## PREFACE

This volume contains the full-length papers presented in the 8<sup>th</sup> International Conference on Computational Methods in Structural Dynamics and Earthquake Engineering (COMPDYN 2021) that was streamed from Athens, Greece on June 28-30, 2021.

COMPDYN 2021 is one of the 32 Thematic Conferences of the European Community on Computational Methods in Applied Sciences (ECCOMAS) which were held in 2021 and is also a Special Interest Conference of the International Association for Computational Mechanics (IACM). The purpose of this Conference series is to bring together the scientific communities of Computational Mechanics, Structural Dynamics and Earthquake Engineering, to act as a forum for exchanging ideas in topics of mutual interests and to enhance the links between research groups with complementary activities. We believe that the communities of Structural Dynamics and Earthquake Engineering will benefit from their exposure to advanced computational methods and software tools which can highly assist in tackling complex problems in dynamic and seismic analysis and design of structures, while also giving the opportunity to the Computational Mechanics community to be exposed to very important engineering problems of great social interest.

The COMPDYN 2021 Conference is supported by the National Technical University of Athens (NTUA), the European Association for Structural Dynamics (EASD), the European Association for Earthquake Engineering (EAEE), the Greek Association for Computational Mechanics (GRACM).

The editors of this volume would like to thank all authors for their contributions. Special thanks go to the colleagues who contributed to the organization of the Minisymposia and to the reviewers who, with their work, contributed to the scientific quality of this e-book.

**M. Papadrakakis**

National Technical University of Athens, Greece

**M. Fragiadakis**

National Technical University of Athens, Greece

## ACKNOWLEDGEMENTS

The conference organizers acknowledge the support towards the organization of the “8<sup>th</sup> International Conference on Computational Methods in Structural Dynamics and Earthquake Engineering”, to the following organizations:

- European Community on Computational Methods in Applied Sciences (ECCOMAS)
- International Association for Computational Mechanics (IACM)
- European Association for Structural Dynamics (EASD)
- European Association for Earthquake Engineering (EAEE)
- Greek Association for Computational Mechanics (GRACM)
- Hellenic Society for Earthquake Engineering (HSEE)
- School of Civil Engineering, National University of Athens (NTUA)

### Plenary Speakers and Invited Session Organizers

We would also like to thank the Plenary and Semi-Plenary Speakers and the Minisymposia Organizers for their help in the setting up of a high standard Scientific Programme.

**Plenary Speakers:** Sondipon Adhikari, Peter Betsch, Hong Hao, Boris Jeremic, Geert Lombaert , Gabriele Milani , Shinobu Yoshimura

**Semi-Plenary Speakers:** Denis Duhamel, Fernando Fraternali, Muneo Hori, Alexander Idesman , Jean-Mathieu Mencik, Giuseppe Muscolino

**MS Organizers:** Christoph Adam, Hamid Ahmadi, Ada Amendola, Giulia Angelucci, António Arêde, Davide Arezzo, Nikolaos P. Bakas, Rui Carneiro Barros, Manuel Braz-César, Bruno Briseghella, Eleonora Bruschi, Bruno Calderoni, Guido Camata, Luca Caracoglia, Sandro Carbonari, Donatello Cardone, Claudia Casapulla, Serena Cattari, Nicola Cavallaghi, Liborio Cavaleri, Dimitrios Chronopoulos, Francesco Clementi, Marco Gaetani d’Aragona, Mario D’Aniello, Dario De Domenico, Maria Teresa De Risi, Matt DeJong, Carlo Del Gaudio, Ciro Del Vecchio, Pedro Delgado, Mariano Di Domenico, Raffaele Di Laora, Marco Di Ludovico, Luigi Di Sarno, Fabio Di Trapani, Beatrice Faggiano, Marco Filippo Ferrotto, Amedeo Flora, Antonio Formisano, Michalis Fragiadakis, Fernando Fraternali, Fabio Freddi, André Furtado, Stefano Galassi, Emanuele Gandelli, Linda Giresini, José A. González, Chiara Iacovino, Alper Ilki, Maria Iovino, Konstantinos Katakalo, Jin-Gyun Kim, Radek Kolman, Daniele Losanno, George C. Manos, Giuseppe Carlo Marano, George Markou, Angelo Masi, Konstantinos G. Megalooikonomou, Gabriele Milani, Lucia Minnucci, Fabrizio Mollaioli, Michele Morici, Lukas Moschen, Jiří Náprstek, Vanni Nicoletti, Ehsan Noroozinejad, Roger Ohayon, K. C. Park, Carlo Pettorruso, Vagelis Plevris, Maria Polese, Virginio Quaglini, Giuseppe Quaranta, Laura Ragni, Gian Andera Rassati, Paolo Ricci, Hugo Rodrigues, Emmanouil Rovithis, Juan Chiachío Ruano, Manuel Chiachío Ruano, Antonio Sandoli, Fabrizio Scozzese, Salvatore Sessa, Anastasios Sextos, P. Benson Shing, Castorina Silva Vieira, Aram Soroushian, Enrico Spacone, James Swanson, Francesca Taddei, Kumar Tamma, Marco Tanganelli, Roberto Tartaglia, Anton Tkachuk, Savvas Triantafyllou, Grigorios Tsinidis, Yiannis Tsompanakis, Enrico Tubaldi, Filippo Ubertini, Nicolò Vaiana, Humberto Varum, Michalis Vassiliou, Ilaria Venanzi, Gerardo M. Verderame, Stefania Viti, Marco Vona

## SUMMARY

<b>Preface</b> .....	iii
<b>Acknowledgements</b> .....	iv
<b>Contents</b> .....	ix

## VOLUME I

<b>PLENARY</b> .....	1
<b>SEMI-PLENARY</b> .....	28

### Minisymposia

<b>MS 1: INFLUENCE OF INFILL MASONRY WALLS IN THE RESPONSE AND SAFETY OF BUILDINGS</b> .....	63
<i>Organized by Humberto Varum, Hugo Rodrigues, Enrico Spacone</i>	
<b>MS 2: REPAIR AND RETROFIT OF STRUCTURES</b> .....	111
<i>Organized by Ciro Del Vecchio, Marco Di Ludovico, Alper Ilki</i>	
<b>MS 3: RECENT ADVANCES AND CHALLENGES IN GEOTECHNICAL EARTHQUAKE ENGINEERING</b> .....	202
<i>Organized by Castorina Silva Vieira, Yiannis Tsompanakis</i>	
<b>MS 4: ADVANCEMENTS IN NUMERICAL MODELLING AND SEISMIC INTERVENTION TECHNIQUES OF HISTORICAL MASONRY STRUCTURES</b> .....	231
<i>Organized by Francesco Clementi, Nicola Cavalagli, Antonio Formisano, Gabriele Milani, Vagelis Plevris</i>	
<b>MS 6: ADVANCES ON SEISMIC ASSESSMENT AND LOCAL COLLAPSE MECHANISMS OF RIGID BLOCKS IN STRUCTURES AND INFRASTRUCTURES</b> .....	637
<i>Organized by Claudia Casapulla, Linda Giresini, Francesca Taddei, Ehsan Noroozinejad</i>	
<b>MS 7: NEW ADVANCES IN COMPUTATIONAL MODELLING AND EXPERIMENTAL TESTING OF INFILLED FRAMES (2ND EDITION)</b> .....	779
<i>Organized by Fabio Di Trapani, Liborio Cavaleri, Guido Camata, P. Benson Shing</i>	
<b>MS 8: A MATTER OF SCALE: FROM REAL-TIME MONITORING TO AREA-WIDE SEISMIC RISK ASSESSMENT</b> .....	987
<i>Organized by Konstantinos G. Megalooikonomou</i>	
<b>MS 9: NONLINEAR MODELLING AND ASSESSMENT OF EXISTING REINFORCED CONCRETE ELEMENTS</b> .....	1016
<i>Organized by Mariano Di Domenico, Paolo Ricci, Gerardo M. Verderame</i>	

<b>MS 10: VULNERABILITY OF MUSEUM'S COLLECTIONS DYNAMIC RESPONSE, SAFETY ASSESSMENT AND DIGITAL INNOVATIONS .....</b>	<b>1125</b>
<i>Organized by Stefania Viti, Marco Tanganelli, Stefano Galassi</i>	
<b>MS 11: RECENT FINDINGS AND OPEN ISSUES IN SEISMIC PERFORMANCE ASSESSMENT OF AS-BUILT AND RETROFITTED EXISTING RC BUILDINGS .....</b>	<b>1188</b>
<i>Organized by Maria Teresa De Risi, Carlo Del Gaudio, André Furtado, Gerardo M. Verderame, Humberto Varum</i>	
<b>MS 12: ADVANCES IN COMPUTATIONAL MODELLING, EXPERIMENTAL TESTING AND OPTIMIZATION OF SEISMIC RETROFITTING.....</b>	<b>1322</b>
<i>Organized by Liborio Cavaleri, Marco Filippo Ferrotto, Fabio Di Trapani, Giuseppe Carlo Marano</i>	
<b>MS 13: MODELLING AND SOLUTION STRATEGIES FOR DYNAMIC PROBLEMS .....</b>	<b>1416</b>
<i>Organized by Aram Soroushian, Kumar Tamma</i>	
<b>MS 14: SEISMIC ASSESSMENT AND RETROFITTING OF EXISTING STEEL STRUCTURES .....</b>	<b>1492</b>
<i>Organized by Luigi Di Sarno, Fabio Freddi, Mario D'Aniello</i>	
<b>MS 16: DYNAMIC RESPONSE ASSESSMENT IN RAIL TRACK ENGINEERING .....</b>	<b>1550</b>
<i>Organized by Lukas Moschen, Grigorios Tsinidis, Christoph Adam, Anastasios Sextos</i>	
<b>MS 17: RECENT DEVELOPMENTS IN ROCKING STRUCTURES .....</b>	<b>1574</b>
<i>Organized by Matt DeJong, Michalis Vassiliou</i>	
<b>MS 19: ADVANCES IN THE OPTIMUM DESIGN AND CONTROL OF LARGE STRUCTURES UNDER DYNAMIC LOADS .....</b>	<b>1712</b>
<i>Organized by Fabrizio Mollaioli, Giulia Angelucci, Bruno Briseghella, Giuseppe Carlo Marano, Giuseppe Quaranta</i>	
<b>MS 20: COMPUTATIONAL DESIGN AND MODELING OF TENSEGRITY SYSTEMS FOR APPLICATIONS IN SCIENCE AND ENGINEERING .....</b>	<b>1825</b>
<i>Organized by Fernando Fraternali, Ada Amendola</i>	
<b>MS 22: CONDITION BASED MAINTENANCE AND POST-PROGNOSTICS OF COMPOSITE STRUCTURES: AN ENHANCED PLATFORM .....</b>	<b>1874</b>
<i>Organized by Dimitrios Chronopoulos, Savvas Triantafyllou, Juan Chiachío Ruano, Manuel Chiachío Ruano</i>	
<b>MS 23: ADVANCED MODELS AND NUMERICAL METHODS IN DYNAMICS, WAVE PROPAGATION AND COUPLED PROBLEMS .....</b>	<b>1892</b>
<i>Organized by José A. González, Radek Kolman, Anton Tkachuk, Jiří Náprstek, K. C. Park</i>	
<b>MS 24: LIFE-CYCLE RISK-BASED STRUCTURAL ASSESSMENT AND COST ANALYSIS .....</b>	<b>1941</b>
<i>Organized by Ilaria Venanzi, Filippo Ubertini, Luca Caracoglia</i>	
<b>MS 25: MONITORING, IDENTIFICATION AND VIBRATION CONTROL OF STRUCTURES .....</b>	<b>2014</b>
<i>Organized by Rui Carneiro Barros, Manuel Braz-César</i>	
<b>MS 26: SEISMIC SAFETY ASSESSMENT OF STRUCTURES .....</b>	<b>2157</b>
<i>Organized by Pedro Delgado, António Arêde</i>	

<b>MS 27: TIMBER-BASED ELEMENTS: RECENT ADVANCEMENTS FOR NEW AND EXISTING SEISMIC-RESISTANT STRUCTURES .....</b>	<b>2195</b>
<i>Organized by Antonio Sandoli, Bruno Calderoni, Beatrice Faggiano</i>	
<b>MS 29: SEISMIC PROTECTION OF NON-STRUCTURAL COMPONENTS: RECENT DEVELOPMENTS AND FUTURE CHALLENGES .....</b>	<b>2388</b>
<i>Organized by Luigi Di Sarno, Michalis Fragiadakis</i>	
<b>MS 30: DYNAMIC PROTECTION SYSTEMS AND DEVICES: EXPERIMENTAL TESTS, MATHEMATICAL MODELING AND DESIGN METHODS .....</b>	<b>2435</b>
<i>Organized by Nicolò Vaiana, Daniele Losanno, Salvatore Sessa</i>	
<b>MS 32: SIMPLIFIED METHODOLOGIES FOR PERFORMANCE AND LOSS ASSESSMENT AT BUILDING OR TERRITORIAL SCALE .....</b>	<b>2557</b>
<i>Organized by Maria Polese, Marco Gaetani d'Aragona</i>	

## VOLUME II

### Minisymposia

<b>MS 33: EXPERIMENTAL MEASUREMENTS AND NUMERICAL SIMULATION ON PROBLEMS IN THE FIELD OF EARTHQUAKE ENGINEERING AND STRUCTURAL DYNAMICS .....</b>	<b>2718</b>
<i>Organized by George C. Manos, Konstantinos Katakalos</i>	
<b>MS 34: FRAGILITY CURVES FOR EXISTING BUILDINGS: OPEN CHALLENGES IN THEIR DEFINITION AND USE FOR SEISMIC RISK ANALYSES .....</b>	<b>3059</b>
<i>Organized by Serena Cattari, Angelo Masi</i>	
<b>MS 35: RECENT ADVANCES IN SEISMIC ISOLATION AND SUPPLEMENTAL DAMPING SYSTEMS FOR VIBRATION CONTROL .....</b>	<b>3187</b>
<i>Organized by Virginio Quaglini, Eleonora Bruschi, Emanuele Gandelli, Carlo Pettoruso</i>	
<b>MS 36: METHODOLOGIES AND ADVANCED TOOLS FOR SEISMIC RISK ASSESSMENT, MANAGEMENT, AND MITIGATION: ADVANCES AND OPEN CHALLENGES .....</b>	<b>3305</b>
<i>Organized by Marco Vona, Donatello Cardone, Amedeo Flora, Chiara Iacovino</i>	
<b>MS 37: RISK ASSESSMENT OF BRIDGES AND ROAD NETWORKS SUBJECTED TO NATURAL HAZARDS .....</b>	<b>3377</b>
<i>Organized by Michele Morici, Fabrizio Scozzese, Lucia Minnucci</i>	
<b>MS 38: DYNAMIC SOIL-FOUNDATION-STRUCTURE INTERACTION: DEVELOPMENTS AND EMERGING ISSUES .....</b>	<b>3577</b>
<i>Organized by Emmanouil Rovithis, Raffaele Di Laora, Maria Iovino</i>	
<b>MS 39: THE CONTRIBUTION OF DYNAMIC TESTS AND STRUCTURAL MONITORING ON THE SEISMIC RISK ASSESSMENT AND MITIGATION .....</b>	<b>3697</b>
<i>Organized by Davide Arezzo, Sandro Carbonari, Vanni Nicoletti</i>	

<b>MS 40: ARTIFICIAL INTELLIGENCE &amp; MACHINE LEARNING IN DESIGN AND ASSESSMENT OF STRUCTURES .....</b>	<b>3795</b>
<i>Organized by George Markou, Nikolaos P. Bakas</i>	

<b>MS 41: SEISMIC PERFORMANCE OF STRUCTURES WITH ISOLATION AND/OR ENERGY DISSIPATION DEVICES .....</b>	<b>3912</b>
<i>Organized by Enrico Tubaldi, Laura Ragni, Dario De Domenico, Hamid Ahmadi</i>	

<b>MS 42: ADVANCES IN MODEL REDUCTION TECHNIQUES OF COMPUTATIONAL AND STRUCTURAL DYNAMICS .....</b>	<b>4111</b>
<i>Organized by Jin-Gyun Kim, K. C. Park, Roger Ohayon</i>	

<b>MS 43: ANALYSES AND DESIGN OF STEEL JOINTS UNDER CYCLIC ACTION .....</b>	<b>4134</b>
<i>Organized by Roberto Tartaglia, Mario D'Aniello, Gian Andera Rassati, James Swanson</i>	

## **Thematic Sessions**

<b>TS 5: DYNAMICS OF CONCRETE AND MASONRY STRUCTURES .....</b>	<b>4226</b>
<b>TS 14: NUMERICAL SIMULATION METHODS FOR DYNAMIC PROBLEMS .....</b>	<b>4331</b>
<b>TS 15: OPTIMUM DESIGN AND CONTROL IN STRUCTURAL DYNAMICS AND EARTHQUAKE ENGINEERING .....</b>	<b>4428</b>
<b>TS 17: PERFORMANCE-BASED EARTHQUAKE ENGINEERING .....</b>	<b>4558</b>
<b>TS 19: REPAIR AND RETROFIT OF STRUCTURES .....</b>	<b>4729</b>
<b>TS 20: SEISMIC ISOLATION .....</b>	<b>4816</b>
<b>TS 21: SEISMIC RISK AND RELIABILITY ANALYSIS .....</b>	<b>4853</b>
<b>TS 27: STEEL STRUCTURES.....</b>	<b>4906</b>
<b>TS 28: STOCHASTIC DYNAMICS.....</b>	<b>4926</b>
<b>TS 31: NUMERICAL SIMULATION OF GEOTECHNICAL PROBLEMS.....</b>	<b>4946</b>

<b>TS 34: NONLINEAR AND IMPACT DYNAMICS.....</b>	<b>5307</b>

# CONTENTS

## VOLUME I

### PLENARY

SEISMIC VULNERABILITY OF MASONRY HISTORICAL STRUCTURES: A SIMPLE ADAPTIVE NURBS FE APPROACH FOR THE LIMIT AND THE SUBSEQUENT NON-LINEAR STATIC ANALYSIS WITH FEW DOFS .....	1
<i>Nicola Grillanda, Gabriele Milani</i>	

### SEMI-PLENARY

SOME RECENT ADVANCES IN THE WAVE FINITE ELEMENT METHOD .....	28
<i>Denis Duhamel, B. Claudet, T. Hoang, G. Foret, Jean-Mathieu Mencik</i>	
DYNAMIC ANALYSIS OF PERIODIC STRUCTURES AND METAMATERIALS VIA WAVE APPROACHES AND FINITE ELEMENT PROCEDURES .....	42
<i>Jean-Mathieu Mencik, Denis Duhamel</i>	

### Minisymposia

#### MS 1: INFLUENCE OF INFILL MASONRY WALLS IN THE RESPONSE AND SAFETY OF BUILDINGS

IMPACT OF MASONRY INFILL VARIABILITY ON THE ESTIMATION OF FLOOR RESPONSE SPECTRA IN RC BUILDINGS .....	63
<i>Gianrocco Mucedero, Daniele Perrone, Emanuele Brunesi, Ricardo Monteiro</i>	
EFFECT OF IN-PLANE/OUT-OF-PLANE INTERACTION IN INFILL WALLS ON THE FLOOR SPECTRA OF REINFORCED CONCRETE BUILDINGS .....	84
<i>Mariano Di Domenico, Paolo Ricci, Gerardo M. Verderame</i>	
SEISMIC LOSS ANALYSIS OF A CODE-DESIGNED INFILLED RC BUILDING ACCOUNTING FOR INFILL MODEL CLASS UNCERTAINTY .....	102
<i>Fabio Romano, Mohammad S. Alam, Maria Zucconi, Marco Faggella, Andre R. Barbosa, Barbara Ferracuti</i>	

#### MS 2: REPAIR AND RETROFIT OF STRUCTURES

SEISMIC BEHAVIOR OF SUBSTANDARD EXTENDED RECTANGULAR RC COLUMNS JACKETED WITH SPRAYED GFRM .....	111
<i>Muhsin Can Lülecı, Bilal Sari, Ugur Demir, Muhammed Maraslı, Alper İlki</i>	
DAMAGE EVOLUTION FOR REPAIRABILITY OF SUBSTANDARD BEAM-COLUMN JOINTS .....	120
<i>Özgür Yurdakul, Ciro Del Vecchio, Marco Di Ludovico, Ladislav Řoutil, Özgür Avşar</i>	

EXPERIMENTAL RESPONSE AND NUMERICAL MODELLING OF TWO-STOREY INFILLED RC FRAME .....	131
<i>Ciro Del Vecchio, C. Moliterno, Marco Di Ludovico, Gerardo Mario Verderame, Andrea Prota, Gaetano Manfredi</i>	
DEFENCE OF ARCHITECTURAL HERITAGE: EXPERIMENTAL CAMPAIGN ON MASONRIES REINFORCED WITH NATURAL FRCM COMPOSITE MATERIALS .....	141
<i>Riccardo Liberotti, Nicola Cavalagli, Federico Cluni, Massimiliano Gioffrè, Chiara Pepi, Vittorio Gusella</i>	
NUMERICAL MODELLING AND ANALYSIS OF ECCENTRIC BRACING WITH VERTICAL SHEAR LINKS .....	151
<i>Gaetano Cantisani, Emilio Rodontini, Gaetano Della Corte</i>	
PERFORMANCE OF EXISTING REINFORCED CONCRETE ARCH BRIDGES UNDER CURRENT NON SEISMIC LOADS .....	164
<i>Giovanni Crisci, Francesca Ceroni, Gian Piero Lignola, Andrea Prota</i>	
A SUSTAINABLE SOLUTION FOR THE SEISMIC STRENGTHENING OF RC EXISTING BUILDINGS THROUGH THE HPDF SYSTEM (HPDF): A CASE STUDY .....	180
<i>Giuseppe Ventura, Vincenzo Manfredi, Angelo Masi, Giuseppe Santarsiero, Andrea Digrisolo</i>	
APPLICATION OF C-FRP SHEETS FOR STRUCTURAL REPAIRING OF RC BEAM-COLUMN CONNECTIONS DAMAGED UNDER CYCLIC LOADING – EXPERIMENTAL STUDY .....	191
<i>Emmanouil Golias, Stavroula Katsimante, Eirini Ziavra, Konstantinos Kirtsonis, Constantin E. Chaliotis, Chris C. Karayannis</i>	
 <b>MS 3: RECENT ADVANCES AND CHALLENGES IN GEOTECHNICAL EARTHQUAKE ENGINEERING</b>	
SEISMIC VULNERABILITY OF SHALLOW UNDERGROUND CAVITIES IN SOFT ROCK .....	202
<i>Stefania Fabozzi, Filomena De Silva, Marco Nocentini, Edoardo Peronace, Emilio Bilotta, Massimiliano Moscatelli</i>	
EFFICIENCY OF SEISMIC LIQUEFACTION MITIGATION METHODS FOR EXISTING STRUCTURES .....	212
<i>Alexandros Valsamis, Taxiarchoula Limnaiou, Achilleas Papadimitriou</i>	
PREDICTING RAILWAY TRACK DISPLACEMENTS WITH THE HARDENING SOIL SMALL STRAIN MODEL NEAR CRITICAL SPEED .....	222
<i>Jesús Fernández-Ruiz, Pedro Alves Costa</i>	
 <b>MS 4: ADVANCEMENTS IN NUMERICAL MODELLING AND SEISMIC INTERVENTION TECHNIQUES OF HISTORICAL MASONRY STRUCTURES</b>	
NON-DESTRUCTIVE AND DESTRUCTIVE TESTS ON OPUS INCERTUM MASONRY PANELS .....	231
<i>Francesca Autiero, Giuseppina De Martino, Marco Di Ludovico, Andrea Prota</i>	
PRELIMINARY NONLINEAR STATIC AND DYNAMIC ANALYSIS OF THE MAIN PYRAMID OF HUACA DE LA LUNA, PERU .....	244
<i>Selman Tezcan, Miguel a. Pando, Rafael Aguilar, Benjamin Castañeda, Carol Rojas, Renato Perucchio</i>	

MODELING STRATEGIES FOR NON-LINEAR SEISMIC ANALYSES: COMPARISON AMONG EFM AND FEM RESULTS ON AN EXISTING URM CASE STUDY .....	258
<i>Marco Pegoraro, Elisa Saler, Matteo Salvalaggio, Maria Rosa Valluzzi</i>	
ANALYSIS OF THE DAMAGE STATE OF A MONUMENTAL BUILDING BY CONSIDERING THE VARIATIONS IN SOIL CONDITIONS .....	268
<i>Erica Lenticchia, Gaetano Miraglia, Stefania Coccimiglio, Rosario Ceravolo</i>	
ADVANCED NUMERICAL PREDICTION OF UNREINFORCED U-SHAPED MASONRY WALLS LOADED OUT-OF-PLANE .....	278
<i>Jacopo Scacco, Luís C. Silva, Graça Vasconcelos, Gabriele Milani, Paulo B. Lourenço</i>	
LOW-COST BASE ISOLATION SYSTEMS FOR UNREINFORCED MASONRY BUILDINGS IN DEVELOPING COUNTRIES .....	286
<i>Nagavinothini Ravichandran, Daniele Losanno, Fulvio Parisi</i>	
NONLINEAR STATIC ANALYSIS OF MASONRY BUILDINGS THROUGH FIBRE-BASED CAPACITY MODELLING .....	298
<i>Elia Acconcia, Valentina Buonocunto, Fulvio Parisi</i>	
A DISCRETE-MACRO-ELEMENT-MODEL FOR THE IN-PLANE ANALYSIS OF MASONRY STRUCTURES STRENGTHENED BY FRCMS .....	309
<i>Paolo Zampieri, Riccardo Piazzon, Bartolomeo Pantò, Carlo Pellegrino</i>	
NUMERICAL MODELLING OF DIAGONAL COMPRESSION TESTS ON MASONRY PANELS STRENGTHENED BY FRCM .....	318
<i>Francesca Ferretti, Francesco Saverio Murgo, Claudio Mazzotti</i>	
EMPIRICAL AND MECHANICAL ANALYSIS METHODS FOR SEISMIC VULNERABILITY ASSESSMENT OF CLUSTERED BUILDINGS OF HISTORICAL CENTRES: A CASE STUDY .....	331
<i>Antonio Formisano, Giovanni Mochi, Nicola Chieffo</i>	
SETTLEMENT-INDUCED DAMAGE ASSESSMENT IN UNILATERAL MASONRY-LIKE STRUCTURES: A PIECEWISE RIGID DISPLACEMENT APPROACH .....	338
<i>Ida Mascolo, Antonio Fortunato</i>	
ON THE USE OF DIGITAL TWINS FOR SEISMIC STRUCTURAL HEALTH MONITORING OF A MONUMENTAL MASONRY TOWER .....	346
<i>Alban Kita, Nicola Cavalagli, Ilaria Venanzi, Filippo Ubertini</i>	
MICROMECHANICAL ANALYSIS OF UNREINFORCED AND REINFORCED MASONRY ARCHES .....	354
<i>Daniela Addressi, Cristina Gatta, Mariacarla Nocera, Domenico Liberatore</i>	
ANALYTICAL AND NUMERICAL ANALYSIS OF S. MARTINO'S DEI GUALDESI CHURCH DAMAGED DURING THE 2016 CENTRAL ITALY SEISMIC SEQUENCE .....	367
<i>Ivis Cescatti, Michol Rampado, Veronica Follador, Francesca da Porto, Claudio Modena</i>	
A NURBS-BASED NUMERICAL APPROACH FOR THE ASSESSMENT OF MASONRY VAULTS UNDERGOING DIFFERENTIAL SETTLEMENTS .....	380
<i>Andrea Chiozzi, Nicola Grillanda, Gabriele Milani, Antonio Tralli</i>	

NUMERICAL MODELLING OF BONDED BRICKWORK UNDER CYCLIC COMPRESSION LOADING .....	387
<i>Mohammad Asad, Tatheer Zahra, Julian Thamboo</i>	
FULL 3D CAD PROCEDURE FOR THE LIMIT ANALYSIS OF LONGHU PAGODA IN CHINA .....	398
<i>Peixuan Wang, Alessandro De lasio, Jacopo Scacco, Gabriele Milani, Shengcai Li</i>	
ROLE OF REPEATED SEISMIC EVENTS ON THE COLLAPSE OF TWO CALIDARIA IN ROME DATING BACK TO THE IMPERIAL AGE .....	406
<i>Francesca Faleri, Nicola Grillanda, Selman Tezcan, Renato Perucchio, Gabriele Milani</i>	
3D ADVANCED NUMERICAL MODELLING OF A CATALAN-LAYERED MASONRY VAULT UNREINFORCED AND REINFORCED WITH GLASS-TRM MATERIALS AND SUBJECTED TO VERTICAL SUPPORT MOVEMENTS .....	415
<i>Elisa Bertolesi, Gabriele Milani, José M. Adam, Pedro A. Calderón</i>	
DYNAMIC ANALYSIS OF MASONRY CHIMNEYS BY MEANS OF A SIMPLE RIGID BEAM MODEL .....	423
<i>Daniele Baraldi, Gabriele Milani, Vasilis Sarhosis</i>	
COMPARATIVE ANALYSIS AMONG DIFFERENT ANALYSIS PROGRAMS FOR SEISMIC VULNERABILITY EVALUATION OF A MASONRY BUILDING COMPOUND IN THE DISTRICT OF NAPLES .....	433
<i>Generoso Vaiano, Antonio Formisano</i>	
TERRITORIAL ANALYSIS OF SEISMIC PERFORMANCE OF ANCIENT CHURCHES: METHODS AND APPLICATION TO CASE STUDIES .....	447
<i>Michele D'Amato, R. Laguardia, Rosario Gigliotti, Antonio Formisano</i>	
FE MODELING OF A SEISMIC ISOLATOR MADE OF HDR AND REGENERATED EPDM .....	456
<i>Gaetano Pianese, Gabriele Milani, Antonio Formisano</i>	
INFLUENCE OF CROSSLINKING ON THE SEISMIC PERFORMANCE OF UNBONDED FIBER REINFORCED ELASTOMERIC ISOLATORS (UFREI) MADE OF REGENERATED RUBBER .....	463
<i>Gaetano Pianese, Davide Torrini, Gabriele Milani, Antonio Formisano</i>	
COMBINING OPERATIONAL MODAL ANALYSIS AND GENETIC ALGORITHMS TO UNDERSTAND THE ACTUAL STRUCTURAL BEHAVIOR OF HISTORICAL CONSTRUCTIONS .....	470
<i>Gianluca Standoli, Georgios Panagiotis Salachoris, Maria Giovanna Masciotta, Francesco Clementi</i>	
SEISMIC ASSESSMENT OF MASONRY CROSS VAULTS THROUGH NON-LINEAR STATIC ANALYSES .....	487
<i>Marco Alforno, Alessia Monaco, Fiammetta Venuti, Chiara Calderini</i>	
“SCAGLIA ROSSA” EXPERIMENTAL CAMPAIGN AND MODEL UPDATING FOR NUMERICAL DAMAGE EVALUATION .....	497
<i>Georgios Panagiotis Salachoris, Erica Magagnini, Francesco Clementi</i>	
BEHAVIOUR FACTOR ASSESSMENT OF ANCIENT MASONRY TOWERS THROUGH AN INNOVATIVE SIMPLIFIED PUSHOVER METHOD .....	508
<i>Alessandro De lasio, Peixuan Wang, Gabriele Milani, Bahman Ghiassi</i>	

FE PUSHOVER ANALYSES OF A 20TH-CENTURY MASONRY CHIMNEY IN SPAIN: COLLAPSE BEHAVIOR AND NUMERICAL UNCERTAINTIES .....	519
<i>Alessandro De Iasio, Gabriele Milani, Jose M. Adam</i>	
FINITE ELEMENT ANALYSIS OF JUMA MOSQUE IN UZBEKISTAN BASED ON LASER SCANNING AND AMBIENT STUDIES .....	530
<i>Shakhzod Takhirov, Bahodir Rakhmonov</i>	
CONTINUOUS AND DISCONTINUOUS DESCRIPTIONS OF BLOCKED STRUCTURES: THE CASE STUDY OF SANTISSIMO CROCIFISSO CHURCHES IN PRETARE (ITALY) .....	539
<i>Francesco Clementi, Angela Ferrante, Ersilia Giordano, Stefano Lenci</i>	
LATTICE DISCRETE MODELING OF OUT-OF-PLANE BEHAVIOR OF IRREGULAR MASONRY .....	546
<i>Micaela Mercuri, Madura Pathirage, Amedeo Gregori, Gianluca Cusatis</i>	
NUMERICAL STUDY ON SEISMIC RETROFIT OF URM WALLS USING TIMBER PANELS .....	563
<i>Davide Cassol, Ivan Giongo, Maurizio Piazza</i>	
OPTIMIZATION OF EMPIRICAL SEISMIC VULNERABILITY ASSESSMENT FOR MASONRY BUILDINGS FOLLOWING NONLINEAR ANALYSIS .....	581
<i>Eugen Onescu, Iasmina Onescu, Marius Mosoarca</i>	
NONLINEAR SIMULATION OF MASONRY VAULTS UNDER EARTHQUAKE LOADING .....	595
<i>Adam Plavsic, Bartolomeo Pantò, Corrado Chisari, Lorenzo Macorini, Bassam A. Izzuddin, Ingrid Boem, Natalino Gattesco</i>	
LOW-COST RUBBER COMPOUNDS FOR FIBER-REINFORCED ELASTOMERIC ISOLATORS: RECOVERED POWDERS AND WASTE OILS FROM RUBBER MANUFACTURING PROCESSES .....	607
<i>Gaetano Pianese, Gabriele Milani, Federico Milani, Ahmad Basshofi Habieb</i>	
HORIZONTAL FORCE CAPACITY OF A HEMI-SPHERICAL DOME .....	614
<i>Carlo Olivieri, Anna Castellano, Isabella Elia, Antonio Fortunato, Ida Mascolo</i>	
SEISMIC RETROFITTING TECHNIQUES FOR EXISTING MASONRY BUILDINGS .....	626
<i>Ida Mascolo, Antonio Fortunato, Carlo Olivieri, Antonio Gesualdo</i>	
 <b>MS 6: ADVANCES ON SEISMIC ASSESSMENT AND LOCAL COLLAPSE MECHANISMS OF RIGID BLOCKS IN STRUCTURES AND INFRASTRUCTURES</b>	
PRELIMINARY DESIGN METHOD FOR ROCKING AND NEGATIVE STIFFNESS SYSTEMS .....	637
<i>Natalia Reggiani Manzo, Michalis Vassiliou</i>	
PREFABRICATED REINFORCED CONCRETE CLADDING PANELS SUPPORTS: DESIGN AND NUMERICAL MODELLING .....	649
<i>Flavio Stochino, Fausto Mistretta, Mario Lucio Puppio, Mauro Sassu</i>	

INFLUENCE OF THE ELASTO-PLASTIC BEHAVIOR OF TIE-RODS IN THE RESPONSE OF ROCKING MASONRY WALLS THROUGH SEISMIC DEMAND HAZARD CURVES .....	664
<i>Fabio Solarino, Linda Giresini, Pietro Croce</i>	
GRAPHICAL METHODS, KINEMATIC AND FINITE ELEMENT ANALYSIS OF THE PREMILCUORE MASONRY BRIDGE ...	682
<i>Linda Giresini, Daniela De Paola, Mario Lucio Puppio, Giovanni Buratti</i>	
REDUCTION OF HOUSNER'S COEFFICIENT OF RESTITUTION FOR MASONRY WALLS UNDER ONE-SIDED ROCKING .....	702
<i>Linda Giresini, Pietro Croce</i>	
AN EQUIVALENT VISCOUS DAMPING PROPOSAL FOR BLOCK-BASED ROCKING MODELS .....	717
<i>Georgios Vlachakis, Carla Colombo, Anastasios Giouvanidis, Anjali Mehrotra, Nathanael Savalle, Paulo B. Lourenço</i>	
PROBABILISTIC SEISMIC FRAGILITY FOR ROCKING MASONRY FAÇADES USING CLOUD ANALYSIS .....	727
<i>Armando Benenato, Stefania Imperatore, Gian Piero Lignola, Barbara Ferracuti</i>	
MODELLING OF THE OUT-OF-PLANE BEHAVIOUR OF UNREINFORCED MASONRY PANELS USING THE DISCRETE MACRO-ELEMENT METHOD (DMEM) .....	738
<i>Valeria Cusmano, Bartolomeo Pantò, Ivo Calì, Paulo B. Lourenço</i>	
VISUAL PROGRAMMING FOR MACRO-BLOCK ANALYSIS OF MULTI-STOREY MASONRY BUILDINGS .....	752
<i>Elham Mousavian, Luca Umberto Argiento, Claudia Casapulla</i>	
OUT-OF-PLANE RESPONSE OF T-SHAPED MASONRY WALLS STRENGTHENED WITH CFRP INJECTED ANCHORS: MODELLING AND DESIGN PROVISIONS .....	764
<i>Alessandra Maione, Claudia Casapulla, Francesca Ceroni, Marco Di Ludovico, Andrea Prota</i>	
<b>MS 7: NEW ADVANCES IN COMPUTATIONAL MODELLING AND EXPERIMENTAL TESTING OF INFILLED FRAMES (2ND EDITION)</b>	
NUMERICAL MESO-MODEL FOR REINFORCED CONCRETE FRAMES WITH RETROFITTED MASONRY INFILL .....	779
<i>Gianni Blasi, Daniele Perrone, Maria Antonietta Aiello</i>	
ASSESSMENT OF OUT-OF-PLANE STRENGTH OF MASONRY INFILLS ACCORDING TO EC6 .....	795
<i>Laura Liberatore</i>	
INFLUENCE OF PRIOR IN-PLANE DAMAGE ON THE OUT-OF-PLANE RESPONSE OF NON-LOAD BEARING UNREINFORCED MASONRY WALLS UNDER SEISMIC LOAD .....	808
<i>Bogdan Šakić, Aleksa Milijaš, Marko Marinković, Christoph Butenweg, Sven Klinkel</i>	
EXPERIMENTAL INVESTIGATION OF BEHAVIOUR OF MASONRY INFILLED RC FRAMES UNDER OUT-OF-PLANE LOADING .....	829
<i>Aleksa Milijaš, Bogdan Šakić, Marko Marinković, Christoph Butenweg, Sven Klinkel</i>	
STRUCTURAL CONCEPTS IN THE DESIGN OF MASONRY-INFILLED STEEL FRAMES .....	847
<i>Dario Sokic, Damir Markulak, Tihomir Doksanovic, Ivan Radic</i>	

A SIMPLE METHODOLOGY FOR THE INFILL MASONRY WALL STIFFNESS ESTIMATION .....	860
<i>Vanni Nicoletti, Davide Arezzo, Sandro Carbonari, Fabrizio Gara</i>	
ASSESSMENT OF DAMAGE TO MODERN REINFORCED CONCRETE BUILDINGS – ENGINEERING ANALYSIS OF THE M6.4 ALBANIA EARTHQUAKE, 26TH OF NOV. 2019 .....	871
<i>Lars Abrahamczyk, Davorin Penava, Melad Haweyou, Filip Anić, Arturo E. Schultz, Jeff Rautenberg</i>	
INFLUENCE OF THE INFILL TYPOLOGY IN THE EVALUATION OF THE ANNUAL LOSSES OF RC STRUCTURES THROUGH THE APPLICATION OF A NEW METHOD .....	886
<i>Andrea Rossi, Paolo Morandi, Riccardo R Milanese, Guido Magenes</i>	
LOCAL EFFECTS DUE TO THE SEISMIC INTERACTION BETWEEN INNOVATIVE DUCTILE MASONRY INFILLS AND RC ELEMENTS .....	899
<i>Riccardo R. Milanese, Valentino Bolis, Simone Pelucco, Paolo Morandi, Guido Magenes, Marco Preti</i>	
A DEGRADING BOUC-WEN DATA-DRIVEN MODEL FOR THE CYCLIC BEHAVIOR OF MASONRY INFILLED RC FRAMES .....	913
<i>Matteo Pellicciari, Stefano Sirotti, Fabio Di Trapani, Bruno Briseghella, Giuseppe Carlo Marano, Camillo Nuti, Angelo Marcello Tarantino</i>	
SEISMIC PERFORMANCE OF PAKISTANI-TECHNIQUE INFILLED REINFORCED CONCRETE FRAMES .....	923
<i>Nisar Ali Khan, Alessandro Vittorio Bergami, Camillo Nuti, Giorgio Monti, Marco Vailati, Bruno Briseghella</i>	
GENERATION OF OUT-OF-PLANE FRAGILITY FUNCTIONS FOR IN-PLANE DAMAGED UNREINFORCED MASONRY INFILLS .....	935
<i>Bharat Pradhan, Liborio Cavaleri, Vasilis Sarhosis, Marco Filippo Ferrotto</i>	
EMPIRICAL FORMULATION OF THE OUT-OF-PLANE RESISTANCE OF INFILLED FRAMES .....	955
<i>Fabio Di Trapani, Alessandro Vizzino, Giovanni Tomaselli, P. Benson Shing</i>	
MECHANICAL VS EMPIRICAL MODELS FOR MODELS IN-PLANE RESPONSE OF INFILLED FRAMES: RELIABILITY 7 COMPARISON AND VALIDATION OF A NEW DATA-DRIVEN MODEL .....	970
<i>Fabio Di Trapani, Giovanni Tomaselli, Gabriele Bertagnoli</i>	
 <b>MS 8: A MATTER OF SCALE: FROM REAL-TIME MONITORING TO AREA-WIDE SEISMIC RISK ASSESSMENT</b>	
EARTHQUAKE EARLY WARNING AND RAPID RESPONSE SYSTEM BASED ON SMART SEISMIC AND MONITORING SENSORS EMBEDDED IN A COMMUNICATION PLATFORM AND COUPLED WITH BIM MODELS .....	987
<i>Georgios Balaskas, Benno Hoffmeister, Christoph Butenweg, Marco Pilz, Anna Bauer</i>	
MONITORING OF A PRESTRESSED BRIDGE MODEL BY ULTRASONIC MEASUREMENT AND VIBRATION RECORDINGS .....	999
<i>Chun-Man Liao, Falk Hille, Daniel Fontoura Barroso, Ernst Niederleithinger</i>	

COMPARATIVE NON-STRUCTURAL VULNERABILITY ASSESSMENT METHODS FOR HISTORICAL RESIDENTIAL MASONRY BUILDINGS .....	1008
<i>Filippos Alogdianakis, Konstantinos G. Megalooikonomou, Georgios S. Papavasileiou</i>	

## **MS 9: NONLINEAR MODELLING AND ASSESSMENT OF EXISTING REINFORCED CONCRETE ELEMENTS**

STUDY OF BIAxIAL SHEAR FAILURE ENVELOPE OF REINFORCED CONCRETE COLUMNS .....	1016
<i>Beatrice Belletti, Simone Ravasini, Andrea Alberici</i>	

EVALUATION OF THE SEISMIC VULNERABILITY OF EXISTING PRE-CODE RC CORE STRUCTURAL SYSTEMS THROUGH NON-LINEAR PUSHOVER ANALYSES .....	1027
<i>Beatrice Belletti, Enzo Martinelli, Elena Michelinì, Francesca Vecchi</i>	

CALIBRATION AND VALIDATION OF AN OVERDAMPED DISPLACEMENT ADAPTIVE PROCEDURE FOR SEISMIC ASSESSMENT OF INFILLED RC FRAMES .....	1039
<i>Francesca Barbagallo, Melina Bosco, Aurelio Gheris, Edoardo Michele Marino, Pier Paolo Rossi</i>	

CYCLIC TESTING OF 1:40 SCALE CANTILEVER RC ELEMENTS WITH DIGITALLY MANUFACTURED REINFORCEMENT .....	1053
<i>Lorenzo Del Giudice, Rafal Wrobel, Antonios Katsamakas, Christian Leinenbach, Michalis Vassiliou</i>	

R/C COLUMN MODELLING USING ANSYS AND LOADING RATE AND MESH METHOD INFLUENCE STUDIES .....	1063
<i>Theodora Mitkou, Theodoros Chrysanidis</i>	

CALIBRATION AND NUMERICAL MODELING OF RC BEAM-COLUMN JOINTS DESIGNED FOR GRAVITY LOADS .....	1085
<i>Marcello Sabene, Maria Zucconi, Stefano Pampanin, Barbara Ferracuti</i>	

ASSESSMENT OF THE RESPONSE ENVELOPE OF REINFORCED CONCRETE MEMBERS WITH DIFFERENT FAILURE MODES .....	1097
<i>Mariano Di Domenico, Paolo Ricci, Gerardo M. Verderame</i>	

SEISMIC ASSESSMENT OF AN EXISTING RC BUILDING AFFECTED BY SLOW-MOVING LANDSLIDES INDUCED DISPLACEMENTS MONITORED BY REMOTE SENSING TECHNIQUE .....	1112
<i>Annalisa Mele, Andrea Miano, Diego Di Martire, Donato Infante, Andrea Prota, Massimo Ramondini</i>	

## **MS 10: VULNERABILITY OF MUSEUM'S COLLECTIONS DYNAMIC RESPONSE, SAFETY ASSESSMENT AND DIGITAL INNOVATIONS**

VULNERABILITY OF ART WORKS TO BLAST HAZARD: THE FOUNTAIN OF NEPTUNE IN FLORENCE .....	1125
<i>Marco Domaneschi, Marco Tanganelli, Stefania Viti, Gian Paolo Cimellaro</i>	

SIMPLIFIED ANALYSES FOR THE MODEL SETTING OF SCULPTURES: THE "OCEANO" BY GIAMBOLOGNA .....	1135
<i>Marco Tanganelli, Stefano Galassi, Stefania Viti</i>	

VULNERABILITY ASSESSMENT OF MONUMENTAL ARTWORKS USING CONTACT TIME-HISTORY ANALYSIS .....	1145
<i>Raffaele Gagliardo, Michele Godio, Lucrezia Cascini, Francesco Portioli, Raffaele Landolfo</i>	

THE TARANTOLA ETRUSCAN PEDIMENT: NDT AND 3D MODEL CONTENT .....	1153
<i>Anna Livia Ciuffreda, Massimo Coli, Tessa Donigaglia, Paola Ilaria Mariotti, Teresa Salvatici, Gabriela Simoni</i>	
CORRELATION OF VULNERABILITY AND CONSERVATION BETWEEN ARTISTIC ASSETS AND STRUCTURAL ELEMENTS: CAMPAIGN OF THERMOGRAPHIC SURVEYS ON THE FRESCOS OF THE TEMPLAR CHURCH OF SAN BEVIGNATE .....	1170
<i>Riccardo Liberotti, Federico Cluni, F. Faralli, Vittorio Gusella</i>	
 <b>MS 11: RECENT FINDINGS AND OPEN ISSUES IN SEISMIC PERFORMANCE ASSESSMENT OF AS-BUILT AND RETROFITTED EXISTING RC BUILDINGS</b>	
EVALUATION OF A NUMERICAL MODELLING APPROACH FOR THE SIMULATION OF RETROFITTED RC ELEMENTS .....	1188
<i>Ines Sousa, Rita Couto, Rita Peres, José Miguel Castro, Rita Bento</i>	
EXPERIMENTAL INVESTIGATION ON ANCHORAGE PERFORMANCE OF EMBEDDED SMOOTH REBARS SUBJECTED TO CYCLICNG LOADING .....	1201
<i>Anthony Paderno, Simone Pelucco, Marco Preti</i>	
OUT-OF-PLANE TESTING OF MASONRY INFILL WALLS MADE WITH LIGHTWEIGHT CONCRETE BLOCKS .....	1212
<i>M. Agante, André Furtado, Hugo Rodrigues, António Arêde, P. Fernandes, Humberto Varum</i>	
SELECTION OF OPTIMAL SEISMIC RETROFITTING FOR EXISTING SCHOOL BUILDINGS THROUGH MULTI- CRITERIA DECISION MAKING .....	1223
<i>Wilson Carofilis, Nicholas Clemett, Giammaria Gabbianelli, Gerard O'Reilly, Ricardo Monteiro</i>	
NUMERICAL INVESTIGATIONS ON THE RESIDUAL CAPACITY AND ECONOMIC LOSSES OF EARTHQUAKE- DAMAGED REINFORCED CONCRETE WALL STRUCTURES .....	1242
<i>Cristiana Ceccarelli, Simona Bianchi, Livio Pedone, Stefano Pampanin</i>	
SIMPLIFIED LOSS ESTIMATION IN INFILLED RC BUILDINGS: MECHANICAL METHOD AND VALIDATION .....	1261
<i>Carlo Del Gaudio, Maria Teresa De Risi, Gerardo Mario Verderame</i>	
SEISMIC PERFORMANCE ASSESSMENT OF AS-BUILT AND RETROFITTED RC BUILDINGS CONSIDERING THE INFLUENCE OF INFILLS: PRE-'70 LOW-MIDE RISE CASE-STUDIES .....	1275
<i>Maria Teresa De Risi, Santa Anna Scala, Carlo Del Gaudio, Gerardo Mario Verderame</i>	
MAPPING PERFORMANCE-TARGETED RETROFITTING TO SEISMIC FRAGILITY REDUCTION .....	1301
<i>Karim Aljawhari, Roberto Gentile, Carmine Galasso</i>	

## **MS 12: ADVANCES IN COMPUTATIONAL MODELLING, EXPERIMENTAL TESTING AND OPTIMIZATION OF SEISMIC RETROFITTING**

EXPERIMENTAL STUDY ON THE IN-PLANE RESPONSE OF ADOBE MASONRY WALLS STRENGTHENED WITH TEXTILE REINFORCED MATRIX SYSTEMS .....	1322
<i>Paolino Cassese, Luigi Fenu, Domenico Asprone, Antonio Occhiuzzi, Fulvio Parisi</i>	
GENETIC OPTIMIZATION FOR THE DESIGN OF SEISMIC RETROFITTING OF PLANE RC FRAMES WITH BUCKLING RESTRAINED BRACES (BRBS) .....	1333
<i>Giovanni Minafò, Gaetano Camarda</i>	
INFLUENCE OF THE EFFECTIVENESS FACTORS IN ASSESSING THE SHEAR CAPACITY OF RC BEAMS STRENGTHENED WITH FRP .....	1345
<i>Piero Colajanni, Salvatore Pagnotta</i>	
OPTIMIZATION OF STEEL-JACKETING RETROFITTING OF SHEAR-CRITICAL AND DUCTILITY CRITICAL RC FRAME STRUCTURES BY A NOVEL GENETIC ALGORITHM FRAMEWORK .....	1368
<i>Antonio Pio Sberna, Fabio Di Trapani, Giuseppe Carlo Marano</i>	
EXPECTED ANNUAL LOSS ORIENTED SEISMIC RETROFITTING OPTIMIZATION OF RC FRAME STRUCTURES USING A NEW AI-BASED FRAMEWORK .....	1383
<i>Fabio Di Trapani, Antonio Pio Sberna, Giuseppe Carlo Marano</i>	
THE ROLE OF THE SUSTAINED LOADS ON THE BEARING CAPACITY OF REINFORCED CONCRETE COLUMNS RETROFITTED BY STEEL JACKETS .....	1401
<i>Marco Filippo Ferrotto, Bharat Pradhan, Liborio Cavaleri</i>	

## **MS 13: MODELLING AND SOLUTION STRATEGIES FOR DYNAMIC PROBLEMS**

CASE STUDY OF CONNECTIVITY OF DIGITAL TWINS AND EXPERIMENTAL SYSTEMS .....	1416
<i>Matthew Bonney, Paul Gardner, David Wagg, Robin Mills</i>	
AN ADAPTIVE FAST NONLINEAR ANALYSIS (AFNA) ALGORITHM FOR RAPID TIME HISTORY ANALYSIS .....	1426
<i>Bowei Li, Wei-Chu Chuang, Seymour M.J. Spence</i>	
A NOVEL METHOD FOR THE GENERATION OF FULLY NON-STATIONARY SPECTRUM COMPATIBLE ARTIFICIAL ACCELEROGRAMS .....	1437
<i>Federica Genovese, Giuseppe Muscolino, G. Biondi, E. Cascone</i>	
AN APPLICATION OF THE PROPER ORTHOGONAL DECOMPOSITION METHOD FOR NONLINEAR DYNAMIC ANALYSIS OF REINFORCED CONCRETE STRUCTURES SUBJECTED TO EARTHQUAKES .....	1445
<i>Naim Ayoub, Walid Labri, Joseph Pais, Lucie Rouleau, Jean-François Deu</i>	
MULTI-RESOLUTION FINITE WAVELET DOMAIN METHOD FOR FAST TRANSIENT DYNAMIC ANALYSIS IN HOMOGENEOUS AND HETEROGENEOUS RODS AND BEAMS .....	1458
<i>Dimitris K. Dimitriou, Christos V. Nastos, Dimitris A. Saravanos</i>	

A TECHNIQUE FOR TIME INTEGRATION WITH STEPS LARGER THAN THE EXCITATION STEPS: REVIEW OF THE PAST AND ADDRESSING THE EXISTING CHALLENGES AND A PERSPECTIVE OF THE FUTURE .....	1476
<i>Aram Soroushian</i>	

#### **MS 14: SEISMIC ASSESSMENT AND RETROFITTING OF EXISTING STEEL STRUCTURES**

A SIMPLIFIED APPROACH FOR THE ESTIMATION OF SEISMIC VULNERABILITY OF STEEL MOMENT RESISTING FRAMES .....	1492
<i>Rosario Montuori, Elide Nastri, Vincenzo Piluso, Paolo Todisco</i>	

PRELIMINARY NUMERICAL ANALYSIS OF THE SEISMIC RESPONSE OF STEEL FRAMES WITH MASONRY INFILLS RETROFITTED BY BUCKLING RESTRAINED BRACES .....	1506
<i>Fernando Gutiérrez-Urzúa, Fabio Freddi, Luigi Di Sarno, Jing-Ren Wu, Mario D'Aniello, Raffaele Landolfo, Stathis Bousias</i>	

NUMERICAL MODELLING OF MASONRY INFILL WALLS IN EXISTING STEEL FRAMES .....	1519
<i>Luigi Di Sarno, Jing-Ren Wu, Fabio Freddi, Mario D'Aniello, Stathis Bousias, Fernando Gutiérrez-Urzúa, Raffaele Landolfo, Nikolaos Stathas</i>	

HYBRID COLD-FORMED/TUBULAR MODULAR STRUCTURAL SYSTEM WITH INNOVATIVE JOINTS .....	1532
<i>Luís Carlos Silva, Hélder David Craviero, Trayana Tankova, Rui Simões, Ricardo Costa, Mario D'Aniello, Raffaele Landolfo, Luís Simões da Silva</i>	

SEISMIC ASSESSMENT OF BEAM-TO-COLUMN JOINTS FOR A NON-CONFORMING MRF EXISTING STRUCTURE ....	1542
<i>Roberto Tartaglia, Mario D'Aniello, Aldo Milone, Raffaele Landolfo</i>	

#### **MS 16: DYNAMIC RESPONSE ASSESSMENT IN RAIL TRACK ENGINEERING**

APPLICATION AND ASSESSMENT OF A DYNAMIC SOIL-BRIDGE-TRAIN INTERACTION MODEL .....	1550
<i>Benjamin Hirzinger, Christoph Adam</i>	

SEISMIC FRAGILITY ANALYSIS OF RAILWAY RC BRIDGES. ACCOUNTING FOR BRIDGE-TRAIN INTERACTION BASED ON A NOVEL FORMULATION FOR CONSTRAINED DYNAMICAL SYSTEMS AND A CO-SIMULATION TECHNIQUE .....	1562
<i>Sotiria Stefanidou, Elias Paraskevopoulos</i>	

#### **MS 17: RECENT DEVELOPMENTS IN ROCKING STRUCTURES**

REDUCTION OF LOCAL DAMAGES IN PRECAST POST-TENSIONED SEGMENTAL BRIDGE PIERS .....	1574
<i>Parya Ahmadi, Ehsan Ahmadi, Mohammad M. Kashani</i>	

BASE VERSUS TOP ACTIVE CONTROL TO IMPROVE DYNAMIC AND SEISMIC PERFORMANCES OF RIGID BLOCKS .	1583
<i>Angelo Di Egidio, Alessandro Contento, Stefano Pagliaro</i>	

UNIFORM RISK SPECTRA FOR NEGATIVE STIFFNESS SYSTEMS .....	1596
<i>Natalia Reggiani Manzo, Christos Lachanas, Michalis Vassiliou, Dimitrios Vamvatsikos</i>	
SEISMIC BEHAVIOR OF ARCHAEOLOGICAL MULTIDRUM COLUMNS AT THE POMPEII SITE .....	1607
<i>Francesca Autiero, Giuseppina De Martino, Marco Di Ludovico, Andrea Prota</i>	
THE INFLUENCE OF IMPACT MODELLING ASSUMPTIONS ON THE DYNAMIC BEHAVIOUR OF FLEXIBLE ROCKING OSCILLATORS .....	1618
<i>Huanian Zhu, Manolis Chatzis, Sinan Acikgoz</i>	
QUANTIFYING SEISMIC RESILIENCE OF SINGLE-COLUMN ROCKING BRIDGES – A COMPARATIVE STUDY .....	1626
<i>Anastasios Giouvanidis, You Dong</i>	
DYNAMIC RESPONSE OF MULTI-STOREY STRUCTURES SEISMICALLY ISOLATED USING KINEMATIC BEARINGS ....	1641
<i>Kosmas E. Bantilas, Ioannis E. Kavvadias, Lazaros Vasiliadis, Anaxagoras Elenas</i>	
THE EFFECT OF IMPACT MODELING ON THE SEISMIC RESPONSE OF MULTI-STOREY PODIUM STRUCTURES .....	1657
<i>Ioannis E. Kavvadias, Kosmas E. Bantilas, Lazaros Vasiliadis, Anaxagoras Elenas</i>	
3D ROCKING MOTION: BLIND PREDICTION CONTEST RESULTS AND INFLUENCE OF EVALUATION METRIC ON THE RANKINGS .....	1672
<i>Michalis F. Vassiliou, Marco Broccardo, Cihan Cengiz, Matt Dietz, Luiza Dihoru, Selim Gunay, Khalid M. Mosalam, George Mylonakis, Anastasios Sextos, Bozidar Stojadinovic</i>	
FINITE ELEMENT MODELLING OF A RC ROCKING WALL WITH ADDITIONAL STEEL REBARS .....	1688
<i>Michele Egidio Bressanelli, Andrea Belleri, Jose Ignacio Restrepo</i>	
CYCLIC TEST OF A PRECAST BRIDGE COLUMN FOR SUSTAINABLE BRIDGE DESIGN .....	1700
<i>Natalia Reggiani Manzo, Michalis Vassiliou</i>	
 <b>MS 19: ADVANCES IN THE OPTIMUM DESIGN AND CONTROL OF LARGE STRUCTURES UNDER DYNAMIC LOADS</b>	
STUDY OF THE INFLUENCE OF SEISMIC ACTION ON THE CONSTRUCTION COST OF THE LOAD-BEARING STRUCTURE OF A TEN-STOREY R/C BUILDING .....	1712
<i>Panagiotis Sioulas, Theodoros Chrysanidis, Nikolaos Alamanis, Grigorios Papageorgiou</i>	
ASSESSMENT AND RETROFITTING OF A RC BUILDING THROUGH A MULTI-HAZARD APPROACH: SEISMIC RESISTANCE AND ROBUSTNESS .....	1725
<i>Martina Scalvenzi, Fabio Freddi, Fulvio Parisi</i>	
OPTIMAL LATERAL RESISTING SYSTEMS FOR HIGH-RISE BUILDINGS UNDER SEISMIC EXCITATIONS .....	1737
<i>Giulia Angelucci, Giuseppe Quaranta, Fabrizio Mollaioli</i>	
NON-INVASIVE VIBRATING CONTROL OF THE ZOSER PYRAMID .....	1751
<i>Masoud Shadlou, Pierfrancesco Cacciola, Ashraf Ayoub, Youssef Rashed, Alessandro Tombari</i>	

OPTIMUM DESIGN OF A HYBRID ISOLATION DEVICE FOR SERVER RACKS USING CONSTRAINED DIFFERENTIAL EVOLUTION ALGORITHM .....	1767
<i>Luca Aceto, Giuseppe Quaranta, Guido Camata, Bruno Briseghella, Enrico Spacone</i>	
INNOVATIVE MASS-DAMPING-BASED APPROACHES FOR SEISMIC DESIGN OF TALL BUILDINGS .....	1778
<i>Elena Mele, Diana Faiella, Mario Argenziano</i>	
DIAGRID SYSTEM COUPLED WITH SHEAR WALLS: ANALYTICAL INVESTIGATION ON THE DYNAMICAL RESPONSE IN TALL BUILDINGS .....	1793
<i>Giuseppe Lacidogna, Giuseppe Nitti, Domenico Scaramozzino, Alberto Carpinteri</i>	
OPTIMUM DAMPING OF SLENDER MONOPOLE TOWERS BY GYROSCOPIC STABILIZER .....	1803
<i>Gian Felice Giaccu, Luigi Fenu, Bruno Briseghella, Camillo Nuti</i>	
VIBRATION CONTROL OF WIND TURBINE TOWERS WITH KDAMPER-BASED DESIGNS .....	1812
<i>Konstantinos Kapasakalis, Ioannis Antoniadis, Evangelos Sapountzakis</i>	
 <b>MS 20: COMPUTATIONAL DESIGN AND MODELING OF TENSEGRITY SYSTEMS FOR APPLICATIONS IN SCIENCE AND ENGINEERING</b>	
ADAPTIVE BENDING-ACTIVE MODULES FOR A TENSILE SOLAR SHADING SYSTEM .....	1825
<i>Alessandro D'Ambrosio, Maria Matheou, Rosario Montuori, Elide Nastri</i>	
A MESOSCALE TENSEGRITY MODEL OF SPIDER DRAGLINE SILK FIBER .....	1834
<i>Ada Amendola, Narinder Singh, Cornelia Rodenburg, Chris Holland, Fernando Fraternali</i>	
GEOMETRIC PATTERNS AND DYNAMICS OF FOLDABLE MODULI FOR ADAPTIVE FAÇADES .....	1840
<i>Veronica Abbate, Enrico Babilio, Filipe Amarante dos Santos, Narinder Singh, Fernando Fraternali</i>	
MODELING AND DESIGN OF PERIODIC LATTICES WITH TENSEGRITY ARCHITECTURE AND HIGHLY NONLINEAR RESPONSE .....	1848
<i>Andrea Micheletti, Claudio Intrigila, Nicola Nodargi, Edoardo Artioli, Fernando Fraternali, Paolo Bisegna</i>	
A DYNAMIC-STIFFNESS APPROACH FOR DAMPED LOCALLY-RESONANT TIMOSHENKO BEAMS .....	1856
<i>Andrea Francesco Russillo, Giuseppe Failla, Antonina Pirrotta, Fernando Fraternali</i>	
SEISMIC METAMATERIALS WITH TENSEGRITY ARCHITECTURE .....	1867
<i>Filipe Santos, Narinder Singh, Ada Amendola, Fernando Fraternali, Andrea Micheletti</i>	
 <b>MS 22: CONDITION BASED MAINTENANCE AND POST-PROGNOSTICS OF COMPOSITE STRUCTURES: AN ENHANCED PLATFORM</b>	
RECONSTRUCTION OF MATERIAL STIFFNESS PROPERTIES FROM DISPERSION RELATIONS USING GENETIC ALGORITHMS .....	1874
<i>Victor Thierry, Wen Wu, Dimitrios Chronopoulos, Sergio Cantero-Chinchilla</i>	

PARTICLE FILTER-BASED HYBRID DAMAGE PROGNOSIS CONSIDERING BIAS .....	1881
<i>Tianzhi Li, Francesco Cadini, Claudio Sbarufatti</i>	

### **MS 23: ADVANCED MODELS AND NUMERICAL METHODS IN DYNAMICS, WAVE PROPAGATION AND COUPLED PROBLEMS**

DISPERSION ANALYSIS OF BULK ACOUSTIC WAVES IN PIEZOELECTRIC MEDIA DISCRETIZED BY ENERGY-ORTHOGONAL FINITE ELEMENTS .....	1892
<i>Francisco J. Brito Castro</i>	

DISPERSION DESIGN OF 1D PERIODIC DISCRETE SYSTEMS USING LOG-DET HEURISTICS .....	1922
<i>Anton Tkachuk, Mykola Tkachuk</i>	

AN EFFICIENT PRECONDITIONER FOR MODAL FREQUENCY RESPONSE .....	1934
<i>Tobias Willerding</i>	

### **MS 24: LIFE-CYCLE RISK-BASED STRUCTURAL ASSESSMENT AND COST ANALYSIS**

FRAGILITY ASSESSMENT OF WIND-EXCITED VIDEO SCREEN ROOMS IN HIGH-RISE BUILDINGS .....	1941
<i>Fabio Rizzo, Laura Ierimonti, Stefano Sacconi, Ilaria Venanzi</i>	

FRAGILITY OF EXISTING ITALIAN BRIDGES TO TRAFFIC LOADS .....	1950
<i>Giacomo Miluccio, Daniele Losanno, Fulvio Parisi, Edoardo Cosenza</i>	

TOWARDS THE DEVELOPMENT OF A COMPREHENSIVE FRAMEWORK FOR LIFE CYCLE COST ANALYSIS OF BRIDGES SUBJECTED TO MULTIPLE HAZARDS .....	1961
<i>Stefano Sacconi, Laura Ierimonti, Ilaria Venanzi, Filippo Ubertini</i>	

LIFE-CYCLE COST ANALYSIS OF TALL BUILDINGS IN SYNOPTIC, MIXED WIND LOAD CLIMATES BY LAYERED STOCHASTIC APPROXIMATION MONTE-CARLO METHOD .....	1973
<i>Lei Zhang, Luca Caracoglia</i>	

APPLICATION OF BAYESIAN FE MODEL SELECTION FOR SHM OF A MONUMENTAL MASONRY PALACE THROUGH SEMI-SUPERVISED LEARNING .....	1988
<i>Laura Ierimonti, Nicola Cavalagli, Enrique García-Macías, Ilaria Venanzi, Filippo Ubertini</i>	

A NEURAL NETWORK-BASED APPROACH FOR SEISMIC-INDUCED DAMAGE ASSESSMENT OF STEEL LIQUID STORAGE TANKS .....	2003
<i>Laura Micheli, Mahmoud Faytarouni</i>	

### **MS 25: MONITORING, IDENTIFICATION AND VIBRATION CONTROL OF STRUCTURES**

APPLICATION OF WAVELET TRANSFORMS ON ACCELERATION RECORDS: PRACTICAL APPROACH .....	2014
<i>Vladimir Vukobratović, Trevor Yeow, Koichi Kusunoki</i>	

NUMERICAL INVESTIGATION ON THE PRINCIPAL STRESS ROTATION EFFECT UNDER EARTHQUAKE LOADINGS ..	2022
<i>Zhe Wang, Yunming Yang</i>	
ENRICHED BEAM FINITE ELEMENT MODELS WITH TORSION AND SHEAR WARPING FOR DYNAMIC ANALYSIS OF FRAME STRUCTURES .....	2033
<i>Daniela Addessi, Paolo Di Re, Cristina Gatta</i>	
EARTHQUAKE-INDUCED STRUCTURAL POUNDING BETWEEN TWO INELASTIC SDOF STRUCTURAL SYSTEMS .....	2058
<i>Pedro Folhento, Rui Barros, Manuel Braz-César</i>	
INFLUENCE OF STRUCTURAL INELASTIC BEHAVIOR IN THE STUDY OF COLLIDING SDOF STRUCTURES .....	2085
<i>Pedro Folhento, Rui Barros, Manuel Braz-César</i>	
VIRTUAL SENSING AND STRAIN ESTIMATION ON AN OFFSHORE WIND TURBINE USING SUPERVISED LEARNING .....	2112
<i>Marius Tarpø, Sandro Amador, Evangelos Katsanos, Mattias Skog, Johan Gjørdvad, Rune Brincker</i>	
SIMPLIFIED METHODS FOR FREQUENCY ESTIMATION OF SMALL WIND TURBINE TOWER .....	2121
<i>Anelise Dick, Rui Carneiro-Barros, Manuel Braz-César</i>	
FINITE ELEMENT MODEL CALIBRATION EFFECTS ON THE STATIC AND DYNAMIC RESPONSE OF A METALLIC HOLLOW TOWER .....	2132
<i>Anelise Dick, Rui Carneiro-Barros, Manuel Braz-César</i>	
PARAMETRIC STUDY OF LATTICE TOWERS ON THE INFLUENCE OF WIND ACTION FOR DIFFERENT TYPOLOGIES OF BRACING .....	2143
<i>Rui Carneiro-Barros, Luís Barros</i>	
 <b>MS 26: SEISMIC SAFETY ASSESSMENT OF STRUCTURES</b>	
EXPERIMENTAL IN-PLANE LATERAL RESPONSE OF A FULL-SCALE ADOBE MASONRY WALL WITH OPENING .....	2157
<i>Paolino Cassese, Luigi Fenu, Domenico Asprone, Antonio Occhiuzzi, Fulvio Parisi</i>	
INFLUENCE OF BEAM-TO-COLUMN CONNECTIONS IN SEISMIC VULNERABILITY ASSESSMENT OF STEEL STRUCTURES .....	2170
<i>Giammaria Gabbianelli, Daniele Perrone, Emanuele Brunesi</i>	
ASSESSMENT OF RC HOLLOW-PIERS FOR SEISMIC LIMIT STATE OF DAMAGE - DIRECT REPAIR COSTS .....	2185
<i>Pedro Delgado, Naiara Silva, Mário Marques, António Arêde</i>	
 <b>MS 27: TIMBER-BASED ELEMENTS: RECENT ADVANCEMENTS FOR NEW AND EXISTING SEISMIC-RESISTANT STRUCTURES</b>	
OPTIMIZATION OF THE SLIP FORCE IN A NOVEL FRICTION-BASED CONNECTION FOR THE E-CLT TECHNOLOGY ..	2195
<i>Angelo Aloisio, Francesco Boggian, Roberto Tomasi</i>	

EXPERIMENTAL AND NUMERICAL INVESTIGATION OF INNOVATIVE DUCTILE AND REPLACEABLE ANCHORING SYSTEMS FOR WOOD SHEAR WALLS UNDER SEISMIC LOADS .....	2211
<i>Georgios Balaskas, Vera Wilden, Benno Hoffmeister</i>	
ANALYTICAL AND NUMERICAL MODELLING OF THE IN-PLANE RESPONSE OF TIMBER DIAPHRAGMS RETROFITTED WITH PLYWOOD PANELS .....	2227
<i>Michele Mirra, Marianthi Sousamli, Michele Longo, Geert Ravenshorst</i>	
MOMENT-CURVATURE DIAGRAMS FOR CLT PANELS ACCOUNTING FOR ORTOGONAL TO GRAIN COMPRESSION TIMBER PROPERTIES .....	2254
<i>Antonio Sandoli, Claudio D'Ambra, Maria Lippiello, Carla Ceraldi, Bruno Calderoni, Andrea Prota</i>	
REINFORCING STOP-SPLAYED SCARF JOINTS WITH TIMBER PEG: ROLE OF SLENDERNESS .....	2272
<i>Carla Ceraldi, Claudio D'Ambra, Maria Lippiello, Antonio Sandoli, Andrea Prota</i>	
IMPACT OF RETROFIT OF RC FRAMES BY CLT PANELS AND FRICTION DAMPERS .....	2287
<i>Francesca Barbagallo, Giuseppe Margani, Edoardo M. Marino, A. Moretti, Carola Tardo</i>	
SEISMIC STRENGTHENING OF EXISTING URM STRUCTURES THROUGH CLT ELEMENTS: NUMERICAL ANALYSIS OF THE APPLICATION OF A NOVEL INTERVENTION TECHNIQUE .....	2300
<i>Matteo Salvalaggio, Marco Pegoraro, Elisa Saler, Umberto Turrini, Maria Rosa Valluzzi</i>	
POST-TENSIONED LOW DAMAGE TIMBER WALLS WITH DISSIPATIVE DEVICES BEHAVIOUR: NUMERICAL PREDICTION .....	2314
<i>Valentina Tomei, Maria Zucconi, Barbara Ferracuti</i>	
MANSORY-INFILLED RC FRAMES STRENGTHENED WITH CROSS-LAMINATED TIMBER PANELS .....	2323
<i>Zabih Mehdipour, Jorge Branco, Iztok Sustersic, Leonardo Filipe Rodrigues, Paulo Lourenço</i>	
INFLUENCE OF PERPENDICULAR WALLS ON THE LATERAL STIFFNESS OF CLT SHEAR WALLS .....	2336
<i>Elisabetta Maria Ruggeri, Giuseppe D'Arenzo, Marinella Fossetti, Werner Seim</i>	
POST-TENSIONED LOW DAMAGE CLT WALLS WITH REPLACEABLE HYSTERETIC DEVICES – CONCEPT, EXPERIMENTAL AND NUMERICAL CHARACTERIZATION .....	2352
<i>Luca Pozza, Luca Benedetti, Valentina Tomei, Barbara Ferracuti, Maria Zucconi, Claudio Mazzotti</i>	
TIMBER BEAM-TO-COLUMN JOINT WITH STEEL LINK: DESIGN AND MECHANICAL CHARACTERIZATION THROUGH NUMERICAL INVESTIGATION .....	2359
<i>Giacomo Iovane, Beatrice Faggiano</i>	
A NUMERICAL STUDY ON A TIMBER-BASED SEISMIC RETROFIT INTERVENTION FOR MASONRY INFILLED CONCRETE FRAMES .....	2366
<i>Francesco Smirolto, Davide Viel, Ivan Giongo, Maurizio Piazza</i>	

**MS 29: SEISMIC PROTECTION OF NON-STRUCTURAL COMPONENTS: RECENT DEVELOPMENTS AND FUTURE CHALLENGES**

COMPREHENSIVE NONLINEAR ANALYSIS OF FAILURES OF FIRE-SPRINKLER SYSTEM BASED ON FINITE ELEMENT MODELLING AND AMBIENT VIBRATION TESTS .....	2388
<i>Shakhzod Takhirov, Amir Gilani</i>	
IMPROVEMENT OF DYNAMIC AND SEISMIC BEHAVIOUR OF CABINETS THROUGH CONTROLLED DEFORMATION .....	2396
<i>Stefano Pagliaro, Angelo Di Egidio, Alessandro Contento</i>	
NUMERICAL MODELING OF ROCKING AND SLIDING CYLINDRICAL COLUMNS UNDER SEISMIC EXCITATION .....	2408
<i>Antonios Katsamakas, Michalis Vassiliou</i>	
SEISMIC RISK ASSESSMENT OF ROCKING BUILDING CONTENTS .....	2421
<i>Michalis Fragiadakis, Spyridon Diamantopoulos</i>	

**MS 30: DYNAMIC PROTECTION SYSTEMS AND DEVICES: EXPERIMENTAL TESTS, MATHEMATICAL MODELING AND DESIGN METHODS**

SOME RECENT ADVANCES ON THE MODELING OF THE HYSTERETIC BEHAVIOR OF RATE-INDEPENDENT PASSIVE ENERGY DISSIPATION DEVICES .....	2435
<i>Nicolò Vaiana, Ciro Napolitano, Luciano Rosati</i>	
SEISMIC PROTECTION OF CULTURAL HERITAGE ARTEFACTS BY MEANS OF ELASTOMERIC ISOLATORS: A CASE STUDY .....	2446
<i>Davide Pellecchia, Stefania Lo Feudo, Nicolo Vaiana, Jean-Luc Dion, Luciano Rosati</i>	
TUNING THE LATERAL RESPONSE OF UNBONDED FIBER REINFORCED ELASTOMERIC ISOLATORS (U-FREIS): EXPERIMENTAL-NUMERICAL FINDINGS .....	2456
<i>Simone Galano, Andrea Calabrese, Daniele Losanno</i>	
ON THE VERTICAL RESPONSE OF FIBER REINFORCED ELASTOMERIC ISOLATORS (FREIS) UNDER COMBINED VERTICAL AND LATERAL LOADING .....	2468
<i>Simone Galano</i>	
SEISMIC ISOLATION OF LIGHTWEIGHT STRUCTURES THROUGH WIRE ROPE DEVICES: PRELIMINARY EXPERIMENTAL RESULTS AND SIMULATION .....	2488
<i>Mariacristina Spizzuoco, Giorgio Serino</i>	
REAL-TIME HYBRID SIMULATION OF A STRUCTURE WITH CIRCULAR FIBER REINFORCED ISOLATORS .....	2498
<i>Carlos Riascos, Semion Klopov, Johannio Marulanda, Peter Thomson, Giorgio Serino</i>	
A COMPARATIVE STUDY ON THE ACCURACY AND EFFICIENCY OF TWO BIAXIAL HYSTERETIC MODELS SUITABLE FOR ELASTOMERIC BEARINGS .....	2511
<i>Nagavinothini Ravichandran</i>	

LABORATORY CHARACTERIZATION OF A RECLAIMED RUBBER COMPOUND FOR LOW-COST ELASTOMERIC ISOLATORS .....	2525
<i>Fabrizia Cilento, Daniele Losanno, Luigi Piga</i>	
EFFECT OF EXTREMELY LOW TEMPERATURE ON MECHANICAL PROPERTIES OF A LARGE SIZE LRB .....	2536
<i>Gokhan Ozdemir, Esengul Cavdar, Volkan Karuk</i>	
STIFF DYNAMIC ABSORBERS FOR THE VERTICAL SEISMIC PROTECTION OF STRUCTURES .....	2543
<i>Marina Kalogerakou, Konstantinos Kapasakalis, Ioannis Antoniadis, Evangelos Sapountzakis</i>	
 <b>MS 32: SIMPLIFIED METHODOLOGIES FOR PERFORMANCE AND LOSS ASSESSMENT AT BUILDING OR TERRITORIAL SCALE</b>	
ACCURATE COLLAPSE CAPACITY QUANTIFICATION FOR INFILLED RC FRAME BUILDINGS .....	2557
<i>Al Mouayed Bellah Nafeh, Gerard O'Reilly</i>	
DEVELOPMENT OF A PYTHON-BASED STOREY LOSS FUNCTION GENERATOR .....	2573
<i>Davit Shahnazaryan, Gerard O'Reilly, Ricardo Monteiro</i>	
ASSESSMENT OF POST-EARTHQUAKE DAMAGES ON ITALIAN SCHOOL BUILDINGS PORTFOLIO OVER THE LAST 50 YEARS .....	2591
<i>Sergio Ruggieri, Chiara Tosto, Daniele Perrone, Giuseppina Uva, Maria Antonietta Aiello</i>	
SEISMIC RISK ASSESSMENT FOR THE ITALIAN RESIDENTIAL MASONRY BUILT STOCK AND EFFECTIVENESS OF DIFFERENT MITIGATION STRATEGIES .....	2606
<i>Pietro Carpanese, Veronica Follador, Elisa Saler, Francesca da Porto</i>	
THE USE OF STICK-IT MODEL FOR EDP ASSESSMENT IN EXISTING RC INFILLED TYPOLOGIES .....	2619
<i>Marco Gaetani d'Aragona, Maria Polese, Marco Di Ludovico, Andrea Prota</i>	
APPLICATION OF THE EMPIRICAL PREDICTIVE DAMAGE MODEL OF HISTORICAL CHURCHES .....	2631
<i>Claudia Canuti, Michele Morici, Andrea Dall'Asta, Graziano Leoni</i>	
A SEISMIC RISK ASSESSMENT FRAMEWORK FOR LOSS ESTIMATION OF CRITICAL INFRASTRUCTURE – HOSPITALS CASE .....	2643
<i>Paolo Basso, Saimir Osmani, Matteo Scolari, Ruben Valsecchi</i>	
CAESAR II: AN ITALIAN DECISION SUPPORT TOOL FOR THE SEISMIC RISK. THE CASE STUDY OF TORRE PELLICE, VILLAR PELLICE AND PINEROLO MUNICIPALITIES .....	2659
<i>Giulio Zuccaro, Francesca Linda Perelli, Daniela De Gregorio, Daniele Masi</i>	
OPEN MODELS AND SOFTWARE FOR ASSESSING THE VULNERABILITY OF THE EUROPEAN BUILDING STOCK .....	2678
<i>Helen Crowley, Vitor Silva, Luis Martins, Xavier Romão, Nuno Pereira</i>	

PELL-SCHOOLS A STANDARDIZED AND INTEROPERABLE PLATFORM FOR THE SEISMIC VULNERABILITY AND ENERGY EFFICIENCY DATA MANAGEMENT OF ITALIAN SCHOOLS .....	2689
<i>Laura Blaso, Sonia Giovinazzi, Simona Bianchi, Livio Pedone, Chiara Ormando, Paolo Clemente, Stefano Pampanin, Nicoletta Gozo, Giuseppina Giuliani, Maurizio Pollino</i>	

EFFECT OF BUILDING SAMPLE SELECTION ON SEISMIC FRAGILITY CURVES FOR RC BUILDINGS AT TERRITORIAL SCALE .....	2707
<i>Maria Zucconi, Fabio Romano, Barbara Ferracuti</i>	

## VOLUME II

### Minisymposia

#### MS 33: EXPERIMENTAL MEASUREMENTS AND NUMERICAL SIMULATION ON PROBLEMS IN THE FIELD OF EARTHQUAKE ENGINEERING AND STRUCTURAL DYNAMICS

ANALYTICAL INVESTIGATION OF THE TENSILE EXPERIMENTS MODELING THE ELONGATION DEGREE OF R/C WALLS FOR STUDYING THE LATERAL BUCKLING PHENOMENON .....	2718
<i>Theodoros Chrysanidis, Vassilis Panoskaltsis</i>	

ANALYTICAL INVESTIGATION OF THE TENSILE EXPERIMENTS TO PRISMS WITH VARYING LONGITUDINAL RATIO FOR STUDYING THE LATERAL BUCKLING OF R/C WALLS .....	2730
<i>Theodoros Chrysanidis, Vassilis Panoskaltsis</i>	

PRELIMINARY CONSIDERATIONS ON THE LOSS OF SUPPORT FOR PRECAST BEAM ELEMENTS .....	2744
<i>Marius Eteme Minkada, Simone Labò, Alessandra Marini, Andrea Belleri</i>	

SEISMIC PERFORMANCE OF BELL TOWERS .....	2754
<i>George C. Manos</i>	

STUDYING THE PERFORMANCE OF STONE MASONRY ARCH BRIDGES EMPLOYING IN-SITU MEASUREMENTS AND NUMERICAL PREDICTIONS .....	2769
<i>George C. Manos, N. Simos</i>	

EXPERIMENTAL IDENTIFICATION OF MECHANICAL AND DYNAMIC CHARACTERISTICS OF 3D PRINTING SPECIMENS .....	2791
<i>Ioannis E. Kavvadias, Konstantinos Tsongas, Dimitrios Tzetzis, Kosmas E. Bantilas, Lazaros Vasiliadis, Anaxagoras Elenas</i>	

INVESTIGATION OF LOW COST SMAS UNDER ELEVATED TEMPERATURES .....	2800
<i>Sofia Piliafa, Lazaros Melidis, Lambros Kotoulas, Nikolaos Makris, Konstantinos Katakalos</i>	

EXPERIMENTAL AND NUMERICAL INVESTIGATION OF THE PLASTIC CYCLIC BEHAVIOUR OF SIMPLE STEEL COUPONS .....	2808
<i>Alexandra Nalmpantidou, George C. Manos</i>	

EXPERIMENTAL TESTS AND NUMERICAL STUDY OF THE PLASTIC CYCLIC BEHAVIOUR OF A STEEL BEAM-TO-COLUMN CONNECTION .....	2824
<i>George C. Manos, Alexandra Nalmpantidou</i>	
DYNAMIC AND VIBROACOUSTIC RESPONSE OF TIMBER FLOOR PANELS. MEASUREMENTS AND NON-LINEAR NUMERICAL SIMULATIONS .....	2843
<i>Magdalini Titirla, Sarah Benakli, Walid Larbi</i>	
THE USE OF INTELLIGENT FACADES FOR UPGRADING ENERGY AND SEISMIC DEMANDS OF EXISTING R/C STRUCTURE .....	2852
<i>Lazaros Melidis, Efthymios A. Kechagias, Konstantinos Katakalos, George C. Manos</i>	
EXPERIMENTAL AND NUMERICAL INVESTIGATION OF FRP STRENGTHENED R/C BEAM-TO-COLUMN JOINTS SUBJECTED TO CYCLIC SEISMIC-TYPE LOADING .....	2863
<i>Lazaros Melidis, George C. Manos, J. Maranos, Konstantinos Katakalos</i>	
THE BEHAVIOR OF PARTIALLY GROUTED MASONRY WALLS SUBJECTED TO OUT OF PLANE SEISMIC TYPE LOADS. LABORATORY MEASUREMENTS AND NUMERICAL SIMULATIONS .....	2875
<i>George C. Manos, Lazaros Melidis, Lampros Kotoulas, Konstantinos Katakalos</i>	
IN PLANE BEHAVIOR OF PARTIALLY GROUTED MASONRY WALLS USING A NEW CLAY UNIT. LABORATORY MEASUREMENTS AND NUMERICAL SIMULATIONS .....	2885
<i>George C. Manos, Lazaros Melidis, Lampros Kotoulas, Konstantinos Katakalos</i>	
EXPERIMENTAL AND NUMERICAL INVESTIGATION OF THE OUT OF PLANE BEHAVIOR OF THERMAL INSULATED MASONRY WALLS .....	2895
<i>George C. Manos, Lazaros Melidis, Konstantinos Katakalos, Anthimos Anastasiadis</i>	
EXPERIMENTAL & NUMERICAL INVESTIGATION OF LAP-SPLICED R/C COLUMNS UNDER THREE POINT BENDING & AXIAL COMPRESSION .....	2903
<i>Pelagia Kastiza, Lazaros Melidis, Konstantinos Katakalos</i>	
DEVELOPMENT OF AN EXPERIMENTAL SETUP FOR MEASURING THE EFFECTIVENESS OF STRENGTHENED PRESTRESSED CONCRETE CYLINDER PIPES (PCCP) .....	2913
<i>Sofia Gkaraklova, Lazaros Melidis, George C. Manos, Konstantinos Katakalos</i>	
MECHANICAL PROPERTIES CHARACTERISATION OF FRPS UNDER ELEVATED TEMPERATURES .....	2922
<i>Christina Papadimitriou, Lambros Kotoulas, Nikolaos Makris, Lazaros Melidis, Konstantinos Katakalos</i>	
EXPERIMENTAL TESTING CAMPAIGN AND NUMERICAL MODELLING OF AN INNOVATIVE BASE-PLATE CONNECTION FOR PALLET RACKING SYSTEMS .....	2934
<i>Bonaventura Tagliaferro, Rosario Montuori, Ioannis Vayas, Sofia Antonodimitraki, Magdalini D. Titirla, Marco Simoncelli, Xenophon Lignos</i>	
STUDY OF THE INFLUENCE OF UNDERLYING SOFT-SOIL LAYERS ON THE DYNAMIC AND EARTHQUAKE RESPONSE OF BELL TOWERS .....	2943
<i>George C. Manos</i>	

THE INFLUENCE OF WOODEN ROOF CONNECTION ON THE DYNAMIC AND EARTHQUAKE RESPONSE OF OLD INDUSTRIAL STONE MASONRY BUILDINGS .....	2965
<i>George C. Manos, Lampros Kotoulas</i>	
EXPERIMENTAL AND ANALYTICAL INVESTIGATION OF THE STRENGTHENING OF TRADITIONAL TIMBER FRAMES .....	2983
<i>Ioannis Stavrou, Panayiotis Demosthenous, Stelios Papastilianou, Milton Demosthenous</i>	
NUMERICAL SIMULATIONS OF THE EXPERIMENTAL RESULTS OF STEEL FRAME MODEL WITH ROOF ROLLER SYSTEM SUBJECTED TO DYNAMIC BASE EXCITATIONS .....	2997
<i>Nikodemos Kouroufexis, Milton Demosthenous</i>	
EXPERIMENTAL AND NUMERICAL INVESTIGATION OF A MASONRY MODEL BUILDING SUBJECTED TO DYNAMIC BASE EXCITATIONS .....	3007
<i>Stefania Demosthenous, Milton Demosthenous</i>	
PASSIVE CONTROL ISSUES ON THE LONGITUDINAL AND TRANSVERSE VIBRATIONS OF FLEXIBLE PYLONS .....	3021
<i>George Manolis, George Dadoulis</i>	
PSEUDO-DYNAMIC ANALYSES OF INFILLED REINFORCED CONCRETE FRAMED STRUCTURES WITH PRIOR DAMAGES AFTER ADVANCED RETROFIT .....	3036
<i>Theodoros Rousakis, Evgenia Anagnostou, Theodora Fanaradelli</i>	
EXPERIMENTAL AND NUMERICAL STUDY OF SELF-SUPPORTING DOUBLE SKIN METAL FACED MINERAL WOOL PANELS .....	3049
<i>Sofia Gkaraklova, Lazaros Melidis, George C. Manos, Konstantinos Katakalos</i>	
 <b>MS 34: FRAGILITY CURVES FOR EXISTING BUILDINGS: OPEN CHALLENGES IN THEIR DEFINITION AND USE FOR SEISMIC RISK ANALYSES</b>	
SEISMIC FRAGILITY ASSESSMENT FOR A CLASS OF RC SCHOOL BUILDINGS IN ITALY LEVERAGING DETAILED AND REDUCED-ORDER MODELS .....	3059
<i>Sergio Ruggieri, Giuseppina Uva</i>	
FRAGILITY CURVES FOR RC FRAMED BUILDINGS CONSIDERING CUMULATIVE DAMAGE DUE TO EARTHQUAKE GROUND MOTION AND SLOW-MOVING LANDSLIDES .....	3073
<i>Fulvio Parisi, Elia Acconcia</i>	
FRAGILITY CURVES FOR ITALIAN RESIDENTIAL MASONRY BUILDINGS WITH RETROFIT INTERVENTIONS .....	3083
<i>Veronica Follador, Marco Donà, Pietro Carpanese, Francesca da Porto</i>	
FRAGILITY MODELS FOR EXISTING MASONRY INFILLED RC FRAMES IN THE EMILIA AREA .....	3098
<i>Gianluca Salamida, Nicola Buratti</i>	
FRAGILITY ASSESSMENT OF THE ITALIAN MASONRY SCHOOL BUILDING ASSET FOR RISK EVALUATION AT NATIONAL SCALE .....	3113
<i>Elisa Saler, Veronica Follador, Pietro Carpanese, Francesca da Porto</i>	

DERIVATION OF SEISMIC FRAGILITY CURVES OF A GRAVITY-LOAD DESIGNED RC SCHOOL BUILDING THROUGH NLTHA .....	3127
<i>Elisa Saler, Pietro Carpanese, Veronica Follador, Francesca da Porto</i>	
TYPOLOGICAL ANALYSIS AND VULNERABILITY CURVES FOR MASONRY CHURCHES .....	3141
<i>Elvis Cescatti, Veronica Follador, Francesca da Porto</i>	
COMPARATIVE STUDY ON TWO ANALYTICAL MECHANICAL-BASED METHODS FOR DERIVING FRAGILITY CURVES TARGETED TO MASONRY SCHOOL BUILDINGS .....	3155
<i>Serena Cattari, Sara Alfano, Daria Ottonelli, Elisa Saler, Francesca da Porto</i>	
ROLE OF DESIGN LEVEL AND INFILL ARRANGEMENT ON THE SEISMIC FRAGILITY CURVES OF ITALIAN RC EXISTING BUILDINGS .....	3176
<i>Angelo Masi, Vincenzo Manfredi, Giuseppe Nicodemo, Andrea Digrisolo</i>	
 <b>MS 35: RECENT ADVANCES IN SEISMIC ISOLATION AND SUPPLEMENTAL DAMPING SYSTEMS FOR VIBRATION CONTROL</b>	
EXPERIMENTAL AND NUMERICAL ASSESSMENT OF ISOLATION SEISMIC DEVICE FOR RETROFIT OF INDUSTRIAL EXISTING SHED .....	3187
<i>Luca Mari, Virginio Quaglini, Carlo Pettoruso, Eleonora Bruschi</i>	
INVESTIGATION OF THE BREAKAWAY FRICTION INFLUENCE ON THE SEISMIC RESPONSE OF BUILDINGS ISOLATED WITH CURVED SURFACE SLIDERS .....	3204
<i>Eleonora Bruschi, Virginio Quaglini, Emanuele Gandelli</i>	
SUPPLEMENTAL ENERGY DISSIPATION WITH PRESTRESSED LEAD EXTRUSION DAMPERS (P-LED): EXPERIMENTS AND MODELING .....	3216
<i>Carlo Pettoruso, Eleonora Bruschi, Virginio Quaglini</i>	
AN INNOVATIVE STEEL DAMPER WITH ADAPTIVE HYSTERETIC BEHAVIOR .....	3230
<i>Emanuele Gandelli, Johan Distl, Peter Huber, Christian Braun</i>	
INVESTIGATIONS ON INTER-STOREY SEISMIC ISOLATION AS A TECHNIQUE FOR ADDING UPPER STOREYS .....	3248
<i>Enrico Bernardi, Marco Donà, Francesca da Porto, Ping Tan</i>	
FUNCTIONAL ACCEPTANCE TESTS FOR THE SEISMIC ISOLATION DEVICES OF THE NEW SAN GIORGIO BRIDGE IN GENOA .....	3267
<i>Marcello Cademartori, Andrea Miano, Antimo Fiorillo, Alessandro Aliotta, Marco Di Ludovico, Andrea Prota, Simone Dellacasagrande, Alaeddine Fatnassi, Daniele Pastorelli</i>	
MODELING STRATEGIES FOR THE LATERAL RESPONSE OF CURVED SURFACE SLIDER DEVICES UNDER EXTREME DISPLACEMENT DEMANDS .....	3281
<i>Marco Furinghetti, Alberto Pavese</i>	
ASSESSMENT OF THE SHEAR PROPERTIES OF HDRBS UNDER DIFFERENT COMPRESSION LEVELS .....	3294
<i>Eleonora Bruschi, Emanuele Gandelli, Carlo Pettoruso, Virginio Quaglini</i>	

## **MS 36: METHODOLOGIES AND ADVANCED TOOLS FOR SEISMIC RISK ASSESSMENT, MANAGEMENT, AND MITIGATION: ADVANCES AND OPEN CHALLENGES**

A FRAMEWORK FOR THE ASSESSMENT OF SEISMIC DAMAGE SCENARIOS IN THE EMILIA-ROMAGNA REGION, ITALY .....	3305
<i>Elena Simoni, Nicola Buratti, Claudio Mazzotti</i>	
THE USE OF AN INTEGRATED APPROACH FOR BUILDING INVENTORY AND EFFECTS ON RISK ESTIMATIONS AT THE TERRITORIAL SCALE .....	3323
<i>Maria Polese, Marco Di Ludovico, Gabriella Tocchi, Andrea Prota</i>	
SEISMIC ASSESSMENT OF MASONRY BUILDINGS AT TERRITORIAL SCALE .....	3338
<i>Chiara Iacovino, Amedeo Flora, Donatello Cardone, Marco Vona</i>	
INVESTIGATING GROUND-MOTION DURATION EFFECTS ON BUILDING PORTFOLIO LOSS ESTIMATES .....	3360
<i>Kenneth Otárola, Roberto Gentile, Luis Sousa, Carmine Galasso</i>	

## **MS 37: RISK ASSESSMENT OF BRIDGES AND ROAD NETWORKS SUBJECTED TO NATURAL HAZARDS**

RELIABILITY-BASED ASSESSMENT OF A MASONRY ARCH BRIDGE UNDER FLOOD EVENTS .....	3377
<i>Carlos Andres Mendoza Cabanzo, Monica Patricia Santamaria Ariza, Hélder S. Sousa, Jose Antonio Campos e Matos</i>	
SIMPLIFIED FRAGILITY ANALYSIS OF MULTI-SPAN ISOSTATIC RC-BRIDGES CONSIDERING AN INCOMPLETE KNOWLEDGE LEVEL .....	3389
<i>Andrea Nettis, Domenico Raffaele, Giuseppina Uva</i>	
SCOUR-INDUCED DYNAMIC PROPERTIES MODIFICATION OF MASONRY ARCH BRIDGES WITH DIFFERENT GEOMETRY .....	3407
<i>Fabrizio Scozzese, Laura Ragni, Enrico Tubaldi, Fabrizio Gara</i>	
INFLUENCE OF THE PIERS' HEIGHT ON THE FRAGILITY ASSESSMENT OF ITALIAN R.C. LINK SLAB BRIDGES .....	3418
<i>Lucia Minnucci, Fabrizio Scozzese, Andrea Dall'Asta, Sandro Carbonari, Fabrizio Gara</i>	
PERFORMANCE-BASED EARTHQUAKE ENGINEERING ANALYSIS OF SHORT-MEDIUM SPAN STEEL-CONCRETE COMPOSITE BRIDGES .....	3430
<i>Daniele Corritore, Fabrizio Paolacci</i>	
SEISMIC VULNERABILITY ANALYSIS OF THE HISTORICAL SS FILIPPO E GIACOMO MASONRY ARCH BRIDGE IN ASCOLI PICENO (ITALY) .....	3445
<i>Graziano Leoni, Fabrizio Gara, Michele Morici</i>	
ROC-BASED PERFORMANCE EVALUATION OF DATA CLEANSING TECHNIQUES FOR FALSE ALARM RISK REDUCTION IN CONTINUOUSLY MONITORED BRIDGES .....	3458
<i>Valentina Giglioni, Enrique García-Macías, Ilaria Venanzi, Laura Ierimonti, Filippo Ubertini</i>	
RC TIED-ARCH BRIDGES: TYPOLOGICAL ANALYSIS FOR THE DEFINITION OF RETROFIT INTERVENTIONS .....	3470
<i>Valentina Pernechele, Elisa Saler, Francesca da Porto, Claudio Modena</i>	

APPLICATION TO AN URBAN BRIDGE STOCK OF A PRIORITIZATION PROCEDURE BASED ON SEISMIC ASSESSMENT COMPARED WITH THE NOVEL ITALIAN GUIDELINES .....	3484
<i>Elisa Saler, Valentina Pernechele, Giovanni Tecchio, Francesca da Porto</i>	
ANALYTICAL PROBABILISTIC RESILIENCE ESTIMATION FOR BRIDGES UNDER NEAR-FAULT EARTHQUAKES .....	3499
<i>Yang Liu, Da-Gang Lu, Fabrizio Paolacci</i>	
SIMPLIFIED ANALYTICAL-MECHANICAL METHODOLOGY FOR STRUCTURAL-SEISMIC SAFETY ASSESSMENT OVER TIME OF RC BRIDGES AFFECTED BY CORROSION PHENOMENA .....	3520
<i>Matteo Gentile, Filippo Molaioni, Stefano Pampanin</i>	
REAL-TIME ASSESSMENT OF PERFORMANCE INDICATORS FOR BRIDGES TO SUPPORT ROAD NETWORK MANAGEMENT IN THE AFTERMATHS OF EARTHQUAKE EVENTS .....	3536
<i>Chiara Ormando, Ugo Ianniruberto, Paolo Clemente, Sonia Giovinnazzi, Maurizio Pollino, Vittorio Rosato</i>	
DIAGNOSTICS OF HISTORICAL STEEL BRIDGES: THE CASE OF THE VALENCIAN RAILROAD NETWORK .....	3551
<i>Valentino Sangiorgio, Andrea Nettis, Giuseppina Uva, Juan A. García-Cerezo, Pedro A. Calderón, Humberto Varum, Jose M. Adam</i>	
TOWARDS A UNIFIED SEISMIC- FLOOD HAZARD MODEL FOR RISK ASSESSMENT OF ROADWAY NETWORKS IN GREECE .....	3569
<i>Anna Karatzetzou, Sotiria Stefanidou, Stefanos Stefanidis, Grigorios Tsinidis, Dimitrios Pitilakis</i>	
<b>MS 38: DYNAMIC SOIL-FOUNDATION-STRUCTURE INTERACTION: DEVELOPMENTS AND EMERGING ISSUES</b>	
DYNAMIC CROSS-INTERACTION BETWEEN TWO CLOSELY-SPACED SHALLOW FOUNDATIONS .....	3577
<i>Enza Zeolla, Filomena de Silva, Stefania Sica</i>	
ON THE SITE-AMPLIFICATION AND SOIL-STRUCTURE INTERACTION IN URM STRUCTURES: USE OF FRAGILITY CURVES TO ASSESS THE SIMPLIFIED CODE-APPROACH .....	3589
<i>Andrea Brunelli, Filomena de Silva, Serena Cattari</i>	
ELASTODYNAMIC ANALYSIS OF LATERALLY LOADED PILES: MODIFICATIONS TO A SIMPLIFIED ENERGY APPROACH .....	3605
<i>Jamie J. Crispin, George Mylonakis</i>	
ON THE EFFECTIVENESS OF EXPERIMENTALLY-DERIVED FOUNDATION IMPEDANCE FUNCTIONS .....	3617
<i>Chiara Amendola, Filomena de Silva, Dimitrios Pitilakis, Francesco Silvestri</i>	
NUMERICAL ANALYSIS ON THE INFLUENCE OF DYNAMIC SOIL-STRUCTURE INTERACTION IN SORIA ARCH DAM: A CASE STUDY .....	3633
<i>J.C. Galván, L.A. Padrón, J.J. Aznárez, O. Maeso</i>	
SOIL-CAISSON-BRIDGE PIER-DECK DYNAMIC INTERACTION UNDER STRONG EARTHQUAKES: THE INFLUENCE OF PRIMARY AND SECONDARY SOIL NONLINEARITIES .....	3645
<i>Domenico Gaudio, Sebastiano Rampello</i>	

INFLUENCE OF SCOUR ON DYNAMIC IMPEDANCES OF BRIDGE SHALLOW FOUNDATIONS .....	3658
<i>Christos Antonopoulos, Enrico Tubaldi, Sandro Carbonari, Fabrizio Gara, Francesca Dezi</i>	

KINEMATIC PILE-HEAD BENDING UNDER LARGE EARTHQUAKE-INDUCED SHEAR STRAINS .....	3671
<i>Stefano Stacul, Emmanouil Rovithis, Raffaele Di Laora</i>	

ASPECTS OF SEISMIC SOIL-PILE-STRUCTURE INTERACTION IN SOFT CLAY BY CENTRIFUGE TESTING .....	3685
<i>Maria Iovino, Emmanouil Rovithis, Raffaele Di Laora, Cristiano D'Alterio, Luca de Sanctis, Thejesh K. Garala, Stuart Haigh, Gopal S. Madabhushi</i>	

### **MS 39: THE CONTRIBUTION OF DYNAMIC TESTS AND STRUCTURAL MONITORING ON THE SEISMIC RISK ASSESSMENT AND MITIGATION**

LONG TERM MONITORING OF THE SANTA MARIA DI COLLEMAGGIO BASILICA .....	3697
<i>Angelo Aloisio, Riccardo Cirella, Antonacci Elena, Rocco Alaggio</i>	

AMBIENT VIBRATION TEST ON AN EXISTING PRESTRESSED CONCRETE BRIDGE .....	3720
<i>Alessandra De Angelis, Giacomo Esposito, Giuseppe Maddaloni, Edoardo Cosenza, Maria Rosaria Pecce</i>	

MODAL ANALYSIS OF THE HISTORICAL SS FILIPPO E GIACOMO MASONRY ARCH BRIDGE IN ASCOLI PICENO (ITALY) .....	3731
<i>Fabrizio Gara, Graziano Leoni, Michele Morici</i>	

THE TRACKING OF MODAL PARAMETERS FOR A REINFORCED CONCRETE BUILDING DURING LOW-MEDIUM INTENSITY EARTHQUAKES .....	3743
<i>Davide Arezzo, Vanni Nicoletti, Sandro Carbonari, Fabrizio Gara</i>	

FIRST RESULTS OF LONG-TERM MONITORING OF PORTICO VARANO IN THE CAMERINO DUCAL PALACE (ITALY) .....	3752
<i>Leonardo Cipriani, Andrea Dall'Asta, Graziano Leoni, Michele Morici, Alessandro Zona</i>	

DEVELOPMENT OF LOW COST SENSORS FOR MONITORING OF STRUCTURES .....	3762
<i>Giuseppe Maddaloni, Alessandra De Angelis, Francesco Minicozzi, Claudio Martino, Maria Rosaria Pecce</i>	

CALIBRATION OF NUMERICAL MODELS TO SUPPORT SHM: THE CONSOLI PALACE OF GUBBIO, ITALY .....	3778
<i>Serena Cattari, Daniele Sivori, Sara Alfano, Laura Ierimonti, Nicola Cavalagli, Ilaria Venanzi, Filippo Ubertini</i>	

### **MS 40: ARTIFICIAL INTELLIGENCE & MACHINE LEARNING IN DESIGN AND ASSESSMENT OF STRUCTURES**

RAPID DESIGN OF R/C COLUMNS USING MACHINE LEARNING TECHNIQUES .....	3795
<i>Vassilis Papanikolaou, Aristotelis Charalampakis</i>	

DEVELOPMENT OF A NEW FUNDAMENTAL PERIOD FORMULA BY CONSIDERING SOIL-STRUCTURE INTERACTION WITH THE USE OF MACHINE LEARNING ALGORITHMS .....	3801
<i>Vicky-Lee Taljaard, Dewald Z. Gravett, Christos Mourtas, George Markou, Nikolaos Bakas, Manolis Papadrakakis</i>	
PREDICTING THE SHEAR CAPACITY OF REINFORCED CONCRETE SLENDER BEAMS WITHOUT STIRRUPS BY APPLYING ARTIFICIAL INTELLIGENCE ALGORITHMS .....	3810
<i>Zelda Spijckerman, Nikolaos Bakas, George Markou, Manolis Papadrakakis</i>	
STRUCTURAL DAMAGE PREDICTION UNDER SEISMIC SEQUENCE USING NEURAL NETWORKS .....	3820
<i>Petros C. Lazaridis, Ioannis E. Kavvadias, Konstantinos Demertzis, Lazaros Iliadis, Antonios Papaleonidas, Lazaros K. Vasiliadis, Anaxagoras Elenas</i>	
AUTOMATED ESTIMATION OF BUILDING HEIGHT THROUGH IMAGE PROCESSING .....	3837
<i>Pietro Carpanese, Marco Donà, Francesca da Porto</i>	
MACHINE LEARNING TECHNIQUES FOR THE ESTIMATION OF LIMIT STATE THRESHOLDS AND BRIDGE-SPECIFIC FRAGILITY ANALYSIS OF R/C BRIDGES .....	3848
<i>Sotiria Stefanidou, Vassilis Papanikolaou, Elias Paraskevopoulos, Andreas Kappos</i>	
LINKS OF AESTHETIC VALUE OF MULTI-CURVATURE ARTIFACTS, WITH THEIR STRUCTURAL BEHAVIOR, UTILIZING MACHINE LEARNING ALGORITHMS .....	3857
<i>Nikolaos Bakas, Neofytos Christofi, John Bellos, Dimitrios Antoniou, George Markou</i>	
PERFORMANCE AND SCALABILITY OF DEEP LEARNING MODELS TRAINED ON A HYBRID SUPERCOMPUTER: APPLICATION IN THE PREDICTION OF THE SHEAR STRENGTH OF SLENDER RC BEAMS .....	3878
<i>Nikolaos Bakas, George Markou, Dimos Charmpis, Kyriakos Hadjiyiannakou</i>	
PREDICTION OF THE EIGENPERIODS OF MDOF SHEAR BUILDINGS USING NEURAL NETWORKS .....	3894
<i>Vagelis Plevris, German Solorzano</i>	
 <b>MS 41: SEISMIC PERFORMANCE OF STRUCTURES WITH ISOLATION AND/OR ENERGY DISSIPATION DEVICES</b>	
SEISMIC PERFORMANCE OF STRUCTURES EQUIPPED WITH BRB .....	3912
<i>Paolo Castaldo, Enrico Tubaldi, Laura Gioiella</i>	
EFFECT OF LEAD RUBBER BEARING (LRB) MODELING TECHNIQUE ON THE SEISMIC RESPONSE OF BASE-ISOLATED BRIDGES .....	3930
<i>Vahid Aghaeidoost, Ahm Muntasir Billah</i>	
AN ADVANCED MODEL FOR THE FLUID VISCOUS DAMPER BRITTLE FAILURE .....	3942
<i>Laura Gioiella, Fabrizio Scozzese, Enrico Tubaldi, Laura Ragni, Andrea Dall'Asta</i>	
SEISMIC PERFORMANCE OF STEEL MRFS RETROFITTED WITH BRBS: INFLUENCE OF THE DESIGN DECISIONS FOR THE DEVICES .....	3957
<i>Fernando Gutiérrez-Urzuá, Fabio Freddi</i>	

EXPERIMENTAL INVESTIGATION OF SPHERICAL RUBBER SEISMIC ISOLATION BEARINGS .....	3970
<i>Antonios Katsamakas, Gabriel Belser, Michalis Vassiliou, M. Blondet, Božidar Stojadinovic</i>	
EXPERIMENTAL SEISMIC POST-TENSIONING PERFORMANCE AND LONG-TERM EFFECTS OF A POST-TENSIONED TIMBER FRAMED MODEL WITH DISSIPATIVE SYSTEMS .....	3982
<i>Antonio Di Cesare, Felice Carlo Ponzo, Nicla Lamarucciola, Domenico Nigro</i>	
EXPERIMENTAL COMPARISON BETWEEN FLAT AND CURVED SLIDING CONDITIONS FOR THE RESPONSE EVALUATION OF CURVED SURFACE SLIDER DEVICES .....	3992
<i>Alberto Pavese, Marco Furinghetti</i>	
THE NEW CAMERINO UNIVERSITY RESEARCH CENTER: DESIGN OF THE BASE-ISOLATED BUILDING AND DYNAMIC TESTING .....	4005
<i>Andrea Dall'Asta, Graziano Leoni, Fabio Micozzi, Laura Gioiella, N. Ceccolini, Laura Ragni</i>	
VARIATION IN RESPONSE OF A BRIDGE SEISMICALLY ISOLATED WITH LRBS UNDER THE EFFECT OF LOW AMBIENT TEMPERATURE .....	4015
<i>Esengul Cavdar, Volkan Karuk, Gokhan Ozdemir</i>	
SEISMIC PROTECTION OF MULTI-STORY STRUCTURES WITH NOVEL VIBRATION ABSORPTION DEVICES COMBINING NEGATIVE STIFFNESS AND INERTER .....	4026
<i>Konstantinos Kapasakalis, Georgios Florakis, Ioannis Antoniadis, Evangelos Sapountzakis</i>	
MULTI-LEVEL OPTIMISATION OF NONLINEAR VISCOUS DAMPERS FOR SEISMIC RETROFIT OF SUBSTANDARD STEEL FRAMES .....	4046
<i>Dario De Domenico, Iman Hajirasouliha</i>	
SEISMIC RETROFIT OF EXISTING PRECAST RC BUILDINGS WITH DISSIPATIVE DEVICES BASED ON CARBON WRAPPED STEEL TUBES .....	4058
<i>Lucia Praticò, Andrea Vittorio Pollini, Devis Sonda, Nicola Buratti</i>	
METAMODELING CHOICES FOR SEISMIC VULNERABILITY ASSESSMENT OF BRB-RETROFITTED LOW-DUCTILITY RC FRAMES .....	4078
<i>Jayadipta Ghosh, Fabio Freddi</i>	
NUMERICAL INVESTIGATION OF RUBBER BEARINGS WITH LOW SHAPE FACTOR UNDER SEISMIC EXCITATION .....	4091
<i>Alessandra Orfeo, Enrico Tubaldi, Alan Muhr, Daniele Losanno</i>	
INELASTIC RESPONSE MODES OF SEISMICALLY ISOLATED STRUCTURES: FAILURE OF THE ISOLATORS OR DAMAGE IN THE ISOLATED STRUCTURE? .....	4100
<i>Anastasios Tsiavos, Tomislav Markić, David Schlatter, Božidar Stojadinović</i>	
 <b>MS 42: ADVANCES IN MODEL REDUCTION TECHNIQUES OF COMPUTATIONAL AND STRUCTURAL DYNAMICS</b>	
A NEW PARALLEL ALGORITHM FOR THE OPTIMUM EMBEDDED REBAR MESH GENERATION FOR LARGE-SCALE REINFORCED CONCRETE STRUCTURES .....	4111
<i>Dewald Gravett, George Markou</i>	

ON THE APPLICATION OF GENERALISED SCHUR COMPLEMENTS TO SUBSYSTEM-LEVEL VARIABILITY QUANTIFICATION .....	4120
<i>Vladimir Yotov</i>	

#### **MS 43: ANALYSES AND DESIGN OF STEEL JOINTS UNDER CYCLIC ACTION**

BEHAVIOUR OF LAP SHEAR RIVETED CONNECTIONS WITH CONSTRUCTIONAL IMPERFECTIONS .....	4134
<i>Aldo Milone, A. De Martino</i>	

BEHAVIOR OF INNO3D JOINTS UNDER MONOTONIC AND CYCLIC LOADING .....	4142
<i>Arash Poursadrollah, A. De Martino</i>	

DESIGN AND ANALYSIS OF FREEDAM FRAMES: COMPARISON WITH TRADITIONAL CONNECTIONS .....	4149
<i>Maria Maglio, Camilla Naddei, Elide Nastri, Rosaria Russo, Paolo Todisco</i>	

COMPONENT MODELLING OF CONNECTIONS BETWEEN CIRCULAR-HOLLOW-SECTIONS AND THROUGH- ALL MEMBERS .....	4177
<i>A. Saldutti, Sabatino Di Benedetto, Massimo Latour, Gianvittorio Rizzano</i>	

SEISMIC RESPONSE OF INNOVATIVE CFS WALLS BRACED WITH UHS STEEL BARS: EXPERIMENTAL INVESTIGATION .....	4185
<i>Alessia Campiche</i>	

VALIDATION OF NOVEL SEISMIC DESIGN CRITERIA FOR LIGHTWEIGHT STEEL BUILDING IN EUROPE .....	4199
<i>Sarmad Shakeel, Marica Navarra, Alessia Campiche</i>	

BEHAVIOUR OF T-STUB UNDER MODE 2 AND 3 WITH HV AND HR BOLTS .....	4212
<i>Roberto Tartaglia, Mario D'Aniello</i>	

INFLUENCE OF THE JOINT BEHAVIOUR ON THE PERFORMANCE OF ORTHOGONAL EXOSKELETONS FOR SEISMIC RETROFIT .....	4219
<i>Roberto Tartaglia, Gianmaria Di Lorenzo, Antonio Formisano, Raffaele Landolfo</i>	

#### **Thematic Sessions**

##### **TS 5: DYNAMICS OF CONCRETE AND MASONRY STRUCTURES**

EVALUATION OF THE SEISMIC BEHAVIOR OF HISTORICAL CHURCHES REINFORCED BY CROSS-LAM ROOF- STRUCTURES .....	4226
<i>Nicola Longarini, Pietro Crespi, Marco Zucca</i>	

SEISMIC RESPONSE OF SEVEN EXISTING REINFORCED CONCRETE CHIMNEYS EQUIPPED WITH TUNED MASS DAMPERS UNDER FIVE STRONG SEISMIC EVENTS .....	4248
<i>Pietro Giuseppe Crespi, Nicola Longarini, Marco Valente, Marco Zucca</i>	

SHAKING TABLE TEST ON THE EFFECTS OF SHEAR WALLS FOR LONG-SPAN KOREAN TRADITIONAL TIMBER STRUCTURE .....	4262
<i>Yeong-Min Kim</i>	
INVESTIGATION OF THE IMPACT OF SEISMIC ZONE TO THE COST OF CONSTRUCTION OF A 5-STOREY R/C BUILDING .....	4272
<i>Theodoros Chrysanidis, Nikolaos Alamanis, Grigorios Papageorgiou, Georgia Kaouri</i>	
FLEXURAL PERFORMANCE OF CONCRETE BEAMS UNDER CYCLIC LOADING .....	4283
<i>Waseem Khan, Saleem Akhtar, Aruna Rawat, Anindya Basu</i>	
A MULTILAYER SHELL ELEMENT FOR NONLINEAR ANALYSIS OF R/C SHEAR WALLS .....	4294
<i>Vassilis Papanikolaou, Christos Karakostas, Konstantinos Morfidis, Emmanouil Baboukas</i>	
COMPARISON OF THE EFFICIENCY OF MINIMUM-THICKNESS CIRCULAR AND PARABOLIC ARCHES FOR VARIOUS GRAVITY CONDITIONS .....	4302
<i>Nicos Kalapodis, Georgios Kampas, Thomas McLean, Christian Malaga-Chuquitaype</i>	
LARGE-DISPLACEMENT RESPONSE OF UNREINFORCED MASONRY STRUCTURES: COMPARISON BETWEEN ANALYTICAL SOLUTIONS AND DEM MODELS INCLUDING OPEN-SOURCE SOFTWARE .....	4317
<i>Igor Bouckaert, Michele Godio, João Pacheco de Almeida</i>	
<b>TS 14: NUMERICAL SIMULATION METHODS FOR DYNAMIC PROBLEMS</b>	
NONLINEAR FINITE ELEMENT MODELS FOR EMBEDDED BASE CONNECTIONS .....	4331
<i>Nicolas Mora Bowen, Pablo Torres Rodas</i>	
LOCAL SCALE DAMPING MODEL FOR REINFORCED CONCRETE ELEMENTS .....	4341
<i>Clotilde Chambreuil, Cédric Giry, Frédéric Ragueneau, Pierre Léger</i>	
NUMERICAL STUDY ON THE DAMPING CHARACTERISTICS OF A SHOCK ABSORBER VALVE UTILIZING DIFFERENT VELOCITIES THROUGH CFD ANALYSIS .....	4353
<i>Yousif Badri, Thaer Syam, Sadok Sassi, Mohammed Hussein, Jamil Renno, Saud Ghani</i>	
ENERGY HARVESTING FROM RAILWAY VIBRATIONS – A NUMERICAL STUDY BASED ON BEAM-ON-ELASTIC-FOUNDATION UNDER QUASI-STATIC LOADING .....	4363
<i>Shahd Elshafei, Mohammed Hussein, Jamil Renno, Asan Mutalif</i>	
IMPACT FACTORS DERIVED FROM INTERNAL FORCES IN TIMOSHENKO BEAMS SUBJECTED TO CONCENTRATED MOVING LOADS .....	4373
<i>Benjamín Pinazo, Salvador Monleón, Carlos Lázaro, Pedro Museros</i>	
ON THE DEVELOPMENT OF A NOVEL APPROACH FOR SIMULATING ELASTIC BEAMS IN DUALSPHYSICS WITH THE USE OF THE PROJECT CHRONO LIBRARY .....	4385
<i>Salvatore Capasso, Bonaventura Tagliafierro, Iván Martínez-Estévez, José M. Domínguez, Joe El Rahi, Vasiliki Stratigaki, Alejandro J.C. Crespo, Rosario Montuori, Peter Troch, Moncho Gómez-Gesteira, Giacomo Viccione</i>	

DIGITAL SIMULATION OF WIND FIELD VELOCITY FOR EVALUATING PROPER STIFFNESS INDICATORS OF WINDOW MULLIONS .....	4400
<i>Gian Felice Giaccu, Antonio Cazzani</i>	
ANALYTICAL/NUMERICAL SOLUTIONS TO THE PROBLEM OF THE DYNAMIC RESPONSE OF AN ELASTIC PLATE ON A CONTINUOUSLY NON-HOMOGENEOUS CROSS-ANISOTROPIC VISCOELASTIC SOIL TO A MOVING LOAD .....	4407
<i>Niki D. Beskou, Edmond V. Muho</i>	
 <b>TS 15: OPTIMUM DESIGN AND CONTROL IN STRUCTURAL DYNAMICS AND EARTHQUAKE ENGINEERING</b>	
OPTIMAL DESIGN OF TID-BASED SYSTEM FOR THE CONTROL OF WIND-INDUCED VIBRATION IN TALL BUILDINGS THROUGH CULTURAL ALGORITHM .....	4428
<i>Luis Lara-Valencia, Mateo Ramírez-Acevedo, José Brito, Daniel Caicedo, Yosef Farbiarz</i>	
A PARAMETRIC ANALYSIS OF THE SEISMIC PERFORMANCE OF BRIDGES AS A FUNCTION OF THE DCFP DEVICE PROPERTIES .....	4439
<i>Paolo Castaldo, Guglielmo Amendola</i>	
SEISMIC PERFORMANCE OF BRIDGES ISOLATED WITH FPS .....	4452
<i>Paolo Castaldo, Guglielmo Amendola</i>	
CRITICAL ACCELERATION, SEISMIC SLIDING DISPLACEMENT AND SMART DESIGN OF CANTILEVER WALLS .....	4467
<i>Loukas C. Katsenlis, Constantine A. Stamatopoulos, Vassilis P. Panoskaltis</i>	
COMPARISON OF CONTROL ALGORITHMS APPLIED TO AN HYBRID MASS DAMPER ATTACHED TO AN WIND TURBINE TOWER .....	4481
<i>Pedro Rocha, Suzana Avila</i>	
PRELIMINARY STUDY OF AN ARDUINO CONTROLLED SHAKE TABLE TO LOW-FREQUENCY TEST .....	4494
<i>Ledymar F. Moreno, Marcus V. G. de Moraes, Suzana M. Avila</i>	
EFFICIENT DAMPER DESIGN METHOD FOR ELASTIC-PLASTIC MDOF STRUCTURES UNDER CONSECUTIVE-LEVEL EARTHQUAKES .....	4508
<i>Hiroki Akehashi, Izuru Takewaki</i>	
DIFFERENTIATION OF THE CONSTRUCTION COST OF A FIFTEEN STOREY R/C BUILDING DEPENDING ON THE SEISMIC HAZARD ZONE .....	4520
<i>Paulina Tselempi, Theodoros Chrysanidis</i>	
DOES THE SEISMICITY OF THE AREA HAVE AN IMPACT ON THE CONSTRUCTION COST OF THE LOAD-BEARING STRUCTURE OF R/C BUILDINGS? .....	4535
<i>Thomas-Erik Makris, Theodoros Chrysanidis</i>	

IMPROVING ENERGY DISSIPATION CAPACITY OF NATURALLY BUCKLING BRACES UNDER LOW-CYCLE FATIGUE LOADS .....	4547
<i>Shadiya Jamshiyas, Kazuhiro Hayashi, Xiaopo Yang, Konstantinos Skalomenos</i>	

## **TS 17: PERFORMANCE-BASED EARTHQUAKE ENGINEERING**

NUMERICAL MODELING OF SLIP RESPONSE OF Laterally SWAYING BRIDGE PIERS' TENSILE REINFORCEMENT .....	4558
<i>Konstantinos G. Megalooikonomou</i>	

SEISMIC RISK ASSESSMENT OF A PROCESS PLANT UNIT ACCOUNTING FOR DYNAMIC INTERACTION .....	4568
<i>George Karagiannakis, Luigi di Sarno</i>	

A COMPARATIVE STUDY ON SEISMIC RESPONSE OF A SUPER HIGH-RISE BUILDING USING CONVENTIONAL AND MODAL PUSHOVER ANALYSIS .....	4582
<i>Xianlong Zhang, Hao Wu, Qiao Yu, Yang Liu, Lingzhi Li, Wannan Xu, Junyan Zhou</i>	

NUMERICAL PARAMETRIC STUDY OF GRILLE-TYPE STEEL CONCRETE COMPOSITE SHEAR WALL FOR SEISMIC REGIONS .....	4593
<i>Tian Wang, Qiao Yu, Hao Wu, Yang Liu, Lingzhi Li, Xianlong Zhang</i>	

SEISMIC RELIABILITY OF BRIDGES ISOLATED WITH FPS .....	4607
<i>Paolo Castaldo, Guglielmo Amendola, Luca Giordano, Diego Gino, Elena Miceli</i>	

INTENSITY MEASURES PROPERTIES AND SELECTION FOR RISK ANALYSIS ON STRUCTURES SUBJECTED TO EARTHQUAKE INDUCED BUILDING POUNDING WITH A NON SMOOTH CONTACT DYNAMICS METHOD .....	4621
<i>Thomas Langlade, David Bertrand, Stéphane Grange, Gabriel Candia, Juan Carlos de la Llera</i>	

ESTIMATION OF DUCTILITY IN ASYMMETRIC-PLAN STRUCTURES .....	4633
<i>Kaan Kaatsiz, Halûk Sucuoğlu</i>	

A MULTI-OBJECTIVE DISPLACEMENT-BASED DESIGN PROCEDURE OF VISCOUS AND HYSTERETIC DAMPED BRACES FOR THE SEISMIC PROTECTION OF RC BUILDINGS .....	4646
<i>Fabio Mazza, Carlo Pasceri</i>	

EFFECT OF THE DAMPING RATIO OF THE NON-STRUCTURAL COMPONENTS ON FLOOR ACCELERATION DEMANDS IN TORSIONALLY IRREGULAR BUILDINGS .....	4660

### Abstract

*In the context of the present work, the influence of the degree of tension on the phenomenon of transverse instability of reinforced concrete walls is examined. The present investigation is basically analytical but it contains experimental results of 4 test specimens published from the first author in the past. These specimens simulate the extreme boundary edges of structural walls. All columns simulate only the extreme reinforced areas of the walls, in order to study the basic mechanism of the phenomenon. The detailing of the specimens consists of 4 rebars with a diameter of 8 mm for each bar. The geometric dimensions are the same for all specimens. What differentiates the specimens from each other is the degree of tension they have sustained. More specifically, the tensile degrees used are 10%, 20%, 30%, 50%. The loading stages of each specimen for all specimens are as follows: (a) Uniaxial central tensile loading on each test specimen, (b) Uniaxial central compression loading on each specimen till its failure due to buckling or due to an excess of its cross-section compressive strength. The present study focuses on the tensile loading stage only. Extreme tensile strains are also used, e.g., 30% and 50%, to take into account the cases of extreme seismic excitations. First, the experimental results from a previous publication are presented and afterwards they are followed by the numerical investigation of these 4 specimens using appropriate finite element software. Useful conclusions are drawn regarding the precision of the experimental tests investigating the influence of the degree of elongation on the phenomenon of transverse buckling. These conclusions are substantiated both experimentally and analytically, as the results of the tensile experiments are compared with the corresponding results of the analytical investigation.*

**Keywords:** Degree of elongation, Lateral buckling, Structural walls, Tensile loading

## 1 INTRODUCTION

Structural behavior and soil-structure interaction has troubled engineers worldwide for various types of structures [1]–[10]. Structural walls play an important role in the structures' behavior and safety against horizontal loads and especially against earthquake cyclic loading [11], [12]. It is well-known that the vast part of seismic loading is resisted by seismic walls in reinforced concrete structures [13]–[26]. One critical mode of failure which can appear during earthquake cyclic loading is the out-of-plane buckling of R/C shear walls [27]–[36]. It has been observed that such type of failure is so critical that can lead to partial or total collapses of multi-storey reinforced concrete buildings [37]. This phenomenon can appear when the boundary edges of seismic walls have sustained a large size of tensile loading during the first semi-cycle of seismic loading and then are subjected to a compressive loading during the second semi-cycle of earthquake loading [38]–[41]. Transverse buckling appears when the cracks formed during the first stage of tensile loading have such a large width that makes it impossible to be closed during the second stage of compressive loading [42]–[51]. The fact that the cracks cannot close when compression loading is applied leads to the wall buckling transverse to its plane. This phenomenon is called in international bibliography lateral buckling or transverse buckling or out-of-plane buckling and sometimes instead of using the word “buckling”, the word “instability” is preferred.

The present study uses experimental tests performed in the past by the first author trying to investigate the mechanical parameters affecting the transverse instability [28]. These specimens were subjected to tensile strain equal to 10‰, 20‰, 30‰ and 50‰. In the framework of the present work, the four specimens subjected to tensile loading are modelled using finite element software and the results of this analytical investigation are compared to the existing experimental results concerning the tensile loading stage. It is noted that the experiments have taken place in the Laboratory of Strength of Materials of Aristotle University of Thessaloniki and the analysis of the results has taken place in Demokritos University of Thrace.

## 2 EXPERIMENTAL RESEARCH

### 2.1 Test specimen characteristics

The experimental investigation for the four test specimens has been described in detail by the first author in the past [28]. Figure 1a shows the geometrical characteristics of the four test specimens, while Figure 1b displays the load test setup used for the application of the tensile loading. It is noted the fact that the tensile loading is the first stage of the two loading stages. In the framework of the present study, only the experimental results of the tensile loading stage are compared to the analytical ones. Table 1 shows the test specimens' characteristics.

N/A	Specimen	Dimensions (cm)	Longitudinal reinforcement	Transverse reinforcement	Longitudinal reinforcement ratio (%)	Degree of elongation (‰)
1	L-10	15x7.5x76	4xD8	D4.2@33 mm	1.79	10.00
2	L-20	15x7.5x76	4xD8	D4.2@33 mm	1.79	20.00
3	L-30	15x7.5x76	4xD8	D4.2@33 mm	1.79	30.00
4	L-50	15x7.5x76	4xD8	D4.2@33 mm	1.79	50.00

Table 1: Dimensions of the test specimens.

(a)

(b)

Figure 1: (a) Vertical reinforcement layout, (b) Test setup for tensile loading.

## 2.2 Materials

For all test specimens, materials used for their construction and their characteristics were also described by the first author in the past [28]. Table 2 displays the concrete resistance for all test specimens at 28 days and at the day that the compression test has taken place while Table 3 shows the mechanical properties for the longitudinal steel and the transverse ties.

N/A	Specimen	Concrete cube resistance (28 days) (MPa)	Concrete cube resistance (Compression test day) (MPa)	Concrete cylinder resistance (Compression test day) (MPa)
1	L-10	24.89	28.00	23.00
2	L-20	24.89	28.00	23.00
3	L-30	23.33	25.56	20.56
4	L-50	24.89	28.00	23.00

Table 2: Concrete mechanical properties.

Reinforcement	Yield strength (MPa)	Ultimate strength (MPa)
D8 (Longitudinal reinforcement)	603.77	743.10
D4.2 (Transverse ties)	552.02	670.91

Table 3: Reinforcement mechanical properties.

## 2.3 Experimental results

Each one of the four test specimens has been subjected to a different degree of elongation according to Table 1 and the results published by the first author in the past [28]. Figure 2 displays the shape of test specimens after the uniaxial tensile test has taken place. It is obvious that several cracks of different width have formed after the tensile loading according to the degree of elongation applied to each specimen.

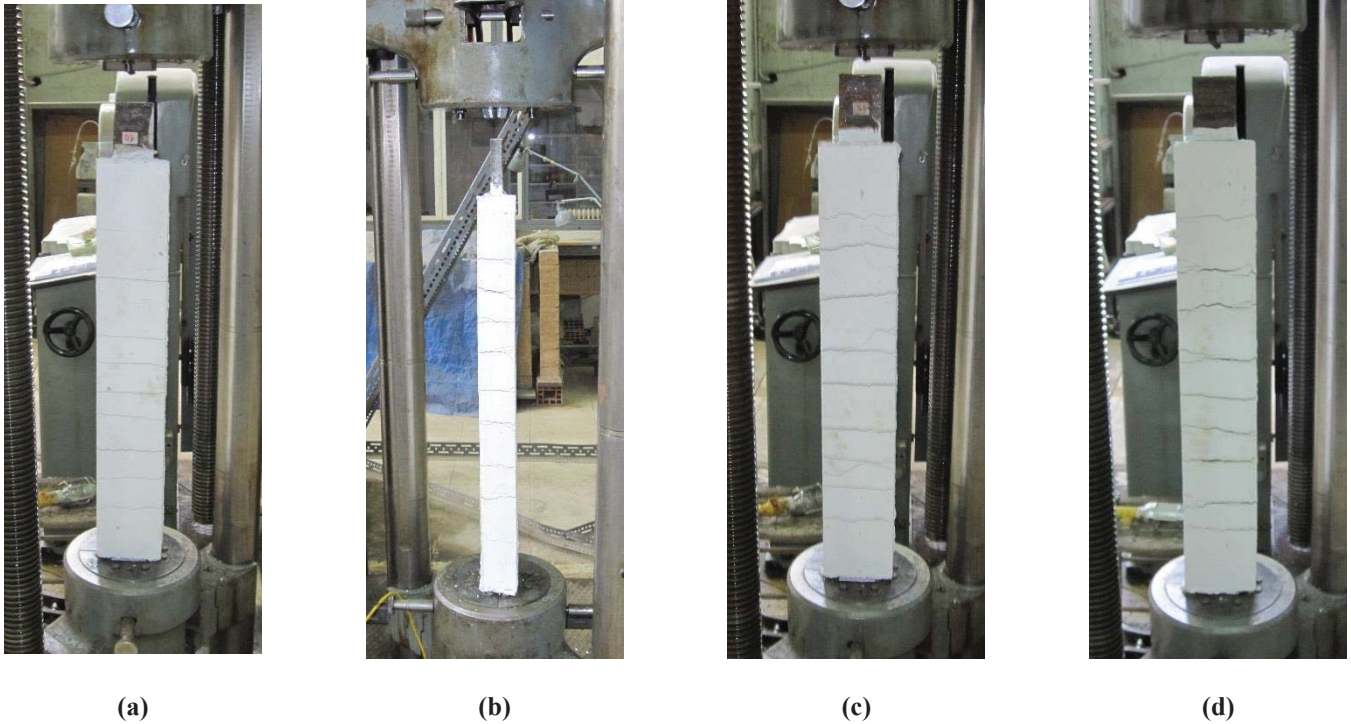

Figure 2: Specimens with low reinforcement ratio after the uniaxial tensile test: (a) L-10, (b) L-20, (c) L-30, (d) L-50

## 3 ANALYTICAL RESEARCH

### 3.1 Modeling of test specimens

The analytical research has taken place using a finite element software. 3D elements were used in this software to model all four test specimens subjected to tensile loading. It is noted, as it has been said before, that the present work focuses on modeling only the first stage of loading; meaning the tensile loading path till certain preselected and different degrees of elongation. For the concrete material, the inelastic concrete model found in the software library of isotropic plasticity has been chosen. For the reinforcement bar material, the properties derived from experiments are inserted in the software to model the inelastic behaviour of reinforcement steel. A bilinear isotropic model has been chosen for the behaviour of rebar steel. The same inelastic model has been selected to model the behaviour of the steel used for the transverse ties. This model is again the bilinear isotropic model. 3D finite elements having an edge of 2 cm are used for the modeling of the concrete column section. Both the longitudinal reinforcement and the transverse ties are modeled using 3D finite elements having a length equal to 1 cm. Figure 3 shows the 3D model of the column either for the whole column section or the reinforcement steel only. The column model is considered fixed at its base.

Figure 3: (a) 3D model for column, (b) 3D model for the column reinforcement.

### 3.2 Analytical results

Figure 4 displays the displacement along the column height after the end of the tensile loading test for all four test specimens. The displacement is zero at the fixed column base.

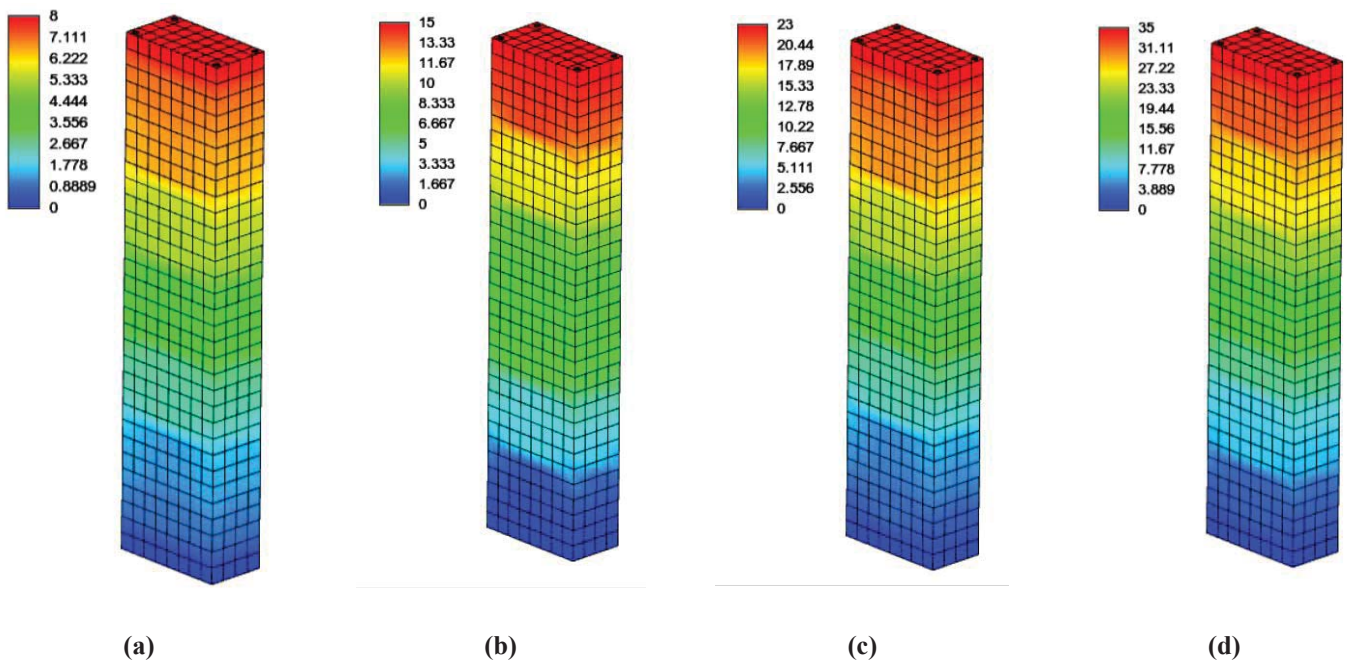

Figure 4: Displacement along the column axis at the end of the tensile test: (a) L-10, (b) L-20, (c) L-30, (d) L-50

## 4 ANALYSIS OF RESULTS

### 4.1 Analytical versus experimental results

A comparison takes place between the load versus elongation diagrams which have resulted from the experimental tensile tests and the tests applied to the analytical models of the four specimens modeling the boundary edges of seismic walls (Figures 5-8).

Figure 5: Load versus elongation diagram for specimen L-10.

Figure 6: Load versus elongation diagram for specimen L-20.

Figure 7: Load versus elongation diagram for specimen L-30.

Figure 8: Load versus elongation diagram for specimen L-50.

## 4.2 Analysis of results

The analysis of the previous results leads to the following:

1. Figure 4 displays the displacement along the vertical axis which is the Z-axis and coincides with the height of the prism specimens modeling the boundary edges of structural walls. It can be seen that each specimen is strained till the preselected displacement according to the preselected degree of elongation.
2. The vertical displacement is zero at the base of the prisms since the base is rigid (Figure 4). The maximum vertical displacement is found towards the upper part of the specimens where the tensile load is applied. The same phenomenon takes place in the tensile experiments where the tensile load is applied at the upper part of the test specimens while at the bottom part the test specimens are held rigidly by the grapples of the tensile machine.
3. It is obvious that there is an almost perfect correlation between the experimental and the analytical results for all test specimens (Figures 5-8). The elastic branch is the same both in the experiments and the analysis. The same thing applies for the plastic branch after the yielding. The plastic branch of the analyses coincides with the plastic branch from the tensile tests.
4. Yielding takes place almost at the same load both for the tests and the analyses for all test specimens.
5. There is only one exception concerning test specimen L-20 (Figure 6). The plastic branch for this specimen is almost the same both for the experiment and the relevant analysis. There is a noticeable deviation for the elastic branch of the diagrams. This can be explained probably due to a slip that might have taken place during the onset of the application of the tensile load for this specimen. Probably, an initial slip and a relevant error to the measured elongation might have led to an experimental elastic branch with smaller inclination.
6. The effective length of the test specimens is the one which has been modelled only since this is the length in which the tensile elongation appears (Figure 1). The effective length is equal to 640 mm (Figure 1).

## 5 CONCLUSIONS

The results stemmed from the tensile experiments and the relevant analytical procedures concerning the behavior of the boundary edges of seismic walls under the tensile stage of load application has led to the following conclusions:

1. There is an almost excellent correlation between the experimental results and the analytical results concerning the tensile loading. The analysis has taken place using 3D finite elements.
2. The elastic branch, the yielding point and the plastic branch coincide almost perfectly for almost all specimens except one where the deviation noticed for the elastic branch only can be attributed probably to slip effects and thus, to deviations concerning the measuring of the elongation.
3. The degree of elongation is a very crucial mechanical parameter that affects tremendously the behavior of the boundary edges of structural walls and its investigation has to be applied in the proper and right way following a correct procedure. The convergence between the experimental and the numerical results proves that the procedure applied, probably, follows the right path.
4. A future research could and should model the whole test specimen and not only the effective length in order to simulate even more precisely the experimental behavior.

### Abstract

*In the context of the present work, the influence of the longitudinal reinforcement ratio on the phenomenon of lateral buckling of reinforced concrete walls is examined. The present investigation is basically analytical but it contains experimental results of 6 test specimens published from the first author already. These specimens simulate only the extreme boundary edges of structural walls to study the basic mechanism of the transverse instability phenomenon. The elongation degree used for all six specimens is equal to 30‰. The geometric dimensions are the same for all specimens. What differentiates the specimens from each other is the longitudinal reinforcement ratio. More specifically, the longitudinal reinforcement ratios used are 1.79%, 2.68%, 3.18%, 3.68%, 4.02% and 4.19%. The loading stages for all specimens are as follows: (a) Uniaxial central tensile loading on each test specimen, (b) Uniaxial central compression loading on each specimen till its failure due to buckling. The present study focuses on the tensile loading stage only. Extreme tensile strain of 30‰ is used to take into account the cases of extreme seismic excitations. First, the experimental results from an already accepted publication are presented and afterwards they are followed by the numerical investigation of these 6 specimens using appropriate finite element software. Useful conclusions are drawn regarding the precision of the experimental tests investigating the influence of the longitudinal reinforcement ratio on the phenomenon of transverse buckling. These conclusions are substantiated both experimentally and analytically, as the results of the tensile experiments are compared with the corresponding results of the analytical investigation.*

**Keywords:** Longitudinal reinforcement ratio, Lateral buckling, Seismic walls, Tensile load

## 1 INTRODUCTION

Engineers worldwide have been troubled for the structural behavior and soil-structure interaction for various types of structures [1]–[10]. Structural walls play an important role in the structures' behavior and safety against horizontal loads and especially against earthquake cyclic loading [11], [12]. It is well-known that the vast part of seismic loading is resisted by seismic walls in reinforced concrete structures [13]–[26]. One critical mode of failure which can appear during earthquake cyclic loading is the lateral buckling of R/C shear walls [27]–[36]. It has been observed that such type of failure is so critical that can lead to partial or total collapses of multi-storey reinforced concrete buildings [37]. This phenomenon can appear when the boundary edges of seismic walls have sustained a large size of tensile loading during the first semi-cycle of seismic loading and then are subjected to a compressive loading during the second semi-cycle of earthquake loading [38]–[41]. Transverse buckling appears when the cracks formed during the first stage of tensile loading have such a large width that makes it impossible to be closed during the second stage of compressive loading [42]–[50].

The present study uses experimental tests performed already by the first author trying to investigate the mechanical parameters affecting the transverse instability [51]. These specimens were all subjected to tensile strain equal to 30‰ but they had a different longitudinal reinforcement ratio. In the framework of the present work, the six specimens subjected to tensile loading are modelled using finite element software and the results of this analytical investigation are compared to the existing experimental results concerning the tensile loading stage. It is noted that the experiments have taken place in the Laboratory of Strength of Materials of Aristotle University of Thessaloniki and the analysis of the results has taken place in Demokritos University of Thrace.

## 2 EXPERIMENTAL RESEARCH

### 2.1 Test specimen characteristics

The experimental investigation for the six test specimens has been described in detail by the first author already [51]. Figure 1a shows the geometrical characteristics of one of the six test specimens and more specifically the test specimen detailed with longitudinal reinforcement of 4 bars of 8 mm diameter and 2 bars of 10 mm diameter. Figure 1b displays the load test setup used for the application of the tensile loading. It is noted the fact that the tensile loading is the first stage of the two loading stages. In the framework of the present study, only the experimental results of the tensile loading stage are compared to the analytical ones. Table 1 shows the test specimens' characteristics.

N/A	Specimen	Dimensions (cm)	Longitudinal reinforcement	Transverse reinforcement	Longitudinal reinforcement ratio (%)	Elongation degree (‰)
1	S-1.79-4Ø8	15x7.5x76	4xD8	D4.2@33 mm	1.79	30.00
2	S-2.68-6Ø8	15x7.5x76	6xD8	D4.2@33 mm	2.68	30.00
3	S-3.19-4Ø8+2Ø10	15x7.5x76	4xD8+2xD10	D4.2@33 mm	3.18	30.00
4	S-3.68-4Ø10+2Ø8	15x7.5x76	4xD10+2xD8	D4.2@33 mm	3.68	30.00
5	S-4.02-4Ø12	15x7.5x76	4xD12	D4.2@33 mm	4.02	30.00
6	S-4.19-6Ø10	15x7.5x76	6xD10	D4.2@33 mm	4.19	30.00

Table 1: Dimensions of the test specimens.

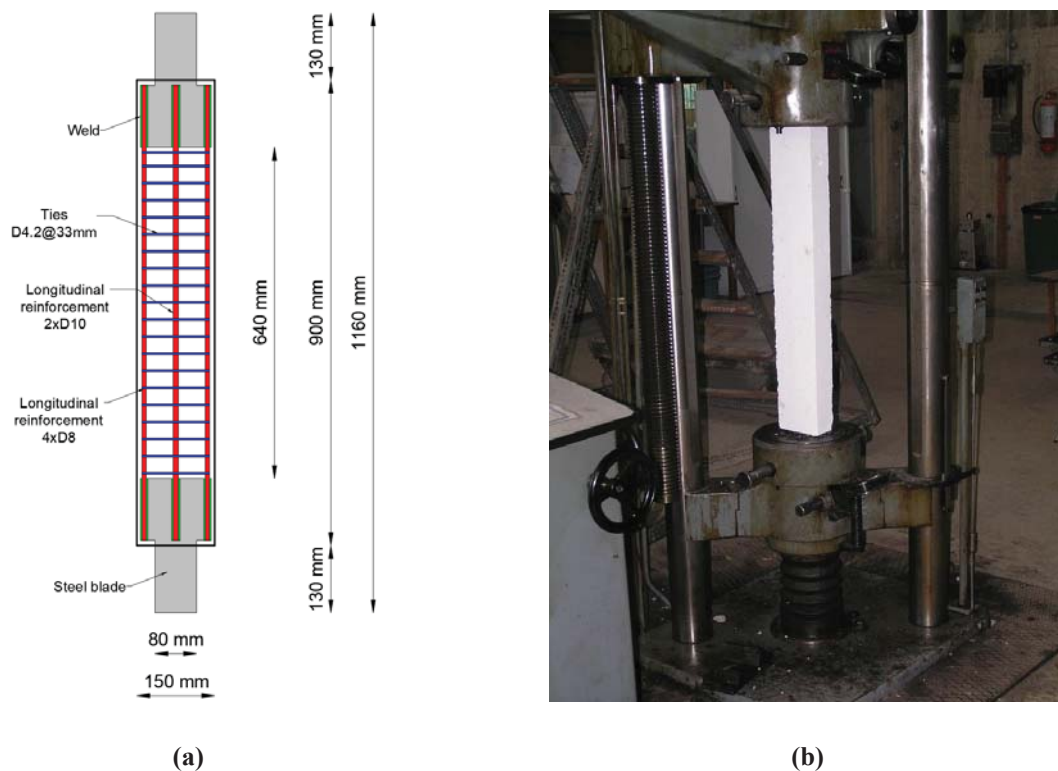

Figure 1: (a) Vertical reinforcement layout (Reinforcement differs for each specimen. Example shows a typical longitudinal reinforcement 4xD8+2xD10.), (b) Test setup for tensile loading.

## 2.2 Materials

Materials used and their characteristics were also described by the first author already [28]. Table 2 displays the concrete mechanical properties and Table 3 the steel characteristics.

N/A	Specimen	Concrete cube resistance (28 days) (MPa)	Concrete cube resistance (Compression test day) (MPa)	Concrete cylinder resistance (Compression test day) (MPa)
1	S-1.79-4Ø8	23.33	25.56	20.56
2	S-2.68-6Ø8	22.22	27.55	22.55
3	S-3.19-4Ø8+2Ø10	22.82	25.78	20.78
4	S-3.68-4Ø10+2Ø8	22.82	25.78	20.78
5	S-4.02-4Ø12	23.26	27.85	22.85
6	S-4.19-6Ø10	23.26	27.85	22.85

Table 2: Concrete mechanical properties.

Reinforcement	Yield strength (MPa)	Ultimate strength (MPa)
D8 (Longitudinal reinforcement)	603.77	743.10
D10 (Longitudinal reinforcement)	552.02	670.91
D12 (Longitudinal reinforcement)	560.27	666.43
D4.2 (Transverse ties)	552.02	670.91

Table 3: Reinforcement mechanical properties.

### 2.3 Experimental results

Each one of the six test specimens has been subjected to the same degree of elongation according to Table 1 and the results have been published by the first author already [51]. Figure 2 displays the shape of test specimens after the uniaxial tensile test has taken place. It is obvious that several cracks of different width have formed after the tensile loading according to the longitudinal reinforcement ratio that each specimen has.

Figure 2: State of specimens after the end of the tensile experiment: (a) S-1.79-4Ø8, (b) S-2.68-6Ø8, (c) S-3.19-4Ø8+2Ø10, (d) S-3.68-4Ø10+2Ø8, (e) S-4.02-4Ø12, (f) S-4.19-6Ø10

### 3 ANALYTICAL RESEARCH

#### 3.1 Modeling of test specimens

The analytical research has taken place using 3D elements to model specimens subjected only to tensile loading. Inelastic models are used both for concrete and steel. Figure 3 shows the 3D model both for the whole column section and its corresponding reinforcement steel.

Figure 3: 3D model for column and reinforcement for: (a) S-1.79-4Ø8, (b) S-2.68-6Ø8, (c) S-3.19-4Ø8+2Ø10, (d) S-3.68-4Ø10+2Ø8, (e) S-4.02-4Ø12, (f) S-4.19-6Ø10

### 3.2 Analytical results

Figure 4 displays the displacement along the column height after the end of the tensile loading test for all six test specimens. The displacement is zero at the fixed column base.

Figure 4: Displacement along the column axis at the end of the tensile test (mm): (a) S-1.79-4Ø8, (b) S-2.68-6Ø8, (c) S-3.19-4Ø8+2Ø10, (d) S-3.68-4Ø10+2Ø8, (e) S-4.02-4Ø12, (f) S-4.19-6Ø10

## 4 ANALYSIS OF RESULTS

### 4.1 Analytical versus experimental results

Figures 5-10 show the comparison between the experimental and the analytical diagrams of load versus elongation for specimens modeling the boundary edges of R/C walls.

Figure 5: Load versus elongation diagram for specimen S-1.79-4Ø8.

Figure 6: Load versus elongation diagram for specimen S-2.68-6Ø8.

Figure 7: Load versus elongation diagram for specimen S-3.19-4Ø8+2Ø10.

Figure 8: Load versus elongation diagram for specimen S-3.68-4Ø10+2Ø8.

## 4.2 Analysis of results

The analysis of the previous results leads to the following:

1. Figure 4 shows that the vertical displacement is zero at the base of the prisms since the base is rigid. The maximum vertical displacement is found towards the upper part of the specimens where the tensile load is applied. The same phenomenon at the tensile experiments, too.
2. It is obvious that there is a very good correlation between the experimental and the analytical results for all test specimens (Figures 5-10). This very good correlation can be noticed both for the elastic and the plastic branch, as well as for the point of yield.
3. The 640 mm effective length of the test specimens is the one which has been modelled only since this is the length in which the tensile elongation appears (Figure 1).

## 5 CONCLUSIONS

The conclusions resulted from the tensile experiments and the relevant analytical procedures concerning the behavior of the extreme edges of R/C walls are:

1. There is a very good correlation between the experimental results and the analytical results concerning the tensile loading. This very good correlation has to do with the elastic branch, the yielding point and the plastic branch for all six specimens.
2. The longitudinal reinforcement ratio is a significant mechanical parameter that affects the behavior of the extreme edges of seismic walls and its investigation has to be applied in the proper and right way following a correct procedure. The good convergence between the experimental and the numerical results proves that the procedure applied, probably, follows the correct methodology.
3. A future research could and should model the whole test specimen and not only the effective length in order to simulate even more precisely the experimental behavior.

### Abstract

*One of the main objectives to be achieved for the safety of industrial precast buildings with simple friction beam-to-column connections is the reduction of their relative displacement. This goal is generally achieved through a global strengthening of the building or by locally introducing mechanical connecting devices between the elements. However, for low seismicity areas, these interventions may not be required, and it could be interesting to evaluate the level of safety achieved by simple friction; such an information would allow for instance the prioritization of the retrofit interventions.*

*This paper aims to establish criteria for evaluating the loss of support probability in existing precast buildings in the case of a seismic event. The behavior of the friction connection is evaluated through a simplified model that describes the behavior of a portal frame composed of two columns and one beam. The equations of motion are derived, and a parametric analysis is performed by investigating the influence of the geometry of the structural elements, the non-linear behavior of the columns, and the friction coefficient used in the column-beam connections for varying horizontal and vertical seismic acceleration. The objective of the sensitivity analysis is to provide some preliminary considerations about the influence of the main parameters that characterize the existing precast structure on the loss of the support probability.*

**Keywords:** Precast buildings; friction connection; beam-to-column connection; simplified models.

---

## 1 INTRODUCTION

The Italian building stock encompasses many precast concrete structures; the main advantage of this construction technology lies on high quality control materials and the short construction time. The typical structural layout of these buildings consists of a single story with a rectangular plan in which the bearing structure is made of prefabricated columns supporting double tapered prestressed beams. A great share of these buildings was designed before the enforcement of modern anti-seismic regulation codes and, therefore, they were not designed to withstand the horizontal loads.

The seismic events that occurred in 2012 in Emilia-Romagna, Veneto and Lombardy, highlighted the main vulnerabilities of existing precast industrial buildings [1, 2, 3, 4, 5, 6, 7, 8, 9]; the main vulnerabilities consist in the breaking of the fork, the overturning of the infill panels, the reaching of the ultimate rotation of the column, the loss of the beam-to-column support and/or the loss of the support of other roofing elements [10, 11, 12, 13, 14, 15, 16, 17]. The loss of the support is due to the absence of adequate structural detailing in the connection between beam and columns.

To date, in Italy, the implementation of mechanical devices between the structural elements of precast buildings (e.g. column and beam at the beam-to-column support) is required for new buildings and new technological solution have been studied in recent years [18]; such a detailing was not common practice in the past. However, for low seismicity areas, the seismic retrofit of these connections may not be necessary, and it could be interesting to evaluate the level of safety achieved by simple friction; such an information would allow for instance the prioritization of the retrofit interventions.

The problem of loss of support in friction beam-column connections has been previously addressed: Magliulo et al. [6] and Belleri et al. [1] evaluated the minimum value of the friction coefficient required to avoid the sliding of the beam under the hypothesis of perfect correlation between the maximum values of the horizontal and vertical components of the seismic inputs; Demartino et al. [19] approached the problem by defining simplified numerical finite element models of the friction beam-column connection, starting from the equations of motion of the friction connection considering a rigid block model having two degrees of freedom. Furthermore, the effect of the seismic-hazard disaggregation was considered. The results showed that the minimum friction coefficient required to prevent the sliding of the beam depends on the period of the structure and the damping coefficients used in the equations.

In this paper, a new analytical model is proposed for the evaluation of the seismic response of a simple portal frame with friction beam-column connections. The portal frame is described by means of a dynamic system with four degrees of freedom (DOF), 3 horizontal and 1 vertical. The main novelty introduced by the present work relies on the simplified model proposed and on the evaluation of the influence of various parameters. Section 2 describes the proposed numerical model. In section 3, parametric analyses are carried out to evaluate the influence of the main parameters on the global response of the simplified model. In section 4, the analytical model is compared with finite element nonlinear time history analyses, carried out on a selected reference structure. Finally, a concise discussion of the results obtained in sections 3 and 4 and some considerations on possible improvements of the proposed model are made.

## 2 SIMPLIFIED SYSTEM DEVELOPMENT

The simplified 4DOF system used to describe the transverse portal-like response of a typical precast industrial building is here introduced and described. Similar models were adopted in previous research work [20, 21, 22, 23, 19].

## 2.1 Simplified model

The lateral displacement of the 2 columns and the displacement of the beam is described through a system characterized by 3 horizontal DOFs plus 1 vertical DOF (Figure 1b); the simplified system consists of 3 masses connected by springs ( $k_1, k_{12}, k_{23}, k_3$ ) and viscous dampers ( $c_1, c_{12}, c_{23}, c_3$ ) and subjected to the ground horizontal and vertical accelerations ( $\ddot{X}_g, \ddot{Y}_g$ ). The chosen degrees of freedom to describe the behavior of the system are the horizontal displacements of the top of the two columns ( $u_1, u_3$ ), and the horizontal and vertical displacement of the beam ( $u_2, v_2$ ). The simplified system is drawn in Figure 1b.

Figure 1: a) layout of a typical portal-like precast industrial building; b) simplified 3DOF system adopted.

The parameters used to describe the considered simplified systems are here presented; the subscripts refer to the element considered (i.e. 1 for the left-side column; 2 for the beam; 3 for the right-side column) or, in the case of connections, the elements that are connected by the link (e.g. subscript- $i$  refers to the DOF of the element- $i$ , while the subscript- $ij$  refers to the link describing the relative displacement between the element- $i$  and the element- $j$ ). The element-1 and the element-3 are described by the masses  $m_1$  and  $m_3$ , the elastic stiffnesses  $k_1$  and  $k_3$ , the damping coefficients  $c_1$  and  $c_3$ , and, to consider the nonlinear behavior of the columns, the yielding forces  $F_{y,1}$  and  $F_{y,3}$ , respectively. The element-2, represented by the mass  $m_2$ , is connected to the element-1 and element-3 by means of friction connections. The elastic stiffnesses  $k_{12}$  and  $k_{23}$  are associated for instance with the neoprene pads. The friction forces are  $F_{y,12}$  and  $F_{y,13}$ .

As for the vertical component of element-2, the generalized mass ( $M_n$ ) and the generalized stiffness ( $K_n$ ) are introduced to represent the participating mass and stiffness of the  $n$ -th vertical mode of the beam. In this work only the first vertical mode is considered; consequently, the subscript - $n$  is set to be equal to 1 ( $M_1, K_1$ ).

In the analyses described in the following section, the main parameter investigated is the relative displacements between the beam and the supporting columns ( $\delta_{12}, \delta_{13}$ ). For sake of clarity,  $\delta_{12}$  can be calculated as the difference between  $u_2$  and  $u_1$ ; similar considerations can be drawn for  $\delta_{13}$ .

## 2.2 Equations of motion and solving method

The free-body model of the 4DOF system is represented in Figure 2.

Figure 2: Free-body diagrams of the 3DOF system.

By enforcing balance to horizontal translation of element-1, element-3, it yields:

$$m_1 \ddot{u}_1 + k_1 u_1 + c_1 \dot{u}_1 - k_{12}(u_2 - u_1) - c_{12}(\dot{u}_2 - \dot{u}_1) = -m_1 \ddot{X}_g \quad (1)$$

$$m_3 \ddot{u}_3 + k_3 u_3 + c_3 \dot{u}_3 + k_{13}(u_3 - u_2) + c_{13}(\dot{u}_3 - \dot{u}_2) = -m_3 \ddot{X}_g \quad (2)$$

The horizontal equilibrium on element-2 is

$$m_2 \ddot{u}_2 + k_{12}(u_2 - u_1) + c_{12}(\dot{u}_2 - \dot{u}_1) - k_{13}(u_3 - u_2) - c_{13}(\dot{u}_3 - \dot{u}_2) = -m_2 \ddot{X}_g \quad (3)$$

The vertical component of element-2, expressed through its time-derivative in principal coordinates [24], is

$$\partial v / \partial t = [-K_1 v_2 - M_1 \ddot{v}_2] \cdot \frac{1}{M_1} \quad (4)^1$$

For a simply supported beam [24]

$$\begin{aligned} M_1 &= m_2 / 2 \\ K_1 &= \frac{\pi^4 EI}{2L^3} \end{aligned} \quad (5)$$

Where  $E$  and  $I$  are the elastic modulus and the moment of inertia of the horizontal beam, respectively, and  $L$  is the length of the beam.

From the vertical displacement expressed in principal coordinates, the shear at the beam ends ( $V(0, t)$  and  $V(L, t)$ ) can be derived as a function of the time ( $t$ ).

$$V(0, t) = \left[ -EI \cdot \left( \frac{\pi}{L} \right)^3 \right] \cdot v(t) \quad (6)^2$$

$$V(L, t) = -V(0, t) = \left[ EI \cdot \left( \frac{\pi}{L} \right)^3 \right] \cdot v(t)$$

It is worth noting that  $V(x, t)$  does not account for the mass  $m_2$ ; the total vertical force on the column  $-i$  ( $N_i$ ) can be calculated by the algebraic sum of  $V(x, t)$  and the generalized mass multiplied by the gravity constant ( $M_1 g$ ).

The inelastic behavior of element-1, element-3 and of the link simulating the simple beam-column friction support is modeled by the Bouc-Wen hysteresis law [25]. The nonlinear behavior of the columns is accounted for by substituting  $k_i u_i$  (Eq. 1 and Eq. 2) with  $P(t)$

$$P(t)_{column} = \alpha \cdot k_i \cdot u_i + (1 - \alpha) k_i \cdot \delta_{y,i} \cdot Z(t) \quad (7)$$

where  $-i$  is 1 for element-1 and 2 for the element-2,  $\alpha$  is the post yielding stiffness ratio, and  $Z$  is an internal variable whose behavior is described by its derivative:

<sup>1</sup>  $\ddot{v} = \partial^2 v / \partial t^2$

<sup>2</sup>  $\Phi'' = \partial^2 \Phi / \partial x^2$

$$\frac{dZ}{dt} = \left( \frac{1}{\delta_{y,i}} \right) \cdot (\dot{u}_i - \gamma \cdot |\dot{u}_i| \cdot Z(t) \cdot |z(t)|^{n-1} - \nu \cdot \dot{u}_i \cdot |z(t)|^n) \quad (8)$$

$n$ ,  $\nu$ , and  $\gamma$  are dimensionless quantities,  $n$  governs the smoothness of the curve in the proximity of the yielding point,  $\nu$  and  $\gamma$  control the size and the shape of the hysteretic loop ( $|\nu| + |\gamma| = 1$ ). In this case, the yielding force of the hysteresis model is derived as a function of the columns features and it is introduced through the parameter  $F_{y,i} = k_i \cdot \delta_{y,i}$  (Eq. 7).

A similar procedure can be followed for the friction beam-to-column support; in this case, the subscript  $-ij$  is set equal to 12 and 23 for the left and right connection, respectively, and the displacements  $u_{12}$  and  $u_{23}$  refer to the relative displacement between the 2DOFs ( $u_2 - u_1$  and  $u_2 - u_3$ ). Moreover, to simulate the simple friction support, the yielding forces of the links ( $F_{y,12}$  and  $F_{y,13}$ ) are derived according to the Coulomb's Law. Defining a friction coefficient  $\mu$  to characterize the contact between the column and the beam, the Coulomb's Law define the friction force ( $F_{y,ij}$ ) as the product between  $\mu$  and the total vertical force acting on the top of the column- $i$  ( $N_i$ ). Eq. 7 becomes

$$P(t)_{friction} = \alpha \cdot k_{ij} \cdot u_{ij} + (1 - \alpha) \cdot (\mu \cdot (\pm V(0, t) + M_1 g)) \cdot Z(t) \quad (9)$$

The equations of motion are solved with the function Ode45 [26], a versatile ordinary differential equation solver that adopts the Runge-Kutta method with a variable time step. The algorithm requires the conversion of the second-order differential equations into an equivalent system of first-order equations.

### 3 PARAMETRIC ANALYSIS

The input parameters varied in the parametric analyses are summarized in Table 1.

Parameter	Symbol	Value or range	
Behavior factor	$q$	1, 1.75, 2.5, 3.25, 4.0	[ - ]
Damping ratio	$\zeta_i$	1,3	[%]
Friction coefficient	$\mu$	0.1337, 0.5	[ - ]
Vertical component	$V_{mode}$	No, 1 <sup>st</sup> Mode	[ - ]
Ground Motion	GM	Mirandola, Amatrice	[ - ]

Table 1: Input parameters varied in the parametric analyses.

For the sensitivity analyses, the masses  $m_1$  and  $m_3$  are assumed equal to half of the self-weight of the single column, the elastic stiffnesses  $k_1$  and  $k_3$  are calculated from the geometry of the columns and account for a 50% reduction of the elastic modulus of the reinforced concrete due to cracking. All these parameters can be derived by the layout and the column cross-section of the reference case described in the next Section. A viscous damping model is considered; the damping coefficients  $c_1$  and  $c_3$  are considered equal and they are calculated in the parametric analyses by varying the damping ratio  $\zeta_i$  as indicated in Table 1 (with  $-i$  equal to 1 or 3), while the damping ratio of the vertical mode of the beam ( $\zeta_2$ ) is set equal to 0.01 [19]. As for the nonlinearity,  $n$ ,  $\nu$ , and  $\gamma$  are assumed, for the columns, equal to 1, 0.5, 0.5, respectively, while equal to 25, 0.5, 0.5, for the simple friction support, respectively. In both cases the post yielding ratio is set equal to 0.001. The friction coefficient  $\mu$  is varied among the values 0.1337 to simulate a neoprene-concrete interface [17] and 0.5 to consider a concrete-concrete interface [27]. The stiffness of the Bouc-Wen hysteresis of the friction support is set equal to  $k_{12} = k_{23} = 49000$  [N/m] [17] for  $\mu = 0.1337$ , while it is assumed equal to 1832461 [N/m] when the

friction coefficient is set equal to 0.5. The cases with and without the vertical DOF are both performed to evaluate the influence of the vertical component. The analyses are performed considering as seismic input the main shocks recorded in the L'Aquila station (Italy) during the 2008 seismic events, and in the Mirandola station (Italy) during the 2012 seismic events.

### 3.1 Parametric analyses and preliminary considerations

The results of the parametric analyses are reported in Figure 3 as a function of  $q$  in terms of ratio between the relative displacement ( $\delta_{12} = u_2 - u_1$ ) and  $\delta_R$ , corresponding to the value  $\delta_{12}$  obtained in the reference case with  $\zeta_I = \zeta_3 = 3\%$ ,  $\mu = 0.1337$ ,  $q = 1$ , and without the vertical component (indicated in the plot with a full black circle). Considering the geometric symmetry of the system, the same results would be obtained plotting  $\delta_{13}$ .

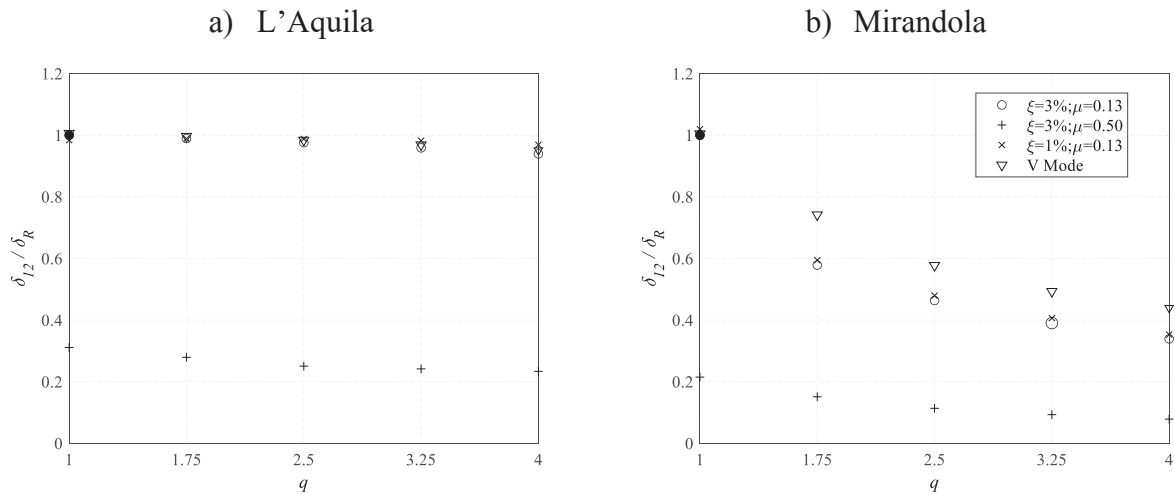

Figure 3: Parametric analyses results for the different ground motions considered. For both the GM the results are plotted as a function of  $q$  as the ratio between the relative displacement ( $\delta_{12}$ ) and  $\delta_R$  corresponding to  $\delta_{12}$  of the reference case ( $\zeta_I = \zeta_3 = 3\%$ ,  $\mu = 0.1337$ ,  $q = 1$ , No V Mode).

Increasing the behavior factor ( $q$ ) the relative displacement ( $\delta$ ) decreases following an almost linear trend;  $q$  affects more the case of Mirandola (with  $q = 4$ , almost 60% reduction) than the case of L'Aquila (with  $q = 4$  almost 10% reduction).

The friction parameter ( $\mu$ ) significantly affects the relative displacement between the beam and the columns; increasing  $\mu$  such relative displacement decreases.

The relative displacements increase by considering the vertical component; the maximum increasing value is shown in the case of Mirandola (+30%); this is considered a reasonable result observing that Mirandola is the site in which the maximum values of the vertical component were recorded. As for the case of L'Aquila, the increase is lower. Introducing  $\zeta = 0.01$  leads to variations that range between  $\pm 2\%$  with respect to the reference case.

## 4 REFERENCE CASE

To validate the simplified model presented, time history analyses have been carried out on a reference case study resembling a typical '70s precast industrial building. The building is supposed to be located in Mirandola (Emilia-Romagna, Italy). The building has a rectangular plan and story height (under the beam) equal to 5.35 (m). The bearing structure is made of precast frames designed according to the regulation codes at that time. The main frame of the building is composed of 2 columns and a double-tapered beam with a net span equal to 10.65 (m); accordingly, an I-section beam with a variable height between 0.40 (m) and 1.50 (m) is supposed.

The portal-to-portal distance is about 6.70 (m) and an overall roof weight of 2.40 (kN/m<sup>2</sup>) is assumed. The columns have a square cross-section 0.34x0.34 (m<sup>2</sup>) with a longitudinal reinforcement ratio equal to 0.8 (%). Furthermore, each column has a RC fork at the top, in which the beam is housed thus creating a simple-friction connection. A C28/35 concrete (28 MPa characteristic cylindrical strength), and Feb38k (380 MPa characteristic yield strength) steel are considered.

#### 4.1 Finite Element Model

The model and the analyses are carried out with the finite element software MidasGen 2020 [28]. Beams and columns are modeled as beam elements; the double-tapered beam is modeled as an elastic element with equivalent rectangular cross-section 0.12x0.85 (m<sup>2</sup>). Being simply lying on the columns, it should not be directly damaged by seismic loading. To account for the nonlinear behavior of the columns, Takeda lumped plastic hinges are introduced.

As for the constraints, the columns are fixed at the base while the beam-to-column connection is modeled using a “Friction Pendulum” general link with a very high radius of curvature. The link in the global vertical direction of the beam-column connection is set to behave as a rigid compression-only element.

Parametric analyses are carried out for four different cases by varying the parameters  $\zeta$ ,  $\mu$ , and  $V Mode$  reported in Table 1; the main shock recorded in the Mirandola station during the 2012 seismic events and a behavior factor ( $q$ ) equal to 2.5 are assumed. The considered cases are summarized in Table 2.

#### 4.2 Results and discussion

Figure 4 shows the results in terms of the ratio between the relative beam-column displacement and the beam support length indicated by the code ( $\Delta = \delta_{ij} / \delta_{REF}$ ). In this case,  $\delta_{REF} = 11.55\text{cm}$  is considered [29].

According with the preliminary consideration made in Section 3, the results show that the relative displacement decreases when the friction coefficient increases (-16%),  $\Delta$  increase when the vertical component (1<sup>st</sup>  $V Mode$ ) is considered; in particular, the relative displacement increases by 17% compared to the reference case. By varying the damping ratio (from  $\zeta_i=3\%$  to  $\zeta_i=1\%$ ) an increase of the relative displacement of approximately 5% compared to the reference case is showed.

Second, with the empty circle, the results obtained from the finite element model and the simplified model are compared. From the comparison, it can be observed that the simplified model can accurately predict the relative displacement between the beam and the column at the beam to column support. In this case, the maximum variation is about -10% with respect to the FEM model; the underestimation of the relative displacement could be due to the different models used for describing the beam-column connection in the two models and to the higher number of degrees of freedom in the FE model.

	$\zeta_i$	$\mu$	$V Mode$
case 1	3%	0.13	No
case 2	3%	0.50	No
case 3	1%	0.13	No
case 4	3%	0.13	Yes

Table 2: Considered cases in the parametric analyses.

Figure 4: Parametric analyses results for the different model considered and comparison between the FEM and the simplified model. The results are expressed in terms of ratio between the relative displacement ( $\delta_{ij}$ ) and the length of the support ( $\delta_{REF}$ ).

## 5 CONCLUSIONS

In this paper, a simplified model to evaluate the behavior of precast portal frames with beam-to-column simple friction connection is presented. The behavior of the portal frame has been investigated through a 4DOF model and parametric analyses have been carried out by varying the main parameters of the frame and of the simple friction connection ( $q$ ,  $\zeta$ ,  $\mu$ ,  $V Mode$ ).

The results of the parametric analyses showed that the friction coefficient ( $\mu$ ) is the parameter that most significantly affect the relative displacement between the columns and the beam. The vertical component of the ground motion is another parameter that should be accurately considered in the evaluation of the beam- loss of support is; if the vertical component of the ground motion is not considered, there is an underestimation of the relative displacements between the beam and the columns, thus resulting in an unconservative approach. Finally, the more the non-linear behavior of the structure, the less is the relative displacement between the beam and the column; the parameter  $\zeta$  (i.e. damping ratio) does not significantly affect the relative displacement. The results of the parametric analyses have been validated and assessed through a 2D finite element model.

### Abstract

*The dynamic and earthquake response of bell towers is examined here. The dynamic characteristics of two bell tower were measured in-situ through a series of free vibration tests that were performed following a strong earthquake sequence. Subsequently the dynamic and earthquake response of one of these bell towers was numerically simulated employing a 3-D elastic numerical simulation shell of the bell tower and its foundation. The earthquake response is examined for a variety of load combination conditions employing design spectra as well as the ground motion recorded at a small distance from this bell tower during a prototype earthquake motion. This study is further included to examine the influence of the soil-foundation interface. Towards this end, the non-linear uplift mechanism of the foundation block from the underlying soil is numerically simulated. The earthquake response is examined comparatively in terms of global response parameters, such as base shear, overturning moment, and top displacements as well as peak stress values at particular parts of the bell tower that stress concentration occurs. These response values are studied in a comparative way in order to validate these numerical simulations with the observed performance.*

## 1 INTRODUCTION

Bell towers are structures that are of particular interest regarding their dynamic and earthquake response, which has been the subject of research in the past ([3] to [10]). A large number of bell towers with dimensions much larger than the ones examined here are located in numerous cities in Italy and elsewhere. The largest percentage of these bell towers is built by stone or brick masonry. In many cases earthquake activity constitutes the major cause of serious damage for bell towers that many times leads to partial or total collapse ([1] and [2]). Consequently, there is a major international concern for the stability of numerous bell towers. This resulted to significant international research effort that includes in-situ monitoring of the response of bell towers on a temporary basis, like the one attempted here, or more sophisticated and on a permanent basis ([3] to [10]). Foundation problems for bell towers are evident in many case the most celebrated being Pisa's grand bell tower in Italy, that is quoted as a major medieval engineering error. Therefore, the soil flexibility is also an area of research interest for these structures especially when their dynamic and earthquake response is under investigation ([12] to [20]).

The purpose of this investigation is to study the seismic performance of relatively new bell towers compared to the old ones. Two of these relatively new bell towers, namely the bell tower of Agios Gerasimos at Lixouri [21] and the bell tower of Panayia Argiliotissa at Havriata, are selected for further in-depth study. Both structures are made of reinforced concrete and are distinct for the following reasons. A review of the seismic performance of bell towers and especially those located in Kefalonia, Greece is presented in [21] and [22].

Figure 1b. Partial collapse of the bell tower at the village of Kourouklata during the recent 2014 earthquake sequence

## 2 IN-SITU MEASUREMENTS

In the present work a summary of in-situ measurements is presented again for two bell towers located in the island of Kefalonia. These bell towers are : a) The bell tower of Agios Gerasimos at Lixouri. b) The bell tower at the village of Havriata. Information on these two bell towers are also included in [21] and [22]. The basic geometrical features of these two bell towers are depicted in figure 2. Both bell towers were constructed after a catastrophic earthquake sequence in 1953 which destroyed numerous bell towers in this island. Both bell towers

are made of reinforced concrete and did not sustain any structural damage during the recent 2014 earthquake sequence despite the severity of the earthquake ground motion.

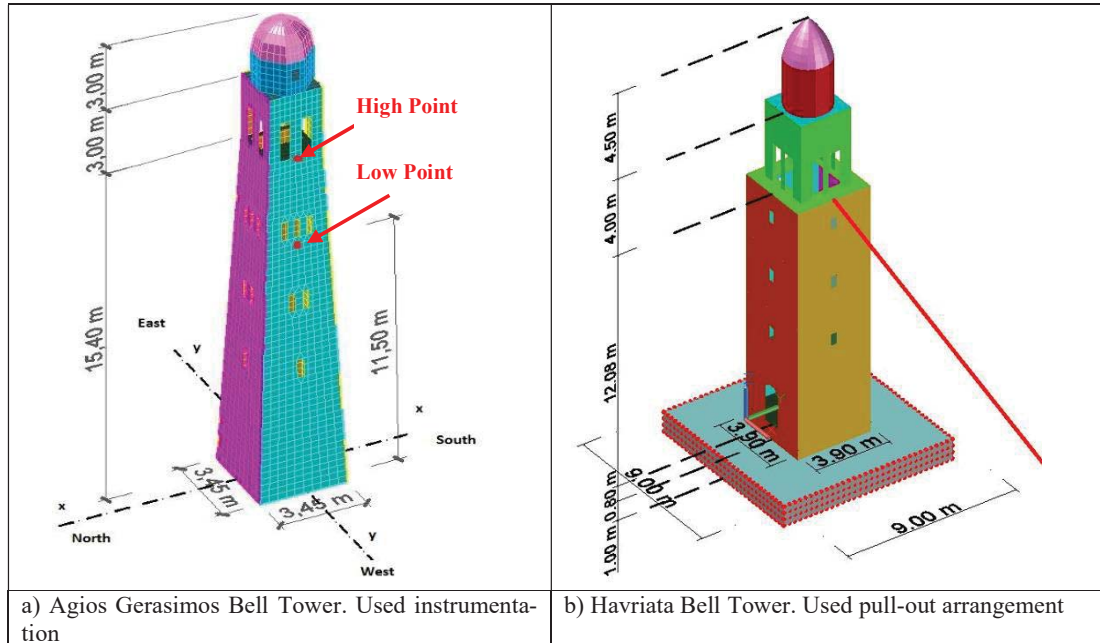

Figure 2. The Agios Gerasimos bell tower at Lixouri (left) and the Panagia Agriliotissa Bell tower at Havriata (right)

### 2.1. In-situ Measurements of Agios Gerasimos Bell Tower

The dynamic characteristics of this bell tower were measured in-situ through a series of free vibration tests that were performed following the damaging earthquake sequence 3<sup>rd</sup> of February 2014 seismic. The dynamic characteristics of this bell tower were measured in-situ through a series of free vibration tests that were performed following the damaging earthquake sequence 3<sup>rd</sup> of February 2014 seismic. A set of two tri-axial accelerometers were utilized together with a digital data acquisition system. These accelerometers were fixed at two locations along the height of the bell tower. The first accelerometer was fixed on a horizontal reinforced concrete (R/C) slabs which was built internally on this bell tower and was connected in a monolithic way with all four peripheral R/C walls. This R/C slab was immediately below the bells and could be reached through a R/C staircase which was also built internally and was also connected in a monolithic way with the peripheral R/C walls. This R/C slab was located at 15.4m from the ground level, which is named here “High Measuring Point (up)” and the accelerometer fixed at this level is depicted in figure 2a. The second tri-axial accelerometer was also fixed internally on the West R/C wall at a location 11.5m from ground level, which is named here “Low Measuring Point (down)”. It can be seen that both instruments were located at an axis of symmetry of this structure named y-y in figure 2a (East-West).

The bell tower was excited by a pull-out free vibration test sequence ([20], [21] and [22]). More details are included in [21]. Figure 3 depicts the measured bell tower response at the low and high measuring point during a pull-out in-situ test. The presence of a quite dominant frequency is quite clear in these free vibration dynamic acceleration responses. This dominant response frequency, which is equal to 2.343Hz (0.427 sec. period), was extracted from transforming the obtained measurements in the frequency domain through a Fast Fourier Transform (FFT) algorithm.

Figure 3. Free vibration horizontal acceleration response at the “Low and High measuring points” of the Agios Gerasimos bell tower at Lixouri

### 2.3. In-situ Measurements of the Bell Tower belonging to the Panayia Agriliotissa.

The church of Panayia Agriliotissa church at Havriata village, built in 1693, is partially supported by a backfill and a system of retaining walls depicted in figure 4. The dynamic characteristics of this bell tower were measured in-situ through a series of pull-out excitations tests (see Manos et al, [21]), which were performed on 10<sup>th</sup> October, 2015, approximately twenty (20) months after the damaging earthquake sequence of 3<sup>rd</sup> of February 2014. This type of excitation that was also employed for the bell tower of Agios Gerasimos at Lixouri [21], namely pull-out excitation. The level of this pull-out excitation was capable of producing horizontal vibrations by exciting mainly the horizontal translational eigen-modes of this bell tower. This dynamic response could be capture by the employed tri-axial velocity sensors with a sensitivity of 0.001mm/sec and a data acquisition system with a sampling frequency of 400Hz. The velocity response measurements were made by securing the velocity sensors at 5 levels along the height of the bell tower. This is depicted in figure 4 whereby for each level the vertical distance from level 0 is also indicated e.g. at 0.80m (level 1), 3.84m (level 2), 6.78m (level 3), 9.83m (level 4), 12.88m (level 5).

Figure 4. FFT velocity response amplitudes along the height of the Havriata bell tower for the main eigen-frequencies.

From the analysis of the measured velocity response in the frequency domain the main eigen-frequency values were obtained equal to 4.59Hz for the N-S (x-x) and 4.639Hz for the E-

W (y-y) directions, respectively. These frequency values, as will be explained, correspond to the 1<sup>st</sup> and 2<sup>nd</sup> horizontal translational modes. This is concluded from the same frequency analysis by selecting and plotting along the height in figure 4 (left) the FFT amplitudes that correspond to these frequency values, as obtained from the measured vibration response along the height of the bell tower at each one of the five (5) selected levels. The plotted in figure 4 FFT amplitude variation along the bell tower height for these specific eigen-frequency values are normalized, thus representing the mode shapes of the two N-S and E-W eigen-modes. As can be seen in this figure, the resulting mode shapes have an almost linear variation along the height from level 0 to level 5 thus representing the translational horizontal mode-shapes of the bell tower in the N-S (x-x) and E-W (y-y) directions.

### 3 NUMERICAL SIMULATION OF THE DYNAMIC AND EARTHQUAKE RESPONSE OF THE PANAYIA AGRILIOTISSA BELL TOWER AT HAVRIATA

The dynamic response of this bell tower was numerically simulated employing a linear elastic dynamic analysis utilizing shell elements assumed to be of reinforced concrete as an isotropic material with a Young's Modulus equal to  $E=10000\text{MPa}$  and typical to reinforced concrete. The bells were assumed to weight 500kgf. They were simulated with a steel beam that was placed at the right location and height where the actual steel beam supporting the bells is located. A mass and weight multiplier was used for this beam to account for the extra mass and weight of the bells. The geometry and thickness of the external walls, the slabs and the top vault of this bell tower were included in this numerical simulation.

a) Foundation block simply-supported      b) Foundation block supported with 3-D links  
Figure 5. 3-D numerical simulation of the Havriata bell tower

The foundation was assumed to be a mass-less concrete block of total thickness equal to 1m that was numerically formed by the following parts (figure 5):

- Two mass-less and stiff horizontal slabs with a thickness 0.45m were located one at zero (0) level and the other at a depth of 1.0m from zero (0) level. These slabs represent the upper and lower horizontal planes of the foundation concrete block. In addition, four mass-less and stiff vertical slabs having a thickness 1.0m were also added. Two of these slabs were placed at the x-z plane and the other two at the y-z plane of the numerical model. These ver-

tical slabs represent the peripheral vertical planes of the foundation block facing the East-West (x-z plane) and the North-South (y-z plane) directions. In this way the foundation block was formed that represents in itself a very rigid part of the whole structure. In order to approximate the possibility of a flexible interface between this foundation block and the surrounding soil volume two types of boundary conditions were introduced in this numerical model. In the first case all the points of the bottom slab of this foundation block were simply supported whereas in the second case all these points were connected to the supporting media with 3 directional linear springs with a stiffness equal to 5000000KN/m, a value that corresponds to a very stiff soil (see also Manos and Kozikopoulos [21]).

Figure 6. Comparison of measured and predicted dynamic characteristics of the Havriata bell tower.

In figure 6 the numerically predicted N-S / E-W eigen-frequencies values and eigen-mode shapes (SAP Mode-1) are compared with the corresponding measurements (N-S x-x and E-W y-y). Only the numerical results for the x-x 1<sup>st</sup> mode are plotted in this figure because the corresponding results for the second y-y mode are almost identical, due to the geometric symmetry of this bell tower. The plotted eigen-mode shape is limited to that part of the bell tower where measurements of its dynamic response were obtained from the in-situ campaign, as already described, from level 0 to level 5. As can be seen in this figure reasonably good agreement can be seen between both the measured and numerically predicted eigen-mode shape as well as the eigen frequency values. The numerical results obtained from the simply supported foundation block are almost identical to the corresponding results obtained from the numerical model whereby the foundation block is supported by 3-D stiff links (5000000KN/m), as already described. Thus, in the case of the Havriata bell tower it was not necessary to employ less stiff 3-D links at the soil foundation interface in order to reach a reasonably good agreement between measured and numerically predicted dynamic response characteristics for this structure. On this point it is important to underline that in the case of the bell tower of Agios Gerasimos at Lixouri [21], whereby the authors followed an identical methodology for in-situ measurements and numerical simulation, it was necessary in-order to reach such a reasonable degree of agreement between measured and predicted dynamic response to use 3-D links with a stiffness value equal to 21000KN/m. The obvious conclusion is that in the case of the Havriata bell tower the flex-

ibility of the surrounding soil volume exercised much less influence on its dynamic response than in the case of the Agios Gerasimos at Lixouri bell tower. This observation is in good agreement with the overall picture of the two locations as the Havriata bell tower is located at the top of a hill whereas the Agios Gerasimos bell tower is located at a close distance from the harbor almost at sea level. However, it must also be underlined that this conclusion is based on in-situ dynamic response measurements generated from relatively very low level excitations and it should not be extended to the very intense excitation that both structures were subjected to during the earthquake sequence of 3<sup>rd</sup> February, 2014. On the contrary, as will be described in the following, both structures were subjected to very intense earthquake excitations during the 3<sup>rd</sup> of February 2014 seismic event [1].

Figure 7a. The damaged longitudinal peripheral masonry South wall of the church after the seismic event of 3<sup>rd</sup> February 2014

Figure 7b. The failure of the retaining wall and the backfill at the South side of The Theotokos church of Havriata

Figure 7b show the failure of the retaining wall and the backfill at the South side of the Theotokos church of Havriata, at a distance of less than 50m from the bell tower. Moreover, the church of Panayia Agriliotissa of Havriata developed also significant structural damage (figure 7a). These observations represent visual evidence of the severity of the ground motion of this seismic event. In addition, both in Lixouri as well as in Havriata the seismic excitation was recorded [1, 21, 22], by strong motion accelerographs located at close distance from either bell tower (approximately 300m).

It must be underlined that the Havriata bell tower was designed and constructed well after 1996, when the provisions of the new Greek seismic code became mandatory ([11], [23], [24]). The adopted in the case of Agios Gerasimos bell tower design acceleration/force levels for its seismic design could not be ascertained up to now. However, in this case from eye witness reports the foundation block in the case of Agios Gerasimos bell tower was much thicker and as such was included in the numerical simulation.

a) Theotokos bell tower at Havriata.

Translational mode N-S (x-x)

T=0.220sec, f=4.54Hz, (stiff soil)

b) Agios Gerasimos bell tower at Lixouri.

Translational mode N-S (x-x)

T=0.425sec, f=2.35Hz, (medium soil)

Figure 8. Comparison of translational eigen-modes and eigen-frequencies of the Theotokos bell tower at Havriata and the Agios Gerasimos bell tower at Lixouri.

In figure 8, the mode-shape of the 1<sup>st</sup> translational eigen-mode of the Havriata bell tower is shown, as predicted numerically for the full height of this bell tower (from level 0 to the top). In the same figure the measured 1<sup>st</sup> eigen-frequency and eigen-mode in either the North-West or the North-South direction is also indicated. A good agreement can be seen between the measured and the numerically predicted values. It must be underlined that in the case of the Havriata bell tower the foundation block was supported at its base to the soil with a series of link elements representing stiff-soil conditions. In figure 8a and 8b, the mode shapes of the 1<sup>st</sup> translational eigen-mode for the Havriata and the Agios Gerasimos bell towers are depicted, respectively. As can be seen in these figures, the flexible soil in the case of the Agios Gerasimos bell tower leads to an increase in the flexibility of the whole structure. On the contrary, the stiff soil in the case of the Havriata bell tower results to a relatively stiff structure and leads to a more pronounced response of its upper part which is relatively more flexible than its lower part.

#### 4.1. Results from the design spectral curves

In this section the performance of the Havriata bell tower will be studied adopting earthquake force levels according to the type-2 Euro-Code 8 design spectra for soil category D. Moreover, the design ground acceleration for the island of Kefalonia, as specified by the seismic zoning map of the new seismic code of Greece, equal to 0.36g (g the acceleration of gravity) is also adopted. The importance factor for the bell tower is set equal to 1. A critical point is the value of the behaviour factor (q).

$$q = q_0 k_w \geq 1.5$$

where:  $q_0$  is the basic value of the behaviour factor, dependent on the type of the structural system and on its regularity in elevation;

$k_w$  is the factor reflecting the prevailing failure mode in structural systems with walls

For reinforced concrete structures that are formed by uncoupled walls, as one can classify the Havriata bell tower, the minimum value for the behaviour factor is  $q_0 = 3$  [23]. This value can become even higher when the detailing ensures behaviour of high ductility. At the same time, because of the dimensions of the bell tower and the presence of the bells at its upper part, such a structure could be considered as partly resembling an inverted pendulum in which case the behaviour factor value ranges from  $q_0 = 1.5$  to 2.0. The value of  $q_0$  given for inverted pendulum systems may be increased, if it can be shown that a correspondingly higher energy dis-

sipation is ensured in the critical region of the structure. The value of  $k_w$  for the bell tower can range from 1 to 1.43. Part of the concept of high values for the behaviour factor is based on the fact that the strong seismic ground motion effect will be absorbed from ductile inelastic hysteretic response of its structural members and thus reduce the overall structural response in a way similar to that of an overdamped elastic response associated to reduced levels of seismic forces. For the purposes of this study a value of  $q=3$  could be adopted for the behaviour factor considering this bell tower as an RC wall system. In a complementary study the inelastic response spectral curves were derived for the two horizontal components of the ground motion recorded at Havriata at a small distance of the bell tower during the strongest event on the 3<sup>rd</sup> of February, 2014. These inelastic spectral curves were derived for an assumed ductility factor value  $m=3$ , to be in accordance with the adopted value of the behaviour factor adopted for the design spectra derived from the provisions of Euro-Code 8, as described above. These are depicted in the following figure 9 for the East-West and the North-South horizontal components of the named recording of the ground motion at Havriata.

Figure 9. The response and the design spectra for the Havriata Bell tower

In figure 9, the eigen-period values of the 1<sup>st</sup> and 2<sup>nd</sup> eigen-modes in either the North-South or the East-West directions are also indicated. Apart from the Euro-Code-8 design spectral curves and the inelastic ( $m=3$ ) constant ductility spectral curves of the Havriata strong motion record in the two horizontal directions, the corresponding elastic spectra curves are also plotted. As can be seen from these plots, the inelastic constant ductility curve values are larger than the corresponding Euro-Code 8 design spectral values for both eigen-periods and for both directions. Similarly, the elastic response spectral curve values are much higher than the corresponding inelastic constant ductility ( $m=3$ ) spectral curves. Moreover, the following observations can be made.

- The 1<sup>st</sup> eigen-period value for the Havriata bell tower corresponds to the period range with the relatively large spectral values. This is also the case for the Agios Gerasimos bell tower.
- The presence of the relatively flexible soil in the case of the Agios Gerasimos results in a larger eigen-period value (0.425sec) than the corresponding eigen-period value for the Havriata bell tower (0.220sec). These numerically predicted eigen-period values were validated by the in-situ measurements.
- The presence of the flexible soil in the case of the Lixouri also influenced the seismic ground motion as can be seen when the response spectral curves of Lixouri ground motion

record [1] are compared with the corresponding response spectral curves of Havriata ground motion record. Thus, it can be seen that in the case of the Havriata ground motion the period range with the largest spectral values is from 0.15sec to 0.4sec whereas in the case of the Lixouri ground motion record this period range was sifted to 0.3sec to 0.6sec.

The modal analysis results of the numerical model of the Havriata bell tower resting on links representing stiff soil conditions are listed in the following table. In this numerical model the part that simulates the foundation block which is below the ground surface is represented by a rigid box formed by relatively rigid finite elements in a way that the weight of the actual foundation block is realistically approximated. At the same time these elements are assumed to be practically mass-less as not to interfere in an unrealistic way with the dynamic system of this structure. Moreover, in order to account for the influence of soil deformability the link elements supporting the foundation block to the soil were provided with a damping ratio equal to 10% of critical.

Table . Modal Participating Mass Ratios

Mode	Period	UX	UY	UZ	SumUX	SumUY	SumUZ

6. Dead+(RSEW + 0.3RSNS) m=3	LinRespSpec	Max	<b>27.3</b>	<b>104.4</b>	534,6 / 225,6*
7. Dead+(RSEW + 0.3RSNS) m=3	LinRespSpec	Max	<b>90.9</b>	<b>31.3</b>	534,6 / 225,6*

- with and without the weight of the foundation block. The listed percentage values in this table were derived from comparing the base shear values in each case with the total weight of the bell tower including the foundation

As can be seen from the modal participating mass ratio values listed in the above table the 1<sup>st</sup> and second translational modes in the x-x (North-South) and the y-y (East-West) direction mobilize a considerable part (more than 72%) of the total mass of the superstructure. The rest of the higher order modes used in the subsequent dynamic spectral analyses (up to 10 modes) mobilize up to 87% and 78.5% of the total mass of the superstructure in the x-x and y-y horizontal directions, respectively. Therefore, no further amplification of the dynamic response was employed. The resulting base shear values are listed in Table . The listed percentage val-

ues in this table were derived from comparing the base shear values in each case with the total weight of the bell tower including the foundation. As can be seen, the seismic force levels when the constant ductility response spectra curves are employed are higher (20% of the total weight) than those employing the Euro-Code-8 design spectral curves (13% of the total weight). The same is obviously valid when the load combinations, described in load cases No. 6 and 7 (constant ductility response spectra) are compared with load cases No. 4 and 5 (Euro-Code-8 design spectra).

Load Cases	Top of Tower Hor. Displ. (mm)	Base Shear (tnf)	Over Moment (tnf-m)	Vertical link force* (tnf)
4. Dead + EC8x-x + 0.3EC8y-y	U <sub>x</sub> =14.75 / U <sub>y</sub> =4.48	Q <sub>x</sub> =70 Q <sub>y</sub> =20	M <sub>x</sub> =1301 M <sub>y</sub> =-1911	0.14 / -2.09
5. Dead + 0.3 EC8x-x + EC8y-y	U <sub>x</sub> =4.43 / U <sub>y</sub> =14.69	Q <sub>x</sub> =21 Q <sub>y</sub> =67	M <sub>x</sub> =1900 M <sub>y</sub> =-1305	0.06 / -2.06
6. Dead + (RSEW + 0.3RSNS) m=3	U <sub>x</sub> = 5.72 / U <sub>y</sub> =23.11	Q <sub>x</sub> =27 Q <sub>y</sub> =104	M <sub>x</sub> =2389 M <sub>y</sub> =-1381	0.60 / -2.06
7. Dead + (RSNS + 0.3RSEW) m=3	U <sub>x</sub> =19.06 / U <sub>y</sub> =7.01	Q <sub>x</sub> =91 Q <sub>y</sub> =31	M <sub>x</sub> =1449 M <sub>y</sub> =-2164	0.55 / -2.50

\* The vertical force that develops at the link connecting the foundation block with the soil located at the North-West corner of this foundation block

Figure 10. Structural detailing of the columns at the level supporting the bells

Figure 10 depicts the structural detailing of the part of the bell tower with the columns above the level 12.00m, which as depicted in figures 11, is highly stressed both in tension and shear from the load combinations that include either the EuroCode-8 design spectral curves or the constant ductility response spectral curves of the recorded ground motion during the strongest earthquake event of the 2014 sequence. This bell tower was designed according to the provisions of the Euro-code 8 by a designer civil engineer (see acknowledgements) assuming design ground acceleration 0.36g, behaviour factor  $q=3$ , importance factor  $\gamma=1$ , and soil category B according to the provisions of the new Greek seismic code. The quality of the concrete was C20/25 and the reinforcing steel S400s (assumed yield stress equal to 400MPa). As was shown in figure 10, the inelastic spectral acceleration curves derived from the recorded ground motion assuming ductility factor equal to  $m=3$  re-

sult in base shear values approximately 50% higher than the corresponding base shear values derived from the Euro-Code-8 design spectral values (see Table ). It was underlined that no structural damage could be seen at this bell tower after the event despite the fact that it was subjected to earthquake forces exceeding the level of the assumed earthquake forces in the design. The same can be seen when one compares the maximum displacement response values predicted to develop at the top of the bell tower employing the Euro-Code-8 design spectra with the corresponding constant ductility response spectra curves. The same can be seen when one compares the stress levels that develop at the columns of the part of the bell tower below the level where the bells are located. This part of the structure is selected because the columns located at this part of the whole structural system develop relatively high level of stresses. These stress levels can be met successfully by the reinforcing details of these columns.

Figure 11. Stress levels that develop at the part of the bell tower supporting the bells for the various loading conditions

#### 4 CONCLUSIONS

- The measured 1<sup>st</sup> eigen-period values compare well with the numerically predicted values for both bell towers. The 1<sup>st</sup> eigen-period value for the Havriata bell tower corresponds to the period range with the relatively large spectral values. This is also the case for the Agios Gerasimos bell tower.
- The presence of the relatively flexible soil in the case of the Agios Gerasimos results in a larger eigen-period value (0.425sec) than the corresponding eigen-period value for

the Havriata bell tower (0.220sec). The employed numerical simulations recognized this fact by employing the appropriate support conditions of the foundation block.

- The seismic force levels when the constant ductility response spectra curves are employed are higher (20% of the total weight) than those employing the Euro-Code-8 design spectral curves (13% of the total weight).
- The bell tower columns above the level 12.00m, represent the part of the bell tower which is highly stressed both in tension and shear.
- No structural damage could be seen at this bell tower after the event despite the fact that it was subjected to earthquake forces exceeding the level of the assumed earthquake forces in the design.

## ACKNOWLEDGEMENTS

The authors would like to thank Civil Engineer L. Rouchotas for providing information relevant to the design of the Havriata bell tower. Moreover, the authors would like to thank the priest and the council of the Theotokos church during the in-situ measurements.

### Abstract

*The present study presents a series of in-situ measurements conducted at selected old stone masonry bridges, using up-to-date system identification techniques, in an effort to identify their dynamic characteristics in terms of eigen-frequencies, eigen-modes and damping properties. All these information is part of a data base that can be used in the future as a reference for identifying noticeable changes in these dynamic characteristics as part of a structural health monitoring effort for these bridges. Moreover, this information provides a basis for building realistic numerical simulations towards studying the structural behaviour of such stone masonry bridges and assessing their expected structural behaviour in extreme future seismic events. Selected in-situ measurements are presented together with their use in building numerical models of various levels of complexity. These numerical models are finally utilized in assessing the expected performance of specific case studies of stone masonry bridge structures in Greece towards meeting the demands of extreme events that include design earth-quake loads. The described system identification technique can also be linked to specific actions, such as earthquake activity, and thus serve as warning for specific maintenance counter-measure.*

## 1 INTRODUCTION

In what follows selective results are presented from an extensive study, which focused on old stone masonry bridges that are located mainly in the prefectures of Western Macedonia and Epirus and Thessaly in Greece (Gialeridis 1995, Grassos 2007, Milas 2016, Psimarni et al 2000). These bridges are examples of out-standing stone-masonry construction that was dominant for a long period in these parts of Greece (Figs. 1a and 1b).

Figure 1a. Konitsa Bridge, Ipiros, Greece.

Figure 1b. Plaka Bridge, Ipiros, Greece. (Before its collapse in 1<sup>st</sup> February 2015)

The use of the stone masonry arch that is utilized in forming stone masonry bridges was extensively used in the times of the Roman Empire as part of the transportation system that was established and linked the various provinces of the Roman Empire. Evidence of stone masonry arch bridges prior to Roman times is not known although stone masonry structures in the East Mediterranean area for other uses date to prehistoric times. A well known use of arch/vault stone masonry structural form is the one that can be seen at the royal tombs which have been excavated during the last 200 years in many places in Greece.

The royal tomb of Atræus at Mycenae-Greece utilized stone masonry to form an underground vaulted structure with a diameter at its base of 14.60m and a height of 13.30m constructed with 33 subsequent series of stone masonry along the height. The use of such vaulted stone masonry structures demonstrates the efficient utilization of this structural form in order to bear efficiently the dead loads as well as the weight of the overlying soil volume in a state of stress dominated by compression. The use of the stone masonry arch/vault type formation is also evident in the structural system of the royal tombs of the Macedonian kings at Vergina in Northern Greece, dated from 350 B.C. and excavated during the last 30 years. Despite the use of arch/vaulted stone masonry structural formations for these underground Macedonian royal tombs at Vergina in Northern Greece there is no evidence of such structural formations being used for bridges at that time. The remains of an ancient Roman bridge is located between Vergina and Thessaloniki. These remains correspond today to only one main arch with a span of 15m and height of 7.5m. This surviving part of a Roman stone masonry bridge is dated between 50 A.D. and 150 A.D. and it is located at a close distance (25km) from the Macedonian palaces of Vergina and Pella and 30km from the city of Thessaloniki.

The old stone masonry bridges that survive today have been built during the 18th and 19th century. They were used to connect villages located in rough mountainous terrain bridging currents that could be quite turbulent during part of the year. This type of transporting people, animals and goods was accomplished using a relatively narrow deck with width vary-ing from 2.0m to 3.0m. On the contrary, their size spans from 8m to 40m when a single arch is employed (Konitsa) or over 70m for multi-arch structures (Plaka). More information on the

geometry, construction characteristics and mechanical properties of the employed materials are given by Manos et al. (2016). Today, these structures have retain but only a small part of this primary function, as new roads and bridges have been built to facilitate the contemporary transportation needs. Despite this fact they have recently attracted considerable attention as cultural heritage structures together with an effort to become parts of a network of mountain trails. Because a number of people use these structures as visitors a conservation effort was also initiated for their maintenance. Our study has also partly such an objective. That is to obtain information through in-situ instrumentation and measurements on the vibration characteristics of these structures at a given time in a health monitoring framework, as described in section 2. In addition, these in-situ measurements are complemented with a numerical investigation that has as first target to form realistic numerical simulations of such old stone masonry structures. Moreover, to employ next such realistic numerical simulations in order to assess the behaviour of these old stone masonry bridges to a combination of loads that include accidental actions, such as forces generated from earthquakes or flooding.

Figure 2a. The studied old stone masonry bridge of Saint Vissariona 23rd August, 2017. Span of main arch 28.9m and height 16.3m

Figure 2b. The studied old stone masonry bridge of Aziz Aga 31st August, 2016. Span of main arch 28m and height 13.5m.

## 2 IN-SITU MEASUREMENTS OF THE DYNAMIC CHARACTERISTICS OF THE STUDIED STONE BRIDGES

In measuring the dynamic response of all the studied stone bridges two types of excitation were mobilized. The first, namely ambient excitation, mobilized the wind, despite the variation of the wind velocity in amplitude and orientation during the various tests. Due to the topography of the areas where these stone bridges are located, usually a relatively narrow gorge, the orientation of the wind resulted in a considerable component perpendicular to the longitudinal bridge axis. This fact combined with the resistance offered to this wind component by the façade of each bridge produced sufficient excitation source resulting in small amplitude vibrations that could be recorded by the employed instrumentation. The second type of excitation that was employed, namely vertical in-plane excitation, was produced from a sudden drop of a weight on the deck of each stone masonry bridge (Aoki 2007, Manos 2015a, 2015b, 2016, 2017, Ozden et al 2012, Ruocci et al. 2013).

The level of this second type of excitation was capable of producing mainly vertical vibrations; however, depending on the location of the stone-bridge that such an excitation was applied, horizontal vibratory response components could also be recorded. From the recorded three-component response the in-plane and out-of-plane eigen-frequencies and eigen-modes of each studied stone masonry bridge structure could be identified. The employed tri-axial velocity sensors had a sensitivity of 0.001mm/sec and a data acquisition system with a sam-

pling frequency of 800Hz. The wind orientation relative to the geometry of each bridge structure coupled with the bridge stiffness properties could excite mainly the 1st symmetric out-of-plane eigen-modes. The variability of the wind orientation could also excite, although to a lesser extend, some of the other in-plane and out-of-plane eigen-modes. The drop weight excitation in various locations combined with the placement of the sensors in selected locations was capable of capturing the in-plane as well as out-of-plane modes of response. A careful study of the numerous in-situ response measurements together with the assistance of numerical simulation tools and a back analysis process resulted for such stone bridges in their dynamic system identification. This process is presented in what follows for two old masonry bridges, namely the Saint Vissariona Bridge at Pile, in Trikala prefecture (figure 2a) and the bridge of Aziz-Aga, at Grevena prefecture (figure 2b).

Due to space limitations only selective measurements of the out-of-plane response, which was recorded utilizing either the wind or the drop weight excitation are included here. More information is reported by Manos et al. (2016).

Figure 3. Wind excitation Saint Vissariona Bridge 9th September, 2018. Out-of-plane horizontal component.

Figure 4. Drop weight excitation Saint Vissariona Bridge 9th September, 2018. Out-of-plane horizontal component.

In figure 3, the out-of-plane horizontal component response of the Saint Vissariona bridge is presented due to wind excitation. The time history plot is shown at the left hand side of this figure with the corresponding FFT plot shown at the right hand side. As dominant frequency

the value of 2.7832Hz can be identified. Figure 4 depicts the corresponding out-of-plane horizontal component response, in terms of time history and FFT plots, for the same bridge due this time to the drop weight excitation. The dominant frequency value is this time equal to 2.7344Hz. For the Aziz Aga stone bridge the out-of-plane horizontal component response, in terms of time history and FFT plots, due to the drop weight excitation is depicted in figure 5. As can be seen in this figure the dominant eigen-frequency is equal to 3.4668Hz. By studying further the FFT plots of figures 4 and 5 one can also identify through the other two distinct peaks the eigen-frequencies of two more high-order out-of-plane response eigen-modes.

Figure 5. Drop weight excitation Aziz-Aga Bridge 19th May, 2019. Out-of-plane horizontal component

### 3 NUMERICAL SIMULATION OF THE DYNAMIC RESPONSE RECORDED IN-SITU UTILIZING LINEAR-ELASTIC RESPONSE ASSUMPTIONS.

Initially, in the following section an attempt is made to employ a variety of linear-elastic numerical simulations for a relatively simple arch bridge.

Figure 6. The single arch stone masonry bridge at Kryineri (Molista).

This structure bridges one of the streams that flows towards Sarantaporos river between the mountains of Grammos and Smolikas at the prefecture of Ipirous. This valley was and still is

one of the main links between the prefectures of Macedonia and Ipirous in Greece. Apart from this bridge there were other bridges in this valley that do not exist today. One of these bridges that survive today, which bridges the upper part of Sarantaporos river near its origin (Eptachori) is the two-arch bridge of Drosopigi, located near the village with the same name, the birth place of the second author of this work (figure 7). Both Drosopigi bridge and the Kryoneri bridge were initially studied numerically by Simos and Manos [24]. In section 3.1. the numerical simulation of the Kryoneri Bridge is again presented together with corresponding measurements performed in-situ.

Figure 7. The two-arch stone masonry bridge at Drosopigi.

### 3.1 The stone masonry bridge at Kryoneri

This is a relatively simple stone masonry bridge of a single arch, as shown in figure 6. The clear span of this bridge is 8.25m, the height from the river bed to the key of the arch (bottom fiber) 5m and the width of this bridge at the key of the arch 2.4m. Figures 8a and 8b depict the main out-of-plane and in-plane eigen-modes of this bridge, respectively.

Figure 8a. Out-of-plane 12.744Hz Damping 3.7%

Figure 8b. 1st In-plane 17.578 Hz Damping 4.6%

As can be seen in figures 8a and 8b the first out-of-plane eigen frequency was measured in-situ to be equal to 12.744Hz, whereas the first in-plane eigen-frequency was measured to be equal to 17.578, which is considerably higher than the 1<sup>st</sup> out-of-plane. It must be underlined here that the drop weight excitation process was utilized in situ to obtain these eigen-frequency values. Moreover, from stone samples taken in-situ the following mechanical characteristics were obtained from laboratory tests.

Table 1. Molista stone cubes. Compression test results November 2018

Code No	Width (mm)	Thickness (mm)	Area (mm <sup>2</sup> )	Height (mm)	Slenderness ratio H/l	Ultimate Compression (KN)	Ultimate Compressive stress (MPa)
1	61	57	3477	61	1.000	363.0	104.4
2	57	60.5	3448.5	48	0.817	392.4	113.8
3	59	57	3363	70	1.207	412.0	122.5
4	50	60.5	3025	64	1.164	255.1	84.3
<b>Average compressive strength value (MPa)</b>							<b>106.25</b>
<b>Standard deviation (MPa)</b>							<b>16.4</b>
<b>Young's Modulus E=40GPa, Average Tensile Strength = 6.56MPa</b>							

The subsequent numerical analysis followed three different numerical simulations. All of them assumed linear-elastic behaviour and homogenization of the stone masonry. The first approach is the simplest of the three simulating the bridge through the middle longitudinal plane of symmetry utilizing thick shell finite elements, as shown in figure 9. The supports for all the nodes forming the horizontal abutment base contact was assigning zero translations ( $u_x=u_y=u_z=0$ ) and zero rotations ( $\phi_x, \phi_y, \phi_z$ ) along all three axes. The supports for all the nodes forming the inclined abutment base contact was assigning only zero translations along all three axes ( $u_x=u_y=u_z=0$ ). The second approach uses brick finite elements and in this way the full geometry of the bridge is portrayed, as shown in figure 10a. In the third approach the numerical simulation includes also the valley substrate as a continuation of the abutments of this bridge in a way shown in figure 10b. In all these analyses the homogenized masonry Young's modulus was assumed equal to 2000MPa and the homogenized masonry special density 25.5KN/m<sup>3</sup>

Figure 9. 3-D numerical simulation of the single-arch stone masonry bridge at Kryoneri (Molista) employing thick shell finite elements.

