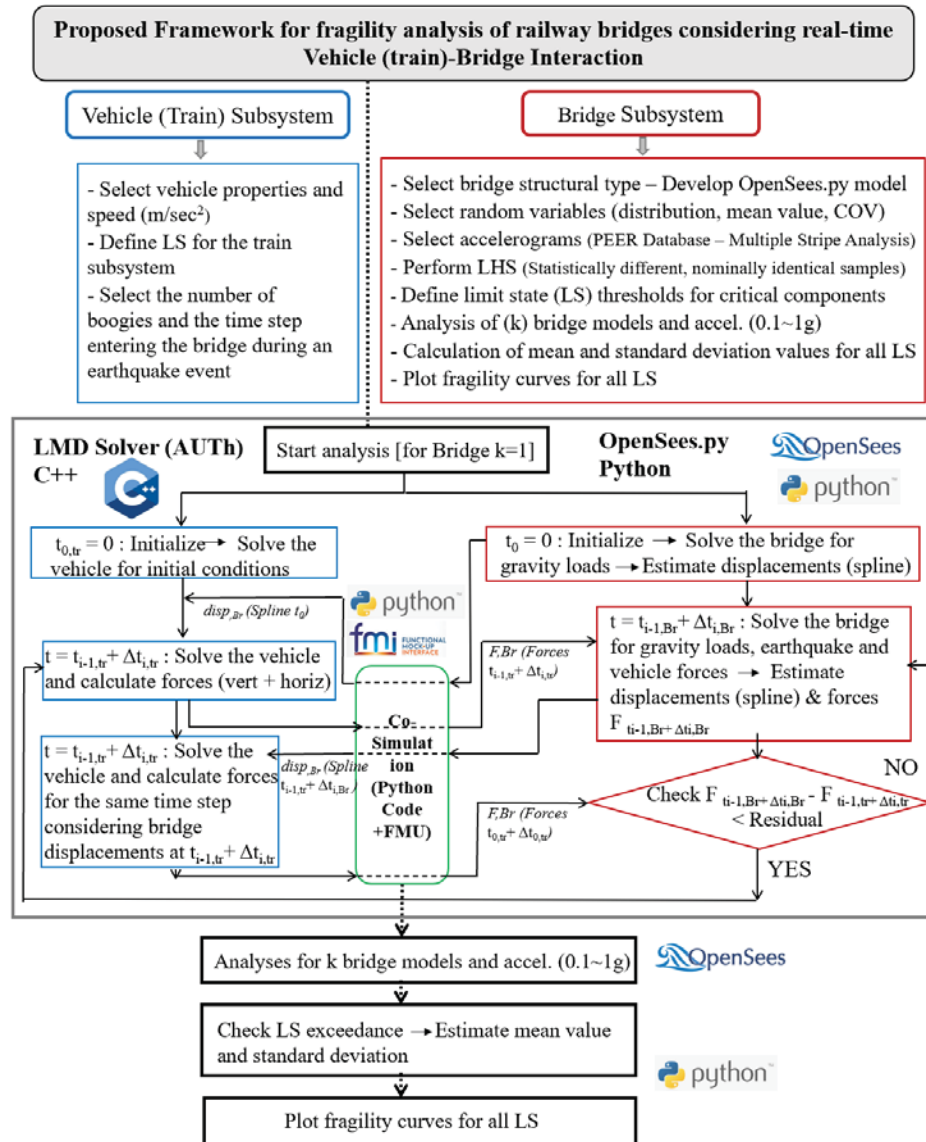

Figure 2: Outline of the methodology for dynamic high-speed train-track-bridge interaction.

The Tirothea - Domokos bridge is a two-way railway bridge of the Athens-Thessaloniki railway network, located at Central Greece, near Lamia (Figure 3). Responsible for the management of the project is ERGOSE SA, Greece. The bridge is designed for train speed equal to $v \leq 200$ km/h and PGA equal to 0.24g, while it should be outlined that it is located at a 175m distance from the seismically active Atalanti fault; therefore, the probability of the occurrence

of an earthquake event when the train crossing the bridge is relatively higher. The Tirothea - Domokos bridge has a total length of 505.26 (m) and fifteen (15) spans (approx. 34.0m length each) consisting of precast-prestressed beams simply supported on single and multicolumn piers with heights ranging from 2.67(m) to 6.57(m). All multicolumn piers consist of two cylindrical piers supporting the two decks through pot bearings and stoppers. The first five pairs of piers are single column cylindrical (or rectangular) piers (Fig. 3), supporting the deck through pot bearings and stoppers. The abutments are seat type; the seismic gap is considered along the longitudinal direction but not the transverse one to prevent derailment. The bridge is modelled using linear and nonlinear elements and material laws, as described at the relevant section above and depicted in Fig.3.

Figure 3: Description of Tirothea-Domokos railway bridge and details of the structural model

Regarding the effect of VBI consideration on the seismic fragility of critical bridge components, it is obvious from Fig.4 that the component seismic fragility (i.e. the probability of damage for different levels of earthquake intensity) is decreased, mainly for higher limit states, in case that the train is considered to move on the bridge during the earthquake and vehicle-bridge interaction is accounted for. The latter is attributed to the fact that the consideration of the vehicle during analysis differentiates the dynamic characteristics of the bridge, resulting in a different earthquake response that is additionally related to the structural system and the properties (ductility, inelastic performance, etc.) of the components.

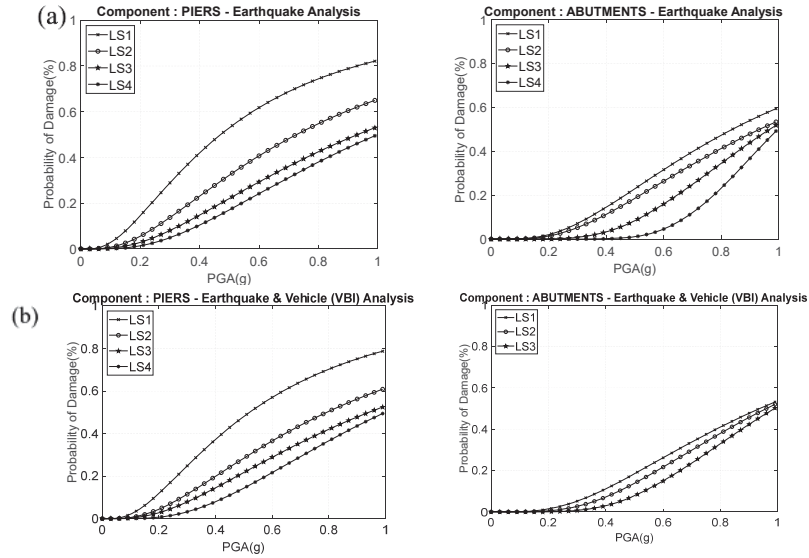

Figure 4: Seismic fragility curves of the critical components of the bridge subsystem with (a) and without (b) VBI consideration for the Tirothea-Domokos Railway Bridge and x-direction