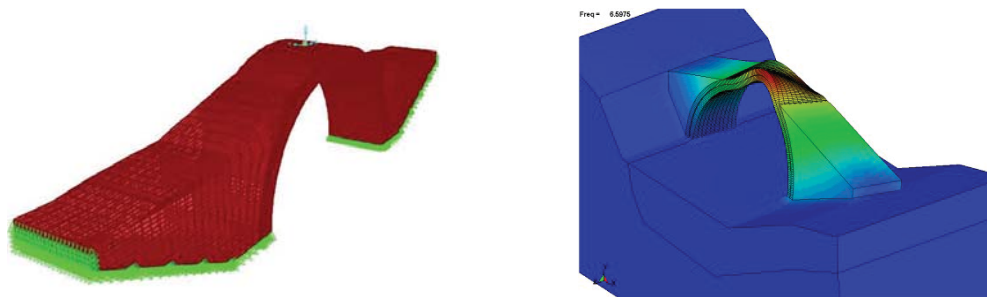

Figure 10. a) 3-D numerical simulation of the single-arch stone masonry bridge at Kryoneri (Molista) employing brick finite elements. b) 3-D numerical simulation of the single-arch stone masonry bridge at Kryoneri (Molista) together with part of the valley substrate employing brick finite elements.

From the eigen-frequency values listed in figure 11 good agreement is reached between the eigen-frequency values obtained by the 3-D numerical simulation of the single-arch stone masonry bridge at Kryoneri (Molista) employing either thick shell finite elements or the 3-D numerical simulation employing brick finite elements.

Figure 11. Comparison of numerically obtained eigen-frequencies from the three numerical approaches between themselves and with specific in-situ measured values.

When comparing the numerical results of the 3-D numerical simulation of the single-arch stone masonry bridge at Kryoneri (Molista) together with part of the valley substrate employing brick finite elements it can be observed that the inclusion of the soft alluvium substrate introduces a considerable flexibility in the structural system as a whole. Moreover, a number of the first in-plane and out-of-plane significant eigen-modes are influenced by the flexibility of the abutments as they are supported on the alluvium substrate. This is underline in both figures 11 and 12. It must be underlined that the used method of excitation is of such an intensity that is unable to mobilize such an interaction between the abutments of the Kryoneri bridge and the alluvium substrate that can be of significance. This is the reason that these numerical values are not compared in figure 11 with the corresponding measured in-situ values.

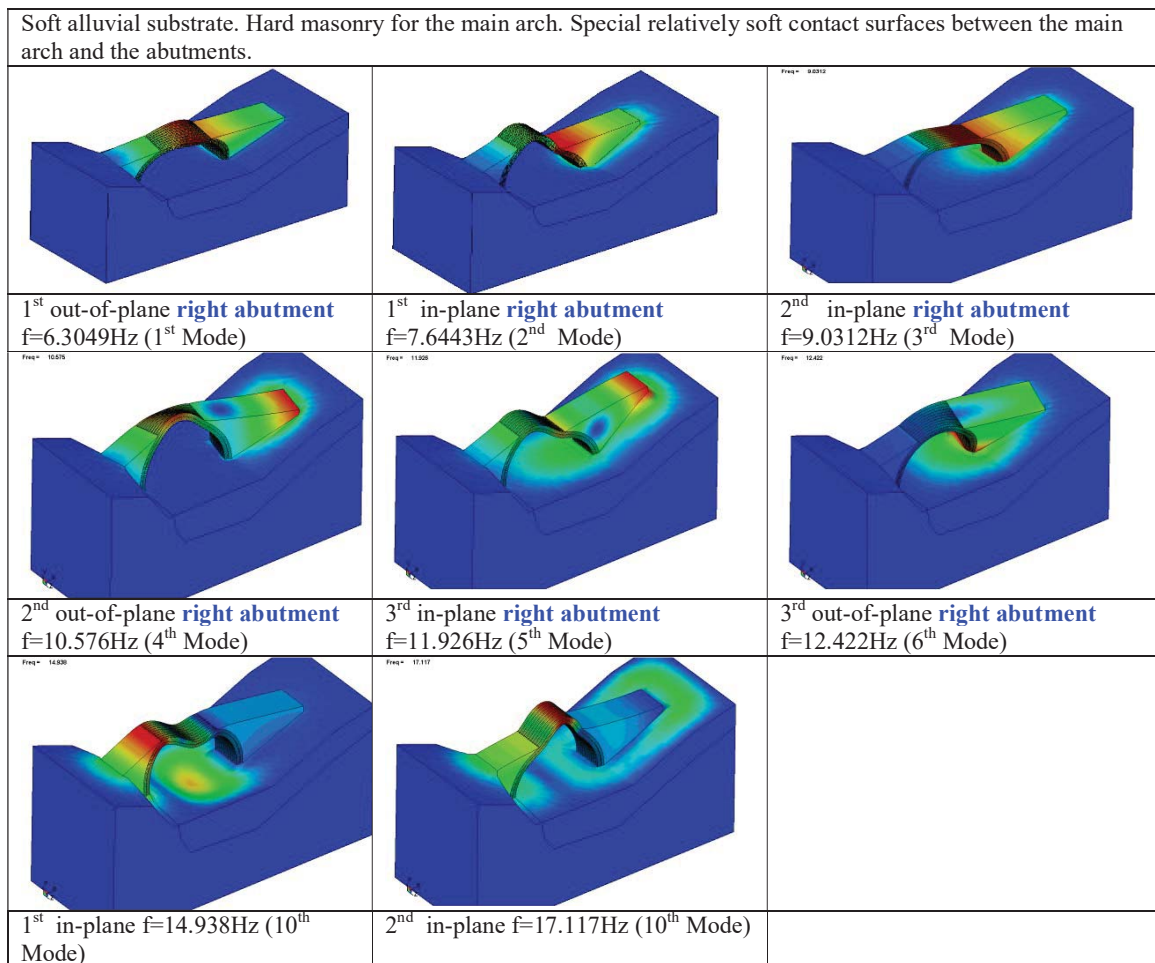

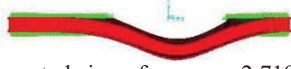

Figure 12. Eigen-modes and eigen-frequencies obtained from a 3-D numerical simulation of the single-arch stone masonry bridge at Kryoneri (Molista) together with part of the valley substrate employing brick finite elements.

### 3.2 The numerical simulation of relatively large stone masonry arch bridges

In this section numerically simulate the eigen-frequencies and eigen-modes of Saint Vissariona and Aziz Aga stone masonry bridges, as they resulted from the dynamic system identification process, based on the measured in-situ numerous dynamic response records. These

stone masonry arch bridges are much larger than the simple arch bridge examined in section 3.1. At this initial stage the basic assumption of the numerical simulation is the linear elastic response approximation. The overall geometry of the various parts as well as their overall thickness was reproduced as was measured in-situ. The numerical simulation tried to reproduce the primary arch and the secondary arch separately. Moreover, separately were reproduced the abutments and the foundation footings. Thin layers of more flexible material (mortar layers) were introduced in regions where such main parts were connected. Reported by Manos et al. (2016) is a limited study of the mechanical characteristics of stone and mortar samples taken from a prototype bridge which collapsed in 2015 and is currently rebuilt. More information of this bridge's performance is presented by Manos et al. (2019).

Initially, for simplicity purposes, these numerical simulations are made in the 3-D domain representing the bridge structure with its mid-surface employing thick shell finite elements (SAP2000).

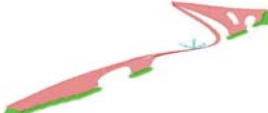

Table 2. Measured and predicted eigen-frequencies for Saint Vissariona stone masonry bridge		
Eigen-modes and measured eigen-frequencies	3-D numerical simulation with <b>shell elements</b> representing the longitudinal mid-section	3-D numerical simulation with <b>solid elements</b> representing the full geometry of the stone bridge
(1)	(2)	(2)
<b>1<sup>st</sup> Out-of-plane</b> Measured eigen-frequency 2.832Hz	 Pred. eigen-frequency 2.784Hz, $m_y=40.3\%$	 Computed eigen-frequency 2.719Hz
<b>2<sup>nd</sup> Out-of-plane</b> Measured eigen-frequency 5.029Hz	 Pred. eigen-frequency 5.270Hz, $m_y=0.0$	 Computed eigen-frequency 5.240Hz
<b>1<sup>st</sup> In-plane</b> Measured eigen-frequency 7.129Hz	 Pred. eigen-frequency 8.38Hz, $m_x=9.27\%$ $m_z=0.4\%$	 Computed eigen-frequency 8.392Hz
<b>3<sup>rd</sup> Out-of-plane</b> Measured eigen-frequency 8.839Hz	 Pred. eigen-frequency 9.184Hz, $m_y=20.5\%$	 Computed eigen-frequency 8.202Hz
<b>2<sup>nd</sup> In-plane</b> Measured eigen-frequency 9.570Hz	 Pred. eigen-frequency 9.45Hz, $m_x=0.002\%$ $m_z=9.7\%$	 Computed eigen-frequency 9.475Hz
<b>3<sup>rd</sup> In-plane</b> Measured eigen-frequency 13.037Hz	 Pred. eigen-frequency 12.69Hz, $m_x=0.01\%$ $m_z=14.1\%$	 Computed eigen-frequency 12.712Hz

The predicted eigen-frequency values obtained from this type of numerical simulation are listed in column 2 of tables 2 and 3 for the stone masonry bridges of Saint Vissariona and Aziz Aga, respectively. The corresponding modal mass participation ratio values are also listed in this table. The out-of-plane and the in-plane horizontal directions are denoted with the axes y-y and x-x, respectively, whereby z-z is the vertical axis. At a second stage an alternative 3-D numerical was carried out whereby all the various parts of each bridge were represented employing solid prismatic finite elements. The predicted eigen-frequency values

obtained from this type of numerical simulation are listed in column 3 of tables 2 and 3 for the stone masonry bridges of Saint Vissariona and Aziz Aga, respectively.

The corresponding eigen-mode shapes are also included in these tables. The various main parts of this stone masonry bridge, that is the primary and the secondary arches, the abutments, the deck, the mandrel walls and the parapets were simulated in such a way that narrow contact surfaces could be introduced between them, representing in this way a different “softer” medium. All available information, measured during the in-situ campaign, on the geometry of each one of these parts was used in building up these numerical simulations. The mechanical property values obtained from the stone and mortar sample tests were utilized (see Manos et al. (2016). Moreover, there is important information that is needed in order to form with some realism the boundary conditions at the river bed and banks. The lack of specific studies towards clarifying in a systematic way all these uncertainties represents a serious limitation in the numerical simulation process. The approximation adopted in this study is a process of back simulation (Manos et al. 2015a, 2015b, Simos et al. 2017, 2018). This is done by adopting values for these unknown mechanical stone masonry properties, respecting at the same time all the measured geometric details, which result in reasonably good agreement between the measured and predicted in this way eigen-frequency values.

Table 3. Measured and predicted eigen-frequencies for Aziz Aga stone masonry bridge

Eigen-modes and measured eigen-frequencies	3-D numerical simulation with <b>shell elements</b> representing the longitudinal mid-section	3-D numerical simulation with <b>solid elements</b> representing the full geometry of the stone bridge
(1)	(2)	(3)
<b>1<sup>st</sup> Out-of-plane</b>		
Measured eigen-frequency 3.4670Hz	 Computed eigen-frequency 3.360Hz	 Computed eigen-frequency 2.618Hz
<b>2<sup>nd</sup> Out-of-plane</b>		
Measured eigen-frequency 6.250Hz	 Computed eigen-frequency 5.857Hz	 Computed eigen-frequency 4.399Hz
<b>1<sup>st</sup> In-plane</b>		
Measured eigen-frequency 8.398Hz	 Computed eigen-frequency 7.920Hz	 Computed eigen-frequency 7.776Hz
<b>3<sup>rd</sup> Out-of-plane</b>		
Measured eigen-frequency 7.764Hz	 Computed eigen-frequency 8.024Hz	 Computed eigen-frequency 6.150Hz
<b>2<sup>nd</sup> In-plane</b>		
Measured eigen-frequency 9.375Hz	 Computed eigen-frequency 9.440Hz	 Computed eigen-frequency 9.332Hz

Following this approximate process the boundary conditions introduced in both numerical simulations at all the boundaries, either at the river bed or the river banks, were constraining to zero the translational displacement in the two horizontal and the vertical direction. It was observed from a sensitivity analysis that was performed by Manos et al. (2016) for a number of stone masonry bridges that introducing fixity boundary conditions for the first type of numerical simulation influences, as expected, the out-of-plane and not the in-plane stiffness of the studied stone masonry bridges. Moreover, for the Saint Vissariona and Aziz Aga Bridge whereby the main central arch is supported at the North end in adjacent arches rather than in a rocky river bank the influence of the variation of the boundary conditions, as expected, is again less pronounced.

The value of the corresponding measured eigen-frequency values is included in the first column of tables 2 and 3. These values, as already mentioned, were obtained from the system identification study for each bridge based on the numerous measurements of the vibratory response recorded in-situ utilizing either wind or drop weight excitations (see figures 3, 4 and 5). When the predicted eigen-frequencies obtained from the shell elements numerical simulation of Saint Vissariona bridge (Table 2 column 2) are compared with those obtained from the solid elements numerical simulation (Table 2 column 3) a good agreement is observed for all the listed numerically predicted eigen-modes apart for the third out-of-plane eigen-mode. When this comparison is made between the numerically predicted eigen-frequency values with the ones deduced from the in-situ measurements (Table 2 column 1), a good agreement can be observed for the 1st and 2nd out-of-plane and for the 2nd and 3rd in-plane eigen-modes, for both types of numerical simulations. For the 3rd out-of-plane eigen-mode the numerical simulation employing shell element is in better agreement with the measured value than the numerical simulation employing solid elements. Both types of numerical simulation predict an eigen-frequency value for the 1st in-plane eigen-mode that differs substantially for the measured value. This discrepancy is of need of further research. When the predicted eigen-frequencies obtained from the shell elements numerical simulation of Aziz Aga bridge (Table 3 column 2) are compared with those obtained from the solid elements numerical simulation (Table 3 column 3) a good agreement is observed for all three in-plane numerically predicted eigen-modes but not for the corresponding three out-of-plane eigen-modes. When this comparison is made between the numerically predicted eigen-frequency values with the ones deduced from the in-situ measurements (Table 3 column 1), a good agreement can be observed between the measured and predicted values for the 1st type of numerical simulation employing shell finite elements. The predicted values employing solid finite elements are in reasonable agreement with the measured values only for the in-plane eigen-modes but not for the out-of-plane eigen-modes. This must be attributed to the effect of the boundary conditions for the numerical simulation employing solid elements.

#### 4 SEISMIC BEHAVIOUR OF THE SAINT VISSARIONA BRIDGE

This section includes results from a series of simplified numerical simulations of the Saint Vissariona stone masonry bridge when it is subjected to a combination of actions that include the dead weight (D) combined with extreme actions generated from seismic ground motions (Sevim Baris, et al., 2011, Kiyono J., et al. 2012). The seismic forces were defined by making use of the current definition of the seismic forces by EURO-Code 8 (2004). Towards this horizontal design spectral curves were derived (figure 13) based on the horizontal design ground acceleration. This value, as it is defined by the zoning map of the current Seismic Code of Greece, is equal to 0.16g (g the acceleration of gravity) for the location of the Saint Vissariona bridge located at Pyle Trikala Prefecture of Greece (EAK 2000, ITSAK 2019). Further-

more, it is assumed that the soil conditions belong to category B because of the bridge is founded near the banks of the river bed and not directly at a rocky sub-terrain. The importance factor was assigned to a value equal to 1.2 whereas the foundation coefficients was assigned a value equal to one (1.0); the damping ratio is considered equal to 5% and the behaviour factor is equal to 1.5 (unreinforced masonry).

It must be pointed out that the flexibility of the foundation that was taken into account in the numerical simulation of stone masonry bridges in the past was not considered here. Two types of numerical analyses were performed. In the first type of numerical analysis, the dynamic spectral method was employed making use of the contribution of twelve modes, which include the dominant in-plane and out-of-plane eigen-modes. Moreover, an amplification factor was introduced in order to compensate for the fact that only a portion of the total mass is mobilized by these eigen-modes in the in-plane and out-of-plane directions. In the second type of numerical analysis equivalent horizontal seismic forces are applied either in the in-plane ( $E_x$ ) or in the out-of-plane ( $E_y$ ) directions. These forces are of an almost triangular distribution along the height of this bridge with the maximum value applied at the key of the central arch. Moreover, the base shear that results by applying these equivalent horizontal seismic forces is approximately equal to the base shear that results from the dynamic spectral analyses (Manos 2015c). This is done by adjusting the amplitude of the equivalent horizontal seismic forces. In what follows results from this second type of analyses are presented and discussed.

Figure 13. Design acceleration spectral curves.

Load combinations which included the simultaneous application of the dead load ( $D$ ) and the equivalent horizontal seismic forces either in the in-plane ( $D + E_x$ ) or in the out-of-plane ( $D + E_y$ ) directions have been considered. The obtained deformation and stress results for the Saint Vissariona stone masonry bridge as obtained from these load combinations are shown in the following figures 14 to 16. Figure 14 shows the deformation and in-plane stress distribution patterns of Saint Vissariona bridge due to its dead load. As can be seen in this figure, the deformation of the key of the central arch due to dead load is relatively small ( $u_z = -3.46\text{mm}$ ). In addition the maximum tensile stress value is also relatively small ( $\sigma_{\max} = 0.200\text{MPa}$ ) and develops at a confined region at the deck of the bridge above the left and right abutments. The minimum compressive stress value is of the order of  $\sigma_{\min} = -0.70\text{MPa}$  that can be easily sustained by such stone masonry construction. Figure 15 shows the deformation and in-plane stress distribution patterns of Saint Vissariona bridge due to the load combination including the dead load and the in-plane equivalent horizontal seismic forces. Again, the in-plane deformation of the key of the central arch due to this load combination is relatively small ( $u_x = 1.70\text{mm}$   $u_z = -4.51\text{mm}$ ). However, it can be seen that the region at the deck above the left abutment develops a considerable increase in the maximum tensile stress value

( $\sigma_{\max}=0.500\text{MPa}$ ). Such tensile stress values represent a relatively high tensile stress demand for stone masonry. The region that this high tensile stress value develops correlates with the deformation pattern of the bridge for this load combination. Again, the minimum compressive stress value is of the order of  $\sigma_{\min}=-0.70\text{MPa}$  that can be easily sustained by such stone masonry construction.

#### **Dead Load**

Figure 14. Deformation and in-plane stress distribution patterns of Saint Vissariona bridge due to the dead load

#### **Dead Load + Ex**

Figure 15. Deformation and in-plane stress distribution patterns of Saint Vissariona bridge due to dead load and equivalent in-plane seismic horizontal forces

#### **Dead Load + Ey**

Figure 16. Deformation and out-of-plane stress distribution patterns at the facades (top and bottom) of Saint Vissariona bridge due to dead load and equivalent out-of-plane seismic horizontal forces

Figure 16 shows the deformation and out-of-plane stress distribution patterns at the two extreme faces (top and bottom) of Saint Vissariona stone masonry bridge due to the load combination of the dead load and the out-of-plane horizontal equivalent seismic forces. As can be seen in this figure, the out-of-plane horizontal deformation of the key of the central arch due to this load combination is relatively large ( $u_y=35.0\text{mm}$   $u_z=-3.88\text{mm}$ ). As a result, large maximum tensile stress values develop at the central region of the main arch (Bottom face  $\sigma_{\max}=2.07\text{MPa}$ ) as well as at the region where the left abutment joins the foundation. Such tensile stress values represent a relatively very high tensile stress demand for stone masonry. Again, the minimum compressive stress value is of the order of  $\sigma_{\min}=-5.00$  that, despite the relatively large amplitude, can be easily sustained by such stone masonry construction. As can be seen from the results of such a simplified numerical analysis the Saint Vissariona bridge can be quite vulnerable for earthquake ground motions that are dictated from the current seismic code. According to historical information this stone masonry bridge was built on 1514 A.D. In 1967 this stone masonry bridge was declared cultural monument by the Greek Ministry of Culture and in 2000 the surrounding area was also declared as a region in need of special protection by the same Ministry (Greek Government Gazette 1967). During the last century the most intense earthquake activity related to this bridge must be considered the Sofades in Karditsa earthquake sequence on 30th of April 1954 which is assigned by Papazachos et al. (1989) a magnitude of 7.0 at the Richter scale with an epicenter approximately 50km from the site of Saint Vissariona bridge. It was not possible up to now to find any record of structural damage relating this earthquake to Saint Vissariona bridge despite the fact that there are reports of substantial structure damage which was widespread in the Thessalia prefecture.

## 5 INFLUENCE OF THE FOUNDATION DEFORMABILITY.

In the preceding sections 3 and 4 the piers and the abutments of the examined stone masonry bridges were assumed to be supported in non-deformable soil-foundation interface. In what follows a preliminary study of the influence of deformable soil where a stone masonry is found is carried out. The Plaka stone masonry bridge collapsed on the 1st of February 2015 due to the flooding of the Arachthos river. Figure 17a depicts this bridge as it was standing before this collapse whereas figure 17b shows the remains of the abutments after the collapse of the bridge due to the flooded river which is also shown in the same figure. Figure 17c depicts the collapsed bridge ten months afterwards (12th December 2015) whereas figure 17d depicts the picture (19th October 2019) of the reconstruction of the old bridge in the same overall geometry and using materials and constructions techniques as close as possible to the original construction. Recently (7th December 2019), it was announced that the primary arch of the reconstructed new Plaka stone masonry bridge was completed by placing the top key stones at the top-middle of this primary arch. Manos et al. (2017) investigated, through a simplified linear analysis approach, the effect of the flooding forces acting on the Plaka bridge structure adopting the assumption that the foundation of its mid-pier footing was on a relatively flexible soil.

In addition, the damage suffered by the main arch during an explosion that occurred in 1944, was also included in this study. More information can be found in Manos et al 2017.

Figure 17. Collapse from flooding and reconstruction of the Plaka stone masonry bridge

Figures 18a,b,c depict the displacement and stress response of the Plaka bridge under the combined action of the gravity and flooding forces, taking into account the arch damage as well as the deformability of the soil under the footing of the mid-pier. The maximum vertical deflection response, shown in figure 18a, is equal to 21.95mm at the top middle of the central arch. At the same location, the horizontal in-plane displacement is equal to 4.5mm ( y-y direction), whereas the out-of-plane horizontal displacement (x-x direction, flow of river) is equal to 0.87mm. The maximum (tensile) stress response is depicted in figures 18b and 18c. As can be seen, at the central arch region (figure 18c) the maximum stress value is equal to 0.764MPa whereas at the left relief arch region the maximum stress value is equal to 2.579MPa (figure 18b).

Simos et al. (2017). Investigated the collapse of the Plaka Stone Bridge due to extreme flooding using high fidelity, three-dimensional non-linear numerical analysis and sensitivity studies. The potential of a number of postulated scenarios in initiating failure and leading to the eventual collapse of the bridge were explored aided by sensitivity analyses relying on non-linear finite element modeling, augmented by actual material properties of the structural elements deduced from laboratory tests following the collapse. More information can be found in Simos et al. 2017.

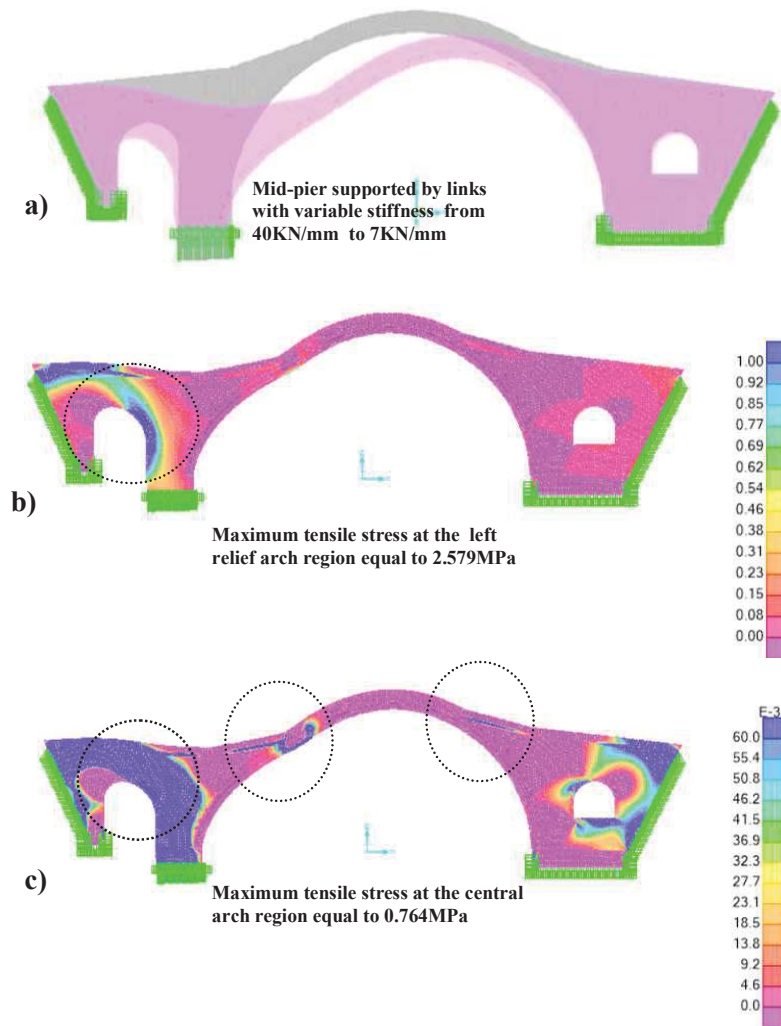

Figure 18. Displacement and stress response of the Plaka stone masonry bridge

The numerical analysis and the failure scenario postulated and presented in detail in this study tend to support that the triggering of the collapse and the most-likely cause was the undermining by the flood (scouring of the river bed and hydrodynamic loads) of the central pier. In what follows the Plaka Bridge is numerically simulated this time together with a volume of soil under its foundation of the piers and the abutments within the river bed, as is shown in figure 19. Elastic properties are assigned to this volume in an effort to approximate the flex-

ibility of the foundation under the footings of the piers located within the river bed and to further research on the collapse mechanisms.

Figure 19. Numerical simulation of the Plaka bridge together with a volume of soil.

Apart from numerically simulating the flexibility of the foundation in these way seven critical cross sections, five at the central arch, one at the left relief arch and one at the right relief arch, were numerically simulated employing contact surfaces which could allow a non-linear plasticification response to develop, according to an assumed cohesive constitutive law. In order to check how this numerical model reproduces the effect of the foundation flexibility, simulated as described, the gravity forces were gradually applied till they reached a final level equal to the gravity forces amplified by a factor of 2. The obtained response, in terms of amplified displacement response is shown in figure 20a whereas figure 20b is indicating the plasticification of the mentioned contact surfaces.

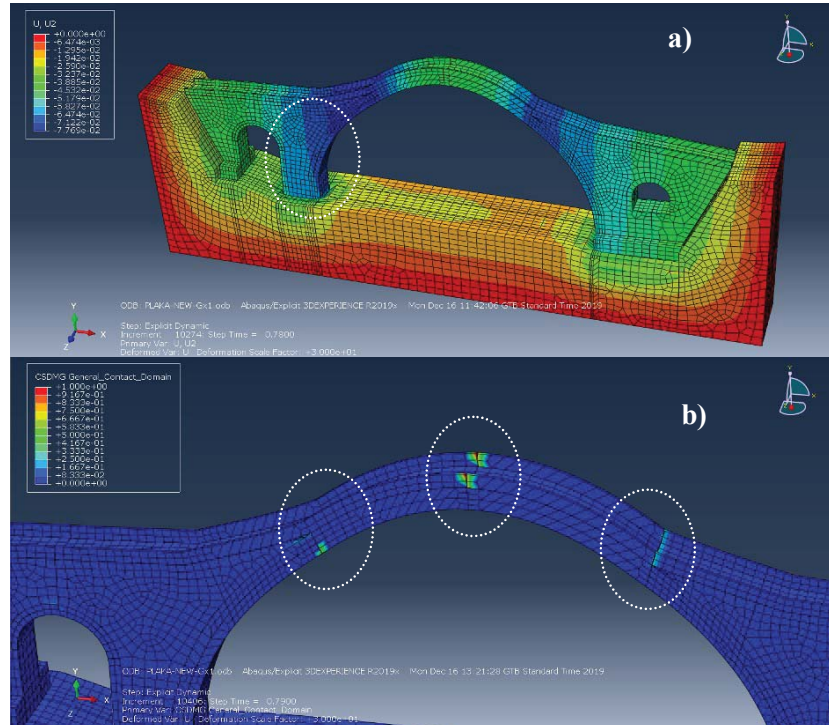

Figure 20. Vertical deflection of the mid-pier footing (a) together with the corresponding plastification (b) of critical cross-sections of the Plaka bridge for vertical forces 80% of gravity.

Figures 20a and 20b depict the numerical response when the applied forces reach the level of 80% of gravity. At this stage the vertical deflection of the footing of the mid-pier, due to the flexibility of the underlying soil, is approximately 30mm. This deflection of the footing is sufficient to cause the initiation of plastification in three contact surfaces at the encircled critical regions of the central arch, indicated in figure 20b. It is of interest to observe that two of the locations of the plastification of figure 20b coincide with the regions of tensile stress concentration in figure 18c.

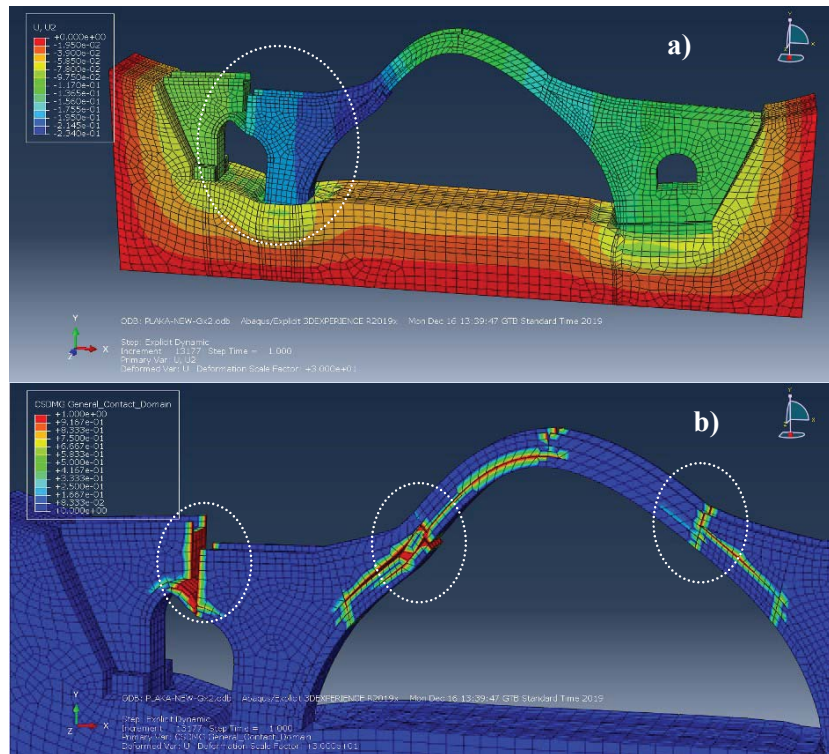

Figure 21. Vertical deflection of the mid-pier footing (a) together with the corresponding plastification (b) of critical cross-sections of the Plaka bridge for vertical forces 200% of gravity.

Figures 21a and 21b depict the numerical response when the applied forces reach gradually the level of 200% of gravity. At this stage the vertical deflections of the footing of the mid-pier, due to the flexibility of the underlying soil, reach the level of 200mm. Such level of deflections of the footing are detrimental to the structure as can be seen figure 21b. The plastification is widespread in all the contact surfaces being more pronounced at the left and right critical regions of the mid-pier. These plotted deformation pattern of the bridge bears resemblance to the collapse mechanism of the Plaka bridge depicted in figures 17b, 17c. Thus, the numerical response obtained at the end of the described gradual loading sequence shows signs of non-linear structural response which can be considered as realistic. This investigation is still under way. Stone bridge behaviour employing advanced non-linear analyses tools were also utilized by Drosopoulos et al (2006), Korompilias (2015), Simos et al. (2018).

## 6 CONCLUSIONS

- Stone masonry construction has a long tradition in many places worldwide. Stone masonry bridges built many centuries ago are one such example. Despite the rigidity and resilience of stone masonry bridges they are in need of maintenance in order to preserve them as part of

the built cultural heritage. Towards this end in-situ measurement campaigns were conducted on a number of stone masonry bridges in order to identify their dynamic characteristics in terms of eigen-frequencies, eigen-modes and damping properties. This information is believed to represent a valuable basis for building realistic numerical simulations of the structural behaviour of such bridges as well as for their structural health monitoring.

- The simplified numerical analyses yielded numerical predictions of bridge deformations and stresses that are useful in understanding the structural behaviour and the structural damage potential for such masonry structures.

- The peak tensile values predicted when design seismic forces were applied for the Saint Vissariona bridge are many times above the tensile strength of the stone masonry thus indicating the severe potential structural damage for this old stone masonry bridge from the design earthquake. The most vulnerable parts of the bridge, as obtained from the location of the peak tensile stress concentration, is a wide area at the crest of the main central arch of the bridge as well as at the abutment near the foundation.

- The integrity of the stone masonry in various parts of the bridge is an additional maintenance issue of considerable importance. Intervention recommendations for such stone masonry bridges should include clauses for applying preparatory actions of measurements and analyses like the ones included here together with established principles that govern a major retrofitting / maintenance effort for cultural heritage together with effective retrofitting / maintenance techniques that are proven to be durable.

- The described system identification technique can also be utilized in identifying changes of stiffness that may be linked to specific actions, such as earthquake activity, and thus serve as warning for certain maintenance counter-measures.

- As shown from the numerical predictions, the flexibility of the foundation, which may be partly attributed to long or short term erosion of the bridge footings, results in detrimental response for the Plaka bridge. These predicted peak tensile stress values are well beyond the stone masonry strength. Consequently, they could well have contributed towards the February 2015 collapse.

- The peak tensile values predicted when design seismic forces were applied for the Plaka bridge are many times above the tensile strength of the stone masonry thus indicating the severe potential structural damage for this old stone masonry bridge from the design earthquake. The most vulnerable parts of the bridge, as obtained from the location of the peak tensile stress concentration, is a wide area at the crest of the main central arch of the bridge as well as the mid-pier internal side footing. Thus, these earthquake vulnerability predictions for the Plaka bridge indicate that had the bridge not collapsed from flooding the design earthquake would have led to its structural damage and its partial collapse.

- Results from advanced non-linear numerical analyses show that such numerical simulations can reproduce in a realistic way the collapse failure scenario and support the hypothesis that the most-likely cause of the collapse of the Plaka bridge.

### Abstract

*Additive manufacturing is at the forefront of research activities worldwide, as the commercial exploitation of this technology is expected to displace some traditional manufacturing methods over the next few years. The aim of this research is the identification of the dynamic characteristics of three-dimensional printing specimens. The specific specimens, composed of 3D printed parts, correspond to elastic single and multiple degree of freedom oscillators. Moreover, parts that represent rigid rocking columns are constructed. Bending tests are performed in order to identify the stiffness of the elastic oscillators. Moreover, experimental results of free vibrations are presented in order to investigate the dynamic response of the rocking parts. The dynamic behavior verification through analytical solutions will highlight the adequacy of 3D printing specimens for conducting experimental research in structural dynamics.*

**Keywords:** Additive Manufacturing, Fused Deposition Modeling, Structural Dynamics, Earthquake Engineering, Rocking Structures, Experimental Investigation.

---

## 1 INTRODUCTION

Additive manufacturing technology is widely applied to optimize products in several industries and more specifically in the field of civil engineering [1] where the efforts have been intensified recently towards the implementation and testing of prototypes. Additive Manufacturing (AM), also known as 3D Printing, allows the fabrication of fully personalized designs with geometrical complexity, while it decreases the use of tools, the cost during prototyping steps and the fabrication time [2]. No requirement of molds, costly tools, milling, and sanding processes are the main reasons why it is a low-cost production method. Even though the basic methods of thermoplastics forming (extrusion, injection molding, thermoforming) are the mainstream in the polymers industry, 3D printing is more efficient, time saving, and minimizes the use of raw materials [3]. During the past few decades, different applications of 3D printing have been investigated in various industries, due to the interest of scientists, engineers, and the medical community [4]. The extensive use of 3D printing in recent years has increased the interest in Fused Deposition Modelling (FDM), which is a widely used method for 3D printing, due to good efficiency, easy material deposition and low costs [5]. Over the last years, bio-based polymers, such as poly (lactide acid) (PLA), have attracted much attention in 3D printing, replacing petroleum-based polymers, due to its availability from renewable and environmentally friendly resources as well its outstanding properties as high tensile strength and modulus [6, 7], demonstrating simultaneously high-stiffness and high-damping properties, worthy of further functional studies [8]. The application of PLA in FDM technology raises year by year [9]. The mechanical response of 3D printed PLA was found better than injection-molded PLA [10]. However, PLA has some disadvantages, such as poor thermal stability and surface, as well as brittleness which make it unsuitable for some large-scale end uses.

In the present research project, the exploitation of 3D printing in seismic testing was investigated. Especially, the seismic response of rocking podium strictures (RPSs) [11-13] was experimentally investigated. RPSs are comprised of an elastic superstructure placed on the top of a rocking story. Thus, 3D printed parts representing rocking columns and elastic oscillators were constructed. Evaluating the mechanical and the dynamic properties of the specimens by comparing the behavior with the analytical solution results, significant remarks arise regarding the capability of 3D printing in earthquake engineering experimental research. In the current study, preliminary results obtained by bending tests of the elastic members, as well as free rocking oscillation tests of rocking columns and frames are presented and discussed.

## 2 ROCKING PODIUM STRUCTURES

The first detailed study of the dynamic response of structures seismically isolated using a purely rocking floor at the base, considering that the superstructure behaves like a single degree of freedom elastic oscillator, was carried out by Bachmann et al. [11]. Based on the sdof model of the superstructure, Bantilas et al. [12] investigated the parameters that affect the elastic demands of RPSs. Later studies of Bantilas et al. [13] highlighted the critical effect of the higher vibration modes on the dynamic response of RPSs consisted of multiple degree of freedom (mdof) elastic superstructure. Experimental investigation of RPSs consisted of sdof superstructure has been also conducted [14]. The presence of curved extensions at the base of the rocking columns results in rolling and rocking rocking response [15]. The idealization of the model of mdof elastic oscillator fixed on the top of a rocking frame which is comprised of kinematic bearings is illustrated in Figure 1(a). Moreover, a typical configuration of the kinematic bearings is presented in Figure 1(b).

The rigid frame consists of a cap beam with mass  $m_b$  and  $N$  freestanding columns with mass  $m_c$ , semi-diagonal length  $R = \sqrt{H^2 + B^2}$ , rotational moment of inertia around its center of mass  $I_{cm}$ , and slenderness  $\alpha = \arctan(B/H)$ . In case of kinematic bearings with curved wedges and total slenderness  $\tan \alpha' = B'/H$ , the post uplift stiffness during rolling response depends on the radius of curvature  $r$  of the extensions, while the wedge's angle  $\beta$  sets the limit between rolling and rocking response. The superstructure is determined by the mass matrix  $\mathbf{M}$ , the stiffness matrix  $\mathbf{K}$  and the damping matrix  $\mathbf{C}$ . The equations of motion of the examined structural system are presented in the aforementioned literature.

Figure 1: (a) Schematic representation of the analytical model, (b) geometric configuration of a typical kinematic bearing.

For the scope of the experimental investigation, rocking podium structures comprised by a couple of kinematic bearings, and superstructures which were formed by stiff plates and two flexible walls were designed. In total, three different sets of kinematic bearings were constructed. Moreover, a one storey superstructure, a three storey superstructure and a rigid superstructure were configured. In order to obtain comparable response results, the total mass of the superstructures is equal, while the flexible superstructures demonstrate the same fundamental vibration period.

Each rocking column has height  $2H = 150$  mm and slenderness  $\alpha = 0.15$  rad. Thus, the width was  $2B = 22.5$  mm. Regarding the kinematic bearings with the curved extensions, the total width was  $2B' = 45$  mm and the wedges' radius of curvature  $r = 50$  and  $75$  mm. The rocking parts were placed on the top of a stiff plate.

The dynamic properties of the elastic oscillators should be in accordance with the scale of the rocking parts. Thus, taking into account that the height of the rocking parts is scaled down by a factor of 20, the period of the elastic oscillators must be scaled down by in order to represent a full size podium structure. Assuming that a typical three storey structure demonstrate period  $T_t = 0.3$  s, the period of the specimens should be  $T_t = 0.07$  s. The elastic oscillators are comprised of stiff plates and flexural walls. The stiff plates have dimensions  $150 \times 150 \times 6$  mm.

The vertical parts have height and width equal to 150 mm. The most important dimension, which is defined by the targeted period, is the thickness of the walls. Considering that in typical structures the distribution of floor masses is constant, the translational stiffness distribution throughout the structure affects the lateral displacement profile and the effective mass of the fundamental vibration mode. Due to the assembly of the superstructure the plates should be considered as rigid, while the walls as flexible. As such, only translational Dofs were considered. The relative translational stiffness between the floors was determined by solving the eigenvalue problem [17]. Regarding the mdof superstructure, the eigenvalue problem was solved in reverse

assuming triangular lateral displacement profile [16]. As such, given that the Young's modulus of PLA is  $E = 3.2$  GPa, the thickness of the walls of the sdof superstructure was 4.85 mm, while for the mdof superstructure the thicknesses were 6.35 mm, 5.83 mm and 4.80 mm for the walls of the 1st, the 2nd and the 3rd storey respectively.

The individual structural members of the examined structural system were designed in SolidWorks CAD software (Dassault Systèmes, SolidWorks Corporation, Waltham, MA, USA). Except of the geometric characteristics referred above, of great importance was the detailed design of the regions where the assembly of the kinematic bearings with the base plate and the cup beam, and the plates with the flexible walls took place. In Figure 2 indicative structural members, as well as the details of the plates, as they are designed, are illustrated.

Figure 2: CAD models of (a) a kinematic bearing, (b) a plate and (c) an elastic wall.

### 3 EXPERIMENTAL METHODS

#### 3.1 Fabrication of 3D printed specimens

All specimens tested in this study were produced on a BCN3D Sigma R17 3D printer (BCN3D, Barcelona, Spain) with a 2.85 mm filament diameter. BCN3D Cura was used as slicing Software. Only system integrated (default) variations of production parameters were used in the comparative analysis. The printing parameters used were: nozzle extrusion temperature of 220° C, heat bed temperature of 60°C, deposition line (layer) height 0.3 mm, deposition line width 0.8 mm and printing speed of 60 mm/s. Deposition speed was therefore not considered a variable in this study and a constant extrusion velocity was selected for all specimens, based on device parameters (e.g., effective printing range). Also, 3D printing was performed in a standard laboratory without temperature or humidity control.

The kinematic bearing specimens have been 3D printed with an infill density of 20%, as illustrated in Figure 3a. For the plates, an infill density of 30% was considered optimal (Figure 3b). Figure 3c demonstrates the elastic wall specimens that were 3D printed as hollow sections. For all specimens two lines were printed on the perimeter to form the outer shell, which is typical in FDM prints. Figure 3d shows an assembly of a rocking podium structure consisted of a three storey superstructure. It has to be mentioned that in order to avoid sliding, a low friction tape has been applied over the contact region between the bearings and the plates.

Figure 3: 3D printed (a) kinematic bearing, (b) plate, (c) elastic wall and (d) assembly of a rocking podium structure.

### 3.2 Bending tests

The 3D printed wall structures were subjected under 3-point bending tests using a universal Testometric M500-50AT testing machine equipped with 50 kN load cell, according ASTM D590. The support span was set to be 110 mm. At least three specimens were prepared and

tested. The loading and supports noses have a diameter of 10 mm. The crosshead speed was set to be 5 mm/min.

### 3.3 Free oscillation tests

The kinematic response of a kinematic bearing and a rocking frame, under free oscillation, was measured by motion tracking analysis of image sequences. For this scope the dynamic behavior is captured by a Canon EOS 5D MKIV camera with a Canon EF 24-70mm f/2.8 L USM II lens. The measurement of the displacements was performed using the Kinovea [18] software. Kinovea is a free and open source 2D motion tracking software that analyzes video files, even without markers. However, in order to improve the reliability of the measurements passive markers were assigned on the specimens.

## 4 MECHANICAL AND KINEMATIC BEHAVIOR OF 3D PRINTED SPECIMENS

Preliminary investigation of the identification of mechanical and kinematic properties of 3D printed specimens has been performed. These 3D printed parts will be used to construct the examined RPSs for the purpose of the current research program.

Orientation can also have a significant impact on print time. The 3D printing direction was purposely selected. For functional parts, it is important to consider the application and the direction of the loads. FDM parts are much more likely to delaminate and fracture when placed in tension in the Z direction compared to the XY directions.

Figure 4: Typical force-displacement curve of a 3D printed elastic wall.

The force-displacement response of a 3D printed elastic wall has been determined with flexural tests. The typical force-displacement curve is illustrated in Figure 4. It can be observed that the maximum force that was applied on the 3D printed elastic wall was 205 N. The deflection at break was 0.95 mm. The flexural stiffness is a criterion of measuring deformability. The flexural stiffness of a structure is a function based upon two essential properties: the elastic modulus,  $E$  (stress per unit strain) of the material that composes it, and the moment of inertia,

$I$ , a function of the cross-sectional geometry. In terms of flexural stiffness  $EI$ , the mean measured value was  $8.5 \times 10^6 \text{ Nmm}^2$ , while the theoretical calculations during the design process were given at  $9 \times 10^6 \text{ Nmm}^2$ .

In Figure 5 the experimental time histories of an individual kinematic bearing and a rocking frame under free oscillation are presented comparatively with the analytical solution. Regarding the kinematic bearing with radius of curvature  $r = 50 \text{ mm}$ , the responses are demonstrated in terms of horizontal displacement of its center of mass (Figure 5a). The analytical response was calculated given the design properties of the bearing, while the coefficient of restitution that defines the energy dissipation during impact was assumed as provided by Bachmann et al. [15]. Given the geometry of the kinematic bearing and the printing properties, the non-dimensional moment of inertia  $\bar{I}_0 = 1.354$ . Where  $\bar{I}_0 = I_0 / (m_c R^2)$ , and  $I_0$  is the rotational inertia of the column with respect to the pivot point. In Figure 5b the response of a rocking frame consisted of the kinematic bearings with radius of curvature  $r = 50 \text{ mm}$  is displayed. The analytical solution was derived by Makris and Vassiliou [19]. The time history is given in terms of the cap beams' horizontal displacement. In general, the analytical solution predicts well enough the response time histories. Furthermore, the coefficient of restitution seems to provide with high precise the energy dissipation during impact. However, the differences between the responses, especially in case of the kinematic bearings, lead to significant remarks. It has to be mentioned the fact that although the amplitude of the negative values of the responses are in good agreement, the measured positive displacements are higher than those of the analytical solution. Moreover, the peak positive value after impact is almost equal to the negative extreme value before impact. These remarks imply a non-symmetric specimen. Although the initial design was totally symmetric, the eccentricity may occur due to imperfections of the external geometry or due to non-symmetric pattern of the infill. In order to capture the response of the specimens with higher accuracy, validation of the analytical solution is needed.

Figure 5: Response under free oscillation of (a) a kinematic bearing and (b) a rocking frame.

## 5 CONCLUSIONS

In the present research project, the exploitation of 3D printing in seismic testing is investigated. 3D printed parts representing rocking columns and elastic oscillators were manufactured with Fused Deposition Modeling technology. The mechanical and the dynamic properties were assessed. The measured mechanical response was very close to the designed. Considering the dynamic behavior, minor deviations to the designed geometry were observed. Therefore, the 3D printing procedure can be potentially utilized for seismic testing. In a future study, the construction of a redesigned and more complex structural system could be done, through the process of additive manufacturing, along with a thorough examination of the dynamic behavior via the utility of proper experiments.

## ACKNOWLEDGEMENTS

This research is co-financed by Greece and the European Union (European Social Fund-ESF) through the Operational Programme «Human Resources Development, Education and Lifelong Learning» in the context of the project "Reinforcement of Postdoctoral Researchers - 2nd Cycle" (MIS-5033021), implemented by the State Scholarships Foundation (IKY).

### Abstract

*Nowadays much emphasis has been placed on studying smart materials because of their ability to change their particular properties in a controlled manner by external stimuli. Shape memory alloys belong to the wider category of intelligent materials and exhibit two unique characteristic behaviors, superelasticity and shape memory effect, making them differ from conventional materials. These effects are due to diffusionless transformations between austenitic and martensitic phases. The SME occurs because a temperature-induced phase transformation reverses deformation and the pseudoelasticity achieves large, recoverable strains with little to no permanent deformation, as well, but it relies on more complex mechanisms. Innovative, low cost iron-based shape memory alloys (Fe-Mn-Si SMAs) with good workability, machinability, and weldability have been drawing much attention during the last two decades regarding to their potential application in engineering such as prestressing of concrete or coupling devices. In the present work we carried out experiments on monotonic mechanical loading, low-cycle fatigue and thermal loading in the laboratory of Experimental Strength of Materials and Structures of Aristotle University of Thessaloniki, so as to investigate in practice their behavior and all their special characteristics that already exist in the current literature.*

**Keywords:** low cost iron-based shape memory alloys, thermomechanical characterization, civil engineering applications.

---

## 1 INTRODUCTION

Shape memory alloys (SMAs) are metallic materials which belong to the wider category of smart materials. The last decades they have attracted the interest regarding to their potential application in engineering, due to their good mechanical properties including fatigue behavior, corrosion resistance and their ability to damp and absorb energy. [1-3] Shape memory alloys display two distinct crystal structures or phases (austenitic and martensitic phase), which depend on temperature and internal stress. Martensite exists at lower temperatures while austenite exists at higher temperatures. When an SMA is in martensite form at lower temperatures, the metal can easily be deformed into any shape. When the alloy is heated, it goes through transformation from martensite to austenite. In the austenite phase, the memory metal «remembers» its initial shape, before deformation [4]. Because of that, shape memory alloys exhibit two unique characteristic behaviors, superelasticity and shape memory effect. The loading–unloading cycle typically shows a pronounced hysteresis loop. In the shape memory effect, a large residual strain remains after unloading, which can be recovered by heating [5]. The two most prevalent shape-memory alloys are copper-aluminium-nickel and nickel-titanium (NiTi) which are preferable for most applications due to their stability and practicability [6]. However, low-cost, iron-based Shape Memory Alloys (Fe-Mn-Si SMAs) have been drawing much attention during the last three decades[7,8]. Fe-Mn-Si SMAs can be passive or active components in civil structures to reduce damage caused by environmental impacts or earthquakes [3]. Other possible applications of SMAs in civil engineering are passive vibration damping and energy dissipation, active vibration control, actuator applications, and the utilization of the SME (Shape memory effect) for prestressing or tensioning. Among those possible applications, the pre-stressing of structures using fixed shape memory alloys has attracted a considerable attention [8]. In contrast to conventional prestressing, neither anchoring systems nor hydraulic devices are necessary for applying the prestressing force, since prestressing is achieved by the shape memory effect produced by heating. This heating can be implemented by electrical resistance heating (Joule heating). However, to be suitable for prestressing, an SMA needs to have certain properties, such as a large and stable recovery stress [10,11]. The aim of this work is to broaden the knowledge of iron-based Shape memory alloys' mechanical behavior, which is now limited, through laboratory tests. The experimental work presented in this paper focuses on characterizing the thermo-mechanical response of the Fe-SMA through experiments on monotonic mechanical loading, low-cycle fatigue and thermal loading, carried out in the laboratory of Experimental Strength of Materials and Structures of Aristotle University of Thessaloniki. Stress and temperature were the investigation parameters.

## 2 MATERIALS AND METHODS

To characterize the thermo-mechanical response, four dog-bone shaped tensile specimens with a gauge length of 60 mm and cross-section of 1.5 x 9 mm<sup>2</sup> were prepared from the original (Fe-SMA) plate. (see table 1) Then, unidirectional mechanical tests were performed using the Instron tensile testing machine equipped with a climate chamber which can be operated in a temperature range between 20°C (RT-Room Temperature) and 250°C. Instron machine contains also an integrated static load cell of 50 kN capacity and the Bluehill software which gives us the results of an experiment in a diagram form of load – strain. (see figure 1) During the tests, the strain evolution was measured with a clip-on extensometer. The stress–strain behavior of the alloy was characterized by applying tensile mechanical loading and unloading, in the two first specimens, under displacement-controlled conditions with a loading rate of 1 mm/min. The

recovery stresses as a function of the temperature were also measured in strain-controlled tests in the two other specimens. Firstly, the samples were subjected to 4 and 1% tensile strain and then heated to 160 and 250°C, respectively, and subsequently cooled down to RT, keeping the gauge length constant during the whole experiment. In Table 1 we depict all details of the experimental sequence. The heating rate was set to 6°C/min. As far as cooling is concerned it was held in a physical way, so the coolest temperature reached was approximately 20°C and the cooling rate was slow. (see figure 2)

Table 1: Detailed information of experiments

Name	Dimensions (mm)		Loading	T (°C)	Target strain	Comments
	t	b				
<b>Specimen 1</b>	1.50	9.15	MUT <sup>*1</sup>	RT(=23)	Up to failure	
<b>Specimen 2</b>	1.56	9.68	LCF <sup>*2</sup>	RT	Strain 4‰	
	1.56	9.68	LCF	RT	Strain 9‰	
	1.56	9.68	LCF	RT	Strain 3.5%	
	1.56	9.68	LCF	RT	Strain 6.5%	
	1.56	9.68	MUT	RT	Up to failure

	1.55	9.41	MUT	RT	Up to failure	

\*1Monotonic Uniaxial Tension, \*2Low Cycle Fatigue (n=3), \*3Thermal Loading (n=1)

Figure1. Experimental setup with climate chamber

As mentioned before, the two first specimens (specimen 1 & 2) are tested under displacement-controlled conditions. Each one is placed carefully in suitable grips for its cross-

section, so as not to have slip losses and tension loads be applied right. Their dimensions are measured (1.5 x 9.15) mm and (1.56 x 9.68) mm, respectively, using a caliper. The first one is tested under monotonic, uniaxial tension loading up to failure. Specimen 2 is submitted to five low – cycle fatigue tests of three loading – unloading cycles with a different target strain each time. Target and residual strains of each cycle are given collectively in the table 2 below:

Table 2: Target and residual strains of each low-cycle fatigue test.

No of Cycle	Target strain	Residual strain
1st cycle	4‰	1.8‰
2nd cycle	9‰	5‰
3rd cycle	3.5%	2.8%
4th cycle	6.5%	5.8%

When four cycles are completed a gradual increase of loading is applied with the same rate of 1mm/min, as before.

Following the previous investigations, specimens 3 and 4 are tested in thermal loading. Each one is placed carefully in suitable grips for its cross-section, so as not to have slip losses and tension loads be applied right. Their dimensions are measured (1.52 x 9.03) mm and (1.55 x 9.41) mm, respectively, using a caliper. We have applied an initial pre-strain and total unloading to both specimens. When the protocol set is activated, the temperature starts increasing from 20°C (RT-Room Temperature) to the default values of 160 and 250°C with a rate of 6°C/min. When the heating is completed, the temperature is held for a few minutes, in order to achieve uniform temperature distribution in the specimen. When opening the climate chamber, cooling starts naturally and a Room Temperature of 20°C is reached. (details in table 3) After that, the extensometer is placed again, and monotonic uniaxial loading is forced to the specimen up to failure. Figure2 present the aforementioned thermal protocol.

Table 3: Required time for heating and cooling.

Target temp. (°C)		Heating time (min)	Constant time (min)	Cooling time (min)
Temp. (°C)	150	20	5	10
	260	60	5	40

Figure 2: Time – Temperature diagram for heating to 250°C and cooling to RT

### 3 RESULTS

The following table 4 summarizes the results obtained from the experimental campaign occurred in the Laboratory for Strength of Materials and Structures.

Table 4. Summarized results

Name	Max. Load (kN)	Max. Stress (Mpa)	Max. Strain (%)	T (°C)	Residual strain (‰)
<b>Specimen 1</b>	13,734	1000	33	RT(=23)	Up to failure
<b>Specimen 2</b>	5,540	367	0,4	RT	1,8
	7,816	518	0,9	RT	5,0
	10,133	671	3,5	RT	29
	11,085	734	6,5	RT	58
	14,481	959	33	RT	Up to failure
<b>Specimen 3</b>	2,750	180	0,15	160	None
	9,230	672	35	RT	Up to failure
<b>Specimen 4</b>	3,870	250	0,19	250	None
	13,546	928	37	RT	Up to failure

Specimen 1 was monotonically loaded at room temperature up to failure. Figure 3 depicts the strain-strain graph of this coupon. An ultimate load of 13,734kN, which corresponds to 1000 MPa was recorded. The maximum measured strain was equal to 33%. It is obvious that at room temperature Fe-SMAs exhibit a high strength value together with high plasticity.

Figure 3.  $\sigma$ - $\epsilon$  graph for specimen 1

Specimen 2 was loaded for several cycles (see table 1), at room temperature but at different loading rates. The first 3 cycles were performed up to a strain limit of 4‰. The following at a strain limit of 9‰, value which was increased to 35‰ and 65‰. Finally, specimen 2 was loaded up to failure. Figures 4a to 4

Figure 4a.  $\sigma$ - $\epsilon$  graph for specimen 2 (4‰ target strain)Figure 4b.  $\sigma$ - $\epsilon$  graph for specimen 2 (9‰ target strain)Figure 4c.  $\sigma$ - $\epsilon$  graph for specimen 2 (35‰ target strain)Figure 4d.  $\sigma$ - $\epsilon$  graph for specimen 2 (65‰ target strain)

Concerning the pre-strain of 4‰ we noticed that the residual strain changed significantly when we slightly increased the target strain value, which means the investigated Fe-SMA is sensitive to the defined pre-strain value, leading to very different residual strains.

The further increase of the target strain from 4 to 9‰, leads to a gradient change of the  $\sigma$ - $\epsilon$  graphs' inclination (initial yield of the material), shortly after 4‰. The target strain remained stable to 9‰ at both three cycles, so loops follow a more regular behavior, having the same values of residual strains.

The following pre-strain levels are reaching 3.5% and 6.5% respectively. The mechanical behavior of alloy becomes clearly elastoplastic and the residual strains after unloading are becoming significant. (see figures 3c and 3d) Finally a loading-unloading sequence 12 cycles we applied monotonic uniaxial tension to the coupon specimen up to failure. When the sample reaches its fracture point stress of 959 MPa we measure an ultimate strain of 33%.

Comparing the overall behavior of specimen 1 and specimen 2 we could say that the loading-unloading of 12 cycles (low-cycle fatigue) did not affect the Fe-SMA's mechanical behavior.

Specimens 3 and 4 were used to investigate the thermomechanical behavior of the tested Fe-SMA's alloy. Specimen 3 was pre-strained to a level of 4% and was unloaded to RT conditions. A low stress of 25 MPa is kept constant to avoid grips' slip. Then the temperature was increased from RT to 160°C. When heating is activated a low increase of load is noticed which is soon decreased until we reached the target temperature of 160°C. From that temperature level until the cooling to room temperature (20°C) conditions, the load starts increasing. The increase of almost 180 MPa depicts the prestress effect of the coupon. The aforementioned behavior is demonstrated in figure 5b. Similarly, specimen 4 was heated to 250°C and left to cool to RT. For the target temperature of 250°C we measured an imposed

stress equal to 250MPa. (see figure 6b). Finally, both specimens after the thermal loading-unloading were imposed to uniaxial tension up to failure. Figures 5a and 6a show the overall  $\sigma$ - $\epsilon$  behavior of the tested specimens 3 and 4.

Figure 6a.  $\sigma$ - $\epsilon$  graph for specimen 4

Figure 6b. Thermomechanical behavior of specimen 4

## 4 CONCLUSION

- At room temperature Fe-SMAs exhibit a high strength value together with high plasticity.
- The investigated Fe-SMAs are sensitive to the imposed pre-strain value, leading to different residual strains
- The loading-unloading of 12 cycles (low-cycle fatigue) did not affect the Fe-SMA's mechanical behavior.
- Different levels of target temperature lead to different prestress levels

### Abstract

*Steel beam-to-column connections under a cyclic sinusoidal loading history were studied. The investigation of the cyclic response of the steel beam-to-column connections contained an experimental and numerical part. The experimental part included a number of full-scale specimens having a cross section of IPE240 or IPE300 and a height of 1.0m which were rigidly connected to a much stiffer steel beam thus representing a steel beam-to-column connection. These specimens were tested to failure being subjected to a cyclic sinusoidal point load of continuously increasing amplitude. Next, a numerical study is performed in an effort to simulate the observed behaviour of these steel beam-to-column connections and their response is presented and discussed. The material test data for the numerical simulation of the steel beam-to-column connection were provided from simple steel coupons which were taken from the T-Beam specimens after testing. The cross-section of these coupons was 6.2mm x 8.0mm and their height equal to 16.5mm. A number of such simple steel coupons were tested having as main variable the nature of the load (monotonic or cyclic) and the variation of the loading frequency. From the observed behaviour it can be concluded that an increase in the strain rate results in an increase of the stress values beyond the yield. Next, a numerical study is performed in an effort to simulate the observed behaviour of these simple steel coupons. Experimental and numerical results of the material steel coupons are presented in this paper. It can be concluded that the combined constitutive law can be quite successful in yielding realistic prediction of the cyclic response provided the appropriate values for the parameters defining this constitutive law from the experimental test data, in combination with the option of the dynamic increase factor (DIF) in order to take into account the strain rate effect.*

## 1 INTRODUCTION

Moment resistant frames are commonly used in seismic areas because of their excellence on seismic resistance whereby the performance of beam-to-column connections are of particular importance especially when these structures are subjected to strong earthquake ground motions ([1], [2], [3]). Usually these connections undergo large moment reversals during the earthquake excitation, thus it is important to exhibit stable plastic flexural response in order to provide dissipative capability, without the development of undesired damage patterns, and in this way prevent any kind of local or global instability.

In a previous investigation by Manos, Nalmpantidou and Anastasiadis ([10]) the performance of steel beam-to-column joints was studied first by examining steel beam-to-column welded joint specimens at the laboratory subjecting them to cyclic seismic-type low-cycle fatigue loading and then by numerically simulating the observed performance of the same specimens. Similar studies have been performed in the past by other researchers. Despite the fact that many similar experiments have been performed in the past ([4], [5]), this investigation provided at first hand all the information required for the numerical analyses. That is, the exact geometric and material characteristics of the specimens as well as specific information on the type of loading conditions and on the measured response. The numerical simulation was performed utilizing a commercial software package that is thought to be suitable to simulate the observed response and the non-linearity that developed and included large plastic strains and local instabilities.

One parameter that was found to be of significance in this investigation was the definition of the material characteristic of the steel T-Beam specimens that were investigated ([6], [8], [10], [11]). In order to assess the performance of structural steel components it is important to know the material properties. Quasi-static material tests are usually performed to obtain these parameters, however they may no longer represent the dynamic behaviour of the material during an earthquake, because as expected the loading frequency during an earthquake exceeds the loading frequency during the quasi-static material tests. In order to predict the response of a structure during an earthquake a good knowledge of the material behavior for the numerical simulation is important.

The T-Beam specimens were tested under cyclic load with the frequency of this loading being one of the variables that was studied. For this reason, it was necessary to study the material properties in light of the fact that the imposed cyclic loading was not of the constant slow-rate monotonic type that usually characterizes the material properties of steel structural elements. For this purpose, the following experimental sequence was carried out. From each of the tested steel T-Beams a number of coupon samples were taken, as is described in section 2. These samples were tested in axial tension/compression under cyclic loading with the frequency of the loading being one of the main variables. In addition, apart from these samples being tested by cyclic load additional samples of the same T-Beam specimens were tested applying the tension in a monotonic way. From all these tests results were obtained that shed some light on the influence of the nature of loading (cyclic or monotonic) as well as on the frequency of this loading. The results have been used to develop cyclic hardening parameters and dynamic increase factors suitable for incorporation into numerical models in order to predict the material behavior of structural members subjected to cyclic loading under several different frequencies. Summary results of this experimental sequence are presented and discussed in section 3. The numerical analysis of the observed performance is presented in section 4. The ABAQUS commercial software package was utilized for this purpose.

## 2 MATERIALS AND EXPERIMENTAL SETUP

The coupon samples for the tests aiming for the material characterization were obtained by removing parts of the flanges from the previously tested T-Beam specimens that were located away from the locations of the plastic hinge locations which developed during the T-Beam tests ([10],[12]). The testing of these T-Beam specimens is described in the work by Manos et al. ([10]) and is not repeated here.

Figure 1a. Coupon 6R1-6 (6.7mm x 6.7mm,  $\ell = 16\text{mm}$ )    Figure 1b. Coupon 6R1-5 (7.95mm x 7.80,  $\ell = 16\text{mm}$ )

The coupons to be tested were formed by machining the parts removed from the flanges, as shown in figures 1a and 1b. These coupons had a narrow central part of relatively small cross section with a small length ( $\ell = 16\text{mm}$ ) and this part was designed to provide the necessary information for the material characterization. Through the two larger parts, which were provided with holes in order their attachment to the loading reaction frame to approximate pinned support conditions, the coupon was attached to the loading reaction frame. At the top and bottom of the coupon steel brackets are employed to attach the coupon sample using cylindrical pins. These brackets are in turn firmly attached to the reaction loading frame. At the top bracket a load cell is also attached that monitors the variation of the applied axial load.

The cross section of the narrow part remained constant all along its 16mm length. Its dimensions (x, y) were accurately measured (figures 2a, 2b and 2c). Moreover, strain gauges were attached at the middle of all the sides of this rectangular prismatic narrow part. These strain gauges were placed in the longitudinal direction of this steel prismatic part in order to measure the variation of the axial strain that developed during the variation of the axial load. The dimensions of the cross section of this narrow part combined with its length dictated almost uniform tension / compression conditions prohibiting the development of any distortions from local buckling, especially when large plastic strains developed in this narrow central part. Through the readings of the strain gauges the eccentricity of the axial load application could be checked and controlled.

### 3 OBSERVED PERFORMANCE AND CORRESPONDING MEASUREMENTS.

As already mentioned, one of the main variables of this investigation was the nature of loading, being either cyclic or monotonic. The second variable was the frequency of the cyclic loading or the rate that the monotonic loading was applied, as will be indicated in what follows.

#### 3.1 Monotonic loading

A summary of the results obtained when the specimens were subjected to monotonic axial tensile loading is presented below. The characterization of the applied load in terms of loading rate (slow or fast) and the origin code name of the T-Beam are mentioned in the presentation of these test results. In figure 3a the axial stress versus axial strain response is shown from two coupons taken from T-Beam 9R1; one of them was tested with slow strain rate whereas the other one with fast strain rate. As can be seen from this figure, this variation of the strain rate during the monotonic application of the applied load resulted in a significant change in the yield stress value as well as in the plasticized part of the response beyond the yield point. Next, figure 3b shows the response of axial stress versus axial strain from two coupons tested both at slow strain rate; one of them was taken from T-Beam 9R1 while the other from T-Beam 10R1. As can be seen from this figure, the response obtained from these two coupons is rather similar. By studying the two figures, we are led to the conclusion that increasing the strain rate from slow to fast leads to an increase in the yield stress as well as in the stress values beyond the yield point.

Figure 3a. Coupons taken from T-Beam 9R1 tested with slow and fast strain rate

Figure 3b. Coupons taken from T-Beam 9R1 and T-Beam 10R1 both tested with slow strain rate

### 3.2 Cyclic loading

Following on from our previous work ([12]), this paper will present results from the material test coupons taken from the flanges of the T-Beam 8R1. In figure 4 and 5 the obtained axial stress versus axial strain responses are shown as they were measured and subjected to a number of cyclic loading tests. The strain rate during all these tests varied from fast to slow, as it resulted from the application of the axial tensile/compressive load from a sinusoidal variation with a frequency of 0.005Hz to 2.0Hz.

In figure 4a the cyclic response of a coupon taken from T-Beam 8R1 is shown. This response resulted by applying the axial load in a sinusoidal way with a frequency of 2.0Hz thus producing a rather fast strain rate. In figure 4b the cyclic response of a coupon also taken from T-Beam 8R1 is shown. This response resulted by applying the axial load in a sinusoidal way with a frequency of 0.005Hz thus producing a slow strain rate. Figure 5 shows the cyclic response of a coupon taken from T-Beam 8R1 obtained by applying the axial load in a sinusoidal way with a frequency ranging from 0.005Hz to 2.0Hz. The response obtained during the test whereby the cyclic load was varied with a frequency equal to 0.05Hz is considered as a rather slow strain rate test whereas the one with a frequency equal to 0.1Hz as a rather moderately fast strain rate test. Finally, the response obtained during the test whereby the cyclic load was varied with a frequency equal to 2.0Hz is considered as a rather fast strain rate test.

Figure 4a. Cyclic response with axial load varying in a sinusoidal way with a frequency of 2.0Hz. Coupon taken from T-Beam 8R1 tested with a rather fast strain rate

Figure 4b. Cyclic response with axial load varying in a sinusoidal way with a frequency of 0.005Hz. Coupon taken from T-Beam 8R1 tested with a slow strain rate

As can be seen from these figures (4a, 4b, and 5) the yield point can be hardly distinguished from the obtained axial stress versus axial strain response. However, as can be seen in figure 5, the variation of the strain rate during the cyclic application of the applied load resulted in a significant change in the plasticized part of the response beyond yield as it was also observed in figure 3a for the monotonic application of the load. It can be concluded from both figures 3a and 5 that the increase in the strain rate results in a noticeable increase both at the yield stress as well as at the stress values beyond the yield point for strain values larger than the yield strain.

Figure 5. Cyclic response when axial load is varying in a sinusoidal way with frequency values in the range from 0.005Hz to 2.0Hz. Coupons taken from T-Beam 8R1 tested with slow as well as with fast strain rate

In figure 6, a comparison between the axial stress versus axial strain response from four coupons under cyclic and monotonic loading is shown; one of them is taken from T-Beam 8R1, one of them is taken from T-Beam 10R1 and two of them are taken from T-Beam 9R1. Coupon 8R1 was tested with a cyclic loading frequency equal to 2.0Hz (Tests 3, 4, 5) producing a rather fast strain rate. Two coupons from T-Beam 9R1 were tested by applying the tensile

load in a monotonic way; one of them with a slow strain rate (INSTRON static 9R1-5) and the other one with a fast strain rate (INSTRON quick 9R1-5). Finally, the fourth specimen was taken from T-Beam 10R1 and was tested by applying monotonic load with a slow strain rate (INSTRON static 10R1-3). The two main observations that were made before can also be seen in this figure.

Figure 6. Monotonic / cyclic axial stress - strain response. The cyclic axial load is varying in a sinusoidal way with frequency value equal to 2.0Hz (T-Beam 8R1). Monotonic response from coupons taken from T-Beam 9R1 and 10R1 tested either with slow or with fast strain rate

From the above observed performance it can again be concluded that,

- a) During the monotonic application of the load an increase in the strain rate resulted in an increase in the yield stress value as well as in the stress values of the plasticized part of the response beyond the yield point. In addition to this the observed axial stress versus axial strain response from different coupons subjected to the same slow strain rate monotonic load is quite similar.
- b) The application of the cyclic load with slow, moderately fast or rather fast strain rate resulted in axial stress versus axial strain response whereby the yield point is hardly distinguishable but despite of this the strain rate effect can be clearly seen. Furthermore the application of the cyclic load with slow, moderately fast or rather fast strain rate resulted in axial stress versus axial strain response that has stress values beyond the yield point that exhibit a noticeable increase with the increase in the strain rate.
- c) From the limited results presented here the effect of the cyclic nature of the loading results in a more pronounced increase of the stress values with the increase in the strain rate than when the load is applied in a monotonic way.

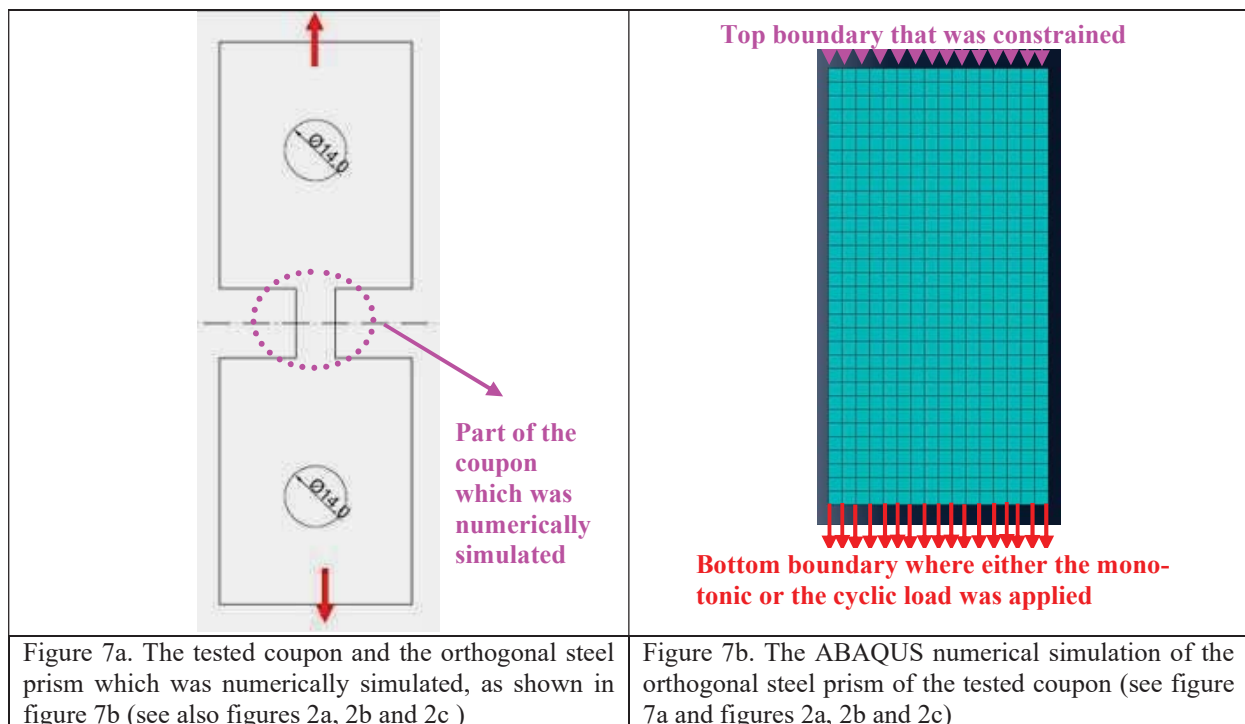

## 4 NUMERICAL SIMULATION OF THE TENSION AND CYCLIC TESTS

### 4.1 Numerical modeling.

As mentioned in section 2 simple specimens having the shape of an orthogonal prism were taken from the flanges and were applied to monotonic tension or / and to cyclic tensile / compressive load with a sinusoidal time variation having a given amplitude and frequency. A

number of such simple specimens were tested and their results are presented and discussed in section 3 having as main variable the variation of the loading frequency and the nature of the loading (monotonic or cyclic). In order to simulate numerically the behavior of these specimens a numerical study was performed utilizing the commercial software package ABAQUS [7].

The orthogonal prism of the experimental sequence (figure 7a), which was represented through the finite element 2-D mesh, is shown in figures 7b. The prism was considered to be represented with absolute fixity conditions in the numerical simulation on the top side whereas on the bottom side either the monotonic or the cyclic load was applied. The other two sides were left unconstrained. However, the rigid body in-plane as well as the out-of-plane horizontal displacement response was also constrained.

In order to simulate the variation of the load in time as either fast or slow monotonic load or as cyclic load with varying sinusoidal cyclic frequency, the displacement control option was utilized whereby an imposed displacement was defined as a function of time and displacement amplitude. Dynamic implicit analyses were in-order for this software to take into account the different load frequencies. Following the load variation that was applied during testing the numerical analyses were also performed with monotonic load (with either slow or fast strain rate) and with cyclic load (again with either slow, moderate or fast strain rate). The imposed displacement variation was introduced to the software in tabular form identical with the one that was applied to the corresponding specimen during the experimental sequence. The adopted discretization scheme (figure 7b) is believed to be considerably fine in an effort to capture numerically the observed behavior.

## 4.2 Material modeling

In the framework of the numerical investigation a parametric study was conducted that focused on the way the steel material properties were introduced in the numerical simulation. In our previous work two different approaches were tried ([12]). According to the first approach

the measured tensile steel properties were modified accordingly in order to be introduced in the numerical simulation through the ABAQUS combined hardening material constitutive law whereas in the second approach the measured properties were introduced in the numerical simulation through the ABAQUS isotropic hardening constitutive law. Furthermore in both cases different yield stress ratios for different strain rates were taken into account.

In this work the focus lies in the numerical simulation of the material tests through the ABAQUS combined hardening material constitutive law. There are several ways in this commercial software package [7] to define a combined hardening material constitutive law in order to capture the cyclic response of a specimen. The evolution law of this model consists of two components: a nonlinear kinematic hardening component, which describes the translation of the yield surface in stress space through the back-stress, and an isotropic hardening component, which describes the change of the equivalent stress defining the size of the yield surface, as a function of plastic deformation [7]. In the present study the combined hardening constitutive law is defined through the values that are given to certain relevant parameters. For the nonlinear kinematic hardening component these parameters are a)  $\sigma|_0$ , the yield stress at zero equivalent plastic strain, b)  $C_k$  and  $\gamma_k$  (material constants that can be calibrated from test data) and for the isotropic hardening model these parameters are c)  $\sigma|_0$ , equivalent yield stress, d)  $Q_\infty$  and  $b_{iso}$  (material constants that can be calibrated from test data). Values for these parameters were calculated from the test data that were obtained from the experimental process from the tests of steel samples and were utilized in the parametric study that was performed in the present work. The nonlinear kinematic hardening component of the model defines the change of back-stress  $\alpha$  and is given by Equation (1). All stress strain data are taken from a stabilized cycle from the test data as shown in figure 8.

$$\alpha_k = C_k / \gamma_k (1 - e^{-\gamma_k \epsilon^{pl}}) + \alpha_{k,1} e^{-\gamma_k \epsilon^{pl}} \quad (1)$$

Figure 8. Stress strain data for a stabilized cycle

The isotropic component defines the change of the size of the yield surface  $\sigma^0$  as a function of equivalent plastic strain  $\epsilon^p$  as shown in figure 9 and is given by Equation (2).

$$\sigma^0 = \sigma|_0 + Q_\infty (1 - e^{-b_{iso} \epsilon^p}) \quad (2)$$

Figure 9. Symmetric strain cycle

Abaqus allows the specification of strain rates effects with the option of rate dependent data at combined and isotropic hardening constitutive law. In order to define the strain rate effect the use of a dynamic increase factor (DIF) was utilized based on the work of Malvar and Crawford [9]. The same values for DIF that were calculate and introduced as input in tabular form in terms of a ratio of the yield stress versus the equivalent plastic strain rate to be used in the particular case being analyzed, from our previous work [12] are also being used in this paper. The work of Malvar and Crawford [9] is based on numerous experimental data from a literature review on the effects of strain rates on the properties of steel reinforcing bars for reinforced concrete structural elements. The dynamic increase factor (DIF) is the amplification by DIF of the value a certain mechanical property (yield stress or maximum stress) has under low strain rate loading conditions (static) to another condition whereby because of the nature of loading (dynamic) the strain rate has a larger value than before. A relationship is proposed by Malvar and Crawford ([9]) that a DIF value can be derived for a given strain rate increase and thus evaluate through this DIF the corresponding for this increased strain rate amplified yield and ultimate stress values. This formulation is valid for bars with yield stresses between 290 and 710 MPa and for strain rates between  $10^{-4} \text{ sec}^{-1}$  and  $225 \text{ sec}^{-1}$ . Figure 10 depicts the variation of DIF with the variation of the strain rate. This approach was presently followed use as reference control properties the yield stress found for the slow rate monotonic axial tension test with coupon 9R1-5 (see figure 5).

Figure 10. Dynamic increase factor which has been considered for the numerical investigation

### 4.3 Numerical results for monotonic axial tensile load cases

Figure 11 shows a comparison between the axial stress – axial strain monotonic tensile response obtained from the numerical analysis of coupon 9R1-5 and 10-3 loaded under slow strain rate conditions (duration of loading 700 seconds) and coupon 9R1-5 loaded under fast strain rate conditions (duration of loading 2.5 seconds) for both constitutive laws of isotropic hardening and combined hardening together with the option of the DIF.

Figure 11a. Monotonic axial tension numerical simulation with isotropic hardening constitutive law for coupon 9R1-5 and 10R-3 for strain values up to 40000 microstrains.

Figure 11b. Monotonic axial tension numerical simulation with combined hardening constitutive law for coupon 9R1-5 for strain values up to 40000 microstrains.

As can be seen in figure 11a, the numerical simulation including the isotropic hardening with the DIF option is quite sensitive to the effect of the strain rate variation. Moreover, the numerical response agrees quite well with the observed response for strain values smaller than 6000 micro-strains. In the case of the slow strain rate there is a certain discrepancy between predicted and observed stress values for strains larger than 10000 micro-strains and smaller than 20000 micro-strains. Similarly, in the case of the fast strain rate there is again a certain discrepancy between predicted and observed stress values for strains larger than 6000 micro-strains and smaller than 25000 micro-strains.

In figure 11b depicts the axial stress-strain numerical response employing combined hardening constitutive law together with the DIF options for coupons 9R1-5 submitted to monotonic tension load with slow strain rate conditions (duration of loading 700 seconds) and with fast strain rate conditions (duration of loading 2.5sec). The material parameters that were calculated from test data from test coupons that were taken from T-Beam 9R1 and were used to define the combined hardening constitutive law with cycling hardening are:

Combined hardening parameters:

Yield stress at plastic strain  $\sigma|_0=200\text{Mpa}$ ,  
Kinematic Hardening Parameter  $C_k=28300$

Gamma  $\gamma_k=250$

Cyclic hardening parameters:

Equivalent stress  $\sigma|_0=200\text{Mpa}$

Q-Infinity parameter  $Q_\infty=81$

Hardening parameter  $b_{iso}=6.5$

As indicated in figure 11b there is no good agreement between numerical simulation and measured response. The reason for that could be that the kinematic hardening model, which includes the combined hardening, is for simulating the cyclic loading of metals and not monotonic tensile behaviour (Abaqus). From the relevant graph it can be easily seen that a value for the yield point equal to 200Mpa is assigned for the slow strain rate tension test (duration of loading 700 sec) which is the same value of the yield stress at zero equivalent plastic strain from a stabilised cycle  $\sigma|_0=200\text{Mpa}$ . This value was obtained from the test data of the cycling loading. Furthermore, the numerical simulation is quite sensitive to the effect of the strain rate variation, as can be seen in the plotted response. An increase of the yield and ultimate stress can be seen from the case when the specimen is subjected to a relatively slow loading (which corresponds to a slow strain rate) to the case when the specimen is subjected to a relatively fast loading (which corresponds to a fast strain rate).

#### 4.4 Numerical results for cyclic axial tension / compression load cases

This section presents numerical results of the experimental investigation carried out with material test coupons obtained from T-Beam 8 under cyclic axial tension /compression load cases. The necessary material parameters for the numerical simulation were calculated from the experimental data based on Equations (1) and (2) mentioned in section 4.2. These values are as follows:

Combined hardening parameters:

Yield stress at plastic strain  $\sigma|_0=200\text{-}220\text{Mpa}$ ,

Kinematic Hardening Parameter  $C_k=34000$

Gamma  $\gamma_k=250$

Cyclic hardening parameters:

Equivalent stress  $\sigma|_0=200\text{-}220\text{Mpa}$

Q-Infinity parameter  $Q_\infty=85$

Hardening parameter  $b_{iso}=6.5$

Figures 12a and 12b depict the axial stress-strain numerical response employing combined hardening constitutive law with cyclic hardening together with the DIF options for coupons 8R1-5 and 8R1-3 submitted to cyclic tension / compression load resulting in a slow strain rate condition (variation in time of the sinusoidal cyclic load equal to 0.005Hz) and in a moderately slow strain rate condition (variation in time of the sinusoidal cyclic load equal to 0.01Hz). As indicated in these figures a reasonably good agreement between numerical predictions and measured response was achieved for values of the parameters  $\sigma|_0=220\text{Mpa}$ ,  $C_k=34000$ ,  $\gamma_k=250$ ,  $Q_\infty=85$ ,  $b_{iso}=6.5$  for a cyclic load equal to 0.005Hz and a cyclic load equal to 0.01Hz. This good agreement between measured and predicted values can be seen for the yield and ultimate stress values as well as for the shape of the hysteretic loops.

Figure 12a. Numerical axial stress strain response employing combined hardening constitutive law for coupons 8R1-5 submitted to cyclic tension/compression load resulting in a slow strain rate

Figure 12b. Numerical axial stress strain response employing combined hardening constitutive law for coupons 8R1-3 submitted to cyclic tension/compression load resulting in a moderately slow strain rate

Figures 13a and 13b depict the axial stress-strain numerical response employing combined hardening constitutive law with cyclic hardening together with the DIF options for coupons 8R1-2 and 8R1-4 submitted to cyclic tension / compression load resulting in a moderately fast strain rate condition (variation in time of the sinusoidal cyclic load equal to 0.1Hz) and in a fast strain rate condition (variation in time of the sinusoidal cyclic load equal to 2.0Hz). As indicated in these figures, reasonably good agreement between numerical predictions and measured response was achieved adopting values of the parameters  $\sigma_0=200\text{Mpa}$ ,  $C_k=34000$ ,  $\gamma_k=250$ ,  $Q_\infty=85$ ,  $b_{iso}=6.5$  for cyclic loads applied with frequencies equal to either 0.1Hz or 2.0Hz. For numerically simulating these relatively high loading frequency tests the value of  $\sigma_0$  equal to 200Mpa was adopted the yield stress at plastic strain and the equivalent stress instead of 220Mpa, which was used in the numerical simulation for the relatively load loading frequencies of 0.005Hz and 0.01Hz. This value of 200Mpa led to a better agreement between the experimental results and the numerical simulation for the yield and ultimate stress values as well as for the shape of the hysteretic loops.

Figure 13a. Numerical axial stress strain response employing combined hardening constitutive law for coupons 8R1-5 submitted to cyclic tension/compression load resulting in a slow strain rate

Figure 13b. Numerical axial stress strain response employing combined hardening constitutive law for coupons 8R1-3 submitted to cyclic tension/compression load resulting in a moderately slow strain rate

From this numerical study it can again be concluded that a numerical simulation based on the combined constitutive law employing values of the necessary parameters from test data (such as  $\sigma_0$ , the yield stress at zero equivalent plastic strain, and  $C_k$  and  $\gamma_k$  the material constants) is quite successful in yielding realistic predictions of the cyclic response. Moreover, utilising the an inclusion of the DIF option, such a numerical simulation can be also sensitive to the observed strain rate effect. Therefore, it is reasonable to believe that it would also be successful in simulating the behaviour of more complex structural elements under a variety of loading which can result in different strain rate conditions.

## 5 CONCLUSIONS

- An extensive experimental sequence was conducted testing relatively small dimension coupons to axial monotonic or cyclic loading with a variety of strain rate conditions. These coupons were formed from steel parts taken from the flanges of T-beam steel section that were previously tested to destruction by cyclic seismic-type loading. The current study is an extension of the previous research in an effort to first quantify the strain rate effect in a controlled way and next to be able to effectively simulated utilizing existing numerical tools. From the current investigation the following findings could be stated.
- An increase in the strain rate during the monotonic application of the load resulted in an increase in the yield stress value as well as in the stress values of the plasticized part of the response beyond the yield point.
- Additional experimental data from the analysis of more T-Beams under cyclic loading to be added to the existing ones led to the same conclusion as before that
  - a)The application of the cyclic load with slow, moderately fast or rather fast strain rate resulted in axial stress versus axial strain response whereby the yield point is hardly distinguishable. Thus the strain rate effect can be clearly seen.
  - b)The application of the cyclic load with slow, moderately fast or rather fast strain rate resulted in axial stress versus axial strain response that has stress values beyond the yield point that exhibit a noticeable increase with the increase in the strain rate.

- From the subsequent numerical study it can be concluded that the combined constitutive law is quite successful in yielding realistic prediction of the cyclic response but not of the monotonic tensile response; the appropriate values of the parameters defining this constitutive law (such as  $\sigma|_0$ , the yield stress at zero equivalent plastic strain,  $C_k$ ,  $\gamma_k$ ,  $Q_\infty$  and  $b_{iso}$  the material constants) must be calibrated from test data. In this case, the numerical simulation employing the same material constitutive law together with an DIF inclusion is reasonable to believe that it would also be successful in simulating the behaviour of more complex structural elements for loading introducing a variety of strain rate conditions.
- Both the experimental and the numerical part of this study are still under way; thus the above conclusions should be considered as preliminary.

## ACKNOWLEDGEMENTS

The authors would like to acknowledge the assistance of M. Theofanous, Dr. Civil Engineer, Lecturer at the Department of Civil Engineering of the University of Birmingham, for all his valuable advice related to the numerical simulation. The technical assistance of T. Koukouftopoulos in preparing the experimental arrangement is also gratefully acknowledged.

### Abstract

*Steel beam-to-column connections under a cyclic sinusoidal loading history were studied. The investigation of the cyclic response of the steel beam-to-column connections contained an experimental and numerical part. The experimental part included a number of full-scale specimens having a cross section of IPE240 or IPE300 and a height of 1.0m which were rigidly connected to a much stiffer steel beam thus representing a steel beam-to-column connection. These specimens were tested to failure being subjected to a cyclic sinusoidal point load of continuously increasing amplitude. Each specimen experienced yielding and plastic rotation till the final damage, which occurred either in the form of local instability of the flanges or fracture. Next, a numerical study is performed in an effort to simulate the observed behaviour of these steel beam-to-column connections and their response is presented and discussed. The material test data for the numerical simulation of the steel beam-to-column connection were provided from simple steel coupons which were taken from the T-beam specimens after testing. Experimental and numerical results of the beam-to-column connections are presented and discussed in this paper. It can be concluded that the employed numerical simulation can be quite successful in yielding realistic prediction of the cyclic response of the steel beam-to-column, provided that the material model in this numerical simulation was equipped with the appropriate values for the parameters defining the material constitutive law from the experimental test data.*

## 1 INTRODUCTION

Steel frame structures are commonly used in seismic areas because of their excellence on seismic resistance. This type of structures are usually composed of moment resistant frames whereby the performance of beam-to-column connections are of particular importance especially when these structures are subjected to strong earthquake ground motions [1, 2, 5]. Usually these connections undergo large moment reversals during the earthquake excitation, thus it is important to exhibit stable plastic flexural response in order to provide dissipative capability, without the development of undesired damage patterns, and in this way prevent any kind of local or global instability. However, two recent earthquakes, in Northridge, California 1994 and Kobe Japan 1995, revealed the vulnerability of this type of construction. Premature cracks were observed at welded connections of steel beam-to-column joints leading to brittle failure without prior warning (obvious yielding) at the area around the weld. Such a failure mode or the development of local buckling when beam-to-column connections undergo low-cycle fatigue seismic-type of loading is of particular research interest [3, 4, 9, 14].

The fatigue life of steel beam-to-column joints depends on the amplitude of the imposed loading cycles and the hysteretic behavior of the constituent material that is linked with the amplitude and rate of the developing plastic strains. In order to investigate the fatigue life of steel beam-to-column joints several fatigue testing investigations have been proposed leading to tests that can be categorized in two groups. Testing regimes in which the elastic strain amplitude is higher than the plastic strain amplitude and testing regimes in which the plastic strain dominates. The first type of tests is generally referred as high cycle fatigue (HCF); these tests typically involve more than  $10^6$  cycles to cause failure. The second type of tests is named low cycle fatigue (LCF) test and the number of cycles to failure generally ranges from  $10^2$  to  $10^4$  cycles and this is usually employed for testing the seismic performance of steel beam-to-column joints [6, 8, 11, 12, 15].

The current work studies the performance of steel beam-to-column joints first by examining steel beam-to-column welded joint specimens at the laboratory subjecting them to cyclic seismic-type low-cycle fatigue loading as is explained in section 2. Next, the performance of the same specimens is simulated numerically. Similar studies have been performed in the past by other researchers. Despite the fact that many similar experiments have been performed in the past [6, 8], the current experimental investigation was considered as necessary in order to provide at first hand all the information required for the numerical analyses. That is, the exact geometric and material characteristics of the specimens as well as specific information on the type of loading conditions and on the measured response. The numerical simulation is performed utilizing a commercial software package that is thought to be suitable to simulate the observed response and the non-linearities that developed and included large plastic strains and local instabilities.

## 2 MATERIALS AND EXPERIMENTAL SETUP

### 2.1 Tested specimens

Two full-scale specimens, namely T-Beam 8 and T-Beam 8R1 INV have been constructed with prototype steel cross sections in order to form a beam-to-column joint. Both specimens were of the same geometry and used as the beam part a IPE 300 steel section and as the column part a HEA 300 steel section. These two parts were welded together, as shown in figures 1 and 2, to form the beam-to-column connection to be tested .

The IPE 300 beam was to a steel base plate having a thickness of 20mm welded and this steel plate in turn was bolted to the HEA 300 column (figure 1 and 2). Furthermore, in order

to avoid the brittle type of failure at the welds joining the IPE 300 beam part with the base steel plate two or six 20mm thick steel stiffeners of triangular shape (with a height of 150mm and width of 150mm) were welded at either side of the IPE 300 section connecting its flanges with the base plate as shown in figures 1 and 2. The T-Beam 8 specimen had in total two identical triangular steel stiffeners on each side of the flanges welded and the T-Beam 8R1 INV specimen had in total 6 steel stiffeners 3 evenly spaced on each side of the flanges. The height of the IPE 300 beam part was 1200mm and was connected on its upper part with the forcing fixtures that were provided by a double acting hydraulic actuator. This actuator was controlled by a servo-hydraulic digital electronic controller providing the desired imposed cyclic horizontal displacement amplitude at a distance of 1000mm from the base plate. The two IPE 300 beam-to-column connection specimens were tested as shown in figures 1 and 2. Both specimens were of the same overall geometry having webs with thickness equal to 7mm. The flange thickness varied from 10.2mm for the west flange and 10.5mm for the east flange.

Figure 1. Details of the experimental setup with the tested IPE 300 T-Beam 8 beam-to-column joint specimen

Figure 2. Details of the experimental setup with the tested IPE 300 T-Beam 8R1 INV beam-to-column joint specimen

## 2.2 Loading arrangement

The tested specimens were subjected to a cyclic seismic-type loading arrangement. An extensive discussion on the loading protocols was presented by Krawinkler [11]. This is a very important and difficult issue as on one hand it is believed that it influences the resulting performance and on the other hand it poses demands on the capabilities of the experimental facility [6, 7, 8, 11, 12, 15]. As this work at its present stage aims to produce results that will be utilized for validating the numerical capabilities of existing software rather than checking the validity of code provisions the used loading protocol does not comply exactly with ones suggested by Krawinkler and other researchers [6, 7, 11, 15]. Instead, a series of sinusoidal horizontal cyclic displacements were used and were imposed on the top of the IPE 300 beam part, as shown in figures 1,2 and 4. Both specimens were rigidly attached on the strong floor of the Laboratory of Strength of Materials and Structures of Aristotle University. The hydraulic actuator was attached on the strong metal frame which together with the strong floor forms this experimental facility. The imposed horizontal displacement and the resulting horizontal load leads to the development of a bending moment at the beam-to-column connection which, if of sufficient amplitude, is expected to bring this part of the beam-to-column connection to a certain limit state condition, as will be explained in section 3. The imposed horizontal displacement in amplitude and frequency content is controlled by the electronic servo-controller. A relatively simple imposed displacement protocol is depicted in figure 3. It consists of thirteen (13) groups of 3 full sinusoidal cycles. In each group the imposed maximum displacement amplitude remains constant and keeps gradually increasing from one group to the next in a prescribed manner, as a percentage of the maximum target displacement. The difficulty in imposing this protocol accurately lies on the fact that the target displacement is known at best through predictions that may differ considerably from the actual target displacement that,

when imposed, will produced the desired phenomena. The protocol depicted in this figure was adopted in the current study in a general sense. That is, the amplitude of the imposed horizontal displacement kept increasing from one group to the next till the plastification of the tested specimens led to some type of failure, as will be described in section 3. One distinct difference in the followed loading protocol for the specimen T-Beam 8 is the fact that the frequency content was relatively low (0.005Hz) as to allow this test to be characterized as a dynamic test accompanied with low level of strain rate. On the contrary, the loading protocol for T-Beam 8R1 INV specimen was relatively high (0.1Hz) that is characterized as cyclic test of relatively medium level strain rate.

Figure 3. Typical cyclic seismic-type imposed displacement protocol for low fatigue loading

### 2.3 Instrumentation

Instrumentation was provided capable to record the dynamic response of the specimen at the top in terms of imposed horizontal displacement (LVDT 01, figure 4) and horizontal force. In addition, four displacement transducers (LVDT 02, LVDT 03, LVDT 04 and LVDT 05) were attached to the specimen in order to record the relative vertical displacement of two sets of horizontal cross sections of each specimen near the plastification zone (figures 1, 2 and 4). The first set of horizontal cross sections was that at the base, where the IPE 300 part was welded at the base steel plate) and the one 500mm higher. Utilizing LVDT 02 and LVDT 03 the relative elongation or shortening between these two cross sections of the specimen was measured at the flanges of both sides of the IPE 300 section. The second set of horizontal cross sections was that at 150mm from the base, where the triangular stiffeners ended, and the one 100mm higher. Utilizing LVDT 03 and LVDT 04 the relative elongation or shortening between these two cross sections of the specimen was measured at the flanges of both sides of the IPE 300 section. In this way, it became possible to deduce from the measured response the rotation between the first and the second set of these horizontal cross sections. The second set of horizontal cross sections is of particular importance as the highly plastified region (plastic hinge), which was expected to develop during the experimental sequence, lies between the

horizontal cross-sections of the second set. Indeed, the used instrumentation was able to capture the plastification of this region from the initial stages of yielding till the final stages of local instability. In addition, a set of strain gauges was also provided in order to control in a different way the initiation and development of plastification in this zone.

Figure 4. Experimental set-up with the geometry of the specimens, the instrumentation and loading

Figures 5 and 6 depict the instrumentation of this zone near the beam-to-column joint. The used hydraulic actuator can also be seen in figure 5 whereas in figure 6 the vertical displacement transducer utilized to measure the relative elongation or shortening between two horizontal cross sections above the stiffener having a distance between them equal to 100mm can also be seen (second set of horizontal cross sections).

Figure 5. Instruments located near the beam-to-column joint.

Figure 6. Measuring the relative elongation/shortening between two horizontal cross sections above the stiffener

## 2.4 Steel tensile properties

In order to input the proper information related to the steel characteristic in the finite element program monotonic tensile tests from similar T-Beam IPE300 beams and cyclic tests from T-Beam 8 with different loading frequencies were performed with coupons taken from the specimens. These coupons were taken from the flanges of the specimens after the completion of the relevant test sequence. In order to measure the material properties of the virgin steel prior to any plastification and permanent straining these coupons were taken from the upper part of the IPE 300 beam sections near the section where the imposed displacement was applied. More detailed information about the material steel coupons and the corresponding results are given in the work of Manos G.C. and Nalmpantidou A. [18].

## 3 OBSERVED PERFORMANCE AND CORRESPONDING MEASUREMENTS.

### 3.1 Observed over-all performance and actual damage

Each specimen experienced plastic rotation above the stiffeners that was captured by the employed instrumentation. Despite the fixity of the attachment of the specimens on the strong floor part of the imposed horizontal displacement was consumed by the rotation of the specimen at its fixed base as well as of the elastic response along the height apart from the plastic rotation that developed at the desired location above the stiffeners. Fortunately, despite the limitations of the capabilities of the experimental facility it was possible to attain the plastic limit state for both studied specimens and produce the expected form of damage. This is depicted in figures 7 for specimen T-Beam 8 and figure 8 for specimen T-beam 8R1 INV.

Figure 7. Plastification of specimen T-Beam 8 at the end of test - 11

Figure 8. Plastification of specimen T-Beam 8R1 INV at the end of test - 14

### 3.2 Measured response in terms of plastic rotations at the plastic hinge.

Figure 9, depicts the full loading sequence in terms of horizontal displacement at the top of the specimen T-Beam 8 that could be deduced from the employed instrumentation as directly linked with the elastic/plastic rotation at the zone of the specimen extending at a length of 100mm above the stiffeners of the IPE 300 beam (figures 4 and 6). The corresponding development of the plastic rotation with time in this plastic hinge region is shown in figure 10. The imposed loading history in terms of plastic hinge rotation and the corresponding horizontal displacement at the top of specimen T-Beam 8R1 INV is shown in figure 11 and 12.

Figure 9: Horizontal displacement at the top of specimen T-Beam 8 due to the plastic rotation at the plastic hinge region.

Figure 10: Plastic rotation at the plastic hinge region due to horizontal displacement at the top of specimen T-Beam 8.

Figure 11: Horizontal displacement at the top of specimen T-Beam8R1 INV due to the plastic rotation at the plastic hinge region.

Figure 12: Plastic rotation at the plastic hinge region due to horizontal displacement at the top of specimen T-Beam 8R1 INV.

As can be seen in figures 10 and 12 specimen T-Beam 8 reaches the flexural plastic limit for plastic hinge rotations of the order of 0.027 radians and specimen T-Beam 8R1 INV of the order of 0.015 radian, having undergone a considerable number of low-fatigue cycles

[10, 13, 14]. Moreover, both specimens failed by developing local instability at the plastic region in the form of flange local buckling and eventually fracture. Figures 13 and 14 portray the observed cyclic response in terms of bending moment and plastic hinge rotation, for specimens T-Beam 8 and T-Beam 8R1 INV, respectively. The bending moment values were deduced at a section above the stiffeners from the measured horizontal load.

Figure 13: Measured cyclic response of the plastic hinge for specimen T-Beam 8.

Figure 14: Measured cyclic response of the plastic hinge for specimen T-Beam 8R1 INV.

In both figures 13 and 14 a corresponding envelop curve is also plotted with a dashed blue line for T-Beam 8 specimen and a green line for T-Beam 8R1 INV specimen. As can be seen, both specimens developed large cycles of stable plastic response before reaching their failure mode thus dissipating considerable energy in terms of hysteretic damping. Figure 15

depicts this hysteretic cyclic response through the corresponding envelop curves. As can be seen from the comparison of these two envelope curves in figure 17 there is a slight difference in the specimens performance in terms of maximum flexural baring capacity and plastic hinge rotation corresponding to that flexural capacity. The measured flexural capacity is of the order of 244 KNm and 248 KNm for specimens T-Beam 8 and T-Beam 8R1 INV, respectively. The plastic hinge rotation values corresponding to these flexural capacity values are for the T-Beam 8 specimen approximately 0.018 rad and for the T-Beam 8R1 INV specimen approximately 0.012 rad. Consequently, it can be concluded that the variation in the loading frequency from 0.005Hz of the T-Beam 8 specimen to 0.1Hz of the T-Beam 8R1 INV specimen led to a decrease in the value of the plastic hinge rotation of the maximum flexural baring capacity with the increase of the loading frequency. Finally from the overall envelope curve a slight increase in the flexural capacity of T-Beam 8R1 INV specimen can be observed with increasing loading frequency and increasing strain rate.

Figure 15: Measured cyclic response of the plastic hinge in terms of envelop curves for both specimens T-Beam 8 and T-Beam 8R1 INV.

## 4 NUMERICAL SIMULATION OF THE OBSERVED CYCLIC RESPONSE AND PERFORMANCE

### 4.1 Numerical modeling.

The commercial software ABAQUS [16] was utilized in this numerical simulation effort. In doing so, the IPE 300 beam part of the experimental sequence was reproduced through the finite element representation as accurately as possible. This is shown in figure 16 whereby it can be seen that the numerical simulation extended all the way from the top section where the horizontal load was imposed to the bottom horizontal section where the IPE 300 beam was welded to the base plate. Moreover, the triangular stiffeners with their actual thickness and geometry were also included in this numerical simulation. The whole surface of the IPE 300 and the stiffeners at the bottom level where the specimens were welded to the base plate was considered to be represented with absolute fixity conditions in the numerical simulation. In addition, the horizontal displacement of the specimen outside the loading plane was con-

strained. The discretization scheme that was adopted was considerably fine in an effort to be able to catch numerically the observed local modes of buckling of the flanges in the plastic hinge region.

Figure 16: Employed numerical model.

## 4.2 Material modeling

In the framework of the numerical investigation a parametric study was conducted that focused on the way the steel material properties were introduced in the numerical simulation. Two different approaches were tried. According to the first approach the measured tensile steel properties were introduced in the numerical simulation through the Abaqus isotropic hardening parameters whereas in the second approach the measured properties were modified accordingly in order to be introduced in the numerical simulation through the ABAQUS combined hardening material model [16]. More information on this approach can be obtained from the previous work by Manos G.C. et al [19].

In this work the focus relies in the numerical simulation of the material tests through the ABAQUS combined hardening material constitutive law. There are several ways in this commercial software package [16] to define a combined hardening material constitutive law in order to capture the cyclic response of a specimen. The evolution law of this model consists of two components: a nonlinear kinematic hardening component, which describes the translation of the yield surface in stress space through the back-stress, and an isotropic hardening component, which describes the change of the equivalent stress defining the size of the yield surface, as a function of plastic deformation [16]. In this study the combined hardening constitutive law is defined through the values that are given to certain relevant parameters. Values for these parameters were calculated from the test data that were obtained from the experimental process from the tests of steel samples that were taken from the T-Beam specimens and can be seen in the work by Manos G.C and Nalmpantidou A. [18].

This software (Abaqus) allows the specification of strain rates effects with the option of rate dependent data at combined and isotropic hardening constitutive law. In order to define the strain rate effect the use of a dynamic increase factor (DIF) was utilized based on the work of Malvar and Crawford [9]. The work of Malvar and Crawford [20] is based on numerous

experimental data from a literature review on the effects of strain rates on the properties of steel reinforcing bars for reinforced concrete structural elements. The dynamic increase factor (DIF) is the amplification by DIF of the value a certain mechanical property (yield stress or maximum stress) has under low strain rate loading conditions (static) to another condition whereby because of the nature of loading (dynamic) the strain rate has a larger value than before. A relationship is proposed by Malvar and Crawford [20] that a DIF value can be derived for a given strain rate increase and thus evaluate through this DIF the corresponding for this increased strain rate amplified yield and ultimate stress values. Figure 17 depicts the dynamic increase factor considered for the numerical simulation.

Figure 17. Dynamic increase factor which have been considered for the numerical investigation

#### 4.3 Numerical results from the parametric study

This section will present numerical results of the experimental investigation carried out with T-Beam 8 and T-Beam 8R1 INV under cyclic tests. The necessary material parameters for the numerical simulation were calculated from the experimental data of simple steel coupons taken from T-Beam 8 and are the following:

Combined hardening parameters:

Yield stress at plastic strain  $\sigma|_0=180\text{-}200\text{Mpa}$ ,

Kinematic Hardening Parameter  $C_k=34000$

Gamma  $\gamma_k=250$

Cyclic hardening parameters:

Equivalent stress  $\sigma|_0=180\text{-}200\text{Mpa}$

Q-Infinity parameter  $Q_\infty=85$

Hardening parameter  $b_{iso}=6.5$

Combined hardening parameters:

Yield stress at plastic strain  $\sigma|_0=100\text{-}140\text{Mpa}$ ,

Kinematic Hardening Parameter  $C_k=51800$

Gamma  $\gamma_k=250$

Cyclic hardening parameters:

Equivalent stress  $\sigma|_0=100\text{-}140\text{Mpa}$

Q-Infinity parameter  $Q_\infty=305$

Hardening parameter  $b_{iso}=6.5$   
 Combined hardening parameters:  
 Yield stress at plastic strain  $\sigma_0=140\text{Mpa}$ ,  
 Kinematic Hardening Parameter  $C_k=59520$   
 Gamma  $\gamma_k=250$   
 Cyclic hardening parameters:  
 Equivalent stress  $\sigma_0=140\text{Mpa}$   
 Q-Infinity parameter  $Q_\infty=30$   
 Hardening parameter  $b_{iso}=6.5$

Figure 18. Numerical predictions of the cyclic response of the plastic hinge for specimen T-Beam 8

Figure 19. Predicted cyclic response of the plastic hinge in terms of envelope curves for specimen T-Beam 8 together with the measured response

Figure 20. Numerical predictions of the cyclic response of the plastic hinge for specimen T-Beam 8R1 INV

Figure 23. Predicted cyclic response of the plastic hinge in terms of envelope curves for specimen T-Beam 8R1 INV together with the measured response

In figure 18 and 20 are the results of the numerical simulation of T-Beam 8 and T-Beam 8R1 INV and the corresponding envelope curves shown. As can be seen specimen T-Beam 8 reaches the flexural plastic limit for plastic hinge rotations of the order of 0.027 radians and

specimen T-Beam 8R1 INV of the order of 0.015 radian, having undergone the same number of low-fatigue cycles [10, 13, 14] as the experimental setup.

Figure 19 and 21 compare the envelop curves predicted by the numerical simulation for specimens T-Beam 8 and T-Beam 8R1 INV, respectively, with the corresponding envelop curves of the measured cyclic response for the same specimens. The predicted response was obtained by using the combined hardening material model and as can be seen there is a small variation between the measured flexural capacity and rotation at the plastic hinge and the numerical simulation with higher values of the numerical simulation for T-Beam 8 specimen. Furthermore the predicted cyclic response of T-Beam 8R1 INV has a quite good agreement between the measured flexural capacity and rotation at the plastic hinge and the numerical simulation.

## 5 CONCLUSIONS

- The seismic performance of a steel beam-to-column connection was studied by subjecting two specimens of such steel beam-to-column connection specimens to imposed cyclic displacements with a variety of low to medium range strain rates. The tested specimens were constructed with prototype steel sections welded in a typical fashion.
- Both specimens developed local flange buckling modes of failure for plastic hinge rotation values approximately equal 0.027 radians for T-Beam 8 specimen and 0.015 radians for T-Beam 8R1 INV specimen. For values of plastic hinge rotation higher than 0.027 radians for T-Beam 8 specimen and 0.15 radians for T-Beam 8 R1 INV specimen the deterioration of the flexural capacity became substantial for both specimens as the local flange buckling mode of failure prevailed.
- The consequence of the previous observation is that the employed strain rate variation in the used loading sequence of specimen T-Beam 8 with 0.005Hz from that of the loading sequence of specimen T-Beam 8R1 INV with 0.1 Hz led to a decrease in the value of the plastic hinge rotation of the maximum flexural baring capacity with the increase of the loading frequency. From the overall envelope curve a slight increase in the flexural capacity of T-Beam 8R1 INV specimen can also be observed with increasing loading frequency and increasing strain rate. However, this is a partial conclusions based on rather limited data. Therefore more research is needed to further investigate the strain rate influence on the beam-to-column connections earthquake performance.
- The numerical simulation of the tested specimens utilizing the capabilities of a commercial software package yielded reasonable good agreement between both the measured and predicted cyclic response in terms of maximum flexural capacity, dissipation characteristics and deterioration of the flexural capacity. It is of utmost importance to have realistic estimates of the values of the parameters are  $\sigma_0$  (yield stress at zero equivalent plastic strain),  $C_k$  and  $\gamma_k$  (material constants) which define the steel combined hardening material behaviour.

## ACKNOWLEDGEMENTS

The authors would like to acknowledge the assistance of M. Theofanous, Dr. Civil Engineer, Lecturer at the Department of Civil Engineering of the University of Birmingham, for all his valuable advice related to the numerical simulation. The technical assistance of T.

Koukouftopoulos in preparing the experimental arrangement is also gratefully acknowledged.

- To the memory of Hiroshi Akiyama, Professor of the University of Tokyo, Japan and of Heki Shibata, Professor of Industrial Science, University of Tokyo, Japan.

### Abstract

*The present work concerns the dynamic and vibroacoustic response of timber floor panels as well as the study of the effect of material nonlinearities and damping. Each panel is composed of glued laminated beams and wood constituting the floor. The dimensions of the panels are defined to ensure appropriate implementation and transport conditions. For these reasons, the width of the panels is fixed at 2.40 m, and the length is 7.2 m. Two types of floor panels were investigated with and without struts. A numerical approach based on 3D finite element method is used to solve the problem. Our finite element model and the mechanical properties of the used materials are first validated from comparisons with experimental tests carried out in statics [1]. A dynamic non-linear analysis of the timber floor panels has been then conducted under a walking time history and the vibroacoustic response of the system is finally investigated.*

**Keywords:** Timber structures, dynamic analysis, vibroacoustic, numerical and experimental measurements, non-linear.

---

## 1 INTRODUCTION

The use of wood as construction material increased in Europe during the last decades. Compared to steel or reinforced concrete buildings, the timber buildings are more sensitive to dynamic loading, especially in terms of vibroacoustic comfort. Furthermore, due to the complexity of wood material and different structural details it is more difficult to predict the accurate response due to dynamic loading.

Floor vibrations and structure-borne sound in residential buildings can be induced by several sources such as people walking indoors, machines vibration. Excessively high sound and/or vibration levels cause annoyance and discomfort for residents. Low frequency prediction tools are needed to access the dynamic behavior of a timber floor in an early design phase to ultimately reduce the low frequency impact noise. This highlights the need to improve the design of multi-story timber buildings such that vibration levels and the need of further investigation on this field.

In the European countries, the vibration of timber floors is regulated by the serviceability limit states (SLS) requirements of Eurocode [2]. In addition, a lot of researchers have started to investigate this field. Initially, the vibration issues of different types of flooring systems (composite, concrete, steel with timber) was identified under the action of human activities by Bachmann & Ammann [3], Williams & Waldron [4], Da Silva et al. [5] and Ebrahimpour & Sack [6].

In the present work attention is focused on the dynamic and vibroacoustic response of timber floor panels as well as the study of the effect of material nonlinearities and the damping ration. The first part of this study focuses on the validation of the finite elements (FE) model with the appropriate selected experimental results, in order to be a reliable tool for the further part of this study. After the validation, dynamic analyses were conducted under a walking load time history of a person in the middle of each floor panel, and then the vibroacoustic of these panels are presented.

## 2 A SHORT DESCRIPTION OF THE INVESTIGATED TIMBER FLOOR PANELS

Two types of floor panels were investigated (with and without struts). The floor panels have been proposed by Fuentes et al [1] and analyzed only in static analysis. The dimensions of the panels were defined to ensure appropriate implementation and transport conditions. For these reasons, the width of the panels was fixed at 2.40 m, and the length was 7.2 m. Each floor panel was consisted of glued laminated beams, joists and floor of 25mm. The first one, referred to herein as PAN\_Fl, consisted of two (2) beams, thirteen (13) joists and the floor, while the second one, referred to herein as PAN\_Fl\_struts, was like the previous one but with struts (Figure 1). The design of these floor panels meted the requirement of Part 1-1 of Eurocode 5 [2]. The material of the main parts of the floor panels was categorized in the class GL32h.

Figure 1: Geometric configuration of: (a) PAN\_Fl, (b) PAN\_Fl\_struts (values in mm).

### 3 VALIDATION OF FEM FOR FLOOR PANELS IN STATIC ANALYSIS

The FE method is a widely employed approach to develop numerical prediction models in construction industry and more and more researchers are used it [7-9]. By performing numerical simulations, experimental acoustical tests can be reduced, and parametric studies can also be carried out to investigate the influence of specific geometrical changes in construction as well as the influence of the variations/uncertainties in material properties, which always have a mark able influence on the results [10-12].

The FE analysis calibration study included analytical modelling of the two panels. Elastoplastic orthotropic material models were used with non-linear hardening associated with material densification. Table 1 summarises the details of the material properties.

Table 1: Main material parameters.

Quality	$E_1$ (MPa)	$E_2$ (MPa)	$E_3$ (MPa)	$f_{m,k}$ (MPa)	$\nu_{12}$	$\nu_{13}$	$\nu_{23}$	$\rho$ (kg/m <sup>3</sup> )
GL32h	13500	450	450	32.5	0.35	0.35	0.09	420

The 3D FEM model geometry reproduced the actual geometry of the experiments, as well as the simulation used the same boundary conditions and loading as in the experimental program (see Figure 1 and 2).

Figure 2: Configuration of floor panels PAN\_Fl\_struts.

Alternative finite element models were conducted to identify the best meshing. It is known that a finer mesh density provides higher accuracy but also increases the computational time without improving substantially the accuracy of the results, therefore, a tradeoff between time and accuracy becomes crucial. In our model tetrahedral solid elements were used with high level of optimization in order to avoid inverted curved elements, too large or too small elements. In total 16335 elements were used for the PAN\_Fl and 21954 for the PAN\_Fl\_struts.

In this section, static analyses have been performed with increasing load until the failure of the panels. The nonlinear solver uses an affine invariant form of the damped Newton method. The numerical results were compared with the experimental ones and the validation of the model was based on: (i) the force-displacement curves, and (ii) the deformation shape of the bottom beam during different loads, for the both floor panels.

Figures 3 and 4 compare the experimental and the numerical results of the panels PAN\_Fl and PAN\_Fl\_struts respectively. Part (a) presents the force – displacement curves at the middle of the panel, part (b) illustrates the shape of the deflection along the bottom beam of each panel, while part (c) shows the deformation shape of each panel for a selected force (45kN for the panel PAN\_Fl and 65kN for the panel PAN\_Fl\_struts). It is important to notice that in the Figures 3c and 4c the panels are illustrated without the floors in order to verify the shape of the beams and the joists. As it is shown, the numerical monotonic curve follows the envelope

of the experimental response. Therefore, the numerical loading curve can be reliably used to assess the stiffness and strength of the investigated panels and the proposed FE model in order to establish the individual and combined effects of various parameters on the response of the panels and, in so doing, to identify the significance of the numerical contribution to produce results that are harder to obtain experimentally.

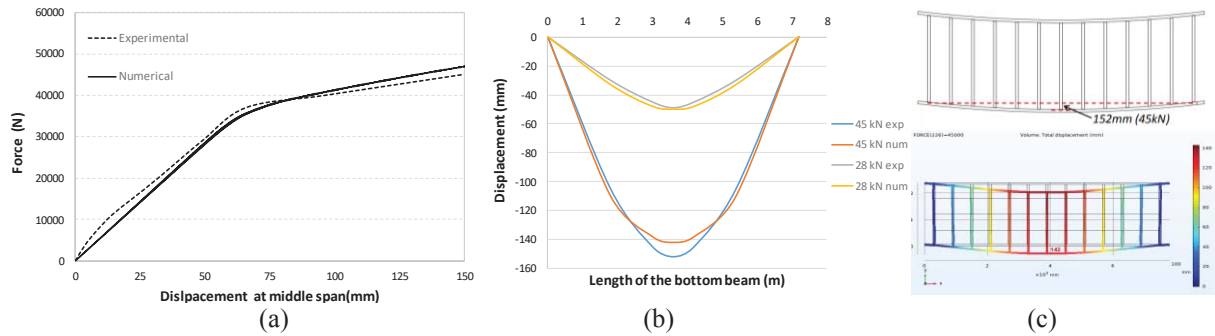

Figure 3: Comparison of experimental and numerical results for the panel PAN\_Fl.

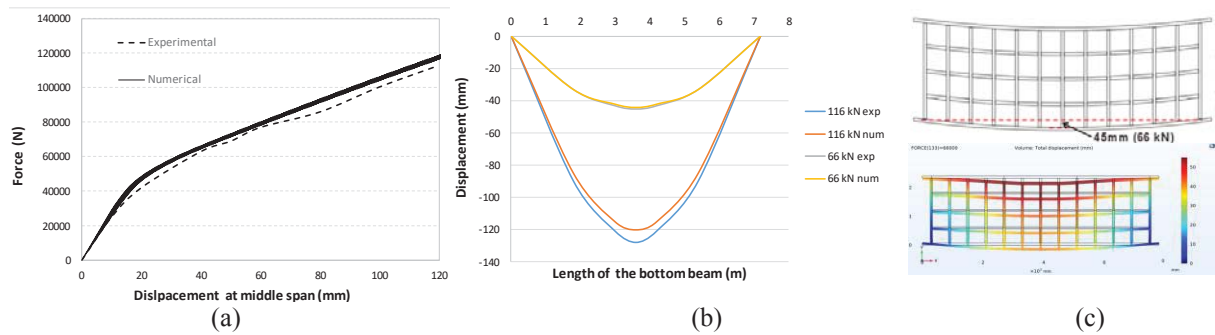

Figure 4: Comparison of experimental and numerical results for the panel PAN\_Fl\_struts.

#### 4 DYNAMIC ANALYSIS

The aim of this section is to use the proposed FE model in order to investigate the dynamic response of these panels in different vibration loading. A dynamic analysis of a structure differs from a corresponding static analysis mainly in two ways. While a static analysis assumes that a structure is in complete equilibrium with its surroundings a dynamic analysis takes into consideration the structure's true response when subjected to a force. Furthermore, a static analysis treats the loads as static, which means that they varies sufficiently slowly with time. On the other hand, there are a lot of loads that in fact are dynamic, that is, they varies rather quickly with time [13]. Vibrations may be described as oscillations around the statically equilibrium of a structure [14]. Vibrations arise when time-varying disturbances, either forces or displacements, interact with the inertia properties of an affected medium. The dynamic response of a structural system is affected by the material properties, the damping, the properties of the system as whole, and the presence of non-structural elements, such as floor coverings, ceilings etc [15].

Damping is the most important parameter which significantly influences the response of occupants to floor vibrations even though it hardly affects the fundamental frequency  $f_i$ . This is because damping is an intrinsic property of structural systems that influences oscillation amplitudes and the rate of decay under forced and free vibrations, respectively [16]. Previous research has shown that the timber floors constructed with engineered I-joists had a damping ratio  $\zeta = 2 - 4\%$  [17] while the floors with metal-webbed joists only had a very low damping

ratio  $\zeta = 0.86\%$  which is below  $1\%$  [18]. This indicates that the design damping ratio  $\zeta = 1\%$  proposed in EN 1995-1-1 [2] may not cover all timber floor types so an average damping ratio  $\zeta = 2\%$  is proposed in order to cover most practical cases [19].

#### 4.1 Case study

In this study the two panels of PAN\_Fl and PAN\_Fl\_struts were analysed under a walking loading time history of one person 75kg in the middle of each panel (on the spot) with a total duration of 2.6 sec. In this study only the effects of a damping ration were presented. Figure 5 describes the investigated panels with the details of boundary conditions, load time histories, while Table 2 summarizes the investigated cases. The beams of the panels are the part that is being connected with the columns of the structures. The stiffness of these connections can varies as it depends on the type of the connection as Titirla et al have been presented [20-23], but in this study only the case of a rigid connection was presented.

Each harmonic of the loading function can cause resonance with a natural frequency of the floor, and it is the walking pace frequency that gives the worst-case response that should be used for design. The pace frequency ( $f_p$ ) for walking has a mean value of 2.0 Hz. The standard walking load of a person can then be described as a series of consecutive steps, where each step is given by a polynomial function which is proposed by Harpel et al. [24].

Figure5: Walking time history and boundary condition of the panels.

Table 2: Description of the case studies.

Panel	Boundary conditions	Damping	Name
PAN_Fl	Rigid	0%	PAN_Fl
PAN_Fl	Rigid	1%	PAN_Fl_d
PAN_Fl_struts	Rigid	0%	PAN_Fl_struts
PAN_Fl_struts	Rigid	1%	PAN_Fl_struts_d

#### 4.2 Comparison of the results

In the present numerical study a damping ratio equal to  $1\%$  was selected, according to EN 1995-1-1 [2]. The comparison of the results, given in Figure 5, shows that the maximum vertical displacement was reduced  $1.4\%$  for the PAN\_Fl and  $0.5\%$  for the PAN\_Fl\_struts according to damping, while the maximum acceleration in the middle of the span was reduced equal to  $10\%$  and  $2.5\%$  respectively. It can be observed that each transient vibration signal contains a high initial peak and decays. The peak values of a transient vibration are governed by system stiffness and mass, but not by damping. Damping is a measure of how quickly the

response of vibrating system decay after the loading period; as a result the effects of the damping during the walking loading of 2.6sec were not as much remarkable.

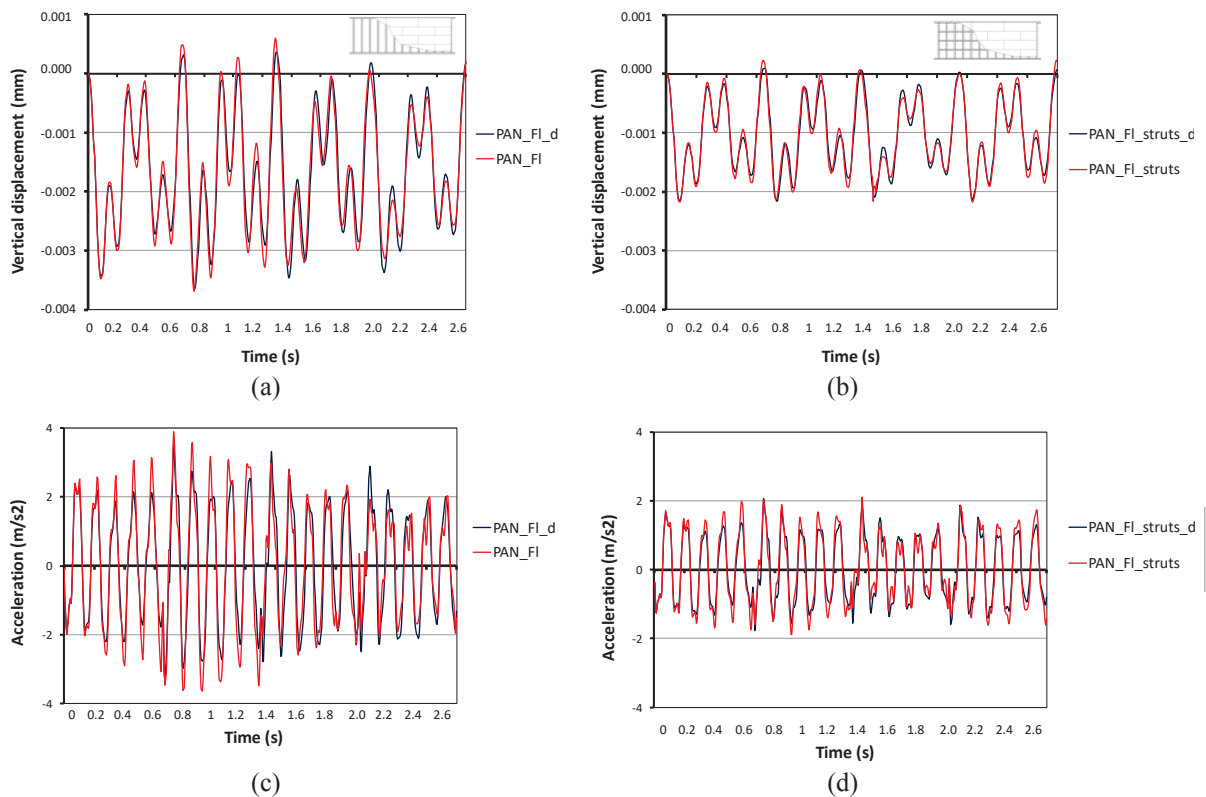

Figure 5: Time histories of (a) the vertical displ. at the middle of the panel PAN\_Fl, (b) the vertical displ. at the middle of the panel PAN\_Fl\_struts, (c) the acceleration at the middle of the panel PAN\_Fl, (d) the acceleration at the middle of the panel PAN\_Fl\_struts.

## 5 VIBROACOUSTIC

Structures when subjected to time varying loads will vibrate and generate acoustic waves. The characteristics of the acoustic waves generated by the structure may depend on the vibration behavior of the structure, which in turn depends on different factors such as the properties of structural materials, types of loads, location of load application, structural configuration, boundary conditions, etc. The determination of the true vibro-acoustic characteristics of a structure is essential for the correct prediction of the actual vibration and sound radiation behaviors of the structure. Therefore, because of its importance, the vibro-acoustic characterization of structures has drawn close attention and a lot of researchers are working in this field [25-27].

The aim of this session is to study the influence of the two configurations (PAN\_Fl and PAN\_Fl\_struts) on the impact sound transmission of a floor. For this reason the previous panels with the rigid connections were investigated; but this time the analyses were focused on the frequency domain. The Acoustics interface uses the Pressure Acoustics, Frequency Domain module to solve the governing wave equation that is complemented with sound sources as boundary condition. The speed of the sound in the air equal to 343 m/s and the density of 1.2 kg/m³ were taken into account in this study.

The radiated sound power level for the reference case is shown in Figure 7. The large amplitude peaks observed in the frequency response make it possible to identify the critical resonance frequencies to be avoided.

Figure6: (a) the model with the additional mass and the boundary conditions, (b) the mesh for the floor elements and the air.

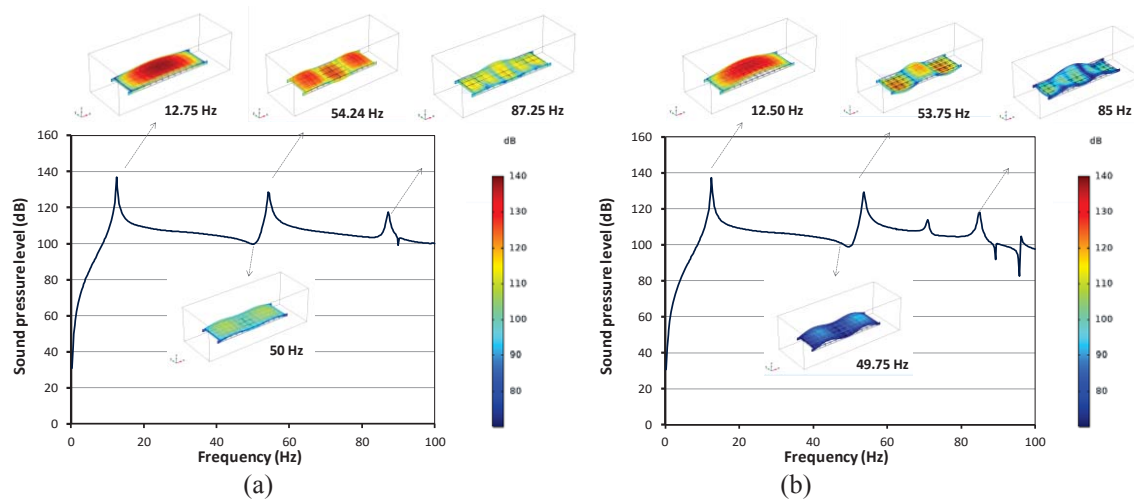

Figure 7: The radiated sound power level of the plate surface for the panel (a) PAN\_Fl and (b) PAN\_Fl\_struts.

## 6 CONCLUSIONS

In the present work attention is focused on the dynamic and vibroacoustic response of timber floor panels as well as the study of the effect of the damping ration. In this study the two panels of PAN\_Fl and PAN\_Fl\_struts were analysed in static and dynamic analyses. Based on the findings of this study new conclusions are drawn :

- The validation of the numerical simulation is based on the envelope experimental behavior of the two difference floor panel. The response of the panel PAN\_Fl was used to build the numerical model while the response of the panel PAN\_Fl\_struts was used to validate the previous model.
- The success of the deployed numerical simulation is fully demonstrated by comparing the shape of the load–displacement curves with the experimental ones. Therefore, it is a reliable tool for the simulation of the hysteretic behavior of these timber floor panels and can be used in further studies.
- The peak values of a transient vibration are governed by system stiffness and mass, but not by damping. Damping is a measure of how quickly the response of vibrating system decay after the loading period; as a result the effects of the damping during the walking

loading of 2.6 sec were not as much remarkable. The comparison of the results shows that the maximum vertical displacement was reduced 1.4 % for the PAN\_Fl and 0.5% for the PAN\_Fl\_struts according to damping, while the maximum acceleration in the middle of the span was reduced equal to 10 % and 2.5% respectively.

- iv. The analysis of the vibroacoustic response of the system made it possible to identify the most radiant resonance frequencies.

### Abstract

*The installation of exterior facades made of metal elements in buildings is a dual function application: On one hand it alters the facade, through architectural modifications, and on the other it creates the conditions for the improvement of energy efficiency of the building, utilizing the gap that develops between old and new facade. In order to ensure that the suspension and anchoring system can safely receive both static and dynamic loads, which will strain the construction during its life cycle, it is necessary to carry out a set of controls that will ensure exactly this: the static and anti-seismic adequacy of the used suspension and anchoring system. For this reason, a building consisting of frames was chosen, on the perimeter of which masonry was placed and, then, the metal facades were hung on the masonry, through the use of appropriate joints. Through Dynamic Spectral Analysis and Time History Analysis, the adequacy or not of the suspension system was examined, but also the effects that the system had on the modal, strain and deformation sizes of the building. In the end, it was concluded that the attachment of elements to the facade of the building, although it is done for architectural or other purposes, brings about significant changes in its seismic response and, therefore, must be adequately studied.*

## 1 INTRODUCTION

### 1.1 Ventilated facades

In modern times, architectural design invests heavily in facade cladding, considering them often part of the original design of the building but also an appropriate solution in cases of reconstruction or renovation of exterior facades and siding. In addition, facade cladding panels are used as partial interventions in facades, in balcony cladding, fencing or the creation of awnings and blinds. There is a plethora of materials that can be used in facade cladding! Examples include titanium zinc, copper, aluminum, bakelites, HPL (High Pressure Laminates) panels, ceramic tiles and colored fiber reinforced cement boards. A ventilated facade is a construction method whereby a physical separation is created between the outside of the facade and the interior wall of the building. This separation creates an open cavity allowing the exchange of the air contained between the wall and the outer cladding.

Figure 1: Titanium zinc facade.

Figure 2: Copper facade.

Figure 3: Ceramic tiles facade.

Figure 4: Colored fiber reinforced cement boards facade.

### 1.2 Fixing brackets

To support the facade, a suspension system or fixing brackets system is required. In order for the system in use to be deemed as sufficient, it must first be examined whether the fixing bracket can safely receive the required loads (axial and shear) and then whether it can safely transfer them to the concrete frame and/or masonry infill. Thus, at first, the strength of the fixing bracket is examined, based on the requirements arising from the analysis model and depending on the specifications set by the bracket's manufacturer. It is then checked whether these requirements are covered by the capacities set by the regulations, in this case KAN.EPE.

Figure 5: Fixing bracket.

## 2 BUILDING GEOMETRY AND CHARACTERISTICS

The external dimensions of the building are 22.20x22.20 m. In the direction of the X-axis there are 6 frames, with a net opening of 17.00 m and a distance of 3.50 m between them. The columns have dimensions 1.10x0.30 m, with the large dimension parallel to the X-axis. The class of the concrete used was evaluated, in current terms, in category C20 / 25 and the reinforcement steel in S135 / 150 [1]. The building has previously been deemed in need of seismic reinforcement [1].

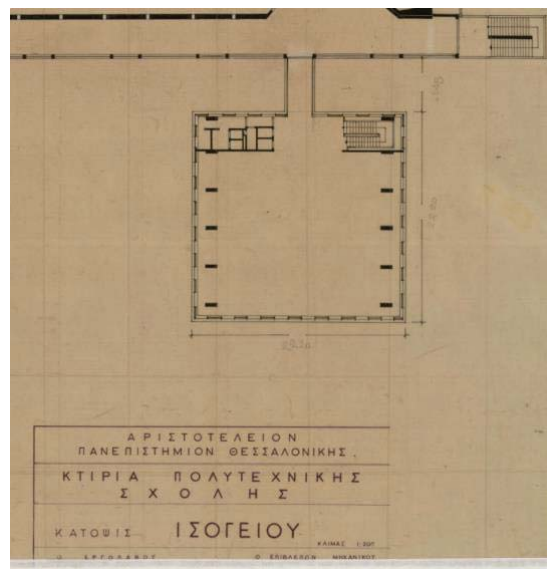

Figure 6: Ground floor plan.

### 3 ANALYSIS

#### 3.1 Analysis Methods

To assess the dynamic characteristics of the building, the Dynamic Spectral Analysis was applied in a fully elastic model, in order to evaluate the adequacy of the support joints and the anchoring system. Furthermore, a Dynamic Time History Analysis was performed on an elastic-partially plastic, non-linear model, in which the joints would yield if they exceeded a certain limit, in order to better analyze the response of the structure in an earthquake scenario.

Figure 7: Accelerometer of the Thessaloniki earthquake of 1978.

The E.C. 8 [2] spectrum was used for the Dynamic Spectral Analysis as well as the spectrum obtained from the accelerometer of the 1978 Thessaloniki earthquake. The accelerometer of the Thessaloniki earthquake of 1978 was used for the Dynamic Time History Analysis. The area of Thessaloniki is categorized as ground type B, where  $a_g = 0.16g$ . The accelerometer was obtained from a ground type D area and therefore had to be properly adjusted to ground category B, in order to be compatible with the soil conditions present at the building site. Below, a graph showcasing the acceleration expressed in g in regard to the oscillation period is depicted, for the spectrum of E.C. 8 in ground category B, as well as the spectrum obtained from the accelerometer for ground category D and ground category B.

Figure 8: Design Spectrums used in analysis.

### 3.2 Analysis Models

Three analysis models were used:

- The first model consisted mainly of linear elements, beams and columns, which simulates the current state of the building.
- In the second model, a perimeter of filling masonry was added, in order for the metal facades to be added in a later state, which was also the reference model for the comparisons made.
- In the third model the metal facades were added and comparisons were made.

The analyzes were performed with the help of SAP2000.

Figure 9: Basic linear model.

Figure 10: Masonry infilled model.

Figure 11: Metal facade model.

### 3.3 Vibration Periods

A sufficient number of eigenmodes was used for each scenario during the analysis. For the first case 6 eigenmodes were used, which activated 60 % of the oscillating mass. For the second case 9 eigenmodes were used, which activated 60% of the oscillating mass. For the third case, significantly more eigenmodes were needed, a total of 30, due to the excessive

number of elements added by the exterior facades. The activated mass in this case amounted to 55 % of the oscillating mass. Appropriate multiplying factors were used in the Dynamic Spectral Analysis, according to the specifications of E.C. 8 to accommodate the activated oscillating mass.

Eigenmode	Vibrating Period [s]		
	Without masonry	With masonry	With facades
<b>1</b>	2.179	0.717	0.453
<b>2</b>	2.136	0.687	0.423
<b>3</b>	1.634	0.285	0.391
<b>4</b>	0.689	0.177	0.390
<b>5</b>	0.591	0.168	0.383
<b>6</b>	0.494	0.161	0.376
<b>7</b>	-	0.112	0.376
<b>8</b>	-	0.111	0.374
<b>9</b>	-	0.097	0.370
<b>20</b>	-	-	0.244
<b>30</b>	-	-	0.171

Table 1: Vibrating Periods for analysis scenarios.

It is worth noting that the first model is very flexible, which leads to high vibrating periods and low spectral accelerations. The addition of masonry infill leads to a significant reduction of the vibrating period. Furthermore, the addition of metal facades makes the building even more rigid and leads to the development of maximum spectral accelerations, according to E.C. 8.

## 4 ANALYSIS RESULTS

### 4.1 Base shear

For each scenario, the base shear was calculated in both directions, as the base reaction from the analysis.

Case	Base Reaction [kN]		
	Without masonry	With masonry	With facades
<b>E.C.8-X</b>	5128	13969	24625
<b>E.C.8-Y</b>	5524	14740	21857
<b>Thess-X</b>	3117	8861	27597
<b>Thess-Y</b>	2744	9703	21221

Table 2: Base reactions for analysis scenarios.

With the addition of the masonry infill the base reaction almost triples. The addition of the metal facades further doubles the base reaction, in the case of E.C. 8, and triples it in the Thessaloniki 1978 scenario.

### 4.2 Reference column strain

In order to assess the influence that the metal facade has on the seismic response of the building, a corner column was used as a reference point. The axial, shear and moment that was calculated in each scenario was compared, at the level of each floor.

Figure 12: Metal facade model.

The addition of masonry infill multiplied the axial load by an average factor of 6, while the shear and moment loads dropped by 50 % in average. This was due to the redistribution of strain to the intermediate columns.

The addition of the metal facades had almost no effect to the axial load, but it increased the shear and moment loads by 35 % in average.

#### 4.3 Reference column top displacement

The top displacement for the first model was relatively high, mainly due to the low stiffness of the building. The second model, although with a higher base shear, developed a lesser top displacement, due to the increased stiffness offered by the masonry infill. The third model had slightly increased top displacement, due to the higher base shear and the fact that the facades did not contribute significantly to the stiffness of the model.

Case	Top displacement [cm]		
	Without masonry	With masonry	With facades
<b>E.C.8-X</b>	17.8	8.7	7.0
<b>E.C.8-Y</b>	15.6	8.4	7.0
<b>Thess-X</b>	14.5	5.1	7.8
<b>Thess-Y</b>	12.4	5.3	6.8

Table 3: Top displacements for analysis scenarios.

## 5 ASSESSMENT OF BEARING CAPACITY

### 5.1 Fixing brackets

The manufacturer's strengths were taken for the assessment of bearing capacity and were compared with the results of the analysis. For a 2 mm displacement, the bracket was considered to have failed.

Code	Type	Size(mm)	Support	Loading direction	Loadbearing capacity	
					At elastic behavior of material (without residual displacement)	At displacement 2 mm
ET710001.00 (07varioQ172)	double	62/40/160	fixed	vertical	6,40 kN	14,45 kN
ET710002.00 (07varioQ82)	double	62/75/160	fixed	horizontal	6,07 kN	10,86 kN
ET710002.00 (07varioQ82)	double	62/75/160	movable	horizontal	5,04 kN	10,95 kN
ET710002.00 (07varioQ82)	double	62/75/160	fixed	vertical	6,04 kN	10,33 kN
ET710003.00 (07varioQ102)	double	60/100/160	fixed	vertical	4,65 kN	7,03 kN
ET710003.00 (07varioQ102)	double	60/100/160	fixed	horizontal	1,45 kN	6,38 kN
ET710005.00 (07varioQ152)	double	60/150/160	fixed	vertical	3,67 kN	5,03 kN
ET710004.00 (07varioQ172)	double	60/125/160	fixed	vertical	3,42 kN	6,67 kN
ET710004.00 (07varioQ172)	double	60/125/160	fixed	horizontal	5,17 kN	10,93 kN
ET710004.00 (07varioQ172)	double	60/125/160	movable	horizontal	7,15 kN	10,15 kN
ET710014.00 (07varioQ18)	single	60/180/90	fixed	vertical	0,38 kN	0,46 kN
ET710006.00 (07varioQ182)	double	60/180/160	fixed	vertical	2,40 kN	3,32 kN
ET710015.00 (07varioQ21)	single	60/210/90	fixed	vertical	0,36 kN	0,41 kN

Figure 13: Fixing brackets' loadbearing capacities.

Case	Axial		Shear	
	Yields	Failures	Yields	Failures
E.C.8-X	30	0	88	0
E.C.8-Y	48	0	10	0
Thess-X	31	0	90	0
Thess-Y	50	0	5	0

Table 4: Number of brackets yield and failed.

In total, 644 elements were examined. In the worst scenario, 90 of them surpassed the yield limit and none failed.

## 5.2 Anchorage system

The ultimate force under tension the anchor can bear is calculated [3]:

$$N_{ud} = \pi \cdot d \cdot l_b \cdot f_{bd} \quad (1)$$

Where  $N_{ud}$  is the ultimate force under tension the anchor can bear,  $d$  the diameter of the anchorage,  $l_b$  the anchorage length and  $f_{bd}$  the tensile strength of the material anchorage takes place.

The ultimate force under shear the anchor can bear is calculated [3]:

$$F_{ud} = 0.65 \cdot d^2 \cdot \sqrt{f_{cd} \cdot f_{yd}} \quad (2)$$

Where  $F_{ud}$  is the ultimate force under shear the anchor can bear,  $d$  the diameter of the anchorage,  $f_{cd}$  is the compressive strength of the material anchorage takes place, in this case masonry, and  $f_{yd}$  is the steel tensile strength.

For the interaction of the two phenomena the formula used is [3]:

$$\left(\frac{N_{sd}}{N_{ud}}\right)^{3/2} + \left(\frac{F_{sd}}{F_{ud}}\right)^{3/2} = 1 \quad (3)$$

Where  $N_{sd}$  is the axial load from the analysis,  $N_{ud}$  is the ultimate force under tension the anchor can bear, as calculated above,  $F_{sd}$  is the shear force from the analysis and  $F_{ud}$  is the ultimate force under shear the anchor can bear, as calculated above.

All anchorages were deemed sufficient, with the maximum ratio of demand to capacity being  $\eta_{max}=77.4\%$ .

## 6 DYNAMIC TIME HISTORY ANALYSIS

For the Dynamic Time History Analysis, the accelerometer from the earthquake of Thessaloniki of 1978 was used as a ultimate limit scenario and 60% of it as a serviceability limit scenario, according to KAN.EPE. The links were assigned non-linear properties. Three scenarios were designed, earthquake by the X-axis, earthquake by Y-axis and their SRSS directional combination. Approximately 20 % of the elements surpassed their yield limit during the SRSS directional combination of the ultimate limit scenario. None failed. For the serviceability limit scenario 4 % of the elements surpassed their yield limit during the SRSS directional combination. None failed. In both cases, the brackets used were deemed sufficient.

Figure 14: Ultimate Limit Scenario Results.

Figure 15: Serviceability Limit Scenario Results.

## 7 CONCLUSION

- The addition of masonry infilled increases the building's stiffness.
- Exterior facades further increase, to a lesser extent, the building's stiffness, the strain developed at the building's frames and its top displacement.
- Retrofitting may be needed in some cases.
- The links used were deemed sufficient.

**Keywords:** R/C beam-to-column joints, Flexural behaviour, FRP strengthening, FRP jackets mechanical anchored

### Abstract

*The behaviour of R/C beam-to-columns joints is experimentally and numerically investigated here. A 1:3 scaled specimen is constructed and tested under cyclic seismic type loading at the Laboratory of Strength of Materials and Structures (Aristotle University of Thessaloniki). The reinforcing details prohibit the appearance of shear failure modes. Thus, this study focuses on the bending behavior of the structural members forming the R/C joint as built and strengthened with FRP jacketing. The main focus of this study is the effectiveness of the strengthening system adopted here. The FRP layers are mechanically anchored using steel sections in the joint region in order to prevent the premature delamination of the FRP layers and the proper distribution of stresses through the anchoring system to the structural members. The observed at the laboratory behaviour is portrayed in terms of horizontal load versus horizontal displacement cyclic response as well as bending moment cyclic response that develops at the beams and columns forming this R/C joint. Apart from the observations of this R/C joint behaviour based on the laboratory measurements this R/C subassembly was numerically simulated. The used numerical models include detailed modeling of all material used assigned with nonlinear constitutive laws derived by material testing. By comparing the numerical results with the corresponding experimental measurements, the validity of the employed numerical simulation is validated. Both experimental and numerical results demonstrate the satisfactorily behavior of the strengthening system used here.*

## 1 INTRODUCTION

The behavior of RC beam to column joints subjected to seismic type cyclic loading is studied here ([2], [7], [9]). For this purpose, a 1:3 scaled 3-D reinforced concrete (RC) joint specimen was constructed and tested at the laboratory of Strength of Materials and Structures of Aristotle University ([4], [5], [6], [10], [11]), shown in figure 1. The experimental campaign included testing of the joint specimen at 3 stages. Firstly, the virgin joint, following the same specimen with retrofitted beams applying FRP sheets and the retrofitted specimens with both beams and columns strengthened using FRP sheets. In order to achieve the desired flexural strengthening of the structural members an anchoring system, formed by steel angles and bars around the joint core, is used to mechanically anchor the FRPS sheets.

Figure 1. Interior RC joint model at Aristotle University – Experimental set-up.

In addition, 3-D numerical simulations of the tested specimens are also formed. These numerical models were subjected to monotonic loading instead of the cyclic loading sequence adopted at the experimental procedure resembling the envelope curve measured during testing. The reinforcing detailing of the tested specimen was such as to prohibit the development of any shear mode of failure. Therefore, this study focuses on numerically simulating the flexural response and mode of failures of the structural members that form this 3-D joint and

not on the failure of the joint core. The numerical models follow a micro-modeling approach. The concrete volume is represented together with the embedded longitudinal and transverse reinforcement in an explicit way. Both materials are governed by nonlinear material laws which have been derived by material testing. For the strengthened models the FRPs sheets are simulated by shell elements given an elastic constitutive law, as the predominant mode of failure of the FPP sheets is the debonding from the structural member's surface and not the FRP's rupture. Thus, the debonding failure is predicted by the non-linear interface assigned between the FRP sheets and the concrete's surfaces given a tensile and shear stress limit. Nonlinear Static analysis (pushover analysis) is next conducted to determine ultimate load, deflection capability and failure mechanisms. By comparing the measured behaviour with the corresponding numerical predictions an attempt is made to check the validity of the employed numerical simulations.

## 2 FEATURES OF THE EXPERIMENTA SEQUENCE

In what follows a brief description of a 1:3 scaled specimen of RC beam-to-column joint is presented. This scaled model was constructed and tested at the Laboratory of Strength of Materials of Aristotle University. The specimens tested at Aristotle University did not include an RC slab. Details of this specimen are shown in figures 1 and 2. Further details are included in the published works by Manos et al. ([4], [5], and [6]). The East (E) and West (W) longitudinal beams have at their ends a hinge support which is also provided with a load cell capable of recording the vertical (upwards or downwards) reaction at these supports. The transverse beam North (N) and South (S) ends are free to deflect vertically as well as to slide horizontally at the E-W direction of the cyclic horizontal load (as is shown in figure 1) being in contact with a sliding surface at these locations. The horizontal movement of these transverse beam ends at the N-S directions is restrained. The end of the bottom column is restrained in the two horizontal as well as at the vertical direction though a hinged support.

Figure 2. Interior RC joint model at Aristotle University – Experimental set-up and instrumentation scheme.

The top of the column is attached to the horizontal dynamic actuator capable of applying an imposed cyclic horizontal displacement in the E-W directions, as depicted in figures 1 and 2. The corresponding horizontal load is measured in this location by a horizontal load cell. Before any horizontal displacement is applied at the top of the column, a vertical load of 5.0tnf is applied through a jack and kept constant throughout each test. This load is monitored through a vertical load cell. These vertical load cell and jack were supported on top of the column through a set of sliders in such a way as not to restrict the horizontal movement of the top of the column (figure 1).

Apart from the load cells described before a number of displacement transducers were also provided in order to monitor the horizontal displacement of the top of the column at the point of horizontal cyclic load application as well as the horizontal displacement of the axis of the longitudinal beam. In addition, for both left and right longitudinal beams as well as top and bottom columns displacement transducers were provided capable of recording the relative extension or contraction of their top and bottom fiber near the joint in an effort to measure directly the rotation of each part of these structural elements during the flexural response of the whole RC joint. The geometry of the cross-sections of the beams and columns of this specimen are shown in figures 1 and 2 together with the details of the used reinforcing arrangement (see also table 1). The mechanical properties of the concrete and the steel used to build this specimen are listed in table 2 from axial compression and tensile tests with coupons taken during the construction. All RC beams and columns were provided with steel stirrups spaced in a way to prohibit the development of any form of shear failure. Both the longitudinal and transverse reinforcement was formed by smooth small diameter reinforcing bars according to similitude requirements ([4], [5], and [6]).

Columns		Longitudinal beams		Transverse beams	
width b (mm)	height h (mm)	width b (mm)	height h (mm)	width b (mm)	height h (mm)
110	110	100	160	100	160
Longitudinal Reinforcing bars Number / diameter (mm)					
4 / Ø5.5mm		2 / Ø5.5mm + 2 / Ø5.5mm			

Table 1. Details of RC joints (figure 1)

Steel reinforcing bars	Yield stress $f_y$ (MPa)	Yield strain $\epsilon_y$	Ultimate stress $f_u$ (MPa)	Ultimate strain $\epsilon_u$
Diameter Ø5.50mm longitudinal	311	0.08	425	0.22
Diameter Ø5.50mm (stirrups)	360	0.06	542	0.20

Table 2. Mechanical properties of used reinforcing bars (figure 1)

### 3 RESULTS AND OBSERVATION FROM THE MEASURED BEHAVIOUR

Figure 3a depicts the variation of the applied horizontal cyclic load versus the corresponding horizontal displacement of the tested RC beam-to-column joint that develops either at the top of the column or at the axis of the longitudinal beam (approximately at the mid-height of the specimen). The maximum load measured was equal to 8.69KN. The observed damage at the East beam cross-section is depicted in figure 3b.

Figure 3. a) Cyclic load versus the corresponding horizontal displacement response of the RC beam-to-column interior joint model tested at Aristotle University. b) observed cracking at the East beam cross-section

Following, a strengthening technique was adopted only for the longitudinal beams. In these members two CFRP sheets were bonded in both faces. Near the joint core steel angles were placed together with circular bars in order to support mechanically the FRP layers and prohibit the premature delamination as depicted in figure 4. The response of the specimen with strengthened beams in terms of applied load versus the horizontal displacement at the top of the column is given in figure 5 together with the observed damage pattern. In this case, the cracking occurs at the bottom column's cross-section near the joint core. The maximum load measured was equal to 12.54KN.

Figure 4. The examined strengthening method: The anchoring system consisting of steel parts is placed around the joint area and the CFRP sheets are bonded to the longitudinal beam faces.

Next, the same strengthening technique was used for the column sections as well. Three CFRP sheets were bonded at each face of the column members. Again the specimen was subjected to cyclic horizontal loading. The variation of the applied horizontal cyclic load versus the corresponding horizontal displacement of the tested RC beam-to-column joint that

develops at the top of the column is shown in figure 6. The maximum load observed was equal to 16.63KN.

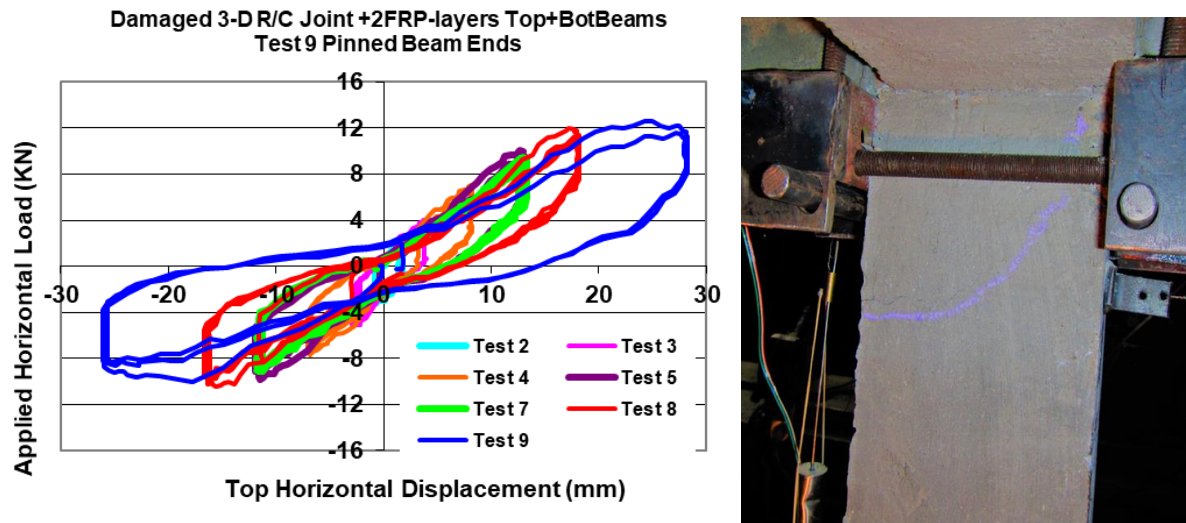

Figure 5. a) Cyclic load versus the corresponding horizontal displacement response of the RC beam-to-column joint with FRP strengthened beams. b) observed cracking at the East beam cross-section

Figure 6. a) Cyclic load versus the corresponding horizontal displacement response of the RC beam-to-column joint with FRP strengthened beams and columns. b) observed cracking at the East beam cross-section

#### 4 NUMERICAL SIMULATIONS OF THE OBSERVED BEHAVIOUR

The numerical models discussed here utilize solid elements for the concrete volume as shown in figure 7a, together with wire elements for the numerical representation of the reinforcing bars as shown in figure 7b. Reinforcing bars were added within the concrete volume representing the actual reinforcing bars. The reinforcing bars were in full contact with the surrounding concrete through the relevant option (embedded region) provided in the software [1].

Non-linear constitutive laws were adopted in this numerical simulation for either the concrete or the steel elements. These stress-strain constitutive laws are based on the corresponding measured axial compression or tension tests performed with specimens taken during the

construction of the RC beam-to-column mock-up at the laboratory of Strength of Materials and Structures of Aristotle University. The vertical load of 5.0tnf was initially applied and kept constant, while the horizontal force at the top of the column was applied in a gradually increasing manner, following a step-by-step time history pushover analysis. The response of the virgin joint model is given in figure 8 in comparison with the corresponding experimental measurements in terms of applied load versus the horizontal displacement at the top of the column. Figure 9 depicts the formation of plastic hinges at beam cross sections. As can be seen in this figure, large principal plastic strains appear to develop at the edges of the beam ends near the joint faces corresponding to areas of the concrete volume that develops flexural cracks (figure 9a). In figure 9b the reinforcing bars, at the same locations where the concrete develops high principal plastic strains, develop high tensile stress that have values larger than the yield stress of the reinforcing steel ( $f_y=311\text{MPa}$ , Table 2). The yielded reinforcing longitudinal bars are marked with red color. Therefore, in this 3-D numerical simulation the plastic hinges in the beams are numerically represented explicitly in this detailed manner.

Figure 7. 3-D numerical simulation of the RC beam-to-column joint tested at the laboratory of Strength of Materials and Structures of Aristotle University. a) The numerical simulation of the concrete volume. b) The numerical simulation of the longitudinal and transverse reinforcement.

Figure 8. Comparison between the measured horizontal force versus horizontal displacement at the top for the virgin RC joint tested with the 3-D numerical predictions

Figure 9. Virgin RC joint numerical response. a) The distribution of plastic strains at the beams near the region that they meet the RC joint. b) Distribution of axial stress at the longitudinal reinforcement of longitudinal beams. The yielded reinforcing longitudinal bars are marked with red color.

Following, the anchoring system was simulated with simple contact with the R/C joint and the FRP sheets were bonded to the beams and attached at the anchoring system (figure 10a). The response of this model in terms of applied load versus the horizontal displacement at the top column is depicted in figure 10b together with the corresponding experimental measurements. Figure 11 shows the plastic strains developed at concrete's volume. Large plastic strains develop at the column cross sections near the joint. At the same location the vertical reinforcing bars develop high tensile stresses, larger than the yield limit (table 2). Thus, plastic hinges are formed in column's cross section.

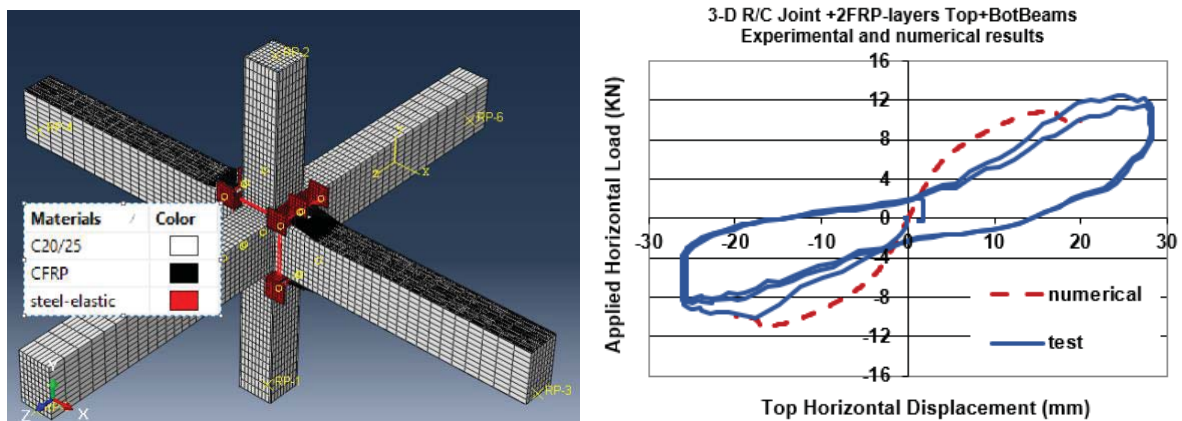

Figure 10. a) The numerical model of joint with FRP strengthened beams. b) Comparison between the measured horizontal force versus horizontal displacement at the top for the joint with FRP strengthened beams and the corresponding numerical prediction

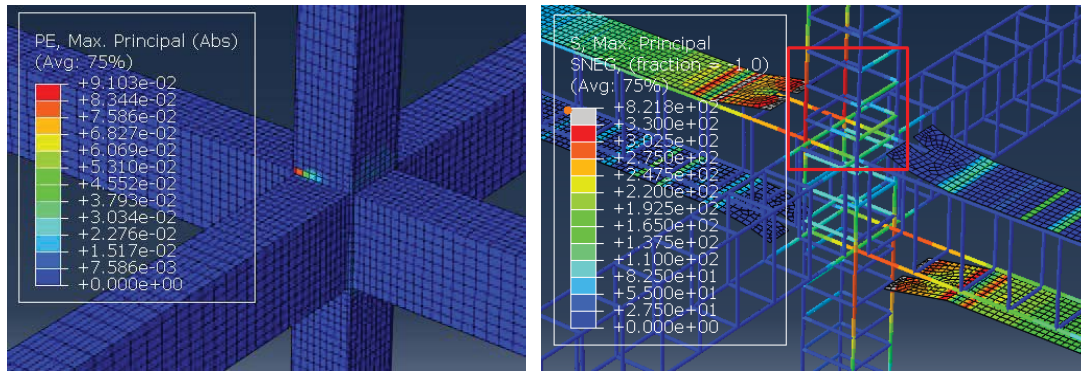

Figure 11. Joint with strengthened beams. a) The distribution of plastic strains at the column near the region that meet the RC joint. b) Distribution of axial stress at the longitudinal reinforcement and FRP sheets of longitudinal beams. The yielded reinforcing longitudinal bars are marked with red color.

Next, FRP sheets were attached at the two faces of the top and bottom column following the same methodology as previously described, 2 CFRP sheets to beams and 3 CFRP sheets to columns (figure 12a). The response of this model in terms of applied load versus the horizontal displacement at the top column is depicted in figure 12b together with the corresponding experimental measurements. Figure 13 shows the plastic strains developed at concrete's volume. Large plastic strains develop at the beam cross sections near the joint. At the same location the reinforcing bars develop high tensile stresses, larger than the yield limit (table 2). Thus, plastic hinges are formed in column's cross section.

Figure 12. a) The numerical model of joint with FRP strengthened beams and columns. b) Comparison between the measured horizontal force versus horizontal displacement at the top for the joint with FRP strengthened beams and columns and the corresponding numerical prediction

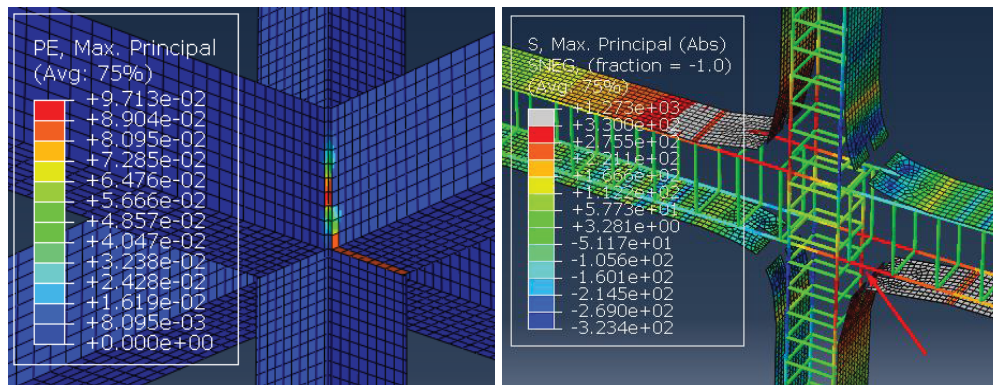

Figure 13. Joint with strengthened beams and columns. a) The distribution of plastic strains at the beam, near the region that meet the joint core. b) Distribution of axial stress at the longitudinal reinforcement and FRP sheets. The yielded reinforcing longitudinal bars are marked with red arrow.

## 5 DISCUSSION OF THE OBTAINED RESULTS.

In section 3 the experimental results of the tested R/C joints are given. The virgin 3D joint was tested under cyclic horizontal load with a constant vertical load equal to 50KN. Following, the damaged specimen was strengthened with 2 CFRP sheets bonded at the longitudinal beams. Subsequently, 3 FRP sheets were placed to the column as well. In all cases the FRP layers were attached to the examined anchoring system placed near the joint core region. The virgin joint exhibited a maximum load equal to 8.69KN, while cracking appeared at the beam cross sections near the joint. The beam strengthened joint exhibited greater maximum load, 12.54KN, while cracking was observed at the bottom column. Finally, the joint with both beams and columns strengthened exhibited a maximum load equal to 16.63KN.

Afterward, numerical models were developed using all the geometrical and the mechanical properties of the tested specimen. Three models are examined with correspondence with the above mentioned tests. The virgin model exhibited a maximum load equal to 8.70KN, while cracking appeared at the beam cross sections near the joint. The beam strengthened joint exhibited greater maximum load, 10.96 KN, while cracking was observed at the bottom column. Finally, the joint with both beams and columns strengthened exhibited a maximum load equal to 12.55 KN, while the beam cross section showed cracking.

Specimen	Experimental results		Numerical results	
	Maximum load (KN)	Observed mode of failure	Maximum load (KN)	Observed mode of failure
Virgin	8.69	Cracking of beam sections	8.70	Plastic strains at concrete and rebar of beams
Beams Strengthened (2 sheets)	12.54	Cracking of column sections	10.96	Plastic strains at concrete and rebar of column
Columns Strengthened (3 sheets)	16.63	Cracking of beam sections	12.55	Plastic strains at concrete and rebar of beams

Table 3 Summary experimental measurements and numerical predictions

## 6 CONCLUSIONS

The behavior of RC beam-to-column joints subjected to seismic type cyclic loading is studied here as built and subsequently strengthened using CFRP sheets. The strengthening methodology aims to upgrade the flexural capacity of the structural members and for this purpose an anchoring system near the joint area is used. The observed behaviour is portrayed in terms of horizontal load versus horizontal displacement cyclic response. Apart from the laboratory observations numerical simulations were conducted. The main conclusions are enlisted below:

- The anchoring system employed in the discussed experimental campaign successfully prohibited the delamination of FRP sheets near the joint core and ensured the stresses distribution. Thus, the structural subassembly bearing capacity is increased by 44% and 91% for the beam strengthened specimen and the both beams and columns FRP strengthened specimen.
- The used 3-D numerical simulations of the tested RC joint successfully represented the observed flexural non-linear response of this RC structural sub-assembly, as for each case satisfactorily captured the mode of failure.

- Regarding the bearing capacity predicted by these numerical models again the numerical simulation can be considered successful up to point. The strengthened models exhibited an increase of maximum load by 27% and 44% for the beam strengthened specimen and the both beams and columns FRP strengthened models, which are smaller than the corresponding laboratory measurements. This can be explained by the fact that during the analysis damage on the interface between FRP sheets and R/C members was observed, while the experimental procedure did not exhibit such a failure. Thus, the bearing capacity's increase is limited. Therefore, the properties of these interfaces should be further investigated.

### Abstract

*A number of ungrouted and grouted masonry walls were built at the laboratory of Strength of Materials and Structures of Aristotle University using an innovative clay unit vertically perforated. This vertically perforated clay unit was designed and produced with the proper holes in order to host the required horizontal and vertical reinforcing steel bars. At the same time the remaining holes are filled with expanded polystyrene parts capable to provide sufficient thermal insulation and drastically reduce the energy consumption. The specimens constructed with the thin mortar method using a high strength mortar and employing vertical reinforcing bars of different diameters. The measured behavior is depicted here in terms of horizontal applied load versus the horizontal displacement at mid height. Furthermore, numerical models were developed in order to simulate the observed behaviour of the tested specimens by modeling separately the masonry panels as homogenized material and linear beam elements representing the employed longitudinal (vertical) reinforcement. The numerically simulated behavior resembles the measured load-deformation response of the tested specimens and the observed actual damage at the end of the tests.*

## 1 INTRODUCTION

The vulnerability of unreinforced masonry walls subjected to seismic loads was highlighted during past earthquake events [1, 2]. The employment of reinforcing bars to construct earthquake resistant partially grouted masonry structures with acceptable performance is one possible solution. The in-plane behavior of such structures has been widely investigated. Manos et al. [3, 4] tested partially reinforced piers with different reinforcing schemes under in plane cyclic loads. Recent studies investigate the in-plane behavior of reinforced masonry walls using new clay units with the appropriate thermal properties in an effort to improve the structures energy consumption [5, 6]. Over the literature there are both experimental and numerical investigations about the out of plane response of reinforced masonry walls focusing on the effect of the aspect ratio, boundary conditions, reinforcing ratio etc. [7, 8].

An ongoing research of Laboratory of Strength of Materials and Structures deals with partially grouted reinforced masonry walls constructed with a novel clay unit. A key issue in the construction of these walls is the masonry unit employed. The geometry of this new unit was defined using parametric numerical predictions taking into consideration not only the mechanical properties, but also parameters like thermal properties, production cost and ease of construction practice [9, 10]. In this paper the out of plane behavior of ungrouted and partially grouted masonry wallets is discussed. Results are presented from tests of unreinforced masonry wallets or reinforced with vertical rebars of different diameters, which are subjected to cyclic out of plane bending. The mechanical properties of all the employed materials are defined through testing. Following, numerical models were developed utilizing all the geometrical and mechanical properties in order to replicate the experimentally measured out of plane behaviour. All these results are presented and discussed focusing on the influence of the reinforcing arrangement in the overall in plane response.

## 2 SPECIMEN CONSTRUCTION AND MATERIAL PROPERTIES

The geometry of the employed clay unit is depicted in Figure 1. The basic mechanical properties of this unit were measured at the Laboratory. More specific, unit's compressive strength perpendicular to the bed joint and parallel to the bed joint are measured by compression test according to EN772-1 [11]. The proposed reinforced masonry system uses the construction technique of thin mortar joint. The mechanical properties of the mortar material used, were obtained by material testing according to EN1015-19 [12]. The same mortar is used as grout to fill the vertical holes when a rebar is placed. Additionally, tensile tests for the used reinforcing steel bars with diameter 10mm, 14mm and 16mm were conducted. The above mentioned properties are listed at table 1 and table 2.

The used vertically perforated units with nominal dimensions length=210mm, height=240mm and thickness=300mm form a vertical hole between the units with dimensions about 75x75mm aiming to be used for the placement of the concentrated vertical reinforcing bar (figure 1).

All specimens were built by builders following the relevant prototype work conditions. The constructed specimens (length 970mm, height 1700mm and a thickness of 300mm) were tested under cyclic out of plane bending. Before the out of plane loading, all specimens were subjected to uniform compressive load equal to  $4t_n$ , which was kept constant during the out of plane loading sequence and was measured by a load cell. The horizontal load was applied at the mid height of each wallet by an actuator and was measured by a load cell. Displacement transducers were also used to measure the out of plane deflection of each specimen. All measurements were used to obtain the performance of each specimen in terms of out of plane load applied at mid-height versus the out of plane deflection, as it is showed below (section 3).

<b>Brick unit</b>	
mean compressive strength perpendicular to bed joints ( $f_b$ )	8.12 MPa
mean compressive strength parallel to bed joints ( $f_{b,h}$ )	2.73 MPa
<b>Mortar</b>	
compressive strength ( $f_m$ )	13.47 MPa
flexural strength ( $f_{mt}$ )	2.80 MPa

Table 1: mechanical properties of masonry materials used.

steel bar's diameter	yield stress (MPa)	ultimate stress (MPa)	yield strain	ultimate strain
D10mm	580	680	2.9‰	10‰
D14mm	540	670	2.7‰	12‰
D16mm	530	640	2.6‰	11‰

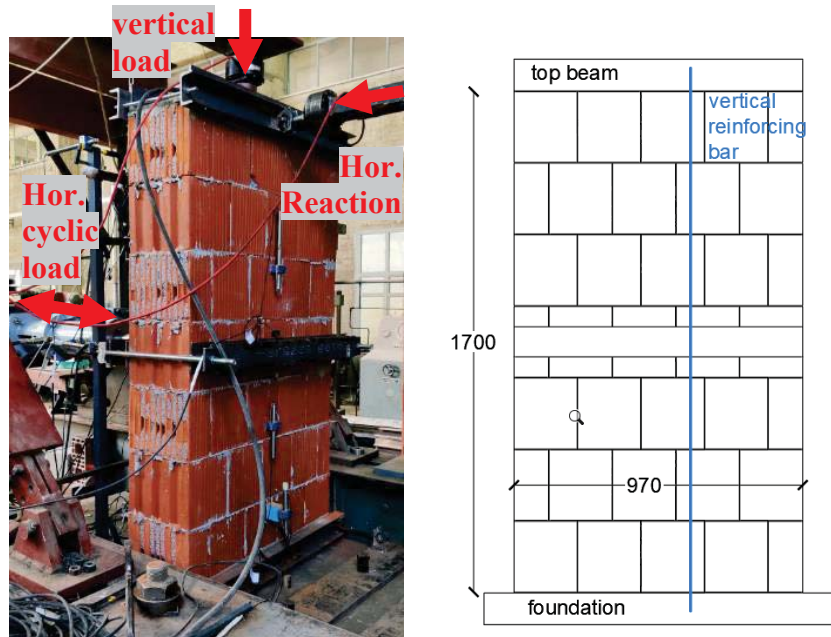

Figure 2: Experimental set-up (left) and the geometry of tested specimens (right)

### 3 EXPERIMENTALLY OBSERVED BEHAVIOR

The observed out of plane performance of the tested specimens with or without vertical reinforcing bars is presented and discussed in terms of the variation of the out of plane load applied at mid-height versus the out of plane deflection together with the observed damage. Firstly, the performance of the unreinforced wallet is given. Figure 3 (right) depicts the observed performance of the unreinforced masonry wallet without any reinforcement, which represents the control specimen. As can be seen a linear behavior is observed till the first cracking at the minimum load (-5.0KN). At this point the flexural failure of the bed joint develops and it is followed by a sudden decrease of bearing capacity. Following, for the next cycles the bearing capacity is almost constant (+2.3KN, -3.0KN). This performance can be characterized rather brittle. At the same figure (figure 4 left) the formation of horizontal cracking along the bed joint at mid height is depicted.

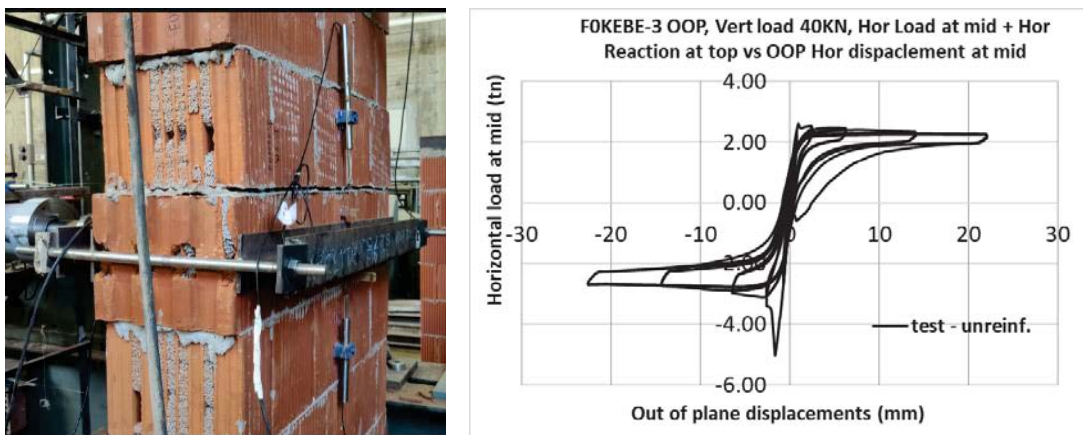

Figure 3: Damage pattern of bare wallet (left) and its response in terms load versus deflection (right)

Following, the response of the tested specimens with vertical reinforcing bars is presented. Figure 4 depicts the observed damage and the variation of the out of plane load applied at mid-height versus the out of plane deflection for a specimen with a vertical rebar of diameter 10mm placed at a vertical grouted hole. The bed joint failure develops again for a negative load about -5.0KN, but for the next cycles a ductile behavior is observed with maximum and minimum measured load +4.8KN and -6.0KN respectively. The formation of horizontal crack at the mid-height bed joint characterizes the observed mode of failure for this specimen.

Figure 4: Damage pattern of reinforced wallet with D8mm reinforcing bars and its response in terms load versus deflection (right)

The response of the tested specimens with vertical reinforcing bars with diameter 14mm and 16mm is depicted in figures 5 and 6 in terms of variation of the out of plane load applied at mid-height versus the out of plane deflection and the observed damage pattern. In both cases, the bed joint failure develops again for a negative load about -5.0kN and for the next cycles a ductile behavior is observed with a maximum and minimum measured load +5.9kN/-6.1kN and +6.1kN/-6.2kN for the wallets with reinforcing bar with diameter 14mm and 16mm respectively. The formation of horizontal crack at the mid-height bed joint characterizes the observed mode of failure for these specimens. For the latter stages of the cyclic loading compressive failure of the outer face of bricks developed.

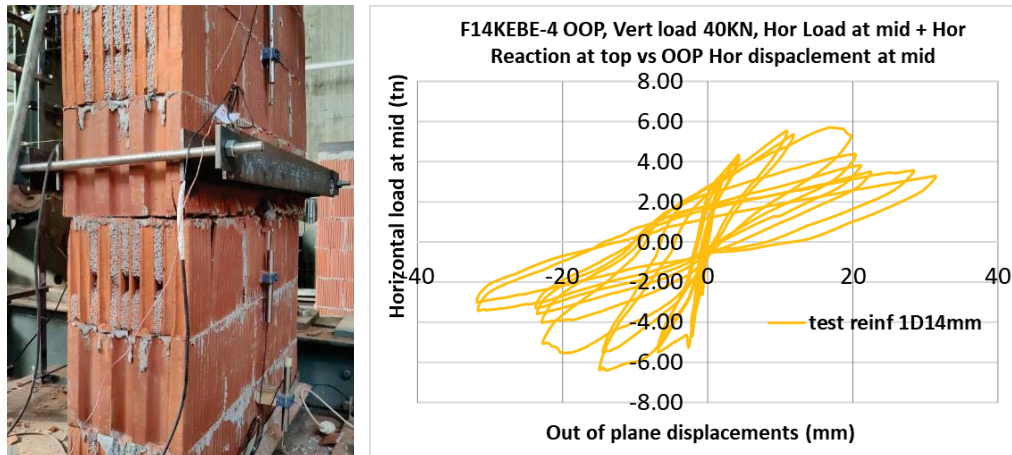

Figure 5: Damage pattern of reinforced wallet with D8mm reinforcing bars (left) and its response in terms of load versus deflection (right)

Figure 5: Damage pattern of reinforced wallet with D8mm reinforcing bars (left) and its response in terms of load versus deflection (right)

#### 4 NUMERICAL MODELING

Three-dimensional finite element numerical models were formed, adopting a macro modeling approach with a homogenized material obeying the Concrete Damaged Plasticity (CDP) constitutive law for the masonry, that can satisfactorily represent the behaviour of brittle materials, like concrete or masonry, with different stress – strain laws for compression and tension. Two different material laws were formed resembling the ungrouted and grouted masonry parts. These two laws differ in the Young's Modulus and the compressive strength. The material properties assigned to material laws are listed in table 3 and they were obtained by ma-

terial testing on prism masonry specimens according to corresponding EN Standrads [13,14]. The vertical reinforcing bars were simulated by wire elements given an elasto-plastic material law obtained by the laboratory measurements (see table 2). A perfect bond between masonry and reinforcing bars were assumed. The geometry and details of the numerical model are depicted in figure 6. The numerical predictions includes two monotonic pushover analysis for “negative” and “positive” deflection.

Figure 6: 3D view of the numerical model of the reinforced masonry wallet with a vertical D16mm reinforcing bar.

Concrete Damaged Plasticity – material model assigned to masonry panel		
	UngROUTED masonry	Grouted masonry
Young's Modulus (MPa)	4000 MPa	4700 MPa
Compressive strength (MPa)	3.6 MPa	4.30 MPa
Flexural strength (MPa)	0.2 MPa	0.2 MPa

Table 3: Parameters of CDP constitutive law for masonry material

The damaged pattern of the unreinforced wallet’s numerical model is depicted in figure 7 together with the comparison of the variation of horizontal applied load with out of plane deflection response with the corresponding tested specimen. A very good agreement both in load – displacement curve and in the observed mode of failure.

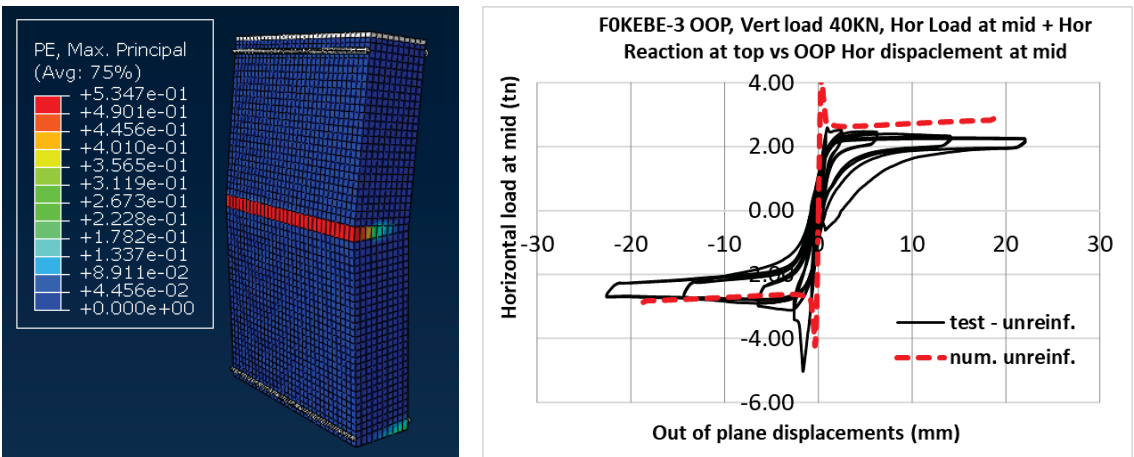

Figure 7: Plastic strains – damage pattern of unreinforced numerical model at the end of loading (left) and its response in terms horizontal applied load versus out of plane deflection (right)

Following, in the previous model a vertical reinforcing bar is added as shown in figure 6 with wire elements. The reinforcing bar is of diameter 10mm, 14mm or 16mm as in the tested

specimens. Figures 8, 9, 10 depict a comparison between experimental results and the corresponding numerical predictions for the 3 above mentioned reinforced wallets. In general, a good agreement is observed both in the load – deflection response and in the damage pattern. Additionally, rebar's and masonry's panel plastic strains at the end of the analysis, for an out of plane displacement about 30mm are depicted. The reinforced wall with 1D10mm has relatively large plastic strains developed in the vertical rebars at the bottom and at the mid-height. On the other side, reinforced walls with 1D14mm and 1D16mm developed greatly smaller and no plastic strains at the rebar elements respectively. In these two models significant plastic strains are developed at the compressive zone at the mid-height cross-section indicating compressive failure.

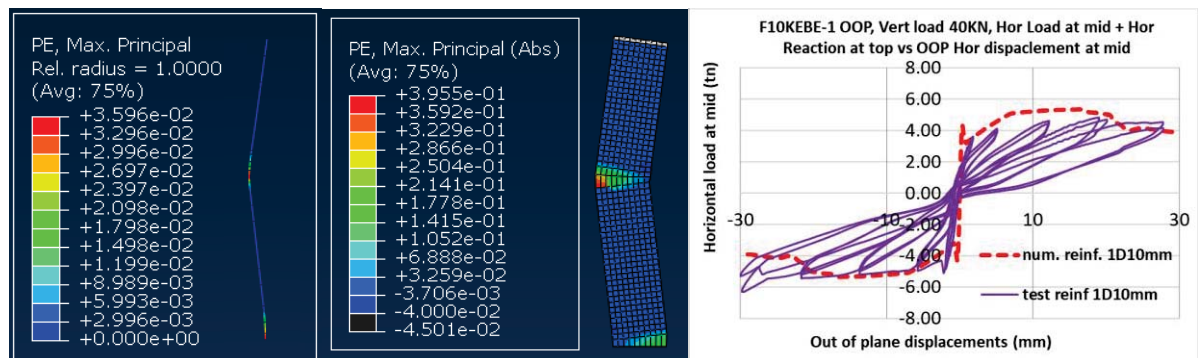

Figure 8: Plastic stains at rebar and masonry panel (left) and horizontal applied load versus out of plane deflection response of numerical model with 1D10mm vertical reinforcing bar, compared with the corresponding experimental measurements (right).

Figure 9: Plastic stains at rebar and masonry panel (left) and horizontal applied load versus out of plane deflection response of numerical model with 1D14mm vertical reinforcing bar, compared with the corresponding experimental measurements (right).

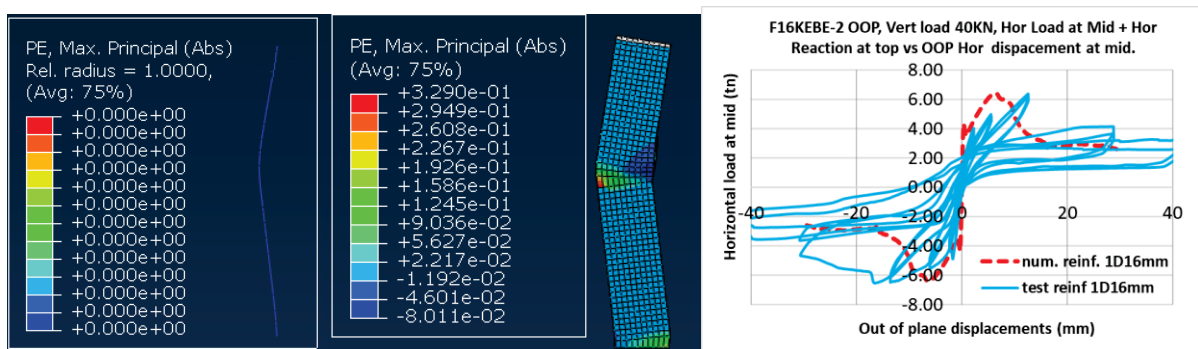

Figure 10: Plastic stains at rebar and masonry panel (left) and horizontal applied load versus out of plane deflection response of numerical model with 1D16mm vertical reinforcing bar, compared with the corresponding experimental measurements (right).

## 5 DISCUSSION

Figure 3 depicts the response of the unreinforced masonry wall. The applied load is increasing till the bed joints failure starts followed by a sudden drop of the applied load, which from this point and for greater out of plane displacements remains almost constant. As it is showed in figures 4, 5, 6 the existence of a vertical reinforcing bar leads to a further increase of the applied load after the bed joint's failure and as the out of plane deflection is increased. The table below includes the maximum / minimum load for each specimen and the corresponding deflections. For all specimens the mode of failure was the same and was characterized by the bed joints cracking at the mid-height section.

Apart from the bearing capacity increase, the existence of vertical reinforcing bars contributes to relatively fat hysteresis loops under the cyclic loading compared to the unreinforced specimen's performance. This fact indicates that the reinforcing rebars have exceeded their yield limit and developed plastic strains contributing in that way to a much more ductile response for the reinforced specimens. Vertical rebar's yield is also confirmed by the numerical predictions. Figures 8, 9, 10 depicts the developed plastic strains of reinforcing bars for an out of plane imposed deflection about 30mm.

Specimen detail	Experimental measurements		Numerical predictions	
	Minimum load (corresponding displacement)	Maximum load (corresponding displacement)	Minimum load (corresponding displacement)	Maximum load (corresponding displacement)
Unreinforced	-5.04 tn (-1.63mm)	2.59 tn (0.94mm)	-4.23tn (-0.38mm)	4.23tn (0.38mm)
Reinforced 1D10mm	-6.31 tn (-30.20mm)	4.85 tn (22.63mm)	-5.35 tn (-16.62mm)	5.35 tn (16.62mm)
Reinforced 1D14mm	-6.40 tn (-10.92mm)	5.72 tn (22.62mm)	-6.31 tn (-7.31mm)	6.31 tn (7.31mm)
Reinforced 1D16mm	-6.54 tn (-16.50mm)	6.37 tn (12.54mm)	-6.43 tn (-6.25mm)	6.43 tn (6.25mm)

Table 2: Summary results of all tested and numerically simulated wallets. Maximum/minimum load is given together with the corresponding displacement

## 6 CONCLUSIONS

The behavior of reinforced masonry wallets under out of plane bending is discussed here, mainly focusing on the contribution of the vertical reinforcing bars in the overall wallet's response. Apart from the experimental observations, numerical models were developed using all the available information about the mechanical properties of the materials used and the geometrical details in an effort to numerically reproduce the behavior observed at the laboratory. The main conclusions are listed below:

- The observed mode of failure of all specimens was the cracking along the bed joint at mid-height joint
- The existence of reinforcing bar, placed vertically at a grouted hole, contributed in an increase of maximum load measured, proportional to the rebar's cross section.
- The unreinforced masonry wallet exhibited a rather brittle performance, as after the bed joint's crack a sudden loss of the applied load occurred. On the contrary, reinforced masonry walls performed much more ductile exhibiting an "elastic – plastic" response.

- The vertical rebar of diameter 14mm and 16mm, while leading to a further increase of maximum load, exhibit a less ductile behavior compared to the reinforced wall with 1D10mm vertical rebar, due to the failure of the compressive zone at the mid height.
- The developed numerical models discussed here can satisfactorily capture the observed mode of failure, the maximum load measured and up to a point the force – deflection curves.

## ACKNOWLEDGEMENTS

All materials for the construction of the specimens were provided by “KEBE S.A. (Northern Greece Ceramics)”. Part of the aforementioned research “Innovative construction system of reinforced masonry with anti-seismic, thermal-insulating and environmental friendly characteristics (TheSeisMas)” has been co-funded by Greece and European Union through the Operational Program “Erevno - Dimiourgo - Kainotomo” (project code: T1EDK-03314) which are gratefully acknowledged.

Co-financed by Greece and the European Union

### Abstract

*A new innovative clay brick unit is used for the construction of partially grouted masonry walls. This new unit aims to provide both the required mechanical properties and thermal insulating properties. The behavior of masonry specimens constructed with this unit and thin mortar method under in plane loads is discussed here. The basic mechanical properties of the examined construction system are measured by a series of material tests, prism tests under combined shear and compression and wallets under compression tests. The laboratory measurements are compared with the defined by EC6 values. Following, diagonal compression tests were conducted at the Laboratory of Strength of Materials and Structures (Aristotle University of Thessaloniki) to ungrouted and grouted masonry wallets with different reinforcing details employing horizontal reinforcing steel bars placed at the prefabricated holes of the clay unit. The effect of the reinforcing steel bars in the bearing capacity and in the post peak behavior is investigated. Apart from the experimental investigation, numerical models simulating these tests were developed utilizing all the geometrical properties of the specimens and the mechanical properties of the materials used. The numerically simulated behavior resembles the measured load-deformation response of the tested specimens and the observed actual damage at the end of the tests.*

## 1 INTRODUCTION

The vulnerability of unreinforced masonry walls subjected to seismic loads was highlighted during past earthquake events [1, 2]. The employment of reinforcing bars to construct earthquake resistant partially grouted masonry structures has been widely investigated. Manos et al. [3, 4] tested partially reinforced piers with different reinforcing schemes. For the tested piers with a height over length ratio equal to 1 and horizontal reinforcing ratio values larger than 0.085%, the flexural response together with the rather ductile plastic rotation response at the bottom of the wall, similar to a plastic-hinge mechanism. Additionally, some of the specimens exhibited extensive compressive failures on the compression zone. Other researchers [5, 6] investigated the influence of the horizontal shear reinforcement in partially grouted masonry piers subjected to combined horizontal and vertical loads. It was observed that shear reinforcement not only provided additional resistance, but also improved the post-cracking performance. Recent studies investigate the behavior of reinforced masonry walls using new clay units with the appropriate thermal properties in an effort to improve the structures energy consumption together with an acceptable structural performance [7, 8]. Again, the importance of bricks mechanical properties was noted as the deformation of walls appeared to be limited by the brittleness of the units, as toe crushing develops for some walls, leading also to a low dissipation of energy.

An ongoing research of Laboratory of Strength of Materials and Structures deals with partially grouted reinforced masonry walls constructed with a novel clay unit. A key issue in the construction of these walls is the masonry unit employed. The geometry of this new unit was defined using parametric numerical predictions taking into consideration not only the mechanical properties, but also parameters like thermal properties, production cost and ease of construction practice [9, 10]. In this paper the in-plane behavior of ungrouted and partially grouted masonry wallets is discussed. Results are presented from tests of unreinforced masonry wallets or reinforced with horizontal rebars of different diameters, which are subjected to in-plane diagonal compression. The mechanical properties of all the employed materials are defined through testing. Following, numerical predictions of this measured in-plane behaviour are also included. All these results are presented and discussed focusing on the influence of the reinforcing arrangement in the overall in plane response.

## 2 SPECIMEN CONSTRUCTION AND MATERIAL PROPERTIES

The geometry of the employed clay unit is depicted in Figure 1. The basic mechanical properties of this unit were measured at the Laboratory. More specific, unit's compressive strength perpendicular to the bed joint and parallel to the bed joint are measured by compression test according to EN772-1 [11]. The proposed reinforced masonry system uses the construction technique of thin mortar joint. The mechanical properties of the mortar material used, were obtained by material testing according to EN1015-19 [12]. Additionally, tensile tests for the used reinforcing steel bars with diameter 6mm and 8mm were conducted. The above mentioned properties are listed at table 1 and table 2.

The used vertically perforated units with nominal dimensions length=210mm, height=240mm and thickness=300mm had properly shaped to form two horizontal channels in order to embody the horizontal reinforcement (figure 1). Additionally, vertical holes are formed between the clay units used for the vertical reinforcing bars.

All specimens were built by builders following the relevant prototype work conditions. The constructed specimens (1340mm by 1340mm and a thickness of 300mm) were tested under diagonal compression. The used experimental set up are depicted in figure 2. This simple loading scheme to study the in-plane performance of masonry panels is specified by ASTM

E519-15 [13] and by RILEM Technical Recommendations for “Testing and Use of Construction Materials” [14].

<b>Brick unit</b>	
mean compressive strength perpendicular to bed joints ( $f_b$ )	8.12 MPa
mean compressive strength parallel to bed joints ( $f_{b,h}$ )	2.73 MPa
<b>Mortar</b>	
compressive strength ( $f_m$ )	13.47 MPa
flexural strength ( $f_{mt}$ )	2.80 MPa

Table 1: mechanical properties of masonry materials used.

steel bar's diameter	yield stress (MPa)	ultimate stress (MPa)	yield strain	ultimate strain
D6mm	605	650	3.00‰	4%
D8mm	550	657	2.75‰	15%

Table 2: mechanical properties of steel reinforcing bars

Figure 1: The geometry of the novel brick unit (left) and the employed of horizontal bars (right)

Figure 2: Experimental set-up (left) and the employed of horizontal bars (right)

The vertical compressive load was monotonic and was applied at a relative slow rate being measured by a load cell. Displacement transducers were also used to measure the vertical and horizontal variation of the length of the two main diagonals at both facades of the loaded specimen. By utilizing these displacement transducers, the variation of the diagonal lengths was monitored together with the variation of the applied vertical load throughout the whole of the loading sequence employing an automatic data recording acquisition system. The observed performance for each tested specimen is presented in section 3 in terms of the variation of the equivalent shear stress versus the corresponding shear strain, obtained as described before.

All measurements were used to obtain the performance of each specimen in terms of the variation of the equivalent shear stress ( $\tau_s$ ) versus shear strain ( $\gamma$ ) calculated through equations 1 and 2, as is described in ASTM E519-15 [13]. Each specimen was designed to be tested under diagonal compression along one of its main diagonals having a concrete block at the top and bottom corner of the vertical diagonal of each specimen in order to facilitate the application of the compressive diagonal load (fig. 3).

$$\tau_s = (0.707 * P) / [0.5 * (L1 + L2) * t] \quad (1)$$

$$\gamma = |\delta l1| / l1 + |\delta l2| / l2 \quad (2)$$

*P*: the applied vertical load.

*L1 and L2*: the length of the sides of the wallet as indicated in figure 2.

*l1 and l2*: the length of the vertical and horizontal diagonals the variation of which is monitored with displacement transducers attached on the brick façade of the wallet as indicated in figure 2.

$\delta l1$  and  $\delta l2$ : the variation of the relevant lengths *l1* and *l2* as they occur during the variation of the applied load (*P*).

*t*: the thickness of the masonry panel (neither the thickness of the thermo-insulating attachment nor the thickness of the adhesive mortar are included).

### 3 EXPERIMENTALLY OBSERVED BEHAVIOR

The observed diagonal compression performance of the tested specimens with or without horizontal reinforcing bars is presented and discussed in terms of the variation of the equivalent shear stress ( $\tau_s$ ) versus shear strain ( $\gamma$ ) (equations 1 and 2) together with the observed damage. Firstly, the performance of the unreinforced wallets is given. Figure 4 (right) depicts the observed performance of the unreinforced masonry wallet without any reinforcement, which represents the control specimens. As can be seen the shear strength value is of the order of 0.56MPa and the equivalent shear-stress versus shear strain variation characterizes this performance as being rather brittle. At the same figure (4a) the formation of a typical diagonal tension crack characterizes the observed mode of failure.

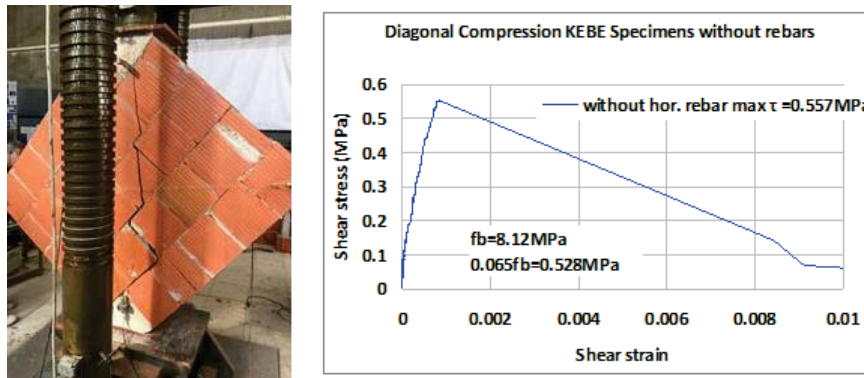

Figure 3: Damage pattern of bare wallet (left) and its response in terms of shear stress versus shear strain (right)

Following, the response of the tested specimens with horizontal reinforcing bars is presented. Figure 4 depicts the observed damage and the variation of the equivalent shear stress ( $\tau$ ) versus shear strain ( $\gamma$ ) (equations 1 and 2) for a specimen with 2 horizontal bars of diameter 6mm at each bed joint. Figure 5 depicts the observed damage and the variation of the equivalent shear stress versus shear strain for a specimen with 2 horizontal bars with diameter of 8mm at each bed joint. As can be seen the shear strength value for the reinforced specimens is slightly increased. The formation of a typical diagonal tension crack characterizes the observed mode of failure for these specimens.

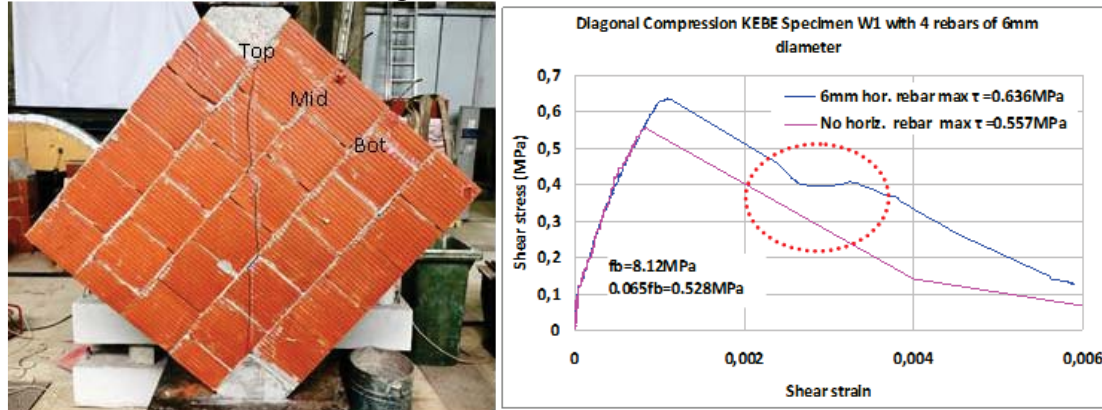

Figure 4: Damage pattern of reinforced wallet with D8mm reinforcing bars and its response in terms of shear stress versus shear strain (right)

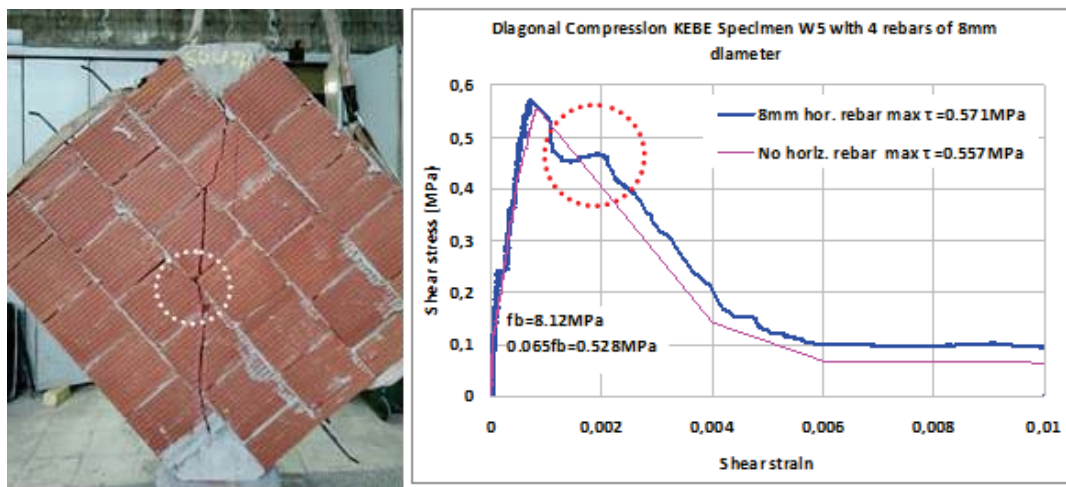

Figure 5: Damage pattern of reinforced wallet with D8mm reinforcing bars (left) and its response in terms of shear stress versus shear strain (right)

#### 4 NUMERICAL MODELING

Three-dimensional finite element numerical models were formed, adopting a macro modeling approach with a homogenized material obeying the Concrete Damaged Plasticity (CDP) constitutive law for the masonry, that can satisfactorily represent the behaviour of brittle materials, like concrete or masonry, with different stress – strain laws for compression and tension. The numerical model resembling the unreinforced wallet was calibrated in order to capable follow the behavior observed at the laboratory. All the parameters used for the constitutive law are listed at table 3. The geometry and details of the numerical model are depicted in figure 6.

Concrete Damaged Plasticity – material model assigned to masonry panel					
Elastic properties		Compressive behavior		Tensile behavior	
Young's Modulus (MPa)	4000	Yield stress MPa	Plastic stain	Yield stress MPa	Plastic stain
Poisson's ratio	0.15	3.60	0	0.48	0
		0	0.01	0	0.01

Table 3: Parameters of CDP constitutive law for masonry material

Figure 6: Numerical model. Front view and top view (left) and 3D view of the model with the embedded reinforcing steel bars (right)

The damaged pattern of the unreinforced wallet's numerical model is depicted in figure 7 together with the comparison of shear stress - shear strain response with the corresponding tested specimen. A very good agreement is observed both in the stress – strain response and in the damage pattern observed.

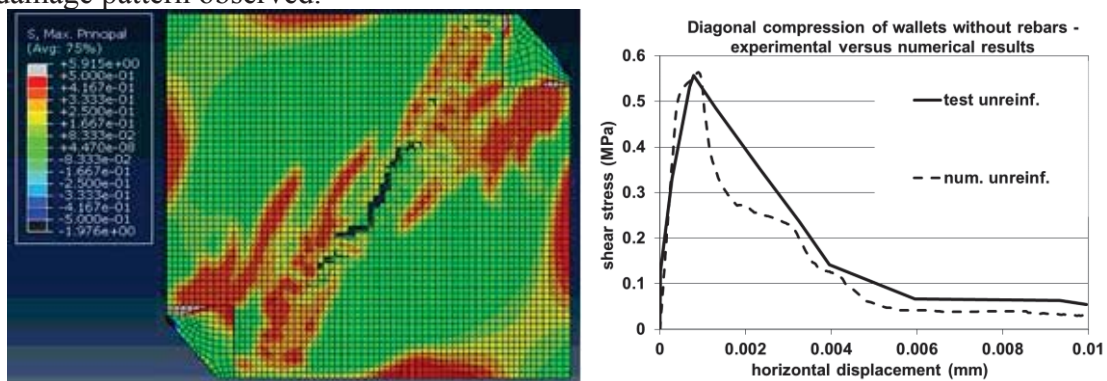

Figure 7: Maximum principal stress (MPa) and damage pattern of unreinforced numerical model at the step of maximum load (left) and its response in terms of shear stress versus shear strain (right)

Following, in the previous model horizontal reinforcing bars are added as shown in figure 6 with wire elements. The reinforcing bars are of diameter 6mm or 8mm as in the tested specimens. These bars are assigned with an elasto-plastic material law obtained by material testing

(section 2). A perfect bond between rebars and the masonry panel is assumed. The damaged pattern of the numerical model and a comparison of shear stress - shear strain response with the corresponding tested specimens is shown in figure 8 and 9 for the model with horizontal bars with diameter 6mm and 8mm respectively. In general, a good agreement is observed both in the stress – strain response and in the damage pattern. Additionally, the developed axial stresses of the horizontal rebars are depicted in figure 10 at the step of maximum load for both reinforced models, in an effort to explain the contribution of the horizontal reinforcing bars in the overall response.

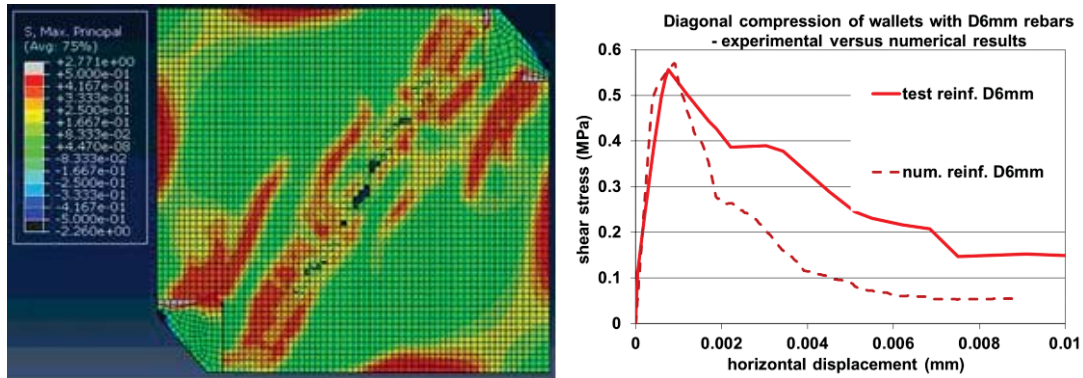

Figure 8: Maximum principal stresses (MPa) and damage pattern of reinforced with D6mm horizontal bars numerical model at the step of maximum load (left) and its response in terms of shear stress versus shear strain (right)

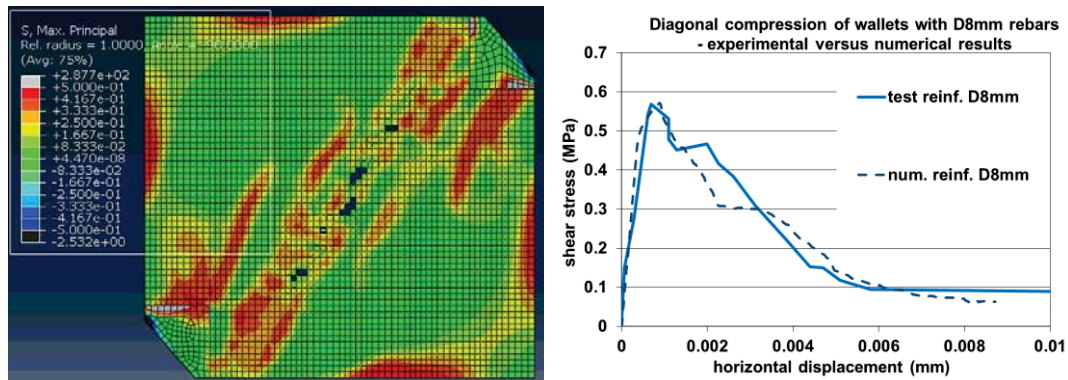

Figure 9: Maximum principal stresses (MPa) and damage pattern of reinforced with D8mm horizontal bars numerical model at the step of maximum load (left) and its response in terms of shear stress versus shear strain (right)

Figure 10: Developed axial stresses (MPa) of reinforcing bars at the step of maximum load for D6mm bars (left) and D8mm bars (right)

## 5 DISCUSSION

Figure 12 depicts the response in terms of equivalent shear stress versus shear strain for unreinforced and reinforced with horizontal reinforcing steel bars with diameter either 6mm or 8mm. The corresponding numerical predictions are also shown in the same figure. In all cases it is clear that there is no remarkable increase of shear strength due to the reinforcing steel bars. Over the literature there are studies reporting similar observations by diagonal compression test either on reinforced masonry wallets [15] or on strengthened wallets with steel bars mounted near masonry's surface [16]. This is explained by the fact that till the maximum load, reinforcement's stresses are not great. When the non-linear behavior occurs and masonry's cracks are widening the reinforcing bars develop greater stress. Thus, the existence of horizontal reinforcing bars seems to improve the post peak response leading to a less brittle declining brunch.

The shear strength is highly affected by the clay unit's compressive strength as the diagonal cracking propagates through the clay units. This mode of failure is predicted in Eurocode 6 [17] as the shear strength is prevailed by an upper limit of  $0.065 \cdot f_b$  (units' mean compressive strength). In the examined case this limit is calculated 0.528 MPa, pretty close to the shear strength values obtained by the diagonal compression tests.

Figure 11: Response of both tested specimens and numerical models for unreinforced and reinforced configuration

## 6 CONCLUSIONS

The behavior of reinforced masonry wallets under diagonal compression is discussed here, mainly focusing on the contribution of the horizontal reinforcing bars in the overall wallet's response. Apart from the experimental observations, numerical models were developed using all the available information about the mechanical properties of the materials used in an effort to numerically reproduce the behavior observed at the laboratory. The main conclusions are enlisted below:

- The horizontal reinforcing bars are not clearly increase masonry's shear strength, but they contribute for the increase on the ductility.
- The observed damage pattern of the diagonal cracking does not change when horizontal reinforcing bars are added and it is directly linked with the compressive strength of clay units used.

- The developed numerical models, after calibrated with the unreinforced specimen's response, can satisfactorily capture the observed behavior of reinforced masonry wallets both in terms of shear stress – shear strain response, but also in the damage pattern.

## ACKNOWLEDGEMENTS

All materials for the construction of the specimens were provided by “KEBE S.A. (Northern Greece Ceramics)”. Part of the aforementioned research “Innovative construction system of reinforced masonry with anti-seismic, thermal-insulating and environmental friendly characteristics (TheSeisMas)” has been co-funded by Greece and European Union through the Operational Program “Erevno - Dimiourgo - Kainotomo” (project code: T1EDK-03314) which are gratefully acknowledged.

### Abstract

*Multi-story buildings are composed of multi-bay steel or R/C frames having unreinforced masonry panels considered as non-structural elements not included in the structural design. Such structures are subjected to strong earthquake motions, leading to potentially damaging conditions for the masonry in the form of in-plane damage or/and its dislocation and partial collapse. This study focuses on the out of plane response of unreinforced masonry panels built with clay bricks units horizontally perforated representing a typical masonry infill subassembly. The examined masonry panels constructed and tested at the Laboratory of Strength of Materials and Structures (Aristotle University of Thessaloniki) are subjected to cyclic out of plane bending as built or attached with different thermal insulating facades. The response of these tests is presented in terms of horizontal load applied versus the corresponding horizontal displacement in an effort to record the influence of the thermal façade on masonry's response. Moreover, numerical models were developed in order to replicate the observed at the laboratory behavior. These models include non linear constitutive material laws together with non linear interfaces to represent the debonding of the thermal insulating facades. The measured response is presented and discussed together with the corresponding effort to numerically simulate the observed performance.*

**Keywords:** ETICS, Thermal insulation, Out of plane behavior of masonry wallets, numerical investigation

## 1 INTRODUCTION

Unreinforced masonry panels are used in multi-story buildings made of steel or reinforced concrete (R/C) to form the exterior facades or the interior partitions. Thermo-insulating panels are also attached on the exterior facades of these masonry panels in order to improve the energy efficiency of these building as well as to reduce noise and moisture penetration. This type of masonry façades is widely applied in many countries ([1, 2]). These masonry infills are considered as non-structural elements and they are not included in the structural design. However, they interact with the surrounding structural members, when such structures are subjected to strong earthquake motions. This is because masonry infills are forced to follow the displacement response of the supporting surrounding structural members (slabs, columns and beams) leading to potentially damaging conditions due to simultaneous in plane and out of plane loads. One of the most serious consequence of either of these forcing scenarios, when the seismic forces are considered as acting either separately (in-plane or out-of-plane) or combined, is the dislocation and partial collapse of such unreinforced masonry panels ([3, 4]). Figure 1a depicts a typical damage pattern observed in numerous multi-story buildings in Durres, Albania due to the recent strong earthquake sequence (26th November, 2019). Similar damage patterns have been observed in many past strong earthquake sequences in Greece (Athens 1999) and Italy (L' Aquila 2009).

Figure 1. Typical damage pattern observed in masonry infills. a) Albania, Durres 2019. b) Italy, L' Aquila 2009. c) Greece, Athens 1999.

EuroCode 6 ([5]), while accepting that vertical unreinforced masonry panels are subjected to both in-plane and out-of-plane seismic forces, includes design provisions based on the assumption of un-coupled in-plane and out-of-plane limit states. This simplification has been adopted in the large majority of relevant past research either for masonry walls or for infill masonry panels, similar to the ones studied here. The current research follows this simplification in the effort to study the influence of thermo-insulating attachments on the seismic performance of masonry panels [6, 7]. Only the out of plane behaviour for a thermo-insulated masonry panel is studied here. This is done by subjecting in the laboratory masonry wallets to simple loading conditions in order to generate stress fields within such specimens simulating similar stress fields in a masonry panel out-of-plane direction. The influence of a thermo-insulating attachment for the in-plane behaviour of masonry panels has been investigated and discussed before [3,4 8]. Results are presented from tests employing unreinforced masonry wallets, having relatively simple boundary conditions, which are subjected to out of plane bending. The mechanical properties of all the employed thermo-insulating materials are defined through testing. Following, numerical models were developed utilizing all the geometrical and mechanical properties in order to replicate the experimentally measured out of plane

behaviour. All these results are presented and discussed focusing on the influence of the external thermal insulation system (ETICS) in the overall out of plane response.

## 2 SPECIMEN CONSTRUCTION AND MATERIAL PROPERTIES

The specimens are masonry sub-assemblies which are constructed and tested at the Laboratory of Strength of Materials and Structures (Aristotle University of Thessaloniki, Greece). The thermo-insulating materials are produced by “FIBRAN Anastasiadis Dimitrios S.A.” and are applied on the specimens to be tested in the same way that are applied in prototype construction. A cross section of a masonry wallet attached with ETICS is depicted in figure 2. All specimens were built with the same 12-hole clay brick unit of nominal dimensions length=320mm, height=180mm and thickness=150mm. This brick unit is commonly used in prototype construction for this type of un-reinforced masonry panels in multi-story buildings in Greece. Similarly, a relative weak general-purpose mortar was used for all specimens. The thermo-insulating layer was added to one side of all specimens two months following their construction following the relevant construction practice. Three different thermo-insulating materials, with code names XPS, EPS and Petro, were investigated, having a panel thickness of 100mm. Specimens of all materials used for building these specimens were taken during construction and tested for determining the relevant mechanical characteristics. The mechanical properties of masonry materials are listed in table 1. Due to space limitations, the mechanical properties of ETICS materials are not reported here. However, their mechanical properties and the bond strength between ETICS and masonry substrate together with the in-plane behavior of thermal insulated masonry wallets are extensively discussed before [8].

Figure 2 Typical cross-section of a thermal insulated infill wall.

<b>Brick unit</b>	
mean compressive strength perpendicular to bed joints ( $f_b$ )	2.97 MPa
<b>Mortar</b>	
compressive strength ( $f_m$ )	2.15 MPa
flexural strength ( $f_{mt}$ )	1.16 MPa

Table 1 mechanical properties of masonry materials used

The behavior of 4 wallets subjected to out of plane bending is discussed here. The first one is bare without any thermal insulation. The other three specimens are thermal insulated with MW, EPS and XPS panels with thickness 100mm respectively. The dimensions of these wallets are depicted in figures 3a and 3b. The out-of-plane load was applied at a horizontal cross-

section located at the mid-height of wallet as depicted in figure 3. The applied out-of-plane load and the corresponding out-of-plane displacement at the mid-height central point of the wallet was recording during the test with a data acquisition system.

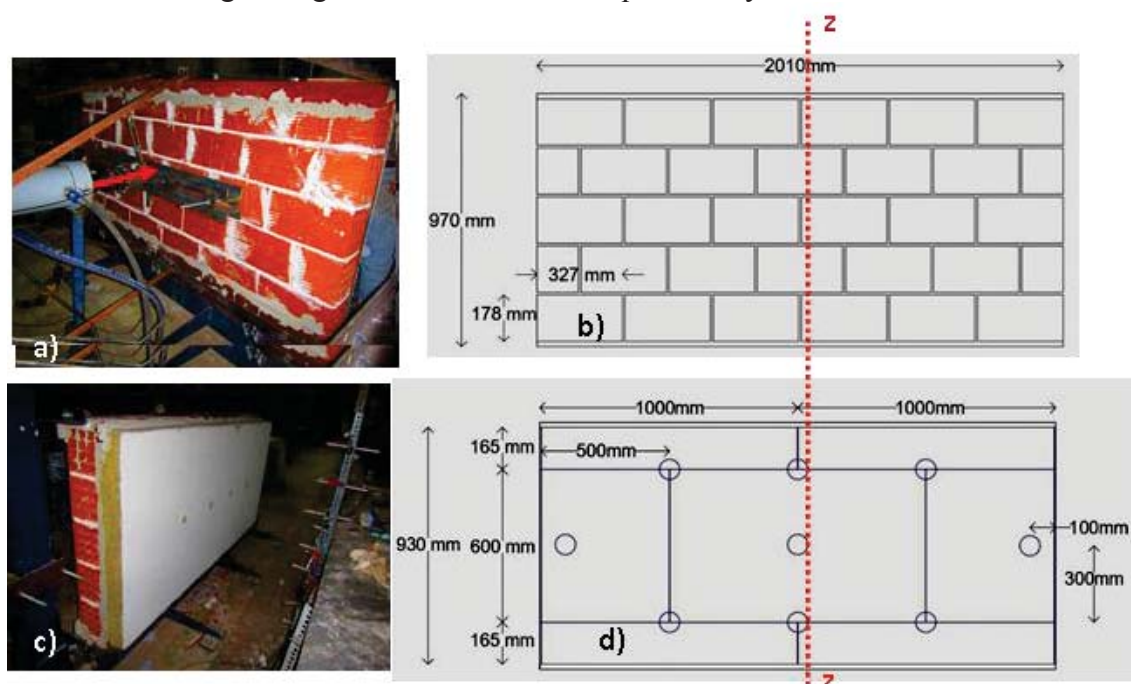

Figure 3. Out-of-plane flexure of a masonry wallets. a) and b) View from the brick façade. c) and d) View from the thermo-insulating (mineral wool) façade. The circles indicate the location of the anchors.

### 3 EXPERIMENTALLY OBSERVED BEHAVIOR

The observed out of plane performance of the tested specimens with or without thermal insulations is presented and discussed in terms of the out of plane load applied at mid-height versus the out of plane deflection together with the observed damage. Firstly, the observed performance of the bare masonry wallet without any insulation, which represents the control specimen. A linear behavior is observed till the first cracking at the minimum load (8.81kN) for an out of plane deflection about 2mm. At this point the flexural failure of the bed joint develops and it is followed by a sudden decrease of bearing capacity (figure 4).

Following, the response of the tested specimens with external thermal insulation panels are presented. The masonry specimen attached with MW panels with thickness of 100mm exhibited a maximum load 14.77kN for an out of plane deflection 5mm. The masonry wallets insulated with EPS and XPS with thickness 100mm reached a maximum load 35.62kN and 38.91kN respectively for out of plane deflection 5mm and 3mm respectively. The mode of failure of the thermal insulated panels included bed joint flexural cracking followed by a partial debonding of the thermal façade's panels.

Figure 4. Damage pattern of bare wallet

#### 4 NUMERICAL MODELING

Three-dimensional finite element numerical models were formed, adopting a macro modeling approach with a homogenized material obeying the Concrete Damaged Plasticity (CDP) constitutive law for the masonry, that can satisfactorily represent the behaviour of brittle materials, like concrete or masonry, with different stress – strain laws for compression and tension. The material law resembling the masonry part was calibrated to match the response of the corresponding wallet specimen. The attachment of the thermal insulation panels to the masonry is done with a layer of adhesive mortar which is numerically simulated with two layers of interfaces; the first interface is joining the mortar joint with the numerical simulation of the masonry and it is assigned with a perfect bond whereas the second interface is joining the mortar joint to the numerical simulation of the thermo-insulating panel and it is assigned with a cohesive-friction interface. The thermo-insulating panels were numerically simulated by 3-D finite elements. The ETICS properties and interface properties were defined from results obtained from material testing [8]. In this way, the measured flexural response was numerically simulated, utilizing the capabilities of commercial software [9]. The numerical predictions include one monotonic pushover analysis for deflection where the thermal panel are on the tensile face. All the numerical prediction for the bare and the insulated models are depicted in figure 5. The corresponding damage patterns are depicted in figure 6. In this figure, the plastic strains of the model are depicted resembling the horizontal cracking of the bare wallet of the mid bed joint (6a) and the detachment of the thermal panel following the bed joint failure (6a), as that was the predicted mode of failure for all insulated wallet models.

Figure 5. Numerical predictions of the tested specimens in terms of applied load versus the out of plane deflection at mid-height

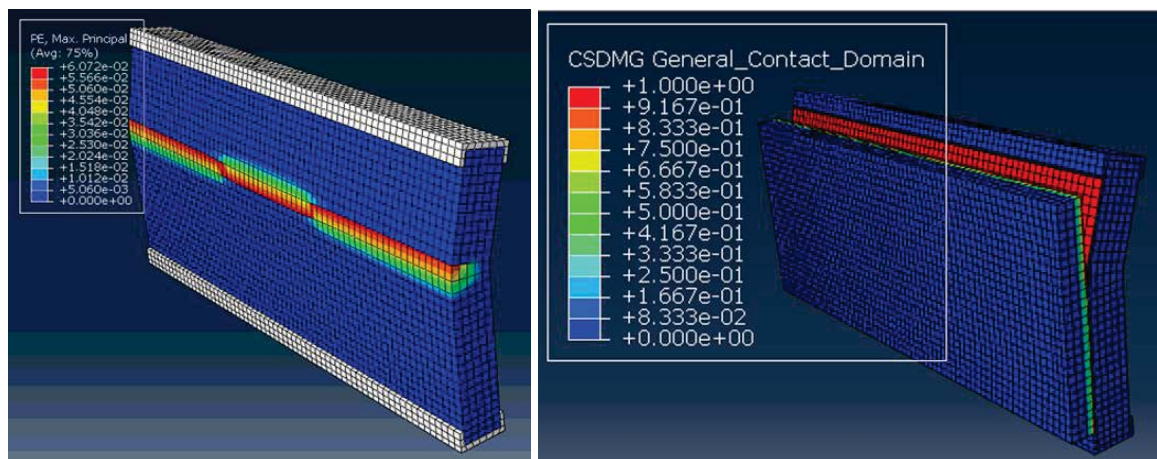

Figure 6. Plastic strains of the bare wallet model (a). The failure of the interface between adhesive mortar and insulation panel appeared for all insulated panels (b).

## 5 DISCUSSION

The behavior of 4 wallets, one bare and three attached with different insulating panels with thickness 100mm is discussed here. For these wallets both experimental results and numerical predictions are given. The table below (table 2) includes the absolute maximum load for each specimen and the corresponding deflections. For all specimens the mode of failure was the same and was characterized by the bed joints cracking at the mid-height section. Both the tested specimens and the numerical models exhibited partial detachment of the external thermal insulation following the bed joints crack.

Specimen detail	Experimental measurements		Numerical predictions	
	Absolute maximum load (KN)	Deflection at maximum load	Absolute maximum load (KN)	Deflection at maximum load
Bare	8.81	2mm	8.96	0.4mm
MW 100mm	14.77	5mm	17.55	0.8mm
EPS 100mm	35.62	5mm	26.09	2.8mm
XPS 100mm	38.91	3mm	43.59	8.1mm

Table 2. Summary results of all tested and numerically simulated wallets. Absolute maximum load is given together with the corresponding displacement

## 6 CONCLUSIONS

The behavior of thermal insulated wallets under out of plane bending is discussed here, mainly focusing on the response and the contribution of the ETICS employed in the overall wallet's response. Apart from the experimental observations, numerical models were developed using all the available information about the mechanical properties of the materials used and the geometrical details in an effort to numerically reproduce the behavior observed at the laboratory. The main conclusions are listed below:

- The observed mode of failure of all specimens was the cracking along the bed joint at mid-height joint. However, the existence of ETICS contributed in an increase of maximum load measured. The thermal insulated wallets exhibited larger bearing capacity. This increase differs depending on the panels used. The measured increment of load increase is 68%, 304% and 342% for MW, EPS and XPS insulating panels respectively.
- The developed numerical models discussed here can satisfactorily capture the observed mode of failure. All models exhibited plastic strains in a horizontal cross section resembling the failure of the tested specimens. Following the detachment of the thermal panels occurred, as it was observed during the experimental sequence. Additionally, the models discussed here can satisfactorily capture the maximum load increase and the force – deflection curves up to a point.

## ACKNOWLEDGMENTS

### Abstract

*There is a valuable research work around the strength capacity of lap spliced rebars in columns specifically in accordance with bond-slip behavior or column's seismic response. Nonetheless, lap splicing of rebars with anchored ends under combined bending and compressive loads has not yet been fully explored with due consideration of its components. It is imperative to investigate a column's behavior under bending for different levels of axial load ratio and with different reinforcing configurations employing either plain or ribbed steel bars. This paper comparatively demonstrates the results of experimental and non-linear numerical simulations pertaining to the effect of splice strength and anchoring on the compression lap splicing of rebars in concrete column. The experimental specimens are composed by prototype-scale square columns with dense or sparse stirrups, measuring 250x250 mm and 2000 mm in length, while the steel reinforcement includes a lap splice length of 400mm. Some of the tested specimens were reinforced with plain spliced bars with anchored ends; while others included ribbed spliced bars with free ends. All the specimens were tested under simultaneous bending and constant concentric, axial loading of  $\nu=0.1$ . Finally, the investigation results outline the influence of lap splice to the structural integrity of the column as a part of a composite system and generally evaluate the resistance of the lap splices in a plastic joint area, under parametric analysis.*

**Keywords:** column, lap-splices, non-linear parametric analysis, plastic joint, three points bending, axial load ratio

## 1 INTRODUCTION

In multistorey buildings, the columns of every single storey bear different levels of axial loading because of the scaled weight of the overhead storeys and it would be ideal if each of the column's longitudinal rebars could be placed as one single piece throughout the structure's entire height. This however cannot be accomplished in many cases for practical reasons and indicates the necessity of lap splices. Straight lap splices are employed in reinforced concrete to transfer loads from one steel reinforcing bar to another through the bonding between the embedding concrete and the two bars along a lapped length. Moreover, it is convenient to lengthen the steel bar via lap splice in a variety of cases, but when lapping steel bars from successive stories, it is essential to ensure the correct transmission of forces from the rebars of the superjacent floor to the rebars of the subjacent floor. This can be achieved by welding; however, this method has a few technical difficulties and it is used only in special occasions. As a result, the practice usually followed is the rebar lap-splicing as for instance with the help of anchorage hooks in the lap splice ends. ([1], [2]) As long as the cooperation between concrete and lap-spliced rebars is ensured and during the column's loading combination of bending and axial loading, the spliced bars interact with each other, following a complex force transfer mechanism, unlike the behavior of the individual ones. As a result, three stages of stresses development arise as shown in fig.1. Experimental studies have shown, however, that the bond slip behavior (associated with either splitting or pullout) in a lap splice region is similar to that of individual embedded bars and it is generally accepted that there is a small deviation between the load-carrying capacity of lap-spliced rebars and an individual bar.([1],[3]) A critical issue is when lap splices are located at potential plastic hinge regions and it is essential to study the factors which influence the structural integrity of those columns. This paper focuses on different parameters affecting the bearing capacity of R/C columns. The rebars type, the presence of internal anchorages (hooks) and the stirrups density for a stable interface stiffness coefficient are investigated. The steel-concrete interface properties are formed under the scope of the CEB-FIB bond stress-slip behavior pattern while the models include longitudinal reinforcement with ribbed or smooth bars, dense or sparse stirrups. ([4], [5])

Figure 1: Components of compression lap spliced bars inside a column

## GEOMETRY OF SPECIMENS & MATERIAL PROPERTIES

The column specimens include longitudinal reinforcement of eight steel bars (plain and ribbed) of  $\Phi 12\text{mm}$  diameter, four for every side of the column due to the lap splice of the rebars, while there is also a transverse reinforcement of  $\Phi 8$  steel stirrups. The nominal yield stress value of steel occurred from the experimental process of tension of a steel rebar equal to  $f_y=549\text{MPa}$ . The Young's modulus of the steel is  $200000\text{ MPa}$  and the Poisson's ratio is  $0.3$ . The reinforcement includes straight lap splices, which are employed in reinforced concrete to transfer loads from one steel reinforcing bar to another by bond between the embedding concrete and the two bars along the overlap length of  $L_b, t=33D_b=400\text{ mm}$ . The compressive strength of concrete is given in terms of the characteristic compressive strength of  $150\text{ mm}$  size cubes tested at  $28\text{ days}$  ( $f_{ck}$ ) and is equal to  $20\text{ MPa}$ . The result has been derived from the

laboratory experimental process of the compression of three, cubic, concrete specimens. As far as the steel concrete interface operation is concerned, a bond-slip model is used to assess the anchorage capacity of a bar. The bond failure pattern follows the three stages of CEB-FIB proposed model and it is schematically represented in Fig.2. Its failure is characterized by the initiation and propagation of cracks in the concrete-steel interface. [2]

Figure 2: Bond-slip behavior relationship

Concrete	
Compressive strength $f_{ck}$	20 MPa
Reinforcing steel bars	
Yield stress $f_y$	549 MPa
Ultimate stress $f_u$	672 MPa
Ultimate strain $\epsilon_u$	0.10

Table 1: Column specimens' structural identity

The investigation refers to a column part of a square cross section of 25x25cm, which constitutes a member of a bigger and more complex columns-plate system. Specifically, the investigation area is a two meters region between two columns, interrupted by an integrated slab, including a lap splice length of 400mm, starting from the middle of the slab (50 cm away from the inferior and 125cm from the superior support, respectively). One half of the tested column specimens included longitudinal reinforcement of plain rebars with anchored ends sparse or dense stirrups, while the other half included ribbed rebars with free ends, with sparse or dense stirrups. The specimens were subjected to a loading combination of a three point bending, and a constant, axial loading equal to the first floor weight. The bending load was applied as horizontal displacement through a jack and was imposed in the inferior end of the lap spliced rebars, just in the middle of the bottom slab. What follows is the experimental and numerical investigation of the loading combination effects on the column specimens.

### 3 EXPERIMENTAL INVESTIGATION & RESULTS

The laboratory experimental process included the test of eight column specimens of a prototype-scale, by being placed in a laboratory experimental setup with maximum loading capacity of 600tn. The specimens were subjected to a three-point bending with a simultaneous axial, concentric loading which was kept constant during the test. Specifically, two actuators were installed on the top and bottom of a column specimen so as to impose the axial load and one hydraulic jack was placed vertically at the bottom end of the lap spliced rebars of the column specimen, to apply a constant displacement throughout the test, on an area of the column where a plastic hinge was going to form. That displacement represents the horizontal force that column accepts by the bottom slab. The tested column specimens developed similar failure modes. [6]

The vertical load – displacement experimental results show that the presence of plus stirrups in the specimens with plain rebars, did not significantly ameliorate the structural correspondence of the specimen, while the presence of the axial loading lead to the rise of the load capacity of the column up to 30kN and the displacement of the area of interest was increased by 2mm, while the widen of the cracking in the vulnerable areas of the lap splice was mitigated. [7]

Figure 3: The geometry of the tested specimens

Spec ID	Altered parameters						
	Axial load ratio	Anchor age	Rebars type		Stirrups	Exp P (tn)	Exp D (mm)

## 4 NUMERICAL SIMULATION & RESULTS

### 4.1 Simulation of the column model

The presented modeling approach utilizes all the geometrical and mechanical properties described above (section 2). A detailed modeling is used. Concrete and longitudinal rebars are represented with 3D finite elements assigned with a Concrete Damaged Plasticity constitutive law and an elasto-plastic constitutive law respectively. Stirrups are simulated using wire elements and elasto-plastic material law. Between concrete and longitudinal rebars a cohesive – friction behavior (see figure 2), while stirrups is assumed to be perfectly embodied into the concrete. Two different models are investigated. The first one represents column with plain bars and anchors at rebars edges and the second one with free edges simulating the column reinforced with ribbed rebars. Additionally, different bonding strength between concrete and steel bars is given. The relatively poor bond strength between concrete and smooth rebars is given  $1\text{MPa}$ , while the bond strength between concrete and ribbed rebars is given  $5\text{MPa}$ . Below all numerical predictions carried out are listed together with the reinforcing detail and the column's axial compressive load (table 3).

Specimen ID	Altered parameters					Load capacity (tn)		Displacement range (mm)	
	Axial load ratio	Anchorage presence	Rebars type		Stirrups presence	Exp P	Num P	Exp D	Num D
			smooth	ribbed					
1-2	0	x	x	-	sparse	4	4.1	10	14.6
2-2	0	x	x	-	dense	3.3	4.3	8	15.5
3-2	0	-	-	x	sparse	4	4.1	3.3	3.3
4-2	0	-	-	x	dense	5	3.8	6.5	3
1-1	0.1	x	x	-	sparse	6	5.6	13.8	14.14
2-1	0.1	x	x	-	dense	6.2	5.8	10	14.75
3-1	0.1	-	-	x	sparse	6.9	5.5	6	3.8
4-1	0.1	-	-	x	dense	6.5	5.1	6	3.9

Figure 9: Failure modes: Plastic strains of concrete and CSDMG for specimens 1-1, 2-1 ( $v=0.1$ ) & 1-2, 2-2 ( $v=0$ ) with plain rebars and internal anchoring

Figure 10: Plots of numerical results for  $v=0$  &  $v=0.1$ , of specs 3-1, 3-2 (left) and of specs 4-1, 4-2 (right)

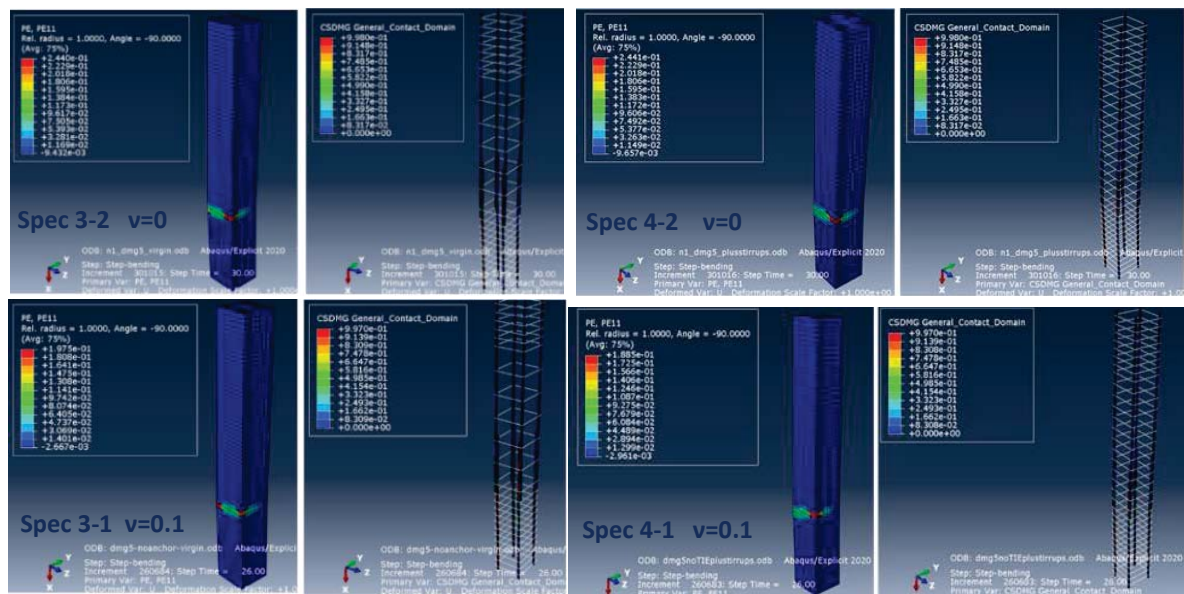

Figure 11: Failure modes: Plastic strains of concrete and CSDMG for specimens 3-2, 4-2 ( $v=0$ ) & 3-1, 4-1 ( $v=0.1$ ) with ribbed rebars

#### • Numerical results evaluation

Spec ID	experimental results		numerical results		exp-num deviation rate		
	P(tn)	d(mm)	P(tn)	d(mm)	P(tn)	P(%)	d(mm)
1-1	6	8-13	5.6	14	0.4	7.14	1-4
1-2	4	9-11	4.1	14.6	0.1	2.5	3.6-5.6
2-1	6.2	10	5.8	14.8	0.4	6.9	4.8
2-2	3.3	7-10	4.3	15.5	1	30.3	5.5-8.5
3-1	6.9	6	5.5	4	1.4	25.5	2
3-2	4.1	3.3	4.1	3.3	0	0	0
4-1	6.5	6	5.1	4	1.4	27.5	2
4-2	5	6.5	3.8	3	1.2	31.6	3.5

Table 4: Validation of the numerical results

The maximum undertaken loads and displacements for the numerical investigation for  $v=0$  and 0.1 lie between 3.8-5.8tn and 3-15.5mm respectively and are higher for the anchored specimens. There is also a satisfactory exploitation rate of the concrete's and steel's load-bearing capacity for the plain reinforced specimens as it is observed a strong anchorages' resistance which causes local damage to the concrete at the lap splice ends, the plot also shows delayed load drop and increased steel deformation and displacement. However, when the rebars are laid out freely without anchoring at the ends, the strength of the concrete steel interface is reinforced only by the interface bond between the surface of the rebar and the circumferential concrete. A premature load drop is observed for a smaller displacement due to the weak resistance of the steel ribs against anchors. It is concluded that the presence of anchors at the rebars' ends, contributes in a significant rate to the utilization of the bearing capacity of the individual materials, steel and concrete, prolonging increase in load intake and deformation for the specimen. The plastic deformation of the concrete and the steel stress at the anchors' areas

are intensified due to the exceeding of the concrete tensile strength by the stress intensity of the surrounding steel.

## 5 DISCUSSION ON THE INVESTIGATIONAL RESULTS

A general convergence is observed between the experimental and the numerical results, included the failure modes. The same loading combination with displacement control was used in both experimental tests and numerical simulation. As far as the failure patterns are concerned, Fig.12 compares the tensile damage nephogram obtained from the numerical simulation with the surface cracks obtained from the experimental test of the same specimen. The two failure modes are similar with extended cracks being concentrated on the bottom lap spliced end where the developed stress is higher for the ribbed reinforced specimens 3, 4. While, in the case of specimens 1 and 2, the cracking was developed on the concrete surface of both the anchored lap splice ends. According to the plots of the numerical and experimental results of undertaken load and displacement, a satisfactory convergence rate was achieved in the terms of the maximum load, the corresponding displacement, and the slope of the curves. (*Table 5*) In addition, the strength of the interface was simulated by realistic cohesion stresses and the expected forms of failure were induced. As a result, a reliable numerical tool has been developed and quantified so as to predict the response of critical RC members under the influence of various loading factors.

Figure 12: Comparison of the numerical and experimental failure modes of the ribbed (left) and plain with internal anchoring (right), reinforced specimens

Spec ID	Test results (tn)	Simulation results (tn)	Convergence rate (%)
1-2	4	4.1	97.6
2-2	3.3	4.3	76.7
3-2	4	4.1	97.6
4-2	5	3.8	76
1-1 v1	6	5.6	93.3
2-1 v1	6.2	5.8	93.6
3-1 v1	6.9	5.5	79.7
4-1 v1	6.5	5.1	78.5

## 6 CONCLUSIONS

An experimental and a numerical study was performed on full scale RC column specimens to evaluate the behavior of lap splices as a part of a complex structural system under the load combo of three point bending and a constant compression on the edges. The type of longitudinal reinforcement, the presence of stirrups, the free and anchored ends of the lap spliced rebars and the magnitude of the load ratio, were the main parameters considered in this study. According to the tests results, including the global behavior of the splices and the failure modes that the column specimens develop, the major findings of this study are as follows:

- The absence of anchorage leads to the premature slip of the lap spliced rebars and to early load drop under the insufficient exploitation of the materials' properties.
- The presence of dense stirrups does not essentially contribute to the rise of the undertaken load but it reduces the deformation of the concrete, by restricting the opening of the surficial cracking.
- The proposed finite element model of Abaqus for RC column is in good agreement with the experimental results such as load carrying capacity, displacement, failure mode and CEB-FIB bond stress-slip behavior pattern.
- The maximum undertaken load and the respective displacement are getting greater for both the plain and ribbed reinforced specimens as the axial load ratio rises from 0 to 7tn.
- The main difference among the results for specimens with ribbed and plain rebars, is the fact that the absence of anchoring leads to early load drop and a low exploitation of material properties, as the slip of the ribbed rebars happens prematurely.
- The presence of the lap splice implies a failure mode connected with the slip of the reinforcing bars.
- The higher degree of failure in the column specimens, for both the numerical and experimental results, is located in the plastic joint area, on the bottom end of the lap splice length.

### Abstract

*This paper presents the results of a numerical investigation on the behavior of Prestressed Concrete Cylinder Pipes (PCCP) under the Three Edge Bearing Test (TEBT) (diametrical compression test). The main goal is to develop an experimental setup in the lab in order to evaluate the efficiency of different strengthening schemes with Fiber Reinforced Polymer (FRP) repair methods. The PCCP specimens under evaluation are assumed to be prefabricated parts of an existing water infrastructure network. For practical reasons we chose to define a typical length of 1.0m for all investigated numerical specimens. On the whole, four (4) pipe models are considered: a non-prestressed initial specimen, a prestressed virgin specimen, a strengthened prestressed specimen with internally applied FRP sheet and a last strengthened prestressed specimen with externally applied FRP sheet. The numerical assessment of External Load Crushing Strength by the Three Edge Bearing Test Method is realized using 3D FEM software and in compliance with the terms of ASTM C-497 standard. The developed experimental setup will be fabricated in the Laboratory for Strength of Materials and Structures “LSMS” of Civil Engineering Faculty of Aristotle University of Thessaloniki (AUTH). For all four (4) numerically examined models we employed all the geometrical and mechanical properties of materials from existed PCCP pipes, that LSMS had the chance to measure in the past. The numerically simulated models were evaluated and discussed in terms of load-deformation response and observed limit states of damages.*

**Keywords:** Prestressed Concrete Cylinder Pipes (PCCP), External Load Crushing Strength, Three Edge Bearing Test, Numerical simulation.

---

## 1 INTRODUCTION

Prestressed Concrete Cylinder Pipes (PCCPs) were first manufactured in 1942 as lined cylinder pipe. The prestressing wire in lined cylinder pipe is wrapped directly around the steel cylinder. A second type of PCCP was developed in 1952 that has concrete encasement of the steel cylinder on both sides. Known as embedded cylinder pipe, it differs from lined cylinder pipe by the encapsulation of its steel cylinder in a concrete core. Therefore, the prestressing wire is wrapped around the concrete core rather than the steel cylinder as in lined cylinder pipe. The typical diameter ranges for lined and embedded cylinder pipe are between 0.40 to 1.50 meters and 0.75 to 6.50 meters, respectively. PCCPs are typically manufactured according to the American Water Works Association (AWWA) standard C304. [1,9]. With the onward maturity of the prestressed concrete technology of the latest years, PCCPs have been used in oil, water conservancy, hydropower engineering and other areas. Also, it has been demonstrated that in the sector of large diameter pipes, PCCPs are more competitive than any other type of pipes [2-4]. In recent years, research has been conducted in the field of experimental and numerical study of concrete pipes utilizing the Three Edge Bearing Test (TEBT) and Finite Element Method (FEM) simulation respectively [5-7]. Another interesting and growing segment of scientific study is the investigation of the strengthening repair methods of PCCPs implementing novel FRP and CFRP technology [8-10].

The “Laboratory of Strength of Materials and Structures” of Aristotle University of Thessaloniki has commenced a research project, which scope is to investigate both experimentally and numerically the mechanical behavior of PCCPs. This project aspires to address issues such as the response of PCCPs under the Three Edge Bearing Test (TEBT) and under internally applied fluid pressure, as well as the effectiveness of specific strengthening repair methods. In the current paper part of these results are presented. More specifically, the behavior of two (2) pipes specimens (one with and one without prestress) under TEBT is examined experimentally and numerically and the efficiency of two (2) strengthening methods (internal and external confinement of PCCPs with FRP double mantle) is assessed.

## 2 EXAMINED SPECIMENS AND EXPERIMENTAL SETUP

The geometry of the examined pipes is depicted in Figure 1 and the denomination of the four (4) specimens alongside with their main dimensions is presented in Table 1. All specimens have the same internal diameter, i.e., 1.80m, while the external diameter is 2.16m for Spec 2, Spec 3, Spec 4 and 1.98m for Spec 1.

The External Load Crushing Strength of the examined pipes specimens is calculated by utilizing the Three-Edge Bearing Test Method in accordance with ASTM C-497 standard. The experimental setup scheme is outlined in Figure 2, along with the real experimental configuration developed at the “Laboratory of Strength of Materials and Structures” of Aristotle University of Thessaloniki. In total, an instrument which measures the applied load (load cell) and four (4) Linear Variable Differential Transducers (LVDTs) were installed. Also, deformation strips were selectively placed at some points in order to have better control of the loading process and enhance the accuracy of the experimental device, especially in the area of the failure.

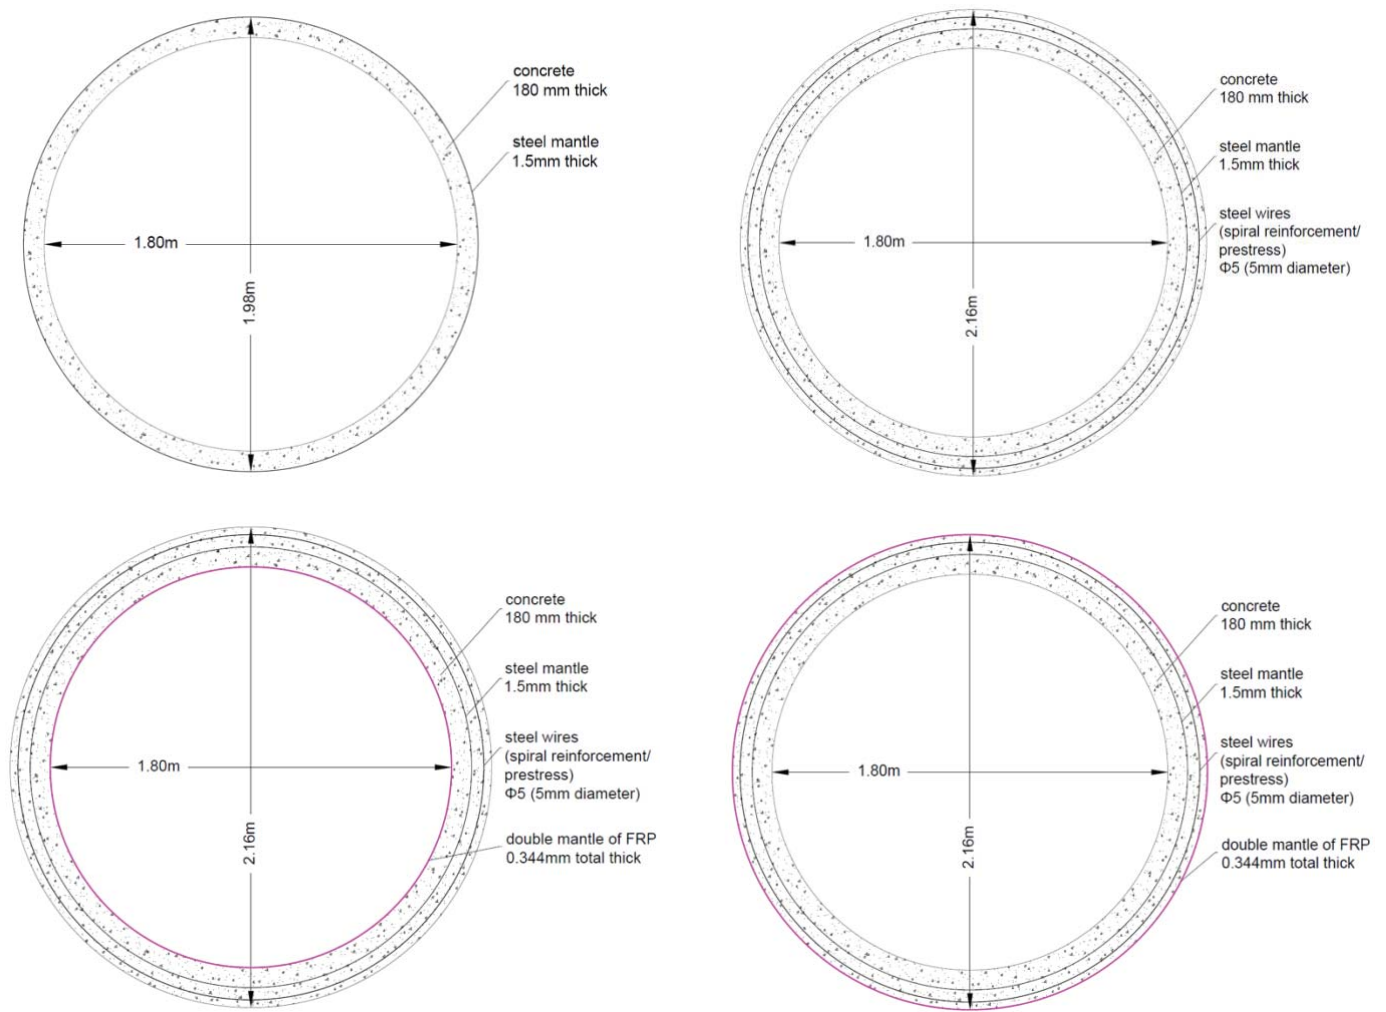

Figure 1: Geometry of the four (4) examined models: unprestressed maternal – Spec 1 (top-left), prestressed maternal – Spec 2 (top-right), FRP internally strengthened prestressed – Spec 3 (bottom-left) and FRP externally strengthened prestressed – Spec 4 (bottom-right)

Specimen Name	Description	External Diameter/ Internal Diameter
Spec 1	Maternal unprestressed specimen	1.98/1.80
Spec 2	Maternal prestressed specimen	2.16/1.80
Spec 3	FRP internally strengthened, prestressed specimen	2.16/1.80
Spec 4	FRP externally strengthened, prestressed specimen	2.16/1.80

### 3 NUMERICAL MODELING

Three-dimensional finite element numerical models have been built adopting a macro modeling approach with homogenized non-linear material laws. It should be underlined that all materials that compose the pipe specimens have been tested at the “Laboratory of Strength of Materials and Structures” of Aristotle University of Thessaloniki and have been adopted in the Finite Element Analysis (FEA) software in order to non-linear realistic numerical models. All the parameters used for the constitutive law are listed at table 2. The models of the four (4) specimens are presented in Figure 3.

Material law assigned to concrete – Concrete Damaged Plasticity					
ELASTIC PROPERTIES		COMPRESSIVE BEHAVIOR		TENSILE BEHAVIOR	
Mass Density (ton/mm <sup>3</sup> )	2.5E-09	Yield Stress (MPa)	Plastic Strain	Yield Stress (MPa)	Plastic Strain
Young's Modulus (MPa)	39000	11.88	0	1	0
Poisson's ratio	0.25	35.3	0.0012	0	0.005
		43	0.0021		
		48	0.0028		
		43.2	0.0043		

		9.6	0.02		
Material law assigned to steel mantle – Plastic					
ELASTIC PROPERTIES		TENSILE BEHAVIOR

Poisson’s ratio	0.30	1500	0.0007		
		1600	0.0012		
		1700	0.0022		
		1800	0.0047		
		30	0.015		
Material law assigned to Fiber Reinforced Polymer (FRP) - Elastic					
ELASTIC PROPERTIES					
Mass Density (ton/mm³)	1E-09				
Young’s Modulus (MPa)	240000				
Poisson’s ratio	0.15				

Table 2: Parameters of constitutive laws for concrete, mantle steel, wires steel and FRP materials

Figure 3: FEM Models of the four (4) examined specimens: maternal unprestressed – Spec 1 (top-left), maternal prestressed – Spec 2 (top-right), FRP internally strengthened & prestressed – Spec 3 (bottom-left) and FRP externally strengthened & prestressed – Spec 4 (bottom-right)

The numerically obtained results were initially evaluated in terms of applied load – developed deformations graphs, as presented in figures 4. It is depicted that for all 4 models we manage to get a non-linear behavior. In addition, the adopted numerical methodology, of applying loads and imposing restrains (experimental setup in the lab) resulted to very rational data since we were able to yield the utilized materials, obtain the bearing capacity of all models and get the post maximum decrease behavior.

Moreover, we see that the bearing capacity is increasing by adding, initially the prestress (Spec2) then by applying internally FRP sheets (Spec3) and finally by applying externally FRP sheets. It has to be mentioned that the depicted results are estimations of the real performance of the PCCP pipes and they aim to predict in a realistic way the performance of a PCCP pipe and evaluate the efficiency of strengthening schemes.

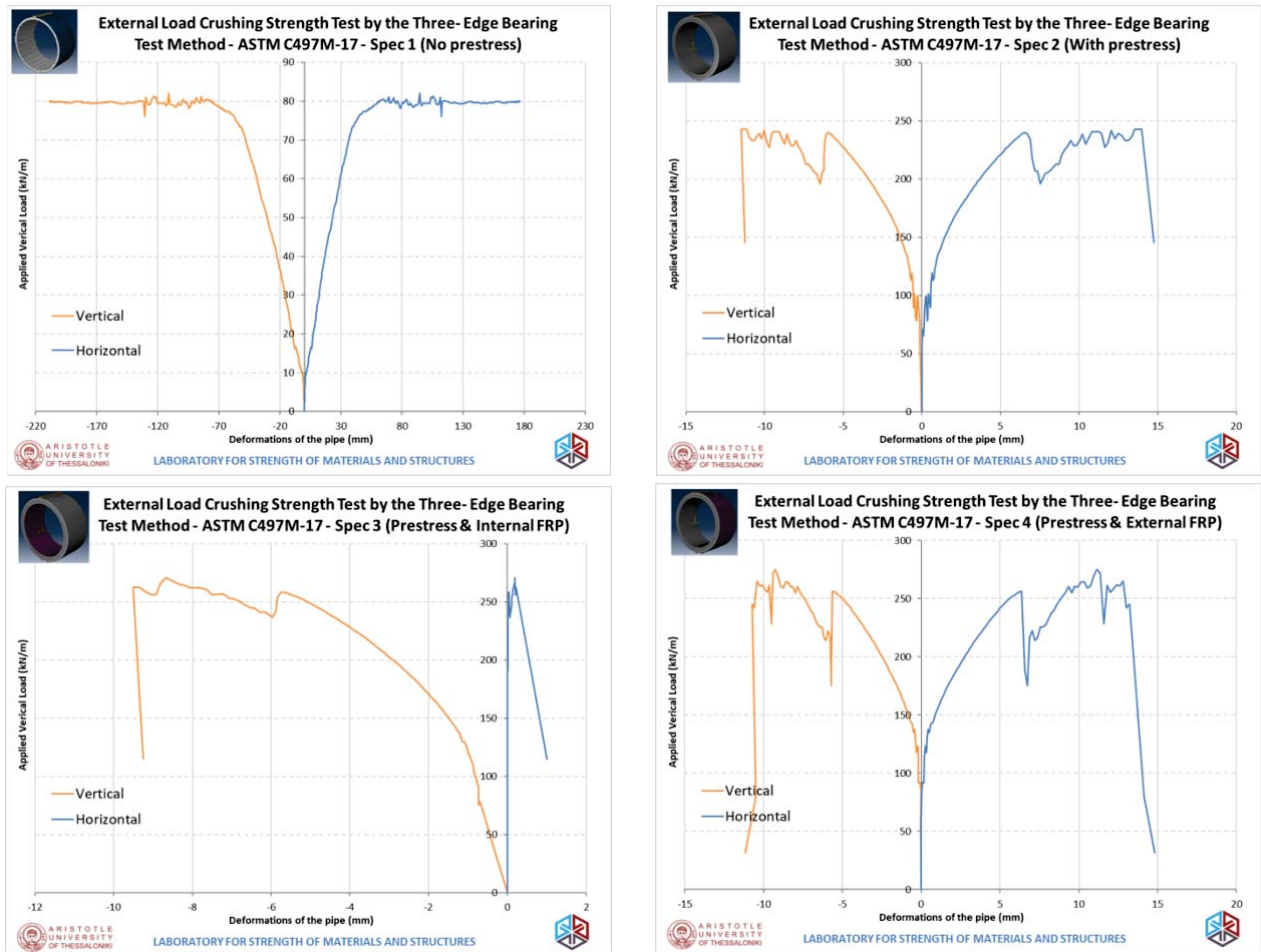

Figure 4: Numerical results - diagrams of applied force, vertical deflection and horizontal swelling of Spec 1 (top-left), Spec 2 (top-right), Spec 3 (bottom-left) and Spec 4 (bottom-right)

Figure 5 presents (plastic strain components) the damage pattern that is attained in the numerical simulations. It is depicted that plastic strains are developed on the faces of PCCP model that suffers from tension. These are the regions that we expect to get the developed cracks, under the present loading conditions. The developed damage pattern indicates the qualitatively realistic FE model.

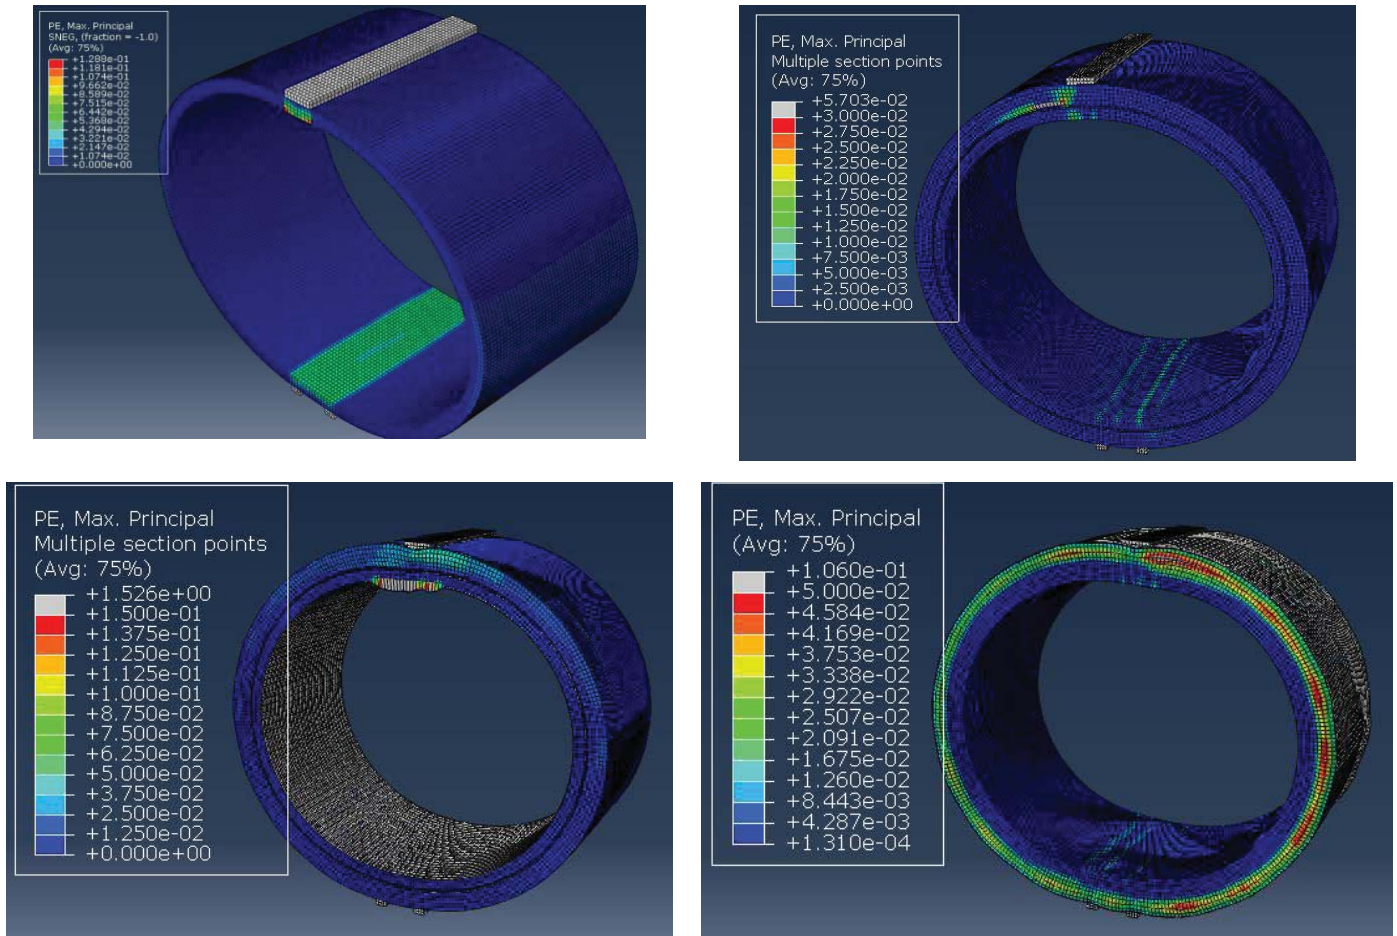

Figure 5: Numerical results - plastic strain components (PE) of Spec 1 (top-left), Spec 2 (top-right), Spec 3 (bottom-left) and Spec 4 (bottom-right)

Taking under consideration the aforementioned results, it is clear that the maternal prestressed specimen (Spec 2) develops 3 times larger strength than the maternal unstressed specimen (Spec 1). This is indicative of the highly significant contribution of the perimetric prestress and how important it is that it remains active and is not disabled by any damages or corrosion. Also, as expected, the strengthened specimens (Spec 3 and Spec 4) demonstrate greater bearing capacity than the maternal prestressed specimen (Spec 2). More specifically, the FRP internally strengthened specimen (Spec 3) indicated an increase of 12.4% in maximum bearing capacity compared to the maternal prestressed specimen (Spec 2), while the FRP externally strengthened specimen (Spec 4) demonstrated a similar behavior.

## 4 CONCLUSIONS

The behavior of Prestressed Concrete Cylinder Pipes (PCCPs) under the Three Edge Bearing Test (TEBT) is discussed here, mainly focusing on the contribution of the FRP strengthening method in the PCCPs response. Numerical models were developed using all the available information about the mechanical properties of the materials used in an effort to numerically reproduce the realistic behavior of the pipe. The goal is to estimate the bearing capacity of the

models, their damage patterns and finally quantify the experimental setup that has to be constructed in the Lab. The main conclusions are enlisted below:

- The perimetric spiral prestress is very significant as it increases the bearing capacity of the concrete pipe by 3 times.
- The strengthening of the PCCP with FRP is efficient and results in a 12,5% growth of the bearing capacity
- The developed 3-D FEM models, are considered realistic and can be utilized to built the experimental setup in the Lab

### Abstract

*Fiber-reinforced polymers (FRP) are rapidly gaining acceptance from the construction sector due to their large effectiveness. They are mainly used as confining reinforcement for concrete columns and as tensile reinforcement for concrete beams and slabs. FRPs are already used to a large extent at applications such as bridges and parking lots, where elevated temperatures are not the main risk. Their increasing use as structural reinforcement is hampered by the concern related with their behavior at elevated temperatures as the relevant research is deficient. Thanks to the significant advantage of FRPs' mechanical properties, further investigation into the influence of heating on their mechanical behavior may solve many doubts. The present study examines the influence of temperatures of 50, 100 and 250°C on the tensile strength of FRP laminates with carbon fibers (CFRP). In addition, the resistance of CFRP specimens to low-cycle thermal loading at the temperatures of 50, 100 and 250°C under constant tensile load was investigated. The experiments carried out in the laboratory of Experimental Strength of Materials and Structures of Aristotle University of Thessaloniki.*

---

## 1 INTRODUCTION

The FRPs are composite materials consisting of continuous high-strength fibers, which are embedded into a polymer matrix (usually organic) [1]. The fibers are the reinforcing elements, whereas the polymer matrix is the connecting material which protects them and transfers the loads to and between the fibers [1]. In the construction sector, the main types of fibers used are glass, carbon (inorganic) and aramid fibers (organic polymers). The use of these materials in civil engineering applications is constantly expanding, due to their important advantages. High resistance to corrosion, high strength-to-weight ratio, high stiffness, appropriate fatigue performance, electric insulation and easy installation are some of them [2],[3]. However, FRPs, according to surveys, show sensitivity to high temperatures. Elevated temperatures cause reduction in elastic modulus and strength [2]. These possibly result in large deflections, loss of reinforcement and eventually collapse [2].

Specifically, the glass transition temperature  $T_g$  is an important parameter to be considered, as above this the mechanical characteristics of the FRPs are reduced dramatically [4]. The polymer is converted from a hard, glassy material to a soft and rubbery one [2]. This leads to loss of adhesion and fibers' removal from the matrix. The resin is no longer able to transfer the loads evenly to the fibers [4]. As a result, some of the fibers are being further loaded, probably exceed their strength and fail [4]. It is also marked that a significant increase in temperature, except in the case of fire, can be caused by direct exposure to sunlight [4]. Especially, dark surfaces are able to reach temperatures of 70°C [4].

The effects of elevated temperatures on the mechanical properties of FRPs are of concern and research into this is limited. However, thanks to the significant advantages of FRPs it is worth further investigation. The present experimental work focuses on the thermo-mechanical behavior of the CFRPs laminates under monotonic mechanical loading, low-cycle fatigue and thermal loading. The experiments carried out in the laboratory of Experimental Strength of Materials and Structures of Aristotle University of Thessaloniki and the investigation parameters were the tensile stress and the temperature.

## 2 MATERIALS AND METHODS

The material of the specimens which were used in the current research was FRP laminate with unidirectional carbon fiber layers embedded in organic matrix with  $T_g=58$  °C. According to the manufacturer data sheet, layer's thickness was 0.129 mm, and the tensile strength and the elastic modulus of dry fibers were 4,000 MPa and 230,000 MPa, respectively. Twenty CFRP specimens of 250 mm length, 15 mm width and 1.8 mm thickness were prepared for the tests. (see figure 1) Their dimensions were measured using a digital caliper. Nine of them were tested at room temperature ( $RT=16$  °C) and they were used as controls while the rest of the specimens were exposed to elevated temperatures (50, 100, 250 °C).

Figure 1: Investigated specimens.

The tensile tests were performed using a universal testing machine Instron of 50 kN maximum capacity. Concurrently, the Bluehill software was used for the data export. (see figure 2) A clip-on extensometer was installed in order to measure the strain values. The tensile testing was conducted using a standard head stroke rate of 2.0 mm/min until failure. The Instron machine was equipped with an electric furnace for the heating of the specimens. The maximum operating temperature of the furnace is 260 °C and the applied heating rate was 10 °C/min. The cooling up to the room temperature was held in a physical way, so the cooling rate was relatively slow. While the furnace was closed the deflection was measured by the Instron machine head stroke. The experimental setup for both room and elevated temperatures is shown in figure 3.

Figure 2: Experimental setup with climate chamber [5].

Figure 3: Experimental setup for room temperature and for elevated temperatures.

As mentioned, nine tests were occurred at room temperature (16 °C). The first five specimens (FRPspec1-5) were tested under monotonic, uniaxial tension until failure. From the average value of these specimens' strength, their maximum tensile strength was determined. Subsequently, four specimens were submitted to low-cycle fatigue tests of fifty loading-unloading cycles. The maximum load of the cycle was equal to the 50% of the average tensile strength for the two specimens (FRPspec6,14) and 75% for the other two specimens (FRPspec7,15). The rate of the tensile loading was 1000 N/min for the cyclic tests. After the fatigue loading the four specimens were tested under monotonic, uniaxial tension up to failure. The information of experiments under room temperature is shown in table 1.

Table 1: Detailed information of experiments under room temperature.

\*1Monotonic Uniaxial Tension, \*2Low Cycle Fatigue (n=50)

The rest eleven specimens were exposed under elevated temperatures. The first six of them were submitted to thermal loading at temperatures of 50 °C (FRPspec8,11), 100 °C (FRPspec9,12) and 250 °C (FRPspec10,13). Once the furnace reached the target temperature, each specimen remained at this temperature for 30 min in order to obtain a uniform temperature distribution. When the specimen FRPspec8 was heated at 50 °C, the uniaxial tensile test was performed at that temperature level. However, the tensile tests for the FRPspec11, the FRPspec9,12 and the FRPspec10,13 at 50 °C, 100 °C and 250 °C, respectively, were performed after the specimens left to cool down to room temperature (16 °C). The cooling process was achieved by opening the door of the furnace. After the cooling, the specimens were tested under monotonic, uniaxial tension until failure, as described before.

In fact, CFRPs applied in concrete structures are usually under both imposed load and elevated temperatures from the environmental changes. Therefore, we decided to investigate the last five specimens under cyclic thermal loading while applying at the time uniform axial tensile loading. These specimens were subjected to monotonic, uniaxial tension constantly at 50% of their average tensile strength. A standard head stroke rate of 2.0 mm/min was used until the target load value. Then, the specimens remained under this constant axial load. After three minutes, cyclic thermal loading was imposed to the specimens. We reached the temperatures of 50 °C (FRPspec16), 100 °C (FRPspec17,18) and 250 °C (FRPspec19,20). The low-cycle thermal loading consisted of heating-cooling cycles up to failure. The maximum number of the cycles was three. Each cycle concluded the heating process with a rate of 10 °C/min, a holding time of 15 min at the target temperature and the cooling process to the room temperature (16 °C). Figure 4 presents the thermal protocol for each temperature. Specifically, the FRPspec16, which completed successfully the three thermal loading cycles, was additionally subjected to monotonic, uniaxial tension until failure at the temperature of 50 °C. The information of experiments under elevated temperature is shown in table 2.

Figure 4: Time – Temperature diagram for cyclic thermal loading (heating to 50, 100 and 250°C and cooling to RT=16°C).

### 3 RESULTS

Table 4 presents the results of all the CFRP specimens. Concerning to the control specimens, the average tensile strength of dry fibers of the specimens FRPspec1-5, which were monotonically loaded at room temperature up to failure, was 4,410.82 MPa, their average ultimate strain was 17.47‰ and their average elastic modulus of dry fibers was 252.52 GPa. Their stress-strain curves are shown in figure 5.

Table 4: Summarized results

Name	Loading	T (°C)	Max Tensile Stress (MPa)	Max Tensile Stress of dry fi- bers (MPa)	Max Strain (‰)	Elastic Modu- lus of dry fibers (GPa)	Comments / Mode of failure

Figure 5: Stress-strain curves for monotonic uniaxial tension at room temperature.

The specimens FRPspec6,14 and FRPspec7,15 were submitted to fatigue tests of fifty loading-unloading cycles with maximum load of 50% and 75% of the average tensile strength, respectively. (see figure 6) Resulted from the monotonic, uniaxial tension that followed, the average tensile strength of dry fibers was 4,438.88 MPa and 4,237.14 MPa for the FRPspec6,14 and the FRPspec7,15, respectively. Consequently, the low-cycle fatigue did not affect the specimens FRPspec6,14, but it reduced the CFRPs tensile strength of dry fibers by 3.94% for FRPspec7,15. Besides, the average ultimate strain did not appear significant change as its value was 21.07‰ and 17.48‰ for the FRPspec6,14 and the FRPspec7,15, respectively. It should also be mentioned that low-cycle fatigue does not affect the stiffness of the CFRPs as their elastic modulus of dry fibers remain at the same level. The stress-strain curves of monotonic tensile loading of the specimens are shown in figure 7.

Figure 6: Stress-strain curves for low-cycle fatigue with max load 50% (FRPspec6) and 75% (FRPspec7) of the tensile strength.

Figure 7: Stress-strain curves of monotonic, uniaxial tension at room temperature after low-cycle fatigue.

The specimens FRPspec8-13,16-20 were exposed to different temperatures during the experiments as it mentioned before. Figure 8 presents the stress-strain curves of monotonic, uniaxial tensile tests which were conducted after the specimens' heating and cooling (FRPspec8-13). FRPspec8 is an exception as the tensile test was possible to be held at the temperature of 50 °C without slip of the specimen. The specimen's tensile strength of dry fibers was 3,615.14 MPa and its ultimate strain was 13.67‰. Observing the samples after heating, those exposed to 100 and 250 °C softened a lot and the resin turned easily into powder with the application of pressure by the machine. In addition, the FRPspec10,13 acquired a dark black colour. However, it was observed that the samples regained their hardness after cooling and the resin was no longer frail. A worth noting conclusion is that the tensile strength of dry fibers of the specimens after exposure at the temperatures of 50, 100 and 250 °C for 30 min did not appear decrease.

The fact that the samples were left to cool significantly contributed to this result. The ultimate strain and the elastic modulus of dry fibers of these specimens did not appear any important change, too.

Figure 8: Stress-strain curves of monotonic, uniaxial tensile tests after exposure to the temperatures of 50 °C (FRPspec8,11), 100 °C (FRPspec9b,12) and 250 °C (FRPspec10,13) and then cooling.

The specimens FRPspec16-20 were under both constant tensile load and thermal loading of maximum three heating-cooling cycles. The stress-strain curves of these tests are shown in figure 9. The only sample which managed to complete three heating-cooling cycles without failure was FRPspec16. The maximum temperature of each cycle at this test was 50 °C. After the thermal cyclic loading, FRPspec16 was tested under monotonic tension. The specimen's tensile strength of dry fibers was 3,269.66 MPa, its ultimate strain was 19.32 % and its elastic modulus of dry fibers was 169.27 GPa. According to this, the tensile strength and the elastic modulus of dry fibers are decreased after the heating-cooling cycles.

At higher temperatures, heating combined with the continuous loading had an important impact on the CFRPs' strength as the four samples failed during the first cycle. FRPspec17 failed at the heating process at 64 °C, FRPspec18 failed at the cooling process at 31 °C, FRPspec19 failed at the heating process at 61 °C and FRPspec20 failed at the heating process at 151 °C. The first two of these samples were supposed to be exposed to maximum temperature of 100 °C and the last two to maximum temperature of 250 °C.

It is necessary to mention that the heating rate was 10 °C/min. Because of this slow rate, the specimens remained at high temperature for a long time. If the heating rate was faster, may the FRPs resisted for more thermal loading cycles. The deterioration of the CFRP, due to the long time remaining at high temperature, was also obvious from the mode of failure of the FRPspec20 and its fibers' dark colour. Some of the specimens which were exposed to elevated temperatures are shown after their failure in figure 10.

From the specimens which were supposed to be exposed to maximum temperature of 100 °C and 250 °C, the FRPspec18 and FRPspec20 remained at high temperatures for a longer time than the FRPspec17 and the FRPspec19, which failed earlier. It is also evident from the figure 9 that staying at high temperatures under constant load for longer time causes greater deflections and significant reduction in the modulus of elasticity. The ultimate strain and the elastic

modulus of dry fibers of the FRPspec18 were 24.14 % and 87.23 GPa, respectively, and of the FRPspec20 were 23.63 % and 100.36 GPa, respectively.

Figure 9: Stress-strain curves of low-cycle thermal loading under constant tensile load. The maximum temperatures of heating-cooling cycles were 50 °C (FRPspec16), 100 °C (FRPspec17,18) and 250 °C (FRPspec19,20).

Figure 10: Specimens, exposed to elevated temperatures, after their failure.  
FRPspec11,12,13 were exposed to 50,100 and 250 °C, respectively (TL, MUT).  
FRPspec16, FRPspec17,18 and FRPspec19,20 were exposed to 50,100 and 250 °C, respectively (MUT and LCTL).

#### 4 CONCLUSION

- At room temperature CFRP laminates appear high tensile strength and elastic modulus.
- Low-cycle fatigue at room temperature reduces in a small percentage the CFRP laminates' tensile strength. This reduction is obvious when the maximum load of the cycle is high enough.
- Low-cycle fatigue at room temperature does not affect the stiffness of the CFRPs, as their elastic modulus remain at the same level.

- When CFRP laminates are exposed to elevated temperatures (100 °C, 250 °C) the resin softens and turns easily into powder if pressure is applied. In addition, the FRPs acquire a dark black colour at 250 °C.
- Because of the resin's deterioration under elevated temperatures, the CFRP specimens slip from the machine's grips during the tensile testing. Therefore, better gripping is needed.
- CFRPs cooled after exposure to elevated temperatures, regain their hardness and the resin is no longer frail. Their tensile strength does not show decrease.
- The cyclic thermal loading under constant tensile load causes degradation of CFRP laminates, as their tensile strength is reduced after the heating-cooling cycles.
- The cyclic thermal loading under constant tensile load reduces the elastic modulus of CFRP laminates. The higher temperatures the CFRPs are exposed to, the greater reduction of the elastic modulus is caused.
- The longer time the CFRP laminates remain at high temperatures under constant tensile load, the greater deflections and reduction in their elastic modulus are caused.

## ACKNOWLEDGEMENTS

Part of the research “MECHANICAL PROPERTIES CHARACTERISATION OF FRPS UNDER ELEVATED TEMPERATURES” has been co-funded by Greece and European Union through the Operational Program “EDBM-103: SUPPORT FOR RESEARCHERS EMPHASIZING YOUNG RESEARCHERS – 2<sup>nd</sup> CYCLE” (project code: 5047899) which are gratefully acknowledged.

**Keywords:** Steel Structures, Adjustable Pallet Racks, Seismic Standards, Eurocode

**Abstract.** *The problem of the high fragility of upright frames of pallet racking systems against lateral forces raises an important question for researchers. This lack of seismic performance can be attributed to a small degree of internal overdetermination of the system, as is also acknowledged by the European Standard for adjustable pallet racking structures (EN16681), which only takes into account the low-dissipative behaviour for these structures. This paper presents an innovative base-plate connection that can provide the upright frames of pallet racking systems with a certain degree of global ductility, thus improving the seismic attitude of these structures when seismically stimulated along the cross-aisle direction. A design procedure for the specimens to be tested is proposed, which aims at guiding the system design toward localizing yielding strains in the plates of the base connections, as the principles of the capacity design posit. The proposed base-plate connection is tested under monotonic and cyclic loads to better understand its properties and, by inference, its dynamic characterization, which could be utilized in a lighter numerical model in order to study overall performance improvement. Additionally, a numerical model of the specimen, as tested in the Laboratory of Steel Structures at the National Technical University of Athens (Greece), which has been calibrated and validated in accordance with experimental tests results, is presented.*

## 1 INTRODUCTION

The structural frames of racking structures are often composed of open cold-formed thin-walled steel members, that typically do not guarantee plastic capacities of their cross section [1, 2]. This poses a new issue: it is well-known that the capacity of structure systems to resist seismic actions in the nonlinear range generally permits their design for forces smaller than those corresponding to a linear elastic response. Another issue is related to the behaviour of structures in the post-elastic range; it becomes vital to control the force distribution [3] in order to control the structure collapse, as well the lateral displacements [4, 5]. Such approach is what allows designing building with design spectra [see 6], which generally correspond to an onset of elastic spectra by introducing a conventional parameter that accounts for the capacity of the structure to dissipate energy. Nevertheless, storage racks can still provide a degree of energy dissipation if other non-conventional mechanisms are considered [7, 8, 9]. For example, if designed so, beam-to-column and base-plate connections can exhibit an inelastic behavior which could be used to keep using the same approach [10, 11]. Nonetheless, the European Framework for steel structures does not allow yet to concentrate any damage on beam-to-column connections [12].

Cross-aisle frames often have a truss-like structure system: two uprights are laced up by different diagonal patterns, the most common of which are *X*-shaped diagonal and *D*-shaped diagonal. The cross-aisle structural scheme tends to have fewer internal degrees of freedom, thus making fragile collapse modes most likely. Hence, as also shown by many works [13], the lateral resistance of the overall frame is greatly affected by the flexural behaviour of the base-plate connections, which may be as well the only place where plastic deformation can safely take place [14]. The high lateral stiffness of the upright frames is also cause of concern for the happenstance of excessive accelerations at decks level. It is safe to say that the sliding of pallets on the supporting beams can be the most serious threat to the shedding of goods, which can either endanger the health of workers/customers or even damage some structural parts thus leading to cascading effects. In the cross-aisle direction, the fundamental period is generally short, comprised between 0.7s and 1.0s [15].

The seismic responses of the two principal directions of pallet racking structures are rather different. In the down-aisle direction, the great flexibility provided by connections and the absence of spine bracings reflect in significantly high value of the fundamental period of vibrations

Figure 1: (a) and (b) Warehouse stores with pallet racks (courtesy of NEDCON B.V.).

( $T$ ), sometimes up to 3.50s, which are the typical values observed for high-rise and tall steel buildings. The adherence of this structural scheme with ordinary structures has made a great body of research focus on this subject and its performance is well understood although it needs to manage a great variety of numerical special features [16].

Under lateral dynamic loads, owing to the presence of open thin-walled cross-sections, rack bearing elements are often prone to local and/or distortional buckling phenomena, which largely precede the attainment of the cross section yielding capacity. Therefore, to enforce classical design procedure, it is important to rely exclusively on the post-yielding capacity of connections. Cross-aisle frames can hardly locate plastic deformations within their inner connections, though it might be possible to design such a connection with that in mind. On the other hand, the connections between upright and building slab are characterised by a very limited degree of flexural stiffness and bending resistance, mainly limited by the column cross-section ultimate resistance capacity. In most of the cases, when the cross-aisle direction is considered, the seismic action can pose a risk for the overturning, which becomes the most dangerous limit state. Nevertheless, as it happened for the beam-to-column connections, the nonlinear cyclic behaviour can provide a non-negligible ductility to the structure. For this reason, as suggested by [17], attention must be paid on the design of base-connections to be allowed to use a behaviour factor  $q$  greater than 1 (but however lower than 2) in the seismic structural analysis;

Upright frames can be designed as *low-dissipative structural behaviour* (DCL), as recognised by EN 16681. This circumstance is addressed by EC8, and a *behaviour factor* is as well allowed, used to allow designers to perform elastic analyses and, at the same time, account for nonlinear phenomena. EC8 clearly identifies the use of  $q \leq 1.50$  for this class. It is stated that such value accounts for overall structural *overstrengths*. With reason, for example, for DCL class, it is advised to avoid cross sectional class 4, for it does not guarantee enough overstrength. In contrast with this last clause, EN 16681 affirms that the behaviour factor accounts for the *energy dissipation capacity* of the structure.

This work presents the results of a experimental tests and numerical simulations to investigate the cyclic response of a base-plate connection designed for adjustable pallet racking systems. The experimental tests, which were carried out in the Laboratory of Steel Structures, NTUA (Athens, Greece), are described, and results for a monotonic and a cyclic load path are reported. Hence, the specimen was reproduced in a mesh-based numerical framework, giving further insight about the mechanical behaviour of the specimen under study.

## 2 EXPERIMENTAL CAMPAIGN

### 2.1 Specimen

A base-plate connection for adjustable pallet racking systems was conceived to provide structures with energy-dissipation capacity. The behavior of this type of connection is reminiscent of a T-stub mechanism mainly subjected to axial load, which is generally used to model the top and bottom tee of beam-to-column connections; in such situations, the working principles are well-understood and the performance under cyclic loads proved to be quite remarkable (Piluso and Rizzano 2008) [18]).

All specimens have been assembled by welding steel plates composing the base plate, 6mm thick, and the bracket, 5mm thick, made of S235 ( $f_y = 235 \text{ MPa}$  and  $f_u = 415 \text{ MPa}$ ) steel fastened through the flanges by means of two M20 bolts made of 8.8 class high strength steel [6]; the upright, supplied by NEDCON B.V. (The Netherlands), having an overall depth of 120 mm and an overall width of 94 mm, was made of steel S350D and is connected to the bracket

by means of 8 M8 bolts 8.8 class. The photographic image and the schematic view representing the test specimen are given in Fig. 2. In order to guarantee an optimal stress distribution in the profile, the upright was cut 425 mm long ( $\approx$  four times its depth). Its upper cross section is welded to an end-plate that is hence bolted to the actuator head, where the load cell is located.

The base-plate connection was tested under monotonic and cyclic loads in the Laboratory of Steel Structures, NTUA (Athens, Greece). In Fig. 2(a), the experimental setup is shown, where the testing machinery and the specimen are indicated. The static actuator has a stroke of  $\pm 150$  mm and can reach up to  $300 \text{ kN}$ ; the accuracy of measuring equipment belongs to the 1 class of accuracy, thus giving an expected error on the measurement of  $\pm 1.5 \text{ kN}$ . Aiming at assessing the axial performance solely, the degree of freedom activated by the actuator is along the axis of the column stub (vertical).

## 2.2 Results

The monotonic test was performed by applying a displacement time history from 0 – 28 mm, with a constant velocity equal to  $v = 0.15 \text{ mm/s}$ . The cyclic protocol was defined in accordance with the AISC Seismic Provisions (AISC 2002), which provides a test sequence given as a function of the peak deformation  $\delta_y$ , with a decreasing number of cycles as the load step increases (Fig. 3(a)). The specimens were instrumented with two LVDTs located on both sides of the base plate to measure the uplift displacement.

The results of the tests are reported in Fig. 3. The two tests show an overall good agreement in terms of overall behaviour, providing good performance accounting for the cyclic consistency of the loops. The post-elastic performance of the tested specimen arises from the exploitation of

Figure 2: (a) Photographic image of the specimen as in the experimental setup. (b) 3D view of the base-plate assembly.

the dissipative failure mechanism (Type 1 mechanism [12]), which can be promoted by design guaranteeing strong-bolt weak-flange resistance relationship. It is characterized by the formation of a plastic hinge in the T-stub flanges, plus a circular pattern around the bolt's axis (ref. Fig. 4).

As it can be noticed, the shape of the cycles can be related to similar experimental results, in which the performance of T-stub connections was studied, accounting for energy dissipation capacity and stiffness degradation for the pinching of the hysteresis loops [18].

### 3 NUMERICAL MODELLING

As the finite element (FE) method is widely employed as an approach to develop numerical prediction models, many researchers have been using it to support their investigation [19, 20, 21]. In this study, the COMSOL software has been used. The Johnson-Cook hardening law was used to model the strain rate dependency of the plastic hardening; the material properties are presented in Section 2.1 of this study. The 3D FE model geometry reproduced the half geometry of the experiments, using symmetric conditions in order to minimize the computation effort. As well as the simulation used similar boundary conditions and loading as in the experimental

Figure 4: Lateral view of the specimen at the end of the monotonic test

program. A sensitivity analysis was conducted to identify the best meshing and, in total, 79759 elements were used (4-nodes solid elements). Contact conditions between two surfaces are governed by kinematic constraints in the normal and tangential directions. The normal stress at contact is either zero when there is a gap between the two surfaces, or compressive when the surfaces are in contact. The contacts are defined in the augmented Lagrangian method with the penalty factor controls. In addition, material and geometric nonlinearities have been taken into account. The nonlinear solver uses an affine invariant form of the damped Newton method. In this section, static analyses have been performed with increasing displacement, in the same fashion of the experimental test. The numerical results were compared with the experimental ones and the validation of the model was based on: (i) the force-displacement curves, and (ii) the deformation shape of the specimen (Figure 5).

Figure 5: Top (a) and 3D (b) view of the specimen at the end of the monotonic test; the right hand side picture highlights the plastic hinge in correspondence of the T-stub web and a circular pattern around the bolt.

#### 4 CONCLUSIONS AND FUTURE RESEARCH NEEDS

This work explores the performance of a T-stub-like connection that can be used to improve the seismic performance of pallet racking systems, with the aim of increasing the energy dissipation capacity of the upright frames. The sample was shown to have similar performance to a standard T-stub, which is widely used to model the overall 3D behaviour of beam-to-column connections of steel structures. This type of connection can be used for the construction of new lateral resisting structures, as well as for the retrofitting of existing ones, where lateral loads are

a problem.

## 5 ACKNOWLEDGEMENTS

The first author's Ph.D. scholarship is granted by the Italian Ministry for Education, University and Research (MIUR) as part of the program "Dottorati Innovativi a caratterizzazione industriale", ID DOT 1328490–3, funded by the European Union (Structural Funding ERDF-ESF for "Research and Innovation" 2014-2020). The authors are grateful for the support.

Parts of the test set-up were delivered gratis by J Dimitriou Ltd Kataskevastiki. This support is acknowledged.

Part of the material used for the testing campaign was provided by NEDCON B.V. (The Netherlands). The authors would like to express their very great appreciation to Ir. Jan Hermanek.

## 6 CONFLICTS OF INTEREST

The authors declare no conflict of interest. The funders had no role in the design of the study; in the collection, analyses, or interpretation of data; in the writing of the manuscript, or in the decision to publish the results.

## **STUDY OF THE INFLUENCE OF UNDERLYING SOFT-SOIL LAYERS ON THE DYNAMIC AND EARTHQUAKE RESPONSE OF BELL TOWERS**

**G.C. Manos<sup>1</sup>**

<sup>1</sup> Emeritus Professor and Ex-Director of the Lab. of Strength of Materials and Structures, Aristotle  
University  
e-mail: gmanos@civil.auth.gr

---

### **Abstract**

The dynamic and earthquake response of a bell towers founded on soft soil layers is examined here. The dynamic and earthquake response of such a bell towers is numerically simulated together with a number of layers of the underlying soil. The earthquake response is examined for a variety of load combination conditions employing design spectra as well as the ground motion recorded at a small distance from this bell tower during a prototype earthquake motion. Towards this end, the variation of the recorded ground motion due to the flexibility of these underlying soil layers is also examined. The earthquake response is examined comparatively in terms of global response parameters, such as base shear, overturning moment, and top displacements as well as peak stress values at particular parts of the bell tower that stress concentration occurs. These response values are studied in a comparative way in order to validate these numerical simulations with the observed performance.

## 1 INTRODUCTION

Bell towers are structures that are of particular interest regarding their dynamic and earthquake response, which has been the subject of research in the past. A large number of bell towers with dimensions much larger than the ones examined here are located in numerous cities in Italy and elsewhere. The largest percentage of these bell towers is built by stone or brick masonry. In many cases earthquake activity constitutes the major cause of serious damage for bell towers that many times leads to partial or total collapse ([1] to [16]). Consequently, there is a major international concern for the stability of numerous bell towers. This resulted to significant international research effort that includes in-situ monitoring of the response of bell towers on a temporary basis, like the one attempted here, or more sophisticated and on a permanent basis. Foundation problems for bell towers are evident in many cases the most celebrated being Pisa's grand bell tower in Italy, that is quoted as a major medieval engineering error. Therefore, the soil flexibility is also an area of research interest for these structures especially when their dynamic and earthquake response is under investigation ([19] to [28]).

This investigation was initiated by the observed performance of two relatively new bell towers. Both these bell towers, built by reinforced concrete (RC) and founded on an RC foundation block did not sustain any structural damage. They were both founded on relatively flexible soil although they were not any visible signs of soil deformation at the aftermath of the strong seismic ground motion. For both towers in-situ measurements were performed aiming to investigate their main dynamic characteristics. From these measurements it became apparent that the flexibility of the underlying soil layers could have exerted an influence on the seismic performance of these bell towers that should not be ignored. This was initially attempted by altering the flexibility of the supports of the RC foundation block utilizing linearly flexible links between the foundation block and the underlying soil. This was successful, up to a point, as shown by comparing the numerically predicted in this way fundamental translational periods of these bell towers to the corresponding values found from the in-situ measuring campaign. However, in this way the adopted approach did not address the influence of the existing structures to the assumed earthquake ground motion, which was recorded at some distance from these structures which were of considerable height (23m) with a foundation block of considerable dimensions (4.5m x 4.5m in plan and more than 1m thick). Moreover, it was interesting to observe that in the case of one of these bell towers (Havriata) the nearby church was damaged as well as the South slope of the hill that both the bell tower and the church were located showed signs of distress (see figures 1). In what follows, an investigation is performed aimed to study the bell tower dynamic and earthquake response by numerically simulating the structure of the bell tower and its foundation together with a considerable volume of the underlying soil. This investigation, for simplicity purposes, is performed in the 2-D domain and assumes linear behaviour of both the soil and the superstructures. At a later stage, this study can be extended at a later stage to a more complex numerical simulation in the 3-D domain which could also include a more realistic behaviour of the soil volume than that which is assumed at present. In what follows initially the acceleration at the bedrock is approximated. Next, the response of the soil volume is studied in three different configurations; the first assumes only the given soil volume the second this soil volume with a simple superstructure numerically simulating the church and the third configuration includes the given soil volume together with simple numerical simulations of both the church and the bell tower. The obtained numerical predictions are presented and discussed.

## 2 ESTIMATING THE ROCK ACCELERATION.

In what follows a study is performed using the ground acceleration (figure 2) recorded during the 3rd of February 2014 earthquake sequence at Havriata village in Kefalonia island [3]. The two horizontal and the vertical components of this record are used as input together with a soil volume that is assumed to be 30m deep. For layers deeper than 30m it is assumed that these layers have mechanical properties close to those of a rocky formation. The soil volume above this rocky substrate is divided in three layers having a 10m depth each. Three dif-

ferent soil profiles are studied whereby the properties of the upper layer are only varied whereas the properties of the other two underlying layers remain constant. Two types of analyses are performed using a 2-D software for this purpose. The first type of analysis assumes linear behaviour of the soil volume that depends on the given elastic mechanical properties of the soil layers. The second type of analysis assumes a certain soil non-linear behaviour as it is simulated by given options in this software [17].

## 2.1 Linear behaviour of the underlying soil layers.

Initially, linear behaviour of the underlying soil layers are assumed with elastic properties listed in table 1. The following values of the soil properties are listed in this table. Young's Modulus  $E$  (Mpa), Shear Modulus  $G$  (Mpa), Mass density  $\rho$  (KNsec<sup>2</sup>/m<sup>4</sup>), and Shear wave velocity  $v$  (m/sec) given by equation 1.

$$v = (G / \rho)^{0.5} \quad (1)$$

Depth (m)	Soil Profiles	E (MPa)	G (MPa)	$\rho$ (KNsec <sup>2</sup> /m <sup>4</sup> )	$v$ (m/sec)
0 to -10	1 <sup>st</sup> Profile	465	194	1.835	325
0 to -10	2 <sup>nd</sup> Profile	300	125	1.835	261
0 to -10	3 <sup>rd</sup> Profile	100	41.67	1.835	150
-10 to -20	1 <sup>st</sup> , 2 <sup>nd</sup> and 3 <sup>rd</sup> Profiles	1000	417	1.835	477
-20 to -30	1 <sup>st</sup> , 2 <sup>nd</sup> and 3 <sup>rd</sup> Profiles	2000	833	1.835	674
Deeper than -30m	1 <sup>st</sup> , 2 <sup>nd</sup> and 3 <sup>rd</sup> Profiles	50000	20833	1.835	1066

Table 1. Elastic properties of the soil layers

Figure 2. The recorded at Havriata earthquake ground motion in terms of two horizontal and the vertical acceleration components.

In what follows, the software STRATA [17] assuming linear behaviour of all the underlying soil layers with values of these elastic properties listed in table 1. Based on these values and using as input information the acceleration components of the recorded ground motion at the surface of the Havriata town the corresponding components are obtained at bedrock, assumed to be at layers deeper than 30m from the soil surface. The results are obtained in two forms, either as acceleration time history or as the relevant acceleration elastic response spectral curve (for 5% damping ratio). Along these lines a parametric study is performed whereby the 3 three soil profiles listed in table 1 were analyzed. The obtained results in terms of either acceleration time history components at bedrock or acceleration elastic response spectral curves (for 5% damping ratio) are depicted in

figure 2 (soil profile 1) for the two horizontal and the vertical component of the Havriata 3<sup>rd</sup> of February 2014 record of the earthquake ground motion. For soil profiles 2 and 3 the corresponding results are depicted in figures 3 and 4, respectively. As it is listed in figures 2, 3 and 4 as well as from the values listed in Table 1 soil profile 1 corresponds to a relatively stiff soil, soil profile 2 to a moderately stiff soil whereas soil profile 3 corresponds to a relatively flexible soil.

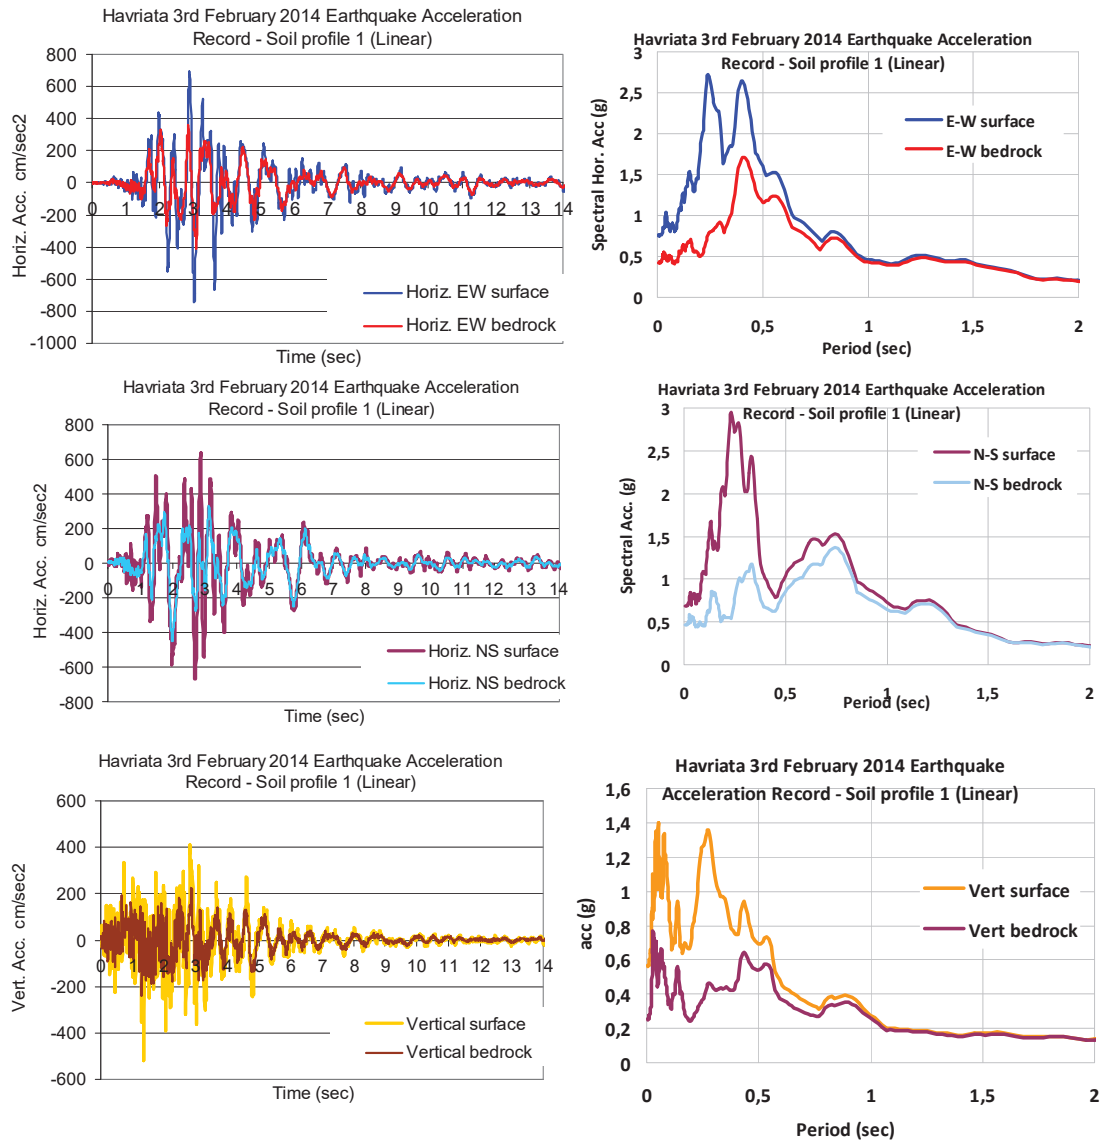

Figure 2. The obtained acceleration components at the bedrock for the Havriata earthquake ground motion in terms of two horizontal and the vertical acceleration components or the corresponding elastic response spectral curves (for 2% damping ratio). **Soil Profile 1 (Linear) Upper layer relatively stiff.**

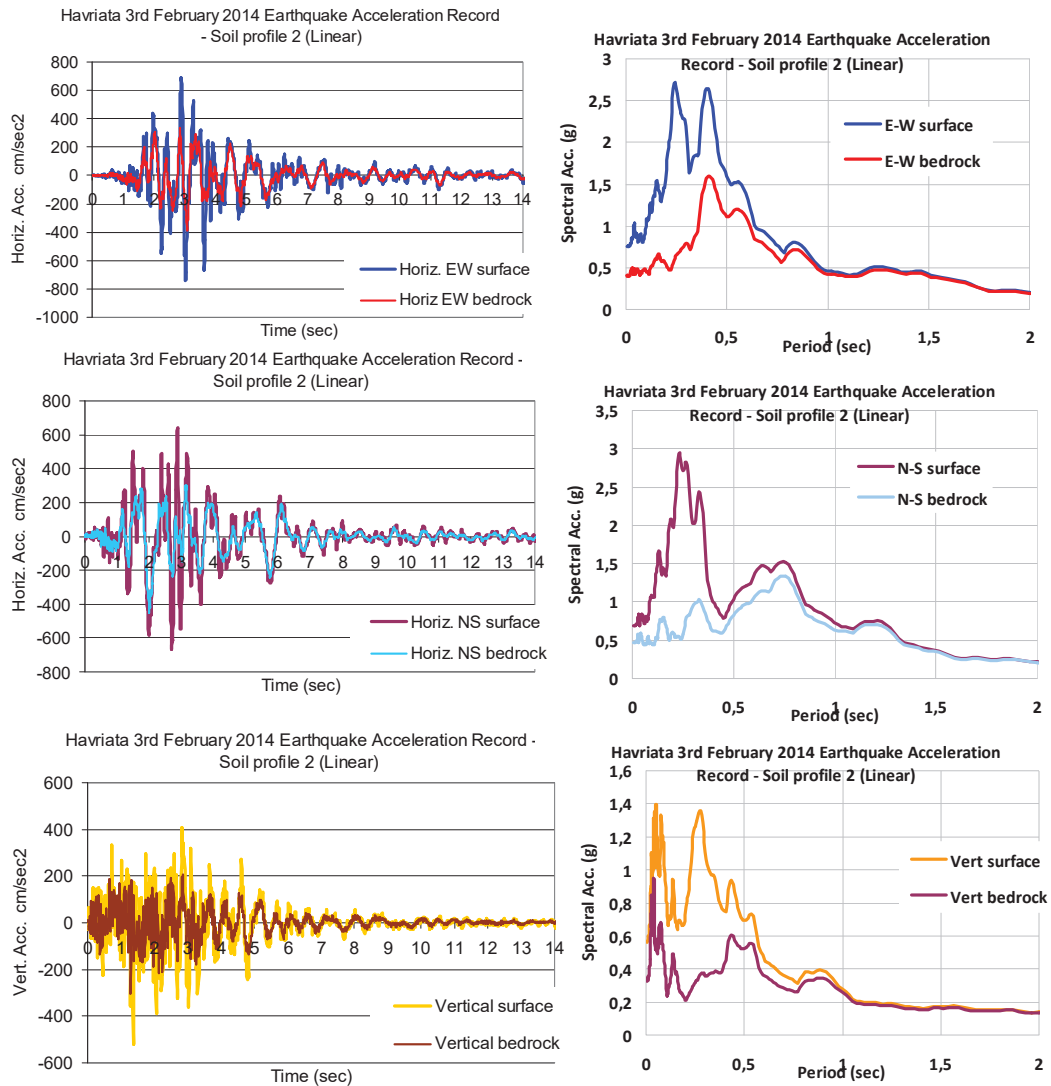

Figure 3. The obtained acceleration components at the bedrock for the Havriata earthquake ground motion in terms of two horizontal and the vertical acceleration components or the corresponding elastic response spectral curves (for 2% damping ratio). **Soil Profile 2 (Linear) Upper layer moderately flexible.**

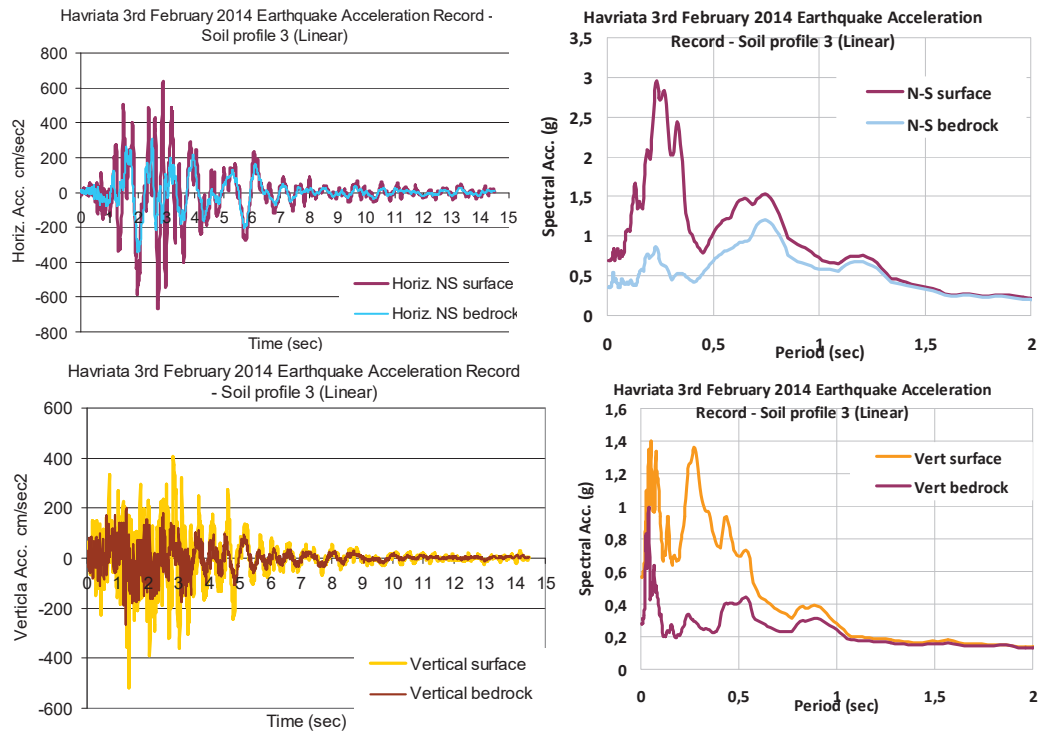

Figure 4. The obtained acceleration components at the bedrock for the Havriata earthquake ground motion in terms of two horizontal and the vertical acceleration components or the corresponding elastic response spectral curves (for 2% damping ratio). **Soil Profile 3 (Linear) Upper layer relatively flexible.**

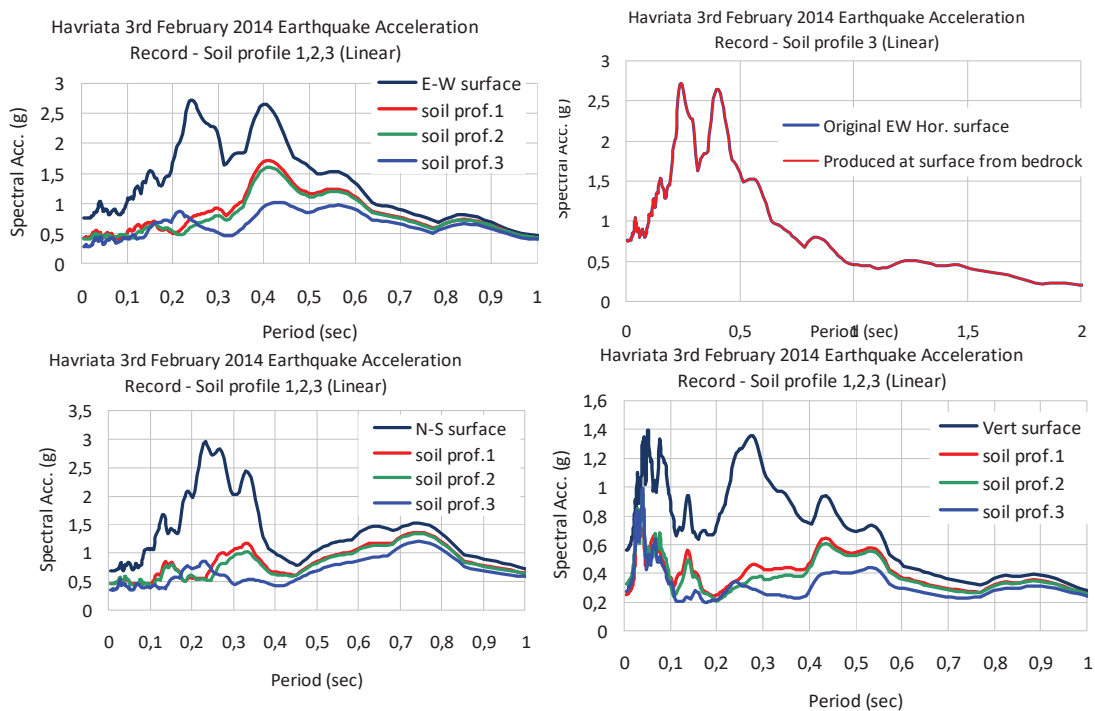

Figure 5. Comparison of the acceleration spectral curves obtained from the recorded components of the seismic ground motion at Havriata and the corresponding acceleration spectral curves from the acceleration components obtained from STRATA software at the bedrock for the three soil profiles.

Figure 5 summarizes the results of figures 2, 2 and 4 in terms of acceleration spectral curves derived from the acceleration components obtained at bedrock by utilizing STRATA software assuming soil properties for three soil profiles listed in table 1 and assuming linear behaviour. In the same figures the spectral curves at the surface of the soil volume derived from the three components of the recorded seismic ground motion at Havriata are also plotted. Moreover, at the top right of this figure the spectral curve of the East-West component of the recorded during the seismic event ground motion is compared with the corresponding spectral curve found by applying the STRATA software in the inverse way. That is, using as bedrock acceleration the one found for soil profile 3 is used as input to obtain through this software the acceleration at the surface of the soil-volume. Then, the spectral acceleration curve for 5% damping ratio is found and potted. As can be seen, these two spectral acceleration curves, the original one from the actual record and the one employing STRATA software, combining the direct and the inverse process, are identical. Moreover, from the results depicted in figures 2, 3, 4 and 5 it can be seen that that both the acceleration time histories and the corresponding acceleration spectral curves are deflated when they are compared with the corresponding values at the soil volume surface of the originally recorded ground acceleration. It can also be observed, that this deflation, is larger for soil profile 3 than for either soil profile 2 or soil profile 1. Inversely, the more flexible the soil profile the more intense the amplification of the ground acceleration at the surface either in terms of time history or acceleration spectral values.

## 2.2 Non-Linear behaviour of the underlying soil layers

The linear analyses with the STRAT software, previously described, were followed by additional analyses assuming non-linear properties for the underlying soil layers. Two additional soil profiles were used here, as a non-linear variation of the linear 3<sup>rd</sup> soil profile listed in table 1. First, the 4<sup>th</sup> soil profile is formed by assuming at the upper soil layer (0 to -10m depth) the soil properties representative of “Imperial Valley soil”, which is an option included in the software and represents relatively stiff soil. Next, the 5<sup>th</sup> soil profile is formed by assuming at the upper soil layer (0 to -10m depth) the soil properties representative of the “Idriss weak clay”, which is another option included in the software and represents relatively flexible soil. These two soil profiles are listed in table 2. Again, the properties of the layers deeper than -10m are the same for both the 4<sup>th</sup> and the 5<sup>th</sup> soil profile as listed in table 2. In reference [18] a study on the influence of the plasticity index (PI) on the cyclic stress-strain parameters of saturated soils needed for site-response evaluations and seismic microzonation is presented. Ready-to-use charts are included, showing the effect of PI on the location of the modulus reduction curve  $G/G_{max}$  versus cyclic shear strain  $\gamma_c$ , and on the material damping ratio  $\lambda$  versus  $\gamma_c$  curve. The charts are based on experimental data from 16 publications encompassing normally and overconsolidated clays ( $OCR=1-15$ ), as well as sands. It is shown that PI is the main factor controlling  $G/G_{max}$  and  $\lambda$  for a wide variety of soils; if for a given  $\gamma_c$  PI increases,  $G/G_{max}$  rises and  $\lambda$  is reduced. Similar evidence is presented showing the influence of PI on the rate of modulus degradation with the number of cycles in normally consolidated clays. It is concluded that soils with higher plasticity tend to have a more linear cyclic stress-strain response at small strains and to degrade less at larger  $\gamma_c$  than soils with a lower PI. Possible reasons for this behavior are discussed. A parametric study is presented showing the influence of the plasticity index on the seismic response of clay sites excited by the accelerations recorded on rock in Mexico City during the 1985 earthquake”. For the 4<sup>th</sup> and 5<sup>th</sup> soil profiles the non-linear variation of the assumed shear modulus and damping depending on the strain amplitude is depicted in figures 5 and 6.

Layer No. Depth (m)	4 <sup>th</sup> Non-linear Profile Relatively stiff soil	5 <sup>th</sup> Non-linear Profile Relatively flexible soil
Layer 1 (0 to 10m)	Imperial Valley (Soils 0-300ft)	Idriss, Weak-Clay
Layer 2 (-10m to -20m)	Vucetic & Dobry PI=100	Vucetic & Dobry PI=100
Layer 3 (-20m to -30m)	Vucetic & Dobry PI=200	Vucetic & Dobry PI=200

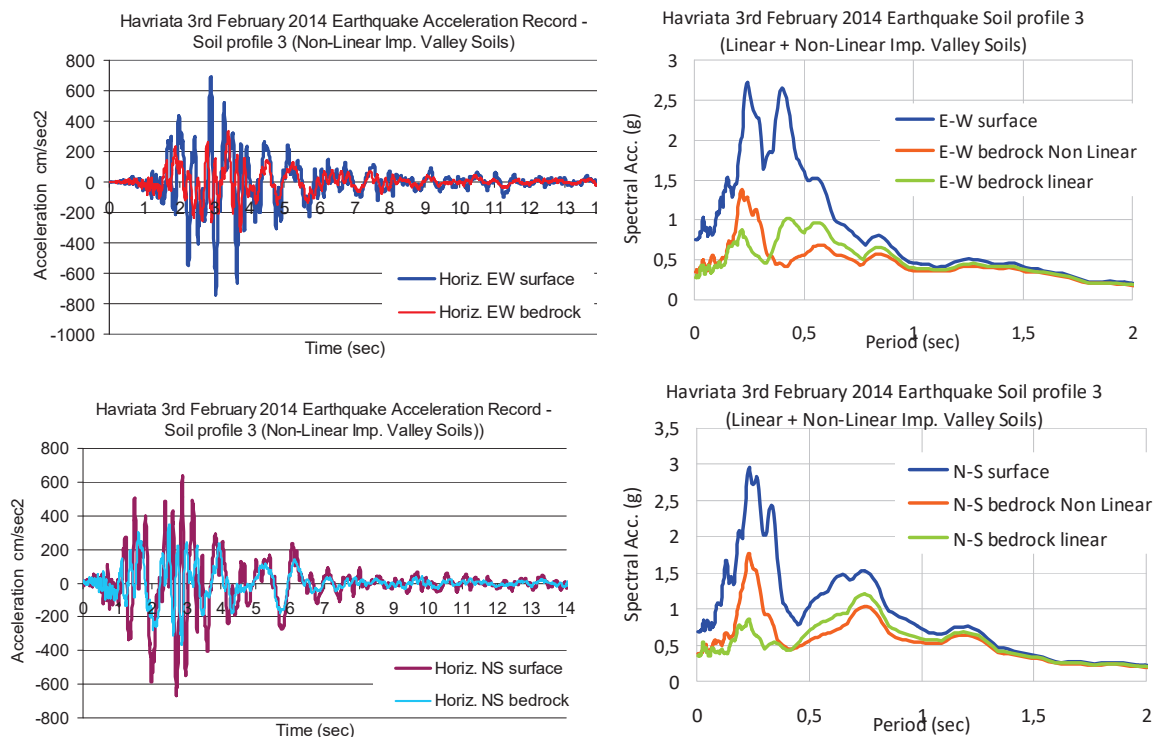

Table 2. Non-linear soil profiles 4<sup>th</sup> and 5<sup>th</sup>.

Figure 6. The assumed non-linear variation of the shear modulus with strain amplitude (left). The assumed non-linear variation of the damping ratio with strain amplitude (right).

Figure 7. The obtained acceleration components at the bedrock for the Havriata earthquake ground motion in terms of two horizontal and the vertical acceleration components or the corresponding elastic response spectral curves (for 2% damping ratio). **Soil Profile 4<sup>th</sup> (Non-Linear) Upper layer relatively stiff.**

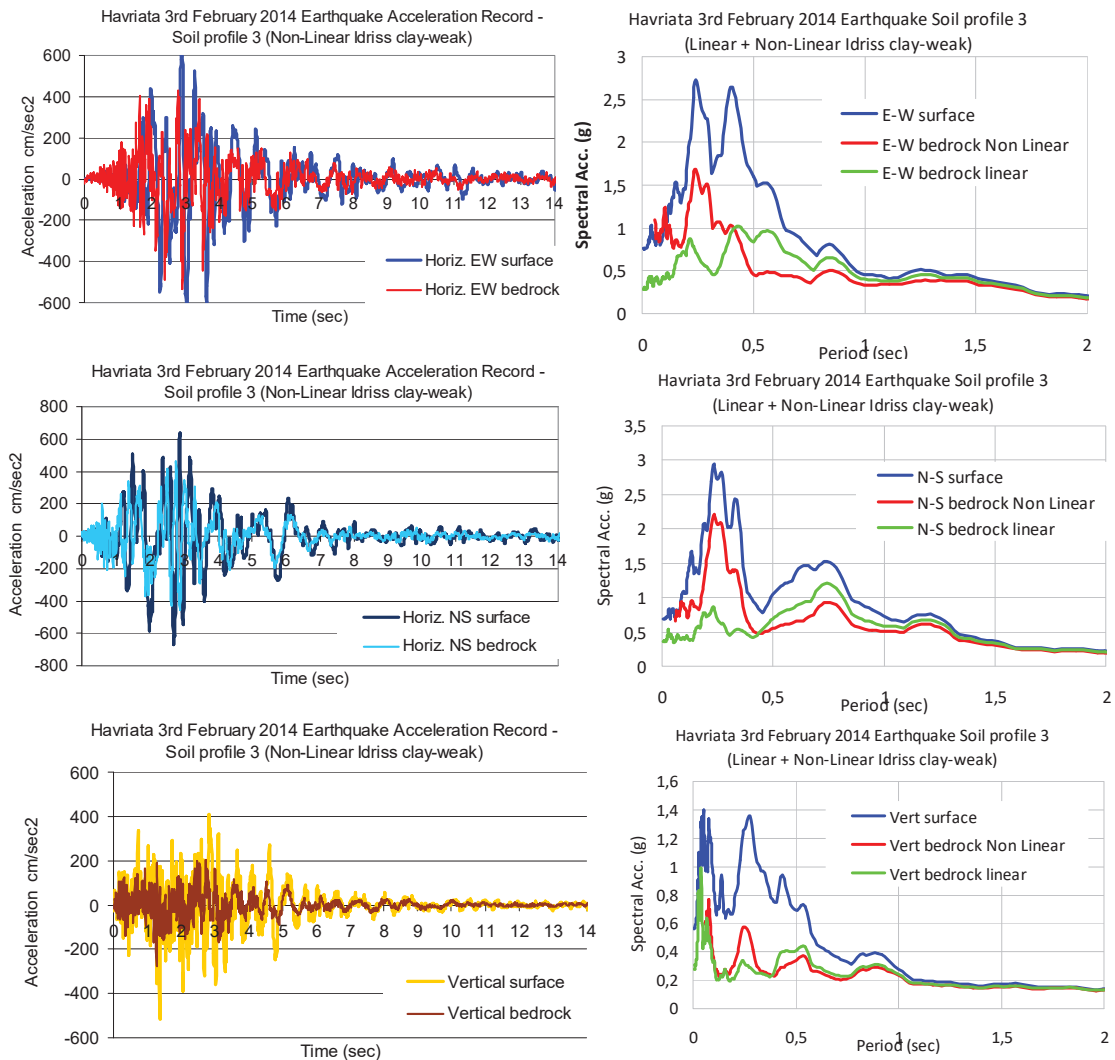

Figure 8. The obtained acceleration components at the bedrock for the Havriata earthquake ground motion in terms of two horizontal and the vertical acceleration components or the corresponding elastic response spectral curves (for 2% damping ratio). **Soil Profile 5<sup>th</sup> (Non-Linear) Upper layer relatively flexible.**

The obtained acceleration at bed rock, in terms of either acceleration time histories or response spectral curves are depicted in figures 7 and 8 for soil profiles 4<sup>th</sup> and 5<sup>th</sup>, respectively. In the spectral curves plots the corresponding spectral curves for soil profile 3 assuming linear behaviour are also plotted. In the same plots the corresponding seismic ground acceleration recorded during the February 2014 earthquake sequence, either in terms of time history or in terms of the corresponding acceleration spectral curves for 5% damping ratio are also shown. Moreover, in figure 9 the spectral curve of the East-West component of the recorded during the seismic event ground motion is compared with the corresponding spectral curve found by applying the STRATA software in the inverse way. That is, using as bedrock acceleration the one found for soil profile 4 (left of figure 9) or soil profile 5 (right of figure 9) is used as input to obtain through this software the acceleration at the surface of the soil-volume. Then, the spectral acceleration curve for 5% damping ratio is found and plotted in this figure. As can be seen, these two spectral acceleration curves, the original one from the actual record and the one employing STRATA software, combining the direct and the inverse process, are differing with the best agreement achieved for soil profile 5. As was observed from the results obtained assuming linear behaviour from the results depicted in figures 7 and 8 it can be seen that that assuming non-linear behaviour both the acceleration time histories and the corresponding acceleration spectral curves are deflated when they are compared with the corresponding values at the soil volume surface from the originally recorded ground motion. It can also be observed, that for small eigen-period values (0.1 to 0.4 sec) this deflation, is smaller when assuming non-linear (soil profiles 4 and 5) than when assuming linear behaviour (soil profile 3). Inversely, the non-linear soil behaviour the less intense the amplification of the ground acceleration at the surface either in terms of acceleration spectral values for small eigen-period values (0.1 to 0.4 sec). The opposite is true for relatively large period values (0.4 to 1.0 sec). Following the inverse approach for soil profile 4 and 5 and assuming non-linear behaviour it can be seen that for soil profile 5 (figure 9, right) the predicted spectral values in the period range from 0.3sec to 0.4 sec there are amplified when compared with the corresponding values of the original record. The opposite is true for soil profile 4 (figure 9, left).

ground motion at Havriata and the corresponding acceleration spectral curves from the acceleration components obtained from STRATA software at the bedrock for the three soil profiles.

### 3 TWO DIMENSIONAL (2-D) NUMERICAL SIMULATION OF THE SOIL LAYERS, THE CHURCH AND THE BELL TOWER.

In what follows an 2-D numerical simulation is presented of the soil layers studied in section 2 assuming linear behaviour. Again, three soil layers are numerically simulated with a depth of 10m each having mechanical properties the ones listed in Table 1 for soil profile 3.

Fig. 10. 2-D Numerical simulation of the soil layers under the bell tower and the church (up to 30m depth and 120m long)

At the depth of 30mm from the surface the boundary is considered with fixed base conditions. At this boundary, the North-South acceleration time history was applied, obtained for the bedrock through STRATA software for soil profile 3, as described in section 3. The length of the soil formation is equal to 120m, with the vertical boundaries being confined with horizontal links having a finite stiffness of 1000KN/mm. An attempt is made to numerical simulate the slope of the hill present at the South side of the damaged church at Havriata (see fig 1). An attempt was also made to have a 2-D numerical representation of the bell tower and the church respecting their basic dimensions and the relative distance between them. Moreover, the eigen-period values for the fundamental North-South translational eigen-modes. The dynamic characteristics of these simple representations of either the bell tower or the church are in good agreement with corresponding values found from more detailed 3-D numerical representations of these structures being also partially validated with in-situ measurements.

Fig. 11. 2-D Numerical simulation of the soil layers under the bell tower and the church (up to 30m depth) together with simple numerical models of the church, the bell tower and its foundation.

### 3.1. Study of eigen-modes and eigen-periods

In figures 10 and 11 the studied 2-D numerical simulations for the three configurations, namely “only Soil”, “only Church” and “Church+Bell Tower” are shown. In all these configurations the numerical simulation of the soil volume remains the same. Moreover, in all the analyses the employed excitation also remains the same, that is bedrock horizontal component that was derived by applying STRATA software for soil profile 3 (linear behaviour – Table 1) using as input the North-South horizontal component of the seismic ground motion recorded in the village of Havriata during the 3rd of February 2014 earthquake sequence (see figure 4).

In what follows first the numerically predicted eigen-modes and eigen-periods are shown for the previously described three configurations. These are presented in the form of a table (Tables 3, 4 and 5) listing the first seven (7) eigen-modes in terms of eigen-period values with the corresponding modal mass participation ratio values. These eigen-modes are with respect

to one horizontal (x-x) and one vertical (z-z) directions. Figures 13, 14 and 15 depict the corresponding mode-shapes.

Table 8. Eigen-periods and modal mass participation ratio – Church + Bell Tower (Soil-1)

Fig. 17. Eigen-modes, eigen-periods and modal mass participation ratio–Church+Bell Tower (Soil-1)

For soil profile 3 it can be seen from tables 3,5 and 7 and from figures 12, 14 and 16 the main horizontal translational x-x eigen-modes are at 0.3sec period range whereas the corresponding main vertical z-z translational eigen-modes are at the period range of 0.2sec for all three studied configurations. Both these modes mobilize approximately 30% of the total mass. For soil profile 1 it can be seen from tables 4,6 and 8 and from figures 13, 15 and 17 the main horizontal translational x-x eigen-modes are at 0.22sec period range whereas the corresponding main vertical z-z translational eigen-modes are at the period range of 0.14sec for all three studied configurations. Both these modes mobilize approximately 50% of the total mass.

Table 9. Summary of the main eigen-periods and modal mass participation ratio values

Figure 18. Summary of the main eigen-modes, eigen-periods and modal mass participation ratio – for all three configurations. (**Soil-3**)

Figure 19. Summary of the main eigen-modes, eigen-periods and modal mass participation ratio – for all three configurations. (**Soil-1**)

These eigen-mode and eigen-period results are also summarized in table 9 and figure 18 (Soil profile 3) and figure 19 (Soil profile 1). As can be seen from table 9 and from figures 18 and 19 the presence of the bell tower together with the church introduces a larger number of eigen-modes that participate in a significant way either in the x-x or in the z-z translation. The values of the eigen-periods of these eigen-modes for the configuration of the “bell tower + church” are quite close to the corresponding period range of either the configuration of “only soil” or the “soil and church”. It is also interesting to note that for the configuration of the “bell tower + church” the first translational x-x eigen mode involves mainly the bell tower whereas the second and the third translational x-x eigen-modes involve both the bell tower and the church. As was expected, the eigen-periods of the main eigen-modes or the relatively stiff soil profile (soil-1) have smaller values (0.22sec) than the corresponding values (0.3sec) for the relatively flexible soil profile (soil-3). It is interesting to note that for both soil profiles the most significant horizontal translational eigen-modes involve the bell tower together with the church. Therefore, from the study of these eigen-modes it can be concluded that the flexibility of the soil results in vibratory modes coupling both the bell tower and the church. The detrimental effect of the foundation-soil flexibility has been demonstrated in many cases of Greek Orthodox stone masonry churches damaged from past earthquake activity ([19] to [30]).

#### 4 CONCLUSIONS

- The increased flexibility of the upper soil layers of the studied soil formation results in the coupling of the dynamic response of the bell tower and the church. This is evident from the study of the significant mode shapes.
- The increased flexibility of the upper soil layers of the studied soil formations and the coupling of the dynamic response of the bell tower and the church results in a vertical acceleration response at the locality between the bell tower and the church which of comparable amplitude to that of the vertical acceleration recorded at the soil surface directly from the seismic event.
- The above conclusions may partly explain the severity of structural damage that was observed at the church of the Panagia Agriliotissa at Havriata, Kefalonia-Greece, as depicted in figure 1.
- Attention should be given in erecting new bell towers of considerable height at location close to existing masonry churches. The amplification of the seismic response of the church, due to such dynamic coupling effects, could be critical especial for old masonry structures having relatively small resistance to considerable seismic forces, as was the case for the studied church at Havriata.

### Abstract

*Unreinforced masonry made of stone and low strength mortar has been used for centuries in forming the structural system of old type buildings. Wooden roofs were also used as part of such structural systems. The influence of the connections of such wooden roofs with the vertical masonry walls is the objective of this study. A number of old stone-masonry buildings used as leather factories in the island of Samos-Greece are employed in this investigation. The wooden roofs of these buildings collapsed either partly or totally during the recent earthquake of October 2020. Initially, the dynamic behaviour typical forms of such buildings with wooden roofs are studied. A variation of the connections of such a wooden roof with the vertical stone masonry walls is studied in a parametric way. Next, the earthquake response of the same structural formations are also studied using again the variation of these connections as the main parameter. Towards this end earthquake design spectra are used as well as the acceleration recordings of this earthquake ground motion by an instrument located in the Samos island. Numerical simulation results are presented and discussed. Through the comparison of the obtained numerical predictions with the observed behaviour the validity of the numerical approach is discussed.*

**Keywords:** Wooden roof, Stone masonry; weak mortar; Gravitational forces, Seismic actions,

## 1 INTRODUCTION

An earthquake occurred 16km North from the Greek island of Samos on the 30<sup>th</sup> of October 2020 (11:51GMT) with a magnitude of M6.7 (Fig. 1). This island is located at the East side of the Aegean Sea an area seismically active ([1], to [7]) The main event caused widespread structural damage mainly at numerous low-rise old unreinforced masonry buildings of this island. It all also caused heavy damage and collapse of multi-story reinforced concrete (R/C) buildings at the city of Izmir located at the coastline of mainland Turkey towards the North-East, approximately 60km from the epicenter of this earthquake. This study focuses on the effects of this seismic strong motion on the Greek island of Samos. The Institute of Engineering Seismology and Earthquake Engineering (ITSAK) operates a strong motion accelerometer at the city of Vathi, the capital of Samos. The ground accelerations at Vathi due to the main shock were recorded by this instrument (see preliminary report of ITSAK, [6] and ETAM [7]) having peak horizontal ground acceleration 227cm/sec<sup>2</sup> and peak vertical ground acceleration 134cm/sec<sup>2</sup>. The main event was followed by a considerable number of aftershocks, with the aftershock sequence being still active. (Fig. 2).

Figure 1. Map indicating the epicenter of the 30<sup>th</sup> of October 2020 seismic event

Figure 2. The epicenter of the 30<sup>th</sup> of October 2020 main event and the following aftershock sequence

The most spectacular structural damage could be observed at the two main cities in the island, its capital (Vathi) and Karlovaisi 25km to the West (Fig. 3). Due to the location of the epicen-

ter, having the same epicentral distance from both Vathi and Karlovasi, and due to the generating mechanism of this earthquake that followed an almost East-West fault line, as can be seen from the aftershock sequence, it can be reasonably assumed that the strong motion characteristics at Karlovasi would be quite similar to those of the recorded strong motion at Vathi. This assumption will be made use of in the section presenting selected numerical analyses predictions of the structural response of damaged buildings [8].

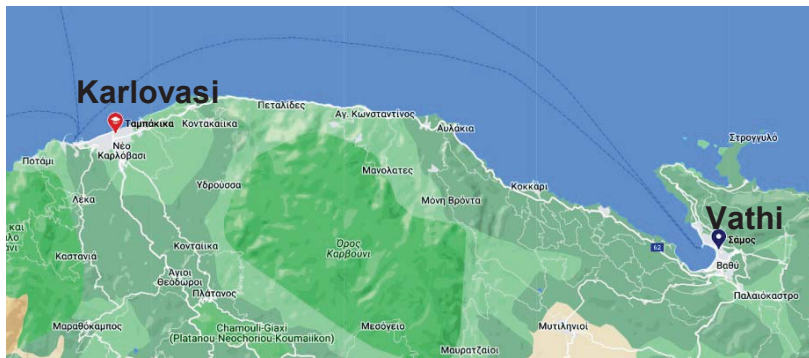

Figure 3. Map of the North coast-line of the island of Samos where the two main cities of Vathi and Karlovasi are located.

### 1.1 The recorded ground motion

In figure 3 the recordings of the earthquake ground motion, in terms of ground acceleration, velocity and displacement in the two horizontal directions are shown [6]. Due to the location of the epicenter, the same epicentral distance of both the city of Vathi and the city of Karlovasi from the epicenter (see figures 1, 2, 3) and due to the generating mechanism of this earthquake that followed the almost East-West fault line, as can be seen from the aftershock sequence it can be reasonably assumed that the strong motion characteristics at Karlovasi would be quite similar to those of the recorded strong motion at Vathi.

Figure 4. Horizontal ground acceleration recorded at 30<sup>th</sup> October 2020 at Vathi by an instrument managed by the Institute of Earthquake Engineering and Engineering Seismology (ITSAK, see reports [6] and [7]).

Figure 5 depicts the inelastic acceleration response spectral curves of the two horizontal components of the recorded ground motion at Vathi (Fig. 4) for 5% damping ratio and ductility factor  $m=1.5$ . In the same figure the design spectral curves as predicted by Euro-Code 8 are also shown. These design spectral curves were obtained for ground design acceleration equal to  $0.24g$  ( $g$ = the acceleration of gravity) and for two different soil categories either soil C (flexible soil) or soil D (very flexible soil). This peak design ground acceleration is in accor-

dance with the seismic zoning map of Greece [ ]. It is also assumed that the soil conditions near the coastline either at Vathi or at Karlovasi will belong to either one of these two soil conditions. Moreover, these design spectral curves are employing damping ratio equal to 5% and response modification factor  $q=1.5$  (the same as the ductility factor value for the inelastic spectral curves) and importance factor equal to 1 ( $\gamma=1$ ). Finally, the design spectral curves are obtained for either type 1 or type 2 earthquake design motion, as specified by Euro-Code 8 [ ]. Type 2 is suppose to represent an earthquake hazard from an event with a magnitude lesser than  $M=5.5$  on the Richter scale.

Figure 5. Comparison of inelastic response spectra (based on the horizontal ground acceleration recorded at 30<sup>th</sup> October 2020 at Vathi. [ ]) and Euro-code 8 design spectra.

From the comparison between these inelastic response spectra (based on the horizontal ground acceleration recorded at 30th October 2020 at Vathi and the corresponding Euro-code 8 design spectra (either Type 1 or 2 and either soil category C or D, [9] to [14]) the following observations can be made. **a)** Type 1 design spectra agree better with the inelastic response spectra (based on the recorded ground motion) than type 2 design spectra. **b)** The type 1 design spectra for soil category D have spectral acceleration amplitudes that are larger in almost all the plotted period range than the corresponding inelastic response spectra values (based on the recorded ground motion). **c)** The type 1 design spectra for soil category C have spectral acceleration amplitudes that are larger in almost all the plotted period range, apart from the period range between 0.45sec. and 0.61sec., than the corresponding inelastic response spectra values (based on the recorded ground motion).

## 2 ANALYSED STRUCTURES

In many Greek islands as well as at the old part of city-centers in many Greek cities a considerable number of old buildings still survives despite the destruction due to the military operations or the frequent earthquake activity. A considerable number of such buildings were demolished to give room to the extended urban development that took place after World War II and the tourism activity that followed, particularly in the islands. However, during the last four decades a conservation effort became quite strong endorsing a number of such building in a conservation register being under special legislative protection. In this category belong the buildings depicted in figures 6 and 7. These buildings were used as leather processing factories an activity that was prominent in Samos island from the end of the 9<sup>th</sup> century till World War II when started declining. A number of these buildings were left unoccupied and without any maintenance, which makes them vulnerable to strong earthquake excitations apart from the used construction system which unreinforced stone masonry walls covered by a wooden roof

Figure 6. Old industrial buildings under conservation status

Figure 7. Old industrial buildings (Tambakia) at the coastline of Karlovasi

The earthquake performance of this type of structures is dominated by certain response mechanisms that can be characterized as “global”. These mechanisms include a) the connection of the wooden roof to the masonry walls b) the interconnection of the masonry walls at the corners and c) the foundation deformability including the potential of partial uplifting at the foundation due to tensile forces arising from excessive overturning moment response and uneven foundation settlements (see [13], [17]). All these mechanisms are non-linear in nature and it is many times difficult to quantify them in order to include their influ-

the top of the roof is assumed equal to 10m. Eight (8) trusses are assumed to form the wooden roof equally spaced along the x-x direction, as shown in figure 9. This wooden roof is connected to both the longitudinal walls at certain location through the transverse beams forming the bottom part of these wooden trusses. Moreover, This wooden roof is also connected by a series of longitudinal wooden beams with the gables of the two transverse wall (parallel to the y-y direction). In the subsequent numerical analysis the x-x direction is presumed to coincide with the N48W component of the recorded ground motion whereas the y-y direction with the N42E component.

Figure 9. Simplified numerical model of a typical industrial building

10. A two-story twin industrial building of unreinforced masonry

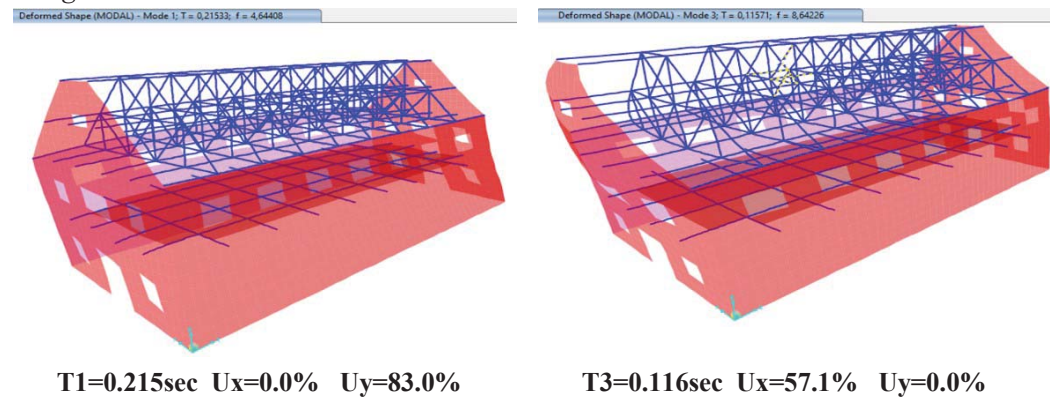

As already mentioned, the influence of the connections of the wooden roof with the peripheral masonry walls is the objective of this parametric simplified numerical simulation. This is done as follows. Initially, the wooden beams are considered as pinned to the masonry walls, capable of transferring axial and shear forces (not bending moments) in a way that the displacements of the wooden end is the same as the point of the masonry wall it is connected to (rigid connection). Next, this connection is done through flexible 3-D links with limited stiffness thus allowing a relative displacement between the end of the wooden beam at its connecting location of the masonry wall. By decreasing the stiffness of these 3-D links the level of force that can be transferred between these two media can be limited. Moreover, by decreasing the stiffness of these 3-D links the restraint that is enforced by the interaction between the wooden roof and the masonry walls is also decreased. These effects will be shown in the following discussion. It should be recognized that is a simplification of the actual interaction that is a more complex non-linear mechanism than what is described here. Despite this simplification, the influence of such a flexible connection is being presented and discussed here.

## 2.2 Modal analysis.

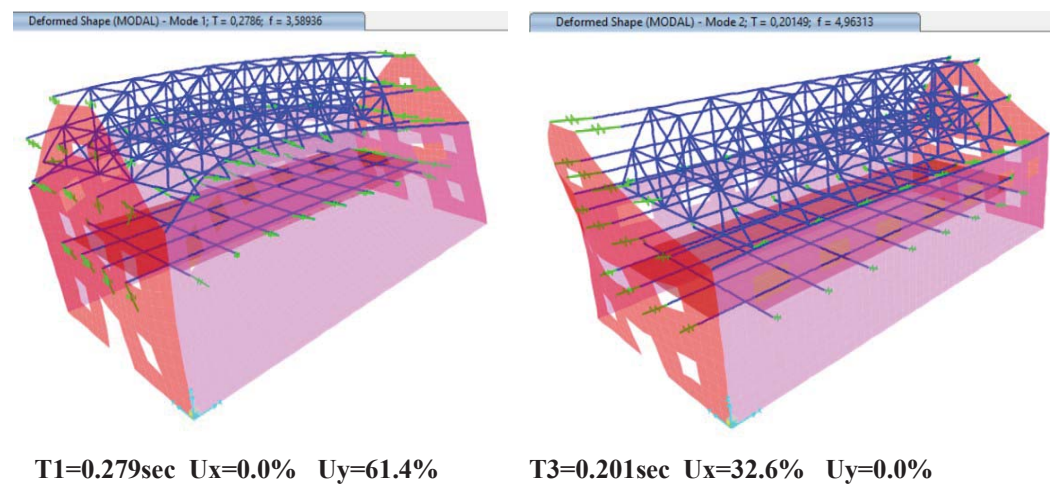

Initially, the most significant eigen-modes of the simplified numerical model depicted in figure 9 having three different wooden-beam to masonry-wall connections is studied. As mentioned, these connections are: 1-Rigid, 2-Moderately flexible and 3-Flexible. The obtained modal shapes, modal periods and modal mass participation ratio values are presented in what follows.

### 1-Rigid connections

### 2-Moderately flexible connections

### 3-Flexible connections

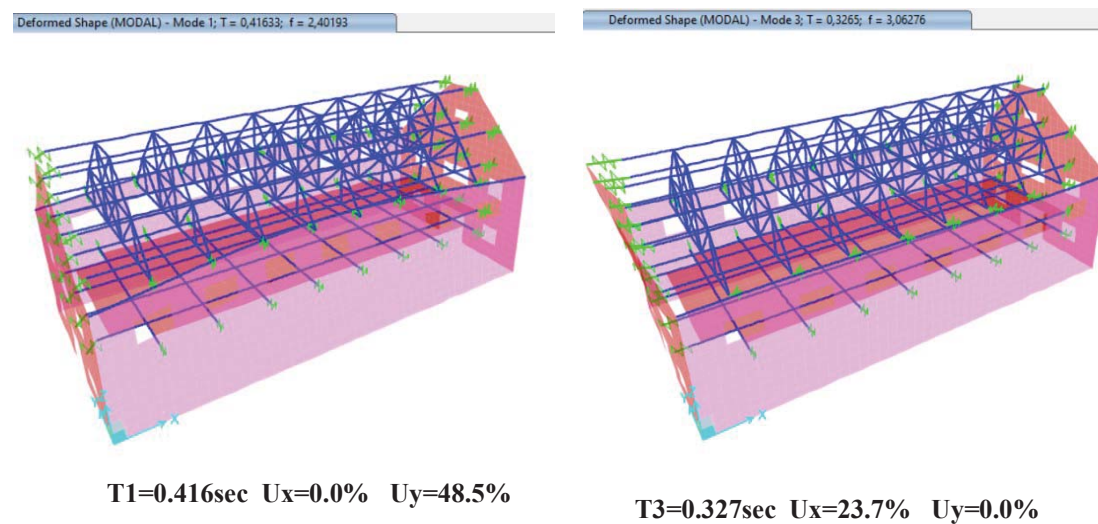

Figure 11. Eigen-modes for the simplified numerical model of the industrial building for Rigid, Moderately flexible and Flexible connections between the wooden roof beams and the masonry walls.

The following summarize the influence of the attempted simplified relaxation of the connections between the wooden roof beams and the masonry walls on the dynamic characteristics of the studied structural system.

- As expected, the increase in the flexibility of the connections between the wooden roof beams and the masonry walls results in an increase of the corresponding eigen-period values of the studied system from 0.215 sec. to 0.416 sec. for the mainly translational eigen-mode in the transverse y-y direction and from 0.116sec. to 0.327 sec. for the mainly translational eigen-mode in the longitudinal x-x direction.
- The increase in the flexibility of the connections between the wooden roof beams and the masonry walls results in a decrease in the corresponding modal mass participation ratio value. This is pronounced for the transverse y-y translational 1<sup>st</sup> eigen-mode (from 83% to 48.5%) but even more pronounced for the longitudinal x-x translational 3<sup>rd</sup> eigen-mode (from 57.1% to 23.7%).

Figure 12. Inelastic acceleration response spectral curves ( $m=1.5$ ) based on the recorded ground acceleration together with the variation of the eigen-periods for the main y-y and x-x translational eigen-modes as they resulted from the simplified numerical model of the industrial building for Rigid, Moderately flexible and Flexible connections between the wooden roof beams and the masonry walls.

In figure 12 the variation of the eigen-periods for the main y-y and x-x translational eigen-modes, as they resulted from the simplified numerical model of the industrial building for Rigid, Moderately flexible and Flexible connections between the wooden roof beams and

the masonry walls, are plotted together with the corresponding inelastic acceleration response spectral curves ( $m=1.5$ ). These inelastic acceleration spectral curves are based on the recorded ground acceleration together for the Samos island earthquake (30<sup>th</sup> October 2020). As can be seen from these plots the increased flexibility of the connections between the wooden beam roofs and the masonry walls will also result in an increase of the corresponding spectral acceleration value thus leading to a relevant increase on the seismic force levels for the studied structure. At the same time these increased inelastic spectral acceleration values are more in agreement with the corresponding Euro-Code 8 design spectral values, as already discussed on the basis of figure 5, than those of the rigid connections.

### 3 NUMERICAL EARTHQUAKE PERFORMANCE

In this section the numerical earthquake performance of the studied structure is presented in terms of a) maximum displacement values at the top of the masonry walls b) maximum normal and shear stress values of the masonry walls c) maximum axial force values that developed at the connections between the wooden roof beams and the masonry walls. All these values were obtained through dynamic spectral elastic analysis using the inelastic spectral curves depicted in figure 12. The presented results are for two specific load combinations:

1<sup>st</sup> Load Combination: Dead + ResSp N42E + 0.3 ResSp N48W

2<sup>nd</sup> Load Combination: Dead + ResSp N42E + 0.3 ResSp N48W

Dead= The dead load of the masonry walls and the roof.

ResSp N42E = The earthquake forces resulting from the dynamic spectral analysis in the y-y (transverse direction).

ResSp N48W = The earthquake forces resulting from the dynamic spectral analysis in the x-x (longitudinal direction)

As was done for the modal analysis the earthquake performance is examined utilizing the simplified numerical model depicted in figure 9 having the described before three different wooden-beam to masonry-wall connections (e.g. 1-Rigid, 2-Moderately flexible and 3-Flexible). In figure 13 includes the results obtained from the simplified numerical simulation assuming rigid connections of the wooden roof beams with the masonry walls. In figure 13a and 13b the displaced masonry walls of the structure are depicted in figures 13a and 13b for load combinations with the seismic forces applied either mainly in the transverse N42E or mainly in the longitudinal N48W directions, respectively. Figures 13c depicts the normal stress (S22) distribution whereas figure 13d the shear stress (S12) distribution for a load combination with the seismic forces applied mainly along the transverse N42E direction. Figure 13e depicts the normal stress (S22) distribution for a load combination with the seismic forces applied mainly along the longitudinal N48W direction. Figure 13f depicts the distribution of the axial forces that develop at the roof wooden beams for a load combination with the seismic forces applied mainly along the transverse N42E direction whereas figure 13g depicts the axial forces that develop at the roof wooden beams for a load combination with the seismic forces applied mainly along the longitudinal N48W direction. The results for moderately flexible (figures 14) or for flexible connections (figure 15) are also shown.

\* the relative axial displacement between the wooden roof beam and the masonry wall at the location of their connection

Table 1 summarizes all the peak response values from the results plotted in figures 13, 14 and 15. In the first column of this table each of the three analyzed cases of connection between the wooden roof beams and the masonry walls is denoted. At the same column the peak horizontal base shear values are also listed for each case, as they resulted from the dynamic spectral (see figure 12) analyses along the x-x (N48W perpendicular to the transverse walls) and y-y (N42E perpendicular to the longitudinal walls) directions (see figure 9). As already discussed, because of the variation of the amplitudes of the employed inelastic spectral curves with the eigen periods values (figure 12) the structural system with the flexible roof-to-masonry connections is subjected to the highest seismic force amplitudes in both x-x and y-y directions. Consequently, part of the significant amplification of the obtained displacement and stress response for this case as compared with the cases of either the rigid or the moderately flexible connections is partly due to this fact. However, another large part of this amplification must be attributed to the fact that the flexible connections exercise limited restraint in prohibiting the masonry walls to displace, especially in the out-of-plane direction. This is evident by comparing the out-of-plane peak displacement values of either at the top of the longitudinal walls (column 2 of table 1) or at the top of the transverse walls (column 3 of table 1). As can be seen, an increase flexibility in these wooden roof beam to masonry wall connections result in a large increase in the out-of-plane displacements at the top of either the longitudinal or the transverse masonry walls. This in turn results in a corresponding increase in the peak (tensile) axial stress values normal to the bed joints (S22) for either the longitudinal masonry walls (column 4 of table 1) or the transverse masonry walls (column 5 of table 1). In contrast, the moderate variation in the peak shear stress value of the transverse masonry walls is in line with the corresponding variation of the base shear value in the y-y direction (Qy, column 1 of table 1). Finally, the increase in the flexibility of the wooden roof beam to masonry wall connections result in a decrease, as expected, in the axial force value that is transmitted through these connections (columns 7 and 8 table 1). It is also interesting to note that the rigid connections between the wooden roof beams and the masonry walls, which is an unrea-

listic ideal case, results in relatively small out-of-plane displacement values, despite the fact that the resulting axial forces at the connection locations are also relatively small. On the contrary, the increase in the flexibility of these connections from moderately flexible to flexible results in a decrease at the level of axial force which is in agreement with the resulting increase of the out-of-plane displacement at the top of the masonry walls. In columns 7 and 8 of table 1 the relative axial displacement between the wooden roof beam and the masonry wall at the location of their connection is also listed. As can be seen, the increase flexibility of this connection means in a sense a large relative displacement between the wooden roof beam and the masonry wall. This practically means that there is a possibility of a loss of support of the wooden roof beam when this relative displacement becomes excessive, as is the case of the flexible connection assumed in this simplified numerical simulation. This is the case portrayed by the collapsed roof in figures 7 and 10. Obviously, this simplified analysis is only qualitative. In order to obtain realistic numerical predictions it is necessary to include in the numerical analysis a valid numerical description of the non-linear connection mechanism ([31] to [36]).

#### 4 CONCLUSIONS

- The recent earthquake sequence in the Greek island of Samos gave the opportunity of assessing the earthquake performance of various types of structure in Greece. It can be stated that the enforcement in 1995 of the “New Greek Seismic Code” together with the provisions of the Euro-Codes has substantially increased the safety level of structures against earthquakes. A significant expansion of the strong motion network of accelerographs that covers the whole of Greece provides very important information on the characteristics of the earthquake strong ground motion that is very useful in assessing the consequences of the intense earthquake activity to the built environment. The relevant data base is enriched with valuable information on the characteristics of the earthquake strong ground motion that is very useful to designers and contractors.
- A source of seismic risk that can result in human loss was highlighted by this earthquake event. It is generated by old and weak unreinforced masonry structures which are left unoccupied and not maintained by their owners due to various social-economic non-incentives and complications. This category includes numerous old buildings that belong to culture heritage being listed in conservation status. The group of old stone- masonry buildings with wooden roof that were used as leather processing factories at Karlovassi-Samos belong to this category.
- Numerical tools combined with realistic measurements of the seismic forces generated by a strong earthquake ground motions can be utilized to explain the observed structural damage. They can also be utilized in the subsequent retrofitting effort. Towards this objective, the present numerical study investigated the influence of the flexibility of the connections between the wooden roof beams and the masonry walls of such old stone masonry industrial buildings.
- The flexible connections exercise limited restraint in prohibiting the masonry walls to displace, especially in the out-of-plane direction. Consequently, such increased flexibility results in relatively large displacement and stress response demand for the masonry walls that could be detrimental leading to mainly flexural type failures. This is to be expected for masonry construction with low flexural capacities. At the same time, the increase in the flexibility of these connections results in a decrease of the level of axial force which

is in agreement with the resulting increase of the out-of-plane displacement at the top of the masonry walls.

- At the same time, the increased flexibility of wooden roof beams to masonry wall connections also results in large relative displacement between the wooden roof beam and the masonry walls. This practically means that there is a possibility of a loss of support of the wooden roof beam when this relative displacement becomes excessive, as is the case of the flexible connection assumed in this simplified numerical simulation.
- The present simplified analysis is only qualitative. In order to obtain realistic numerical predictions it is necessary to include in the numerical analysis a valid numerical description of the non-linear connection mechanisms. Moreover, there is also need to obtain measured capacities of such connections through laboratory measurement focusing to this problem.

### Abstract

*This paper deals with the experimental investigation of the behavior of timber frames with or without infill panels. The examined infill panels are diagonal timber bracers, masonry infill and OSB. The main scope of this effort is the investigation of the influence of the infill panels to the strengthening and the global behavior of these frames. At the first stage the mechanical properties of the used materials, such as timber, brick, mortar and masonry were defined through experimental tests. An additional number of tests were completed in order to define the capacity of the joints between two timber members focused on the shear capacity and the extraction of nails which used for the connection of timber members. All these data will be used for the numerical simulations of the experimental studied timber frames. At the second stage, eight timber frames were designed, constructed and tested at the metallic reaction frame of Frederick University under lateral monotonic loadings until the ultimate limit state. The lateral loading as well the lateral displacement and the uplift of the column which was under tension were measured and recorded using a data acquisition system. At the same time the observed modes of failures were reported. At last, but not least, the evaluation of these measurements through various analytical methods was completed. Through this effort the relation between the lateral displacement and the uplift is examined, the absorbed energy from each timber frame is estimated and the contribution of each infill system to the global behavior of the timber frame systems is defined and discussed.*

**Keywords:** Timber frame, infill panels, experimental investigation, analytical evaluation

## 1 INTRODUCTION

The majority of the historic buildings, both in Eastern Mediterranean region and throughout Europe, were built with load-bearing masonry wall system. Of particular interest, is the timber frame with masonry infill. A masonry timber frame is consisted by many parts created by horizontal, vertical and diagonal timber elements (fig. 1). The ease of construction, on one hand and the availability of the natural material, on the other hand, played an important role, on the wide use of the system throughout the world. The long term existence of this system, proves its efficiency and its durability throughout the centuries. Even today, the timber frame system, in various forms and types, still plays a leading role in the Building industry. Many experimental and numerical investigations have dealt with the behavior and response of this system. Many of them are presenting a qualitative evaluation of this system, under static and seismic loading. While, this study evaluates, with the aid of experimental approach, the behaviour of various strengthening typologies of the system, in a way that this would be helpful to the maintenance and even strengthening procedures of existing structures [ 1, 2, 3, 4 ].

An experimental investigation approach, aiming to the strengthening techniques of historic timber frames is designed and is under develop at the Frederick University in Cyprus. The present study is focused on the basic part of a timber frame as explained above, as the first step of this effort in order to understand well the behavior of such systems under lateral seismic loadings, the mechanisms of failure as well the contribution of various techniques for the strengthening of masonry timber frames. Therefore, eight (8) different timber frame specimens with various techniques of strengthening were designed, constructed and tested under monotonic lateral static loading. At the first stage the mechanical properties of the used materials, such as timber, brick, mortar and masonry were defined through experimental tests. An additional number of tests were completed in order to define the capacity of the joints between two timber members focused on the shear capacity and the extraction of nails which used for the connection of timber members. All these data will be used for the numerical simulations of the experimental studied timber frames. During the experimental sequence of frame specimens, a monitoring and data acquisition system was used for the recording of the lateral loading and the horizontal displacement on the top of the frames. In addition to that, the uplift of column which is under tension was recorded during the loading procedure. All these results are evaluated, presented and discussed in what follow with emphasis on the contribution of various strengthening techniques on the behavior of these frames.

Figure 1. Masonry timber frames on the upper storey of building structure in Cyprus

## 2 DESIGN AND CONSTRUCTION OF THE EXPERIMENTAL TIMBER FRAMES

### 2.1 Mechanical properties of the materials

A number of tests were completed for the definition of the mechanical properties of the used materials such as timber, brick, mortar and masonry. The properties of these materials will be used for the numerical simulations and structural analysis of experimental frame specimens.

For the construction of masonry walls, lime mortar and bricks were used. Their mechanical properties were defined according to the provisions of European standards. The compressive strength of masonry was defined using triplet specimens (consisted by three bricks connected with mortar) and was founded out equal to 13.2 Mpa.

It is well known that timber is orthotropic material. Therefore, the used timber for the construction of timber frames was tested under compression loadings in two cases, parallel and perpendicular to the grain, again according to the provisions of European standards. For each case three specimens were tested. The results from these tests are presented in figure 2 in terms of stress - strain.

Figure 2. Stress - strain curves of timber under compression

### 2.2 Capacity of the joints of timber elements

All the timber elements were connected with nails. The capacity of these joints is characterized by the shear resistance and resistance to the extraction of the nails under axial tension. Therefore a number of experimental tests were completed to define the shear capacity and the capacity to the extraction of nails. In both cases (shear and extraction capacity) the tests includes various number of nails (one, two or three) for the connection of timber elements.

For the extraction of the nails six specimens were tested. In three of them the timber elements were connected with two nails and in the case of the other three specimens three nails were used. For the shear capacity five specimens were tested. Each specimen was consisted by three timber elements arranged in parallel configuration. The central one was connected

with the external timber elements using nails. For two specimens two nails were used (1+1) and for three specimens four nails (2+2).

During the tests, the applied loading (shear or tension) and the displacement between the connected timber elements were measured. In any case, after the completion of each test, the capacity corresponds to one nail was estimated. These results are noted in figures 3 & 4. In the same figures, the average value of the capacity of one nail is given with a solid line.

Figure 3. Experimental measurements from the extraction of nails tests

Figure 4. Experimental measurements for the shear capacity nails

### 2.3 Design and construction of experimental timber frames

As mentioned above, the experimental specimens examined in this paper represent a basic part of a real timber frame (see figure 1) in order to understand well the behavior and the failure mechanisms of such sub-system as basic background to understand and explain these topics of a whole frame system as well to understand and record the influence of various strengthening techniques to the behavior of timber frames such as diagonal timber bracers, masonry infill and the OSB as infill panel. Therefore, eight (8) timber frames in various forms were designed and constructed (figure 5). All experimental timber frames have rectangular shape with height 0.77m (77cm) and the same bay between the two vertical timber columns (77cm).

- The first frame, which will be referred as reference frame in what follow (2CTF), consisted by an horizontal timber beam as base level. Two vertical columns are connected at the base beam with nails. The top level of these columns are connected also with a timber beam using nails.
- The second one has the same configuration, however one more timber column is attached at the middle of the bay (3CTF).
- The third one has also the same configuration with the reference frame including diagonal timber bracers (2CXTF).
- The fourth one is the same with the reference one but with masonry infill (2CMTF).
- The fifth one, as timber frame, is the same with the third one including also masonry infill (2CXMTF).
- The sixth one has the same timber skeleton with the reference one however two OSB panels were used as infill panel attached in both sides of the frame (2CTF - 2- OSB).
- The seventh one has the same timber skeleton with the third one (with diagonal bracers) but only one OSB panel was attached at one side (2CXTF - 1- OSB).
- The eight one has the same timber skeleton with third one (with diagonal bracers) but in this case two OSB panels were used as infill panel attached in both sides of the frame (2CXTF - 2- OSAB).

The facade of all the above experimental timber frames are presented in figure 5.

## 3 EXPERIMENTAL TESTS OF TIMBER FRAMES

### 3.1 Experimental setup

All experimental timber frames were attached at the metallic reaction frame of Frederick University and were subjected to lateral monotonic loading (figure 6). The timber beam at the base of the frames was fixed at the horizontal steel beam of the reaction frame. The lateral loading was applied at the top of the timber frame using an hydraulic jack. In order to avoid local modes of failures due to the point load, an additional timber beam was fixed at the top beam of the frames with an expansion to the hydraulic jack. Therefore, the lateral load was applied in uniform distribution to the top beam of the timber frames.

Two displacement transducers (LVDT) were used to measure the displacements of the timber frames. The first one measured the horizontal displacement at the top of the timber frames. The second one was attached at the base of the frame in order to measure the uplift of the timber column which was under tension during the experimental loading. This uplift was happened due to the extraction of the nails which connected the timber column with the beam at the base level. The measurements of the LVDT' s as well the loadings applied from the hydraulic jack were restored in a data acquisition system in time domain.

Figure 5. Configuration and dimensions of experimental timber frames

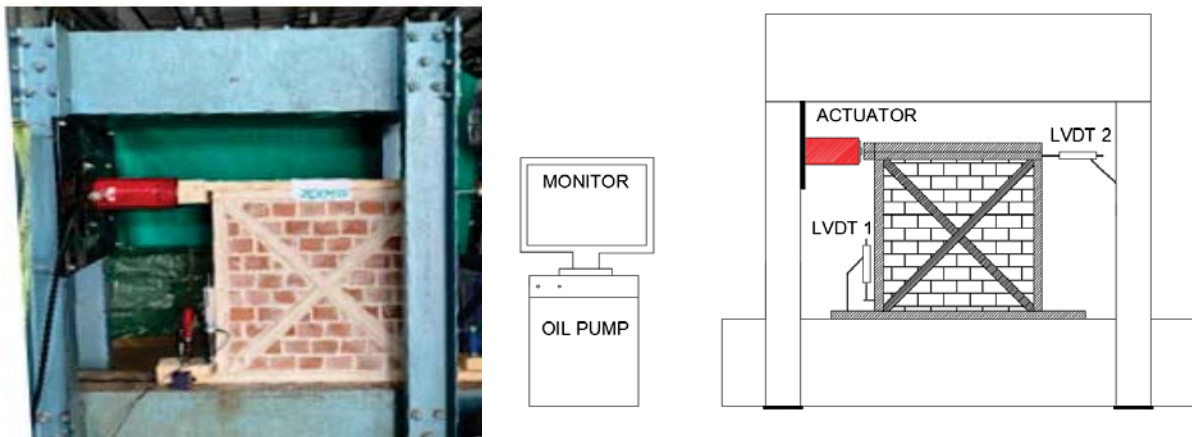

Figure 6. Experimental setup

### 3.2 Experimental measurements

The lateral horizontal load vs the horizontal displacements for all the timber frames are presented in figure 7. We can see that the timber frames 2CTF and 3CTF (pure frames) have almost the same behavior with the lower level of the lateral received load but with higher level of lateral displacements without uplift. The timber frames with OSB can receive the higher level of the external loading. The other timber frames (with masonry infill or/and diagonal bracers), simulating traditional timber frames, have a capacity between the two previous categories as mentioned above (pure timber frames and timber frames with OSB). Similar observations can be made and for the measurements of the uplift at the bottom of the left timber column with tensile stress (figure 8).

Figure 7. Horizontal monotonic load vs horizontal displacements

Figure 8. Horizontal monotonic load vs Uplift of the left timber column

### 3.3 Observed damages

The pure frames consisted only by columns and beams (2CTF & 3CTF) developed only horizontal displacements without any uplift at the left column. After the un-load of these frames a remain displacement was observed. The deformation shape of these frames it looks like pure shear deformation which is mean that the actual resistance during the test was the shear resistance of the nails which connected the timber structural elements (figure 9).

In the case of timber frames with diagonal bracers (2CXTF & 2CXTF (1-OSB)) the behavior is characterized by horizontal displacements and uplift of the left column at the base level as well the uplift of the diagonal timber element connected at this joint. After the un-load of these frames a remain displacement was observed as well uplift at the base level due to the extraction of the nails (figure 9).

The timber frames with masonry infill develop similar behavior with those with diagonal timber bracers including remain uplift and horizontal displacement after un-loading. However in this case it was founded out that there are significant damages on the masonry infill characterized by disconnection from the timber frame as well diagonal shear cracks were observed. These damages are more serious in the case of timber frame without diagonal timber bracers (2CMTF). In addition to that, a flexural deformation on the left column was observed due to the interaction between the masonry infill and the left timber column (figure 9).

The last two timber frames with OSB infill (2CTF - 2- OSB & 2 CXTF -2 -OSB) developed much difference behavior. Due to the OSB infill panel which was connected with the surrounding frame (columns and beams), the beam at the base level developed flexural deformation created by vertical loadings applied through the connections of the beam with the OSB. After the un-load of these frames the remain displacement and uplift was observed to be much smaller than the previous cases. However, a flexural deformation is remained at the beam at the base level (figure 9).

Figure 9. Modes of the observed failures of the timber frames

## 4 EVALUATION AND ANALYSIS OF THE EXPERIMENTAL MEASUREMENTS

### 4.1 Evaluation and analysis of the horizontal displacements of the timber frames

In this section the horizontal displacements of the timber frames are examined until the max. lateral load ( $F_{max}$ ) with the assumption of linear behavior. From this point of view, the total horizontal displacement ( $X$ ) of each frame is consisted by two parts ( $X_1 + X_2$ ). The first one ( $X_1$ ) is created due to the uplift. Assuming of a rigid body rotation of the frame system, the  $X_1$  is equal to the uplift ( $X_1 = \text{uplift}$ ). However, an additional horizontal displacement ( $X_2$ ) is created due to the shear and bending deformation of the timber frame. This approach is presented in figure 10. The values of the  $X$  (total displacement), the  $X_1$  and the  $X_2$  are presented in figure 11 for six timber frames which developed uplift during the tests.

At a second step, the values of the  $X_1$  and  $X_2$  are divided by the total displacement ( $X$ ) in order to find the contribution of each part to the total displacements in percentage (figure 12). As can be seen, in the case of masonry infill timber frame without diagonal bracers (2CMTF) the contribution from the uplift to the total displacement is more than 75%, however in the case of masonry timber frame with diagonal bracers (2CXMTF) this contribution is reduced approximately up to 55%. In the case of timber frame with diagonal bracers (2CXTF) the contribution from the uplift is approximately about 33%. The more significant observation from this analysis is that, all the frames with OSB infill panel the contribution from the uplift ( $X_1$ ) to the total displacement ( $X$ ) is almost the same in all the cases, approximately up to 42%. From this point of view it can be said that the behavior of timber frames with OSB infill panel is more predictable. However, this observation must be verified through a numerical investigation.

Figure 10. Analysis of the total displacement

Figure 11. Analysis of the total displacement

Figure 12. Percentage contribution of uplift and shear and bending deformation to the total horizontal displacement

#### 4.2 Evaluation and analysis of the global behavior of the timber frames and contribution of the strengthening techniques

The main scope of this effort is to investigate the influence of the strengthening techniques to the global behavior of the studied timber frames. For that, the quantity of energy absorbed by each frame and the correlation of this energy with that of the reference frame (2CTF) is presented. For each timber frame, the absorbed energy was estimated by the area below the curve of Lateral Force Vs Horizontal Displacement as defined by the experimental measurements. This absorbed energy was estimated until 40mm horizontal displacement for all the studied frames (figure 13). After that, the absorbed energy of each frame is correlated with absorbed energy of the reference frame (2CTF). The results from this effort are presented in table 1.

Figure 13. Procedure for the estimation of the absorbed energy for each timber frame

Timber Frame	Absorbed Energy (J)	Ratio of Absorbed Energy (frame i / 2CTF)	Increasing of Absorbed Energy
2CTF	32.5	1.00	0.0 %
3CTF	40.6	1.24	24 %
2CMTF	73.75	2.26	126 %
2CXTF	113.0	3.47	247 %
2CMXTF	114.0	3.50	257 %
2CXTF (1 - OSB)	277.35	8.53	753 %
2CTF (2 - OSB)	363.4	11.21	1021 %
2CXTF (2 - OSB)	429.7	13.22	1222 %

Table 1. Result from the estimation of the absorbed energy and correlation with the reference frame (2CTF)

At a second step, the contribution of each strengthening technique to the increasing of the absorbed energy is examined. For that, the contribution of an additional vertical timber column, the masonry infill, the diagonal timber bracers and the OSB as infill panel are examined. In the first stage the difference in absorbed energy between two timber frames with only difference the examined strengthening technique is estimated. If there were more cases with that, the average value of them was taken in the account. Finally the amplification factor for each intervention technique was estimated. This amplification factor describes how many times there is increasing of the absorbed energy of the reference frame (2CTF) if the strengthening technique would be applied on the reference frame. The results from this procedure are summarize in table 2. According to these results, it can be said that the panel of one OSB has much higher contribution to the absorbed energy than the other strengthening techniques. Actually the contribution of one panel of OSB is more than two times than that from the diagonal bracers and almost four times than that from the masonry infill. At last, but not least, it can be said that the additional vertical timber column has very low contribution to the absorbed energy, however this technique must be examined in various cases and structural configurations for more safety and realistic conclusions.

Strengthening Technique	Formula	Absorbed Energy (J)	Average value	Amplification factor (Str. tech./2CTF)
Additional one vertical column	$3CTF - 2CTF$	8.1	8.1	0.25
Masonry infill	$2CMTF - 2CTF$	41.25	41.25	1.3
Diagonal bracers	$2CXTF - 2CTF$	80.5	73.5	2.25
1 OSB panel infill	$2CXTF (2OSB) - 2CTF (2OSB)$	66.3		
	$2CXTF (1OSB) - 2CXTF$	164.35	162.7	5.0
	$[2CXTF (2OSB) - 2CXTF] / 2$	158.35		
	$[2CTF(2OSB) - 2CTF] / 2$	165.45		

Table 2. Contribution of each strengthening technique to the absorbed energy

## 5 CONCLUSIONS

The behavior of eight (8) timber frames was investigated under lateral monotonic loadings through an extended experimental investigation accompanied by the analysis and the evaluation of the experimental measurements. The reference timber frame was consisted by two vertical columns connected at the base level and at the top level with horizontal beams. The timber elements were connected with nails. All the other timber frames were strengthened using various strengthening techniques, such as additional vertical timber column, masonry infill, diagonal timber bracers and OSB as infill panel. According to the observed damages and the evaluation of the experimental results, the followed conclusions can be made:

- The predominant modes of the observed failures can be characterized by the uplift of the vertical timber column which was under tension, due to the extraction of the nails at the base level, as well by shear and bending deformation of the frame. After the unloading of the experimental frames, significant remained displacement of all the examined frames was observed.
- In the case of the timber frames with masonry infill, sliding and disconnection of the masonry infill from the surrounding frame accompanied also by cracks of the masonry infill were occurred.
- In the case of timber frames with OSB as infill panel, a flexural deformation at the bottom beam was observed due the connection of this beam with the OSB.
- It was founded out that the max. values of the received lateral load ( $F_{max}$ ) is strongly depended by the strengthening technique with those of the timber frames with OSB to received much higher max. horizontal load than the other cases.
- The total displacement is consisted by two parts. The first one is the contribution from the uplift and the second one is the contribution from the shear and bending deformation of the frames. This contributions are varied however in the case of timber frames with OSB were founded to be constant.
- Finally, the increasing of the absorbed energy by the OSB it was founded out that is much higher than the absorbed energy by the frames strengthened with other techniques. Also, the diagonal bracers has almost two times higher contribution in the absorbed energy than that by the masonry infill.

### Abstract

This paper deals with the experimental and numerical investigation of the effectiveness of a Rolling Mass to the reducing of the resonance response of an experimental and a numerical model of one storey structural system utilizing the shaking table of Frederick University. At the first stage, a sweep test including a range of frequencies of excitations was completed in order to define the resonance response of a steel experimental model simulating one storey building. At the second stage the design and the manufacture of a simple Rolling Mass was completed and its dynamic properties were defined through a sequence of experimental tests with sinusoidal base excitations. At the third stage, the Rolling Mass was attached at the roof of the steel experimental model structure and the influence of that to the resonance response of the model structure was investigated in various cases. Through this investigation the stiffness and the mass ratio of the Rolling Mass system to those of the model structure were defined in order to have the higher level of the reduction of the resonance response. At last but not least, based on the results from the experimental investigation, a numerical model of one storey real structure was designed with or without Rolling Mass at the roof level. This numerical model was subjected also under sinusoidal base excitations in order to study the effectiveness of the Rolling Mass to the resonance response. The normalized results from the experimental investigation of the experimental model structure and those from the numerical investigations of the real model structure were founded out in enough good correlation. The results of this effort are presented and discussed.

**Keywords:** Shaking table, Rolling Mass, Resonance Response

---

## 1 INTRODUCTION

During dynamic loading of structures, such as winds, earthquakes or vibrations due to the operation of machines installed on the structures, a resonance response can be occurred, when the frequency of vibration is equal, or almost equal, with the predominant natural frequency of the structure. The level of forces (or accelerations and displacements) generated by resonance vibration are generally too large and usually they don't be acceptable, both for the operation and the safety of the structure. This response is related also with the damping of the structure so as the damping is increased the resonance response is decreased .

The more practical way to reduce the vibration of a structural system is to change its dynamic properties through the strengthening or changing the mass of the system. However, these interventions are very difficult to be applied in many structural systems. In this case, the most effective and economic way to reduce the vibration is to apply an additional dynamic system at a discrete location of the existing structure to change its dynamic properties in order to avoid the resonance. Tuned Mass Dampers (TMDs) belongs into this category of devices. The TMD system is designed taking in the account many parameters and especially the frequency of resonance. It is effective only over a narrow frequency band very close to the resonance frequency. This problem was under investigation in many research efforts [1, 2, 3, 4]. The design, manufacture and installation of TMD is a very complicated and expensive procedure. Therefore, for these reasons, today they can have applications only on very specific structures. The sliced mass (SM) and the Rolling Mass (RM) have similar behavior and effects with the TMD. Except of the effectiveness, these specific systems have many differences with the TMD such as the manufacture procedure, the installation on the structures, the cost as well the design and the control of their response. On the other hand, the sliced mass (SM) and the rolling mass (RM) can easily be manufactured and installed on a structure but very difficult to be controlled in the way for the reduction of the resonance response.

This paper deals with the experimental and numerical investigation of the effectiveness of a Rolling Mass (RM) to the reducing of the resonance response of un experimental [5] and a numerical model of one storey structural system. For the purposes of this effort the shaking table of Frederick University was used.

- At the first stage, a sweep test including a range of frequencies of excitations was completed in order to define the resonance response of a steel experimental model simulating one storey building.
- At the second stage the design and the manufacture of a simple Rolling Mass (RM) was completed and its dynamic properties were defined through a sequence of experimental tests with sinusoidal base excitations.
- At the third stage, the RM was attached at the roof of the steel experimental model structure and the influence of that to the resonance response of the model structure was investigated in various cases. Through this investigation the stiffness and the mass ratio of the RM to those of the model structure were defined in order to have the higher level of the reduction of the resonance response.
- At last but not least, based on the results from the experimental investigation, a numerical model of one storey real structure was designed with or without Rolling Mass (RM) at the roof level. This numerical model was subjected also under sinusoidal base excitations in order to study the effectiveness of the RM to the resonance response. The normalized results from the experimental investigation of the experimental model structure and those from the numerical investigations of the real model structure were founded out in enough good correlation.

## 2 EXPERIMENTAL INVESTIGATION

### 2.1 Experimental model structure and results from sweep test

For the purpose of this investigation, a flexible steel frame system in small scale was used consisted by two flexible vertical elements and a rigid slab. From this point of view we can assume that this model represent a Single Degree of Freedom (SDOF) system. Before any test, the mass and the stiffness of this model were measured. This model was fixed at the platform of the shaking table and was subjected on a range of frequencies of excitations (1.5 - 8.5Hz) with step 0.5Hz, including of course in this range of frequencies the predominant frequency of this steel frame. In all the cases the max. base acceleration was kept constant ( $2.0\text{m/sec}^2$ ). The base acceleration as well the acceleration response of the experimental model were measured in time domain and restored using a data acquisition system (figure 1). Through this sequence of tests (well known as sweep test) the resonance response of the SDOF system was defined as well the predominant frequency and the viscous damping of the experimental model. The results of the resonance response from this test are summarized in figure 2.

Figure 1: The experimental setup with the model structure

Figure 2: The resonance response of the experimental model

## 2.2 Experimental Rolling Mass (RM) and results from sweep test

At the second stage the design and the manufacture of a single Rolling Mass (RM) was completed. It is a symmetrical system with four rollers, free standing in a metallic plate and able to roll in horizontal direction. At the edge of this plate two rigid metallic systems were fixed. The rolling mass was connected with these rigid metallic systems with springs arranged in symmetrical configuration (figure 3). This system was attached at the platform of the shaking table and was subjected to a range of frequencies of excitations with constant max. base acceleration but with various values of mass of the RM and various values of stiffness of the springs. Before any test the stiffness of the used springs were measured. For each test, the base acceleration as well the response acceleration of the RM were measured and restored. Using these data, the resonance response of the RM, the predominant frequency and the viscous damping were estimated. The results from one case from this sequence of tests are presented in figure 4.

Figure 3: The rolling mass on the shaking table

Figure 4: Resonance response of the Rolling Mass (RM)

### 2.3 Experimental model structure with RM and results from sweep test

At the third stage, the system with the RM was attached at the roof of the model structure and was subjected in a large number of sinusoidal base excitations using the same range of frequencies and max. base acceleration as in the previous tests (figure 5). The results from a test are presented in figure 6 and correlated with those from the resonance response of the experimental model without the RM. As can be seen the response of the experimental model with RM is reduced drastically in a narrow band of frequencies closed to the resonance frequency (figure 6). However, two other peaks of the response of this system with RM are occurred but with lower level of amplitudes, one at the left of the resonance frequency with frequency F1 and one at the right with frequency F2. The left one represent the case with in-phase response of the RM with that of the model structure and the right one the case of the out-of-phase response.

Figure 5: The experimental model with the RM on the shaking table

Figure 6: Correlation of the resonance response of the experimental model without the RM (SMF) with the response of the same model with the RM (SMR)

## 2.4 Results from experimental parametric investigations

An extended parametric investigation with 13 sweep tests were completed in order to examine the influence of the mass and the predominant frequency of the RM to the response of the model structure. In the first case, the mass ratio ( $k = \text{mass of RM} / \text{mass of model structure}$ ) was kept constant ( $k=16\%$ ) but the frequency of RM was changed from test to test ( $\delta = \text{natural frequency of RM} / \text{natural frequency of model structure}$ ) using different springs. Seven sweep tests were completed in the same range of frequencies and constant max. base acceleration as before. The results from this investigation are presented in figure 7. As can be seen, the response of the model structure with RM is changed drastically from test to test. In the second case, the ratio of frequencies was kept constant and equal to one ( $\delta=1$ ) and the ratio of mass ( $k$ ) was changed from test to test fixing additional masses on the RM. The results from six sweep tests are presented in figure 8. As can be seen, in this case the response of the model structure with RM is more constant. However, it was founded out that the lower amplitude of the response is occurred in the case when the ratio of the mass of the RM over the mass of the model structure is 10% ( $k=10\%$ ).

Figure 7: Experimental results of the experimental model with RM from seven sweep tests with constant ratio of masses ( $k=16\%$ )

Figure 8: Experimental results of the experimental model with RM from six sweep tests with constant ratio of frequencies ( $\delta=1$ )

## 2.5 Prediction of the fundamental frequencies of experimental model with RM

At first, the assumption that the experimental model without the RM is a Single Degree of Freedom (SDOF) system is adopted. Therefore, the case of the experimental model with RM assumed that is a Two Degree of Freedom (2DOF) system. Using analytical methods from structural dynamic theories, the prediction of the fundamental frequencies of the experimental model with RM ( $F_1$ ,  $F_2$ ) and the difference between these two frequencies ( $F_2 - F_1$ ) are estimated. The  $F_1$  corresponds to the 1st mode with the in-phase response of the model structure and the RM and the  $F_2$  corresponds to 2nd mode with out-of-phase response. The predicted results from the analysis of 13 experimental sweep tests are presented in figures 9 and correlated with those which measured during the experimental tests. As can be seen from the diagrams of this figure, there are enough good correlation between experimental results and the predicted values. These observations allowed us to continue the investigation of this problem through numerical simulations as will be presented in the follow section.

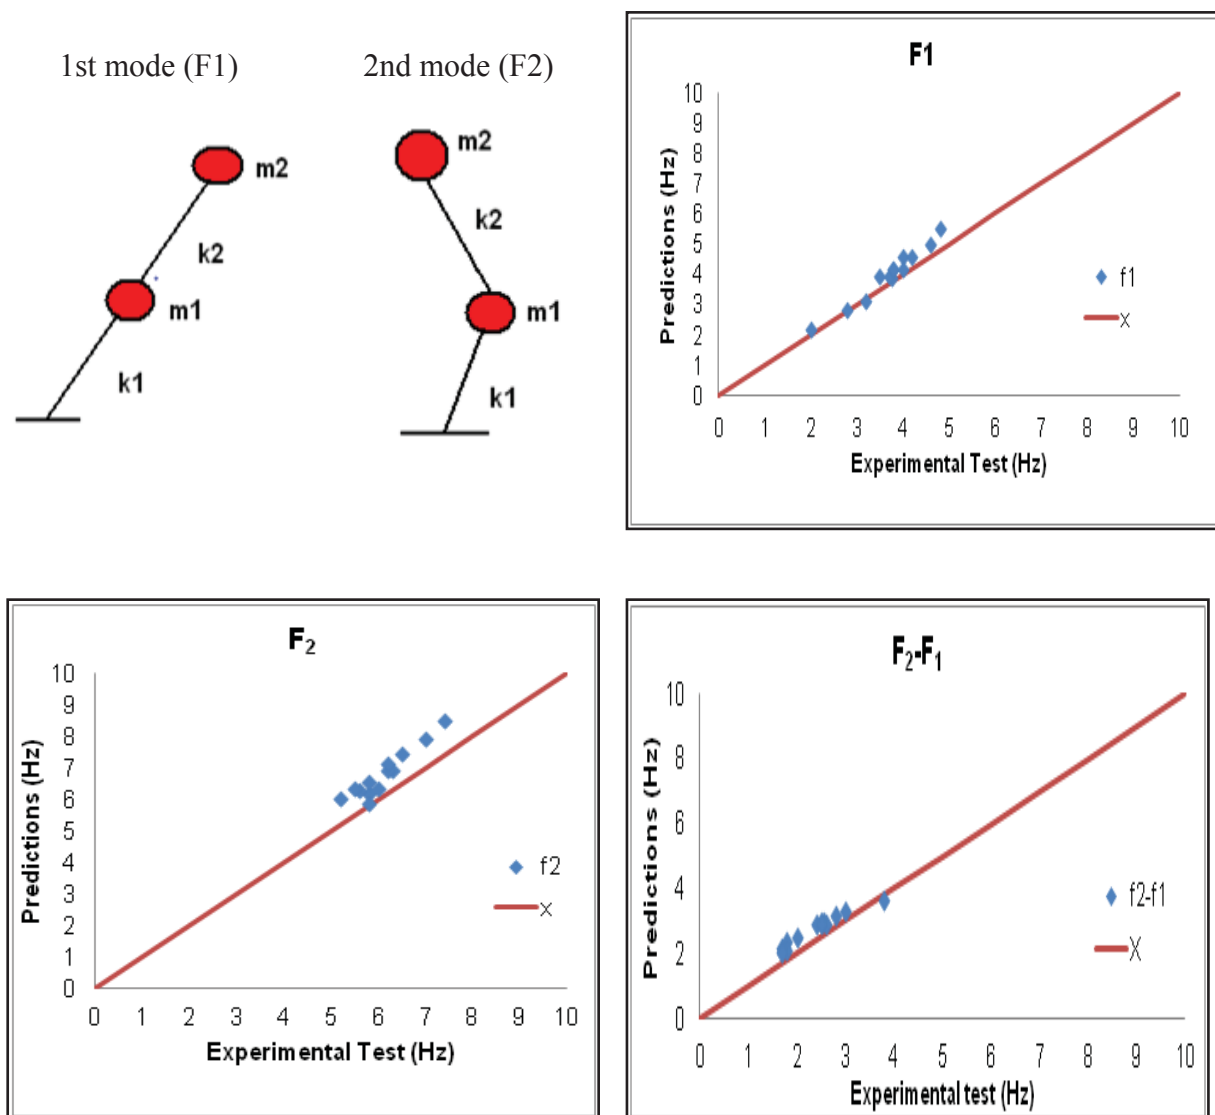

Figure 9: Prediction of fundamental frequencies of the experimental model with RM and correlation with the experimental result

### 3 NUMERICAL INVESTIGATION

#### 3.1 Description of the numerical model

Based on the results from the experimental investigation, a numerical model of one storey frame of a real structure with height 3.0m was designed with or without Rolling Mass (RM) at the roof level. This structural model is consisted by two columns and an horizontal rigid beam. At the first stage, through a modal analysis the predominant frequency of the structural system without the RM was founded out ( $f_0=2.85\text{Hz}$ ). The two columns are expanded over the beam as rigid elements. The mass of the RM was defined to be equal to 10% of the mass of the model of the real structure and to be very stiff using horizontal and diagonal braces. The attach of the RM at the middle of the beam was done through specific supports. The restrictions of these supports were defined in order to allow the horizontal displacement in two horizontal directions but without creation of bending moments, simulating the roller supports of the experimental model. Using horizontal springs, the RM was connected with the rigid elements over the columns in both directions (figure 10). Through an extended numerical investigation the characteristics of the horizontal springs as well those of the specific supports were defined with the main scope the predominant frequency of the RM to be equal to the predominant frequency of the numerical model of the frame structure (2.85Hz). This model structure with RM was subjected in a sweep test for various frequencies keeping constant the max. base acceleration. The shape of the used sinusoidal signal was similar to that developed by the shaking table as it is presented in figure 11.

Figure 10: Numerical model of frame system with the RM at the roof

Figure 11: Shape of the sinusoidal base acceleration

#### 3.2 Modal and step by step time history analysis

An extended modal analysis of the numerical models was completed to define the predominant modes of them because the final design of the numerical model with RM is based on the modal characteristics, both the structural system and the RM. As has been mentioned above, at the first stage the predominant frequency of the frame structure without the RM was founded out. At the second stage the characteristics of the used springs and the those of the supports of the RM on the rigid beam were defined with the main scope the fundamental frequency of the RM to be equal to that of the frame system. Finally, the predominant modes of the frame system with the RM were estimated using SAP2000. The first two mode shapes of this model are presented in figure 12 giving also the corresponding values of frequencies. As can be seen, the 1st mode describes an in-phase response of the structural system with that of the RM with  $f_1=2.43\text{Hz}$  and the 2nd mode an out-of-phase response with  $f_2=3.45\text{Hz}$ .

After that, a step by step time history analysis of the structural system with RM was completed using as time history of the base acceleration the shape which was presented in figure 11 and for various values of frequencies and max. base accelerations. The results from two cases are presented in figures 13 & 14. In the first case (figure 13) the frequency excitation was equal to the fundamental frequency of the 1st mode,  $f_1=2.43\text{Hz}$ . The black line correspond to the base acceleration (excitation), the red one to the acceleration response of the frame system and the blue one to the acceleration response of the RM. As can be seen from this figure, there is in-phase response of the frame system with the RM however, the max. acceleration of the RM is much higher than that of the frame system. In the second case (figure 14) the frequency excitation was equal to the fundamental frequency of the 2nd mode,  $f_2=3.45\text{Hz}$ . In this case, out-of-phase response is occurred between the RM and the frame system but also in this case the max. acceleration of the RM is much higher than that of the frame system. All these observations are in a good agreement with those from the experimental investigation.

Figure 12: Mode shapes of 1st mode ( $f_1=2.43\text{Hz}$ ) and 2nd mode ( $f_2=3.45\text{Hz}$ ) of the structural model with RM

Figure 13: In-phase response - freq. ex.  $f_1=2.43\text{Hz}$

Figure 14: Out-of-phase response- freq. ex.  $f_1=3.45\text{Hz}$

### 3.3 Results for sweep analysis and correlation with experimental results

The numerical models of the frame structure with and without RM attached at the roof beam were subjected in a sweep analysis in a range of frequencies of excitation and constant max. base acceleration. The results from these analyses are summarized in figure 15 in normalized form (response acceleration / resonance max. acceleration response) together with the corresponding normalized results of the experimental model from the sweep tests. As can be seen from this figure there is a good agreement between numerical and experimental results. Some differences between the results of the two models are under investigation.

Figure 15: Correlation of numerical and experimental results

#### 4 CONCLUSIONS

Through the experimental and numerical investigation of this paper, the follow conclusions can be made:

- During the experimental investigation it was founded out that the Rolling Mass (RM) can be used in experimental models in order to reduce the resonance response.
- The reduction of the resonance response becomes higher when the mass ratio (mass of the RM / mass of the structure) is equal to 10% and the frequency of the rolling mass is equal to that of the structure.
- In phase and out-of-phase response of RM to that of the frame structure can develop but in both cases the response is much lower than that developed during resonant response of the structure without the RM.
- A good correlation was observed between numerical and experimental normalized results, therefore similar conclusions can be made also from the numerical investigation

### Abstract

*Many research efforts are continued nowadays around the world to validate numerical tools for masonry structures using at the same time results from experimental works. The present paper belongs in these efforts. At the first stage, this paper deals with the design of a simple masonry building in prototype scale (1:1) including earthquake resistance design. After that, the same structure was also designed in scale 1:10 in order to have the same distribution of stresses under vertical and earthquake loadings, the same level of tensile stresses gravity loadings at the critical zones and the same modes of vibrations under dynamic loadings. From this point of view, it was assumed that this model building in scale 1:10 can develop the same structural behavior with the corresponding prototype. Therefore, this model building in scale 1:10 was constructed and tested using the shaking table of Frederick University. During these tests, the acceleration of the base excitation and the acceleration response of the structure were recorded. Using these measurements from the case of 0.3g response acceleration, the max. dynamic loading of the model was estimated by multiply the response acceleration with the mass of the model. This load was applied to the numerical model with surface finite elements and structural analysis was completed. By the evaluation of the numerical results using Mohr-Coulomb failure criterion, the locations and the type of damages were specified which founded out in a good correlation with the observed damages during the experimental tests. Finally, the same cases of loadings were used for the structural analysis of the prototype structure as well the same procedure for the evaluation of the numerical results. These results developed by the prototype model are correlated with those from the numerical model of the experimental model and discussed.*

**Keywords:** Masonry, finite elements, shaking table, numerical simulations, failure criterion

## 1 INTRODUCTION

The protection of the ancient monuments and historical structures is in the main interest for more than 100 years. In order to protect them from bad and catastrophic interventions, international chapters and relevant codes have been adopted and they are in practice in various countries. The documentation of these structures, as the first stage of the works for their protection, includes the structural analysis of them under vertical, seismic and other cases of loadings with the main scope the assessment and evaluation of their existing capacity. At the second stage, one more structural analysis must be completed to examine their capacity for the suggested intervention scheme. However, it is well known that the majority of monumental and historical structures are masonry structures, consisted by stones or bricks which are arranged in various formations and connected with mortars. Therefore, the masonry is a synthetic and inhomogeneous material. In addition to that, the masonry can be characterized as orthotropic and brittle material. On the other hand, the masonry structures are consisted by 2D and 3D structural elements such as walls, piers, arches, vaults, cross vaults and domes having a global behavior during earthquakes much deferent than that of contemporary structures.

For all these reasons, the simulation and the structural analysis of masonry structures is a very complicated procedure. In the past, many techniques were suggested based on many assumptions and with many questions about the accuracy of the results from these methods. The same problems are existing also for the design of new masonry structures, as described by the EC6 (EN1996). The last 40 years, the used methods for the simulation and structural analysis of masonry structures are based on the Finite Element Method (FEM) utilizing computer software. At the first period the 2D models of structures were used simulating the structural elements with linear elements. Approximately, after 1990 the surface finite elements are the most common used elements for the simulation of masonry structures and more recently the solid elements.

However, many research efforts are continued nowadays around the world to validate numerical tools for masonry structures using at the same time results from experimental works. These works use various experimental methods for the testing of materials, masonry walls and models of masonry building structures studied and tested with compressive machines, lateral static or cycling loadings on a reaction frame and using a shaking table to produce dynamic and earthquake base excitations of studied models. In parallel to the experimental tests, various numerical techniques are used, utilizing software of finite elements to simulate the experimental models and study them under the same loading conditions such as those used during experimental investigation. Through this procedure and by the correlation of experimental and numerical results the numerical tools are calibrated and after that they are used for extended numerical and parametric investigations [1, 2, 3, 4].

Following the previous examples and for the same scope, an extended research effort has been established at the Laboratory of Mechanics of Frederick University including testing of materials, experimental tests on models of masonry structures and numerical simulations. The present paper, at the first stage, deals with the design, the construction and testing on the shaking table of a masonry model structure in scale 1:10 [5]. At the second stage numerical simulations and structural analyses of the experimental model was completed using various levels of seismic actions as recorded during the test. The results from structural analyses were evaluated using Mohr-Coulomb failure criterion and the estimated locations of failures are correlated with those observed during the experimental tests. At last, but not least, the same procedure of structural analysis was developed for the corresponding prototype structure (scale 1:1) and the results are correlated with those from the numerical model of the experimental model in scale 1:10 and discussed.

## 2 DESIGN AND CONSTRUCTION OF THE EXPERIMENTAL MODEL

### 2.1 Mechanical properties of the materials

A usual limestone for the construction of monumental and historical structures in Cyprus was used for the construction of the model structure. This stone belong to the Pachna Geological Formation (located at the Tochni area) and was supplied by the Tochni Quarries in units with dimensions of 0.04mx0.03mx0.02m as required for the construction of the model structure in scale 1:10. A lime/sand ratio 1:4 was used for the lime-mortar mixture that was used for bonding the bricks using the thin sand produced from crashing of the Tochni's stone. The dimensions of the timber used for the roof beams were 0.009mx0.019x0.45m.

An extended experimental sequence of tests was performed on the stones, mortar, masonry units and timber, in order to define the mechanical properties of these materials. Three compressive tests of model stone/brick were performed in order to find its compressive strength ( $f_{bc}$ ) and its modulus of elasticity ( $E$ ). Table 1 summarizes these tests for each specimen. The compressive strength of mortar was founded out  $f_{cm}=0.303\text{Mpa}$ . In addition, three compressive tests of masonry triplets were performed in order to find the compressive strength of masonry wall ( $f_{wc}$ ) and the modulus of elasticity ( $E$ ) (table 2). Apart from compressive tests, shear stress tests were also performed in order to identify the shear strength without compression ( $f_{ws}$ ) of the masonry wall (table 3). The masonry tensile strength ( $f_{wt}$ ) was assume to be equal to the shear strength. These properties were used for the simulation, structural analysis and evaluation of numerical results for both, the prototype building structure (scale 1:1) and the experimental model (scale 1:10).

STONE 4cm X 3cm X 2cm	$f_{bc}$ (MPa)	$E_b$ (MPa)

## 2.2 Design of the prototype masonry building in scale 1:1 and the experimental model in scale 1:10

At first stage a single storey masonry building was designed with dimensions of those of typical traditional houses as build before and until very early of the 20<sup>th</sup> century in Cyprus [5]. The architectural design of such houses was usually consisted by an open plan type of space with dimensions 4.0m x 7.0m and a height of approximately 3.0m. Two door openings with a width of 1.4m are presented at the center of the larger dimension of the plan, while the thickness of the masonry wall is 0.4m. The two opposite large walls are connected at the roof level with timber beams supporting a traditional horizontal roof system covered by soil materials. The structural and earthquake resistance design of this building was completed according to the provisions of EN-1996 (EC6) and EN-1998 (EC8) and the corresponding National Annexes of Cyprus [5]. For that, the same materials properties (stone, mortar, masonry & timber) as used for the construction of the experimental model in scale 1:10 were used.

After that, the same structure was also designed in scale 1:10 and constructed (fig. 1). As can be seen, additional masses were attached at the roof level according to basic rules for the design of experimental models in small scaling. Through this effort the final design of model structure was defined in order to have similar distribution of stresses under vertical and earthquake loadings, similar level of stresses at the critical areas and the similar shapes of the predominant modes of vibrations under dynamic loadings. From this point of view, it is assumed that this model building in scale 1:10 can develop the same structural behavior with the corresponding prototype. The correlation of the first three modes of the prototype structure (scale 1:1) and the model one in scale 1:10 are presented in figure 2. As can be seen there is a good agreement between the two models.

Figure 1: Drawings with the dimensions of the experimental model in scale 1:10

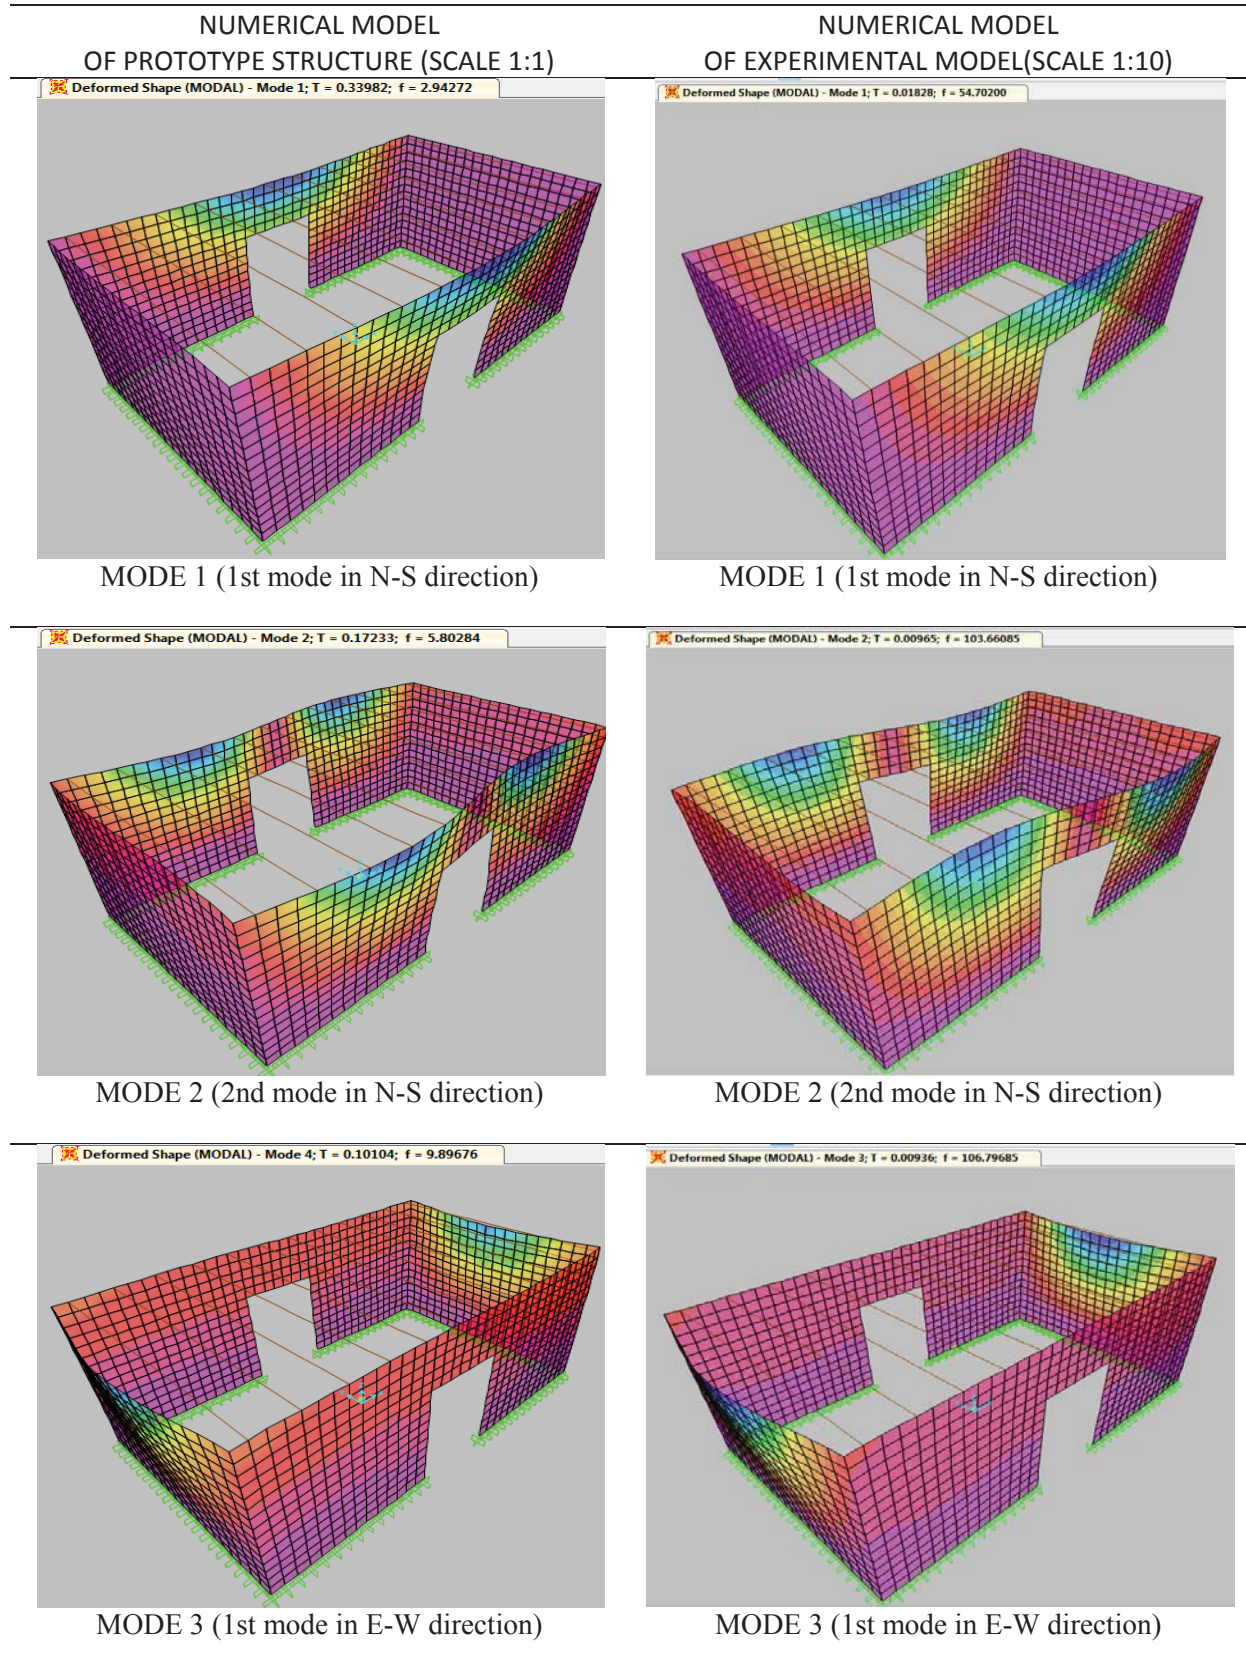

Figure 2: Correlation of the first three modes of the numerical models of the prototype structure (scale 1:1) and the experimental model (scale 1:10)

### 3 EXPERIMENTAL TESTS

#### 3.1 Experimental setup

The model structure was attached at the expanded platform of the shaking table of Frederick University which can move in one direction (E-W) (figure 3). Four accelerometers were used for the recording of the base excitation (CH. 1) and the response of the experimental model at the top of the masonry walls (CH.2, CH.3 and CH.4) (figure 4). One of them attached at the middle of the west wall (CH.2) and one at the middle of the north wall (CH.3). The last one (CH. 4) attached at the edge of the west wall. By the evaluation of the records from this accelerometer with the one from CH. 2, the possible torsional response or out of phase response of the model can be estimated. All these instruments were connected with the data acquisition system for the recording the signals from the excitation and the response of the model.

- CH3: Mid Top of North wall – (N-S)
- CH4: Edge of West Wall – (E-W)

Figure 4: Instrumentation of the experimental model

### 3.2 Sequence of the experimental tests

The main scope of this effort is to examine the behavior of the model structure under earthquake base excitations. However, at the present investigation, the model structure was tested in various other cases with the main scope to understand its behavior under dynamic loadings. Therefore, the experimental sequence includes:

- Impulse tests for the estimation of the dynamic properties (period and viscous damping) (figure 5). However after the evaluation of these results it was founded out much differences with those from numerical simulations due to the interaction of the system with the shaking table platform. Therefore, an extended sequence of tests are under progress.
- Sinusoidal base excitations in a various range of frequencies and amplitude of the excitations but in low level to avoid the occurrence of damages
- Random white noise base excitations in various levels in order to moderate the occurrence of damages (figure 6). During these tests, damages were occurred when the max. acceleration response in E-W direction was 0.3g.

Figure 5: Acceleration records from impulse test in N-S direction

Figure 6. Base acceleration during random white noise

### 3.3 Observed damages

As has been mentioned, during random white base excitations tests, the first damages were observed in masonry walls located in direction E-W. These damages can be divided in two groups. The first group includes cracks at the mortar joints close to the upper corners of the openings which are expanded in diagonal direction up to the roof level. The second group includes also cracks at the mortar joints at the bottom of the corners of the masonry walls (figures 7 & 8). As has been also mentioned in the previous paragraph, these cracks were observed when the max. acceleration response was 0.3g in E-W direction. However, maybe these cracks were created as micro cracks during previous lower level of acceleration response.

Figure 7: Observed diagonal cracks at the corner of the opening and at the bottom corner of the walls

Figure 8: Location of cracks on the facade of the experimental model

## 4 NUMERICAL SIMULATIONS AND STRUCTURAL ANALYSIS

### 4.1 Simulations of loadings and structural system

During the experimental tests it was founded out that the damages were observed when the max. response acceleration was 0.3g. The created loadings on the structural model were estimated through a simple method as explain in what follow (fig. 9). The horizontal seismic force ( $F$ ) at the top of the masonry walls was estimated by multiply the additional masses with the max. value of the recorded acceleration. This force is distributed as horizontal load at the timber beams ( $f_i$ ). The horizontal force from the additional masses creates also a bending moment at the top of the masonry walls ( $M$ ). The vertical loading from the additional masses ( $N$ ) is also distributed at the timber beams ( $N_i$ ) in combination with those created by the bending moment ( $N_{mi}$ ). In addition to that, horizontal loadings are created also on the masonry walls ( $f_{wi}$ ). All these loadings with the gravity load of the masonry wall were used for the study of a masonry wall in E-W direction under vertical loads and horizontal static loadings. A mesh with 2cmX2cm finite elements was used for the simulation of the masonry wall with the assumption of isotropic material using the software SAP200 (fig. 10).

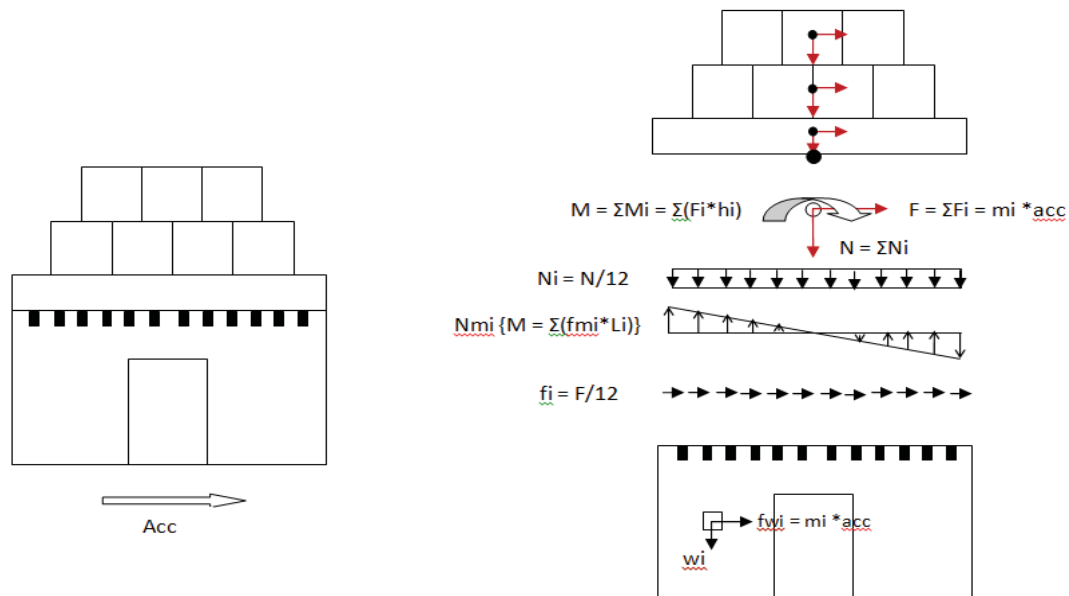

Figure 9. Estimation of the seismic loads

Figure 10. Numerical model under lateral seismic loadings

#### 4.2 Structural analysis and evaluation of the results of the experimental model

The vertical stresses (S22) (compression or tension) of the numerical model are shown in figure 11 as well the shear stresses (S12) in figure 12. From these figures, it can be seen that at the left bottom of the wall significant tensile stress is created however the compressive strength is in lower level in the opposite site. Exactly the opposite will be occurred if the lateral load is applied to the opposite direction. The results of the stresses (S22 & S1) from this analysis were evaluated using Mohr - Coulomb failure criterion ( $\tau$ -  $\sigma$ ). For the design of the envelope of the failure criterion the tensile, the shear and the compressive strength of masonry wall were used as defined from the experimental tests. This evaluation is presented in figure 13. Each point presents the corresponding results of the of shear (S12) and normal (S22) stresses of a joint of a finite element. The points which are in outside area of the failure criterion is mean that the corresponding joint of the finite element is failed. These finite elements are colored in the mesh (figure 13). By the correlation of this mesh with the figure 8 it can be said that the numerical results are in a good agreement with the locations and the type of the observed damages during the experimental test showing only tensile mode of failures.

Figure 11. Vertical normal stress (S22) due to vertical and horizontal seismic loadings

Figure 12. Shear stress (S12) due to vertical and horizontal seismic loadings

Figure 13. Mohr Column Criterion - Maximum base acceleration 0.3g

Figure 14. Evaluation of the numerical results with Mohr - Coulomb failure criterion and colored of the finite elements with failure of the experimental model (scale 1:10)

### 4.3 Structural analysis and evaluation of the results of the prototype structure

The same procedure for the simulation of the loadings and the structural system was applied also for the prototype structure defining the max. response acceleration 0.3g. However this system is without additional masses therefore the loadings due to the response acceleration are created only on the roof system and the masonry walls. Although the we have the same distribution of vertical normal stresses (S22) and shear stresses (S12), the max. values of these stress were founded much higher than those developed in the case of the experimental model. Also, for the evaluation of the numerical results the Mohr - Coulomb failure criterion was used with the main scope to find the location and the type of failures.

As can be seen in figure 14, the combination of vertical normal stresses (S22) with the shear stresses (S12) of more joints of the finite elements were founded to exceed the failure criterion. On the other hand, we can see that except of the exceed of the tensile stresses there is also a significant exceeding of the shear strength at the area with lower level of normal stresses which define cracks of the joint mortars. The joints of finite elements and the corresponding finite elements with exciding of the level of stresses defined by the envelope of the failure criterion are colored in the mesh (figure 14). By this figure we can see that the tensile failures on the numerical model of prototype structure are in a good agreement with those occurred on the numerical model of the experimental model. However, and in addition to that as have been mentioned above, shear failures are founded out especially in an horizontal line at the bottom of the wall which can be characterized as sliding mode failures, as well the initiation of diagonal cracks can be mentioned.

Figure 15. Evaluation of the numerical results with Mohr - Coulomb failure criterion and colored of the finite elements with failure of prototype structure (scale 1:1)

## 5 CONCLUSIONS

Through this effort, a simple masonry building (prototype building in scale 1:10) was designed and at the same time an experimental model building was designed and constructed in scale 1:10 of the prototype building. Specific rules were adopted for that focused on the modal analysis results, the distribution of stresses under vertical loadings and the level of the tensile stresses. The experimental model was subjected in various base excitations using the shaking table of Frederick University. However, before the design and the construction of the experimental model, the mechanical properties of the used materials (stone, mortar, masonry and timber) were defined through experimental tests. The scopes of this effort was:

Firsts, to validate the numerical results from the structural analysis of the experimental model with those from the experimental tests, focus on the correlation of the type and the location of the observed damages, using the Mohr - Coulomb failure criterion for the evaluation of the numerical results. which designed according to the mechanical properties of the used materials. From this point of view it was found out enough good correlation between the experimental and numerical results which both of them developed only bending modes of failures by the exceeding of the tensile strength.

Second, the numerical results of the experimental model (in scale 1:10) to be able to reproduce similar behavior of the prototype one (in scale 1:10), again focus on the observed location and type of damages. From this point of view it can be said that it was founded out differences between two numerical models. Although, in both of them were founded out tensile mode of failures at the same locations of the numerical models, the model of prototype structure developed also shear failures. Due to that, the quantity and the effectiveness of the additional masses applied to the experimental must be checked and resigned.

### Abstract

*The influence of passive mass dampers and base isolators on the vibratory motion of flexible beams with uniform cross-section, viewed as a special case of the non-uniform one, is examined herein for both axial and flexural vibrations. Use of such beams is widespread, both in a mechanical engineering setup (e.g., wind turbines, aircraft blades) as well as in a civil engineering setup (e.g. pylons, antennas). We start with an analytical solution to the governing equations of motion to recover the eigenproperties of a cantilevered pylon in the presence of a top mass and base springs. This is followed by the complete solution for the case of harmonic ground motion using modal analysis. Results are finally presented in term of transmissibility functions, defined as the ratio of the top pylon displacement amplitude to that of the base motion, so as to identify the frequency range where the presence of these external control devices is beneficial.*

---

## 1 INTRODUCTION

The kinematic and stress fields that develop in elastic beams are dependent on the material properties, the geometry and on the external loads. For dynamic loads, retaining a continuous distribution of the mass of the beam along its length yields an elastic waveguide [1,2] that can exhibit flexural, axial and torsional vibrations. Beams in flexure with a non-uniform cross-section are governed by a fourth order, linear partial differential equation (PDE) with variable coefficients, while for the other two modes of vibration the equations of motion are PDE of second order. It is also possible to have coupling between the axial and flexural vibrations, which requires solution of two coupled PDE. Furthermore, if a lumped mass is placed at the top of the beam, or if its foundation is elastic, then the boundary conditions change and are no longer homogeneous. These two additions modify the structural response of the beam and their presence can be viewed as a means of passive structural control. A discussion of the circumstances under which the effects of rotatory inertia and shear deformation must be considered, and whether or not coupling of flexural and axial vibrations is important, have been found elsewhere [3,4]. In general, for flexible pylons serving as part of power transmission lines and as telecommunication antennas, and for the frequency range of ambient vibrations generated by traffic, the aforementioned effects seem to be of minor importance. We note that this frequency range is roughly *20-200 Hz*, with flexural vibrations occurring in the lower part and axial vibrations in the higher part of the spectrum. On the other hand, the Bernoulli-Euler beam theory fails and has to be upgraded to Rayleigh's model with the rotatory inertia of the cross-section included in the equations of motion, for high vibration frequencies in excess of *500 Hz*.

The literature is rich in the solution of continuous beams under dynamic loads [5], but research interest remains strong, because these elements play a pivotal role in structural engineering (e.g., column elements) and in mechanical engineering (e.g., blades). In the interest of brevity, we simply mention here a recent paper [6] on an exhaustive analysis of wind turbines in an offshore environment under all three response modes (bending, compression, torsion) to a variety of environmentally-induced loads. From our perspective, the field of application of this work, which is continuation of a previous publication [4], is structural health monitoring (SHM). More specifically, modern advances in hardware have rendered possible the use of wireless sensors that send signals to a central processing unit, which in turn evaluates them to decide if the integrity of the structure in question has been compromised [7,8]. To stem the flow of large data over time, it is essential that these sensors be equipped with software based on reliable and efficient numerical models representing the structure in question. This way, computations can be carried out locally to produce results against which the recorded signals may be compared. This allows for a first evaluation of the recorded data, which can be discarded if it just shows a routine response of the structure to ambient vibrations. Furthermore, an SHM system can be placed within an artificial intelligence (AI) environment [9], which would serve to monitor the structural response in the absence of an overseer and give alert signals when it becomes evident that the structure in question is experiencing duress due to environmentally induced loads and needs to be inspected.

In here, we examine simple methods for passive vibration protection of a cantilevered pylon used as part of an electric transmission line for railways by formulating the equations of motion for flexural and axial vibrations. The pylon is then augmented with either of two elementary passive structural control devices, namely a lumped mass at the top and a base isolator in the form of springs at the base. The magnitude of the lumped mass has to be relatively small compared to the total mass of the pylon so as to serve as a secondary system [10] whose fixed-base natural frequency can be tuned with respect to the eigenfrequencies of the pylon.

## 2. MATHEMATICAL MODELS FOR NON-UNIFORM BEAMS

We will formulate the mathematical models for the tapered cantilevered pylon shown in Fig. 1, where placement of a lumped mass at the top and of springs at the base serve as rudimentary passive damping devices. Then, the uniform cross-section cantilevered pylon can be recovered as a special case. By considering in Fig. 1 the force and moment equilibrium of a differential segment  $dx$  under distributed longitudinal  $p(x, t)$  and transverse  $f(x, t)$  loads, we obtain the coupled governing equations of motion as

Figure 1. Cantilevered pylon with (a) ring cross-section of variable radius  $R$ ; (b) length  $L$  with added mass and springs at the ends and (c) the free body diagram.

$$\frac{\partial}{\partial x} \left( EA(x) \frac{\partial u(x, t)}{\partial x} \right) - \frac{\partial}{\partial x} \left[ Q(x, t) \frac{\partial w(x, t)}{\partial x} \right] - m(x) \frac{\partial^2 u(x, t)}{\partial t^2} = p(x, t) \quad (1a)$$

$$\frac{\partial^2}{\partial x^2} \left( EI(x) \frac{\partial^2 w(x, t)}{\partial x^2} \right) - \frac{\partial}{\partial x} \left[ N(x, t) \frac{\partial w(x, t)}{\partial x} \right] + m(x) \frac{\partial^2 w(x, t)}{\partial t^2} = f(x, t) \quad (1b)$$

In the above,  $u(x, t)$  and  $w(x, t)$  are the axial and transverse displacements, respectively and  $m(x)$  is the distributed mass. Next, the axial force, bending moment and shear force are defined as  $N = EA(x)(\partial u / \partial x)$ ,  $M = -EI(x)(\partial^2 w / \partial x^2)$  and  $Q = -E \frac{\partial}{\partial x} (I(x) \partial w^2 / \partial x^2)$ .

Initial conditions are assumed to be zero, and three sets of boundary conditions are considered, which respectively address the fixed base case, the fixed base case with a lumped mass at the top, and the base isolated case:

$$M(a, t) = Q(a, t) = N(a, t) = 0 \text{ and } w(b, t) = \partial w(b, t) / \partial x = u(b, t) = 0 \quad (2a)$$

$$M(a, t) = 0, Q(a, t) = M_L \ddot{w}(a, t), N(a, t) = M_L \ddot{u}(a, t) \text{ and } w(b, t) = \partial w(b, t) / \partial x = u(b, t) = 0 \quad (2b)$$

$$M(a, t) = Q(a, t) = N(a, t) = 0 \text{ and } M(b, t) = -K_\theta \partial w(b, t) / \partial x, Q(b, t) = -K_Y w(b, t), N(b, t) = -K_X u(b, t) \quad (2c)$$

In the above,  $x = a$  is the top and  $x = b$  is the base of the cantilevered pylon with length  $L = b - a$ . The lumped mass  $M_L$  placed at the top influences both axial and flexural vibrations, whereas the base springs  $K_X, K_Y, K_\theta$  respectively influence the longitudinal motion, the transverse motion and the base rotation.

## 2.1 Harmonic vibrations

By ignoring the coupling terms  $\frac{\partial}{\partial x} \left[ Q \frac{\partial w}{\partial x} \right]$  and  $\frac{\partial}{\partial x} \left[ N \frac{\partial w}{\partial x} \right]$  for the range of frequencies considered in here, and by differentiating the variable stiffness terms, we recover the following equations:

$$EA(x)u'' + \left[ \frac{\partial EA(x)}{\partial x} \right] u' - m(x)\ddot{u} = -p(x, t) \quad (3a)$$

$$EI(x)w'''' + 2 \left[ \frac{\partial EI(x)}{\partial x} \right] w''' + \left[ \frac{\partial^2 EI(x)}{\partial x^2} \right] w'' + m(x)\ddot{w} = f(x, t) \quad (3b)$$

In the above,  $EA(x)$  and  $EI(x)$  are the aggregate axial and flexural stiffness that varies along the pylon length  $a \leq x \leq b$ . The notation introduced now involves primes (') and dots (·) to denote differentiation with respect to the spatial coordinate  $x$  and time  $t$ .

We now consider a slender, circular cylindrical pylon with a cross-section in the form of an annulus of constant thickness  $d$  and variable radius  $R(x)$ , which is a rather common design for pylons. The reference radius is the mean radius of the cross-section defined as  $R = R_{ext} - d/2$ , where  $R_{ext}$  is the external radius, see Fig. 1. For small thickness  $d$ , the cross-section area, moment of inertia and polar moment of inertia are closely approximated as  $A = 2\pi dR$ ,  $I = \pi R^3 d$ ,  $J = 2I$ , while the mass per unit length is  $m = \rho A$ . We adopt a general representation of a radius that changes quadratically with height, i.e.  $R(x) = R_a \cdot (x/a)^2$ , with  $R_a$  the mean radius at the top. Then, the following expressions for the pylon stiffness and mass are recovered:

$$EA(x) = (EA)_0 \left( \frac{x}{a} \right)^2, \quad EI(x) = (EI)_0 \left( \frac{x}{a} \right)^6, \quad m(x) = m_0 \left( \frac{x}{a} \right)^2 \quad (4)$$

where  $(EA)_0, (EI)_0, m_0$  are reference values computed at the top, i.e. for  $R(x = a) = R_a$ . Note that it is possible to handle material properties that are also position dependent, so long as the aggregate stiffness and mass values obey Eq. (4). We finally note in passing that torsional vibrations are of minor importance as ambient ground vibrations are unlikely to elicit torsion at the base of the shaft.

Assuming a time harmonic environment, the input and the response can be written in terms of position dependent amplitudes times the exponential term  $\exp(i\omega t)$ ,  $i = \sqrt{-1}$ , where  $\omega$  (rad/s) is the frequency of vibration. Therefore, the dependent variables are now the amplitudes of the axial and flexural vibration  $W(x), U(x)$  and we also define the corresponding amplitude of the external distributed forces as  $F(x), P(x)$ . The governing equations for harmonic motion are now

$$[x^2 U'' + 2x U'] + \omega^2 m_0 \left( \frac{x}{a} \right)^2 \frac{a^2}{(EA)_0} U = - \frac{a^2}{(EA)_0} \cdot P(x) \quad (5a)$$

$$[x^6 W'''' + 12x^5 W''' + 30x^4 W''] - \omega^2 m_0 \left( \frac{x}{a} \right)^2 \frac{a^6}{(EI)_0} W = \frac{a^6}{(EI)_0} \cdot F(x) \quad (5b)$$

which respectively are a Bessel equation of fractional order for the axial motion and Euler's equation for the flexural motion.

### 3. SOLUTIONS FOR LONGITUDINAL AND TRANSVERSE VIBRATIONS

To recover analytical solutions to the above equations, we first derive the homogeneous solution and then solve for the eigenvalue problem to recover the eigenproperties of the pylon, first for axial and then for flexural vibrations. The general form of the homogeneous solutions to Eq. (5) in the frequency domain are

$$U(x) = x^{-\frac{1}{2}} \cdot \{A_1 J_{(-\frac{1}{2})}(\alpha x) + A_2 J_{(+\frac{1}{2})}(\alpha x)\}, \quad x > 0 \quad (6a)$$

$$W(x) = B_1 |x|^{r_1} + B_2 |x|^{r_2} + B_3 |x|^{r_3} + B_4 |x|^{r_4} \quad (6b)$$

In the above,  $J_{(q)}$  are the Bessel functions of first kind and fractional order  $q$ , while exponents  $r_i$ ,  $i = 1, 4$  are non-repeated complex numbers. Also,  $A_i, B_i$  are constants of integration to be determined from the boundary conditions.

For flexural vibrations, Euler's equation (5b) requires a preliminary transformation of variables as  $x = e^y$ ,  $y = \ln(x)$  to convert it into a differential equation with constant coefficients. The characteristic polynomial for this differential equation that must be solved for determining the exponents  $r_i$  is  $r^4 + 6r^3 + 5r^2 - 12r - \beta^4 = 0$ . Solution to the aforementioned quartic polynomial yields complex roots in the form  $B_j x^{r_j} = B_j x^{a_j + i b_j} = B_j x^{a_j} \{\cos(b_j x) + i \sin(b_j x)\}$ ,  $i = \sqrt{-1}$ . In our case,

$$\begin{aligned} r_1 &= -\frac{3}{2} + \frac{\sqrt{(17 + 4\sqrt{(4 + \beta^4)})}}{2}, r_2 = -\frac{3}{2} - \frac{\sqrt{(17 + 4\sqrt{(4 + \beta^4)})}}{2} \\ r_3 &= -\frac{3}{2} + i \frac{\sqrt{(4\sqrt{(4 + \beta^4)} - 17)}}{2}, r_4 = -\frac{3}{2} - i \frac{\sqrt{(4\sqrt{(4 + \beta^4)} - 17)}}{2} \end{aligned}$$

with  $W(\xi) =$

$$= \xi^{-\frac{3}{2}} \left( B_1 \xi^{\frac{\sqrt{(k+17)}}{2}} + B_2 \xi^{-\frac{\sqrt{(k+17)}}{2}} + B_3 \sin\left(\frac{\sqrt{(k-17)}}{2} \ln \xi\right) + B_4 \cos\left(\frac{\sqrt{(k-17)}}{2} \ln \xi\right) \right) \quad (7)$$

where  $k = 4\sqrt{(\beta^4 + 4)}$  and for a dimensionless spatial parameter  $\xi \in [1, b/a]$ .

We adopt the Kelvin solid model with a complex elasticity modulus in the form  $E^* = E(1 + i\delta)$ ,  $\delta = \eta\omega/2E$ , where  $E$  is the original real-valued elasticity modulus and  $\eta$  is a constant in the viscoelastic stress-strain law. For concrete, the dimensionless damping coefficient  $\delta$  values have been experimentally determined to range as 1% – 5%, values which respectively correspond to pre-stressed and to weathered concrete. This complex number representation of the elastic modulus filters into the pressure and shear wave speeds  $c_p, c_s$ , and into the wave numbers for axial and flexural vibrations.

If tapering is ignored and the pylon cross-section is uniform with radius  $R_a$ , then the above homogeneous solutions reduce to

$$U(x) = A_1 \cos(\alpha x) + A_2 \sin(\alpha x), \alpha^2 = \omega^2/c_p^2 \quad (8a)$$

$$W(x) = B_1 \cos(\beta x) + B_2 \sin(\beta x) + B_3 \cosh(\beta x) + B_4 \sinh(\beta x), \beta^4 = \omega^2 \frac{\rho A_0}{EI_0} \quad (8b)$$

### 3.1 The eigenvalue problem

The eigenvalue problem derives from imposing homogeneous boundary conditions, see Eq. (2a). The boundary conditions corresponding to the lumped mass and the elastic springs can be rendered homogeneous as well, leading to a more complicated solution for the eigenfunctions  $\Phi_n(x), n = 1, 2, \dots, \infty$ . The corresponding eigenvalues  $f_n$  (Hz) are recovered during this process by solving for the roots of a transcendental equation. More specifically, the solutions given in Eq. (6a) for axial vibrations and in Eq. (7) for flexural vibrations can be respectively recast in matrix form as

$$[G(\omega)][A] = \{0\}, [H(\omega)][B] = \{0\} \quad (9)$$

respectively, with the former matrix size being  $2 \times 2$  and the latter being  $4 \times 4$ . These matrices respectively contain Bessel functions and trigonometric functions evaluated at the two ends  $x = a, b$  of the pylon. By setting the matrix determinants equal to zero and solving for the roots of resulting transcendental equations using the Newton-Raphson method, the eigenvalues of the pylon are recovered. Finally, the eigenfunctions are evaluated starting with a back-substitution of the eigenvalues in Eq. (9) and usually setting one of the coefficients of the vectors  $\{A\}, \{B\}$  equal to one.

### 3.2 External loads

When external loads are present, one can opt to either employ modal analysis or to find a particular solution for the right-hand sides (RHS) of Eq. (5) corresponding to time harmonic forces, in which case the complete solution is the addition of the homogeneous and particular parts. For ambient vibrations in the form of ground motion, a complication arises due to the fact that one must distinguish between the displacement of the cantilever relative to its base, and its total displacement which is the addition of both. The generic form of ground motion, be it in the vertical or horizontal directions, is  $x_g(t) = x_{go} \exp(i\Omega t)$ , where  $X_{go}(m)$  is a mean value for the ground displacements and  $\Omega$  (rad/s) is the frequency of vibration. Assuming  $U, W$  are relative to the base, then the RHS of Eq. (1) are  $f(x, t) = p(x, t) = m(x) \cdot \Omega^2 \cdot x_{go} \cdot \exp(i\Omega t)$ . Two frequency ranges are relevant to the pylons considered here due to the passage of high speed trains: (i) High frequency base accelerations in the vertical direction in the range  $f = \Omega/2\pi = 100 - 200$  Hz that result from the train's wheels running across rails that have minor imperfections and (ii) low frequency base accelerations in the horizontal direction in the range  $f = 20 - 40$  Hz as the train moves rapidly and generates forward travelling elastic waves in the soil.

### 3.3 Mass dampers and base springs

If the pylon has a lumped mass  $M_L$  at the top, one boundary condition for each of the axial and flexural vibrations involves the acceleration at  $x = a$ . In a steady-state environment, these acceleration amplitudes are  $-\omega^2 U(x), -\omega^2 W(x)$ , to which the amplitude of the base acceleration  $\Omega^2 \cdot x_{go}$  must be added. This still allows for a reformulation of the boundary conditions of Eq. (2b) in the homogeneous form specified by Eq. (9). The boundary conditions of Eq. (2c) involving the base isolation springs  $K_X, K_Y, K_\theta$  are simpler to implement because they involve relative displacements. For the flexural vibration case, each of the translational and rotational springs are examined separately. Since the eigenvalue formulation matrix equations resulting from the imposition of the boundary conditions are complex, there is some economy in computation to be gained if their inversion is carried out in closed form. This is trivial for the  $2 \times 2$  matrix  $G(\omega)$  that yields constants  $A_1, A_2$ . It becomes more involved

for the  $4 \times 4$  matrix  $H(\omega)$  that yields constants  $B_1, B_2, B_3, B_4$ , and we give as example in the Appendix the transcendental equation that yields the flexural eigenfrequencies for a lumped mass  $M_T$  at the top of the pylon.

#### 4. EIGENPROPERTIES OF PYLONS WITH PASSIVE CONTROL DEVICES

Following the modal analysis approach previously discussed, we will focus on pylons with a uniform cross-section, as being the more general reference case.

##### 4.1 Longitudinal vibrations

The transient axial displacement for the damped catilevered pylon is as follows:

$$u(x, t) = \{\sum_{n=1}^{\infty} b_n^* \Phi_n(x)\} \cdot (e^{i\omega t}) \quad (10a)$$

$$b_n^* = x_{g0} z^{*2} \cdot \int_0^L \Phi_n(x) dx / \{(k_n^2 - z^{*2}) \int_0^L \Phi_n^2(x) dx\} \quad (10b)$$

In the above, summation is over all  $n = 1, 2, \dots \infty$  eigenmodes, while complex coefficient  $z^*$  has real and imaginary parts given by

$$Re(z^*) = \omega \sqrt{\frac{\rho}{E}} \frac{1}{D} \sqrt{\frac{D+1}{2}}, \quad Im(z^*) = -\omega \sqrt{\frac{\rho}{E}} \frac{1}{D} \sqrt{\frac{D-1}{2}} \quad (11)$$

with  $D = (1 + \delta^2)$ . The eigenfunction is defined in the interval  $0 \leq x \leq L$  as  $\Phi_n(x) = \cos(k_n x)$ .

If a lumped mass  $M_L = R_M M_T$  is placed at the top of the pylon, the axial displacement is

$$u(x, t) = \{\sum_{n=1}^{\infty} b_n^* \Phi_n(x) + ax\} \cdot (e^{i\omega t}) \quad (12a)$$

$$b_n^* = x_{g0} z^{*2} \cdot \{\int_0^L \Phi_n(x) dx + a \int_0^L x \Phi_n(x) dx\} / \{(k_n^2 - z^{*2}) \int_0^L \Phi_n^2(x) dx\} \quad (12b)$$

with coefficient  $a = \frac{x_{g0}/L}{\{(\Gamma^2/\omega^2) - 1\}}$ ,  $\Gamma^2 = \frac{E^*}{\rho R_M L^2}$  and complex coefficient  $z^*$  given by Eq. (11).

##### 4.2 Transverse vibrations

As in the above, reconstitution of the transverse displacement using modal analysis for the damped, flexible pylon with uniform cross-section is given as

$$w(x, t) = \{\sum_{n=1}^{\infty} b_n^* \Phi_n(x)\} e^{i\omega t}, \quad b_n^* = \frac{x_{g0} z^{*4} \int_0^L \Phi_n(x) dx}{(k_n^4 - z^{*4}) \int_0^L \Phi_n^2(x) dx} \quad (13)$$

with the real and imaginary parts of the complex coefficient  $z^*$  given as

$$Re(z^*) = \sqrt{\frac{\omega}{r}} \sqrt[4]{\frac{\rho}{E}} \sqrt{\frac{1}{2\sqrt{D}} + \frac{\sqrt{D+1}}{2\sqrt{2}D}}, \quad Im(z^*) = -\sqrt{\frac{\omega}{r}} \sqrt[4]{\frac{\rho}{E}} \sqrt{\frac{1}{2\sqrt{D}} - \frac{\sqrt{D+1}}{2\sqrt{2}D}} \quad (14)$$

and where  $r = \sqrt{I/A}$  is the radius of gyration of the cross-section. The general form of the eigenfunctions is

$$\Phi_n(x) = \sin(k_n x) + \sinh(k_n x) + C_n \cdot (\cos(k_n x) + \cosh(k_n x)) \quad (15)$$

When a horizontal base spring  $K_Y$  is placed at the pylon's base, then constants  $C_n$  appearing in the eigenfunctions are given below as

$$C_n = \frac{\sin(k_n L) + \sinh(k_n L) - (EI/K_Y) \cdot k_n^3 \cdot (-\cos(k_n L) + \cosh(k_n L))}{-(\cos(k_n L) + \cosh(k_n L)) + (EI/K_Y) \cdot k_n^3 \cdot (\sin(k_n L) + \sinh(k_n L))} \quad (16)$$

Next, when a rotational spring  $K_\theta$  is placed at the base, the new constants  $C_n$  are now

$$C_n = \frac{\cos(k_n L) + \cosh(k_n L) + (EI/K_\theta) \cdot k_n \cdot (-\sin(k_n L) + \sinh(k_n L))}{-(-\sin(k_n L) + \sinh(k_n L)) - (EI/K_\theta) \cdot k_n \cdot (-\cos(k_n L) + \cosh(k_n L))} \quad (17)$$

## 5. NUMERICAL STUDIES FOR A FLEXIBLE PYLON

The aim here is to derive transmissibility ( $TR$ ) functions for both axial and flexural vibrations of a cantilevered pylon serving as part of the network for electrified railway lines. The pylon material is pre-stressed concrete, and the relevant geometric and mechanical properties are given in Table 1 below, including  $M_T$ , the total mass of the pylon. All subsequent computations were carried out in a Python programming environment [11], where computation times did not exceed **8 sec** for the  $TR$  functions that follow, which are parametric in the mass ratio  $R_M = M_L/M_T$  and in the spring  $K_X, K_Y, K_\theta$  constants.

$a$ (m)	$b$ (m)	$d$ (m)	$R(a)$ (m)	$R(b)$ (m)
39.5	49.5	0.0875	0.215	0.3375

$E$ (kPa)	$\rho$ (tn/m <sup>3</sup> )	$m_0$ (tn/m)	$M_T$ (tn)	$\delta$ (%)
$44.4 \cdot 10^6$	2.55	0.301	3.84	5.0

Table 1: Properties of the pre-stressed R/C cantilevered pylon

### 5.1 Preliminary calculations

We define an equivalent, uniform cantilevered pylon that has a constant cross-section defined by the base radius  $R(b)$  through-out its height. This is simply done for comparison purposes with the tapered one, and Table 2 lists the first three axial and flexural eigenfrequencies for both types of pylons. We observe that the difference in the first fundamental frequency of the pylon is in the neighborhood of **5%** between the tapered and the uniform cross-section variants. Further such comparison studies can be found in Ref. [4].

Pylon type	$f_1$ (Hz) axial	$f_2$ (Hz) axial	$f_3$ (Hz) axial	$f_1$ (Hz) flexural	$f_2$ (Hz) flexural	$f_3$ (Hz) flexural
Uniform	104.3	312.9	521.6	5.57	34.92	97.78
Tapered	114.0	316.5	523.7	5.84	30.47	80.85

Table 2: Comparison of the eigenvalues between R/C pylon uniform and tapered cross section.

### 5.2 The eigenvalue problem for a base-isolated pylon with a uniform cross-section

For illustrative purposes, Fig. 2 below shows the pylon's first three flexural eigenmodes for the case of a translational spring  $K_Y$  whose value increases so that in Fig. 2(c) the fixed-base pylon case is recovered.

(a)

(b)

(c)

Figure 2: First three eigenfrequencies and eigenfuntions of a flexible pylon under transverse vibrations as a function of the translational base spring magnitude: (a) Soft spring,  $K_Y=500$  kN/m, (b) intermediate spring,  $K_Y=5,000$  kN/m and (c) stiff spring  $K_Y=50,000$  kN/m.

Also, Fig. 3 is a convergence study on how the first three flexural eigenfrequencies of the base isolated pylon converge to the values for the fixed-base case as the magnitude of the translational and rotational base springs increases

Figure 3: Convergence study on the first three flexural eigenfrequencies of the base-isolated pylon as a function of spring stiffness: (a) translational spring  $K_Y$  and (b) rotational spring  $K_\Theta$ . Note: The dotted red line is for the fixed-base pylon.

### 5.3 Transmissibility functions for longitudinal vibrations

We next proceed to recover  $TR$  functions for the reference case of the equivalent uniform pylon, keeping in mind that tapering basically acts as a perturbation of the first eigenfrequencies of an equivalent pylon with a uniform cross-section. Since the eigenfrequencies of pylons are widely spaced, we resort to  $\log\text{-}\log$  plots. Starting with Fig. 4, we observe that until the first axial eigenfrequency is reached, the presence of the lumped mass at the top is of minor

consequence, but still somewhat detrimental. However, as the frequency continues to go up, the lumped mass starts actively reducing the motion by as much as an order of magnitude, and even a small mass of 10% of  $M_T$  is effective. Note here the emergence of a new eigenfrequency, otherwise absent when there is no top mass. The situation with the vertical base spring is quite different, because at low frequencies, below the first eigenfrequency, we have substantial decrease in the  $TR$  values as compared to the fixed base, which roughly corresponds to the spring with the largest values, namely  $K_X=5 \cdot 10^6 \text{ kN/m}$ . As the frequency goes up, the  $TR$  exhibit minor fluctuations but the motion de-amplification is still substantial.

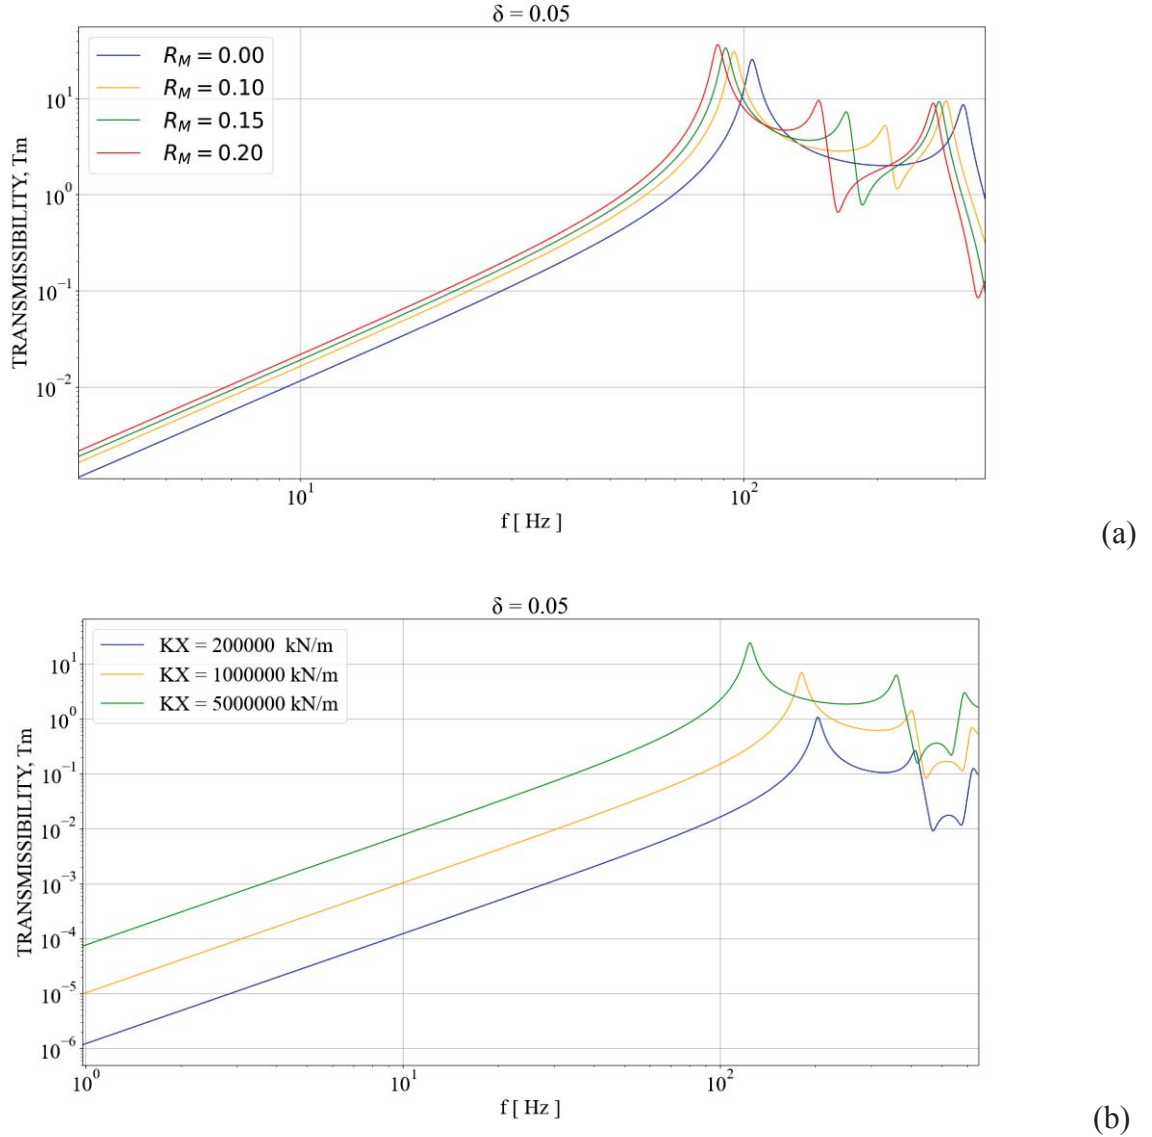

Figure 4: Transmissibility functions  $TR$  between top and ground displacement amplitudes versus frequency  $f$  for longitudinal pylon vibrations under a normalized sinusoidal ground acceleration input and for a damping  $\delta$  value of 5% as a function of: (a) mass ratio  $R_M=M_L/M_T$ ; (b) vertical base spring  $K_X$  values.

#### 5.4 Transmissibility functions for transverse vibrations

We continue with Fig. 5 for flexural vibrations, where the  $TR$  functions for the base isolation springs present a rather complicated situation. Assuming that the highest spring values

approach the fixed-base case, then base isolation springs are ineffective at low frequencies, i.e. those below the first flexural eigenfrequency. As we move past that value, only the horizontal spring is effective in producing de-amplification of motion. Finally, the rotational spring remains ineffective at both the low and high ends of the frequency spectrum, where it shifts the fixed-base dominant eigenfrequency to lower values. It is effective only when the external frequency of vibration approaches a narrow frequency range around the fixed-base pylon eigenfrequencies.

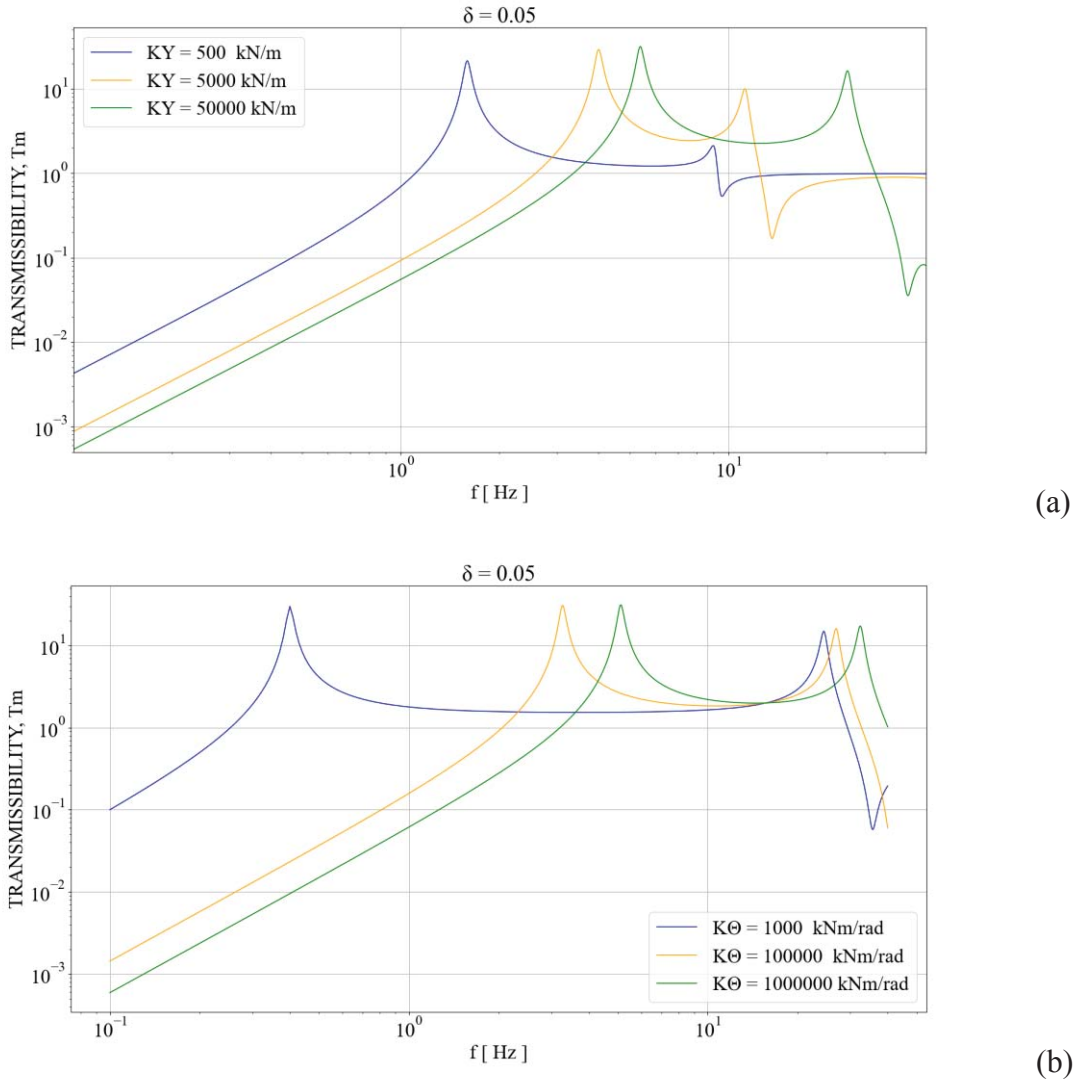

Figure 5: Figure 4: Transmissibility functions  $TR$  between top and ground displacement amplitudes versus frequency  $f$  for transverse pylon vibrations under a normalized sinusoidal ground acceleration input and for a damping  $\delta$  value of 5% as a function of: (a) horizontal base spring  $K_Y$  values and (b) rotational base spring  $K_\Theta$  values.

## 6. CONCLUSIONS

In this work, we have derived solutions for the transmission of motion between the top and base of a cantilevered pylon, to which either a lumped mass is attached at the top or springs are inserted at the base for the purpose of acting as passive control devices. Of course, it may be that a lumped mass is already attached to the pylon, as would for lighting devices, cable

supports, signal transmission apparatus, etc., which implies that the results generated here are still applicable. The same holds true if the pylon is founded on soft soil, in which case we have soil-structure-interaction phenomena and the ground is replaced by an equivalent set of springs.

For a typical R/C pylon used in electric rail lines, with vibrations induced by passing trains in both the vertical direction and on the horizontal plane, the presence of the lumped mass at the top of the pylon is beneficial in the high frequency range, where we see an amplitude reduction in the pylon displacements. Conversely, in the low frequency range as compared to the pylon fundamental eigenfrequency, the presence of a lumped mass ranges is of minor significance and may even be detrimental. Similar conclusions can be drawn in reference to the presence of base isolation springs that become effective in the higher frequency range. In the low frequency range, however, their presence is detrimental, as they result in an increase in amplitude at the top for transverse vibrations, but beneficial for longitudinal vibrations.

The presence of a lumped mass and of base isolation springs becomes important when viewed in terms of SHM, because these passive damping mechanisms can be upgraded to a semi-active status [9]. For instance, it may be possible to allow for the lumped mass to fluctuate as the pylon structural vibrations unfold with time, provided a suitable mechanism can be added for this purpose. In addition, there would have to be a control algorithm, as for instance a predictor-corrector method that computes the imminent displacement at the top of the pylon and energizes the mechanism if this displacement exceeds a prescribed limit. A similar situation can be envisaged for the case of a base isolation mechanism. In both cases, the use of control algorithms pre-supposes the existence of robust and efficient structural analysis capabilities, as would be the case for the analytical solutions presented herein.

## APPENDIX

We derive here the transcendental equation for flexural vibrations of a tapered pylon with a lumped mass  $M_L$  at the top, whose numerical solution by the Newton-Raphson method yields the eigenfrequencies. This derivation assumes that this mass is activated by the relative transverse motion  $w(x, t)$  of the pylon, which is the case that appears often in the literature. We should note, however, that the mass is influenced by the total motion that includes the base motion  $x_g(t)$ . Finally, recovery of the first three eigenmodes is usually deemed sufficient for any subsequent dynamic analysis. More specifically, we start with the shear force boundary condition

$$Q(a, t) = M_L \ddot{w}(a, t) \Rightarrow -EI'(a)w''(a, t) - EI(a)w'''(a, t) = M_L \ddot{w}(a, t)$$

We follow with a substitution for  $w(x, t)$  in terms of the generalized coordinates  $q(t)$  and the eigenfunctions  $\Phi(x)$ :

$$-EI'(a)W'''(a)q(t) - EI(a)W''''(a)q(t) = M_L W(a)\ddot{q}(t)$$

However, the generalized coordinates obey the single degree-of-freedom equation as

$$\ddot{q}(t) + \omega^2 q(t) = 0 \Rightarrow \ddot{q}(t) = -\omega^2 q(t)$$

Since the bending moment at the pylon's top is zero, we have that  $M(a) = 0 \Rightarrow \Phi''(a) = 0$ . Manipulation of the boundary condition equation yields

$$-EI(a)W''''(a)q(t) = M_L W(a)\ddot{q}(t) = M_L W(a)(-\omega^2)q(t) \Rightarrow EI(a)W''''(a) = M_L W(a)\omega^2$$

Next, we use the dimensionless length  $\xi = \frac{x}{a}$ ,  $\xi \in [1, b/a]$  and of moment of inertia of the tapered pylon  $I = I_0(x/a)^6 = I_0 \xi^6$  to recover the following equation:

$$EI_0 \Phi''''(1)/a^3 = M_L W(1)\omega^2 \quad (\text{A.1})$$

The total mass of the pylon  $M_T$  is then computed as

$$M_T = \int_{x=a}^{x=b} \rho \, 2\pi d R_O \left(\frac{x}{a}\right)^2 dx = \int_{\xi=b/a}^{\xi=1} \rho \, 2\pi d R_O \xi^2 a d\xi = (2\pi R_O d) \frac{a}{3} \rho \left(\frac{b^3}{a^3} - 1\right) = A_O \frac{a}{3} \rho \left(\frac{b^3}{a^3} - 1\right) = \rho A_O \Lambda, \text{ where } \Lambda = \frac{a}{3} \left(\frac{b^3}{a^3} - 1\right), R = \frac{M_L}{M_T}, \text{ and } \beta^4 = \frac{\rho A_O a^4}{EI_O} \omega^2.$$

By inserting the above expressions in Eq. (A.1) we recover that

$$-\left(\frac{M_L}{\rho A_O \Lambda}\right) \left(\frac{\omega^2 \rho A_O a^4}{EI_O}\right) \frac{\Lambda}{a} W(1) + W''''(1) = -R \cdot \beta^4 \cdot \left(\frac{\Lambda}{a}\right) \cdot W(1) + W''''(1) = 0$$

We now introduce the homogeneous solution for flexural vibrations as

$$W(\xi) = \xi^{-\frac{3}{2}} \left\{ B_1 \xi^{\frac{\sqrt{(k+17)}}{2}} + B_2 \xi^{-\frac{\sqrt{(k+17)}}{2}} + B_3 \sin\left(\frac{\sqrt{(k-17)}}{2} \ln \xi\right) + B_4 \cos\left(\frac{\sqrt{(k-17)}}{2} \ln \xi\right) \right\}$$

where  $k = 4\sqrt{(\beta^4 + 4)}$ . Now we can define the following quantities:

$$A_1(\xi) = \xi^{-\frac{3}{2}} \xi^{\frac{\sqrt{(k+17)}}{2}}, A_2(\xi) = \xi^{-\frac{3}{2}} \xi^{-\frac{\sqrt{(k+17)}}{2}}, \\ A_3(\xi) = \xi^{-\frac{3}{2}} \sin\left\{\frac{\sqrt{(k-17)}}{2} \ln(\xi)\right\}, A_4(\xi) = \xi^{-\frac{3}{2}} \cos\left\{\frac{\sqrt{(k-17)}}{2} \ln(\xi)\right\}$$

The full set of boundary conditions for the lumped mass at the top is

$$W(b/a) = 0, W'(b/a) = 0, W''(1) = 0, -R \cdot \beta^4 \cdot \Lambda \cdot a^{-1} \cdot W(1) + W''''(1) = 0$$

Finally, to recover the wave numbers, the determinant of the  $4 \times 4$  matrix is set equal to zero:

$$\det = \begin{bmatrix} \alpha_1 & \alpha_2 & \alpha_3 & \alpha_4 \\ \beta_1 & \beta_2 & \beta_3 & \beta_4 \\ \gamma_1 & \gamma_2 & \gamma_3 & \gamma_4 \\ \delta_1 & \delta_2 & \delta_3 & \delta_4 \end{bmatrix} = 0 \quad (\text{A.2})$$

The matrix terms appearing in Eq. (A.2) are as follows:

$$\alpha_1 = A_1(b/a), \alpha_2 = A_2(b/a), \alpha_3 = A_3(b/a), \alpha_4 = A_4(b/a) \\ \beta_1 = A_1'(b/a), \beta_2 = A_2'(b/a), \beta_3 = A_3'(b/a), \beta_4 = A_4'(b/a) \\ \gamma_1 = A_1''(1), \gamma_2 = A_2''(1), \gamma_3 = A_3''(1), \gamma_4 = A_4''(1) \\ \delta_1 = -R \left(\frac{k^2}{16} - 4\right) \cdot \left(\frac{\Lambda}{a}\right) A_1(1) + A_1''''(1), \delta_2 = -R \left(\frac{k^2}{16} - 4\right) \cdot \left(\frac{\Lambda}{a}\right) A_2(1) + A_2''''(1) \\ \delta_3 = -R \left(\frac{k^2}{16} - 4\right) \cdot \left(\frac{\Lambda}{a}\right) A_3(1) + A_3''''(1), \delta_4 = -R \left(\frac{k^2}{16} - 4\right) \cdot \left(\frac{\Lambda}{a}\right) A_4(1) + A_4''''(1)$$

## PSEUDO-DYNAMIC ANALYSES OF INFILLED REINFORCED CONCRETE FRAMED STRUCTURES WITH PRIOR DAMAGES AFTER ADVANCED RETROFIT

### Abstract

*This study investigates suitable models for the analysis of innovative retrofits in infilled (and bare) reinforced concrete frames. It focuses on the detrimental effects of prior damages and deficiencies in frames such as corroded steel reinforcements or inadequate lap-splices in columns that may lead to premature failures and structural collapses. It investigates numerically the beneficial effects of innovative interventions on deficient RC frames, through pseudo-dynamic 3-dimensional finite element analyses. The intervention involves infill wall with special thermal insulating clay brick orthoblocks, having at the boundary interface with the RC frame, an advanced seismic joint made of highly deformable polyurethane. The technique has been already validated experimentally in frames without corroded or lap-spliced bars [1] (as well as for a four-column structure in project named “INfills and MASONry structures protected by deformable POLyurethanes in seismic areas” – INMASPOL [2,3]). The analyses suggest that the 3dimensional FE models may reproduce with satisfactory accuracy the mechanical behavior of FRP retrofitted deficient columns. Further, they suggest that the deficient RC frames after the innovative composite retrofit achieve higher base shear load than the original bare RC frame without corroded or lap-spliced bars, at comparable top displacement ductility.*

**Keywords:** Finite Element, retrofit, reinforced concrete frame, brick infill, polyurethane seismic joint

---

## 1 INTRODUCTION

Reinforced concrete (RC) structures in seismic and coastal regions often present accumulated damage due to corrosion of steel reinforcement [4] among others. Further, the columns may include several deficiencies such as inadequate lap-splices of bottom steel bars [5, 16] among others. Available innovative materials and intervention techniques such as steel fiber systems or fiber reinforced polymers (FRPs) in the form of sheets, strips and ropes are widely used. Suitable diagnosis and retrofit of deficient members can improve their strength, delay further corrosion of the reinforcement as well as reduce deformations at the serviceability limit stage [5-11, 17].

Furthermore, the behavior of RC frames with masonry infills is significantly affected by the stiffness and the difference in yield-failure deformation between the RC frames and the masonry infills. The majority of buildings are constructed by brittle materials (clay bricks or concrete). Flexible frames cannot support high loads at low excitations and this can cause damage to the infills in normal (frequent) earthquakes. In the case of aftershocks, damaged infills may fail in and/or out of plane and collapse, causing human injuries. On the other hand, if the infill is too strong compared to the columns, it may cause their detrimental shear failure. Seismic isolation of the infills through structural Polyurethane Flexible Joints (PUFJ) may result in desirable RC frame – infill interaction enhancing the elastic stiffness and base shear while maintaining significant displacement ductility of the composite frames [1-3]. PUFJs can be used to fill cracks or joints or to bond composite materials (for masonry see [12]). In cases the fiber retrofit is applied with standard epoxy resins or inorganic matrices, the sequence of failures of the infilled RC frames remains unchanged, revealing a significant accumulation of damage for relative displacement of the frame between 0.5% - 1.5% [13]. Recent analytical studies have shown that strengthening with PUFJs may delay infill damage and thus enables the engagement of multiple different infills in a building frame. This aspect increases their shear capacity significantly [3].

However, during an experimental campaign involving large scale frames, only a few parameters can be investigated due to the high demand of resources and time. 3D finite element modelling and analyses may help address the effects of critical design parameters or deficiencies or damages in frames, by further developing already validated models in RC columns and in half RC column-foundation specimens retrofitted or not (see [14,15]).

This study investigates analytically the performance of bare RC frames with corroded reinforcements or inadequate bar lap-splices. Further, their corresponding RC frame counterparts with an innovative infill and PUFJ seismic joint are included in the parametric investigation. The infill wall is made of special thermal insulating clay bricks (orthoblocks with vertical direction of holes), having at the boundary interface with the RC frame an advanced seismic joint made of highly deformable polymer (PUFJ). The technique has been already validated experimentally in frames without corroded or lap-spliced bars in [1] (as well as for a four-column structure in INMASPOL [2,3]). The parametric analyses reveal the effects of damages and deficiencies on the performance of seismic resistant frames and the potential of innovative retrofits with seismic polymer joints.

## 2 FINITE ELEMENT MODELLING

This study develops suitable models for the analytical investigation of innovative retrofits in infilled (and bare) framed structures with prior structural deficiencies, based on the prior numerical validation of 3D FE models of isolated columns with deficiencies.

## 2.1 Concrete

The behavior of concrete is captured with the Riedel–Hiermaier–Thoma (RHT) model [18–20] (ANSYS, Autodyn [21]), suitable for similar geological materials under dynamic loading situations. The RHT is a constitutive model for brittle materials and is a combined plasticity and shear damage model in which the deviatoric stress in the material is limited by a generalized failure surface of the form (Eq. 1)

$$f(P, \sigma_{eq}, \theta, \dot{\varepsilon}) = \sigma_{eq} - Y_{TxC(P)} * F_{CAP(P)} * R_{3(\theta)} * (F)_{RATE(\dot{\varepsilon})} \quad (1)$$

where  $\sigma_{eq}$  is the uniaxial compressive strength,  $Y_{TxC(p)}$  is the fracture surface,  $F_{CAP(P)}$  is a dimensionless cap function which activates the elastic strength surface within the RHT material model at high pressures,  $R_{3(\theta)}$  is the third invariant dependence term and  $(F)_{RATE(\dot{\varepsilon})}$  is the strain rate effect represented through fracture strength with plastic strain rate.

## 2.2 Longitudinal and Transverse Steel Bars

In Explicit Dynamics analyses, plastic deformation is computed by reference to the Von Mises yield criterion (also known as Prandtl–Reuss yield criterion). This states that the local yield condition is (Eq. 2)

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = 2Y^2 \quad (2)$$

where  $\sigma_1, \sigma_2, \sigma_3$  are the first, second and third principal stresses and  $Y$  is the yield stress of steel reinforcement under tension.

For the elastic part of the response of the longitudinal and transverse steel was chosen the “Isotropic Elasticity” model. The “Bilinear Isotropic Hardening” model was used to define the yield stress ( $Y$ ) as a linear function of plastic strain,  $\varepsilon_p$  (Eq. 3)

$$Y = Y_0 + A * \varepsilon_p \quad (3)$$

where  $Y_0$  is the yield strength and  $A$  is the tangent modulus.

## 2.3 Brick

Brick is modeled with Young’s modulus equal to 3800 MPa and Poisson’s Ratio equal to 0.25. The orthotropic elasticity material properties with tensile strength in X, Y and Z directions are 1.49 MPa, 3.89 MPa and 1.49 MPa, respectively.

## 2.4 Fiber Reinforced Polymers (FRP)

The retrofitted isolated specimens were externally confined with 2 layers of carbon FRP [5]. The FRP jacket was applied over a height of 600 mm at the base of the column. The thickness of one layer of CFRP was  $t_f=0.13$  mm, the elastic modulus was  $E_f=230$  GPa and the failure strain was  $\varepsilon_{uf}=0.015$ , while the corners of the section were rounded with radius of  $r=30$  mm. FRP jacket was modelled as an orthotropic elastic material. For the analyses, the material properties were reduced to 59,160 MPa for the elastic modulus along the direction of carbon fibers in order to take into account both the fibers and impregnation polymer. In addition, the thickness of the jacket was suitably increased so that the elastic modulus multiplied by the thickness of the jacket, in both cases, provides the same axial rigidity value.

## 2.5 Polyurethane

The frame specimen is the brick infilled RC frame with polymer joints of 2cm thick at 3 sides, simulating application to existing buildings. The 3-sided gap was filled in with PUFJ polymer through by injection. Polymer for PUFJ was of type Sika PM. The elastic modulus, strength and ultimate elongation of the polymer were 4 MPa, 1.4 MPa and 110%, respectively in a tensile test and the Poisson ratio 0.47. Polyurethane is modeled as an isotropic elasticity material.

## 2.6 Element Type

Concrete and bricks were eight-node elements "Hexahedral Solid Elements". The internal steel reinforcement was 2-node element "Beam (Line) Elements" with the ability to develop large axial deformations. More details on the FE modelling and analysis procedure can be found also in [14, 15].

## 3 VALIDATION OF FE MODELS

The analytical study presented herein includes two phases. At the first phase the accuracy of the prediction performance of the constructed 3D FE models are validated against the experimental results of 2 selected real scale RC frames from the study by [1]. Specimen A1F is the bare RC frame of the series and it is designed according to current Eurocodes. This real scale frame has plane dimensions of 270 cm long beam with extensions of 30 cm in both sides and height of 245 cm (245 cm to the level of the diaphragm). The columns are of cross section dimensions of 25 cm×25 cm and have 8Φ16 longitudinal continuous rebars (without lap-splices) and Φ10/100 mm closed stirrups (peripheral and rhombic). The columns have two top extensions of 30 cm as well as a common foundation beam with dimensions 30 cm×40 cm×355 cm. The top beam has cross section dimensions of 25 cm×25 cm and is reinforced with 8Φ14 longitudinal rebars and Φ10/100 mm closed stirrups (peripheral). The dimensions of the RC frame and the detailing of the internal steel reinforcement are depicted in Figure 1a.

Figure 1: (a) Dimensions of the RC frame and detailing of internal steel reinforcement and (b) Specimen B2 with 3-sided polymer joint applied on existing infill (adapted by [1]).

Specimen B2 is identical to the A1F frame with addition of infill wall with special thermal insulating clay bricks (orthoblocks with vertical direction of holes), having at the boundary interface with the RC frame, advanced seismic joint made of highly deformable polymer. The polyurethane joint is 2 cm thick, placed at 3 sides (at 2 vertical interfaces and at top interface) which is depicted in Figure 1b. The two columns of the frame have been subjected to 375 kN concentric load each. Then, the horizontal actuator imposed cycles of gradually increased displacements at the top beam. More details on the experimental setup and test results of the 2 selected frames can be found in [1].

Figures 2a and 2b show in black and black-grey curves the experimental envelope base shear – top displacement curves of the two frames for (+) and (-) push respectively. It should be mentioned that the innovative orthoblock infill with the PUFJ seismic joint increased the elastic stiffness of the frame as well as the maximum base shear of the frame from 164 kN (A1F frame push +) and 134 kN (A1F frame push -) to 192.8 kN (B2 frame push +) and 167 kN (B2 frame push -) when the orthoblock-PUFJ is used. Further, the top displacement ductility of the infilled frame B2 was remarkable, with negligible base shear reduction up to 3.5% drift for push (+).

The analytical predictions of the FE analyses are in red color and compare well with the experimental ones in terms of maximum and ultimate base shear as well as in terms of top displacement at maximum bearing load and at ultimate (see figure 2).

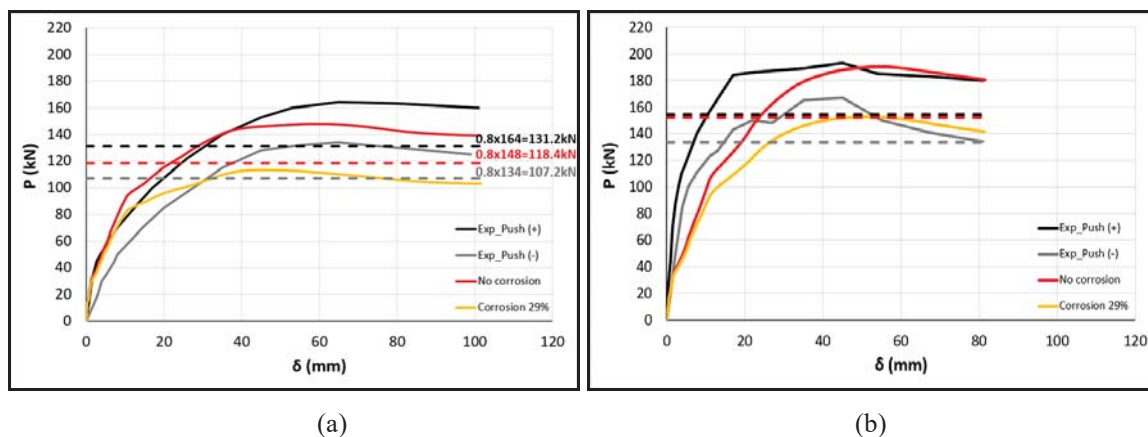

Figure 2: Analytical base shear force -displacement curve for (a) A1F and (b) B2 with no and 29% corrosion, compared against the experimental ones.

## 4 PARAMETRIC FE ANALYTICAL INVESTIGATION

At the second phase, the study utilizes the modelling approach presented in [15] for RC columns with lap-spliced steel bars or with corroded reinforcements. The corresponding developments are introduced in the frames A1F and B2 to investigate the effects of the implementation of orthoblock infill with seismic PUFJ on the P-d performance of deficient frames in need of retrofit.

### 4.1 Corrosion of steel reinforcement

Anagnostou and Rousakis [15] validated the simplified FE approach on the analysis of RC columns with corroded steel bars of varying degree of corrosion utilizing the experiments by [5]. The half column specimens had section dimensions 20 cm x 30 cm and height 120 cm. The concrete strength and steel yield stress was  $f_c=25.5$  MPa and  $f_{yL}=460$  MPa and the normalized axial load  $\nu=0.18$ . Four different degrees of corrosion were investigated experimen-

tally. The FE analytical results in [15] suggest there is reduction of the force received by the longitudinal bars under tension compared to the uncorroded column, as the degree of corrosion increases (in accordance with the mass loss of the steel). The strength and the ductility of RC column decrease and the reduction of strain in corroded steel bars is significant. Finally, for a high degree of corrosion, fracture of steel longitudinal bars is expected.

A corrosion of about 10% results in negligible reduction of the ultimate chord rotation [5] while a higher than 20% leads to a dramatic reduction of the yielding and ultimate strength. The column NS-X16 presented a reduction in experimental ultimate displacement of about 28% and in strength about 10% with respect to uncorroded one. This corrosion level is considered in this study the limit one for a column satisfying the seismic code requirements.

Herein, the analytical and experimental results (for both directions, push + and push -) of specimens NS-X0 and NS-X16 (0 and 16% corrosion, respectively) for the maximum and ultimate lateral force ( $P_{\max}$ ,  $P_u$ ) and the corresponding displacements ( $\delta_{P_{\max}}$ ,  $\delta_{P_u}$ ) are presented and compared in Table 1. The parameter used for the comparisons in all tables is the Absolute Divergence (AD), also known as Absolute Error (AE). It is defined as follows:

$$AD = \frac{|a_{anal.} - a_{exp.}|}{a_{exp.}} \quad (4)$$

AD requires the absolute experimental values ( $a_{exp.}$ ) to be subtracted by the analytical ones ( $a_{anal.}$ ) and then divided by the experimental ones ( $a_{exp.}$ ). The divergence between the experimental and analytical values at characteristic states for the columns is low (Table 1). All comparisons with loads and displacements at characteristic states suggest the analytical predictions are satisfactory. More details can be found in [15].

	NS-X0			NS-X16		
	Exp.	Anal.	AD (%)	Exp.	Anal.	AD (%)
$P_{\max}$ (+) (kN)	60.70	54.56	10.11	50.90	49.56	2.64
$\delta_{P_{\max}}$ (+) (mm)	20.00	20.87	4.35	18.00	42.12	134.00
$P_{\max}$ (-) (kN)	52.00	54.56	4.92	50.00	49.56	0.88
$\delta_{P_{\max}}$ (-) (mm)	15.00	20.87	39.13	30.00	42.12	40.40
$P_u$ (+) (kN)	51.60	46.38	10.12	43.27	42.13	2.63
$\delta_{P_u}$ (+) (mm)	81.10	73.75	9.06	55.10	52.86	4.07
$P_u$ (-) (kN)	44.20	46.38	4.92	42.50	42.13	0.88
$\delta_{P_u}$ (-) (mm)	70.00	73.75	5.36	55.00	52.86	3.89

Table 1: Comparative results for specimens NS-X0 and NS-X16 with different corrosion levels.

The same approach was adopted for the frames A1F and B2. The scenario concerns 29% mass loss due to corrosion for all the steel bars and stirrups, including the two columns along with the beam. All analyses are stopped at the same displacement, as the experimental one. Figure 2a presents the analytical base shear force – displacement curve of frame A1F with 29% corrosion while figure 2b the curve of B2 with 29% of corrosion, both in yellow color.

The dashed lines mark the 20% drop of the maximum values of the analytical and experimental base shears (for both directions, push + and -), considered as the lowest acceptable threshold of base shear at failure according to several seismic codes. In particular (see Table 2), for frame A1F without corrosion these experimental limit values for push (+) and (-) are  $0.8 \times 164 = 131.2$  kN and  $0.8 \times 134 = 107.2$  kN respectively. The analytical prediction is  $0.8 \times 148 = 118.4$  kN, being around the average of experimental ones. Analysis for A1F with

29% corrosion reveals maximum base shear of 113.35 kN which is around the analytical 80% value at failure for uncorroded frame. Further, the ultimate base shear is 103.26 kN, lower than the experimental limits and far lower than the analytical failure limit of 118.4kN. It seems that the base shear degradation at ultimate because of 29% corrosion in bare frame A1F is 30.2% (i.e. from 148 kN to 103.26 kN), concluding corroded A1F as insufficient. This load drop is far higher than in isolated columns (15.6%) as all steel reinforcements of the frame are considered corroded.

	A1F (No corrosion, No lap)			A1F (29% corrosion)		A1F (11d <sub>bL</sub> lap length)	
	Exp.	Anal.	AD (%)	Anal.	AD (%)	Anal.	AD (%)
P <sub>max</sub> (+) (kN)	164.00	148.00	9.76	113.35	23.41	139.67	5.63
δP <sub>max</sub> (+) (mm)	65.00	59.93	7.80	46.25	22.83	53.34	11.00
P <sub>max</sub> (-) (kN)	133.40	148.00	10.94	113.35	23.41	139.67	5.63
δP <sub>max</sub> (-) (mm)	65.00	59.93	7.80	46.25	22.83	53.34	11.00
P <sub>u</sub> (+) (kN)	159.90	139.14	12.98	103.26	25.79	131	5.9

P <sub>u</sub> (-) (kN)	124.70	139.14	11.58	103.26	25.79	131	5.9
δP <sub>u</sub> (-) (mm)	99.00	101.50	-	101.50	-	101.5	-

Table 2: Comparative results for specimens A1F with different corrosion levels and lap lengths.

For frame B2 without corrosion, the corresponding experimental limit values for push + and - are  $0.8 \times 192.8 = 154.2$  kN and  $0.8 \times 167 = 133.6$  kN respectively (Table 3). The corresponding analytical prediction is  $0.8 \times 190.25 = 152.2$  kN, being around the experimental push + value. Analysis for B2 with 29% corrosion reveals maximum base shear of 152.66 kN which is around the analytical value at failure for uncorroded frame. Further, the ultimate base shear is 141.48 kN, which is higher than the limit experimental value for push – direction. However, this base shear degradation at ultimate because of 29% corrosion, is 25.6% (i.e. from 190.25 kN to 141.48 kN), concluding corroded A1F marginally as insufficient. Interestingly, if B2 frame is considered the retrofitting scenario for A1F corroded bare frame, then the analytical behavior of corroded A1F retrofitted with orthoblock infills and PUFJ (corroded B2) is somewhat better than the analytical behavior of uncorroded A1F. Indeed, the maximum base shear of B2 corroded is 152.66 kN (higher than 148kN in A1F uncorroded). Further, the ultimate base shear is also higher. Given the unique characteristics of PUFJ for emergency retrofits providing a short curing period of some hours [1-3], this innovative retrofit could enable the corroded frame to sustain P-d demands equivalent to the uncorroded one.

	B2 (No corrosion, No lap)			B2 (29% corrosion)		B2 (11d <sub>bL</sub> lap length)

Table 3: Comparative results for specimens B2 with different corrosion levels and lap lengths.

Figures 3 and 4 present the concrete damage of the specimens A1F and B2. Frames A1F with 29% corrosion and uncorroded present similar damage accumulation. Damage occurs mostly at the bottom and the top of the columns (critical regions) and inside the joints. Specimen B2 with 29% corrosion presents damage at similar regions but of lower severity as the damage is also distributed inside the orthoblock infill.

Figure 3. Concrete damage of specimen A1F with (a) no corrosion/no lap splices, and specimen B2 with (b) no corrosion/no lap splices (magnification factor 2).

Figure 4. Concrete damage of specimen A1F with (a) 29% corrosion at total displacement 101.50 mm and specimen B2 with (b) 29% corrosion at total displacement 81.40 mm (magnification factor 2).

#### 4.2 Lap-spliced longitudinal bars

Anagnostou and Rousakis [15] have verified the 3D FE models of columns with lap-spliced longitudinal bars utilizing the experiments by [22]. The half columns had section dimensions 25 cm×50 cm and height 160 cm. The concrete strength varied among columns  $f_c=26.9\text{--}32.9$  MPa, and steel yield stress  $f_{yL}=514$  MPa. The normalized axial load was  $\nu=0.26\text{--}0.30$ , while three different lap-splice lengths of 15 times the diameter of the longitudinal bar ( $15d_{bL}$ ),  $30d_{bL}$  and  $45d_{bL}$  were examined. Table 4 cites the analytical and experimental results of columns with no bar laps or with bar lap lengths of  $15d_{bL}$  and  $30d_{bL}$  confined with 2 layers of FRP. All comparisons with loads and displacements at characteristic states suggest the analytical predictions are satisfactory. Column with  $15d_{bL}$  lap-splices (R-P2L1) shows a significantly reduced base shear (a mean reduction of about 20%) and reduced deformation capacity

compared with the column without laps (R-P2L0). Column with 30d<sub>bL</sub> (R-P2L3), achieves ultimate displacement similar to that of R-P2L0 but at marginally lower base shear (around 4%). Similarly, the analytical maximum axial force developed on the bars under tension at the lap region at the base of column R-P2L3 is 134.63 kN. This force is 9% lower than the axial force of 147.89kN in R-P2L0. For the column R-P2L1 the corresponding axial force is 85.49 kN, being 57% of the one in column R-P2L0. Therefore, the steel bars in the lap do not yield (analytical yield tensile force on the bar is 130.8 kN).

	R-P2L0			R-P2L1			R-P2L3		
	Exp	Anal	AD (%)	Exp	Anal	AD (%)	Exp	Anal	AD (%)
P <sub>max</sub> (+) (kN)	240.00	217.73	9.28	175.00	176.86	1.06	215.00	209.11	2.74
δP <sub>max</sub> (+) (mm)	48.50	34.84	28.16	19.50	27.77	42.41	48.50	38.13	21.38
P <sub>max</sub> (-) (kN)	194.00	217.73	12.23	168.00	176.86	5.27	208.00	209.11	0.53
δP <sub>max</sub> (-) (mm)	38.50	34.84	9.51	19.00	27.77	46.16	34.50	38.13	10.52
P <sub>u</sub> (+) (kN)	192.00	174.18	9.28	140.00	141.49	1.06	172.00	167.29	2.74
δP <sub>u</sub> (+) (mm)	70.40	75.37	7.06	54.40	58.46	7.47	75.20	66.85	11.10
P <sub>u</sub> (-) (kN)	155.20	174.18	12.23	134.40	141.49	5.27	166.40	167.29	0.53
δP <sub>u</sub> (-) (mm)	64.00	75.37	17.77	50.00	58.46	16.92	65.00	66.85	2.85

Table 4: Comparative results for specimens R-P2L0, R-P2L1 and R-P2L3 with different lap lengths.

The same approach was adopted for the frames A1F and B2. The scenario concerns the insufficient lap-splice case of 15d<sub>bL</sub>. However, this lap length is further reduced to 11d<sub>bL</sub> accordingly, based on the different concrete strength of the frames (C30 quality) that corresponds to higher bond strength of the bars inside concrete than the one in the columns by [22] (C20 quality). All analyses are stopped at the same displacement, as the experimental one. Figure 5a presents the analytical base shear force – displacement curve of frame A1F with 11d<sub>bL</sub> lap length while figure 5b the curve of B2 with 11d<sub>bL</sub> lap length, both in green color.

Analysis for A1F with 11d<sub>bL</sub> lap length reveals maximum base shear of 139.67 kN (see Table 2) which is only 5.63% lower than the analytical value at maximum for the frame without laps (148 kN). The corresponding ultimate base shear is 131 kN (only 11.4% lower than 148 kN, correspondingly). The ultimate base shear in A1F with laps is higher than all limit values of 20% drop (experimental or analytical), being sufficient globally, despite insufficient laps. It seems that the base shear degradation at ultimate because of insufficient lap-splices is higher in isolated half column specimens revealing a shear force of 141.49 kN. The corresponding maximum base shear in column without lap-splices is 217.13 kN, denoting a drop of 34.8% (3 times higher). The reason for this, may be attributed to the engagement of the sections on the top of the columns of the frame at higher extend, to compensate for the insufficiency of the bottom sections (redistribution effects).

Analysis for B2 with 11d<sub>bL</sub> lap length reveals maximum base shear of 165.04 kN which is 14.4% lower than the analytical value at maximum for the frame B2 without laps (Table 3). The ultimate base shear in B2 with laps is 147.76 kN (22.3% lower, correspondingly). This value is around the analytical limit value of 20% drop for frame B2 without laps (152.2kN), being only marginally insufficient globally, despite heavily insufficient laps. Further, if B2 frame is considered the retrofitting scenario for A1F bare frame with laps, then the analytical behavior of corroded A1F retrofitted with orthoblock infills and PUFJ (corroded B2) is far better than the analytical behavior of A1F without laps. Indeed, the maximum base shear of B2 with laps is 165.04 kN (higher than 148kN in A1F without laps). Further, the ultimate base shear is 147.76 kN (Table 3), compared with 139.14 kN in A1F without laps (Table 2).

In this case, orthoblock-PUFJ emergency retrofit [1-4], could enable the lap-spliced frame to sustain P-d demands higher than the A1F frame without laps.

Figure 5. Analytical base shear force -displacement curve for (a) A1F and (b) B2 with no and 11dbL lap length, compared against the experimental ones.

Figure 6a presents the undeformed lap length region of 11dbL while figures 6b and 6c the slippage of the bars of frames A1F and B2 at ultimate. In both cases the analyses suggest that the lap-spliced bars reach their yielding force under tension (96.5 kN) despite the slip.

Figure 6. (a) Undeformed 11dbL lap length, (b) Slippage of longitudinal steel bars of specimen A1F at ultimate displacement of 101.5 mm and (c) B2 at ultimate displacement of 81.4 mm (magnification factor 10).

Figures 7a and 7b suggest that both frames present similar damage accumulation. Damage occurs mostly at the bottom and the top of the columns (critical regions) and inside the joints. Specimen B2 with 11dbL lap-splices presents damage of higher severity than in A1F, at the upper left beam-column joint region and at the bottom of the right column. However, the maximum shear force does not drop below 80% of the maximum experimental and analytical values.

Figure 7. Concrete damage of specimens with  $11d_{bL}$  lap length of (a) A1F and (b) B2.

## 5 CONCLUSIONS

The analytical results of the developed FE models for frames A1F and B2 compare well with the experimental results. Further, the frames are suitably integrated to assess analytically their performance when they suffer 29% mass loss of their steel reinforcements due to corrosion or when the bottom column reinforcements have insufficient lap-splices of  $11d_{bL}$  length. Reference experiments of the international literature in half column specimens are utilized to validate the produced models.

The analytical results are mainly assessed based on the lowest acceptable threshold of 20% drop for the base shear at failure when compared with the maximum base shear of the frame (according to several seismic codes) without damages or deficiencies. Further, the investigated deficiencies cause no significant degradation of the elastic stiffness of the frames.

The corrosion of 29% steel mass loss to all reinforcements in bare frame A1F, results in ultimate base shear that is 30.2% lower than the maximum base shear in uncorroded A1F. Therefore, the frame is in need of retrofit as insufficient. In corroded B2 the corresponding drop is lower, 25.6%, considering it marginally as insufficient. However, if corroded B2 is considered the retrofit scenario for corroded A1F with orthoblocks and PUFJ, then the base shear at maximum and at ultimate are both higher than the corresponding values in A1F uncorroded, at comparable top displacement ductility. Therefore, it can be considered an efficient retrofit (especially as emergency one). However, such high levels of corrosion should be treated with caution.

The insufficient lap-splice of  $11d_{bL}$  to the bottom bars of the columns in bare frame A1F results in ultimate base shear that is only 11.4% lower than the maximum base shear in A1F without laps. The ultimate base shear in A1F with laps is higher than all limit values of 20% drop (experimental or analytical), being sufficient globally, despite insufficient laps (in isolated half column specimens the drop was 3 times higher). In B2 with lap-splices, the corresponding drop is 22.3%, considering it as marginally insufficient, despite insufficient laps. Further, if B2 frame is considered the retrofitting scenario for A1F bare frame with laps, then the analytical behavior of A1F with insufficient laps and retrofitted with orthoblock infills and PUFJ (B2 with lap-splices) is far better than the analytical behavior of A1F without laps. Orthoblock-PUFJ could enable the frame with lap-splices to sustain P-d demands higher than the A1F frame without laps, at comparable top displacement ductility.

### Abstract

*The present study presents the results of experimental and numerical investigation on the behavior of self-supporting, double skin metal faced insulating sandwich panels under compression, tension and shear. More specifically, appropriate number of specimens is subjected to compression, tension and shear loads at the “Laboratory for Strength of Materials and Structures” (LSMS) Department of Civil Engineering of Aristotle University of Thessaloniki (AUTH) in compliance with the terms of BS EN 14509:2013 standard. In addition, numerical models simulating the compression and tension tests are developed and the mechanical properties of the materials composing the insulating panels are calibrated. As a result, stress – strain laws for both compression and tension behaviours of the product are determined. Moreover, numerical model simulating the shear test is built by implementing the previously formed material laws with analytical stress-strain relations for compression and tension. Finally, the response of the numerical model under shear test is compared to the experimental one and consequently the accuracy of determined material laws is assessed.*

## 1 INTRODUCTION

Sandwich panels are modern pre-fabricated construction components used as cladding elements for different types of buildings. Sandwich panels consist of an insulating core material covered by two faces which are typically made of thin metal sheets. The materials can be configured in many possible combinations. For instance, for the cover layers thin metal faces, timber-based plates or glass fiber reinforced plastics can be used. The insulating core layer in most cases is made of structured foams like polyurethane (PUR), polystyrene (PS) or of mineral wool (MW). Sandwich panels are used as light-weight roofs and wall claddings in industrial and commercial buildings. Usually, the structures are loaded by permanent loads, like self-weight, snow and wind loads. However, additional loads like temperature differences between external and internal metal faces or creep of the core must be taken into account for statical calculations of sandwich panels structures. The high load bearing capacity of sandwich panels is the result of a rigid connection between the core material and the cover layers. The bending moment is distributed to the two faces (e.g., for panels with flat faces in the form of axial forces) and the shear loads are borne by the core layer. In standard applications, the panels are mounted and fixed on a load-bearing substructure of beams or purlins. Sandwich panels can reduce the problem of lateral torsional buckling of this substructure of beams or purlins by providing stabilization either by shear stiffness or by torsional restraint. [1,2].

For the structural behavior of sandwich panels, it is necessary to consider all of the potential failure modes: tensile failure of the faces (due to tensile stress), local buckling (wrinkling) of the faces (due to compressive stress), and shear failure of the core or the adhesion between the core and face. In sandwich panels with thin strongly profiled faces, two additional failure modes are introduced: shear strength of the webs in a profiled face and the support reaction capacity of a profiled face [3,4].

The European standard BS EN 14509:2013 [5], or European Recommendations published by the European Convention for Constructional Steelwork (ECCS) and the International Building Council (CIB) do not provide detailed design methods for sandwiches with strongly profiled faces. Determination of the load bearing capacity required for the design of sandwich panels is to a large degree based on test results [6].

Pokharel and Mahendran [7,8] implemented Finite Element Analysis Method (FEM) in order to investigate the structural behavior of flat and lightly profiled sandwich panels. The investigation of structural behavior and failure analysis of composite structures through the use of finite element analyses have also been presented in [9] and [10].

The objective of this paper is to investigate experimentally and numerically lightly profiled insulating panels but most importantly develop a methodology for calibrating and determining materials' law that would enable an accurate simulation and estimation of the structural behavior of these composite panels.

## 2 EXAMINED SPECIMENS AND EXPERIMENTAL PROCEDURE

All the experimental tests are executed at the "Laboratory of Strength of Materials and Structures" of Aristotle University of Thessaloniki (AUTH) in compliance with EN 14509:2013 standard. The insulating panel under examination is in fact a sandwich section that consists of two metal faces of thickness 0.45mm, called "lamellas" and a core material between them which is Mineral Wool (MW). This panel is denominated as SP. The profile of the studied section is depicted in Figure 1. Three (3) panel thickness values,  $d_c$ , are considered in the present research: 50mm, 80mm and 100mm.

Figure 1: Profile of the examined self-supporting, double skin metal faced insulating SP

The compressive strength ( $f_{cc}$ ) and elasticity modulus ( $E_{cc}$ ) of the examined panel is measured by testing six (6) specimens of each thickness in compliance with the procedure described in paragraph A.2 of EN 14509: 2013 standard. The specimens, as recommended in EN 826 standard (compressive behavior of thermal insulation products) should have a square cross-section of dimensions between 50 and 300mm. In the present study prisms of 100x100mm are used. Also, six (6) specimens of the same dimensions are tested for evaluating the tensile behaviour of the panels and measuring their tensile strength ( $f_{ct}$ ) and elasticity modulus ( $E_{ct}$ ) in accordance with the paragraph A.1 of EN 14509: 2013. Finally, the terms of paragraph A.3 of the aforementioned paragraph are implemented for testing three (3) SP specimens of length of 1000mm and width of 100mm under “shear test with two-point loads” and estimating the ultimate shear strength ( $f_{cv}$ ) and shear modulus ( $G_c$ ). The properties of the specimens and details of the procedures are listed below in Table 1.

Examined Characteristics	Test Method/Procedure	Specimens' dimensions			min number of tested specimens
		thickness $d_c$ (mm)	length (mm)	width (mm)	
Compressive strength and modulus	EN 14509:2013 A.2	50, 80, 100	100	100	6
Tensile strength and modulus	EN 14509:2013 A.1	50, 80, 100	100	100	6
Shear strength and modulus	EN 14509:2013 A.3	50, 80, 100	1000	100	3

Table 1: Properties of tested specimens and experimental procedures

### 3 EXPERIMENTAL RESULTS

In this section the results of the experimental tests are presented. Figures 2, 4 and 6 illustrate the damage pattern of compression, tension and shear, respectively. In Figure 3 the compression stress – strain curve is depicted and the average values of strength and elasticity modulus are presented. The same applies to Figure 5, which refers to tensile behavior, while Figure 7 illustrates the maximum applied load – deflection curve of the examined specimens and shear strength and modulus average rates are displayed.

Observing Figure 3, one can see that the thickness of insulating panels has little effect on their performance under compression test as the characteristic values of compressive strength and elasticity modulus have little difference for the three examined width rates. Also, it is not clear if this little impact is negative or positive since the compressive strength of SP 80mm thick is smaller than that of 50mm, but greater than that of 100mm.

Figure 2: Indicative photographs of SP specimen before (left) and after (right) compression test

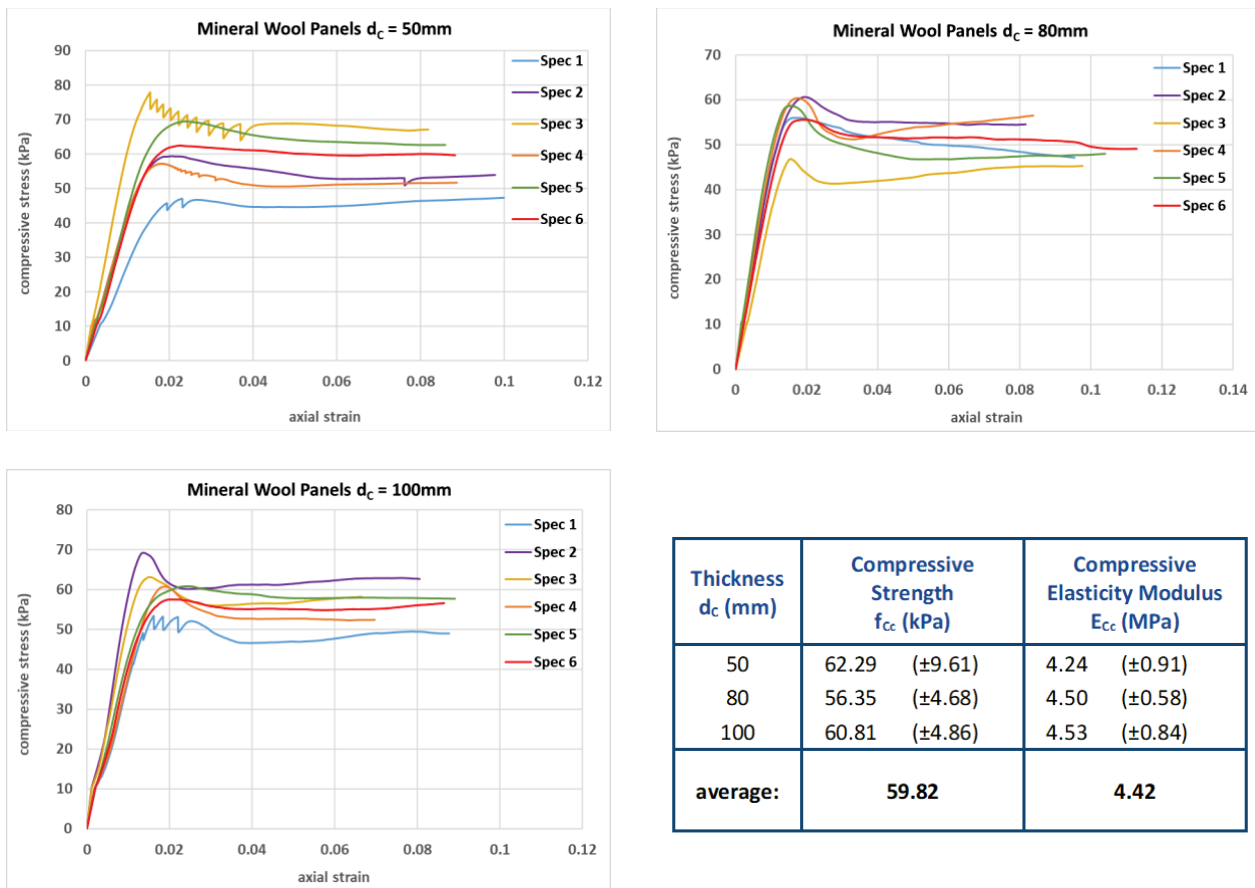

Figure 3: Compressive strength-strain diagrams of six (6) specimens of thickness  $d_c=50\text{mm}$  (top-left),  $d_c=80\text{mm}$  (top-right),  $d_c=100\text{mm}$  (bottom-left) and table of average compressive strength and elasticity modulus values (bottom-right)

The experimental results revealed that the performance of SP under tension test (Figure 5) is deteriorate to that under compression (Figure 3) as the average tensile strength amounts approximately to 10kPa while the average compressive strength is about 60kPa, i.e., 6 times greater. Another interesting finding is that the tensile elasticity modulus of the examined

insulating panels is roughly 1/8 of the compressive modulus, fact that is depicted in the corresponding curves' slope angle.

Figure 4: Indicative photographs of SP specimen before (left) and after (right) tension test

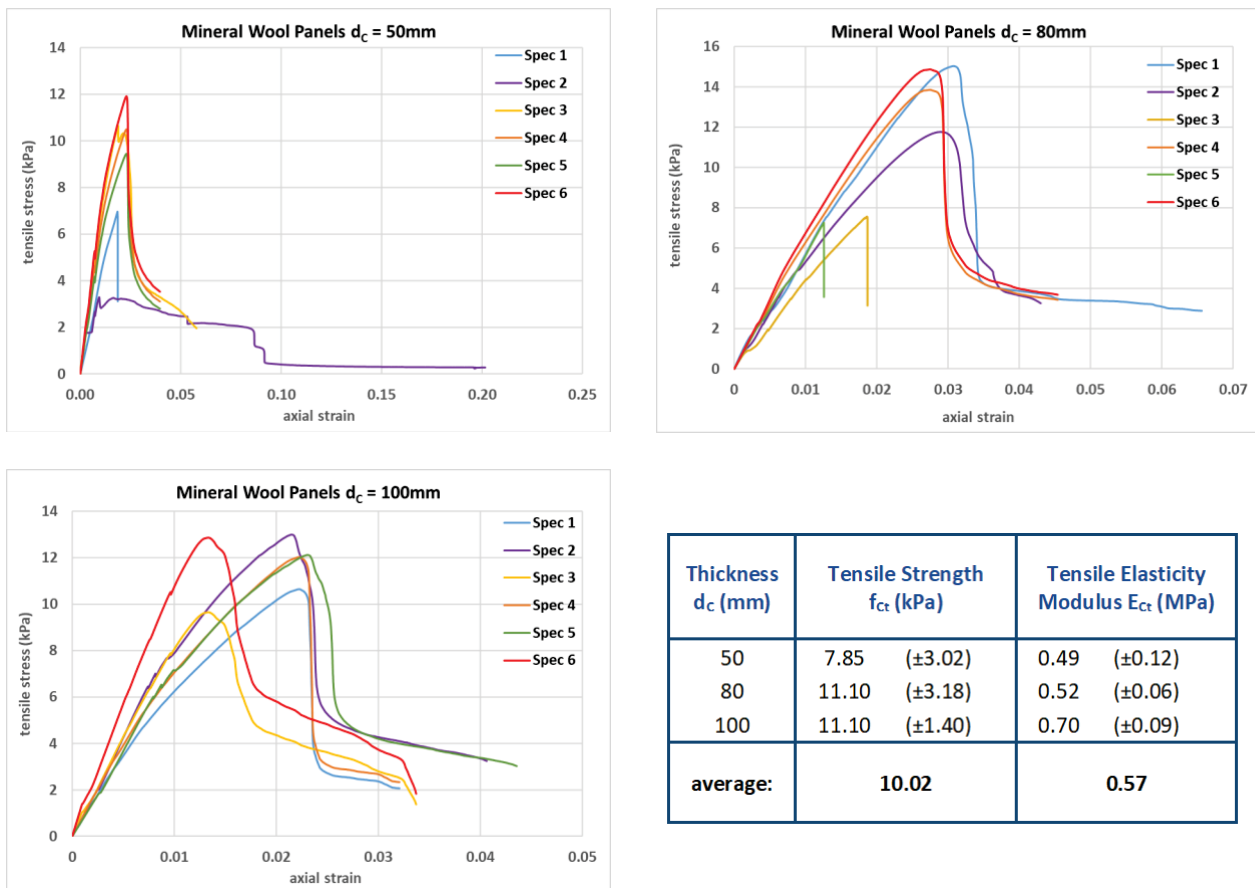

Figure 5: Tensile strength-strain diagrams of six (6) specimens of thickness  $d_c=50\text{mm}$  (top-left),  $d_c=80\text{mm}$  (top-right),  $d_c=100\text{mm}$  (bottom-left) and table of average tensile strength and elasticity modulus values (bottom-right)

The performance of SP under shear test is very sound as shown in Figure 7. The shear strength average value amounts to 3255kPa, 54 times greater than the compressive strength and

325 than the tensile strength. This happens because of the high contribution of lamellas (steel panels) to the tensile behavior of SP product (lamella material's properties listed in section 4).

Figure 6: Indicative photographs of SP specimen before (left) and after (right) shear test

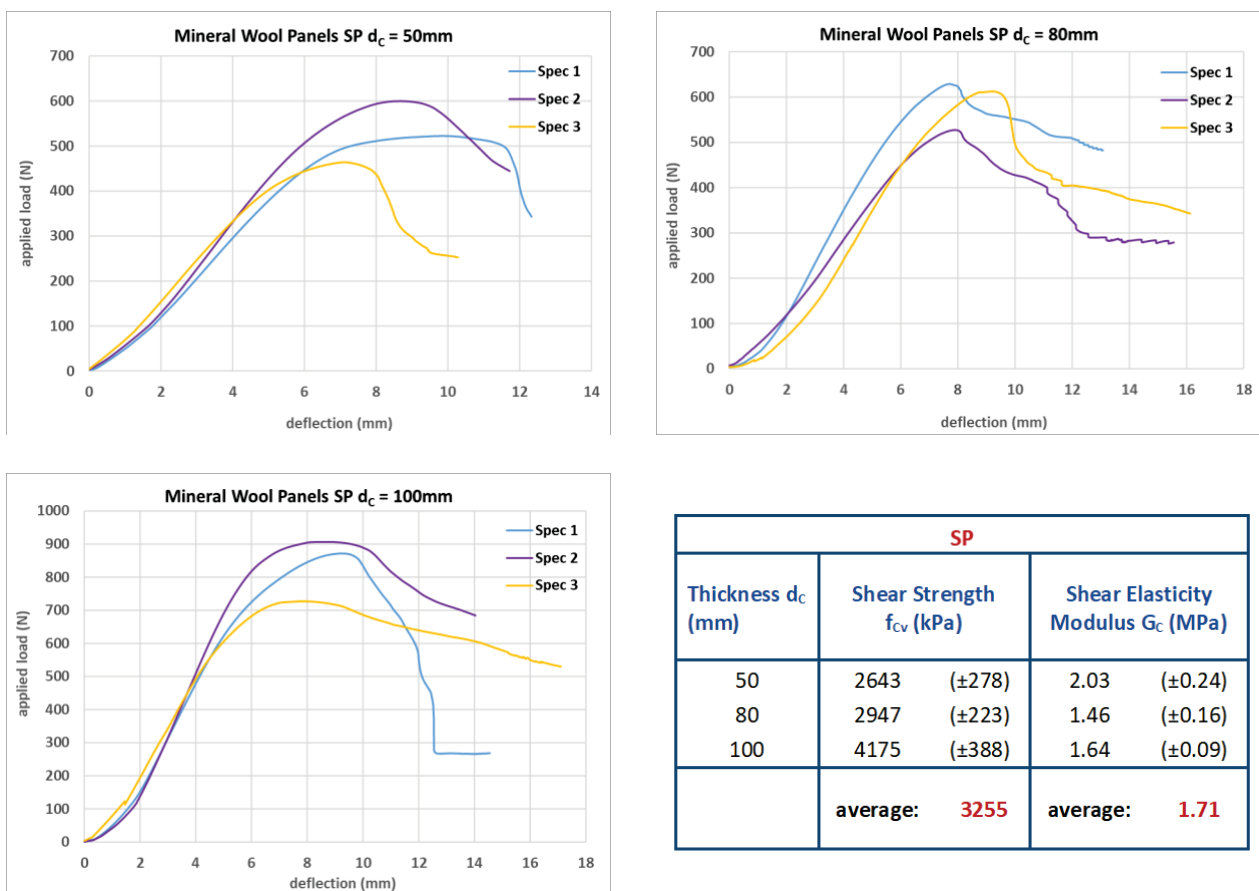

Figure 7: Applied load-deflection diagrams of three (3) specimens of thickness  $d_c=50\text{mm}$  (top-left),  $d_c=80\text{mm}$  (top-right),  $d_c=100\text{mm}$  (bottom-left) and table of average shear strength and elasticity modulus values (bottom-right)

#### 4 NUMERICAL MODELING

Three-dimensional finite element numerical models have been developed adopting a macro modeling approach with homogenized non-linear material laws. It should be underlined that the steel face (lamella) of the insulating panel has been at first tested separately at the “Laboratory of Strength of Materials and Structures” of Aristotle University of Thessaloniki and the

material's mechanical properties have been calibrated in a Finite Element Analysis (FEA) software. The results of this calibration are presented in Figure 9 and the material's properties are listed in Table 2. After that, the compression and tension tests have been simulated and both the compressive and tensile characteristics of the core material (MW) have been calibrated in order to achieve the actual behaviour of the panels, observed at the laboratory. For indicative reasons and in order to avoid a lengthy paper, only the calibration of panels of width  $d_c=50\text{mm}$  under compression is demonstrated below. The same procedure is followed for each thickness value for both compression and tension tests. Finally, a material law that satisfies all cases is determined and its parameters are presented in Table 3 and these parameters become the input for FEM simulation of shear tests.

tension	
stress (MPa)	plastic strain
380	0
500	0.1581
50	0.1881

Table 2: The calibrated material law for lamellas of SP

Figure 9: Calibration of tensile behavior of lamellas (steel panels of thickness of 0.45mm)

Figure 10: Calibration of compression behavior of the insulating panels of thickness  $d_c=50\text{mm}$

compression		tension	
stress (MPa)	plastic strain	stress (MPa)	plastic strain
0.035	0	0.0075	0
0.0175	0.05176	0.0020	0.03324

Table 3: The calibrated material law for Secret Fix Panels (SP)

Figure 11: Applied load-deflection curves for numerical FEM simulation of SP

Comparing Figures 7 and 11, one can observe a very good correlation as the results of numerical simulation approach adequately the experimental ones. More specifically, the maximum load values achieved in FEA simulation for SP of thickness of 50mm and 80mm are very close to the real ones (Figure 7), while the maximum load of 100mm thick SP is a little lower than the experimental (600N against 750N – Figure 7). Moreover, the load-deflection curves achieved in numerical simulation have greater slopes angle, which possibly can be attributed to elasticity modulus scarce assess. This could be investigated further. Finally, the damage pattern under shear test in FEA software is illustrated below (Figure 12), which is very realistic, comparing to the one observed in laboratory (Figure 6)

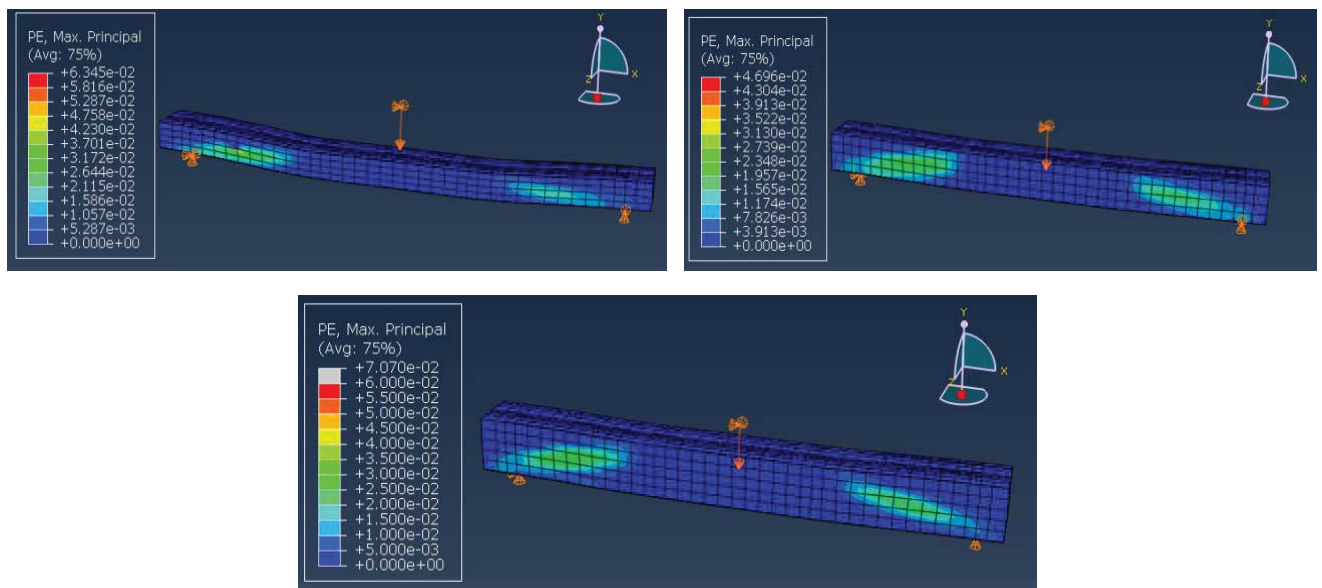

Figure 12: Illustrated damage pattern in FEM simulation models for SP of width  $d_c=50\text{mm}$  (top-left),  $d_c=80\text{mm}$  (top-right) and  $d_c=100\text{mm}$  (bottom)

## 5 CONCLUSIONS

The performance of insulating MW Panels SP behavior under compression, tension and shear loadings is discussed here, mainly focusing on the FEM simulation capacity to accurately approach the experimental results. The main conclusions are enlisted below:

- The compressive strength of SP is about 6 times greater than the tensile strength. The shear strength of SP is about 54 times greater than the compressive strength and 325 than the tensile, which is mainly attributed to the high contribution of lamellas (steel panels) to shear behavior.
- The thickness of SP has little impact on its performance under compression and tension tests.
- The developed 3-D FEM models, after experimental tests and numerical validation of the materials, can satisfactorily capture the observed shear behavior of the insulating panels, especially in terms of the maximum load bearing capacity, but also in the damage pattern.

### Abstract

*A study is presented on the seismic fragility analysis of a class of existing RC school buildings in Puglia, Southern Italy. Firstly, we defined a taxonomy for identifying a homogenous building class, through the collection of typological data, such as construction age, number of storeys and construction materials. After, by means of the available Census data on Italian school buildings, we selected 735 units in the focused area to assembly a proper database to involve in the phase of numerical modelling and analysis. To assess fragility, we employed two modelling options: (a) a single-degree-of-freedom approach, by evaluating the backbone of the simplified models; (b) a multi-degree-of-freedom approach, by means of some index buildings of the class for which a full knowledge of geometrical and mechanical properties is available, as well as their spatial nonlinear numerical models. Nonlinear time history analyses were performed on all simplified models to define specific class fragility, accounting for any source of variability (record-to-record and building-to-building). The results of the investigation are compared in terms of class fragility curves, in order to highlight the differences between the two modelling approaches.*

**Keywords:** Class Fragility Curves, Typological Data, SDOF Models, MDOF Models.

---

## 1. INTRODUCTION

The studies about seismic fragility at class-level of buildings have recently become increasingly numerous among researchers, which try to individuate the main sources of vulnerability and to reduce the related risk of several typologies of building portfolios. Of growing interest are the investigations focused on the existing building stock, which is often characterized by an high probability of damage, especially if subjected to earthquakes. Several examples of the catastrophic effects given by earthquakes are available, with regard to different building typologies having different social importance, such as residential [1-2], strategic (e.g., schools [3-4] or hospital), precast and ecclesiastical buildings [5]. A myriads of approaches can be employed for defining fragility functions for class-level assessment purposes, in which four macro-categories can be identified: (i) empirical [6-7], (ii) mechanical [8-11], (iii) judgemental [12] and (iv) hybrids methods. Among these, in this study we are going to argue about mechanical ones, focusing on the results achievable by different modelling approaches.

Generally, the mechanical methods allow to perform fragility/vulnerability assessment through a direct derivation of the relationship between seismic intensity and damage states/losses. This is possible by means of the analysis results (usually nonlinear dynamic or static) carried out on numerical models, which simulate a single or a class of buildings. The results of a fragility function, elaborated for large-scale purpose, is strictly related to the quantity and the quality of the numerical models at disposal, which in turn depends from the available data. With this regard, Silva et al. [13] defined the two extreme options: (a) few detailed multi-degree-of-freedom (MDOF) models; (b) many single-degree-of-freedom (SDOF) models. The first option consists in the selection of few real (or idealized) archetypes representative of a certain building class, characterized by a detailed knowledge of all structural components and all geometrical and mechanical properties. This is the case of the so-called index-buildings, which are usually selected through the expert opinions of the analyst, as made in [10,14]. Obviously, an incorrect selection of the index-building properties can lead to a misleading fragility evaluation, frustrating the related analysis efforts. The second option consists in an extensive analysis process on a large number of reduced-order models, generated on the base of few data and outlined through simple computations. The easy management and the evident discount in terms of analysis efforts makes the SDOF models the most attractive option, as shown in several literature works [15-16], although the loss of accuracy in each single model (e.g. local responses, structural irregularities) assumes a key role in the fragility estimate. In the middle, other methods are available from the scientific literature, balancing accuracy vs. complexity and quantity vs. quality of numerical models [17-19].

In all cases, by referring to class-level fragility, the starting point is the definition of a building taxonomy, which can vary on the basis of the sample size. As a matter of fact, to represent the overall fragility of a specific class via simple SDOF models, few data are necessary, such as the construction material, the year of construction or the number of storeys. On the other hand, the adoption of complex MDOF models requires the knowledge of detailed information, which implies a not always sustainable economic and computational burden in the investigation and analysis phases.

Anyway, the goodness of the fragility function is strongly influenced by two not negligible aspects: (a) the analysis method (b) the uncertainty treatment. On the analysis side, static pushover (SPO) analysis [20] and nonlinear response history analysis (NRHA) contend for the title of best, where the first approach wins in simplicity and intuitiveness, while the second approach dominates the first one in the prediction of seismic response of buildings, accounting for the real nature of earthquakes (use of ground motions) and for the features variability of any kind of buildings (e.g., structural irregularities, influence of higher modes). On the uncertainty side, NRHA approach can be preferred in class-fragility analysis, where record-to-record variability can be taken into account by

evaluating its contribute on the basis of the number of records employed, the selected intensity measure (IM) and the investigated engineering demand parameter (EDP). In addition to this kind of uncertainty, the intra-building and the inter-building uncertainties are to consider, where the first one refers to the uncertainty in the knowledge of each investigated building and the second one aims to define the variability of each building in the selected ensemble to represent the class.

In this wide range of options, a study on the fragility function of a class of real school buildings in Puglia (Southern Italy) is provided, by exploring the two abovementioned modelling extremes: many simple SDOF models vs. few complex MDOF models. Given a building taxonomy, the comparison among fragility curves at safety limit-states is provided, by using the results of 10 complex MDOF models selected from the work by Ruggieri et al. [21] and the response of 735 SDOF models elaborated from the information contained in some freely available exposure databases (ISTAT Census data [22], ARISTOTELES Project [23], Open Data about Italian schools provided by Italian Ministry of University and Research (MIUR) [24]). Fragility functions will be developed by opting for a NRHA approach, as well as by running cloud analyses on MDOF models and incremental dynamic analyses (IDAs) on SDOF models [25]. For the case at hand, we can anticipate that the seismic behaviour of SDOF models (e.g., backbone curve), which could be evaluated through any number of methods proposed by the scientific literature, has been evaluated looking at the MDOF models, their modelling assumptions and their seismic response.

## 2. MODELLING METHODOLOGIES FOR SDOF SYSTEMS FOR CLASS-LEVEL ASSESSMENT PURPOSES

The use of SDOF models for developing class fragility/vulnerability functions has been often adopted by researchers to limit the computational burden for larger sets of buildings [15-16]. The parametrization of the inelastic behaviour of SDOF, as well as the backbone shape, can be elaborated through different fairly popular procedures. For example, Ruiz-García and Miranda [26] elaborated a probabilistic approach to estimate the maximum inelastic displacement demands of SDOF systems, by providing a new version of the  $R$ - $\mu$ - $T$  (strength ratio-ductility-period) relationship [27], through the definition of the constant-strength inelastic displacement ratios. Vamvatsikos and Cornell [28] proposed a pushover-based approach to investigate the dynamic behaviour of SDOF models, simulated through a quadri-linear backbone and contextually, authors developed the SPO2IDA tool. The same approach was involved in the analytical studies developed in FEMA P440A [29], which presents the force-displacement capacity of some spring typologies to employ in SDOF systems for simulating different building behaviours, expressed in terms of maximum inter-story drift ratio ( $\theta_{max}$ ) vs. the normalized base shear on the yield value ( $V_b/V_{b,y}$  or  $F/F_y$ ). Lagomarsino and Giovinazzi [30], proposed the relationships to relate macro-seismic and mechanical-based approaches, in which authors provided criteria to trace the SDOF backbone curves for several class of European buildings. Vamvatsikos and Aschheim [31] adopted the paradigm of Performance-Based Design, by means of Yielding Frequency Spectra approach, to define an equivalent SDOF model from a MDOF one, as well as after applied by Kohrangi et al. [32] in the vulnerability model for buildings in the municipality of Isfahan, Iran.

Herein, we are adopting the procedure suggested in [32], by assuming a backbone curve of SDOF models (and the boundary control points for the spring to employ, in terms of  $\theta_{max}$  vs.  $F/F_y$ ) according to the seismic behaviour of full MDOF models, given a building taxonomy. With regard to the building taxonomy, it is necessary that both SDOF and MDOF models are belonging to same class, which is defined by the parametrization of at least five parameters, usually available in freely online databases: construction typology ( $CT$ ), year of construction ( $CY$ ), number of storeys ( $NS$ ) and

two values among in-plan area ( $A$ ), total volume ( $V$ ), interstorey height ( $H_i$ ) and total height ( $H_{TOT}$ ). Within the online databases containing the required information, the parameters  $A$  and  $V$  are often available and they can be employed by means of simple equations and assumptions, to estimate all the key features of the building taxonomy. In particular, knowing  $CT$ ,  $CY$  and  $NS$ , the other parameters can be found with the following equations (or with the inverse formulations):

$$H_{TOT} = \frac{V}{A} \quad (1)$$

$$H_i = \frac{H_{TOT}}{NS} \quad (2)$$

In addition, assuming the typical values of gravity loads ( $L$ ) for the selected building class, it is possible to compute the total mass ( $M$ ) and the total weight ( $W$ ) of the buildings:

$$L = G + \psi_{k2} \cdot Q_k \quad (3)$$

$$W = A \cdot L \cdot NS \quad (4)$$

$$M = \frac{W}{g}; m_i = \frac{M}{NS} \quad (5)$$

where  $G$  and  $Q$  are, respectively, the dead and the accident loads,  $\psi_{k2}$  is the combination coefficient for the quasi-permanent  $k^{th}$  load,  $g$  is the gravity acceleration and  $m_i$  is the mass of the  $i^{th}$  storey. While  $Q$  can be defined on the basis of the prescriptions provided by the current building code,  $G$  is an unknown parameter, which can be established on the basis of the typical features of the building typology investigated. To support the definition of  $G$ , the knowledge of the technologies and the loads detected on some MDOF buildings is fundamental, in order to identify the most employed typologies of slabs, external and internal masonry infills, floor tiles and other finishes.

To define the SDOF behaviour, the formulation defined in [31] and developed in [32] can be employed, where the parameters of an equivalent SDOF are provided. In particular, given the building taxonomy, the approach consists in the definition of eight parameters and a SDOF backbone shape. Among the eight parameters,  $NS$  and  $H_i$  are directly identified from the input building database. Three of the eight parameters can be fixed a-priori, as well as the participation factor ( $\Gamma$ ) and the mass participation factor ( $a_1$ ) for the first vibration mode and the conventional damping ratio ( $\zeta$ ). For the case at hand, both  $\Gamma$  and  $a_1$  can be fixed equal to 1, as suggested in [32]. The remaining three parameters are:

- The base shear coefficient,  $C_y$ , identified as the ratio between the yield base shear and the total weight of the structure ( $V_{b,y}/W$ );
- The yield storey drift,  $\theta_y$ , evaluated on the real elastic behaviour of MDOF building;
- The coefficient of distortion,  $\alpha_{COD}$ , which represents the ratio between the peak interstorey drift and the related roof drift, as following defined:

$$\alpha_{COD} = \frac{\theta_{max}}{\theta_R} \quad (6)$$

Operationally,  $C_y$  can be defined on the yield code spectrum given the yield displacement ( $\delta_y$ ), because it is equivalent to yield spectral acceleration (expressed in unit of  $g$ ). To define  $\delta_y$  as suggested in [31], the following equation can be adopted:

$$\delta_y = \frac{\theta_y \cdot (NS \cdot H_i)}{\Gamma \cdot \alpha_{COD}} \quad (7)$$

Eq. 7 depends from the parameters  $\theta_y$  and  $\alpha_{COD}$ , where the first one can be defined by observing the behaviour of the available MDOF structures, while  $\alpha_{COD}$  can be defined according to [33, 34]. This parameter is the simpler way to define the deformation behaviour of buildings and, for a generic MDOF system,  $\alpha_{COD}$  ranges between 1.1 and 1.4 as long as the building behaves as elastic. After the

yielding and for higher values of  $\theta_{max}$ ,  $\alpha_{COD}$  tends to increase, as shown in [31]. For a one-storey building  $\alpha_{COD}$  is equal to 1. Once that all the eight parameters are defined, the period of each SDOF system ( $T^*$ ) can be evaluated as:

$$T^* = 2\pi \cdot \sqrt{\frac{\delta_y}{c_y \cdot g}} \quad (8)$$

Finally, to define the backbone shape of SDOF system, it is possible to pursue different options, basing on the expected behaviour of the simulated buildings. The simpler option is the elastic-plastic shape, while to better simulate the post-elastic behaviour it is possible to refer to the parametric capacity curve shapes provided by FEMA-P440A [29]. The presented SDOF models can be employed in the fragility function, by means of the results provided by the analysis phase. Some additional remarks can be added for the development of the procedure. Firstly, for a class-level purpose, different seismic actions can be considered within the focused area and the definition of the yield spectral acceleration can be differentiated on the basis of the buildings localization. After, some of the eight parameters, such as  $\theta_y$ , can be established a-priori on the basis of the *CY* of the buildings and the reference building code [32]. Nevertheless, the detailed knowledge of the structural behavior of some MDOF structures, representative of the building class, can be used for having a reliable indication about the effective values to employ in the procedure. In the end, also the adoption of the FEMA-P440A backbone curves [29] could represent a simplification. Also for this aspect, the seismic response of few MDOF structures belonging to the identified class can be employed for a calibration of a specific-class backbone curve shape, to involve in the fragility function through the simplified modelling approach.

### 3. DEFINITION OF AN HOMOGENEOUS CLASS OF SCHOOL BUILDINGS IN PUGLIA, SOUTHERN ITALY

The starting point of this study is represented by 15 real RC school buildings in the province of Foggia, Puglia, Southern Italy. In particular, for these buildings, which present a generalized in plan irregularity, a near-full information of the geometrical and mechanical features is available and, according to the work by Ruggieri et al. [21], the 3D numerical models of buildings and the related pushover analyses in both directions are at disposal. Following the procedure in Section 2, within this sample of buildings, it is possible to define an homogenous subset aimed to identify a building taxonomy, according to some key parameters and additional historical information.

Firstly, all buildings present a *NS* ranging from 2 to 3, which suggest that the entire sample is constituted by low-rise buildings, also according to the classification provided by HAZUS [35]. After, concerning to the *CT*, all buildings are RC moment-frame buildings, which do not present RC walls and all buildings present infill panels (in some cases, the eternal frames are totally infilled, while in others they are partially infilled and presenting ribbon windows). The discriminant parameter is the *CY*. Despite all buildings were designed between 60' and 80', three main historical aspects have to be considered to define the building taxonomy [23]:

- After some modifications occurred in 1935 and in 1969, the Apulian seismic map was upgraded in 1981, and some municipalities of the Province of Foggia (North of the Region) were redefined from non-seismic to low-seismic areas, as shown in Figure 1.
- Between 1972 and 1979, Italian governments released a new version of the Italian building code, in which new design rules were introduced accounting for the first anti-seismic requirements.
- In the subsequent years to the Second World War (from 1945 to 1950), new buildings difficultly presented RC moment-frame structural systems, because it was very likely the

presence of masonry structural parts. This evidence was caused by the aftermaths of the Fascism that previously forbade the use of the steel in Italy.

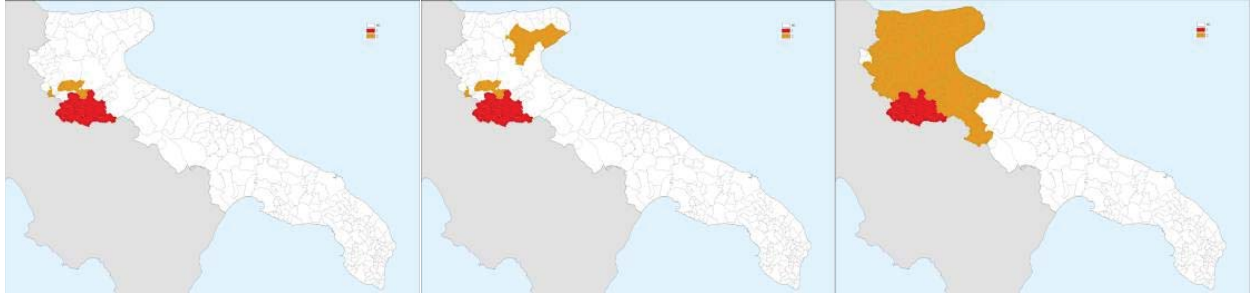

Figure 1 – Evolution of the seismic classification in Apulian Region with reference to, respectively, 1935/03/25, 1962/11/25 and 1981/3/7 [23]. The white part indicates non-seismic areas, the orange part indicates a low-seismic areas (zone 2) and the red part indicates a medium-high seismic areas (zone 1)

Then, with regard to *CY*, the buildings belonging to homogenous class are the ones built between the 1950 and 1979 and located in the municipalities classified as non-seismic areas (according to the seismic classification provided by Italian governments and shown in Figure 1), within the indicated time period. According to the identified building taxonomy, 10 of 15 school buildings fall under the homogenous class. Figure 2 reports the pushover curves in both main directions (X and Y, according to the reference system adopted in [21]) for the new subset of buildings, labelled as B1-B10 (From the total sample, B3, B4, B5, B6 and B10, as defined in [21], have been excluded and the remaining 10 buildings have been renumbered).

Figure 2 – Pushover curves in both directions (X,Y) of the 10 RC school buildings, belonging to the identified building class

For a purpose of class-level assessment, given the building taxonomy, several buildings can be identified from freely available databases, for which few data are at disposal. For the case at hand, two open databases have been consulted and elaborated: (a) database developed in ARISTOTELES Project [23] and (b) Open Data about Italian schools provided by Italian Ministry of University and Research (MIUR) [24]. From the first database, which was based on the ISTAT Census data [22], information about all the existing schools in Puglia have been gathered with reference to 2001. In particular, data on *CY*, *CT*, *NS*, *V*, *A*, municipalities where buildings are located and the related seismic evolution in the time were extracted. From the second database, information about all the existing

schools in Italy have been collected with reference to 2019. In detail, it presents only the exact location of each school building (municipality, address, postal code) and information on  $CY$ ,  $A$  and  $V$ . In both databases, each unit presents an univocal code to identify the school. By matching the two databases through the comparison of the common data (univocal code, municipality,  $CY$ ,  $A$  and  $V$ , evaluated with a certain tolerance) and with regard to the given building taxonomy, 735 existing RC school buildings have been selected. All data have been elaborated according to the Eqs. 1-5. More in detail, after the evaluation of  $H_i$  and  $H_{TOT}$  for all buildings, a value of  $L$  equal to  $6 \text{ kN/m}^2$  has been supposed, given by the assumption of a value of  $G$  equal to  $5 \text{ kN/m}^2$ , a unique value of  $Q_k$  equal to  $3 \text{ kN/m}^2$  and a value of  $\psi_{k2}$  equal to 0.3 in accordance with the Italian Building code (NTC18) [36]. Figure 3 reports the geographical distribution of all identified buildings, where the greater part of the units are located in the South and in the Central of the Region, while only few buildings have been considered in the North, accounting for the existing seismic zoning in the assumed time interval.

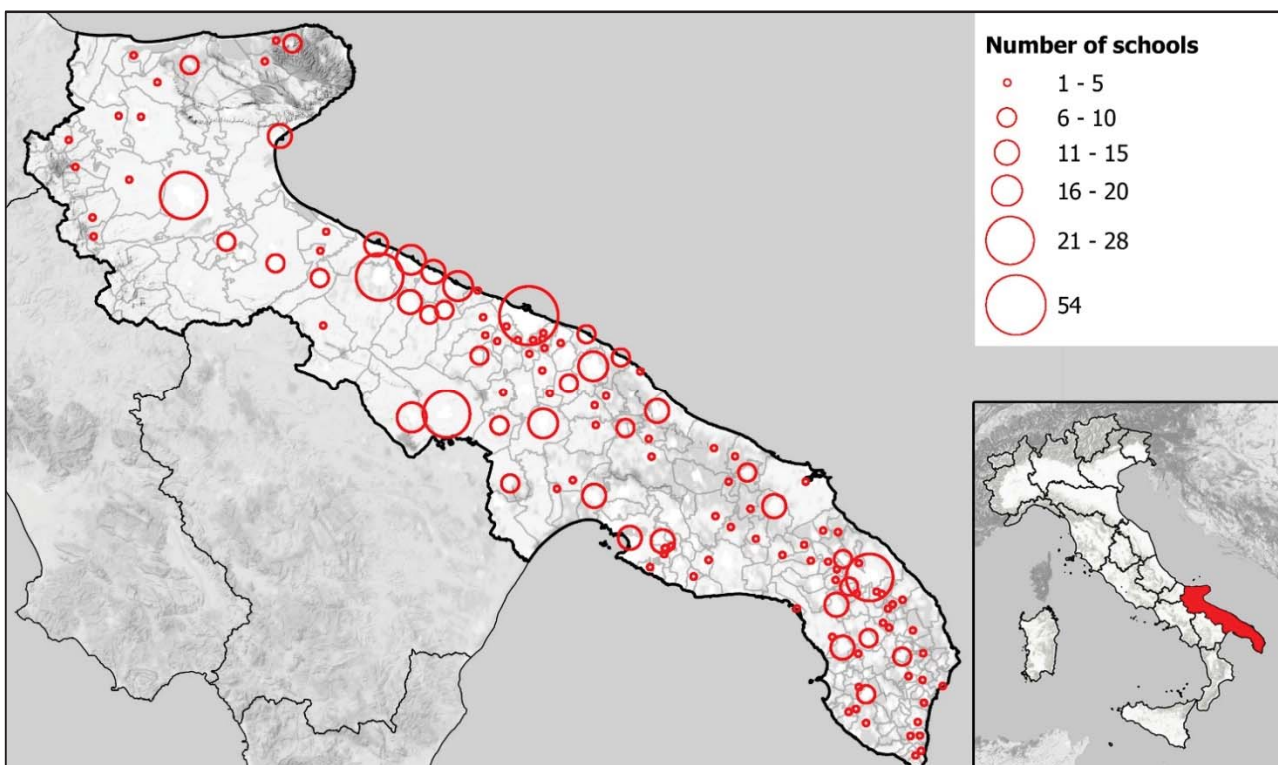

Figure 3 – Distribution of the selected 735 school buildings along the Region, according to the given taxonomy

#### 4. SEISMIC FRAGILITY ASSESSMENT AT CLASS-LEVEL

##### 4.1 Numerical models

For both samples made by 10 MDOF and 735 SDOF systems, different modelling strategies have been employed. Concerning to the modelling of the 10 full models of the known school buildings, the reference is the work made in Ruggieri et al. [21], where the nonlinear MDOF models were carried out through a lumped plasticity approach and by implementing all the geometrical and mechanical features at disposal. As just shown in Figure 2, a ductile behaviour is assumed, by neglecting for simplicity the influence of shear mechanisms and infill panels. Nevertheless, as declared in [21], shear failures given by low transversal reinforcement of structural elements can be evaluated a posteriori, by checking the brittle mechanisms of beams and columns. After, all the 735 buildings belonging to the homogenous class have been elaborated for a SDOF approach. More in detail, looking at the SPO curves of the 10 MDOF structures, a value of  $\theta_y$ , equal to 0.25% has been

fixed while, according to [32], the values of  $\alpha_{COD}$  are assumed equal to 1, 1.25 and 1.35, respectively for 1-storey, 2-storeys and 3-storeys buildings. Using Eq. 7, the values of  $\delta_y$  have been defined for all buildings. Later, assuming an elastic code spectrum, the values of  $C_y$  have been defined, which are the same values of the spectral accelerations. Finally, by means of Eq. 8, the values of  $T^*$  have been determined. With regard to the assumed elastic code spectrum, the seismic actions in the regional capital (Bari, which is in the Central of the Bari) has been considered, as good compromise between the higher seismicity in the North and the lower seismicity in the South. Still, in the elastic code spectrum has been computed by using an unitary behavior factor and by considering an usage class adequate to school buildings, with a coefficient equal to 1.5. Lastly, no any amplification factors due to e.g., soil and topography categories have been considered. For few cases of the buildings investigated, high values of  $V_{by}$  are obtained, considering high values of  $A$ , as typical for school buildings in the focused geographic zone. In addition, a large set of  $T^*$  is identifiable, which ranges about from 0.3 s to 0.8 s and given by the different  $NS$  that characterize buildings in the considered sample.

Therefore, all 735 buildings have been modelled through nonlinear SDOFs oscillators. In particular, the springs of the SDOF systems have been simulated by using OpenSees software [37], opting for a Pinching4 material to define the quadri-linear force-displacement capacity boundaries. Regarding to the backbone capacity of the springs employed in the SDOF models, “spring 3b” provided by FEMA-P440A [29] has been considered. As a matter of fact, according to the modelling strategy adopted for the MDOF structures, a ductile behaviour has been accounted for, as visible in the backbone curve shape reported in Figure 4 (right), which also reports the boundary control points of the backbone curve. All coordinates of the normalized hinge (each point is indicated with a letter, labelled from  $A$  to  $G$ ) are specified in Table 1 and they are reported in terms of  $\theta_{max}$  vs.  $F/F_y$ . In conclusion, the results about SDOF models are displayed in Figure 4 (left), where capacity curves of 735 models are displayed in terms of  $C_y$  and  $\delta_R^*$  (light grey lines) as well as the mean and the standard deviation of all realizations (black lines).

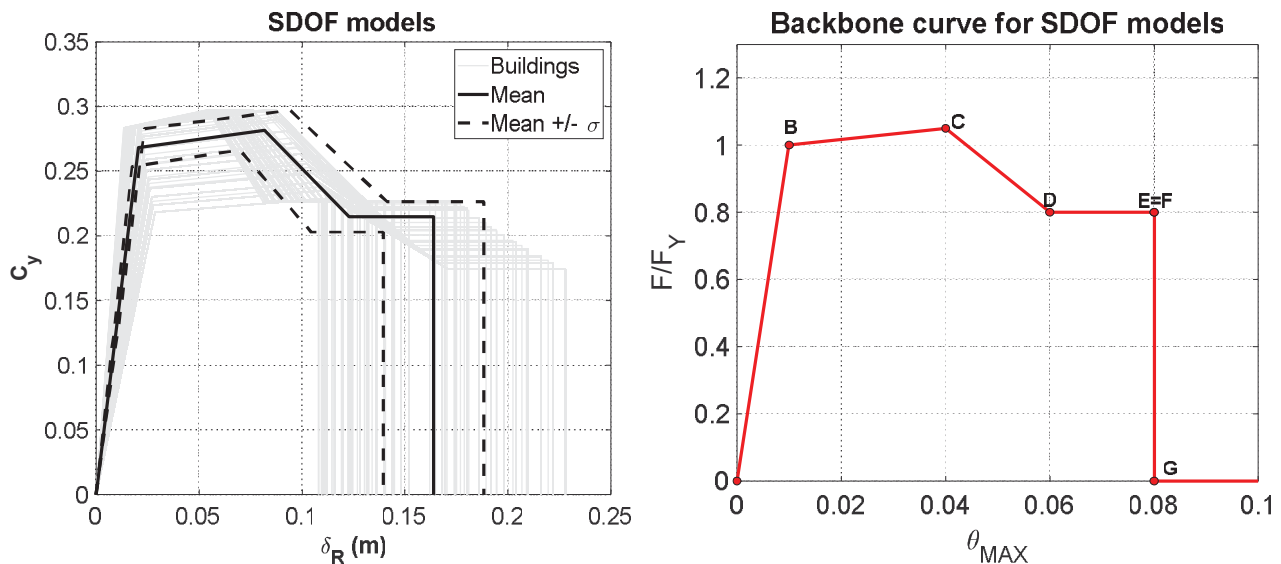

Figure 4 – Capacity curves of the 735 SDOF models generated, displaying mean and standard deviation (left); Backbone curve of SDOF models, according to the prescriptions provided by FEMA-P440A [29] (right)

Table 1. Coordinates of the boundary control points of the Spring “3b” by FEMA-P440A [29], expressed in terms of  $F/F_y$  vs.  $\theta_{max}$ 

Structural system	Quantity	B	C	D	E	F	G
Spring 3b - FEMA-P440A [29]	$F/F_y$	1.00	1.05	0.80	0.80	0.80	0.00
	$\theta_{max}$	0.01	0.04	0.06	0.08	0.08	0.08

#### 4.2 Seismic analysis and class fragility function

The structural response of the 735 SDOF models have been investigated through NRHAs, according to the IDA methodology, while the MDOF models were investigated through SPOs analyses and NRHAs [21]. These latter analyses were performed according to a practice-oriented principle (computational cost reduction) and, for this reason, only few NRHAs have been carried out. With regard to the number of records employed, MDOF models were subjected to a set of 11 ground motion records characterized by two horizontal components, to investigate 3D models in both main directions. For sake of comparison, the same set of 11 ground motion records has been employed herein, by running IDAs with all the 22 horizontal components to each SDOF model. Figure 5 shows an example of the analyses performed on the numerical models, both for SDOF and MDOF systems, by assuming as IM the average spectral acceleration ( $AvgSa$ ) evaluated in a range period from 0.2 s to 2 s and as EDP, the values of  $\theta_{max}$ . In particular, IDAs on the SDOF model n. 10 are shown in the left graph while cloud analyses on B1 are shown in the right graph, where black and red dots indicate, respectively, non-collapsed and collapsed points (Both models are characterized by a  $NS$  equal to 2). Regarding to the cloud analyses on 3D models, the results have been recorded in both main directions and, for sake of comparison they are expressed in a unique IM-EDP plane, by considering as response the square-root-of-sum-of-squares rule of the  $\theta_{max}$  in both main directions. Having the structural responses for both sets of models, fragility analysis have been performed. In particular, the fragility functions are differently developed for the two modelling extremes. For identifying the EDP distribution conditioned by the IM value, a power law approximation has been developed on the structural responses of MDOF systems [38], while an IM-basis approach has been employed to IDA results of SDOF systems.

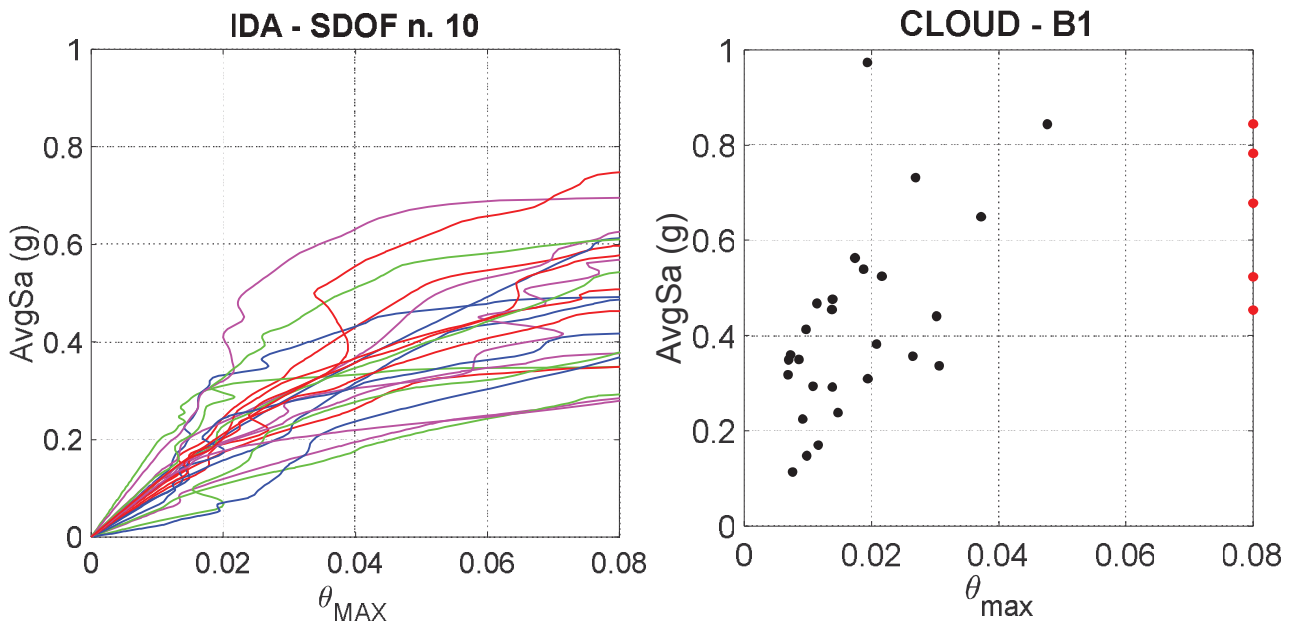

Figure 5 – IDAs on SDOF models (plot for SDOF model n. 50) vs. cloud analysis on MDOF model (plot for building B1, where black and red dots indicate, respectively, non-collapsed and collapsed points)

With regard to the limit-states to investigate, in this study all evaluations have been referred to the safety limit-states, considering that the collapse mechanisms can be given by brittle and ductile failures. In a practice-oriented view, three limit-states have been defined, as well as near-collapse (NC) for brittle and ductile mechanisms and life-safety (LS) for ductile mechanisms. While the achievement of the limit-states can be evaluated independently on each MDOF system by observing the effective structural behaviour of the simulated buildings, a different approach needs to be employed for SDOF models. As a matter of fact, despite a large sample of SDOF models allows to provide a good coverage of all buildings falling into the entire class, this modelling approach does not guarantee an accurate structural failures prediction, especially in the cases of structural irregularities and of higher modes relevance. To establish a valid approach that combines the effective local and global behaviours provided by MDOF models and the simplified estimates provided by SDOF models, fixed values of  $\theta_{max}$  have been assumed for both the involved modelling approaches. In particular, a  $\theta_{max}$  equal to 0.5% has been assumed for NC-brittle limit-state, while thresholds equal to 3.2% and 4.3% have been assumed, respectively, for LS- and NC-ductile limit-states.

These limits are selected by extending the mean values of the thresholds obtained for the buildings selected from the work by Ruggieri et al. [21] to the overall behaviour of the backbone curves for SDOF models. Looking at the boundary control points in the backbone capacity curve (Figure 4, right), NC ductile limit-state is fixed on the branch *C-D*, which identifies the softening part that leads to the residual lateral strength, while LS is fixed in the branch *B-C*, precisely at the end of the hardening phase.

Once that fragility curves have been evaluated for all units of the identified class, accounting for all limit-states of interest (NC - brittle, LS and NC - ductile) and for the two modelling and analysis approaches (cloud on 10 MDOF vs. IDAs on 735 SDOF), class fragilities are estimated by virtue of the laws of total expectation and total variance. In particular, the ensemble lognormal mean ( $\mu_C$ ) is given by the mean of all individual lognormal means, while the related dispersions ( $\beta_C$ ) are evaluated through the sum of the squares of the intra-building and inter-building dispersions. The class fragility curves are displayed in Figure 6, in terms of probability of exceedance of the building capacity conditioned by the IM value assumed for the limit-state considered ( $P[IM > IM_C | IM]$ , where  $IM_C$  is the capacity IM), both for the 735 SDOF models (left, with all fragility curves for all individual units, displayed in light grey) and the 10 MDOF models (right). Table 2 reports the values of the fragility curves parameters, in terms of  $\mu_C$  and  $\beta_C$ .

The comparison among the two modelling options shows that for the NC-brittle limit-state, the values of  $\mu_C$  and  $\beta_C$  are similar while for the LS-ductile and NC-ductile limit-states, the values of  $\mu_C$  and  $\beta_C$  obtained by SDOF models are lower than the ones provided by MDOF models. Nevertheless, considering the percentage difference obtained in terms of  $\mu_C$  for NC-brittle limit state, which is in the order of 50%, it is evident how the two modelling approaches do not return comparable results. This is mainly due to the structural irregularity presented by MDOF structures (and by school buildings in general), which cannot be predicted by a simple SDOF modelling approach. As a matter of fact, as shown in Figure 5, the results obtained by SDOF models are conservative, also for lower values of  $\theta_{max}$  and for an elastic behaviour, which should return similar values of  $\mu_C$  for a fixed EDP value. These disparities in results lead to improve the simplified modelling approaches for fragility analysis at class-level, especially for irregular buildings. Other reasons can justify the obtained differences, considering that the higher dispersions of the fragility curves obtained by the MDOF models can be addressed to the combination of some aspects: (i) few models are available for representing the class; (ii) few NRHAs have been performed on MDOF structures; (iii) the continuous IM-EDP representation through power law is characterized by a certain approximation degree. Obviously, the choice of running few NRHAs on MDOF models allow to reduce the computational cost related to the analysis, which represents a limit in a large-scale analysis. On the SDOF approach

side, the main advantage of the approach is the possibility to consider the differences in median responses of the sample (inter-building dispersion) and the structural responses given by the set of records employed (intra-building dispersion). On the other hand, the knowledge of the structural behaviour of some MDOF structures could play a key role in the SDOF system definition, because it could allow to better fix some parameters, e.g. backbone curve shape, limit-state thresholds, besides to account for the structural irregularities. In the end, the proposed comparison shows advantages and disadvantages of the two modelling and analysis extremes in the seismic fragility prediction at class-level, with different results that require further investigations, especially for the SDOF modelling.

Figure 6 – Fragility curves for the specific-class investigated, accounting for safety limit-states (NC - brittle, LS and NC - ductile) and for the two modelling approaches (SDOF and MDOF)

Table 2.  $\mu_c$  and  $\beta_c$  values for fragility curves of the specific-class investigated, accounting for safety limit-states (NC - brittle, LS and NC - ductile) and for the two modelling approaches (SDOF and MDOF)

Model	NC (Brittle)		LS (Ductile)		NC (Ductile)	
	$\mu_c$	$\beta_c$	$\mu_c$	$\beta_c$	$\mu_c$	$\beta_c$
SDOFs	0.045	0.466	0.246	0.340	0.296	0.362
MDOFs	0.077	0.763	0.533	0.488	0.753	0.557

## 5. CONCLUSION

A study on the seismic fragility of existing RC school buildings in Southern Italy is presented, by leveraging on few detailed MDOF models and a large sample of simplified SDOF models. In the first step, a building taxonomy for the specific-class has been investigated, by defining the ranges of some typological parameters, such as the construction typology, the year of construction and the building height. After, by using the available data from some freely databases containing information about Italian school buildings and based on the Census data, 735 buildings have been selected and a SDOF modelling approach has been employed. The lateral behaviour of the 735 models has been defined on the basis of methodology developed in [31, 32], and they have been compared with 10 buildings belonging to the class, for which a full modelling and the nonlinear analyses results are available [21]. The entire sample of 735 reduced-order models have been generated and investigated through IDAs. The comparison among the safety fragility curves obtained by the two modelling

approaches, the two analysis methods and the two samples of buildings having a different size, provides different results for safety limit-states, as well as brittle and ductile ones. The differences confirm the evidence that the SDOF modelling herein adopted is low accurate to predict the behaviour of irregular buildings, also for low EDP values, which imply an elastic behaviour of buildings. Generally, conservative estimates are provided by SDOF models, with higher values of medians and dispersions for MDOF models. From the MDOF side, the choice of index buildings that effectively represents the class is the main hurdle, as well as the complexity and the effort for an extensive analysis phase. On the other hand, MDOF system represents the best way to reproduce the seismic response of the class, accounting for global and local behaviour. From the SDOF side, the methodology allows to consider a more accurate estimate of the structural responses for the given building class, accounting for any source of variability (record-to-record and building-to-building). In the end, the characterization of the simple models could require the knowledge of the overall behaviour of more complex structures belonging to the class, which drives to find future calibration processes, especially for irregular structures as school buildings. The employment of the two modelling extremes in class fragility studies and subjected to different nonlinear analyses suggests advantages and disadvantages of both methodologies, as well as the necessity to further investigations to improve the approaches at class-level.

## ACKNOWLEDGMENTS

Authors thank Prof. Dr. Dimitrios Vamvatsikos for his kind help and insightful suggestions in the development of the work. The research presented in this article was funded by the Italian Department of Civil Protection in the framework of the national project DPC-ReLUIs 2019-2021.

**Abstract.** *Differential settlements during earthquake ground shaking at the base of framed buildings located on the crest of slopes can produce heavy damage. This reflects the importance of considering ground shaking and co-seismic vertical displacements as interacting hazards in seismic fragility assessment. Slow-moving landslides are indeed secondary hazards of earthquakes that can induce significant damage accumulation, increasing the seismic vulnerability of structures. This paper presents the main findings of a seismic fragility analysis that was carried out on RC framed structures representative of low-rise, pre-code, residential Italian buildings. The methodology behind this study made use of fibre-based structural models and sequential nonlinear static analysis, which allowed the simulation of structural response to both earthquake ground motion and differential settlements with acceptable computational cost. Based on multivariate regression models available in the literature and random sampling of structures, seismically-induced settlements at the base of each structure were simulated considering multiple intensity measures (IMs) of seismic ground shaking. The correlation between the selected IMs was derived through a recent database of 250 accelerograms, which allow a wide representation of seismic hazard in the whole Italian territory for seismic risk assessment. The buildings were analysed with OpenSees software, assuming four performance limit states for characterization of seismic fragility at multiple levels of structural damage. The comparison between fragility curves associated with earthquake ground shaking only and those derived considering differential settlements allows the impact of cumulative damage to be evaluated.*

---

## 1 INTRODUCTION

Post-earthquake reconnaissance missions have shown that earthquakes often produce slope instability, resulting in landslides that can exacerbate seismic damage to buildings and infrastructure and hence both life and economic losses. Buildings located on the crest of slopes can experience co-seismic displacements associated with slow-moving earthquake-induced landslides. This suggests considering the interaction between earthquake ground shaking and such landslides in seismic risk assessment of buildings. In this context, the development of probabilistic methodologies allows engineers, decision makers and stakeholders to carry out a multi-hazard risk analysis accounting for different sources of uncertainty in shaking and landslide hazards, vulnerability, and exposure.

In recent years, research developments in this field have been made, particularly in the case of reinforced concrete (RC) buildings but usually neglecting the uncertainties on their geometry and material properties that play a role in performance-based seismic assessment of existing structures. Foutopoulou and Pitilakis [1–3] studied the vulnerability of buildings to earthquake-induced landslides, making use of three-dimensional finite element (FE) modeling and nonlinear time history analysis of both the slope and building. Nonetheless, that computational strategy can be too computationally demanding for seismic vulnerability assessment of building classes that are spatially distributed within a region.

In this study, a computationally efficient method for probabilistic vulnerability assessment of RC buildings subjected to earthquake-induced landslide hazard is presented. The proposed methodology builds upon a recent selection of strong ground motions oriented towards large-scale risk assessment of buildings, which allows incorporating correlation between different intensity measures (IMs) used for earthquake ground shaking and slow-moving landslides.

## 2 METHODOLOGY

The vulnerability assessment described in this paper is based on a probabilistic procedure that allows modelling and propagation of uncertainties through fragility analysis, which is a well-established method in earthquake engineering [4]. After that a class of buildings with RC frame structure was selected, the correlation between two IMs used to describe the intensity of earthquake ground shaking and slow-moving landslide was investigated. In this respect, the selected IMs were the peak ground acceleration (PGA) and peak ground velocity (PGV), the correlation of which was investigated via 250 accelerograms that were recently selected in the ReLUIIS-DPC 2019-2021 research project. The accelerograms were characterized by a wide amplitude range reflecting design spectra for L'Aquila, Italy (with return period ranging from 50 to 10,000 years), which was found to give a good representation of seismic hazard over the entire Italian territory [5]. Each accelerogram was characterized by a (PGA, PGV) pair, so the correlation between those IMs was studied over a set of 250 data points. More specifically, PGA and PGV were selected to measure the intensity of shaking and landslide, respectively.

After that seismic input was defined, the authors modelled the uncertainties in structural properties of the selected buildings, creating the basis for random generation of structural models. Random sampling was based on Monte Carlo simulation, which was fully implemented in MATLAB [6]. The structural capacity of RC buildings was defined through a fibre-based FE modelling approach using OpenSees software [7]. The seismic performance assessment of each random model of the RC structure was carried out by means of a sequence of nonlinear static analyses, in which the structural system was first subjected to incremental vertical differential settlement associated with the landslide, and subsequently to incremental horizontal displacement associated with earthquake ground shaking. Hence, the sequential nonlinear static analysis consisted of a nonlinear static analysis under incremental vertical settlement and a pushover

analysis of the structure. The range of settlements impressed to the structure was based on the study by Foutopolou and Pitilakis [8], who proposed a predictive model that allows the prediction of peak co-seismic displacement based on the slope's characteristics and seismic input IMs. This allowed seismic displacement demand associated with slow-moving landslide to be predicted. Seismic displacement demand associated with ground shaking was evaluated according to the N2 method [9]. Seismic fragility of the selected buildings was evaluated with respect to four performance limit states corresponding to increasing damage levels. Each fragility point was derived under increasing PGA, allowing subsequent fitting of lognormal probability distribution to fragility data for development of fragility curves.

In the following sections, the methodology used in this study is described in detail.

## 2.1 Selection of buildings

The building class under study is that of low-rise residential buildings with RC frame structure built in Italy. The uncertainty modelling of those buildings involved consideration of both geometric and material properties. The case-study buildings had two storeys and rectangular plan, with frame systems consisting of 2 spans parallel to the slope crest and 3, 5, or 7 spans in the perpendicular direction. Beams were assumed to have the same span length in each longitudinal and transverse frame of the structure.

Figure 1: Case-study building with geometric random properties.

The mechanical properties of materials were identified by grouping the buildings by construction time according to the evolution of Italian codes. Both buildings built before 1971 (i.e., the year that marked the transition from design to gravity loads only to design for earthquake resistance) and those built between 1971 and 2008 in non-seismic areas according to past seismic zoning of Italy, were considered as pre-code. Low-code buildings were assumed to be those built in seismic areas between 1915 and 2008 according to old seismic design criteria (first-generation earthquake-resistant buildings). Medium-code and high-code buildings are those built after 2008, the former designed in low ductility class (second-generation earthquake-resistant buildings) and the latter in a high ductility class (third-generation earthquake-resistant buildings).

This study investigated the fragility of pre-code RC buildings built before 1971, assuming the following material properties: concrete with compressive strength having a mean value

$f_{cm} = 16.0$  MPa and coefficient of variation  $CoV = 31\%$  [10]; and reinforcing steel with yield strength having a mean value  $f_{ym} = 369$  MPa and  $CoV = 20\%$  [11].

## 2.2 Simulated design of structures

The design of the structural elements was carried out using the design methods used at the time of construction [12,13] and the Italian code in force in the same period [14] (Table 1).

Item	Variable	Value
Columns	$b$ [m]	Derived by simulated design
	$h$ [m]	
	$h_i$ [m]	3.00
	$c$ [mm]	30
Beams	$b$ [m]	Derived by simulated design
	$h$ [m]	
	$l$ [m]	[4, 6]
	$c$ [mm]	30

Table 1: Geometric properties.

The selected buildings were designed against gravity loads only according to the permissible stress method, which was based on the assumption of permissible stresses, linear elastic behaviour of materials, and effects superposition. Table 2 outlines the properties adopted for sizing of beams and columns.

Item	Property	Value
Concrete	$R_{ck}$	160 kg/cm <sup>2</sup>
	$\sigma_{c,adm,c}$	45 kg/cm <sup>2</sup>
	$\sigma_{c,adm,b}$	50 kg/cm <sup>2</sup>
Steel	$\sigma_{f,adm}$	1400 kg/cm <sup>2</sup>
Beams	$A_{c,min}$	300×300 mm <sup>2</sup>
	$A_f$	0.8% $A_{min}$
	$B$	300 mm
	$H$	$r\sqrt{M/b}$
	$A_f$	$t\sqrt{Mb}$
	$r$	0.446
	$t$	0.00174
	$A_{f,min}$	4 Ø12
	Stirrups	Ø6 @ min( $L_{min}/2$ ; $10\phi_{min}$ )

Table 2: Parameters for simulated design of beams and columns.

## 2.3 Definition of performance limit states

The displacement approach used for vulnerability assessment suggests defining the performance limit states (LS) in relation to the strain capacity of the elements considered. According

to the literature [3,12], the strain thresholds listed in Table 3 were assumed in terms of maximum strains of steel ( $\varepsilon_s$ ) and concrete ( $\varepsilon_c$ ) as a function of the construction period. This definition of limit states is in line with the fibre-based FE modelling of the structure, which allows axial strain in materials to be monitored during structural analysis.

Limit State	Analytical definition
LS1	$\varepsilon_{ct,max} = \varepsilon_{ctp}$
LS2	$\varepsilon_{s,max} = 0.0125$ ; $\varepsilon_{cc,max} = 0.0045$
LS3	$\varepsilon_{s,max} = 0.025$ ; $\varepsilon_{cc,max} = 0.006$
LS4	$\varepsilon_{s,max} = 0.045$

Table 3: Definition of limit states.

LS1 was associated with slight damage and was assumed to be attained when the maximum tensile strain in concrete  $\varepsilon_{ct,max}$  reached the cracking strain  $\varepsilon_{ctp}$ . LS2 was associated with moderate damage and was assumed to be attained when either the maximum tensile strain in steel  $\varepsilon_{s,max}$  reached 0.0125 or the maximum compressive strain in concrete  $\varepsilon_{cc,max}$  reached 0.0045. Similar criteria were adopted for LS3 and LS4, which were respectively associated with severe damage and near collapse. In detail, LS3 was assumed to be attained when either  $\varepsilon_{s,max}$  reached 0.025 or  $\varepsilon_{cc,max}$  reached 0.006. The collapse limit state, i.e. LS4, was assumed to be attained when  $\varepsilon_{s,max}$  reached 0.045.

### 3 DISPLACEMENT DEMAND DUE TO EARTHQUAKE-INDUCED LANDSLIDE

As briefly discussed in Sect. 2, 250 accelerograms compatible with design spectra for L'Aquila, Italy (with return period ranging from 50 to 10,000 years), were selected to cover a very wide range of shaking intensities and to allow risk assessment at any site of Italy. Figure 3 shows a bi-logarithmic scatter plot of PGA and PGV for selected ground motions.

Figure 2: Correlation between PGV and PGA of selected accelerograms.

A regression analysis was performed using the power function as model, which on the bi-logarithmic plane is represented by a straight line. Based on the ( $PGA$ ,  $PGV$ ) pairs of the selected accelerograms, the following equation was obtained:

$$PGV = 121.3PGA^{1.097} \quad (1)$$

with a coefficient of determination  $R^2 = 0.799$  and standard deviation  $\sigma_{PGV} = 8.79$  cm/s. Such a regression model allows the random generation of PGV conditioned upon PGA as expected conditional value of PGA plus a sample of the model error, the latter being assumed as lognormal random variable with zero mean and standard deviation equal to  $\sigma_{PGV}$ . Figure 4 shows the distribution of PGV given  $PGA = 0.25g$ .

Figure 3: Probability distribution of conditional PGV given  $PGA = 0.25g$ .

In order to evaluate the permanent displacement  $D$  induced by the earthquake, the study conducted by Fotopoulou and Pitilakis [5] was taken into account. Those researchers developed 5 different predictive models based on single or multiple IMs. In this study, the following predictive model was used:

$$\ln(D) = -8.360 + 1.873 \ln(PGV) - 0.347 \ln(k_y/PGA) - 5.964 k_y \pm 0.64 \epsilon \quad (2)$$

which allows the prediction of  $D$  given  $PGA$ ,  $PGV$  and  $k_y$ , assuming  $k_y$  as yield acceleration coefficient of the slope,  $\epsilon$  is the standard normally distributed variable with zero mean and unit standard deviation and 0.64 is the logarithmic standard deviation.

To take into account the different configurations of the slope, reference was made to the yield acceleration coefficient  $k_y$  that summarizes the effects of both geometric and mechanical characteristics of the slope, the relative location of the building with respect to the slope, and the effects of gravity loads transmitted from the building to the slope.

To cover the majority of cases, 5 values of the parameter  $k_y$  were considered, namely, 0.05g, 0.10g, 0.15g, 0.20g, and 0.25g. For each  $k_y$ -value, 10 levels of PGA between 0 and 1.0g were considered, resulting in 50 combinations. For each value of  $k_y$  and  $PGA$ ,  $10^3$  samples of the building class were randomly generated through Monte Carlo method in order to obtain a sample that is representative of the existing buildings.

#### 4 SEQUENTIAL STRUCTURAL ANALYSIS

The analysis was conducted using the OpenSees opensource software [7]. OpenSees allows users to simulate the response of structural and geotechnical systems subjected to seismic input and/or other types of actions. The construction of a finite element model and subsequent analysis must be implemented in OpenSees through a code in TCL or with more recent versions in Python. For this reason, OpenSees is well suited for applications in the research field, especially when using parametric models for the evaluation of building classes.

Once the geometric, mechanical and load models were defined, the analysis procedure consisted in the application of gravity loads through a first analysis step with force control.

Afterwards, a modal analysis was carried out to identify the first-mode shape to define the corresponding profile of horizontal seismic actions.

The second analysis stage consisted in the application of the settlement at the base of the columns subjected to the landslide. That analysis was carried out with displacement control, assuming a gradually increasing displacement with step equal to 1 mm. In each analysis step, the reaction force at the base of the columns affected by the settlement was computed to check whether columns were compressed. Otherwise, the support at the base nodes was removed in the subsequent analysis phases.

At this point, a nonlinear incremental static (pushover) analysis was performed with displacement control to assess the structural performance under horizontal seismic actions. The roof centroid was assumed as a control point and the first-mode shape of the structure was used to generate the lateral load profile proportional to the product of modal displacements by inertia masses. Pushover analysis was carried out by increasing the roof displacement by 10 mm until a peak base shear degradation of 75% was attained.

Structural performance was assessed during each analysis stage, checking whether axial strains in frame members reached their limit states thresholds outlined in Table 3. In that way, the capacity in terms of displacement associated with each limit state was evaluated.

Whilst seismic demand in terms of vertical displacement was predicted through the model into Eq. (2), the seismic demand associated with horizontal ground shaking was estimated according to the N2 method [9]. Accordingly, the base shear versus roof displacement curve derived through pushover analysis was transformed into the corresponding capacity curve of an equivalent single-degree-of-freedom (SDOF) system, allowing the seismic demand assessment by means of inelastic displacement spectra. The displacement demand was computed for each considered PGA level and compared to the capacity associated with each limit state, allowing the authors to assess whether each limit state was exceeded.

## 5 DEVELOPMENT OF FRAGILITY CURVES

Given a prescribed value of  $k_y$ , for each PGA level the conditional probability of exceeding a prescribed limit state was estimated as the ratio of the number of failure cases  $N_f$  to the total number of simulations (i.e.,  $N_{sim} = 10^3$ ). This allowed the computation of counted fragility under varying PGA. A lognormal probability distribution was then fitted to fragility points to develop a fragility curve for each limit state. Figure 6 shows the fragility curves corresponding to  $k_y = 0.15g$  for all limit states, considering either ground shaking only (dashed lines identified as EQ in the figure legend) or both the combined effect of seismic ground shaking and co-seismic settlement due to slow-moving landslide (solid lines identified as EQ + L in the figure legend). Table 4 outlines the median value of PGA, denoted by  $PGA_{50}$ , and dispersion  $\beta$  corresponding to each limit state.

LS	Ground shaking		Ground shaking + landslide	
	$PGA_{50}$ [g]	$\beta$	$PGA_{50}$ [g]	$\beta$
LS1	0.0055	0.7535	0.0055	0.7535
LS2	0.1312	0.4327	0.1054	0.4125
LS3	0.1752	0.4292	0.1403	0.4120
LS4	0.7233	0.4051	0.3034	0.4204

Table 4: Median and dispersion of fragility curves.

Figure 4: Fragility curves.

The fragility curves show a high vulnerability of the case-study building class even without considering the effect of co-seismic settlement. As expected, slight damage (LS1) consisting of concrete cracking takes place at very low levels of  $PGA$ . For the limit state of collapse (LS4), the co-seismic settlement has a major impact on seismic vulnerability, reducing  $PGA_{50}$  from 0.72g to 0.30g. A lower increase in median  $PGA$  with decreasing dispersion is found for the limit states of moderate damage (LS2) and severe damage (LS3).

The horizontal distance between median values of the fragility curves is a measure of the ductility available in the structure of the case-study buildings. In this respect, the relatively small distance between the fragility curves corresponding to LS2 and LS3 indicates a rather limited ductility of pre-code RC buildings.

## 6 CONCLUSIONS

In the present study, the seismic vulnerability of existing RC buildings subjected to earthquake-induced landslides has been assessed. Buildings placed upstream of the slope and therefore exposed to the effects of co-seismic settlements were considered. Lumping the geometric and geotechnical characteristics of the slopes as well as the presence and relative distance of buildings through the yield acceleration coefficient, 1000 building samples were randomly generated, based on Monte Carlo method. For each sample, a simulated design was carried out to determine the dimensions of the member cross-sections and their reinforcement. Each building model was modelled and analysed in OpenSees by first imposing co-seismic vertical displacements associated with slow-moving landslide and then horizontal displacements associated with seismic ground shaking. Seismic performance under both earthquake-induced landslide and horizontal ground shaking was evaluated through nonlinear static analysis with displacement control. For each sample, the displacement capacity corresponding to four limit states was evaluated and compared to demand, allowing fragility estimation under varying  $PGA$ . The lognormal distribution was fitted to fragility points to develop fragility curves.

The proposed methodology makes it possible to assess the vulnerability of RC frame buildings to seismically-induced landslides through a fully mechanics-based approach. This allows drawbacks of empirical vulnerability assessment methods to be overcome, particularly when observed damage data on buildings struck by earthquake-induced landslides are lacking. It is

also emphasised that the proposed methodology based on fibre-based FE modelling and sequential nonlinear static analysis has a very low computational cost with respect to nonlinear time history, allowing a very large number of simulations on 3D building structures. For each case study (i.e., yield acceleration coefficient), 10,000 analyses on 1000 structural models subjected to 10 levels of seismic intensity were carried out on a personal computer equipped with 8 cores, a 3.6 GHz processor and 32 GB RAM. This allowed 1 analysis per minute, leading to a total duration of 7 days for the entire fragility analysis to be completed.

## ACKNOWLEDGMENTS

This study was developed in the framework of POR GRISIS project (Gestione dei rischi e sicurezza delle infrastrutture a scala regionale), which was funded by Campania Region through POR FESR 2014-2020 programme.

### Abstract

*The earthquakes of the last decades have shown that the Italian residential masonry built heritage has high seismic vulnerability, in particular when considering structures built before 1919. For this reason, it is necessary to develop effective large-scale risk mitigation strategies in order to reduce the huge losses that could occur in the aftermath of an earthquake. In this paper some retrofit interventions applicable mainly to old buildings are presented, explaining their advantages and potential. These interventions are then implemented, through Vulnus 4.0 software, on a database of 205 buildings built before 1919, previously analyzed in their as-built state.*

*Fragility curves are then developed for each building, and are processed in order to create a vulnerability model for different construction periods that takes into account the possible retrofit intervention strategies. Therefore, this procedure allows a comparison between pre and post retrofit intervention fragility, and the results in terms of curves can be used for large scale damage and risk simulations.*

**Keywords:** Residential Masonry Buildings, Territorial-Scale Seismic Vulnerability, Fragility Model, Retrofit intervention.

---

## 1 INTRODUCTION

Over the last decades, Italy has been affected by very impactful seismic events, which caused thousands of casualties and around 180 billion euros of economic losses, in terms of recovery and reconstruction costs [1]. It is clear that those high economic and human costs are no longer sustainable, and large-scale mitigation policies need to be pursued.

In this context, Italian institutions (in particular the Department of Civil Protection - DPC) are working in synergy with the scientific community to find effective seismic risk mitigation strategies [1-3]. In particular, the work presented in this paper is part of a project carried out by ReLUIS (Network of University Laboratories for Earthquake Engineering) and EUCENTRE (European Centre for Training and Research in Earthquake Engineering), and coordinated by DPC. The aim of the project is to develop large scale vulnerability models for consolidated buildings, and then to perform cost-benefit analyses that can give an estimate of the payback time of seismic retrofit interventions. The final purpose is to elaborate mitigated risk maps that simulate different preventive strategies, thus making it possible to identify prioritization and convenience ranking for the different interventions.

In order to do so, one must assess the variation of seismic vulnerability between the as-built configuration and the case where particular seismic retrofit interventions were performed. The estimation of seismic vulnerability, i.e. the propensity of structures to suffer damage after a seismic event of a given intensity, is usually defined by fragility curves. A fragility curve is a probabilistic distribution that expresses the probability of occurrence of a certain damage state in relation to seismic intensity. Usually, lognormal cumulative fragility curves are used [4].

In literature there are several methods to define fragility curves: a) empirical methods, in which fragility curves are calibrated from damage data survey in areas affected by seismic events [5-8]; b) analytical (mechanical) methods, based on structural models and analyses that simulate the seismic behavior of buildings [9-13]; and c) hybrid methods, which have characteristics from both a) and b) methods [14].

In this study, a mechanical simplified procedure was used to obtain fragility curves for Italian residential masonry buildings with eight different types of intervention. This study focuses on residential historical buildings: these are usually stone (mainly random) and solid brick masonry buildings, with timber floors and roofs and in most cases without any retaining elements, such as tie-rods or beams. In particular, buildings dating from before 1919 were analyzed, as they represent the 29.4% of the Italian masonry heritage and the 18.1% of the entire Italian residential building stock [15], but made for the most of damage observed in recent events.

The paper firstly presents the most common seismic retrofit interventions in Italy for the analyzed building type, and defines the main modifications that these interventions produce in structural and mechanical parameters. Then, the selected interventions were simulated in a database composed of 205 Pre-1919 masonry buildings. The program used for the analysis and the elaboration of the fragility curves is the *Vulnus vb 4.0* software [16, 17].

Then, the curves obtained by *Vulnus* are post-processed according to the Donà et al. [18] methodology, in order to obtain a single fragility model.

## 2 INTERVENTIONS FOR SEISMIC RETROFIT OVERVIEW

Interventions for seismic improvement can be grouped in the following categories [19, 20] according to their aim: a) interventions targeting strength and compactness of walls; b) interventions that improve connections, and c) interventions aimed at strengthening and stiffening horizontal diaphragms.

## 2.1 Masonry strengthening and compacting

In case of historical ordinary buildings, the materials that compose the load-bearing stone masonry structure are often not very performing in terms of mechanical characteristics. Several techniques can be applied to improve masonry performance, provided a careful evaluation of the most suitable intervention with respect to the typology and the quality of the masonry is previously carried out [19-21].

When the stone masonry is inconsistent and characterized by the presence of voids (two or three leaves masonry), the most used and effective interventions are grout or mortar injections [22-24]. This type of intervention consists in the grouting of the wall's core through a regular pattern of drilled holes, previously cleaned by water or compressed air. Injections are performed from the bottom to the top of the walls with controlled pressure.

In case of damaged or inconsistent masonry, it is also possible to realize reinforced concrete jackets [25] made of cement or lime-based mortars and a steel mesh or fabrics reinforcement. To the ends of a successful intervention, the reinforcements on both sides need to be well anchored to the wall by the means of transversal connections (Figure 1a).

With stone ashlar or brick masonry, but either with poorly performing resistant elements or poor quality mortars, the most suitable interventions are bed-joint repointing (also reinforced with metal bars) or the application of FRCM-TRM (Fibre/Fabric Reinforced Cementitious Matrix/Mortar – Textile Reinforced Mortars) plasters [26, 27]. The latter consists of reinforced plasters made with glass, carbon, aramid or polypropylene fiber meshes, coated in inorganic matrices based on lime or cement mortar. These reinforcements can be widespread to the entire surface of the walls or applied locally (Figure 1b) [28, 29].

Figure 1: Reinforced concrete jackets (a) and example of application of FRCM-TRM (b).

The condition of multiple leaves that are not adequately connected to each other can occur in both brick and stone masonry. In order to guarantee the overall functioning of the wall, it is possible to insert artificial transverse elements in its thickness (made of reinforced concrete or metal profiles), or metal tie-rods (made of smooth or threaded bars) with an anti-expulsion function [22, 22]. This type of intervention is feasible only if the masonry is consistent enough to ensure the solidarization between the faces.

## 2.2 Improvement of connections and box-like behavior

The seismic behavior of existing masonry buildings also depends on the connections between structural elements (wall-to-wall and wall-to-floor). These connections are necessary to

enable the global behavior of the building and to prevent the activation of out-of-plane mechanisms, however they are generally inadequate in more ancient buildings.

The connections among the walls can be obtained through local interventions, although the application of connecting elements between parallel opposite walls (such as steel tie-rods and cables or external confining rings) has proved to be one of the most effective [19, 25]; moreover, tie-rods are a traditional technique which is also highly compatible. Usually, steel threaded bars are placed at floor levels, in the two main directions of the building, along the load-bearing walls, although in more recent times they may also have been combined with diagonally crossed systems. Tie-rods must be positioned at floor level in conjunction with the nodes (along external and inside walls, Figure 2a).

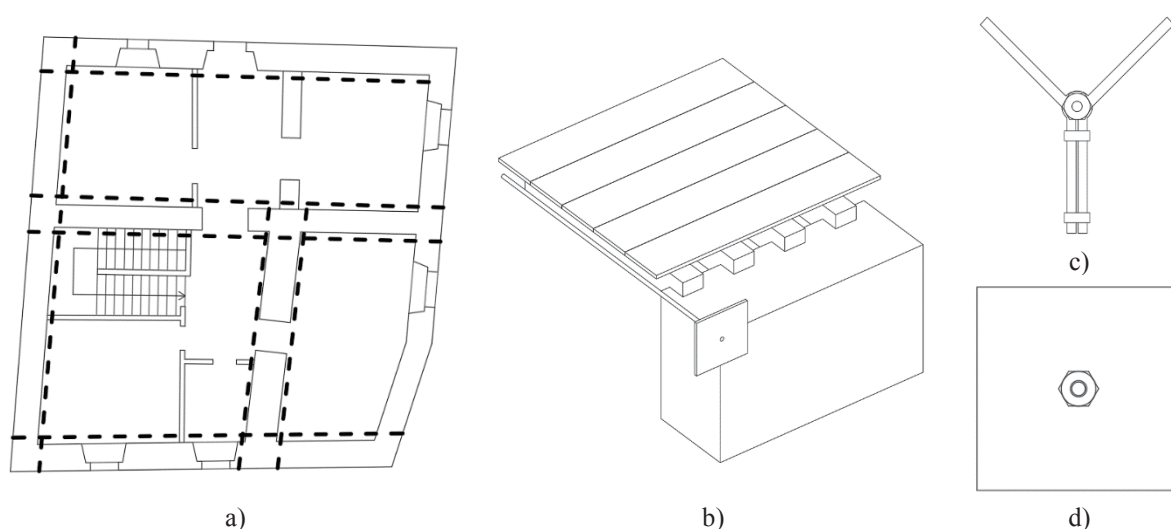

Figure 2: Ties positioning (a, b) and examples of external anchors (c, d).

In general, the tie-rods placed on the upper levels of the building have a crucial role for the local equilibrium of the walls. For an effective intervention, the contrasting masonry must be sufficiently consistent and resistant to sustain the local force applied by a tie's anchor; for this reason, localized interventions are recommended, such as hydraulic mortar injections, reinforcement or replacement of individual degraded elements, assuming that the general state of the masonry is sufficiently good.

Another possible intervention is the insertion of tie-beams just at the top or at all levels of a building. According to past Italian seismic codes [30, 31] they must have been made of reinforced concrete, but this was recently proved to be more detrimental than beneficial to seismic behavior as a consequence of high weight and poor compatibility with random masonry [19, 20, 32]. Therefore, a new generation of tie beams was proposed, adopting reinforced masonry or steel structural shapes [33].

### 2.3 Strengthening and stiffening of horizontal diaphragms

Horizontal diaphragms in seismic conditions should redistribute horizontal loads from load-bearing walls orthogonal to the earthquake direction to those parallel to it, in order to oppose the highest strength.

Timber floors are based on the assembly of overlapping elements, which are able to withstand and distribute vertical stresses, but not horizontal ones. This is due to the lack of adequate connections between the elements of the horizontal structure (inadequate in-plane stiffness) and between the horizontal structure and the vertical one (inadequate wall to floor connection).

Considering the fundamental partitioning action of floors, interventions aim at not only decreasing plan deformability, but also strengthening the connections between floors and walls have to be performed. However, an excessive strengthening, like that obtained by floor replacement with reinforced concrete slabs, would be ineffective, or even pejorative from a seismic retrofit point of view [20, 34].

For what concerns historical buildings, several techniques have been developed respecting traditional construction practice and avoiding at the same time the negative increase of weight at the floor level [26].

Some examples of interventions that improve the diaphragm action are wooden planking and application of diagonal metallic belts or composite material strips. These interventions can be executed on the intrados or on the extrados of the floor. With regard to residential buildings without valuable floors, interventions on the extrados are preferable.

In order to increase the in-plane stiffness, the addition of single or double wooden planks over the existing one can be considered (in orthogonal direction or at  $45^\circ$ , using tongue-and-groove joints with nails or screws as connectors) [35, 36] (Figure 3).

Figure 3: Reinforced timber floor with single planking inclined at  $45^\circ$  (a); reinforced timber floor with double planking crossed at  $+45^\circ$  and  $-45^\circ$  (b).

Interventions that do not modify floor stiffness but assure an adequate connection with walls are perimeter steel plates anchored with dowels to the walls [37] and distributed anchors at the ends of floor joists. These have to be injected with mortars or resins on the wall, or anchored externally; on the inner side, they have to be nailed to joists or upper boards, thus binding the floor to the wall (Figure 4) [38, 39].

Figure 4: Example of connection floor-to-wall.

### 3 ANALYSIS TOOL AND IMPLEMENTATION OF INTERVENTIONS

Once the best performing retrofit interventions were analyzed, it was possible to select the most suitable method and tools to start the implementation phase.

#### 3.1 Analysis method

The software used for the analysis is Vulnus vb 4.0 [16, 17], originally developed by A. Bernardini, R. Gori and C. Modena (University of Padova). Vulnus can analyze load-bearing masonry structures through limited information (geometry, material properties, construction details, qualitative information) by means of limit analysis.

The Vulnus methodology is based on the calculation of the critical horizontal accelerations that cause the activation of the main out-of-plane collapse mechanisms for each wall, and in-plane shear failure of the two main parallel wall systems. These critical accelerations are then normalized to gravity acceleration  $g$  and returned in terms of indices  $I1$  and  $I2$  for the in-plane and out-of-plane response, respectively.

More specifically, the index  $I1$  represents the shear resistance calculated on the weakest direction of the building, eventually corrected in case of irregularities that may cause non-uniform distributions of normal and tangential stresses. On the other hand, the index  $I2$  depends on the possible out-of-plane kinematic mechanisms and it corresponds to the minimum value of the sum of two sub-indices,  $I2'$  and  $I2''$ . In particular,  $I2'$  evaluates a building's resistance to mechanisms which involve a vertical strip of its walls (overall overturning of the wall, overturning and flexural failure of the top storey).  $I2''$  instead evaluates the resistance to mechanisms developing across the breadth of a walls (horizontal masonry strips): a) bending and arching mechanism failure, b) overturning and flexural collapse of the arch shoulders, and c) detachment of the transverse walls, always at the last storey.

In addition, a third index  $I3$  represents qualitative features of the building (not included in the other two indices).  $I3$  is calculated as the weighted normalized sum (between 0 and 1) of the scores derived by the "Second Level" form of GNDT [40]. Specifically, the form consists of 11 parameters, to which a quality class from A to D (where A is the best condition) is assigned; each qualitative class is then associated to a numerical score.

Once the three indices  $I1$ ,  $I2$  and  $I3$  have been calculated, Vulnus performs a vulnerability analysis using the fuzzy sets theory. The fuzzy approach allows to consider uncertainties associated to those parameters which are not directly measured and to the variability of the mechanical characteristics of the materials.

Using this approach, Vulnus calculates three fragility curves, which represent the mean (White curve) and the extreme probabilities (Lower-Bounds and Upper-Bounds curves) of reaching or exceeding the triggering acceleration of in-plane or out-of-plane mechanisms. For this reason, the damage state (DS) associated to the resulting fragility curves is a DS2-3, with reference to the scale proposed by the European Macroseismic Scale (EMS-98) [41].

#### 3.2 Implementation of retrofit interventions

On the basis of the considerations presented in section 2 and of direct field observations [32, 42], some interventions were considered as the most effective for Pre-1919 buildings. These interventions are presented in Table 1.

Vulnus allows to carry out simplified vulnerability analyses of masonry buildings. This implies that interventions must also be implemented in a simplified way. In fact, some intervention could be directly implemented by the options already present in the software, whereas others had to be implemented indirectly, reproducing the effect of the intervention on the building's overall behavior.

The implementation methodology of the selected interventions is presented below. Some interventions were also implemented in combination (as shown in Table 1).

*individual interventions*

MSN1	1 <sup>st</sup> stage	of masonry strengthening (stone: injection – brick: reinforced plaster)
MSN2	2 <sup>nd</sup> stage	
TR	addition of tie-rods	
FLR	stiffening of floors (light interventions)	

*combined interventions*

MSN1+TR	first stage of masonry strengthening + addition of tie-rods	
MSN1+FLR	first stage of masonry strengthening + stiffening of floors	
MSN2+TR	second stage of masonry strengthening + addition of tie-rods	
MSN2+FLR	second stage of masonry strengthening + stiffening of floors	

Table 1: Implemented retrofit interventions.

Two stages of retrofit interventions of strengthening of masonry are proposed. The first stage (MSN1) considers the application of light or single interventions, whereas the second one (MSN2) implies the concurrent application of more types of intervention or the implementation of a single intervention with all possible expedients to ensure the best results. The masonry interventions proposed in this study, according to the type of masonry, are: on random multi-leaf stone mainly injections are suggested, whereas the application of FRCM-TRM reinforced plaster is preferred in the case of stone ashlar or brick masonry. To simulate these interventions through Vulnus, the corrective coefficients shown in Table 2 were applied. The coefficients refer to table C8.5.II available in [43], and represent a medium increase of the mechanical characteristics of the materials composing the building owing to different type of intervention. It can be observed that the first step brings a similar improvement among different masonry types. Instead, the implementation of more invasive and heavy interventions on stone masonry, characterized by values of the mechanical parameters lower than the ones associated to brick masonry, gives greater improvements, although not exceeding the values of the mechanical characteristics of brick masonry. Lastly, the interventions considered require the addition of material, which is estimated to determine an average increase of masonry specific weight by 5%.

	MSN1	MSN2
Stone masonry	1.7	2.4
Solid brick masonry	1.5	1.8
Tuff masonry	1.6	1.9

Table 2: Multiplicative coefficients used.

The insertion of tie-rods (TR) was directly implemented in Vulnus. In fact, the software provides the possibility to enter the number of ties present in both main directions of the building. TR intervention was implemented by placing, for each main direction of the building, an adequate number of rods (two rods, one per side, placed parallel to the internal partitions, and one rod to the perimeter walls).

As regards to floor interventions (FLR), the most effective solutions for historical buildings are the insertion of bracing systems or the installation of double wooden planks, in order to increase the stiffness without overloading. Since in Vulnus floor types determine just the dead loads on walls, diffuse chains have been placed to simulate the improved box-like behavior when floors are stiffened. In addition, to further increase the diaphragms' reaction of the model, the floor-to-wall friction coefficient was increased to account for the improved connection achieved by the intervention.

In order to update the class of the Second Level GNDT form parameters, used by Vulnus to elaborate the final curves, the modifications that each intervention brings to the as-built configuration were studied. Of the 11 parameters of the form, those linked to the interventions analyzed are: quality of the resistant system, floor type, roof type and state of maintenance. The value assigned to other parameters in as-built conditions was maintained in strengthened ones. In Table 3 the adopted changes, made with reference to the manual of the form [40], are reported.

GNDT parameter	MSN1 MSN2	TR	FLR	MSN1+TR MSN2+TR	MSN1+FLR MSN2+FLR
Resistant system	<b>A</b>			<b>A</b>	<b>A</b>
Floors			<b>A</b>		<b>A</b>
Roof		+ 1 class	+ 1 class	+ 1 class	+ 1 class
State of maintenance	<b>A</b>			<b>A</b>	<b>A</b>

Table 3: Modified classes for the GNDT parameters considered.

## 4 FRAGILITY MODEL WITH RETROFIT INTERVENTIONS

The present study is in continuity with past analyses [44, 45] in which a database of more than 500 buildings was analyzed using Vulnus 4.0 and fragility sets were obtained for ten macro-types (five age and two height classes) of as-built residential masonry buildings. Specifically, the eight interventions identified in the previous chapters have been implemented on those 205 buildings which belonged to the Pre-1919 macro-typology of the original database. Then, the elaboration of the specific fragility sets for each intervention was carried out following the procedure proposed by Donà et al. [18].

### 4.1 Methodological approach

As already mentioned, the Vulnus software produces three fragility curves associated with an average probability (White) and two extreme probabilities (Upper- and Lower-Bounds), corresponding to a damage state DS2-3.

In order to define a single fragility model for the two macro-typologies considered in this study (Pre-1919 Low-Rise buildings, i.e. 1 and 2 floors, and Pre-1919 Mid-Rise buildings, i.e. 3, 4 and 5 floors), in the first place the White, Upper- and Lower-Bounds curves were processed separately. The curves of each building were averaged firstly by municipality, in order to maintain a geographical representativeness, and then by number of floors and age of construction, considering for each sub-typology the actual real distribution obtained from 2001 ISTAT census data [15].

Subsequently, the fragility model of Lagomarsino and Cattari [10] was calibrated on the mechanical fragility model obtained for DS2-3, in order to represent seismic fragility over the five damage states (from DS1 to DS5). In this way, a new mechanically based heuristic fragility model was derived.

Lastly, the different sets obtained for White, Upper- and Lower-Bounds were combined, with the aim of developing a single fragility set (LUW). This operation allows to maintain the average fragility defined by the White curves (assumed as the most likely fragility), but at the same time to increase the dispersion parameter, thus resulting more suitable to represent the vulnerability of the built stock on a large scale.

In Figure 5, the main steps of this procedure [18] are presented.

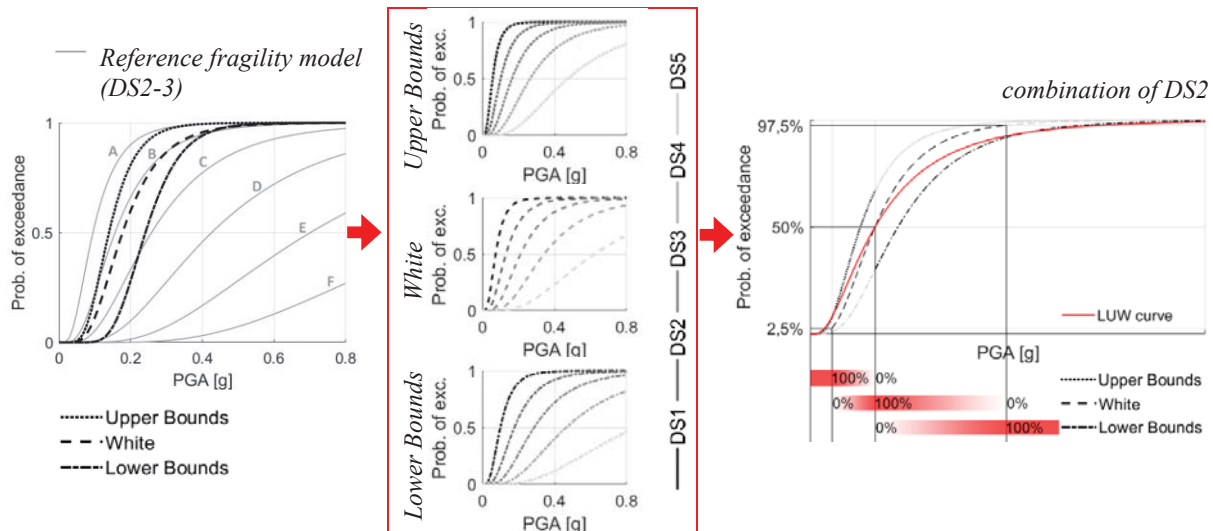

Figure 5: Procedure used to define the mechanical-heuristic fragility model from the mechanical one obtained through Vulnus [18].

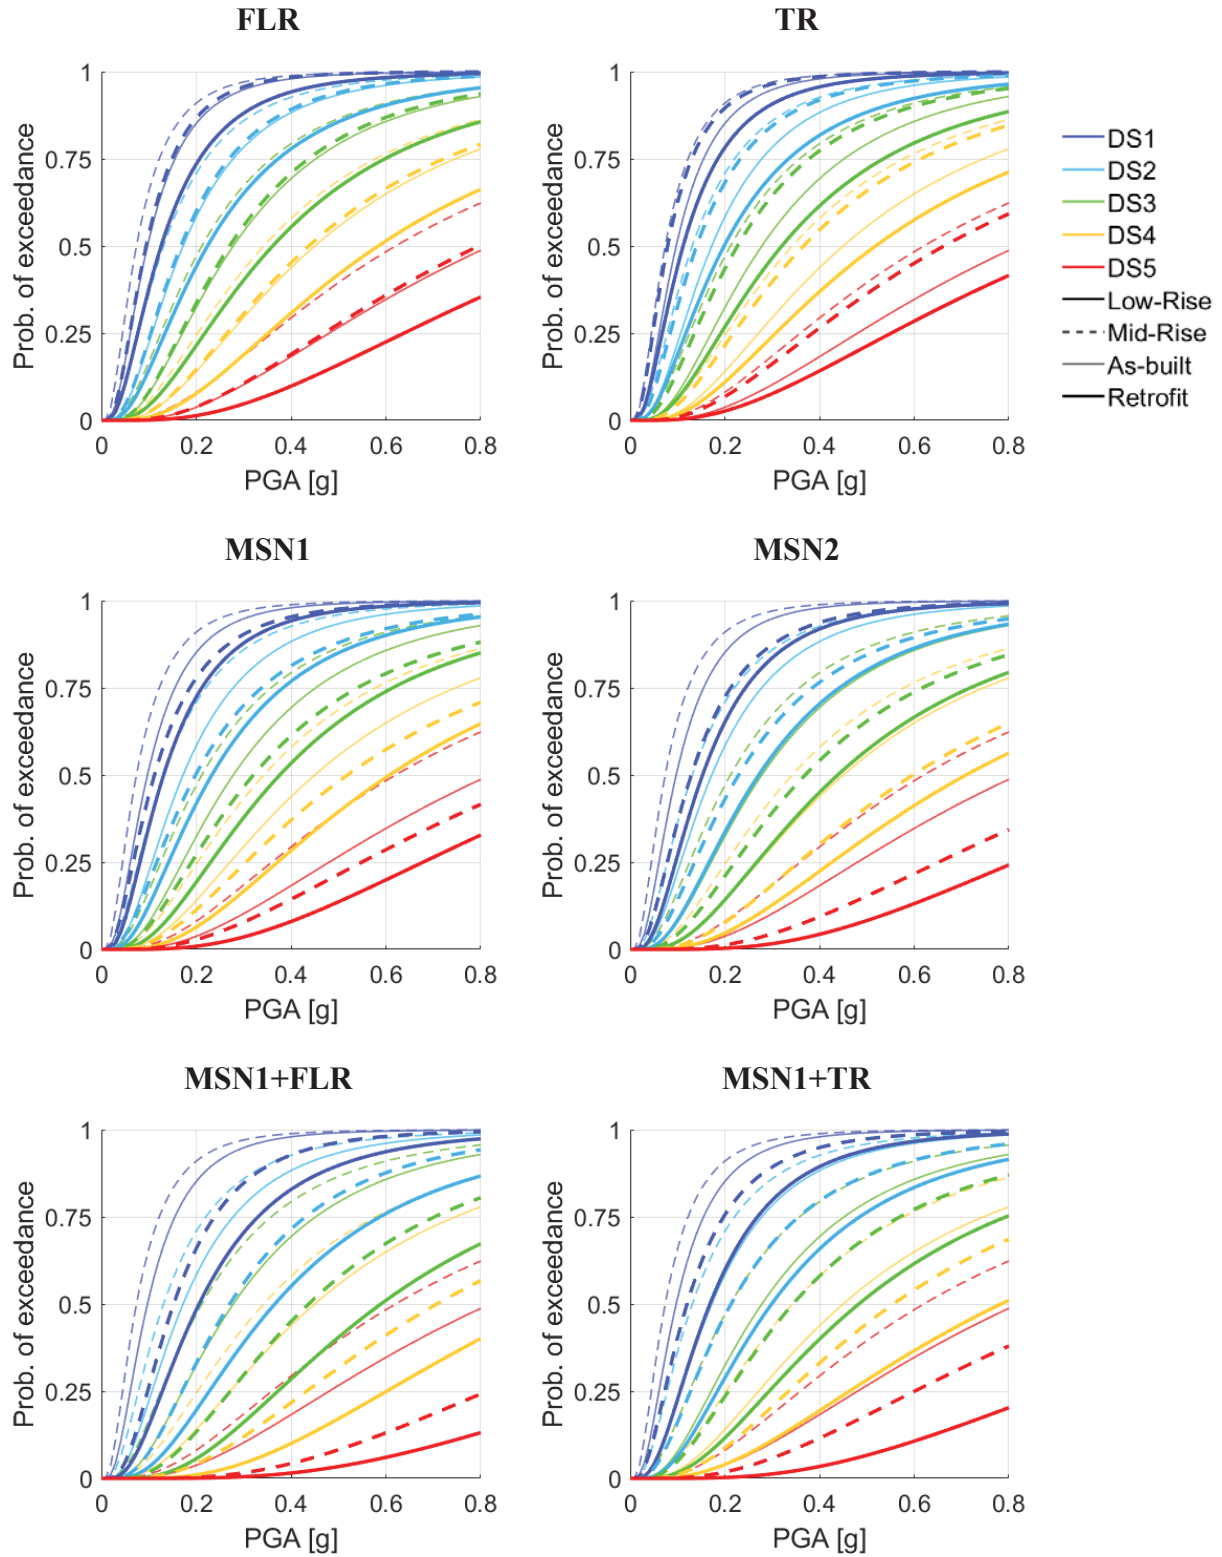

## 4.2 Fragility sets and results

The procedure presented in §4.1 was recursively carried out for each intervention considered. In this way, the fragility sets related to the Pre-1919 buildings for the two height classes Low-Rise (1 and 2 storeys) and Mid-Rise (3, 4 and 5 storeys) were obtained, and it was possible to compare the fragility curves of the as-built configuration with the curves obtained after the simulation of the interventions.

It should be noticed that, despite the validity of the method [18], the models presented below (Figure 6) do not allow to evaluate the effects that the interventions may produce limited to some DSs (e.g. reduction of severe damage but not of slighter one), but provide just an overall indication of their effectiveness.

As expected, the graphs in Figure 6 show that the greatest variation in vulnerability occurs with the application of combined interventions. Considering individual interventions, the insertion of tie-rods (TR) produces underperforming results, while the intervention on floors (FLR) gives slightly better outcomes. The greatest effectiveness derives from two-steps interventions applied to increase masonry strength and compactness (MSN1, MSN2). When the floors or ties interventions are combined with masonry strengthening (MSN1+FLR, MSN1+TR, MSN2+FLR, MSN2+TR), the floors interventions appears to be more effective than the tie-rods ones.

Furthermore, the different effectiveness of interventions in Low-Rise and Mid-Rise buildings can be examined. The interventions on the floors and those related to the insertion of tie-rods are more effective if applied to Low-Rise buildings, whereas for Mid-Rise buildings the vulnerability reduction is smaller. This leads to the conclusion that the height of the building plays a fundamental role in the variation of vulnerability.

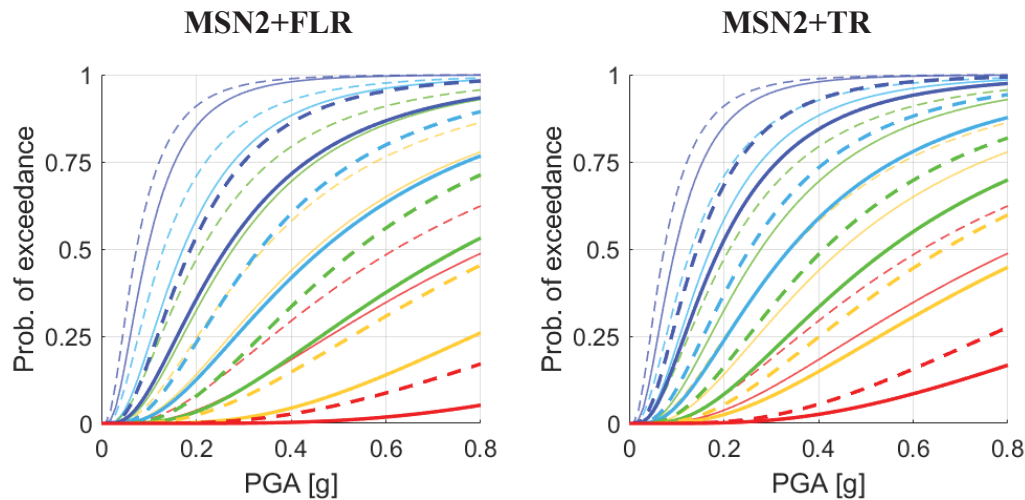

Figure 6: Comparison of fragility sets developed for Pre-1919 buildings in as-built condition and with retrofit for the interventions analyzed.

## 5 CONCLUSIONS

- The paper presents a study that provides mechanical-heuristic seismic fragility curves of Pre-1919 Italian residential masonry buildings, subject to seismic retrofit interventions. In particular, eight type of intervention were analyzed: two steps of intervention concerning the strengthening of the walls (MSN1, MSN2), insertion of tie-rods (TR), stiffening and improvement of diaphragm behavior of the floors (FLR), as well as the combination of these interventions (MSN1+TR, MS1+FLR, MS2+TR, MS2+FLR).
- The software Vulnus 4.0 was used, and the fragility curves (White, Upper-Bound and Lower-Bound) were obtained for eight retrofit solutions, on a dataset of 205 buildings. Then, the procedure by Donà et al. [18] was applied and fragility sets for the retrofit interventions have been derived, so that they could be compared with the as-built fragility curves.
- In general, the results show that masonry strengthening is overall more effective than any other intervention. Moreover, combined interventions are more effective than single ones. It should be noticed that the reduction of vulnerability deriving from a combination of two interventions is not the simple sum of that obtained from individual ones.
- Possible future developments are the extension of this study to residential masonry buildings belonging to construction periods starting from 1919, which have different characteristics and may require different retrofit interventions.

## ACKNOWLEDGEMENTS

Special thanks are due to the Italian Department of Civil Protection (DPC), which funded this study in the framework of the *ReLUIS-DPC Project 2019-2021 – Work Package 4: MARS (Maps of Risk and Scenarios of seismic damage) – Task 6: Preventive strategies: comparative analysis in terms of risk on a national scale (Strategie preventive: analisi comparata in termini di rischio a scala nazionale)*.

### Abstract

*Fragility models are important tools for seismic risk assessment and seismic damage scenarios estimation. Some models are already available in the literature, however, in the case of infilled RC frames, further investigations are necessary, given the high uncertainty about their behaviour. In fact, damage observations following seismic events, suggest that the presence of masonry infills can strongly influence the response of reinforced concrete (RC) frames and affect their collapse mechanisms. The main goal of this work is to contribute to the seismic vulnerability assessment of the existing building stock in the Emilia-Romagna region in northern Italy, developing fragility models for infilled RC frame buildings. On the basis of an analysis of both census data on the existing building stock and on damage survey forms after the 2012 Earthquake, a set of representative structures was defined and modelled with finite elements, adopting a concentrated plasticity approach. Different modelling approaches of the infill walls were considered, using single and multi-strut models, in order to simulate shear failure in columns. Non-linear static (push-over) analyses were then carried out on these models to obtain their capacity curves. Displacement demands were computed using simplified procedures (IN2 method). The definition of damage levels in the models was based on the achievement of local deformation capacity limits of structural and non-structural elements, according to the classification provided by the EMS-98 Macro-seismic scale. Fragility curves were finally obtained by considering uncertainties in material properties, by means of the Response Surface method, as well as ground-motion record-to-record variability.*

## 1 INTRODUCTION

Many of the buildings currently present in the European area date back to several decades ago and were built without seismic design criteria, due to changes in the seismic classification of the territory and to the considerable evolution of structural design codes in the most recent years; hence the interest and the need for studies on existing buildings. Within a probabilistic framework, an important tool for assessing the seismic vulnerability of existing buildings are fragility curves, which associate the probability of exceeding a certain damage level to different levels of a certain measure of ground-motion intensity.

After the Emilia earthquake (northern Italy) in May 2012, many of the studies on existing buildings focused on masonry buildings [1] and prefabricated structures [2, 3], i.e. the types on which the most severe damage was observed. Studies have also been carried out on reinforced concrete frames with masonry infills [4]; in particular, fragility curves have been developed in [5], for some models of representative buildings, based on capacity limits associated with the damage levels defined by the EMS-98 macro-seismic scale. Furthermore, this study provided a damage scenario for the area hit by the Emilia earthquake, also making predictions on the cumulative damage caused by multiple seismic events. The typical damage observed following seismic events raises the need to use models capable of describing the local interaction phenomena between frames and infill panels [6, 7]. Preventive considerations are necessary on the choice of materials characteristics, with particular attention to the masonry infill properties, which can strongly influence the structural behaviour of the building and, consequently, the assessment of its vulnerability [8].

The present work presents the fragility curves for existing residential Reinforced Concrete (RC) frame structures with masonry infills, and is part of a larger study aimed at assessing the seismic vulnerability of the existing building heritage in the Emilia area. These fragility curves are obtained analysing, by means of nonlinear static analyses and Response Surface metamodells [9], a series of case study structures, which in terms of geometry, dimensions and mechanical characteristics, can be considered representative of the fraction of the existing building stock under study.

## 2 REFERENCE BUILDINGS

### 2.1 Characteristics of the building stock

In order to define the case study buildings, preliminary investigations were made to acquire information about the main characteristics of the existing building stock: in particular, reference was made to the data of the AEDES forms (i.e. post-earthquake damage evaluation forms used in Italy), compiled following the Emilia earthquakes, occurred in May 2012, and census data provided by ISTAT (National Institute of Statistics), from the 15th general population and housing census, for the areas of Bologna, Ferrara and Modena. Analysing the available data on existing buildings, once the construction type and intended use of interest have been identified, all data was filtered by construction period, number of storeys, average floor surface and regularity.

The data from the AEDES forms and census, restricted to RC frame structures for residential use, involve sample consisting of 1573 and 58980 buildings, respectively: it is clear that the census data offer a broader and more general vision than the AEDES data, which instead concern a small part of the building stock, as they are compiled only for a subset of the buildings affected by the earthquake, i.e., in general, for buildings that have shown some damage. On the other hand, AEDES data can provide important information of the structural features of the

buildings that were most susceptible to damage. Figure 1 shows the distribution of the number of floors in the dataset.

Figure 1: Number of storeys of existing building stock.

There is a clear prevalence of low-rise buildings, with less than 2 floors, for the ISTAT data, in contrast to the AEDES forms data, which show an opposite trend for buildings with a greater number of floors (in detail 4 or greater than or equal to 5): this can suggest that, in general, buildings with a higher number of floors, although they constitute a smaller percentage of the building stock, also constitute the most fragile part. According to ISTAT data, almost 58% of the RC frame structures were built between the 50s and 70s, a time period characterized by the complete lack of seismic design criteria in the area affected by the 2012 earthquake.

For the definition of the geometry in plan and elevation of the models to be studied, the data on the average floor surface was analysed and correlated with the number of floors (as shown in Figure 2). It should be noticed that only the AEDES forms provide this data. The range of floor areas between 100 m<sup>2</sup> and 170 m<sup>2</sup> is common for buildings with a low number of floors, while it is not very frequent in buildings with 5 or more floors. The range of surfaces between 170 and 300 m<sup>2</sup> characterizes a large part of the sample of buildings, being present in a relatively high percentage in all categories based on the number of floors (between 23.7% and 39.2%), in particular for structures with a number of floors equal to or greater than 4. Floor areas from 300 to 500 m<sup>2</sup> mainly characterize buildings with a number of floors greater than or equal to 4.

Figure 2: Average floor area and number of storeys (AEDES data).

It should be specified that the relationship between the average floor area and the number of floors may not fully represent the actual building stock, but only a subset of it, as only the

AEDES forms makes this information available. However, as specified above, it can be thought that these data provide more direct information on the most fragile part of the building stock and is therefore of greatest interest in the context of assessing the seismic vulnerability of existing buildings.

## 2.2 Definition of case study structures

On the basis of the characteristics observed, two types of building were defined: in particular a 2-storey and a 4-storey building. The plan surface area of each building (see Table 1) was chosen in such a way as to obtain structures that are as representative as possible of the existing stock.

In order to conduct non-linear static analyses, two-dimensional models were created. However, since the existing buildings in the area under consideration often feature frames with different features in different horizontal directions, two models were considered for each structure. The direction indicated with X corresponds to the one of main frames, while Y corresponds to the one of slabs, which are assumed as one-way.

MODEL	<i>X direction</i>			<i>Y direction</i>			Plan surface [m <sup>2</sup> ]
	n° bays	span length [m]	Lx [m]	n° bays	span length [m]	Ly [m]	
2 storey	3	4.5	13.5	3	4	12	162
4 storey	4	4.5	18	3	4	12	216

Table 1: Main geometric features of benchmark buildings.

## 2.3 Simulated design

A simulated design was carried out on the reference buildings, to define the size of the cross-sections of the structural elements and the relative reinforcements. To this purpose, it is of primary importance to place the buildings in an appropriate regulatory context. Based on the ISTAT census data on the construction period for the sample of buildings analysed, it is believed that the period of greatest interest, spans from the 50s to the 70s.

In the simulated design of the structures, the method of admissible stresses was used, respecting the requirements set out in the Italian structural design code issued in 1976 [10], thus considering it the reference standard. All the structures have been designed for vertical loads only; unlike the perimeter beams, shallow wide beams were considered for the internal frames, a typical solution of residential buildings, in which, due to architectural requirements, the thickness of beams is maintained within the thickness of slabs. Permanent loads were assumed equal to 5 kN/m<sup>2</sup> while live loads to 2 kN/m<sup>2</sup>. A concrete with a characteristic compressive strength  $R_{ck}$  equal to 25 MPa was considered for the simulated design. For the characterization of the reinforcing bars, reference was made to a series of studies on the mechanical characteristics of the steels used in RC structures in the 1960s [11]: in particular, smooth bars were used, with a median yield stress equal to 369.9 MPa, which lead to an allowable stress of 155 MPa. The stirrup spacing in columns is assumed equal to 25 cm. The size of columns depends on their axial stress, evaluated on the basis of tributary areas, while the beams were designed only for the bending moment due to the vertical loads. In particular, the perimeter beams have a section with dimensions 30x50 cm, while the cross-section of roof beams are 30x45 cm. The internal main beams have a section of 75x24 cm. Secondary beams, i.e. in the Y direction, are also considered, but of reduced dimensions.

### 3 MODELLING

The case study buildings must be schematized in a finite element model that is able to simulate the nonlinear structural response under to horizontal loads, both for structural elements (beams and columns) and non-structural elements, such as masonry infills. An approach based on lumped plasticity was adopted in the modelling. Finite element modelling was carried out through the OpenSees software [12]. The model of each structure was not limited only to one infilled frame (external frame), but involved the modelling of two frames side by side (Figure 3): one infilled and one bare frame, bound to undergo the same floor displacements, under a rigid diaphragm assumption.

Figure 3: Example of the adopted modelling scheme.

#### 3.1 Frame elements

The frame elements (beams and columns) have been modelled using linear elastic elements, with rotational springs at their ends (*ZeroLength* elements). A moment-rotation relationship characterized by a three-linear envelope was adopted, defined by three characteristic points, which represent the yield condition, the ultimate condition, and the complete loss of strength. the latter is defined by the slope of the degrading branch, until zero moment, based on the Ibarra, Medina and Krawinkler model [13]. For each hinge the rotation capacity, corresponding to the yield ( $\theta_{y,s}$ ) and ultimate ( $\theta_{u,s}$ ) conditions was evaluated based on the approach suggested by Eurocode 1998-part 3 [14] for estimating the yield ( $\theta_y$ ) and ultimate ( $\theta_u$ ) chord rotations of RC members:

$$\theta_y = \phi_y \frac{L_v + a_v z}{3} + 0.0014 \left( 1 + 1.5 \frac{h}{L_v} \right) + \frac{\varepsilon_y}{d - d'} \frac{d_{bl} f_y}{6 \sqrt{f_c}} \quad (1)$$

$$\theta_u = \frac{1}{\gamma_{el}} 0.016 (0.3^v) \left[ \frac{\max(0.01; \omega')}{\max(0.01; \omega)} f_c \right]^{0.225} \left( \min \left( 9; \frac{L_v}{h} \right) \right)^{0.35} 25^{\alpha \rho_{sx} \frac{f_{yw}}{f_c}} (1.25^{100 \rho_d}) \quad (2)$$

where  $\phi_y$  is the yield curvature of the element cross-section,  $L_v$  is the shear span length,  $h$  is the cross-section depth;  $\omega$  and  $\omega'$  are, respectively, the mechanical reinforcement ratio of the tension and compression longitudinal bars;  $f_c$ ,  $f_y$  and  $f_{yw}$  are the concrete compressive strength, the longitudinal reinforcement yield tension and the stirrup yield tension, respectively, (MPa);  $\varepsilon_y$  is the steel elastic modulus;  $d_{bl}$  is the mean diameter of longitudinal tension reinforcement;  $d$  and  $d'$  are the depths to the tension and compression reinforcement, respectively;  $z$  is the internal lever arm length and  $a_v$  is equal to 1.0 if shear cracking is expect to precede the end section flexural yielding and it is equal to 0 otherwise;  $\rho_{sx}$  is the ratio of transverse reinforcement in loading direction (x);  $\rho_d$  is the diagonal reinforcement ratio;  $\alpha$  is the confinement effectiveness ratio;  $\gamma_{el}$  is equal to 1.5 for primary seismic elements and it is equal to 1.0 otherwise;  $v$  is the normalized axial force.

Some of the parameters in Eqns. 1 and 2 are not constant during a pushover analysis, however, given the limited number of storeys of the case study buildings, the axial force in the columns was assumed as constant, and due to non-seismic gravitational loads only. The shear span length  $L_v$  was defined on the basis of some preliminary analyses that led to the choice of the following values: half the length of the element for beams and columns, with the exception of the first storey columns, for which a point of contraflexure placed at 2/3 of the length, starting from the base, was assumed. Values of  $\theta_y$  and  $\theta_{um}$  were corrected, according to Eurocode 1998-part 3 rules, in order to consider lapping of reinforcing bars, the presence of smooth bars and the lack of seismic details.

In modelling the beam-spring assembly, the flexural behaviour of each element of the frame has been traced back to that of two equivalent cantilever beams. The effective moment-rotation relationship for the rotational springs was defined by subtracting from the total chord rotation (beam-spring system) the chord rotation due to the elastic deformation of the element, as reported below:

$$\theta_{y,s} = \theta_y - \frac{M_y L_v}{3EJ} \quad (3)$$

$$\theta_{u,s} = \theta_{um} - \frac{M_u L_v}{3EJ} \quad (4)$$

$$\theta_{uc,s} = \theta_{u,s} + \frac{M_u \theta_y}{\alpha_c M_y} \quad (5)$$

where  $\theta_{y,s}$  is the spring rotation at yielding,  $\theta_{u,s}$  is the spring rotation at ultimate condition and  $\theta_{uc,s}$  is the spring rotation corresponding to the complete loss of strength;  $\alpha_c$  is a percentage of the elastic branch stiffness of the backbone curve and it defines the slope of the degrading branch.

### 3.2 Masonry infills

Masonry infills were modelled adopting equivalent struts, using *Truss* elements, which follows the constitutive law proposed by Panagiotakos and Fardis [15] (as shown in Figure 4), implemented in the form of a three-linear force-displacement curve through the *Hysteretic* material of the OpenSees library.

Figure 4: Example of the adopted force-displacement relationship for masonry infills.

The initial behaviour of the infill depends on the initial shear stiffness of the panel, defined as:

$$K_I = \frac{G_w L_w t_w}{h_w} \quad (6)$$

in which  $G_w$  is the masonry shear elastic modulus,  $L_w$  and  $h_w$  are the effective length and height of the panel, respectively and  $t_w$  is its thickness. The horizontal force corresponding to the first shear cracking depends on the shear cracking strength  $\tau_{cr}$ :

$$F_{cr} = \tau_{cr} A_w = \tau_{cr} L_w t_w \quad (7)$$

The stiffness of the second branch of the backbone curve corresponds to the axial stiffness of the equivalent masonry strut, as follows:

$$K_2 = \frac{E_w b_w t_w}{d_w} \quad (8)$$

where  $E_w$  is the masonry elastic modulus,  $d_w$  is the diagonal length of the infill panel and  $b_w$  represents the width of the equivalent strut, which was calculated with the formulation proposed in [16]:

$$b_w = d_w \cdot 0.175 (\lambda h_w)^{-0.4} \quad (9)$$

$$\lambda = \sqrt[4]{\frac{E_w t_w \sin(2\theta)}{4E_c J_p h_w}} \quad (10)$$

The parameter  $\lambda$  defines the relative stiffness of the RC frame and the infill panel, according to the formulation developed in [17], in which  $E_c$  is the concrete elastic modulus,  $J_p$  is the moment of inertia of the columns of the surrounding frame and  $\theta$  is the inclination angle of the panel with respect to the horizontal. The overstrength ratio, i.e. the ratio between the maximum strength of the masonry strut and the shear cracking strength, is equal to 1.3, while the stiffness of the degrading branch is 3% of the initial elastic stiffness, until a residual strength assumed as 1% of the peak force.

Different equivalent truss geometries were considered; in particular, single- and three-strut models (Figure 5). The first is able to adequately describe the global behaviour of an infilled frame, characterized by an increase in stiffness and resistance compared to a bare frame, but it is not able to simulate the local shear-failure mechanisms in columns due to the interaction with masonry infills. The second one, on the other hand, is capable of taking into account the local interaction phenomena between the frame and the infill panel.

Figure 5: (a) single-strut model; (b) three-strut model.

In the three-strut models the total strut area is distributed among the three truss elements, considering 50% for the centre element and 25% for the others. The end node distance of side

truss elements from a frame node  $h_z = z / 2$  (see Figure 5) is based on an estimate of the size of the contact area between the infill and the frame, where  $z$  is calculated as follows:

$$z = \frac{\pi}{2\lambda} \quad (11)$$

The mechanical characteristics of masonry, such as the elastic modulus, the shear elastic modulus and the shear cracking tension, were defined after [6]. In particular,  $E_w$  and  $G_w$  were set to 1495 MPa and 598 MPa, respectively, while  $\tau_{cr}$  was set to 0.36 MPa.

The presence of openings in masonry infills was considered, assuming a percentage of openings  $\alpha_w = 14\%$ , evenly distributed. Therefore, simple relationships based on the definition of reduction coefficients directly applicable to the strut areas were used; in particular, reference was made to the following formulation [18]:

$$\lambda_{op} = 1 - 2\alpha_w^{0.54} + \alpha_w^{1.14} \quad (12)$$

## 4 ANALYSIS METHODOLOGY

Non-linear static analyses were carried out using OpenSees software. For each case study structure, pushover analyses were performed both in X and Y directions, assuming two different distributions for the horizontal forces: one proportional to the storey masses (uniform distribution), and one dependent on the shape of the first mode of vibration (linear distribution). The outputs of the pushover analyses were then processed using the MATLAB<sup>®</sup> software, with which a procedure for calculating the displacement demand was also implemented (see Section 4.2).

### 4.1 Damage levels for numeric models

Five levels of damage were defined, deriving them from the EMS-98 macro-seismic scale [19]. Each of these damage states (from DS1 to DS5) was associated to with the achievement of a certain local capacity in terms of displacement. On the basis of the modelling choices made, it was convenient to define the damage to the structural elements as a function of the deformation of the rotational springs that represent the plastic hinges. Damage on the infill panels was defined based on the deformation in the corresponding truss elements. The criteria adopted are as follows:

- DS1 – slight damage: is reached when the first cracks appear in the masonry infills, i.e. when the cracking force of the struts is reached.
- DS2 – moderate damage: this state occurs when either one RC member yields or one truss element reaches its peak strength.
- DS3 – heavy damage: this state occurs when either one of the truss elements reaches its ultimate displacement or one plastic hinge reaches a rotation corresponding to 3/4 of the ultimate rotation capacity.
- DS4 – very heavy: this state occurs when in one of the columns there is a resisting moment degradation of 20% after the peak resisting moment.
- DS5 – collapse: this state occurs when the total resisting base shear of the structure becomes equal to 20% of the residual capacity of the bare frames.

In addition to the five damage states described above, a further level of damage (DS5<sub>shear</sub>) was considered based on to the achievement of the shear strength in the structural elements (typically in the columns). Shear failure is a fragile failure mechanism which, although not specifically mentioned on the EMS-98 scale, represents very heavy damage. The shear strength

has been defined according to the current Italian structural design code [20]. Each level of damage was associated to a specific displacement of the control point.

## 4.2 Capacity curves

Sample results for the buildings studied are reported in Figure 6. These plots contrast the different behaviour of bare frames and the infilled frames, the latter being characterized by higher initial stiffness and maximum strength as well as by a relevant loss of strength, after the masonry struts failure. The capacity curve of the entire building was obtained combining infilled and bare frames, as discussed in Section 3.

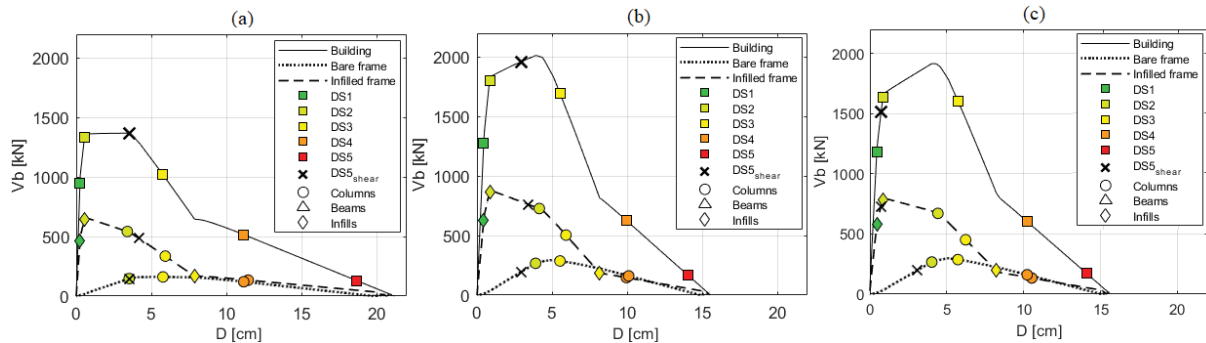

Figure 6: Capacity curves for in the X direction with mass proportional force distribution for the 2-storey single-strut model (a); 4-storey with single-strut model (b); 4-storey building, three strut model (c). For further details about geometrical characteristics see Table 1.

The observed collapse mode is predominantly characterized by soft floor mechanisms at the base of buildings. This behaviour is favoured by several factors: the low quality of detailing; the lack of capacity design criteria in design; furthermore, the failure of the infill panels in one floor tends to create a soft storey condition. These factors favour the formation of plastic hinges in columns rather than in beams. The plots in Figure 6 also show the capacity limits associated to the five damage levels under consideration. In the curves shown in Figure 6, it can be observed that the damage level DS2 is characterized by the rupture of the infills rather than by the yielding of the frame elements; conversely DS3 occurs first in the frame. In the 3-strut model (Figure 6-c) it can be observed that the columns shear failure occurs approximately when the peak resistance of the infills is reached, i.e. when the pressure of the panel on the contact area with the frame is maximum. It should be noted that also in the single-strut models shear failures can occur, but these models are not able to simulate the local interaction between the frames and the masonry infills occurring at the ends of columns and beams.

## 4.3 Evaluation of the displacement demand

In pushover analyses the displacement demand on a structure, associated with a certain IM value, such as PGA or spectral acceleration, is computed based on the definition of an equivalent SDOF system and specific  $R-\mu-T$  relationships. The present study was based on the IN2 method [21], which is applicable to systems characterized by a significant strength degradation as infilled frame structures. The method requires a preliminary multi-linearization of the pushover curve, respecting the underlying areas equality criteria, as shown in Figure 7.

Figure 7: Example of multi-linearization of the 4-storey building capacity curve.

Given an elastic spectrum in terms of acceleration the calculation of the displacement demand first passes through the study of an equivalent SDOF system, and the evaluation of an appropriate inelastic demand spectrum. For the calculation of this latter and of the required ductility, reference was made to the relation  $R-\mu-T$  proposed in [22]. This procedure requires an elastic spectrum with a standard Newmark-Hall shape. The elastic spectrum adopted in the present study was defined according to the current Italian structural design code [20], considering a return time of 475 years and assuming a position of the site close to the epicentres of the main shocks that stroke the Emilia area. The IN2 curves in terms of PGA are shown in Figure 8, for 2 and 4 storey buildings, considering a single strut model for masonry infills.

Figure 8: IN2 curves for the 2-storey (a) and 4-storey building (b) single-strut models.

## 5 FRAGILITY ANALYSIS

This section is dedicated to the seismic fragility assessment of the case study buildings. Considering the numerical models presented, a fragility analysis was conducted, with the aim of obtaining fragility curves that relate the probability of reaching the damage levels discussed in Section 4.1 to the values of Peak Ground Acceleration (PGA). To this aim it is necessary to consider the uncertainties that affect the problem under consideration. These are mainly related to: material properties, modelling uncertainties, record-to-record variability and prediction capacity of the analysis method adopted. Random Variables (RV) were used in order to describe these uncertainties. The RVs chosen are (see Table 2): concrete compressive strength  $f_c$ ; steel yielding stress  $f_y$ ; chord rotation at yielding  $\theta_y$ ; chord rotation at ultimate condition  $\theta_{um}$ ; coefficient  $\alpha_c$ , which determines the slope of the post capping stiffness of RC members; lateral force  $F_{inf}$  and lateral drift  $D_{inf}$  of the infills force-displacement relationship. In particular, different variabilities have been assumed for  $F_{inf}$  and  $D_{inf}$  relatively to the cracking point and

the peak point of the infills behaviour curve. The variables described above influence the behaviour of the building, in particular, affecting the capacity curve. However, the  $R-\mu-T$  relation used to determine the inelastic spectra in the calculation of the displacement demand, provides an average value of the required ductility. Therefore, a certain variability was assumed also for the ductility demand [22], this represents both the uncertainty on the prediction provided by the adopted analysis method and record-to-record variability. A log-normal distribution has been assumed for all RVs and the corresponding coefficients of variation are shown in Table 2. The coefficient of variation for concrete compressive strength was evaluated in order to fall within the limit values set for the concrete acceptance criteria, while that relating to the coefficient  $\alpha_c$  was defined in order to obtain a median value comparable with the formulation reported in [23], and extreme values contained within the range tested in [24].

For each building model, given a set of random values of the RVs, defined a loading direction and a distribution of forces it is possible to compute a capacity curve, which can then be used to find scaling factor for the elastic response spectrum that leads to a displacement demand equal to the capacity associated to a certain DS. The PGA of the so obtained scaled spectrum represents a measure of the structural capacity for the DS under consideration. By repeating this procedure for more samples of the RVs is possible to obtain a sample of the PGA capacity values associated to a certain DS, the cumulative probability distribution of these values represents, the fragility curve relative to the considered damage level. However, such a procedure is computationally inefficient because it requires a large number of samples. Therefore, Response Surface (RS) models were introduced in order to find empirical relationships between the structural capacities for each of the DSs under consideration and the values of the RV. A RS is a statistical regression model that interpolates, within a certain domain, the values of a response variable – PGA capacity for a certain DS in this case – as a function of a set of independent variables.

RV	Distribution	CoV	Reference
$f_c$	Log-normal	0.20	
$f_y$	Log-normal	0.08	[11]
$\theta_y$	Log-normal	0.331	[5]
$\theta_{um}$	Log-normal	0.54	[23]
$\alpha_c$	Log-normal	0.55	
$F_{inf} = [F_{cr}; F_{max}]$	Log-normal	[0.3; 0.3]	[5]
$D_{inf} = [D_{cr}; D_{max}]$	Log-normal	[0.3; 0.7]	[5]
$\mu$ (ductility)	Log-normal	0.70	[22]

Table 2: Random Variables and uncertainty parameters.

In order to obtain data for fitting the RS models, the Central Composite Design (CCD) criterion was used in order to define a set of values of the RVs to be used for the pushover analyses. Since, as discussed later, the ductility demand was not considered in the RS models, the number of RVs is 7, which according to CCD correspond to  $2^7 + 2 \cdot 7 + 1 = 143$  combinations of the RV values to be used for pushover analyses. These are carried out for each model, for each direction and for each distribution of forces. The form of RS model adopted for each structure, for the  $i$ -th DS associated to a loading direction and a force distribution is:

$$\ln(PGA_{DS \geq DS_i}) = b_0 + b_1 \ln(f_c) + b_2 \ln(f_y) + b_3 \ln(\theta_y) + b_4 \ln(\theta_{um}) + b_5 \ln(\alpha_c) + b_6 \ln(F_{inf}) + b_7 \ln(D_{inf}) + \varepsilon \quad (13)$$

where  $b_0$  to  $b_7$  are unknown regression coefficients, and  $\varepsilon$  is a normal error term. Their values were estimated by means of linear regression. The standard deviation of the error term was the

augmented considering the uncertainty on the ductility demand [22]. Since a log-normal distribution for the RVs was assumed,  $\ln(PGA_{DS} \geq DS_i)$  is a linear combination of normally distributed variables and therefore assumes a normal distribution which is fully defined by its mean value and standard deviation. The cumulative distribution function for  $\ln(PGA_{DS} \geq DS_i)$  represents the fragility curve for the  $i$ -th DS. As mentioned above, fragility curves are obtained for the different main directions of the building and for the different horizontal force profiles (Figure 9).

Fragility curves for the X and Y directions of each building (Figure 9-a) were obtained by considering the highest probability value (worst case) between the curves associated to the two different lateral load distributions. In order to provide a global assessment of the building's seismic vulnerability, direction-independent fragility curves were also evaluated; these curves were obtained as the average exceedance probability for generic DS for the two different directions (Figure 10). Considering the worst case between the X and Y directions would in fact lead to a systematic overestimation of the building's vulnerability. The fragility curves obtained for 2 and 4-storey buildings show that the latter is more vulnerable than the former, with differences in the probability of damage higher than 30%, in particular for the DS3, DS4, DS5 and DS5<sub>shear</sub> in the PGA range between 0.2 g and 0.6 g.

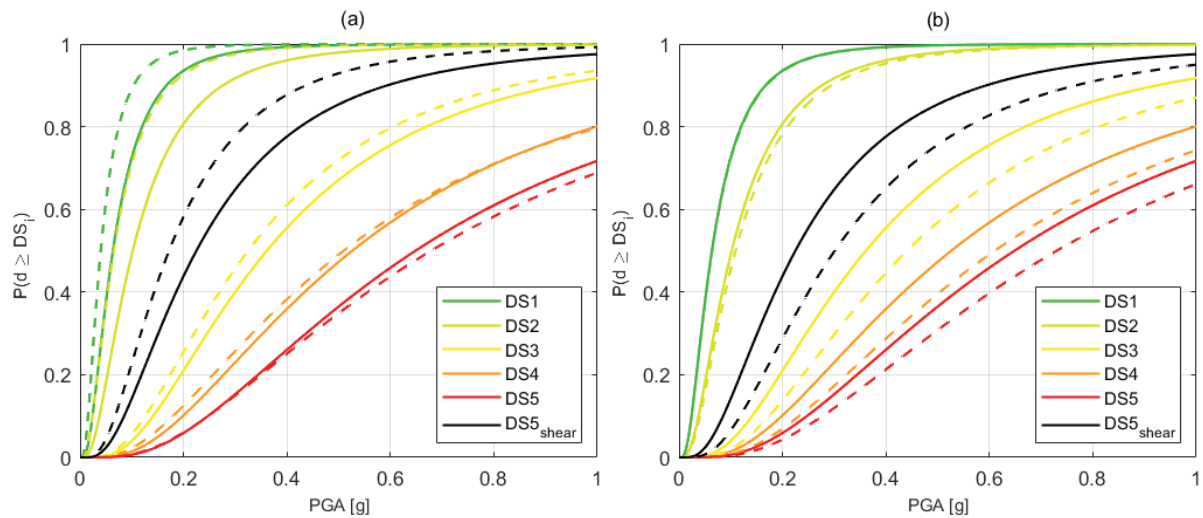

Figure 9: Fragility curves for the 4-storey building: (a) X (solid line) and Y direction (dashed line); (b) force distribution proportional to storey masses (solid line) and to the first mode (dashed line).

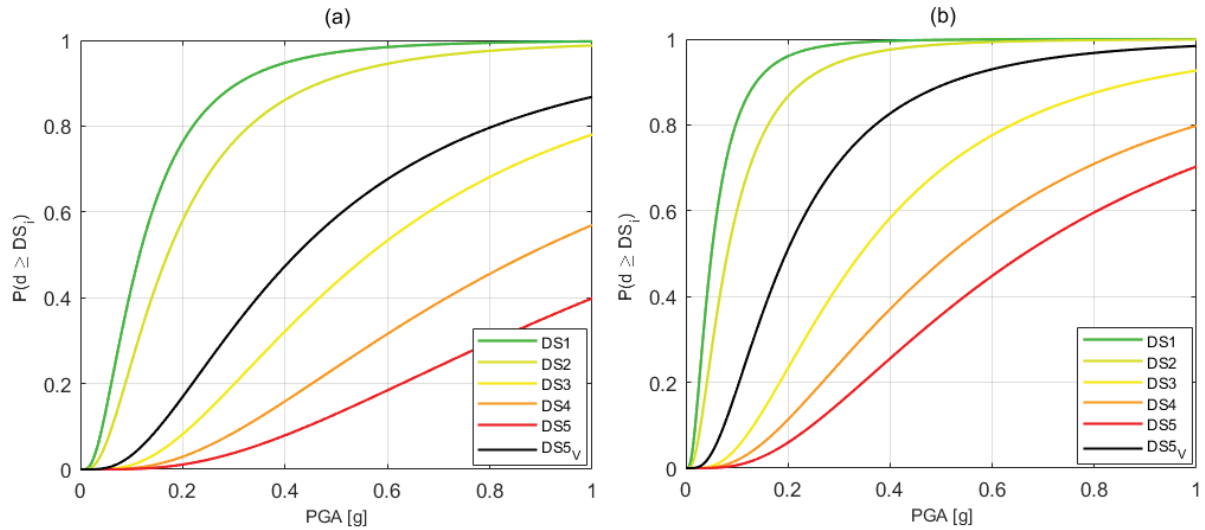

Figure 10: Global capacity curves (single strut model): 2-storey (a) and 4-storey building (b).

The fragility curves for the 4-storey building modelled with 3 equivalent struts are shown in Figure 11. For the frame members a flexural behaviour similar to the case of the single strut model was observed, however, with this model, an anticipated shear failure at the ends of the columns can be triggered, due to the local interaction between the infill panel and the surrounding frame. The fragility curve associated with shear failure is very close to the curve associated with DS2, corresponding to the first condition to occur between the infill peak strength and yielding of the frame elements. In the three-strut model the shear failure of the columns tends, therefore, to occur at the maximum strength in the masonry struts and to anticipate the columns yielding.

Figure 11: Global capacity curves for the 4-storey building (three strut model).

## 6 CONCLUSIONS

With this work we have contributed to the seismic vulnerability assessment of RC frames with masonry infills. Starting from a study on the characteristics of the existing building stock in the Emilia area, case study buildings were defined, then modelled with finite elements considering the contribution of masonry infills. Non-linear static analyses were carried out on

the obtained models and the capacity in terms of PGA associated with different DSs was evaluated. Fragility curves were finally developed for the examined buildings using RS models. Different infills models were considered, in order to simulate the fragile shear failure in the columns. However, the three-strut modelling used here, while capturing the local interaction described, are not able to adequately describe the behaviour of the structure after the shear failure has been detected. Fragility curves have also been presented for shear failure, but in these terms, more work is needed.

### Abstract

*Seismic risk and scenario assessments at large-scale provide important science-based tools to support governments and civil protection departments in investment policies and emergency planning. In this framework, school buildings are particularly significant due to the consequences of their damage or collapse and their relevance, as public buildings, in emergency planning. The evaluation of risk requires the definition of its components, i.e., hazard, exposure and vulnerability. To assess the seismic vulnerability of masonry school building assets, this paper presents the fragility curves derived for 265 building types, based on the Italian school building census. Parametric analyses were carried out on 14 representative prototype schools, using a mechanics-based model which considers both in-plane and out-of-plane mechanisms. More than 7500 sample fragilities were calculated and linearly combined to obtain fragility curves representing the Italian taxonomy of masonry school buildings. A macro-seismic heuristic model from the literature was then calibrated to derive a fragility set for each school type, for five damage states, from slight damage to complete collapse. Finally, the paper compares the outcome fragility curves and fragility sets from the literature for residential buildings, highlighting the specificities of school seismic vulnerability. Indeed, masonry school buildings are frequently characterized by intrinsic geometric deficiencies due to significant inter-story height and great distance between transverse walls, both affecting the out-of-plane response and, therefore, the overall seismic fragility.*

## 1 INTRODUCTION

School buildings are crucial elements of structural and infrastructure assets for communities. The social impact of their collapse associated to seismic events is huge, in terms of both casualties and social dispersion. After the collapse of a primary school in San Giuliano di Puglia (Italy) in 2002 [1], the Italian government issued a national plan to evaluate the seismic vulnerability of the entire stock of relevant and strategic structures, including school buildings [2].

Detailed modeling and analyses are very time consuming, and therefore not suitable to manage large stocks of buildings, while tools based on fragility curves of building types better respond to this need. Fragility curves provide a correlation between a seismic intensity measure, such as the Peak Ground Acceleration (PGA), and the probability that a structure exceeds a damage state (DS). Fragility curves for school buildings were obtained for Nepalese schools, after processing data on observed damage caused by the 2015 Nepal earthquake [3], while Gentile et al. [4] derived fragility curves for Indonesian schools by means of non-linear dynamic analyses.

Different approaches are available to define fragility curves: empirical, based on observed damage after a seismic event [5–8]; mechanical, based on structural modeling, either detailed [9] or simplified [10–13]; and hybrid, based on both empirical data and models [14, 15]. These methods have been largely applied to ordinary and residential buildings. Moreover, vulnerability assessment at urban scale of the built asset specific for a regional area [16] has aroused a large interest, as it allows a more precise estimation of risk.

The taxonomy of buildings exposed to risk is fundamental to define building types and their distribution at large scale, requiring typological analyses of the building census of the analyzed area. In particular for Italy, regional taxonomies have been provided in the literature, while the evaluation of national macro-classes representative of the entire national school asset has yet to be defined. A typological study of masonry school buildings in the crater of the Central Italy seismic sequence (2016) was provided by Ottonelli et al. [17], while masonry school types were classified for the Friuli-Venezia Giulia region by Gattesco and Boem [18].

Especially for the Italian framework, the fragility analysis of specific classes of structures, such as school buildings, based on an extensive taxonomy describing the national stock, is required to assess risk at large scale and to optimize the allocation of funds for mitigation strategies. This aim is carried out by a cooperative national project (*ReLUIS-DPC Project 2019-2021*) by will of the Italian Department of Civil Protection, in which this contribution is included.

This paper presents the derivation of seismic fragility curves for unreinforced masonry (URM) school buildings by means of extensive parametric analyses carried out by applying a mechanics-based model [19, 20] which considers both the in-plane (IP) and the out-of-plane (OOP) mechanisms, as well as an index of the structural quality [21]. The approach has been already effectively applied to residential URM buildings and validated by simulating the damage scenario caused by the 2009 L'Aquila earthquake [22, 23]. In the present paper, a set of 14 representative prototype school buildings were analyzed, varying different parameters, i.e., number of stories, quality of construction details, floor weight, type of masonry and related panel thickness. The contribution aims to provide fragility curves which cover all the macro-classes based on the Italian school census, defined by a limited number of parameters, i.e., construction age, number of stories, plan area, and type of masonry.

## 2 ITALIAN SCHOOL BUILDING ASSET

A general taxonomy of Italian school buildings was derived according to the School Building Registry (SBR) of the Italian Ministry of Education [24], which classifies a large amount of the Italian school asset, based on a limited number of parameters, i.e., construction material and age, number of stories, plan area, and types of floors and roof. In this framework, data from the Italian SBR (2005) for masonry schools, amounting to more than ten thousand buildings, were used to define the macro-classes for which the fragility model, presented hereinafter, was derived.

Figure 1 illustrates the distribution of typological characteristics of masonry school buildings comprised in the national census. In particular, Figure 1a shows the distribution of construction ages, which appears to be covered quite evenly. Then Figure 1b provides the distribution of the number of stories, with a peak corresponding to the case of two-story buildings, and Figure 1c shows the prevalence of small to medium schools, according to their plan area. Lastly, the combinations of couples of these parameters are shown in Figure 1d with the number of stories given the construction age, Figure 1e with the distribution of plan area given the construction age, and Figure 1f with the number of stories associated to the plan area.

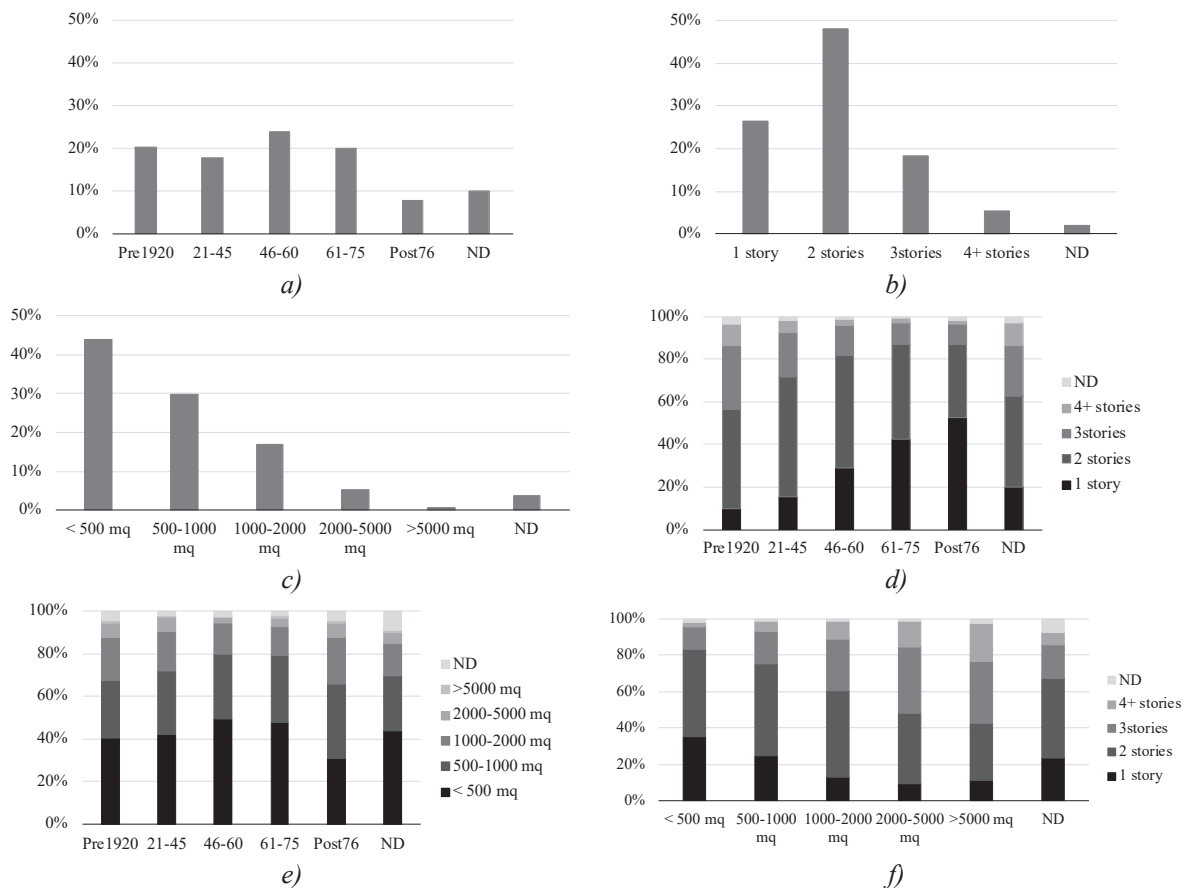

Figure 1: Distribution of typological characteristics of masonry buildings in Italian School Building Registry.

The analysis of the distribution of the typological characteristics of the masonry school buildings in the SBR allowed the definition of a finite number of prototype buildings to be used in the derivation of fragility curves, as described in the following sections. Considering significant combinations of the typological parameters, 14 masonry school buildings were selected from the databases collected by research groups from the Universities of Genova, Pa-

dova, and Trieste, so as to ensure a good representativeness of the national school building taxonomy; their typological characteristics are reported in Table 1. The typical shapes of school building plans, included in the analysis by choosing representative prototype buildings, are shown in Figure 2.

School ID	Age	N. stories	Plan area [m <sup>2</sup> ]	Plan shape
S1	Before 1920	3	<500	Rectangular
S2	Before 1920	2	>2000	U-shape
S3	Before 1920	2	1000-2000	Cloister
S4	Before 1920	3	1000-2000	U-shape
S5	1921-1945	2	500-1000	Rectangular
S6	1921-1945	2	<500	Rectangular
S7	1921-1945	2	<500	T-shape
S8	1921-1945	2	1000-2000	U-shape
S9	1921-1945	2	500-1000	T-shape
S10	1946-1960	2	1000-2000	L-shape
S11	1946-1960	2	<500	Rectangular
S12	1946-1960	2	<500	Rectangular
S13	1961-1975	1	<500	Square
S14	After 1976	1	<500	Square

Table 1: Typological characteristics of prototype school buildings.

Figure 2: Typical shapes of school building plans.

N. stories	Construction details	Floor weight	Type of masonry	Thickness of masonry [cm]
1	No ring-beam, no tie-rod (LQD)	Light	Random rubble	30-70
2	Tie-rods (MQD)	Heavy	Stone ashlar	30-70
3	Ineffective ring-beam (HQD ineff)		Clay bricks w/ lime mortar	25-50
4	Effective ring-beam (HQD)		Clay blocks w/ cement mortar	30-45

Table 2: Parameters and ranges of variation considered in parametric analyses.

Preserving the geometric properties of each building, a parametric analysis was carried out, increasing the size of the school dataset, which lead to more than 7500 realizations imple-

mented through the simplified mechanical model. Table 2 reports parameters and their range of variation included in the analyses.

The mechanical properties of masonry were assumed according to Italian Code [25], considering two values for the masonry strength: the minimum value reported in the regulation, and a maximum value obtained by applying code-compliant improving coefficients, to take into account possible interventions carried out during the lifetime of the structure.

### 3 MECHANICS-BASED APPROACH FOR FRAGILITY ASSESSMENT

The simplified mechanics-based approach *Vulnus 4.0* [19, 20], which allows the implementation of a significant amount of analyses with a limited computational effort, was applied for the fragility assessment of the above described prototype schools. The modeling procedure allows seismic analyses to be implemented accounting for both the In-Plane (IP) shear resistance of the building and the trigger of potential Out-Of-Plane (OOP) mechanisms, together with a vulnerability rate deriving from the II level GNDT form [21]. *Vulnus 4.0* provides three outcome indexes: i) the first index ( $i_1$ ) expresses the ratio, for the weakest plan direction, between the IP shear resistance and the weight of the building; ii) the second index ( $i_2$ ) describes the susceptibility to OOP mechanisms (i.e., overturning, flexural failure, and arch compression failure), calculated by means of kinematic analyses; and iii) the third index ( $i_3$ ) considers qualitative factors, included in II level GNDT form, which can affect the seismic vulnerability of a building, such as the masonry quality as well as the type of floors, also considering those configurations which strongly worsen the seismic response (i.e., heavy and rigid floor on weak random masonry).

Then, the combination of the indexes is carried out through fuzzy set theory, allowing the probabilistic evaluation of the influence of both not quantifiable parameters, summarized in the  $i_3$  index, and uncertainties of quantifiable parameters (e.g., mechanical properties of masonry), which are considered in the calculation of indexes  $i_1$  and  $i_2$ . The outcome of vulnerability analysis with *Vulnus 4.0* consists in three fragility curves: an average curve, called *white*, which describes the most probable distribution; and two extreme conditions, defined as *lower* and *upper*, representing the lower and the upper bounds, respectively.

Fragility curves, which expresses the probability of exceedance of a damage state, are derived as log-normal cumulative probability functions, which are described by two parameters: the mean value ( $IM_{mean}$ ) and the standard deviation ( $\beta$ ).

The resulting set represents the cumulative probability of exceeding a medium-severe damage state (DS), according to the definition provided by the European macro-seismic scale (EMS98) [26], which is an intermediate DS between 2 (i.e., trigger of OOP mechanisms) and 3 (i.e., IP global shear failure). The DS identified by the *Vulnus 4.0* fragility set is therefore conventionally referred to as DS2-3, hereinafter.

As mentioned before, the parametric analysis generated more than 7500 realizations and thus, the same amount of DS2-3 fragility sets, which were then combined to finally derive 265 fragility sets, to be associated with school macro-classes, according to the typological parameters included in the Italian school building census. An exposure matrix was assumed, based on expert judgement, to linearly combine curves obtained from each case of the parametric analysis, keeping the *white*, *lower* and *upper* curves separate. Table 3 reports the percentage of the exposure matrix used for the recombination in macro-classes starting from subtypes of masonry, while Table 4 shows the percentage of recombination for different level of quality details, whose definition has been given in Table 2.

The fragility sets for macro-classes describing the damage state 2-3 were then extended to a complete set of five fragility curves, capable of describing the probability of exceedance of

the five damage states given by the EMS98 [26], from DS1 (slight damage) to DS5 (complete collapse).

The final complete sets took into account both the average *white* curve and the extreme bounds, by means of a geometric combination, detailed as follows. The above described procedure was developed for residential buildings [27] and afterwards, in the present work, applied to school buildings.

	Before 1920	1921-45	1946-60	1961-75	After 1976
Random rubble	30%	30%	10%	10%	-
Stone ashlar	35%	35%	27%	27%	10%
Clay bricks	35%	35%	54%	44%	27%
Clay blocks	-	-	9%	19%	63%

Table 3: Assumed exposure matrix of type of masonry during construction ages.

	Before 1920	1921-45	1946-60	1961-75	After 1976
LQD	20%	15%	10%	-	-
MQD	50%	35%	50%	30%	15%
HQD ineff	30%	30%	-	-	-
HQD	-	20%	40%	70%	85%

Table 4: Assumed exposure matrix of quality of construction details during construction ages.

To obtain fragility sets representing five DSs, each DS2-3 fragility set was referred to the fragility model proposed by Lagomarsino and Cattari, in 2014 [13], which was derived from a previously presented macro-seismic model [15]. For the present application, the correlation law between the Peak Ground Acceleration (PGA) and the macro-seismic intensity was set according to Margottini et al. [28]. The reference model represents fragility distributed on five DSs for the six vulnerability classes (from A to F) defined by EMS98 [26], on the basis of the intrinsic correlation between macro-seismic intensity and damage state. The macro-seismic reference model was thus calibrated on the macro-class fragility sets obtained with the mechanical procedure *Vulnus 4.0*, through the steps described as follows:

1. An average curve DS2-3 was derived for the six vulnerability classes, through the linear combination of the available DS2 and DS3 fragility curves. Figure 3a shows fragility curves from macro-seismic model for all vulnerability classes, with DS2 and DS3 curves highlighted in solid blue lines, and DS2-3 highlighted in solid black lines.
2. Each fragility set from the mechanical model was then represented through a combination of compatible DS2-3 curves of two vulnerability classes, calculated at the previous step. A genetic algorithm (NSGA-II [29]) was implemented to evaluate the optimal linear combination, by minimizing both the absolute and the relative errors between the curves, calculated through the least squares and the difference between the areas, respectively.
3. A set of five fragility curves (i.e., representing five DSs) was derived for each macro-class of school buildings through the optimal coefficient that was previously calculated, for the linear combination of vulnerability classes. Figure 3b reports, as an example, the fragility curve DS2-3 from the mechanical model for two-story masonry schools built before 1920 (solid red line), which resulted to be an optimal combination of DS2-3 curves for vulnerability classes B and C, which are represented in blue and black solid lines, respectively. Fragility curves for DSs from 1 to 5, for the school macro-class, was then derived as a combination of each DS curves from the macro-seismic model, in this case considering the curves associated with vulnerability classes B and C.

This procedure was applied to each macro-class of school buildings for all the curves previously derived through *Vulnus 4.0*, namely the *white*, *lower* and *upper* curves.

Finally, a procedure for geometric combination (named LUW [22, 23]) was implemented in order to include, in the proposed fragility model, the uncertainties considered in *Vulnus 4.0* analysis by means of fuzzy theory. Thus, the procedure allowed *white*, *upper* and *lower* curves to be combined for each macro-typology and for each DS.

The LUW procedure preserves the mean value of the *white* curve; it uses *upper* and *lower* distributions in 2.5% and 97.5% fractals of the *white* probability, respectively. Between 2.5% and 50% of the *white* probability, it linearly combines *white* and *upper* curves, while a linear combination of *white* and *lower* curves is calculated between 50% and 97.5%.

For example, Figure 4 illustrates how LUW procedure was applied to two-story masonry schools built before 1920 and, thereby, the final fragility set was derived.

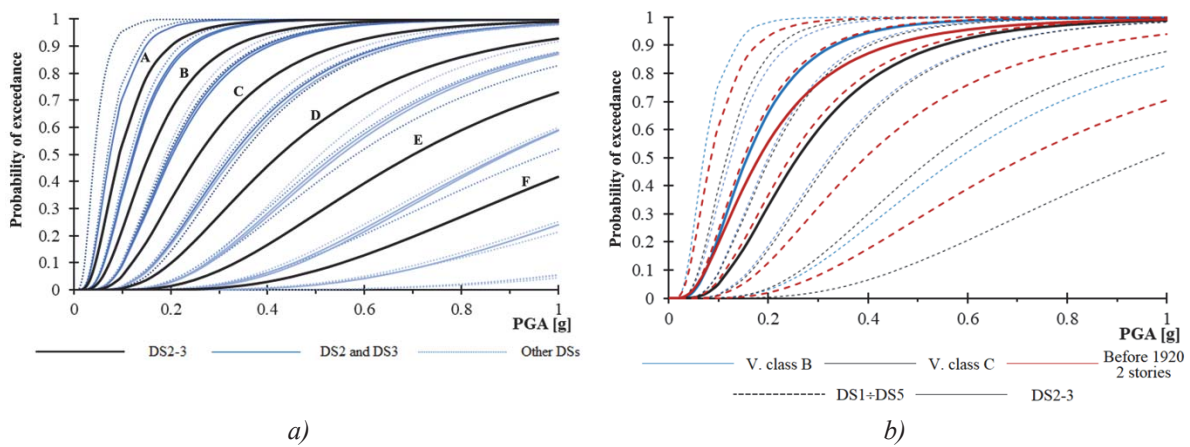

Figure 3: a) Average curves DS2-3 for macro-seismic reference model, b) calibration of macro-seismic model for one school macro-class.

Figure 4: Application of LUW procedure on a set of fragility curves.

#### 4 RESULTS AND PROPOSED FRAGILITY MODEL

This section presents the outcomes of this study, starting from the fragility sets associated to a Damage State 2-3, which were obtained through the mechanical approach *Vulnus 4.0*. Figure 5 illustrates the mechanical fragility curves obtained from the combination, according to the above-described exposure matrix, of the fragility curves resulting from the above-

described extensive parametric analysis. The figure reports a summary of the results considering two parameters (i.e., number of stories and construction age).

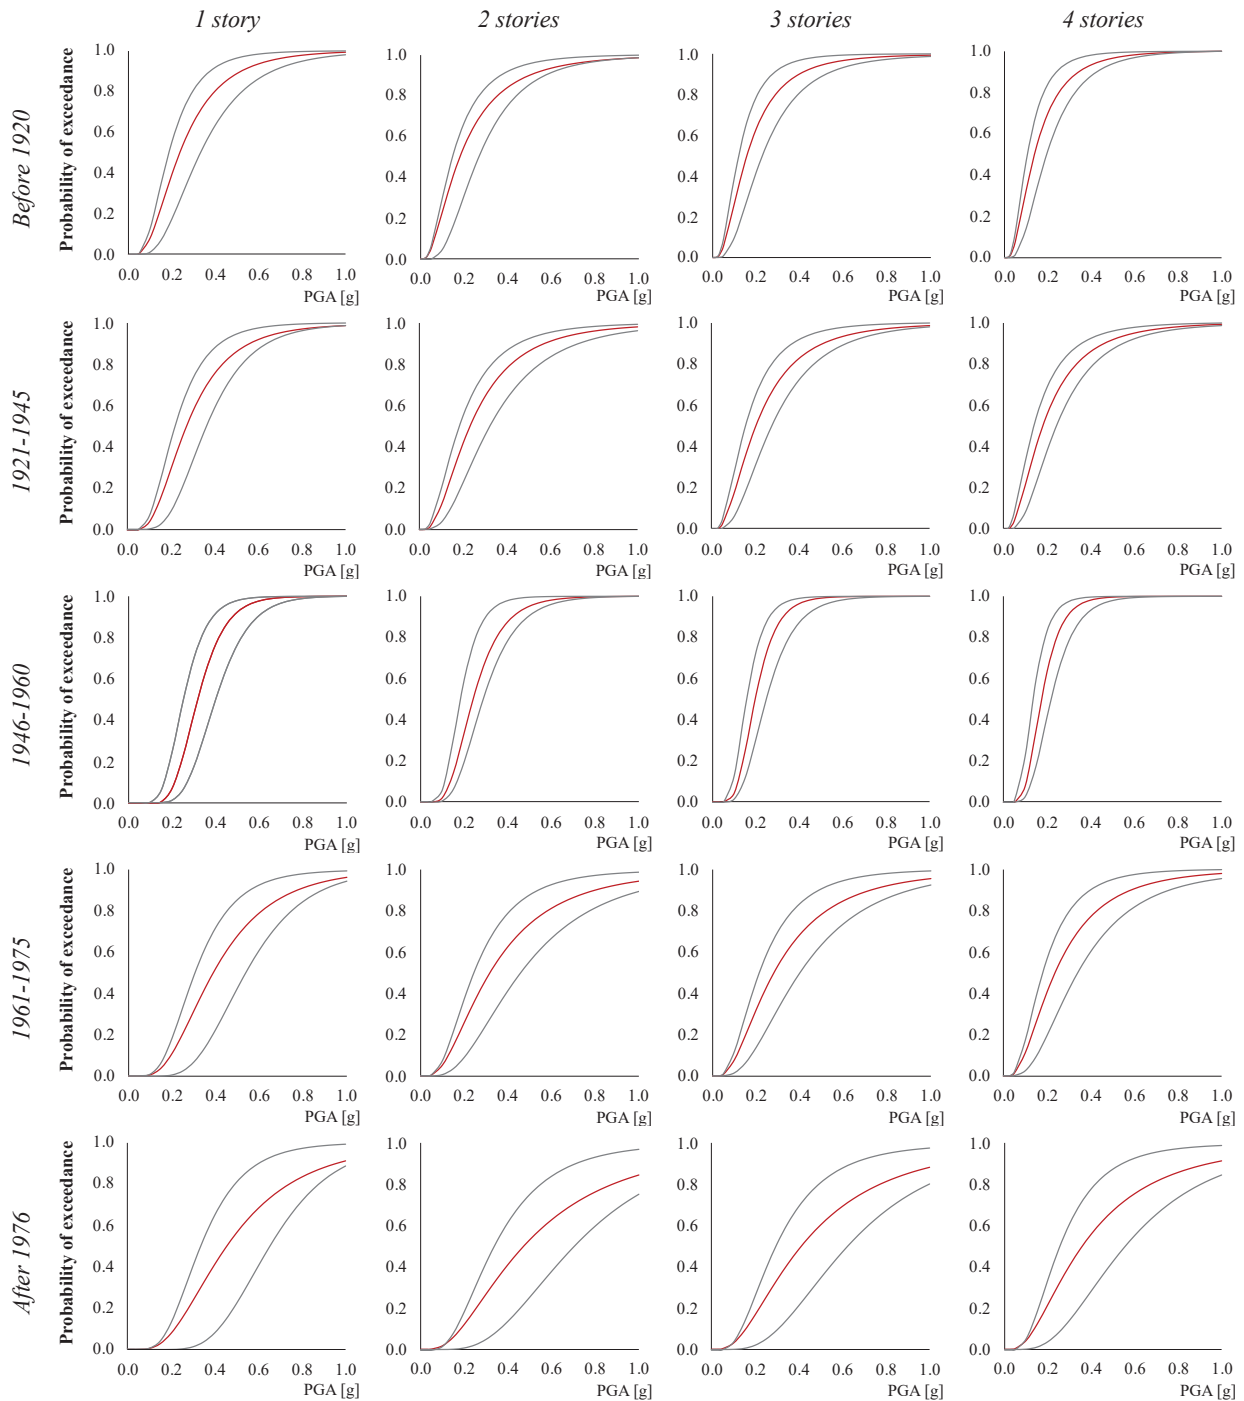

Figure 5: Mechanical fragility curves for DS2-3; white curves in red between upper and lower bounds.

Macro-class fragility tends to slightly increase as the number of stories increases, while it appears to be more evidently influenced by the construction age. Furthermore, an increase in the dispersion was observed as the overall fragility decreases (e.g., for more recent construction ages).

A novel fragility model was derived for Italian masonry school buildings for macro-classes based on a limited number of parameters included in the SBR (i.e., number of stories, con-

struction age, plan area, and type of masonry). In addition, more general classes were derived from the aggregation of specific school types, for instance all single-story masonry schools built before 1919 (in this case, curves for specific plan area and type of masonry were combined together).

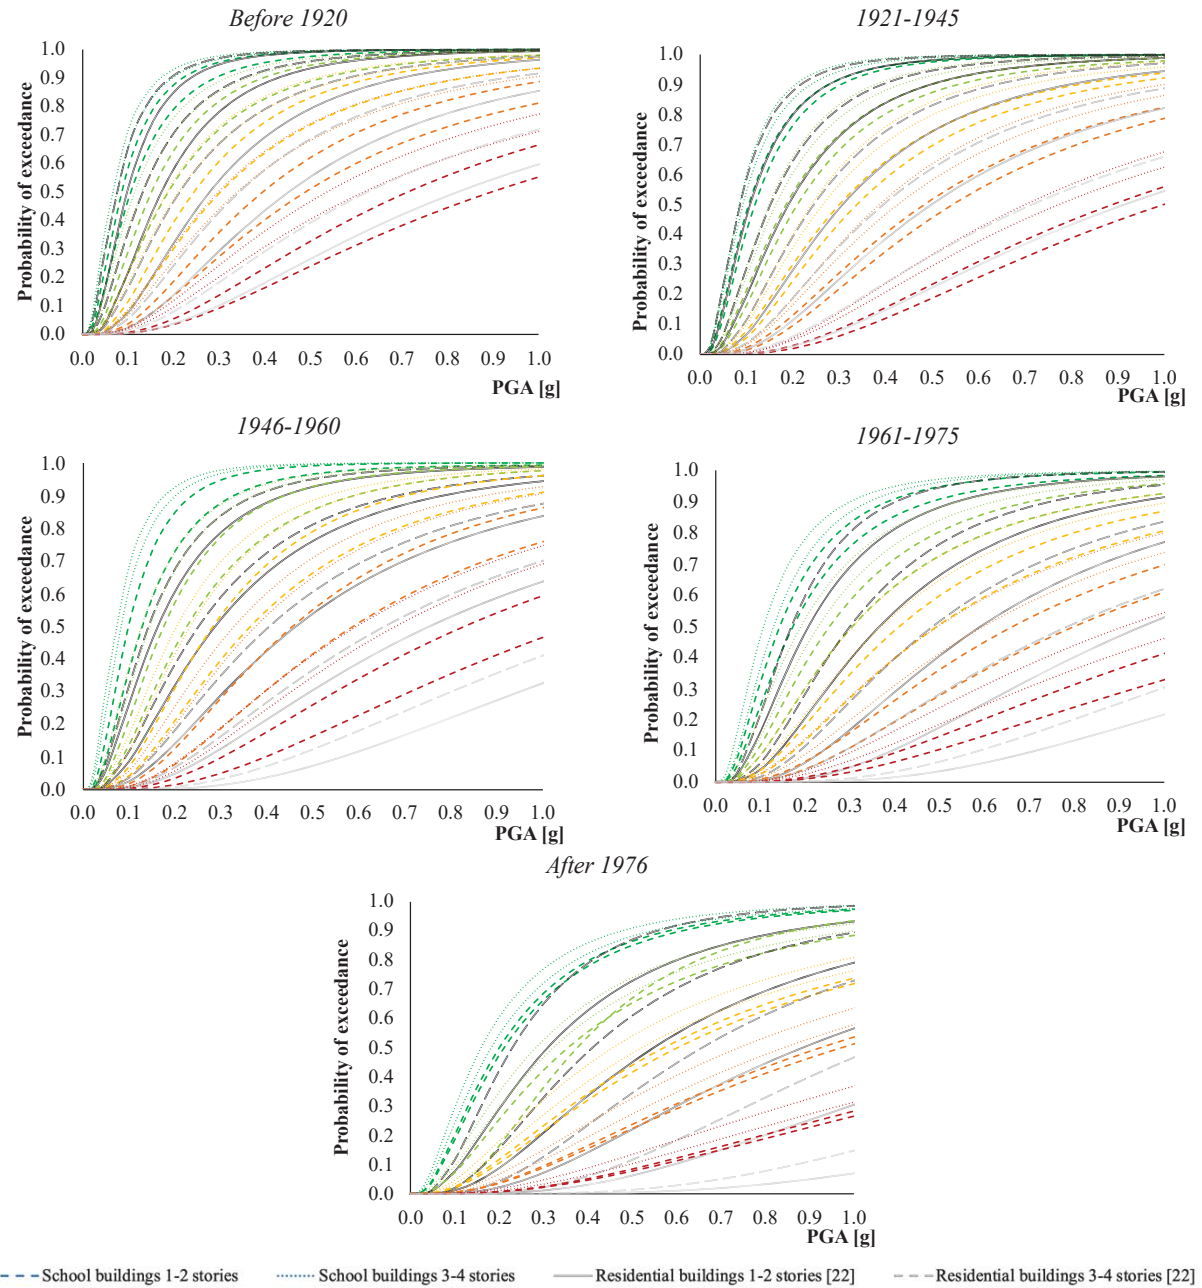

Figure 6: Comparison between fragility models for masonry schools and for masonry residential buildings [22].

The reduction in the number of parameters allowed the proposed fragility model to be compared to fragility curves from the literature, previously derived for residential buildings by Donà et al. [22]. Since the development methodology was the same, the differences in the fragility models are due to the variation of building types. Figure 6 reports the proposed fragility model for the Italian masonry school buildings classified, according to the number of stories and the construction age, and their comparison to fragility curves for residential buildings of comparable macro-classes.

It can be observed that, before 1945, the fragilities of schools and residential buildings are similar. On one hand, in fact, better material quality and more frequent applications of retrofit and restoration interventions can be expected for public relevant buildings such as schools; on the other hand, school buildings present an intrinsic geometric vulnerability (i.e., higher inter-story and great distance between transverse walls, orthogonal to façades) which increase their susceptibility towards OOP mechanisms. After 1945, also the residential construction industry improved, as described in the reference study by Donà et al. [22]. Thus, the geometric vulnerability factors of schools prevailed in the fragility model and, therefore, school structures appear to be more fragile than residential buildings. A note of caution is due regarding the interpretation of results as they are strongly influenced by the assumed exposure matrix for the combination of school macro-classes.

The trends of the mean value of the proposed fragility curves are reported in Figure 7 to highlight how they can be affected by the different parameters taken into account. The factors increasing vulnerability were confirmed to be the age, the great number of stories, the plan area, which is often related to plan complexity, and the poor quality of the material.

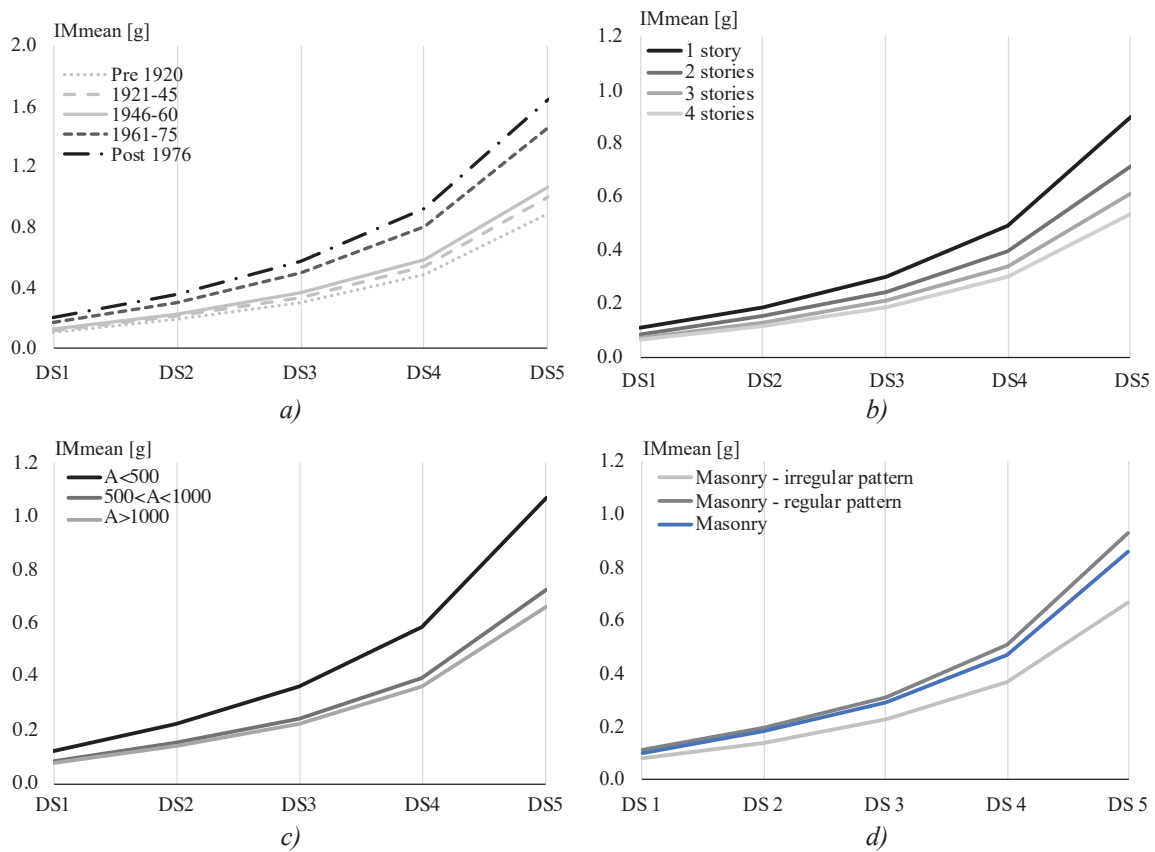

Figure 7: Trend of mean value as following parameters vary: a) construction age, b) number of stories, c) plan area in square meters, and d) type of masonry.

Focusing on construction age, two groups can be identified due to a perceptible gap in the trends of mean values: before 1960 and after 1960, when modern clay blocks and high-quality construction details began to spread in the construction use, years before code provisions (which started, in Italy, in the 1980s) [30]. Plan area appeared to affect the vulnerability and two groups can be identified based on their response: small buildings and, on the other hand, medium-large structures. Thus, for plan area greater than 500 m<sup>2</sup>, an increased vulnerability due to plan complexity shall be expected.

## 5 CONCLUSIONS

- The present paper has illustrated the derivation on fragility curves for the Italian masonry school building asset, on the basis of a limited number of parameters included in the Italian school building registry: the construction age, the number of stories, the plan area, and the type of masonry.
- The simplified mechanical modeling procedure *Vulnus 4.0* was used, as it allows a large amount of analyses to be performed in a suitably short time. The mechanical model considers both IP and OOP mechanisms, together with an index which summarizes qualitative vulnerability factors, according to the II level GNDT form [21].
- A parametric analysis was implemented through *Vulnus 4.0*, resulting in a fragility set, comprised of three fragility curves (i.e., average *white* curve, a lower-bound and an upper-bound), for each macro-class of school structures. Fragility sets were associated to an intermediate DS between 2 and 3, and therefore called DS2-3. Then, a macro-seismic model from the literature [13, 15] was calibrated to extend the mechanical fragility sets to five damage states, according to EMS98 [26]. Lastly, average *white* curves were combined to upper and lower bounds increasing dispersion, thereby leading to a better treatment of uncertainties.
- A novel fragility model was proposed and compared to a likewise developed fragility model from the literature for masonry residential buildings [22]. Interestingly, for the construction period before 1919 and between the two World Wars, school buildings and residential structures present similar fragilities, suggesting that the intrinsic geometric vulnerability of schools was balanced by the better quality of public construction industry. Otherwise, after 1945, also the residential construction industry had improved and, therefore, school buildings appear to be more seismically fragile than ordinary buildings.
- This research contributes to current knowledge of seismic risk assessment and mitigation by providing a broad fragility assessment of a particular type of relevant structures (i.e., school buildings), at national scale. This study was focused on the Italian building asset and construction use, to which both the database analysis and the exposure matrix are referred. A limitation of this study was the lack of information regarding the distribution of masonry quality and construction details during the ages at national scale; this additional information would have allowed the exposure matrices, here based on expert judgement, to be calibrated. Further investigations are requested to retrieve data, consistent at national scale, for specific types of structures.
- This contribution will be used to develop maps of seismic risk and damage scenario for Italy. The proposed fragility sets will represent the vulnerability component in the convolution with hazard and exposure to evaluate seismic risk. This evaluation will be possible thanks to the IRMA platform [31], specifically developed by Eucentre, within the framework of a cooperative national project. The final aim will be a deep knowledge of seismic risk, to mitigate the impact of earthquakes which have caused casualties, huge economic losses on the residential asset [32,33] and on the production sector [34, 35] and, above all for schools, an unquantifiable social impact.

## ACKNOWLEDGEMENTS

Special thanks are due to the Italian Department of Civil Protection (DPC), which funded this study in the framework of the *ReLUIIS-DPC Project 2019-2021 – Work Package 4: MARS (Maps of Risk and Scenarios of seismic damage) – Task 7: Fragility models and curves for schools and other strategic or relevant buildings*. A special thanks to the Work Group for the effective cooperation, especially to the research units of the Universities of Genova, coordinated by Prof. Serena Cattari, and Trieste, coordinated by Prof. Natalino Gattesco, for sharing data of prototype schools included in the study.

### Abstract

*School buildings are considered relevant structures and their safety towards seismic actions shall be verified in consideration of the significant consequences of their collapse. With reference to Italy, most reinforced concrete (r.c.) schools were built after the second world war and in the later years of the economic boom, before a widely applied seismic regulation. In fact, seismic classification of Italy was a long process developing throughout the XX century, with significant areas which were not considered seismic until the early 2000s.*

*The paper presents the evaluation of the seismic behavior of a representative 2-story Italian r.c. school building designed for gravitational loads only, and the derivation of a fragility curve set describing the seismic behavior of the macro-class of buildings. A series of Non-Linear Time History Analyses (NLTHA), with sets of natural ground motion records of increasing intensity, were implemented on two fiber models, developed in Midas GEN, representing the bare frame (BF) and the infilled frame (IF) configurations, respectively. Inter-story drift ratio (IDR) was chosen as demand parameter to identify the Damage State (DS) exceeded by each analysis and explicitly calculated for the analyzed structure. Fragility curve sets, describing five increasing DSs, were derived, for both the BF and the IF configurations, through the statistical processing of NLTHA results. A comparison of the calculated fragilities, between BF and IF models, is finally provided.*

## 1 INTRODUCTION

Italy is one of the most seismic prone countries of Europe, where earthquakes have caused casualties, unusable buildings, huge economic losses for both the residential [1,2] and the industrial [3,4] assets, and damage to the cultural heritage with heavy repercussions on the tourism sector [5]. Furthermore, the global impact of strong seismic events on communities is hardly quantifiable. In this framework, schools play a crucial role due to the high social impact of their collapse, threatening children and youth, and their unusability in the aftermath of a seismic event [6,7]. Thus, an estimation of seismic risk and damage scenario related to school buildings is required to deepen knowledge of disaster risk (Priority 1 of the *Sendai Framework for Disaster Risk Reduction 2015–2030* [8]).

With this aim, a national project has been established by the Italian Department of Civil Protection (DPC) and the Laboratories University Network of seismic engineering (ReLUIS consortium), to develop maps of seismic risk and damage scenarios for different classes of buildings (e.g., ordinary buildings, schools, and churches) at a national scale [1,9].

Risk estimation requires the definition of hazard, exposure and vulnerability of the built asset. Various methodologies have been developed to assess vulnerability at large scale, and they are mainly based on the derivation of fragility curves (i.e., cumulative density function expressing the probability of exceeding a damage state). Empirical approaches provide the description of damage probability (through damage probability matrices – DPM) based on the post-event observed damage [10–13]. These methods provide realistic fragility estimates, which however strongly depend on collected data, and thus on the building taxonomy of the region interested by the seismic event. Lack of damage data (e.g., for certain levels of seismic intensity or for specific building types) can be overcome using hybrid methods [14,15], based on both empirical data and mechanical models, of which some examples are presented as follows. Numerous studies have focused on developing fragility curves by means of mechanics models. Among the others, mechanics-based vulnerability assessment of structures can be based on simplified procedures [16–19], including Displacement-Based approaches [20–22], as well as on non-linear time history analyses (NLTHA) [23,24].

This contribution provides a proposal of vulnerability assessment of a specific class of school buildings (i.e., two-story r.c. frame designed for gravitational loads only), by deriving fragility curves through NLTHA performed on a finite element (F.E.) model of a prototype school. To investigate the influence of infills on the seismic response, two different models were implemented to simulate the dynamic behavior of both bare frame (BF) and infilled frame (IF).

Seven ground motion suites, each consisting of 10 accelerograms, were selected based on spectrum-similarity criteria, with reference to the elastic spectrum of L'Aquila, Italy, for seven increasing return periods. The investigated demand parameter was the interstory drift ratio, which was associated to damage states (DSs) through threshold values from the literature [9,25]. Then, the statistical processing of NLTHA outcomes was carried out to estimate the parameters (i.e., median value and standard deviation) of the log-normal cumulative density function (CDF), allowing fragility curves to be derived, and then compared.

The IF model shows a regular distance among DS fragility curves, while the slightly higher ductility of the BF configuration is found in the distribution of fragility curves, resulting more spaced.

## 2 ITALIAN SCHOOL BUILDING ASSET

The reference dataset for the risk assessment at national scale is the Italian school building registry (SBR) of the Ministry of Education [26] which gathers almost 50,000 school build-

ings, of which 16,522 are r.c. structures. School buildings are registered on the basis of a limited number of parameters: construction material and age, number of stories, plan area, and types of floors and roof. The distributions of typological characteristics of the r.c. schools are reported in Figure 1. Reinforced concrete schools result to be built mainly after 1961, with a prevalence of low-rise structures, with one or two stories. Similarly, the distribution of plan area shows a prevalence of small to medium buildings, up to 2,000 m<sup>2</sup>. However, the amount of larger buildings is not negligible, and moreover they present a significant exposure.

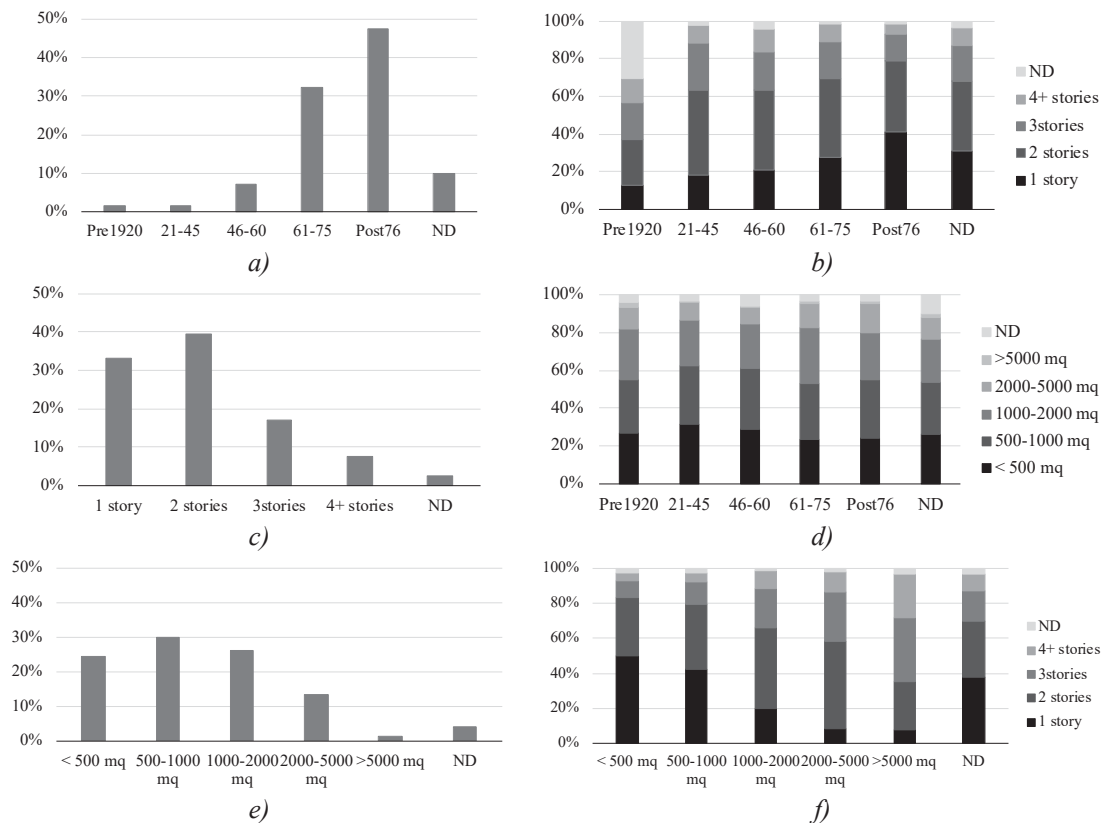

Figure 1: Typological characteristics of r.c. buildings in Italian SBR: a) construction age; b) number of stories given age; c) number of stories; d) plan area given age; e) plan area; f) number of stories given plan area

The processing of the dataset allowed the identification of a series of macro-classes adequate for risk analyses at a national scale, i.e., based on a limited number of parameters which distribution is available on the country (construction material, number of stories, and age). Each macro-class is assumed to be homogeneous from a seismic vulnerability point of view; thus, a single set of fragility curves, describing the probability of exceeding various damage states, can be assigned to each macro-class. Fragility models of macro-classes can be developed through the analysis of prototype structures, selected on the basis of representativeness criteria, so that results can be extended on a national scale.

This paper presents, as case study, the fragility assessment for a prototype r.c. school, representative of the macro-class of two-story school buildings built between 1961 and 1975.

## 2.1 Selected prototype r.c. school building

The selected school building consists in a two-story r.c. bi-directional frame (weak columns/strong beams), designed in 1966 for gravitational loads only. The retrieved original project documentation reported both the detail of reinforcement for each structural element and

the class of smooth rebars (i.e., AQ50), while no data was found regarding the concrete class. Thus, a mean cylinder compressive strength ( $f_{cm}$ ) equal to 20 MPa was assigned according to Masi et al. [27].

The school, which plan is shown in Figure 2, presents significant openings on the façades of classrooms, with five bays of the frame entirely infilled with hollow clay bricks with modest void area, approximately equal to 35% (Figure 3). Infills panels are 13 cm thick (one header).

Figure 2: School plan with indication of infilled bays (in red).

Figure 3: Hollow clay brick used for infill panels and photo of coeval school construction site.

### 3 FRAGILITY ASSESSMENT THROUGH NLTHA

#### 3.1 Modelling of bare frame and of masonry infills

Two numerical models of the prototype building were implemented through the software Midas GEN [28]. For r.c. structural elements a fiber model [29] was developed, on the basis of the original project documentation. The constitutive laws of materials were assumed according to Mander [30] for concrete, accounting for confinement, and Menegotto and Pinto [31] for steel, considering an hardening behavior.

To investigate the influence of infills on the global behavior of the structure, two different models were implemented: a first one simulating the bare frame, and a second one representing the infilled frame (as shown in Figure 4a).

Prior studies have experimentally defined the seismic response of both thin masonry infills [32–34] and thick panels [35,36], with reference to hollow blocks with high void area. Thus far, no experimental data were available on masonry infill walls with low void area. The seismic behavior of masonry infills is affected by the interaction of in-plane (IP) and out-of-plane (OOP) responses. Some detailed models have been developed to catch this combined effect through numerical simulations [37,38], however, up to now, hardly applicable to fragility assessment.

For the purposes of this study, a single-strut macro-model was implemented for infill panels, as it allows an efficient simulation of the infill influence on the global structural behavior, with limited numerical effort [39]. The equivalent thickness of the infill strut was estimated according to Stafford Smith (1967) [40] and Mainstone (1974) [41], through the following equations.

$$\frac{w}{d} = 0.175\lambda_h^{-0.4} \quad ; \quad \lambda_h = \left[ \frac{E_{inf}t_{inf}\sin(2\theta)}{4E_cI_cH_{inf}} \right]^{\frac{1}{4}} \quad (1)$$

The ratio between the equivalent thickness ( $w$ ) and the length ( $d$ ) of the strut is expressed as a function of the relative stiffness  $\lambda_h$ , which depends on Young's Modulus of both infill ( $E_{inf}$ ) and columns ( $E_c$ ), thickness ( $t_{inf}$ ) and height ( $H_{inf}$ ) of the infill panel, moment of inertia of r.c. columns ( $I_c$ ), and infill diagonal inclination ( $\theta$ ).

Due to the lack of experimental tests to calibrate the constitutive law of masonry infill struts, the model proposed by Panagiotakos and Fardis was assumed [42]. The infill strut constitutive law is shown in Figure 4b.

Results of the eigenvalue analysis are reported in Table 1 for the first three vibration modes. The infilled frame model has lower vibration periods and presents lower torsional deformation. Hence, the presence of infills, besides increasing the stiffness of the model, regularizes it.

Figure 4: a) F.E. model with infills and b) infill strut constitutive law.

Figure 5: Results of non-linear static analyses for BF and IF models.

Mode	$T [s]$	<i>Bare frame model</i>			$T [s]$	<i>Infilled frame model</i>		
		$m_{Tx} [\%]$	$m_{Ty} [\%]$	$m_{Rz} [\%]$		$m_{Tx} [\%]$	$m_{Ty} [\%]$	$m_{Rz} [\%]$
1	1.111	-	81.93	-	0.844	-	87.58	-
2	1.037	-	-	81.40	0.708	26.32	-	62.62
3	0.758	82.32	-	-	0.592	60.92	-	27.56

Table 1: Dynamic properties for first three vibration modes.

A preliminary non-linear static analysis (NLSA) was performed on the model to evaluate the response of both bare and infilled frame in the two main directions. Capacity curves resulting from NLSA are reported in Figure 5 in terms of acceleration (i.e., base shear normalized with respect to building mass) and global drift (i.e., top displacement normalized with respect to building height). As it can be expected, X-direction has a higher stiffness than Y-direction, which instead appears to be more ductile even in the IF configuration. The effect of infills is more evident for X-direction (which presents three infilled bays) than for Y-direction (two infilled bays).

### 3.2 Definition of ground motion records

The selection of ground motion suites was carried out through the procedure *Select&Match*, proposed by Paolucci et al. [43], with the aim of providing a large set of input ground motion records for a wide range of intensity levels to be used for the derivation of site-independent fragility curves. For this purpose, a target spectrum referring to the site of L'Aquila, Italy, for increasing return periods (i.e., 50, 100, 200, 475, 975, 2475, and 5000 years) was defined to select ground motions of increasing intensity. A suite of ten spectrum-similar ground motion records was defined for each reference return period, with a similarity criteria less strict than the code-compliant spectrum compatibility [44,45], in order to define site-independent ground motion sets.

The values of peak ground acceleration (PGA) of the selected ground motions are reported in Figure 6, compared to PGAs of the reference spectrum, for increasing return periods. A higher dispersion can be observed for greater return periods.

Figure 6: PGAs of selected accelerograms (grey) compared to PGAs of reference spectrum (red).

Seventy accelerograms were selected and applied to models (both BF and IF) separately in the two main directions, in order to more clearly associate each level of PGA to the investigated engineering demand parameter (EDP). Thus, for each model, 140 NLTHA were carried out.

### 3.3 Definition of the EDP

Fragility assessment by means of numerical analyses requires the definition of reference demand parameters, which should have a good correlation with damage. In this case, the maximum interstory drift ratio (IDR) was selected to describe both structural and non-structural damage, as reported in the macro-seismic scale EMS98 [46] for five increasing damage states (DSs).

Research in the field of fragility curves for existing reinforced concrete buildings has proposed IDR thresholds to distinguish between DSs which can be reached and exceeded by a structure: slight damage, moderate damage, severe damage, partial collapse and complete collapse. Masi et al. [9] proposed five IDR thresholds in r.c. frames designed for gravitational loads only, considering both structural and non-structural elements. The correlation between IDR thresholds and DSs was evaluated by means of parametric non-linear dynamic analyses, where the global damage was quantified in terms of ductility demand and capacity of structural elements.

More recently, the observation of RC buildings damaged by seismic events led to the definition of IDR thresholds which take into account the seismic response of infills for the first three DSs. An extended review and processing of the available experimental data from the literature, in terms of drift capacity of infill panels, was presented in Del Gaudio et al. [25], providing novel median IDR capacities, which were then validated based on the assessment of losses caused by the L'Aquila earthquake [47].

Table 2 compares IDR thresholds from the aforementioned studies. It can be observed that the first set is more conservative for the second, third, and fourth limits, thus including the exceeding of DSs by infill panels of the second proposed set. Thus, in the present study, the IDR thresholds were assumed according to Masi et al. [9], except for the first threshold which resulted to be more conservative according to Del Gaudio et al. [25]

A shortcoming of this selected set is that the same IDR thresholds were assumed for both BF and IF models, even though different modelling strategies affect the development of story displacements. The difference mainly regards lower DSs, while it tends to decrease for higher DSs, where the contribution of infills is strongly reduced. Further investigations are needed to evaluate the most suitable set of thresholds, distinguishing between BF and IF model. In this framework, BF model is here presented only for comparison purposes.

	DS <sub>0</sub>	DS <sub>1</sub>	DS <sub>2</sub>	DS <sub>3</sub>	DS <sub>4</sub>	DS <sub>5</sub>
Masi et al. [9],	0.1%	0.25%	0.5%	1.0%	2.5%	
Del Gaudio et al. [25]	0.08%	0.32%	0.94%	1.78%	-	
Selected IDR	0.08%	0.25%	0.5%	1.0%	2.5%	

Table 2: IDR thresholds for five damage states for RC frames designed for gravitational loads only.

### 3.4 Derivation of fragility curves

The outcomes of NLTHA are presented in Figure 7 using cloud plots, reporting each resulting maximum interstory drift ratio associated with the PGA that generated it, with the indication of IDR thresholds.

The BF model shows higher IDR values associated to ground motions of moderate intensity compared to IF model, thus more realizations overcome IDR thresholds for DS<sub>3</sub> and DS<sub>4</sub>. As a consequence, the DS<sub>3</sub> threshold in particular is exceeded in advance in the BF model, as it will become evident from the comparison of the derived fragility curves. The most populated damage state for BF configuration results to be DS<sub>4</sub> (partial collapse). On the contrary, infilled model appears to have a lower general dispersion, and more homogeneously populated

DSs. For the selected seismic input, no NLTHA provides a maximum IDR smaller than the first threshold ( $DS_0$ ).

NLTHA results falling between two IDR thresholds represent the cases in which the building reached or exceeded the DS enclosed by the thresholds. PGA values for each IDR range were processed in order to estimate parameters of fragility curves (i.e., log-normal CDF), expressed as follows:

$$P(D \geq DS_i | PGA) = \Phi \left[ \frac{\ln(PGA/\mu_{DS_i})}{\beta_{DS_i}} \right] \quad (2)$$

where  $P(D \geq DS_i | PGA)$  indicates the conditional probability of exceeding a damage state  $DS_i$  given a PGA value,  $\Phi$  is the standardized normal CDF, and  $\mu_{DS_i}$  and  $\beta_{DS_i}$  are the parameters of the CDF (i.e., the median value and the logarithmic standard deviation, respectively).

Figure 7: Cloud plots of resulting maximum IDR associated with generating PGA for a) BF and b) IF.

The standard deviation of the proposed fragility curves was computed through the SRSS (i.e., Square Root of Sum of Squares) combination of three different component: i)  $\beta_D$  expressing dispersion due to record-to-record variability; ii)  $\beta_C$  related to uncertainties associated to structural capacity, assumed equal to 0.3 according to HAZUS-FEMA [48] for Pre-Code buildings; and iii)  $\beta_{M(DS)}$  related to uncertainties in the estimation of median value of EDP thresholds for each DS, assumed equal to 0.4 according to HAZUS-FEMA [48].

$$\beta_{DS_i} = \sqrt{\beta_D^2 + \beta_C^2 + \beta_{M(DS)}^2} \quad (3)$$

The estimation of the probability of exceedance towards global collapse by means of mechanical models might be affected by convergence problems which can be expected in strongly non-linear field [49]. According to the proposal by Jalayer et al. [50], it was assumed that  $DS_5$  is reached through two separate conditions: i) IDR greater than the last threshold (i.e., 2.5%), identified hereinafter as *NoC* cases, since the model did not numerically “collapse”; or ii) dynamic instability (due to large displacements as well as failed convergence of the software) [51], identified hereinafter as *Col* cases. Both conditions contributed to derive the  $DS_5$  fragility curve, estimated by implementing the following equation based on total probability theorem:

$$P(D \geq DS_5 | PGA) = P(D \geq DS_5 | PGA, NoC)(1 - P(Col | PGA)) + P(Col | PGA) \quad (4)$$

NLTHA results for which dynamic instability occurred are shown in Figure 7 with a red border, and their probability of occurrence was computed through a logistic regression model. Please refer to Jalayer et al. [50] for further details.

The derived fragility curves are shown in Figure 8, which compares, for both BF and IF models, probability functions with logarithmic standard deviation for either record-to-record variability or all the dispersion components. The values of the estimated parameters are reported in Table 3. Figure 9 provides a comparison between BF and IF models in terms of plotted fragility curves and trend of median value  $\mu_{DSi}$ .

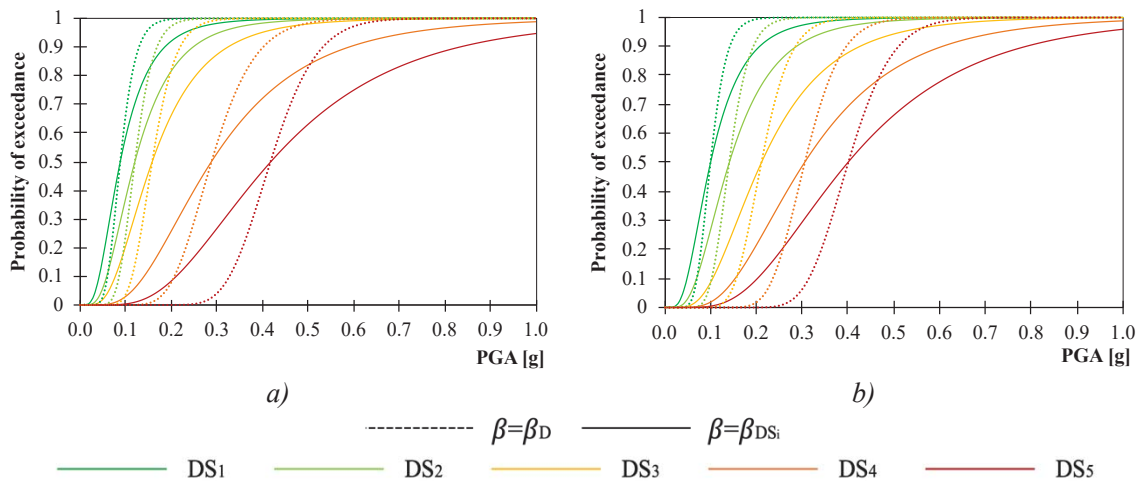

Figure 8: Fragility curves derived from a) BF and b) IF models.

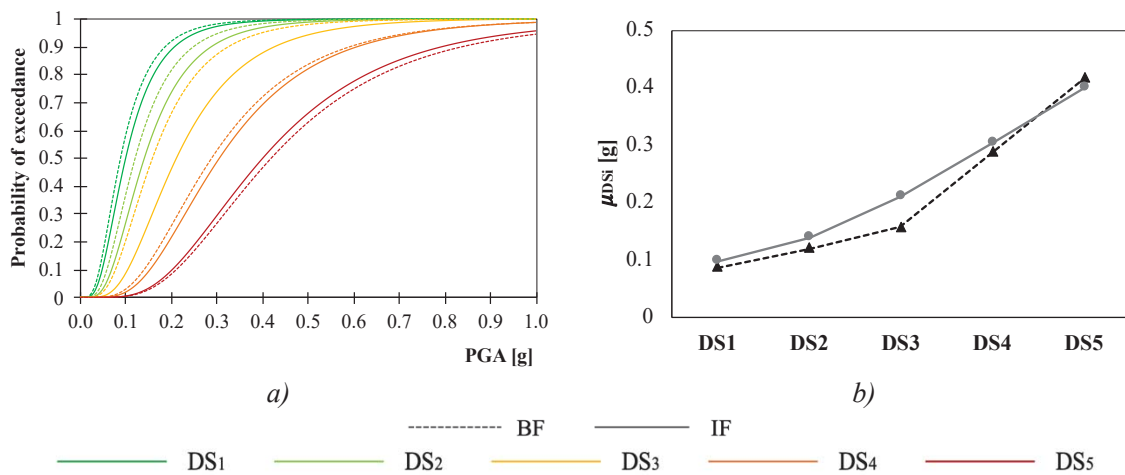

Figure 9: Comparison between BF and IF models in terms of a) fragility curves and b) median value  $\mu_{DSi}$ .

	<i>Bare frame model</i>			<i>Infilled frame model</i>		
	$\mu_{DSi}$	$\beta_D$	$\beta_{DSi}$	$\mu_{DSi}$	$\beta_D$	$\beta_{DSi}$
DS <sub>1</sub>	0.088	0.300	0.583	0.099	0.278	0.572
DS <sub>2</sub>	0.120	0.265	0.566	0.140	0.250	0.559
DS <sub>3</sub>	0.158	0.256	0.562	0.211	0.236	0.553
DS <sub>4</sub>	0.288	0.259	0.563	0.305	0.203	0.540
DS <sub>5</sub>	0.417	0.190	0.535	0.400	0.189	0.535

Table 3: Estimated median values and logarithmic standard deviations.

Infilled frame model showed a more homogeneously distributed behavior, with regular distance between different DSs. On the contrary, outcome from bare frame model provided the anticipation of the first three DSs, which can be related to threshold values not adapted to the BF configuration.

Results suggest a slightly more ductile behavior of the BF configuration, with a greater distance among DS curves, in accordance with both results of aforementioned NLSA and previous studies [52,53].

#### 4 CONCLUSIONS

- The present paper has discussed the derivation of fragility curves for a macro-class of school buildings starting from a representative prototype building. The case study is a two-story r.c. frame school, built in the 1960s and designed for gravitational loads only.
- The fiber model of both the bare frame and infilled frame configurations were developed through Midas Gen software [28] to implement a series of non-linear time history analyses. For the IF configuration a single-strut macro-model of the infills was implemented. Due to the significant presence of openings, only five bays on each story were modelled as infilled.
- A suite of 70 ground motion records was selected based on the procedure proposed by Paolucci et al. [43], based on spectrum-similarity, instead of spectrum-compatibility, in order to obtain a site-independent set.
- The selected ground motions were applied to both BF and IF models in the two main directions and the maximum interstory drift ratio was recorded and chosen as demand parameter, related to the damage state of the structure. IDR thresholds to distinguish among different damage states were assumed according to previous studies from the literature [9,25].
- Results from NLTHA were plotted in terms of maximum IDR and the peak ground acceleration of the ground motion that generated it. The statistical post-processing of resulting cloud plot provides the derivation of fragility curves (i.e., log-normal CDF of the probability of exceedance) for five damage states from EMS 98 [46].
- This research contributes to the current knowledge of seismic risk of a relevant class of structures (i.e., school buildings). This contribution will be part of a study that aims to develop maps of seismic risk and damage scenario for Italian school asset, thanks to the IRMA platform [54], specifically developed by Eucentre for this purpose.

#### ACKNOWLEDGEMENTS

Special thanks are due to the Italian Department of Civil Protection (DPC), which funded this study in the framework of the *ReLUIIS-DPC Project 2019-2021 – Work Package 4: MARS (Maps of Risk and Scenarios of seismic damage) – Task 7: Fragility models and curves for schools and other strategic or relevant buildings*. A special thanks to the Work Group for the effective cooperation, especially to the task coordinators, Prof. Serena Cattari and Prof. Angelo Masi.

### Abstract

*Masonry churches have a high intrinsic seismic vulnerability, demonstrated by the effects of the last earthquakes in Italy. In the present study a database of 1391 II level post-earthquake survey form (A-DC) has been analyzed. The forms were filled by the University of Padua, the University of Naples Federico II and the University of Naples Parthenope, under the coordination of the Department of Civil Protection, the Cultural Heritage Ministry (MiBACT) and the Italian Laboratories University Network of Seismic Engineering (Re-LUIS). The form were filled after the 2016/2017 Central Italy seismic sequence (889 forms), the 2012 Emilia earthquake (264 forms) and after the 2009 L'Aquila earthquake (238 forms). A typological investigation has been done as preliminary phase, and some vulnerability modifiers have been determined, with the aim of developing vulnerability and fragility curves dependent of poor but effective typological characteristics of the buildings.*

## 1 INTRODUCTION

In the last decades, great losses have occurred to the artistic and cultural heritage as a result of seismic events. In particular, serious damage has been suffered by churches [1-6], object of the present study. With the purpose of assess the safety conditions and collect the data of the damage suffered by ecclesiastical buildings, a specific form for the survey of damage churches [7, 8] was developed. The current version (A-DC form [9, 10]) consists of several sections, in which identification data, context description, damage data, safety evaluations and basic geometric information of the building are reported. As concern the damage survey, the form is based on the identification of the damage level (from 0 to 5) of 28 possible collapse mechanisms of macro-elements. Then, it is possible to obtain an overall damage index  $i_d$  (from 0 to 1) as a normalized average of the damage level of each mechanism.

The seismic events considered in this study are those in which the form for the damage survey of churches has been used in its actual version: the 2009 L'Aquila earthquake, the 2012 Emilia earthquake and the 2016/17 Central Italy seismic sequence. The surveys have been carried out under the coordination of the Department of Civil Protection (DPC) and the Ministry of Cultural Heritage and Tourism (MiBACT) by group of technicians (structural engineers, officials of the superintendence, fireman if the safety level was low). In particular, the authors have used A-DC forms filled mainly by the University of Padua, and in part by the University of Naples Federico II and the University of Naples Parthenope.

Churches are a peculiar type of building which has intrinsic seismic vulnerability due to its constructive and typological features (i.e. great lights, absence of intermediate diaphragms, large height to width ratio of walls, thrusting horizontal structures) [11]. Thus, in order to elaborate large-scale analysis, churches must be approached differently than ordinary buildings [2, 13, 14]. Usually, the evaluation of seismic risk at territorial scale requires the identification of different classes of buildings which have similar behavior [12]. For ordinary buildings, those classes are generally defined by the type of load-bearing structure (e.g. masonry, reinforced concrete, etc.) and by the constructive techniques and building regulations (mainly identifying with age of construction ranges). On the other hand, churches are usually load-bearing masonry buildings, distinguished by typological features more than constructive ones (e.g. presence of macro-elements, type of plan and façade, etc.). Therefore, the aim of this work is to identify typological characteristics that affect the vulnerability of the churches, in order to allow the elaboration of typological vulnerability and fragility curves that could account for different churches vulnerabilities and therefore be applied on large-scale seismic risk assessment according to the churches features.

## 2 TYPOLOGICAL DESCRIPTION OF THE SAMPLE

The database considered in the present study includes a total of 1391 post-earthquake survey A-DC forms [9, 10], filled mainly by the University of Padua, and in part by the University of Naples Federico II and the University of Naples Parthenope. Of these, 889 were collected following the 2016/2017 Central Italy earthquake sequence [6], 264 following the 2012 Emilia earthquake [4], and finally 238 following the 2009 L'Aquila earthquake [3]. Table 1 shows the geographical distribution of the surveys.

As already mentioned, in order to carry out the vulnerability analysis of churches it is necessary to consider the great geometrical and typological differences that they may present, which could lead to a very different seismic response. In particular, using the information collected from the A-DC forms and the photos of the post-earthquake surveys, the typological distributions of the churches affected by the three 2009, 2012 and 2016/17 earthquakes have been analyzed.

<i>Earthquake</i>	Regions (number of churches): province
<i>Central Italy 2016/17</i>	Marche (602): Ancona (AN), Ascoli Piceno (AP), Fermo (FM), Macerata (MC), Pesaro e Urbino (PU) Abruzzo (111): L'Aquila (AQ), Chieti (CH), Pescara (PE), Teramo (TE) Umbria (110): Perugia (PG), Terni (TR) Lazio (66): Frosinone (FR), Rieti (RI), Viterbo (VT)
<i>Emilia 2012</i>	Emilia Romagna (138): Bologna (BO), Ferrara (FE), Modena (MO), Reggio Emilia (RE) Lombardia (82): Cremona (CR), Mantova (MN) Veneto (44): Rovigo (RO)
<i>L'Aquila 2009</i>	Abruzzo (238): L'Aquila (AQ), Teramo (TE)

Table 1: Geographical distribution of the sample.

Specifically, the distribution of the following database parameters was studied [6]: a) type of plan (Figure 1); b) type of façade; c) masonry type; d) type of bell structure; and e) dimensions (volume).

The results in terms of the distribution of the analyzed features are collected in Table 2 and the typologies associated with each church belonging to the database, geographically located, are presented in Figure 2.

As regards to the type of plan, seven types were identified based on the number of naves, the presence of apse, transept and side chapels (Figure 1). Specifically: type 1 represents one nave churches with, simple rectangular plan, without apse or aggregated elements; type 2 is similar to type 1, with the addition of the apse; type 3 represents the most complex possibility for one nave churches (apse, transept and/or side chapels); type 4 is three or more naves church, with very complex plan (transept, chapels, apses at the end of naves and transept); type 5 is also a three or more naves church, with medium complex plan; type 6 represents the less complex typology of three naves churches (includes also the 2 naves churches); type 7 is circular or central plan (polygonal) church.

Figure 1: Schematic representation of the seven type of plan considered in this study.

The analysis of the sample showed that in Central Italy simpler churches are predominant. The most common types are 1 and 2, whereas with very small percentages are found types 3, 5 and 6; types 4 and 7 are just over 1%. Table 2 and Figure 2 show that the churches affected by the 2009 L'Aquila earthquake have many similarities with the ones of the 2016/17 Central Italy seismic sequence (both affect the central Apennine belt). In fact, the most widespread are type 1 and 2 churches (82.8 % CI and 66.9% AQ), but also, type 6 and type 3 are common. The trend identified in the Central Italy region changes considerably for the churches located in the Po Valley: the percentage of type 1 is very small (mostly oratories and minor private chapels). Instead, the more complex typologies (type 3, 6 and 5) are more widespread with a cumulative percentage of 61.4%. The numbers of types 4 and 7 remain marginal. Analyzing the geographical distribution, it can be observed that in the Apennine region there is a predominance of single nave churches (mainly typologies 1 and 2); the cases of churches with more naves are located in the less mountainous areas and in Abruzzo, and they belong to typology 6, so they

have a not excessively complex geometry. In the Po Valley the typologies present are distributed in the territory, and are not visibly dependent on geographical location.

The second feature analyzed is the type of façade. Four main types of façade have been identified: gabled, salient façade, quadrangular and polygonal. The cases that was not possible to trace back to one of these four types (e.g. churches with side entrances connected to adjacent buildings on several sides or churches with a large prothyrum or narthex) were excluded from the present analysis, because of the different seismic behavior of the façade macroelement.

With regard to the sample of Central Italy, there is a clear majority of gabled type, whereas the church façades of the L'Aquila earthquake belong in large part to the gabled and the quadrangular type. Instead, most of the churches in the Po Valley have salient and gabled façades.

The type of façade seems to have no correlation with geographical location (Figure 2) probably due to similar geographical conditions of the inspected area all enclosed in the plain.

Another important typological characteristic is the masonry type. Since the masonry texture is often covered by plaster, it is not always possible to determine the constituent material of the walls, unless more in-depth investigations are carried out. As for the façade, also for the masonry typology, the not identified cases have been excluded from the typological analysis.

Four masonry types have been distinguished: random stone, stone ashlar, brick masonry and mixed stone and brick masonry. The masonry parameter distribution is the most clearly readable: in Central Italy and L'Aquila samples, stone is the most common material (mainly random rubble), whereas in Emilia no cases of stone masonry but an almost totality of brick masonry have been identified. Figure 2 shows that the type of masonry depends almost exclusively on the geographical/topographical location. In the lowland areas and in the coastal strip only brick masonry (or mixed masonry at most) is present, whereas rising to a higher altitude and moving away from the coast, bricks begin to be flanked by the stone until it is completely replaced by it (this is particularly evident in the Central Italy earthquake).

Regarding the type of bell tower, four types have been identified: isolated bell tower, bell tower integrated or partially integrated with the church structure, bell gable and absence of bell tower. The samples of Central Italy and L'Aquila have similar distributions: the most common types are integrated bell tower and bell gable, whereas isolated bell tower is very uncommon. L'Aquila sample has also a 10% of cases in which the bell tower is absent. Also, for this parameter, the Emilia database is visibly different from the others, presenting for the most part integrated and isolated bell tower, and only few cases of bell gable. Figure 2 shows that, in this case, the differences between the distributions of the samples depend more on the territorial/regional area, rather than on altimetric or topographical factors.

The last of the typological features analyzed is the volume of the church. Since many forms were incomplete in the section related to the geometric survey, also this parameter is not identified for the all database. Six ranges of volume have been chosen: two ranges of very small and small churches (from 0 to 250 and from 250 to 500 m<sup>3</sup>), two of medium size churches (from 500 to 1000 and from 1000 to 2500 m<sup>3</sup>) and two ranges of large churches (from 2500 to 5000 and from 5000 m<sup>3</sup> upwards). Table 2 shows that in Central Italy and L'Aquila the most widespread churches are those of medium size, followed by small churches and lastly those of large size. Instead, in Emilia, the most of the churches have a large or medium volume. From a territorial distribution point of view, large churches are typically located in lowland areas or in correspondence of cities or important centers (Figure 2).

Table 2: Statistical distribution of plan shape, façade type, masonry type, bell tower typologies and volume for the earthquake of Central Italy 2016/17, L'Aquila 2009 and Emilia 2012.

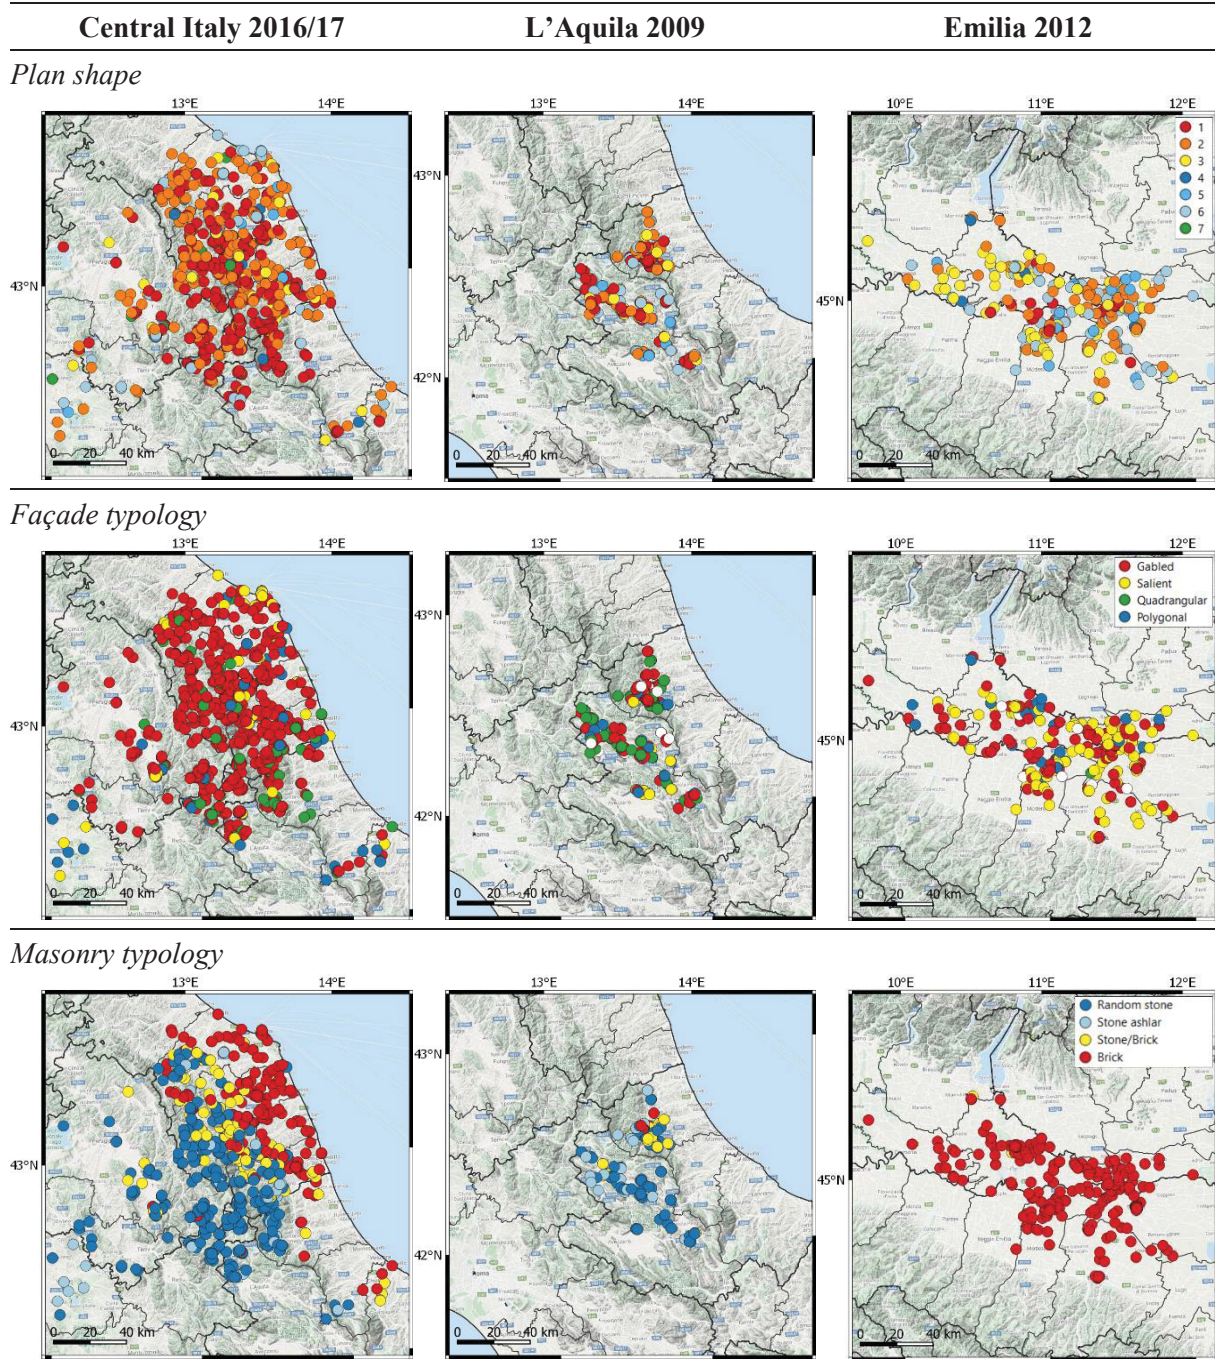

It can be concluded that Emilia churches are typologically very different from Central Italy and L'Aquila ones. The latter, belonging to the same geographical area, have more homogeneous characteristics, with some differences due to the proximity to the coast and to altimetric/topographical factors. In particular, the feature that the most depends on altitude is the masonry type, as a direct consequence of the availability of the different materials on site. The other parameters analyzed are not directly dependent on the altimetry, but are more related to the territorial/regional building traditions, especially evident in the type of façade and bell tower.

In summary, it emerges that the churches of Central Italy are mainly simple, medium size and single nave, with a gabled façade and a bell gable or a bell tower integrated into the structure of the church, built in stone (mostly random) in the Apennine area and brick in the coastal strip. Very similar are the churches affected by the L'Aquila earthquake, with the only difference that prefer a quadrangular façade and the cases with more than one nave are more widespread, although maintaining a very simple plan. Very different are the churches of Emilia and the Po

Valley regions, which have large complex plans with gabled or salient façades, with the presence of isolated or integrated bell tower and built almost exclusively in brick.

To compare several features, the maps in Figure 2 show that in Emilia there is a good correspondence between volume and complexity (typology of plan shape), whereas in Central Italy even when the churches are large the complexity is never high (particularly evident on the coastal strip).

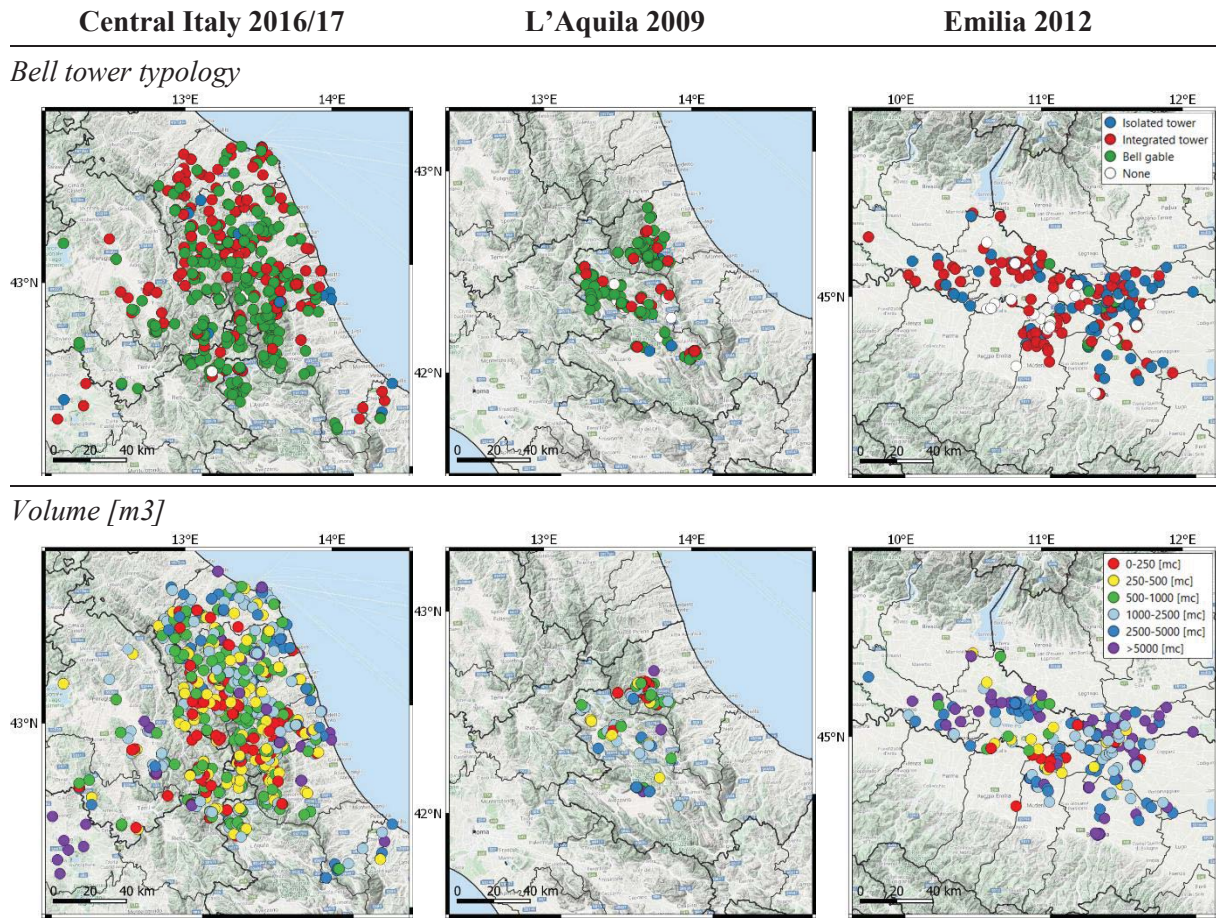

Figure 2: Map of the geographical distribution of different typological features for the earthquake of Central Italy 2016/17, L'Aquila 2009 and Emilia 2012.

### 3 VULNERABILITY CURVES

The seismic vulnerability of a building is defined as the propensity of the structure to suffer damage after a seismic event of a given intensity. It could be represented by a continuous function called vulnerability curve that relates the expected mean value of damage of a class of buildings to the seismic intensity. The latter is usually presented in terms of macroseismic intensity, but it can also be provided as peak ground acceleration-PGA values.

The formulation originally provided by [15] for residential buildings and further adapted to churches by Lagomarsino and Podestà [13] (1) was taken as reference to develop typological vulnerability curves.

$$\mu_d = 2,5 \left[ 1 + \tanh \left( \frac{I + 3.4375 \cdot \bar{i}_v - 8.9125}{q} \right) \right] \quad (1)$$

where  $\mu_d$  represents the mean damage grade ( $0 \leq \mu_d \leq 5$ ) as function of: the macroseismic intensity  $I$  expressed in accordance with the MCS scale [16], the mean vulnerability score  $i_v$  derived from the second level survey form for churches [17], and the ductility index  $q = 3$ .

In particular, a fitting procedure of the observational damage data collected was carried out using (2):

$$\mu_D = 2,5 \cdot [1 + \tanh(\alpha \cdot I_{MCS} + \beta)] \quad (2)$$

$$\text{with } \alpha = 1/q \quad (3)$$

$$\text{and } \beta = a \cdot i_v + b \quad (4)$$

and optimizing the value of  $\alpha$  and  $\beta$ .

The formulation (2) is equivalent to (1), but expressed in terms of the two parameters  $\alpha$  (3) and  $\beta$  (4). In this way, from the fitting procedure on mean damage values, the resulting vulnerability curve inherently includes the average value of  $i_v$  on the whole dataset. Indeed, as suggested below, the evaluation of different vulnerabilities classes or typologies could be related to a selected subset of homogenous churches.

### 3.1 Consideration on the damage index $i_d$

As mentioned before, the A-DC survey form allows to calculate an overall damage score (damage index)  $i_d$  for each church. In particular:

$$i_d = \frac{1}{5} \frac{\sum_{k=1}^n d_k}{n} \quad (5)$$

where  $n$  is the number of mechanisms that can be potentially activated in the church and  $d_k$  is the damage recorded in the  $k$ -th mechanism (from 0 to 5).

In order to be used for vulnerability and fragility analysis, the damage index  $i_d$  has to be converted to a damage level from 0 to 5, according to the EMS scale [18]. One of the most used correlation [13] is reported in Table 3.

Damage index $i_d$	0-0.05	0.05-0.25	0.25-0.4	0.4-0.6	0.6-0.8	0.8-1
Damage level (EMS98)	DS0	DS1	DS2	DS3	DS4	DS5
Description of the damage	<i>no damage</i>	<i>slight damage</i>	<i>moderate damage</i>	<i>heavy damage</i>	<i>very heavy damage</i>	<i>collapse</i>

Table 3: Correlation between the damage index  $i_d$  of the A-DC form and the damage level according to the EMS98 scale [13].

Using the correlation in Table 3, a process of discretization of a continuous quantity is carried out. This process is required to relate the result of the A-DC form to a damage level and to build damage probability matrices (DPM), but inevitably, it implies a great loss of detail. Moreover, this discretization slightly varies the overall mean description of the damage. For instance, considering a dataset of 101 churches equally distributed in the damage index  $i_d$  from 0 to 1, due to the different dimensions of each damage state, that discretization leads to an average  $\mu_D$  damage of 2.87 instead of the mathematical mean of 2.50. Figure 3 reports the real case of the 2016/17 Central Italy database with  $i_d$  multiplied by 5 to have a comparison. The graph shows how different the damage results can be: as expected, in general the mean damage obtained through the correlation proposed by Lagomarsino and Podestà [13] is higher then that obtained directly by the damage index  $i_d$ , but not in a consistent way. Indeed, in correspondence of some intensities (e.g  $I_{MCS}=8$  and  $I_{MCS}=9.5$ ) the difference is very low (about 0.15), while for others (e.g  $I_{MCS}=7.5$ ,  $I_{MCS}=8.5$  and  $I_{MCS}=10$ ) the difference is very impacting (0.5). This is a consequence of the specific distribution of the sample, and therefore it can generate unreliable results in terms of comparison analysis.

Figure 3: Comparison between the mean value of the damage expressed in terms of  $\mu_D$  and  $i_d$  for the Central Italy churches.

Therefore, since this study works directly on the average damage to figured out the vulnerability curve, and does not use the DPMs, it was decided to build the vulnerability curve in terms of damage index, using in place of the usual mean value  $\mu_d$  (2) the average  $i_d$  values (6):

$$i_d = 0,5 [1 + \tanh(\alpha \cdot I_{MCS} + \beta)] \quad (6)$$

The value of 2.5 is assumed as 0.5 accordingly to the domain of  $i_d$ . This choice has been made both to have more possibilities to adapt the curve to the observational values, and to use in a direct way the information obtained from the damage surveys, avoiding the loss of information deriving from the discretization of the value of  $i_d$ .

### 3.2 Fitting procedure

Once defined the formulation (6), some specification about the adopted fitting procedure are herein reported.

The two coefficients  $\alpha$  and  $\beta$  have been calibrated with the minimization of the total error. The ductility related coefficient  $\alpha$  was not keep fixed to  $q = 3$  since the observation of three different earthquakes and an extended sample shows a variability of this factor as reported in Table 4. As concern the  $\beta$  parameter, it was derived by the mean value of the observational damage indices of the A-DC forms, with a fitting procedure based on the minimization of the total error resulting from the sum of the square residual.

Table 4 reports values obtained from the fitting of eq. (6) and Figure 4 plot each vulnerability curve on the experimental data observed. As is possible to notice there is a good agreement between the observed data and the continuous curves with very limited errors.

	Central Italy 2016/17	L'Aquila 2009	Emilia 2012
$\alpha$	0.263	0.316	0.360
$\beta$	-2.205	-2.678	-2.471
<i>error</i>	$9.86 \times 10^{-04}$	$4.83 \times 10^{-04}$	$1.82 \times 10^{-03}$
$q$	3.807	3.161	2.778

Table 4: Value defined for the three analyzed earthquakes according to eq. (6)

Figure 4: Vulnerability curves obtained from the three analyzed earthquakes

## 4 INFLUENCE OF TYPOLOGIES

Since the previously observed curves are defined on the whole dataset, hence accounting for the average vulnerability, the selection of homogenous dataset of churches with the same vulnerability may improve the overall evaluation.

Once defined the vulnerability model and the fitting method, it was possible to analyze the influence on seismic vulnerability of different typology characteristics that may lead to the homogenous subset above seek. Specifically, in this paper, the influence of masonry type and the number of naves are presented.

On the basis of the results reached in section 2 about the typological distribution of the churches belonging to the database, the following analyses have been carried out limited to the churches of Central Italy and L'Aquila, in order to guarantee the uniformity of the sample. Future more accurate analysis will allow to study the entire database, and come to overall results not affected by possible errors due to not considered features.

### 4.1 Influence of masonry type

The first typological parameter to be analyzed is the type of masonry. The categories already identified in the context of typological characterization have been further simplified and reduced to three: stone masonry (both ashlar and random rubble masonry), brick masonry and mixed stone and brick masonry.

Figure 5a shows that the two extreme categories (i.e. stone masonry and brick masonry) have a marked difference in terms of damage, whereas the behavior of the intermediate one (i.e. mixed masonry) seems to be less linear and tends to overlap with the former in correspondence of some  $I_{MCS}$ . This can be attributed to the great variability that mixed masonry can presents, sometimes with a predominance of stone, sometimes of brick. Moreover, it is possible that in some cases the particular disposition of the different materials composing the masonry leads to both particularly unfavorable and favorable consequences.

Therefore, this parameter proves to be relevant for the definition of seismic vulnerability. In Figure 5b the results of the fitting procedure are shown. In this elaboration, the behavior of mixed masonry churches emerges to be very similar to stone masonry ones, although those constructed in brick masonry proves to have a much better response to seismic actions.

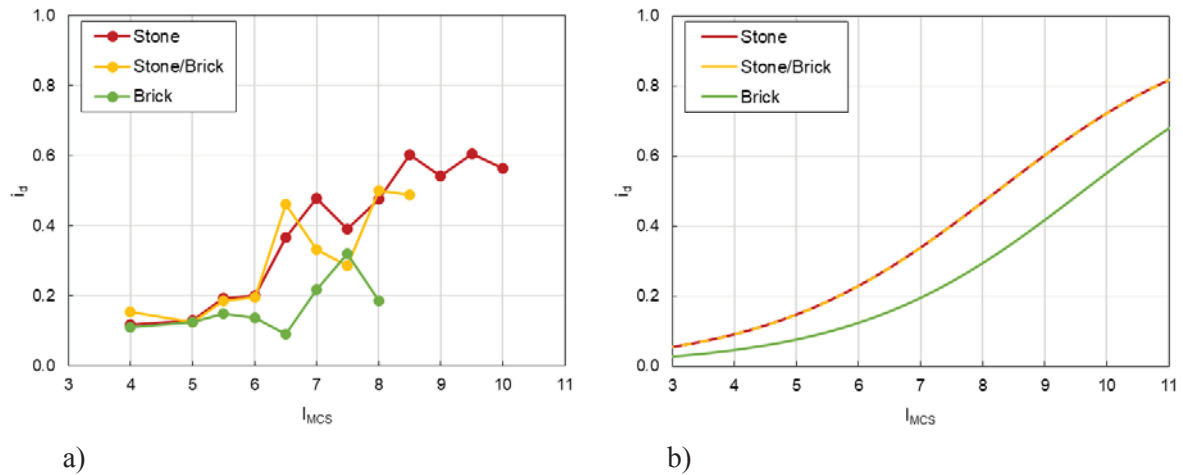

Figure 5: Mean  $i_d$  values for stone, mixed (stone/brick) and brick masonry churches (a) and resulting vulnerability curves (b).

#### 4.2 Influence of number of naves

The number of naves is the second typological feature analyzed. In particular, two classes were defined [19, 20]: one nave churches and more than one nave.

Figure 6a shows that for low value of  $I_{MCS}$  the damage observed for the two classes is similar. Then, with the increase of the intensity, the different behavior of the different types clearly emerges: churches with more than one nave tend to be less vulnerable compared to those with one nave. The different vulnerability is justified by the greater possibility of churches with several naves to absorb horizontal forces, thanks to the presence of colonnades and more widespread connections. On the other hand, the presence of such elements also makes less likely that all of them are damaged in a marked way; in fact, as the complexity increases, the weight of each macro-element decreases on the overall evaluation of the damage, leading on lower damage indices.

In Figure 6b, the vulnerability curves calibrated on the observed damage of both one and more than one nave churches.

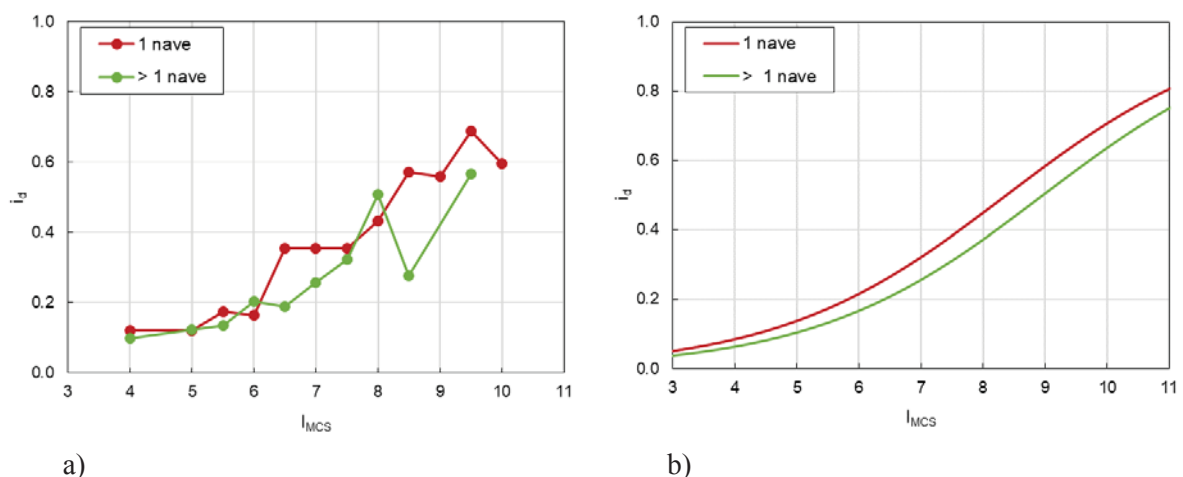

Figure 6: Mean  $i_d$  values for one nave and more than one nave churches (a) and resulting vulnerability curves (b).

## 5 CONCLUSIONS

- The present paper has presented a detailed typological distribution analysis of 1391 churches, affected by the 2009 L'Aquila earthquake, the 2012 Emilia earthquake and the 2016/17 seismic sequence of central Italy. The considered features have been plan shape, type of façade, masonry type, typology of bell tower, and volume of the church. It was figured out that the greater differences are due to the geographical and the altimetric/morphological location. In particular, churches of Central Italy regions are mainly simple, medium size and single nave, with a gabled or quadrangular façade and a bell gable or a bell tower integrated into the structure of the church, built in stone (mostly random) in the Apennine area and brick in the coastal strip. On the contrary, the churches located in the Po Valley regions generally have large complex plans with gabled or salient façades, with the presence of isolated or integrated bell tower and built almost exclusively in brick.
- Then, a methodology to derive vulnerability curves from damage data collected by the A-DC survey forms were defined starting from [13] and adapting the formulation to large scale and typological evaluation needs. Specifically, a reflection on the relation between the damage index  $i_d$  and the discrete damage value  $\mu_d$  was made and the vulnerability curves for the three analyzed earthquakes were provided.
- Lastly, the impact on seismic vulnerability related to the type of masonry and the number of naves of the churches was analyzed. Three different masonry typologies were defined (i.e. stone masonry, brick masonry and mixed stone and brick masonry), with the result that stone masonry and mixed masonry churches have a similar vulnerability, significantly higher than the one of brick masonry churches. Regarding the number of naves, one nave churches result more vulnerable of more than one nave ones, probably thanks to the presence of colonnades and widespread connections.
- Possible future developments are, first of all, the analysis of the influence of more typological parameters on the seismic vulnerability of churches. Then, an important further study is the extension of the procedure to the overall database, inclusive of Emilian churches.

## ACKNOWLEDGEMENTS

### Abstract

*Seismic events across several countries in the world have highlighted that strategic buildings, such as schools, may exhibit vulnerability levels that are in some cases higher than those of ordinary buildings. It follows the urgent need of reliable risk analyses to support the decision-making for large-scale mitigation policies. To this aim, the derivation of fragility curves, able to capture typological and constructive characteristics, constitutes an essential requisite. Within this context, the paper presents a comparative study on the use of two analytical-mechanical based methods for assessing fragility curves of Italian masonry school buildings. These are very often characterized by a number of stories rarely higher than three, presence of rigid floors, significant inter-story height, and great distance between transverse walls. Among the others, analytical approaches, either based on numerical or mechanical models, are more suitable to capture the effects of such features on the seismic vulnerability. The two methods discussed in the paper are “Vulnus Vb 4.0-2009”, developed at the University of Padova and based on the integrated use of mechanical and macroseismic approaches, and “DBV-Masonry (Displacement Based Vulnerability)”, a pure mechanical-based model developed at the University of Genoa. Both methods are applied to a stock of 14 masonry schools, selected as prototypes of Italian school masonry buildings. The critical review and comparative application of the two methods allow highlighting their similarities and differences in assessing the fragility associated to in-plane and out-of-plane failure mechanisms. Moreover, as some of the selected schools had been hit by the 2016-17 Central Italy earthquake sequence, the evidence of the real response allows assessing the actual reliability of the methods.*

## 1 INTRODUCTION

Schools constitute a key stone for the social and cultural life of people, beside to represent an essential place for supporting the growing of new generations. Despite the role they play, reconnaissance surveys of damage after many seismic events (*e.g.* as documented in Italy [1], [2]) have highlighted how strategic buildings or high-exposure buildings, such as schools, can present high levels of vulnerability and inadequate performance, in some cases comparable to those of ordinary ones. This has been confirmed also by vulnerability studies carried out in various countries across the world (*e.g.*, for Nepal [3], and for Iran [4]). The attention to the topic is also testified by various recent studies addressed to reduce risk and enhance resilience of schools (*e.g.*, [5],[6]), as well as some worldwide programs aimed to promote “safer schools” (*e.g.*, [7],[8]).

As known, derivation of fragility curves, able to capture the typological and constructive characteristics of the examined building stock, is a key point for reliable risk analyses, in order to support decision-making for large-scale mitigation policies. To date, few studies available in the literature have focused on fragility of unreinforced masonry (URM) schools. Fragility curves based on empirical approaches constitute a valuable resource, being based on the direct observation of damage (*e.g.*, derived for Peruvian [9] and Nepalese [10] schools). However, being usually based on a limited stock, their derivation faces the critical issues of less robust data, from a statistical point of view, than ordinary buildings. As a consequence, analytical approaches, either based on numerical or mechanical models [*e.g.*, [6], [11], [12], [13], [14]], are more suitable to capture the effects of specific features that affect the seismic vulnerability of such buildings.

Focusing on URM schools in Italy, the inventory of the Italian Ministry of Education, dated to 2005, indicates about 50,000 schools on the Italian territory, of which about 21% are masonry buildings. With respect the total URM stock, the distribution across the age is: 20% Pre1920, 18% 1921-45, 24% 1946-60, 20% 1961-75, 8% Post76; moreover, for the 10% the age is not available (indicated as NA in Figure 1). These schools are very often characterized:

- by low-rise, *i.e.*, the number of stories is rarely higher than three (see Figure 1);
- irregular plan: plans characterized by “T”, “L”, “C” shapes or with internal court. The latter is more frequently found for buildings that date back before 1920, in case their use changed along time;
- significant inter-story height;
- great distance between transverse walls;
- presence of rigid floors.

Figure 1. Distributions of Italian schools present in the Italian Ministry of Education inventory dated to 2005.

Within this context and being aware of the aforementioned high relevance of risk and resilience assessments of the national school asset, the Italian Civil Protection Department (DPC) conveyed the effort of several Italian Universities to update the National Risk Assessment already released in 2018 ([15], [16]), in order to include not only residential buildings but also other strategic classes, such as schools and churches. Thus, within the 2019–2021 research agreement between the Civil Protection Department (DPC) and the Network of University Laboratories for Earthquake Engineering (ReLUIS), the work package WP4 “Seismic Risk Maps -MARS” has been specifically conceived to address this scope [17]. One of the aims of the project is the derivation of seismic fragility models, able to describe the vulnerability of classes of schools characterized by seismic homogenous behavior.

Within this framework, the paper presents a comparative study on the use of two analytical-mechanical based methods for assessing fragility curves of schools; both of them have been adopted in the MARS project.

The two methods discussed in the paper are “Vulnus Vb 4.0-2009”, a hybrid model developed at the University of Padova, based on the integrated use of mechanical and macroseismic approaches [18], and the “DBV-*Masonry* (Displacement Based Vulnerability)”, a pure mechanical-based model originally developed at the University of Genoa [19] and further developed within the MARS project. Both methods assume a lognormal cumulative distribution to define fragility curves, that is thus defined by two parameters: the median value (i.e., the intensity measure, in this case the Peak Ground Acceleration, associated to the 50% probability of attaining the damage level under examination, indicated as  $IM_{DLi}$ ); and the log-normal standard deviation ( $\beta_{DLi}$ ). The fragility curves are associated to five damage levels ( $DL_i$ ,  $i = 1 \dots 5$ ), aimed to be consistent with those proposed in the EMS98 scale [20].

In this study, both methods were applied to a stock of 14 masonry schools, selected as prototypes of Italian school masonry buildings and described in §2. The assumptions on which the two methods are based are briefly recalled in §3, while the main aim of this contribution, which is the critical review and comparative application of the two methods, is presented in §4 by adopting – when possible – analogous hypotheses to estimate the seismic fragility of the schools under examination. Moreover, as some of the selected schools had been hit by the 2016-17 Central Italy earthquake sequence, the evidence of the real response allows some considerations on the reliability of the methods to be provided (§5).

## 2 DESCRIPTION OF THE ANALYZED PROTOTYPE SCHOOLS

The stock analyzed in the following is composed of 14 school buildings selected from three regional databases provided by the University of Naples and Genoa (database A) [21], the University of Padua (database B) [22] and the University of Trieste (C) [23]. Database A [21] includes school buildings from various areas of Central Italy; it groups data collected during support activity made by the ReLUIS consortium and DPC [24], requested by the Reconstruction Commissioner, nominated after the 2016/2017 Central Italy earthquake. Instead, database B and C refer to the data collected in the municipal area of Padua (B) and in the regional area of Friuli-Venezia Giulia (C). Database A, B and C contain 54, 25 and 92 masonry schools, respectively.

The 14 school buildings extracted from these databases were identified to be representative of Italian masonry schools. They were used within the MARS project – Task 4.7 [17] to derive fragility curves representative of sub-types with homogeneous seismic behavior, adopting them as “prototype buildings”.

The taxonomy for identifying these sub-types is based on the data available in the inventory set by the Italian Ministry of Education dated to 2005, namely: structural material (e.g.,

reinforced concrete, masonry, steel) and seismic resistant system (e.g., frame, shear walls); number of stories (i.e., 1,2,3, >4); plan area (i.e., <500 m<sup>2</sup>, 500-1000 m<sup>2</sup>, 1000-2000 m<sup>2</sup>, 2000-5000 m<sup>2</sup>, and >5000m<sup>2</sup>); diaphragm type (e.g., concrete slab with clay units, wooden floor); and roof type (i.e., flat, inclined, or mixed). Starting from this inventory, specific sub-types were defined to cover most of the Italian school building asset. In fact, as shown in Figure 1, the Italian URM school stock is mostly represented by low structures (mainly 2-story), with limited floor area (in most cases < 1000 m<sup>2</sup>), and mainly built before 1975.

These criteria addressed the choice of the 14 prototype schools. Table 1 gives an overview of the analyzed set in terms of construction age, plan shape, plan gross area, and inter-story height; nine schools date back to 1945, while the 65% of the stock is characterized by two floors, to better represent the national asset. Each school is identified by an alphanumeric ID, while the database from which the school was extracted is indicated in brackets.

While other literature works are dedicated to derive fragility curves representative the overall URM school taxonomy [25], as already specified in §1, this paper focuses on their derivation by explicitly referring to the original features of each prototype school (referred as the “as it is state” in the following): this is to facilitate a more accurate comparison between the two methods adopted in the paper and briefly recalled in §3.

ID School	Age	N. floors	Inter-story height [m]	Plan configuration	Plan gross area [m <sup>2</sup> ]
S1 (A)	Before 1919	3	NA	Elongated rectangular	< 500
S2 (B)	Before 1919	2	5.8 – 5.4	U-shape	> 2000
S3 (A)	Before 1919	2	NA	Cloister	1000-2000
S4 (A)	Before 1919	3	NA	C-shape	1000-2000
S5 (A)	1921-1945	2	4.4	Elongated rectangular	500-1000
S6 (A)	1921-1945	2	4.5 – 3.5	Rectangular	< 500
S7 (C)	1921-1945	2	4.6	Rectangular	< 500
S8 (C)	1921-1945	2/3	4.1 – 4.1 – 7.3/6.5	C-shape	1000-2000
S9 (A)	1921-1945	2	4.3 – 4.5	T-shape	500-1000
S10 (B)	1946-1960	2	3.15	L-shape	1000-2000
S11 (A)	1946-1960	2	3.0 – 2.9	Rectangular	< 500
S12 (C)	1946-1960	2	3.8	Rectangular	< 500
S13 (A)	1961-1975	1	3.5	Squared	< 500
S14 (A)	After 1976	1	3.0	Squared	< 500

Table 1. General data of examined prototype school buildings (NA stands for Not Available).

Figure 2 shows, for some prototype schools, a view of the plan, together with photos aimed to provide a general overview of the building. The variety of plans confirms what already introduced in §1 about the recurrence of irregular shapes.

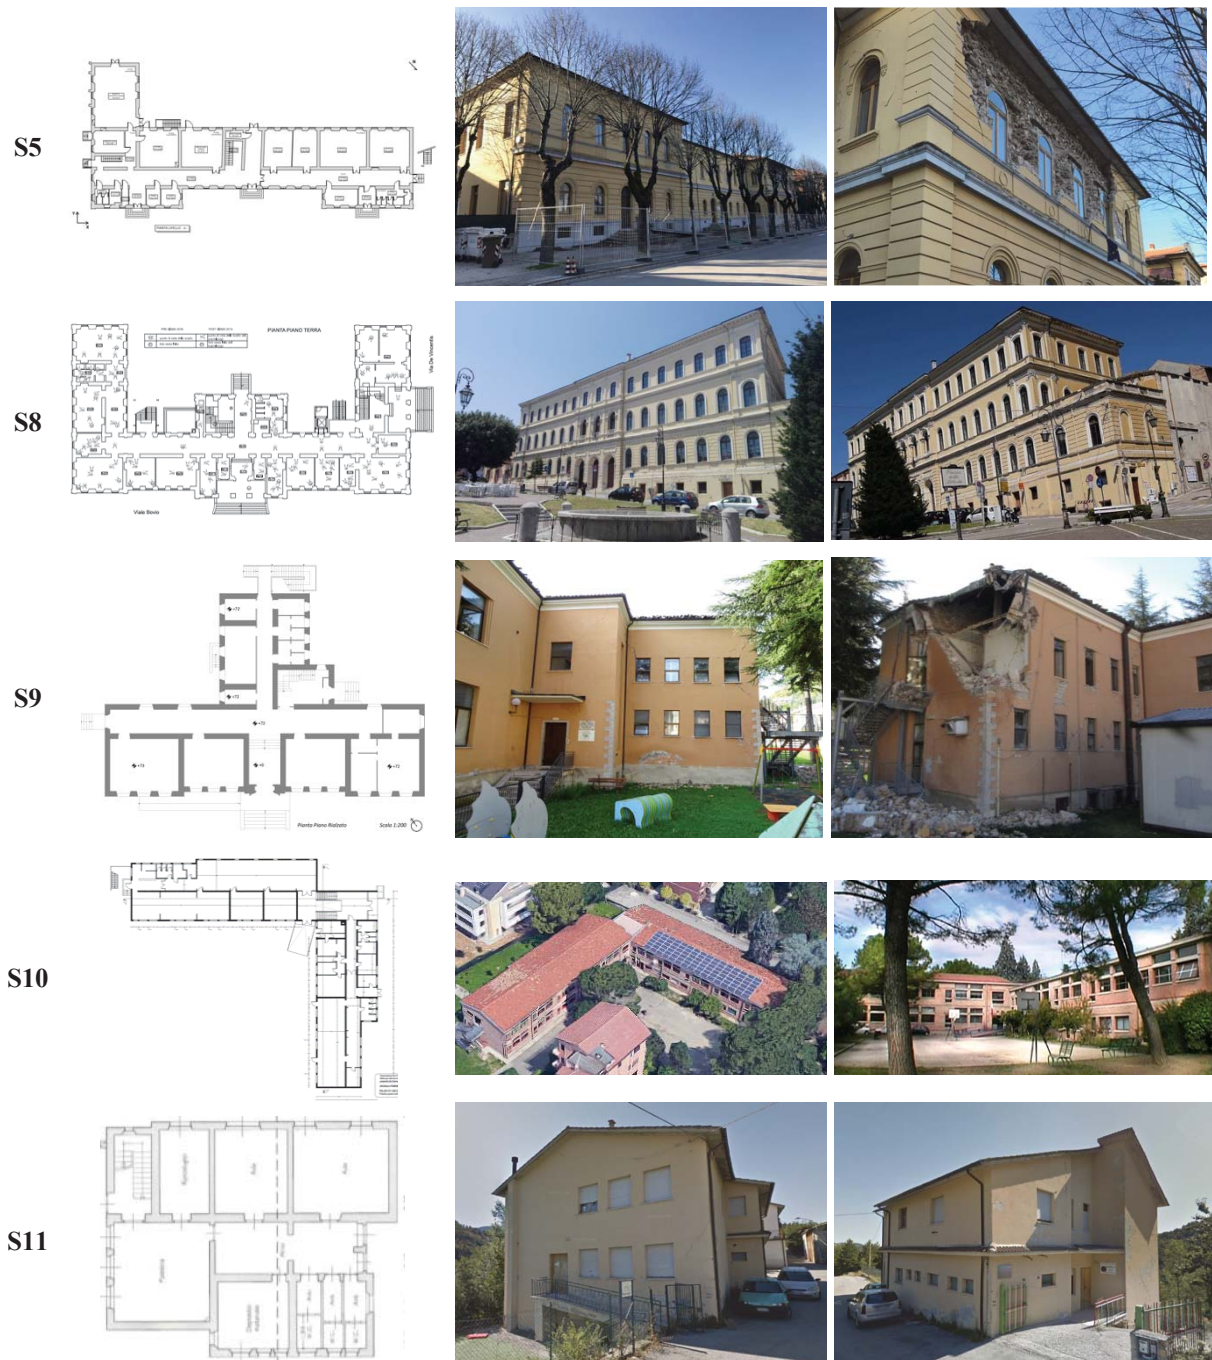

Figure 2. Plan shape and photos of some analyzed prototype schools.

For each prototype school, the basic data required for their typological and constructive characterization, as well as for the application of the two examined methods were collected, such as: the masonry type; the type of intermediate floors and roof; the resistant area for each story (in both directions); and the systemic presence of structural details, such as the presence of reinforced concrete (r.c.) ring beams or steel tie rods. Masonry type resulted quite heterogeneous. Conversely, intermediate floors was mainly ascribable to concrete slab with hollow clay blocks.

ID School	Resistant area [%]		Masonry type	Floor diaphragms	Roof	Structural Details
	X	Y				
S1	2.9	9.7	Solid bricks and lime mortar	Wooden floor	Wooden roof	Neither ring beams nor tie-rods systematic
S2	5.7 5.1	4.3 4.1	Solid bricks and lime mortar	r.c. slab	Wooden roof	r.c. ring beams
S3	9.7	8.0	Rubble stone	Vaults / Vaults with steel beams / r.c. slab with hollow clay blocks	Wooden roof	Partial presence of tie rods
S4	8.9 8.8 8.3	6.6 5.5 5.5	Solid bricks and lime mortar	Vaults	Wooden roof	Neither ring beams nor tie-rods systematic
S5	12.0 7.4	11.0 5.9	Rubble stone	Vaults with steel beams / r.c. slab with hollow clay blocks	Concrete slab with hollow clay blocks	r.c. ring beams along the perimeter of the roof
S6	6.9 7.6	4.2 4.3	Solid bricks and lime mortar	Concrete slab with hollow clay blocks	Concrete slab with hollow clay blocks	Neither ring beams nor tie-rods systematic
S7	5.9 5.9	4.8 4.6	Rubble stone with courses made by solid bricks	Concrete slab with hollow clay blocks / wooden floor / r.c. slab	Concrete slab with hollow clay blocks	r.c. ring beams
S8	5.4 5.0 6.8	6.9 5.6 8.7	Stone ashlar well-arranged	Concrete slab with hollow clay blocks / wooden floor	Wooden roof	r.c. ring beams on the first floor
S9	10.2 9.1	7.7 6.6	Stone ashlar well-arranged	Concrete slab with hollow clay blocks	Concrete slab with hollow clay blocks	r.c. ring beams along the perimeter of the roof
S10	2.7	1.9	Solid bricks and lime mortar	Concrete slab with hollow clay blocks	Concrete slab with hollow clay blocks	r.c. ring beams
S11	9.4 9.8	8.8 9.4	Simple stone with courses made by solid bricks	Concrete slab with hollow clay blocks	Concrete slab with hollow clay blocks	r.c. ring beams
S12	7.0	4.1	Solid bricks and lime mortar	Concrete slab with hollow clay blocks	Concrete slab with hollow clay blocks	r.c. ring beams
S13	3.7	3.7	Hollow blocks with cement mortar	Concrete slab with hollow clay blocks	Concrete slab with hollow clay blocks	r.c. ring beams
S14	Na	Na	Regular masonry	Rigid floor	Rigid floor	Neither ring beams nor tie-rods systematic

Table 2. Typological and constructive features of analyzed prototype schools.

## 2.1 Mechanical parameters adopted for prototype schools

For the application of the methods referred to in §3, the range of variation of the mechanical parameters of the masonry must be defined, in particular: the shear strength ( $\tau_0$ ), the masonry compressive strength ( $f_c$ ), and the tangential modulus of elasticity ( $G$ ). Since for most cases, direct mechanical characterization data were not available, reference values (plausible for the masonry types under examination) were assumed according to literature data ([26], [27], [28],

[29], [30], [31]). More specifically, the intervals recommended in the Italian Technical Code [32] were taken as reference. In particular, this Code provides firstly a basic range of values representative for a masonry that doesn't strictly follow the rules of thumbs (Table C8.5.I in [32]). Then corrective coefficients, which in most cases lead to an increase to the basic values, are proposed too (Table C8.5.II in [32]) with the aim of accounting for specific features which may influence the response of the masonry ([27], [33]), such as good quality mortar; good transversal connection between leaves; the presence of courses aimed to improve the horizontality of layers. The list of such corrective coefficients is summarized in Table 3 for sake of completeness.

Correction coefficient for the state of the art	Masonry Types							
	A	B	C	D	E	F	G	H
<b>Good quality mortar</b>	1.5	1.4	1.3	1.5	1.6	1.2	( <sup>b</sup> )	1.2
<b>Courses or borders <sup>a</sup></b>	1.3	1.2	1.1	1.2	-	-	-	-
<b>Transverse connections <sup>a</sup></b>	1.5	1.5	1.3	1.3	1.2	1.2	1.3 ( <sup>b</sup> )	-

<sup>a</sup> Correction coefficient relate solely to strength parameters

<sup>b</sup> "Good mortar" corresponds to a mortar with an average compressive strength ( $f_{mj}$ ) greater than 2 MPa. In this case the corrective coefficient can be set equal to  $f_{mj}^{0.35}$  ( $f_{mj}$  in Mpa).

Legend of masonry types: A – Random rubble stone masonry (pebbles, erratic, irregular stone); B – Uncut stone masonry with facing walls of irregular thickness; C – Ashlar masonry with good bonding; D – Irregular soft stone masonry (tuff, limestone, etc.); E – Regular soft stone masonry (tuff, limestone, etc.); F – Dressed rectangular stone masonry with no-soft stone; G – Solid bricks with lime mortar; H – Hollow blocks with cement mortar

Table 3. Correction coefficient for different types of masonry as proposed in [32].

Following this approach, for each school, the most plausible ranges of mechanical parameters were adopted. Smaller intervals of variation correspond to higher level of knowledge (see for example S9 and S5 in Figure 3). Conversely, in case of scarce data, the lack of knowledge lead to a higher residual uncertainty (i.e., a larger range of variation of the parameters). In particular, the highest range of variation was defined as follows (see for example S6 in Figure 3): the minimum value corresponds to the minimum proposed in Italian Technical Code [32]; the maximum value corresponds to the maximum proposed in the code, to which all the possible corrective coefficients were applied. The mechanical parameters of each school building used for the application of the analytical-mechanical models are reported in Table 4.

ID School	Specific feature of the masonry types of the school	fc [MPa]	$\tau_0$ [MPa] (min- max)		G [MPa] (min-max)	
		MEAN	MIN	MAX	MIN	MAX
<b>S1</b>	Low quality of mortar joints and stone texture	2.4	0.035	0.091	320	480
<b>S2</b>	NA	2.6	0.05	0.253	400	900
<b>S3</b>	NA	2.0	0.032	0.126	344	858
<b>S4</b>	Good mortar	2.6	0.075	0.253	600	900
<b>S5</b>	Low quality of mortar joints and stone texture	2.0	0.0245	0.0357	272	384
<b>S6</b>	NA	2.4	0.05	0.253	400	900
<b>S7</b>	Brick courses	2.4	0.043	0.072	346	492
<b>S8</b>	NA	2.7	0.056	0.074	500	660
<b>S9</b>	Good mortar and good transversal connection	3.4	0.0945	0.125	650	858
<b>S10</b>	NA	2.7	0.05	0.253	400	900
<b>S11</b>	Brick courses	2.9	0.062	0.106	500	858
<b>S12</b>	Good mortar	4.8	0.075	0.195	600	900
<b>S13</b>	NA	6.0	0.08	0.204	875	1680
<b>S14</b>	NA	2.6	0.05	0.253	400	900

Table 4. Mechanical parameters adopted for each school building (NA stands for Not Available).

Young's modulus was conventionally assumed to be three times the shear modulus ( $G$ ). Due to the limited influence of the masonry compressive strength in case of low-moderate axial load acting on walls (as usually the case of existing buildings), it was assumed deterministic and equal to the mean value of the range proposed in Italian Code [32] .

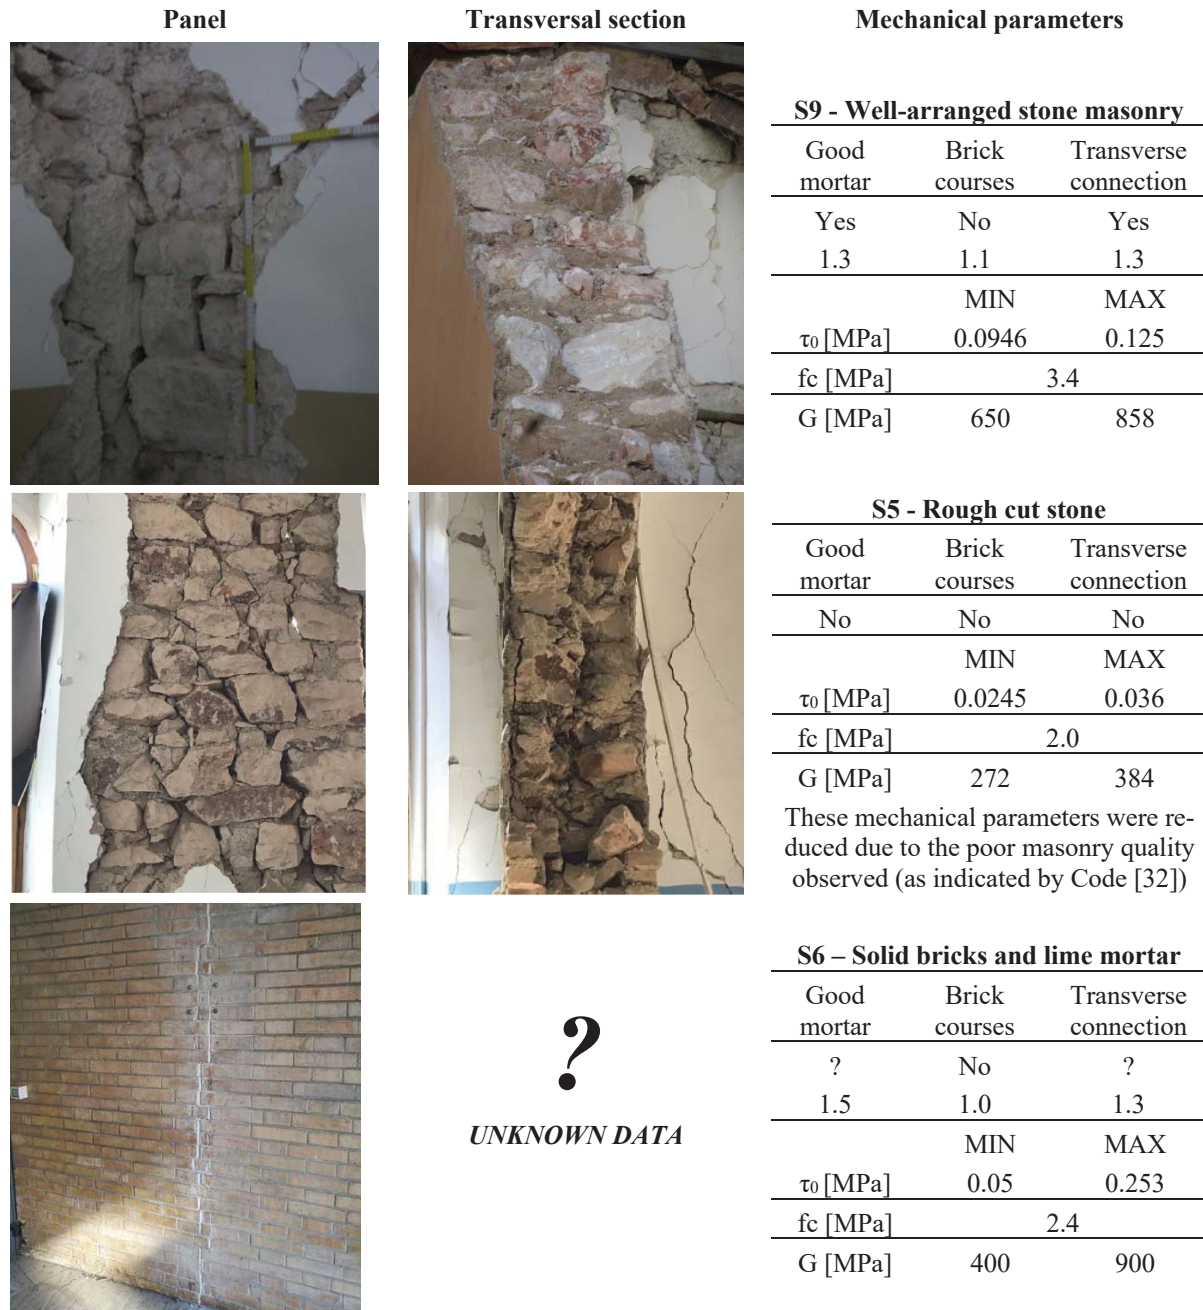

Figure 3. Frontal view and transversal section of masonry types of some prototype schools and final range of variation adopted for mechanical parameters.

### 3 BRIEF MENTION OF ANALYTICAL-MECHANICAL METHODS USED

#### 3.1 Mechanics-based modelling procedure *Vulnus*

The first simplified modelling procedure applied to the selected prototype schools was the mechanics-based approach developed at the University of Padova, which has been already

effectively applied to different territorial areas (i.e., from an urban area [34] to a national scale [18]). The approach is based on the simplified mechanical modelling procedure *Vulnus 4.0* [35] [36], which allows fragility assessment of unreinforced masonry buildings (URM) to be carried out considering both in-plane (IP) and out-of-plane (OOP) mechanisms, together with an index of the structural quality from 2<sup>nd</sup> level GNDT form [37]. The analysis of a URM building provides three indexes:

- $i_1$ , expressing the ratio between the IP shear resistance and the weight of the building for the weakest plan direction;
- $i_2$ , expressing the susceptibility to OOP mechanisms (both overturning and flexural failures), through the implementation of linear kinematic analyses;
- $i_3$ , quantifying vulnerability factors which affect the structural behavior (e.g., irregularity in elevation).

Then, the indexes are combined through fuzzy set theory, obtaining three fragility curves (derived as log-normal cumulative probability functions): one expressing the most probable distribution, called *white*, a lower- and an upper-bound. The fragility analysis of prototype schools was carried out referring to *white* curves. The resulting fragility refers to a medium-severe damage level (DL2-3), intermediate DS between 2 (given by trigger of OOP mechanisms) and 3 (given by IP global shear failure), according to the European macro-seismic scale (EMS98) [20].

Each DL2-3 curve was then extended to five fragility curves, from DL1 (slight damage) to DL5 (complete collapse), through the calibration of a fragility model proposed in [19], based on a previously presented macro-seismic model from the literature [38].

Figure 4 synthetically summarizes the basics of the procedure. For further details on the procedure, please refer to [1].

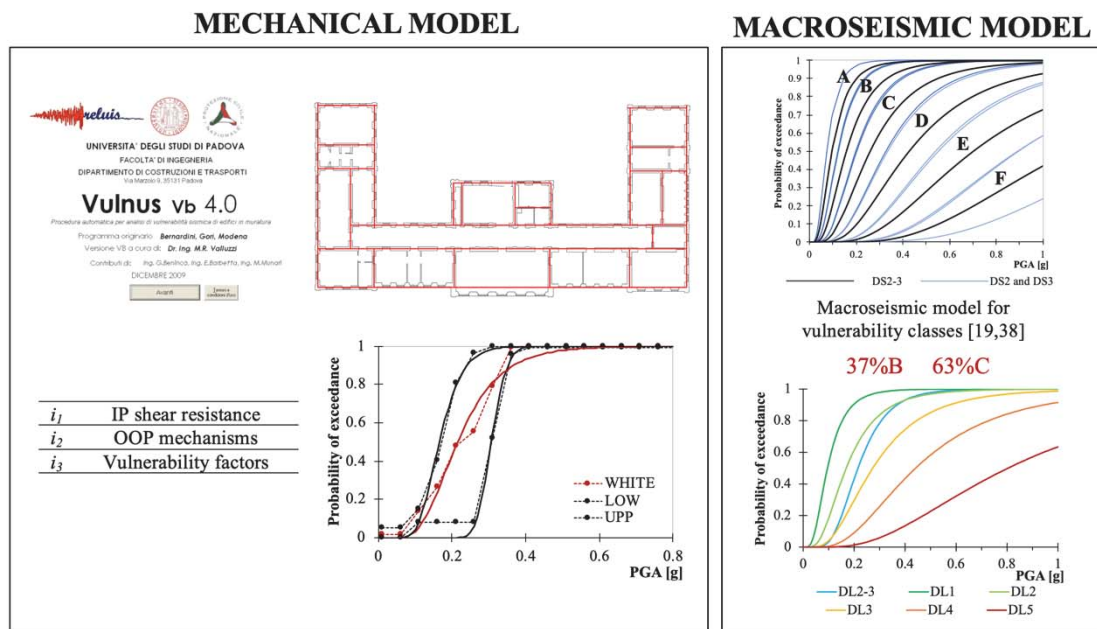

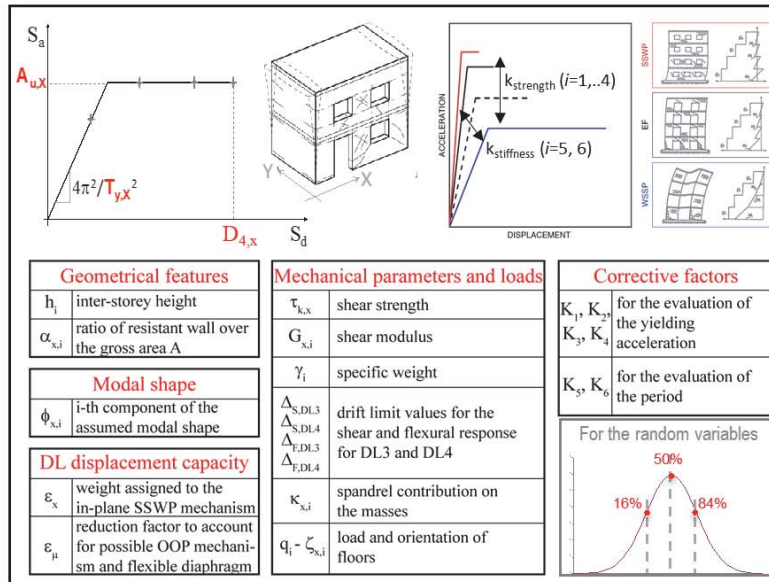

Figure 4. Basics of the *Vulnus* procedure.

### 3.2 DBV– *Masonry* model

The second simplified modelling procedure applied to the selected prototype schools was the mechanics-based approach developed at the University of Genoa [19].

The original approach was developed to derive fragility functions exclusively referring the global behavior of URM buildings associated to the in-plane walls response. The model firstly defines the capacity curve representative of the structural seismic response based on three variables (as in Figure 5): 1) the pseudo-elastic period of the structure  $T_y$ ; 2) the spectral acceleration at yielding  $A_y$  (equal to the ultimate one  $A_u$ , as no hardening is assumed); 3) the displacement capacity (associated to DL3 and DL4). The evaluation of these variables requires the definition of a limited number of mechanical and geometrical parameters, together with the assumption of a fundamental modal shape and the attribution of specific corrective factors ( $K_i$ ), aimed to account for the effects induced by the large set of constructive and morphological details that usually characterize existing buildings. The analytical formulation basically makes reference to the Strong-Spandrels Weak-Piers (SSWP) behavior, thus under the simplified assumption, for the evaluation of the overall base shear, that all masonry piers fail at the same time. Then, some of the aforementioned factors ( $K_i$ ) aims to correct this estimate in order to account for other possible behavior (like the Weak-Spandrels Strong-Piers – WSSP – or intermediate) induced by the lack of tie-rods and r.c. ring beams, or by the poor quality of spandrel elements (see [19] for further details). Once computed the capacity curve, the nonlinear static procedure based on the use of over-damped spectra [39] is adopted to compute the value of the IM that produces the attainment of DLs ( $IM_{DL}$ ). To this aim, proper rules are introduced to define the intermediate DLs on the capacity curve (i.e., DL1 and DL2) and the corresponding equivalent damping values ( $\xi_{DL}$ ) are evaluated. Finally, for the uncertainty propagation, various contributions are considered [19] and in particular the uncertainty associated to the structural capacity is computed by using the response surface method [40]. Figure 5 illustrates the basics of the method.

### CAPACITY CURVE

### FRAGILITY CURVE

Figure 5. Basics of DBV-masonry model.

Starting from the original proposal of the model [19], within the MARS project as briefly summarized in the following, the authors from the University of Genoa made further refinements of the method that mainly concern, on the one hand, the estimate of the DLs displacement capacity, and, on the other hand, the evaluation of  $IM_{DL}$ .

As for the first issue, specific coefficients ( $\varepsilon_{\mu}$ ) aimed to limit the displacement capacity to introduce, even if in a simplified way, the possible activation of out-of-plane (OOP) mechanisms. At the current state of research, these coefficients only affect the DL3 and DL4 displacement capacity; their values vary from 0.4 to 0.9 and were defined on expert judgement, benefitting from the evidence of empirical fragility curves. They are applied when structural details, such as tie rods or r.c. ring beams, are absent, with values that as a function of both the masonry quality (more punitive in case of irregular masonry) and the floor types (more punitive in case of vaults or very flexible floors). Moreover, drift thresholds for defining DL3 and DL4 were updated and differentiated according to the masonry type to be consistent with the up-to-date experimental evidence ([28], [29], [31]) and the EMS98 damage levels (see Table 5).

As for the evaluation of  $IM_{DL}$ , a corrective factor was introduced to  $IM_{DL}$  in order to account for the approximation that nonlinear static procedures imply with respect to more refined methods, as nonlinear dynamic analyses. In particular, on basis of the work done by Marino et al. [41] a corrective factor equal to 1.45 was applied. The values of  $\xi_{DL}$  were computed according to Cattari and Lagomarsino [42] varying the structural details of the schools. Moreover, the ADSR spectral shape was refined including, in the branch usually adopted at constant velocity, the dependence on an  $\alpha$  coefficient (ranging from 1.1 to 1.4) to make it more consistent with evidence from actual recordings (see also [43]).

	Drift limit values for the shear (S) and flexural (F) response panels			
	S – DL3	S – DL4	F – DL3	F – DL4
<b>Min</b>	0.0025	0.0045	0.0035	0.007
<b>Max</b>	0.006	0.011	0.009	0.018

Table 5. Range of variation of drift thresholds adopted in *DBV-masonry* model.

#### 4 COMPARISON OF RESULTS

The results obtained from the two analytical-mechanical methods are compared as follows, in terms of both intermediate calculation ratios and parameters describing the fragility curves ( $IM_{DLi}$  and  $\beta_{DLi}$ ).

As for the first type of comparison, Figure 6 compares the parameter  $i_1$  from the *Vulnus* approach, to for the value of the base shear capacity normalized to the total mass from the *DBV-Masonry* model.

Figure 6. Comparison in terms of base shear normalized to total mass.

In general, a good correspondence is observed for most of schools. The highest difference, depicted in the cases S1, S3 and S4, is due to the strong penalization in the overall base shear capacity in the *DBV-Masonry* model given by the coefficients  $K_1$ ,  $K_2$ ,  $K_3$  and  $K_4$ , accounting

for poor structural details (e.g., the absence of tie rods and r.c. ring beams) and geometric irregularities. The complete set of corrective coefficients assigned to each school and applied to the overall base shear capacity are shown in Table 6. In the *Vulnus* procedure, in case of irregular buildings, the resistance area of walls is divided by a corrective factor (equal to 1.1) to consider the effects of the uneven distribution of stresses on the shear strength.

Ki factors of DBV- Masonry model	ID School													
	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	S11	S12	S13	S14
<b>K<sub>1</sub></b>	0.9	1.2	0.8	0.9	1.1	1.2	1.1	0.9	1	1.2	1.2	1.2	1.2	0.9
<b>K<sub>2</sub></b>	0.85	0.9	0.85	0.9	0.83	0.85	0.9	0.9	0.81	0.85	0.85	0.85	0.85	0.85
<b>K<sub>3</sub></b>	0.75	0.75	0.75	0.75	0.8	0.85	0.9	0.75	0.99	0.75	0.9	0.85	0.75	0.75
<b>K<sub>4</sub></b>	0.65	1	0.55	0.65	1	1	1	0.8	0.95	1	1	1	1	0.65

Table 6. Corrective factors used by DBV-Masonry model and applied to base shear capacity.

Figure 7 shows instead the comparison in terms of  $IM_{DLi}$  values. As recalled in §3.1, in the case of *Vulnus* approach, the value reported corresponds to a medium-severe damage level (DL2-3), whereas, in the case of the *DBV-Masonry* model, both values corresponding to DL2 and DL3 are reported separately. The comparison shows that in most cases the two models provide a good correspondence (such as for schools S1, S3, S4, S5, S9, S11 and S12), while in other cases the *DBV-Masonry* model provides greater median (less vulnerable structures) with respect to the *Vulnus* approach. This difference stems from the more significant role of the out-of-plane mechanisms, which are differently treated by the compared methods.

The values of the three indexes defined by the *Vulnus* approach are reported in Table 7; for schools with lower indexes  $i_2$ , also with respect to their  $i_1$  index, (i.e., structures more susceptible to OOP mechanisms) greater differences in the resulting  $IM_{DLi}$  values are found.

Figure 7. Comparison for the prototype schools in terms of median  $IM_{DLi}$  value (i.e., PGA in [g]).

Indexes Vulnus	Schools													
	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	S11	S12	S13	S14
<b>i1 [a/g]</b>	0.15	0.31	0.33	0.34	0.11	0.26	0.20	0.23	0.35	0.20	0.35	0.37	0.90	0.50
<b>i2 [a/g]</b>	0.16	0.10	0.09	0.27	0.14	0.18	0.15	0.12	0.31	0.11	0.30	0.20	0.36	0.19
<b>i3</b>	0.67	0.03	0.69	0.24	0.58	0.41	0.31	0.68	0.18	0.32	0.27	0.16	0.40	0.58

Table 7. Indexes obtained from *Vulnus* approach.

Indeed, in the *Vulnus* approach, the vulnerability of these schools is dominated by the activation of local mechanisms. Conversely, as described in §3.2, the *DBV-Masonry* model

includes the vulnerability associated to out-of-plane mechanisms only in a conventional way, by limiting the available global ductility.

Lastly, Figure 8 compares resulting fragility curves for some schools. As expected from the results illustrated in Figure 6 and Figure 7, for schools S9 and S11 the match of fragility curves is very good, while for schools S6 and S10 fragility curves derived from *Vulnus* approach are backward (describing a more vulnerable structure). This result is again mainly due to the different ways through which the two approaches treat the OOP mechanisms.

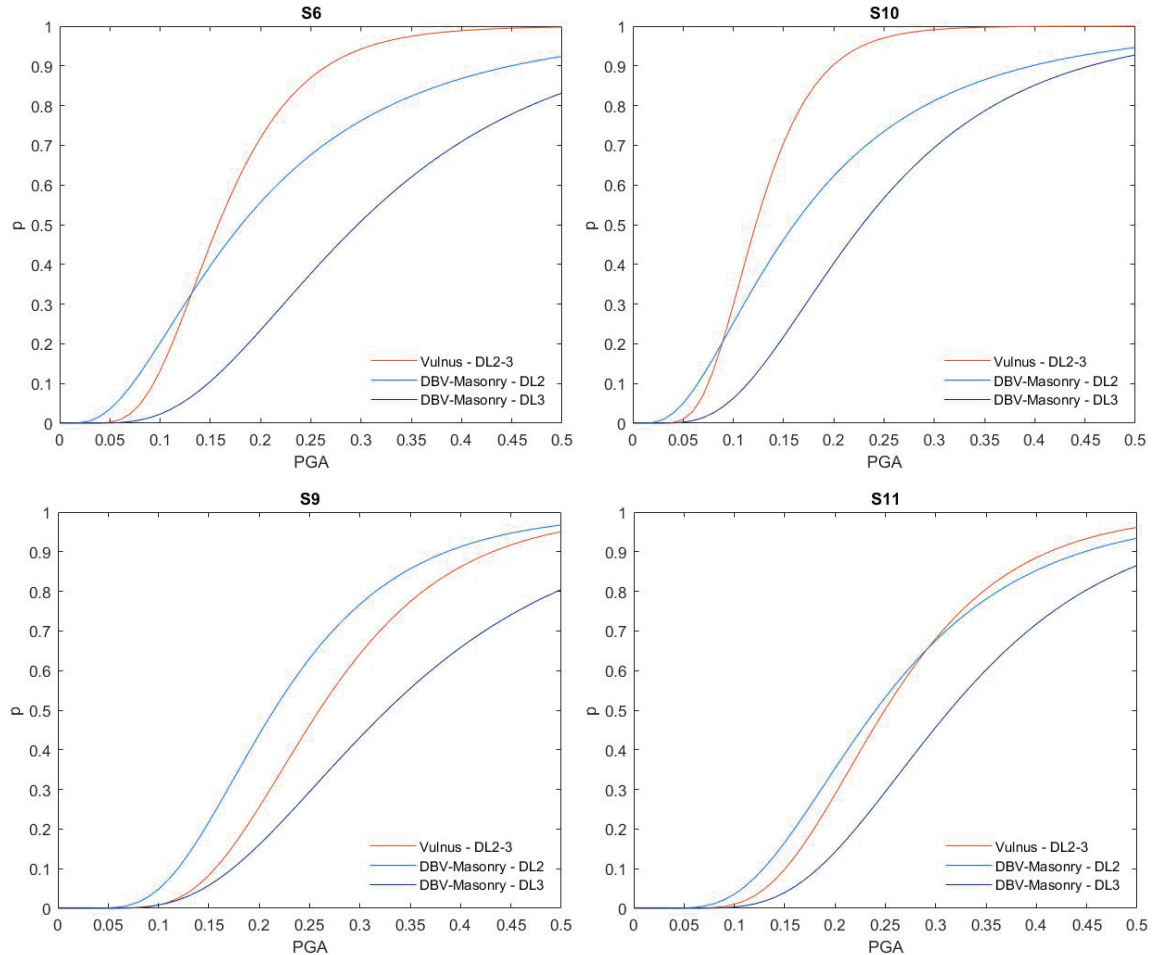

Figure 8. Comparison of fragility curves defined by DBV-Masonry (DL2 and DL3) and *Vulnus* approaches (DL2-3).

## 5 COMPARISON BETWEEN OBSERVED DAMAGE AND DPM ESTIMATED FROM FRAGILITY CURVES

As introduced in §2, some prototype schools were selected from those damaged and declared unusable after the seismic sequence that hit Central Italy in 2016/2017 [21]. Information on the actual damage of these schools was thereby available. These data are really valuable to preliminarily assess the reliability of the damage level estimated by fragility curves. Of course, a number of approximations were made to provide this comparison, since the aim of this study is far from an accurate simulation of the seismic response of these schools (e.g., made in other studies through refined 3D models and by performing nonlinear dynamic analyses [44]). Nevertheless, the comparison is useful in order to verify whether the damage predicted by fragility curves has the same order of magnitude of the observed damage; in addition, possible discrepancies might

emerge in the estimation of the consequences/losses when the fragility curves are then used for risk analyses scopes (e.g., [45]).

Figure 9. View of damaged schools S5, S9, and S11.

In order to make such a comparison, for each school an estimate is provided (Table 8) of the level of global damage observed and of the Peak Ground Acceleration that affected the structure ( $PGA_{2016/2017}$ ). The damage level was derived as part of the survey activities described in Di Ludovico et al. [24], based on a homogeneous approach which is consistent with the damage levels defined by the EMS98 scale [20]. The estimate of  $PGA_{2016/2017}$  is affected by more significant uncertainties. Only in one case (S9), the school, now demolished, was permanently monitored by the Italian Seismic Observatory of the Department of Civil Protection [46]. Thus, recorded data of the events that hit the school are available; in particular, the  $PGA_{2016/2017}$  associated to the most intense recorded seismic event (October 26<sup>th</sup>, 2016) is equal to 0.47g.

Conversely, in other cases, the maximum  $PGA_{2016/2017}$  value was derived from shake maps provided by INGV (Istituto Nazionale di Geofisica e Vulcanologia, INGV, <http://shake-map.rm.ingv.it/shake/index.html>). Attenuation laws and possible phenomena of amplification due to topography and stratigraphy, were considered, as well as third level seismic micro-zonation studies (MZ3), where available.

Specifically, for school S11, the PGA of the most significant event (August 24<sup>th</sup>, 2016) was defined equal to 0.30g, according to the shake maps provided by INGV. It was then multiplied by a coefficient equal to 1.2, in order to consider topographic amplification, consistently with Italian Code [47].

Concerning school S5, the PGA of the most severe event (October 26<sup>th</sup>, 2016) was derived from shake maps, equal to 0.15g. This school was subjected to strong phenomena of site effects, as confirmed by. Thus, a  $PGA_{2016/2017}$  equal to 0.23g was estimated. Further detailed numerical studies confirmed that the combination of structural vulnerability and amplification phenomena played a fundamental role in the response of this school [48].

ID School	Observed DL	Stratigraphic amplification	Topographic amplification	Estimated $PGA_{2016/2017}$ for computing the DPM from fragility curves [g]		
				Event	PGA from shake maps	Adopted PGA
S5	4	FA=1.45-1.63   Soil B	Plain	26/10/2016	0.15	0.23
S9	4	FA=1.37   Soil B	Slight slope	26/10/2016	0.47 (recorded)	0.47 (recorded)
S11	3	Soil B	Ridge	24/08/2016	0.30	0.36

Table 8. Estimated damage level and PGA for damaged prototype schools

The estimated  $PGA_{2016/2017}$  values were used to enter the fragility curves developed in §4 and then calculate the relative Damage Probability Matrix (DPM), and then the average damage level ( $\mu_d$ ) through the following expression:

$$\mu_D = \sum_{k=0}^5 p_k \cdot k \quad (1)$$

where  $p_k$  is the probability of reaching each damage grade  $k$  (from 1 to 5). As introduced in §3.2, the analytic-mechanical *DBV-Masonry* model allows fragility curves to be directly derived only for the first four damage levels. For the sake of comparisons, DL5 fragility curve was defined adopting a distance from DL4 curve consistent with the macroseismic model proposed by Lagomarsino and Giovinazzi [38] and adopted as reference also in the *Vulnus* model.

Figure 10 illustrates, for each school examined in this section, the fragility curves and the relative DPM; the vertical line in the graphs corresponds to the value of the  $PGA_{2016/2017}$  reported in Table 8.

In order to compare the average damage level ( $\mu_d$ ) with the observed damage, the continuous variable  $\mu_d$  shall be converted in a discrete number. To this aim, the binomial distribution was adopted [38], assuming that the upper bounds of each interval correspond to a probability of 0.5 in the associated cumulative distribution function. That leads to the conversion rule summarized in Table 9. The final values of the comparison are summarized in Table 10.

DLi	Conversion rule
1	$0.7 < \mu_d \leq 1.6$
2	$1.6 < \mu_d \leq 2.5$
3	$2.5 < \mu_d \leq 3.4$
4	$3.4 < \mu_d \leq 4.3$
5	$4.3 < \mu_d \leq 5$

Table 9. Criterion to convert the mean damage level into DLi discrete values.

Schools	Level of observed damage from real damage	Average damage level derived from fragility curves			
		Vulnus		DBV-Masonry	
		$\mu_D$	DL	$\mu_D$	DL
S5	4	3.67	4	3.21	3
S9	4	3.30	3	3.13	3
S11	3	2.87	3	2.78	3

Table 10. Comparison between observed and estimated damage levels from derived fragility curves.

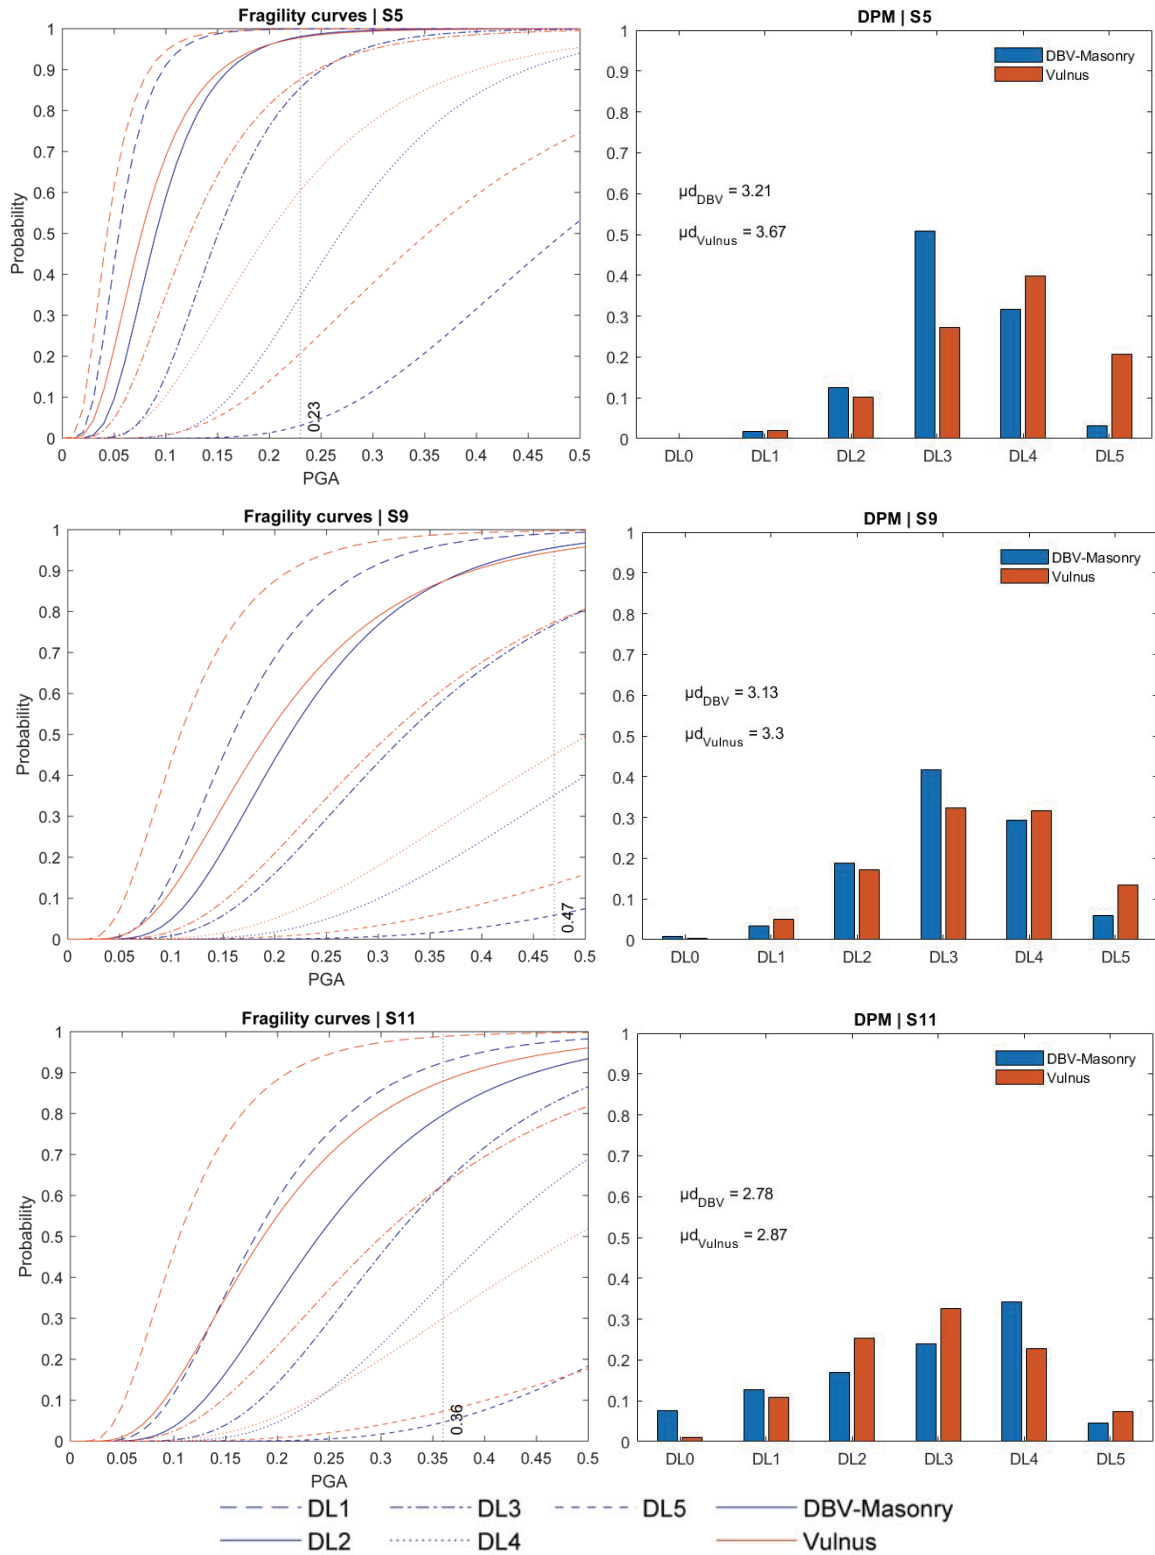

Figure 10. Comparison of fragility curves and DPM of damage prototype school buildings.

The comparison of results is satisfactory, in line with the general good correspondence discussed in §4.

In the case of school S5, the *DBV-Masonry* model slightly underestimates the damage level. In that case, the actual damage testified a clear dominance of the in-plane response of walls

(with very severe diagonal cracks in most piers of the first level, as shown in Figure 9) but also the activation of the out-of-plane response of part of the main façade. Thus, the aforementioned slight underestimation could be associated to the conventional way through which the *DBV-Masonry* model includes OOP mechanisms.

Concerning school S9, the results of both analytical-mechanical approaches slightly underestimate the actual damage level (i.e., the value of  $\mu_D$  is close to the lower threshold value for DL4); however, it is worth highlighting that the school suffered from damage accumulation phenomena [44], neglected by the derived fragility curves. In fact, although the  $PGA_{2016/2017}$  was associated to the most severe event, indeed some moderate damage already occurred due to the first shock (August 24<sup>th</sup>, 2016).

## 6 CONCLUSIONS

This paper has reported the comparison of results obtained from the application of two mechanical-analytical vulnerability models to a sample of 14 prototype schools, representative of the Italian school asset. In particular, the hybrid model based on the integrated use of mechanical and heuristic approach *Vulnus Vb 4.0-2009*, developed by the University of Padova, and the mechanical model *DBV-Masonry* developed by the University of Genoa were used. These vulnerability models aim at providing seismic vulnerability assessments of masonry buildings at territorial scale, to support seismic risk evaluations.

In this contribution, these approaches were applied to the selected prototype schools in their "as it is" configuration, to facilitate the comparison and without introducing the assumptions made necessary by the propagation of prototype buildings for the scopes of large scale assessment (as those addressed in MARS project illustrated in [17]).

The examined methods were compared in terms of derived fragility curves, as well as by analyzing intermediate parameters, such as the value of the base shear normalized to the total mass.

Results highlighted a good match between the two methods. The most relevant differences were found for buildings of which seismic vulnerability is potentially dominated by the trigger of local mechanisms; in these cases, the *DBV-Masonry* model, which takes into account the activation of out-of-plane mechanisms only conventionally, estimated a lower damage of the structure.

Lastly, the comparison between DPM estimated from fragility curves and observed damage has been provided for three schools of the sample, hit by the Central Italy earthquake. Results are promising and show a good capability of methods in forecasting the expected damage.

## ACKNOWLEDGEMENTS

The results presented in the paper were achieved in the national research project ReLUIS-DPC 2019 -2021 ([www.reluis.it](http://www.reluis.it)), supported by the Italian Civil Protection Department and, in particular, in the Work Package 4 (WP4 – “Seismic Risk Maps -MARS”, Coord. Proff. S. Lagomarsino and A.Masi). Moreover, the Authors thank the members of research units of UniNA (University of Naples Federico II - Coord. Prof. M.Di Ludovico) and UniTS (University of Trieste, Coord. Prof. N.Gattesco) for the data provided regarding prototype schools examined in the paper.

### Abstract

*Assessing the seismic vulnerability of existing buildings is a fundamental step in order to define mitigation programs in prone earthquake areas. In Italy, in 2019 the National Department of Civil Protection supported an ongoing research project involving its “Center of Competence” on seismic risk, ReLUIIS (Network of University Laboratories for Earthquake Engineering), with the cooperation of Eucentre (European Centre for Training and Research in Earthquake Engineering) to update the 2018 version of the National Risk Assessment. In this context, new fragility curves are being derived by using different approaches, whose results will be properly combined. In the paper, the purposely set up methodology for deriving analytical fragility curves through Non-Linear Dynamic Analyses (NLDAs) has been described. Further, results relevant to some Italian Reinforced Concrete (RC) building types have been shortly presented and analyzed, emphasizing the role of some key parameters affecting seismic vulnerability such as design level and infill arrangement.*

**Keywords:** RC existing buildings, seismic vulnerability assessment, non-linear dynamic analyses, fragility curves

---

## 1 INTRODUCTION

Past earthquakes have clearly pointed out the high level of seismic risk in Italy. According to the 2018 National Risk Assessment (NRA) [1, 2] released by the Department of Civil Protection (DPC), seismic risk mainly depends on the high vulnerability of the existing building stock, which was mostly built before the seismic classification of large part of the Italian territory and, consequently, without seismic rules. Seismic risk analyses in the 2018 NRA were carried out through the “Italian Risk Maps” (IRMA) platform [3], by combining the results obtained by different research units (RUs) belonging to two “Centers of Competence” of DPC, such as ReLUIIS (Network of University Laboratories for Earthquake Engineering) and Eucentre (European Centre for Training and Research in Earthquake Engineering). These results are mostly based on the empirical information reported in the Da.D.O. (Database of Observed Damage) database [4] collecting damage data relevant to the most damaging Italian earthquakes occurred in the last fifty years. Within the ongoing 2019-2021 DPC-ReLUIIS research project, the Work Package WP4 “Seismic Risk Maps - MARS” aims at preparing an updated version of the 2018 NRA by considering additional vulnerability models [5]. Specifically, in order to overcome the limited amount of observational damage data, in particular for Reinforced Concrete (RC) buildings, new sets of fragility curves (FCs) are being derived by using different approaches whose results will be properly combined [5]. In the present paper, the methodology for deriving analytical FCs especially for RC buildings through Non-Linear Dynamic Analyses (NLDAs) has been briefly described. Subsequently, the results for some RC building types have been analyzed in order to highlight the role of some key parameters affecting seismic vulnerability such as design level (i.e., gravity load design and earthquake resistant design) and infill arrangement (i.e., infills regularly arranged along the height and pilotis configuration).

## 2 METHODOLOGY

In the MARS research activity, a cloud-like approach has been adopted for deriving analytical Fragility Curves (FCs) through Non-Linear Dynamic Analyses (NLDAs). The methodology is based on ten main steps, as follows:

1. Identification of building classes
2. Selection of building types
3. Simulated design of building types
4. Modelling
5. Selection of Intensity Measure
6. Selection of representative ground-motion records
7. Non-linear dynamic analyses
8. Definition of relationship “structural response - damage level”
9. Treatment of fragility curves dispersion
10. Generation of analytical fragility curves

In order to identify building classes and typologies (steps 1-2), the knowledge of the attributes mainly affecting seismic vulnerability and its distribution over a building stock are crucial aspects in large-scale vulnerability studies [6, 7]. In this context, several sources of information are available in Italy (e.g., ISTAT census data [8], post-earthquake inspections [9], interview-based surveys [10]), each one characterized by different quality and accuracy of data. According to the 2011 ISTAT census of population and houses [8], the Italian building stock amounts to about 12 million buildings, most of them are masonry structures (more than 7 million) while about 4 million are RC ones. Due to the large number of masonry structures, almost half of the

Italian buildings have 2 storeys (i.e., low-rise type) while, for taller buildings, RC resisting frame structures were generally adopted. In terms of construction period, masonry buildings were mostly built up to the end of the 1970s while RC buildings became the structural type mainly adopted in Italy after the 1970s. Due to the low percentage of the Italian territory classified as seismic until 1980 (about 25%), most of the existing residential buildings were designed only for gravity loads. In case of seismic design, moderate lateral forces (i.e., equal to either 7% or 10% of the “seismic weight”) without anti-seismic criteria were used. Generally, both materials’ quality and design practice have growth over time. Similarly, as a result of the increasing attention to thermal and sound insulation requirements, different types of infills can be found, as reported in [11].

Summarizing the previous remarks, analytical FCs for Italian RC buildings have been derived by considering the following parameters (Figure 1):

- **period of construction**, three periods: ‘50s, ‘70s and ‘90s (consistent with the ranges 1946-70, 1971-90 and >1991 defined by ISTAT 2011);
- **design level**, two types: GLD buildings (i.e., designed only for gravity loads) and ERD buildings (i.e., earthquake resistant design);
- **number of storeys**, three types: Low-rise (i.e., 1-2 storeys, Figure 2a,d), Mid-rise (i.e., 3-5 storeys, Figure 2b,e) and High-rise ( $\geq 6$  storeys, Figure 2c,e);
- **infill arrangement**, three types: Regularly Infilled-frame (IF); Pilotis-frame (PF) and Bare frame (BF).

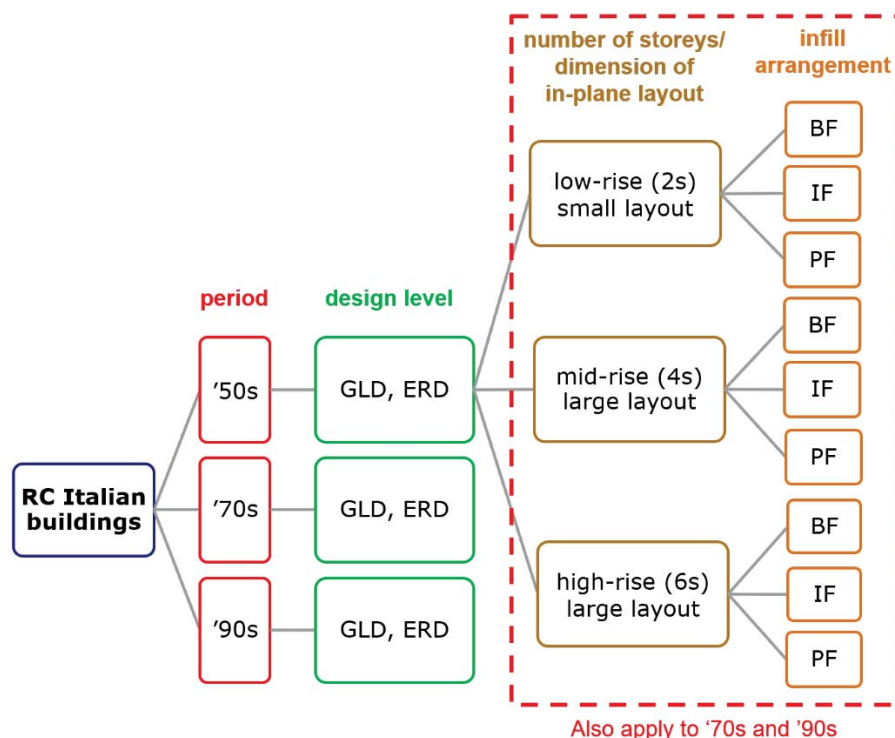

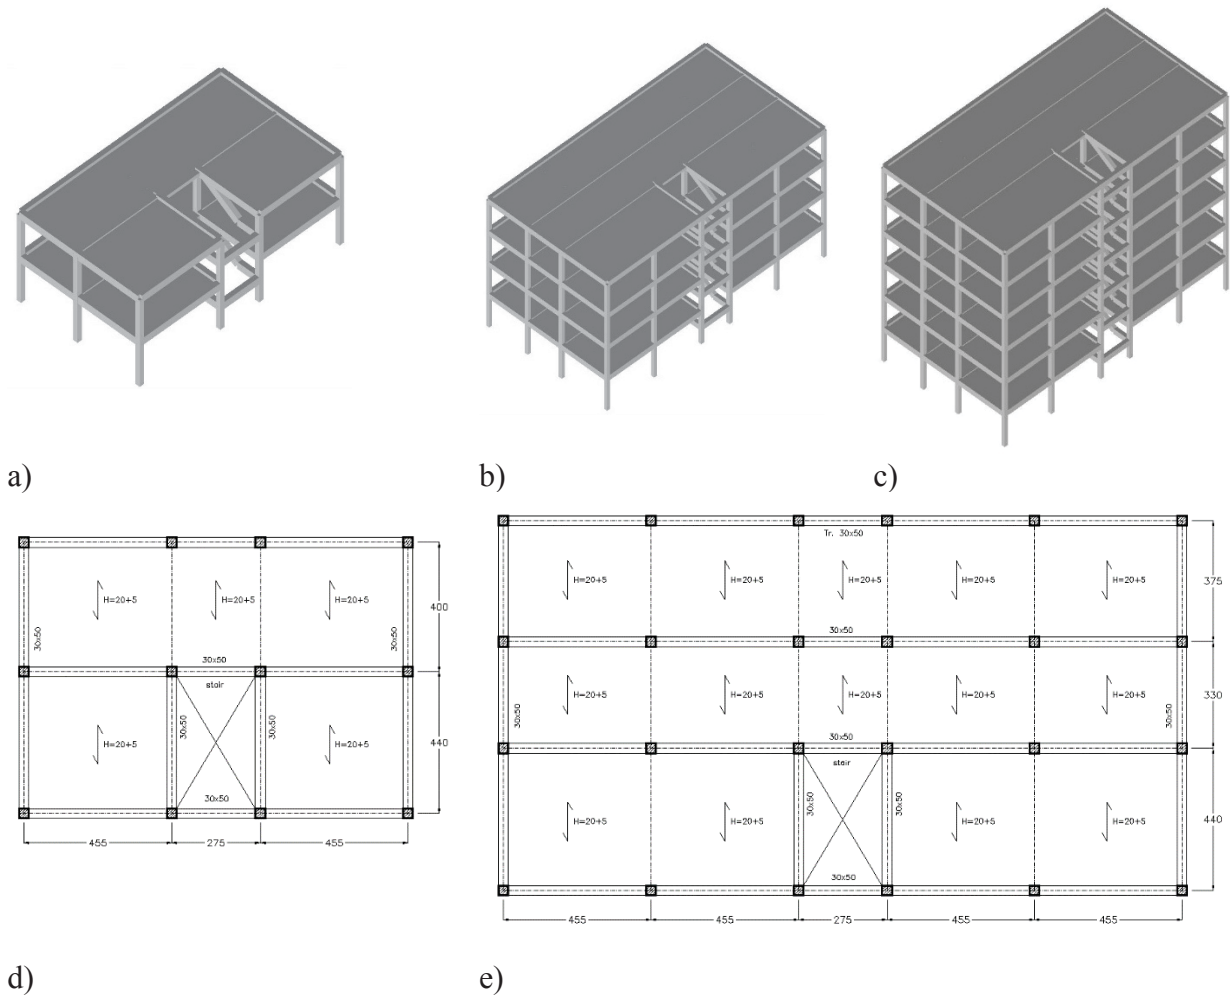

Figure 1: RC building types (from Masi et al. [5])

According to the above reported parameters, some building prototypes have been selected and detailed by means of the simulated design [12] carried out by taking into account the code in force, the quality of the typical materials and the design practice of the period. The selected structural layout is regular in-plan with different dimensions for low rise (Figure 2a,d) and mid/high rise (Figure 2b,c,e) types. For the ‘50s and ‘70s building types (both GLD and ERD

types), lateral load resisting frames (i.e., having rigid beams) are present only along the X direction and on the exterior frames. On the contrary, the '90s types show two frames (with flexible internal beams) along the two orthogonal in-plan directions. For all the considered building types, infills are double layers with empty cavity having different effective thickness (from 20 to 28 cm, ranging from '50s to '90s types) values and consistency (i.e., solid and hollow clay bricks).

Structural analyses have been performed by using the finite element code OpenSees [13]. A macro-modelling based on lumped plasticity has been adopted according to Ricci et al. [14]. Specifically, at both ends of each structural member, a bending moment–rotation ( $M-\theta$ ) relationship has been defined by adopting the Ibarra, Medina and Krawinkler model [15]. When a brittle failure is predicted (e.g., this typically occurs in the short columns of the staircase structure), the above-mentioned  $M-\theta$  relationship has been appropriately modified considering a bending moment value calculated as a function of the ultimate shear capacity according to the Sezen model [16]. On the basis of the mechanical properties of the constituent materials typically found in real buildings of the period under consideration [17, 18], mean strength values have been assumed in evaluating the structural capacity. Infill panels have been modelled by using an equivalent diagonal whose mechanical properties has been assumed according to [11, 19].

**Figure 2:** 3D view of 2 storey (a), 4 storey (b) and 6 storey (c), and in-plane layout of 2 storey (d), 4 storey and 6 storey (f) types (from Masi et al. [5])

A special attention has been paid to the selection of representative ground motion records for Non-Linear Dynamic Analyses (NLDAs). Specifically, a large set of real signals consistent with the Italian seismic hazard for soil condition consistent with A/B categories according to DM 17/01/2018 [20] has been selected and considered in terms of Peak Ground Acceleration (PGA). Although more effective Intensity Measures (IMs) could have been chosen (e.g., [21]), PGA represents the best compromise between a good correlation with the non-linear seismic response and practical constraints (i.e., data available from the Italian hazard map and standards of the IRMA platform). The considered signals with increasing intensity levels allow to reach all the EMS-98 damage levels [22] with an adequate number of data. Note that, for higher intensity levels (i.e., PGA values higher than 0.5-0.6g), a spectral matching procedure of real recorded motions has been adopted [23].

According to the lognormal cumulative distribution functions employed to define FCs, the standard deviation of the natural logarithm of the considered IM has been used to describe the total variability associated with a given damage level. In this framework, the overall uncertainty ( $\beta_{TOT}$ ) has been computed by considering three main sources of uncertainty, i.e., seismic demand ( $\beta_D$ ), inter/intra building capacity ( $\beta_C$ ) and damage thresholds' definition ( $\beta_{DS}$ ), and combined through a square root sum-of-the-squares (SRSS) rule, as follows:

$$\beta_{TOT} = \sqrt{\beta_D^2 + \beta_C^2 + \beta_{DS}^2} \quad (1)$$

Since  $\beta_D$  is directly evaluated from NLDAs as a function of the selected ground motion records, for the other sources of uncertainty (i.e.,  $\beta_C$  and  $\beta_{DS}$ ), suitable (deterministic) values from literature (e.g., [24]) and consistent with the Italian context have been considered.

In order to derive analytical FCs, the maximum interstorey drift (IDR) value along the height has been considered as earthquake demand parameter (EDP). From each NLDA, IDR value along the two in-plan directions has been evaluated and referred to the corresponding PGA value. For IDR value falling into a given damage level as defined according to a suitable relationship between damage levels and interstorey drift values, the median and the logarithmic standard deviation of the PGA value have been evaluated. An example of the relationship adopted for GLD building types is shown in Table 1 [21].

	D0	D1	D2	D3	D4	D5
<b>EMS-98 definition</b>	 SD = null NSD = null	 SD = null NSD = slight	 SD = slight NSD = moderate	 SD = moderate NSD = heavy	 SD = heavy NSD = very heavy	 Destruction
<b>Interstorey drift (%)</b>	< 0.1	0.1 – 0.25	0.25 – 0.5	0.5 – 1.0	1.0 2.5	>2.5

**Table 1:** Relationship between damage levels and interstorey drift values adopted for mid- and high-rise GLD buildings (from Masi et al. [21])

Finally, the FC related to a given damage level has been obtained by applying the well-known expression [24]:

$$P(D_k|PGA) = \Phi \left[ \frac{1}{\beta_{D,Dk}} \cdot \ln \left( \frac{PGA}{\overline{PGA}_{Dk}} \right) \right] \quad k=1,\dots,5 \quad (2)$$

where  $P(D_k|PGA)$  is the probability of exceedance of the  $k$ -th damage level  $D_k$  given a PGA value,  $\Phi$  is the standard normal (Gaussian) cumulative distribution function,  $\beta_{D,Dk}$  and  $\overline{PGA}_{Dk}$  denote the logarithmic standard deviation and median values, respectively. Note that  $\beta_{D,Dk}$

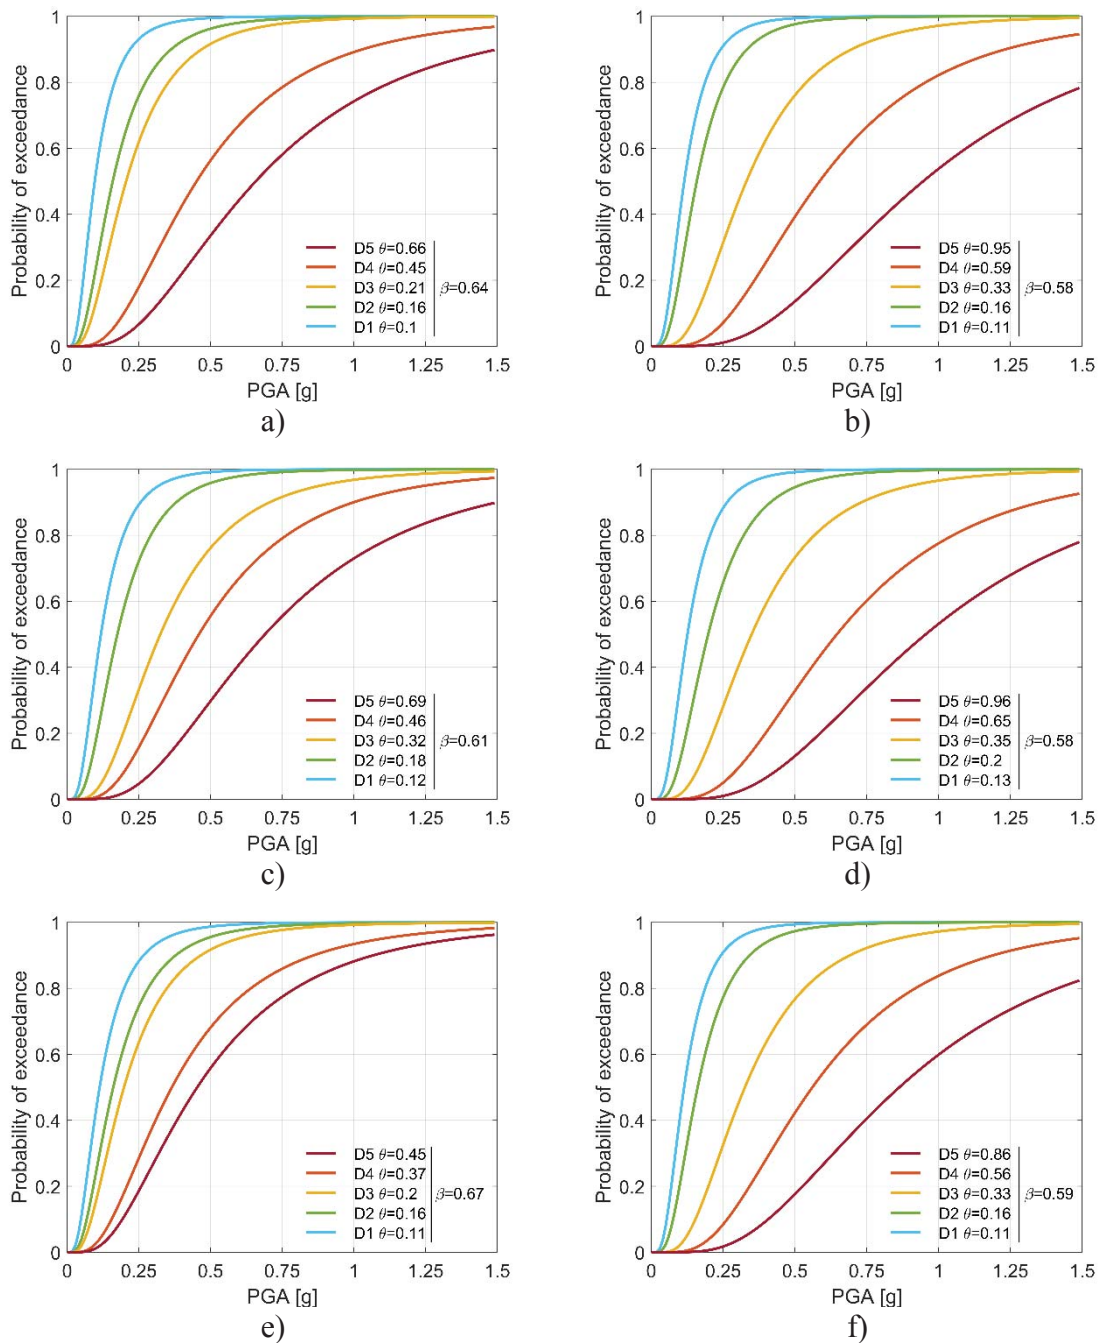

accounts for only the record-to-record variability as obtained from the NLDAs. In order to consider all sources of uncertainty, the values related to  $\beta_C$  and  $\beta_{DS}$  have to be added according to expression (1). Finally, in order to avoid unrealistic shapes of FCs (e.g., the intersection of the curves relevant to different damage levels), for each building type,  $\beta_{TOT}$  value has been evaluated as the mean of the results from each damage level.

### 3 ANALYSIS OF RESULTS

On the basis of the proposed methodology, fragility curves (FCs) for all the typological classes described previously have been derived. For sake of brevity, in the present paper only the FCs for the four-storey (4s) building type designed according to the 1970's standards have been shown. Results have been analyzed in order to highlight the role of some parameters such as infill arrangement and design level on seismic fragility. FCs related to the considered parameters (i.e., GLD and ERD design levels, presence/arrangement of infills according to BF, IF and PF configurations) are shown in Figure 3, as follows:

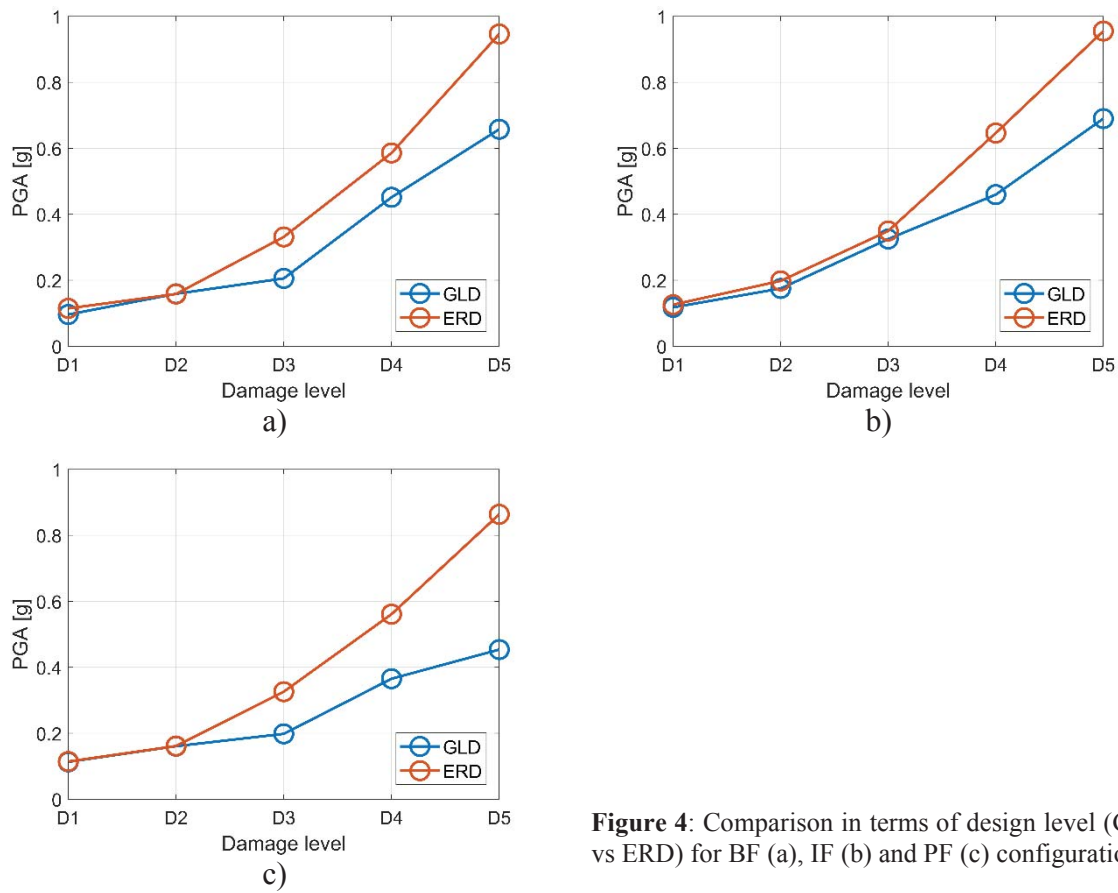

- GLD-BF in Figure 3a;
- ERD-BF in Figure 3b;
- GLD-IF in Figure 3c;
- ERD-IF in Figure 3d;
- GLD-PF in Figure 3e;
- ERD-PF in Figure 3f.

In the same figure, results in terms of median value of PGA (denoted as  $\theta$  and corresponding to the previously described  $\overline{PGA}_{DK}$ ) and dispersion ( $\beta$ , corresponding to the overall uncertainty  $\beta_{TOT}$  described above) for each damage level are reported. First of all,  $\beta$  values are in the range 0.58-0.67, with higher values for GLD types and lower ones for ERD. Further, for these latter types, similar values equal to about 0.58 are found. As for  $\theta$  values, the first damage level (D1) is reached at about 0.1g, irrespective of both design level and infill configuration, while greater differences are found for higher damage levels. In order to emphasize the role of the design level, Figure 4 shows a comparison in terms  $\theta$  values evaluated for each damage level. As expected, ERD types show better performance than GLD ones, especially for higher damage levels. Specifically, for IF configuration (Figure 4b),  $\theta$  value related to D5 (global collapse) is 0.96g for ERD and 0.69g (about -30%) for GLD. It is worth noting that, for lower damage levels (i.e., up to D3), similar  $\theta$  values are obtained for both ERD and GLD. This result mainly depends on two factors, that are i) no infill damage prevention design was required by the code considered for ERD types, thus providing a similar lateral stiffness value between ERD and GLD, ii) the same type of infills was adopted for both ERD and GLD types. These aspects are also confirmed from the results obtained for BF type, for which similar  $\theta$  values are found up to D2. The better performance of ERD with respect to GLD is even more emphasized in case of PF configuration. Indeed, the PGA median value at D5 evaluated for ERD type is approximately two times higher than for GLD type (0.86g and 0.45g, respectively for ERD and GLD).

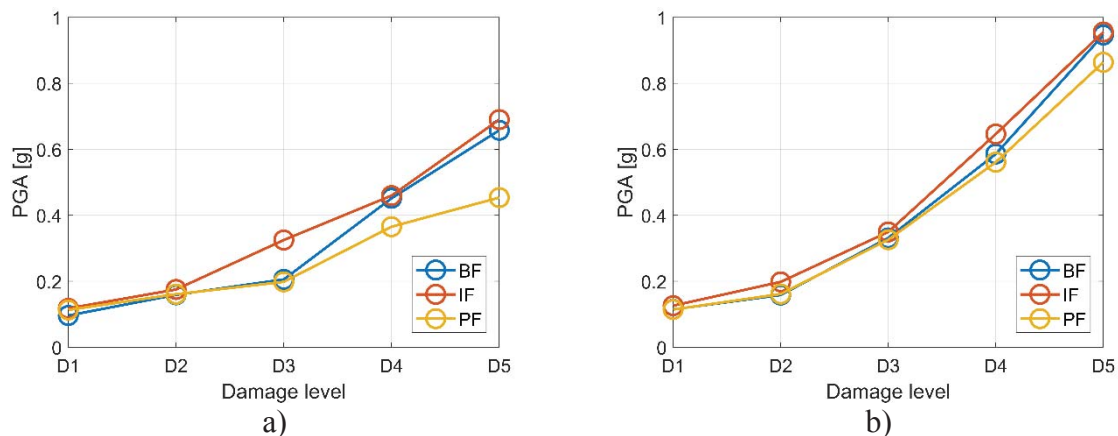

**Figure 3:** Fragility curves for the considered building types: GLD-BF (a); ERD-BF (b); GLD-IF (c), ERD-IF (d), GLD-PF (e), ERD-PF (f)

In order to highlight the role of infills on seismic performance, a comparison in terms of PGA median value by varying presence/arrangement of infills is shown in Figure 5a, for GLD type, and Figure 5b for ERD one. In general, IF types have better performance than PF ones, while intermediate results are found for BF. For GLD types, infills regularly arranged remarkably increase  $\theta$  values, especially for higher damage levels. On the contrary, for all damage levels, lower differences between IF and PF are found in case of ERD types. For example, for D5 evaluated for GLD,  $\theta$  value is equal to 0.69g for IF and 0.45g (about -35%) for PF. In case of ERD,  $\theta$  value related to IF is 0.96g while it is equal to 0.86g (about -10%) for PF.

**Figure 4:** Comparison in terms of design level (GLD vs ERD) for BF (a), IF (b) and PF (c) configurations

It is also noteworthy that, for higher damage levels, IF and BF types show similar seismic performance. Specifically,  $\theta$  values evaluated at collapse (D5) are equal to 0.69g and 0.66g for GLD-IF and GLD-BF, respectively, and 0.96g and 0.95g for ERD-IF and ERD-BF. To this purpose, it should be recalled that infills are very brittle components whose contribution to the lateral capacity of buildings decreases at higher IDR values associated with D4 and D5 damage levels.

**Figure 5:** Comparison in terms of presence/arrangement of infills for GLD (a) and ERD (b) building types

#### 4 FINAL REMARKS

Within the Work Package WP4-MARS of the 2019-2021 DPC-ReLUIIS research project, one of the main goals is to enrich the vulnerability models adopted in the 2018 National Risk Assessment by deriving additional fragility curves (FCs) from different approaches. In this context, a large set of analytical FCs through non-linear dynamic analyses has been obtained by considering some prototypes representative of the Italian building stock. Four main parameters have been considered to identify building classes, that are: (i) period of construction (three periods: '50s, '70s and '90s), (ii) design level (two levels: gravity load design, GLD, and earthquake resistant design, ERD), (iii) number of storeys (three heights: Low-rise, Mid-rise and High-rise), and (iv) infill arrangement (three configurations: Regularly Infilled-frame, IF, Pilotis-frame, PF, and Bare frame, BF).

In the paper, after a short description of the methodology, analytical FCs for the 4-storey RC building types designed according to 1970's standards have been analyzed in order to highlight the role of some parameters affecting seismic vulnerability, and specifically design level and infill arrangement.

As expected, although the '70s ERD types were poorly designed for lateral loads, significant differences (about 30%) in terms of PGA median values at collapse (D5) have been found between ERD and GLD types. On the contrary, similar performance has been found for the lower damage levels according to the EMS-98 classification (i.e., D1 and D2). This latter result mainly depends on two factors, that are: (i) no infill damage prevention design was required by the code considered for the '70s ERD types, thus providing a similar lateral stiffness value between ERD and GLD, (ii) the same type of infills was adopted for both ERD and GLD types in the '70s.

The presence of infills regularly arranged improves seismic performance, especially for buildings designed only for gravity loads (GLD type). As an example, for D5 damage level, PGA median value is equal to 0.69g for IF types, and 0.45g for PF ones, with a reduction around 35%. On the contrary, lower differences (about 10%) have been found in case of ERD types. The comparison between IF and BF types shows that the infill contribution to the lateral capacity of buildings is more appreciable for lower damage levels while, due to the brittle behaviour of infills, it becomes negligible at collapse.

#### ACKNOWLEDGEMENTS

The work reported in this article has been developed under the financial support of the Italian Department of Civil Protection, within the ReLUIIS-DPC 2019-21 Research Project, WP4 – Seismic Risk Maps (MARS), which is gratefully acknowledged.

### Abstract

*Prefabricated industrial sheds featured a high seismic vulnerability during the 2012 Emilia earthquake (Italy). The buildings typically exhibited a rigid collapse mechanism that was a consequence of the lack of connection between columns, beams and roof elements.*

*The study presents an experimental and numerical assessment of a novel isolation device which has been designed to improve the seismic performance of industrial sheds. The device, which is placed on the top of the column, exploits the movement of a rigid body on a sloped surface to provide horizontal stiffness and control the lateral displacement of the beam.*

*Biaxial tests are performed to investigate the effect of the vertical load, the velocity of sliding and the number of cycles on the force – displacement response of the device. To cope with the capacity of the testing equipment, the experimental campaign is carried out on a scaled model of the device, and the protocol is designed accounting for similarity requirements. The backbone curve of the tested prototype is eventually derived from the experimental data.*

## 1 INTRODUCTION

In Italy, the seismic events of L'Aquila 2009, Emilia 2012 and Central Italy 2016 highlighted the vulnerability of the Italian stock on structures and infrastructures that were not designed according to modern seismic regulations.

The Emilia earthquake of May 2012 hit an area with a high density of productive activities, affecting mainly industrial buildings in precast reinforced concrete (RC) [1, 2] rather than in steel [3]. This seismic event caused a global economic damage of 13.27 billion of euros and estimates show that the loss of direct and indirect income was between 3 and 3.8 billion [4].

After Emilia earthquakes, the Italian Civil Protection Department prepared a summary (WG 2012) [5] of the main deficiencies of the precast industrial building structural performance. In this regard, it is worth also mentioning the study by Rossi et al. [6] about long-span-beam structure, which proposed a damage characterization to construct empirical fragility functions, cost and loss ratio curves referring to precast RC industrial buildings.

The existing industrial buildings in Italy are mainly characterized by a simple structural layout with columns pin-connected to beams that support the roof, which is an extremely vulnerable configuration under a seismic event. Indeed, the most severe damage, observed also during the event of Emilia 2012, is the loss of support and the consequent collapse of structural and non-structural elements [1, 2]. This kind of connections usually rely solely on friction and are inadequate to properly transfer the horizontal loads [7, 8, 9] and accommodate compatible rotations and displacements [10, 11, 12, 13, 14, 15].

In order to improve the seismic performance of poorly designed or deficient structures, a retrofit intervention needs to be planned and implemented at either local level or global one [3]. Local interventions usually consist of structural strengthening, applying rigid and resistant reinforcement that increase the capacity of deficient elements; such a reinforcement can be made of either steel, or high-strength fibers embedded into a cementitious or a polymeric matrix [16]. Conversely, global interventions are implemented by inserting in the structure particular devices, which either reduce the seismic input, by separating the motion of the superstructure from the motion of the ground (namely seismic isolation systems) or increase the total energy dissipation capacity (namely energy dissipation devices) [17,18] by concentrating on special elements out of the main load bearing structure the dissipation of most of the energy transmitted by the earthquake.

The study presents an experimental and numerical assessment of a novel isolation device which has been designed to improve the seismic performance of industrial sheds. The device, which is placed on the top of the column, exploits the movement of a rigid body on a sloped surface to provide horizontal stiffness, control the lateral displacement of the beam and dissipate with a friction mechanism part of seismic energy.

## 2 DEVICE DESCRIPTION

The isolation device is composed by two steel elements one concave and the other convex, truncated-pyramidal in shape. The two elements are coupled through the contact, total or partial, of their respective flat surfaces.

This isolation device is designed to be inserted at the junction between the columns and beam of a building and is intended to transmit the vertical load in the node. The horizontal displacement of the beam with respect to the column produced by an earthquake causes the sliding of the convex surface of the first element on the concave surface of the second element. This relative movement generates dissipation of a portion of the seismic energy introduced into the system through the friction generated in correspondence of the sliding contact.

The device is designed to transmit an axial load  $N_{\text{design}} = 360 \text{ kN}$  and perform a maximum displacement  $d_{\text{design}} = 60 \text{ mm}$ .

To make the loads developed by the device compatible with the capacity of the test equipment, the characterization was conducted on a prototype scaled by a geometric factor  $SL = 0.4$  and fabricated in steel (unit scale factor for modulus of elasticity  $SE = 1$ ). Applying the principle of similarity, the scaling factors for all mechanical quantities are determined (Table 1).

Size	Dimension	Scale factor
Length	[L]	$S_L = 0,4$
Elastic Modulus	[F] [L] <sup>-2</sup>	$S_E = 1,0$
Force	[F]	$S_F = (S_L)^2 = 0,16$
Pressure	[F] [L] <sup>-2</sup>	$S_p = 1,0$
Displacement	[L]	$S_d = 0,4$
Time	[T]	$S_T = (S_L)^{1/2} = 0,6324$
Velocity	[L] [T] <sup>-1</sup>	$S_V = (S_L)^{1/2} = 0,6324$
Frequency	[T] <sup>-1</sup>	$S_f = (S_L)^{-1/2} = 1,5811$

Table 21 Scale factor

This results in the following relationships between the design values of device force and displacement and the values that should be applied in tests to the scaled prototype (Table 2).

Size	Real scale	Prototype
Axial load	$N_{\text{design}} = 360 \text{ kN}$	$N_{\text{test}} = 57,6 \text{ kN}$
Displacement	$d_{\text{design}} = 60 \text{ mm}$	$d_{\text{test}} = 24 \text{ mm}$

### 3 EXPERIMENTAL PROGRAM

#### 3.1 Tests setup and instrumentations

The test is performed on a pair of prototypes of equal size, mounted in an upside-down configuration to minimize the moment arising on the test machine due to the eccentricity of the load applied on the specimen while it is in a translated position.

The concave component is mounted on the moving slide, while the convex component is clamped to a fixed part of the testing machine, to the vertical actuator and the base respectively. The test configuration is shown in Figure 3.

Figure 3 Setup configuration: on the left in centered configuration, on the right in translated position

The tests were conducted on a pair of prototypes with lubrication. Applying the axial load  $N_{test}$ , kept constant during the test, and simultaneously imposing a horizontal displacement through cycles of amplitude  $d_{test}$  at constant speed  $V_{test}$ . The test protocol, articulated in the execution of static and dynamic tests, reproduced for each combination of prototypes and type of lubrication is specified in Table 3a for the static and Table 3b for dynamic tests.

Table 3b Dynamic test

Tests were conducted using a biaxial testing system installed at the “Laboratorio Prove Materiali e Strutture per le Costruzioni del Politecnico di Milano”. The testing machine consists of a rigid frame with 4 columns and two fixed crossbeams, one lower and one upper, which form a closed ring in which the forces are confined [19].

The main characteristics of the test equipment are:

- Vertical load capacity: 500 kN
- Horizontal load capacity: 75 kN
- Horizontal displacement capacity: 100 mm

### 3.2 Results

The typical shape of the hysteretic horizontal force (F) - displacement (d) diagram of the prototype seismic device obtained in the cyclic tests is shown in Figure 4. In the force-displacement diagrams, the total force acting in the horizontal direction on the pair of prototypes is shown on the y-axis; the reaction force of the individual prototype corresponds to half of the force shown on the diagram.

Figure 4 Hysteretic loop

The prototype device has a rigid-plastic constitutive law, characterized by an approximately constant reaction force up to the design displacement. The reaction force is provided by the sum of two contributions, each of which is ideally independent of the magnitude of the displacement: the first is the reaction force to the sliding of the convex element on the inclined plane formed by the surfaces of the concave element, and the second is the friction force generated during sliding.

In order to identify the characteristic parameters of the prototype, the hysteretic cycle is approximated by two cycles of rectangular shape placed in the first and third quadrant of the plane  $F - d$ , and such that the sum of their areas equals the area ( $A$ ) of the hysteretic cycle itself. Based on energy equivalence considerations, the following parameters are defined:

Energy dissipated in a cycle:

$$E_{diss} = \frac{A}{k_0} \quad (1)$$

Equivalent stiffness:

$$K_{eff} = \frac{E_{diss}}{2 (d_{test})^2} \quad (2)$$

Equivalent dynamic friction coefficient:

$$\mu_{eff} = \frac{E_{diss}}{4 d_{test} N_{test}} \quad (3)$$

where  $A$  [Nm] is the area of the hysteretic cycle, and the factor  $k_0 = 2$  takes into account the fact that the test is conducted simultaneously on two identical prototype devices (Figure 4).

## 4 NUMERICAL MODEL

### 4.1 Numerical description

Numerical model of the seismic isolation device described above was developed using the Abaqus CAE finite element calculation program [20].

The geometry of the numerical model of the prototype represents the one described previously that was subjected to experimental characterization tests at the Politecnico di Milano.

The numerical model takes into account only one device, and so there is only two elements, one convex and one concave. To simulate the behavior of the prototype it is developed an implicit dynamic analysis with full Newton solution technique.

The FEM model, like the prototype, is subject to a biaxial load. The boundary conditions that characterize the convex element are the distributed pressure of 11 MPa, whose resultant is 57,6 kN, applied on the external face, and the harmonic displacement with amplitude 24 mm. The concave element is fixed.

The numerical model was meshed with elements C3D8 (three-dimensional hexahedral element with 8 nodes) with maximum dimension equal to 8 mm. A total of #1016 elements were used for the convex element and #2034 elements for the concave element (Figure 8). The contact between the surfaces in creeping contact was modeled through the surface-to-surface contact command, defining the convex element as the master element, and formulating a hard contact constitutive behavior in the direction perpendicular to the contact surface, and a penalty constitutive behavior tangentially the contact surface [21]. The elements have elastic properties, Young modulus equal to  $E = 210'000$  MPa and Poisson's coefficient  $\nu = 0.30$ , corresponding to the characteristics of steel. The friction coefficient between the surfaces of the concave and convex element, based on experimental tests conducted on a device with lubricated surfaces, is assumed to be  $\mu = 0.10$ .

In the numerical modeling, in the absence of precise indications, it was assumed that in the initial configuration with perfectly centered concave and convex elements the two elements are in contact through the two flat faces.

Figure 8 FEM model of the seismic energy dissipation device:(a) convex element; (b) concave element

## 4.2 Numerical result

The results of the numerical analyses are shown below for different motion trajectories of the convex component with respect to the concave component defined by angle  $\theta$  (Figure 9). The seismic dissipation device has four axes of symmetry, defined by the angles  $\theta = 0^\circ$ ,  $\theta = +90^\circ$ ,  $\theta = +45^\circ$ , and  $\theta = -45^\circ$ , the motions along two unidirectional trajectories were analyzed, directed according to the directions corresponding to the angles  $\theta = 0^\circ$  and  $\theta = 45^\circ$ , since the other two have the same characteristics as the two considered.

The results are expressed in the form of:

- force-displacement curves:
- reaction force vs. displacement
- reaction moment vs. displacement
- contact pressure distribution

Figure 9 Definition of the reference system for the displacements

Figures 10 and 11 illustrate the force-displacement diagrams related to the analyses conducted imposing a unidirectional movement along the symmetry directions  $\theta = 0^\circ$  and  $\theta = +45^\circ$ .

Figure 10 Force-displacement curve for unidirectional trajectory in direction  $\theta = 0^\circ$

Figure 11 Force-displacement curve for unidirectional trajectory in direction  $\theta = 45^\circ$

The characteristic curve of the device moving according to a direction of symmetry presents the classical flag-shaped that characterizes a constant reaction force independent of the imposed displacement, but dependent on the direction of displacement. This behavior is consistent with the theoretical behavior corresponding to the movement of a solid on an inclined plane with friction, which provides a reaction force of the type

$$F = N [\sin \alpha \cdot \text{sign}(d) + \mu \cos \alpha \cdot \text{sign}(V)] \quad (4)$$

where  $F$  is the horizontal reaction,  $d$  is the imposed displacement,  $N$  is the vertical compressive load,  $\alpha$  is the tilt angle of the sliding surface,  $\mu$  is the coefficient of friction,  $V$  is the sliding velocity, and  $\text{sign}(\cdot)$  is the sign function. The first term on the right in Eq. (4) represents just the reaction force produced by motion on an inclined surface and the second term on the right the friction force:

- the effective angle of inclination  $\alpha$  of the device surface along the direction in which the trajectory develops is not constant but varies as the direction of motion defined by the angle  $\theta$  varies according to the relation

$$\alpha(\theta) = \max\{\arctan(h/L_0 \cdot \cos\theta); \arctan(h/L_0 \cdot \sin\theta)\} \quad (5)$$

where  $h$  and  $L_0$  are defined in figure 12.

Figure 12 Descriptive geometric parameters of surface inclination along a generic direction  $\theta$

The equation (4) expresses the reaction force developed by the seismic dissipation device in the direction of motion, parallel to the trajectory of the convex component with respect to the concave component. On the other hand, the reaction force developed in the direction perpendicular to the trajectory is zero (Figure 13), and this is justified by the symmetry of the contact surfaces with respect to the direction of motion.

Figure 13 Reaction force parallel and perpendicular to the direction of motion: (a)  $\theta = 0^\circ$ ; (b)  $\theta = 45^\circ$

The reaction bending moment evaluated at the top of the column is shown in Figures 14. In agreement with the results presented in Figure 13, the moment acts only in the plane parallel to the direction of displacement, while the moment  $M_y$  acting in the perpendicular plane is zero. The moment has two contributions, one due to the horizontal reaction force  $F$  produced by the movement along the inclined plane, and the other due to the eccentricity of the vertical force  $N$  due to the displacement of the convex element.

The moment presents non-negligible values (equal to about 50% of the moment at maximum displacement) already for very small movements starting from the initial centered configuration, given by the product of the force  $F$  for the distance of its center of application from the base of the concave element (equal to the thickness of the plate), and grows further with the horizontal displacement  $d$  due to the vertical displacement of the center of application and especially by the eccentricity of the vertical force  $N$  that grows linearly with the displacement  $d$ .

Figure 14 Bending moment at the top of the column: (a)  $\theta = 0^\circ$ ; (b)  $\theta = 45^\circ$

Figure 15 shows the distribution of contact pressures on the surface of the concave element for different values of displacement  $d$ , relative to the analysis with trajectory in the direction  $\theta = 0^\circ$ . As can be seen, the contact initially occurs at the horizontal plane at the bottom of the concave surface, but as the convex component begins to move, the contact is transferred to the inclined surface along which the motion develops. However, the contact remains localized over a limited area of the surface, corresponding to the area over which the tapered end of the convex member crawls, resulting in high contact pressures that, although below the yield strength of the steel, can potentially accelerate surface wear.

Figure 15 Contact pressures on the surface of the concave element for different values of displacement  $d$

## 5 DISCUSSION AND CONCLUSIONS

The force-displacement curves obtained from the numerical analyses carried out on the prototype and the corresponding experimental curves obtained in the experimental tests are compared in Figure 16.

Figure 16 Experimental and numerical force-displacement curve: (a)  $\theta = 0^\circ$ ; (b)  $\theta = 45^\circ$

An acceptable correspondence between the experimental curves and the results of the numerical analyses is apparent. The biggest deviations are near the origin of the displacements and are attributed to the effective geometry of contact between the surfaces in the centered configuration of the device. Since the construction drawings provided by the customer and used for the formulation of the numerical model do not give indications on the construction tolerances, it was not possible to define a priori the characteristics of the initial contact to be reproduced in the analysis.

The horizontal reaction force is kept constant for displacements increasing in modulus and is only weakly influenced by the direction of the trajectory ( $\theta = 0^\circ$  vs.  $\theta = 45^\circ$ ), moreover this response is perfectly consistent with that predicted by a simplified analytical model that takes into account the reaction generated by the movement on an inclined plane and the reaction due to friction between surfaces.

Starting from the compared curves, the numerical model results validated. This allows to proceed to the development of the same starting first from a numerical study, to highlight possible criticalities of this device.

Among the developments will be interesting the study of one-dimensional trajectories along non-symmetrical axes and possible two-dimensional trajectories. In addition, as shown in the results of numerical analysis, a problem to be solved is the presence of the moment at the top of the column; it is possible through the development of this model to evaluate the possibility of introducing a hinge under the concave element in order to avoid eccentricity of the load.

Finally, it will be possible to model an industrial shed with the seismic dissipation device in order to evaluate the actual benefits induced by the presence of the devices.

### Abstract

*Under a seismic excitation the response of a building isolated with curved surface sliders (CSSs) is highly influenced by the breakaway friction coefficient, which is a parameter that governs the transition between the sticking and the sliding behaviour of the isolators. Its effect is detrimental especially in case of low-to-moderate earthquakes; in fact, the inertia forces are not able to overcome the breakaway frictional resistance of the CSS isolators and the structure behaves as a fixed-base building, thus experiencing higher acceleration, inter-storey drifts and internal forces than the isolated building. Usually this parameter is disregarded because the majority of structural analysis programs implement the dynamic friction coefficient only throughout the response history analysis; this leads to a possible overestimation of the displacement demand for the isolation system but a likely unsafe design for the superstructure.*

*In this contribution, the frictional resistance to sliding before the breakaway is simulated through a bidirectional plasticity domain, coded in a finite element of the isolator formulated in OpenSees. Based on this formulation, an exhaustive parametric analysis comprising a range of friction coefficients and superstructure properties is implemented considering a number of natural spectrum-compatible bidirectional ground motions of different intensity levels and frequency contents.*

*Through the review and discussion of the results, the study provides insight into the implications of including the breakaway coefficient in non-linear time history analyses, and recommendations useful to predict the trigger acceleration at which sliding motion starts.*

## 1 INTRODUCTION

The Curved Surface Slider (CSS) is one of the most popular isolation hardware, whose behaviour depends on two fundamental parameters, namely the coefficient of friction ( $\mu_{dyn}$ ) and the effective radius of curvature ( $R_{eff}$ ) of the sliding surfaces.

During the motion of the CSS, the dynamic friction coefficient at sliding surface  $\mu_{dyn}$  usually increases from a minimum value  $\mu_{LV}$ , in the low-velocity regime, to a steady value  $\mu_{HV}$ , in the high-velocity range, as described by the Eq. (1) of Constantinou et al. [1]:

$$\mu_{dyn} = \mu_{HV} - (\mu_{HV} - \mu_{LV})e^{(-\alpha v)} \quad (1)$$

where  $\alpha$  is the transition rate parameter and  $v$  is the velocity. Nowadays, available commercial FE codes, such as SAP2000 [2] and MIDAS GEN [3], are still based on the friction model of Eq. (1).

However, this formulation is not able to predict the actual response of CSS isolators in the sticking phase preceding the triggering of the sliding motion. In fact, experimental findings reveal that at the beginning of the motion and at any momentary sticking of the sliding surfaces, e.g. at motion reversal, the friction coefficient attains a higher value than  $\mu_{dyn}$ , which is known as the static friction coefficient  $\mu_{ST}$ . This parameter is governed by chemical bonds arising at the interface between the contact surfaces during the sticking phase and the number and strength of these bonds increases with the duration of sticking; indeed, the static coefficient of friction that contrasts the start of the motion (usually denoted as the breakaway friction coefficient  $\mu_B$ ) is reasonably larger than the value observed at motion reversal  $\mu_{rev}$ . Therefore, to properly simulate the actual response of CSSs during both the breakaway and the sliding phase, the numerical formulation should include the breakaway friction coefficient besides the dynamic friction coefficient [4]. Disregarding  $\mu_B$  from the friction model leads to an underestimation of the peak floor accelerations and maximum inter-storey drifts transferred to the superstructure, which are likely to be experienced in the sticking phase before the breakaway.

Some authors ([5] and [6]) developed friction models suitable to account for both forms of static coefficient of friction, at breakaway and at motion reversal. However, both formulations have some drawbacks: in [5] the study was limited to unidirectional trajectories (underestimating the decrease in damping capability induced by frictional heating [7]) and there was no distinction among the different contributions of friction coefficients at the breakaway and at motion reversal, as it implicitly assumed  $\mu_B = \mu_{rev} = \mu_{ST}$ . Also in [6], the work consisted in unidirectional non-linear time history analyses (NLTHAs) and the low-velocity friction coefficient  $\mu_{LV}$  was replaced by the static coefficient of friction  $\mu_{ST}$ , leading to a possible underestimation of the maximum displacement of CSS  $d_{max}$ , as well as an overestimation of the residual displacement  $d_{res}$  [4].

Gandelli et al. [8] studied the effect of different breakaway levels and friction materials on the response of a mid-rise building protected by means of CSS isolators, confirming that the breakaway friction has a major effect on the peak floor acceleration and on the shear at the isolation level, whereas the influence on the maximum displacement of CSS  $d_{max}$  is usually modest. However, the study was conducted only on one building prototype under unidirectional ground-motion, therefore the authors could not claim a general validity for its conclusion.

The present work consists in a more extensive parametric study comprising a significant number of NLTHAs in which different properties of both superstructure and CSS isolation system are taken into account, in order to draw more general conclusions on the effect of the breakaway friction on the seismic response in terms of peak floor acceleration, inter-storey drift, base shear and CSSs displacement demand.

## 2 PARAMETRIC STUDY

A broad parametric study is carried out, performing 9072 bidirectional NLTHAs with the structural analysis program OpenSees [9]. The analyses include different properties of the superstructure, namely number of storeys and base mass to floor mass ratio ( $m_b/m_f$ ), as well as different properties of the CSS isolation systems, considering three friction classes representative of low friction (LF), moderate friction (MF) and high friction (HF) sliding materials. The analyses are performed considering a large group of natural ground motion records having different intensity levels and frequency contents.

### 2.1 Structural models

The case-study structures consist of three RC buildings, conceived as moment-resisting frames of two-storey, four-storey, and six-storey. The structures are designed in compliance with the Italian Building Code NTC2018 [10] and are characterized by a double-symmetric, square plan with three bays of 6 m in both horizontal directions and a constant inter-storey height of 3 m, **Figure 1**.

Figure 1: Plan view and front view of representative four-storey building

The concrete compressive strength  $f_c$  is equal to 25 MPa and the steel yield strength  $f_y$  is equal to 450 MPa. Additional information regarding geometry of the structural elements, design loads and fundamental periods are reported in [4].

The structures are modelled in OpenSees [9] as linear elastic systems with *ElasticBeamColumn elements* [11] for beams and columns with appropriate cross-sectional characteristics. The floor slabs are modelled as rigid diaphragms, by using the *RigidFloorDiaphragm* [11] multi-points constraint, imposing the nodes belonging to the same floor to have the same displacement. Therefore, the floor mass ( $m_f$ ) can be lumped at a master node located at the centroid of each floor, along with a mass moment of inertia about vertical axis.

The buildings are isolated with sixteen CSS isolators located underneath each column and connected to each other via a base slab of mass  $m_b$  acting as a rigid diaphragm, which prevents differential displacements. Two base mass to floor mass ratios ( $m_b/m_f = 1.0$  and  $= 2.0$ ) are considered for each building, thus including six different building configurations in the parametric study, in order to verify if this parameter has an influence on the seismic response of the case-study structures.

The damping of the base-isolated system is modelled with a substructure approach, by separating the superstructure component alone from the base isolation system [12] and the superstructure is characterized by a stiffness proportional damping.

The CSSs have an effective radius of curvature  $R_{eff} = 3000mm$ , which corresponds to an undamped period  $T_{iso} = 2\pi(R_{eff}/g)^{0.5} = 3.48s$ , and are modelled with a reduced version of the *BVNC* element developed by Gandelli et al. [13]. The reduced version of this element (hereinafter referred as *BV* element, **Figure 2**) accounts for the breakaway and the velocity effects only. The transition between static and dynamic friction is accomplished by two distinct plastic material models, one for the static friction ruling the breakaway phenomenon, and the other for the dynamic friction after the initiation of the sliding motion. In particular, the *VelDependent* friction model of the *SingleFPSSimple3d* element [11] is used to describe the dynamic friction coefficient, according to the exponential formulation of Eq. (1), excluding the influence of the normal force and of the heating phenomena on the variation of the friction coefficient.

Figure 2: The *BV* element adopted in the present study: relevant bidirectional plasticity domain (left), associated friction model (centre) and response of the element to a sinusoidal excitation (adapted from Gandelli et al. [13])

The study includes three friction classes representative of low friction (LF), moderate friction (MF) and high friction (HF) sliding materials; each friction class has different low-velocity  $\mu_{LV}$  and high-velocity  $\mu_{HV}$  friction coefficients (**Table 1**) with a ratio  $\mu_{HV}/\mu_{LV} = 2.5$ , as indicated in previous literature studies ([14] and [15]). The case  $\mu_B/\mu_{LV} = 1$  corresponds to no-breakaway and is used as baseline reference for comparison, corresponding to the friction models usually implemented in structural analysis programs. The second case  $\mu_B/\mu_{LV} = 2$  corresponds to intermediate breakaway that typically occurs with lubricated sliding material; while, the third case  $\mu_B/\mu_{LV} = 4$  is the high breakaway, that may be caused by unfavourable effects induced by low temperature, poor maintenance conditions of the sliding surfaces, mounting defects [16], as well as possible permanent setting of the surfaces. The value  $\mu_B/\mu_{LV} = 4$  is selected according to the work of Constantinou et al. [1].

For all friction classes, the transition rate parameter  $\alpha$  from the low-velocity to the high-velocity friction is set to 0.0055s/mm.

Friction class	Friction coefficient ( $\mu_{LV}, \mu_{HV}$ )	Breakaway class	Breakaway friction ( $\mu_B$ )	Friction ID
LF	(0.01, 0.025)	$\mu_B/\mu_{LV}=1$	0.01	LF_1
		$\mu_B/\mu_{LV}=2$	0.02	LF_2
		$\mu_B/\mu_{LV}=4$	0.04	LF_4
MF	(0.03, 0.075)	$\mu_B/\mu_{LV}=1$	0.03	MF_1
		$\mu_B/\mu_{LV}=2$	0.06	MF_2
		$\mu_B/\mu_{LV}=4$	0.12	MF_4
HF	(0.05, 0.125)	$\mu_B/\mu_{LV}=1$	0.05	HF_1
		$\mu_B/\mu_{LV}=2$	0.10	HF_2
		$\mu_B/\mu_{LV}=4$	0.20	HF_4

Table 1: Parameters of the dynamic friction and of the breakaway considered in the parametric study

## 2.2 Seismic input

Non-linear dynamic analyses have been performed considering natural ground motions characterized by two horizontal components, whereas the vertical component of the seismic input is ignored. The accelerograms are selected from the European strong-motion database [17] by means of the software REXEL v. 3.5 [18].

The parametric study is performed considering two installation sites: Lamezia Terme (latitude  $38.58^\circ$ , longitude  $16.18^\circ$ ) and Naples (latitude  $40.86^\circ$ , longitude  $14.28^\circ$ ), which respectively belong to the seismic zone 1 (high probability of occurrence of strong earthquakes) and the seismic zone 2 (moderate probability of occurrence of strong earthquakes) of the old national classification [19]. The accelerograms are consistent with the elastic spectrum associated to an ordinary structure with nominal life  $V_n = 50$  years and functional class II corresponding to  $c_u = 1.0$ . Both serviceability limit state (SLD) and life-safety limit state (SLV) are used for the selection of the accelerograms; a topography condition  $T_1$  and two different soil conditions, designated as soil class A and soil class C, are considered. For each installation site, soil class and limit state, a suite of 21 independent bidirectional natural ground motion records are selected with a magnitude range  $M_w$  between 5 and 8. In order to include different fault distances, these 21 records include 7 events recorded at epicentral distance  $R_{ep}$  between 0 and 10 km, 7 events with  $R_{ep}$  between 10 and 20 km and the remaining 7 events with  $R_{ep}$  between 20 and 50 km. Additional details pertaining to the input ground motions are provided in [4] and **Figure 3**.

### 3 RESULTS AND DISCUSSION

The output of the NLTHAs on the base-isolated structure is analysed in terms of four response parameters representative of both the superstructure response and the base isolation system response, namely (i) Peak Floor Acceleration (*PFA*), (ii) Inter-storey Drift Ratio (*IDR*),

(iii) displacement of the base isolation system ( $d_{iso}$ ), and (iv) shear force carried by the isolation system normalized to the total seismic weight  $V_{iso}/W_{tot}$ , where  $W_{tot}$  is given by the sum of  $W_{ss}$  (equal to the sum of the seismic weight of each floor) and  $W_{bs}$  (equal to the seismic weight of the base). The maximum values of each parameter are extracted from the 9072 NLTHAs and then statistically processed to obtain average maximum response quantities.

**Figure 4** and **Figure 5** show the average response parameters of the base-isolated buildings in terms of *PFA*, maximum *IDR*, isolators' displacement  $d_{iso}$ , and normalized shear force carried by the isolation unit  $V_{iso}/W_{tot}$ , for serviceability earthquakes at SLD and life-safety earthquakes at SLV respectively. The results are organized distinguishing between the three friction classes (LF, MF and HF) and the three breakaway classes  $\mu_B/\mu_{LV} = 1.0, 2.0, 4.0$ , where  $\mu_B/\mu_{LV} = 1.0$  represents the baseline reference model.

Referring to SLD case (**Figure 4**), the breakaway friction tends to increase the *PFA*, maximum *IDR* and maximum normalized  $V_{iso}$ , in comparison to the baseline reference model  $\mu_B/\mu_{LV} = 1.0$ . MF and HF friction class isolators show a similar trend for all the three parameters with a more relevant increase than that LF friction class isolators, especially for  $\mu_B/\mu_{LV} = 4.0$ . On the other hand, the isolators' peak displacement  $d_{iso}$  does not seem to be affected by the breakaway friction, indeed, the three curves do not show substantial differences compared to the baseline reference model  $\mu_B/\mu_{LV} = 1.0$ .

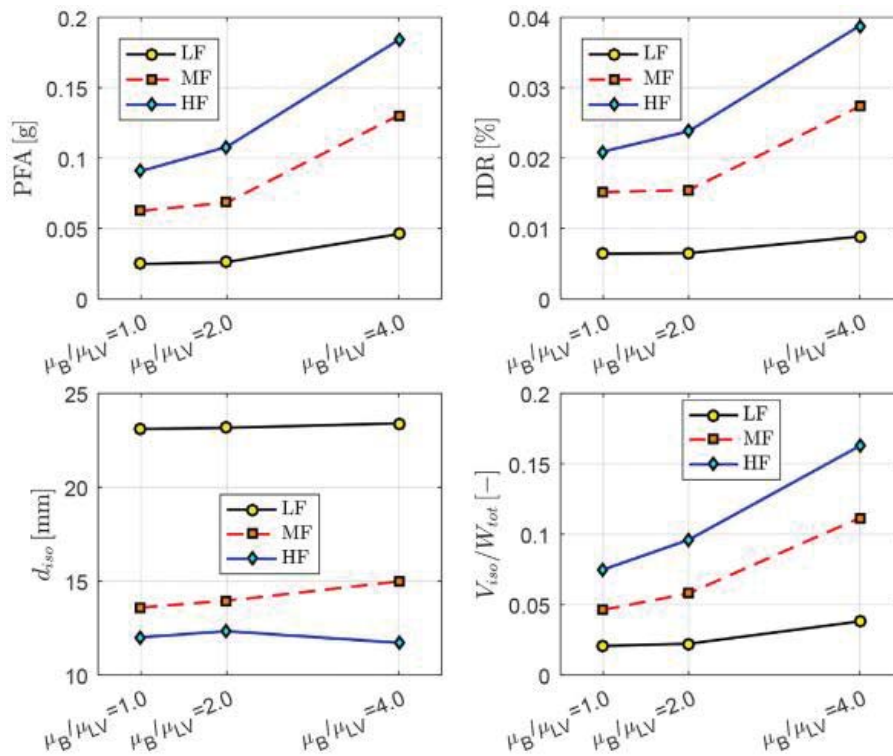

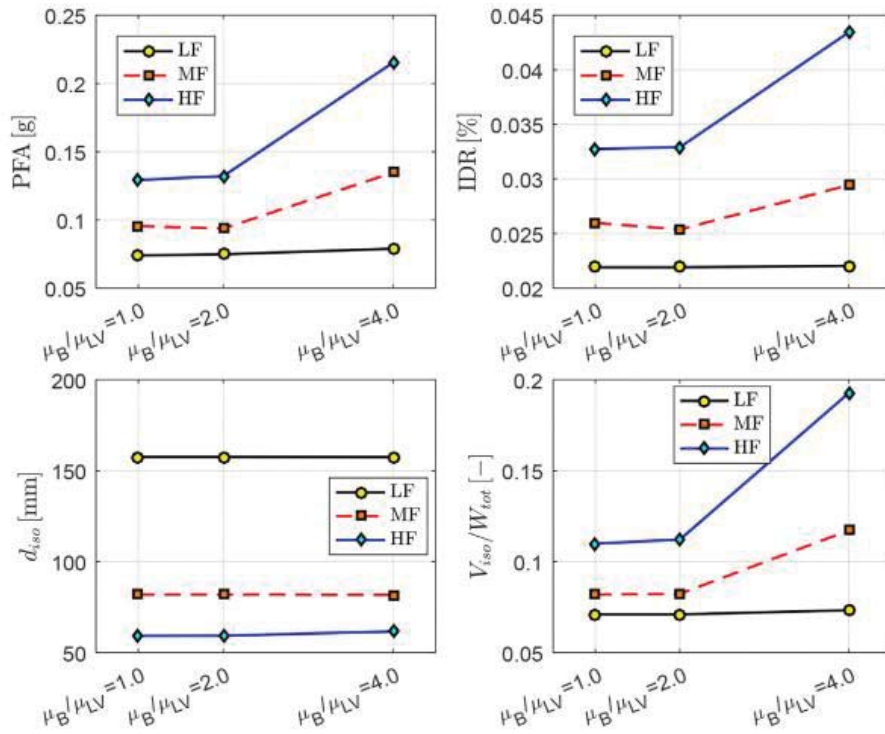

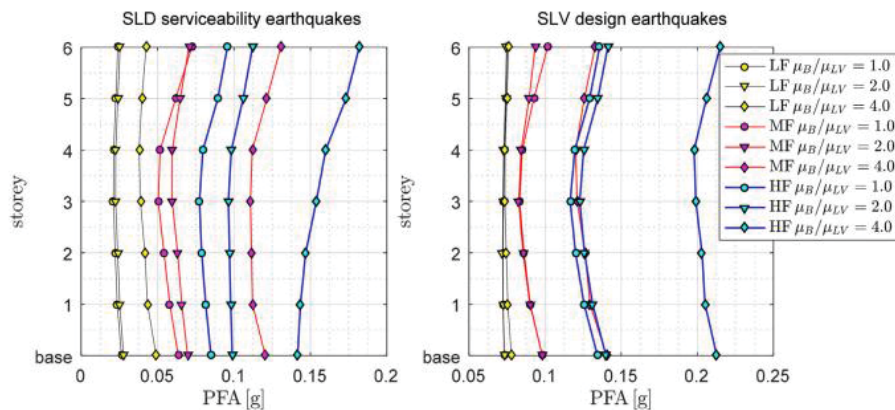

Figure 4: Average response parameters (*PFA*, *IDR*,  $d_{iso}$ ,  $V_{iso}/W_{tot}$ ) at SLD

With regard to SLV case (**Figure 5**), LF friction class isolators seem not influenced by the breakaway friction, while both MF and HF friction class CSSs increase significantly the *PFA*, maximum *IDR* and maximum normalized  $V_{iso}$ , especially for  $\mu_B/\mu_{LV} = 4.0$ . Also for SLV, as in SLD, the maximum displacement of the isolators  $d_{iso}$  is not influenced by the breakaway friction coefficient.

Figure 5: Average response parameters (PFA, IDR,  $d_{iso}$ ,  $V_{iso}/W_{tot}$ ) at SLV

The results of **Figure 4** and **Figure 5** are confirmed by looking at the overall behaviour of the superstructure in terms of *PFA*s, **Figure 6**. The superstructure model analysed in NLTHAs experiences higher *PFA*s due to the delayed engagement of the isolators at both SLD and SLV. **Figure 6** shows that under low-to-moderate intensity earthquake, typical of SLD, the breakaway friction has a major influence especially in case of MF and HF friction class; in fact, CSSs with higher coefficient of friction may remain in the sticking phase over the entire duration of the ground motion, consequently the structure behaves as a fixed-based building and the *PFA*s are much higher than the isolation building scenario.

Figure 6: Average PFA profiles at SLD (left) and SLV (right) along the height of the 6-storey building for different friction classes and  $\mu_B/\mu_{LV}$  ratios

Based on the previous considerations, a fundamental design parameter is the trigger acceleration  $a_{trigger}$ , meant as the minimum value of the ground acceleration capable of activating the sliding motion; indeed, for earthquakes characterized by a peak ground acceleration lower than  $a_{trigger}$ , the isolation system would not be activated, with potential detrimental conse-

quences on the internal forces in the superstructure. The most simple way to analytically determine  $a_{trigger}$  is referring to the simple two-degree-of-freedom (2DOF) system, consisting of two masses, namely superstructure mass  $m_s$  and base mass  $m_b$ , connected to the ground by a CSS bearing with coefficient of friction at breakaway  $\mu_B$  [8]. The sliding motion is triggered when the shear force through the CSS exceeds the resisting breakaway frictional force  $F_B$  evaluated as  $\mu_B(m_s+m_b)g$ , where  $g$  is the acceleration of gravity [4] and this condition is achieved when the ground motion acceleration  $a_g$  is larger than the trigger value  $a_{trigger}$ .

In 439 out of 9072 NLTHAs the CSSs were not engaged at all over the duration of the ground motion, meaning that the inertia force induced by the ground motion acceleration was not able to overcome  $F_B$ . As expected, all these cases belong to the low-intensity serviceability earthquakes, SLD.

**Figure 7** shows the relationship among the no-activation cases with the breakaway friction coefficients  $\mu_B$ , the soil class and the epicentral distance. The number of no-activation cases increases with increasing of  $\mu_B$ , and all the cases are concentrated in the range 0.10 – 0.20. No-activation cases seem marginally influenced by the epicentral distance of the earthquake, as the trend is almost equally distributed among the three values  $R_1$  ( $0 \text{ km} \leq R_{ep} \leq 10 \text{ km}$ ),  $R_2$  ( $10 \text{ km} \leq R_{ep} \leq 20 \text{ km}$ ) and  $R_3$  ( $20 \text{ km} \leq R_{ep} \leq 50 \text{ km}$ ). Whereas the soil class show a significant influence on the occurrence of no-activation condition, since 374 out of the 439 cases are obtained for rigid soil condition (soil A), and only the remaining 65 cases are observed for medium soil conditions (soil C), typically characterized by higher values of  $PGA$  (Peak Ground Acceleration) and of spectral acceleration corresponding to the fundamental period of the superstructure.

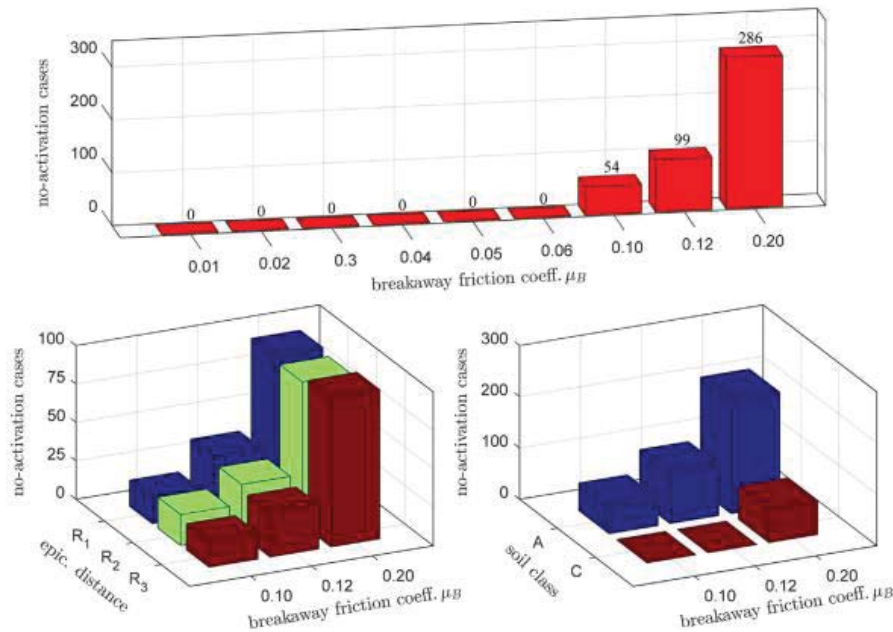

Figure 7: No-activation cases in relationship to the breakaway friction coefficient (top) and sub-analysis depending on the epicentral distance (bottom left) and soil class (bottom right)

The parametric study has also included two values of the mass ratio  $m_b/m_f$ , however the influence of this parameter on the results in terms of  $a_{trigger}$  as well as in terms of the considered seismic response parameters did not show a clear trend, and seems to be marginal at least for the building configurations and seismic excitations considered in this study.

## 4 CONCLUSIONS

The study investigated the influence of the breakaway friction coefficient  $\mu_B$  on the seismic response of base-isolated buildings, by implementing in OpenSees [9] a friction model capable to reproduce the transition between the breakaway friction  $\mu_B$  in the sticking phase and the velocity-dependent friction model in the subsequent sliding phase.

In order to draw the most general conclusions, an extensive parametric study comprising more than 9000 bidirectional NLTHAs has been performed, including three case-study buildings with increasing number of stories (2, 4 and 6), two different mass distributions ( $m_b/m_f = 1.0$  and  $= 2.0$ ), three friction classes (LF, MF and HF) and three breakaway friction classes ( $\mu_B/\mu_{LV} = 1.0, 2.0$  and  $4.0$ ), **Table 1**. For the characterization of the seismic input, two intensity levels of the earthquake excitations, associated to either serviceability SLD or life-safety SLV limit states, two soil characteristics (class A and class C), three epicentral distances ( $R_{ep} = 0\div 10\text{km}$ ,  $10\div 20\text{km}$  and  $20\div 50\text{km}$ ) and two installation sites (Lamezia Terme and Naples) have been considered, thus including 168 spectrum-compatible bidirectional components of ground motion acceleration.

The results showed that in both SLD and SLV conditions, the sliding motion may be delayed by a high breakaway frictional resistance, and the CSSs may persist in the sticking phase for a relatively long part of the ground motion, affecting significantly the seismic response of the superstructure and of the isolation system. In fact, the buildings experienced higher inter-storey drifts *IDRs* and peak floor accelerations *PFA*s, as well as the isolation system engaged significantly higher normalized shear force  $V_{iso}$ , whereas was marginally affected in terms of displacement  $d_{iso}$ .

Especially when the breakaway coefficient is relatively high and the base-isolated structures are subjected to low-to-moderate intensity earthquakes (typical of SLD), the CSSs may persist in the sticking phase over the entire duration of the ground motion. This phenomenon was observed in 439 out of the 9072 NLTHAs included in the parametric study, and the majority (85%) occurred for ground motions relevant to soil class A. It is likely that this occurs because both the *PGA* (Peak Ground Acceleration) and the spectral acceleration corresponding to the fundamental period of the superstructure are higher in the soil class C than in the soil class A.

Although these conclusions are confined to the examined cases, the present work provides some insight into the effects of breakaway friction coefficient on the seismic response of base-isolated buildings, highlighting the necessity to include this parameter in the NLTHAs.

### Abstract

*Supplemental energy dissipation devices are employed both in new and retrofitted constructions in order to prevent structural damage, increase life-safety and achieve a desired level of performance. Among these devices, hysteretic dampers have been proven to be an appropriate and economically affordable solution to reduce the vulnerability of ordinary structures, such as residential, school and industrial buildings. The study presents an experimental and numerical investigation of a Prestressed Lead Extrusion Damper (P-LED), an emerging energy dissipation device which provides energy dissipation by means of the plastic extrusion of lead through an orifice created between a containing tube and a moving shaft and achieves high specific output force by preloading of the working material.*

*The experimental investigation is performed following the provisions set in the European standard EN 15129 for Displacement Dependent Devices. A damper prototype is tested in cyclic tests at different displacement amplitudes and in a monotonic ramp up to the amplified design deformation. The damper shows a rigid-plastic behavior, without strength degradation regardless of the imposed deflection; the shape of the hysteresis loops is essentially rectangular, resulting in an effective damping of 0.55, very close to the maximum theoretical level; the device is able to sustain multiple cycles of motion at the basic design earthquake displacement, anticipating a maintenance-free operation even in presence of repeated ground shakes. A 3D finite element model of the P-LED is formulated in Abaqus and validated upon the results of the experimental tests. The model enlightens that the output force of the damper accounts for two contributions, namely the extrusion force of the lead and the friction force between the lead and the moving shaft. The model is then used in a parametric study to investigate the influence of the device dimensions, namely the diameters of the shaft, of the containing tube and of the bulge, and the length of the shaft, on the output force. The numerical data points are fitted by a simple model which can be used for design of the damper to a specific quasi-static force.*

## 1 INTRODUCTION

Supplemental energy dissipation is employed both in new and retrofitted constructions in order to prevent structural damage, increase life-safety and achieve a desired level of performance ([1],[2]), appearing an appropriate and economically affordable solution to reduce the vulnerability of ordinary structures, such as residential, school and industrial buildings [3]-[6].

Current energy dissipation devices can be classified in two main categories [7]: (i) the so-called fluid viscous dampers, where the dissipation is achieved through the lamination of a viscous fluid forced by a piston to pass through an orifice or a valving system, and whose behavior strictly depends on the fluid velocity; (ii) the hysteretic dampers, which are further classified in hysteretic steel dampers, friction dampers and metal extrusion dampers, depending on the mechanism actually used to dissipate the seismic energy.

Most of the dampers used in residential, school and industrial buildings belong to the hysteretic damper's category ([2],[4],[6],[8] and [9]), whose constitutive law mainly depends on the displacement.

Supplemental energy dissipation is typically implemented by providing the structure with dissipative bracing systems, made of steel braces incorporating dissipation devices [10]. This approach is aimed at achieving two effects, namely increase the structural stiffness, which reduces the structural displacement, and dissipate much of the seismic energy, which reduces the structural acceleration [11].

However, though in principle dissipative braces represent a viable solution to protect any kind of building, they show some drawbacks such as increased internal forces in beams and columns, modification of the building layout, and in case of retrofit, the need of a significant amount of construction work, resulting in heavy disturbance to the occupants [12]. For these reasons, their application is more feasible in new constructions, where the provision of the dissipative braces can be planned since the beginning, rather than for retrofit, because of architectural issues posed by the braces, like interference with the design of the façade and position of the openings [12]. Another issue concerns the fact that the design of dissipative bracing systems is performed respecting the "structural safety requirement" at the Ultimate Limit State only ([2],[10],[13]-[15]); indeed, the devices are designed not to be engaged under normal service loads and weak seismic excitations [12]. Consequently, under small earthquakes, a structure equipped with dissipative braces is subjected to greater accelerations than the bare configuration [5]. Moreover, tests carried out at the University of Basilicata (Italy) [16] have shown that the significant reduction of the frame lateral deformation, brought by the introduction of the hysteretic braces, is counteracted by a huge increase of Peak Floor Accelerations [5]. Similar results were obtained also from the numerical analyses performed by Gandelli et al. [17] on a hospital building equipped with dissipative bracing systems. This phenomenon has detrimental consequences especially to acceleration-sensitive non-structural components [5],[17]. In recent years, some researchers suggested using new kind of systems to control multi-levels of earthquake energy [6], to achieve stable deformation, increase structural ductility, and increase energy dissipation capacity with different stiffnesses [5], [18], [19] and [20].

Moreover, because of low-cycle fatigue and residual stresses of steel dampers, or large permanent deformations of friction and extrusion dampers, after a severe earthquake hysteretic dampers need to be replaced or restated, with consequent costs but also with a potential threat to the safety of the structure, which is left exposed to aftershocks which may occur in the aftermath of the main event.

In conclusion, a more robust form of energy dissipation is needed that satisfies several objectives [21]: (i) more compact and architecturally less invasive design in order to be ideally

located within the beam-column joint region; (ii) should not require maintenance after a major earthquake, in order to guarantee a high safety level and maintain an economical appeal, especially for the retrofitting of conventional buildings; (iii) should not be at risk of low-cycle fatigue bar fracture; (iv) should ensure the re-centering of the structure; and (v) the cost of devices should be economical compared with conventional design solutions.

An emerging energy dissipation device likely to satisfy these conditions is the lead extrusion damper [22], [23], which dissipates energy through the plastic extrusion of lead, forced to flow through an annular restriction (Figure 1) provided either from a constriction of the tube (a), or a bulged shaft (b).

**Figure 1: Longitudinal sections of lead extrusion damper: (a) constricted tube type; (b) bulged shaft type. Adapted from [24]**

Two forces contribute to the overall output force of the device, namely the frictional resistance of the working material against the moving shaft, and the extrusion resistance of the lead that is forced to flow through the annular orifice [25], [26], making the device weakly dependent upon the velocity [27]. A part of the energy is immediately dissipated as heat, which induces softening of the working material and reduces its strength. However, the effect is temporary, because when the device is allowed to cool down, the original value of resistive force is recovered [26]. The other part of the energy is stored in the deformed lead which quickly recrystallizes and regains its original properties, resulting in consistent force across multiple cycles of response without any strain hardening or loss of strength or stiffness [23].

The main drawback of this device is the formation of voids within the working material during extrusion, which is attributed to compression of the lead: as the shaft moves, the material is compressed into a smaller volume leading to the formation of a trailing void [28], causing a decrease of the energy dissipation. For this reason, the lead extrusion dampers used in the first structural applications were quite large, in order to provide sufficient reaction force [22], [23]. Only in the first decade of the 21st century, Rodgers ([28], [29]) proposed an improved version called HF2V (High Force to Volume) where a substantial increase in the specific force was achieved by preloading the working material during the assembly. Increasing the internal pressure of the system reduced the formation of trailing voids and increased the reaction force and the force-to-volume ratio, allowing a more compact design. This device presents an essentially rectangular hysteretic curve, which maximizes the amount of energy dissipation for a given applied force and displacement with a stable and repeatable behavior, an insignificant sensitivity to aging and environment, compact dimensions, and low cost [29]-[31].

The present study deals with the Prestressed Lead Extrusion Damper (P-LED), which achieves high specific output force by preloading of the working material [28]. The performance of the damper is assessed experimentally to verify the compliance to the requirements of the European standard [32]. Then, a finite element model is formulated and used to investigate the influence of the device dimensions on the output force. The numerical data points are

fitted by a simple model which can be used for design of the damper to a specific quasi-static force.

## 2 EXPERIMENTAL INVESTIGATION

### 2.1 Description of the prototype

A bulged-shaft type Prestressed Lead Extrusion Damper has been experimentally investigated in the study. The prototype has four main components, namely the bulged shaft, the tube, the cap and the working material (Figure 2). Tube, shaft and cap are made of structural steel, while the working material is 99.99% pure lead. The shaft is plated with hard chromium (70  $\mu\text{m}$  thickness) in order to minimize friction and wear when sliding through the bushing provided in the cap. The cap is fixed to the tube wall by means of eight screws.

The characteristic dimensions of the device are: shaft diameter  $D_s = 32$  mm; bulge diameter  $D_{blg} = 42$  mm; inner diameter of the tube  $D_{cyl} = 60$  mm; length of shaft in contact with the working material  $D_s = 95$  mm. The design deflection is  $d_{bd} = 20$  mm in either direction (i.e., 40 mm total stroke). To maintain the reaction aligned along the major axis of the device and avoid bending of the shaft, self-lubricating spherical hinges with a minimum rotation capacity of  $\pm 2^\circ$  are provided at both ends of the damper, namely at one end of the shaft and on the bottom of the tube.

During the assembling process, the working material was prestressed to a nominal force of 280 kN (corresponding to an average pressure of 138 MPa on lead) by tightening the screws connecting the cap to the tube wall. Pre-stressing the working material was aimed at increasing the friction between the tube and the shaft and preventing coring out of the lead as the bulge is forced through.

Three thermocouples were inserted into  $\varnothing 5$  mm blind holes drilled in the lateral wall of the containing tube, about 5 mm away from the chamber filled with the working material, in order to measure the temperature rise during the extrusion process.

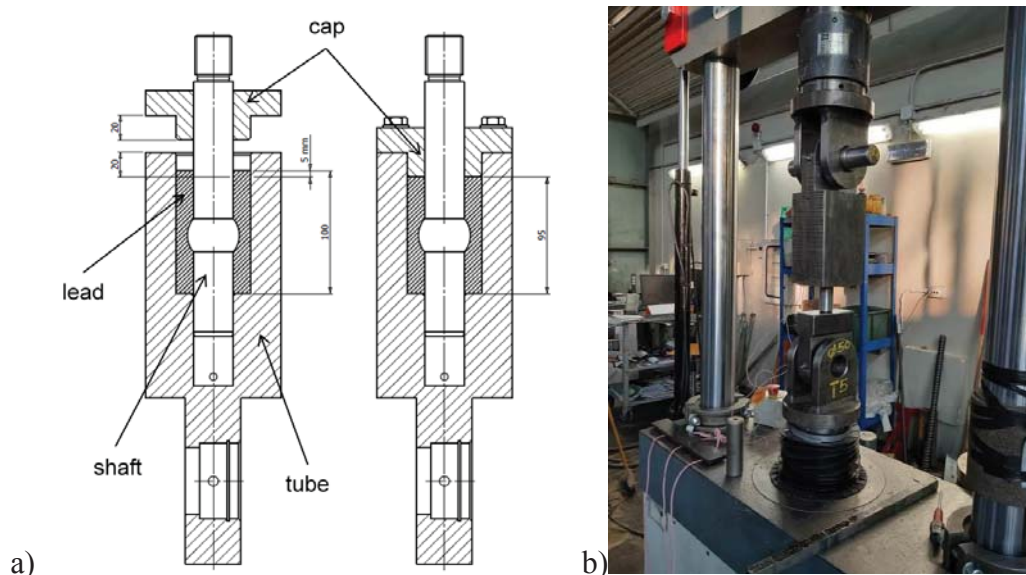

Figure 2: (a) Cross-section of the bulged-shaft P-LED; (b) prototype on the testing machine

### 2.2 Experimental procedure

The experiments were performed at the Materials Testing Laboratory of Politecnico di Milano, using a 500 kN servohydraulic testing machine (MTS Systems, Eden Prairie, MN).

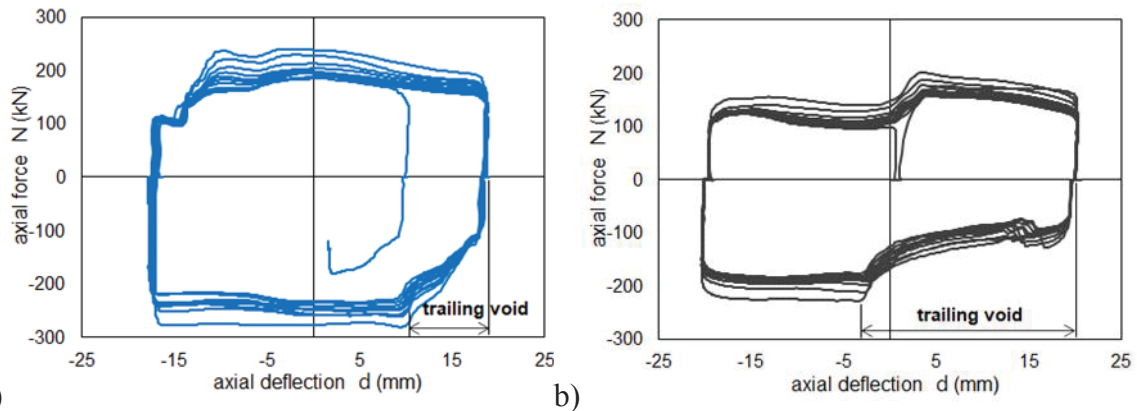

The specimen was subjected to the type testing protocol prescribed in the European standard EN 15129 [32] for assessment of Displacement Dependent Devices, i.e. damping systems whose reaction force depends essentially on the displacement. The hysteretic force-deflection response was evaluated by imposing harmonic cycles of increasing amplitude at 25%, 50% and 100 % of the design deflection  $d_{bd} = 20$  mm, at a loading frequency of 0.5 Hz. Five cycles for each intermediate amplitude and ten cycles for the maximum amplitude were applied. Eventually, a ramp test at 0.1 mm/s rate was performed to the amplified design displacement  $\gamma_b \gamma_x d_{bd} = 26.4$  mm (where  $\gamma_b = 1.1$  and  $\gamma_x = 1.2$  are the amplification factor and the reliability factor given in the standard, respectively), to assess the failure condition under quasi-static condition.

It is here noted that according to the standard the type tests performed on one specimen of a device can be deemed valid also for new models of the device with same geometry, working materials and constraints, provided that the geometrical linear differences between the new and the tested model are less than 20% and the results can be suitably extrapolated to the new device.

In order to assess the recovery of the original output force after cooling of the working material, at the end of the experimental protocol requested by the standard the prototype was left at rest for 45 minutes and then subjected to a second series of 10 cycles to  $d_{bd}$ .

### 3 RESULTS AND DISCUSSION

The force–displacement behavior of the P-LED prototype at the design deflection  $d_{bd} = 20$  mm is shown in Figure 3: in Figure 3(a) the prototype is subjected to the preload of 280 kN to prestress the lead, while in Figure 3(b), the prototype was tested without application of the preload. The hysteresis loops in Figure 3(a) have an almost rectangular shape, but for some “cut-outs” at motion reversals which are attributed to a small trailing void, that occurred in the lead in spite of the initial prestress. However, after the cut-out, the force achieves an essentially constant level, thus maximizing the amount of energy dissipation. From the shape of the hysteresis loop the length of the trailing void created behind the bulge is estimated to be approximately 9 mm over a total stroke of 40 mm. In Figure 3(b), the size of the trailing void increases to about 23 mm, significantly reducing the dissipated energy; also the output force is substantially smaller than in the previous case (e.g., 187 kN vs. 228 kN at the third cycle) due to the lower confinement of lead and the decrease in the extrusion resistance.

**Figure 3: (a) Hysteresis loops of the P-LED prototype preloaded at 280 kN and tested to the design deflection  $d_{bd} = 20$  mm; (b) hysteresis loops of the prototype without prestressing**

The strength of the device declines as the number of cycles proceeds due to heating of lead (Figure 4); the output force  $N_b$  (evaluated as the average force on each branch, after the cut-out) shrinks from 205 kN at the first cycle to 170 kN at the tenth cycle in extension, and from 243 kN to 193 kN in compression. The largest decrease occurs between the first and the third

cycle (-13%), and then the force tends to approach a steady value. It must be here recalled that the temperature reported in the panel in Figure 4 was measured in the steel wall of the tube, about 5 mm away from the lead, and therefore underestimates the actual temperature of the working material.

**Figure 4: Progress of output force (mean value between extension and compression) and temperature within the tube wall vs. number of cycles**

Two quantities are calculated at each cycle and used to characterize the response of the P-LED, namely the effective stiffness  $K_{\text{eff}} = N_b/d_b$  and the effective damping  $\xi_{\text{eff}} = 2A_{\text{cycle}}/(\pi 4 K_{\text{eff}} d_b)$ , where  $N_b$  is the output force of the prototype,  $d_b$  is the maximum cycle deflection and  $A_{\text{cycle}}$  is the area of the hysteresis loop.

The European standard [32] requires that both  $K_{\text{eff}}$  and  $\xi_{\text{eff}}$  remain essentially constant as the cycles proceed <sup>(a)</sup> subscript 3 is relevant to quantities assessed at the third load cycle, and subscript  $i$  is relevant to quantities at the  $i$ -th cycle, excluding the first cycle ( $i \geq 2$ )

Table 1); in particular, except for the first cycle, the difference among the cycles must remain within the 10%.

Requirement <sup>(a)</sup>	Test results		
	$d_b = 5\text{mm}$	$d_b = 10\text{mm}$	$d_b = 20\text{mm}$
$ K_{\text{eff},i} - K_{\text{eff},3}  / K_{\text{eff},3} < 0.10$	0.024	0.035	0.098
$ \xi_{\text{eff},i} - \xi_{\text{eff},3}  / \xi_{\text{eff},3} < 0.10$	0.012	0.046	0.024

<sup>(a)</sup> subscript 3 is relevant to quantities assessed at the third load cycle, and subscript  $i$  is relevant to quantities at the  $i$ -th cycle, excluding the first cycle ( $i \geq 2$ )

**Table 1: Stability requirements for Non Linear devices [32] and results of the tests on the P-LED prototype**

The average value of  $\xi_{\text{eff}}$  evaluated over 10 cycles performed at the design deflection is 0.55, i.e. 86% of the effective damping of an ideally rectangular loop, confirming the good dissipation capacity of the P-LED. After cooling lead recrystallizes and recovers its original properties, thereby providing a reliable and consistent response even in case of multiple loading sequences occurring within short time: after the execution of the experimental program prescribed by the standard, the prototype was left at ambient temperature for 45 minutes and then subjected to a second sequence of cycles at  $d_{b,i}$ ; the stiffness and damping were practically unchanged from the previous sequence, with a -4% difference on  $K_{\text{eff}}$  and 0% on  $\xi_{\text{eff}}$  at the third cycle (curves labelled as “ $d_b = 20\text{ mm}$  (2)” in Figure 5).

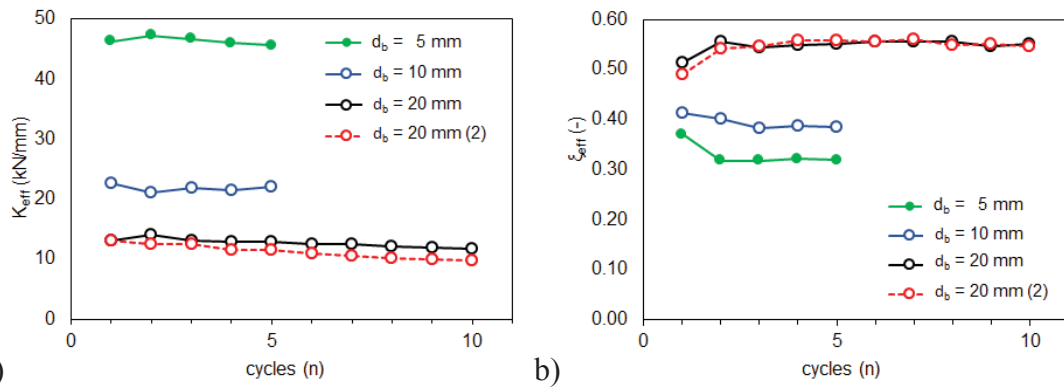

Figure 5: Plots of (a) effective stiffness  $K_{eff}$ , and (b) effective damping  $\xi_{eff}$  of the P-LED vs. number of cycles at different deflection amplitudes  $d_b$

Eventually, in the monotonic ramp test (Figure 6) the prototype was able to sustain the amplified design deflection  $\gamma_x \gamma_{bd} d_{bd}$  without leakage of working material. The force–deflection curves presents an initial peak which is ascribed to the transition from the static to the kinetic friction between lead and shaft [26] and then stabilizes at a constant level, demonstrating the ability to accommodate the prescribed displacement without any damage or deterioration of stiffness.

Figure 6: Force–deflection relationship of P-LED under quasi-static condition

## 4 NUMERICA INVESTIGATION

### 4.1 FE model

A 3D finite element model of the prototype presented in Section 2 was formulated in the general-purpose software Abaqus/CAE 6.14-2 [33], using 4-node bilinear axisymmetric elements type C4X4. By exploiting the symmetry of the system about its longitudinal axis, only half of the prototype is modelled.

The model includes four parts: the shaft, the tube, the plug and the working material (Figure 7). The region of the working material is meshed with fine mesh (maximum size 3.3 mm) along the shaft region where large deformation is expected, in order to allow realistic simulation of lead flow around the shaft (Figure 7(b)), without severe distortion of the elements, which may cause abortion of analysis.

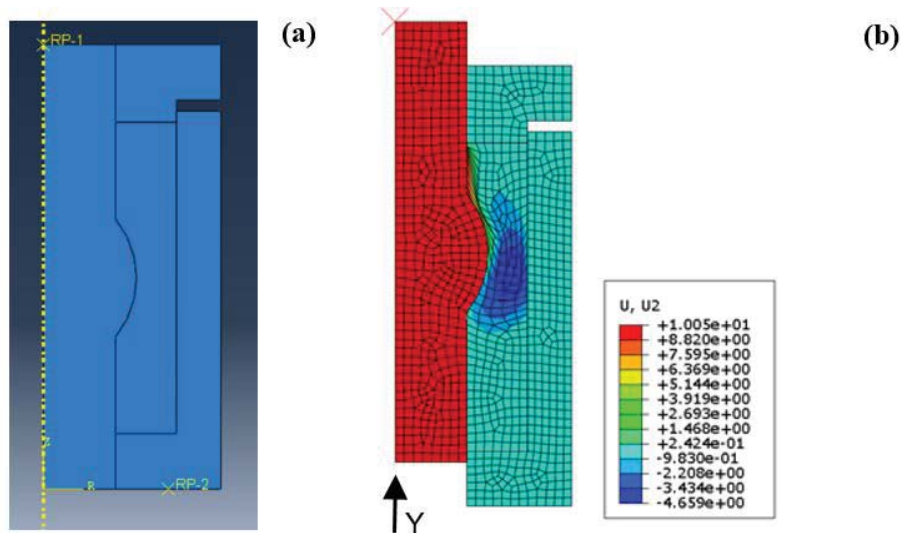

Figure 7: (a) Physical model of P-LED; (b) lead flow through the orifice between bulge and containing tube during motion of the shaft (U2: displacement in Y direction, unit: mm)

Lead is modelled as an elastic-almost perfectly plastic material (a small hardening is introduced in order to avoid convergence issues), and S450 steel is assumed for shaft, tube and cap regions. The modelling parameters of the FE model are as tabulated in Table 2 [34]. Hard contact is introduced at the interface between shaft and tube and between shaft and cap, while hard contact in normal direction, and frictional behavior in shear direction is assumed at the interfaces between lead and shaft and between lead and containing tube, where the coefficient of friction counts  $\mu = 0.15$  and  $\mu = 0.30$  respectively. The analyses are performed in two steps. In the first step, prestressing of the working material is simulated by applying a constant force of 280 kN uniformly distributed on the upper surface of the cap, pressing the cap on the lead. In the second step, dynamic implicit analysis is performed by imposing a cyclic displacement history to the shaft. Three analyses are conducted, with displacement amplitude of 5 mm, 10 mm and 20 mm, respectively.

Properties	Steel		Lead	
E [GPa]	210		16.4	
$\nu$ [-]	0.33		0.44	
$\rho$ [kg/mm <sup>3</sup> ]	$7.85 \times 10^{-6}$		$8 \times 10^{-6}$	
Plastic behavior	Plastic Strain		Stress [MPa]	
	0		450	
	0.2		500	
	0.001		20.5	
	0.002		21.5	
	0.1		22.0	
	0.3		22.5	
			23.0	

$E$ =Young's Modulus [GPa],  $\nu$  = Poisson's Ratio [-],  $\rho$  = density [kg/mm<sup>3</sup>]

Table 2: Material properties used in the FE model

The quasi-static output force vs. deflection curves calculated from the model are compared to the experimental curves evaluated at the third cycle of each test. The agreement between model and experimental data is good in the first and in the third quadrant of the diagram, but some deviation is observed at motion reversals (Figure 8). This is due to the fact that the numerical model does not account for trailing void, i.e. no gap can occur between working material and shaft as the bulge passes through the lead.

Figure 8: Comparison between calculated (NUM) and experimental (EXP) hysteresis loop

#### 4.2 Effect of device dimensions

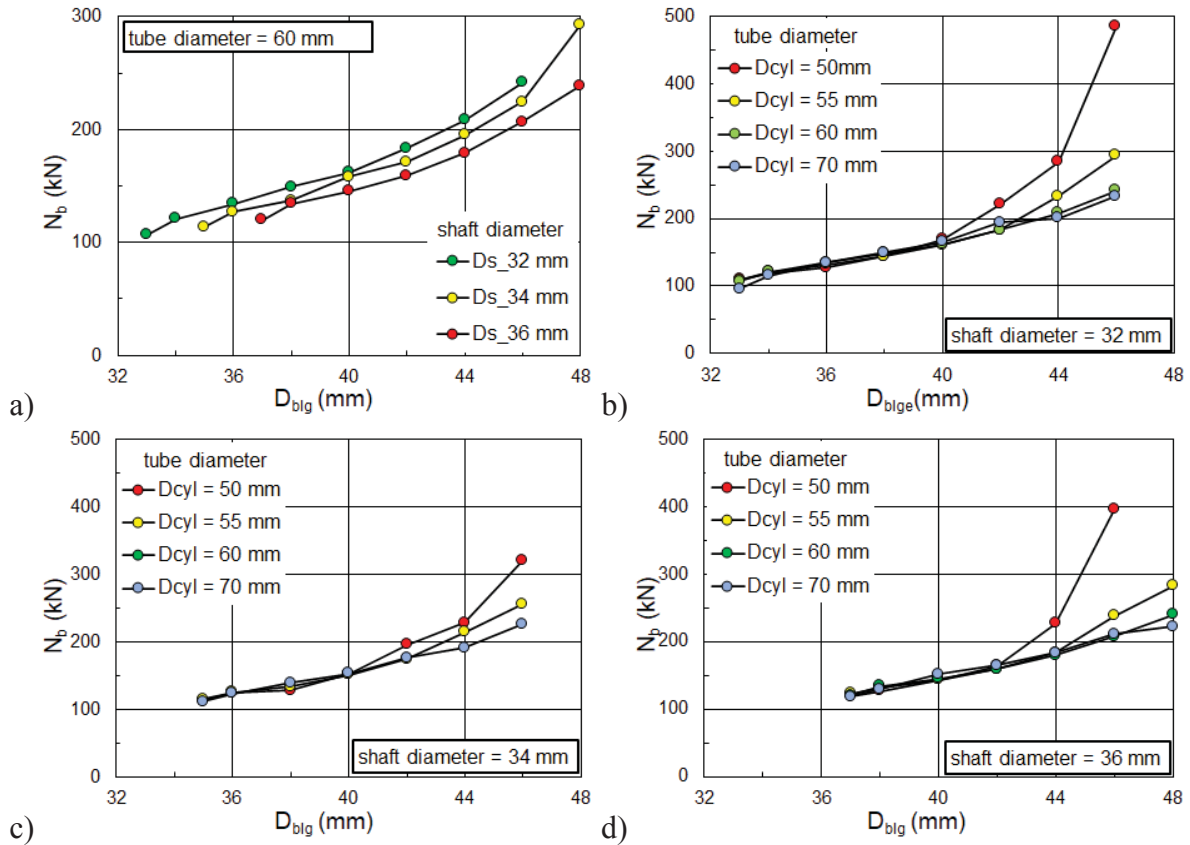

The numerical model is then applied to investigate combinations of a wide range of device dimensions (Table 3), to enable device optimization and further delineate the contributions of friction and extrusion forces to the overall reaction force produced by the device. In each analysis the compressive force on the lead is adjusted to the actual cross-section of the working material in order to provide an average pressure of 138 MPa.

Dimensions [mm]		Values
$D_s$		32 – 34 – 36
$D_{blg}$	33 – 34 – 35 – 37 – 38 – 40 – 42 – 44 – 46	
$D_{cyl}$		50 – 55 – 60 – 70
$L_s$		75 – 95 – 115

$D_s$  = Shaft diameter,  $D_{blg}$  = Bulge diameter,  $D_{cyl}$  = tube diameter,  $L_s$  = shaft length

Table 3: Device dimensions investigated in the study

The importance of either force contribution can be appreciated in Figure 9(a), where the first data point of each plot represents the situation where the extrusion force is negligible ( $D_{blg} \approx D_s$ ), and the output force is essentially provided by the frictional resistance of the prestressed lead on the lateral surface of the moving shaft (the relative velocity on the tube surface is almost null); a larger shaft diameter corresponds to a larger contact area and hence a larger frictional force. In contrast, increasing the bulge diameter  $D_{blg}$  reduces the area of the annular orifice through which lead flows, and thereby increases the extrusion resistance; this contribution is independent of  $D_s$  and becomes more important as  $D_{blg}$  approaches  $D_{cyl}$ . It is worth noting that only for large values of  $D_{blg}$ , i.e.  $D_{blg} > 44$  mm, the contribution from extrusion becomes equal to, or larger than, the frictional resistance. A similar conclusion (i.e. the friction force is a large part of the overall response) was reported in previous studies which compared the response of bulged, constrained and straight (i.e. without bulge) shafts [25], [27]. Figure 9(b), 9(c) and 9(d) show the effect of the tube diameter. When  $D_{blg}$  is small in comparison to  $D_{cyl}$  ( $D_{blg}/D_{cyl} \leq 0.8$ ), the output force is not influenced by the diameter of the tube; in contrast when the gap is small (less than 4 mm in the examined cases) the extrusion resistance has a steep increase, inducing large forces that can eventually lead to structural failure of the rod or the cap screws.

**Figure 9: Influence of device dimensions of P-LED on the quasi-static output force  $N_b$ : (a) influence of shaft diameter  $D_s$  and bulge diameter  $D_{blg}$  for assigned tube diameter  $D_{cyl} = 60$  mm and shaft length  $L_s = 95$  mm; (b) (c) (d) influence of tube diameter  $D_{cyl}$  and bulge diameter  $D_{blg}$  for assigned shaft diameter  $D_s = 32$  mm,  $D_s = 34$  mm, and  $D_s = 36$  mm, respectively**

## 5 CONCLUSIONS

The study investigated the behavior of an emerging energy dissipation device, namely Pre-stressed Lead Extrusion Damper (P-LED). The device provides energy dissipation through the plastic extrusion of lead through an orifice created between a containing tube and a bulged shaft, and achieves high specific output force though preloading of the working material during the assembly.

A prototype of the P-LED was experimentally assessed according to the provisions of the European standard EN 15129 [32] for displacement dependent devices. The damper exhibits a consistent rigid-plastic behavior without strength degradation regardless of the imposed displacement up to the amplified deflection prescribed by the standard. The influence of the rate of deflection is weak over the tested range and can be ignored from a practical point. Cyclic tests were used to evaluate the response of the damper at different displacement amplitudes. Neglecting the effects of trailing voids at motion reversals, the hysteresis loops have an essentially rectangular shape with an equivalent damping ratio of 0.55, close to the maximum theoretical value of 0.63.

The tested specimen is able to sustain multiple sequences of motion at the basic design earthquake displacement, demonstrating its ability to provide maintenance-free operation even in presence of repeated ground shakes. Though a certain softening of the working material is observed due to heating, the changes in stiffness and damping capacity over 10 cycles at the design deflection lie within the  $\pm 10\%$  bound. Besides, the effect of heating is only tem-

porary, and when the damper is cooled down to ambient temperature, the stiffness and damping characteristics return to their original value.

A 3D finite element model of the P-LED device was formulated and validated against the experimental data. The numerical formulation was then used, in a parametric study, to investigate the effect of the device dimensions on the output force. The main parameters determining the response of the P-LED are found to be the annular area of lead around shaft and the projected area of the bulge, which are related to the extrusion force of the working material, and the area of the lateral surface of the shaft, which is proportional to the friction force arising from the relative motion between shaft and lead.

### Abstract

*An ideal antiseismic technology should perform at high efficiency independently from the intensity of the ground shaking. However, traditional bilinear hysteretic dampers (BHDs) are commonly designed for severe ultimate limit state earthquakes resulting in a poor efficiency during weak but frequent events since they are engaged in their elastic region offering negligible damping. This can cause high peak floor accelerations (PFAs) that are detrimental for sensitive non-structural components, like elevators, and electric networks, whose integrity is essential for a prompt operation of the building after the quake. This shortcoming can be improved through a second generation of hysteretic dampers capable to produce different yielding levels based on the intensity of the occurring earthquake. Within this framework, the innovative Adaptive Hysteretic Damper (AHD) is presented in this paper. The results of force-displacement tests carried out on a 2.0MN prototype are argued and prove its robustness and reliability under several repeated cyclic motions. A simple design approach for braced frames implementing the AHDs is eventually proposed and applied to a real case-study building to quantify, through NLTH analyses, the enhanced seismic performances offered by this technology compared to traditional BHDs.*

**Keywords:** Steel Dampers, Adaptive Hysteretic Behavior, Serviceability Limit State, Ultimate Limit State, Non-structural Component.

---

## 1 INTRODUCTION

Among most advanced antiseismic design guidelines, the Eurocode 8 [1], embracing Performance Based Design (PBD) procedures [2], establishes two different seismic scenarios and relevant performance requirements:

- the most severe “Ultimate Limit State” (ULS) scenario features 10% of exceedance probability over the reference period  $V_R=50$  years (i.e. return period  $T_R=475$  years). Under ULS seismic events, the structure shall be capable to withstand the seismic loads without any global or local collapse preserving as well a residual lateral strength after the quake (“structural safety requirement” or “no-collapse requirement”);
- the less intense (but more frequent) “Serviceability Limit State” (SLS) scenario provides 10% of exceedance probability over the reference period  $V_R=10$  years (i.e. return period  $T_R=95$  years). Under SLS seismic events, the structure, besides not suffering any structural damage, shall remain fully operational (“damage limitation requirement”).

In order to meet the second requirement, “acceleration sensitive”, “drift-sensitive”, and “displacement sensitive” non-structural components (NSCs) should be protected against detrimental high peak floor accelerations (PFAs), interstorey-drifts ( $\Delta$ ), and absolute displacements (D) [3-5]. A list of most common NSCs grouped into these categories is given in Table 1. It is worth noting that the integrity of “drift-sensitive” NSCs should not represent a challenging target for structural engineers since usually enveloped, in average terms, by narrower or comparable SLS lateral deflection limits for structural elements. For instance, among weakest NSCs [3-6], curtain and infill walls, are characterized by a higher strength ( $\Delta_{lim}$ ) compared to more critical reinforced concrete columns ( $\Delta_{lim} = 0.75\%$  vs.  $\Delta_{lim} = 0.66\%$ ) [7]. Since characterized by several different layouts, the definition of the damage thresholds for “displacement-sensitive” NSCs often needs the “expert judgment”. However, the fulfillment of these checks can be easily ensured through conventional design approaches that usually aim to control the storeys’ lateral displacements [5]. On the contrary, the assessment of the integrity of “acceleration-sensitive” NSCs is more questionable since based on more complex “floor response spectrum” analyses that require the (rarely available) knowledge of the natural frequency and inherent damping of each NSC [8, 9]. Antiseismic technologies capable to minimize the spectral accelerations over a wide range of NSCs’ oscillation periods represent therefore the best option.

nonstructural components’ categories		
acc. sensitive	drift sensitive	disp. sensitive
false ceilings	infill walls	parapets
elevators	glass windows and doors	storage racks
UPS battery cabinets	pipelines	chimneys
UPS switchboard panels		thermal/seismic joints
UPS distribution panels		

Table 1: Most common “acceleration-sensitive”, “drift-sensitive”, and “displacement-sensitive” NSCs [3-5].

Among modern antiseismic technologies, Hysteretic Dampers (HDs), firstly introduced in the ‘70s of the last century [10], are typically installed in braced frames in order to dissipate the seismic energy through the plastic deformation of sacrificial mild steel components. Their force-displacement (F-d) response is not (or only scarcely) affected by velocity and is conventionally modelled by means of bilinear hysteretic models. Over the last thirty years, HDs ex-

exploiting axial loads, shear loads, bending, and torsion have been developed [11] and world-wide applied for the seismic protection of schools and hospitals [12, 13].

Despite the lower costs compared to other technologies (e.g. fluid viscous dampers), the use of HDs not always represents the best option for the protection of high-technological or strategic buildings [5]. Indeed, a recent experimental study [14] has shown that, on one hand, the introduction of the hysteretic braces allows a significant reduction of the frame lateral deformation, on the other hand, can trigger a huge increase (up to 300%) of PFAs. Enhancements in antiseismic technologies and new approaches based on low-damage methodologies are hence needed [15, 16]. Nevertheless, common methods for the design of new structures, as well as for the retrofit of existing ones, account the “structural safety requirement” at the ULS only [17-19]. In order to improve this unacceptable situation, the innovative Adaptive Hysteretic Damper (AHD), a device capable to modulate its effective damping and stiffness based on the intensity of the occurring earthquake, is presented in this paper. The reliability and robustness of the AHD under multiple excitations, is proven through experimental tests carried out on a full-scale 2.0MN prototype. Linear equivalent mechanical parameters to be exploited in simple response spectrum analyses for the design of braced frames implementing the AHDs are argued hereafter and exemplified through a case-study building. The comparison with the response calculated for the same building protected by conventional bilinear hysteretic dampers allows to claim the following achievements: (a) not impaired structural performance under severe ULS earthquakes; (b) enhanced protection of “acceleration-sensitive” NSCs under weak but frequent SLS events.

## 2 WORKING PRINCIPLE OF THE NEW DAMPER

Among common steel dampers, the Shear Hysteretic Panel (SHP) was the starting point for the development of the novel Adaptive Hysteretic Damper (AHD). The SHP consists of a steel plate with equally spaced openings delimiting a set of dissipative laminae (Fig. 1-left) [20]. The relative motion between the bottom and the upper edge of the SHP induces the shear deformation of the laminae first in the elastic and later in the plastic range (Fig.1-center) resulting in a typical bilinear hysteretic response (Fig.1-right). Despite SHPs exhibit a considerable energy absorption capacity and lateral stiffness even under small drift angles ( $\gamma_L = d/L$ ), that makes them very suitable for braced frames, their widespread application has been so far constrained by their unsatisfactory strength against out of plane loads (buckling).

Figure 1: SHP damper: undeformed configuration (left), deformed configuration (centre), and typical bilinear F-d response (right).

The main novelties introduced by the AHD are shown in Fig. 2:

- the three-dimensional “hollow-section” arrangement of multiple laminae with an optimized “hourglass-shape” to form a dissipative core (the orange color element in Fig. 2-

left) capable to withstand high drift angles (hence displacement amplitudes) and overcome buckling problems. The clockwise alternated transmission of tension and compression loads at the corners of the core engages the shear deformation of the laminae;

- the “in series connection” between a minor (D1, green element) and a major (D2, orange element) dissipative core (Fig. 2-left) allows the development of an innovative “two-stages” hysteretic behavior (Fig. 2-right). The different yielding strengths of the minor ( $F_{y,D1}$ ) and major ( $F_{y,D2} > F_{y,D1}$ ) hysteretic cores are obtained by varying the number and/or the geometry of the hysteretic laminae. Two connection plates (CP) are used to link the dissipative cores to the main structural frame while a plate featuring a slotted hole, hereafter referred as “GAP-element”, is introduced to mutually link the two dissipative cores. This connector acts as a very stiff end-stroke stopper that: (a) during minor SLS earthquakes, allows the exclusive plastic engagement of the minor core; (b) during severe ULS events, enforces the activation of the major dissipative core to achieve higher levels of effective stiffness and equivalent damping.

Figure 2: Adaptive Hysteretic Damper: device assembly (left) and innovative “two-stages” hysteretic loop (right).

Assuming that both the CP and the GAP elements offer very stiff elastic reactions ( $k_{el} \rightarrow +\infty$ ) even during the most severe design loads, the F-d backbone curve of the AHD (Fig. 3-left) can be described through an analytical model that depend on the following parameters only: (a) yielding force of the minor ( $F_{y,D1}$ ) and major ( $F_{y,D2}$ ) core; (b) elastic stiffness of the minor ( $k_{el,D1}$ ) and major ( $k_{el,D2} > k_{el,D1}$ ) core; (c) plastic stiffness of the minor ( $k_{pl,D1}$ ) and major ( $k_{pl,D2} > k_{pl,D1}$ ) core; (d) width of the slotted hole of the gap-connector ( $d_G$ ). Four different displacement fields can be distinguished:

- field A ( $d_{max} \leq d_{y,1}$ ): both D1 and D2 operate in their elastic regime ( $d_{y,1}$  denotes the yielding displacement of the minor core). The device reacts as a soft spring to SLS static and dynamic loads;
- field B ( $d_{y,1} < d_{max} \leq d_{ES}$ ): D1 is deformed in its plastic field while D2 still reacts in the elastic region ( $d_{ES} > d_G$  represents the displacement amplitude at the attainment of the contact in the gap-connector element). The device offers a minor effective stiffness and a certain damping level in order to minimize the effects of frequent SLS earthquakes;
- field C ( $d_{ES} < d_{max} \leq d_{y,2}$ ): the attained “contact condition” in the gap-element prevents any further deformation of D1 while, on the contrary, entrusts the incremental loads to D2 that is still reacting in its elastic regime ( $d_{y,2}$  denotes the yielding displacement of the minor core);

- field D ( $d_{y,2} < d_{max} \leq d_u$ ): the gap-element is still effective and D2 is eventually deformed in its plastic field maximizing the energy dissipation capacity of the damper and providing a higher effective stiffness in order to minimize the structural damages under strong ULS earthquakes.

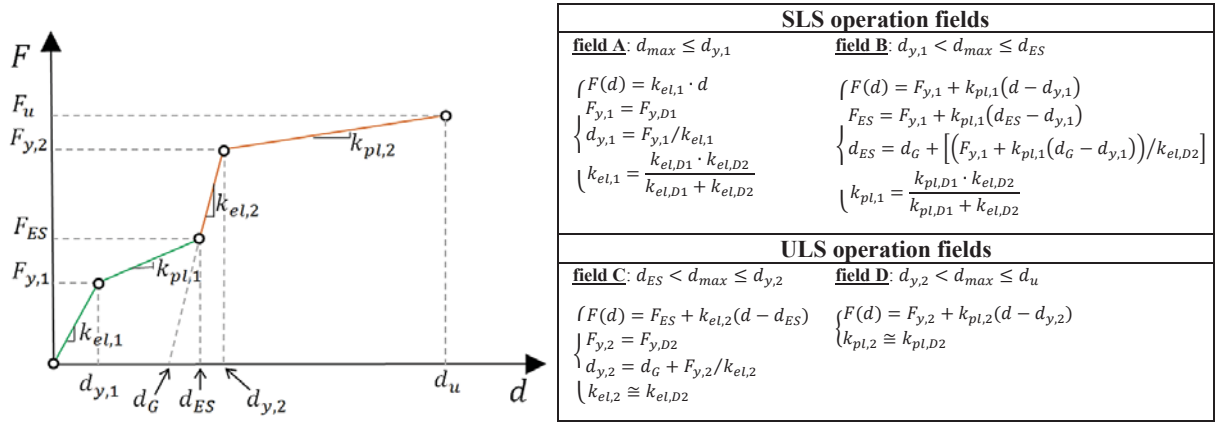

Figure 3: Force-displacement response of the AHD: backbone trend (left) and relevant analytical model (right).

### 3 EXPERIMENTAL TESTS

The force-displacement response of the AHD was assessed in displacement-controlled tests carried out at the Eucentre Lab. (Pavia, Italy) [21] on a full-scale prototype made of structural steel S355 and characterized by: (1) minor hysteretic core featuring  $F_{y,D1} = 450\text{kN}$ ,  $k_{el,D1} = 80\text{kN/mm}$ ,  $k_{pl,D1} = 6.0\text{kN/mm}$  (2) width of the hole in the gap-connector  $d_G = \pm 15\text{mm}$ ; (3) major hysteretic core featuring  $F_{y,D2} = 1350\text{kN}$ ,  $k_{el,D2} = 240\text{kN/mm}$ ,  $k_{pl,D2} = 18.0\text{kN/mm}$ .

According to the European Standard EN15129 (§ 6.2) [22], the testing protocol (Table 2) provided four runs with increasing displacement amplitudes equal to 25%, 50%, 100%, and 132% of the ULS design displacement ( $d_{bd}$ ), respectively. In particular, the first two runs provides “only” 5 cycles and are conceived to assess the response the device for low and medium intensity earthquakes, while the third run (10 cycles at 100% of  $d_{bd}$ ) is exploited to assess the degradation of the offered effective stiffness and damping due to low-cycle fatigue under severe ULS earthquakes. Eventually, in the last run, usually known as “displacement-capacity” test, the robustness of the damper is verified at the overload displacement  $d_{cd}$  obtained amplifying  $d_{bd}$  by a reliability ( $\gamma_x = 1.1$ ) and a safety ( $\gamma_b = 1.2$ ) factor [1].

run	ampl. (mm)	vel. (mm/s)	shape	cycles	notes
1	$\pm 16.3$	10	triangular	5	$= 0.25 \cdot d_{bd}$
2	$\pm 32.5$	10	triangular	5	$= 0.50 \cdot d_{bd}$
3	$\pm 65.0$	10	triangular	10	$= 1.00 \cdot d_{bd}$
4	$\pm 86.0$	10	triangular	1	$= 1.32 \cdot d_{bd}$

Table 2: Testing protocol.

During the tests, the deformations of the AHD were recorded through an electronic displacement transducer (LVDT) while instantaneous values of axial load by means of the load

cell of the testing machine. In this regard, Fig. 4 depicts the device in its maximum compression and elongation configurations (achieved during the “displacement-capacity” test) and Fig. 5 shows the recorded experimental loops (overlapped with the analytical backbone curve). The following results can be appreciated:

- a stable response of the AHD during runs No. 1-3. In particular, since the recorded loops of each run are practically overlapped, in agreement with the requirement of the EN 15129, both the energy dissipated per cycle ( $EDC$ ) and the effective stiffness ( $k_{eff}$ ) of the device did not degrade more than 10% due to the low-cycle fatigue;
- the absence of sudden stiffness-drops at max/min displacement amplitudes of run no. 4 witnessing the capability of the device to withstand even higher loads/deformations;
- a fair agreement between the analytical F-d backbone plot (red-dashed lines obtained through the Equations in the panel of Fig. 3) and the experimental data.

Figure 4: Maximum compression (top) and elongation (bottom) configurations reached by the AHD during run4.

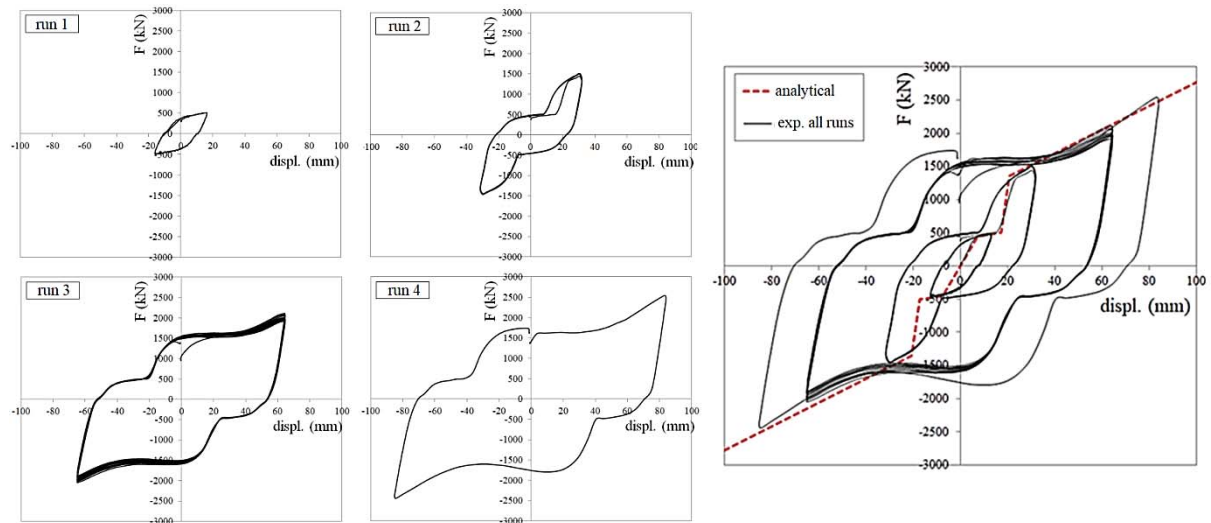

Figure 5: Recorded experimental loops.

#### 4 DESIGN OF BRACED FRAMES THROUGH SPECTRAL ANALYSIS

A recent study [23] has proven that the dynamic response, both in terms of maximum displacement and peak acceleration at roof level, of a multi-storey frame implementing the novel AHDs, can be predicted by means of simple iterative response spectrum analyses, where both the bare frame and the dissipative braces are schematized by means of linear equivalent SDOF systems. The basic assumption of this calculation method is the “a-priori knowledge” of the structural properties of the bare frame. This is always typical of retrofit-projects while for new buildings can be achieved through a preliminary design of the bare frame (e.g. accounting for the gravitational loads only). A modal analysis is hence performed to assess the participation factor  $\Gamma = m^*/\sum m_i\phi_i^2$  and the participating mass  $m^* = \sum m_i\phi_i$  of the fundamental mode shape. The lateral capacity of the bare frame is also appraised through nonlinear static (pushover) analyses under constant gravity loads and monotonically increasing horizontal loads (Fig. 6-left). Two distributions of lateral loads are considered, namely a “modal” pattern (resembling a triangular height-wise profile) and an “uniform” pattern as per EC8 provisions [1]. Among the two obtained capacity curves (base-shear  $F$  versus control-point displacement  $d$ ), the one associated to lowest strength is then processed (Fig. 6-right) in accordance with Annex B of EC8 [1]. The pushover curve ( $F; d$ ) of the MDOF system is then scaled by the modal participation factor  $\Gamma$  to obtain the capacity curve  $F^*-d^*$  of the equivalent single-degree-of-freedom (SDOF) system ( $F^* = \frac{F}{\Gamma}; d^* = \frac{d}{\Gamma}$ ). For clarity, hereinafter the quantities with superscript “\*” will refer to equivalent SDOF systems, and quantities devoid of suffix will refer to real MDOF systems. The yield force  $F_{y,F}^*$ , yield  $d_{y,F}^*$ , and ultimate displacement  $d_{u,F}^*$  (where subscript “F” stands for “frame”) are determined under the equal energy criterion assuming an ideal elastic-perfectly plastic force-displacement relationship.

Figure 6: Qualitative representation of a pushover analysis (left) and definition of equivalent elastic-perfectly plastic SDOF system of the bare-frame (right).

Given a certain displacement demand ( $d_{max}^*$ ) of the seismic motion, the effective stiffness ( $k_{eff,F}^*$ ), and ductility demand ( $\mu_F^*$ ) of the bare frame are calculated as:

$$k_{eff,F}^* = \begin{cases} k_{el,F}^* = F_{y,F}^*/d_{y,F}^* & d_{max}^* \leq d_{y,F}^* \\ F_{y,F}^*/d_{max}^* & d_{y,F}^* < d_{max}^* \leq d_{u,F}^* \end{cases} \quad (1-a,b)$$

$$\mu_F^* = \begin{cases} 1 & d_{max}^* \leq d_{y,F}^* \\ d_{max}^*/d_{y,F}^* & d_{y,F}^* < d_{max}^* \leq d_{u,F}^* \end{cases} \quad (2-a,b)$$

In particular, it has been recently proven [23] that the design parameters of the AHD can be iteratively adjusted in order to achieve a desired displacement target at ULS ( $d_{targ,ULS}^*$ ) selected between two possible ranges: (1)  $d_{targ,ULS}^* \leq d_{y,F}^*$  when the goal is to maintain the frame in the elastic range; (2)  $d_{y,F}^* < d_{targ,ULS}^* < d_{u,F}^*$  when a certain level of plasticization of frame can be accepted.

The spectral analysis is then carried out approximating the response of the braced frame through two linear equivalent SDOF systems working in parallel (Fig. 7-left) and accounting for the frame ( $F^*$ ) and the damper ( $D^*$ ) responses. The effective vibration period of the braced frame ( $T_{eff,F+D}^*$ ) is conventionally calculated as:

$$T_{eff,F+D}^* = 2\pi \sqrt{\frac{m^*}{(k_{eff,F}^* + k_{eff,D}^*)}} \quad (3)$$

where  $k_{eff,D}^*$  is the effective lateral stiffness of the AHD (whose definition is given in next Section).

Adapting the original formulations for “in parallel damping mechanisms” [24], the equivalent viscous damping of the braced frame ( $\xi_{eq,F+D}^*$ ) can be calculated through the following weighted average [25]:

$$\xi_{eq,F+D}^* = \xi_{el,F}^* + \frac{\xi_{eq,F}^* E_{cum,F}^* + \xi_{eq,D}^* E_{cum,D}^*}{E_{cum,F}^* + E_{cum,D}^*} \quad (4)$$

being: (a)  $\xi_{el,F}^*$  the viscous damping offered by the frame in the elastic range (typically 5% and 2% for r.c. or steel structures, respectively); (b)  $E_{cum,F}^*$  and  $E_{cum,D}^*$  the energy dissipated by the frame and the AHD, respectively.

The estimation of the equivalent viscous damping ( $\xi_{eq,D}^*$ ) developed by the AHD is argued in the next Section while the one offered by frame ( $\xi_{eq,F}^*$ ) is calculated as [26]:

$$\xi_{eq,F}^* = \frac{a}{\pi} \cdot \left(1 - \frac{1}{\mu_F^b}\right) \cdot \left(1 + \frac{1}{(T_{eff,F+D}^* + c)^d}\right) \cdot \frac{1}{N} \quad (5)$$

being: (a)  $N = 1 + [1/(0.5 + c)^d]$ ; (b)  $a = 140$ ,  $b = 0.5$ ,  $c = 0.85$ ,  $d = 2$ .

For a generic set of AHD design parameters, i.e.  $i^{th}$  couple of parameters ( $T_{eff,F+D}^*, \xi_{eq,F+D}^*$ )<sup>(i)</sup>, the peak displacement of the braced frame is obtained by reducing the elastic (viscous damping 5%) spectral displacement ( $S_{d,ULS}(T_{eff,F+D}^*, 5\%)$ ) through the spectral reduction factor ( $\eta$ ) proposed in [24]:

$$\begin{cases} S_{d,ULS}(T_{eff,F+D}^*, \xi_{eq,F+D}^*)^{(i)} = \frac{1}{\eta^{(i)}} \cdot S_{d,ULS}(T_{eff,F+D}^*, 5\%) \\ \eta^{(i)} = \sqrt{7/(2 + \xi_{eq,F+D}^*)^{(i)}} \end{cases} \quad (6-a,b)$$

The mechanical parameters of the AHD ( $F_{y,D1}^*, F_{y,D2}^*, k_{el,D1}^*, k_{pl,D1}^*, k_{el,D2}^*, k_{pl,D2}^*, d_G^*$ ) are hence iteratively varied (Fig. 7, right) until the spectral displacement of the braced frame converges to the design target ( $|S_{d,ULS}(T_{eff,F+D}^*, \xi_{eq,F+D}^*)^{(i)} - d_{targ,ULS}^*| \leq tol$ , being  $tol$  a small enough tolerance parameter (e.g.  $tol = 0.01 \cdot d_{targ,ULS}^*$ ).

Since the iterative design process could seem not trivial (seven variable parameters), some “good practice” criteria that guide designers and practitioners to a fast identification of the optimal layout of the AHD are provided in Section 4.2. Moreover, in Section 5, specific rules for the spatial distribution of the AHD units at the different storey levels of the MDOF frame are also provided and applied to a real case-study building.

Figure 7: Proposed calculation method: rheological model (left) and iterative response spectrum analyses (right).

#### 4.1. Linear equivalent properties of the AHD

According to a good design practice, it is assumed hereafter that beam elements used to link the AHDs to the bare frame are very stiff and hence, even under severe earthquakes, undergo negligible elastic deformations without affecting the effective stiffness offered by the dampers [23]. Otherwise, a simple approach to account for the flexibility of link elements can be found in [19].

The effective stiffness provided by the AHD ( $k_{eff,D}^*$ ) reflects the “two-steps” hysteretic behaviour of the device (see Fig. 8) and, depending on the displacement demand ( $d_{max}^*$ ) and strength demand ( $F_{max}^*$ ) of the occurring earthquake (i.e. SLS or ULS), can be calculated as:

$$k_{eff,D}^* = \begin{cases} \frac{F_{y,1}^* + k_{pl,1}^* (d_{max}^* - d_{y,1}^*)}{d_{max}^*} & d_{max}^* \leq d_{ES}^* \text{ (at SLS)} \\ \frac{F_{ES}^* d_{ES}^* + F_{max}^* (d_{max}^* - d_{ES}^*)}{d_{max}^{*2}} & d_{max}^* \geq d_{y2}^* \text{ (at ULS)} \end{cases} \quad (7-a,b)$$

It is worth noting that, embracing the approach proposed in a recent study in [25], Eq. 7-b can be obtained equalizing the total elastic energy stored in the minor and major dissipative cores to the elastic energy stored in a virtually equivalent linear spring ( $E_{e,D}^* = E_{e,D1}^* + E_{e,D2}^*$ ):

$$\frac{1}{2} k_{eff,D}^* d_{max}^{*2} = \frac{1}{2} F_{ES}^* d_{ES}^* + \frac{1}{2} F_{max}^* (d_{max}^* - d_{ES}^*) \quad (8)$$

One can note that Eq. 8 alternatively means that the sum of the two blue shaded areas shown in Fig. 8-right is equal to the grey shaded one.

Despite an apparently simple “in series” arrangement of the two hysteretic cores, the effective damping offered by the AHD obeys to slightly more complex rules. Indeed, during minor SLS earthquakes ( $d_{max}^* \leq d_{ES}^*$ ), only the minor core (D1) is plastically engaged providing a certain energy dissipation (ductility level  $\mu_{D1}^* > 1$ ) while the major (D2) acts as a non-dissipative link ( $\mu_{D2}^* = 1$ ). On the contrary, under more demanding ULS displacements ( $d_{max}^* > d_{y2}^*$ ), the major core is activated experiencing a certain ductility demand ( $\mu_{D2}^* > 1$ )

while the deformation of the minor core is freezed at the maximum level allowed by the gap-connector ( $\mu_{D1}^* = d_{ES}^*/d_{y,1}^*$ ):

$$\mu_{D1}^* = \begin{cases} 1 & d_{max}^* \leq d_{y,1}^* \\ d_{max}^*/d_{y,1}^* & d_{y,1}^* < d_{max}^* \leq d_{ES}^* \\ d_{ES}^*/d_{y,1}^* & d_{max}^* > d_{ES}^* \end{cases} \quad (9-a \div c)$$

$$\mu_{D2}^* = \begin{cases} 1 & d_{max}^* \leq d_{y,2}^* \\ \frac{(d_{max}^* - d_G^*)}{(d_{y,2}^* - d_G^*)} & d_{max}^* > d_{y,2}^* \end{cases} \quad (10-a, b)$$

The equivalent viscous damping offered by the minor ( $\xi_{eq,D1}^*$ ) and major ( $\xi_{eq,D2}^*$ ) dissipative cores are calculated by means of the formulation proposed in [26] for bilinear hysteretic systems:

$$\xi_{eq,D(i)}^* = \frac{a}{\pi} \cdot \left( 1 - \frac{1}{\mu_{D(i)}^*{}^b} - 0.1 \cdot r_{(i)} \cdot \mu_{D(i)}^* \right) \cdot \left( 1 + \frac{1}{(T_{eff,F+D}^* + c)^d} \right) \cdot \frac{1}{N} \quad (11)$$

where: (a) the subscript "(i)" refers to the minor ( $i = 1$ ) or major ( $i = 2$ ) core, alternatively; (b)  $N = 1 + [1/(0.5 + c)^d]$ ; (c)  $a = 140$ ,  $b = 0.5$ ,  $c = 0.85$ ,  $d = 2$ ; (d)  $\mu_{Di}^*$  and  $r_i = k_{pl,Di}^*/k_{el,Di}^*$  are the ductility demand and hardening ratio, respectively.

Eventually, the overall equivalent viscous damping offered by the damper ( $\xi_{eq,D}^*$ ) is calculated through this weighted average [25]:

$$\xi_{eq,D}^* = \frac{\xi_{eq,D1}^* \cdot E_{cum,D1}^* + \xi_{eq,D2}^* \cdot E_{cum,D2}^*}{E_{cum,D1}^* + E_{cum,D2}^*} \quad (12)$$

being  $E_{cum,D1}^*$  and  $E_{cum,D2}^*$  the energy dissipated by the minor and major hysteretic core (Fig. 9), respectively.

Figure 8: Definition of the damper effective stiffness for minor SLS displacements (left,  $d_{max}^* \leq d_{ES}^*$ ), and severe ULS displacements (right,  $d_{max}^* \geq d_{y,2}^*$ ).

Figure 9: Definition of the energy dissipated by the two hysteretic cores for minor SLS displacements (left,  $d_{max}^* \leq d_{ES}^*$ ), and severe ULS displacements (right,  $d_{max}^* \geq d_{y,2}^*$ ).

#### 4.2. Simplified set of AHD design parameters

Due to the large number (seven) of the AHD design parameters ( $F_{y,D1}^*$ ,  $F_{y,D2}^*$ ,  $k_{el,D1}^*$ ,  $k_{el,D2}^*$ ,  $k_{pl,D1}^*$ ,  $k_{pl,D2}^*$ , and  $d_G^*$ ), the definition of the optimal damper layout could seem not easy. To overcome this issue, some criteria to simplify/reduce the variable parameters are provided hereafter. Within this framework, the ratios  $\alpha_F$ ,  $\alpha_k$ , and  $r$  are introduced to link the design parameters of the two hysteretic cores and those of the bare frame [23]:

$$\begin{cases} \alpha_F = F_{y,D1}^*/F_{y,D2}^* \\ \alpha_k = k_{el,D1}^*/k_{el,F}^* \\ r = k_{pl,D1}^*/k_{el,D1}^* = k_{pl,D2}^*/k_{el,D2}^* \end{cases} \quad (13-a \div c)$$

In particular, at designer's discretion,  $\alpha_k$  and  $r$  can be selected within the ranges ( $\alpha_F = 0.3 - 0.6$ ,  $\alpha_k = 2 - 15$ , and  $r = 0.01 - 0.10$ ) suggested in [23] leading to:

$$\begin{cases} F_{y,D1}^* = \alpha_F \cdot F_{y,D2}^* \\ k_{el,D1}^* = \alpha_k \cdot k_{el,F}^* \\ k_{el,D2}^* = (\alpha_k/\alpha_F) \cdot k_{el,F}^* \\ k_{pl,D1}^* = r \cdot \alpha_k \cdot k_{el,F}^* \\ k_{pl,D2}^* = r \cdot (\alpha_k/\alpha_F) \cdot k_{el,F}^* \end{cases} \quad (14-a \div e)$$

Moreover, accomplishing to the “adaptive working principle” of the AHD providing the exclusive engagement of the minor (D1) core during weak SLS events, a suitable criterion for the selection of the width ( $d_G^*$ ) of the gap-connector is [23]:

$$d_G^* = \gamma_x \cdot \gamma_b \cdot S_{d,SLS}(T_{eff,F+D}^*, \xi_{eq,F+D}^*) \quad (15)$$

being: (a)  $S_{d,SLS}(T_{eff,F+D}^*, \xi_{eq,F+D}^*)$  the spectral displacement calculated at SLS; (b)  $\gamma_x = 1.1$ , and  $\gamma_b = 1.2$  a reliability and a safety factor, respectively [1].

The “good practice” design assumptions described in this Section allow to reduce the number of variable parameters to the couple ( $F_{y,D2}^*$ ;  $\alpha_F$ ) leading to a fast identification of most suitable AHD layout.

## 5 A CASE-STUDY

In this Section, a seismic retrofit intervention of the “Piastra building” of the hospital complex of Lamezia Terme, a small city located in southern Italy, is designed through the previously proposed iterative spectral analysis. The beneficial effects offered by the AHDs, compared to traditional bilinear hysteretic dampers (BHDs), are discussed and quantified. For sake of simplicity, only the longitudinal frame of the “block C” is considered hereafter (Fig. 10-a). This building, erected in the early 70's, features a quite flexible r.c. frame (fundamental period equal to 1.06s) and would not be capable to survive the ULS design earthquake [4].

The reference retrofitting solution through conventional BHDs has been already proposed elsewhere [5]. In the same study, the characteristic parameters of both the real MDOF and the equivalent SDOF system of the bare frame are provided (Table 3).

The new retrofitting solution provides the replacement of the traditional BHDs with the innovative AHDs designed to ensure an unaltered degree of structural protection under severe ULS events, and offer an enhanced seismic response to minor SLS earthquakes. In this regard, according to the provisions of the Italian Building code [27], a severe “SLV” (ULS level) and a weak “SLO” (SLS level) design spectrum, featuring respectively  $PGA=0.45g$  and  $PGA=0.17g$ , were defined considering a topographic category T1, a nominal life of the building  $V_N = 100years$  (corresponding to a reference period  $V_R = c_u \cdot V_N = 200years$ ), and foundation-soil type B.

By analogy with the design-assumption of traditional BHDs [5], the ULS displacement target of the new retrofit-project is set to  $d_{targ,ULS} = 50mm$  ( $d_{targ,ULS}^* = d_{targ,ULS}/\Gamma = 36.8mm$ ) in order to maintain the frame in the elastic field and avoid the hammering with the adjacent “block B”. Besides this target, thanks to the iterative spectral procedure and the design criteria provided in the previous Section, the following set of AHD design parameters is detected to ensure minimal spectral accelerations under weak but frequent SLS earthquakes [23]:  $F_{y,D2}^* = 7300kN$ ,  $\alpha_F = 0.38$ ,  $\alpha_k = 15$ ,  $r = 0.075$ , and  $d_G^* = 14mm$ . The relevant effective period and equivalent viscous damping of the braced frame are: (i) at ULS design level,  $T_{eff,F+D}^* = 0.53s$ , and  $\xi_{eq,F+D}^* = 29.2\%$ ; (ii) at SLS design level,  $T_{eff,F+D}^* = 0.46s$ , and  $\xi_{eq,F+D}^* = 23.7\%$ . The (equivalent SDOF) design parameters of the selected AHD layout and those of the original BHD [5] are compared in Table 4.

Table 4: Design parameters of the selected AHD compared to those of the traditional BHD (eq. SDOF systems).

Once defined the design parameters of the equivalent SDOF of the AHD, the the yielding force of the minor ( $F_{y,D1,i}$ ) and major ( $F_{y,D2,i}$ ) cores of the physical AHD devices installed at the  $i^{\text{th}}$  storey of the real MDOF frame are sized through this rule [23]:

$$\begin{cases} F_{y,D1,i} = \left( \frac{F_{y,F,i}}{F_{y,F}^*} \right) \left( \frac{F_{y,D1}^*}{n_{AHD,i} \cdot \cos \vartheta_i} \right) \\ F_{y,D2,i} = \left( \frac{F_{y,F,i}}{F_{y,F}^*} \right) \left( \frac{F_{y,D2}^*}{n_{AHD,i} \cdot \cos \vartheta_i} \right) \end{cases} \quad (16\text{-a,b})$$

and similarly for the elastic stiffness of the two cores:

$$\begin{cases} k_{el,D1,i} = \left( \frac{k_{el,F,i}}{k_{el,F}^*} \right) \left( \frac{k_{el,D1}^*}{n_{AHD,i} \cdot \cos^2 \vartheta_i} \right) \\ k_{el,D2,i} = \left( \frac{k_{el,F,i}}{k_{el,F}^*} \right) \left( \frac{k_{el,D2}^*}{n_{AHD,i} \cdot \cos^2 \vartheta_i} \right) \end{cases} \quad (17\text{-a,b})$$

resulting in the following plastic stiffnesses:

$$\begin{cases} k_{pl,D1,i} = r \cdot k_{el,D1,i} \\ k_{pl,D2,i} = r \cdot k_{el,D2,i} \end{cases} \quad (18\text{-a,b})$$

being: (a)  $F_{y,F,i}$  and  $k_{el,F,i}$  the overall lateral yielding-strength and elastic stiffness of the columns at the  $i^{\text{th}}$  storey level [19], respectively; (b)  $n_{AHD,i}$  the number of AHD units installed at the same level; (c)  $\vartheta_i$  the inclination angle of the dissipative braces (Fig. 10,b).

The “storey-distribution” of  $d_{GAP}^*$  among the AHD units installed at the different storey levels is assumed to reflect the fundamental mode shape [23]:

$$d_{G,i} = \Gamma_{\phi_1} \cdot (\phi_{1,i} - \phi_{1,i-1}) \cdot d_{GAP}^* \cdot \cos \vartheta_i \quad (19)$$

The complete set of design parameters of the real AHD units installed along the diagonal braces of each storey level are listed in Table 5.

The effectiveness of the new retrofitting solution is proven through NLTH analyses carried out in OpenSees FEM code [28] developing a specific modelling strategy for the AHD units [23]. Two sets of seven ground motion records (Fig. 11), one for the SLS and one for the ULS design spectrum, were identified by means of the software REXEL [29] enforcing the “spectrum compatibility” criterion in the range [0.15-2.0s]. According to the reference Standard [27], the structural integrity of the frame is checked at ULS and the serviceability of the hospital at SLS considering the average response over the seven independent history analyses.

level	$n_{\text{AHD},i}$ (-)	$\theta_i$ (°)	$F_{y,D1,i}$ (kN)	$F_{y,D2,i}$ (kN)	$k_{el,D1,i}$ (kN/mm)	$k_{el,D2,i}$ (kN/mm)	$r$ (%)	$d_{G,i}$ (mm)

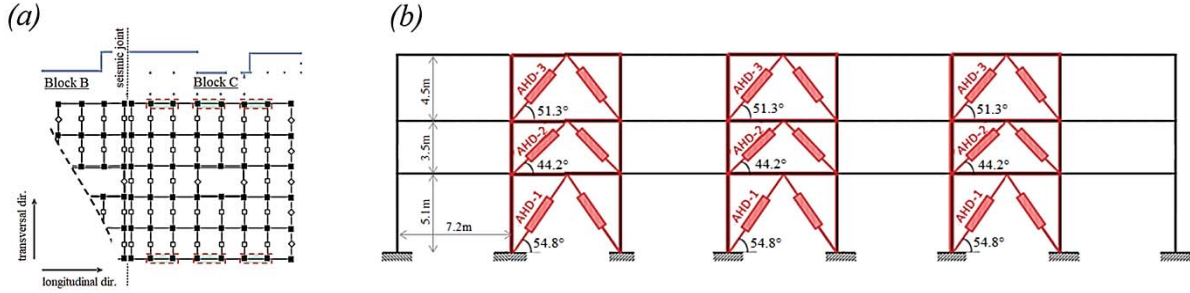

Figure 10: Spatial arrangement of the AHD units: (a) in-plan location; (b) vertical layout.

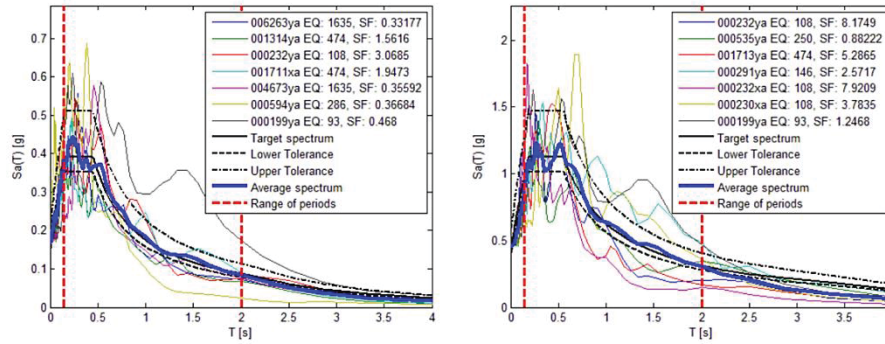

Figure 11: Selected ground motion records for NLTH analyses at SLS (left) and ULS (right).

According to the design assumption (i.e.  $d_{\text{target,ULS}}^* < d_{y,F}^*$ ), r.c. elements of the braced frame react to the seismic shaking remaining always in their elastic range. This is witnessed by Fig. 12 that shows the calculated displacement envelopes over the storey levels: the average peak displacement at roof level is equal to 16mm for SLS events and to 52mm ( $\cong d_{\text{target,ULS}}^*$ ) for ULS earthquakes. In particular at SLS, despite the “AHD solution” is a bit more flexible than the “BHD solution” (16mm vs. 13mm of peak displacement, respectively), thanks to the significant damping offered by the minor hysteretic core ( $\xi_{eq,F+D}^* = 23.7\%$ ), the displacement increase does not represent a hazard neither for “displacement-sensitive” nor for “drift-sensitive” NSCs. Indeed, as shown in Fig. 13-right, the largest inter-storey drift affects the 2<sup>nd</sup> columns level with a peak of 0.17% (practically identical to 0.16% calculated for the “BHD solution”) that is widely below the “immediate occupancy” average limits for both the weakest “drift-sensitive” NSC (0.75% for infill walls) [3] and r.c. column elements (0.66%) [7].

The enhanced protection level offered by the innovative AHDs is evident comparing the envelopes of PFAs at SLS (Fig. 13-left). The PFAs calculated at 3<sup>rd</sup> storey level are 0.20g and 0.42g for the retrofitting solution implementing the AHDs and the BHDs, respectively. This

achievement can be easily explained considering the lower effective period ( $T_{eff,F+D}^* = 0.33s$ ) and minor equivalent viscous damping ( $\xi_{eq,F+D}^* = 8.9\%$ ) offered by common BHDs (i.e. stiffer structure with lower energy dissipation capacity). As shown in Fig. 14, the huge reduction (-52%) of the PFAs leads also to markedly less demanding floor response spectra (calculated assuming a conventional viscous damping equal to 5%). These plots allow to compare the actual acceleration experienced by all NSCs (characterized different fundamental periods) installed at the different storey levels. For all oscillation periods in the range  $[0 - 4.0s]$ , the floor response spectrum of the new “AHD solution” lies practically always below that of the original “BHD solution” ensuring reduced peak values: -20%, -55%, and -53% for NSCs installed at first, second, and third storey level, respectively. Compared to the response offered by traditional BHDs, one can therefore conclude that the innovative AHDs, besides an unaltered protection level for both structural and non-structural drift-sensitive elements, can guaranty a considerably enhanced safeguard of “acceleration-sensitive” elements leading to a more prompt operation of the building after the quake and to likely reduced repairing costs.

## 6 CONCLUSIONS

Traditional bilinear hysteretic dampers (BHDs) dampers are usually designed to guaranty the structural integrity of braced buildings under severe ULS seismic events. As a drawback, under weak but frequent SLS earthquakes, they practically behave as stiff springs causing high PFAs that are detrimental for “acceleration-sensitive” nonstructural components (NSCs).

To overcome this drawback, the innovative Adaptive Hysteretic Damper (AHD), capable to develop a two-steps hysteretic loop and to modulate its effective stiffness and damping based on the intensity of the occurring earthquake, has been presented claiming the following:

- results of experimental force-displacement tests have proven the reliability and robustness (i.e. stable response) of the device under repeated cyclic motions with increasing amplitudes;
- simple response spectrum analyses can be exploited for the design of braced buildings implementing the AHDs whose linear equivalent mechanical properties can be calculated through the analytical formulas provided in this paper;
- the main benefits arising from to the implementation of novel AHDs, rather than common BHDs, in braced frames have been quantified through NLTH analyses carried out on a case-study building. Very similar lateral displacements and inter-storey drifts envelopes have been calculated for the two structural systems, at both ULS and SLS design levels, resulting in the same protection level for structural and nonstructural sensitive elements. On the contrary, at SLS, the adoption of the new AHDs leads to markedly reduced peak floor (up to -52%) and spectral accelerations (up to -55%) ensuring: (a) an enhanced protection of “acceleration-sensitive” NSCs; (b) a more prompt response of the building after the quake; (c) likely reduced repairing costs.

### Abstract

*The inter-storey seismic isolation technique is becoming increasingly attractive for the seismic risk mitigation of buildings, also as alternative strategy to base isolation. The reasons for applying this technique can be various and of different nature, such as: architectural concerns, feasibility of construction, and performance benefits. An interesting application of this technique concerns its use for adding upper storeys to existing buildings, avoiding the increase of seismic forces on the substructure, or even reducing them. Therefore, this technique could also be effective for seismic retrofit applications, using the mass of the superstructure as a nonconventional TMD for controlling the dynamic response of the substructure.*

*Among the main issues concerning this application, there is the need to control the relative displacement between the two structural parts and the acceleration of the superstructure, while improving the seismic performance of the substructure.*

*In this paper, a multi-objective optimization method for the dynamic characteristics of the additional superstructure is presented, which uses a TMD approach and considers the performances of the substructure, isolation system and superstructure. A 3-storey (3 DOF) case study structure was taken as a reference, analysing a wide range of isolated masses, isolation periods and damping ratios. Time-history analyses are finally performed, based on the optimization results, in order to assess the effectiveness of both the optimization method and the isolation technique, also considering the structural non-linearity.*

## 1 INTRODUCTION

The inter-storey isolation system (IIS) is becoming increasingly attractive, as it allows greater freedom in the structural conception of skyscrapers and multi-purpose buildings by defining two independent structures, i.e. substructure and superstructure, which may have different forms, materials and uses (e.g. [1, 2]). This represents both an advantage for architectural design and a sustainable solution for densely populated areas, as it allows significant savings on land use. Furthermore, in some cases, the base isolation technique encounters economic and technical issues that can prevent its application; for example, its application is often difficult and expensive in existing buildings, and generally more than applying isolation between storeys.

Moreover, the IIS technique can be applied to add extra storeys on the top of existing buildings, with appropriate vertical capacity, without increasing the base shear forces (e.g. [3, 4, 5]). In particular, the isolated superstructure, when properly designed, can be used as a Tuned Mass Damper (TMD) to improve the seismic behaviour of the substructure, thus making this technique very advantageous when retrofitting and elevation of the existing building are both required.

From a functional point of view, the IIS technique combines the functions of seismic isolation and mass damping; indeed, the isolation system is a filter for the inertial forces transmitted to the superstructure and, at the same time, induces the isolated superstructure to exert a mass damping action on the substructure, improving the seismic behaviour of the latter. In the literature, two main conceptual approaches can be identified, each of which focuses on one of the two main aspects of the IIS, i.e. seismic isolation or mass damping (TMD).

Studies that address the problem from the point of view of seismic isolation evaluate the interaction between the superstructure and the substructure, the effects of the higher vibration modes and their possible coupling, using frequency and mass ratios as design parameters (e.g. [6, 7, 8, 9, 10, 11, 12]), but also the optimal parameters of additional Fluid Viscous Dampers (FVDs) installed in the IIS (e.g. [2, 13, 14]). 3 degree-of-freedom (DOF) models (e.g. [8, 9]) or multi DOF models (e.g. [2, 10, 12]) are generally adopted, depending on the purpose of the study.

Other researchers, on the other hand, approach the study of the IIS following the strategy of mass damping, which is based on the principle of TMD, and considering the peculiarities of the IIS, namely the fact that the isolated mass also performs structural and housing functions in addition to that of dynamic control. The design parameters are the mass and frequency ratios between the TMD and the primary structure, and the damping ratio provided by the TMD. Generally, frequency and damping ratios are optimized for set values of mass ratio, using simplified 2 DOF models.

The concept of TMD for structural application was first introduced by [15], who applied a secondary mass to a single degree-of-freedom (SDOF) system harmonically excited. [16] first established a TMD design approach to suppress the peak displacement of an undamped SDOF system (primary structure) sinusoidally excited. This approach is based on the observation that all frequency response functions (FRFs) of the combined 2 DOF system (SDOF primary structure with TMD), obtained for various damping ratios of TMD, pass through two specific points (“fixed point theory”). Following the same design approach of [16], [17] derived the TMD design formula to optimize the performance of the undamped SDOF primary structure in the case of harmonic excitation at the base (more useful for earthquake engineering applications). Later, [18] proposed the equations for the optimal tuning parameters of the TMD in the case of damped SDOF primary structures. Then, [19] first conceived the idea of using a heavily damped vibration absorber (or TMD) to reduce the seismic response of the structure.

In particular, he suggested to tune the TMD in resonance with the primary structure and showed that its best performance is obtained when the two complex vibration modes of the resulting 2-DOF system have similar damping ratios, and approximately equal to the mean damping ratio between those of the TMD and the structure.

For several years, studies have focused on TMDs with low mass ratios, which are also often susceptible to tuning problems (e.g. [20]). Only more recently, various investigations have been directed towards TMDs with large mass ratios, also called nonconventional TMDs, given the growing interest in innovative applications such as mega-sub-control-structures (MSCS), inter-storey isolation systems and sliding roof systems (e.g. [21]). These TMDs have shown greater robustness than those with low mass ratios, due to their lower sensitivity to tuning (e.g. [22]). In particular, [23] showed that the design formulas proposed by [19] do not guarantee the equality of the modal damping ratios of the two complex modes in the case of TMD with mass ratios greater than 0.005; therefore, through a numerical procedure, [23] provided new design equations that result in equal damping ratios and equal frequencies for the two vibration modes. [24] validated the TMD tuning equations obtained by [23], proposing an analytical formulation that matches the same results. [25] proposed an alternative approach for tuning TMDs with large mass ratios, still equalizing the damping ratios but, at the same time, minimizing the maximum FRF amplitude associated with the displacement of the primary structure. The TMD damping ratio according to this last approach is significantly lower than that deriving from the model of [23], despite ensuring a similar efficiency of the TMD. [26] proposed an energy-based design methodology for non-conventional TMDs, which maximizes the ratio between the energy dissipated by the isolation system (located between the masses of a 2DOF system) and that of the input earthquake. [27] compared different optimization approaches, minimizing the variance of the responses (i) in displacement or (ii) in acceleration of the primary structure, or (iii) maximizing the energy dissipated by the TMD system (like [26]). [28] provided the equations for optimal TMD tuning, using a 2 DOF reduced-order model without damping in the main structure, minimizing (i) the maximum amplitudes of the base shear force under harmonic excitations, or (ii) the variance of the base shear force under a band-limited random excitation of white noise. [21], similarly to [25], proposed a TMD optimization approach that approximately equals the damping ratios of the 2 DOF system and, at the same time, minimizes its overall response; in particular, in addition to minimizing the FRF of the displacement of the primary structure, as done by [25], [21] simultaneously minimized the FRF of the acceleration of the nonconventional TMD, holding the latter also structural functions.

This paper investigates the inter-storey isolation system (IIS) as a technique for adding upper storeys to an existing building, improving at the same time its seismic behaviour. A 3-storey case study structure (without considering the IIS) is taken as a reference, analysing a wide range of isolated masses, isolation periods and damping ratios. First, some assessments are carried out on the effects that the IIS parameters (normalized to the substructure characteristics) have on the dynamic response of the substructure, using the complex modal analysis and evaluating the FRFs of the equivalent 2 DOF system. An alternative approach for tuning the IIS (or TMD) parameters is then proposed, carrying out two multi-objective optimizations that consider the performance of the substructure along with that of the isolation system (to limit the P- $\Delta$  effects on the substructure, *OPT1*) or along with that of the superstructure (to limit the TMD accelerations, *OPT2*). It is worth noting that high damping values in the IIS are effective in limiting the relative displacement of the isolators (and therefore the P- $\Delta$  effects) but could have negative effects on the overall structural behaviour, especially on the superstructure and its content (e.g. [2, 13, 14, 29]). Parametric time-history analyses are finally performed, based on the optimal solutions obtained for the IIS parameters, in order to assess the

effectiveness of the optimization method and therefore of the isolation technique, also considering the structural non-linearity.

## 2 CASE STUDY STRUCTURE AND PARAMETER DEFINITION

For reasons of clarity, even if the study presented here is of general applicability, reference was made to a generic three-storey structure, representative of regular RC frame buildings with a fundamental period of about 0.3 s. The building is shown in Figure 1 and is characterized by the following floor masses,  $m_1=m_2=350$  t and  $m_3=300$  t, and by the following storey stiffnesses,  $k_1=k_2=k_3=780$  kN/mm. Assuming that the structure can support additional floors (by its own capacity or through appropriate interventions), it is intended to add an isolated superstructure above it (which can therefore be defined as substructure), whose total mass is given by the masses of the isolation layer and the additional floors.

Conceptually, the IIS subdivides the structure into three main parts, i.e. the substructure, the isolation system and the superstructure. As said before, some relevant studies focusing on the aspect of seismic isolation analyse the structure using 3 DOF or multi DOF models, while other studies adopting TMD approaches evaluate the structural response using 2 DOF reduced-order models. However, as demonstrated in various studies (e.g. [7, 12]), when the mass ratio ( $\mu$ ) between the isolated mass and the mass of the substructure is less than 1, there is a “mass damping” behaviour, and therefore it is possible to neglect the higher vibration modes of the superstructure, simplifying the system with an equivalent 2 DOF model.

Thus, considering values of  $\mu$  in this study up to 1, both substructure and isolated superstructure were modelled with an equivalent SDOF model. In particular, the substructure is characterized by an angular frequency ( $\omega_{SDOF}$ ) of 21 rad/s (i.e., vibration period of about 0.3 s) and a damping ratio ( $\xi_{SDOF}$ ) of 5%; its equivalent mass ( $m_{SDOF}$ ) is 606 t and corresponds to the modal mass of the first vibration mode of the 3 DOF structure, calculated as in Equation 1, where  $\phi_1$  is the first eigenvector normalized to 1 and  $\mathbf{M}_{st}$  the mass matrix of the structure. On the other hand, the isolated superstructure is characterized by the parameters  $m_{IS}$  (sum of the masses of isolation and superstructure),  $\omega_{IS}$  and  $\xi_{IS}$  (angular frequency and damping ratio of the isolation system), as shown in Figure 1; the relation between  $m_{IS}$  and  $\omega_{IS}$  is given in Equation 2, where  $k_{IS}$  is the IIS stiffness. Considering the parameters of the isolated superstructure normalized to those of the substructure, as generally done in TMD approaches, the mass ( $\mu$ ) and frequency ( $\nu$ ) ratios in Equation 3 can be defined, which together with  $\xi_{IS}$  represent the dimensionless parameters of the nonconventional TMD to be optimized. Lastly, Equation 4 shows the matrices of mass ( $\mathbf{M}$ ), damping ( $\mathbf{C}$ ) and stiffness ( $\mathbf{K}$ ) of the 2 DOF reduced-order model (Figure 1b), as a function of the aforementioned parameters.

In this study, the optimization is performed for the parameters  $\nu$  and  $\xi_{IS}$ , considering the range from 0.05 to 1 for  $\nu$  and the range from 0.01 to 2 for  $\xi_{IS}$ , for set values of  $\mu$  (0.25, 0.5, 0.75 and 1).

$$m_{SDOF} = \phi_1^T \mathbf{M}_{st} \phi_1 \quad (1)$$

$$\omega_{IS} = \sqrt{\frac{k_{IS}}{m_{IS}}} \quad (2)$$

$$\mu = \frac{m_{IS}}{m_{SDOF}} \quad ; \quad \nu = \frac{\omega_{IS}}{\omega_{SDOF}} \quad (3)$$

$$\mathbf{M} = \begin{bmatrix} 1 & 0 \\ 0 & \mu \end{bmatrix} ; \quad \mathbf{C} = \begin{bmatrix} 2\xi_{SDOF}\omega_{SDOF} + 2\mu\xi_{IS}\nu\omega_{SDOF} & -2\mu\xi_{IS}\nu\omega_{SDOF} \\ -2\mu\xi_{IS}\nu\omega_{SDOF} & 2\mu\xi_{IS}\nu\omega_{SDOF} \end{bmatrix} ; \quad \mathbf{K} = \begin{bmatrix} \omega_{SDOF}^2 + \mu\nu^2\omega_{SDOF}^2 & -\mu\nu^2\omega_{SDOF}^2 \\ -\mu\nu^2\omega_{SDOF}^2 & \mu\nu^2\omega_{SDOF}^2 \end{bmatrix} \quad (4)$$

### 3 ASSESSMENT OF STRUCTURAL BEHAVIOUR IN FREQUENCY-DOMAIN

#### 3.1 Complex modal analysis

In traditional structural design, damping is assumed proportional to mass and stiffness and the results from classical modal analysis are not affected by it (as the  $\mathbf{C}$  matrix is not included in the problem formulation). When using non-proportional damping (e.g., in the case of IIS, where the damping is concentrated in some parts of the structure), the actual modal characteristics are different from the classical ones, and require a non-classical or complex modal analysis for their evaluation (e.g. [30]).

In this study the state-space formulation is adopted, which allows to decouple the equations of motion transforming the system with  $n$  second-order differential equations into a system with  $2n$  first-order differential equations, where  $n$  is the DOF number, namely:

$$\dot{\mathbf{v}}(t) = \mathbf{A}\mathbf{v}(t) + \mathbf{I}_g \ddot{u}_g(t) \quad (5)$$

where  $\mathbf{v}(t)$  is the state space vector at time  $t$ ,  $\mathbf{A}$  is the state space matrix,  $\mathbf{I}_g$  is the input vector and  $\ddot{u}_g(t)$  is the applied input process.  $\mathbf{v}(t)$ ,  $\mathbf{A}$  and  $\mathbf{I}_g$  are defined below:

$$\mathbf{v}(t) = \begin{bmatrix} \mathbf{x} \\ \dot{\mathbf{x}} \end{bmatrix}; \quad \mathbf{A} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C} \end{bmatrix}; \quad \mathbf{I}_g = \begin{bmatrix} \mathbf{0} \\ -\boldsymbol{\tau} \end{bmatrix} \quad (6)$$

where  $\mathbf{x}$  and  $\dot{\mathbf{x}}$  are the relative displacement and relative velocity vectors, respectively;  $\mathbf{I}$  is the unitary matrix of dimensions  $2 \times 2$ ;  $\mathbf{M}$ ,  $\mathbf{K}$  and  $\mathbf{C}$  are the system matrices defined in Equation 4;  $\boldsymbol{\tau}$  is the unitary vector of dimensions  $2 \times 1$ . Therefore, the eigenvalue problem can be defined as:

$$\mathbf{A}\boldsymbol{\psi}_i = \lambda_i \boldsymbol{\psi}_i \quad (7)$$

where  $\lambda_i$  represents the eigenvalues and  $\boldsymbol{\psi}_i$  the eigenvectors.

Since the main objective of this study is the control of the seismic response of the substructure through the IIS, Figure 2 shows the results relating to the second vibration mode of the 2 DOF model (i.e., the mode associated with the deformation of the substructure), for  $\mu=0.5$ , values of  $v$  equal to 0.2, 0.4 and 0.6, and values of  $\zeta_{\text{IS}}$  in the range 0 - 2.

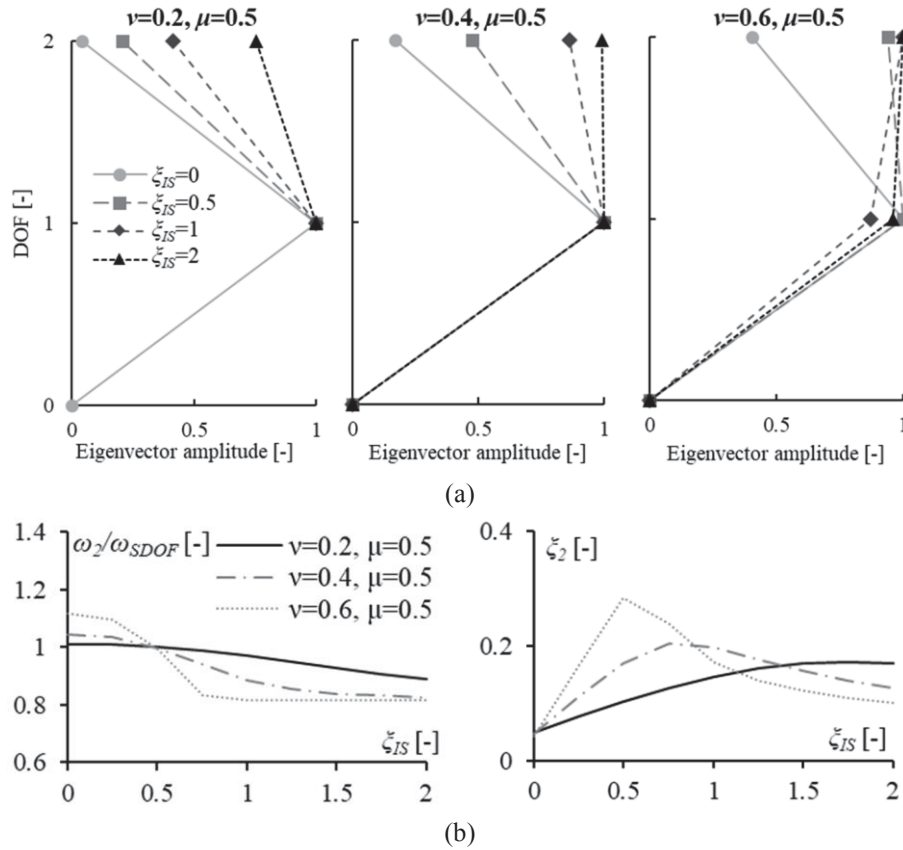

Figure 2: Complex modal analysis results of 2 DOF system, for  $\mu=0.5$ ,  $\nu=0.2, 0.4, 0.6$ ,  $\xi_{IS}=0 - 2$ : (a) eigenvectors of the second mode; (b) normalized frequency  $\omega_2$  and damping ratio  $\xi_2$  of the second mode, as a function of  $\xi_{IS}$ .

Figure 2a shows that, for low to medium values of the frequency ( $\nu$ ) and damping ( $\xi_{IS}$ ) ratios, the masses move in a decoupled way (characteristic behaviour of the isolated structures, due to the filter action exerted by the IIS), while increasing the value of the previous parameters the two masses reduce their relative displacement until, beyond certain values of  $\nu$  and  $\xi_{IS}$ , they move together. Instead, Figure 2b shows that, as  $\xi_{IS}$  increases, the frequency of the second mode ( $\omega_2$ ) is reduced, while the damping ratio of the second mode ( $\xi_2$ ) first increases and subsequently, for high  $\xi_{IS}$  values, it decreases. In particular, the peak of  $\xi_2$  seems to be corresponding to the change in concavity of the  $\omega_2/\omega_{SDOF}$  curve. These variations are greater for higher  $\nu$  values (i.e., for more rigid IIS), as the resulting 2 DOF system is more coupled in terms of mass displacement. In fact, a “perfect coupling” (for sufficiently high  $\nu$  and  $\xi_{IS}$  values) will lead to a single vibration mode having a modal mass equal to  $(m_{IS}+m_{SDOF})$  and a modal damping ratio equal to that of the substructure,  $\xi_{SDOF}$  (which justifies the reduction of  $\xi_2$  for high  $\xi_{IS}$  values).

### 3.2 Frequency Response Functions

To analyse the influence of the parameters  $\mu$ ,  $\nu$  and  $\xi_{IS}$  on the actual structural response, the frequency response functions (FRFs) of the equivalent 2 DOF systems (obtained parametrically by varying the values of  $\mu$ ,  $\nu$  and  $\xi_{IS}$  indicated in Section 2) were evaluated. FRFs express how a sinusoidal signal with a given input frequency is transferred within the system. In particular, the FRFs associated with the displacements ( $\mathbf{H}(\omega)$ ) and accelerations ( $\mathbf{H}_a(\omega)$ ) of the various DOF of the system can be defined as follow, where  $\omega$  is the excitation vibration frequency:

$$\begin{aligned}\mathbf{H}(\omega) &= -(-\omega^2 \mathbf{M} + i\omega \mathbf{C} + \mathbf{K})^{-1} \mathbf{M} \tau \\ \mathbf{H}_a(\omega) &= -\omega^2 \mathbf{H}(\omega) + \tau\end{aligned}\quad (8)$$

Specifically, the investigated FRFs concern the drift of the substructure (i.e., of the lower mass)  $|\mathbf{H}_1(\omega)|$ , the drift of isolation (i.e., between the two masses)  $|\mathbf{H}_2(\omega) - \mathbf{H}_1(\omega)|$ , and the acceleration of the superstructure (i.e., of the upper mass)  $|\mathbf{H}_{a2}(\omega)|$ . Figure 3 shows the trend of the selected FRFs with respect to the variation of  $\omega$  and one of the main parameters ( $\mu$ ,  $\nu$ ,  $\xi_{IS}$ ) at a time – therefore as 3D surfaces – assuming  $\mu=0.5$ ,  $\nu=0.4$  and  $\xi_{IS}=0.5$  as reference values for the other parameters. The following observations can be drawn:

- Increasing the values of  $\mu$  results in a reduction of  $|\mathbf{H}_1(\omega)|$  and  $|\mathbf{H}_{a2}(\omega)|$ , and therefore in a better structural performance in terms of drift of the substructure and acceleration of the superstructure; instead, the influence of  $\mu$  on  $|\mathbf{H}_2(\omega) - \mathbf{H}_1(\omega)|$  (i.e., on the isolation drift) is not very significant.
- Low values of  $\nu$  allow to limit the acceleration of the superstructure; intermediate values of  $\nu$  (e.g., between 0.4 and 0.6) seem the most effective solution to reduce the drift of the substructure; on the other hand, high values of  $\nu$  are optimal for reducing the isolation drift, even if they induce significant amplifications both on the substructure drift and on the superstructure acceleration.
- The increase in the  $\xi_{IS}$  values provides an effective initial reduction of the substructure drift and of the superstructure acceleration, at least up to medium-high values of  $\xi_{IS}$  (about 0.5), beyond which a further increase leads to a significant amplification of both  $|\mathbf{H}_1(\omega)|$  and  $|\mathbf{H}_{a2}(\omega)|$ . Instead,  $\xi_{IS}$  is always effective in reducing the isolation drift, as also confirmed by other studies (e.g., [2, 13, 14]).

Figure 3: Trends of the FRFs as a function of  $\mu$ ,  $\nu$  and  $\xi_{IS}$ ; reference parameters:  $\mu=0.5$ ,  $\nu=0.4$  and  $\xi_{IS}=0.5$ .

## 4 MULTI-OBJECTIVE OPTIMISATION

### 4.1 Proposed approach

As seen in the Introduction, many of the literature studies on the optimization of TMD parameters (at least up to the most recent ones) seek the maximum effect of “mass damping” focusing on the minimization of the response of the primary system, thus neglecting the performance of the tuned mass (i.e., IIS drift and acceleration) in the optimization procedure. However, controlling the deflection of the isolators (and thus also the P-Δ effects on the substructure) and the acceleration of the superstructure can be of significant interest considering that the mass to be tuned is in fact a habitable building.

In order to model the stochastic nature of the seismic input, the Power Spectral Density (PSD) function of a zero-mean Gaussian stochastic process,  $\mathbf{S}(\omega)$ , is generally assumed; considering this type of process, the random vibration theory produces the following covariance matrices:

$$\begin{aligned} \text{Cov}[\mathbf{xx}^T] &= \int_{-\infty}^{\infty} \mathbf{H}(\omega) \mathbf{S}(\omega) \mathbf{H}(\omega)^{*T} d\omega \\ \text{Cov}[\ddot{\mathbf{x}}\ddot{\mathbf{x}}^T] &= \int_{-\infty}^{\infty} \mathbf{H}_a(\omega) \mathbf{S}(\omega) \mathbf{H}_a(\omega)^{*T} d\omega \end{aligned} \quad (9)$$

Furthermore, assuming the seismic excitation also as a white noise process, its PSD function is no longer dependent on  $\omega$  ( $\mathbf{S}(\omega)=S_0$ ); therefore, in order to obtain the optimal TMD parameters (i.e.,  $\mu$ ,  $\nu$ ,  $\xi_{IS}$ , variables of  $|\mathbf{H}(\omega)|$  and  $|\mathbf{H}_a(\omega)|$ ), the minimization of the integrals in Equation 9 is equivalent to the minimization of the integrals in Equation 10, where  $\sigma^2$  and  $\sigma_a^2$  are the displacement and acceleration variance, respectively.

$$\begin{aligned} \sigma^2/S_0 &= \int_{-\infty}^{\infty} |\mathbf{H}(\omega)|^2 d\omega \\ \sigma_a^2/S_0 &= \int_{-\infty}^{\infty} |\mathbf{H}_a(\omega)|^2 d\omega \end{aligned} \quad (10)$$

By defining the FRFs of the reference SDOF system, in terms of displacement ( $H_{SDOF}(\omega)$ ) and acceleration ( $H_{a,SDOF}(\omega)$ ) as:

$$\begin{aligned} H_{SDOF}(\omega) &= -(-\omega^2 + i\omega 2\xi_{SDOF}\omega_{SDOF} + \omega_{SDOF}^2)^{-1} \\ H_{a,SDOF}(\omega) &= -\omega^2 H_{SDOF}(\omega) + 1 \end{aligned} \quad (11)$$

the following Performance Indices ( $PI$ s) can be defined:

$$\begin{aligned} PI_1 &= \frac{\int_{-\infty}^{\infty} |\mathbf{H}_1(\omega)|^2 d\omega}{\int_{-\infty}^{\infty} |H_{SDOF}(\omega)|^2 d\omega} & PI_2 &= \frac{\int_{-\infty}^{\infty} |\mathbf{H}_2(\omega)|^2 d\omega - \int_{-\infty}^{\infty} |\mathbf{H}_1(\omega)|^2 d\omega}{\int_{-\infty}^{\infty} |H_{SDOF}(\omega)|^2 d\omega} & PI_3 &= \frac{\int_{-\infty}^{\infty} |\mathbf{H}_{a,2}(\omega)|^2 d\omega}{\int_{-\infty}^{\infty} |H_{a,SDOF}(\omega)|^2 d\omega} \end{aligned} \quad (12)$$

where,  $PI_1$  and  $PI_2$  are respectively the substructure drift variance and the isolation drift variance both normalized to the drift variance of the equivalent SDOF system, whereas  $PI_3$  is the

superstructure acceleration variance normalized to the acceleration variance of the SDOF system. Therefore, based on these  $PIs$ , the objective functions (OFs) are defined as follow:

$$OF_1 = \min(PI_1(\xi_{IS}, \nu)) \quad OF_2 = \min(PI_2(\xi_{IS}, \nu)) \quad OF_3 = \min(PI_3(\xi_{IS}, \nu)) \quad (13)$$

In particular, two multi-objective optimizations ( $OPT1$  and  $OPT2$ ) are performed, simultaneously minimizing  $OF_1$  and  $OF_2$  ( $OPT1$ ), or  $OF_1$  and  $OF_3$  ( $OPT2$ ), with the aim of controlling the substructure performance but, at the same time, also the deflection of the isolators or the acceleration of the superstructure.

In order to solve these multi-objective optimization problems, the well-known Non-dominated Sorting Genetic Algorithm NSGA-II (e.g. [31, 32]) was used. This algorithm, widely used in practical optimization problems, first creates an initial parent population  $P_0$ , of size  $N$ , with a random process; then, sorts this population according to the non-domination criterion (i.e., assigning to each solution a rank based on its non-domination level – e.g. 1 for the best level, 2 for the next one and so on – and minimising it); subsequently, it generates an offspring population  $Q_0$ , of size  $N$ , through binary tournament selection, recombination and mutation operations. Once the initial parent ( $P_0$ ) and offspring ( $Q_0$ ) populations are defined, an iterative procedure is carried out for a set number of generations (to be defined according to the stability and convergence of solution). This procedure allows to determine the parent and offspring populations at generation  $(k+1)$  starting from those at generation  $(k)$ . In particular, the solution  $P_{k+1}$ , of size  $N$ , is generated starting from the combined population  $R_k = P_k + Q_k$ , of size  $2N$ , based on two cascading criteria: the solutions preferred are (i) those of lesser (non-domain) rank and, among solutions of equal rank, (ii) those located in a less crowded region (selected by a crowding comparison operator). Using the new parent population ( $P_{k+1}$ ), through a binary tournament selection, crossover and mutation operations, the new offspring population ( $Q_{k+1}$ ) is then created. This procedure continues until the last generation required. The main parameters of this algorithm are therefore the number of generations, the size of the population sought and the mutation and crossover probabilities; the values set in this study for these parameters are shown in Table 1.

<i>Parameter</i>	<i>Value</i>
Generations	120
Population	80
Mutation probability	0.1
Crossover probability	0.9

Table 1: Parameters set for the NSGA-II algorithm.

## 4.2 Optimization results

The results obtained by the NSGA-II algorithm, i.e. the Pareto fronts, are shown in Figure 4 for both optimizations ( $OPT1$  and  $OPT2$ ). The main considerations are reported below.

- Overall, for the various cases analysed, the minimum values of  $OF_1$  ( $OF_{1min}$ ) are approximately equal to 0.4 (both for  $OPT1$  and  $OPT2$ ), indicating a clear reduction of the substructure drift due to the application of the IIS (i.e., of the isolated superstructure).
- Then, while the minimization of  $OF_2$  (in  $OPT1$ ) causes values of  $OF_1$  greater than 1, the minimization of  $OF_3$  (in  $OPT2$ ) allows values of  $OF_1$  always less than 1; this means that the solutions aimed at minimizing the superstructure acceleration do not cause an increase in the substructure drift compared to the case without IIS (i.e., the SDOF system), as instead occurs when the minimization of the isolation drift is sought.

- The values of  $OF_3$  show that the superstructure accelerations, when optimized, are significantly reduced compared to those of the existing substructure (i.e., the SDOF system).
- It is also worth noting that, as  $\mu$  increases, the minimum values of  $OF_1$  and  $OF_2$  increase – for *OPT1* (Figure 4a), whereas the minimum values of  $OF_1$  and  $OF_3$  decrease – for *OPT2* (Figure 4b).

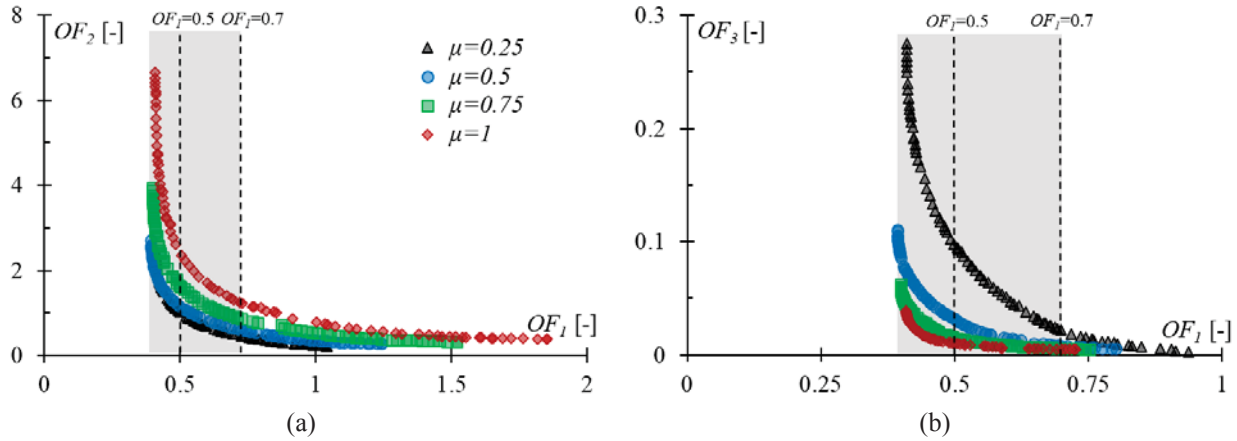

Figure 4: Pareto fronts (minimum values of OFs) for set values of  $\mu$ : (a) *OPT1*; (b) *OPT2*.

Since  $OF_1$  indicates the reduction of the variance of the substructure drift, a range from  $OF_{1min}$  to  $OF_1=0.7$  (i.e., 30% reduction) – as shown in Figure 4 – is considered effective for the purposes of this study; in particular, three values of  $OF_1$  were selected for subsequent evaluations (for both optimizations), namely  $OF_{1min}$ ,  $OF_1=0.5$  and  $OF_1=0.7$ .

Figure 5 shows the optimal values of the IIS (or TMD) parameters, for both *OPT1* (Figure 5a) and *OPT2* (Figure 5b), associated with the selected  $OF_1$  values. In particular, the optimal values of  $\zeta_{IS}$  and  $\nu$  are shown as a function of  $\mu$ , as well as the values of  $OF_2$  for *OPT1* and the values of  $OF_3$  for *OPT2*. The following observations can be derived:

- The  $OF_{1min}$  solutions (which minimize the variance of the substructure drift) are the same for both *OPT1* and *OPT2* optimizations, as expected. For these solutions, as  $\mu$  increases, the values of  $\zeta_{IS}$  increase and those of  $\nu$  decrease; therefore, these optimal solutions range from the “mass damping” behaviour towards that of “intermediate seismic isolation”, as already observed in previous studies.
- As regards the *OPT1* optimization, the reduction of  $OF_2$  (i.e., of the variance of the isolation drift) is associated with the increase of the values of  $\zeta_{IS}$  and  $\nu$ , that is, with solutions that induce a greater coupling between the two structural parts.
- On the other hand, regarding the *OPT2* optimization, reductions of  $OF_3$  (i.e., of the variance of the superstructure acceleration) are possible by increasing the values of  $\zeta_{IS}$  and reducing those of  $\nu$ , even significantly (especially for  $OF_1=0.7$  and low  $\mu$  values).
- Looking at the values of OFs as a function of  $\mu$ , it can be seen that  $OF_2$  is more sensitive for high values of  $\mu$ , whereas  $OF_3$  for low values of  $\mu$ . In these respective  $\mu$  ranges, multi-objective optimization is more effective and beneficial than single substructure performance optimization.
- The minimization of  $OF_3$  (see the case  $OF_1=0.7$ ), in the case of low values of  $\mu$ , is obtained by considerably reducing  $\nu$  (i.e., increasing the filter action offered by the IIS) and significantly increasing  $\zeta_{IS}$  (beyond the critical damping value for the presented study).

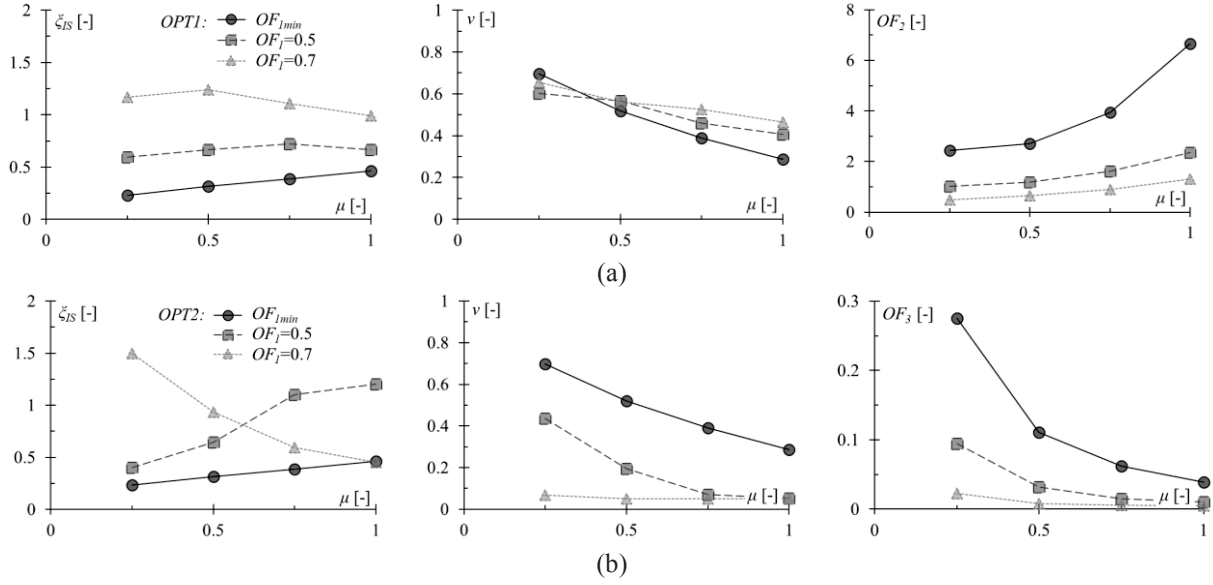

Figure 5: *OPT1* (a) and *OPT2* (b): optimal values of  $\zeta_{IS}$ ,  $\nu$ ,  $OF_2$  and  $OF_3$  as a function of  $\mu$  ( $OF_I=OF_{Imin}$ , 0.5, 0.7).

### 4.3 Comparison with other literature solutions

The optimal values of the IIS parameters ( $\zeta_{IS}$ ,  $\nu$ ) obtained for the  $OF_{Imin}$  solution (equal for *OPT1* and *OPT2*), which minimize the displacement variance of the primary system, are compared in Figure 6 with other relevant literature solutions, as the mass ratio  $\mu$  varies. These solutions are taken from: [17], who provided a closed-form solution for the TMD parameters in the case of an undamped primary SDOF system with base harmonic excitation; [25], who optimized the parameters of TMDs with large mass ratios by matching the damping ratios of the 2 DOF system while minimizing the maximum FRF amplitude associated with the displacement of the primary structure; [27], who proposed different approaches, including the minimization of the displacement variance of the primary structure (displacement approach) and the maximization of the energy dissipated by the TMD system (energy approach).

It is worth considering that the various solutions compared in Figure 6 refer to different values of the damping ratio of the primary structure ( $\zeta_{SDOF}$ ), i.e.: 0% for [17], 5% for [25] and this study, and 2% for [27]. However, as discussed in previous study (e.g. [25, 27, 21]), reasonable variations of  $\zeta_{SDOF}$  do not significantly affect the optimal TMD parameters.

As can be seen from these comparisons, the results obtained for  $OF_{Imin}$  are very similar to those obtained by the other literature approaches, and in particular by [27] (displacement approach).

Figure 6: Optimal IIS parameters obtained in this study compared to other TMD solutions from the literature.

## 5 ASSESSMENTS THROUGH TH ANALYSES

### 5.1 Structure modelling and seismic input

This section shows the results of a Time History (TH) analysis, carried out on the 3 DOF case study structure (see Section 2) without and with IIS, in order to evaluate the optimization solutions previously obtained and therefore the effectiveness of the IIS technique.

The structure (see Figure 7) was modelled as a lumped mass system with a non-linear structural behaviour, assuming the bi-linear hysteretic law of Takeda for the substructure, which is often used to describe the behaviour of ductile RC frames. This hysteretic model was calibrated on the elastic stiffness of each storey, assuming a ratio  $r$  between the post-yield stiffness and the elastic stiffness equal to 0.2, and an inter-storey drift  $\delta_y$  at yield equal to 0.5%. The superstructure was modelled as a linear SDOF system, adopting for the IIS parameters ( $\nu$  and  $\xi_{IS}$ ) the optimal values obtained, associated with the mass ratio  $\mu=0.5$  and the solutions of  $OF_I = OF_{Imin}$ , 0.5 and 0.7, of both the optimizations performed (*OPT1* and *OPT2*).

Figure 7: Hysteretic model of the substructure and optimal parameters of the IIS used for the TH analyses.

Time History analyses were performed for eight natural accelerograms, chosen among those of the European Strong-Motion Database (ESD, [33]). They were scaled to be compatible, on average, with the following elastic response spectrum of EC8: Type 1,  $a_g=0.25g$  (bed-rock acceleration) and soil B (i.e., soil factor  $S=1.2$ ); the peak ground acceleration PGA ( $=a_g \cdot S$ ) is  $0.3g$ . The main details of the natural records chosen are reported in Table 2, and the acceleration spectra are shown in Figure 8, together with that of EC8.

## 5.2 Analysis results

The main results obtained are shown in Figures 9 to 11. Figure 9 (for *OPT1*) and Figure 10 (for *OPT2*) shows the profiles of inter-storey drift and floor acceleration; in particular, they show the maximum values obtained from the analysis of the single accelerograms and the related average values. On the other hand, Figure 11 shows (for both *OPT1* and *OPT2*) the results obtained for the isolation drift ( $D_{IS}$ ). The following considerations can be drawn:

- All the optimal solutions adopted made it possible to significantly reduce both the maximum inter-storey drifts and the maximum floor accelerations in the substructure, compared to the case without IIS. In particular, in the case without IIS, the maximum drift values exceeded the yield limit drift ( $\delta_y=0.5\%$ ), causing inelastic structural deformations; instead, the optimal solutions of the IIS always allowed to remain in the elastic range.
- The  $OF_{Imin}$  solution, common to *OPT1* and *OPT2*, is associated with the better performance of the substructure in terms of inter-storey drift, as expected.
- For *OPT1* optimization, as the accepted value of  $OF_I$  increases (i.e., solutions  $OF_I=0.5$  and then  $OF_I=0.7$ ), the drift profiles of the substructure remain similar to those in the case of  $OF_{Imin}$ , i.e. there is no clear reduction in the substructure performance in terms of drifts, while it improves in terms of floor accelerations; then, as expected, the accelerations of the superstructure increase (albeit slightly), to the advantage of a greater reduction of the isolation drift (see Figure 11), due to the minimization of  $OF_2$  along with  $OF_I$ .
- For *OPT2* optimization, as the accepted value of  $OF_I$  increases (i.e.,  $OF_I=0.5$  and then  $OF_I=0.7$ ), the response of the substructure worsens compared to the case of  $OF_{Imin}$ , both in terms of maximum inter-storey drifts and floor accelerations; then, as expected, the accelerations of the superstructure are considerably reduced, due to the minimization of  $OF_3$  along with  $OF_I$ , at the expense of an increase in the deflection of the isolation system (with however acceptable values, as shown in Figure 11).
- It can be noted that moving away from the  $OF_{Imin}$  solution (e.g.,  $OF_I=0.7$ ), the *OPT1* results tend to give a more uniform response of the substructure along the building height, also reducing its variability with respect to the earthquake, whereas the *OPT2* results provide a greater decoupling between the two structural parts (typical of seismic isolation), reducing the control function on the substructure.

 Figure 9: Profiles of inter-storey drift and floor acceleration, for *OPT1* solutions.

 Figure 10: Profiles of inter-storey drift and floor acceleration, for *OPT2* solutions.

 Figure 11: Isolation drift ( $D_{IS}$ ) values resulting from both optimizations (*OPT1* and *OPT2*).

Figure 12 summarizes the main results obtained from the two optimizations. In particular, it shows the ratio between the average structural responses obtained for  $OF_I=0.5$  and  $OF_I=0.7$  and the respective ones obtained for  $OF_{Imin}$ , considering the following performance parameters: substructure drift ( $\theta_{max}$ , associated with  $OF_I$ ), isolation drift ( $D_{IS}$ , associated with  $OF_2$ ) and superstructure acceleration ( $A_U$ , associated with  $OF_3$ ).

Consistently with what was previously observed, and with respect to the  $OF_{Imin}$  solution (which minimizes the substructure drift), the *OPT1* optimization allows to strongly reduce  $D_{IS}$  (even more than 50%) while maintaining good performances in terms of  $\theta_{max}$  and  $A_U$ , which are only slightly amplified. On the other hand, the *OPT2* optimization allows strong reductions in  $A_U$  (greater than 50%) at the expense of appreciable amplifications of  $\theta_{max}$  and  $D_{IS}$ .

 Figure 12: Average structural responses (for the cases  $OF_I=0.5$  and  $0.7$ ) normalized to the case of  $OF_{Imin}$ .

## 6 CONCLUSIONS

A study investigating the inter-storey isolation system (IIS) as a technique for adding upper storeys to an existing building, while improving its seismic behaviour, is presented. A 3-storey case study structure (without considering the IIS) was taken as a reference.

The first part of the study evaluated the effects of the main parameters of the IIS (or non-conventional TMD) on the dynamic response of the substructure; these parameters are the ratios of damping ( $\xi_{IS}$ ), frequency ( $\nu$ ) and mass ( $\mu$ ), with  $\nu$  and  $\mu$  referring to the substructure characteristics. Given the prevailing “mass damping” behaviour for  $\mu$  values  $\leq 1$ , the structure was modelled with a reduced-order 2 DOF model. The evaluation was performed in the frequency domain, using the complex modal analysis and the frequency response functions

(FRFs) of the substructure drift, the isolation drift and the superstructure acceleration. The variations of the characteristics of the second vibration mode and of the FRFs were evaluated over the entire range assumed for the various parameters of the IIS (i.e.,  $\xi_{IS}$  from 0 to 2,  $\nu$  and  $\mu$  from 0 to 1). These preliminary assessments led to the subsequent definition of the methodology to optimize the IIS parameters.

In particular, two alternative multi-objective optimizations were proposed, named *OPT1* and *OPT2*, minimizing different objective functions (OFs). *OPT1* minimizes the variance of the substructure drift ( $OF_1$ ) along with that of the isolation drift ( $OF_2$ ); *OPT2* still minimizes the variance of the substructure drift ( $OF_1$ ), but together with the minimization of the acceleration variance of the superstructure ( $OF_3$ ).

The NSGA-II algorithm was used to solve the multi-objective problem, searching for the best solutions of  $\nu$  and  $\xi_{IS}$  for set  $\mu$  values. The solutions obtained from *OPT1* and *OPT2* were compared with each other, as well as with other relevant solutions from the literature. To this end, representative optimal solutions were selected from the Pareto fronts on the basis of the value of  $OF_1$ , i.e.  $OF_1 = OF_{1min}$  ( $\approx 0.4$ ), 0.5 and 0.7.

Finally, based on these optimal solutions, time-history analyses were performed, in order to verify the effectiveness of the optimization approach and therefore the beneficial effects of the IIS technique. For this purpose, a set of natural accelerograms was assumed, which is compatible with the EC8-Type1 spectrum, with soil B and PGA=0.3 g, and the substructure was modelled as a lumped mass 3 DOF system with a non-linear structural behaviour. Overall, the following conclusions can be drawn:

- The IIS technique, when its stiffness ( $\nu$ ) and damping ( $\xi_{IS}$ ) parameters are suitably optimized in relation to the isolated mass ratio ( $\mu$ ), seems effective in improving the seismic behaviour of the substructure (or existing structure).
- Considering the optimal solution that minimizes the variance of the substructure drift, i.e.  $OF_{1min}$ , the increase in the mass ratio (if allowed by the substructure in terms of vertical capacity) leads to a reduction of the optimal values of  $\nu$  and to an increase of those of  $\xi_{IS}$ , i.e. solutions that are more similar to those of seismic isolation. Consequently, increasing  $\mu$  reduces the accelerations of the superstructure but increases the drift of the isolation system.
- The *OPT1* optimization provides effective solutions to reduce the isolation drift while containing the maximum values of the substructure drift similar to those of the  $OF_{1min}$  solution. With the solutions of *OPT1*, a more uniform behaviour of the substructure is also obtained, minimizing floor accelerations.
- The *OPT2* optimization provides effective solutions to reduce the superstructure acceleration while containing the maximum values of the substructure drift similar to those of the  $OF_{1min}$  solution. With the solutions of *OPT2*, a more decouple behaviour between the two structural parts is also obtained, and therefore a lower reduction in the substructure accelerations.
- *OPT1* is particularly advantageous for the higher  $\mu$  values (for which the isolation drift is more sensitive –  $OF_2$ ), whereas *OPT2* for the lower  $\mu$  values (for which the superstructure acceleration is more sensitive –  $OF_3$ ). Finally, the solutions for  $OF_1=0.5$  seem a good compromise for both optimizations.

### Abstract

*The New San Giorgio Bridge has been built in a very short time between April 2019 and August 2020 in order to reconnect the highway system of the western part of Italy after the tragedy of the collapse of the Morandi Bridge, built in 1967 by prof. Riccardo Morandi. The new viaduct has a steel concrete composite closed section for the deck, a structural scheme of continuous beam with a total of 19 spans supported by elliptical concrete box piers with a maximum height of 40 m. The bridge is seismically isolated by means of friction pendulum devices and multidirectional bearings. In the transverse direction the seismic devices, except for two piers, are a combination of friction pendulum and shear fuses. The paper describes the construction supervision process for the functional acceptance tests of the bearing devices with respect to the Italian National Law, NTC2018, European norms EN15129 and EN1337, and in fulfilment with the Technical Specifications issued by the Italian Railway system (RFI) and Italian State Road Association (ANAS). The paper highlights the main issues encountered during the application of the several specifications for the certification and acceptance processes. A description of the different functional tests required during the construction supervision process is presented as well as an overview of the different acceptance criteria of the tests results. The aim is to provide useful recommendations for technicians involved in the definition of the seismic acceptance tests for bearing devices for highway bridges in the Italian and European contest.*

## 1 INTRODUCTION

On the 14<sup>th</sup> August 2018 the highway Viaduct of the A10, one of the strategic roads of the northern part of Italy, collapsed. This tragedy caused the death of 43 people that were crossing the bridge in that moment.

The viaduct was designed between the 1964 and 1967 by the famous Italian Engineer prof. Riccardo Morandi and it was a cable stayed bridge structure with reinforced concrete post tensioned cables.

On December 2018, RINA Consulting was charged to develop the Project and Management, the Construction Supervision, the Health and Safety Management for the demolition of the Morandi Bridge and for the reconstruction of the Polcevera Viaduct, the Genoa new San Giorgio Bridge (called for brevity San Giorgio Bridge in the following) designed by the Arch. Renzo Piano. In this process, RINA took the role of technical and administrative support of the Commissioner all along the design process and it has been present during all the activities of demolition and reconstruction from the beginning to the end.

The San Giorgio Bridge has been designed by Italferr, starting from the concept of Arch. Renzo Piano, and has been built by a consortium called PerGenova and composed by WeBuild and Fincantieri. Because of the emergency, the reconstruction of the bridge was a very challenging task as it involved in parallel the project development and the construction phase.

As part of the Construction Supervision role, an important activity is the quality assurance that requires the control of the construction products on site as well as in the factories.

One of the most important task related to the quality control for the San Giorgio Bridge was related to the qualification and acceptance tests of the seismic devices and bearings installed in the viaduct to isolate the steel-concrete deck from the piers. This requires the development of a detailed “Testing Protocol” as part of the quality control activity and this document has been deployed taking into account: i) design specifications according to the design developed by Italferr; ii) drawings developed by the manufacturer Maurer SE and FIP-MEC; iii) European norms and Italian specifications; iv) technical capabilities of the testing devices present worldwide.

Figure 1 shows the San Giorgio Bridge after the construction phase. The testing program according to the construction and project plan aiming at match the main milestones in terms of deck launching and the time required to perform the tests. To this aim, the required functional tests have been organized in compliance with the construction plan requirement with the support and contribution of all the laboratories charged to execute the tests. Differently from other general design projects, in this case the acceptance process corresponds with the certification process, generating many issues normally not present. Indeed, in this case, the devices are not commercially produced elements, but have been realized “ad hoc” for the bridge, due to the requirements from the design specifications (e.g., the presence of the 100 meter spans and the condition of only 2 devices on each pier led to significant dimensions and acting forces for the devices).

This paper presents a detailed description of the whole testing program with a particular focus on the acceptance tests protocol, as well as a summary of the performance of the devices during the specified static and dynamic tests. Despite the demanding testing requirements in the new European norm, the results proved that the proposed design of the isolators successfully fulfilled the performance required for the acceptance of the devices.

Figure 1: Pictures of the San Giorgio Bridge.

## 2 THE SEISMIC ISOLATION SYSTEM OF THE SAN GIORGIO BRIDGE

The San Giorgio Bridge has a length of 1067 m and the road level is at a height of 40 m. The bridge has a steel-concrete composite deck with an overall width of 29.8 m and with a distance between the supports of 7 m. From the structural point of view, the bridge is a continuous beam with all spans' length of 50 m except for the three spans in the center (with a length of 100 m and for the spans near the abutments that are shorter).

The deck is seismically isolated from the piers. The supporting scheme has been designed to withstand the seismic actions, wind actions and thermal actions, particularly relevant in a bridge with a length of 1067 m without intermediate movement joints. Figure 2 shows a plan view of the bridge.

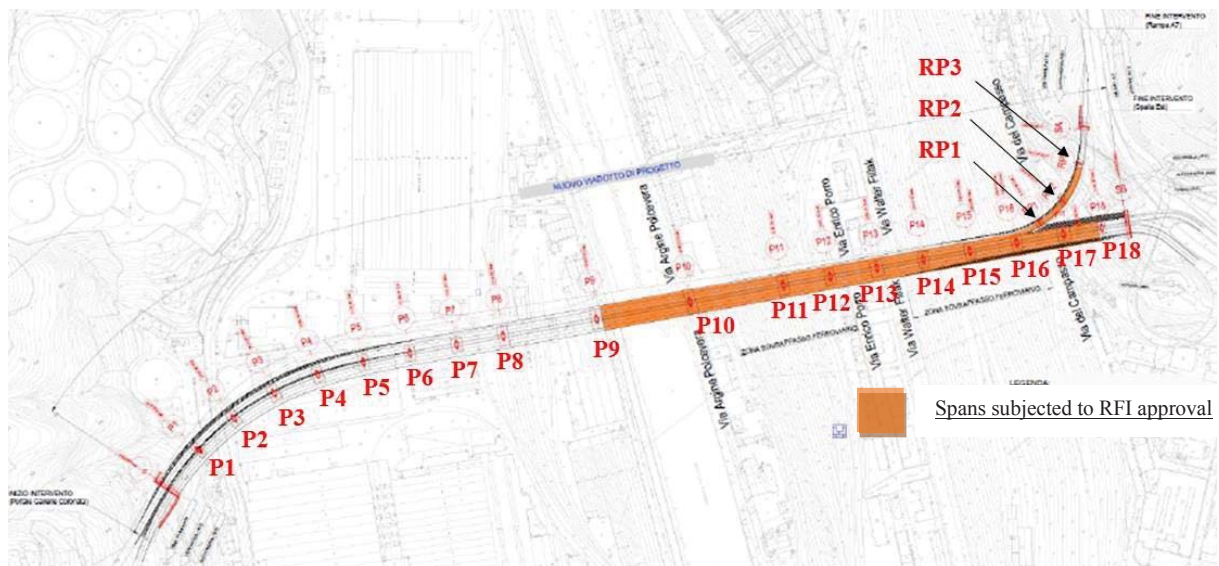

Figure 2: Plane view of the San Giorgio Bridge.

The bridge is equipped with the following devices (between the parenthesis, the nomenclature as per the UNI EN15129 [1] is reported), according to the plan view of Figure 2: i) two curved surface sliders (*friction pendulum*) on each pier from P2 to P17 with shear fuses for the device on the north side (*combined devices: curved surface sliders + fuses*) and without shear fuses for the device on the south side; ii) two multidirectional bearings on pier P1 and P18; iii) two multidirectional bearings on the abutments A, west side, and abutments B, east side; iv) a guided bearing in the center of the abutments; v) two curved surface sliders on the

piers RP1-RP2-RP3 of the ramp; vi) an elastomeric device in the center of the abutment A of the ramp; vii) two multidirectional bearings on the abutment A of the ramp.

The supporting system of the bridge has been designed to guarantee horizontal flexibility of the bridge during the seismic actions; this to increase the structural period of vibration and to reduce the seismic acceleration, while at the same time to limit the movement due to the wind actions. For this reason, the shear fuses are placed on the isolators in the south side of the piers from P2 to P17: these fuses aims at ensuring a fixed behaviour in the transversal direction for the serviceability limit states while they will break off in case of seismic event.

To avoid the direct contact between steel deck and concrete piers in case of extreme seismic events, the deck is also equipped with seismic restraints in the transversal direction in each pier and in the transversal and longitudinal direction in the abutments. Movement joints are provided only at the three abutments.

This paper focuses on the seismic certification and acceptance protocol followed for the curved surface sliders, friction pendulum and, then, for the categories i) and v) previously described. Moreover, a detailed discussion is provided with reference to the acceptance tests for the devices under investigation.

## 2.1 Seismic behavior of the curved surface sliders and combined devices

Curved surface sliders are seismic isolators that provide the four main functions of the base isolation (see UNI EN 15129, 3.1.26) through an appropriate arrangement of curved sliding surfaces; they use the characteristics of a pendulum to increase the natural period of the isolated structure. Several experimental and analytic studies on single and double concave surface sliders are present in literature, concerning different critical issues and the uniaxial and/or the biaxial response (e.g., [2-5]).

The curved main sliding surface of Curved Surfaces Sliders provides a restoring force at displacement  $d$ .

Energy is dissipated by friction due to movement in the main sliding surface. Rotations of the structure are accommodated by the secondary sliding surface.

Figure 3 shows the functional principle and main elements of curved surface sliders for the type A (see Table 1) curved surface sliders of the San Giorgio Bridge.

Figure 3: (a) Functional principle and main elements of Curved Surface Sliders for the type A (see Table 1) curved surface sliders of the San Giorgio Bridge; (b) picture of the device.

The constitutive law of this typology of devices in the horizontal plane, under constant axial load, is usually described with the following relationship [6]:

$$F = Mg \cdot \mu_{dyn} + \frac{Mg}{R} \cdot d \quad (1)$$

where:

F= horizontal force

Mg= N is the vertical force

R=radius of curvature of the device

d= horizontal displacement

$\mu_{dyn}$ =dynamic friction coefficient

The resultant hysteresis loop is reported in Figure 4.

Figure 4: Force-Displacement relationship of the curved surface slider referred to the benchmark-cycle 2 test for one of the bridge devices.

Figure 5 shows the break-away friction, also called stick-slip effect, that is the forces recorded when the motion of the device starts [7], as well as the increase of force that is recorded with the inversion of the velocity.

Figure 5: Experimental behavior of curved surface slider referred to the frictional resistance test for one of the bridge devices.

For the San Giorgio Bridge, the curved surface sliders are combined, in the transversal direction, with shear fuses. In this case, the device acts as a friction pendulum in the longitudi-

nal direction while for the transverse direction is fixed until a specific value of force is reached. Once the break-away force is reached the device has the same behavior in both the horizontal directions. The main objective of the combination of the shear fuses for the viaduct is to guarantee the benefits of the base isolation and to limit horizontal displacement under transversal wind loads.

### 3 THE CERTIFICATION AND ACCEPTANCE PROCESS FOR THE CURVED SURFACE SLIDERS IN THE EUROPEAN REGULATIONS FRAMEWORK

This chapter describes the certification and acceptance process for the curved surface sliders. Clearly, the design is directly linked to the recommendations of the country of realization of the construction. In the case of the San Giorgio Bridge, the Italian national code (NTC 2018, [8]) is inserted inside the context of European codes and specifically the UNI EN 15129 [1] and the UNI EN 1337 [9]. NTC 2018 [8] clearly separate the tests related to the certification process from the tests related to the acceptance process. This separation between certification and acceptance processes and the relative definition of the tests plan for the curved surface sliders is in perfect agreement with the suggestions of the UNI EN15129 [1] and UNI EN1337 [9]. Moreover, according to NTC 2018 [8] specific tests should be added based on the different type of isolators. For the case study of the San Giorgio Bridge, the curved surface sliders, described in Section 2, did not exist at the moment of the bridge design. They have been designed from the company *ad hoc* for the San Giorgio Bridge. Thus, in this case the certification and acceptance processes develop in parallel.

For the certification procedure, NTC 2018 (11.9.2) [8] requires that the anti-seismic devices must comply with the European standard harmonized UNI EN 15129 [1] and have the CE marking. The system of evaluation and verification of the constancy of performance, provided for in the aforementioned UNI EN 15129 [1], is applied. The certification procedures are intended to demonstrate that the device is capable of maintaining its functionality under the conditions of use envisaged throughout the life of the project.

For the acceptance procedure, NTC 2018 (11.9.3) [8] requires mandatory on-site acceptance checks for all the types of devices; furthermore, the Works Supervisor, before in-situ implementation, verifies the required certification documentation, and refuses the non-conforming devices. The Works Supervisor should also carry out the geometric verification and dimensional tolerances. The acceptance tests can be performed and certified by a laboratory that is able to guarantee adequate competence, equipment and organization. For the curved surface sliders, the methodology for the tests acceptance plan definition and for the relative evaluation criteria are those reported in the UNI EN 15129 [1] with reference to the Factory Production Control tests. Then, it is possible to use, for the purposes of acceptance tests, also the Factory Production Control tests carried out within the certification process of the devices in accordance with UNI EN 15129 [1] if (conditions respected for the case study San Giorgio Bridge): i) the sampling of the devices was carried out, on the lots destined for the specific site, by the Works Supervisor of construction site; ii) the tests are performed and certified by a laboratory with adequate expertise, equipment and organization; iii) the aforementioned certificates explicitly indicate the construction site (s) where the supply is used.

Finally, the devices subjected to certification or acceptance tests may be used in construction only if: i) the elements stressed in the non-linear field are replaced or if their resistance to low-cycle fatigue is at least one order of magnitude higher than the number of test cycles; ii) and in any case only after that they are subject to verification of their perfect integrity and full functionality.

The number of devices subjected to acceptance tests for the curved surface sliders is provided in Section NTC 2018 11.9.8.1 [8]. The acceptance tests must involve at least 20% of the

devices, in any case not less than 4 and no more than the number of devices to be implemented.

### 3.1 UNI EN 15129

The UNI EN 15129 [1] standard is the European standard for the description of the process of certification and acceptance for the curved surface sliders. The UNI EN 15129 [1] requirements have been integrated with additional tests required by national recommendations. However, a brief summary of the entire process of certification and acceptance processes is summarized herein. Chapter 10 of UNI EN 15129 [1] concerns the Assessment and Verification of the Constancy of the Performance (AVCP). It specifies that the conformity of the anti-seismic devices to the requirements of UNI EN 15129 [1] and to the performance declared from the producer have to be demonstrated through: i) type-product identification; ii) check of production in factory from the fabricator, including the assessment of the product.

Type-product identification is represented by the type tests that form the certification process together with the acquisition of the CE marking. According to UNI EN 15129 (10.2) [1], all the mechanical features of the sliders needed for the design to guarantee the service life, should be determined through type tests on full scale sliders, also including cyclic tests. The tests results should confirm the representative values of the mechanical features of the sliders.

Check of production in factory is represented by the factory production control (FPC) tests that form the acceptance process. According to UNI EN 15129 (10.3) [1], the fabricator should keep a FPC system to ensure that the sliders are in compliance with the performance declared in their essential features. The FPC includes also some specific tests for the devices and the check on the raw materials. These general rules are valid for all type of sliders, while the curved surface sliders are specifically analysed in Section 8.3.4 of UNI EN 15129 [1], defining the type tests (8.3.4.1) and the FPC tests (8.3.4.2).

Then, coherently with the purpose of this work, a focus is herein dedicated to the FPC tests to complete the acceptance of the devices. Section 8.3.4.2 of UNI EN 15129 [1] presents the tests to be implemented for the curved surface sliders (see Figure 6). In order to complete the FPC checks, the following tests are required:

- a) Vertical load bearing capacity (see Sect. 8.3.1.2.2.2 and 8.3.4.1.2 of UNI EN 15129 [1]);
- b) Frictional resistance force under service conditions (see Sect. 8.3.1.2.2.5 and 8.3.4.1.3 of UNI EN 15129 [1]);
- c) Test run P1, also called benchmark test (see Sect. 8.3.1.2.2.6 and 8.3.4.1.5 of UNI EN 15129 [1]).

The testing of raw materials and constituents shall be carried out in accordance with Tab. 16 of UNI EN 1337- 2:2004 [9] or, in case of other sliding materials, according regulations provided in the respective European Technical Approval (ETA).

In conclusion, Figure 6 summarizes the acceptance protocol of curved surface sliders in an European framework, based on recommendations described in this chapter. Note that in addition to the required tests from the UNI EN 15129 [1], additional tests recommended from the national codes and from other authorities involved in the project can be added to the tests protocol. Indeed, this was one of the main challenge of the acceptance test procedure: to ensure the compliance to all the European and Italian codes and at the same time to guarantee the fulfilment of the technical specifications issued by the Italian Railway system (RFI) and by the Italian State Road Association (ANAS).

Figure 6: Flow-chart of acceptance protocol for the curved surface sliders.

In the case study of the San Giorgio Bridge, the Italian national code (NTC 2018, 11.9.8, [8]) suggests adding to the protocol another test, called Quasi Static test. Moreover, it is to note that in the case study of the San Giorgio Bridge, also the Technical Specifications issued by the Italian Railway system (RFI) and Italian State Road Association (ANAS) have been considered in the acceptance process. In particular, additional tests have been added to the acceptance protocol tests based on the recommendations of RFI, that in some cases proposed tests conceptually similar to the ones from UNI EN 1529 [1], but using different load conditions/setup conditions/acceptance parameters. In this paper, the acceptance tests required by the RFI specifications are not treated.

#### 4 ACCEPTANCE PROTOCOL TESTS: THE SAN GIORGIO BRIDGE CASE STUDY

The main objectives of the testing program carried out for the San Giorgio Bridge were: i) to guarantee the fulfilment of the applicable technical norms; ii) to guarantee the respect of the design planned performances; iii) to investigate the behaviour of the devices with respect to the comments and prescriptions issued by the different authorities during the approval process of the project (e.g. Technical Authority of the Italian Minister of Transportation and comments by the Commissioning Authority); iv) to investigate the durability and long-term behaviour of the devices applying all the tests available as per the most updated state of the art in this field.

All the above objectives have been addressed aiming at the same time at the respect of the project and construction plan.

Pursuing that the codes and specifications cannot regulate every aspects of complex phenomena, a pro-active role of the Construction Supervision team, in strong cooperation with the designer with the manufacturer and with the laboratories, has been deployed with the common purpose to verify the performance of the seismic devices while at the same time respecting the construction program.

The seismic acceptance tests have been performed in different testing facilities depending on their loading and displacement capacity and at the same time to make feasible the execution of different tests in parallel. Each testing facility was used for a similar group of devices to obtain more comparable results for similar bearings. The following laboratories have been involved in the experimental program:

- SismaLab under the supervision of the Polytechnic of Milan for the device of the ramp and for the shear fuses;
- Polytechnic of Milan using the external premises of FIP-MEC in Padua for the break-away tests of the combined device friction pendulum + fuses;
- Eucentre Lab in Pavia for friction pendulum and multidirectional bearings.

This section presents the acceptance protocol (UNI EN 15129 [1] FPC tests plus national code required tests) for the case study of the San Giorgio Bridge. Note that additional tests on the conformity of the characteristics of the materials in accordance with Tab. 16 of UNI EN 1337- 2:2004 [9] have been implemented. Moreover, under the supervision of the RFI specialists, other tests have been carried out based on their protocol. Table 1 reports the under investigation, the type of tests performed and the standard to which each test refers (tests done in accordance with the RFI specifications are not included here).

CURVED SURFACE SLIDERS TYPE	PIER	TEST			
<b>TYPE A:</b> 3 SLIDERS ON THE 100 METERS BAYS	P9/3, P10/3 and P11/2	Load Bearing Capacity UNI EN 15129	Frictional Resistance UNI EN 15129	Benchmark UNI EN 15129	Quasi-Static NTC 2018
<b>TYPE B:</b> 4 SLIDERS ON THE 50 METERS BAYS	P2/3, P13/3, P2/2 and P12/2				
<b>TYPE C:</b> 4 SLIDERS ON THE BRIDGE RAMP	RP3/R2, RP3/R3, RP2/R2 and RP1/R2				

Table 1: Summary of devices under investigation and relevant tests (see Figure 2 for labels).

The following nomenclature is used: the number after “P” refers to the pier number as reported in Figure 2, while the number after the “/” refers to the location of the devices on the pier (“3” for the northern support and “2” for the southern supports). The supports located on the southern side are combined devices (curved surface sliders + shear fuses).

The sliders types have been in depth discussed in Section 2 while the present section focuses on a critical discussion on the main issues occurred during the test program:

- Because the devices were not commercially produced elements, but have been realized “*ad hoc*” for the bridge, due to the requirements from the design specifications, the acceptance tests were carried out in parallel with those related to certification process. The UNI EN15129 [1] does not require full test for the combined devices in the acceptance tests protocol while it suggests only one test in the certification process. This may lead to significant issues in the cases in which the certification and acceptance processes correspond; indeed, high priority should be given to the combined device test, because it is crucial to verify that unexpected interferences between the components of the devices, that can affect the behavior of the whole device, are avoided. For the case study of the San Giorgio Bridge, the Construction Supervision team required the implementation of specific tests for the combined devices (tests in the transversal direction, break away tests on two sacrificial devices among others); however, they are not discussed in detail in this paper. During the combined tests, small modifications/upgrading can be necessary, such as in the case study, and this clearly point out that such a test should occur before the single components tests;
- The vertical loads are sometimes very high in particular for modern bridges (i.e. 1.3  $N_{ULS}$ =axial load from gravity load combination for ultimate limit states is required for the load bearing capacity test). This could imply that testing facilities may have not adequate capacity. These constraints should be taken into account in the design of structures/infrastructures to easily allow to tests the components (potentially in

the same geographical region of the construction), based on the current instrumentations availability of the laboratories; otherwise a significant increase of time and cost for testing not conventional devices should be considered. The norms should also provide specific procedures in such cases in order to simplify the whole procedure, by keeping the same safety level. The same problems may occur in terms of displacement requirements;

- the design of small friction values may imply that the calibration forces of the laboratory equipment can be comparable to forces to be measured; this can strongly affect the tests results.

Furthermore, as discussed in the following sections, the interpretation of some tests of UNI EN 15129 [1] may in some case not univocal or not always quantitative (e.g., see Faverage definition in the next Section).

From here, a specific focus is dedicated to the benchmark test, that is the more important dynamic test inside the requirements of UNI EN 15129 [1] in the acceptance phase.

#### 4.1 Benchmark test

In the context of the curved surface sliders acceptance tests, the benchmark test is required from UNI EN 15129 [1] with two purposes:

- 1) Verification of cycle stability in terms of fluctuation of the test force with respect to the average force;
- 2) Verification of the dynamic friction coefficient.

The load application method (UNI EN 15129 8.3.4.1.5 [1]) is reported as follows in Table 2, where  $d_{bd}$  is defined as the maximum design displacement of the device. During the test, a permanent vertical load  $N_{sd}$  (seismic combination) was applied to the device.

Type of test	Test run	Compression load $N_s$ [kN]	Displacement $d_0$ [mm]	Peak velocity $v_0$ [mm/s]	Number of complete cycles
Benchmark	P1	$N_{sd}$	$1 \times d_{bd}$	50	3

Table 2: Load application method for the benchmark test (UNI EN 15129 8.3.4.1.5 [1]).

About the test acceptance criteria, according to UNI EN 15129 8.3.1.6 [1], the movement in the sliding surfaces shall be regular and uniform and without producing any type of vibrations such as those induced by the stick-slip phenomenon. The force oscillation needs to be contained inside a variation range of  $\pm 5\%$  of the average restoring force, at any level of bearing displacement up to 85% of the maximum displacement required from the test protocol. The average restoring force shall be obtained from the best-fit straight line determined by the least square interpolation of the response between  $\pm 85\%$  of the maximum displacement.

Then the requirement for the satisfaction of the test can be summarized as:

$$\text{for } (-0.85) d_{bd} < d < (+0.85) d_{bd} : F_{\text{regression}} - (0.05 F_{\text{average}}) < F_{\text{test}} < F_{\text{regression}} + (0.05 F_{\text{average}}) \quad (2)$$

Moreover, the dynamic friction coefficient needs to fall within the limits specified by the Structural Engineer under the testing conditions specified in UNI EN 15129 8.3.4.1.5 [1]. Then, it is considered necessary to verify that the dynamic friction coefficient deriving from the test falls within the lower and upper bounds used in the design phase. The following check can be performed by calculating the average dynamic friction using the following formulation:

$$\mu = \frac{H}{2 \cdot (d^+ + |d^-|) \cdot V_{\text{load}}} \quad (3)$$

where:  $H$  = area subtended by the curve,  $d^+$  = maximum displacement,  $d^-$  = minimum displacement,  $V_{load}$  = vertical load. This value should vary inside the lower/upper bound range.

Then, the final requirement is that:

$$\mu_{lower\ bound} < \mu < \mu_{upper\ bound} \quad (4)$$

As for example, the results of the benchmark test on P10/3 slider (label producer MAU112E19-10) is discussed herein. Figure 7 shows the three force-displacement cycles of the test. Moreover, the displacements-time and forces-time plots for the 3 cycles are presented in Figure 8.

Figure 7: Displacement-force plot for the 3 cycles of the benchmark test.

Figure 8: Displacements-time and forces-time plots for the 3 cycles.

Then, the graphical verification of the cycle stability in terms of fluctuation of the test force at each step with respect to the average force is presented in Figures 9-11 for the three cycles. It can be noted a continuous stability of the response has been registered through the 3 cycles investigated.

Figure 9: Stability verification for the cycle 1.

Figure 10: Stability verification for the cycle 2.

Figure 11: Stability verification for the cycle 3.

In accordance with Equation 3, the value of the dynamic frictional coefficient in the three cycles has been calculated and reported in Table 3.

Herein a summary of the dynamic frictional coefficient in the three cycles is reported (Table 3).

Cycle 1	Cycle 2	Cycle 3
0.5%	0.5%	0.5%

Table 3: Summary of the dynamic frictional coefficient in the three cycles.

The UNI EN 15129 [1] states that the average restoring force shall be obtained from the best-fit straight line determined by the least square interpolation of the response  $\pm 85\%$  of the test displacement peak. Fluctuations in horizontal force must be less than  $\pm 5\%$  of the average restoring force, at any level of displacement of the sliding isolator up to  $85\%$  of the test displacement peak. Thus, the procedure to identify for which value of this average restoring force the  $5\%$  interval should be calculated may lead to different interpretations (i.e. with respect to the interval in which the test outcome should be contained in order to satisfy the test). It is clear that this mentioned value should depend on an average of the maximum forces reached during the test in correspondence of the  $\pm 85\%$  of the test displacement peak, but a more straightforward explanation could help the users.

## 5 CONCLUSIONS

The San Giorgio Bridge has been built in a very short time between April 2019 and August 2020 in order to reconnect the highway system of the western part of Italy after the tragedy of the collapse of the Morandi Bridge. The new viaduct has a steel concrete composite closes section for the deck, a structural scheme of continuous beam with a total of 19 spans supported by elliptical concrete box piers with a maximum height of 40 m. The bridge is seismically isolated by means of a composition of friction pendulum devices and multidirectional bearings. One of the most important tasks related to the quality control for the San Giorgio Bridge is related to the qualification and acceptance tests of the seismic devices and bearings planed in the viaduct to isolate the steel-concrete deck from the piers. The testing program for the curved surface sliders was planned also considering the construction and project plan aiming at match the main milestones in terms of deck launching and the time required to perform the test. To do so, the required functional tests have been organized in compliance with the construction plan requirement with the important support and contribution of all the laboratories charged to execute the tests.

A detailed description of the whole testing program with a particular focus on the acceptance tests protocol, as well as a summary of the performance of the devices during the specified static and dynamic tests, has been discussed herein. Despite the demanding testing requirements in the new European norm, the results proved that the proposed design of the isolators successfully fulfilled the performance required for the acceptance of the devices. Differently from other general design projects, in this case the acceptance process corresponds with the certification process, generating many uncommon issues. In fact, in this case, the devices are not commercially produced elements, but have been realized “*ad hoc*” for the bridge, due to the requirements from the design specifications (e.g., the presence of the 100 meter spans and the presence of only two bearing per each pier have conducted to big dimensions and big forces for the devices). During the implementation of the tests program, many issues came out and have been deeply described through the paper.

Different important suggestions arisen from the experience of the preparation of the seismic acceptance tests.

First of all, it is important that the designer considers, since the design stage, to define devices with testable parameters. The vertical loads are sometimes very high in particular for modern bridges and the testing facilities may have not adequate capacity. The designers should design the structures/infrastructures in way that all the components are testable (potentially in the same geographical region of the construction), based on the current instrumentations availability of the laboratories to avoid significant time and cost increase in the certification/acceptance process. Specific standards may be introduced by technical norms and guidelines in such cases in order to simplify the whole procedure, by keeping the same safety level. A strong cooperation between the testing facilities, the designers, the manufacturers and

the Construction Supervision team is required in order to define the adequate tests able to assess the performances of the devices and hence guarantee a high level of quality control while at the same time respecting the construction and manufacturing schedule.

## ACKNOWLEDGMENTS

The authors would like to acknowledge the manufacturers Maurer SE and FIP-MEC for their professional cooperation during the whole project. A special thanks also goes to the laboratories (Eucentre, SismaLab and the Polytechnic of Milan) for their strong support in the definition of the seismic acceptance tests and for the assistance during the testing campaign. Finally, the authors wish to acknowledge the consortium PerGenova, the designer Italferr, the technical department of RFI and the Commissioning Authorities part of ANAS group for their technical support in the definition and interpretation of the tests.

### Abstract

*Base isolation represents one of the most efficient strategy for the reduction of the structural vulnerability of buildings and bridges. Design procedures generally aim to provide the proper period shift, in order to reduce spectral acceleration values and, consequently, the base shear and internal forces. On the other hand, high displacement demands can be achieved, which can be partially limited by providing dissipative capacity through hysteretic behaviors. Although design procedures allow to fairly estimate the design displacement of the adopted devices, extreme seismic event can occur, and displacement higher than the design value can be experienced. Especially for Curved Surface Slider devices, if the displacement demand exceeds a certain geometrical limit, non-negligible damage can occur at the sliding pad, and variations in the force response are consequently noticed.*

*In this work modeling strategies for the computation of the seismic response of base-isolated buildings are presented, by considering extreme earthquake loading conditions. Analytical models are reported for Curved Surface Slider devices, calibrated through the experimental outcomes of tests performed at the Laboratory of EUCENTRE Foundation in Pavia (Italy). In addition, simplified dynamic systems are defined, which allow fast assessments of the global response of a base-isolated structure, even though extreme seismic events are applied. Results have been compared to the response returned by an experimental hybrid simulation, in order to evaluate the accuracy of the presented dynamic systems.*

**Keywords:** Base isolation, Curved Surface Slider, extreme earthquake loading, dynamic system, experimental hybrid simulation.

---

## 1 INTRODUCTION

Recent research works about seismic isolation have led to the definition of several modeling strategies for isolators, models which can be adopted in time history analyses for the assessment to building and bridge structural systems, by reducing significantly the uncertainty of the structural behavior prediction ([1], [7], [16]). The design of the proper period elongation, internal forces in the superstructure elements can be significantly reduced; on the other hand a large displacement demand may occur at the isolation level, even though lower values can be achieved, by means of the hysteretic characteristics of the implemented devices. Curved Surface Slider devices, among the others, represent one of the most suitable solutions for base-isolation ([2], [3], [10], [12], [13], [14]). Such isolators can actually accommodate large displacement demands, with potentially high dissipative capacities, which are provided by the frictional response of the induced sliding motion. In addition, residual displacements are effectively limited by the recentering behavior, due to the spherical shape of the sliding surfaces. However, recent risk assessment studies have shown that the base isolation technique in some cases can lead to higher seismic risk, with respect to their a correspondent fixed-base configuration. This is an unexpected outcome, since the isolation system is supposed to protect the superstructure against the effects of earthquake excitations. The main reason behind such results is related to the definition of the collapse condition that has is commonly assumed for isolation devices, which consists of the achievement of the design displacement. More specifically, a sliding base isolator is assumed to collapse once the internal reaches the edge of the implemented sliding surfaces, which corresponds to the maximum stroke of the device. This condition is generally considered as the maximum limit of the displacement capacity for sliding devices, because it is associated to the loss of functionality of the isolator. However, recent experimental research has led to evidence of extra-displacement capacity for such devices, with a controlled and limited force response ([6][8]); furthermore, the outcomes have been used for both model calibration and vulnerability assessments, in order to account for the effective ultimate conditions of the implemented isolators.

In this work the extra-stroke behavior of Double Curved Surface Slider devices has been modeled, in order to evaluate the response of a base isolated case study structure, subjected to a severe seismic event. An easy to implement analytical model of the extra-design response has been adopted, among the strategies available in the very recent literature, and results have been compared to a hybrid simulation, which has been performed at the Laboratory of EUCENTRE Foundation in Pavia (Italy). The outcomes of both the experimental hybrid and numerical simulations have been analyzed, in terms of isolation displacement and hysteretic responses, cumulative damage at the sliding pads equipped in the physical device and building base shear time series.

## 2 CASE STUDY STRUCTURE

The case study structure adopted in this research work consists of a reinforced concrete frame structure, which has been modeled by means of linear-elastic frame elements, by considering a reinforced concrete slab as an interface between the superstructure and the isolation layer, implemented through a mesh of shell elements (Figure 1).

Figure 1: Case study structure.

The frame structure has four spans along both  $x$  and  $y$  directions with equal span length (6m each), and all floors have an interstorey height of 3m. Concerning the concrete slab, which represents the interface between the implemented isolation devices and the building, a thickness of 500mm has been adopted, and plan dimensions have been designed, by increasing the plan development of the superstructure of 1.5m along all directions (27m x 27m). For all the frame elements the flexural stiffness has been reduced, in order to better fit the linear-elastic branch of the bi-linear approximation of the capacity curve, as shown in Figure 1. The full capacity curve, in terms of base-shear vs. top displacement of the fixed-base configuration of the building has been obtained through a pushover analysis carried out through the software SeismoStruct ([15]), which allows to model force-based frame elements, with distributed plasticity and non-linear constitutive laws for materials (Mander's model for Concrete and Menegotto-Pinto's model for reinforcement steel); in addition, for concrete columns the proper confinement effects within the concrete core has been accounted for, in order to obtain realistic evaluation of both ductility and strength for all the implemented sections. Isolation devices are represented by Concave Surface Slider devices.

### 3 CHARACTERISTICS OF THE PHYSICAL DEVICE

The physical isolator consists of a Double Curved Surface Slider ([5]), which is actually the most typical configuration of sliding devices designed in real practice applications (Figure 2). Two spherical sliding surfaces with the same curvature radius have been implemented, both polished to mirror finish in order to achieve a roughness index  $R_a$  of 0,2 ([10]). Within the equal sliding surfaces, a non-articulated slider is installed, which is made up of a unique steel block (material S355JR): such an element houses two circular sliding pads, having same diameter (360mm) and same material composition, aiming at considering the same contact pressure and the same frictional properties at both the sliding interfaces. Both the radii of curvature of the spherical surfaces are 1600mm each, with internal slider height of 120mm: consequently, the equivalent radius of curvature of the device is approximately equal to 3080mm.

The device has been equipped with an innovative sliding material, which consists of a graded PTFE material, filled with bronze fibers. In addition, the sliding surface of the pad has been realized with dimpled recesses, with a light lubrication, in order to achieve the proper design friction coefficient, equal to 3% ([4]); the corresponding value of applied vertical load is equal to 1500kN. The maximum displacement, given the assumed plan geometric characteristics of sliding surfaces and internal slider, is equal to 172mm.

Figure 2: Tested physical device: definition of maximum displacement.

In order to consider a significant extra-stroke displacement demand, the maximum displacement to be considered for the simulation, which will define the proper scaling of the input signal, is defined according to the design value, increased by 50% of the sliding pad diameter, so that 25% of the pad is uncovered by each sliding surface ([6]). Thus, a maximum displacement of 350mm has been considered.

#### 4 NUMERICAL SUBSTRUCTURE AND DYNAMIC SYSTEM

The case study structure has been numerically modeled as an equivalent Multi Degree of Freedom oscillator, thanks to a special static condensation procedure, which has been applied to the full 3D FEM model of the structure ([9]). In Table 1 the resulting mass and stiffness matrices are reported.

941.3	0.0	0.0	0.0
0.0	589.7	0.0	0.0
0.0	0.0	589.7	0.0

-329731	617351.8	-377915	90295.5
111851.3	-377915	479479.9	-213416
-18776.6	90295.5	-213416	141894.8

Table 1: Mass (left [tons]) and stiffness (right [kN/m]) condensed matrices for the case study structure.

Such matrices allow to obtain dynamic properties almost overlapped of the ones related to the full FEM model; this result is a direct consequence of the adopted static condensation procedure, which allows to account for the actual flexural behavior in the out-of-plane direction for beams, together with torsional behavior of each floor. It is important to highlight that the response of the isolation system is not modeled by the stiffness matrix, since that contribution needs to be accounted for separately, especially for the hybrid simulation.

For both the hybrid test and the numerical simulation, the superstructure has been modeled through the definition of the aforementioned equivalent multi degree of freedom (MDOF) oscillator, with statically condensed mass and stiffness matrices. By adopting such matrices the actual dynamic properties of the overall structural systems are effectively reproduced, and approximately the same response of the full 3D FEM model can be obtained. Consequently, the dynamic system can be expressed as follows:

$$\overline{\overline{M}} \cdot \begin{pmatrix} \ddot{u}_0 \\ \ddot{u}_1 \\ \ddot{u}_2 \\ \ddot{u}_3 \end{pmatrix} + \overline{\overline{K}} \cdot \begin{pmatrix} u_0 \\ u_1 \\ u_2 \\ u_3 \end{pmatrix} + \langle F_{is} \rangle \cdot \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix} = -\overline{\overline{M}} \cdot \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} \cdot \ddot{x}_g \quad (1)$$

Given:

- $\overline{\overline{M}}$  the condensed mass matrix of the system;
- $\overline{\overline{K}}$  the condensed stiffness matrix of the system;
- $u_i$  the translational degrees of freedom at the centre of mass location of the i-th floor;
- $\ddot{x}_g$  the considered ground acceleration time series;
- $\langle F_{is} \rangle$  the isolation force response.

A very low additional viscous damping has been considered for both simulations, namely 2%, modeled by means of the Rayleigh formulation, in order not to underestimate the overall response. The isolation system is considered separately in the dynamic system, and it is modeled as a single device, representative of the whole set of isolators. For the hybrid simulation, the isolation force is computed as a function of the force feedback of the Bearing Tester System, which is then scaled by the ratio between the total structural weight of the system and the applied vertical load to the device. On the other hand, in the numerical simulations, the following analytical expression can be adopted:

$$\langle F_{is} \rangle = W_{tot} \cdot \left( \frac{u_0}{R_{eq}} + k_\mu \cdot \mu \cdot f_{NF} \right) \quad (2)$$

Being:

- $W_{tot}$  the total structural weight of the system;
- $R_{eq}$  the equivalent radius of curvature of the device;
- $u_0$  the translational degree of freedom at the centre of mass location of the concrete slab (isolation level);
- $\mu$  the design friction coefficient;
- $f_{NF}$  a normalized frictional hysteretic parameter;
- $k_\mu = \mu / \mu_o$  a variation scale factor of the friction coefficient.

In order to model the frictional hysteretic response, a hysteretic parameter  $f_{NF}$  has been adopted, by assuming an elasto-plastic rule (Figure 3).

Figure 3: Analytical model of the frictional hysteretic (left) and extra-stroke (right) responses.

Since the overall system is supposed to be subjected to a severe seismic input, and consequently the design displacement of the isolation system is expected to be overcome, the extra-stroke behavior needs to be numerically modeled. Recent research works ([6], [8]) have shown good agreement between some experimental outcomes pseudo-dynamic tests in extra-stroke range for DCSS devices and possible numerical modeling strategies, namely:

- Analytical expression of the friction coefficient increase, for easy and fast structural assessments;
- An opensee link element for the extra-stroke response;
- An opensee link element, modeled for variable friction sliding isolators.

In this work the first strategy has been considered, by applying an analytical function, which increases the friction coefficient value, as the design displacement is exceeded. The increment of the friction coefficient in the extra-stroke range has been assumed equal to 50%.

## 5 SEISMIC INPUT

The input signal for both numerical and experimental hybrid simulations has been selected within the REXEL database ([11]), by checking the peak displacement of an equivalent Single Degree of Freedom (SDOF) system, with the non-linear hysteretic constitutive law of the implemented isolation system. The scale factor of the seismic event has been computed, aiming at obtaining a maximum displacement less than 350mm, which corresponds to the maximum displacement in the extra-stroke range considered in this study. A seismic event with a limited scale factor has been adopted, so that a realistic balance between amplitude and frequency content of the signal is ensured. Below the main characteristics of the selected earthquake are listed:

- Earthquake Name: *Gazli*
- Station ID: *KAR*
- Component: *x*

- Mw: 6.7
- Fault Mechanism: *reverse*
- Epicentral Distance [km]: 12.78
- Original PGA [g]: 0.717
- Scaled PGA [g]: 0.789
- Scale Factor [#]: 1.1

In Figure 4 graphical properties of the seismic event used for all the simulations are provided, in terms of time series of ground displacement and acceleration, together with the acceleration response spectrum at 5% damping.

Figure 4: Characteristics of the adopted seismic event.

The resulting response spectrum show significantly high spectral coordinates at low periods, whereas more limited values can be noticed for high period values, much more related to the designed isolated system.

The hybrid simulation has been carried out by considering the superstructure as the aforementioned MDOF oscillator as a numerical substructure, whereas the full-scale device tested within the Bearing Tester System has been considered as the physical substructure, to carry out an earthquake simulation. To do so, within the hybrid simulation algorithm a time scale factor equal to 32 has been adopted.

## 6 RESULTS

Results of both numerical and experimental hybrid simulations are compared in this section, by focusing the attention on the isolation response, in terms of displacement demand and hysteretic behavior, and damage evidence at the implemented sliding pads has been checked after the test. In addition, the response of the superstructure has been analyzed, in order to assess if

the building has been subjected to excitations within the linear-elastic range. In Figure 5 the displacement time series of the isolation layer are compared, with respect to the design value.

Figure 5: Isolation displacement response.

In Figure 6 the hysteretic response of the isolation system is provided, in terms of isolation force, normalized with respect to the total weight of the whole structural system.

Figure 6: Isolation hysteretic behavior.

In Figure 7 the damage evidence at the sliding pad at the end of the experimental hybrid test are shown.

Figure 7: Damage evidence at the sliding pads.

In the hybrid simulation the full scale device has been subjected to displacement demands higher than the design value three times, at three consecutive peak displacement, under an approximately harmonic motion. The numerical simulation shown approximately an overlapped signal, exception made for the very last portion of the seismic event, where the design displacement is experimentally exceeded for the third time: at those time instants the numerical simulation returns lower displacement values, within the ordinary response of the isolator. The main reason of this final mismatching could be addressed to the degradation of the friction coefficient, which can be graphically noticed in the hysteretic response. Due to the subsequent extra-stroke displacement demands, significant damage occurs at the sliding interfaces, and this results into an increased pressure (caused by detachments of sliding material) and to a continuously decreasing friction coefficient. The degradation of the frictional properties finally leads to higher displacement demands, in comparison to the purely numerical model, which accounts for a constant friction coefficient. Nonetheless, for almost the whole duration of the simulation, the numerical model provides approximately overlapped signals, from both displacement and hysteretic responses, with a good estimate of the peak parameters. The increase of the friction coefficient modeled in the numerical simulation (+50%) due to the extra-stroke behavior fairly capture the experimental response of the full device in the hybrid test. Thus, results for the isolation system seems to suggest that the frictional properties may be influenced by the extra-stroke behavior, depending on the number of subsequent displacement demands exceeding the design value and, consequently, on the entity of the cumulative damage at the sliding pad.

Finally, in Figure 8 the building response is shown.

Figure 8: Building base shear response.

The building base shear response seems not to be significantly influenced by extra-stroke displacement demands at the isolation system, mainly because of the smooth increase of the friction coefficient which occurs, when the design displacement is overcome, according to the technology of devices under investigation. In addition, for the whole duration of the simulations, the building response is within the linear-elastic range, and confirm that the modeling assumptions of the MDOF system of the superstructure is fairly good for the considered system. The numerical simulation returns a slightly higher response in comparison to the experimental hybrid test, even though signals are very close one to each other.

## 7 CONCLUSIONS

In this work the response of a base isolated case study structure has been assessed, through a numerical simulation, by assuming an extreme seismic event. Specifically, the system has been subjected to an ad hoc selected earthquake, in order to overcome the design displacement at the isolation layer. The obtained results have been compared to the outcomes of a corresponding experimental hybrid test, in which the superstructure model represents the numerical substructure, whereas as a physical substructure a full-scale device has been tested within the Bearing Tester System of the Laboratory of EUCENTRE Foundation in Pavia (Italy). In the numerical simulation the extra-stroke behavior has been modeled by means of a specific function, which increases the friction coefficient, as the design displacement is overcome.

By analyzing both the experimental and numerical results, the following findings can be found:

- The numerical model can fairly represent the effective experimental hysteretic behavior of the physical device, when subjected to extra-design displacement demands;
- The displacement time series at the isolation level returned by the numerical simulation is approximately overlapped, in comparison to the outcomes of the hybrid test, exception made for the last phase of the event;
- Toward the end of the earthquake simulation, the numerical model underestimates the displacement response, with displacements within the ordinary stroke of the device, in comparison to the hybrid test, which show an additional extra-design displacement at the same time instants;
- The main reason for possible mismatching at the end of the seismic event could be addressed to the cumulative damage which develops at the implemented sliding pads: due to an increase of the contact pressure the friction coefficient value decreases, and consequently larger displacement demands can be found, in comparison to the numerical simulation which accounts for a constant friction coefficient in the ordinary response;
- Thus, subsequent extra-design displacement demands could lead to excessive cumulative damage, which may imply degradations of the frictional properties;
- The extra-stroke behavior seems to have negligible effects on the building response, in terms of base shear and top displacement signals.

Further experimental investigations are needed on the topic, in order to highlight eventual dependencies of the extra-stroke behavior on the common response parameters considered to characterize sliding isolators, such as sliding velocity and vertical load.

### Abstract

*Despite it is well known that the shear properties of High Damping Rubber Bearings (HDRBs) are affected by the instantaneous compression load developed during the seismic ground motion, only permissible variations of their design properties with frequency, temperature and ageing are prescribed in the standards while the influence of the compression level is usually disregarded.*

*Within this framework, this research addresses this drawback through both experimental and numerical investigations. In the first part of the study, small scale laminated isolators are tested on a custom biaxial machine in order to assess the secant modulus, and damping factor of the elastomeric compound under different compression levels. In the second part, the same phenomenon is investigated through cyclic shear tests on full scale HDRBs under three different levels of axial load. In the last part, a 3D finite element model of the isolator is eventually formulated in Abaqus FEM software. The mechanical response of the elastomer is simulated by means of a hyperelastic strain energy function combined with a relaxation function.*

*The experimental results highlight the substantial influence of the axial load on the damping capacity of the elastomer, while the shear modulus is less affected. The numerical analyses demonstrate that the vertical – horizontal coupled response of HDRBs can be accurately predicted, within the proposed formulation, with constitutive parameters estimated from simple uniaxial tests.*

**Keywords:** High Damping Rubber Bearings, shear modulus, equivalent viscous damping, axial load, experiments, numerical model.

## 1 INTRODUCTION

Base isolation is today a viable solution to mitigate the effects of earthquakes on constructions. The design of the base isolation hardware necessary to implement such strategy, such as elastomeric isolators and sliding bearings, has been developed in the past decades by many researchers and is today regulated by standards.

Rubber bearings have been used as seismic isolators since the mid of the '70s [1]. Today the most popular types of rubber isolators are the High Damping Rubber Bearings (HDRBs) and the Lead Rubber Bearings (LRBs). The mechanical characteristics of HDRBs affecting their performance as seismic isolators, namely stiffness and damping, depend only on the mechanical properties of the rubber compound. On the contrary, in LRBs the elastomer is required to provide the horizontal stiffness to the isolation system as well as a certain restoring capability, while the damping capacity relies on the hysteretic deformation of the lead core. A large variety of elastomeric compounds based on either natural or synthetic rubber is nowadays available for HDRBs and LRBs, with different damping, shear modulus, and vulcanization profile, according to proprietary techniques developed by the manufacturers.

An accurate characterization of the mechanical properties of the elastomer is fundamental for the design of HDRBs and LRBs. Nevertheless, despite of the large diffusion of these devices, some shaded areas still exist that need further investigation. One issue is the dependency of the mechanical properties on the environment [2]. To date, a large part of the studies on the behaviour of rubber for bridge bearings focused on their ageing deterioration [3]. However, the mechanical properties of elastomers can change due to a number of factors other than ageing, such as the strain amplitude, the frequency of loading, the number of cycles, and air temperature variations, and the response of a structure seismically isolated with rubber bearings can be strongly influenced by each of the above parameters [4].

According to the European Standard on anti-seismic devices [5], two sets of design properties must be determined for elastomeric isolators, the Upper Bound Design Properties (UBDP) leading to the maximum forces in the superstructure, and the Lower Bound Design Properties (LBDP) leading to the maximum displacements of the isolation system. Both UBDP and LBDP should be derived from tests performed on full scale devices, but for HDRBs the Standard allows to determine the effects of temperature, frequency and ageing by testing rubber specimens under pure shear, instead of full isolators, as it is acknowledged that the cyclic behaviour of steel reinforced rubber bearings is primarily governed by the mechanical properties of rubber [6]. An important factor that is generally ignored when testing rubber specimens is the influence of the compression stress on the shear properties of the elastomer, which was instead demonstrated to have a fundamental importance and needs to be taken into account for a correct understanding of the behaviour of HDRBs under service conditions [7].

One of the first studies addressing this topic was published by Aiken [8], who tested HDRBs with shape factors (ratio of load area to stress-free area of a single rubber layer) of 8.75 and 20 and design axial stresses of 3.2 and 5.1 MPa, respectively. The bearings were tested at several levels of compression stress, from 0 to 10 MPa for the first geometry and from 0 to 15 MPa for the second geometry, and the results showed an increase of both shear stiffness and damping with the compression load. Kelly [9] evaluated the performance of a rubber isolator characterized by nominal shear modulus of 0.86 MPa, damping of 15% and shape factor of 30. The compression stress was increased from 0 to 10.34 MPa, and the tests showed a negligible influence on the shear stiffness, while the damping increased from 13% to 17% (relative change of 30%).

Mori [10] tested five isolators differing for geometry and rubber mixture. When the axial load was small in comparison with the design value (say 34%), then the shear hysteresis loop

was a different shape from that one under the high applied axial load. Also, the area of the hysteresis loops became larger (i.e. damping increased) as the axial load was increased. On the contrary the influence of the axial load within the range between 0.68 and 1.25 times the design value on the shear stiffness was negligible. Iizuka [11] tested laminated elastomeric bearings with shape factor 20 under four different levels of compression (0; 4.90; 9.81; 19.60 MPa) up to 500% shear strain. The study confirmed the influence of the axial load on the nonlinear large-deformation shear behaviour of rubber, resulting in strain-hardening in the shear direction under small axial forces, but decrease in horizontal stiffness under large axial forces probably due to buckling of the rubber layers. Ryan [12] studied the behaviour of HDRBs with design axial stress of 3.2 MPa and shape factor of 8.27 and 20 respectively, subjected to the combined action of compression and shear force, concluding that in the range 0 to 10 MPa the shear stiffness of HDRBs decreases with increasing of the axial load.

From the review of the above literature it is clear that, though the influence of the axial load on the shear properties of HDRBs is a fact, the sensitivity of the individual bearing can vary significantly depending on the type and amount of fillers and by the amount of cross-linking of the mixture [13].

The paper presents some approaches for investigating the influence of the axial load on the shear properties of HDRBs from both an experimental and a numerical perspective. All the studies are performed on the same natural rubber compound. In the first part of the study, small scale prototypes of HDRBs are tested under varying axial load in the range of 0.5 to about 21 MPa, whereas in the second part the tests are performed on real scale isolators, and some experimental issues are put in evidence. Eventually, a numerical analysis is performed by using as case study the elastomeric isolator tested at full scale.

## 2 SMALL SCALE PROTOTYPES

### 2.1 Test pieces

Small circular test pieces (Fig. 1), with diameter  $D = 80$  mm, are used. Every piece includes 10 rubber layers, 4 mm in thickness each, alternated to 2 mm thick steel plates. The upper and the lower rubber layers are vulcanized to two thick (10 mm) steel plates that fit recessing holes in the plates of the testing machine. The test pieces are made of commercial rubber compound, categorized as “Normal” (hardness between 55 and 65 International Rubber Hardness Degree (IRHD)), with shear modulus  $G = 0.75$  MPa and equivalent viscous damping factor  $\xi = 12\%$ . The total thickness of rubber, which is the parameter that governs the maximum shear displacement, is 40 mm, while the primary and the secondary shape factors are  $S_1 = 5$  and  $S_2 = 2$ , respectively.  $S_1$  is defined as the ratio of the compressed area of the rubber layer divided by the area of lateral surface free to bulge, while  $S_2$  is the aspect ratio, i.e. the bearing diameter divided by the total rubber thickness [14].

Figure 1: Small scale HDRB test piece: picture of a specimen (left), and cross-section (right).

## 2.2 Test set-up

The biaxial testing system is illustrated in Fig. 2-left. The system consists of a stiff four columns steel frame equipped with two servo-hydraulic jacks. The vertical jack, rated 500 kN, applies the compressive load to the test piece, while the horizontal jack, rated 100 kN and with a 100 mm stroke, drives a shear plate that moves horizontally. The system permits to test simultaneously a pair of test pieces, placed symmetrically with respect to the shear plate in a double shear configuration (Fig. 2-right).

Figure 2: Schematic view of the biaxial test set-up (left), and test pieces in double shear configuration (right).

## 2.3 Test procedure

The sequence of tests performed on the pair of HDRB test pieces is outlined in Table 1. By adjusting the vertical load, the compression stress  $p$  is varied from a minimum value of 0.1 MPa to a maximum value of 24 MPa, with 3 MPa increments up to 12 MPa, and 6 MPa increments above 12 MPa. At each stress level, five full cycles of horizontal displacement are imposed with sinusoidal waveform, frequency  $f = 0.5$  Hz and amplitude 40 mm, resulting in a shear strain amplitude  $\gamma_a = 100\%$ . The sequence of tests is carried out in order of increasing vertical loads, with a dwell time of 30 minutes between any pair of tests in order to allow the viscoelastic recovery of the rubber. The tests are performed at a room temperature of  $19 \pm 2^\circ\text{C}$ .

$p$ (MPa)	$\gamma_a$ (%)	$f$ (Hz)	cycles
0.1 – 3 – 6 – 9	100	0.5	5
– 12 – 18 – 24			

Table 1: Test protocol for small scale HDRB test pieces.

## 2.4 Results

Fig. 3 illustrates the hysteretic shear force–displacement curves obtained at different levels of pressure ; in the diagrams, only the curve relevant at the third cycle is reported for each stress level. It is evident the large difference in shape between the curve at 0.1 MPa (i.e. virtually

without axial load), and the curves relevant to tests at  $p \geq 3$  MPa, with a substantial increase of the dissipated energy (i.e., the area enclosed in the loop).

From the horizontal force  $F$  and the horizontal deflection  $d$  of the single specimen, the shear stress  $\tau$  and shear strain  $\gamma$  of rubber are calculated as follows:

$$\tau = \frac{F}{A} \quad (1)$$

$$\gamma = \frac{d}{t_e} \quad (2)$$

where  $A$  is the area of the plan section of a rubber layer parallel to the direction of shear, and  $t_e$  is the total thickness of rubber subjected to shear. From the hysteretic shear stress–strain diagram, the secant shear modulus  $G$  and the equivalent viscous damping factor  $\xi$  are then calculated at each cycle:

$$G = \frac{\tau_2 - \tau_1}{2 \cdot \gamma_a} \quad (3)$$

$$\xi = \frac{EDC}{2\pi \cdot G \gamma_a^2} \quad (4)$$

where  $\tau_1$  and  $\tau_2$  are the stresses at the maximum shear deflections in either direction,  $EDC$  is the energy dissipated per cycle and  $\gamma_a = 1$  is the shear strain amplitude.

Figure 3: Shear force – displacement loops at different pressure levels.

Fig. 4 plots the change of  $G$  and  $\xi$  as a function of the compression stress  $p$ . The secant modulus has a 10% decrease when  $p$  rises from 3 MPa to 6 MPa, and holds constant for higher pressure levels. The equivalent viscous damping factor has a 38% increase when  $p$  is increased from 0.1 MPa to 3 MPa, and a further 10% increase at  $p = 6$  MPa, and then it holds substantially stable up to  $p = 24$  MPa.

Figure 4: Influence of the compression stress on secant shear modulus (left) and equivalent viscous damping factor (right); values are determined at the third cycle.

### 3 FULL SCALE ISOLATORS

#### 3.1 Test pieces

The tests pieces are two HDRBs designed for an axial load  $N_{sd} = 1150$  kN and a seismic displacement  $d_{bd} = 250$  mm. The devices are circular in shape, with a diameter of 500 mm and a total thickness of 218 mm. Each HDRB consists of 14 rubber layers, 9 mm thick each, alternated with 13 steel plates, 4 mm thick, and 2 end plates of 20 mm thickness. The primary and the secondary shape factors are  $S_1 = 18.9$  and  $S_2 = 2$ , respectively. A sketch of the cross section of the isolator is shown in Fig. 5. The raw material is the same rubber compound used to manufacture the small scale test pieces.

Figure 5: Sketch of the HDRD specimen, and cross-section details.

#### 3.2 Test set-up

The tests were performed at the Laboratory for Testing of Materials and Structures (SisLaB) at the University of Basilicata, using a custom bearing tester system (Fig. 6). The facility has load capacity of 8000 kN in the vertical direction and 1000 kN in the horizontal direction, and a displacement capacity of 1000 mm. The system incorporates a plate supported by low-friction bearings which moves in the horizontal direction, and allows to apply a shear force to the isolator. A single device can be tested each time.

Figure 6: The bearing tester system at University of Basilicata.

### 3.3 Test procedure

The sequence of tests performed on the HDRB isolators is illustrated in Table 2. The devices are tested at 0.45, 1.0 and 2.0 times the design axial load  $N_{sd}$ , which correspond to a compressive stress on rubber of 2.63, 5.85 and 11.70 MPa respectively. At each load level, three sinusoidal cycles are performed to a maximum displacement  $d_{bd} = 250$  mm, corresponding to a shear strain amplitude  $\gamma_a = 198\%$ , at a frequency  $f = 0.5$  Hz. The dwell time between two tests is of about 20 minutes. All tests are performed at room temperature.

$N$ (kN)	$d_{bd}$ (mm)	$f$ (Hz)	cycles
1150	250	0.5	3
530	250	0.5	3
2300	250	0.5	3

Table 2: Test protocol for HDRB isolators ( $N$ : axial load;  $d_{bd}$ : displacement amplitude).

### 3.4 Results

Fig. 7 illustrates the variation of the effective stiffness  $k_{eff}$ , evaluated at the maximum shear deflection, and the equivalent viscous damping factor  $\xi$  with the axial load. The shear stiffness at  $N_{sd}$  is found to decrease by 9% when the axial load is halved, and to decrease by 14% when the axial load is increased by a factor of 2. This behaviour, which is inconsistent with the findings of the small scale test, may be ascribed to the insufficient duration of the dwell time between the first and the second tests, at 1150 kN and 530 kN respectively, which could be too short to permit complete cooling of the isolator. Since the modulus of rubber decreases with increasing of temperature, this can explain the unexpected decay of stiffness at 0.45  $N_{sd}$ . The equivalent viscous damping factor has a more regular behaviour, with a negligible change when the design load is halved, and a 25% increase on average when the design load is increased by a factor of 2.

The secant modulus of the rubber can be calculated from the effective stiffness of the isolator. For a compressive stress of 5.85 MPa, corresponding to  $N_{sd}$ , the value of the secant

modulus derived from the tests on isolators counts  $G = 0.87$  MPa, which is 25% higher than the value ( $G = 0.7$  MPa) determined in the small scale tests; similarly, the equivalent viscous factor of the isolator is about 50% less than the relevant figure assessed on the small scale pieces (10.4% against 20%).

Figure 7: Influence of axial load on effective stiffness (left), and equivalent viscous damping factor (right) of full scale HDRBs; values determined at the third cycle.

## 4 FINITE ELEMENT INVESTIGATION

### 4.1 Numerical formulation

A 3D finite element model of the HDRB isolator shown in Fig. 5 has been formulated in the software program Abaqus. Taking advantage from the symmetry of the device, only half of the isolator has been modelled (Fig. 8). The size of the mesh of finite elements for the rubber layers is  $10 \times 4.5$  mm. The mechanical behaviour of the elastomer has been described by using a hyperelastic constitutive law [15] to represent the force-displacement relationship, and an exponential Prony series to represent the viscous behaviour. Model parameters have been calibrated based on experimental data obtained from uniaxial tensile tests and stress relaxation tests on rubber specimens (Fig. 9), according to the procedure described by [16]. Numerical analyses have been performed by simulating the application of an axial load on the isolator, and a concurrent displacement in the horizontal direction. The horizontal displacement is applied according to a sinusoidal waveform, with amplitude  $d_{bd} = 250$  mm and frequency  $f = 0.5$  Hz. Simulations have been performed for three values of axial load, namely  $N = 530$  kN,  $N = 1150$  kN, and  $N = 2300$  kN, with 3 cycles per load level.

Figure 8: 3D finite element model of the HDRB isolator.

Figure 9: Calibration of elastomer constitutive parameters implemented in the finite element model of HDRB: hyperelastic Yeoh model (left), and Prony series (right).

## 4.2 Results

Fig. 10 compares the horizontal force – displacement curves predicted by the numerical code to the experimental curves obtained in the tests on full scale HDRBs. By considering the third cycle of loading, the agreement is fair for both the tests at  $N = 1150$  kN and  $N = 530$  kN, while at  $N = 2230$  kN the numerical model is capable to correctly reproduce the loading branch of the curve, but underestimates the actual damping and the dissipation capability of the isolator.

The effective stiffness and equivalent viscous damping factor calculated in the numerical analyses are eventually compared to the experimental values in Table 3. The numerical model calculates a decrease in stiffness when the axial load is increased from  $N_{sd}$  to  $2 N_{sd}$ , but  $k_{eff}$  does not change substantially when the axial load is reduced to  $0.5 N_{sd}$ . The accuracy of the numerical prediction is good as concern the stiffness (8% deviation at  $2 N_{sd}$ ), but the model underestimates the actual damping capacity of the isolators and is not able to capture the increase in viscous damping when  $N$  passes from  $N_{sd}$  to  $2 N_{sd}$  (30% deviation).

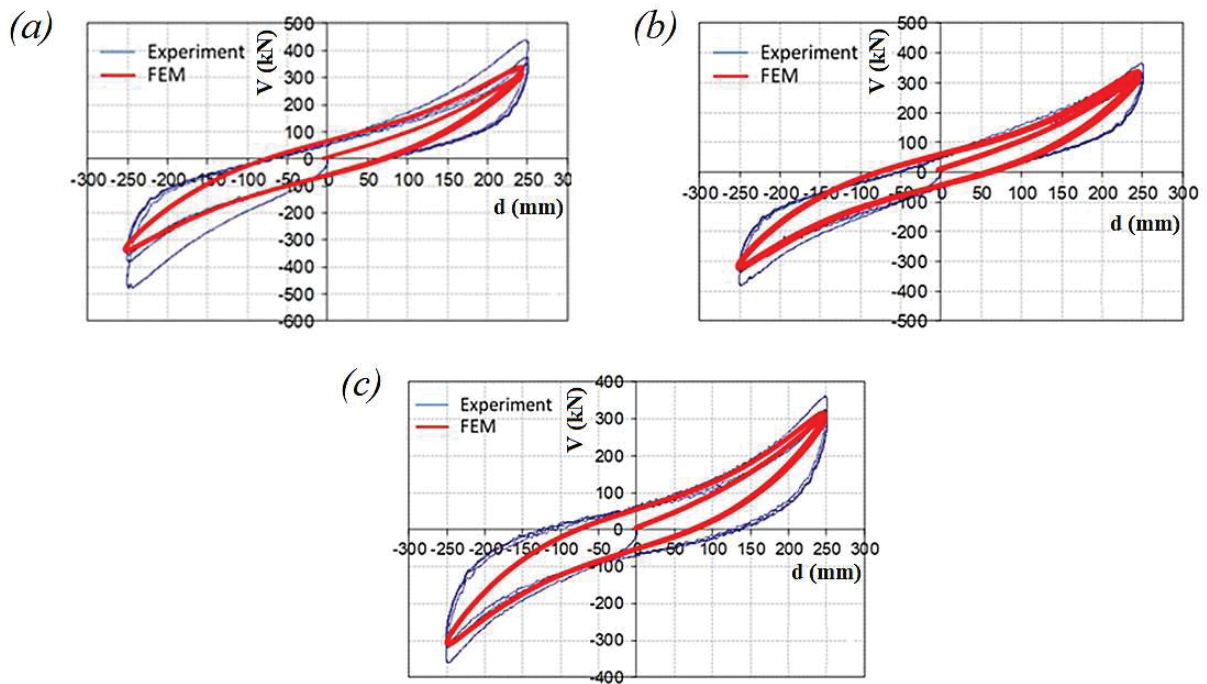

Figure 10: Comparison between experimental and numerical (FEM) force – displacement curves of the HDRB isolator at different levels of axial load: (a)  $N = 1150$  kN; (b)  $N = 530$  kN; (c)  $N = 2300$  kN.

$N$ (kN)	$k_{eff}$ (kN/mm)		$\xi$ (%)	
	EXP	FEM	EXP	FEM
1150	1.36	1.36	10.40	9.17
530	1.25	1.32	9.95	8.33
2300	1.16	1.26	12.95	9.03

Table 3: Experimental (EXP) and numerical (FEM) values of effective stiffness and equivalent viscous damping factor at different levels of axial load.

## 5 DISCUSSION

The study presents three different approaches to investigate the influence of the axial load on the properties in shear of HDRBs.

Experiments on small scale test pieces are rather cheap; indeed, the specimens are small and easy to manufacture, and a wide range of combinations of axial load and horizontal displacement can be tested at an affordable cost. Owing to the small size of the specimens, heating of the elastomer is expected to be small. Consistent results were obtained in the test campaign illustrated in this paper. However scaling effect may limit the accuracy of the extrapolation of the results to the real scale.

Tests on full scale isolators are expensive because require dedicated facilities and because the specimens are large and bulky. Moreover, heating of the isolator and its effect on the shear response may be not negligible in tests involving large energy inputs. Therefore in designing the experimental protocol an appropriate dwell time after each test must be envisaged in order to allow cooling of the specimens. However, since the tests are performed at the real scale, the results can be directly transferred to the application.

Numerical analyses allow to investigate many loading scenarios at a very limited cost, but the numerical model needs to be validated against experimental data to provide reliable results. Whereas accurate hyperelastic models are available to capture the actual stress – strain relationship of standard rubber, the viscous behavior of elastomeric compounds has not yet been effectively implemented into numerical codes.

## 6 CONCLUSIONS

The characterization of the effects of the axial load on the properties in shear of HDRBs is fundamental for developing accurate analyses and design of base isolation systems.

Examples of experimental and numerical approaches to investigate this subject have been presented in the paper. Whereas testing of small scale pieces is convenient at the stage of development and characterization of new rubber compounds, numerical analyses and testing of full scale isolators are most indicated at the final stage of design and validation of isolators for the real application.

Both small scale and large scale tests evidence that the axial load has a more substantial influence on the equivalent viscous damping than on the shear modulus of the elastomer. The numerical analyses demonstrate that the vertical – horizontal coupling of HDRBs can be deducted with a sufficient reliability from the characteristics of the elastomer measured in simple uniaxial tests, though more consistent models for viscous damping need to be formulated.

### Abstract

*In the immediate aftermath of an earthquake, it is essential that emergency plans and damage scenarios are available so that civil protection agencies and risk-management organizations can detect and contain critical situations. These tools rely on the knowledge of the specific features of the potentially affected area, both in terms of intrinsic characteristics (e.g. morphology, near surface geology, etc.) and of elements at risk (e.g. building typologies, population distribution, etc.). All these pieces of information are combined in seismic-risk or damage scenario assessment procedures. This paper presents a framework developed for estimating seismic damage scenarios for the Emilia Romagna region in Northern Italy. Models for estimating ground-motion shake maps, based on regional attenuation relationships, spatial correlation models and soil data are first presented. These maps, which are computed considering different ground-motion intensity measures, are then combined with data on the spatial distribution of buildings, and fragility models. In order to consider the different sources of uncertainty, i.e. ground-motion intensity, definition of the fragility models, etc., a Monte Carlo simulation approach is used for estimating the distribution of buildings with different damage levels in each municipality. Finally, the paper presents comparisons with damage data observed after the 2012 Emilia earthquake.*

**Keywords:** Damage scenarios, Fragility assessment, Shake maps, Spatial correlation, Emilia earthquakes.

---

## 1 INTRODUCTION

Seismic risk assessment has the objective of identifying and highlighting the most vulnerable areas in a territory, and thus providing data to limit as much as possible earthquake-induced losses (e.g. economical, human lives, building stock, etc.). To this aim, damage scenarios can be estimated, both at national and regional scales. They are defined by studying past earthquake data in order to estimate the probability of exceeding different damage states in buildings and to quantify the expected losses. Up to date, there are many examples on how to derive damage scenarios, either based on site-specific analyses [1–5] or on larger-scales assessments [6]. After the 2012 earthquake studies have been focused on the Emilia-Romagna region [3,7]. Verderame et al. derived damage scenarios for reinforced concrete buildings and fragility curves were derived combining the Response Surface Method with nonlinear static analyses. Meroni et al. instead adopted the EMS-98 vulnerability classes definition to characterize the regional building stock and expressed its fragility in terms of macroseismic intensity.

The most commonly adopted procedures for the assessment of damage scenarios first require the identification of building types and the characterization of the building stock at the considered scale (i.e. urban, regional, national). In Italy the only complete catalog of the built heritage is the national Census, updated every ten years by the National Institute of Statistics (ISTAT). This survey, however, has the objective of mapping demographics and thus is very poor in terms of structural details of the investigated buildings. Nevertheless, some data are available concerning structural materials, number of stories and age of construction. Afterwards, estimates of the ground-motion intensity are needed. These are often given in the form of *shake-maps*, i.e. maps providing the spatial distribution of the values of a ground-motion Intensity Measure (IM). Finally, the effects of an earthquake on buildings are predicted combining data from shake maps and fragility models. These latter define the probability of exceeding a certain damage level as a function of the ground-motion intensity. Depending on the methodology employed for their derivation, fragility models can either be (i) *empirical* when obtained by fitting statistical models to observational data; (ii) *analytical* when calibrated upon numerical analyses on structural models; (iii) *experts' judgement-based* when estimated through experts' opinions.

Existing works [3,8] rely on already computed maps to derive vulnerability and exposure models. This study, however, wants to present a comprehensive approach in the definition of damage scenarios for the portion of the Emilia region affected by the 2012 Earthquakes. The adopted computational procedure for the derivation of shake maps is derived by literature studies but relies on specific attenuation relationships calibrated on the available ground motion recordings from the Emilia 2012 earthquakes. Fragility models, which are also specific for the context under consideration, are combined with the ground motion intensity and building distributions through a Monte Carlo simulation approach. This methodology allows to evaluate the damage distribution for each municipality in the area of interest. Outputs obtained with this procedure are then compared with the actual damage distribution observed after the 2012 Emilia earthquakes.

## 2 SHAKE MAPS FOR THE 2012 EMILIA EARTHQUAKES

Shake maps provide a graphical representation of the ground shaking intensity, described by means of an IM, and describe its distribution in an area affected by a seismic event. In the approach adopted here, the ground-motion intensity is first estimated for a regularly spaced grid by means of an attenuation relationship. These values are then combined with data for ground-motion recording stations using a spatial correlation model. The main steps of the procedure, as well as the models adopted, are described in the following.

## 2.1 The 2012 Emilia earthquakes

In May 2012, the provinces of Modena, Bologna and Ferrara, in northern Italy, were affected by a sequence of moderate seismic events which culminated in two main shocks on the 20<sup>th</sup> and 29<sup>th</sup> May, with moment magnitude equal to 6.1 and 6.0 [9], respectively. Ground-motion's data recorded during this seismic sequence was used to fit ground-motion attenuation models. Only the events with  $M_w \geq 5$  were considered to this purpose. Furthermore, since, as discussed in the following Section, the attenuation relationship's form adopted requires the definition of the geometry of the fault rupture plane, shocks for which this information was not available were excluded. Based on these criteria the four events listed in Table 1 were selected.

Event	Date	Municipality	Latitude [°]	Longitude [°]	Depth [Km]	$M_w$	GM records
20 <sup>th</sup> May main shock	2012-05-20 02:03:50	Finale Emilia	44.8955 0	11.26350	9.5	6.1	260
29 <sup>th</sup> May main shock	2012-05-29 07:00:02	Medolla	44.8417 0	11.06570	8.07	6	284
29 <sup>th</sup> May aftershock	2012-05-29 10:55:56	Cavezzo	44.8652 0	10.97950	4.35	5.5	182
29 <sup>th</sup> May aftershock	2012-05-29 11:00:22	San Possidonio	44.8660 0	10.97630	7.2	5.5	149

Table 1: Main information about the select events from the 20<sup>th</sup> and 29<sup>th</sup> May Emilia 2012 sequence [9].

## 2.2 Ground-motion attenuation relationships

Attenuation relationships are empirical statistical models that define the dependency of the values of an IM on seismological parameters as magnitude and source-to-site distance and other parameters such as type of soil at the site, style of faulting, bedrock depth, etc. The functional form employed in this study is

$$\ln(IM) = c_1 + c_2 \cdot M + c_3 \cdot \ln\left(\sqrt{R^2 + c_4^2}\right) + c_5 \cdot \ln(R + 25) + sf + \sigma_w \varepsilon_w + \sigma_b \varepsilon_b \quad (1)$$

where  $\ln(IM)$  is the natural logarithm of PGARotD50, defined according to Boore et al. [10] as the 50<sup>th</sup> percentile of the PGA values obtained rotating the acceleration horizontal components from 0 to 180°,  $M$  is the moment magnitude,  $R$  is the Joyne-Boore distance in km,  $sf$  is a term describing site amplification effects,  $\varepsilon_w$  and  $\varepsilon_b$  are intra- and inter-event standard normal error terms, respectively,  $c_1, \dots, c_5$  are unknown regression coefficients,  $\sigma_w$  and  $\sigma_b$  are unknown standard deviations associated to the intra- and inter-event variability, respectively. The term  $sf$  is defined as:

$$sf = c_6 \cdot S_B + c_7 \cdot S_C + c_8 \cdot S_D \quad (2)$$

where  $c_6, \dots, c_8$  are unknown regression coefficients and  $S_B, S_C$  and  $S_D$  are dummy variables representing different soil classes. In particular,  $S_B$  is 1 for soil class B and 0 otherwise,  $S_C$  is 1 for soil class C and zero otherwise and  $S_D$  is 1 for soil class D and 0 otherwise. The definition of soil classes is based on the Italian Building Code [11]. The values of the unknown coefficients in Equations (1) and (2) are estimated by means of nonlinear mixed effects regression

models, using recorded acceleration data from all the ground-motion recording stations at a distance shorter than 200 km from the epicenters of the earthquakes listed in Table 1. This table also reports the number of ground-motion records associated with each event. The model in Eq. (1) incorporates fixed and random effects. The former are parameters assumed as constant over the different groups of observations (each earthquake is a group), while random effects are random variables that assume a different value for each earthquake. The obtained attenuation relationship is plotted in Fig. 1 together with PGARotD50 data for the four events considered. Random effects do not vary significantly for each separate event which means that the between-event standard deviation is quite limited.

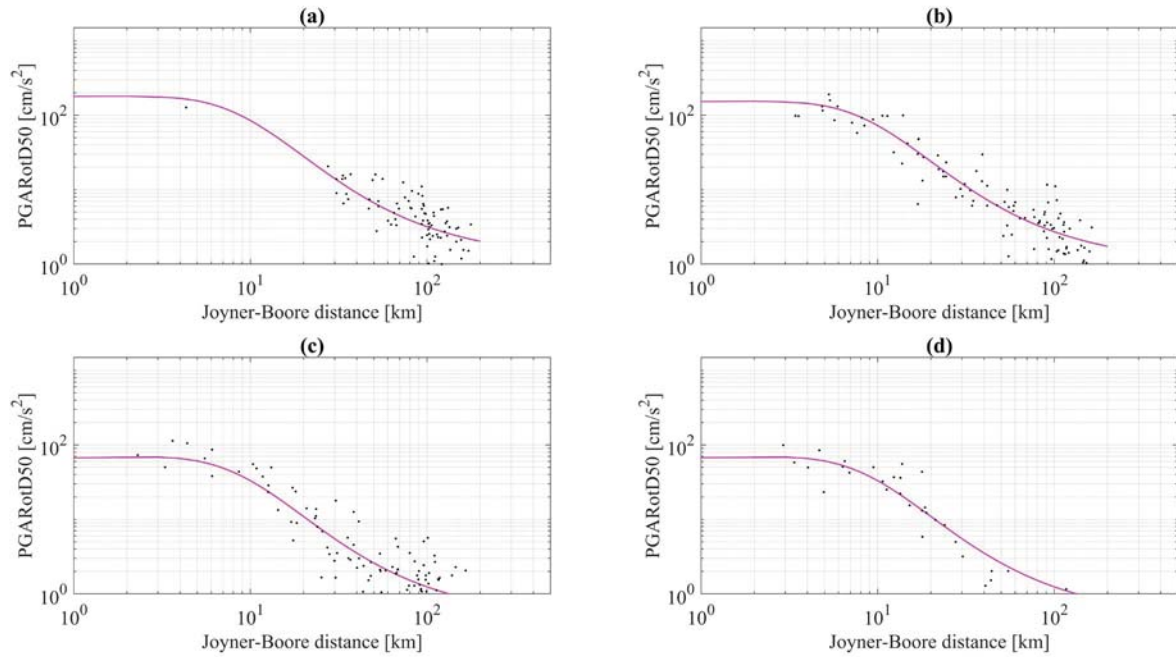

Fig. 1 – Attenuation relationship in logarithmic scale referred to an ideal rigid soil (class A). Blue dots are PGARot50 recordings for each event in terms of Joyner-Boore distance that have been referred to an equivalent soil type A. Event a) and b) are the main shocks of the 20<sup>th</sup> and 29<sup>th</sup> May respectively, while c) and d) are the 29<sup>th</sup> May aftershocks.

### 2.3 Spatial correlation models

Spatial correlation models must be defined for the computation of shake maps. In fact it has been observed that ground motion IM values are spatially correlated [12–14]. Clearly this correlation is not accounted for in the IM prediction given by attenuation relationships, which is for this reason called *unconditioned*. Shake maps instead combine the unconditioned distribution and recorded values, thus providing a *conditioned* distribution. Spatial correlation models were defined based on empirical semivariograms for the residuals obtained from the regression analysis carried out to fit the attenuation model. By visual comparison of different models, the spherical model was selected to fit the sample semivariograms. This model is defined as:

$$\gamma(h) = \begin{cases} \frac{3h}{2a} - \frac{1}{2} \left( \frac{h}{a} \right)^3 & \text{for } 0 \leq h \leq a \\ 1 & \text{for } h > a \end{cases} \quad (3)$$

being  $a$  the range and  $h$  the separation distance, whereas  $\gamma(h)$  is the semivariance. Spatial correlation is then obtained by subtracting the semivariance from unity.

## 2.4 Shake maps computation

As already mentioned in the previous sections, shake maps provide estimates of the spatial distribution of a ground motion IM over a certain area. Since a large number of ground-motion recordings is required in order to have reliable estimates, only the main events from the 20<sup>th</sup> and 29<sup>th</sup> May are considered from now on. Furthermore, it is also assumed that these events are those that contributed the most to building damage. Shake maps combine predictions from attenuation relationships, spatial correlation models and recorded IM values to derive estimates on a regular grid. The computational procedure adopted is derived from Bradley [13] and Worden et al. [15] and relies on the MVN theory. It is based on the hypothesis that the distribution of the natural logarithm of the IM produced by the earthquake  $e$  at site  $s$ , conditioned upon a set of  $N_{SMS}$  ground motion recordings,  $\ln(IM_{es}) | \ln(IM_{eSMS})$ , follows a multivariate normal distribution with mean value  $\mu_{\ln(IM_{es}) | \ln(IM_{eSMS})}$  and standard deviation  $\sigma_{\ln(IM_{es}) | \ln(IM_{eSMS})}$ :

$$\ln(IM_{es}) | \ln(IM_{eSMS}) \sim N(\mu_{\ln(IM_{es}) | \ln(IM_{eSMS})}, \sigma_{\ln(IM_{es}) | \ln(IM_{eSMS})}^2) \quad (4)$$

The mean value of this distribution can be estimated as:

$$\mu_{\ln(IM_{es}) | \ln(IM_{eSMS})} = \mu_{\ln(IM_{es})} + \Sigma_{\ln(IM_{es}), \ln(IM_{eSMS})} \Sigma_{\ln(IM_{eSMS}), \ln(IM_{eSMS})}^{-1} \delta_{W_{es}} + \delta_{B_e} \quad (5)$$

where  $\mu_{\ln(IM_{es})}$  is the unconditioned estimate of the mean value of the logarithm of the IM obtained by means of an attenuation relationship,  $\delta_{B_e}$  is the inter-event residual,  $\delta_{W_{es}}$  is a vector of intra-event residuals with  $N_{SMS}$  components,  $\Sigma_{\ln(IM_{eSMS}), \ln(IM_{eSMS})}$  is a variance-covariance matrix whose general term is defined as:

$$(\Sigma_{\ln(IM_{eSMS}), \ln(IM_{eSMS})})_{i,j} = \rho_{i,j} \sigma_W^2; \quad i = 1, \dots, N_{SMS}; \quad j = 1, \dots, N_{SMS} \quad (6)$$

being  $\rho_{i,j}$  the spatial correlation between the IM values at the  $i$ -th and  $j$ -th ground motion recording stations and  $\Sigma_{\ln(IM_{es}), \ln(IM_{eSMS})}$  is a variance-covariance matrix defined as:

$$(\Sigma_{\ln(IM_{es}), \ln(IM_{eSMS})})_{1,i} = \rho_{s,j} \sigma_W^2; \quad j = 1, \dots, N_{SMS} \quad (7)$$

Intra- and inter-event residuals are here determined by means of the attenuation relationship and are assumed to be normally distributed with null mean. The variance in Eq. (4) is computed as:

$$\sigma_{\ln(IM_{es}) | \ln(IM_{eSMS})}^2 = \sigma_W^2 - \Sigma_{\ln(IM_{es}), \ln(IM_{eSMS})} \Sigma_{\ln(IM_{eSMS}), \ln(IM_{eSMS})}^{-1} \Sigma_{\ln(IM_{eSMS}), \ln(IM_{es})} \quad (8)$$

Maps are computed for one event at time. In Figure 2 and the spatial distribution of PGARotD50 derived with the methodology just described is presented for the main shock of the 29<sup>th</sup> of May 2012, while Figure 3 shows the spatial distribution of the variance associated.

Fig. 2 - Shake map for the 29<sup>th</sup> of May 2012 event in terms of median PGARotD50 assuming uniform soil type C. Black dots are ground motion recording stations. The red polygon indicates the surface projection of the fault plane while the star symbol represents the position of the epicenter.

Fig. 3 - Spatial distribution of the variance associated with the  $\log_{10}(\text{PGARotD50})$  estimate. Variance is null in correspondence of ground motion recordings stations (black dots). The red polygon indicates the surface projection of the fault plane while the star symbol represents the position of the epicenter.

### 3 FRAGILITY MODELS

Fragility is generally referred to as the probability of exceeding a specific damage state conditioned to a certain ground motion IM value. Damage probability matrices (DPMs) describe fragility as a discrete quantity, relating the number of buildings with damage levels to some defined intervals of values of the IM [16,17]. To express fragility as a continuous function, parametric curves are often adopted. They represent the cumulative distribution function of the exceeding probability for the considered damage states. For the Emilia 2012 earthquakes a few specific models are available, both for masonry and reinforced concrete residential buildings. To carry out a damage scenario simulation, fragility models have to be consistent not only in terms of the building typology they refer to, but also in terms of adopted damage scale and ground motion IM considered. The following Sections describe the fragility models adopted in the present work; three different models for Reinforced Concrete (RC) and two models for unreinforced masonry structures.

#### 3.1 Fragility curves for unreinforced masonry structures

The characteristics of existing unreinforced masonry buildings are highly dependent on the quality and type of materials that can be found in a specific geographical area. For this reason, only models that have been derived from the Emilia-Romagna region residential masonry buildings were employed in this study. The first model used has been recently proposed by Ioannou et al. [18], and it is based on the analysis of damage data from the 2012 Emilia earthquake obtained from post-earthquake surveys. This dataset, however, is biased towards damaged buildings and the census [19] was used to complete the building stock with the undamaged buildings. Data was aggregated at the level of municipalities. It has often been highlighted [18,20,21] that this practice, common for empirical fragility assessment, reduces the level of detail in the building typology definition. The ground motion intensity was estimated using the attenuation model proposed by Bindi et al. [22]. Ioannou et al. then define several statistical models that relate 5 damage levels derived from EMS-98 to PGA, to the construction material (masonry, RC and other), to ground failure, and to the construction age. In the present study the model for masonry buildings was used.

The second set of curves was specifically derived by the authors in the present paper, based on statistical analysis of observational damage data. In a similar manner to the approach adopted in Ioannou et al., a complete database for masonry buildings, accounting for both the damaged and undamaged population, was obtained by combining information from post-earthquake surveys and census. The two sources were joined using the nearest neighbor criterion, i.e. for each post-earthquake survey form the nearest census building was deleted so that single entities are not double counted. Ground motion PGA values were estimated using maps derived according to the procedure described in Section 2. The fragility models obtained are based on logistic ordinal models, to avoid overlapping of fragility curves. The proportional odds assumption was introduced, thus considering that the slope of the curves is constant over the different damage levels. Specifically, a link logit function was used, and the covariate of the models was assumed to be constituted by the natural logarithm and squared natural logarithm of PGA, as shown in Eq. (9).

$$\Phi^{-1}(p_{i,j}) = \beta_{0,j} + \ln(IM_i) \beta_1 + \ln(IM_i)^2 \beta_2 \quad (9)$$

being  $\beta_{0,j}$  the intercept for each damage level, while  $\beta_1$  and  $\beta_2$  represent the slopes, constant among the different damage states. The two considered fragility models are shown in Fig. 4.

Fig. 4 – (a) Ioannou et al. [18] fragility curves and curves from the present work (b). Fragility is expressed in terms of PGA [g] for five different damage states.

### 3.2 Fragility curves for RC buildings

The first fragility model used in the present study was proposed by Verderame et al. [3]. These fragility curves were obtained by modeling infilled RC frames with 2 and 4 stories. Their geometry was defined after a detailed analysis of the damage distribution and of the residential building stock in some municipalities of the Emilia region while their structural detailing was derived referring to the post-1945 Italian regulations for RC buildings [23]. The capacity of these models was evaluated by means pushover analysis, while the IN2 method was used to estimate the displacement demand [24]. To derive fragility curves, damage thresholds expressed in terms of displacement capacity were first defined, while the variability of material characteristics or capacity parameters was accounted for by means of Response Surface meta-models. Lognormal fragility curves were obtained in terms of PGA for five different damage states, defined according to a mechanical interpretation of the EMS-98 scale [25].

The second fragility model adopted was developed by Salamida and Buratti [26] by applying nonlinear static analysis to study the structural response of 2- and 4-stories infilled RC frames, found to be the most common reinforced concrete residential building type in the Emilia region. Material properties and construction details were defined by means of simulated design, considering the Italian design adopted between 1950 and 1970. Damage states were defined from the EMS-98 scale as in Verderame et al., and fragility curves were calibrated separately for the different directions of application of the seismic action and for distributions of lateral loads. Overall fragility curves, were then computed as the mean probability of exceedance for the separate curves.

The third model used was proposed by Secci [27] and was developed through statistical analysis of data on the observed damage on RC buildings from the 2009 L'Aquila earthquake in Italy. For RC buildings it can be assumed that material properties are not strictly related to geography and local construction technologies. Furthermore, while analytical fragility models are generally biased though a very specific building typology, empirical models are able to account for the greater variability found in real buildings in terms of structural performance. Secci employed Bayesian regression to estimate the exceedance probability for five different damage states, based on the EMS-98, as a function of PGA. Damage levels were derived from post-earthquake surveys using the procedure proposed by Rota et al. [28]. The three considered fragility models are shown in Fig.5.

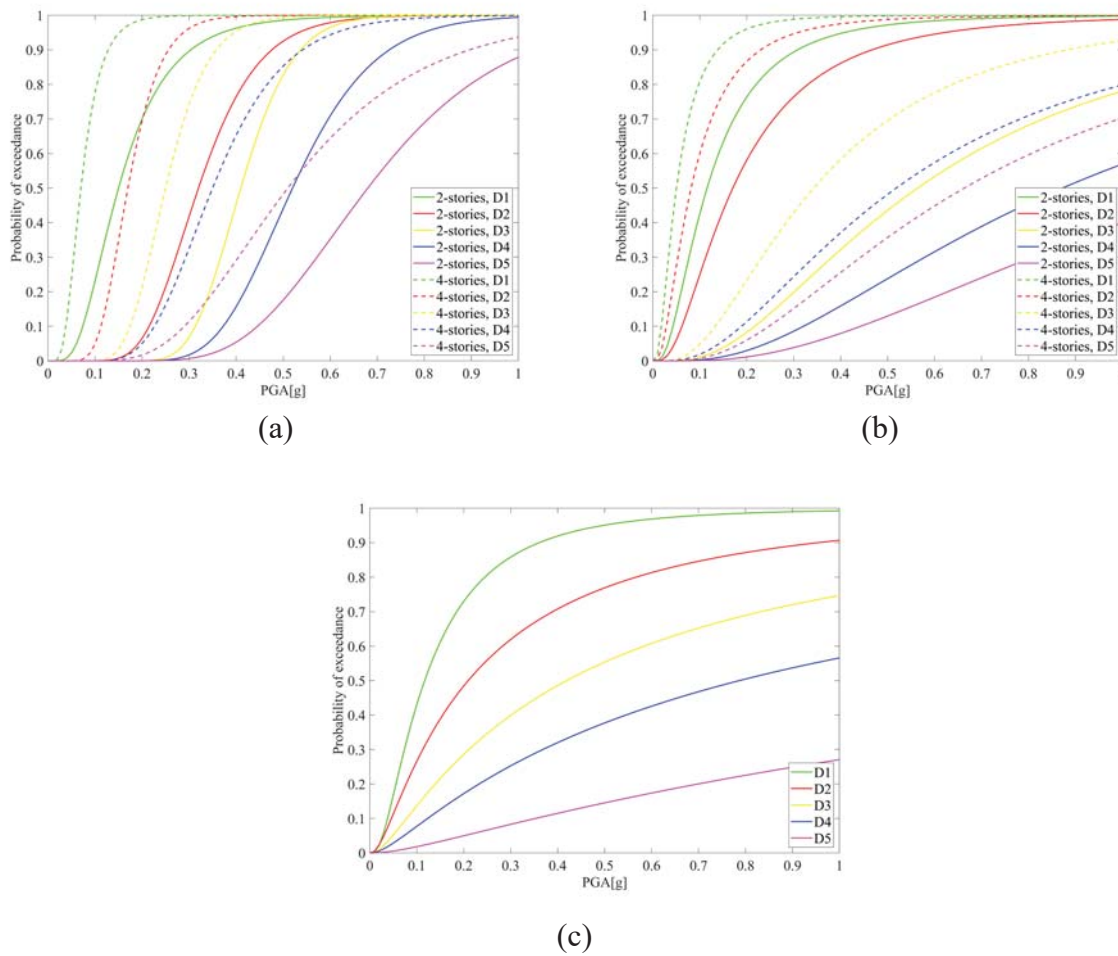

Fig. 5 – Fragility curves for RC buildings used in the present paper a) Verderame et al. [3], b) Salamida and Buratti [26], c) Secci [27]

#### 4 SIMULATION OF DAMAGE SCENARIOS

Damage scenarios are here derived only for municipalities within the epicentral area of the 2012 Emilia earthquake. Information regarding the building stock for each municipality is derived from the 2011 census [19]. The data used concerns geographical coordinates, construction material, age of construction and number of stories.

A Monte Carlo approach is then employed to evaluate a damage scenario in each municipality, for a given earthquake. First, the joint distribution of the ground motion intensity in terms of PGA at the locations of all the  $N_{b,k}$  buildings in the  $k$ -th municipality is estimated using the procedure described in Section 2. In particular, this distribution can be written as

$$\ln(\mathbf{IM})_k \sim N \left( \mathbf{M}_k, \left( \boldsymbol{\Sigma}_{\ln(IM_i), \ln(IM_j)} \right)_k \right) \quad (10)$$

where  $\mathbf{IM}_k$  is a random vector containing the  $N_{b,k}$  ground motion intensities associated to the buildings of the  $k$ -th municipality,  $\mathbf{M}_k$  is a vector containing the mean values of  $\ln(\mathbf{IM}_k)$ , and  $\left( \boldsymbol{\Sigma}_{\ln(IM_i), \ln(IM_j)} \right)_k$  is a variance-covariance matrix. The general element of this matrix is computed as per Eq. (6), though the spatial correlation and the standard deviation are referred to the ground-motion intensities at the locations of the  $i$ -th and  $j$ -th building.

The general iteration of the Monte Carlo simulations is then carried out as follows:

- i. A random sample of ground motion intensities is drawn from the distribution defined by Eq. (10).
- ii. A fragility model is randomly chosen among those defined in Section 3.1 and Section 3.2 for unreinforced masonry and RC buildings, respectively.
- iii. The probability of achieving the different damage levels (as well as no damage) is computed for each building combining data from i. and ii. When either the Verderame et al [3] or the Salomida and Buratti [21] fragility model is selected for RC buildings, the probabilities are computed considering the number of stories of each building (census data).
- iv. For each building a damage state is defined by comparing a random number drawn from a uniform PDF in the interval  $[0, 1]$  to the probabilities computed at step iii.

A number of 10000 simulations is carried out for each municipality. In the following, results are presented separately for masonry and RC residential buildings.

#### 4.1 Analysis of results for unreinforced masonry structures

To represent the simulation outcomes in a compact notation, histograms are used to visualize the mean number of buildings with the different damage levels, in contrast to damage data observed after the 2012 Emilia earthquakes.

Fig. 6, compares the distribution of damage in masonry buildings with reference to municipalities located within 10 km from the epicenter. It can be noted that buildings with low damage levels, such as D<sub>0</sub> or D<sub>1</sub> are overestimated by the simulation. To further investigate the simulated damage scenarios, municipalities outside the immediate epicentral area are considered, located at a distance larger than 10 km but still not further than 30 km. These areas are expected to be subjected to strong ground-motions, according to the computed shake map, but were not highly damaged, according to post-earthquake surveys. As shown in Fig. 7, in these municipalities, simulations predict higher damage levels than those observed. Damage scenarios, in fact, rely on fragility models that are calibrated on the whole observed damage database, thus, representing a mean trend in the damage observations among municipalities. This implies that this type of approach is better employed when evaluating the expected damage on a regional scale, while if used to derive damage scenarios at the municipality level, this could lead to underestimation or overestimation of the expected damage distribution.

Fig. 6 - Comparison between observed (right) and mean values of the simulated (left) damage distribution for masonry buildings for municipalities in the immediate epicentral area (distance from epicenter < 10 km).

Fig. 7 - Comparison between observed (right) and mean values of the simulated (left) damage distribution for masonry buildings for municipalities in the slightly further epicentral area ( $10 \text{ km} < \text{distance from epicenter} < 30 \text{ km}$ ).

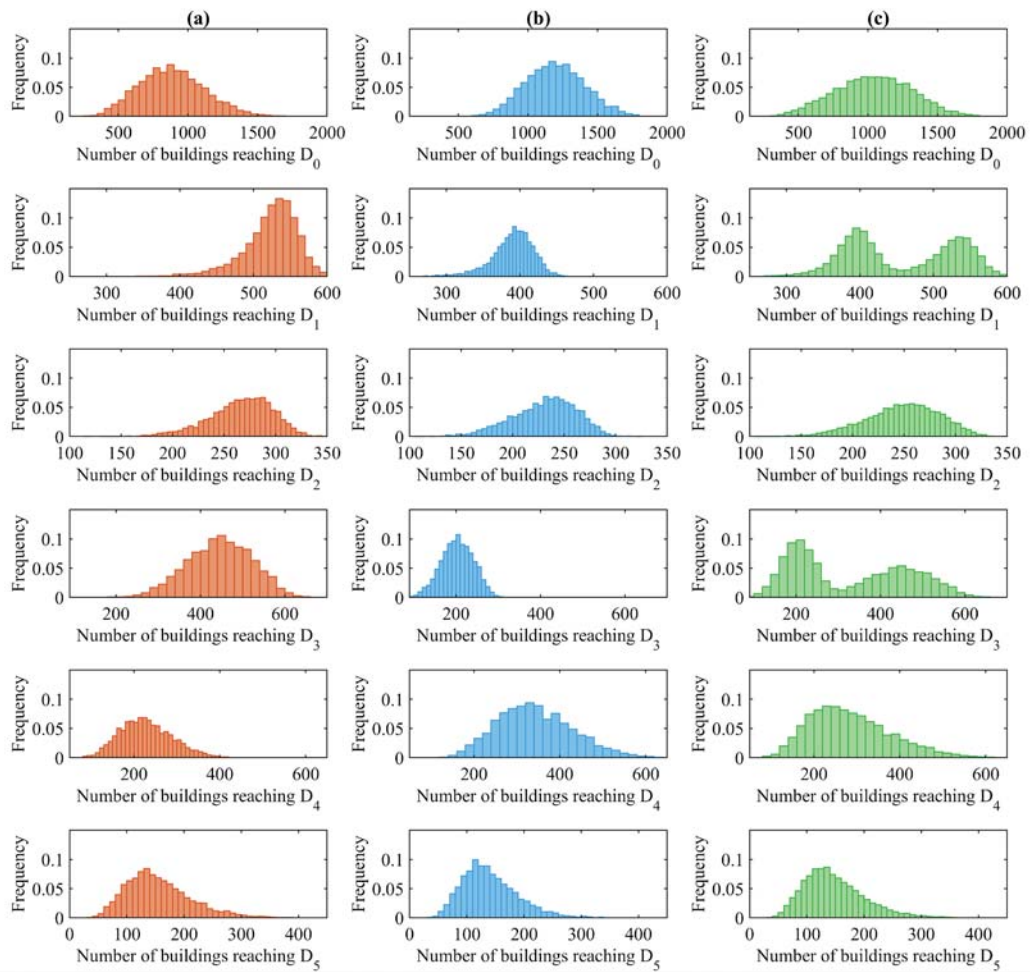

Fig. 8 – Histograms representing the distribution of the different damage levels among the 10000 simulations for the municipality of Mirandola. The a) column figures represent the contribution given by Ioannou et al. [18] fragility model, the b) column is the one given by the fragility model presented in the current paper, while c) represents the totality of the simulations.

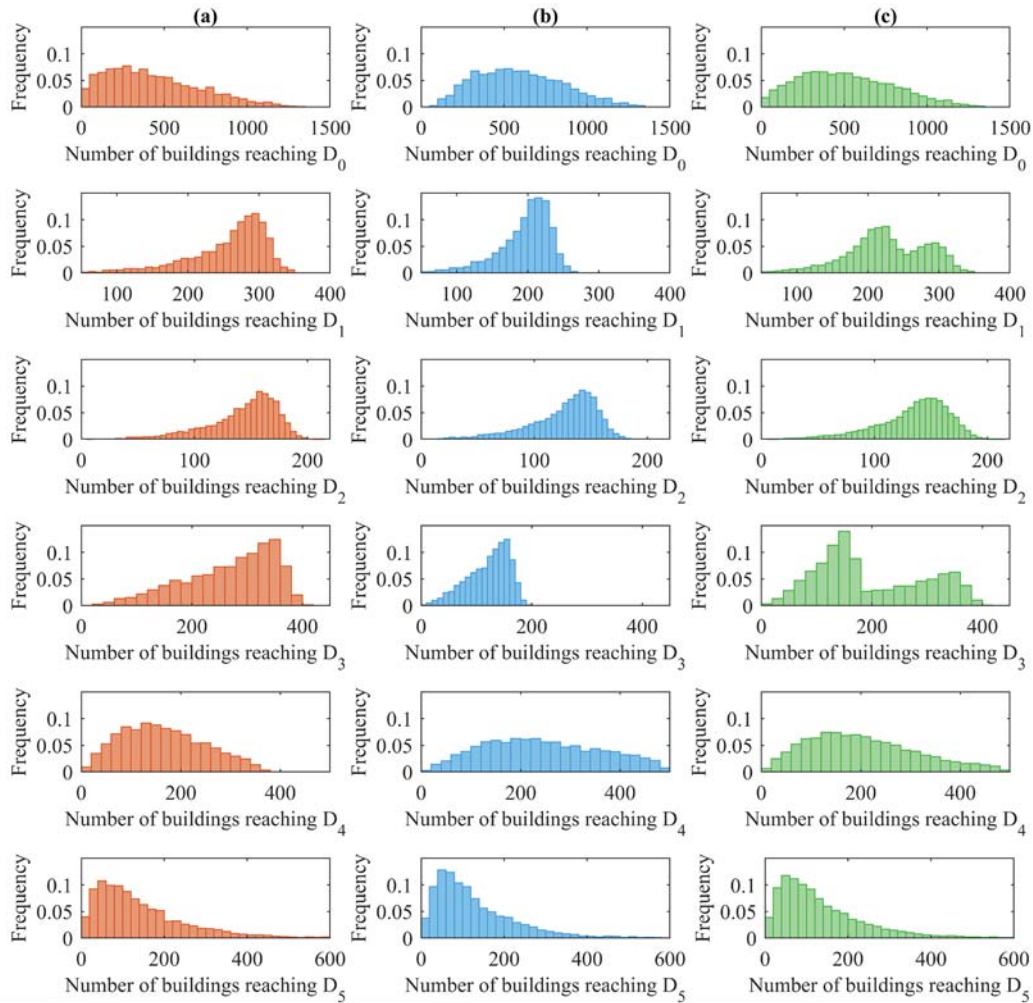

Fig. 9 - Histograms representing the distribution of the different damage levels among the 10000 simulations for the municipality of Sant'Agostino. The a) column figures represent the contribution given by Ioannou et al. [18] fragility model, b) is the one given by the fragility model presented in the current paper, while c) represents the totality of the damage levels distribution accounting for both models.

The variability of the simulation results is analyzed in Fig. 8 and Fig. 9 for the municipalities of Mirandola (MO) and Sant'Agostino (FE). It is evident, from both figures that buildings reaching D<sub>0</sub> have a high variability compared to other damage states. From the figures above, for levels D<sub>1</sub> and D<sub>3</sub> the two fragility models produce different results, while other damage states are quite coherent with each other.

#### 4.2 Analysis of the results for RC buildings

Results for reinforced concrete buildings, differently than those obtained for masonry structures, rely on both empirical and analytical fragility models. Analytical models are highly dependent on the assumptions introduced in the definition of structural models and can be very accurate in describing the behavior of that specific typology, while failing to account for the variability that characterizes the actual building stock. Comparison between observed and simulated damage distributions is presented in Fig. 10 for municipalities within 10 km from the epicenter that sustained significant damage, according to post-earthquake surveys. To further investigate the contribution given by each separate model, simulations are also run considering each fragility model one at a time and the so obtained damage distributions are presented for the same municipalities in Fig. 11.

Fig. 10 - Comparison between observed (right) and mean values of the simulated (left) damage distribution for RC buildings for municipalities in the epicentral area (distance from epicenter < 10 km).

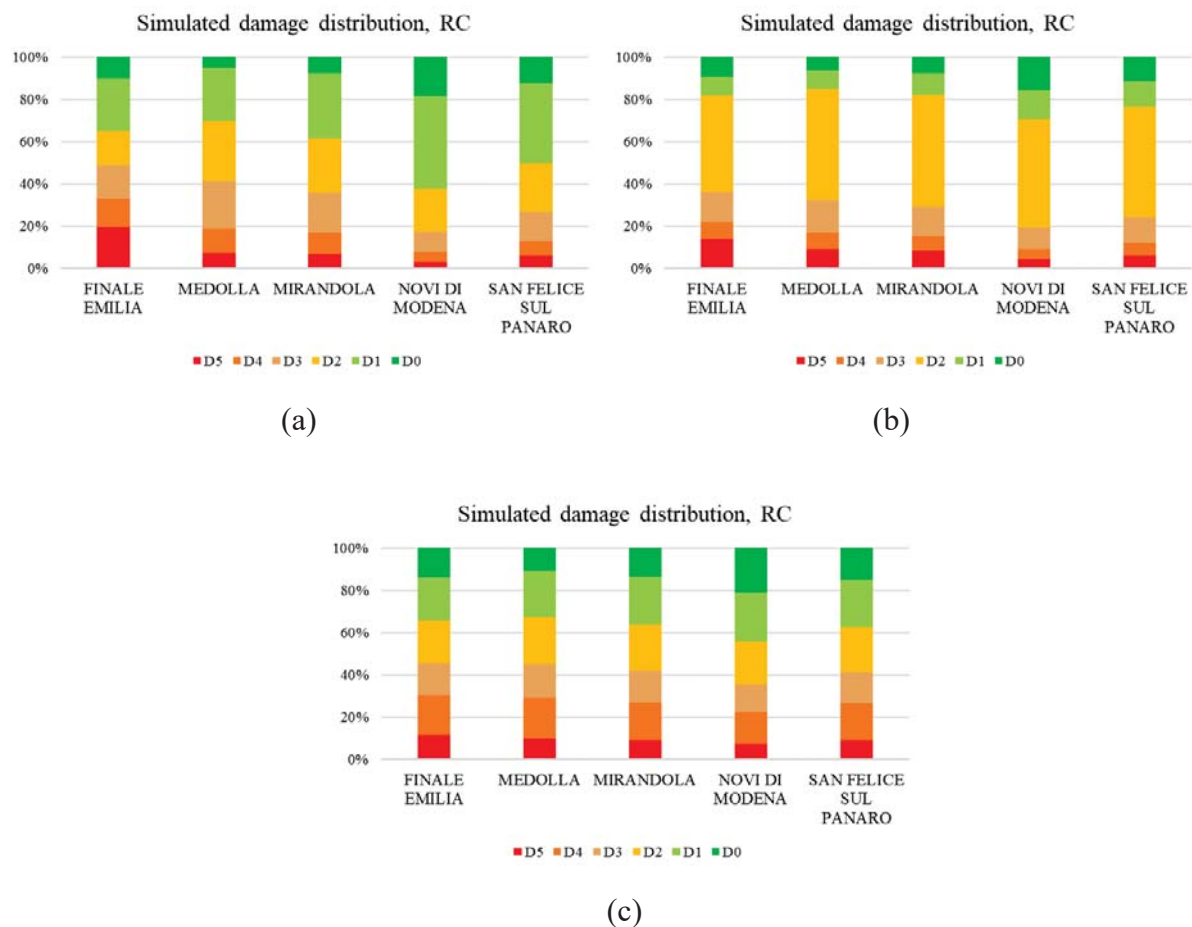

Fig. 11 – Mean value of the simulated damage distribution adopting either (a) Verderame et al. [3], (b) Salamida and Buratti [21] or Secci [27] fragility models.

Substantial differences can be observed comparing the observed and the simulated damage, both considering all fragility models together and separately. As already mentioned, Verderame et al. [3] and Salamida and Buratti [26] models adopt different sets of fragility curves depending on the height of buildings. To study the reliability of the adopted procedure, the number of stories distribution is analyzed in the subset considered and in the overall building database. First the census (Dat1) and the post-earthquake surveys (Dat2) databases are considered with

reference to the provinces of Bologna, Modena and Ferrara. Then the combined database (Dat3) is studied. Results are shown in Table 2.

Database	N. of stories					
	1	2	3	4	5	>5
<b>Dat1</b>	3.45 %	40.06 %	26.04 %	14.95 %	6.70 %	8.81 %
<b>Dat2</b>	29.10 %	18.14 %	17.87 %	14.69 %	7.96 %	11.31 %
<b>Dat3</b>	5.67 %	38.06 %	25.22 %	14.89 %	6.89 %	9.19 %

Table 2: Percentages with respect to the total of buildings separated for number of stories and database. Dat1 is the census dataset, Dat2 is the post-earthquake surveys one and Dat3 is the joint database

<b>Dat1</b>

San Felice sul Panaro	22.22 %	20.37 %	39.81 %	11.11 %	5.56 %	0.93 %	108

Table 3: Total number of buildings and percentages with respect to the number of stories for each municipality and database.

Remembering that Dat2 consists mainly of damaged buildings, and thus percentages can be intended as referring to the most fragile building typology, Dat1 and Dat3 coherently identify 2- and 3-stories structures as the most predominant typology. If the same analysis is conducted with respect to the single municipalities shown in Fig. 10 and Fig. 11, some changes can be observed. Table 3 highlights significant differences for the considered municipalities in the distribution of the number of stories. Specifically, Dat1 consists mainly of 4- and 5-stories structures and the total count is also lower than the corresponding quantity that has been surveyed in the same municipality. Thus, when combining Dat1 and Dat2 in Dat3, this final database

mostly consist of post-earthquake entries and the number of stories distribution reflects this, as well. However, damage scenarios are carried out relying on census data alone, which means that for some municipalities the dimension of the building stock may be underestimated. At the same time, errors may be introduced in the simulation due to misclassification of the number of stories, or of the type of construction material itself. Nonetheless, it has been shown in Table 2 that overall ratios are coherent among the different databases. It can be then said that damage scenarios produce reliable results when considering a regional scale but can lead to large misinterpretations if applied to a single municipality or limited scale. If damage scenarios aim to assess the expected fragility of single municipalities they have to be implemented starting from highly reliable and detailed data, especially with respect to those parameters that influence the chosen fragility models, such as the number of stories or construction age.

Finally, in an analogous way to what was done for masonry structures scenarios, the variability of the outcomes of the simulations is visualized in Fig. 12, disaggregated for the different fragility models considered. Damage level  $D_0$  histograms are similar for all considered models, while for other damage states results vary from model to model.

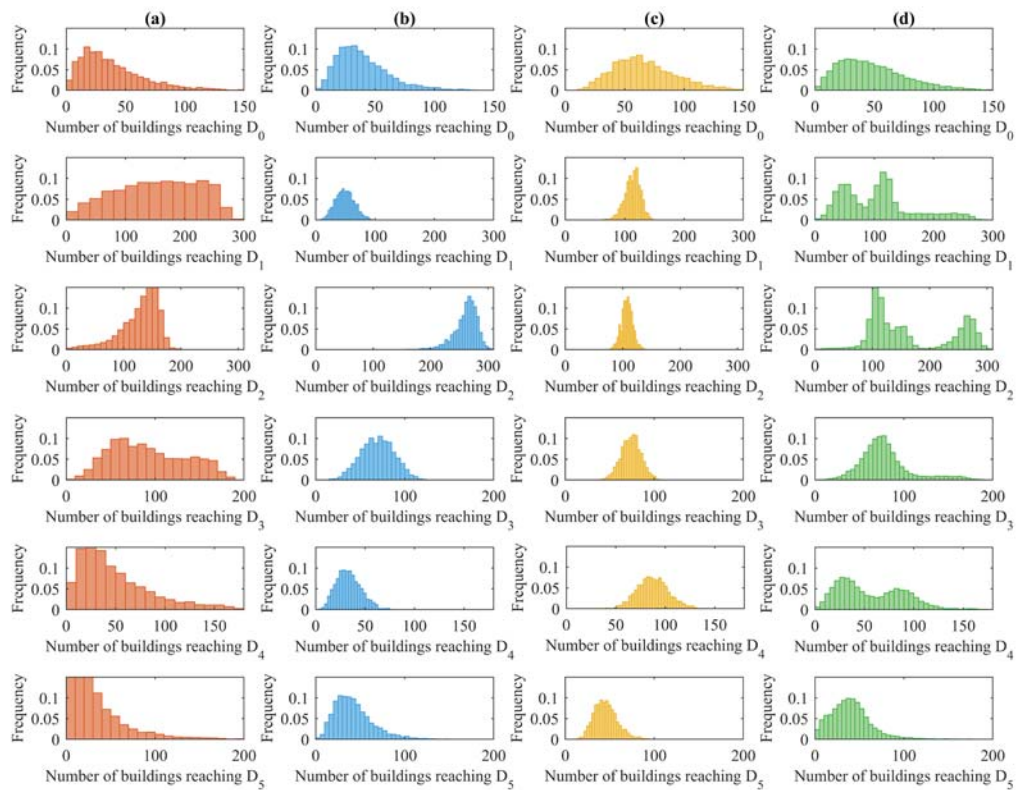

Fig. 12 – Histograms representing the distribution of the different damage levels among the 10000 simulations for the municipality of Mirandola. The a) column figures represent the contribution given by Verderame et al. fragility model [3], b) is the contribution from Salamida and Buratti’s fragility model [26], while c) represent the contribution given by the model proposed by Secci [27]. Finally, the totality of the damage levels distribution accounting for all models is represented in column c) plots.

## 5 CONCLUSIONS

The present paper illustrates a framework for the simulation of seismic damage scenarios in the Emilia Romagna region, in northern Italy. First attenuation relationships are defined as well as spatial correlation models in order to estimate shake maps for the Emilia 2012 earthquakes. These tools are then employed to carry out a Monte Carlo simulation to compute damage

scenarios for masonry and reinforced concrete residential buildings. Building stock information is obtained from the census, while fragility is estimated through models obtained from the available literature for both structural typologies. The simulated damage distribution is then compared to the observed one and results are discussed. It is derived that damage scenarios may be a powerful tool to obtain damage estimates on regional scale but may lead to overestimation or underestimation when applied to a reduced scale, such as at a single municipality level. These results are highly influenced by the quality of the building stock database (i.e. census) that introduces high uncertainties with respect to number of stories and construction material.

### Abstract

*Large-scale seismic risk assessment is probably the most appropriate tool for investigating the consequences of earthquakes in a region of interest. Most of the existing risk-oriented studies focus on the seismic hazard evaluation and vulnerability assessment, while fewer efforts were performed in evaluating the influence of exposure modelling. The large-scale building inventory is generally conducted by relying on readily available sources of information, such as databases based on census data. However, the information contained in census databases are often limited to poor level data, such as building construction material, construction age and (not always available) the storey number. The use of inventory data for large scale application requires suitable rules to assign buildings typologies to vulnerability classes, that is an exposure model. Most of the existing exposure models are calibrated on building typological data available from post-earthquake survey data and therefore are based on data from specific geographic areas, namely the ones hit by damaging earthquakes. It is known that the distribution of building typologies can vary greatly for different areas of a country and the availability of construction material in the area. Furthermore, the evolution of construction techniques and the codes in force at the time of construction may affect the presence of a particular building's typology rather than another one. This study aims to evaluate the influence of a better knowledge level of the building environment on seismic risk at regional scale, investigating the variability of masonry building typologies distribution. The application is presented for two different Italian regions, showing that an improved characterization of regional vulnerability may strongly influence the impacts in terms of risk estimations.*

## 1 INTRODUCTION

In large scale seismic risk assessment, the buildings are clustered in relevant vulnerability classes based on the behavior that is expected during a seismic event, for which different vulnerability functions are defined. A common vulnerability classification is given by the European Macroseismic Scale EMS'98 [1], that categorizes buildings in 6 vulnerability classes (from A to F), based on the type of vertical structures, i.e. the construction material and code design level. Other vulnerability models identify vulnerability classes based on the construction material (masonry, reinforced concrete, steel, wood) taking into account as well other structural and non-structural elements features (e.g. [2]-[4]).

The distribution of buildings within the vulnerability classes in each territorial unit of analysis is given by building inventory. Different sources of information on people and residential buildings are available with global coverage at national and sub-national level (e.g. [5]-[7]); however, in order to compile building inventory Census database is often the primary employed source, thanks to their availability and diffusion on whole national territory. In Italy, census data on population and buildings, allowing to count building numerosness in terms of construction material, number of storeys and construction age, are produced by ISTAT, the national statistical institute. The data for each census tracts are available in aggregated form for privacy reasons, but the disaggregated census data on buildings are also available at provincial or municipality level, as shown in [8]-[9] and [10].

In general, to compile a building inventory at territorial scale starting from census data, a suitable exposure model is required to associate the building typology to vulnerability classes defined according to a vulnerability model. In the methodology adopted within last National Risk Assessment (NRA) for Italy [11], the exposure modelling defines the rules to assign building typology identified by ISTAT to EMS'98 vulnerability classes. Moreover, the methodology allowed to evaluate the risk by combination of the results obtained adopting different vulnerability/exposure models (VEM). Generally, exposure models may be calibrated based on building typological data available from post-earthquake surveys in Italy (e.g. [13] and [14]) or other available building-by-building survey databases (as in [15]) and eventually integrating them with expert judgment (e.g. [16]).

However, due to the high costs and time required, building-by-building survey campaign are generally carried out for limited areas in a country, such as urban districts or small municipalities, and the ones conducted after a noteworthy seismic event usually completely inspect only the municipalities with higher macroseismic intensity [17].

Thus, the exposure model used in national or sub-national risk assessment may be calibrated on data referred to a specific geographic area. However, the buildings' characteristics may be not the same for different areas of a country, likely due to variability in construction material diffusion and in construction techniques use for different regions.

Mostly for unreinforced masonry buildings, the type of vertical structure (e.g. regular, irregular, round stone, regular stone etc.), that has a clear influence on seismic vulnerability, may vary significantly: the type of stones can be influenced by the geography of the territory (e.g. the presence of quarries, waterways and volcanic areas) and in turn construction techniques are influenced by the type of stones, because some types of stones are better suited to be cut into square blocks. In Italy, in inland areas near to Apennine limestone is widespread while bricks are typical of the Adriatic coast and tuff of volcanic areas. This could explain the reason of large presence of irregular layout structures in the internal areas of the country and the presence of regular layout masonry structures in the areas characterized by the presence of bricks, tuff or travertine, as shown in [18]-[20].

A recent approach for the compiling of large-scale inventories is provided by Cartis [21], an interview-based form developed within “Territorial Themes” ReLUIS project financed by the Italian Civil Protection Department. The Cartis approach allows to rapidly survey ordinary building typologies in urban area, collecting information on buildings features useful for the building vulnerability classification. In this paper, we propose the use of Cartis database to improve the exposure modelling at regional scale. Adopting the methodology proposed in [22] and briefly recalled in the next paragraphs, the effects of the improved vulnerability characterization on risk assessment are evaluated for two Italian regions. Two exposure/vulnerability model recently proposed in Italy for unreinforced masonry buildings are adopted and the damage and risk assessment obtained from the original vulnerability/exposure models and from the ones updated through the Cartis-based inventory area compared. It will be shown that not negligible changes of the impacts may be observed, also depending on the analyzed region.

## **2 THE ADOPTED VULNERABILITY/EXPOSURE MODELS**

With the aim to investigate the effect of different typological distribution on the vulnerability assessment at the regional scale, two empirical vulnerability/exposure models that were recently proposed for masonry type buildings are adopted. The model proposed by Del Gaudio et al. [3], referred to as DG2019, is based on the statistical treatment of typological and damage data of masonry buildings damaged after the 2009 L’Aquila earthquake. The authors propose empirical based lognormal fragility curves for 14 masonry buildings classes, defined based on the combination of vertical structures (regular layout or good quality, irregular layout or poor quality structure with or without tie rods/beams) and horizontal structures (vaults with or without tie rods, beams with flexible, semi-rigid or rigid slabs), as shown in Table 1. Moreover, a set of fragility curves directly referred to construction age intervals, usable with a building classification based on census data, are also proposed. These age-dependent fragility curves are derived by a linear combination of the 14 sets of typological fragility curves, using the percentage of occurrence of each class within the 8 times intervals defined by ISTAT (< 1919, 1919-1945, 1946-1961, 1962-1971, 1972-1981, 1982-1991, 1991-2001, > 2001) reported in Table 1 as linear combination coefficients. To find out the distribution of buildings belonging to different age ranges, the data derived from the sample of 22,618 residential masonry buildings surveyed after L’Aquila earthquake are used. From this database analysis, it can be noted that most of the buildings built before 1945 are characterized by irregular layout (class 4B and 5B in Table 1), whit high percentage of vaults in oldest buildings (class 23BC), while modern buildings are characterized by regular layout and rigid floors.

Table 1 - Occurrence percentages of vulnerability classes into 8 time intervals, defined by [3].

	Vaults with or w/o tie rods		Beams with Flexible slab				Beams with Semi-rigid slab				Beams with Rigid slab			
	Irregular layout or poor quality	Regular layout or good quality	Irregular layout or poor quality		Regular layout or good quality		Irregular layout or poor quality		Regular layout or good quality		Irregular layout or poor quality		Regular layout or good quality	
			W/o tie rods or tie beams	With tie rods or tie beams	W/o tie rods or tie beams	With tie rods or tie beams	W/o tie rods or tie beams	With tie rods or tie beams	W/o tie rods or tie beams	With tie rods or tie beams	W/o tie rods or tie beams	With tie rods or tie beams	W/o tie rods or tie beams	With tie rods or tie beams
	23BC	23DE	4B	4C	4D	4E	5B	5C	5D	5E	6B	6C	6D	6E
<19	22%	3%	25%	5%	2%	1%	21%	6%	4%	2%	3%	2%	1%	2%
19-45	8%	2%	23%	3%	4%	1%	23%	6%	9%	4%	4%	3%	3%	7%
46-61	2%	1%	9%	1%	4%	1%	17%	6%	13%	8%	5%	7%	7%	20%
62-71	1%	0%	3%	1%	6%	1%	4%	3%	9%	9%	3%	5%	12%	43%
72-81	0%	0%	2%	0%	4%	1%	2%	1%	6%	8%	1%	2%	11%	62%
82-91	0%	0%	2%	0%	6%	2%	2%	1%	5%	6%	2%	2%	11%	62%
92-2001	2%	1%	4%	1%	7%	4%	3%	2%	5%	5%	2%	2%	10%	53%
>2001	3%	0%	3%	1%	5%	5%	4%	3%	3%	9%	3%	2%	6%	52%

The second model, proposed by Rosti et al. [23] referred to as RO2020, was derived considering the L'Aquila 2009 and Irpinia 1980 post earthquakes data. Eight building typologies were identified, based on quality of the masonry fabric (i.e. irregular layout or poor-quality masonry, regular layout and good-quality masonry), in-plane flexibility of diaphragms (i.e. flexible, rigid), presence (or absence) of connecting devices. These typologies were fused into three vulnerability classes (A: high vulnerability, B: medium vulnerability, C1: low vulnerability) based on classification rules proposed by Rota et al. [4], reported in Table 2. As one of the purposes of this study was to implement the model using IRMA platform [12] for its possible application for national risk assessment in Italy [11], the authors proposed an exposure model that defines the rules to assign the percentage of each census-based typologies for masonry buildings (defined based on construction age - < 1919, 1919-45, 1946-61, 1962-71, 1972-81, > 1981- and height level - L and MH) into the three vulnerability classes A, B and C1.

Table 2 - Definition of vulnerability classes based on type of vertical and horizontal structures and presence of connection devices, as reported in [4]

Horizontal structure	Irregular texture or poor quality masonry		Regular texture and good quality masonry	
	w/o connecting device	with connecting device	w/o connecting device	with connecting device
Flexible	A	A	B	C1
Semi-rigid	A	A	B	C1
Rigid	A	B	C1	C1
Vaults	A	B	C1	C1

This exposure model was calibrated through an optimization problem finalized to minimize the difference among a set of empirical fragility curves, derived by the sole dataset of masonry buildings damaged after 2009 L'Aquila earthquake, and the fragility curves previously derived for A, B and C1 vulnerability classes. The resulting exposure matrix is reported in Table 3.

Table 3 - Composition of the masonry building stock in terms of percentages of macro-categories belonging to the different vulnerability classes, according to [23]

Class of height	Low			Medium-High		
Vulnerability class	A-L	B-L	C1-L	A-MH	B-MH	C1-MH
<19	86%	0%	14%	97%	0%	3%
19-45	45%	44%	11%	22%	78%	0%
46-61	9%	59%	32%	0%	75%	25%
62-71	5%	4%	91%	0%	18%	82%
72-81	0%	0%	100%	0%	0%	100%
82-91	0%	0%	100%	0%	0%	100%

### 3 EXPOSURE MODELLING: A CARTIS-BASED APPROACH

The proposed methodology relies on Cartis form's information to re-calibrate the exposure models in different Italian regions. The 1<sup>st</sup> level "Cartis" form is an interview-based form finalized to the survey of ordinary building typologies in sub-areas of the town denominated Town Compartments TC, characterized by prevailing homogeneity of the built environment in terms of initial period of construction and/or constructive structural characteristics. Using Cartis approach is possible to detect buildings features having strong influence on seismic behavior, allowing a more refined classification for buildings. In addition to age of construction and number of storeys, for masonry building the type of masonry (e.g. irregular layout masonry or regular layout with square stones or bricks), the horizontal slab type (e.g. flexible, rigid or semi-rigid slabs), the type of vaults (if present) and the presence of tie rods or tie beams are some of the vulnerability factors considered in the form. For each TC the form allows to detect up to four different typologies for masonry buildings (MUR1, MUR2, MUR3, MUR4) and four for RC buildings (CAR1, CAR2, CAR3, CAR4).

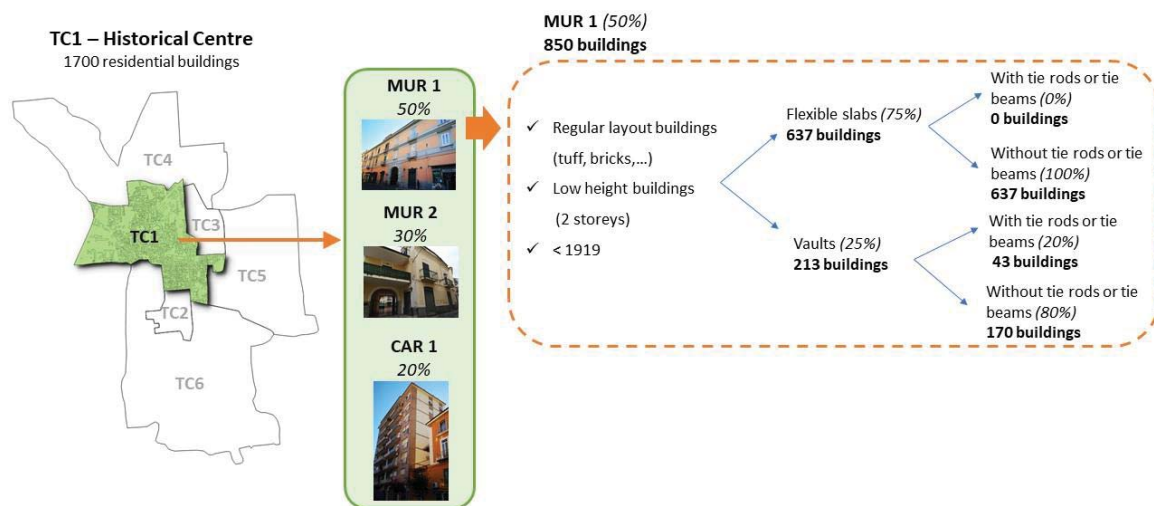

Figure 1 - Town Compartments for a town in the south of Italy and an example of buildings distribution for TC1, based on the related percentages reported in Cartis.

For each typology, the incidence percentages of the typology on the buildings in the TC are given. Therefore, given the total numbers of buildings in each TC, it is possible to derive the number of building belonging to different building typologies, and, consequently, considering all TCs in a town, the inventory at municipal level can be obtained. An example of the proce-

ture to derive the number of building for a masonry typology in a town compartment is reported in Figure 1.

Starting from the inventory compiled in towns where Cartis form is available, the occurrence percentage of building typologies at regional scale can be derived. Once the number of buildings belonging to defined structural types is obtained, it is possible to group them into vulnerability classes, according to the adopted vulnerability model.

In [22], based on the availability of Cartis-based inventory, a methodology for exposure modelling was proposed, that can be reassumed in the following steps:

- a) Compiling of Cartis-based inventory at urban scale, for all the towns where Cartis information is available.
- b) Deriving statistical distribution of building typologies at regional scale considering all the towns in the region for which Cartis-based inventory was compiled.
- c) Recalibration of exposure matrix with the percental distribution obtained by Cartis-based inventories, according to the vulnerability classes considered by the adopted vulnerability model.

Note that the reliability of the procedure is affected by the percentage of investigated towns as well as by their representativeness in terms of building and population number in a region.

As explained in [22], two slightly different approaches for the recalibration of the DG2019 and RO2020 models are applied. In DG2019 the age-dependent fragility curves to use with available ISTAT data was obtained by a linear combination of the fragility curves relative to the 14 building classes; therefore, after the recalibration of the exposure matrix a new set of age-dependent fragility curve has to be derived to evaluate the risk starting by census data. Differently, according to RO2020 model, only the exposure matrix was recalibrated, without modification of the fragility curves used for risk calculation. It is worth noting that the exposure matrices in DG2019 and RO2020 were obtained by statistical analysis of typological data relative to the sole buildings that were inspected after the 2009 L'Aquila earthquake. Thus, these matrices represent the typological distribution of a specific region (i.e. Abruzzo region). Therefore, a more accurate calibration procedure may improve the vulnerability characterization at regional level and consequently may affect the estimation of expected damage and impacts.

#### 4 APPLICATION FOR TWO ITALIAN REGIONS

The proposed procedure is applied for two Italian regions: Toscana and Veneto. In Toscana region 59 towns were surveyed through Cartis form, that represent about 22% of Toscana municipalities and 10% of regional inhabitants. In Veneto 35 towns were surveyed, representing the 6% of the municipalities and covering approximately the 11% of regional population.

According to the procedure previously described, the Cartis-based inventory is compiled for all the towns surveyed by Cartis form. Assuming the surveyed municipalities representative of the entire region, the percentage distribution of building typologies at regional level is obtained. It is worth noting that the Cartis database partially cover the whole regional territory, so this simplifying hypothesis could affect the reliability of estimations at regional scale. However, the present study represents a preliminary application to investigate the variability of vulnerability characterization at regional level and the results are expected to be updated when Cartis form on other municipalities will be compiled.

Figure 2 – Diffusion of the vertical (irregular or regular layout) types on masonry building stock at regional scale, derived by Cartis - based inventory.

The analysis of the regional inventories shows very different distribution of masonry building typologies. In Toscana irregular layout vertical structures are widespread, representing about 76% of masonry buildings, while in Veneto this typology characterizes just the 16% of the total, see Figure 2. Regarding horizontal structures type, the major difference between regional inventories is about the diffusion of semi-rigid slab type in irregular layout structures, about 36% in Toscana and almost absent in Veneto (2%), see Figure 3.

Once obtained the number of buildings with specific structural features (e.g. the number of masonry buildings with regular layout and vaults without tie rods), it's possible to group them into vulnerability classes according to DG2019 and RO2020 models and recalibrate the relative exposure matrices.

Figure 3- Diffusion of horizontal structure types for irregular layout buildings according to Cartis-based inventory, for Tuscany (a) and Veneto region (b).

The comparison with the DG2019 exposure model shows a considerable increase of irregular layout masonry structures in Tuscany for first and second time intervals (<1919, 1919-1945) (see Table 4). In particular, poor quality masonry structures without tie rods or tie beams and with flexible slabs (4B) and semi-rigid slabs (5B) are more widespread in Tuscany than in Abruzzo, according to the DG2019 matrix. Moreover, this type of structures represents a not negligible percentage of more recent built buildings.

For Veneto region, irregular structures represent a significant percentage for older masonry buildings (<1919), but after 1950 almost the whole masonry buildings structures are regular layout structures with rigid floors (see Table 5). According to RO2020 model, it can be noted that for Tuscany region the differences between the original matrix and the recalibrated ones mostly concern masonry structures built between 1919 and 1945 and between 1946 and 1961, with many low-rise buildings classified in more vulnerable classes (Table 6). For Veneto a different distribution of older masonry buildings can be observed, with lower number of them classified as A (Table 7).

#### 4.1 Damage and Risk assessment

The effects of a different vulnerability characterization at regional scale is evaluated with the aid of IRMA platform [12]. In the platform, different exposure/vulnerability models (VEM) and different sets of fragility curves can be employed. Deriving the exposure data from ISTAT 2011 database, the VEM is defined by an exposure matrix that identifies rules to classify the building typologies, derived by census data, into vulnerability classes adopted by the model. Using DG2019 approach the VEM is simply defined by building classes for age of construction, that are combined with the age-dependent fragility curves. In RO2020 approach, the VEM is defined by exposure matrix that provides the occurrence percentage of building classes (for age of construction and class of height) in the vulnerability classes identified in the model (A, B, C1), combined with the relative fragility curves. The improvement provided by the proposed procedure is evaluated comparing the outcomes of damage and risk assessment obtained by the adoption of the original set of age-dependent fragility curves and the exposure matrix, respectively for DG2019 and RO2020 model, with results obtained after the recalibration procedure.

Unconditional damage and risk assessment for 50 years timeframe is performed, that is an assessment obtained considering the probability of ground shaking severity in a selected time observation window according to PSHA based methodology. As both adopted VEM are for masonry buildings, the analyses are performed considering only this typology (masonry). Tables 8, 9, 10, 11 report the number of buildings for each damage state employing the original model (columns DG or RO) and the updated exposure modelling (columns DG+CA or RO+CA). The difference between the Cartis-based model and the original one is indicated as  $\Delta$  and the Regionalization factor RF, that can be considered as a parameter to represent variation in terms of expected damage due to a different exposure modelling, is calculated as the ratio of  $\Delta$  versus DG or RO, respectively for DG2019 and RO2020 model.

Table 8 - Number of buildings for each damage state, adopting the original exposure matrix DG2019 (DG) and the re-calibrated one based on CARTIS data (CARTIS) for Tuscany region.

	DG	DG+CA	$\Delta$	RF
<b>DS0</b>	138784	126798	-11986	-9%
<b>DS1</b>	133272	123662	-9610	-7%
<b>DS2</b>	59770	58576	-1194	-2%
<b>DS3</b>	81715	86155	4440	5%
<b>DS4</b>	88598	95497	6899	8%
<b>DS5</b>	46010	57462	11452	25%

Table 9 - Number of buildings for each damage state, adopting the original exposure matrix RO2020 (RO) and the re-calibrated one based on CARTIS data (CARTIS) for Tuscany region.

	RO	RO+CA	$\Delta$	RF
<b>DS0</b>	374663	340104	-34560	-9%
<b>DS1</b>	101790	111078	9288	9%
<b>DS2</b>	30561	41503	10942	36%
<b>DS3</b>	20040	26479	6439	32%
<b>DS4</b>	15714	21567	5853	37%
<b>DS5</b>	5381	7419	2038	38%

Figure 4 – The variation of number of buildings in each damage state with respect to the original model (i.e. the RF) obtained adopting the Cartis-based procedure (DG+CA for DG2019 and RO+CA for RO2020 model) for Tuscany region.

For Tuscany region, an increased number of building having medium-high damage states (DS3, DS4, DS5) can be observed according to Cartis-based model. Using DG2019 approach, the number of buildings that reach the heaviest damage grade (DS5) increases by +25%, while for the lower damage levels lower variations can be observed (see Figure 4). In reverse, adopting RO2020 model, with Cartis-based approach the numbers of buildings significantly increase for most of damage levels, with a value of RF grader than +30% from DS2 to DS5. This significant difference from DG2019 and RO2020 model is probably due to the different classification criteria. Indeed, according to RO2020 all the masonry buildings with irregular texture are classified as class A, the most vulnerable class, while in DG2019 different classes are identified for irregular layout buildings based on the horizontal structures type, to which different vulnerability level as well as fragility functions are associated. Therefore, for example, if for the second model irregular layout structures with rigid slab are less vulnerable than irregular layout structure without tie roads or tie beams with vaults, according to first one

these building are clustered in an unique class, the most vulnerable class A, greatly influencing the damage distribution.

For Veneto, a decrement of damaged buildings can be observed. Assuming the RF value for DS2 as reference, as it is representative of moderate damage, it can be observed a value of -30% according to DG2019 and -26% for RO2020. Differently to Tuscany region, for Veneto the presence of a small number of irregular layout structures, widespread only among oldest masonry building, leads to similar value of RF for both models (see Figure 5).

Table 10 - Number of buildings for each damage state, adopting the original exposure matrix DG2019 (DG) and the re-calibrated one based on CARTIS data (CARTIS) for Veneto region.

	DG	DG+CA	$\Delta$	RF
<b>DS0</b>	411779	504687	92907	23%
<b>DS1</b>	175772	145021	-30751	-17%

<b>DS2</b>	19676	14530	-5146	-26%
<b>DS3</b>	13587	10010	-3576	-26%
<b>DS4</b>	11031	7792	-3239	-29%
<b>DS5</b>	4493	3132	-1361	-30%

Figure 5 - The variation of number of buildings in each damage state with respect to the original model (i.e. the RF) obtained adopting the Cartis-based procedure (DG+CA for DG2019 and RO+CA for RO2020 model) for Veneto region.

The seismic risk in terms of economic losses is calculated, as well. In IRMA, the impact quantities are provided as a function of expected number of buildings affected by different damage level, according to the consequences model adopted in the recent national risk assessment for Italy (Dolce et al. 2020). The mean value of losses/m<sup>2</sup> among all the municipalities in each region is calculated and chosen as regional loss indicator. Likewise to what done previously, the regionalization factor due to losses RF<sub>L</sub> is evaluated.

Table 12 - Values of economic losses for each region analyzed, according to the different models adopted (DG2019 and the one recalibrated by Cartis-based approach).

	<b>L_DG/mq</b> <b>[€/mq]</b>	<b>L_CARTIS/mq</b> <b>[€/mq]</b>	<b>Δ [€/mq]</b>	<b>RF_L</b>
<b>TOSCANA</b>	566.9	621.1	54.2	<b>0.10</b>
<b>VENETO</b>	267.8	186.0	-81.8	<b>-0.31</b>

Table 13 - Values of economic losses for each region analyzed, according to the different models adopted (RO2020 and the one recalibrated by Cartis-based approach).

	<b>L_RO/mq</b> <b>[€/mq]</b>	<b>L_CARTIS/mq</b> <b>[€/mq]</b>	<b>Δ [€/mq]</b>	<b>RF_L</b>

<b>VENETO</b>	65.1	50.3	-14.8	<b>-0.23</b>

## 5 CONCLUSIONS

The methodology proposed in [22] is adopted in this study to evaluate the effects of adopting improved exposure modelling on risk analysis. Cartis database is used to re-calibrate models relative to two existing empirical vulnerability models (DG2019 [3] and RO2020 [23]) for two Italian regions, Tuscany and Veneto. It is worth noting that this is a preliminary study about regional vulnerability characterization as the proposed exposure models are calibrated on the available Cartis' data on a limited number of municipalities in each region. However, the re-calibration procedure here proposed allows to detect the potential change in vulnerability region by region.

The main outcomes of the adopted approach can be summarized as follows:

- The use of Cartis-based approach leads to different distributions of building typologies at regional scale with respect to exposure models commonly calibrated on the base of empirical data derived on areas recently struck by an earthquake.
- The use of different exposure models at regional level has a significant influence on the damage assessment, also depending on the adopted vulnerability model. To assess such influence a parameter, the regionalization factor RF, may be defined to account for differences in damage assessment due to the use of improved exposure models with respect to original one. The RF referred to an intermediate damage state DS3 for Tuscany region is quite low adopting DG2019 model (5%), while assumes a value of +32% using RO2020 model. The reason of this discrepancy is probably due to the different vulnerability classification proposed by the models, that influence the damage distribution mostly for the regions where irregular layout structures are largely widespread.
- The influence of different exposure modelling at regional scale on economic losses can be effectively represented by regionalization factor associated to economic losses RF\_L. RF\_L may be used for a synthetic representation of the variation of risk estimation that can be obtained with improved exposure characterization.

As this study represents a first application toward the regional exposure assessment, the results obtained provide just a trend about vulnerability and risk at regional level and they can be improved when more data become available.

## ACKNOWLEDGMENTS

This study was performed within the framework of the PE2019–2021 joint program DPC-ReLUIS, WP2: “Inventory of existing building typologies” and WP4 “Risk maps and seismic damage scenarios”.

### Abstract

*In the last decades, a number of methodologies for the performance based-loss assessment of buildings have been proposed and developed. Among those, the PEER Performance-Based Earthquake Engineering (PBEE) methodology represents the most comprehensive approach providing probabilistic estimates of seismic losses. However, those procedures are suitable for building-specific evaluations, appearing extremely time-consuming if applied at the urban scale. Recently, many authors proposed simplified approaches relating the economic losses to the structural response (i.e. Engineering Demand Parameters, EDP) derived from analysis methods within the reach of the most practicing engineers. Many of these procedures have been also implemented in current seismic codes. In this paper a seismic loss assessment of the residential masonry building stock of the city center of Potenza is performed based on the simplified approach currently adopted within the Italian Seismic Risk Classification. After a preliminary typological characterization of the investigated structures, the mentioned methodology has been applied to derive the expected annual loss of masonry buildings, deriving information on the seismic resilience of the examined built heritage at urban scale. Preliminary socio-economic considerations of seismic scenarios at urban scale are discussed. The results presented herein are part of a comprehensive research activity performed within PON-AIM 2014-2020 project aimed at the definition of the seismic resilience of the examined area.*

## 1 INTRODUCTION

Observations from worldwide earthquakes illustrated the severe economic consequences in highly developed regions of society. In general, these economic consequences can be primarily attributed to: (i) direct economic losses associated with repairing damage within a structure [1], (ii) direct losses associated with injuries and casualties and (iii) indirect losses associated with the loss of income due to business disruption [2].

More in details, the economic losses from physical damage strongly influence the community's recovery capability, especially when a relevant portion of the building stock is represented by unreinforced masonry (URM) constructions. As a matter of fact, damage on masonry buildings usually involves expensive and time-consuming repairing activities that can be carried out only by expert builders, thus further enhancing the cost of the interventions. Moreover, the larger is the period of time requested to restore the operativity of the structure, the larger is the downtime, namely, the indirect losses associated with loss of productivity, business interruption and cost of occupants reallocation. All that considered, an appropriate loss estimation of buildings is crucial for the development of resilient communities in seismic prone areas [3], [4], providing risk-based information, which may help Governments, stakeholders and owners to define the priority of interventions or policies for disaster prevention.

In the last decade, several loss estimation methodologies have been proposed, although accurate quantification of loss is still a difficult task subject due to several uncertainties [5]-[8]. In recent years the accurate Performance Based Earthquake Engineering (PBEE) approach proposed by the US FEMA P-58 has been increasingly adopted for the seismic assessment of structures [9]. The method consists of a number steps implemented to provide information regarding the building's performances in terms of probability of exceedance (PoE) of specific Decision Variables (DV), such as monetary losses, casualties, downtime [10]. In the first step, a given site location and local characteristics are related to the seismic hazard expected from the surrounding region. In the second step, a probabilistic description of the seismic demand to the building at increasing levels of ground motion intensity is obtained from the results of a series of Nonlinear Response History Analyses (NRHAs). Subsequently, damage to individual structural and nonstructural components is estimated, through a suite of fragility curves, as a function of selected Engineering Demand Parameters (EDPs) (e.g., peak inter-story drifts, floor accelerations etc.) computed in the second step of analysis. Finally, expected losses are estimated through a set of suitable consequence functions, based on the level of damage sustained by each component.

The main output parameter of the PBEE approach is represented by the expected annual loss (EAL) [11], defined as the average economic loss expected to accrue every year in the structure, considering both the direct repair costs related to damage and the social costs associated to downtime. The synthetic information expressed by these parameters represents a powerful tool for the stakeholders. In particular, the EAL estimations in both the as-built and retrofitted configurations can be assumed as input parameters for a cost-benefit analysis, aimed at the rational choice of the optimal retrofit intervention among different options.

However the PBEE approach is still infrequently employed for the assessment of existing URM constructions. Difficulties in the application of the methodology arise in the calculation of the EAL involving the building's performance assessment at increasing intensity earthquakes. This requires significant computational efforts and is generally unaffordable for applications in the common practice.

Recently, simplified approaches, relating the economic losses to the structural response (engineering demand parameters, EDP) derived from analysis methods within the reach of the most practicing engineers, have been proposed [12], [13]. In particular, the main simplifica-

tion lies in relating a given performance level (PL) to an expected economic loss calculated based on specific story-based loss function [14] or pre-defined based on the actual structural typology [15]. The latter approach has been recently implemented within the Italian Seismic Risk Classification [16] to evaluate the “seismic quality” of existing buildings, providing a specific score system articulated in eight seismic risk classes. Generally speaking, the mentioned procedure appears useful when the amount information regarding the building geometry and structural details is limited and a reliable characterization of the seismic performances is uncertain. The Italian Seismic Risk Classification defines eight seismic performance-based risk classes in terms of EAL and structural collapse capacity. Those classes are employed to give an overall rating on a letter-based scale from A+ to G, similar to the appliances energy consumption scale used in Europe [17].

In this paper, the seismic loss assessment of the residential masonry building stock of the city center of Potenza (southern Italy) is presented. First of all, a complete identification and typological characterization of the residential masonry structures has been performed. Subsequently, different archetype buildings, one for each typology, have been implemented in the 3Muri environment [18] in order to derive their structural response through non-linear static analyses. Finally, based on the main Engineering Demand Parameters obtained in the previous step, the estimation of the EAL is performed according with the Italian guidelines seismic risk classification. The results in terms of monetary losses are then discussed to derive preliminary considerations on the economic and social impacts of probable seismic scenarios. A complementary study regarding the Reinforced Concrete (RC) residential buildings located in the examined area has been recently carried out [19].

## 2 OVERVIEW OF THE CONVENTIONAL APPROACH FOR THE ESTIMATION OF EXPECTED ANNUAL LOSS

The guidelines approved by the High Council of Public Works [16] define the methods addressing the seismic risk classification of constructions and the effectiveness of strengthening interventions. In particular, a conventional method is proposed based on the identification of the seismic performances towards four predefined limit states, namely Operational (SLO), Damage Limitation (SLD), Life Safety (SLV) and Collapse (SLC) [16]. The main novelty of the conventional method is represented by the introduction of two further conventional limit states: the Initial Damage (ID), resulting in a slight initial damage to the structural components and occurring for seismic events featuring a 10 years return period ( $T_r$ ) and the Reconstruction limit state (RLS), referring to seismic events causing a monetary loss corresponding to the total value of the construction [20].

The seismic risk class of the building is defined as the minimum between two classes: the IS-V class, associated to the Safety Index of the structure at the Life Safety Limit State, and the EAL class. The Safety Index is calculated as the ratio between  $PGA_{C,SLV}$  (PGA related to the capacity of the building at the Life Safety Limit State) and  $PGA_{D,SLV}$  (demand PGA prescribed by the code at Life Safety Limit State). The EAL-based score is related to the performances of the structure in terms of seismic losses (namely percentage of Expected Losses towards the total cost of the building, %RC) at different return periods  $T_r$  (namely Mean Annual Frequency of Exceedance, MAFE). More in details, the MAFE ( $\lambda$ ) is calculated according to Equation (1):

$$\lambda = \frac{1}{T_{rc}} = \frac{1}{T_{rd} (PGA_D / PGA_C)^{1/0.41}} \quad (1)$$

where  $T_{rc}$  and  $T_{rd}$  are the return periods related to capacity and demand respectively.

The guidelines [16] also provide conventional %RC, properly calibrated to include all the repair actions associated to a specific damage level.

Figure 1 shows the entire procedure for the EAL index calculation. First of all, a pushover analysis is required to assess the building performances at the four pre-defined limit states (SLO, SLD, SLV and SLC, Figure 1b). At this point, the Multiple Degrees of Freedom (MDOF) System is converted to an equivalent single degree-of-freedom (SDOF) system (Figure 1c). Then, for each limit state, the PGA associated to the building capacity ( $PGA_C$ ) can be calculated in the Acceleration Displacement Response Spectrum (ADRS) plane following the N2 method [21] (Figure 1d). In particular, the  $PGA_C$  is evaluated by scaling the response spectrum until the displacement demand matches the capacity at the reference limit state. Subsequently, based on the seismic hazard model adopted within the reference building code [22], the MAFE values corresponding to the mentioned limit states are determined (Figure 1e) and associated to the Expected Loss Ratios (%RC) prescribed in the guidelines [16]. For what concerns the ID limit state, an Expected Loss Ratio equal to 0% has been conventionally associated to a MAFE value equal to 0.1. Similarly, for the RLS an Expected Loss Ratio equal to 100% has been conventionally associated to a MAFE value equal to that calculated for the SLC limit state. A loss curve (multi-linear function) in the MAFE vs Expected Loss Ratio domain is thus obtained (Figure 1f). Finally, the EAL is computed by integrating the mentioned loss curve. More details about the described procedure are reported in [20]. Table 1 shows the risk classes for safety and economic assessment according to the mentioned guidelines [16].

Figure 1: Steps of the Italian seismic risk classification scheme described in [23].

Safety assessment	Economic assessment	Risk class
IS-V (%)	EAL (%)	
$IS-V \geq 100$	$EAL \leq 0.5$	A+
$80 \leq IS-V < 100$	$0.5 \leq EAL < 1.0$	A
$60 \leq IS-V < 80$	$1.0 \leq EAL < 1.5$	B
$45 \leq IS-V < 60$	$1.5 \leq EAL < 2.5$	C
$30 \leq IS-V < 45$	$2.5 \leq EAL < 3.5$	D
$15 \leq IS-V < 30$	$3.5 \leq EAL < 4.5$	E
$IS-V < 15$	$4.5 \leq EAL < 7.0$	F
	$EAL \geq 7.5$	G

Table 1: Definition of risk classes as a function of both EAL and IS-V according to [16].

### 3 BUILDING TYPOLOGIES IDENTIFICATION FOR THE CITY CENTRE OF POTENZA

This work is carried out on the city of Potenza, located in Basilicata on a hill in the axial-active seismic belt (30 to 50 km wide) of southern Apennines. The city was hit by several strong earthquakes (intensity higher than or equal to VIII MCS). In particular, the 1826 and 1857 events caused severe damage in the entire town imposing a massive demolition and reconstruction activity in the historical city center [24]. In the aftermath of the Irpinia and Basilicata earthquake (November 1980), a massive reconstruction plan, funded by the Italian Government (law 219/81), involved several existing buildings in the Potenza municipality.

In this paper, the seismic assessment is referred to two main areas, namely the “old town center” and the “residential public housing neighborhood”, that can be considered as homogeneous zones (compartments) featuring specific historical, urbanistic and constructive peculiarities. Moreover, such compartments include most of the historical built heritage of the city, developed in two main periods: 1850-1950 and 1945-1990, respectively.

The specific building typologies inventory have been defined by combining the official national census database provided by the Italian Institute of Statistics (ISTAT) as the primary source for the classification of the building stock [25], integrated through secondary sources of information represented by extensive documental and virtual analysis and specific building surveys [26], [27]. More in details, a comprehensive documental analysis has been carried out based on the large database provided by the local organization of Social Housing (Azienda Territoriale per l'Edilizia Residenziale, ATER), directly involved in the residential compartment construction and in the post-seismic reconstruction after the Irpinia Earthquake (1980). Moreover, a number of building-by-building surveys, providing detailed data for both dimensional and structural peculiarities for a single building in an investigated area, have been performed. Finally, further information has been gathered interviewing local technicians with deep knowledge of the construction characteristics.

All that considered, the following main variables emerged as significant classification parameters: (i) masonry texture configuration (regular or irregular), (ii) horizontal structure typology (deformable, semi-rigid or rigid slab), (iii) presence of mixed structures (i.e. mixed masonry-RC structures), (iv) roof types, (v) presence of vaults, (vi) presence of seismic structural intervention. Based on the mentioned parameters, a preliminary macro-typologies inventory for the examined compartments has been defined, retrieving six macro-classes of masonry constructions (MUR).

The MUR1 and MUR2 typologies concern the first urban village built outside the historical center of the city in the 1920s. The MUR1 buildings feature squared local stone or solid brick masonries. Floors are mainly realized with hollow bricks and steel beams. The roof is pitched with wood structure and planking. This typology is characterized by the absence of vaults and mixed structures. Similar features have been retrieved for the MUR2 typology except for the vertical and horizontal structures, which are characterized by barely cut stone and vault floor with bricks and steel beams. The roof is pitched with brick-concrete slab. Over the years, some of the buildings included in the MUR2 typology have been subjected to strengthening interventions, consisting mainly of widespread connections (insertion of metal bars or RC beams). The MUR3 and MUR4 typologies, built in 1940-1960, group masonry constructions featuring solid brick masonry and lime mortar with rigid slab (reinforced brick-concrete) and connections between vertical walls and horizontal elements. In particular, the MUR4 typology is characterized by external masonry walls and internal RC beam-column systems. Both typologies show reinforced concrete pitched roof slab. The MUR5 and MUR6 typologies, built before 1920, are made of disorganized irregular stone masonry with friable mortar.

Such buildings have been retrofitted through different types of interventions (application of diffused tie-roads, filling the voids and/or cracks inside the wall by injecting of new mortar, substitution of damaged elements along cracking lines with new ones, etc.) performed after the Irpinia-Basilicata earthquake. The deformable slabs have been generally replaced by a rigid floor with reinforced brick-concrete slabs.

This preliminary inventory has been further refined considering other significant attributes emerged from the described documental and in situ investigations. Among those, irregularities in plan and the presence of connections between slabs and walls cannot be ignored for a comprehensive evaluation of the building typologies. In particular, based on the gathered data, masonry constructions in the investigated area can be grouped into three main classes: low-rise buildings “Lr” (1-2 stories), medium-rise buildings “Mr” (3-4 stories) and high-rise buildings “Hr” (5-6 stories). The mentioned number of stories ranges (1–2, 3–4, and 5–6) have been defined according with the considerations drawn in [28]. Indeed, all other variables being equal, masonry buildings featuring one to two stories exhibit a similar seismic behavior [28]. A similar criterion can be adopted for medium- and high-rise buildings.

In this optic, seventy-two typologies have been finally identified from the classification approach discussed above, as shown in Table 2.

MACRO-CLASS	Number of stories			Shape in plan		Slab-wall connections		ID
	Lr	Mr	Hr	Reg.	Irreg.	C	Nc	
MUR1	x			x		x		MUR1, Lr, Reg, C
	x			x			x	MUR1, Lr, Reg, Nc
	x				x	x		MUR1, Lr, Irreg, C
	x				x		x	MUR1, Lr, Irreg, Nc
		x		x		x		MUR1, Mr, Reg, C
		x		x			x	MUR1, Mr, Reg, Nc
		x			x	x		MUR1, Mr, Irreg, C
		x			x		x	MUR1, Mr, Irreg, Nc
			x	x		x		MUR1, Hr, Reg, C
			x	x			x	MUR1, Hr, Reg, Nc
			x		x	x		MUR1, Hr, Irreg, C
			x		x		x	MUR1, Hr, Irreg, Nc
MUR2	x			x		x		MUR2, Lr, Reg, C
	x			x			x	MUR2, Lr, Reg, Nc
	x				x	x		MUR2, Lr, Irreg, C
	x				x		x	MUR2, Lr, Irreg, Nc
		x		x		x		MUR2, Mr, Reg, C
		x		x			x	MUR2, Mr, Reg, Nc
		x			x	x		MUR2, Mr, Irreg, C
		x			x		x	MUR2, Mr, Irreg, Nc
			x	x		x		MUR2, Hr, Reg, C
			x	x			x	MUR2, Hr, Reg, Nc
			x		x	x		MUR2, Hr, Irreg, C
			x		x		x	MUR2, Hr, Irreg, Nc
MUR3	x			x		x		MUR3, Lr, Reg, C
	x			x			x	MUR3, Lr, Reg, Nc
	x				x	x		MUR3, Lr, Irreg, C
	x				x		x	MUR3, Lr, Irreg, Nc

		X		X		X		MUR3, Mr, Reg, C
		X		X			X	MUR3, Mr, Reg, Nc
		X			X	X		MUR3, Mr, Irreg, C
		X			X		X	MUR3, Mr, Irreg, Nc
			X	X		X		MUR3, Hr, Reg, C
			X	X			X	MUR3, Hr, Reg, Nc
			X		X	X		MUR3, Hr, Irreg, C
			X		X		X	MUR3, Hr, Irreg, Nc
MUR4	X			X		X		MUR4, Lr, Reg, C
	X			X			X	MUR4, Lr, Reg, Nc
	X				X	X		MUR4, Lr, Irreg, C
	X				X		X	MUR4, Lr, Irreg, Nc
		X		X		X		MUR4, Mr, Reg, C
		X		X			X	MUR4, Mr, Reg, Nc
		X			X	X		MUR4, Mr, Irreg, C
		X			X		X	MUR4, Mr, Irreg, Nc
			X	X		X		MUR4, Hr, Reg, C
			X	X			X	MUR4, Hr, Reg, Nc
			X		X	X		MUR4, Hr, Irreg, C
			X		X		X	MUR4, Hr, Irreg, Nc
MUR5	X			X		X		MUR5, Lr, Reg, C
	X			X			X	MUR5, Lr, Reg, Nc
	X				X	X		MUR5, Lr, Irreg, C
	X				X		X	MUR5, Lr, Irreg, Nc
		X		X		X		MUR5, Mr, Reg, C
		X		X			X	MUR5, Mr, Reg, Nc
		X			X	X		MUR5, Mr, Irreg, C
		X			X		X	MUR5, Mr, Irreg, Nc
			X	X		X		MUR5, Hr, Reg, C
			X	X			X	MUR5, Hr, Reg, Nc
			X		X	X		MUR5, Hr, Irreg, C
			X		X		X	MUR5, Hr, Irreg, Nc
MUR6	X			X		X		MUR6, Lr, Reg, C
	X			X			X	MUR6, Lr, Reg, Nc
	X				X	X		MUR6, Lr, Irreg, C
	X				X		X	MUR6, Lr, Irreg, Nc
		X		X		X		MUR6, Mr, Reg, C
		X		X			X	MUR6, Mr, Reg, Nc
		X			X	X		MUR6, Mr, Irreg, C
		X			X		X	MUR6, Mr, Irreg, Nc
			X	X		X		MUR6, Hr, Reg, C
			X	X			X	MUR6, Hr, Reg, Nc
			X		X	X		MUR6, Hr, Irreg, C
			X		X		X	MUR6, Hr, Irreg, Nc

Lr: low-rise buildings, Mr: medium-rise buildings, Hr: high-rise buildings, Reg: regular shape in plan, Irreg: irregular shape in plan, C: presence of slab-wall connections, Nc: absence of slab-wall connections.

Table 2: Building typologies inventory.

However, the number of masonry buildings actually included in some of the mentioned typologies classes is extremely limited. As a consequence, in order to reduce the computational efforts and also considering the slight incidence of a limited number of cases on the entire seismic assessment of the area, the typologies including a number of elements lower than three have been neglected. Seven typologies have been finally considered in what follows counting 213 buildings in total, distributed as reported in Table 3. For the sake of clarity, it is worth noting that, in this work, only isolated residential buildings have been taken into account. As a matter of fact, considering their inherent peculiarities, specific studies are needed for the seismic assessment of the historical-monumental and masonry aggregates located in the examined area. For the same reason, the MUR5 typology, composed by masonry aggregates, has not been included in Table 3.

Building typology	Number of buildings
MUR1,Hr,Reg,Nc	28
MUR3,Lr,Reg,C	20
MUR3,Mr,Reg,C	59
MUR3,Hr,Reg,C	31
MUR4,Mr,Reg,C	35
MUR4,Mr,Irreg,C	16
MUR6,Hr,Reg,C	24
Total	213

Table 3: Prevalent building typologies distribution.

## 4 CASE STUDIES

### 4.1 Archetype buildings

A series of archetype buildings, one for each typology, has been defined. The archetype referred to the first building typology (MUR1,Hr,Reg,Nc) is a five-story masonry building featuring a floor area equal to 317 m<sup>2</sup> (20.7 x 15.3 m) and a total height equal to 18 m (Figure 2). The vertical structure is composed by solid bricks, except for the first floor featuring an irregular stone masonry. The horizontal structure configuration consists in steel beams and hollow clay bricks. Three archetypes have been defined for the MUR3 building typology (Figures 3 to 5). The same dimensions in plan (23.4 x 12.4 m) have been adopted for all the mentioned archetypes, while different total height values have been considered: 7.1 m, 13.7 m and 20.3 m for “Lr”, “Mr”, and “Hr” building typologies, respectively. The vertical structure of the MUR 3 archetypes is composed by a solid brick masonry and lime mortar. On the other hand, RC floors with tie beams (connecting floors and masonry walls) have been adopted as horizontal structure. The building archetypes shown in Figure 6 and 7 are referred to MUR4. In both cases such archetypes feature a four-story mixed masonry-RC vertical structure. More in details, external masonry walls mixed with an internal RC beam-column system have been adopted. The MUR4 archetype buildings feature the same horizontal structure (reinforced brick-concrete floors) while differ in terms of plan configuration.

The last building prototype (Figure 8) refers to buildings located in the historical city center and involved in the reconstruction plan pursued in the aftermath of the Irpinia-Basilicata earthquake. The performances of the “ancient” masonry, characterized by disordered rubble stone with friable mortar and irregular sub-horizontal courses, were improved through widespread retrofit interventions (e.g., application of diffused tie-roads, injection grouting, damaged elements substitution, etc.). For what concerns the horizontal structure, the deformable

timber floors without steel chains and RC tie-beams were replaced by rigid floors with reinforced brick-concrete slab. The latter configuration has been implemented in the numerical model describing the MUR6 archetype (see Section 4.2).

Figure 2: MUR1,Hr,Reg,Nc building typology: plan geometry of the first story (left) and a picture (right).

Figure 3: MUR3,Lr,Reg,C building typology: plan geometry of the first story (left) and a picture (right).

Figure 4: MUR3,Mr,Reg,C building typology: plan geometry of the first story (left) and a picture (right).

Figure 5: MUR3,Hr,Reg,C building typology: plan geometry of the first story (left) and a picture (right).

Figure 6: MUR4,Mr,Reg,C building typology: plan geometry of the first story (left) and a picture (right).

Figure 7: MUR4,Mr,Irreg,C building typology: plan geometry of the first story (left) and a picture (right).

Figure 8: MUR6,Hr,Reg,C building typology: plan geometry of the first story (left) and a picture (right).

Generally speaking, the number of experimental campaigns aimed at the characterization of the mechanical properties of masonry is very limited if compared to the amount of data referred to concrete and reinforcements. As a matter of fact, the execution of exhaustive tests is frequently difficult due to both built heritage conservation issues and economic aspects [29]. Given the poor amount of data regarding the mechanical properties of the materials constituting the existing masonry buildings located in the examined area, reference to the typical values provided by the current Italian seismic code (Table C8.5.I [30]) have been taken into account. These values refer to historic masonry in poor conditions and have to be modified by corrective coefficients in the evidence of qualified characteristics, such as good mortar, presence of stringcourses etc.. Table 4 summarizes the values of the elastic and mechanical characteristics derived from the mentioned seismic code and adopted in the numerical models for irregular stone, barely cut stone and solid brick masonry panels.

Mechanical properties	Irregular stones	Barely cut stone	Brick and lime mortar
Comp. strength $f_{m,av}$ (MPa)	1.5	2	3.45
Shear strength $\tau_{0,av}$ (MPa)	0.025	0.043	0.09
Young modulus $E_{av}$ (MPa)	870	1230	1500
Shear modulus $G_{av}$ (MPa)	290	410	500

Table 4: Mechanical parameters adopted in the numerical models.

Finally, it is worth noting that all the archetype buildings are assumed to be located on a medium soil classified as soil type B, according with the current Italian seismic code [22]. For each archetype, the site hazard curve, defined based on the data provided by the INGV (Italian Institute of Geophysics and Volcanology), is expressed in terms of Mean Annual Frequency of Exceedance (MAFE<sub>i</sub>) as a function of the considered IM, namely, the Peak Ground Acceleration (PGA).

Figure 9: Hazard curve of the examined site, Potenza Soil Type B.

## 4.2 Numerical modeling

In order to assess the global behavior of the selected archetype buildings, 3d non-linear numerical models have been implemented in the 3Muri environment [18]. The mentioned software has been specifically developed for the evaluation of both local and global seismic response of URM buildings. 3Muri is based on the “Equivalent Frame Model” (EFM) approach. Generally speaking, a generic masonry wall with openings is idealized by identifying two main structural components, namely the piers and the spandrels, in which the non-linear response is concentrated, connected by a rigid area (nodes). The piers are the main vertically resisting elements while the spandrels couple the response of two adjacent piers. The identification of the geometrical properties of piers and spandrels is automatically performed by the software according to conventional criteria. The non-linear macro-element model implemented in 3Muri allows the two main failure modes, governing the response of masonry walls to be reproduced with a limited number of degrees of freedom. In terms of flexural behavior, rocking and crushing mechanisms are considered, whereas diagonal cracking and shear sliding are taken into account for shear failure. In order to define the ultimate shear and bending strength, simplified criteria are implemented in the software. The elastic behavior is defined considering the mechanical and geometrical properties of the masonry and a stiffness reduction factor is introduced to account for cracked conditions. It is worth noting that, in the numerical models of the archetypes included in the MUR4 building typology, the RC structural members have been modeled using non-linear lumped plasticity elements [18].

It is worth noting that the main assumption adopted in the numerical modeling is that the global behavior of the mentioned archetypes is fundamentally governed by the in-plane behavior of walls. In other words, the local mechanisms (mainly out-of-plane mechanisms) are not taken into account. This assumption is considered acceptable for most of the examined archetypes (namely all the archetypes except MUR1), since the systematic presence of RC ring beams is expected to reduce the vulnerability to local mechanisms [31]-[33]. The numerical models of the selected building prototypes are represented in Figure 10. As can be observed, the presence of staircase has been neglected at this step of the study.

Figure 10: 3D view of the building typologies: a) MUR1,Hr,Reg,Nc; b) MUR3,Lr,Reg,C; c) MUR3,Mr,Reg,C; d) MUR3,Hr,Reg,C; e) MUR4,Mr,Reg,C; f) MUR4,Mr,Irreg,C; g) MUR6,Hr,Reg,C.

### 4.3 Analysis Results

Modal analyses have been performed in order to derive the dynamic characteristics of the selected buildings. Table 5 resumes the fundamental periods ( $T$ ) and participation masses ( $M$ ) of the examined numerical models. Each building prototype features similar fundamental periods along the principal directions. The lower period obtained with the MUR4 typology is probably associated to the contribution provided by the internal RC beam-column systems.

Building typology	$T_x$ (s)	$M_x$ (%)	$T_y$ (s)	$M_y$ (%)
MUR1,Hr,Reg,Nc	0.50	66	0.49	81
MUR3,Lr,Reg,C	0.17	77	0.18	72
MUR3,Mr,Reg,C	0.30	80	0.35	78
MUR3,Hr,Reg,C	0.49	78	0.56	78
MUR4,Mr,Reg,C	0.31	63	0.48	80
MUR4,Mr,Irreg,C	0.45	30	0.44	58
MUR6,Hr,Reg,C	0.53	69	0.63	78

Table 5: Modal parameters.

Non-linear seismic analyses have been performed along the main (X- and Y-) directions of the archetype buildings considering two different force distributions: (i) uniform (“Unif”) distribution, proportional to the mass, and (ii) linear (“Triang”) distribution, proportional to the shape of the fundamental mode of vibration.

Figure 11 to Figure 14 show the pushover curves in the two principal directions of each archetype. It is worth noting that the capacity curves in terms of base shear vs. top displacement have been cut off at a peak strength reduction of about 20% on the negative slope.

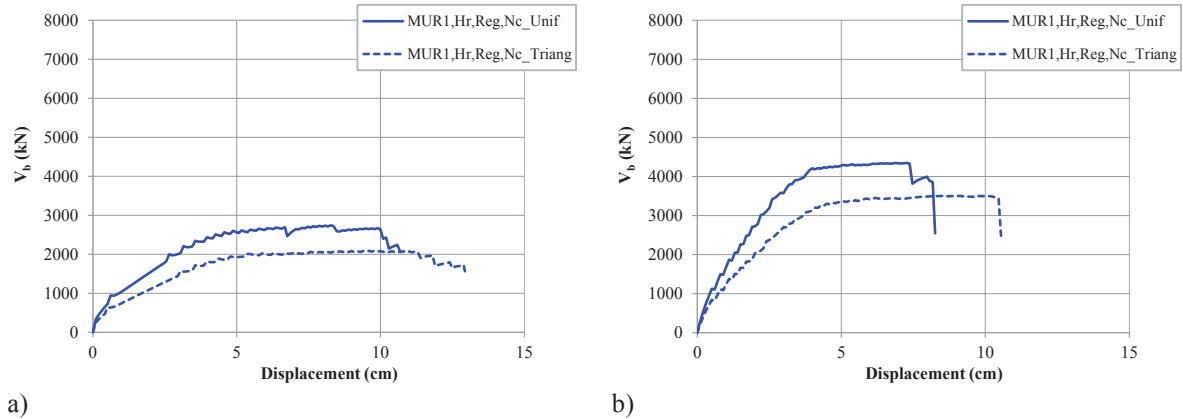

Figure 11: Pushover curves of the selected MUR1 building typology: a) X direction; b) Y direction.

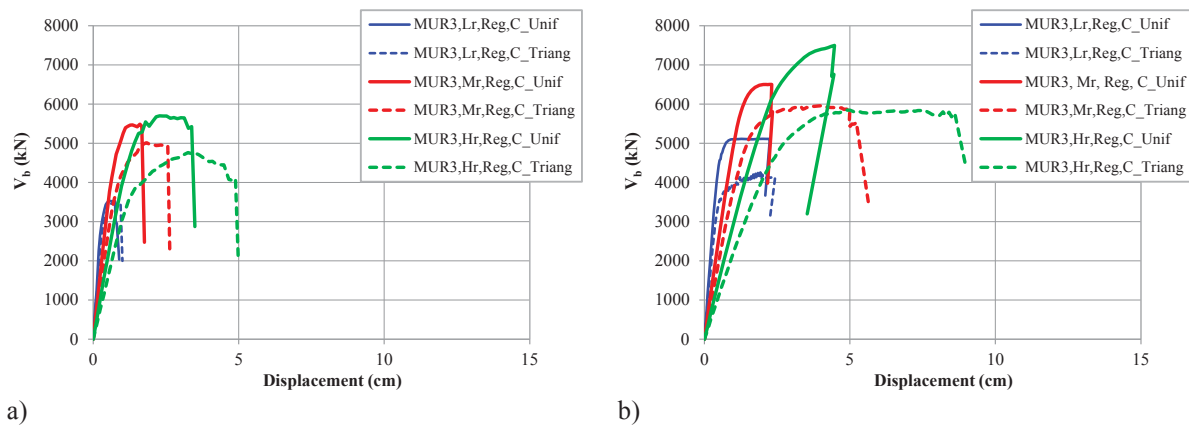

Figure 12: Pushover curves of the selected MUR3 building typologies: a) X direction; b) Y direction.

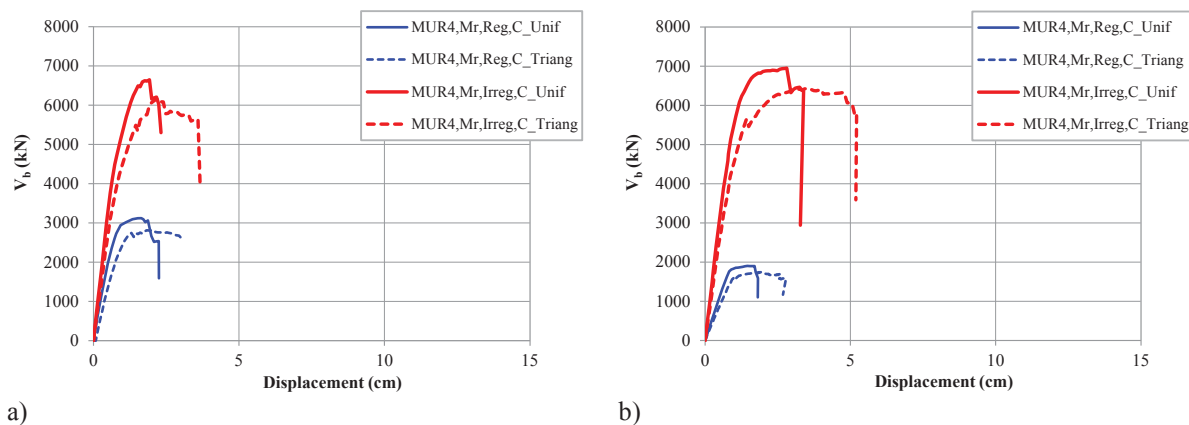

Figure 13: Pushover curves of the selected MUR4 building typologies: a) X direction; b) Y direction.

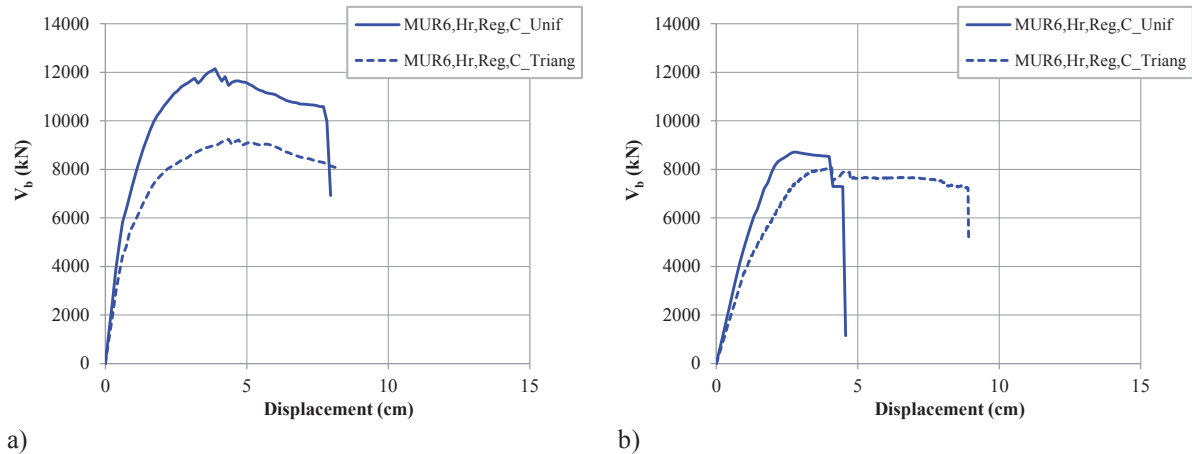

Figure 14: Pushover curves of the selected MUR6 building typologies: a) X direction; b) Y direction.

A different structural response has been obtained by using the two mentioned distributions. Obviously, the top displacement being equal, the maximum strength registered using the uniform distribution is larger than that obtained using the triangular distribution (the resultant of horizontal forces applied at each step of the analysis in the “Unif” distribution is double with respect to that associated to the “Triang” distribution). Moreover, while the uniform pattern produces a force concentration at first floor, a redistribution of loads is obtained with the triangular pattern, thus leading to a larger ductility capacity (of about 50%) of the examined structures. For the archetype buildings associated to MUR1 and MUR3, the lower value of the peak strength is registered in the X-direction (Figures 11 and 12). This is probably due to a lower number of resistant elements coupled with large openings along such direction. For what concerns the MUR4 archetypes, the more uniform distribution of openings and the presence of interior resistant elements (RC frames) counterbalance the structural response (in terms of peak strength) along the two main directions (Figure 13). For the MUR6 archetype, the larger value of the peak strength observed in the X-direction seems to be associated to the presence of a continuous internal masonry wall (with limited openings) along this direction (Figure 14). Finally, it is worth noting that the weakest structural response in terms of strength capacity has been observed for MUR1 and MUR4 archetype buildings. In the first case, such result seems to be related to the poor mechanical properties of the structural materials, compared to those of the remaining archetypes. On the other hand, for what concerns the MUR4 typology, the limited number of vertical resisting elements (in particular along the Y-direction) significantly affects the peak strength values.

Figure 15 to Figure 21 plot the damage patterns of the examined archetypes associated to the final step of the analysis. Different colors have been adopted to represent the failure modes of the involved structural elements.

Figure 15: Damage pattern on the MUR1,Hr,Reg,Nc building: a) and b) front facade wall, respectively, for uniform and triangular load pattern; c) and d) side wall, respectively, for uniform and triangular load pattern; e) legend of the damage states associated to each masonry element.

Figure 16: Damage pattern on the MUR3,Lr,Reg,C building: a) and b) front facade wall, respectively, for uniform and triangular load pattern; c) and d) side wall, respectively, for uniform and triangular load pattern; e) legend of the damage states associated to each masonry element.

Figure 17: Damage pattern on the MUR3,Mr,Reg,C building: a) and b) front facade wall, respectively, for uniform and triangular load pattern; c) and d) side wall, respectively, for uniform and triangular load pattern; e) legend of the damage states associated to each masonry element.

Figure 18: Damage pattern on the MUR3,Hr,Reg,C building: a) and b) front facade wall, respectively, for uniform and triangular load pattern; c) and d) side wall, respectively, for uniform and triangular load pattern; e) legend of the damage states associated to each masonry element.

Figure 19: Damage pattern on the MUR4,Mr,Reg,C building: a) and b) front facade wall, respectively, for uniform and triangular load pattern; c) and d) side wall, respectively, for uniform and triangular load pattern; e) legend of the damage states associated to each masonry element.

Figure 20: Damage pattern on the MUR4,Mr,Irreg,C building: a) and b) front facade wall, respectively, for uniform and triangular load pattern; c) and d) side wall, respectively, for uniform and triangular load pattern; e) legend of the damage states associated to each masonry element.

Figure 21: Damage pattern on the MUR6,Hr,Reg,C building: a) and b) front facade wall, respectively, for uniform and triangular load pattern; c) and d) side wall, respectively, for uniform and triangular load pattern; e) legend of the damage states associated to each masonry element.

The damage of the MUR1,Hr,Reg,Nc archetype building (Figure 15) is characterized by the flexural failure of spandrels triggering a strong piers-weak spandrel mechanism and, as a consequence, a rocking failure mode of piers [34]. In particular, the poor mechanical properties of the ground floor masonry produce a concentration of the flexural damage at the first story. Conversely, for what concerns the MUR3 and MUR4 archetypes, the RC floors with tie beams located at each level of the structure directly affect behavior of spandrels leading to a shear failure mode of such elements (Figures 16 to 20). Moreover, the rigid translation of the RC floors activates story mechanisms associated with shear collapse of the piers. Once again, the first story elements appear as the most vulnerable elements. A similar behavior has been observed for the MUR6 archetype building. However, the enhanced mechanical properties of such building typology lead to a reduced damage in the structural elements with respect to those observed for MUR3 and MUR4 archetypes. Finally, as mentioned above, the redistribution of loads associated to the triangular distribution corresponds to a redistribution of damage along the height of the examined buildings.

## 5 EXPECTED ANNUAL LOSS ESTIMATION

The conventional approach proposed within the Italian Seismic Risk Classification [16] and described in Section 2, has been applied to evaluate the “seismic quality” of the examined archetypes. For each archetype, the procedure has been performed four times (one for each non-linear analysis, i.e. two different load patterns coupled with two different main directions). The main outputs of the mentioned procedure are summarized in Table 6 and Table 7. It is worth noting that only the results corresponding to the non-linear analysis leading to the maximum value of EAL are reported. In particular, the return periods ( $T_r$ ) and MAFE ( $\lambda$ ) values for each target limit state are shown. The EAL values in the as-built configuration are provided in the third column of Table 7 and are expressed as a percentage of the Replacement Cost (RepC) of the building. The latter parameter has been estimated as the average cost of demolition and construction per square meter of similar new buildings, assumed equal to 954 €/m<sup>2</sup> according with [1].

Building typology	$T_{r, SLO}$ (years)	$\lambda_{SLO}$ (%)	$T_{r, SLD}$ (years)	$\lambda_{SLD}$ (%)	$T_{r, SLV}$ (years)	$\lambda_{SLV}$ (%)	$T_{r, SLC}$ (years)	$\lambda_{SLC}$ (%)
MUR1,Hr,Reg,Nc	65	1.54	30	3.33	211	0.47	393	0.25
MUR3,Lr,Reg,C	30	3.33	30	3.33	297	0.34	419	0.24
MUR3,Mr,Reg,C	75	1.33	30	3.33	139	0.72	233	0.43
MUR3,Hr,Reg,C	30	3.33	30	3.33	170	0.59	338	0.30
MUR4,Mr,Reg,C	36	2.78	30	3.33	87	1.15	147	0.68
MUR4,Mr,Irreg,C	46	2.17	30	3.33	119	0.84	207	0.48
MUR6,Hr,Reg,C	65	1.54	30	3.33	211	0.47	393	0.25

Table 6: Return periods ( $T_r$ ) and MAFE ( $\lambda$ ) values for each target limit state.

Building typology	RepC	EAL <sub>As-built</sub> (%RepC)	EAL <sub>Retrofitted</sub> (%RepC)
MUR1,Hr,Reg,Nc	1,812,848	1.60	1.0
MUR3,Lr,Reg,C	553,625	1.41	0.5
MUR3,Mr,Reg,C	1,107,251	1.45	0.5
MUR3,Hr,Reg,C	1,660,876	1.47	0.5
MUR4,Mr,Reg,C	908,399	1.89	1.0
MUR4,Mr,Irreg,C	2,207,556	1.67	1.0
MUR6,Hr,Reg,C	3,045,912	1.32	0.5

Table 7: EAL<sub>As-built</sub> and EAL<sub>Retrofitted</sub> values.

The results in terms of EAL<sub>As-built</sub> are in line with the considerations regarding the structural response of the examined buildings made in Section 4.3. As a matter of fact, the weak structural response observed for MUR1 and MUR4 archetypes produced larger values of EAL. On the contrary, lower values of EAL have been observed for the remaining archetypes, in particular for the MUR6 typology.

A general understanding of the potential socio-economic effects of the seismic scenarios at territorial scale has been obtained by monetizing the EAL<sub>As-built</sub> values, obtained for the each typology, with respect to the effective corresponding Replacement Cost (RepC). The monetary expected annual loss of the two compartments has been calculated by multiplying, for each building typology, the monetized EAL<sub>As-built</sub> value for the total number of elements of this category. As reported in Table 8, the total expected annual loss of the entire compartments (i.e., area's expected annual loss, AEAL) is equal to approximately 483 million Euros. To give some reference for the mentioned value, the latter can be compared to the area's total income (ATI) obtained multiplying the per capita income (PCI) measured in the examined area in the last year (equal to €16,522 [25]), by the total number of occupants (equal to 5730). In this optic, the ratio between AEAL and ATI is equal to approximately 5 (483 million divided by 94.7 million Euros).

Recently, the Italian 2019 Financial Law [35], introduced the so-called “Sisma Bonus” providing incentives, in terms of tax deductions, for seismic strengthening interventions on private buildings. These tax deductions range from 50% to 85% of the retrofit intervention's total cost. The incentives system is directly related to the risk classes of the Italian seismic risk classification guidelines and is associated to specific ranges of EAL (see Table 1 in Section 2). In particular, a 50% tax deduction can be obtained by implementing retrofit interventions without class improvement with respect to the as-built configuration. It can be raised up to 75% and 85% in case of improvement of one or two seismic risk classes, respectively. In any case, the maximum retrofitting expenditure amounts to €96,000 per property unit (single family house, apartment, etc.). Moreover, following the recent COVID19 pandemic, a special “Super Bonus” [36] up to 110% has been issued, with maximum retrofitting expenditure per property unit raised up to €136,000 also allowing the assignment of credit solution. In other words, the accrued credit can be transferred to third parties (financial institutions, banks, lenders), limiting or avoiding the economic burden for the stakeholders.

In this optic, for each building typology, the monetary EAL values obtained considering potential retrofit interventions, aimed at the improvement of two seismic classes with respect to the as-built condition, has been calculated (see the third column of Table 8). The reduction of EAL for each building typology ( $\Delta EAL = EAL_{As-built} - EAL_{Retrofit}$ ) is also reported (last column of Table 8). The total variation of the EAL ( $\Delta AEAL$ ) is thus equal to €264,440,931.

Assuming that all the buildings' owners exploit the maximum retrofit expenditure amount (i.e., 136,000 per property unit), the total cost of the potential interventions is equal to € 311,712,000. Therefore, less than two years would be sufficient to pay back the entire amount of the financial resources involved in the seismic protection improvement of the examined area's built heritage.

Building typology	EAL <sub>As-built</sub> (€)	EAL <sub>Retrofitted</sub> (€)	ΔEAL (€)
MUR1,Hr,Reg,Nc	81,215,592	50,759,745	30,455,847
MUR3,Lr,Reg,C	15,612,233	5,536,253	10,075,980
MUR3,Mr,Reg,C	94,725,285	32,663,892	62,061,394
MUR3,Hr,Reg,C	75,686,112	25,743,576	49,942,537
MUR4,Mr,Reg,C	60,090,581	31,793,958	28,296,623
MUR4,Mr,Irreg,C	58,985,896	35,320,896	23,665,000
MUR6,Hr,Reg,C	96,494,496	36,550,945	59,943,551
AEAL	482,810,195	218,369,264	264,440,931

Table 8: Monetized EAL values estimated for the examined building typologies.

## 6 CONCLUSIONS

The seismic loss assessment of masonry building stock located in the historical city center of Potenza has been performed based on the conventional approach currently used within the Italian Seismic Risk Classification [16]. First of all, the masonry buildings detected on the examined territory have been grouped in 7 typologies. Subsequently, 7 archetype buildings, each one featuring the structural, material and geometrical peculiarities of the corresponding building typology, have been modeled in the 3Muri environment. At this point, the mentioned simplified approach has been performed to derive the EAL of each archetype (i.e. building typology). The socio-economic effects of the seismic scenarios at territorial scale have been assessed, in first approximation, by comparing the EAL of the entire examined area with the current Area's Total Income (ATI) of the actual population. The ratio between EAL and ATI is equal to approximately 5.

Finally, considering the recent economic strategy adopted by the Italian Government to gradually reduce the seismic vulnerability of the existing building stock, a potential global retrofit intervention, aimed at the improvement of two seismic risk classes for all the masonry buildings located in the examined area, has been considered. The potential global intervention could significantly reduce the direct EAL of about 50%, from 483 to 218 million Euros. Moreover, considering that the maximum total amount of the intervention is equal to approximately 310 million of Euros, the pay-back period (namely the time needed to recover the cost of the investment) is about 1.2 years. Obviously, further studies, implementing specific retrofit interventions for each archetype, should be performed in order to precisely evaluate the actual economic effects and the structural performances in the retrofitted configuration. Moreover, further building typologies (historical-monumental and masonry aggregates) should be included to obtain a general understanding and a complete definition of the socio-economic impact at the territorial scale.

## AKNOWLEDGMENTS

This research has been developed within the PON-AIM 2014-2020 project, “Attraction and International Mobility”, Line 1, supported by the Italian Ministry of University and Public Instruction.

### Abstract

*Earthquake-induced ground-motion duration can be an important factor to consider when assessing ground-motion damage potential, as evidenced by recent earthquake events worldwide. In current practice, duration is commonly relegated to implicit, qualitative considerations. This study introduces a framework to explicitly quantify the influence of duration on building portfolio direct economic losses. To this end, a simulation-based probabilistic risk modelling framework is developed for different synthetic building portfolios impacted by a case-study seismic source. Two building typologies, representative of distinct vulnerability classes in southern Europe, are considered. A simulation-based probabilistic seismic hazard analysis is performed, explicitly simulating duration jointly with spectral-shape-related intensity measures. Sets of long and one-to-one spectrally-equivalent short duration ground-motion records are selected and then used jointly to perform nonlinear dynamic analysis and derive fragility models for each considered building typology. Fragility relationships are derived by using average spectral acceleration as the primary intensity measure and: 1) maximum inter-storey drift ratio as a demand parameter, indirectly accounting for ground-motion duration (through the adopted nonlinear modelling strategy); 2) maximum inter-storey drift ratio as demand parameter, explicitly considering duration as an intensity measure together with spectral shape, in a vector-valued format. For each case, vulnerability models are developed by combining the fragility relationships with a building-level damage-to-loss model. The portfolio expected annual losses estimated using the described vulnerability models are critically compared and discussed. Depending on the location/portfolio, the impact of ground-motion duration can be significant, and the proposed approaches allow an analyst to account for it in a practical way.*

**Keywords:** Ground-motion duration; nonlinear dynamic analysis; maximum inter-storey drift ratio; building portfolio loss.

## 1 INTRODUCTION

Earthquake events have been responsible for devastating human, environmental and economic losses in modern societies over the years. Portfolio risk assessment represents the first step towards developing risk reduction and resilience-enhancing strategies for earthquake-prone regions. Earthquake risk assessment generally requires three main modelling components: a probabilistic seismic hazard model (simulating representative earthquake scenarios in time and space and assessing the resulting ground-shaking intensity across a geographical area at risk); a comprehensive exposure dataset (containing details on the location and characteristics of the assets at risk in the geographic area of concern); and a set of (physical) vulnerability models for those exposed assets/asset types (e.g., [1]), quantifying the susceptibility to damage, or other forms of loss (e.g., downtime and casualties), of structures and their contents because of the hazard impact. This latter component plays a significant role in earthquake risk modelling/risk reduction since reducing physical vulnerability leads to a direct decrease in the associated seismic risk. Therefore, understanding and quantifying the various earthquake-induced ground-motion characteristics driving seismic vulnerability becomes crucial.

Current seismic design and risk assessment procedures commonly characterise ground motions in terms of amplitude and frequency-related parameters (e.g., spectral ordinates) without explicitly considering ground-motion duration. Large-magnitude events worldwide, often resulting in long-duration ground motions [2] (e.g., the 2010 Maule Chile earthquake, moment magnitude,  $M_w$  8.8; the 2011 Tohoku Japan,  $M_w$  9.0) caused billions of dollars in losses, emphasising the need to account for ground-motion duration in practical earthquake risk assessment exercises. The importance (and influence) of amplitude and frequency-related parameters on ground-motion-induced damage and losses have been comprehensively investigated and quantified. However, a consensus has not been reached yet concerning the impact of ground-motion duration on structural response, building performance, and resulting damage/losses.

The main difficulty in quantifying the effect of duration on seismic response of structures is related to the challenging task of decoupling this specific effect from the impact of other ground-motion characteristics. Duration is considered an essential factor in assessing a ground-motion damage potential, but its significance remains unclear, partly because of the somehow contradictory and inconclusive results of some past studies (e.g., [3]). Such conflicting findings from prior studies mainly result from the adopted definition of strong-motion duration, the structural demand parameters utilised to quantify damage, and the inadequacy of the numerical models in capturing the stiffness and strength cyclic and in-cycle deterioration of different structural systems.

Some studies (e.g., [4]) have demonstrated that while duration has no significant effect on peak-based demand parameters (e.g., maximum inter-story drift ratio, MIDR), it can have a significant effect on cumulative demand parameters (e.g., dissipated hysteretic energy, EH). On the other hand, studies that utilised analytical models accounting for stiffness and strength cyclic and in-cycle deterioration (e.g., [5]) demonstrated that long-duration ground motions impact cumulative damage and collapse capacities. However, the degree of importance of duration effects may vary depending on the structural system under consideration.

Significant advances on the topic have been recently made due to the increasing availability of reliable long-duration ground-motion records and improved deteriorating nonlinear structural models incorporating the destabilising P- $\Delta$  effects (e.g., [2], [6]). These studies focused primarily on the influence of ground-motion duration on structural collapse capacity and structural collapse risk, using novel ground-motion selection procedures to isolate the effects of duration from the response spectral shape by using “spectrally equivalent” long- and short-duration ground-motion records. This approach assumes a weak correlation between spectral

shape (i.e., spectral acceleration ordinates) and duration (i.e., significant duration), which may not be a realistic assumption in some cases.

Literature describing how duration affects structural fragility for different damage states and their evaluation is not widely available. In [7], this modelling challenge was tackled using two different approaches. In the first approach, the effect of duration was decoupled from the effects of amplitude and spectral shape by assembling sets of spectrally equivalent long- and short-duration ground motions. Those sets of records were employed in comparative incremental dynamic analyses to derive fragility and vulnerability models using realistic SDoF deteriorating nonlinear models. Formal hypothesis testing was also employed to assess the analyses results' statistical significance quantitatively. The second approach employed the generalised conditional intensity measure (GCIM) method to select hazard-consistent ground motions. Those ground motions were used as an input to multiple stripe analyses using realistic MDoF deteriorating nonlinear models. The impact of duration was investigated by variance analysis and in terms of vector-valued fragility and vulnerability models.

Most of the existing studies, as noticed, focus on structural response/building performance assessment, and very few on building-specific loss assessment (e.g., [8]). To the best of the authors' knowledge, no past studies investigated the effect of ground-motion duration on building-portfolio direct economic losses. Accurately quantifying the potential impact of ground-motion duration on portfolios of buildings located in seismically prone regions, as proposed in this study, can be of interest to different stakeholders (e.g., property owners, (re)-insurers).

The study begins with an overview of the simulation-based risk assessment framework employed in the study. The proposed methodology relies on probabilistic seismic hazard analysis (PSHA), incremental dynamic analysis-based [9] fragility derivation (scalar and vector-valued models are considered [10]), and simulation-based loss estimation. The approach is applied to two synthetic portfolios of the same size, located in the fault-parallel orientation with respect to a case-study strike-slip fault. Different structural types are considered for each portfolio, including gravity-designed and seismically-designed reinforced concrete (RC) frames. The results are discussed considering the effects of ground-motion duration on the median loss and expected annual loss (EAL) of the considered location/portfolios at different distances from the case-study fault.

## 2 SIMULATION-BASED SEISMIC LOSS ASSESSMENT

The implemented simulation-based risk assessment framework [11] is schematically illustrated in Figure 1. Sections 2.1 to 2.4 describe the relevant hazard, exposure and vulnerability framework components and the associated direct loss estimations within this framework.

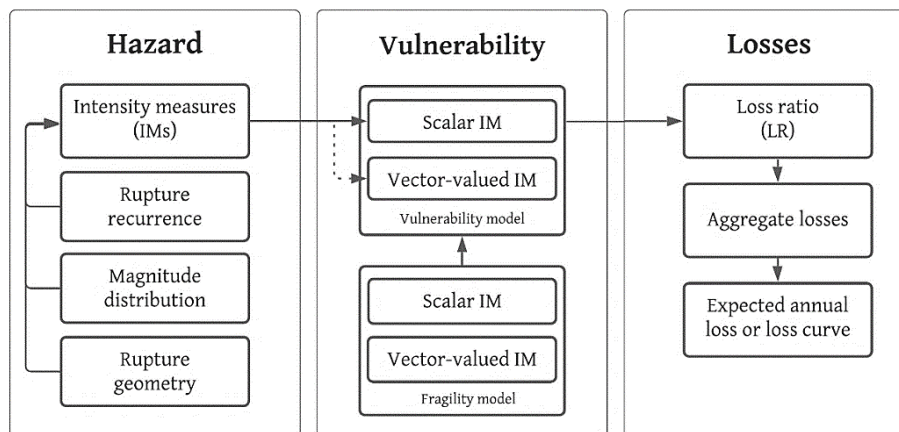

Figure 1: Simulation-based risk assessment framework.

Event-based PSHA [12] is used to simulate 1) seismicity in the considered region as described by a source model; and 2) the resulting ground shaking at the considered set of locations by using a ground-motion model (GMM). Specifically, a stochastic event set (i.e., a stochastic catalogue) is generated for a given time span, chosen based on the minimum rate of exceedance of interest. The number of earthquake occurrences within this period is simulated by sampling the probability distribution for the considered source model's rupture occurrence. The geometry (constraining the earthquake rupture location) and the magnitude-frequency distribution (defining the average annual occurrence rate over a magnitude range) describe the considered source models. For each event in the catalogue, the corresponding magnitude is first simulated from the magnitude-frequency distribution. Next, following the Joyner-Boore source-to-site distance definition, the distance to the rupture for each location of interest is assigned (shallow rupture with a dip angle of  $90^\circ$  and strike of  $0^\circ$ ). Then, ground-motion intensity measures (IMs) of interest are sampled from the probability distributions defined by the GMM, accounting for cross-IM correlation. The set of simulated ground-shaking IMs at the various locations forms a ground-motion field; various ground-motion fields are generated to capture the aleatory variability (both inter- and intra-event) in the GMM.

Given a suite of site-independent ground-motion records with similar spectral shape but different durations, fragility, and vulnerability models (scalar and vector-valued) are derived for each considered building type within the considered portfolios. For each location, building type and simulated IMs, the loss ratio is calculated using the appropriate vulnerability model accounting indirectly or directly for ground-motion duration. The total portfolio loss is calculated by summation over all the building locations in each simulation.

Loss exceedance curves (mean annual frequency, MAF, of exceedance vs loss ratio/loss value) for specific buildings/locations and the entire portfolio can be estimated using the obtained ground-motion fields, leading to lists of events and corresponding loss ratios/loss values. The lists are sorted from the highest loss ratio/loss value to the lowest. The rate of exceedance of each loss ratio/loss value is computed by dividing the number of exceedances of that loss ratio by the length of the event set (eventually multiplied by the number of stochastic event sets, if more than one set are generated). By assuming a Poisson distribution of the occurrence model, the probability of exceedance of each loss ratio/loss value can also be estimated. The portfolio EAL can be calculated by averaging over all the simulations and events.

## 2.1 Hazard

A Poisson model is used to simulate the events' earthquake occurrence on the considered fault. The characteristic earthquake-recurrence model by [13] is adopted to simulate each event associated  $M_w$ . It consists of a log-linear recurrence relationship (i.e., frequency of occurrence vs  $M_w$ ) for moderate (non-characteristic) events and a constant probability branch of occurrence for large (characteristic) events. This model is based on observations that during repeated ruptures occurring on the same fault (or fault system), some characteristics, such as fault geometry, source mechanism, and seismic moment, remain approximately constant over a significant time. The magnitude-dependent length of the rupture is obtained from the equations proposed by [13]. The Joyner-Boore distance is used to define the source-to-site distances for the set of locations of interest.

The amplitude- and duration-based ground-motion IMs (i.e., average spectral acceleration, AvgSa and significant duration,  $D_{S5-95}$ ) are simulated for each seismic event in the stochastic catalogue using the approach presented in [14] for correlated random realisations from a multivariate lognormal distribution (including cross-IM correlation). The AvgSa and  $D_{S5-95}$  realisations are obtained using appropriate GMMs (i.e., [15]; [16]) and empirical correlation models (i.e., [17]; [18]) for spectral acceleration (Sa) ordinates (to estimate AvgSa) and  $D_{S5-95}$ . It is

worth noting that different models should be considered and combined in a logic tree to consider the epistemic uncertainties included in the framework. Nevertheless, one set of models is utilised since the study focuses on introducing the proposed simulation-based loss estimation framework and relative loss results.

It is also worth mentioning that only the combined (intra- and inter-event) GMM uncertainty is considered in this study for simplicity (and computational efficiency), with no consideration of ground-motion spatial correlation (among the locations of the portfolio). Yet, a full correlation for the buildings pertaining to one single site is implicitly assumed since ground shaking is herein simulated for each location (rather than for each building). Many studies (e.g., [19]) have shown that the spatial correlation in ground-motion IMs has important implications on probabilistic seismic hazard and loss estimates of spatially distributed systems (e.g., building portfolios). Inclusion of spatial correlation of IMs into the seismic risk analysis may often result in the likelihood of observing more significant (and in some instances smaller) losses for a portfolio distributed over a typical city-scale when compared against simulations in which this correlation is neglected. Therefore, in practice, the spatial correlation must be included. This is a future development of the current study.

## 2.2 Exposure

Various building portfolios located nearby a causative fault are considered. Each portfolio consists of several equally spaced locations (i.e., sites). In each location, a group of buildings of different typologies (or taxonomy) is collocated (i.e., the exposure is “lumped” at the considered sites). Each portfolio is also moved (utilising 3 km intervals) horizontally through the entire region (perpendicularly to the fault) to assess the ground-motion duration influence on the loss curves/EAL with respect to the distance from the fault.

## 2.3 Vulnerability

Fragility relationships are derived by using incremental dynamic analysis (IDA) with AvgSa as the primary IM and: 1) MIDR as a demand parameter, indirectly accounting for duration, through an advanced nonlinear structural model; 2) MIDR as demand parameter, explicitly considering duration as an IM together with spectral shape, in a vector-valued format. For each case, vulnerability models are developed by combining the fragility relationships with a building-level damage-to-loss model. It is worth noting that MIDR can account indirectly for the duration since the hysteretic models utilised here ([20]; [21]) accounts for the cyclic and in-cycle strength and stiffness deterioration of the structural components based on the EH of the components, following the deterioration rule developed by [22].

When using a scalar IM (i.e., AvgSa), the probability of reaching or exceeding a damage state (DS) at a given IM level can be estimated as the fraction of records for which this DS occurs at a level lower than the defined IM. This probability can be calculated as shown in equation 1, assuming a lognormal distribution.

$$P(DS \geq ds_i | IM) = \Phi \left[ \frac{\ln(IM/\mu)}{\beta} \right] \quad (1)$$

The fragility relationship mean,  $\ln(\mu)$ , and standard deviation,  $\beta$  (i.e., dispersion), are computed with equations 2 and 3 (i.e., by using the method of moments estimator as described in [23]). In these equations,  $n$  is the number of considered ground-motions;  $IM_i$  is the intensity measure value associated with the onset of a DS for the  $i^{\text{th}}$  ground motion.  $\Phi$  is the CDF of the standard Gaussian distribution.

$$\ln(\mu) = \frac{1}{n} \sum_{i=1}^n \ln(IM_i) \quad (2)$$

$$\beta = \sqrt{\frac{1}{n-1} \sum_{i=1}^n \left[ \ln\left(\frac{IM_i}{\mu}\right) \right]^2} \quad (3)$$

When using a vector-valued IM (i.e., [AvgSa, Ds<sub>5-95</sub>] in this study), although only a single IM parameter is scaled during IDA, it is still possible to determine the effects of other IMs. In such context, IM<sub>2</sub> (i.e., Ds<sub>5-95</sub>) can explain part of the variation of the associated IM<sub>1</sub> (i.e., AvgSa). Therefore, the probability of exceeding the IM<sub>1</sub> associated with the target EDP (i.e., MIDR) level can be expressed in terms of a conditional distribution of IM<sub>1</sub> given IM<sub>2</sub>. Linear regression is used to find the conditional mean of  $\ln IM_1$  given  $\ln IM_2$  as shown in equation 4.  $\beta_0$  and  $\beta_1$  are coefficients estimated from linear regression using the data points. The conditional standard deviation ( $\sigma_{\ln IM_1 | \ln IM_2 = \ln im_2}$ ) of  $\ln IM_1$  given  $\ln IM_2$  is estimated computing the standard deviation of the regression residuals (root mean squared error).

$$\mu_{\ln IM_1 | \ln IM_2 = \ln im_2} = \beta_0 + \beta_1 \ln IM_2 \quad (4)$$

If the conditional distribution of  $\ln IM_1$  given  $\ln IM_2$  is assumed to be Gaussian, the conditional mean and standard deviation calculated completely define the conditional distribution of  $\ln IM_1$  associated with reaching an EDP level. Thus, the CDF of this conditional distribution can be estimated as in equation 5, where  $\Phi$  is the CDF of the standard Gaussian distribution.

$$P(IM_1 < im_1 | DS = ds_i, IM_2 = im_2) = \Phi\left(\frac{\ln im_1 - \mu_{\ln IM_1 | \ln IM_2 = \ln im_2}}{\sigma_{\ln IM_1 | \ln IM_2 = \ln im_2}}\right) \quad (5)$$

Damage loss ratios (DLRs) are usually estimated empirically through post-earthquake reconnaissance data or employing expert judgment. These ratios are site-specific and building-type-specific and must be carefully selected while developing vulnerability models (e.g., [24]). For this study, the DLRs suggested by [25] are considered. The definition of the damage loss ratios is shown in Table 1 (from no damage, DS0 to collapse, DS5).

DSs	DS0	DS1	DS2	DS3	DS4	DS5
DLRs	0.00	0.01	0.10	0.35	0.75	1.00

Table 1: Definition of damage-to-loss ratios.

Vulnerability models are expressed here in terms of loss ratio (LR), i.e., the repair-to-replacement cost ratio of the building conditional on the level of ground-shaking IM. Such functions are derived according to equation 6, using the law of total expectation.  $DLR_i$  is the damage-to-loss ratio for the  $i^{\text{th}}$  damage level DS, whilst  $P(DS = ds_i | IM)$  is the probability that the DS is equal to  $ds_i$  (probability of being in each damage state). It is worth noting that IM here could be a single IM composed only by AvgSa, or a vector-valued IM including AvgSa and Ds<sub>5-95</sub> as derived above, resulting in vector-valued vulnerability relationships.

$$LR(IM) = \sum_i DLR_i P(DS = ds_i | IM) \quad (6)$$

## 2.4 Loss assessment

For each event and IM simulation (i.e., ground-motion field), the mean LR is computed using the pertinent vulnerability models. This process is replicated for each location within the portfolio, and each considered building typology,  $t$ . According to [11], for each computed LR, the ground-up loss at each of the  $n_{loc}$  locations is calculated through equation 7, assuming  $N_{b,t}$  buildings of typology  $t$  for which the replacement cost is equal to  $CR_{b,t}$ . Such cost (cost of structural/non-structural component and contents inclusive) is often provided in the exposure model. The loss ratio for every location for a given IM is calculated with equation 8.

$$L_{loc}(IM) = \sum_t LR_{b,t}(IM) N_{b,t} CR_{b,t} \quad (7)$$

$$LR_{loc}(IM) = \frac{L_{loc}(IM)}{CR_{loc}} = \frac{\sum_t LR_{b,t}(IM) N_{b,t} CR_{b,t}}{\sum_t N_{b,t} CR_{b,t}} \quad (8)$$

Assuming that  $CR_{b,t} = CR$  for each  $b$ , the equation 8 is simplified into equation 9, in which  $n_{b,t} = N_{b,t} / \sum_t N_{b,t}$  is the proportion of building typologies,  $t$ . Considering that the distribution of buildings  $n_b$  is uniform through the portfolio, the portfolio LR is calculated as the mean of loss ratios per location (equation 10). Given such assumptions, there is no need to assume any  $CR$  nor the number of buildings at the given location for each building typology without jeopardising the result generality. The outcome is expressed in terms of loss exceedance curves and EAL, representing the expected loss per year (statistical mean loss) and is used as an estimate of the annual insurance premiums to cover the peril [26]. The EAL is calculated, averaging the portfolio LR for each event and simulation in the stochastic catalogue.

$$LR_{loc}(IM) = \frac{\sum_t LR_{b,t}(IM) N_{b,t}}{\sum_t N_{b,t}} = \sum_t LR_{b,t}(IM) n_{b,t} \quad (9)$$

$$L_{loc}(IM) = \frac{\sum_{loc} L_{loc}}{CR_{port}} = \frac{\sum_{loc} LR_{loc} CR_{loc}}{\sum_{loc} CR_{loc}} = \frac{\sum_{loc} LR_{loc}}{n_{loc}} \quad (10)$$

## 3 ILLUSTRATIVE APPLICATION

### 3.1 Considered ground-motion records

The ground-motion dataset employed in this study is a subset of the Pacific Earthquake Engineering Research Center NGA-West2 database [27]. Sets of long and one-to-one spectrally-equivalent short duration ground-motion records are used herein as described by [2]. Firstly, a set of long duration records is selected considering all the records within the NGA-West2 database complying with the following criteria: a)  $10 \text{ km} \leq R_{rup} \leq 250 \text{ km}$ ; b)  $30 \text{ s} \leq D_{s5-95} \leq 60 \text{ s}$ ; c) a minimum  $M_w = 5$ ; d) a minimum  $PGA = 0.1 \text{ g}$ ; and e) a minimum  $PGV = 10 \text{ cm/s}$ .  $R_{rup}$  is the minimum distance to the rupture surface;  $M_w$  is the moment magnitude of an earthquake; and  $PGA$  and  $PGV$  are the peak ground acceleration and peak ground velocity of the ground motions, respectively. Secondly, the companion set of short-duration records is assembled, selecting a corresponding record with  $D_{s5-95}$  smaller than 25 s for each long record, and closely matching the response spectrum of the long-duration record. The ones with the lowest sum of squared errors (SSE vary from 0.19 up to 0.95) are chosen from all the candidate short duration records. Finally, 200 ground-motion records are utilised (see Figure 2). The selected sets of

short- and long-duration records are finally combined together to cover a wide range of relevant IM values in performing nonlinear dynamic analysis of the considered archetype frames.

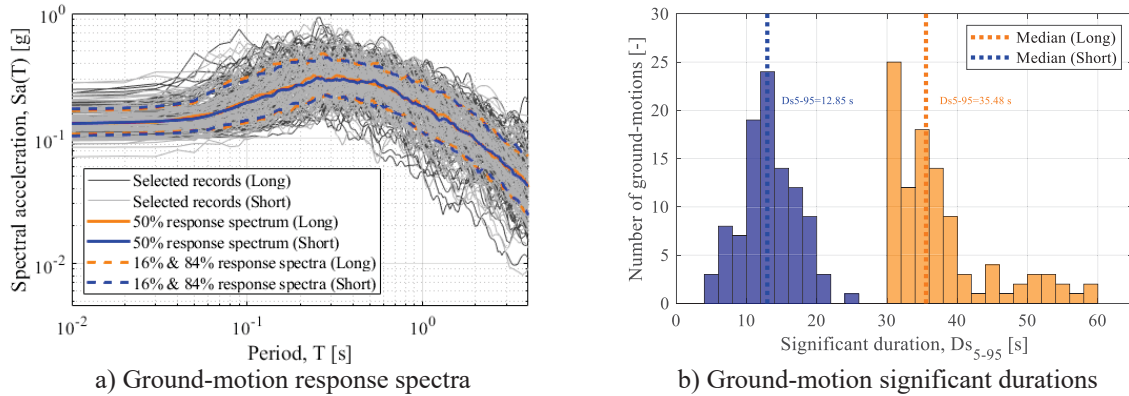

Figure 2: Selected ground-motion records.

### 3.2 Considered building typologies

The considered mid-rise reinforced concrete (RC) building models represent distinct vulnerability classes in southern Europe. The total building height is equal to 13.5 m, with a first storey of 4.5 m, upper storeys of 3 m and a bay width of 4.5 m in both directions [28]. Two moment-resisting frames are considered using the same geometry. The first case-study frame, termed as special-code frame, is designed and detailed according to the seismic provisions of the EC8 for high ductility class [29]. These provisions include capacity design, various requirements in terms of cross-sectional dimensions and seismic detailing to ensure a ductile global performance and preventing the formation of localized brittle failure modes. The other frame, termed as pre-code frame, is designed for gravity loads only as per the Royal Decree n. 2239 of 1939 [30] that regulated the structural design in Italy until 1974. Therefore, this frame does not conform to modern seismic requirements. A non-ductile behaviour characterizes it due to the lack of strength hierarchy rules, sufficient longitudinal reinforcement, poor confinement, and susceptibility to develop brittle failure mechanisms (see [31] for more details). According to this distinction, the two case-study frames include a pre-code bare (PB) frame and a special-code bare (SB) frame. Figure 3a depicts the elevation layout of these frames.

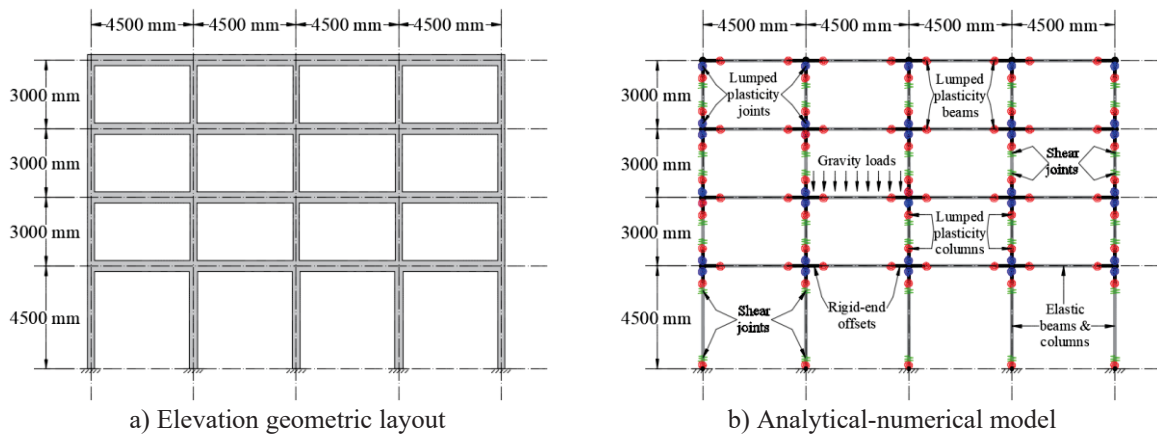

Figure 3: Geometric elevation definition and modelling strategy of the buildings.

Regarding the materials used for each building, their mean mechanical properties, such as the concrete compressive strength and the rebar steel yield strength, represent those typically adopted in southern Europe. For the pre-code frame, mean concrete mechanical properties are

obtained from [32] and [33], while for the special-code frame are obtained from [34] and based on the current practice. The described material properties are summarised in Table 2.

Parameter	Symbol	Units	Pre-code	Special-code
Compressive strength of concrete	$f_{cm}$	MPa	19	37
Modulus of elasticity of concrete	$E_c$	MPa	26670	32600
Yield strength of rebar steel	$f_{ym}$	MPa	360	490
Modulus of elasticity of rebar steel	$E_s$	MPa	200000	200000

Table 2: Properties of the reinforced concrete.

The case-study structure response is simulated by two-dimensional numerical models adopting the finite element software OpenSees [35], as shown in Figure 3b. For all the case studies, gravity loads are uniformly distributed on the beams and masses concentrated at master joints on different floors. Besides, elastic damping is modelled through the Rayleigh model [36], using a 5% viscous damping ratio on the first two vibration modes. Moreover, geometric nonlinearities are included to account for P- $\Delta$  effects.

A lumped plasticity approach is utilised to model both beams' and columns' nonlinear behaviour using zero-length rotational springs. Beam-column end-offsets and floor diaphragms are modelled as rigid. The moment-rotation constitutive relationship for beam and columns is consistent with the models developed by [37]. The peak-oriented hysteretic model (as defined by [20] and further refined by [21]) describes the strength and stiffness deterioration (cyclic and in-cycle). For pre-code frames only, nonlinear shear springs are added in series to the rotational ones to account for brittle mechanisms consistent with the model developed by [38].

Structure-specific MIDR thresholds for five DSs are calibrated via pushover analyses by reviewing multiple measurable criteria according to [31], which are based on [39] and [29]. The pushover load patterns are defined according to the first mode shape, as indicated in [29]. The selected DSs thresholds are shown in Table 3. Some relevant information on the case-study buildings' dynamic behaviour, such as the first- and second-mode vibration periods and the corresponding mass participation ratios, is summarised in Table 4.

Case-study frames	Damage states				
	DS1	DS2	DS3	DS4	DS5
PB	0.15%	0.25%	1.40%	2.00%	3.50%
SB	0.17%	0.40%	2.70%	3.85%	8.00%

Table 3: Definition of damage state thresholds for MIDR.

Parameter	PB frame	SB frame
Fundamental structural period	$T_1=0.83$ s; $T_2=0.25$ s	$T_1=0.50$ s; $T_2=0.15$ s
Mass participation ratio	94.50%	91.96%

Table 4: Fundamental structural periods and mass participation ratios.

### 3.3 Considered building portfolios

Two synthetic building portfolios are considered in this study. As shown in Figure 4, a fault-parallel “zone” is first defined as located next to a case-study strike-slip fault. The zone is defined so that the closest sites are located at 5 km minimum from the fault; each portfolio is moved perpendicularly from the fault to assess the effects of distance on ground-motion duration (and, consequently, losses). Within the considered zone, the centroid of each location in the portfolio is distributed on a uniform lattice approximately 3 km-spaced. Thus, a 9 km<sup>2</sup> area

pertains to each location. Such choice allows attaining a balance between computational burden and accuracy in the outcomes [11].

A 36 km x 36 km base portfolio is used as a standard size and is considered representative of a small region. Two different exposure configurations are also considered, considering that each location has the same building composition. These configurations involve a single building typology (i.e., PB or SB) only.

Figure 4: Geometric definition of building portfolios.

### 3.4 Considerations for the stochastic catalogue

The considered case-study strike-slip fault is defined by the characteristic earthquake-recurrence model shown in [40]. The necessary parameters for this model are assumed as follows:  $m_c=6.4$  (characteristic earthquake magnitude);  $b=1$  ( $b$ -value of the Gutenberg–Richter law);  $M_{\min}=5$ ;  $M_{\max}=6.9$ ; and  $\Delta m_1=1$  (interval below the magnitude level  $m_c$ , required in the considered probabilistic model). A rock soil type is assumed for each portfolio's location with shear wave velocity in the first 30 m of soil  $V_{s30}=800$  m/s.

A 10000-year stochastic catalogue is considered; for each event, 500 realisations of the IMs are generated. This maximum time and the number of simulations is selected based on the current catastrophe risk modelling practice and correspond to a good balance in terms of statistical validity of the loss estimates and computational burden. As discussed, AvgSa is selected as the primary IM, and it is calculated in the period range  $[T_2:2T_1]$  for both case-study frames (consistently with [41]).

## 4 RESULTS

### 4.1 Effects of ground-motion duration on hazard

Ground-motion duration increases with the distance from the source due to the scattering and dispersion of seismic waves and the difference in the arrival times of waves propagating at different velocities and traversing different paths (e.g., [42]; [43]; [44]). However, duration also depends on local site conditions, with longer duration ground-motions typically observed at sites with softer soils due to repeated seismic wave reflections within the soft-soil layer and the respective dynamic amplification [45].

Figure 5a and Figure 5c show the obtained AvgSa and  $Ds_{5-95}$  hazard curves (individual simulations and median); while Figure 5b and Figure 5d show the AvgSa and  $Ds_{5-95}$  ground-motion fields (median), considering 2500-year mean return period (MRP) for one of the two index buildings (i.e., PB). As expected, the AvgSa values decrease, and the  $Ds_{5-95}$  values increase with distance. It is worth noting that the AvgSa ground-motion field varies for each of the index buildings (not shown here for brevity) since AvgSa is structure-dependent. At the same time,

the  $DS_{5-95}$  ground-motion field is the same for every index building. In the PB case, AvgSa ranges from around 0.05 g to 1.10 g; the  $DS_{5-95}$  ranges from approximately 20 s to 70 s.

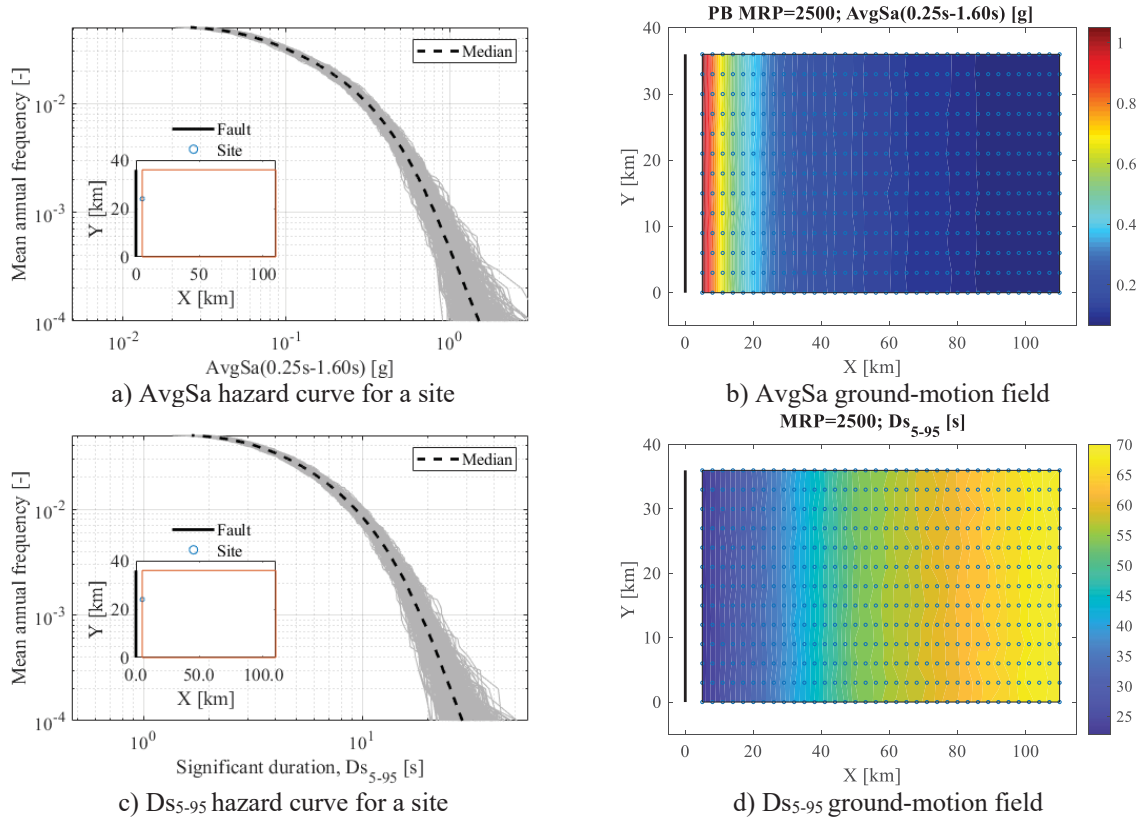

Figure 5: Simulation-based PSHA results for the region.

#### 4.2 Effects of ground-motion duration on vulnerability

Figure 6a-b show the fragility and vulnerability models obtained using AvgSa as an IM after performing the IDA for the PB frame. These relationships implicitly account for the significant duration since the structure hysteretic models can well capture the cyclic and in-cycle strength and stiffness deterioration (using the EH dissipated in each component) and the ratcheting of MIDR accentuated by the  $P$ - $\Delta$  effects. Similar behaviour is presented in different empirical damage models such as the Park and Ang damage index [46].

Figure 6c-d show the fragility and vulnerability models obtained using AvgSa and  $DS_{5-95}$  in a vector-valued format after performing the IDA. The fragility and vulnerability surfaces explicitly account for the ground-motion duration since  $DS_{5-95}$  can describe part of the variability of AvgSa, even if the latter is scaled during the nonlinear procedure. It could be noticed from the results that ground-motion duration mainly affects the higher DSs (i.e., DS3, DS4 and DS5), whilst the lower damage states (i.e., DS1 and DS2) remain approximately unaffected. This explained why the vulnerability surface exhibits a slight but steady increase in the loss ratio due to duration. On the other hand, the fragility relationship surface for DS5 exhibits a more significant (i.e., steeper) increase from short to long durations (i.e., from 1 s up to 60 s as depicted in the figure). In every case, the duration effects are consistently more apparent at lower durations and increase as AvgSa increases.

It is worth mentioning that the previous results are consistent among all the index buildings considered in this study. The fragility and vulnerability models are structure-dependent; therefore, these models vary accordingly per each case study (not shown here for brevity).

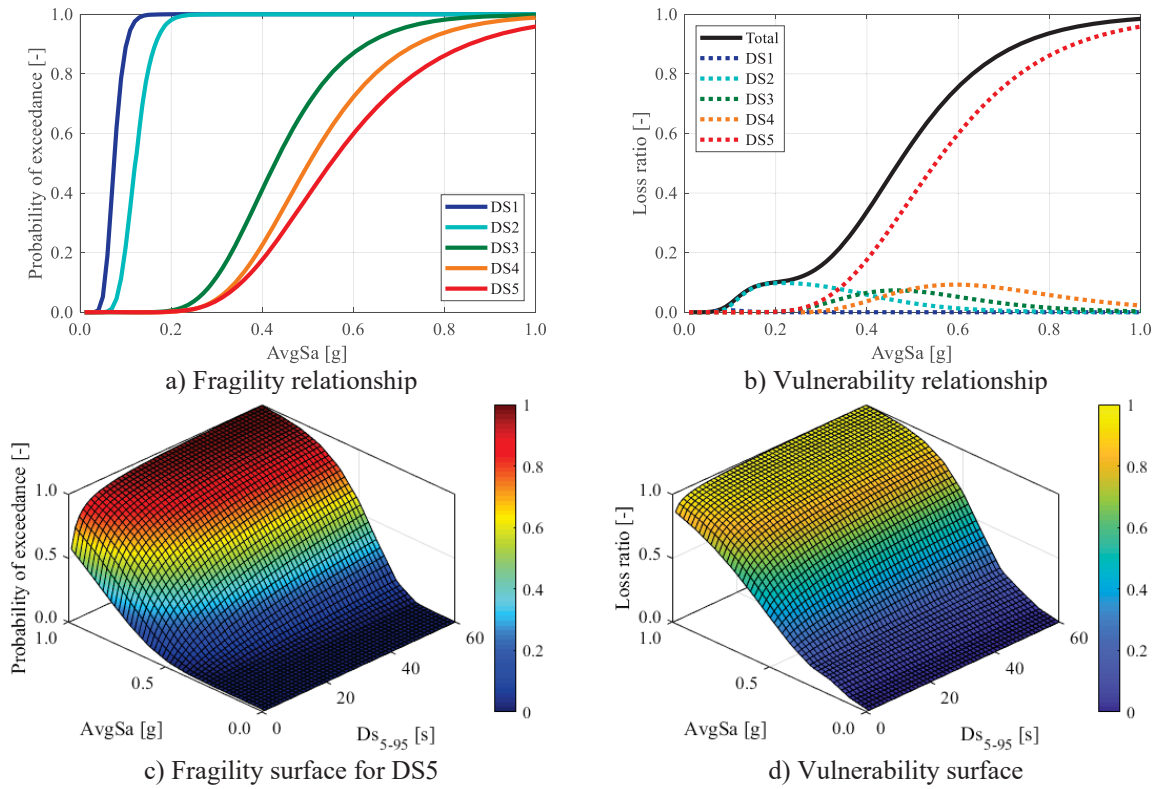

Figure 6: Fragility and vulnerability models for PB frame.

#### 4.3 Effects of ground-motion duration on losses

Figure 7a-b presents the median normalised loss ratio (NLR) corresponding to 2500 years MRP at each location within the region (i.e., normalised loss maps), computed as shown in equation 11. As expected, the NLR increases with distance when the IM explicitly accounts for duration (i.e., utilising the previously described vector-valued IM). The latter result is more apparent for the SB frame case, where the NLR can reach values around 60%. It is important to note that losses decrease dramatically with distance, and low LR values are obtained for sites located far away from the source (e.g., at 100 km from the source). Therefore, small fluctuations in LR estimates at these locations can result in obtaining high NLR values. Thus, these high NLRs may not necessarily represent significant differences in the loss estimates from a practical point of view.

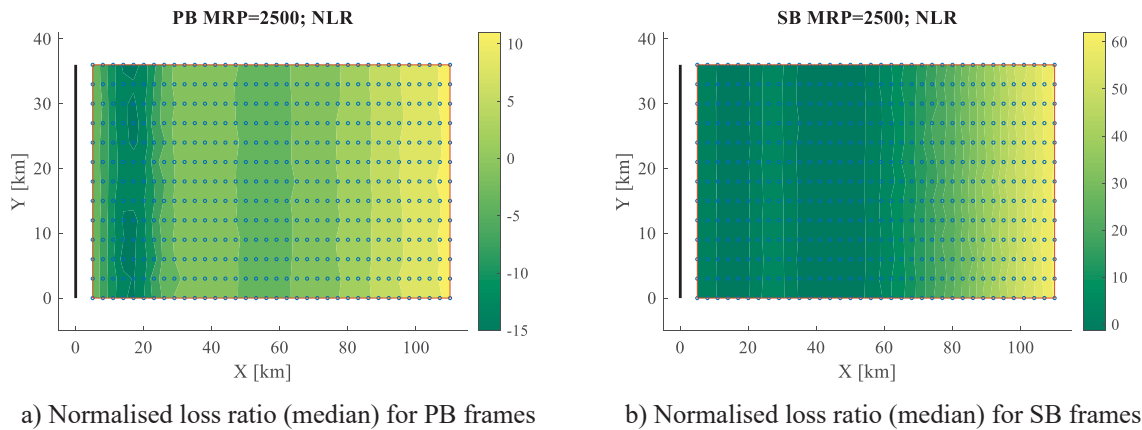

Figure 7: Normalised loss ratio (median) for PB and SB frames (MRP = 2500 years) [%].

It is worth noting that the results obtained for the SB frame are not consistent with the ones obtained when using the PB frame since, for locations relatively near the source (from 5 km to 25 km from the source), the NLR is higher when AvgSa is used as a scalar IM. This indicates that using duration in the vector-valued IM can increase or decrease the NLR value with respect to the scalar IM, given the region seismic hazard, exposure, and vulnerability models under consideration.

$$\frac{[\text{LR}(\text{IM}_{\text{vector}})_{\text{MRP}=2500 \text{ years}} - \text{LR}(\text{IM}_{\text{scalar}})_{\text{MRP}=2500 \text{ years}}]}{\text{LR}(\text{IM}_{\text{vector}})_{\text{MRP}=2500 \text{ years}}} \quad (11)$$

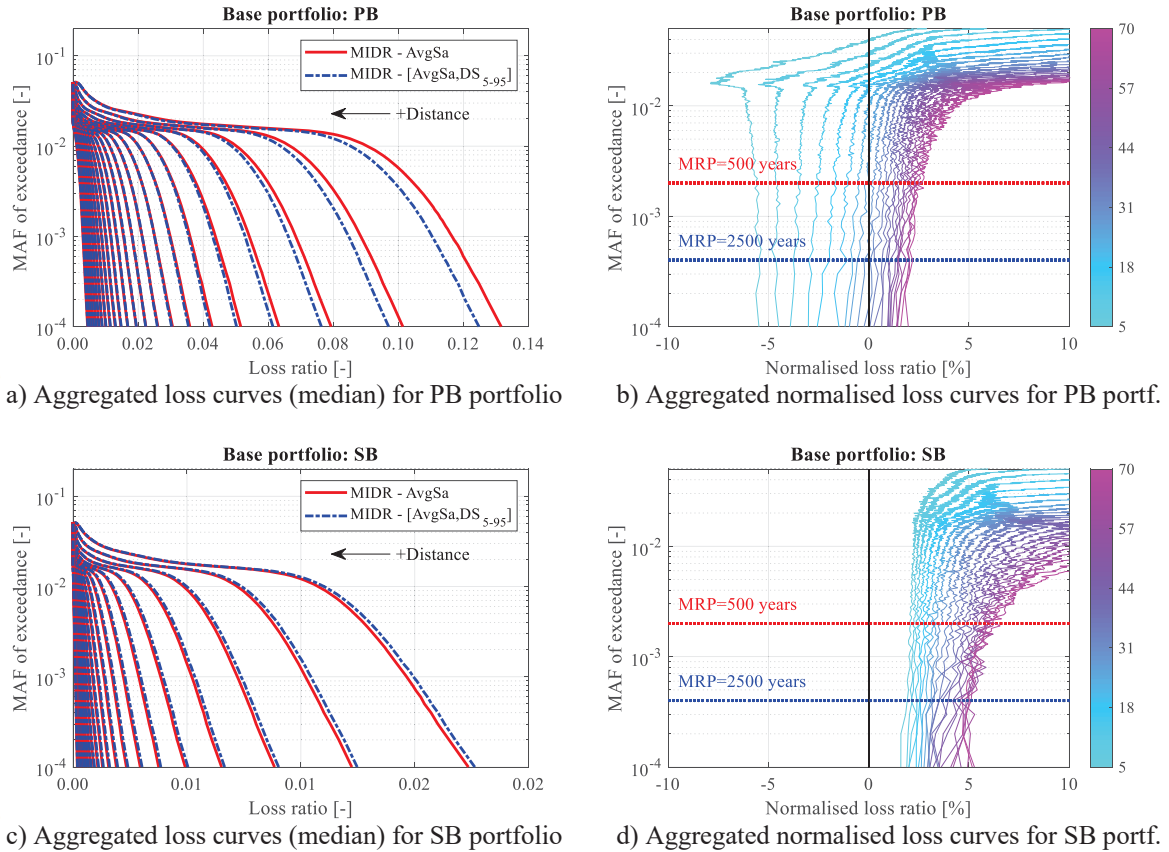

Figure 8: Aggregated loss curves (median) pairs and aggregated normalised loss curves (median) varying with distance for PB and SB portfolios. The colour bar represents the distance from the source [km].

Figure 8a-d offers a better picture of how losses (i.e., LR or NLR as appropriate) and their mean annual frequency of exceedance (for different MRP) vary with distance. The left panels in these figures show the aggregated loss curves (median) for portfolios located at different distances from the source and using AvgSa or [AvgSa, Ds<sub>5-95</sub>] respectively (the distance increase from right to left as indicated). The right panel in these figures show the corresponding aggregated normalise loss curves (median) for selected portfolios (the aggregated normalise loss curves are estimated using equation 11 for every MRP associated with each mean annual frequency of exceedance, MAFE). The results are shown for two portfolios composed of PB (see Figure 8a-b) and SB (see Figure 8c-d) frames for the considered base portfolio size.

Regarding the portfolio made exclusively of PB buildings, when using AvgSa as an IM, the obtained LR are higher in the vicinity of the source than those computed when using [AvgSa, Ds<sub>5-95</sub>] as an IM. Thereby, accounting explicitly (i.e., using the vector-valued IM) for duration near the source provides lower LR estimates. The previous behaviour varies with

distance up to 25 km from the source approximately; in this case, the losses computed using [AvgSa, Ds<sub>5-95</sub>] as an IM are higher than those estimated using AvgSa as IM. The previous results are valid for MAFEs below roughly 1/100 years, as noticed in the figures. For relatively large MAFE value (above 1/100 years), the NLR are higher than 10%, indicating that the vector-valued IM can better capture duration effects for moderate seismic events.

Interestingly for the portfolio made of SB buildings, when using AvgSa as an IM, the resulting LR results are lower than those obtained when [AvgSa, Ds<sub>5-95</sub>] is used as an IM. This may be due to the fact that a special-code frame (i.e., SB frame) with higher levels of strength and ductility can dissipate higher EH levels. Since significant duration is better correlated to structures behaving in such a way, its effect could be more apparent when duration is considering explicitly for intensity levels that are not causing structural collapse. In contrast, a pre-code building (i.e., PB frame) may collapse given the same intensity level without dissipating significant amounts of EH (as it occurs next to the source). These results reinforced the idea that the vector-valued-based vulnerability model can better capture duration effects given the considered seismic hazard, exposure, and vulnerability models.

The EAL is a suitable parameter to represent portfolio losses; therefore, the EAL is computed for all the possible distances within the region for the same portfolios analysed above. The outcome depends strongly on the portfolio composition when using both vulnerability models (i.e., scalar- and vector-valued-based vulnerability models). For the portfolio including only PB buildings, differences between the EAL values are at most 6% (next to the source). In contrast, for the portfolio composed of SB buildings, EAL differences can reach up to 9% (far from the source). The noticeable trend among all distances is that, when EAL is used as a loss metric, there is a non-significant difference between using a scalar IM and a vector-valued IM accounting implicitly and explicitly for ground-motion duration, respectively.

## 5 CONCLUSIONS

This study investigated the influence of earthquake-induced ground-motion duration on estimating seismic losses for building portfolios using a simulation-based risk assessment framework. The aim was to examine how this ground-motion feature influences different loss estimates, investigating whether duration matters (depending on the location/portfolio) and should be included in the seismic risk assessment practice. The main conclusions of this work are summarised as follows:

- As expected, given the utilised GMMs, AvgSa intensity decrease and Ds<sub>5-95</sub> increase with distance from the source;
- Duration can be implicitly or explicitly considered when fragility and vulnerability models are constructed. In general, the outcomes (i.e., loss estimates) do not match;
- Vector-valued fragility and vulnerability models may perform better in capturing the impact of ground-motion duration;
- The loss curves and EAL decrease rapidly with distance from the source; after 25 km-30 km, the differences when using a scalar and a vector-valued IM may be neglected;
- Building portfolio loss assessment is influenced by ground-motion duration, and its effect depends on the portfolio location and composition;

This study provided a first look at how to account for earthquake-induced ground-motion duration in building-portfolio loss estimation, and its results may not be generalised. Essential aspects such as the size of the portfolio, a realistic composition of the portfolio (e.g., mixed building typologies in the considered exposure), the use of more building typologies, complex source models, among others, were not considered in the paper but will be investigated in future developments of the study.

### Abstract

*Natural disasters are unavoidable and can cause serious damage to bridges, which may lead to catastrophic losses both human and economic. In the US more than 45% of bridge collapses are caused by flood events in which more than one-third are caused by scouring effects. In 2015, part of the Tadcaster bridge, a masonry arch bridge in North Yorkshire UK, collapsed during a flooding event. This tragedy was followed by another one in 2019 when a masonry bridge collapsed in the same county. Therefore, the assessment of bridges susceptible to these events is of paramount importance as to identify possible mitigation needs. The objective of the present paper is to present a consistent framework to obtain the reliability index of a masonry arch bridge (MAB), under flood hazard that is subject to local scour, using surrogate models to reduce the computational effort of the probabilistic analysis. The proposed framework is tested on a MAB located in Portugal. A two-dimensional numerical model is constructed where the random variables that affect the structural capacity and the scour geometry were considered. The results show the failure mechanism of the MAB when subjected to scour-induced settlements, therefore allowing to identify the vulnerable zones along the arch's length. The presented methodology can be used to assess the bridge performance under a flood event, thus providing useful information for bridge management and monitoring. Moreover, it can be further developed to include fragility analysis and vulnerability assessment.*

## 1 INTRODUCTION

Bridges have a higher design life than most common structures. During this period, bridge management is fundamental to maintain a satisfactory performance of the structure. To achieve this goal, information regarding the state of the bridges is essential when making decisions that involve the maintenance of the structure [1]. Masonry arch bridges (MAB) represent a large part of the European network (railway and roadway), hence by identifying the safety level of the bridge, suitable maintenance strategies can be applied [2].

Bridges are structures that face harsh environmental condition; therefore, should be able to withstand potential hazards such as flooding, earthquakes, among others [3]. Natural disasters are often unavoidable and can cause serious damage to bridges, which may cause catastrophic losses both human and economic. Floods account for a large percentage of all bridge failures [4]. Nowadays, the effects of climate change may produce larger and more frequent peak river discharges, which could induce the mobilization of sediment from riverbeds, and around piers and abutments (i.e., increased risk of scouring). Bridge collapses have been experienced worldwide. In 2015, part of the Tadcaster bridge, a masonry arch bridge in North Yorkshire, collapsed during a flood event [5]. Therefore, the assessment of bridges susceptible to these phenomena (namely flood, scour, trapped debris, among others) is of utmost importance as to identify possible mitigation needs.

When assessing bridges under loading conditions resulting from environmental conditions, the lack of available information causes high uncertainties when representing the environmental actions and the parameters of the materials [2]. Explicitly considering the uncertainties can mitigate this lack of information. Moreover, limit analysis-based structural assessment in combination with probabilistic-based approaches has been used to predict ultimate loading carrying capacity and safety verification of Portuguese MAB [6]. Thus, a full probabilistic analysis for the reliability-based assessment of MAB under floods for ultimate limit states should be implemented.

Due to the complexity of the probabilistic analysis, the objective of the present work is to propose a consistent framework to reduce the computational costs to obtain the reliability index associated with a failure mode of masonry arch bridges (MAB) under flood hazard. This will allow to assess the performance of bridges that may affect the efficiency of important sections of the roadway network if damaged by a flood event. The proposed framework is tested on a MAB “Ponte da Vala do Carregado” located in Portugal. A numerical model is constructed in LimitState:GEO software (<http://www.limitstate.com>) [7]. The model implemented the random variables that affect the structure capacity [2] and the scour geometry, such as shape and depth derived from flood conditions [8].

## 2 METHODOLOGY

The methodology considered in this work is shown in Figure 1. First, a numerical model is developed using a software based on limit state analysis. Then, a surrogate model is defined to perform a sensitivity analysis which allows to identify the most influent variables on the ultimate capacity of the bridge [2]. Later, a new surrogate model based on the most relevant variables is introduced which uses a low number of evaluations, thus reducing the computational costs of the full probabilistic analysis [6], [9]. Finally, the reliability index is computed based on the subset simulation technique [10].

For this study, the procedure was implemented for different scour profiles. This approach allows assessing the bridge reliability under local scouring from a case study.

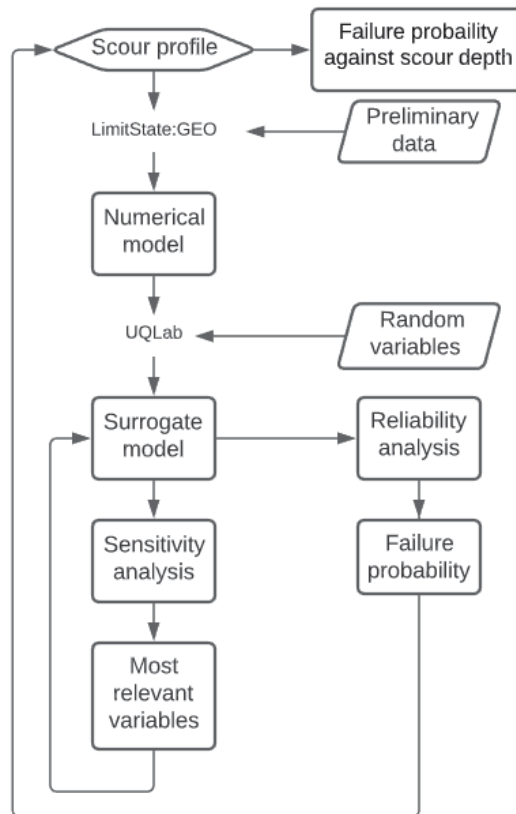

Figure 1: Framework for reliability assessment of MAB under local scouring.

### 3 NUMERICAL MODEL

The case study “Vala do Carregado” is a railway masonry arch bridge located in Vila Franca de Xira, Portugal (see Figure 2). The three-span bridge has a total span of around 30m, and it is supported by direct foundations. Earliest reports of the bridge date from 1881 when the bridge was built. After that, there is information regarding reinforcement of the arch barrel, until subsequent studies were conducted, and it was concluded that the bridge should be replaced [11].

According to the performed studies, it was found that the bridge foundations presented poor soil conditions, which were incompatible with the foundation system, and hydraulic capacity was below the requirements of the design flood (corresponding to a 100-year return period) [11]. For these reasons, the Vala do Carregado bridge before being replaced is considered as representative of the typical Portuguese railway masonry arch bridges which require particular attention.

Figure 2: Case study (dimensions in meters).

A two-dimensional limit state model was developed using LimitState:GEO which is designed to rapidly analyze the ultimate limit state for a wide variety of 2D geotechnical problems by using the computational limit analysis technique named Discontinuity Layout

Optimization (DLO) [12]. The software was selected due to the reliability of its results when assessing the collapse mechanisms of MABs, while allowing to model the soil parts of the bridge and its interaction with other materials (*e.g.*, concrete, masonry) [13]. Moreover, the software allows fast and computational efficiency which is key when performing probabilistic analysis.

Only the parameters defining the yield surface are required for the material models used by LimitState:GEO. The following models were used to define the different components of the case study: (i) a Mohr-Coulomb model was employed to represent the soil parts of the bridge, namely riverbed and backfill; (ii) fully rigid blocks, where no slip-line can pass through it at any load, were utilized for modelling masonry blocks and foundations; and (iii) cutoff materials were used to model joints, which allows modelling tension cracks or crushing by limiting the tensile or compressive stress, respectively [12].

Load models are used to represent the real loading that a bridge is subjected to. Some studies have been made regarding the reliability of Portuguese MABs, which are based on the documentation provided by the Portuguese railway authorities (Infraestruturas de Portugal) [2]. The load model is composed of four-point loads spaced by 1.6 m. Two distributed loads are also defined within the load mode, but studies have shown that even by not considering them the most unfavorable case scenario is still achieved [14].

By assuming that there is no failure (nor excessive deformation) in the spandrel walls, then the bridge capacity will depend mainly on the arch barrel and the backfill. Therefore, 2D limit state analyses are best suited for in-plane assessment of bridge reliability. Nevertheless, it is worth mentioning that bridges with increased backfill height are more vulnerable to out-of-plane failure of the spandrel (*i.e.*, less load carrying capacity) [15].

The water table was assumed to be acting on top of the structure due to the inadequacy of the masonry arch bridge to withstand the design flood (100-year return period) as concluded by the hydraulic modelling [11]. Moreover, studies have been made showing the effects of the water level in MAB, in which for a fully submerged bridge (with backfill fully saturated) a reduction in its load-bearing capacity near 40% was found [7]. Thus, to have the most unfavorable scenario, all soil materials are considered fully saturated and a water table near the surface level is assumed.

Figure 3: Scour profiles (No scour, minor, moderate, and extensive).

The scour cavity is affected by several factors including soil type, flow velocity and turbulence, and foundation geometry [16]. Studies have been made in which several shapes for local scouring were defined and studied [8].

There are three main forms of scour around foundations, upstream, downstream and at the sides. When analyzing in-plane behavior, only the effects of the local scour due to the separa-

tion of the flow (*i.e.*, at the sides) will be considered. The profile geometry was defined by considering not only different damage states but scour depths and shape of the foundation. Figure 3 depicts the proposed scour cavities which represent different damage levels (minor, moderate, extensive) which are related to the ratio between scour depth and foundation height ( $d_s/D$  equal to 0.50, 1.00, 1.36) [8], [16], [17].

By analyzing the ultimate capacity of the bridge in terms of an adequacy factor (see Figure 4), which is based on how many loads increments the structure can withstand before collapsing, it is possible to evaluate the safety level of the bridge. In the following chapter, a stochastic approach is conducted to evaluate the reliability of the structure under the effects of local scouring.

Figure 4: 2D Limit-state model without local scouring (a) geometry (b) failure for an adequacy factor of 4.235

## 4 PROBABILISTIC ANALYSIS

In structural design, there are many uncertainties related to loading and load-carrying capacities. Fundamentally, structures do not have a zero probability of failure due to the random variables involved in the design, construction, and operation processes [18].

To compute the reliability index of the case study, first some random variables that are involved in the load-carrying capacities of the structure must be defined and assessed. Resistance parameters and density of each material comprising the structure are considered. In Table 1, each variable with its distribution type and parameters are presented.

ID	Description	Element	Nominal Values	Units	CV (%)	Type	Reference
FA <sub>S</sub>	Friction angle	Soil	34,61	tan( $\phi$ )	10,0	Lognormal	[19]
SD <sub>S</sub>	Saturated density	Soil	20,50	kN/m <sup>3</sup>	5,0	Lognormal	[19]
D <sub>C</sub>	Density	Concrete	25,00	kN/m <sup>3</sup>	10,0	Gaussian	[20]
SD <sub>B</sub>	Saturated density	Backfill	20,00	kN/m <sup>3</sup>	12,5	Gaussian	[21]
C <sub>B</sub>	Cohesion	Backfill	30,00	kPa	15,0	Gaussian	[6]
FA <sub>B</sub>	Friction angle	Backfill	30,00	°	10,0	Gaussian	[6]
D <sub>M</sub>	Density	Masonry	16,00	kN/m <sup>3</sup>	10,0	Gaussian	[22]

Table 1: Random variables used in the probabilistic analysis.

### 4.1 Surrogate model

The use of reliability methods is limited due to the vast computational cost they often require. Therefore, metamodeling techniques (*e.g.*, polynomial chaos, kriging, among others) have been widely used. Comparisons between different surrogate models have been conducted, and Kriging based metamodels using subset simulations (AK-SS [10]) have been proven

to be efficient to describe non-linear limit state functions, allowing a great representation of the behavior of the function using 19 evaluations [9]. To optimize the probabilistic assessment of the structure by reducing the number of evaluations (*i.e.*, numerical models), a surrogate model was built using UQLab, a general-purpose Uncertainty Quantification framework [23].

The assessment of the load-carrying capacity of a masonry arch bridge can be approximately represented by a non-linear limit state function, as shown traditionally by the Military Engineering Experimental Establishment (MEXE) method. This method has its roots in idealized elastic structural modelling, which mainly depends on geometrical parameters and densities of materials (*e.g.*, masonry and backfill) [24].

Therefore, an experimental design of 20 runs generated by using the Latin Hypercube Sampling Method (LHS) was used [9]. Then, a Kriging metamodel using UQLab was created and validated based on the random variables previously defined. The surrogate model uses a universal trend type, an anisotropic ellipsoidal Matérn 5/2 correlation function, used to define the Gaussian process and cross-validation estimation method. For the validation of the metamodel, two different sources of error estimation were implemented. First, the leave one out method, and second a validation experimental design of 10 runs using LHS; the errors found were  $4.11\text{e-}03$  and  $8.28\text{e-}03$ , respectively.

## 4.2 Sensitivity analysis

To reduce the number of relevant variables in the response of the structure, a sensitivity analysis was performed using UQLab. Analysis of covariance (ANCOVA) was used to produce helpful sensitivity indices for both correlated and uncorrelated input variables using a covariance decomposition method [25].

Figure 5: ANCOVA indices

As it can be observed from Figure 5, the parameters with the most influence over the load-carrying capacity are the ones used to describe the backfill soil. This was expected given that most of the capacity of the bridge for in-plane behavior (and excluding the spandrel) comes from the backfill [15]. Furthermore, the soil underneath the foundation has an impact on the capacity, which is expected as a portion of the soil is being mobilized by the foundation. As the correlated ANCOVA indices are small in magnitude, the correlation among input variables has only a weak effect on the response sensitivity.

Then, the same process used to define the surrogate model is used, but instead of the seven variables, only the main four are used. This gives a more efficient metamodel without compromising its reliability.

### 4.3 Reliability analysis

By using the surrogate model based on the relevant variables, an experimental design of 10000 simulations using Monte-Carlo (MC) sampling method was generated (Figure 6). Then, a Gumbel distribution was fitted based on the generated histogram of adequacy factors (*i.e.*, collapsing loads), which allowed to define the resistance curve  $R$ . Additionally, model uncertainties for limit state models (defined by a Gaussian distribution of mean 1 and COV 1%), was also considered [6]. The loading curve  $S$  was defined using existing data fitted to a Gumbel distribution, which is described by a mean equal to 184.41 kN and a COV of 9.06% [2].

Figure 6: MC experimental design.

To obtain the reliability index of the structure for a given profile of local scour, traditional methods like MC may require numerous simulations to converge with a satisfactory level of accuracy. Therefore, subset simulation techniques are employed herein to overcome this limitation by solving simpler reliability problems with intermediate thresholds (Figure 7) [26].

Figure 7: Subset simulation samples discretization.

Once the reliability analysis is completed, the failure probability and reliability index are obtained. In the following chapter, the different results obtained for each scour profile will be presented and discussed.

## 5 INFLUENCE OF SCOUR DEPTH IN THE RELIABILITY OF THE STRUCTURE

Each scour profile produces a different impact on the reliability of the structure, and it is important to understand how changes in the scour depth ( $d_s$ ) in relation to the foundation

height ( $D$ ) may affect the load-bearing capacities of the bridge. Next, the results for the different scour scenarios are presented.

First, the sensitivity analysis shows some differences among the scour profiles (see Figure 8). It can be seen that the variables related to the backfill are the ones with the most influence on the load-bearing capacity of the bridge (in-plane analysis) [15]. Moreover, due to the removal of soil at the base of the foundation (*i.e.*, changes  $ds/D$ ), the parameters related to the soil beneath the river have less influence when the scour hole increases, as can be observed in Figure 9 by the differences between the failure modes for each scour profile.

Figure 8: Results of the sensitivity analysis for each scour profile (no scour, minor, moderate, and extensive).

Figure 9: Failure modes of each scour profile (no scour, minor, moderate, and extensive).

Among the different scour scenarios, the failure mode remains largely the same, *i.e.*, in each case, failure of the backfill is achieved by incrementing the railroad load applied at surface level. Moreover, failure at the riverbed is reached due to the mobilization of the foundation. Meanwhile, both arch failures show the characteristic shape of the hinging mechanism [27].

Then, the respective surrogate models are defined, and the capacity curve of the structure for each of the scour profiles are built (see Figure 10). It can be observed that the capacity of the bridge decreases with each increment of the scour depth. As expected, the loss of bearing capacity for scour depth values lower than the foundation height is slight, *i.e.*, the capacity curve largely maintains its properties which indicates a slight decrease in the bridge reliability index [8].

Figure 10: Resistance curve R of each scour profile.

However, when analyzing the extensive scour profile, the capacity curve changes drastically which may be occasioned by failure of the soil under the foundation. Finally, the values of reliability and failure probability are plotted against the scour depth ( $ds/D$ ) in Figure 11.

Figure 11: Reliability index and probability failure against scour depth

From Figure 11 it can be seen that the reliability index decreases greatly when the local scour starts to extend below the foundation. This situation may cause problems with extensive settlements of the bridge which may induce instability on the arch barrel and consequently bridge collapse [8]. For none of the scour profiles the structure fulfills the target reliability for safety, i.e.  $\beta_{\text{target}}=4.3$  for structures with consequences involving high human and economic losses, according to the NP 1990 [28].

## 6 CONCLUSIONS

The present work established an efficient framework for reliability assessment of MAB subject to flood-induced scour. The methodology was validated through a case study bridge located in Portugal. Based on the obtained results, the following conclusions can be made:

- By using surrogate model techniques, it is possible to perform several numbers of experiments, that otherwise would be time-consuming and would demand high computational cost, with a satisfactory level of reliability. Thus, optimizing and improving probabilistic analyses. Regarding the study of the reliability of MAB, it was possible to examine different scenarios of local scouring by analyzing different random variables at an efficient computational cost.

- By performing a sensitivity analysis, the most relevant variables when assessing the bridge capacity were obtained and validated by literature. As discussed before, the soil parameters used to describe the behavior of the backfill are the ones that have the most impact when computing the load-bearing capacity of the in-plane performance of a MAB [15].
- To understand the behavior of the bridge under local scouring, the ultimate limit state function was defined by considering the randomness of the bridge loading capacity and different scour profiles, which allowed assessing the bridge performance under floods. In each of the proposed scenarios, failure of the backfill was achieved by incrementing the railroad load applied at the surface level. Moreover, the arches under the mobilized portion of the backfill presented shapes that resemble failure by hinging mechanism [27].
- As expected, the loss of bearing capacity becomes considerable when the scour depth surpasses the foundation depth. Failure of the soil under the foundation may explain the differences of the capacity curve, as found for the extensive scour scenario. It should be noted that the variation of the lateral erosion (*i.e.*, dimension below the foundation) for the same scour depth, even though was not considered, influences the bridge capacity [8].
- The case study presented an initial reliability of 3.82 which indicates a probability of failure of  $6.68e-05$ . When increasing the scour depth up to 1.36 times the foundation height (extensive level), the reliability index decreased up to 2.87 with a failure probability of  $2.07e-03$ . Consequently, none of the scour scenarios fulfill the target reliability in the codes [28], which indicates that the bridge presents a poor performance under flooding events.

This study represents the first approach to assess the reliability of MAB subject to the effects of scour and floods. It is recommended to expand upon this work by analyzing out of plane behavior and investigate the effects of the bridge geometry and other flood-related effects that may influence the bridge performance. Finally, vulnerability analysis considering direct and indirect consequences may provide useful information for bridge management and decision making.

### Abstract

*The prediction of the seismic vulnerability of bridges is a challenging task for road managers which need to include structural risk prioritisation in their Bridge Management Systems. The large number of bridges designed without anti-seismic requirements and the uncertainties resulting from the lack of knowledge data (e.g. design documents and blueprints), strongly affect the feasibility of this process. A simplified approach for performing fragility analysis considering the epistemic uncertainty associated with an incomplete knowledge level is described. Uncertainties are considered through the statistical generation of a population of index-bridges, which are analysed utilizing a simplified modelling approach and the capacity method spectrum method applied with real ground-motion spectra. The proposed approach is applied on a case-study simply supported-girder RC bridge of the Basilicata provincial road network. The modelling and the influence of the epistemic uncertainty on the fragility are discussed for two knowledge levels corresponding to different data collection strategies. Finally, a validation of the proposed approach is carried out through a comparison with a refined modelling approach and non-linear dynamic analyses.*

## 1 INTRODUCTION

Improving the safety of road networks is a challenging task for transportation infrastructure managers in natural-hazard-prone countries. In the aftermath of strong earthquakes, an inadequate seismic response of bridges may provoke direct and indirect losses, e.g. structural damages, economic losses or issues in managing post-event emergency. In most of the developed countries, the majority of the roadway/railway bridges were designed according to old regulatory codes lacking adequate anti-seismic design recommendations. For instance, in Italy, a high amount of bridges was built during the '60s and '70s decades [1] when most of the Italian territory was not considered an earthquake-prone zone. Therefore, road managers have to deal with risk prioritization of large bridges portfolios, to identify structures that could exhibit poor performance in the aftermath of a seismic event. Low cost- and time-demanding analytical approaches for calculating fragility relationships and quantifying the risk of bridges are required.

In this context, many literature studies investigated the adoption of typological fragility assessment approaches for bridges (e.g. [2–5]). The HAZUS model [6] is a well-known reference on this topic. These simplified methodologies, based on a typological classification [7,8] assume that the performance of bridges belonging to the same class is similar. One or more archetype structures, representative of each typological class, are identified and analysed to achieve class fragility curves, possibly considering the variability of geometrical/constructive characteristics within the class. The accuracy of these approaches is strictly linked to the classification scheme adopted, usually defined on a judgemental-empirical basis, that could not be directly related to the expected seismic performance [9]. Furthermore, typological approaches neglect structure-specific components and geometrical features that could be crucial in the vulnerability of bridges belonging to the same class (e.g. specific geometry, deck-pier connection type) [10].

On the other hand, recent studies focus on structure-specific approaches. Among them, simplified displacement-based assessment (DBA) algorithms are proposed and tested. Sadan et al. [11] proposed a simplified DBA approach for multi-span continuous girder RC bridges, which is recently refined by Gentile et al. [12,13] and Perdomo et al. [14]. Cardone [15] proposed displacement-based damage state thresholds for bridge components to be used within the DBA algorithm. These DBA approaches were also extended for simplified fragility function calculations by Cademartori et al. [16]. Stefanidou and Kappos [17] presented a hybrid methodology for bridge-specific fragility analysis suitable for bridge portfolio applications, using simplified elastic analysis. A different approach is adopted by Borzi et al. [18], that, by using a comprehensive database to store bridge data, developed an automated tool to build refined finite element models and to perform nonlinear time history analysis (NLTHA)-based fragility analysis for probabilistic seismic assessment within bridge portfolio applications.

Generally, within both a typological or structure-specific probabilistic seismic assessment framework, aleatory and epistemic uncertainties should be considered. These are respectively associated with the random nature of the seismic action or to the knowledge limit about mechanical properties (geometry, material etc.), modelling assumptions or capacity models. Epistemic uncertainties are modelled as random variables and appropriate statistical distribution. These are generally considered by statistical sampling techniques for generating a population of structures representative of the main one. This process burdens considerably the whole assessment procedure since multiplies the number of required analyses. A preliminary adequate knowledge level of the structure(s) being analysed could beneficially limit the number of uncertainties. However, a refined data collection phase may be unaffordable: on-site diagnostic inspections are time- and cost-consuming and bridge databases are lacking design data and blueprints which mostly were lost by management authority operators or stored into

inaccessible archives. In the case of wide epistemic uncertainty, refined numerical models and analysis techniques are not a feasible solution and simplified fragility analysis methodologies should be applied.

In this study, a bridge-specific fragility analysis approach accounting appropriately for aleatory and epistemic uncertainties is proposed. The method adopts simplified mechanical models and capacity spectrum method (CSM) algorithms to perform cloud-based fragility analysis. The methodology aims to consider the uncertainty connected to the initial knowledge that particularly affects the seismic assessment of RC bridges when the input data are limited. Other types of epistemic uncertainties are neglected.

A refined description of the procedure, which currently is developed for multi-span isostatic (simply-supported) reinforced concrete (RC) bridges, is reported in Section 2. In Section 3, the procedure is applied to a case-study RC bridge for illustrative purpose. Preliminary validation of the simplified seismic performance assessment algorithm for fragility analysis is also provided using NLTHA as a benchmark.

## 2 DESCRIPTION OF THE METHODOLOGY

The simplified methodology to perform fragility analysis of bridges considering aleatory and incomplete-knowledge-based (hereinafter simply knowledge-based) uncertainties is described in this section. It resorts to simplified mechanical models, which are commonly used for the seismic analysis of isostatic multi-span bridges. A population of index-models is generated to consider the knowledge-based uncertainties, while the aleatory ones are represented by an appropriate suite of ground motions. The fragility analysis is performed by using a cloud approach for each index-model. A population of fragility curves representing the fragility of the main bridge can be thus generated and be used for simplified indicators of seismic risk. A synthetic flowchart is reported in Figure 1.

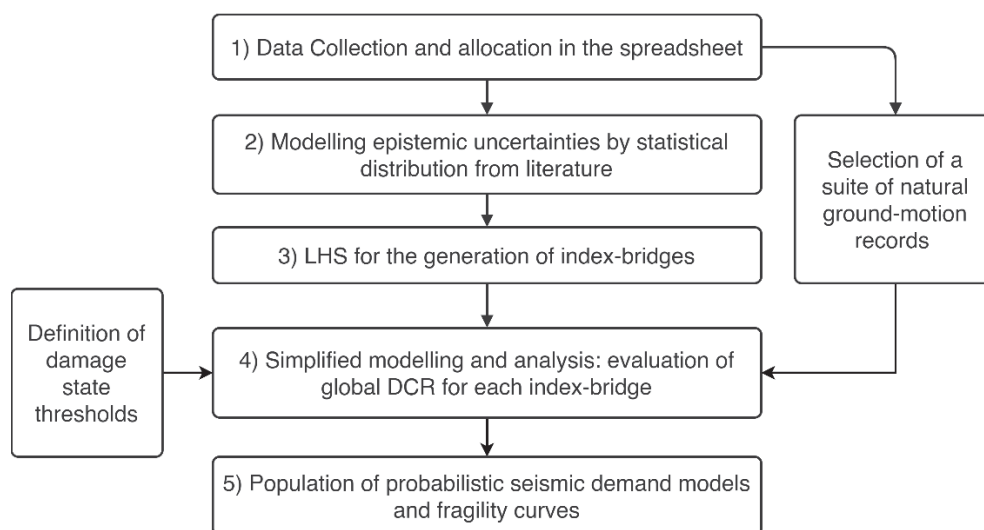

Figure 1: Flowchart of the proposed methodology

### 2.1 Uncertainty modelling

The first step of the methodology involves a data-collection process (Figure 1, step 1) that can be performed through fast in-situ inspections supported by innovative remote-sensing technologies such as drones equipped with optical sensors and photogrammetry algorithms. An example of how these new tools can be applied to effectively and quickly retrieve geometric

and constructive data on bridges is reported in [19]. The completeness of the data collection can be affected by environmental constraints around the investigated bridge or by the proper constructive characteristics (e.g. inaccessible areas for natural obstacles or inability to collect images underneath the deck).

After this process, the knowledge-based uncertainties to be considered in the probabilistic seismic assessment can be identified (Figure 1, step 2). Geometry parameters, mechanical properties of the materials or the structural members, structural details, which are not assumed “deterministic”, can be modelled as uncertainties and represented by random variables with appropriate statistical distributions. The latter can be identified based on literature studies. Zelaschi et al. [20] and Nielson et al. [21] proposed sets of statistical distributions to model appropriately the geometric parameters and the material properties of subclasses of highway bridges in Italy or the US, respectively. If literature references are not available, lacking data should be assumed based on engineering judgement. Furthermore, if more than one bridge is analysed within the same road network, lacking data on one bridge can be assumed for similarity with respect to the other bridges of the same typology within the same road network. Note that only engineering-relevant epistemic uncertainties should be modelled to avoid undesired burdening of the process. As anticipated, other types of epistemic uncertainty (e.g. the capacity models or for the definition of damage state thresholds), which are not considered in this study, can be similarly represented.

Epistemic uncertainties are usually modelled by introducing the random generation of a population of models (herein named index-bridges) “deterministically” characterised by variables selected from the corresponding statistical distributions by using statistical sampling techniques (Figure 1, step 3). To this aim, the standard or Latin Hypercube Sampling (LHS) Monte Carlo methodologies are generally used. The LHS [22] is widely used in literature for the probabilistic seismic analysis of both single or portfolios of bridges (e.g. [23,24]) and is usually preferred over the standard Monte Carlo technique since it requires less computational effort. In the LHS framework, the cumulative distributions of the random variables  $X_j$  are divided into  $N$  equal probability intervals (stratification of the input), where  $N$  is the target number of realizations, and a single value is randomly extracted from each interval. The output samples are  $N$  vectors of size  $j$ , in turn, composed by values randomly paired under the assumption that these belong to different intervals. At the end of the sampling process, convergence in statistics should be checked to reach a number of models being representative of the real distribution and convenient in terms of computational effort. At the end of the simulation process, a set composed of  $N$  bridge realizations is obtained. Each realisation is “deterministically” characterised and can be directly analysed.

In addition to the knowledge-based uncertainty, the (aleatory) uncertainty linked to the random nature of the seismic action (i.e. record-to-record variability) should be modelled (Figure 1, step 4). In the proposed procedure, a cloud-based approach [25] is adopted to perform fragility analysis. To this aim, a wide suite of earthquake-induced ground motions representative of the seismic hazard condition of the site is needed. The selection of ground motions should be addressed reflecting the soil classification of the site and mean values of magnitude and distance of likely seismic events provided by an appropriate hazard de-aggregation for the site of interest. Additional recommendations for the record selection are reported by Jalayer et al. [25].

## **2.2 Simplified approach for seismic performance assessment**

In the following sub-section, the process for calculating the performance of the index-bridges under specific earthquake-induced ground motions, is described. Based on the fundamentals of

nonlinear static procedures, equivalent single-degree-of-freedom (SDoF) capacity curves are attained analytically (in both longitudinal and transverse direction) and subjected to a capacity spectrum-based approach performed with real (un-smoothed) response spectra. Some assumptions of the proposed methodology are reported hereafter. Only the nonlinear response of the substructure members and the deck-substructure connection systems is considered, while the deck is supposed to respond elastically during the earthquake excitation. At this stage of the development, the foundations are modelled as fully-fixed constraints at the pier base according to [18,26]. However, the proposed procedure can be extended to account for soil-structure interactions following the methodology by Ni et al. [27]. The bi-directional effects of the seismic shaking are also neglected and each index-bridge is analysed separately in the transverse and longitudinal directions.

To reduce the necessary computational effort in analysing the index-bridges, a simplified seismic performance assessment strategy should be used within the procedure. The strategy proposed in this study is based on a simplified mechanical modelling approach suitable for multi-span isostatic bridges: the Individual Pier Model (IPM). However, it is worth mentioning that the general scheme of the proposed methodology (Figure 1) can be applied to other bridge typologies if suitable simplified modelling approaches are available (e.g. [28] for continuous-deck bridges). The IPM is a simplified strategy to analyse the seismic response of isostatic bridges with adjacent independent simply supported deck analysed in the transverse direction [1,15,16]. This approach is valid if relative rotations between the deck and the piers along the vertical axis are allowed. The seismic behaviour of each deck-pier/abutment subassembly can be analysed separately and can be represented by an equivalent SDoF multi-linear force-displacement law. This latter is obtained by combining the force-displacement relationships of the connection system (e.g. bearing devices, shear keys) and of the piers, assuming that these components act as a series system.

The force-displacement behaviour of single-column piers can be calculated according to [29,30]. To this aim, bilinear moment-curvature analyses are used, calculated by means of simplified surrogate meta-models [31,32] or programming routines [33]. The force-displacement law of framed piers can be achieved via simplified analytical methods based on mechanism analysis [34] or by simply aggregating the force-displacement laws of the columns acting in parallel in double-bending condition. If the flexibility of the bearings is negligible (i.e. fixed bearings) these can be assumed rigid and only the nonlinear behaviour of the pier is considered in the IPM. However, in most of the existing simply-supported bridges, the behaviour of the bearing devices should be considered. As an example, old fixed bearings (e.g. steel hinges or pin bearings) could experience brittle shear failures, followed by a pure friction (concrete-concrete) behaviour until deck-unseating phenomenon. Moreover, neoprene bearings were widely used in Italy between 1960 and 1990 [35] and can considerably affect the displacement profile of the IPM given their high deformability. Their shear strength is governed only by friction between rubber and concrete surfaces. The slipping of this type of bearings implies a nonlinear behaviour of the subassembly with large relative displacements between the deck and the pier. If present, the contribution of shear keys should be considered. Multilinear force-displacement laws for the mechanical characterisation of bearing devices and shear keys are reported in Cardone [15]. The cumulative force-displacement law of the deck-pier connection system can be attained by the sum of contribution of the bearing devices acting in parallel (i.e. the total base shear is the sum of the shear absorbed by the different devices subjected to the same top displacement).

The capacity curve of the equivalent SDoF representative of each subassembly can be calculated in a simplified way, assuming that its effective mass ( $m_{sub}$ ) is entirely lumped in the centre of mass of the deck. Under the assumption of a series system, for a given value of the

base shear ( $V_b$ ), the effective displacement of the equivalent SDoF system ( $\Delta_{sub}$ ) is given by the sum of the displacements of the pier ( $\Delta_{pier}$ ) and bearing system ( $\Delta_{bear}$ ), obtained by interpolating the respective constitutive laws at  $V_b$ .

To identify the performance of each subassembly under a specific ground-motion record the CSM [36] is applied. Particularly, the algorithm proposed by the authors [37] to apply the CSM with real spectra for fragility analysis is adopted. To this aim, the equivalent SDoF force-displacement law is converted in a capacity spectrum. The equivalent viscous damping of the subassembly ( $\xi_{sub}$ ) associated with each value of  $\Delta_{sub}$  can be computed by Equation (1) aggregating the equivalent viscous damping of the pier ( $\xi_{pier}$ ) and the deck-pier connection system ( $\xi_{bear}$ ). For each  $\xi_{sub}$ , the spectral reduction factor  $\eta_{sub}$  can be calculated to compute overdamped spectra and to identify the performance point (PP). To calculate  $\xi_{pier}$  and  $\xi_{bear}$  the ductility-based formulations by Priestley et al. [29] can be applied. At the end of this process, the seismic performance of each subassembly under a given seismic action can be calculated.

$$\xi_{sub} = \frac{\Delta_{pier}\xi_{pier} + \Delta_{bear}\xi_{bear}}{\Delta_{sub}} \quad (1)$$

The IPM can be used to analyse the response of the bridge in the longitudinal direction if the width of the expansion joints between adjacent decks allows for relative displacement between the subassemblies. This approach is usually suitable for bridges where the expansion joints between the independent decks are seismically designed: each subassembly responds independently until the closure of the joints is reached. In this case, the tributary seismic mass of each subassembly is strictly influenced by the type of bearing devices (fixed or free) and their capacity to transfer shear forces.

Conversely, if a premature closure of the joints is expected (e.g. non-seismically designed joints, designed for thermal dilatations only) or in presence of shock-transmitters, the bridge subassemblies act as a parallel system. In this case, the subassemblies resist a portion of the global seismic action depending on the proper (secant-to-top-displacement) stiffness. If the closure of the deck-abutment joint is expected, the abutment-backfill interaction should be appropriately considered in the simplified model [5]. The force-displacement relationships related to an equivalent SDoF of the entire bridge is calculated: the force-displacement laws of each deck-pier subassembly are aggregated, assuming that all the subassemblies are subjected to the same deck displacement (only one degree of freedom) which is axially rigid. Given a pre-determined target displacement of the deck, the shear force in each subassembly can be achieved by interpolating the corresponding force-displacement laws. These are summed up to calculate the total base shear. Repeating this process for incremental control node displacement, the equivalent SDoF capacity curve is obtained. For each step, the equivalent viscous damping ( $\xi_{eff}$ ) is calculated via Equation (2) where  $N$  is the total number of  $i$  subassemblies. The capacity curve is thus subjected to the CSM [37] to calculate the PP.

$$\xi_{eff} = \frac{\sum_{i=1}^N \xi_{sub,i} V_{sub,i}}{\sum_{i=1}^N V_{sub,i}} \quad (2)$$

### 2.3 Methodology for fragility analysis

After the calculation of the performance demand for each index-bridge subjected to each of the selected ground-motion records, the fragility analysis is performed. Fragility curves express the probability to reach or exceed a damage state (DS) conditioned to a given value of seismic

intensity. Note that fragility analysis of complex systems, like bridges, composed of multiple components, is not a straightforward task, since, the DS of the bridge is related to the DS of the different members (e.g. piers, bearings, abutments). The proposed procedure requires the analyst to define DS thresholds for each bridge member depending on the number of limit states of interest. Recommendations for defining DS thresholds for RC components, bearing devices, shear keys, etc are reported by Cardone [15]. Deterministic DS thresholds are defined in this procedure. However, the uncertainty on the DS thresholds should be easily accounted for according to e.g. [3,23].

The system fragility is defined based on the DS of the different components. In this study, the bridge is simply considered a series system and the weakest member determines the DS of the bridge [25]. The performance of each  $i$ -th bridge component (e.g. pier, bearing system, abutment) under the  $j$ -th ground motion with respect to a given DS, is expressed by a Demand Capacity Ratio ( $DCR$ ) calculated with Equation (3). The global bridge  $DCR_j$  related to the  $j$ -th ground-motion record is the maximum of the  $DCR_{i,j}$  of the different  $i$ -th components. As an example, if only the piers, the bearings and the abutments are considered as critical components, the global  $DCR_j$  is given by Equation (4) where the  $p$ ,  $b$  and  $ab$  subscripts indicate piers, bearings and abutments, respectively.

$$DCR_{ij}^{DS} = \frac{\Delta_{ij}}{\Delta_i^{DS}} \quad (3)$$

$$DCR_j^{DS} = \max (DCR_{p1,j}^{DS}, \dots, DCR_{pN,j}^{DS}, DCR_{b1,j}^{DS}, \dots, DCR_{bN,j}^{DS}, DCR_{ab1,j}^{DS}, DCR_{ab2,j}^{DS}) \quad (4)$$

Various literature studies focus on the definition of optimal intensity measures (IM) for probabilistic seismic analysis of bridges. The appropriate type of IM should be chosen

depending on the scope of the application with reference to its efficiency, sufficiency, practicality and hazard computability. An in-depth study about this is reported in e.g. [21,38].

In this study, fragility functions represent the probability that (the “weakest” member of) the index-bridge reaches a unitary DCR given a determined value of IM and are calculated via a cloud analysis approach [28]. Firstly, the results of the previous analyses are organized in couples of  $IM_j - DCR_j$  (i.e. the “cloud data”). It is assumed that a power-law model ( $DCR = aIM^b$ ) best expresses the relationship between the structural demands and IM [39]. The parameter  $[a, b]$  are estimated fitting a linear model to the cloud data transformed in the natural logarithmic scale using the least square method. This is expressed by Equation (5) where  $\alpha_{DCR|IM}$  represents the median DCR (50% to be exceeded) conditioned to the IM value for a given DS. The dispersion of the demand around the median estimated with the regression model is assumed constant varying the IM and is given Equation (6) where  $M$  is the number of ground motion records. Once,  $\alpha_{DCR|IM}$  and  $\beta_{DCR|IM}$  are calculated (simply  $\alpha$  and  $\beta$  hereinafter), the fragility function,  $P(DCR > 1|IM)$ , and can be expressed by Equation (7) where  $\Phi(\cdot)$  is the standard cumulative distribution functions (CDF).

$$\ln(DCR) = \ln \alpha_{DCR|IM} = \ln(a) + b \ln(IM) \quad (5)$$

$$\beta_{DCR|IM} = \sqrt{\frac{\sum_{j=1}^M (\ln DCR_j - \ln a(IM_j)^b)^2}{M - 2}} \quad (6)$$

$$P(DCR > 1|IM) = \Phi\left(\frac{\ln \alpha_{DCR|IM}}{\beta_{DCR|IM}}\right) = \Phi\left(\frac{\ln a(IM)^b}{\beta_{DCR|IM}}\right) \quad (7)$$

Following this approach, the obtained fragility function is calculated for each index-bridge accounting for demand uncertainty only (i.e. record-to-record variability). The influence of the knowledge-based uncertainty is represented by the variability within the entire dataset of fragility curves related to the index-bridges. This population of fragility curves can be synthesized using specific percentiles of the dataset of the medians and the dispersions [40].

A synthetic fragility curve comprehensive of both aleatory and epistemic uncertainty can be defined by calculating the median  $\alpha_{bridge}$  for a given DS as the median of the population of  $\alpha_k$  related to the  $k$ -th index-bridges with Equation (7). The overall dispersion ( $\beta_{bridge}$ ) should account for both the dispersion of the fragility curves of the single index-models ( $\beta_k$ ) and the dispersion around the medians. These contributions are combined with the SRSS rule.

For risk-based prioritisation purposes, the seismic risk and its variability linked to epistemic uncertainty can be calculated. As an example, the simplified strategies by [41] can be used to calculate the mean annual frequency of exceeding a determined DS ( $\lambda_{DS}$ ).

$$\ln \alpha_{bridge} = \left(\sum_{k=1}^N \ln \alpha_k\right)/N \quad (8)$$

$$\beta_{bridge} = \sqrt{\left(\frac{1}{N} \sum_{k=1}^N \beta_k\right)^2 + \left(\frac{1}{N} \sum_{k=1}^N \ln \alpha_k - \ln \alpha_{bridge}\right)^2} \quad (9)$$

### 3 APPLICATION OF THE PROPOSED METHODOLOGY TO A CASE-STUDY BRIDGE

The proposed framework is applied on a case-study bridge, part of the Basilicata provincial road-network. Two time- and cost-saving approaches are used to perform the data collection, leading to two different levels of knowledge about the geometrical and constructive features of the bridge. The following sections describe the data collection approach, the modelling of uncertainties and the results of the fragility analysis. This section aims to practically describe how to apply the proposed algorithm dealing with real bridges and provide a preliminary validation of the adopted simplified mechanical modelling strategy in fragility analysis.

#### 3.1 Description of the bridge, data collection approaches and uncertainties

The main features of the case-study bridge are reported in Figure 2. The bridge exhibits an isostatic structural scheme with five 30 m-long spans. The superstructure is composed of simply supported independent adjacent decks consisting of precast RC girders having a I-shaped cross section. The height of the single-column piers, having circular cross section (diameter equal to 2.60 m) ranges between 6.6 and 13.6 m. Although the exact year of design is unknown, it is assumed that the bridge was built between the 1980-1984 and designed according to the *D.M. 3 marzo 1975* and *D.M. 2 agosto 1980* [42,43] for seismic and bridge traffic loads, respectively. Note that this information can be easily retrieved from road managers' databases or, if necessary, modelled as knowledge-based uncertainty as follows.

The data collection is performed according to two data collection methodologies. The first exploits open-source Google Earth Street View data and a dataset of images collected on-site and is indicated hereinafter as low-knowledge level (KL1). The geometry was characterized by

means of image processing and measurements by GE data and images. The second data collection approach uses imagery collected by a drone-based survey and photogrammetric elaborations and is identified as high-knowledge level. Further information about this drone-based data collection methodology is reported in [19]. A (Excel-based) data-form is used to store the information in a suitable format to be directly used by a sequence of programming routines developed in MATLAB [44]. These routines perform the statistical sampling for modelling uncertainty and the simulated design of columns (sub-section 2.1) and the fragility analysis according to the simplified mechanics-based approach (sub-sections 2.2 and 2.3).

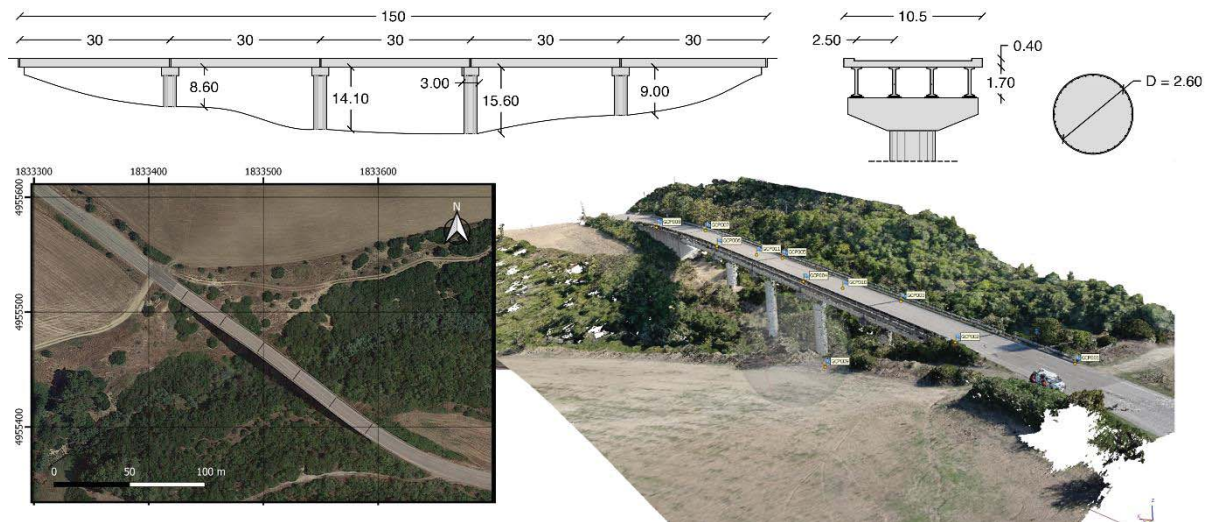

Figure 2: Geometric and constructive characterization of the case-study bridge [19].

Table 1 lists the uncertainties defined via some statistical distributions derived from literature studies [3,20,23,24,45] and engineering judgement. For parameters whose statistical distributions are not available, the maximum uncertainty is assumed using a uniform distribution (continuous or discrete) [40]. Although statistical distributions from different contexts (e.g. United States) are used, it is expected that more data about Italian highway bridges will be available in future, improving the reliability of such an approach. Table 1 differentiates the uncertainties associated with low- and high- knowledge levels (KL1 and KL2). With reference to KL1, no information on the typology of the bearing devices placed between the superstructure and the pier caps is detected. Therefore, in addition to the parameters listed in the table, the variability of two configurations of bearing typology are assumed: fixed/free bearings and neoprene bearings. In the first configuration, the bearings are assumed to be fixed in the transverse direction, while a fixed and a movable bearing line is placed on the top of each pier in longitudinal direction. Also, a variability between three and four devices per bearing line (two lines in total) is assumed. The width of the expansion gaps is low and not measurable at this knowledge level. It is assumed varying according to [3,23] and confirmed by [16] for not seismically designed Italian bridges. Conversely, the KL2 allows for identifying that the deck cross-section is composed of four precast girders (thus four devices per bearing line) and neoprene bearings of 4 cm-thickness; the gap size between the deck and abutments is fixed at 2.5 cm.

The variability in the design class of the materials ( $f_{ck}$  and  $f_{yk}$ ) is modelled. Mean and dispersion of the mean strength values of concrete and steel ( $f_{ck}$  and  $f_{yk}$ ) are calculated depending on the characteristic values assuming a coefficient of variation of 0.09 and 0.18 [24].

The LHS is performed to generate the population of models. For each model, the longitudinal reinforcement layout is calculated by means of a simulated design procedure. An appropriate MATLAB routine was developed to perform this task according to Italian old regulatory codes for bridges. The procedure automatically neglects the couples of design concrete and steel classes which lead to an incompatible design with respect to the old reference code. Since in the '70-'90 decades, the design of transverse reinforcements of bridge columns was dictated by constructive needs rather than mechanical because of the low seismic design actions the volumetric ratio of the transverse reinforcement ( $\rho_t$ ) is modelled with a uniform distribution (Table 1).

The uncertainty about the seismic action is considered via an appropriate ground-motion suite. A dataset of 100 natural ground-motion records is selected from the SIMBAD database [46] consistently with the characteristic of soil type [47], magnitude and distance of expected earthquakes in the site. The magnitude and distance de-aggregation is achieved using the software Rexel [48]. The ground motions compatible with these requirements are firstly collected (176 ground motions). Then, the 100 records with the highest PGA (geometric mean of the two directions) were selected to perform the fragility analysis. The PGA of the selected record varies between 1.77 and 0.16 g.

Parameter	Knowledge Level	Distribution	Distr. Param.	
Characteristic compressive concrete strength ( $f_{ck}$ )	KL1-KL2	Uniform (Discrete)	25-30-35	MPa
Characteristic tensile steel strength ( $f_{yk}$ )	KL1-KL2	Uniform (Discrete)	375-440	MPa
Mean concrete compressive strength ( $f_{cm}$ )	KL1-KL2	Normal	$\mu = 1, \sigma = 0.18$	Factor
Mean steel Tensile Strength ( $f_{ym}$ )	KL1-KL2	Normal	$\mu = 1, \sigma = 0.09$	Factor
Transverse reinforcement volumetric ratio ( $\rho_t$ )	KL1-KL2	Uniform	0.05-0.1*	%
Abutment gap size	KL1	Normal	$\mu = 24.5, \sigma = 5$	mm
Shear modulus of neoprene bearings (G)	KL1-KL2	Uniform	$l = 0.8, u = 1.2$	MPa
Thickness of neoprene bearings ( $t_b$ )	KL1	Uniform	$l = 40, u = 70$	mm
Abutment passive stiffness	KL1-KL2	Uniform	$l = 0.5, u = 1.5$	Factor
Mass variability (G1+G2)	KL1	Uniform	$l = 0.9, u = 1.1$	Factor

Table 1: Variability in geometrical/constructive bridge characteristics depending on the knowledge level (KL)

### 3.2 Modelling assumptions and damage states

Once the models are completely characterised, the seismic assessment is performed according to the CSM-based procedure (sub-section 2.2). To this aim, the moment-curvature relationships of the piers are calculated using CUMBIA [33]. This analysis shows that the flexure governs the seismic behaviour and damage state of the piers. An elastic perfectly-plastic behaviour is assigned to the neoprene bearings, assuming that the maximum strength is reached for slipping between the neoprene and the concrete surfaces, as suggested by Cardone [15] for low-thickness neoprene bearings. The stiffness of each neoprene bearing device is equal to  $k_b = GA/t_b$  (G is the shear modulus, A is the area of the pad) and the slipping strength is calculated assuming a friction coefficient ( $\mu$ ) equal to 0.4. The flexibility of the fixed bearings is neglected together with their shear failure (i.e. it is implicitly assumed that the maximum shear of the subassembly is reached before the shear failure of the fixed bearings). Finally, the

longitudinal response of the abutment-backfill systems for seat type abutments is calculated as proposed in [49,50], while its transverse deformability is neglected.

To provide validation for the simplified performance assessment approach, the bridge is also analysed by means of NLTHA performed in Opensees [51]. A refined numerical modelling strategy is adopted in this case. The RC-piers are modelled via *BeamWithHinges* elements composed of an internal elastic part and a nonlinear hinge at the base. The *Hysteretic* material is used to model the nonlinear cyclic behaviour of the plastic hinges, expressed by means of a sectional moment-curvature law. The deck and the pier caps are represented by elastic beam elements. *TwoNodesLink* elements are utilised to capture the nonlinearity of the bearing devices (*elastic-perfectly-plastic* material) and the abutment-backfill interactions (*impact* material). A tangent stiffness proportional damping is defined for NLTHA [29]. Moreover, a 5% Rayleigh damping model is assigned.

An overview of the local damage state thresholds used to compute the DCR for each component is reported in Table 2. The most damaged component determines the global damage state. The thresholds correspond to slight damage (DS1), severe damage (DS2) and collapse prevention (DS3).

Element	DS1	DS2	DS3	Note
Piers (flexural)	$\Delta_y$	$\Delta_y + 2/3(\Delta_u - \Delta_y)$	$\Delta_u$	$\Delta_y$ and $\Delta_u$ are the yielding and ultimate displacement of the pier.
Neoprene bearings (slipping)	$\Delta_{fr}$	$\Delta_{pad}$	$\Delta_{uns}$	$\Delta_{fr} = (\mu P / k_b)$ is the displacement corresponding to the friction strength attainment, $P$ is the compressive load of the bearing device. $\Delta_{pad}$ is the dimension of the bearing device in the considered direction. $\Delta_{uns}$ corresponds to deck unseating
Sliding bearings	—	—	$\Delta_{uns}$	$\Delta_{sl}$ is the displacement capacity of the bearing device
Abutment-backfill system	$\Delta_{gap}$	$\Delta_{pbw}$	$1.1 \Delta_{pbw}$	$\Delta_{pbw}$ is the displacement at the reaching of passive backfill pressure calculated starting from $k_{bw} = k_i w (h/1.7)$ and $P_{bw} = h_w w p_i (h/1.7)$ , where $h$ and $w$ are the height and width of the abutment backwall, $k_i$ is equal to 11.5 (kN/mm)m and $p_i$ is 239 kPa.

Table 2: Damage state thresholds for each considered components

### 3.3 Convergence in the statistics

Reaching convergence in random sampling is essential for the accuracy of the final fragility estimations. This section aims at identifying the number of index-bridges in the population necessary to achieve robustness in the results, to ensure that the addition of other samples does not involve strong modifications of the final results. This is necessary to identify a sample size which reflects a compromise between computational effort (more index-models, more calculations) and representativeness of the generated population (more index-models, higher accuracy). For this task, the KL1 is considered, where an higher influence of uncertainties is expected with respect to the KL2 case.

First, a first sampling is performed, producing a population of 500 index-bridges. This dataset is analysed, calculating the corresponding set of 500 fragility curves. For this task, PGA is used as IM and DS3 is only considered. A dataset of medians of the fragility curves are collected and their 50<sup>th</sup> percentile ( $\alpha_{opt}$ ) is extracted and assumed as an optimal estimation of the median IM associated with the fragility of the whole population. The 10<sup>th</sup> and 90<sup>th</sup>

percentiles are calculated also, providing optimal estimates of the variability in the median IM of the population leading DS3.

This process is repeated several times reducing the sampling size ( $N_s = [200, 100, 50, 25, 15]$ ). The stability of the counterparts ( $\alpha_{N_s}$ ) with respect to the optimal values is evaluated calculating the relative errors. Figure 3 reports that errors within a range of 10% are achieved when a sample size of 50 realisations is selected. Clearly, this result is strongly related to the adopted uncertainties for this selected bridge, and further studies should investigate the sample size varying the expected influence of the uncertainty.

Figure 3: Relative errors on 50<sup>th</sup>, 10<sup>th</sup> and 90<sup>th</sup> of the median IM with respect to the sample size

### 3.4 Discussion on results

In this subsection, the results of the fragility analysis are discussed to evaluate the influence of the incomplete knowledge level and the reduction of this effect due to a reduction of the general uncertainty. Also, the errors induced by the simplified analysis approach with respect to refined NLTHA are evaluated. The results are numerically listed in Table 3 and graphically shown in Figure 4. Particularly, Table 3 reports the values of the median IM (i.e. PGA) associated with the 50<sup>th</sup> percentile of the fragility population (Eq. (8)) and the per cent relative difference ( $err_{DS}^{10/90th} = (\alpha_{DS}^{10/90th} - \alpha_{DS}^{50th}) / \alpha_{DS}^{50th} * 100$ ) of the 10<sup>th</sup> and 90<sup>th</sup> percentile with respect to the 50<sup>th</sup> one to numerically evaluate the influence of uncertainties. These per cent differences are represented by the amplitude of the “bundle” in Figure 4 representing synthetically the fragility curve population. As expected, the influence of a low-knowledge level, quantified by the 10<sup>th</sup> and 90<sup>th</sup> percentiles, is strongly reduced with a more accurate data collection. This effect is noticeable for the transverse direction, while it is slighter for the longitudinal where the damage is governed by the abutment-backfill interaction that is less affected by the uncertainties. In the transverse direction, the 10<sup>th</sup> and 90<sup>th</sup> percentiles of the median IM of the population change in a range which reaches [-50; +50]% of the 50<sup>th</sup> percentiles regardless of the DS.

Figure 5 better explains this outcome, showing the population of fragility curves for the KL1 case at DS2 (chosen for illustrative purposes). Red curves correspond to index-bridges having fixed/free bearings, while blue ones indicated index-bridges where neoprene bearings are present. Moreover, the pattern of the curve is related to the critical member which reaches DS, i.e. pier (flexure), bearing device or abutment-backfill system. Figure 5a shows that in the transverse direction, the variability in critical member induces wide variability in fragility curve parameters. The group of index-bridges with neoprene bearings (red) are generally associated with lower fragility (lower probability of reaching DS) than the index-bridges where fixed bearings are present and piers are damaged for flexure. The neoprene bearings produce a beneficial effect in the vulnerability in the transverse direction, since their slipping prevents

further increase of shear force in the piers, enhancing the ductility of the bearing-pier subassemblies. This outcome is consistent with [18]. This explains the general increase in  $\alpha_{DS}^{50th}$  for KL2, where only neoprene bearings are modelled, with respect to KL1 (Table 3). In this case, the maximum variability of  $\alpha_{DS}$  is registered at DS3 and corresponds to the range [-30.48; +13.81] %.

Case	$\alpha_{DS1}^{50th}$	$err_{DS1}^{10th}$	$err_{DS1}^{90th}$	$\alpha_{DS2}^{50th}$	$err_{DS2}^{10th}$	$err_{DS2}^{90th}$	$\alpha_{DS3}^{50th}$	$err_{DS3}^{10th}$	$err_{DS3}^{90th}$
Transverse direction									
KL1-CSM	0.64	-41.62	49.77	1.34	-40.59	49.01	2.05	-39.98	49.15
KL2-CSM	0.82	-24.09	12.77	1.66	-28.70	12.91	2.33	-30.48	13.81
KL2-NLTHA	0.80	-19.07	11.67	1.58	-24.11	11.64	2.38	-28.46	19.99
Longitudinal direction									
KL1-CSM	0.26	-34.95	31.05	0.71	-20.44	28.47	0.78	-23.65	35.99
KL2-CSM	0.24	-7.57	5.24	0.64	-13.74	34.59	0.68	-14.29	36.81
KL2-NLTHA	0.25	-5.86	3.66	0.67	-12.90	36.23	0.71	-13.61	37.91

Table 3: Median PGA (50<sup>th</sup>) and per cent shift associated with 10<sup>th</sup> and 90<sup>th</sup> percentiles

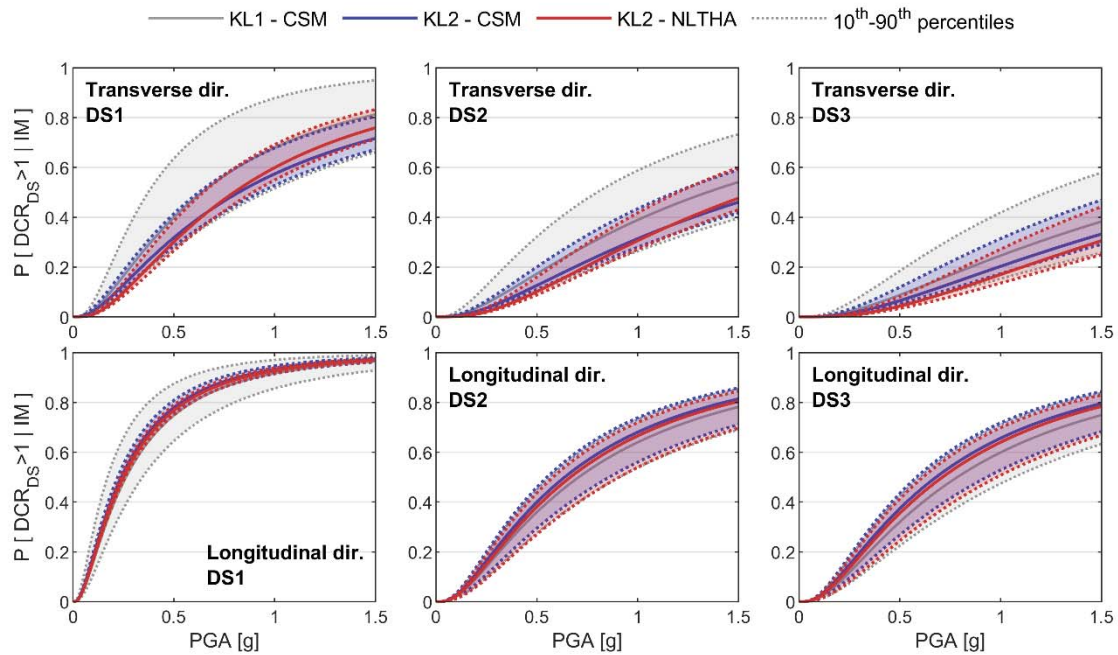

Figure 4: Fragility curves and associated variability for the case-study bridge considering the KL1 (analysed via CSM) and KL2 (analysed via CSM and NLTHA).

As shown in Figure 5b, in the longitudinal direction, it is very common among the analysed index-bridges that the abutment-backfill system induces the DS2. This is confirmed by [5] for non-seismically designed bridges. The presence of neoprene bearings is unfavourable for the fragility of the case-study bridge in this case. Indeed, the index-bridges where fixed bearings are present exhibit a lower probability to be damaged since the piers collaborate with the abutment-backfill system in resisting the total amount of seismic action. Conversely, neoprene bearings decrease the stiffness of the deck-pier subassemblies inducing a higher amount of seismic action directly transferred to the abutment and anticipating the reaching of DS2. It is

observed that in the longitudinal direction, the  $\alpha_{DS}$  ranges in a narrower interval with respect to the transverse direction.

Figure 4 evidences the general accuracy provided by the simplified CSM for fragility analysis with respect to NLTHA. In this case, the relative error between the two approaches on the median IM of the fragility curves (50<sup>th</sup> percentile) is lower than 5% regardless of the DS and the analysis direction. This evidences that, for this case study, the assumptions of the simplified IPM, that neglects the interactions between the subassemblies, and the equivalent viscous damping strategy is appropriate. However, this should be considered as a first outcome and other tests are needed for other case-study bridges or using more efficient IM in the calculation of fragility curves,

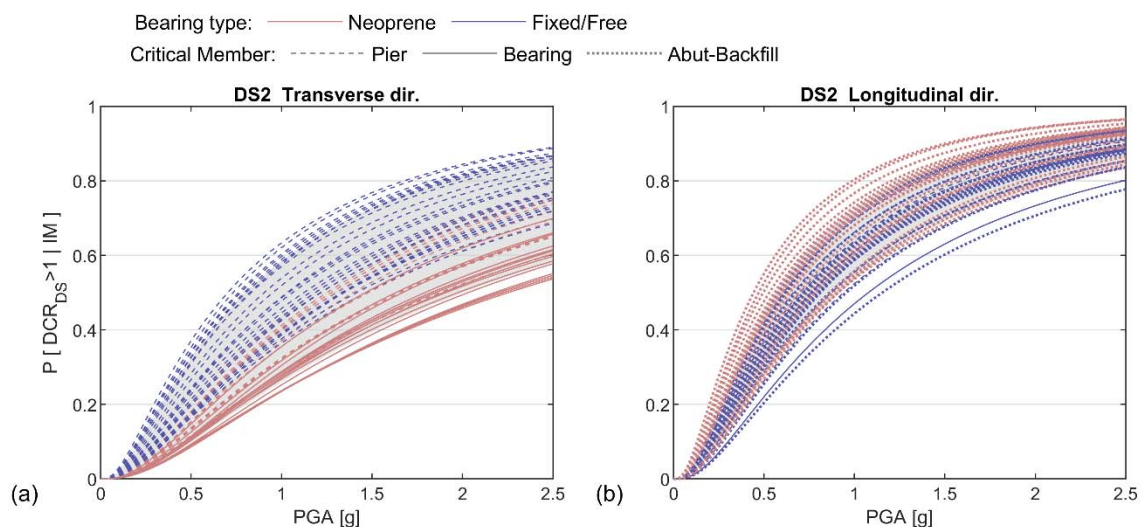

Figure 5: Population of fragility curves for the KL1 case at DS2. Different colours aim to distinguish the bearing type of the index-bridge, different patterns indicate different critical members. The grey area indicated the area between the 10<sup>th</sup> and the 90<sup>th</sup> percentiles.

## 4 CONCLUSIONS

In this study, a simplified methodology to perform fragility analysis of bridges directly accounting for uncertainties linked to an incomplete knowledge level is described. These knowledge-based uncertainties are considered by means of the statistical generation of a population of index bridges. The analysis of index-bridges is based on a simplified modelling approach, suitable for isostatic typical Italian bridges, and the capacity spectrum method used to evaluate the performance of index-bridges under a specific earthquake record. The performance of the single index-bridge is synthesized by a set of Demand-Capacity Ratios which is used to fit regression-based probabilistic seismic demand models and compute fragility curves. The fragility of the main bridge is represented by a population of fragility curves and the influence of knowledge-based uncertainties can be quantified by extracting significant percentile values of the population.

The proposed approach is applied on a case-study bridge of the Basilicata (Italy) provincial road network. The case-study section is aimed at illustrating the different steps of the procedure. Two data collection approaches are performed using different data sources involving two knowledge levels characterised by different degree of completeness. The case-study section tests the appropriate sample size to generate a representative population of index-bridges and provide a validation of the simplified analysis approach by means of the comparison with non-linear time history analysis on a refined numerical model. The fragility analysis shows that the response of the abutment-backfill system in the longitudinal direction is decisive for the

fragility of this case study whose deck-abutment gap size is not seismically designed. In the transverse direction, the fragility of the bridge is affected by the bearing typology and the lack of this information strongly increases the influence of the uncertainties. It can be stated that an adequate preliminary data collection should address the width of the abutment-deck gap and the typology of the deck abutment connections. The employment of typological approaches that neglect these components could involve severe inaccuracies in fragility estimations of bridge portfolios.

Finally, it is worth mentioning that further validations are needed to investigate the accuracy of the simplified fragility analysis methodology for different bridge types as continuous deck bridges.

## 5 ACKNOWLEDGEMENTS

The research presented in this paper was partially funded by the Italian Department of Civil Protection in the framework of the national project DPC-ReLUIIS 2019-2021.

### Abstract

*This paper, focused on the effect of local scour actions on masonry bridges, represents a follow-up of a previous study conducted by the authors aimed at analysing the effect of a localised scour-induced settlement of the pier on the modal properties of the bridge (i.e., frequencies and mode shapes). Results from the previous study showed as the scour phenomenon, even at its early stages could induced a non-negligible variability of the transverse modal shape of a masonry arch bridge selected as case study. In this paper, the work is continued by analysing how the bridge geometry can affect the aforesaid results. To this aim, bridges with three different geometry (130 m length, 100 m length, 50 m length) are analysed by simulating the scour evolution under the piers and by monitoring the modal response at different stages of the excavation. Accurate finite element models are developed in Abaqus, accounting for both mechanical and geometrical nonlinearities.*

**Keywords:** masonry, bridges, scour, Abaqus FEM, arch bridges, modal shapes, OMA.

## 1 INTRODUCTION

Scour is a natural phenomenon caused by the erosion or removal of streambed or bank material from bridge foundations due to flowing water [1-3].

This action is among the most common causes of bridge failure worldwide [2-4], leading to notable direct and indirect losses, as witnessed by the numerous cases of scour-induced collapses occurred worldwide [5-8].

Masonry arch bridges are particularly vulnerable to this phenomenon, due to their high stiffness and the usually shallow footings. The relevance of the problem is also witnessed by the increasing number of works dealing with this issue, e.g., numerical studies employing soil-foundation-structure interaction models with different level of complexity [4, 9], works proposing advanced models for describing the cracking mechanism evolution in the masonry components [10-13], and studies oriented towards dynamic identification and scour monitoring [14-17]. Moreover, besides the studies fully dedicated to the seismic response [18, 19], the literature offers an always growing number of papers focused on vulnerability and resilience assessment of masonry bridges under multiple hazard (mainly earthquakes and floods) [20, 21].

In the recent years, studies have been also carried out to investigate the possibility of detecting scour by tracking the changes of the dynamic properties of the bridge-foundation-soil system (see e.g., the studies of [22, 23] in the context of masonry arch bridges, or the ones of [24, 25] for steel and reinforced concrete bridges).

In particular, the study conducted in 2020 by [5] has shown as the scour phenomenon, even at its early stages could induced a non-negligible variability of the transverse modal shape of a masonry arch bridge selected as case study, thus opening the way to mode-shape based scour monitoring techniques. Very recently (in 2021) the work of [26] presented an approach to detect stiffness loss arising due to scour based on relative changes of vertical-pier mode shape amplitudes, by testing the method through a scaled experimental model of a bridge traversed by a vehicle.

Within this framework and as follow-up of [5], the present paper focuses on the effects of a localized scour-induced settlement of the pier on the modal properties (i.e., frequencies and mode shapes) of multi-span masonry arch bridges. In particular, the investigation initiated in [5] is herein extended to bridges with three different geometries: 7-spans 130 m length, 5-spans 100 m length, 3-spans 50 m length. For each of the three bridges an accurate 3D finite element model is first developed in Abaqus [27], accounting for both mechanical and geometrical nonlinearities; then numerical simulations are performed to assess the modal response sensitivity at different stages of the scour process evolution (a single pier is assumed to experience scour).

## 2 CASE STUDIES

A masonry arch bridge typology very common in the existing Italian infrastructural stock (but also diffused in Europe and worldwide) is considered in this study, and three different geometric schemes are analysed: a 7-spans bridge (131.20 m long), a 5-spans bridge (98.80 m long) and a 3-spans bridge (54.40 m long).

All the bridges have the following features [5, 28] in common: the spans are 16.00 m long; the piers are all identical with a plan size of 9.5 m x 3.2 m, excluding the extreme circular parts with a radius of 2.0 m along the transverse direction (Y direction); the arches have thickness of 0.95 m and a radius of 11.58 m; spandrel walls have thickness of 0.65 m; the pier foundations have a rectangular plan shape of 11.00 m x 3.90 m and their height is 4.15 m. More details about the bridge geometry are given in Figure 1, The longitudinal views of the bridges are provided in Figure 1; two sections (one transversal and one longitudinal) are shown in Figure 2.

Figure 1. Longitudinal view and geometries of the three case studies.

Figure 2. Sections and details common for all the masonry arch bridges.

The materials mechanical properties are taken from [5] and are based on both in-situ and laboratory characterization tests. Table 1 provides a summary of the main mechanical properties of the bridge materials, in terms of density  $\rho$ , Young's modulus  $E$ , yield stress in compression  $f_{y,c}$  (or cohesion  $c$  for what concerns the backfill) and peak tensile stress  $f_{y,t}$ .

Table 1. Material properties.

Material [-]	$\rho$ [t/m <sup>3</sup> ]	$E$ [kN/m <sup>2</sup> ]	$c - f_{y,c}$ [kN/m <sup>2</sup> ]	$f_{y,t}$ [kN/m <sup>2</sup> ]
Masonry (Arches & Spandrels)	1.80	3100000	2000	150
Masonry (Piers)	1.75	2900000	2000	150
Backfill	1.70	250000	10	0
Abutment	1.90	300000	-	-

Riverbed features are assumed according to the case study analysed in [5], where both geophysical and mechanical soil characterizations were achieved through a set of in-situ tests and laboratory tests. The riverbed properties, made of with highly dense gravel and sands (alluvial deposit extending 27 m below the surface), are collected in Table 2 (friction angle  $\phi$ , Young's modulus  $E$ , Poisson's ratio  $\nu$ , shear modulus  $G$ , soil density  $\rho$ , and average shear waves velocity  $v_s$ ).

Table 2. Soil parameters.

$\phi$ [°]	$E$ [kN/m <sup>2</sup> ]	$\nu$ [–]	$G$ [kN/m <sup>2</sup> ]	$\rho$ [t/m <sup>3</sup> ]	$v_s$ [m/s]
38	1065000	0.45	370000	2.0	430

### 3 MODELLING STRATEGY

#### 3.1 General details of the finite element model and material constitutive laws

A 3D model of each case study (Figure 3) is developed in ABAQUS 2017 [27] by following the strategy adopted in [5] and briefly recalled below.

The bridge model is built by using continuum solid linear hexahedral 8-nodes elements of type C3D8R, with 6 degrees of freedom per node.

A coarser mesh is attributed to master parts in defining contact pairs interaction, in order to avoid penetration at the interface. Moreover, the mesh discretisation is set in order to attain of a good trade-off between results' accuracy and computational effort, with element dimensions varying between 0.35 m and 0.75 m.

The model accounts for both geometrical and mechanical nonlinearities.

The behaviour of the masonry components in the linear elastic field is described by assigning the properties summarised in Table 1. The non-linear behaviour is described through the Concrete Damage Plasticity (CDP) model with the parameters reported in [5].

For the fill material, a linear elastic model is employed, together with a Mohr-Coulomb failure criterion, characterized by a friction angle of 55° and a cohesion of 10 kN/m<sup>2</sup>.

As schematically shown in Figure 4, the interaction between the different bridge components is simulated by means of the following nonlinear frictional/cohesive interfaces [4, 5, 10] (see [5] for a detailed discussion of the topic): a frictional interface is used to describe the interaction between the fill and the other bridge components along the tangential direction (the tangential behaviour is characterised by a friction coefficient of 0.60); a “hard-contact” behaviour is assumed along the normal direction, allowing separation but preventing penetration between the parts in contact; cohesive interactions are used for the other interfaces (i.e., spandrel-to-arch, spandrel-to-pier and arch-to-pier), simulating the behaviour of mortar joints between the parts. Moreover, a damage criterion is introduced, whose initiation is governed by the attainment of the maximum nominal stress values along the normal and tangential directions, equal to  $f_{n,max} = 150$  kN/m<sup>2</sup> (Table 1) and  $f_{t,max} = 1.4 \cdot f_{n,max} = 220$  kN/m<sup>2</sup>, respectively. The damage evolution is described by the Benzeggagh-Kenane mixed mode fracture criterion, with a power-law exponent of 2.2, and the values of normal and shear fracture energies are assumed equal to  $G_{f,n} = 0.05$  kN/m and  $G_{f,s} = 0.10$  kN/m, respectively. To improve convergence, a damage stabilization criterion is also used, by defining a viscous coefficient of  $10^{-5}$  kNs/m.

Figure 3. Finite element models: (a) 7-spans, (b) 5-spans and (c) 3-spans bridge.

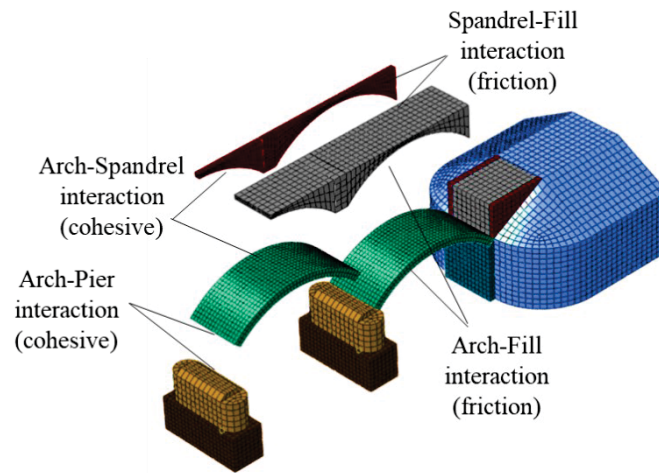

Figure 4. FE model with highlighted materials interface types.

### 3.2 Scour numerical simulation

A Winkler modelling approach is employed to describe the soil-foundation interaction (Figure 5). The relationship between the soil pressure and the corresponding settlement is described through the following set of equivalent soil stiffness constants (Table 3)  $k'_x = \frac{k_x}{A_x}$ ,  $k'_y = \frac{k_y}{A_y}$ ,  $k'_z = \frac{k_z}{A_z}$ , with  $k_x, k_y, k_z$  (kN/m) provided by Gazetas [29] and  $A_x, A_y, A_z$  foundation areas. However, different impedances formulations [30] might also be used.

Figure 5. Impedances along the  $x, y, z$  directions

Table 3. Soil stiffness constants.

$k'_x$ [kN/m <sup>3</sup> ]	$k'_y$ [kN/m <sup>3</sup> ]	$k'_z$ [kN/m <sup>3</sup> ]
220000	420000	940000

The scour process evolution is numerically modelled according to the simplified procedure proposed in [5], which can be synthetised as follows (Figure 6):

- The hole shape is described by a constant inverted pyramidal form [4].
- The vertex of the pyramid is assumed along a vertical line passing through the centre of the upstream face of the pier, the upstream slope of the hole is taken equal to friction angle at rest of the soil,  $\phi$ , whereas the downstream slope is approximately half that value, consistently with [2].
- The scour hole slope along the direction perpendicular to the flow is equal to  $5/6 \cdot \phi$ .
- Being the shape of the scour hole fixed, the hole geometry is completely defined by the maximum scour depth  $y_s$ , identifying the scour hole vertex, and by the value of the friction angle of the soil.
- A time-history analysis is performed in Abaqus in which, at each time step, the level of the maximum scour depth is increased and the depth of the centroid of each cohesive element representing the foundation-soil interaction is compared with the depth of scour at the same location: if the element centroid is within the scour hole, then the element is deactivated.
- In this study, the simulation of the deepening of the scour hole is described by considering 8 discrete steps.

Figure 6. Scheme of scour progression modelling.

Step 0 corresponds to the starting condition, with gravity loads acting on the bridge (self-weight loads plus a uniform pressure of  $6.6 \text{ kN/m}^2$  simulating the road pavement loads) and no scour. From Step 1 to Step 7, the scour development is simulated by considering increments of  $y_s$  equal to  $1.0 \text{ m}$  per step, for a total maximum scour depth of  $7.0 \text{ m}$  attained at Step 7, corresponding to an excavation of  $3.0 \text{ m}$  under the base of the pier's foundation (whose height is  $4.15 \text{ m}$ ).

At the end of step of analysis, a eigenvalues analysis is performed in order to evaluate the modal shapes and the frequencies of the bridges at the current state (i.e., at the current level of scour). Further details about the simulation and the solver setting are given in [5]. In this study,

the scour is assumed to occur on one single pier only, corresponding to the most extreme one (i.e., near the right abutment).

#### 4 SCOUR INFLUENCE ON BRIDGES DYNAMIC PROPERTIES

In this section the influence of the scour progression on the modal properties of the three bridges is assessed. In particular, for each bridge configuration, the modification of the transversal modal shapes is graphically displayed (Figure 7, Figure 8, Figure 9); it is worth noting that the sequence of mode shapes shown in the figures should be read from the top (no scour taking place) to the bottom (maximum scour excavation).

The variation of the corresponding natural frequencies is reported as well (Table 4 and Table 5): Table 4 illustrates the evolution of the frequency with the scour depth progression, while Table 5 collects the percent variation with respect to the reference value at Step 0.

Despite the different values of the reference frequencies observed by three bridges, a common pattern can be found in the results of this investigation. Indeed, the changes of the modal frequency are very low for increasing scour depths between 0.0 m and 4.0 m, with a percentage decrease of 1.5% - 2.44% at Step 4 (i.e., with  $y_s = 4.0$  m). From this point on, the effects of the scour on the modal frequency become more and more significant, with percentage reductions higher than 20% at Step 5 (i.e., 1.0 m of excavation under the pier), while very high reductions (>46%) are observed for  $y_s = 6.0$  m (i.e., 2.0 m of excavation under the pier).

Table 4. Modal frequency evolution (Hz) at different scour levels.

Bridge	Step 0	Step 1	Step 2	Step 3	Step 4	Step 5	Step 6
	0.0 m	1.0 m	2.0 m	3.0 m	4.0 m	5.0 m	6.0 m
7-spans	6.455	6.453	6.445	6.428	6.357	5.077	3.431
5-spans	6.048	6.045	6.031	6.016	5.952	4.750	3.199
3-spans	6.110	6.101	6.067	6.041	5.961	4.750	3.200

Table 5. Modal frequency percent variation (%) at different scour levels.

Bridge	Step 0	Step 1	Step 2	Step 3	Step 4	Step 5	Step 6
	0.0 m	1.0 m	2.0 m	3.0 m	4.0 m	5.0 m	6.0 m
7-spans	0.00	-0.03	-0.15	-0.42	-1.52	-21.35	-46.85
5-spans	0.00	-0.05	-0.28	-0.53	-1.59	-21.46	-47.11
3-spans	0.00	-0.15	-0.70	-1.13	-2.44	-22.26	-47.63

If from one side the frequency changes remain negligible for a “long time” of scour process evolution, the mode shapes (Figure 7, Figure 8, Figure 9) are found to be more sensitive to the effect of scour. Indeed, a non-negligible variability of the transverse mode shapes is observed on all the three bridges starting from the early stages of the scour phenomenon, i.e., for  $y_s$  between 1.5 and 2.0 m, before the stages of excavation under the pier’s foundation. As the scour proceeds, the mode shape becomes always more local and interesting the subsiding pier.

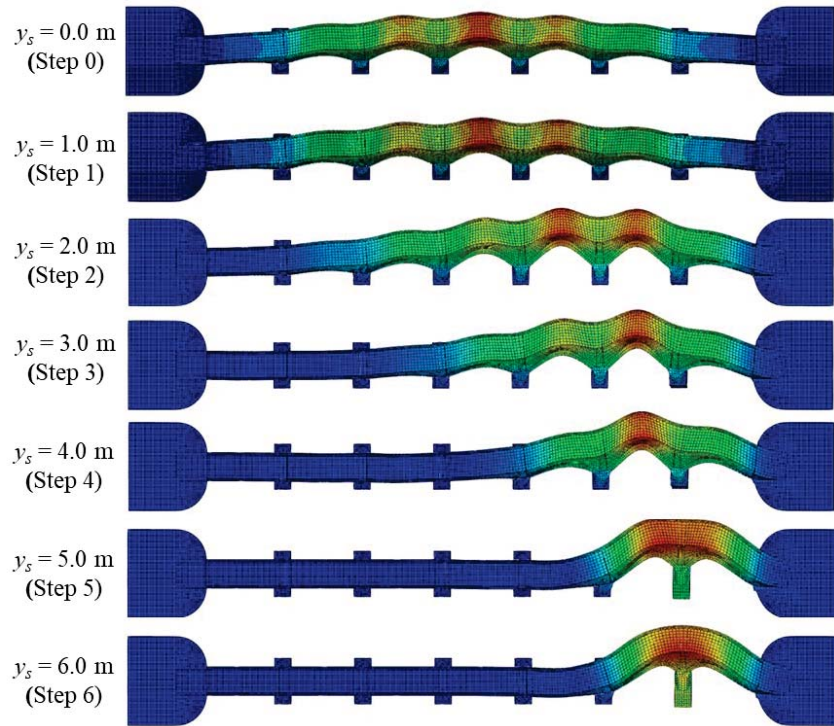

Figure 7. Transverse mode shapes variation for different scour depths.

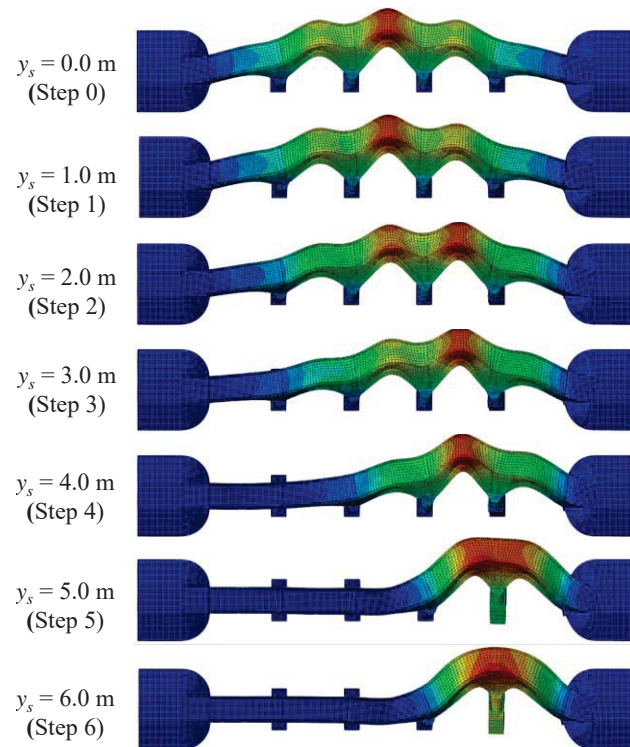

Figure 8. Transverse mode shapes variation for different scour depths.

Figure 9. Transverse mode shapes variation for different scour depths.

## 5 CONCLUSIONS

The effects of a localized scour-induced settlement of the pier on the modal properties (i.e., frequencies and mode shapes) of masonry arch bridges are analysed. As extension of the study of [5], bridges with three different geometries (130 m length, 100 m length, 50 m length) are analysed by simulating the scour evolution under the piers and by monitoring the modal response at different stages of the excavation. Accurate finite element models are developed in Abaqus, accounting for both mechanical and geometrical nonlinearities.

No significative differences are observed among the analysed case studies, characterised by different geometries but equal static scheme, materials and boundary conditions. The results of [5] and the relevant main conclusions thus still hold and can be summarised as follows:

- are negligible if the scour depth involves only the lateral sides of the foundation.
- The modal frequency changes become noticeable (higher than 20%) only when the soil underneath the pier is eroded; for this reason, the suitability of a *frequency-oriented* identification system based on ambient vibrations might be compromised.
- Conversely, the transverse mode shapes exhibit a very high sensitivity to scour, even at the early stages of the phenomenon; in light of this, a *mode shape-oriented* identification system might be appropriate for monitoring the scour evolution over the time and thus intervene timely in order to avoid failure or damage development on masonry bridges.

However, the study shall be extended to a wider set of case studies in order to verify the effectiveness of the proposed OMA-based identification technique as a scour monitoring and early warning strategy in those cases in which scour affects a larger number of piers (scour on a single pier is analysed in this work).

Moreover, an ongoing study is aimed at developing a probabilistic hazard discharge model accounting for the scour refill process due to live-bed flood conditions, based on the recent work [31]. This hazard model will be exploited within a time-dependent risk assessment probabilistic framework for bridges, which may also integrate other source of hazards (e.g., earthquakes [32]).

### Abstract

*Recent seismic events occurred in Central Italy drew the attention towards the resilience of the Italian road network, which is characterized by a significant number of old reinforced concrete bridges and viaducts. In this context, the fragility assessment of existing bridges is crucial, since their collapse or loss in functionality after earthquakes may lead to significant economic and social consequences.*

*This work focuses on the fragility assessment of reinforced concrete multi-span continuous bridges, which is a widespread structural typology in Italy. The study aims to individuate fragilities relevant to both local and global mechanisms, considering bridge components such as piers, bearings and deck members, in order to highlight the most vulnerable ones compromising the whole structural response under the seismic action. A probabilistic framework is developed considering both the site-dependent seismic hazard and the most important Engineering Demand Parameters (EDPs) characterizing the structural response. The first one accounts for the record-to-record variability as well as the parameters governing the seismic scenario in which the structure is located, while the latter ones are individuated depending on the structural typology and the identified vulnerabilities. Multiple Stripe Analyses are performed with the aim of providing insights about the seismic response of the bridge class at hand and of furnishing the fragility curves for all the response parameters relevant for the structural system. Starting from a real case study located in Centre Italy, a couple of reinforced concrete bridge models is developed in order to consider the influence of different heights for the piers and to provide a forecast for the structural behaviour of the selected bridge class. The models are able to capture the failure mechanisms most likely to occur. Performance thresholds are chosen for each bridge component considering the relevant limit state demands according to the current codes and literature. As a result, fragility curves provide useful insights about the main structural deficiencies of the system at hand.*

## 1 INTRODUCTION

Fragility assessment is fundamental for a proper probabilistic characterization of the consequences of natural hazards such as earthquakes or flood-related ones [1]-[2] on existing infrastructures. Concerning the seismic vulnerability of bridges, a common practice is that of defining homogeneous fragility classes for cataloguing bridges based on their geometric and mechanical characteristics, deck cross section, static scheme and typology of vertical supporting elements [3]-[5]. Among the several bridge classes, this paper focuses on the particular but widespread typology of Reinforced Concrete (RC) Link Slab (LS) jointless bridges, which are highly representative of the Italian existing infrastructural network and, at the same time, can be commonly found in the infrastructural stock of many other countries [6]-[10]. The interest in such bridge class, and in general in bridges and viaducts, has grown due to earthquakes occurred in Italy in the recent years as well as due to the catastrophic events involving strategical structures in the regional road network (e.g. the collapse of the Morandi's bridge in Genova in 2018).

To the authors' knowledge, no detailed probabilistic studies have been performed yet to investigate LS RC bridges properly. Thus, the wide use of this engineering solution deserves a deeper investigation, considering that in most cases existing LS bridges were designed according to old standards, which lack attention and detailing with respect to seismic actions. For this purpose, two RC simply supported multi-span LS bridges are considered as representative case studies for the bridge class at hand. The geometries are derived from an existing LS bridge in Central Italy [11] and differ for the height of the piers to compare the response of tall and short piers on the overall behaviour of the structural system. A simulated project is preliminary developed following typical design rules of Italian codes of the 70's [12] and nonlinear finite element models are developed to perform numerical nonlinear Time Histories (TH) analyses. A conditional probabilistic approach is adopted, based on Multiple Stripe Analysis (MSA) [13] and on a stochastic ground motion model for the seismic scenario characterization. Different demand parameters are monitored to properly assess the seismic response of the system, and fragility curves are estimated for the damage mechanisms most likely to occur in LS bridges.

## 2 LS BRIDGES: VULNERABILITIES

LS bridges are characterized by simply supported beams constituted by reinforced or prestressed concrete girders, linked at the slab level by means of steel bars to make the slab continuous. This technical solution, also used as a retrofit technique in existing bridges with separated spans, belongs to the wider category of jointless bridges, where the adoption of links instead of expansion joints is an economical and efficient alternative to reduce the vulnerability of the entire structural system. In fact, water leaking through the joints is the major cause for the deterioration of bearings and supporting structures, while debris accumulation in the joints may causes damage to the deck for the prevented thermal expansion. Consequently, LSs require a lower maintenance effort and costs; an example of link connection is illustrated in Figure 1.

Kinematic links are usually designed considering longitudinal loads acting at the slab level. The effectiveness of link slabs as retrofit intervention in presence of live and thermal loads has been investigated in the literature [6]-[8] but no probabilistic approach useful to the fragility and risk evaluation of this structural component has been employed yet. It is also worth to mention that no evaluation of the performance of links under transverse loads was required by past codes, so that their behaviour is unknown in occurrence of a seismic event. It is well known that structural problems can arise not only in vertical and supporting elements, but also

3420

with  $\Phi(\cdot)$  denoting the standard normal cumulative distribution function,  $\theta$  the median fragility value (i.e., the *IM* level with 50% probability of exceedance),  $\beta$  the *IM* standard deviation. In this paper, the fragility function parameters  $(\hat{\theta}, \hat{\beta})$  are obtained by maximizing the logarithm of the likelihood function, since the maximum likelihood represents an appropriate fragility fitting strategy [28].

## 4 APPLICATIONS

### 4.1 Geometry and structural details of the case studies

Two multi-span simply supported pre-stressed concrete bridges are considered as case studies. To better represent the existing Italian bridge stock, it is assumed that the bridges were constructed in the 70's, before the emanation of seismic design codes at national and European level [23], [29].

The LS bridges are 131 m long, with 5 simply supported 25 m long spans. The case studies present the same superstructure. The bridge deck is composed of a cast-on-site 12.50 m wide slab on three V-shaped pre-stressed concrete girders. This geometry is a typical choice for pre-stressed concrete girder cross-sections and derives from an existing LS bridge in Central Italy. Figure 3 shows the cross-section shape (original design document).

Spans present connections at the slab level realized through the kinematic links, made by DYWIDAG bar groups with diameter  $\varnothing 40$  mm. The bar arrangement is made according to the static scheme in the longitudinal direction presented in Figure 4, where a fixed constraint is located at the abutment on the right side, and according to the relevant distribution of axial forces (due to seismic actions in the longitudinal direction of the bridge).

RC girders, at both piers and abutments, are supported by a set of 3 neoprene semi-rigid bearings. The bearings mechanical behaviour is the same along the two horizontal directions.

Vertical supporting elements are single piers with a full reinforced concrete circular cross section with a parallelepiped cap on top. The two case studies differ for the height of the piers, that is calculated according to a nondimensional ratio  $H/D$  equal to 3 and 7 respectively, where  $H$  is the height and  $D$  the cross-section diameter. The latter is the same for both the case studies and constant along the bridge. The choice of a different height allows to investigate effects of the seismic action in case of short and tall piers.

A simulated design has been performed according to the Italian DM 03.03.1975 [12], considering both gravity and seismic loads. The first derives directly from the deck self-weight, while the latter are modelled as equivalent seismic forces applied separately along the transverse and longitudinal direction of the bridge in order to design piers and link bars. Following the code requirements, the minimum longitudinal reinforcement ratio of 1% is assumed for the piers that have a diameter of 2.0 m. Concerning materials, a  $f_c = 30$  MPa concrete is as-

sumed and effects of the confinement on piers are considered according to [30]. Link bars are made of harmonic steel (DYWIDAG bars) while neoprene bearings are characterized by a shear modulus  $G = 1$  MPa.

Figure 4: Scheme of link bar arrangement at the slab level.

## 4.2 Numerical models

Three-dimensional nonlinear models are developed in OpenSees [31] to perform TH nonlinear dynamic analyses.

Since no plastic deformation is expected on the deck girders, the latter are modelled as *elastic beam-column* elements and the hypothesis correctness is verified a-posteriori.

Link slabs are modelled as displacement-based beam-column elements (*dispBeamColumn element*) with fibre section to catch the bar stress state under the transverse seismic load. Link bars are modelled through fibre elements with *Steel02* elastic-plastic law, while the concrete slabs adopt a fibre cross section with *Concrete01* uniaxial material.

Pier caps are assumed as rigid elements and are modelled by *rigidLink beam* elements connecting the deck beam ends to the bearings. Bearings are modelled through *zero-length* elements with *Steel01* uniaxial material having elastic-plastic law to simulate the deformability of the bearing and the sliding between concrete surface and neoprene once the static friction is exceeded. The constitutive law of neoprene bearings and the value assumed for the friction coefficient ( $\mu_1 = 0.25$ ) are derived from the available literature.

Columns are modelled using displacement-based fibre elements (*dispBeamColumn element*), which are able to take into account the evolution of the plastic hinge at the base of the pier. The pier cross section, a circular reinforced concrete discretised fiber section, is built so that effects of the confinement on the concrete, modelled as *Concrete01*, are considered according to [30]. For the sake of simplicity, piers and abutments are assumed to be fixed at their base although the authors recognise the significance of soil-structure interaction effects in the response of bridges, especially in the case of soft soils [32].

### 4.3 Fragility analysis

In order to examine the most significant damaging mechanisms occurring with seismic action, three Engineering Demand Parameters (EDPs) are selected: 1) the pier top maximum displacement, which controls  $\chi$  ductile mechanisms of the piers; 2) the bearing maximum displacement; 3) the maximum strain on the link-slab steel bars. The performance of these components is assessed referring to two main limit states, corresponding to the occurrence of plastic mechanisms (piers or bars yielding or the onset of sliding phenomena at the bearings) and to the reaching of the ultimate condition at collapse (pier collapse or bars fracture or maximum displacement of the bearings). In the following, the first is indicated as  $d_y$  while the second as  $d_u$ . The performance thresholds associated to the considered limit states are shown in Table 1. Concerning piers, a cross-sectional analysis is performed to evaluate yielding and ultimate curvatures from which the relevant displacement thresholds are computed according to the static scheme of the piers.

Limit State	Link bars $\epsilon_{\text{bar}} [-]$	Piers $u_p [m]$		Bearings $u_b [m]$
		H/D = 3	H/D = 7	
Yielding/Damage ( $d_y$ )	0.0046	0.027	0.152	0.045
Collapse ( $d_u$ )	0.0400	0.111	0.405	0.200

Table 1: Performance levels and related demand threshold values for the bridge components.

## 5 RESULTS

Results are shown in terms of fragility curves. For each investigated component, charts on the left illustrate the structural response for the case with short piers, while charts on the right pertain to the bridge with tall piers. Black curves refer to the damage limit state  $d_y$ , while red curves to the collapse  $d_u$ . Moreover, the label “Bridge Joint” is used in this case to indicate the pier position (Figure 4). Figure 5 compares fragility curves for pier displacements. It is evident that the vulnerability of vertical elements changes between the two structural models and diminishes with the pier height. Piers never reach the collapse limit state; however, short piers present a sensibly higher vulnerability at damaging than tall ones. For H/D = 3, piers 1 and 3 present a similar vulnerability while in the central pier damage occurs at lower *IMs*, that is related to the 1<sup>st</sup> natural vibration mode in the transverse direction, which significantly involves the middle pier. This phenomenon is less evident in the case of long piers. Differences between pier n. 2 and 3 can be attributed to the different capacity of the kinematic links, offered by the link bars on the slab: indeed, the number of link bars on the superstructure changes and influence the pier response. Overall, as the link bars increase in number, the pier demand in terms of displacement decreases (i.e. a higher *IM* is needed to induce damage). In both structural models, pier n. 4 never experiences damage: the phenomenon can be reasonably attributed to the presence of the fixed abutment on the right.

Concerning the link bars, it is possible to notice from Figure 6 that effects of the change of the pier height are slight on the strain at limit state  $d_y$  while much more evident at collapse  $d_u$ . This is particularly evident for joints n. 1 and 2, where the number of bars is minimum, and joint 4. In both configurations, joint n. 2 presents the highest vulnerability, due to the low number of bars and the central position. Due to the fixed abutment on the right, the vulnerability of joint n. 4 is higher than that of joint n. 3. Above results can be explained since the demand in the links due to longitudinal actions (for which they are designed) is sensibly different from the demand due to transverse excitation. For link bars, both damage and collapse

limit states can be reached, denoting the fundamental role of the superstructure response on the definition of an overall behaviour for the bridge. Moreover, it is evident that links are the weakest components of the structural system at both damage and (excepting for bearing n. 1) collapse limit states.

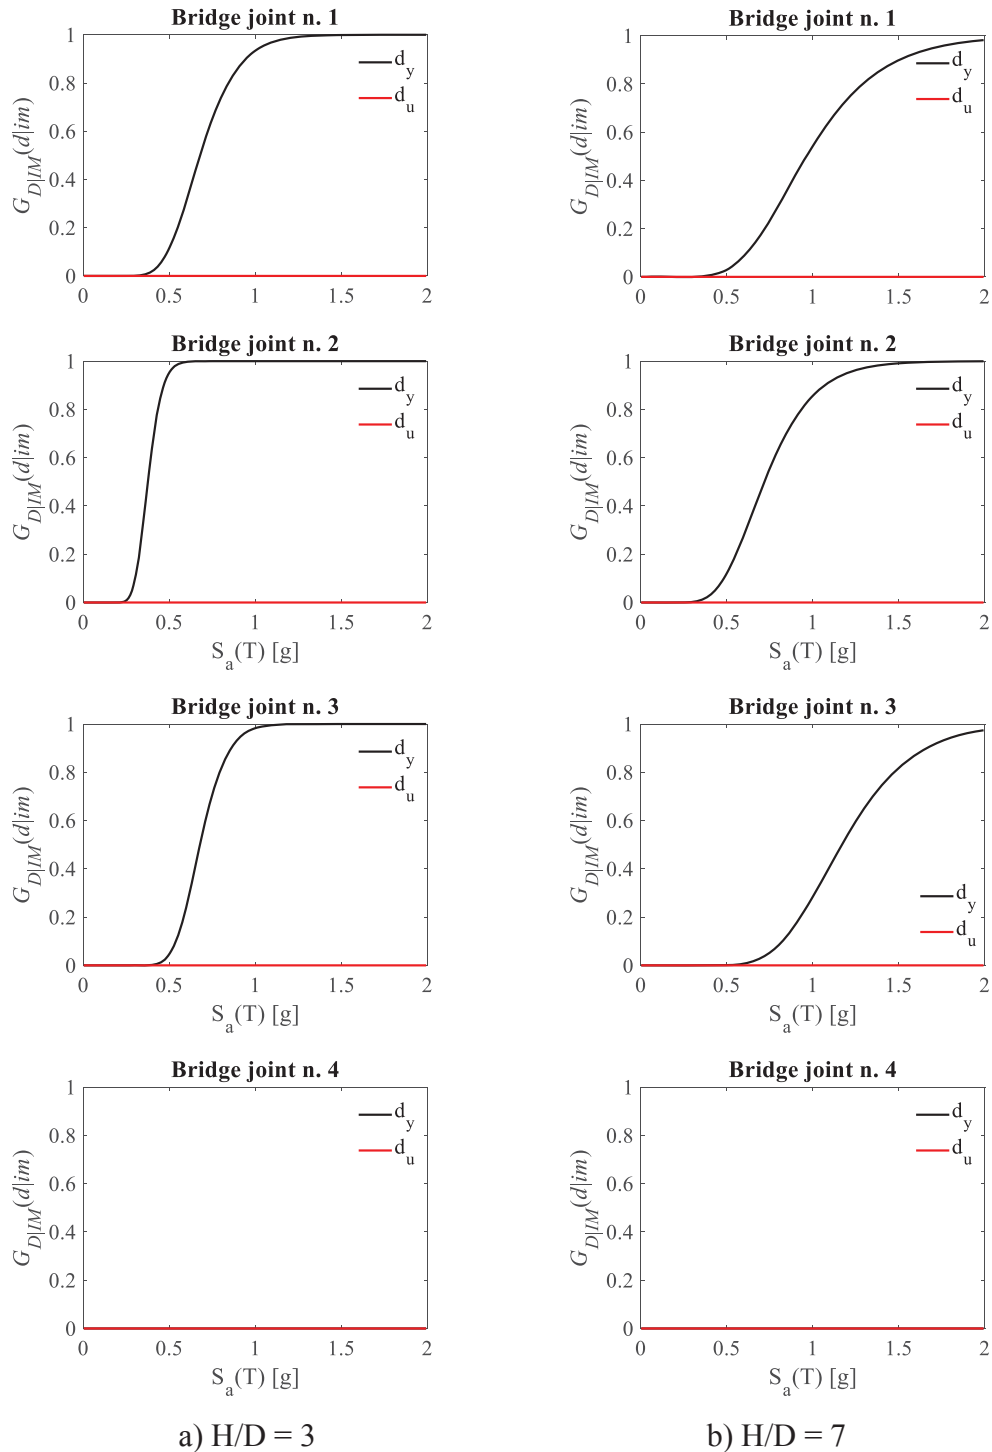

Figure 5: Fragility curves for pier displacements: (a) short piers and (b) tall piers.

Finally, Figure 7 shows fragility curves for bearing displacements. This EDP reveals as the most influenced by the  $H/D$  ratio. For short piers, a higher vulnerability of bearings is obtained. It is worth noticing that, similarly to the behaviour of piers, bearings of joint n. 4 never

collapse since the restraint provided by the fixed abutment influences prevent excessive displacements. The influence of the link disposition can be found on the different response of bearings on joints n. 2 and 3; in detail, bearings at joint n. 2, where the number of bars is the lowest, are more vulnerable than bearings at joint n. 3.

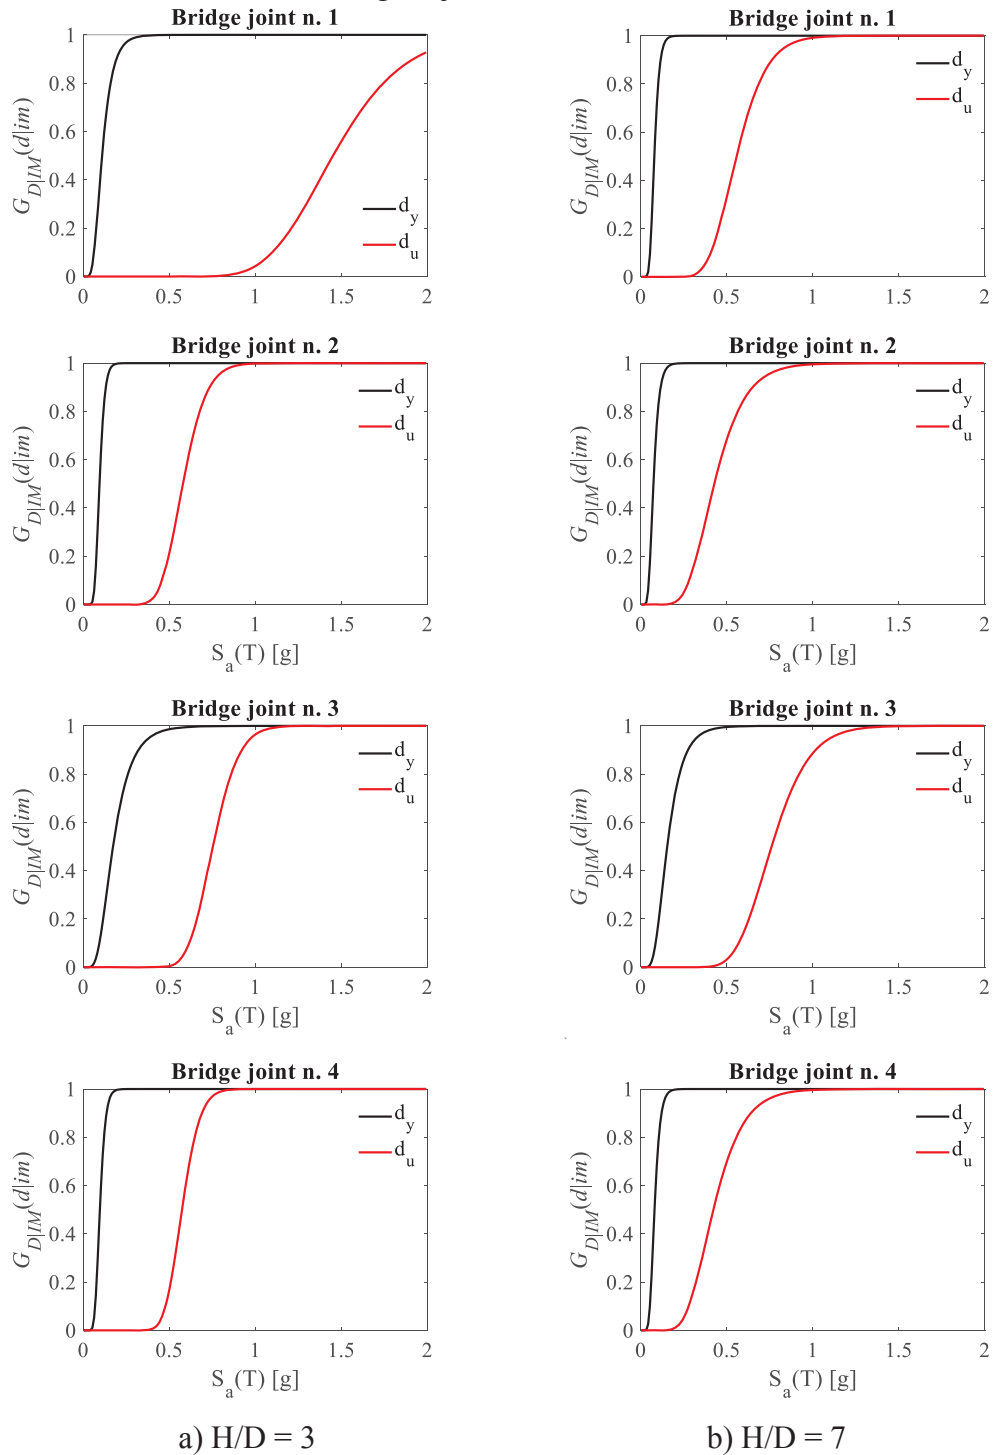

Figure 6: Fragility curves for link bar strain: (a) short piers and (b) tall piers.

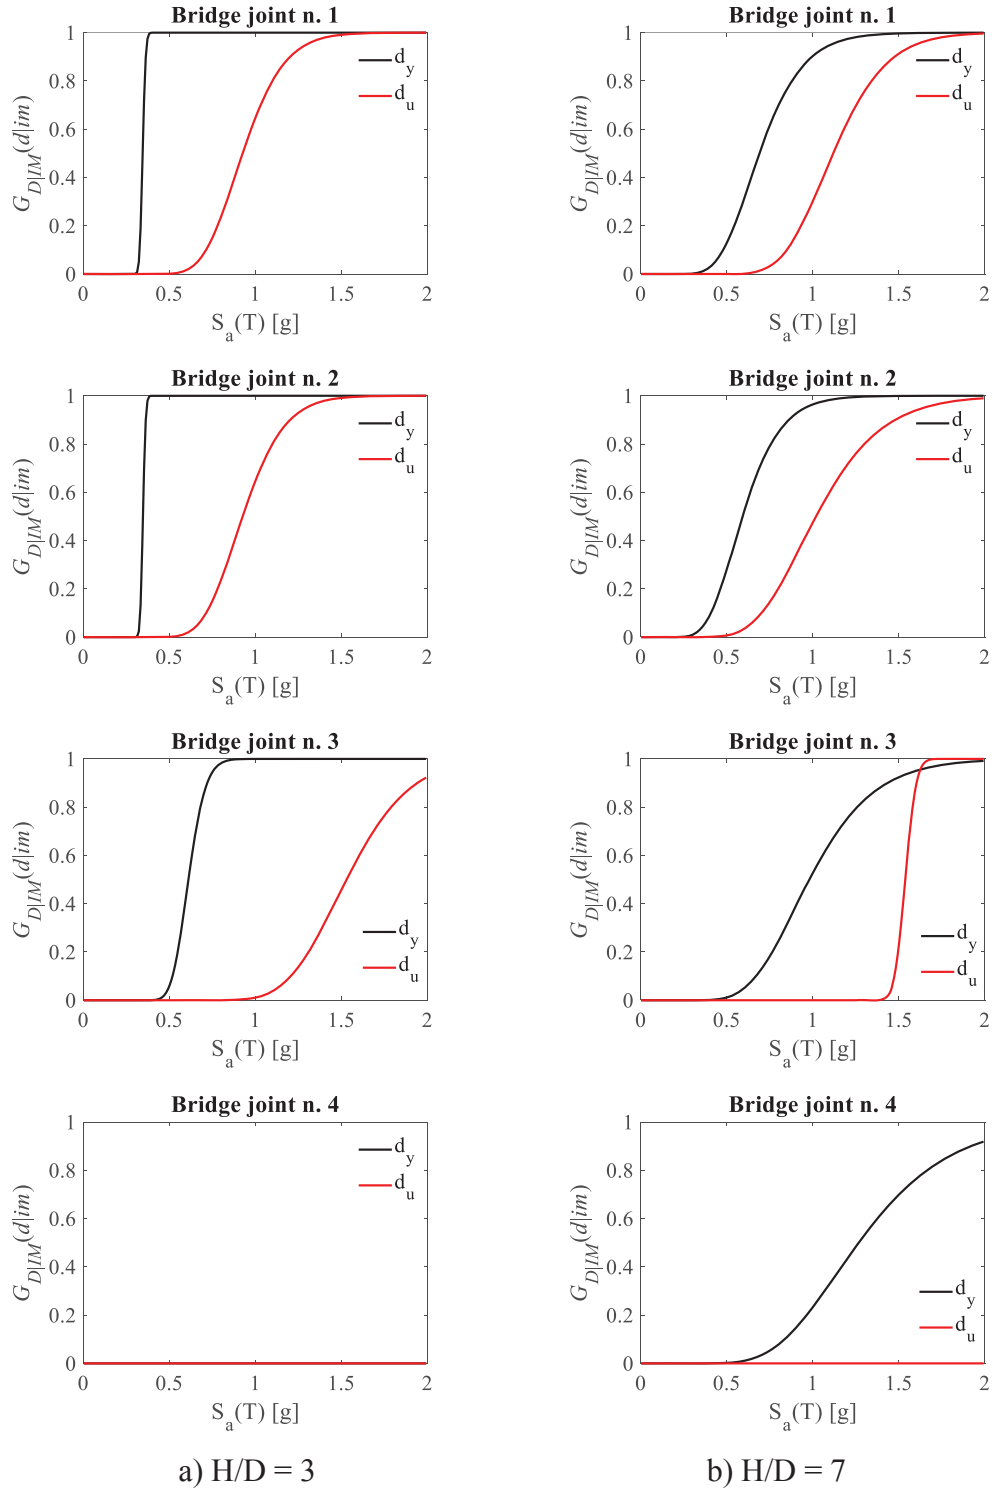

Figure 7: Fragility curves for bearing displacements: (a) short piers and (b) tall piers.

Overall, it should be remarked that a detailed comparison of results between the two different case studies is tough due to their intrinsic different dynamic response to the seismic excitation promoted by the different fundamental periods of the two structural systems. However, results highlight that the seismic vulnerability of links and bearings of LS RC bridges deserves attention. Further data analysis will be carried out to provide a more effec-

tive insight into the effects of the piers' height on the overall bridge typology response through a wider range of the H/D ratio.

## 6 CONCLUSIONS

A first insight into the fragility assessment of LS RC bridges, which is a widespread typology on the Italian national territory, has been investigated in this paper, starting from two representative case studies of the bridge typology. A robust and versatile probabilistic framework based on the use of the multiple stripe analysis tool is adopted to perform seismic analyses. The typical vulnerabilities of the considered structural typology are investigated through three fundamental engineering demand parameters, involving both the superstructure and the supporting structures, such as piers and bearings. Case studies, representative of the typology at hand, are selected to investigate the significance of the damage mechanisms in case of both short and long piers. Detailed numerical models are developed to capture the main vulnerability mechanisms potentially taking place at earthquake occurrence. Results are shown as fragility curves considering two main limit states associated to damage and collapse condition of piers, kinematic links and bearings.

It is possible to conclude that the investigated existing bridge typology may suffer different types of local failures and these affects in a complex way the global structural response and the consequent damage scenario expected for a strong earthquake. Results highlight that the vulnerability of links and bearings of LS RC bridges deserve attention in seismic analysis. In particular, the distribution of damage in the links is quite difficult to predict since they are usually design with only reference to longitudinal actions, which provides a demand distribution sensibly different of that induced by transverse excitations. Further studies on the fragility assessment of LS bridges will be necessary to provide an overall view on the vulnerability of the bridge class at hand and to address the role of the geometric parameters, such as the here investigated H/D ratio, on the overall behaviour of the bridge, as well as on the significance of each damage mechanism.

The approach adopted in this paper for the fragility estimation allows to separately analyse the vulnerability of the different bridge components at the limit states of interest, as a classical strategy in the scientific literature. However, current studies by the authors aim to develop a more detailed procedure for the fragility assessment, concerning the quantification of the damage extension and the evolution of the failure mechanisms within the bridge structure, as fundamental information for a proper and detailed quantification of consequences and costs associated to the seismic risk. The novel procedure can be applied to different bridges configurations or typologies, and also reveals sufficiently general for the analysis of various bridge components and the associated possible failure mechanisms.

### Abstract

*In this paper, the results of the performance-based earthquake engineering (PBEE) analysis, carried out to assess the seismic behaviour of short-medium span steel-concrete composite I-girder bridges, are presented and discussed. The selected case study is part of a group of bridges analysed within the SEQBRI project, funded in 2012 by the European Union, which deals with a systematic development of the PBEE analysis for short-medium span steel-concrete composite I-girder bridges. In this respect, fragility and damage analysis of the selected bridge are performed using a proper component-based numerical model along with wide experimental campaign. These outcomes are then integrated in the decision-making analysis, where the selected decision variable is the repair cost ratio of the bridge. The results show the good performances of short medium span steel-concrete composite bridges, both for minor and major damage scenarios.*

## 1 INTRODUCTION

Nowadays, short-medium span steel-concrete composite I-girder bridges (SCC) made of hot rolled steel beams are very popular, owing to their short construction time and reduced costs. Moreover, they are very adequate for seismic areas for their limited weight. These bridges can be easily designed for static loading, according to Eurocode 4, [1]; however, the effects of seismic loading has not been yet adequately investigated, and thus, they may exhibit damages even in low-seismicity zones.

In general, steel-concrete composite bridges with hot rolled sections for small and medium spans, (range between 25-40 m), exhibit several advantages in terms of: small total depth of composite section, no pre-stressing in concrete slab, low dead weight and limited foundations and settlements of supports, simple erection methods. The SEQBRI project, funded in 2012 by the European Union and conceived on these premises, deals with a systematic development of the Performance-Based Earthquake Engineering, [2], for short-medium span steel-concrete composite I-girder bridges that includes seismic input randomness, demand and damage analysis as well as economic cost-benefit estimations, [3]. In particular, a new type of connection between steel girder and piers that use a transverse concrete cross beam (CCB) is taken into account. The steelwork parts of the composite beams are prepared in factory and equipped with steel elements for connections (plates, holes, welded studs...). The steel girders are placed on the head of the piers without any propping; subsequently, the slab is concreted and the continuity of the composite beam is completed by concreting the beam joints and the transverse beams over the pier. This kind of joint has been studied in the past but only for static load conditions, [4-5]. In this paper, the results of the performance-based earthquake engineering (PBEE) analysis, carried out to assess the seismic performance of short-medium span steel-concrete composite I-girder bridges, are presented and discussed. The selected case study is part of a group of bridges analysed within the SEQBRI project, [3]. In this respect, fragility and damage analysis of the selected bridge are performed based on a proper component-based numerical model and a wide experimental campaign, [6-7]. These outcomes are then integrated in the decision making analysis, where the selected decision variable is the repair cost ratio of the bridge.

## 2 DESCRIPTION OF THE CASE STUDY

The analyzed case study is a straight 2-span deck consisting of 4 main girders HE600B of S460 steel grade with 2.65m in-between distance (Figure1). The bridge is 40.00 m long and consists of 2 spans; the total width of the road cross-section is 10.60 m, with carriageway 6.50 m wide and 2 sidewalks 2.05 m wide. The thickness of the concrete slab is equal to 25 cm. At the abutments, the steel girders are fixed to an end reinforced concrete crossbeam 0.60 m wide. The deck is simply supported on normal damping rubber bearings.

At the intermediate pier, the steel girders are fixed to an intermediate reinforced concrete crossbeam 0.90 m wide (Figure2). A wall type pier 0.60 m thick and 7.00 m wide is used. It is assumed that the foundation soil is categorized as type B according to EN1998. In this example, the SSI effect is neglected.

Different types of CCB configurations have been applied in several occasions, [8]. Many of them are variants of the configurations included in the standard DIN-FB-104, [9]. These configurations are proposed in order to manage mainly vertical dead and live loads, which produce negative moments at supports. For bridges subjected to seismic actions, significant tensile forces might be exhibited also at the bottom flange of the steel girder, especially when monolithic connection between CCB and pier is formed. Because of the CCB configuration is the most crucial detail, in order to identify the better solution for applicability in seismic prone areas, within the SEQBRI project the DIN FB variant C of the CCB has been chosen to be

analytically and experimentally investigated. Moreover, two new variants, based on the DIN FB variant B, have been designed and investigated.

Figure 1. Longitudinal section and cross section at span for selected case study

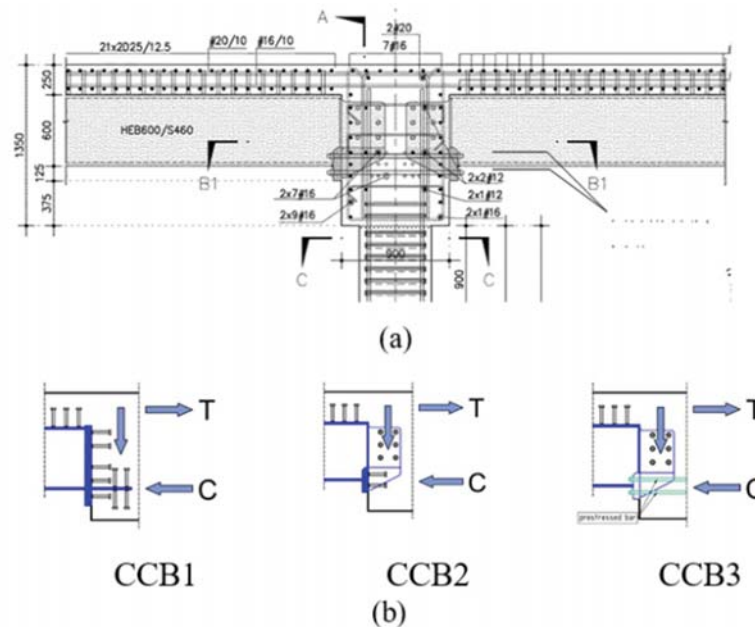

Figure 2. (a) Pier-Deck joint with Concrete Cross Beam, (b) Static behavior of Pier-to-deck Joints

The idea is to transfer the forces from the composite girder to the CCB through contact and dedicated groups of shear studs. For this reason, in the new configurations, the steel flanges are not inserted into the CCB and the height of the head plate is limited (Figure 2). A broad

description of these typologies and of the experimental tests can be found in Abbiati et al., [6] and Paolacci et al., [7]. In what follows the vulnerability of the selected bridge with CCB3 (see Figure 2b) is analyzed in the framework of PBEE. In this kind of CCB, the tensile force at the top flange is transferred gradually to the longitudinal reinforcement (or reversely a potential compression force to the concrete slab) through a group of vertical studs, which are placed on the top flange of the girder before the CCB. The shear force is transferred to the CCB through a group of horizontal studs, transversally placed at the sides of the girder's web, which is inserted into the CCB. These studs are subjected only to pure shear, action that is compatible to their actual function. The tensile stress at the bottom flange of the steel girder is transferred through anchor bars inserted throughout holes present in the web. The bars are tensioned after hardening of concrete and imposition of dead loads and are not bounded. The duct of each anchor should be filled with grease, in order to offer the opportunity for inspection, re-tension or even replacement in case of extreme seismic events.

### 3 NUMERICAL MODELING OF CONCRETE CROSS BEAM –STEEL GIRDER CONNECTION

A component based mechanical model of the CCB3 connection was developed in the code OpeSEES, [10]. This model (Figure 3) was used to analytically reproduce the experimental tests executed on I-girder subassemblies of the bridge. In [7] the results of the test campaign are presented and discussed. The aim was the definition of a refined model that faithfully approximates the real behavior of the sample and that allows the extension of the model to several cases.

Nonlinearities have been explicitly considered in the steel girders, concrete slab, pier, shear headed studs of the CCB, shear headed studs between girder and slab. Steel girder and concrete slab have been modeled using nonlinear beam elements with fiber sections. The steel girder and the slab have been connected by elastic beam elements with high stiffness; whereas, the shear and axial behavior of the vertical connecting studs has been modeled using nonlinear links with elasto-plastic behaviour.

Figure 3. Numerical model of the pier-deck joint with Concrete Cross Beam

Fig. 4 – Experimental setup

Strength of the single shear stud  $Q_u$  has been calculated according to CEN 1994, [1], while the related stiffness has been evaluated by mean of the shear load-slip curves (Q-s) defined in [11]:

$$\frac{Q}{Q_u} = \alpha \sqrt{1 - e^{-\beta s}} + \gamma s \quad (1)$$

with  $\alpha = 0.97$ ,  $\beta = 1.3$ ,  $\gamma = 0.0045 \text{ mm}^{-1}$ .

The vertical head plates welded on the steel girders and directly in contact with the transverse concrete beam have been modeled by rigid links. The CCB have been modeled by elastic beam elements with vertical axis. Nonlinearities in the CCB were considered by modeling shear studs and prestressing bars separately. Moreover, in order to reproduce the constraint in compression due to the presence of the concrete crossbeam, four compression gap elements have been used both at left and right sides of the CCB joints at two different levels, as shown in Figure 3, [12]. A simplified evaluation of the stiffness of the gap has been performed, assuming that the compressive force coming from the girder would act uniformly on a surface equal to the area of the vertical head-plate.

Figure 5. Numerical and experimental hysteretic response

Studs welded in the transverse direction on the web plate entering the CCB are simulated with nonlinear links in the vertical and horizontal direction. Each link simulates the effect of  $\phi 25$  mm shear studs. Their strength and stiffness has been calculated as for the studs in the slab. The two levels of pretension bars (Dywidag type) in the bottom area of the CCB, have been modeled by two elastic truss elements.

The 2-D FE model for concrete cross beam is shown in the following figure. This model has been validated through a wide experimental campaign. The setup of a test and a numerical/experimental comparison of the hysteretic force-displacement cycle are illustrated, respectively, in Figure 4 and in Figure 5.

#### 4 SEISMIC INPUT SELECTION

A group of 14 accelerograms has been selected from the PEER ground motion database in order to best approximate the Eurocode8 type 1 Response Spectrum, [13]. A set of records have been picked out from the database according to the following hazard parameters: magnitude range  $M_w = 5.8-7.0$ , distance from the fault rupture comprised in a range 15-40 km and local soil type B. Successive-ly, 14 records have been selected among these so that their mean spectrum best approximate the target spectrum. A scaling factor has been applied to each input signal in order to minimize the dispersion of the mean spectra compared to the Eurocode spectrum. The scaling factor modifies the original record only in amplitude.

#### 5 PROBABILISTIC SEISMIC DEMAND ANALYSIS OF CASE STUDIES

The author's name should include first name, middle initial and surname. It should be written centered, in 12pt boldface Roman, 12pt below the title.

In the perspective of a Cost-Effective Risk Analysis, as the final goal of the application of the PBEE procedure, the elements (structural or finishing) whose damage and repairing item could be significant must be identified. Accordingly, the damage mechanisms and the Engineering Demand Parameters (EDP) through which they can be quantified by a numerical structural analysis must be defined. The selected EDPs for the chosen representative case study are listed hereafter, according to the classification of Mackie and Stojadinovic [14], and Tubaldi et al. [15]:

1. Global EDPs:
  - Pier drift top displacement of the pier normalized with respect to the total height.
2. Intermediate EDPs
  - Bending moment-curvature ( $M_{max}, \chi_{max}$ ) of the pier at the bottom section.
  - Bending moment-rotation of the CCB connection.
3. Local EDPs
  - Maximum force and relative displacement of shear studs in the CCB in the horizontal direction.

The bending moment and the curvature of the CCB connection have been obtained for both the left and right sides of the joint. The bending moment of the composite section just before the side of interest, has been defined as follows:

$$M_{max} = M_{slab} + M_{girder} + \Delta N \cdot z \quad (2)$$

where  $M_{slab}$  is the bending moment of the slab,  $M_{girder}$  the bending moment of the girder,  $\Delta N$  the axial force in the slab and  $z$  the level arm (distance between girder and slab). The rotation of one side of the joint is given by the rotation of the vertical end plate with respect to the undeformed configuration.

Incremental dynamic analyses have been performed, [16], and multi-record IDA curves of the structural response quantities mentioned above have been built. Since the properties of the seismic response depend on the intensity of the ground shaking, a comprehensive assessment requires numerous nonlinear dynamic analyses at various levels of intensity in order to represent different possible earthquake scenarios. The selected scan of PGA is in the range (0.1g - 2.0g). The multi-record IDA response of the pier drift, obtained as mean value of the multi-record IDA, is shown in Figure 7. The mean value of the drift ratio for a PGA of 2.0g is about 7%. The typical collapse ratio of 4%, [17], is reached around 1.2g of PGA. For a PGA of 0.3g, which corresponds to the PGA of response spectrum type 1 (soil B) chosen for the design of the bridge, the drift ratio is about 1.0%. Analyzing the moment-curvature relationship, not shown here for brevity, it can be noticed the nonlinear behaviour of the section at the base of the pier.

Figure 7. IDA-Drift ratio of the pier

Figure 8. Bending moment-Rotation (mean values) of CCB left side

Pier yields at its base for earthquakes characterized by PGA of 0.4g while plastic hinge develops for stronger seismic actions. Ultimate value is obtained between 1.2 g and 1.4 g.

In Figure 8 the bending moment-rotation relationship (mean value) of CCB at left side, that is the maximum absolute bending moment versus the corresponding rotation of left side of the joint, is shown. It can be noticed that the onset of nonlinear behaviour takes place "after" the yielding of the pier, or rather for higher values of PGA (0.8-0.9 g). Representative force-slip curves of the CCB shear studs, not shown here for brevity, showed that, when the lower group begins to yield, around 0.5g, the upper levels of connectors are subject to smaller levels of stress. In particular, 1st group is still in the elastic range. The bigger deformations of the last line of studs are in agreement with the fact that during the seismic action the neutral axis in the CCB is closer to the first rows of connectors. In conclusion, for events with a PGA of 0.3g or under, the critical part is the pier only with the formation of a plastic hinge at its base while the concrete crossbeam does not seem to be affected by any relevant damage. First level of damage within the intermediate CCB starts to arise from 0.5-0.6g, value of PGA for which the lower group of studs within the CCB yield.

## 6 DAMAGE ANALYSIS AND FRAGILITY CURVES

In order to implement performance-based earthquake engineering method for the representative case of small-medium span composite bridge and investigate its vulnerability, it has been necessary to accurately assess the probability of reaching particular levels of damage. For this purpose, a correlation process between the most representative engineering demand parameters and damage measures has been made. Piers are often the most vulnerable elements in a bridge

and column failure can have catastrophic consequences. Excessive deformations can result in spalling of cover concrete, buckling of longitudinal reinforcement or bar fracture. Concrete cover spalling represents the first flexural damage state, in which there are marginal safety implications, there may be a possible short-term loss of function, and the cost to repair concrete spalling could be significant. Buckling and fracture of the longitudinal bars represent damage states in which safety implications are significant, partial replacement may be required, and a longer term loss of function may occur. In order to quantitatively implement PBEE for the considered reinforced wall-type pier, in this work the three damage conditions above mentioned have been considered as damage measures. The equations proposed by Berry and Eberhard, [18], for damage estimation have been used to relate the pier EDP and DS. Assuming that the DS occur in sequence (with DS1 preceding DS2 which, in turn, precedes DS3 and so on), the corresponding EDP can be ordered ( $EDP_1 \leq EDP_2 \leq EDP_3 \leq \dots$ ). Assuming, as an example, three DS, the joint probability density function of the variables  $EDP_1 \leq EDP_2 \leq EDP_3$  can be assumed as follows:

$$p_{EDP_1, EDP_2, EDP_3}(EDP_1, EDP_2, EDP_3) = \begin{cases} \frac{1}{k} p_L(EDP_1, EDP_2, EDP_3) & \text{if } EDP_1, EDP_2, EDP_3 \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

where  $p_{EDP_1, EDP_2, EDP_3}(\cdot)$  is a joint lognormal distribution function of three random variables. The constant  $k$  in the previous equation is a normalization constant. A more detailed explanation of the previous equation can be found in Alessandri et al., [19]. Figure 9 shows the four probabilities of the DS conditioned to the EDP evaluated for the pier. The correlation between the DS has been considered and the Damage States were assumed to occur in sequence (with concrete spalling preceding bar buckling, which, in turn, precedes bar fracture). For the shear headed studs of the beam-to-beam concrete connection, two levels of damage have been considered. In particular, first level of damage is the yielding of the studs, assumed as the last point of their elastic behaviour in the elasto-plastic constitutive law chosen in the model. The second level of damage corresponds to the complete rupture of the stud, taken from the research work of Gattesco and Giuriani, [11]. The rupture of a shear headed stud, monotonically loaded, takes place for a horizontal slip of 9.7 mm. By assuming that the EDP is log-normally distributed, the probability of damage conditioned to the IM,  $P(DS|IM)$ , known as fragility function, is evaluated by the convolution of the  $P(DS|EDP)$  and  $P(EDP|IM)$ :

$$Pr(DS|im) = \int_{EDP} Pr(DS|EDP) dG(EDP|IM) dEDP \quad (4)$$

The DS0 in the figure corresponds to a negligible damage for which no repair items is considered. As shown in Figure 10, the probability of having cover spalling is over 15% for 0.3g of PGA. It grows then very fast, reaching 80% at 0.75g, then reduces because of bar buckling and bar fracture become more probable. The probability of having bar buckling is under 10% until 0.8g and reaches 30% at 2g. The risk of bar fracture seems to arise only for strongest seismic inputs. The probability of fracture of the reinforcement is under 10% until 0.8g, it is almost 30% for 1.6g and reaches 35% for 2.0g. Figure 10 show the fragility function evaluated for the pier base.

Figure 10. Fragility functions for the pier base

## 7 COST-EFFECTIVE RISK ANALYSIS

Cost-effective risk evaluation is the very last step of the global integrated probabilistic performance-based evaluation procedure used for SEQBRI project. The result of this phase is a decision model, which is based on Decision Variables (DV) pertaining to the use of a structure given a level of sustained damage. Decision models are mathematical relations between damage measures (DMs) and decision variables (DVs). Commonly used decision variables describe losses in terms of repair cost, interruption in service (downtime or repair time), or loss of life: thus, decision models are also called loss models. The decision model may have several parts those that relate DMs to repair quantities (Q) and those that relate Q back to repair cost or repair time. A completely different set of decision variables focuses on the remaining capacity of the structure to function as intended. For example, the return of a highway bridge to differing degrees of functionality in a highway network is also an important loss criterion. Functionality may be measured in terms of lateral load resistance in aftershocks, traffic volume, lane and speed reductions, or access for emergency vehicles. The main DV here adopted is the repair/construction cost ratio (Direct cost). This choice comes from the goal to provide an immediate economic measure of earthquake performance of the assessed structure. Indirect costs like downtimes are not explicitly considered in the analysis. Global earthquake demand is defined in terms of peak ground acceleration (PGA), which represents the most commonly used intensity measure for structural seismic analysis and design issues. Local engineering demand parameters (EDP) consist in variables related to structural elements deformation or load, such as pier drift or bending moments. Damage states are expressed in terms of EDP limit values and associated damage or repair amounts expressed in terms of percentage of structural quantities (concrete cracking surface and/or volume, percentage of broken or yielded reinforcement rebars, percentage of broken studs or rotation angle for example for what concerns CCB). At the end, the ultimate goal is to evaluate the cumulative probability distribution function of the decision variables DV (cost and/or repair duration), as expressed by the PBEE framework Integral defined by Equation (4):

$$\lambda(DV < dv) = \int_{IM} \int_{DM} \int_{EDP} G(DV|DM) dG(DM|EDP) dG(EDP|IM) |d\lambda(IM)| \quad (5)$$

where  $G(\cdot)$  represents the complementary cumulative distribution function of the considered variables.

Most of those different successive analysis parameters and intermediate outcomes, result from the previous tasks, including numerical non-linear analysis and experimental evaluations. At each steps, results are addressed in terms of probabilistic quantities such as mean values,

deviation or probability of exceedance (see previous paragraphs). Repair costs and duration databases are collected from different former projects, US and French repair data, [3]. Additional (but rather sparse) data are also collected from road/bridges maintenance services concerning European recent « real field » seismic events such as Aquila earthquake. Analysis preferentially focuses on direct costs related to structural damages, since indirect costs appears to be very depending on the context (country, location, proximity of big cities, economical/industrial activities, toll-roads) and are not directly related to SEQBRI project bridge typology and specificity (SCC bridges with CCB).

### 7.1 Direct losses evaluation

Direct cost evaluation is essentially based on repair quantities evaluated for different parts or elements of the structure for a given intensity measure or damage scenario and on associated unit repair costs. Repair cost estimation (and loss modeling in general) is almost always a structural system problem, not simply determined at the component level. Therefore, it is often necessary to combine (sum) numerous scalar values in order to obtain, for example, a total cost. For this matter, the bridge system is disaggregated into individual components or ensembles, such as the columns or CCB, denoted as performance groups (PGs) that are damaged, assessed, and repaired together using a specific combination of different repair methods. Each of those performance groups is also sub-divided into individual elements or sub-PGs.

### 7.2 Performance Groups

Different damage-states (DS) are defined for each performance group. The tested case-study is thus broken down into performance groups (PGs) for each major bridge component. Each performance group represents a collection of structural components that act as a global-level indicator of structural performance and that contribute significantly to repair-level decisions. Performance groups are not necessarily the same as load resisting structural components. For example, non-structural components may also be a performance group, since they also suffer damage and contribute to repair costs. The PGs generally correspond to things that are observable as a unit. Grouping bridge components into performance groups allows for more meaningful damage assessment than grouping by component. The definition of the PGs used for the SCC bridges with CCB corresponds to the following structure disaggregation. Four performance groups have been defined for this study (foundations are excluded):

- PG1: Pier (bottom)
- PG2: Pier (top)
- PG3: Concrete Cross beams
- PG4: Deck: including concrete slab, steel girders and superstructures/equipment.

### 7.3 Damage States and associated repair methods and quantities

Each damage state corresponds to only one repair method. Selection of repair methods is a crucial step in computing the repair-related decision variable, repair cost ratios and repair time. A selection of repair methods specific for the damage states has been made based on Caltrans database, [13], of typical repair techniques, since it has been defined to be generalizable and usable for performance-based evaluation of other structures. Each performance group contains a number of discrete damage states (DS) corresponding to repair quantities needed for restoring the bridge. The damage states are numbered from DS0 to DS3 with higher numbers indicating more severe damage. The DS0 damage state corresponds to the onset of damage when repair costs begin to accumulate. For analysis, the repair cost of the bridge is treated as 0 € below the

DS0 level of damage. Damage beyond DS0 are needed to be repaired and costs begin to accumulate. Slight damage less than DS0 is assumed to be insignificant and not needing repair. Damage computation requires the definition of maximum possible repair quantities to define an upper limit to the quantities and costs. The upper limit is called DS3, since it corresponds to the most severe possible damage state for the elements in a performance group. DS3 usually corresponds to complete failure and replacement of all elements in the entire performance group. Details on repair methods here adopted can be found in [3].

#### 7.4 Damage Scenario and loss analysis

To evaluate the expected repair cost of a structure as consequence of a seismic event in a given reference time period, one or more damage scenario must be defined. Its definition, which considers repairing items more or less large, reflects a level of the intensity measure (IM) of the ground motion at the site. Two damage scenarios have been defined; they are described in Table 1 and Table 2.

Table 1. Damage States (DS) for Minor scenario.

Performance Group	DS	Description
PG1 (Pier at base)	DS1	Seal cracks and minor removal and patching of concrete
PG2 (Pier at top)	DS0	----
PG3	DS1	Seal cracks and minor removal and patching of concrete
PG4	DS2	Seal cracks, clean deck and apply methacrylate

Table 2. Damage States (DS) for Minor scenario

Performance Group	DS	Description
PG1 (Pier at base)	DS2	Seal cracks, major patching
PG2 (Pier at top)	DS1	Seal cracks and minor removal and patching of concrete
PG3	DS2	Replacement of CCB
PG4	DS2	Seal cracks, clean deck and apply methacrylate

According to the methodology developed in ([3] and [13], once the scenario has been defined its average cost can be calculated by summing the costs of the repairing items associated to each PG. Figure 11 shows the repair-to-rebuild ratio for both minor and major scenarios. Figure 12 shows the cost disaggregated for PGs. From the results it clearly appears that PG1 (base of piers) contributes most to minor damage scenario expected cost at high value of the PGA, while peak contribution is from PG3 (cross beams) at lower values of PGA for the minor scenario and over the whole range of PGA for the major damage scenario.

Figure 11. Expected repair cost conditioned to IM for the selected scenarios.

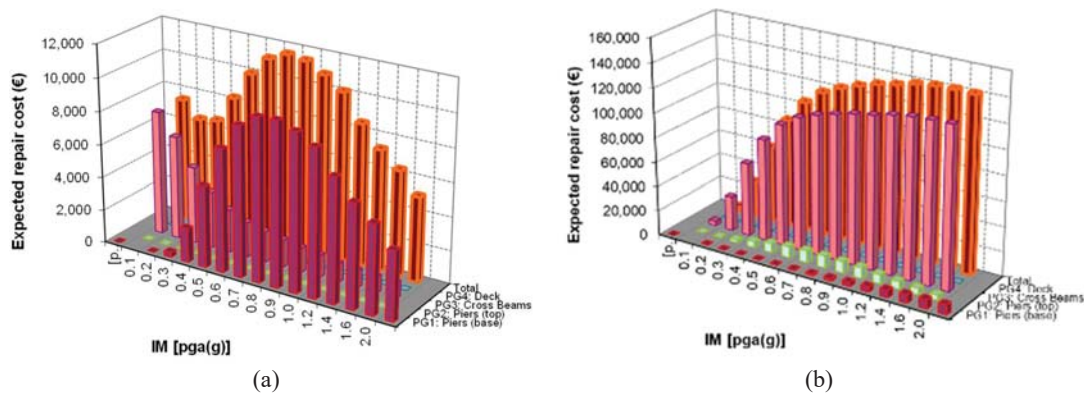

Figure 12. Disaggregation of the expected (a) minor and (b) major scenario repair cost by PG

From these curves it appears that the contribution for the minor damage scenario is mainly from epoxy inject cracks and repairing minor spalls, independently of earthquake intensity. For major damage scenario temporary support of the deck begins to rise rapidly as a contributing cost for higher intensities. It also can be noted that one repair quantity can dominate because several performance groups require that item. Figure 13 shows the probability of occurrence of the selected scenarios.

Figure 13. Probability of occurrence of the expected (a) minor and (b) major scenario

From the application of the methodology to the case study the following observations can be drawn:

- Significant probability of occurrence of the minor damage scenario are due to  $0.3g < \text{PGA} < 0.6g$ ;
- Significant probability of occurrence of the major damage scenario are due to  $\text{PGA} > 0.7g$ ;
- An overall expected repair ratio between 5-8% is obtained for the minor damage scenario and  $>20\%$  for  $\text{PGA} > 0.2g$  for major damage scenario;
- PG1, PG2 (pier) and PG3 (CCB) mainly govern the decision-making analysis given that their associated costs results particularly important. Therefore, any optimization action should act on these elements.

## 8 CONCLUSIONS

The SEQBRI project dealt with the full application of the next-generation Performance-Based Earth-quake Engineering methodology (PBEE) employed for the assessment of a new type of steel concrete composite (SSC) bridges endowed with a special pier-to-deck connection (Concrete Cross Beam).

The development of the PBEE framework for SCC bridges can be considered a novel contribution to the foundation of a new generation of earthquake engineering seismic codes for bridges in Europe. The results are novel. In particular, they entail:

- A better understanding of the seismic behaviour of SCC bridges with CCB;
- A reliable definition of limit states for this new type of bridges
- A proposal of a decision-making tool based on next-generation PBEE methodology for SCC bridges with CCB in moderate/strong seismic prone areas.
- A significant improvement of seismic design state-of-the-art of SCC bridges with CCB, through the development of design guidelines for improving Eurocodes for the assessment of bridges in seismic prone areas.

It is evident that the application of this complex framework can be totally justified only when important damage conditions are expected and for which the adoption of non-linear models and probabilistic analyses appear justifiable. Given the fact that small-medium SCC bridges with CCB exhibit in mean important damage conditions only for  $\text{PGA} > 0.25g$ , it appears reasonable to employ the PBEE methodology only for PGA values of  $0.35g$  or greater. These PGA values characterize the most active prone-areas in Europe. For lower PGA values the design approaches to be adopted can rely on current design approaches prescribed by Eurocodes, where partial safety factors cover aleatory uncertainties. In summary, no specific rules are provided by Euro-codes to design CCBs, so, the design procedure pro-posed in the SEQBRI project can be profitable used for this purpose.

## ACKNOWLEDGMENTS

The Present work is supported by the funds of the Euro-pean Project SEQBRI: “Performance-Based Earthquake Engineering Analysis of Short-Medium Span Steel-Concrete Composite Bridges”, Grant N° RFSR-CT-2012-00032. This project has partially received funding from the Italian Ministry of Education, University and Research (MIUR) in the frame of the Departments of Excellence (Grant L. 232/2016).

### Abstract

*The bridge was built in 14th century and had undergone very complex vicissitudes related mainly to exceptional floods; it was partially rebuilt twice and other strengthening works were carried out over the time. The bridge, which is almost completely built with travertine blocks, has a total length of 146 m and follows a slightly curved path. Six arches, the main of which is semi-circular with span of 25 m and the others are lancet arches with span of about 8 m, support the carriageway that is about 8 m wide. The piers and abutments are founded on the bedrock and consequently some piers are deeply embedded in the sandy gravel deposit. A 3D numerical Finite Element Model has been developed integrating data available from the geometric survey and calibrating the mechanical parameters starting from experimental tests. The global seismic vulnerability of the bridge has been evaluated comparing the capacity curves of the bridge obtained by means a static nonlinear pushover analysis with the Italian Standard seismic demand. In addition, local vulnerability verifications of spandrel walls have been carried out by means a linear kinematic analysis.*

## 1 INTRODUCTION

The presence of unreinforced masonry arch bridges in the Italian roads networks is very widespread and given that high seismic risk of some areas, it is very important for the public network authorities to evaluate their capacity.

Evaluation of the capacity of a historical masonry structure is a difficult task because of many uncertainties associated with the knowledge of the structure in its current conditions (original structure and structural changes due to repair enlargement and retrofit works, different construction systems and different materials, structural and material degradation and damages, soil and foundation modifications) and also due to modelling techniques complexity as well as to analysis methods. In this sense, after a deep historical analysis and a complete geometrical and structural survey, sophisticated measurement techniques are necessary to catch the real behaviour of the structure, especially the mechanical properties of the structural materials and the global dynamic behaviour.

Regarding the material survey, both traditional techniques and innovative methods are available but non destructive techniques are generally preferred when dealing with historic and valuable structures. Numerous procedures for the evaluation of the mechanical properties of structural materials have been proposed and the mapping of the building evolution or construction details that can be adopted even in cases where retrofitting interventions have been carried out. The dynamic tests, the subsequent structural identification and the updating of a numerical model of the structure to match the experimental results [1-3] is the most widely diffused approach. The experimental modal parameters evaluated starting from the dynamic tests, can then be used to update refined finite element models able to describe the real behaviour of structures, which can be required for structural verifications and for designing repair and retrofit works [4-6].

Regarding the modelling techniques, in the last decades several procedure was developed aimed to predict the behaviour to arch masonry bridges. The difficulty to describe the interaction between the filling material and the resistant masonry arch requires the use of a complex and effective structural model [7]. Generally methodologies, based on Limit Analysis [8-11] and non linear incremental techniques [12-15], are usually refer to bidimensional arches. Improved bidimensional models, which take into account the arch-fill interaction, were also developed [17-18]. In addition, three-dimensional FEM models [18-20] allow both a complete description of the bridge geometry and detailed constitutive models. Regarding the seismic assessment of masonry arch bridges, only a few studies are available today concern the procedure to evaluation of the safety of the bridge [21].

This paper presents the global seismic vulnerability of the SS. Filippo and Giacomo Bridge over the Tronto river at Ascoli Piceno, in the centre of Italy. The bridge was built in the XIV century and was then subjected to many changes for repair, strengthening, retrofit, and enlargement works. This results in a large complexity of the structural organism, due to interaction between parts of different age which are made of materials with different mechanical properties. Due to these uncertainties and considering the importance of the bridge an accurate analysis of its current conditions was deemed essential to obtain a reliable predictive finite element model to be used for the design of seismic retrofit. First of all a historic study and geometric survey of the bridge were developed. For the material properties in-situ tests, both destructive and non-destructive, were carried out, to evaluate the quality of the travertine block masonry. These information were used to develop a refined 3D finite element model that was tuned based on the experimental modal parameters; in particular, the Young's modulus of some materials initially defined according to standard values suggested by codes, was calibrated to fit the dynamic behaviour obtained experimentally. Starting from the calibrated

modal, the capacity curves of the bridge obtained by means a static nonlinear pushover analysis are evaluated considering the elastoplastic materials for the bridge and adopting the yield criterion of Mohr–Coulomb. The capacity is compared with the Italian Standard seismic demand, following the well known “N2 method” included in the European codes [22]. In addition, local vulnerability verifications of spandrel walls have been carried out by means a linear kinematic analysis.

## 2 “SS. FILIPPO AND GIACOMO” BRIDGE

“SS. Filippo and Giacomo” Bridge rises in the outskirts of Ascoli Piceno town crosses the Tronto River, and is built between two rock escarpments one of which is characterized by an important slope (Figure 1).

It has a total length of 146 m and maximum height over 20 m, and it is constituted by six arches. The main arch crosses the river during its regular flow and has a semicircular shape with span of about 25 m. The arch barrel has the minimum thickness of 0.90 m at the crown and increases up to 1.40 m at the imposts. The other five arches are lancet shaped with span of about 8 m. The depth of the fill at the crowns of arches is variable from about 6.0 to 7.5 m. The aspect of the present “SS. Filippo and Giacomo” Bridge derives from a complex sequence of events occurred over almost six hundred years life (Figure 2).

Figure 1: Aerial photogrammetric bridge view.

The former bridge, dating back to the second half of XIV century, was probably constituted by four semicircular arches. It was seriously damaged by a flood occurred in 1453 that produced the collapse of three arches at the right side, the bridge rebuilding started around 1464, rebuilding the collapsed section with lancet arches reducing spans with respect to the original arches.

A second exceptional flood, occurred in 1528, produced the collapse of the main arch survived to the previous event. This was rebuilt starting from 1545 by means of two parallel barrel-vaults: the vault placed downstream, about 3 m wide, has remained almost unchanged; the vault placed up-stream, with variable width, underwent an important vertical settlement (of about 0.4 m) and was finally rebuilt in 1667 by placing wooden and iron ties aimed at tightening together the two parts. In 1721, a new flood produced the collapse of a not well specified wall (probably a wing wall or a part of the abutment at the left riverbank).

A cutwater was realized to protect the main pier in 1794. The two arches sustained by the main pier were restored between 1835 and 1836. At the end of these works, two barrel-vaults

were built instead of reinstating the earth fill at the extrados of the main arch in order to facilitate the maintenance of the structure. The two vaults are sustained by the bridge spandrel walls.

Works to reduce the slope of the upper road were carried out between 1849 and 1850: the spandrel walls were raised placing an earth fill in between after having stabilized the system by means of transverse ties placed at two meters from the old top level. At the same time, the ending bend was modified placing side travertine corbels with variable span up to 1 m in order to widen the carriageway. Such corbels were then connected by brick arches having thickness of 0.30 m. A new order of internal lightening rooms was built over the main arch during this phase; the rooms are spaced as the external pensile arches so that the stone corbels are placed in the walls separating the rooms. Each room is vaulted orthogonally to the lower level previously realized.

Figure 2: Synopsys of historical vicissitudes.

## 2.1 Current geometrical configuration and crack pattern

The bridge rises between two rock escarpments produced by erosion of Tronto River (Figure 3). The left escarpment has a rather high slope ( $52^\circ$ ) whereas the right one is less sloping ( $31^\circ$ ). The gorge is characterized by a sandy gravel deposit on the right riverbank, with variable thickness up to 10 m, whereas the sandstone bedrock is outcropping at the left riverbank. Investigations carried out in correspondence of piers P1, P2 and P3 demonstrated that foundations are placed at the sandstone bedrock which is horizontal; despite other specific analyses were not carried out for the other piers (P4 and P5) there is no evidence (vertical settlements) that these are founded over the deposit; the sandy gravel deposit is thus placed around the pier but not under the foundation layer.

The bridge exhibits a crack pattern characterized by cracks with vertical orientation located at the mortar joints. Such cracks are located at the base section of piers P1, P2 and P3 (Figure 4) and may be attributed to stress states due to vertical loads associated to the settling of masonry that is widely characterized by deteriorated mortar joints.

Figure 3: Geological configuration and foundation level.

Figure 4. (a) crack pattern at the bottom of pier P1; (b) cracks of pier P3.

## 2.2 Geometrical and material survey

The range-based survey used to acquire geometrical/metric data was made by means of a 3D-TOF laser scanner technique. Both the external geometry and the geometry of the various internal vaulted rooms over the main arch, at the pier top and at the abutments, were surveyed. Wooden and steel ties, placed to avoid the spandrel wall overturning toward outside were also surveyed in the accessible zones. The acquired data-set was then processed to obtain a refined 3D geometrical model that was later used to generate a structural model with very precise geometry and rigorous mass distributions. Such a kind of survey revealed to be extremely useful in the case under consideration characterized by a very complex geometry.

## 3 TESTS ON MATERIALS

Materials were characterized by onsite tests namely two tests with single flat jacks and one test with double flat jacks. Three compression tests on travertine speci-mens sampled by means of masonry coring were also executed. Sampling and test locations are reported in Figure 5.

Masonry coring permitted to observe that the pier structure is characterized by an external curtain, having variable thickness and realized with Ascoli Piceno travertine squared blocks, and an important inter-nal, rather irregular, rubble stone infill characterized by the presence of water in the lower parts.

Compressive tests carried out on the three specimens gave scattered results with minimum strength  $16.9 \text{ N/mm}^2$ . The double flat jack test carried out at the base of pier P2 provided a linear behavior in the stress range investigated (up to about  $4 \text{ N/mm}^2$ ), characterized by Young's modulus of about  $6600 \text{ N/mm}^2$ . Single flat jack tests carried out at the base of piers P1 and P2 permitted the estimation of the stress state in the external masonry curtains. For pier P1 the stress state obtained is higher than for pier P2, as expected; in particular the normal vertical stress in P1 is about  $1.3 \text{ N/mm}^2$  while for pier P2 it is about  $0.5 \text{ N/mm}^2$ .

For what concerns the masonry of the interior vaulted rooms, tests were not carried out because from the inspection and the laser scanner survey it was evident that it is a good brick masonry. Never-theless, it is worth noticing that such components are not expected to give a significant contribution to the overall behavior of the structure excepting for the mass.

The two kinds of masonry constituting the bridge structure can be classified according to catalogs re-reported in design guidelines and standards. Italian Standards [23-24] provide the mechanical characteristic reported in Table 1.

Figure 5. Location of sampling and onsite tests

Masonry	E ( $\text{N/mm}^2$ )	G ( $\text{N/mm}^2$ )	w ( $\text{kN/m}^3$ )
Curtains of stone squared blocks with poor core	1680 2240	546 658	22
Bricks with lime mortar	1200 1800	400 600	18

Table 1. Mechanical characteristics deriving from on-site tests

In addition the modal parameters of the bridge, i.e. natural frequencies, damping ratios and mode shapes, are experimentally estimated by means of operational modal analysis starting from the accelerations of the deck recorded during ambient vibration measurements which are mainly due to traffic, wind and microtremors. Results obtained from this test was adopted to calibrate the elastic value of the materials used in the model.

#### 4 STRUCTURAL MODEL OF THE BRIDGE

The 3D Finite Element Model (FEM) intended for the structural analyses is developed in Straus7 [25] starting from the data available from the laser scanner survey. In order to avoid excessive refinement of the mesh due to details that do not actually affect the overall behavior of the bridge, the geometry was simplified. Part of the soil portion in the riverbed at the base of internal piers was included in the model, to take into account the particular geological formation and capture the soil-pier interaction phenomena. In addition, all internal rooms and the earth fill was considered in the model to capture the real stiffness and mass distribution in the structure (Figure 6a).

The finite element model is obtained with a mesh of 4-node tetrahedral elements with linear interpolation shape functions (Tetra4). The mesh is generated by importing a closed poly-surface constructed by approximating the geometry obtained with the laser scanner survey. Based on previous consideration, the geometry was simplified imposing the maximum length of the element edge of 1.0 m for the bridge structure, whereas it was increased up to 4.5 m for the elements belonging to the soil deposit (Figure 6b). Fixity restraints are placed at the deposit base and at the structure sections interacting with the sand stone formation. All the materials, including earth fills and the soil deposit, are considered to be linear elastic and isotropic.

Figure 6. (a) Geometrical model; (b) Finite element model.

The mechanical parameters of the finite element model were assumed elastic-plastic, considering the yield criterion of Mohr–Coulomb. Regarding the initial condition, elastic parameters are calibrated by fitting the experimental modal parameters with numerical ones relevant to the finite element model previously discussed. Regarding the soil parameters, they are derived from geotechnical in situ tests, while the infill materials are hypothesized based on construction techniques.

Materials	E (N/mm <sup>2</sup> )	G (N/mm <sup>2</sup> )	w (kN/m <sup>3</sup> )	c (N/mm <sup>2</sup> )	φ [°]
Travertine masonry	7000	2414	22	0.256	76.0
Brick masonry	1282	427	18	0.214	72.0
Earth infill material	666	238	18	0.010	42.5
Base soil deposit	666	243	19	0.010	32.0

Table 4. Mechanical parameters considered in the analyses

## 5 SEISMIC DEMAND

The area where the bridge is located falls within an area of medium seismic hazard. According to the seismic Italian Standard Code [23-24], in Figure 7a is reported the seismic hazard curve at the arch bridge site in terms of Peak Ground Acceleration (PGA)  $a_g$ , varying the return period  $T_R$ . Considering the  $T_R$  equal to 475 years, the PGA assume the value of  $a_g = 0.178g$ . For the site effect, a subsoil category B been assumed for the subsoil condition and category  $T_2$  regarding the topographic condition. In Figure 7b is reported the corresponding elastic response spectrum considering for the site considered in the following analyses.

Figure 7. (a) Seismic hazard curve at the arch bridge site; (b) Elastic response spectrum

## 6 EVALUATIO OF THE SEISMIC CAPACITY

### 6.1 Non linear static analysis

The assessment of the capacity of the masonry arch bridge is evaluated following the methods included in the European codes, based on the N2 method [26], that combines the non-linear static analysis of the multi-degree of freedom model with the response spectrum analysis of an equivalent single degree of freedom system.

Capacity analyses is performed by applying two different distributions of the lateral loads: a “modal” pattern (which will be hereafter referred to as “mode 1”) corresponding to a distribution of the acceleration proportional to the 1<sup>st</sup> modal shape; a “uniform” pattern, based on lateral forces proportional to mass regardless of elevation (uniform response acceleration).

During the loading process, the transversal displacement of the control point located in the position of maximum modal deformation is monitored, in order to trace the pushover curve in terms of the equivalent lateral load. Afterwards, the pushover curve is transformed into a simplified bilinear force-displacement relationship for an equivalent inelastic SDOF system, based on the equivalence of energy between two systems. Results relevant to SDOF system is reported in the plane Acceleration-Displacement Response Spectra (ADRS) and evaluating the inelastic spectrum for the return period  $T_R^*$  consistent with the capacity of the equivalent SDOF (condition of equal displacement).

Figures 10a-b and Figures 11a-b reports the stresses of the component ZZ and XX respectively considering the distribution of lateral loads proportional to 1<sup>st</sup> modal shape at the end of analysis in positive/negative Y direction.

Figures 12a-b and Figures 13a-b reports the stresses of the component ZZ and XX respectively considering the distribution of lateral loads proportional to mass regardless of elevation at the end of analysis in positive/negative Y direction.

Figures 10c-Figures 13c shows the equivalent SDOF evaluated starting from the non-linear pushover analyses, and Figures 10d-Figures 13d shows the verifications in verification in ADRS plane.

Finally, Table 5 summarise the Index Risk ( $I_R$ ) evaluated by the expression [27]:

$$I_R = \frac{T_R}{T_R^*} \quad (1)$$

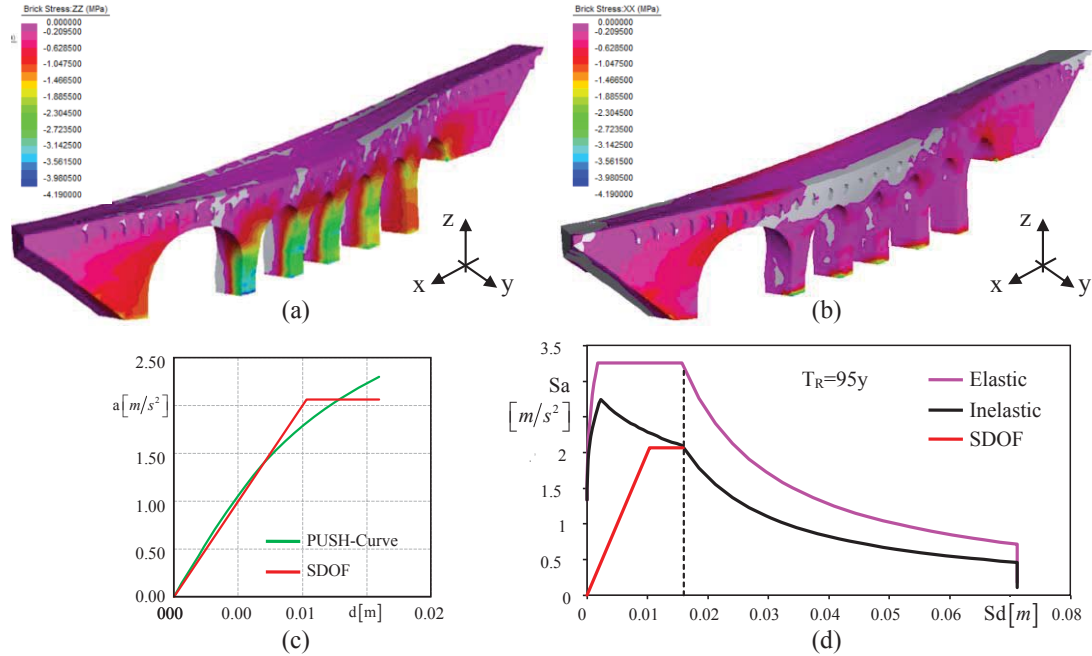

Figure 8. Pushover analysis considering lateral load proportional to 1<sup>st</sup> modal shape (Y+ direction): (a) ZZ stresses components at the maximum displacements; (b) XX stresses components at the maximum displacements; (c) bilinear equivalent SDOF; (d) verification in ADRS plane.

Analysis	$I_R$
MODE Y+	0.20
MODE Y-	0.20
MASS Y+	0.18
MASS Y-	0.13

Table 3. Index Risk

## 6.2 Local analysis

The main local vulnerabilities consist in the overturning of the bridge tympanum characterized by the presence of earth filling, in the portion of the bridge above the secondary arches. Assuming the inefficiency of a head connection of the bridge tympanum, the possibility of overturning of the single wall or single hanging arch is expected; it is assumed that the tie added on the occasion of the raising of the bridge are efficient and that therefore the overturning takes place at the tax rate of the arches.

The assessment of local vulnerability is conducted by means of a linear kinematic analysis with reference to the bridge segment between the axes of two consecutive arches placed in correspondence with the third arch (Figure 14a).

Figure 12. Comparison between experimental and theoretical vibration modes

Figure 14b reported the mechanism single hanging arch, while Figure 14c reported the mechanism relevant to the formation of an active thrust wedge of the infilling material. Regarding the first mechanism the risk index assumed the value  $I_R = 0.08$ , while for the second mechanism  $I_R = 0.09$ . In both evaluations, the seismic demand is evaluated considering the seismic action corresponding the first period of vibration and behaviour factor equal 2.

## 7 CONCLUSIONS

The assessment of the seismic vulnerability of a historical masonry bridge, characterized by an unusual geometry deriving by very complex historical vicissitudes, has been presented. The capacity is compared with the with the Italian Standard seismic demand, following the well-known “N2 method”; furthermore, local vulnerability verifications of spandrel walls have been carried out by means a linear kinematic analysis.

The bridge rises in a gorge and is founded on a sand-stone deposit that is outcropping at the abutments. The bridge is constituted by six different arches whose piers are founded on the sand-stone formation and are embedded for significant sections (up to 10 m) into the fluvial deposit constituted by sandy-gravel soil.

A laser scanner survey was crucial to obtain a model encompassing all main features of the real structure such as the inner lightening rooms, with very irregular geometry, as well as the pensile arches constructed to enlarge the carriageway.

The onsite tests permitted to evaluate the main mechanical characteristics of the materials and to estimate the stress state in critical sections of the piers.

The operational modal analysis, used to detect the dynamic behavior of the bridge, was decisive for tuning a finite element model capable of predicting the overall behavior of the bridge, and adopted to evaluate the seismic capacity of the arch bridge.

**Keywords:** Bridge monitoring, ROC curves, Structural Health Monitoring, Data cleansing, False alarm.

**Abstract.** *Maintenance and prevention of roadway bridges is an important societal and economic challenge where structural health monitoring systems can play a major role. The main reason lies in the significant number of ageing infrastructures requiring a strategy to evaluate their structural integrity and durability as well as to enable structural prognosis. In the context of unsupervised learning processes, damage detection can be accomplished by tracking deviations of dynamic parameters from their normal conditions using specific tools, named control charts. However, the main drawback of dealing with changes in modal properties is represented by their high sensitivity to environmental and operational factors. It follows that these effects must be necessarily removed to obtain suitable damage sensitive features. In this regard, the selection of a particular statistical model for data cleansing inevitably influences the distribution of the residuals, the control chart and therefore the damage detection. To overcome this issue, in the present paper an original methodology is developed, based on Receiving Operating Characteristic (ROC) curves, which provides a new decision-support tool for the definition of the best environmental effects' removal technique. Residuals stemming from the application of different data cleansing methods, plotted in control charts are conceivably distinguished in False Positives, True Positives, False Negatives and True Negatives. Consequently, ROC curves are computed and compared, each one referred to a particular data cleansing procedure, among which Principal Component Analysis, Multiple Linear Regression and more and to a specific damage class. The proposed approach is applied in the illustrative case study of the Z24 Bridge, located in the canton Bern near Solothurn, Switzerland. The results of the application of the procedure demonstrated that ROC curves are a suitable tool for defining the optimal damage threshold and the most effective environmental effects' removal technique, in order to minimize the occurrence of false alarms.*

## 1 INTRODUCTION

Structural Health Monitoring (SHM) has become increasingly popular in the field of Civil Engineering. The main reason lies in the necessity to better manage the significant number of ageing structures and infrastructures. In particular, bridges represent critical elements in modern transport networks, hence the importance to develop strategies ensuring their safety as well as correct prevention [1]. Within this context, long-term vibration-based SHM systems represent a suitable solution [2]. Such methods provide modal parameters' estimate by exploiting OMA analysis and allow to identify damage-induced anomalies through statistical pattern recognition techniques.

However, a major challenge in application of SHM systems to civil structures and infrastructures is represented by the high sensitivity of dynamic properties to environmental and operational conditions [3]. For this reason, in order to minimize the significant risk of masking early stage damages, several techniques to remove environmental effects from monitoring data are continuously being developed in the SHM community. The basic idea is to create a proper statistical model able to reproduce the part of variance in frequency estimates that is associated with changes in environmental conditions. To this aim, common statistical tools such as Multiple Linear Regression (MLR) [3, 4] and Principal Component Analysis (PCA) [5] are broadly investigated in the literature.

Once a proper statistical model is selected, it is possible to compute quantities, called residuals, that are only minimally affected by environmental effects and therefore suitable to be used as damage-sensitive features [6]. In this framework, Novelty Analysis through control charts [7] represents a common statistical process control tool useful to identify the beginning of a damage mechanism. In particular, proper statistical distances between newly acquired data and a baseline population allow to detect any outlier consistently overpassing a fixed threshold. As a consequence, it is clear that the definition of the threshold in the classification (damage or non-damaged) represents one of the major issues, inevitably producing erroneous predictions as False Positives and False Negatives.

Therefore, with the aim to minimize the rate of damage detection errors in view of an effective monitoring, a strategy to select, for the specific case study, the most appropriate technique to remove environmental effects is highly required. Such purpose is accomplished in this paper by proposing a new decision-support tool to optimally solve the statistical model selection problem, which heavily affects the distribution of the residuals and hence, damage detection. The new methodology described in the present work is based on the use of ROC [8] curves as performance metrics, aiming at providing a quantification of damage classification errors. Despite the popularity of ROC in several application fields [9], their use for optimal statistical pattern recognition within the context of damage detection, is still lacking.

In order to bridge this research gap, the basic idea of this paper is to supply objective criteria allowing to define (i) which data cleansing technique would ensure the best damage identification and (ii) which cut-off value minimizes the number of false positives and false negatives.

Preliminarily, residuals are calculated and plotted in different control charts. Then, several ROC curves, each one referred to a particular statistical model and to a specific damage scenario, are computed and afterwards assessed by measuring the entire two-dimensional area underneath the curve (AUC). Hence, this strategy can be formulated as an optimization problem, aiming at selecting the curve with the higher AUC, which corresponds to the most suitable model for data cleansing purposes.

## 2 BACKGROUND

In order to discern damage-induced changes in the natural frequencies time-histories, several tools have been recently used to remove environmental and operational effects. This section briefly presents an overview on MLR, PCA and the Gaussian Mixture Model (GMM) and provides a description of the basic theory of Novelty Analysis, commonly utilized to detect the occurrence of damage by means of proper statistical distances.

### 2.1 Statistical models handling environmental and operational effects

Multiple Linear Regression (MLR) exploits linear correlations between one or more dependent variables, called estimators and a group of independent variables, defined as predictors. In this case, dependent variables are natural frequencies, while independent variables are typically environmental and operational factors. The linear statistical model should be able to study the influence of each predictor on the dependent variables and then, to predict future values of the natural frequencies when only the predictors are known [4].

Another well-established methodology, the Principal Component Analysis, has the primary purpose to reduce the dimensionality of a data set without producing significant losses of data variance. It consists in transforming a set of observations of possibly correlated variables into a group of uncorrelated variables, called principal components (PCs). Firstly, the original data are projected into the vectorial space generated by the PCs. Then, according to this approach, a subset of those PCs providing the largest contributions to the variance of the original data can be retained and assumed representative of the environmental and operational factors. As a result, it is possible to estimate natural frequencies by moving back the reduced subset of PCs onto the original space [5, 6].

In order to handle non-linear environmental/operational effects, Gaussian Mixture Model (GMM) represents an efficient tool, which is based on grouping damage sensitive features (e.g. natural frequencies) in the training period into different clusters. Considering that the data set in the training period is non-normally distributed, this approach consists in introducing  $K$  clusters, described by Gaussian distributions, and assuming a linear superposition of them equal to the probability density function of the data set in the training period [10, 11]. Once the  $K$  clusters have been defined, new acquired data can be assigned to the cluster with minimal Mahalanobis distance.

### 2.2 Novelty analysis

The selection of the proper statistical model, successful in reproducing environmental effects on dynamic signatures, allows to compute the residual error matrix  $\mathbf{E}$  as:

$$\mathbf{E} = \mathbf{Y} - \hat{\mathbf{Y}} \quad (1)$$

which contains quantities that are minimally affected by environmental factors and therefore assumed as damage sensitive features. It follows that any damage pattern can be inferred by observing anomalies in the distribution of  $\mathbf{E}$ .

To this aim, Novelty Analysis through the use of control charts represents a statistical tool able to associate significant deviations of natural frequencies from normal conditions, in terms of statistical outliers, with the occurrence of damage. Firstly, it is necessary to define a reference condition, containing data sets collected in a training period, in which the structure is assumed to remain healthy. Consequently, any new data point is compared with such baseline population by means of properly defined statistical distances. In this framework, the  $T^2$ -statistic is adopted,

defined as:

$$T^2 = r \cdot (\bar{\mathbf{E}} - \bar{\bar{\mathbf{E}}})^T \cdot \Sigma^{-1} \cdot (\bar{\mathbf{E}} - \bar{\bar{\mathbf{E}}}) \quad (2)$$

where  $r$  is an integer parameter referred to as subgroup size,  $\bar{\mathbf{E}}$  is the mean of the residuals computed in the subgroup of the last  $r$  observations, while  $\bar{\bar{\mathbf{E}}}$  and  $\Sigma$  are the mean value and the covariance matrix of the residuals statistically estimated in the training period, respectively. Once several values of the statistical distance steadily overcome the Upper Control Limit (UCL), a change in the distribution of the residuals may have been occurred. Therefore, damage-induced anomalies not encountered in the training period are conceivably identified. In this context, the limit threshold (UCL) is computed as a certain percentage of the standard deviation of the control chart in the training period.

### 3 METHODOLOGY

#### 3.1 ROC curves

A Receiver Operating Characteristic (ROC) curve represents a graphical tool which allows to quantify the performance of a process, varying the threshold position, and to statistically evaluate the erroneous predictions related to false detection.

Firstly, it is necessary to illustrate all the possible outcomes provided by the control chart (Fig. 1 a)):

- True Negative (TN): the data set point before damage lying under the UCL;
- False Positive (FP): the data set point before damage lying above the UCL;
- False Negative (FN): the data set point after damage lying under the UCL;
- True Positive (TP): the data set point after damage lying above the UCL;

The confusion matrix  $C$  can be constructed starting from the knowledge of TP, FP, TN and FN:

$$C = \begin{bmatrix} \text{TP} & \text{FP} \\ \text{FN} & \text{TN} \end{bmatrix}; \quad (3)$$

In order to characterize a ROC curve, some statistical measures, evaluating the performance of a binary classification test, are introduced hereafter.

The true positive rate TPr defines how many correct positive results occur among all positive samples. It is also known as *sensitivity* (SE) or *probability of detection*:

$$\text{TPr} = \frac{\text{TP}}{\text{TP} + \text{FN}} = \frac{\text{True Positives}}{\text{All positive cases}} \quad (4)$$

The false positive rate FPr, or *probability of false alarms*, counts how many incorrect positive results occur among all negative samples:

$$\text{FPr} = \frac{\text{FP}}{\text{FP} + \text{TN}} = 1 - \text{SP} = \frac{\text{False Positives}}{\text{All negative cases}} \quad (5)$$

where SP, called as *specificity* or true negative rate, describes how many correct negative results occur among all negatives samples.

A ROC curve plots the true positive rate (TPr) against false positive rate (FPr) at various classification thresholds. The basic theory is that a very low threshold produces 100% of false and true positives, classifying all the items as positive. On the contrary, a very high threshold could never indicate damage, resulting in 0% of false and true positives. It is important to highlight that the model's accuracy increases when the curve comes closer to the upper-left-hand corner of the ROC space and decreases, vice versa, when the curve comes closer to the 45° diagonal (Fig. 1 b).

The performance of a ROC curve is commonly evaluated by computing the Area Under the Curve (AUC), indicated in Fig. 1 c). Considering normalized units, AUC values go from 0 to 1. It is worth pointing out that this parameter is equivalent to the probability that a classifier will rank a randomly chosen positive instance higher than a randomly chosen negative one [8]. It can be defined as follows:

$$AUC = \int_0^1 ROC(f)df \quad (6)$$

where  $f$  and  $ROC(f)$  indicate, respectively, the false positive rate (FPr) and the corresponding true positive rate (TPr).

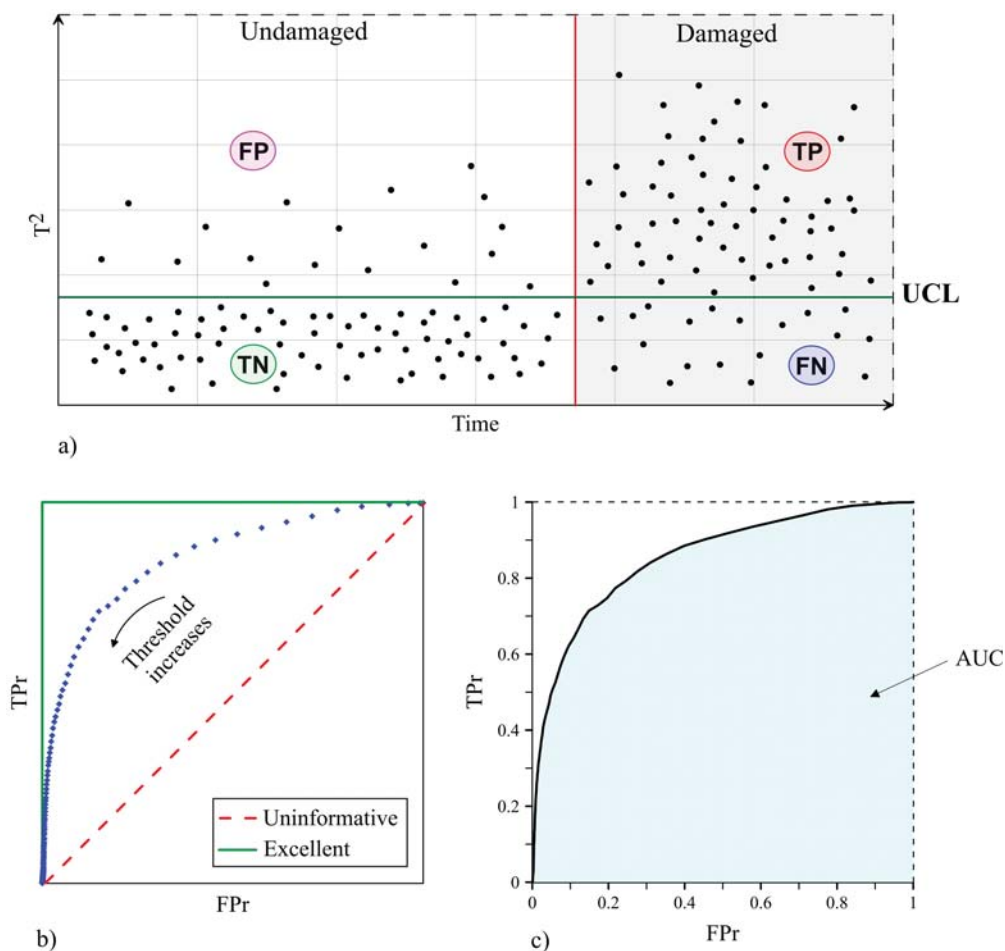

Figure 1: a) control chart items' classification: True Positive (TP), False Positive (FP), True Negative (TN) and False Negative (FN); b) different typologies of ROC curves; c) definition of AUC.

### 3.2 Selection of the best data cleansing technique

The methodology for selecting the best data cleansing technique is provided in Fig. 2 a). Preliminarily,  $m$  statistical models and  $d$  damage scenarios (real or simulated) are taken into account, with the purpose to evaluate and compare models' performance, varying the type of damage.

It is interesting to point out that damage data are rarely available in the field of civil engineering. Therefore, the use of suitable virtual models to simulate different damage scenarios becomes necessary. In these cases, damage-induced variations of modal properties predicted by the structural model can be artificially introduced into the monitoring data through constant shifts in the time series of identified modal frequencies.

By applying Eq. (1), residuals can be computed and then plotted in  $(m \times d)$  control charts. As a result, by counting the data set points belonging to each class, labelled as FP, TP, FN and TN,  $(m \times d)$  ROC curves are obtained, varying the classification threshold. Each curve is referred to a particular statistical model (or data cleansing technique), and to a specific damage scenario. In order to conceivably evaluate the behavior of different curves in a quantitative point of view, AUC is computed to provide a measure of performance across all possible classification thresholds. The basic theory of the proposed approach is to select the curve with the higher AUC, corresponding to the most performing model with an excellent capability in discerning between the positive and negative classes. This translates into an optimization problem:

$$i_{opt} = \arg \max_i (J_i) \quad (7)$$

$$J_i = \sum_{j=1}^d \text{AUC}_{ij} \quad (8)$$

where  $\text{AUC}_{ij}$  represents the area under the ROC curve for the  $i^{th}$  statistical model and the  $j^{th}$  damage scenario, with  $i = 1, 2, \dots, m$  and  $j = 1, 2, \dots, d$ .

### 3.3 Optimal threshold selection

In order to minimize false alarms and missing alarms, the selection of the optimal classification threshold has an extremely important role. To this aim, the proposed methodology, schematically presented in Fig. 2 b), involves the use of *Youden index* ( $Y$ ), which is a useful parameter allowing to provide a summary measure about model's performance. It is calculated in ROC space and conceptually represents the vertical distance between a point on the ROC curve and the  $45^\circ$  line. Typically, a high value of the *Youden index* corresponds to a well performing ROC curve (close to the upper-left-hand corner) leading to a high percentage of true positive rate over false positive rate. The index is calculated as follows:

$$Y = \text{SE} + \text{SP} - 1 \quad (9)$$

Once the most performing model is defined, the idea is to compute *Youden index* for each  $j^{th}$  damage scenario, varying classification thresholds. The maximum values,  $Y_{max}(j)$ , correspond to a specific damage threshold, which is denoted as  $T(j)$ .

However, it is important to underline that such procedure implies the inspection of several thresholds, each one related to a specific damage scenario. As a solution, the strategy proposed in this paper aims at fixing the optimal threshold as the minimum among the  $T(j)$ , so that the SHM system is able to detect even the smallest damage:

$$T_{opt} = \min \{T(j)\} \quad (10)$$

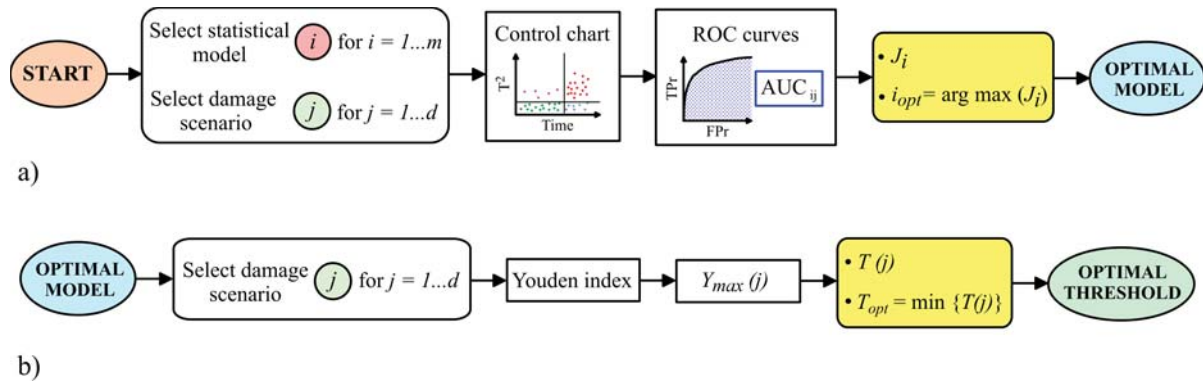

Figure 2: a) flow chart of the proposed methodology to select the most performing statistical model; b) flow chart of the proposed procedure for the optimal threshold selection.

## 4 APPLICATION CASE STUDY: Z24 BRIDGE

This section presents a general overview about the geometry and the monitoring system of the Z24 bridge and discuss, additionally, the results obtained by application of the proposed methodology on the investigated case study. To this aim, the available monitoring data are collected, processed and analysed through a specific MATLAB code, called MOSS, implemented by García-Macías et al. [12].

### 4.1 General description

The Z24 Bridge (Fig. 3) was located in the canton Bern, Switzerland, overpassing the national highway between Bern and Zurich. It was a post-tensioned concrete box girder bridge with a main span of 30 m and two side spans of 14 m. The two triplets of concrete columns at both ends were connected via concrete hinges to the girder, while two concrete piers, representing the intermediate supports of the bridge, were clamped into the girders and situated at the end points of the main span (Fig. 3 b)).

Figure 3: Z24 bridge: a) general view [13], b) longitudinal section [14].

The bridge was demolished at the end of 1998 to build a larger side span bridge. However, before demolition, it was continuously monitored from November 1997 till September 1998, with the aim to provide both environmental and vibration data for dynamic behavior's assessment. In particular, progressive damage tests were carried out during the summer of 1998 (shortly before the complete demolition of the bridge) in order to study the influence of different realistic damage scenarios on the modal properties.

Sensors to measure accelerations as well as environmental parameters were spread across the bridge. More specifically, among 16 accelerometers, only 8 were properly working. Data from all sensors were captured every hour with a sampling frequency of 100 Hz, resulting in 24 measurements per day.

#### 4.1.1 Definition of the damage scenarios

With the aim to evaluate modal parameters' variations in view of a prompt damage detection, frequency tracking has been performed over time, as depicted in Fig. 4.

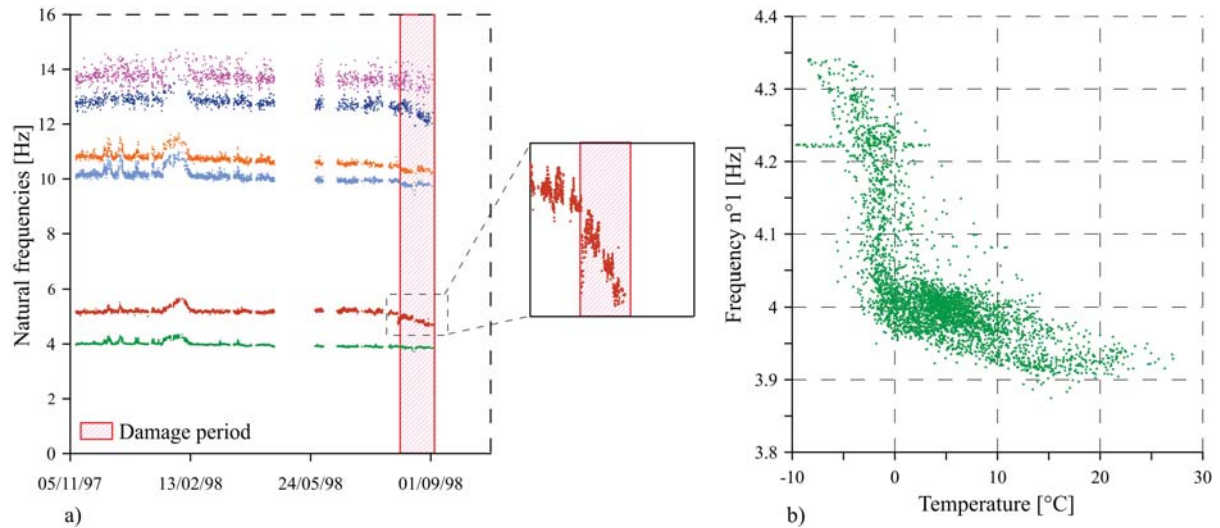

Figure 4: a) frequency tracking of the Z24 Bridge; b) relation between the first natural frequency and the temperature.

Between August 10<sup>th</sup> and September 4<sup>th</sup> 1998, the bridge was subjected to progressive damage tests. In particular, four damage scenarios ( $d = 4$ ) are taken into account in the present work:  $d_1$ ,  $d_2$ ,  $d_3$  and  $d_4$  indicate, respectively, the whole damage period (10<sup>th</sup> August - 4<sup>th</sup> September), the first portion of damage period (10<sup>th</sup> August - 18<sup>th</sup> August), the second portion (19<sup>th</sup> August - 26<sup>th</sup> August) and finally, the third one (27<sup>th</sup> August - 4<sup>th</sup> September).

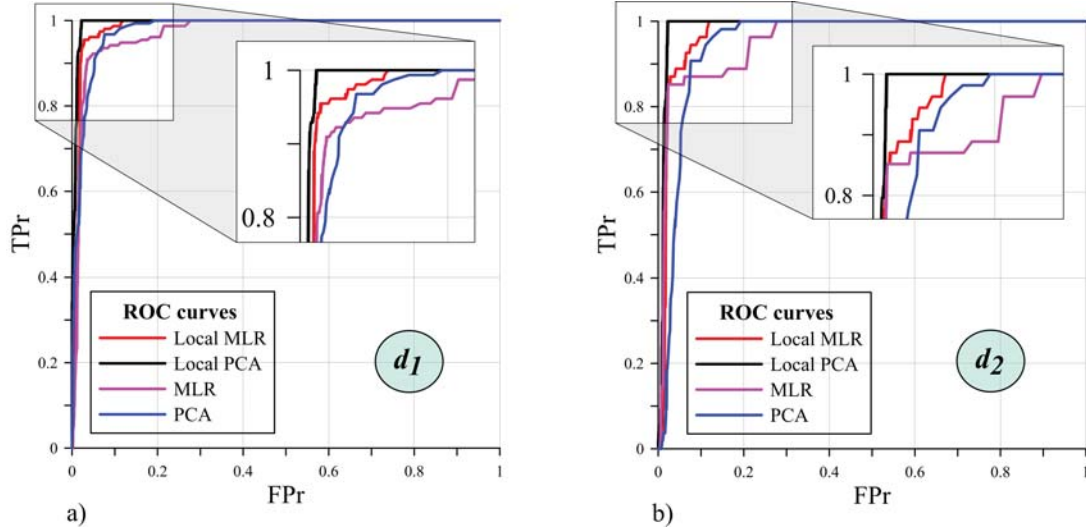

#### 4.1.2 Comparison between different statistical models

In order to get residuals, four data cleansing techniques ( $m = 4$ ) are considered, namely Multiple Linear Regression (MLR), Principal Component Analysis (PCA), Local MLR and Local PCA. The application of every statistical model, varying damage scenarios, leads to different control charts, each one referred to the  $i^{th}$  model and the  $j^{th}$  damage condition. By counting false positives, true positives, false negatives and true negatives, outgoing from every control chart, ROC curves are computed empirically by varying the classification threshold. Following the proposed methodology, AUC values are calculated and afterwards collected in Table 1.

It can be noticed that ROC curves exhibit a good behavior if the whole damage period ( $d_1$ ) is considered (Fig. 5 a)), even though slightly more performing results are visible when dealing with larger damage severity (e.g.  $d_4$ ), since the probability to discern true positive items highly increases. Conversely, when damage to be identified is not so marked (e.g.  $d_2$ ), AUC values get inevitably worse allowing, though, to clearly distinguish various performance levels associated to the  $m$  models, as shown in Fig. 5 b).

d	AUC			
	PCA	Local PCA	MLR	Local MLR
$d_1$	0.979	0.994	0.973	0.984
$d_2$	0.953	0.988	0.959	0.975
$d_3$	0.988	0.996	0.971	0.984
$d_4$	0.997	0.999	0.989	0.993

Table 1: *AUC* values for  $m$  statistical models and  $d$  damage scenarios.Figure 5: Comparison between the different statistical models in terms of ROC curves. a, b) ROC curves computed for the whole damage period ( $d_1$ ) and for the first portion of damage period ( $d_2$ ), respectively.

Since the damage inferred to the bridge was significant, it is necessary to point out that every model managed to yield extremely performing ROC curves, regardless of the selected damage scenario. However, in order to find out which is the best technique to remove environmental effects, the proposed optimization problem is applied. Following Eq. (7), the argument of the maximum of the objective function,  $i_{opt}$ , corresponds to the Local PCA model, the one providing the best performance in terms of AUC.

Due to the fact that the damage inferred to the structure progressively increases during the monitoring time, it could be interesting to identify which technique stands out in detecting damage first. To this aim, each control chart associated to the  $i^{th}$  model is taken into account and the portion corresponding to damage is afterwards divided into a certain number of steps. By computing and plotting AUC values at every step, as shown in Fig. 6, it comes to the light that Local PCA results to be the best model in a global view, while MLR turned out to be the fastest technique to detect damage.

#### 4.1.3 Selection of the optimal threshold

Once Local PCA is identified as the most performing model, it is crucial to minimize damage errors such as false positives and false negatives. This translates into the selection of the optimal threshold, leading to the higher TPr over the FPr within the ROC space. To this aim, *Youden index* is computed for every  $j^{th}$  damage scenario, varying the classification threshold. Table 2

Figure 6: Comparison between  $m$  models in terms of AUC, computed at every step throughout the damage period.

summarizes the maximum values  $Y_{max}(j)$  with the corresponding thresholds  $T(j)$ .

d	Local PCA	
	$Y_{max}$	$T$
$d_1$	0.978	0.196
$d_2$	0.978	0.196
$d_3$	0.990	0.424
$d_4$	0.993	0.493

Table 2: Maximum values of *Youden index* ( $Y_{max}$ ) for every damage scenario and the corresponding thresholds ( $T$ ).

With the growing of damage severity, it is possible to highlight (i) an increase of the optimal threshold and (ii) an enlargement of the interval containing the maximum values of *Youden index*, as clearly visible in Fig. 7 a).

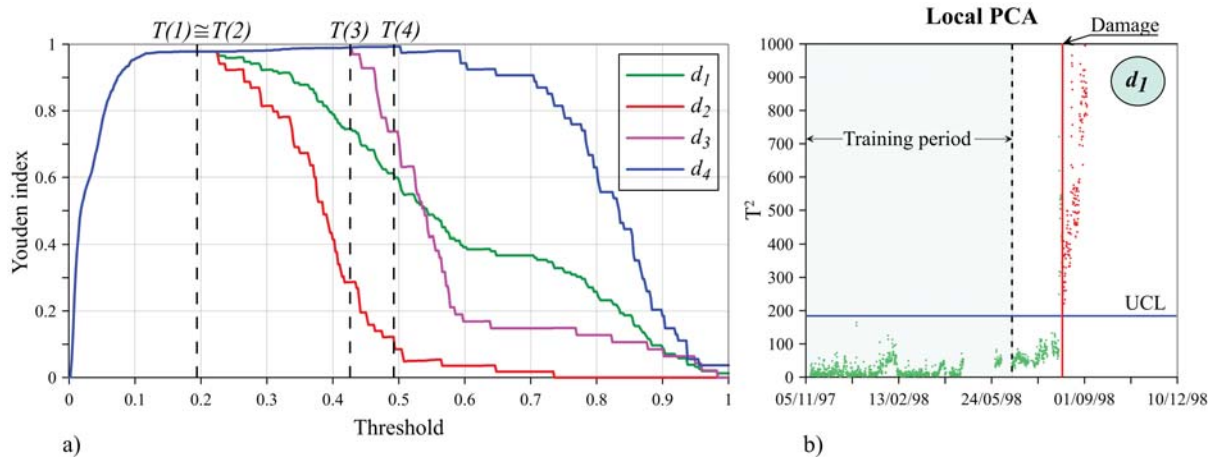

Figure 7: a) *Youden index* for  $d$  damage scenarios, varying the classification thresholds; b) control chart of the Z24 bridge obtained for a specific damage scenario ( $d_1$ ) by setting Local PCA as statistical model and  $T_{opt}$  as UCL.

However, as shown in Table 2, the methodology has provided several thresholds, each one related to a specific damage scenario. To overcome this issue, the optimal value  $T_{opt}$ , required to set the UCL of the control chart, is selected as the minimum:  $T_{opt} = \min \{T\} = 0.196$ . The control chart obtained by considering Local PCA as statistical model and  $d_1$  as damage scenario is depicted in Fig. 7 b), where the UCL is set equal to the optimal threshold computed using Eq. (10). It is easy to point out the excellent capability of this data cleansing technique (i.e. Local PCA) in correctly classifying the outcomes throughout the possible thresholds, notably avoiding the false negatives detection.

## 4.2 Discussion of the results

The relation between the identified natural frequencies and temperature may significantly affect the selection of the best environmental effects removal technique. Regarding the Z24 bridge, such relation is non-linear, as shown in Fig. 4 b). This could be the key for the interpretation of the results, as local approaches are typically useful to handle non-linear environmental/operational effects. In this particular case study, Local PCA (Principal Component Analysis applied to single clusters), in comparison with linear regression analysis (MLR), turned out to be the statistical model with the highest capability in minimizing erroneous predictions in view of a reliable damage detection.

## 5 CONCLUSIONS

The present paper provides a new decision-support tool for the definition of the best technique to remove environmental effects, as well as for the selection of the optimal classification threshold, minimizing false alarms and missing alarms. The proposed methodology is based on the use of ROC curves as performance metrics, which are computed and compared, in terms of AUC, for a variety of statistical models and different damage scenarios. Therefore, the selection of the best statistical model is carried out in the form of an optimization problem. Moreover, keeping fixed the most performing technique, the parameter *Youden index* is introduced to find out the optimal threshold for every damage scenario. Finally, in order to let the SHM system detect even the smallest damage, the strategy is to select the lowest value as optimal UCL.

The developed procedure has been exemplified by application in the Z24 bridge case study. The results illustrate that all the models managed to clearly detect the huge damage progressively inferred to the bridge. Local PCA, though, has showed a higher capability to correctly classify the outcomes of the control chart, proving to be the optimal model to remove environmental effects for an effective damage detection.

In conclusion, the provided methodology represents a valid tool to statistically evaluate the performance of different data cleansing techniques, by supplying reliable performance metrics within unsupervised damage detection under changing environment. The procedure is general and can be implemented in manifold SHM applications, considering different statistical models and different damage scenarios.

### Abstract

*The Italian bridge asset is characterized by aged structures, most of which made of reinforced concrete, needing retrofit interventions to improve both their seismic performance and load-bearing capacity towards the increased traffic volume. In order to provide a series of guidelines for retrofit, a research project, carried out by the ReLUIS consortium supported by the Italian Department of Civil Protection, aims to identifying typological deficiencies and vulnerability of the main type of bridges widespread on the Italian territory, defining typological interventions. This paper presents the outcomes of the ongoing research focusing on RC tied-arch bridges, frequently built in the period between the two world wars. A typological study was carried out to define the main design deficiencies and construction details, and how degradation acts on this type of bridge, besides the main structural vulnerability to both gravitational and seismic loads. Numerical and parametrical analyses were carried out on a representative prototype tied-arch bridge with RC hangers, dating back to 1930s. The structural behavior was assessed by means of numerical analysis on FEM models, allowing the evaluation of the static and seismic capacity, the definition of the most vulnerable elements, and thus, the identification of the most suitable type of retrofit interventions.*

## 1 INTRODUCTION

Bridges are the most critical structures in transportation networks and [1], in many developed countries, such as Italy, most of them were built more than 40 years ago [2]. According to the CNR, the National Council for Research of Italy, many of those structures are at risk nowadays for their age [3]; in addition, structural typologies, technologies, and materials used for bridges were very different from those used today [4].

An out-of-service bridge might cause significant economic losses (i.e., costs for users, owners, and operators); maintaining them in service conditions is therefore desirable [2]. Proper inspections and timely maintenance are too often unfulfilled due to limited economic budgets and a widespread approach based on emergency, which is leading to a progressive deterioration of structures [5].

In the last ten years, a series of tragic collapse of bridges occurred in Italy [6, 7], pointing out the need for a regulatory direction to the problem. Then, in 2019, novel Guidelines for existing bridges [8] were issued, defining a methodology for inspection, prioritization, and verification of existing bridges.

Research has provided scientific-based tools to manage bridge stocks [9, 10, 11, 12] and to prioritize retrofit actions [13, 14, 15, 16], while the investigation of the most suitable types of retrofit has yet to be deepened in a framework of multi-criteria typological analyses.

Hence, a national project, funded by the Italian Department of Civil Protection (DPC), has been carried out by the *ReLUIS* consortium, with the purpose of identifying typological deficiencies of the main type of bridges and thereby defining the more suitable types of retrofit interventions. The present contribution, in particular, focuses on reinforced concrete (r.c.) tied-arch bridges.

R.c. tied-arch bridges are comprised by one or more arches, a tying chord, also called bow-string girder or tie-girder, which often corresponds to the deck system (i.e., girders and slab), and a series of hangers connecting the arches to the bow-string girders. These ones, located below the arches, absorb their horizontal thrust [17], allowing, on a theoretical level, the transmission of only vertical forces to the substructures. Bridges of this type often date back to the period between the two world wars and, due to their age, their safety is jeopardized by both degradation and increasing in the traffic volume [18].

The dynamic behavior and finite element (F.E.) model calibration of this type of bridges were previously studied by Turker et al. [19] and Brisighella et al. [20], which focused their analyses on specific case studies. Similarly, an extensive study including experimental non-destructive tests was carried out on a r.c. bowstring bridge in the Sicily region (Italy) [21, 22]. The influence of the hanger arrangement was investigated by Vlad et al. [23], through numerical simulations on 3D F.E. model.

The present paper proposes a critical examination of the available literature and of retrieved original projects. In order to operate in a typological framework, the most common characteristics of r.c. tied-arch bridges in Italy are illustrated, based on data collection carried out at national scale. Moreover, numerical analyses on a FEM model of a representative case study are presented, considering both gravitational and seismic actions. The identification of typological deficiencies, confirmed by results from the analysis of the case study, allowed classes of intervention to be suggested.

## 2 TYPOLOGICAL STUDY

R.c. arch bridges were widely built starting from the early 20<sup>th</sup> century, especially to overcome rivers where either a significant freeboard was required (e.g., for navigable canals) [24]

or the clearance space between the road level and substructures was limited [21]. These bridges were frequently built in-situ by constructing a temporary centering [24].

Various sub-types of r.c. tied-arch bridges can be identified based on the following geometric and structural characteristics: i) the hanger material (i.e., r.c., prestressed r.c. or steel); ii) the hanger arrangement (i.e., vertical, radial or inclined), iii) type of crossbeams. Hence, these parameters were included in a preliminary data collection carried out at national scale which results are reported in the following section.

## 2.1 Dataset of r.c. tied-arch bridges in Italy

A dataset was collected, comprised of almost 90 r.c. tied-arch bridges, evenly distributed on the Italian area. The distribution of the main geometric and structural characteristics for bridges part of this stock are reported as follows.

Figure 1 reports the distribution of general characteristics of the identified bridges, i.e., the year of construction, the number of spans, and the span length. It was observed that the vast majority of the identified bridges were built in the period 1919-1946, between the two world wars; unfortunately, this datum was not available (NA) for a significant part of the stock. R.c. tied-arch bridges appeared to be mainly single-span, while span lengths were quite heterogeneous. Then, the hanger typology was observed, and Figure 2 reports the distribution of their arrangement, material, and spacing. Finally, the types of crossbeams were investigated (Figure 3). On the basis of the data collected, it was assumed that the most common type of r.c. tied-arch bridge in Italy has r.c. vertical hangers and orthogonal crossbeams.

Some examples of tied-arch bridges in Italy are reported in Figure 4.

## 2.2 Construction details

By consulting original project documentations retrieved for several r.c. tied arch bridges in Italy, it was possible to detect the common construction details and to deduce the design method of the time.

Concrete compressive strength ranges from high resistance (i.e., mean value of cube compressive strength  $R_{cm}$  around 40 MPa) to very low mechanical properties, found in one case [21]; these cases cannot be considered negligible due to the ancient construction age. Reinforcement bars were smooth, consistently with construction age, and small diameters ( $\phi 6-8$  mm) were used for stirrups. Arches are segmental, with different values of the ratio between rise and span. They were designed to resist mainly to compression, based on the design criteria for masonry arches, and therefore they were relatively poorly reinforced.

Figure 1: General characteristics of bridges in dataset: a) years of construction, b) number of spans, and c) span length.

Hanger spacing varies in the range 2 - 4 meters, depending on the span of the bridge, and therefore on the generated stresses. The hanger joints, both to the arch and to the tie-girder, were designed as hinges, with insufficient reinforcement details to transfer flexural actions.

Figure 2: Hanger characteristics for bridges in dataset a) arrangement, b) material, and c) spacing.

Figure 3: Distribution of type of crossbeams for bridges in dataset.

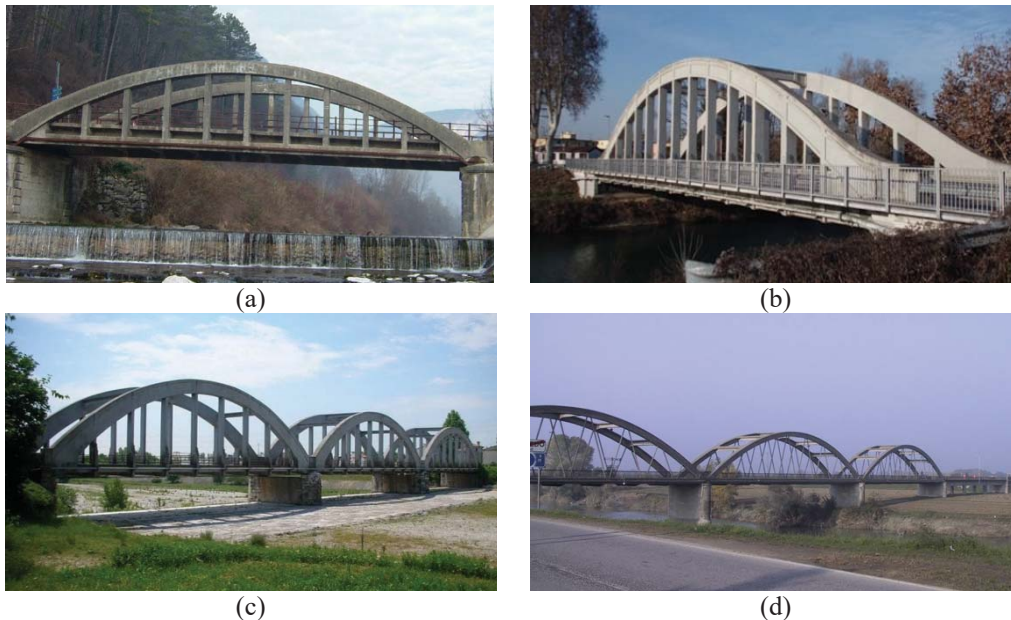

Figure 4: Bridges characterized by a) vertical r.c. hangers [25], b) vertical r.c. hangers and orthogonal crossbeams, c) vertical r.c. hangers and orthogonal crossbeams (multi-span) [25], and d) inclined r.c. hangers and orthogonal crossbeams (multi-span) [25].

### 2.3 Degradation and structural deficiencies

The macro-class of bridges here investigated resulted to be subjected to degradation effects and structural deficiencies, both affected the structural safety. The present section describes the main typical issues that can be found in r.c. tied-arch bridges.

The effects of degradation are caused by environmental actions (i.e., physical, chemical, and biological), and aggravated by many factors, such as incorrect construction details, low quality of materials, and lack or insufficient maintenance. The main and most common effect of degradation on r.c. bridges is the spalling of concrete, with consequent corrosion of the exposed reinforcement bars. Besides the susceptibility to degradation of all the elements of a r.c. tied-arch bridge, the observation of this phenomenon [26] suggests that hangers and deck structure are the most affected elements (Figure 5). To preserve both deck system and substructures, an effective system to drain rainwater is needed. In the case of steel hangers, the degradation of the material can cause the relaxation of hangers, with consequent redistribution of stresses, and the damage of anchors, which might lead to the detachment of the relative hangers.

Figure 5: Spalling of concrete and corrosion of exposed rebars on: a) r.c. hanger and b) deck [25].

Not only is structural safety threatened by degradation, it might be also reduced by structural deficiencies influencing the response to both static and seismic loads.

Considering gravitational loads, substructures can be statically inadequate, as a result of original design deficiency and/or an increase in traffic loads (e.g., an increase in the arch thrust, no longer absorbed by the tie-girder, transferred to the abutments). The low quality of materials, poorly reinforced sections, and inadequate supports are the main static design deficiencies for the superstructure. As commonly found in existing bridges, the supporting system, connecting the substructure to the superstructure, is often inadequate to current traffic loads.

Most of r.c. tied-arch bridges in Italy were built long before the emanation of seismic codes, they were therefore not designed for seismic actions, making these structures intrinsically vulnerable to earthquakes. The most significant inadequacy is found for supports and substructures, due to both high levels of stress born by devices and the risk of support loss that can occurred in simply supported bridges. Poorly reinforced piers are vulnerable to horizontal stresses, towards either flexural or shear mechanisms. Focusing on the arches, the phenomenon of out-of-plane instability due to seismic actions is not negligible, mainly in case of missing or insufficient bracing system.

### 3 CASE STUDY

The case study presented and analyzed hereinafter is an existing r.c. tied-arch bridge, dating back to 1931 and located in the Veneto region, in north-east Italy. The case study was selected

based on representativeness criteria, as it has a series of widespread characteristics, previously illustrated in the national dataset presentation. In detail, it is a single-span bridge, with a span length of almost 40 meters; it has r.c. vertical hangers (spacing 2.5 meters) and three orthogonal r.c. crossbeams (Figure 6 and 7). The deck consists of longitudinal and transverse beams, and a slab. The r.c. abutments founded on piles.

Furthermore, prior to implement analyses, original project documentation was retrieved, including representation of the construction details, which are reported in Table 1. No data was available on concrete, which were then assumed according to a similar bridge built in the region [27]. Two different set of data were available deriving from experimental tests carried out on two r.c. tied-arch bridges in the Veneto region. The one providing lower material strength was chosen based on both conservative criteria and geographic similarity of sites, leading to assume a concrete resistance class C20/25.

Table 1: Section and reinforcements of bridge elements.

In 1994, a restoration intervention was carried out, by rebuilding the deck slab and restoring all the concrete elements, which showed diffused spalling. During this intervention two metal footways were added on the outer sides. Prior to the restoration intervention, experimental tests were performed on the smooth reinforcement bars, which showed a yield strength greater than 450 MPa, and an ultimate strength greater than 600 MPa.

Traffic loads have been limited to 7.5 tons, as a result of the static verification performed in 1994; the limitation persists nowadays, thus it was considered in the definition of loads for the analysis.

### 3.1 FE model

A 3D F.E. models was implemented using the software Midas Civil [28], according to the current configuration, with the external metal footways (Figure 9). All of the bridge members were modelled through *beam* elements.

Figure 9: F.E. model based on current configuration.

Specific attention was paid to the study on the joints between hangers and the tie-girder or the arch, respectively. To study the behavior of these connections, a parametric analysis was carried out, modelling the hangers through either *beam* or *truss* elements.

The assumption of beam elements to model the behavior of hangers undergo the condition that the flexural stresses at the joints does not overcome the resistant bending moment. This condition resulted to be not verified. Moreover, reinforcements of the hangers consist in steel bars hooked at the ends, with insufficient degree of connection to transfer flexural stresses. Thus, it can be stated that hangers mainly have an axial behavior, which is better modelled through *truss* elements.

A comparison was also made of the stresses deriving from the two above-mentioned models, in order to verify that modelling with truss was conservative.

In general, the model with *truss* elements showed increased stresses for both the arch and the tie-girder, and a relative increase in vertical displacements. An exception is given by bending moments acting on both the arch and the tie-girders for self-weight, which were reduced in the model with *truss* elements.

Nevertheless, using *truss* elements to model hangers resulted to be more suitable for this type of bridges, and thus, safety verifications were carried out on this model configuration. Results of the comparison between modelling strategies are shown in Table 2.

		Arch			Tie-girder		
		M	N	Dz	M	N	Dz
		[kNm]	[kN]	[mm]	[kNm]	[kN]	[mm]
Self-weight	<i>Beam</i>	125	-1593	6,8	53	1263	6,9
	<i>Truss</i>	109	-1603	6,9	45	1277	7,1
	$\Delta$ [%]	-13%	+1%	+2%	-15%	+1%	+3%
Permanent and accidental loads	<i>Beam</i>	1229	-4541	24,5	650	3619	27,1
	<i>Truss</i>	1387	-4579	27,9	734	3677	30,6
	$\Delta$ [%]	+12%	+1%	+14%	+13%	+2%	+13%

Table 2: Stress comparison between modelling strategies for hangers: using *truss* or *beam* elements.

### 3.2 Static and seismic assessment

Due to the lack of in situ investigations on materials, the level of knowledge for the structure was defined as limited (KL1) and thus a confidence factor  $CF=1.35$  was assumed [29]. Safety verifications towards both static and seismic load combinations were performed according to Italian regulations, included the novel guidelines for existing bridges [8].

Four traffic load combinations were considered for static verifications, the first was defined according to Italian code [30, 31] and thus referred to as “NTC18” hereinafter. Three load combinations were assumed according to Italian Guidelines for existing bridges [8] to evaluate the level of safety ensured by the structure: operativity, transitivity 1, and transitivity 2. In fact, each of these combinations corresponds to traffic load layouts with decreasing return periods, thus providing an effective tool for the evaluation of measures to be adopted. The load combination transitivity 2 was defined considering a traffic limitation that allows the transit of vehicles up to 7.5 tons.

The values of stresses resulted from the analyses are reported in Table 3. A general relief of the elements can be observed, due to the decrease in traffic loads with respect to NTC18 configuration.

Results of ULS strength verifications are reported in Figure 10, which represents the minimum demand/capacity ratio ( $D_d/C_d$ ) for each element. The tie-girders and the longitudinal beams results to be the most critical elements, which satisfy the verifications only for the less demanding load combination (i.e., transitivity 2). The deck deficiencies stem from the poor distribution capacity of the slab, besides the increased in traffic loads with respect to the period of construction.

Figure 11 compares outcomes from the analyses in terms of axial load and bending moment with the limit domain of tie-girders.

Safety verification towards seismic action were carried out with reference to three decreasing return period  $T_R$  (i.e., 75 years, 30 years, and 5 years); the first one referred to a design working life of 50 years increased of a factor 1.5 for relevant structures, according to Italian Code [30], while lower return period were assumed according to Italian Guidelines for existing bridges [8].

The elastic response spectrum was conventionally referred to L'Aquila, Italy, a site with moderate-high seismicity.

A linear dynamic analysis was carried out. The obtained first three modes of vibration are shown in Figure 12: the first one results to be transverse, which corresponds to the out-of-plane direction of the arches; the second mode is vertical; and the third one have a predominantly torsional component.

<i>Transitability 2</i>	330	38%						

Table 3: Comparison of stresses acting on bridge for the analyzed traffic load combinations.

Figure 12: First three modes of vibration of analyzed bridge.

Figure 13: M-N limit domain of crossbeams with plotted outcomes of seismic analyses.

Figure 14: Safety verifications for seismic load combinations in terms of demand/capacity ratio.

According to the results of seismic verifications, the most stressed elements are the crossbeams, which have the function of preventing the out-of-plane instability of the arches. Crossbeams appear to have a significant seismic vulnerability, showing inadequate safety indices also for low seismic actions (Figure 13). In addition, tie-girders shows a deficiency for seismic actions as well. Figure 14 reports the results of seismic verifications in terms of minimum demand/capacity ratio for each structural member.

Results suggest the most suitable classes of intervention to be applied to r.c. tied-arch bridges. Being aware of specific features of each unique existing structures is fundamental to design the proper retrofit intervention; however, useful direction can stem from typological studies. In the present study the following typological classes of intervention were identified:

- post-stressing the tie-girders, in order to improve the capacity of absorbing the arch thrust;
- replacing supports with a novel isolation system, able to reduce actions on both substructures and superstructures.

In addition, since the r.c. deck slab is commonly inadequate in existing r.c. bridges [26], a strengthening intervention on this element shall be considered.

#### 4 CONCLUSIONS

- A typological study of RC tied-arch bridges in Italy was carried out in order to identify structural characteristics and main deficiencies. Various sub-types of r.c. tied-arch bridges have been identified based on the hanger material and arrangement, and the arch bracing system. On the basis of data collected at national scale, it was assumed that the most common type of r.c. tied-arch bridge has r.c. vertical hangers and orthogonal crossbeams.
- Increasing traffic loads, poorly reinforced sections and degradation (mainly acting on hangers and deck structure) are the main causes of reduced structural safety. In addition, due to their age of construction, most r.c. tied-arch bridges in Italy were not designed for seismic actions, making them intrinsically vulnerable to earthquakes.

- Based on representativeness criteria, a case study was selected and analyzed through numerical modeling. It is a single-span bridge built in 1931; it has r.c. vertical hangers and orthogonal r.c. crossbeams. The tie-girders and the longitudinal beams results to be the most critical elements towards static combinations, while crossbeams have a significant seismic vulnerability, showing inadequate safety indices also for low seismic actions.
- Future developments will focus on improving the knowledge of the case study and on identifying the most suitable type of retrofit interventions. The former will be pursued through a dynamic identification and experimental tests on materials. The presented study suggests that the most suitable types of intervention are the following: i) the application of a post-stress system to the tie-girders, in order to improve the capacity of absorbing the arch thrust, and ii) the replacement of supports with a novel isolation system.

## ACKNOWLEDGEMENTS

Special thanks are due to the Italian Department of Civil Protection (DPC), which funded this study in the framework of the *ReLUIS-DPC Project 2019-2021 – Work Package 5: Retrofit interventions for existing bridges*. In addition, thanks to the municipality of Padova for providing the original project of the case study and thanks to Andrea Gennaro for the support in numerical analysis.

### Abstract

*The challenge of large-stock maintenance with limited budget is faced by administrations in charge which need tools for management and intervention prioritization. This need is especially perceived for bridges which are strategic structures and represent crucial elements in roadway networks. Since 2016, a combined prioritization procedure has been applied to the bridge stock of the Municipality of Padova (Italy) to assess both the condition state, accounting for degradation, and the seismic vulnerability. The proposed methodology evaluates the level of degradation through visual inspections and type-specific forms for the defect survey, while the seismic vulnerability is assessed by means of fragility curves previously obtained by the authors for typical Italian bridges. This contribution focuses on the application of the seismic-based prioritization. The identification of the bridge typologies which appeared to be more seismically fragile is presented, comparing this aspect with results from the recently issued novel Italian Guidelines for the management of existing bridges.*

**Keywords:** Bridge stock, bridge degradation, condition state assessment, bridge seismic vulnerability, prioritization.

---

## 1 INTRODUCTION

Roadway networks represent strategic infrastructures for the civil protection system, since they are fundamental for post-event emergency management. Thus, disaster risk mitigation requires also to improve the reliability of infrastructure networks, especially their most vulnerable elements, such as bridges.

Most of Italian bridges were built before 1980 [1], with no seismic provisions, since the seismic classification of large part of the country was completed only by the early 2000s.

Focusing on seismic vulnerability of bridge assets, fragility curves represent an effective tool to describe the susceptibility of a structure to seismic damage. They express the probability of exceedance of a certain performance level (or damage state [2]) for a given value of intensity measure, for instance the peak ground acceleration (PGA).

An extensive review of the fragility assessment approach in the literature was provided by Muntasir Billah and Shahria Alam [3]. Analytical models are widely used to derive fragility functions, as they can be applied to general taxonomies of structure. One of the most acknowledged analytical approaches is the derivation of fragility curves through non-linear time history analysis (NLTHA) applied to mechanical models (e.g., [4–6]), also considering the effect of degradation on structural performance [7]. Mechanics-based vulnerability assessment of bridges can be also carried out through simplified procedures, such as Displacement-Based approaches [8,9] or limit analysis applied to arch bridges [10,11].

A number of authors have focused on seismic vulnerability assessment of typical bridges of a particular region or country, so as to better catch the local bridge taxonomy [12–14].

Moreover, bridges are particularly subjected to degradation, due to their exposure to environmental agents, as well as other natural hazards (e.g., flood, scour, and landslide) [15]. In addition, some structures, such as orthotropic steel deck bridges, might be subjected to fatigue phenomena, even if recently built [16].

In this framework, structural health monitoring (SHM) systems can be applied to the most critical or strategic structures, to efficiently collect information on structural integrity and durability [17].

Nevertheless, the maintenance and retrofit of large bridge stock is a challenging theme for administrations in charge, that need to allocate limited funds.

A series of scientific-based bridge management systems (BMS) have been proposed since the early 90s [18–21]. In addition, prioritization procedures are commonly required when infrastructure maintenance has been neglected for a long time, leading to the need of an extensive restoration and retrofit campaign which must be first addressed to the most critical structures [20]. Various prioritization approaches have been proposed by researchers, such as, among the others [22–24].

More recently, research has started to focus on combined prioritization approaches, which include seismic vulnerability and degradation. In this framework, in 2020, novel guidelines for existing bridges were issued in Italy [25]. They proposed a novel simplified and multi-level procedure to prioritize further verifications and interventions on bridges part of a stock, based on a multi-risk approach, which considers structural safety accounting for degradation, as well as seismic, hydraulic, and hydrogeological risks. The main limitation of the proposed procedure is that it groups bridges in attention classes, but it has not the purpose of a detailed ranking by rating each structure.

This paper discusses a priority ranking procedure which evaluates both degradation effects and seismic vulnerability (the former through visual inspections and defect survey, and the latter by using fragility curves from the literature), as described by the authors in Saler et al. [26]. The estimate of degradation effects was carried out according to a simplified procedure

available in the literature [27], whereas the proposed seismic assessment approach was devised so as to be consistent with it.

Since 2016, the prioritization approach has been applied to an urban bridge stock consisting of more than 160 bridges. The analyzed urban area, whose specific features are described in the paper, is the Municipality of Padova, in North-East Italy.

This contribution is focused on seismic evaluation, for which a comparison with the procedure proposed by Italian Guidelines is provided [25].

## 2 THE BRIDGE INVENTORY OF PADOVA, ITALY

The current section presents the bridge stock managed by the Municipality of Padova (i.e., comprised of structures for which the local administration is directly in charge, as well as bridges which overcoming roads of the municipality network). Since 2016, an extensive campaign of visual inspection and survey has been carried out, allowing a detailed taxonomy of the stock to be devised.

The bridge inventory of Padova consists of 162 bridges of various types, whose characteristics reflect the topography and urbanization of the area. The city of Padova is very ancient, the first urban settlement was founded in the XII century BC, and surrounded by rivers and artificial canals, useful in the past for both transportation and defense purposes. A certain number of bridges from the Roman and Medieval ages are still operational. Railway network passes across the historical center (HC), where the railway station is located. Thus, a series of bridges were built to overcome railways tracks.

Figure 1 shows some examples of type of bridges of the Padova inventory.

Aggregated distributions of structural and typological characteristics of the bridge inventory are reported in Figure 2, unbundling data related to the HC, so as to highlight its particular features. The related meaning of symbols is reported in Table 1.

Most bridges in the inventory are road bridges, followed by pedestrian bridges, most of which were built in the last 20 years, to enhance pedestrian safety against the increasing traffic volume. The construction age of the asset is quite heterogeneous, with a peak of structures built before 1920, including most of the masonry arched bridges in the historical center. Then, a second peak period of construction is found between 1960 and 1980, due to the expansion outside the historical center of both urbanized and productive areas. Finally, the last period of enlargement of the urban network have occurred in the last 20 years, corresponding to the construction of the most recent part of the suburban beltway, carried out in the early 2000, as well as to the realization of most pedestrian bridges, as aforementioned.

Most bridges in the HC are masonry or r.c. structures. Several cases were surveyed in which an r.c. deck was built next to a masonry arch to allow the carriageway to be widened. Out of the HC, the majority of bridges (almost 60%) has r.c. or prestressed r.c. deck, and the prevalence increases to 70% if only road bridges are considered.

While representing a minority part of the stock, other types of bridges (i.e., with masonry or steel deck) represents a not negligible portion of an urban asset like the Padova inventory. On the contrary, datasets referring to highway networks [13,14] reported bridge types other than r.c. structures to be rarer than in the analyzed case.

Focusing on static scheme, in the HC most bridges are arched (all of masonry structures as well as a number of r.c. arch) or girders, either simply supported or continuous.

Outside the HC the distribution of static schemes appears more heterogeneous, with a peak corresponding to simply supported girders.

In the Padova inventory there are mainly single-span bridges, with also a significant set of structures with two or three spans. A greater number of spans is rare, and mainly located out of the historical center.

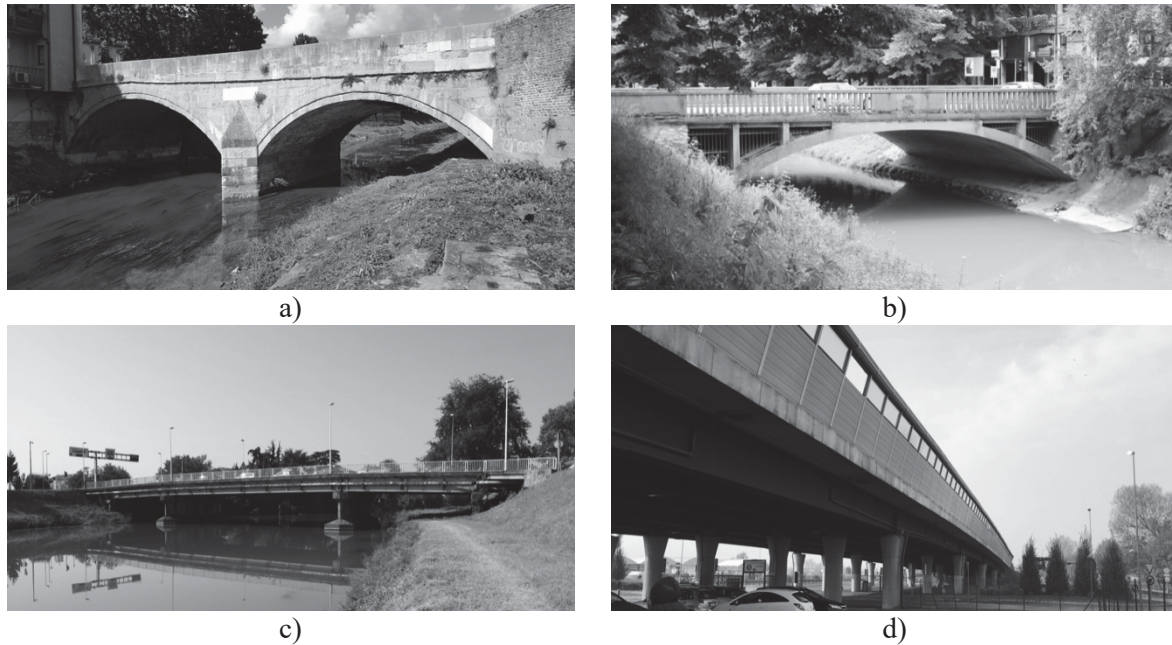

Figure 1: Examples of types of bridges of Padova inventory: a) masonry arch; b) r.c. arch; c) r.c. girder deck; and d) mixed steel-r.c. girder deck.

Small (<20m) to medium (20-40 m) bridges are mainly found in the urban area, also due to its flat topography and high population density. Spans tend to be on average shorter in the HC, with a mode in the range 10-20 meters, while outside the HC the span length mode is in the range 20-30 m (steel and precast r.c. technologies allowed longer spans to be realized). An exception inside the HC is due to the presence of the railway station and tracks, which require greater span length, up to 50 m, to be properly overcome.

Generally, reinforced concrete appears to be the most used material for substructures, although masonry was used for ancient structures. In the historical center is therefore more common to find masonry abutments. Lastly the distribution of height and type of piers is provided (obviously referring to only multi span bridges – 24 in the HC, 50 out of HC). Pier height is mainly shorter than 8 meters, due to the flat topography of the area. Thus, squat configuration is more common for wall piers, which represent the most common type in the HC. Outside the HC also frame piers are fairly common, since this type is more suitable for structures with greater transverse width (i.e., with larger carriageways).

Nevertheless, the following sections are focused only on bridge types which are more susceptible to seismic damage (see the following Table 2), excluding light and flexible structures which are negligibly affected by seismic actions (i.e., steel arch bridges and cabled structures).

<i>DC</i>	Reinforced concrete (r.c.) deck	<i>RET-SIM</i>	Reticular – simply supported
<i>DPC</i>	Prestressed r.c. deck	<i>CBL</i>	Stayed cable or suspended bridge
<i>DM</i>	Masonry deck	<i>AM</i>	Masonry abutment
<i>DS</i>	Steel deck	<i>AC</i>	R.c. abutment
<i>DCS</i>	Mixed steel-r.c. deck	<i>PSC</i>	Circular single pier
<i>ARCH</i>	Arch	<i>PW</i>	Wall pier
<i>SIM</i>	Simply supported	<i>PF2</i>	Two-column frame pier
<i>GER</i>	Gerber scheme	<i>PFM</i>	Multi-column frame pier
<i>CONT</i>	Continuous spans		

Table 1: List of symbols.

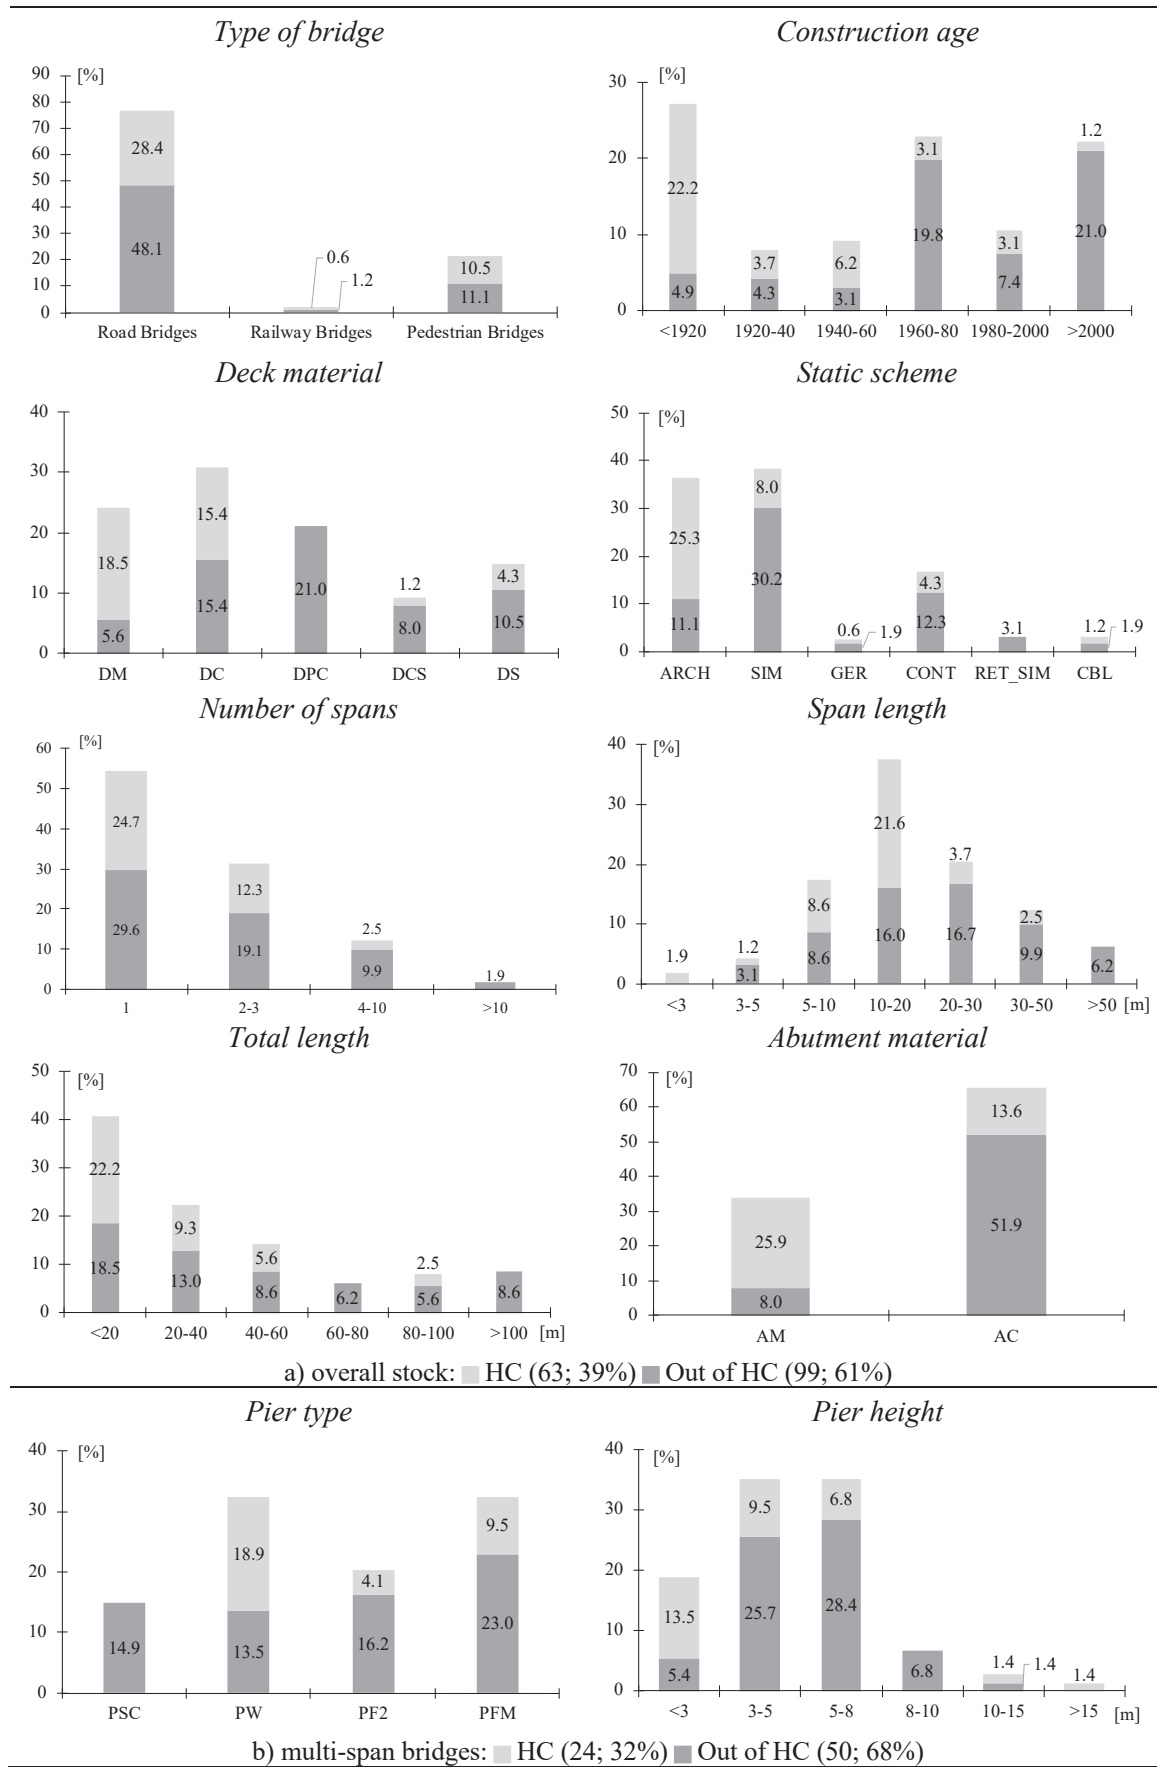

Figure 2: Typological characteristics of bridges of Padova inventory: a) overall stock; b) multi-span bridges.

### 3 SEISMIC-BASED RANKING PROCEDURE

The effects on a structure of both degradation and earthquake depends on its type and on structural members which determine how the structure responses. For instance, some components are more affected by degradation (e.g., Gerber saddles). The identification of bridge macro-classes, based on construction material and static scheme, is reported in Table 2, while Table 3 lists the structural components mainly involved in the structural response and the related mechanisms which were considered in the vulnerability assessment.

The evaluation of seismic vulnerability was carried out through fragility curves previously derived by the authors [8,11], defined for ranges of geometric and structural parameters, for example different fragility curves are assigned for segmental and circular arches. Both Life Safety and Damage limit states (LSLS and DLS, respectively) were considered.

Structural Material	Static Scheme
<i>Masonry</i>	Arch
<i>Reinforced concrete</i>	Arch
	Girder
<i>Steel</i>	Girder
	Reticular

Table 3: Structural components and relative seismic mechanism for bridge macro-classes.

The probability of exceeding each limit state was processed as described in detail in Saler et al. [26], obtaining a rating value (Total Sufficiency Rating – TSR [26,27]) for each bridge, ranging from 1 (highest vulnerability) to 100 (lowest vulnerability). Seismic classes were defined on the basis of seismic rating, as reported in Table 4, which as well provides an interpretation of seismic classes according to the urgency of intervention. This was defined according to a recommendation [28] of the Italian Department of Civil Protection on how to use results of seismic verifications of relevant and strategic structures, made mandatory by Italian Code OPCM 3274/2003 [29].

	Seismic classes	TSR <sub>seismic</sub>	Urgency of intervention
Priority ↓	As	76-100	Long-term intervention – no need for planning
	Bs	51-75	Mid-term planning of intervention
	Cs	26-50	Short-term planning of intervention
	Ds	1-25	Immediate planning of intervention

Table 4: Seismic classes and relative urgency of intervention.

As an example, the calculation of the seismic rating value for one representative bridge is reported as follows. The case study is a precast r.c. girder bridge; it has three spans, each one simply supported (on simple neoprene bearing pads). It has r.c. abutments and squat r.c. wall piers.

The failure mechanisms which were included in the evaluation were both shear and flexural failure of piers and abutments, as well as the failure of supports. For each mechanism the probability of exceeding either LSLs or DLS was calculated by means of fragility curves, based on the expected peak ground acceleration (PGA) for the site of the structure. Then, for each structural element, the probability of exceeding each LS was assumed to be the maximum probability among the potential mechanisms for the specific bridge component.

Then, the exceedance probability associated to the global response of the bridge was computed by combining the probability of its components, through the upper-bound approach proposed by Choi et al. [4]. The upper-bound, which is more conservative and therefore used to calculate the global exceedance probability, is based on the assumption of statistically independent structural components. The values of exceedance probability for the presented case study are reported in Table 5.

For each limit state, the exceedance probability was associated to a Condition Factor (CF) [26,27], assigned as illustrated in Figure 3, which was then used to calculate the above-mentioned seismic Total Sufficiency Rating (TSR<sub>seismic</sub>), including corrective coefficients to take into account the importance of the bridge in the network [27]. The final rating of the structure is obtained as the minimum TSR between the rates calculated for LSLs and DLS; the seismic class of the structure is then assigned accordingly (Table 6).

A seismic class Ds was therefore assigned to the presented case study, which resulted to have a very low seismic rating, and thus a high priority for intervention planning.

Element	DLS	LSLS
Supports	3.523E-04	2.775E-02
Abutments	0.000E+00	1.898E-05
Piers	9.948E-01	1.832E-01
Global	9.948E-01	2.059E-01

Table 5: Exceedance probability of structural components and of entire bridge and for case study.

Figure 3: Condition factors associated to exceedance probability with values for case study for LSL and DLS.

	DLS	LSLS	Final
TSR <sub>seismic</sub>	9	36	9
Seismic Class	Ds	Cs	Ds

Table 6: Evaluated seismic rating and class for case study.

### 3.1 Application to the Padova bridge inventory

The seismic-based ranking procedure was applied to 145 bridges of the Padova inventory belonging to macro-classes identified as prone to seismic damage.

The proposed procedure takes into account the local hazard through the demand PGA which value allows the probability of exceeding a LS to be obtained by using fragility curves. Since, in the current paper, the procedure was applied to an urban area with homogeneous seismic hazard classification (i.e., ground acceleration on soil A  $a_g \simeq 0.1g$  for relevant and strategic structures), no variability in the results is due to different hazard input, while it can be assumed to be linked to structural and typological characteristics.

Results are provided as follows in terms of seismic classes. Figure 4 reports the obtained seismic classes, for both bridges in the historical center and outside of it. The majority of structures in the HC are classified Cs (i.e., needing short-term retrofit interventions), while outside the HC, most bridges (64%) fall in the best two classes (As and Bs).

To better understand these distributions, Figure 5 provided the obtained seismic classes, disaggregated on the basis of construction age, deck material, and static scheme, for the entire stock (graphs) and for either HC or the areas outside it (tables).

Comparing the frequency of seismic classes for bridges inside and outside the HC (observing the distributions based on construction age, deck material, and static scheme) a generalized greater seismic vulnerability of the historical center network is confirmed. Higher frequencies are reported for class Cs in the HC, and for the first two classes (As and Bs) outside the HC.

Figure 4: Distribution of seismic classes obtained for earthquake prone bridges of Padova inventory.

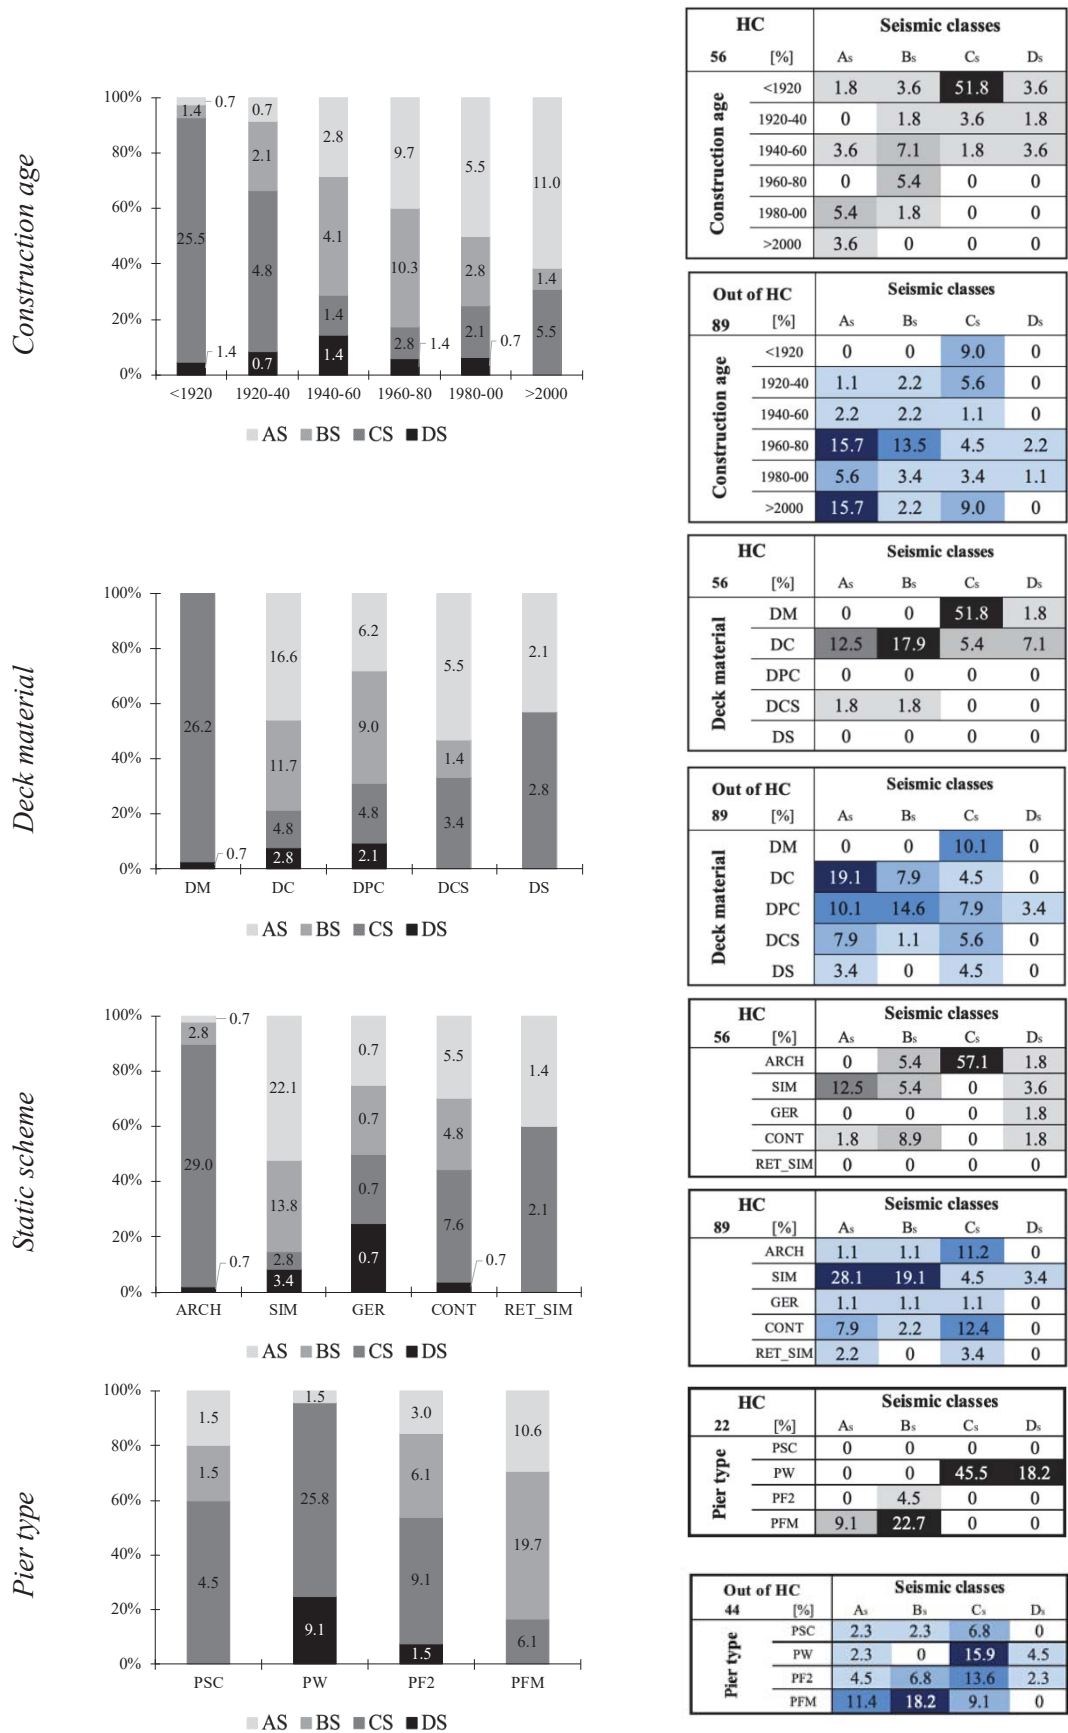

Figure 5: Obtained seismic classes for earthquake prone bridges of Padova inventory disaggregated on the basis of construction age, deck material, and static scheme.

Focusing on the distribution of seismic classes during construction periods, as expected, a larger amount of As-classified structures is found as the age of bridges decreases. The vast majority of bridges built before 1920 falls in seismic class Cs, while various distributions are found in the intermediate ages. Bridges built in the decades 1940s-1960s present the larger portion of structures classified Ds (i.e., needing immediate planning for seismic retrofit interventions).

An interesting correlation emerges analyzing the distribution of seismic classes for different deck materials; most of masonry bridges are classified Cs (leading to the high percentage of structures classified Cs among bridges built before 1920 and with arch static scheme). The critical mechanism for the majority of these bridges was indeed the overturning of spandrel walls, leading to the same seismic class.

R.c. bridges (both ordinary and precast) report the highest percentage of Ds classified structures. The most vulnerable structures, in this case, presents squat wall piers, with high probability of exceeding the trigger of shear mechanism at Damage LS.

A limited number (22) of steel bridges was analyzed in this contribution, since various steel structures were excluded due to their lightness and flexibility. None of this type of structures is classified Ds. Although caution must be applied to the interpretation of results due to the small sample size, a possible explanation for this might be that steel bridges are, on average, of recent construction.

The application of seismic-based prioritization allows typological intervention to be identified, based on specific deficiencies which characterized some types of bridges. Retrofitting all the masonry arched bridges classified Cs by means of tie-rods, to prevent spandrel wall overturning, is a fast intervention, with low impact and cost and great efficiency. Indeed, it allows bridges to change seismic class from Cs to As, with great impact on the global vulnerability of the stock, requiring limited effort.

A common deficiency for girder bridges is given by inadequate support devices. To replace supports with more efficient isolation systems would allow seismic vulnerability of structures to be reduced, with also a decreasing in the forces transferred to substructures.

#### 4 COMPARISON WITH ITALIAN GUIDELINES

Very recently, novel Italian Guidelines for the assessment of bridge stocks were issued [25]. The proposed multi-level approach includes a procedure to classify bridges in five “warning levels” (i.e., high, medium-high, medium, medium-low, low) [30]. The estimation of warning levels, indeed, represent “Level 2” of the guideline procedure, preceded by inventory of the analyzed asset and visual inspection, and followed by detailed evaluations and verifications.

The approach allows the combination, through logical operators, of warning levels referring to various natural hazards (i.e., seismic, hydraulic, and hydrogeological), as well as to degradation effects.

The evaluation of warning levels associated to seismic risk was carried out for the above-described bridge inventory of Padova. In this section results from Italian Guidelines are presented and compared to the outcomes of the proposed seismic-based ranking procedure.

The main difference between the outcomes of these approaches is that the Guidelines group structures in warning levels, in which homogeneous risk is assumed, while the proposed ranking procedure provides a quantitative rating, allowing bridges to be sorted according to the estimated vulnerability.

The approach provided by the Guidelines combines, through logic paths, factors of hazard, exposure and vulnerability, which in turn depend on the following parameters: i) hazard parameters are the peak ground acceleration, topography, and type of soil; ii) exposure parameters are traffic volume, average span length and importance of the bridge; iii) vulnerability parameters

are construction material, static scheme and span length, as well as degradation level and design criteria (whether seismic design was considered or not).

Figure 6 compares the distribution of seismic classes, obtained with the above-described seismic based ranking procedure, and the warning level toward seismic risk obtained from the application of Italian Guidelines [25]. First, the classification of all the seismic prone bridges of the Padova inventory are reported (Figure 6a). The guideline approach provides more conservative results, with most bridges which presents a high or medium-high warning level, and no structure with low warning level. For a local administration in charge with a relatively large stock of structure, it could be challenging to manage the outcomes of guideline prioritization, as the number of bridges requiring urgent verifications remains high. Moreover, when an extensive retrofit campaign must be planned, allocating limited funds, the identification of a manageable number of most critical structures is necessary.

Results of the different approaches are compared also on the basis of deck material (Figure 6b), construction age (Figure 6c), and static scheme (Figure 6d).

Generally, results from the guideline approach are confirmed to be more conservative; an exception is given by masonry arch bridges, which classification according to Guidelines is quite heterogeneous, while they were classified mainly Cs by the proposed seismic-based prioritization. This result may be explained by the fact that the evaluation of warning level according to Italian Guidelines is focused on the Life-Safety LS of the structure, thus some damage mechanisms involving secondary elements (e.g., spandrel walls in masonry arch bridges) may be not directly included. On the contrary, the proposed seismic-based approach includes this kind of mechanisms, which, in case of masonry arch bridges, results to be the most critical, affecting the seismic classification. R.c. bridges report the highest percentage of the worst classified structures, for both the approaches.

The distribution of the most vulnerable structure, according to the analyzed procedure, across the age of construction is slightly different, with a concentration of high warning level [25] in the period 1960-1980, while, as mentioned before, bridges built in the preceding decades (1940-1960) present the peak of Ds-classified structures.

The guideline procedure results to be punitive in particular for bridges with simply supported deck (both simply supported girder and Gerber scheme deck), which however present a peak of worst classified structures also by applying the proposed seismic based ranking procedure.

## 5 CONCLUSIONS

- This paper discusses a priority ranking procedure presented by the authors in Saler et al. [26]. Since 2016, the prioritization approach has been applied to an urban bridge stock managed by the Municipality of Padova, in North-East Italy.
- An extensive campaign of visual inspection was carried out, allowing a detailed taxonomy of the urban stock to be devised and presented in the current contribution by means of aggregated distributions of structural and typological characteristics. Data related to the historical center have been unbundled, so as to highlight its particular features.
- The evaluation of the seismic vulnerability of the stock through fragility curves for various mechanisms allows some indications about typological interventions to be deduced: i) masonry arched bridges are mainly subjected to spandrel wall overturning, thus the application of tie-rods (with low cost and impact) is suitable to improve the seismic response of this type of bridges; ii) girder bridges often have inadequate support systems which replacement with isolation devices can reduce the seismic vulnerability of both substructures and superstructures.

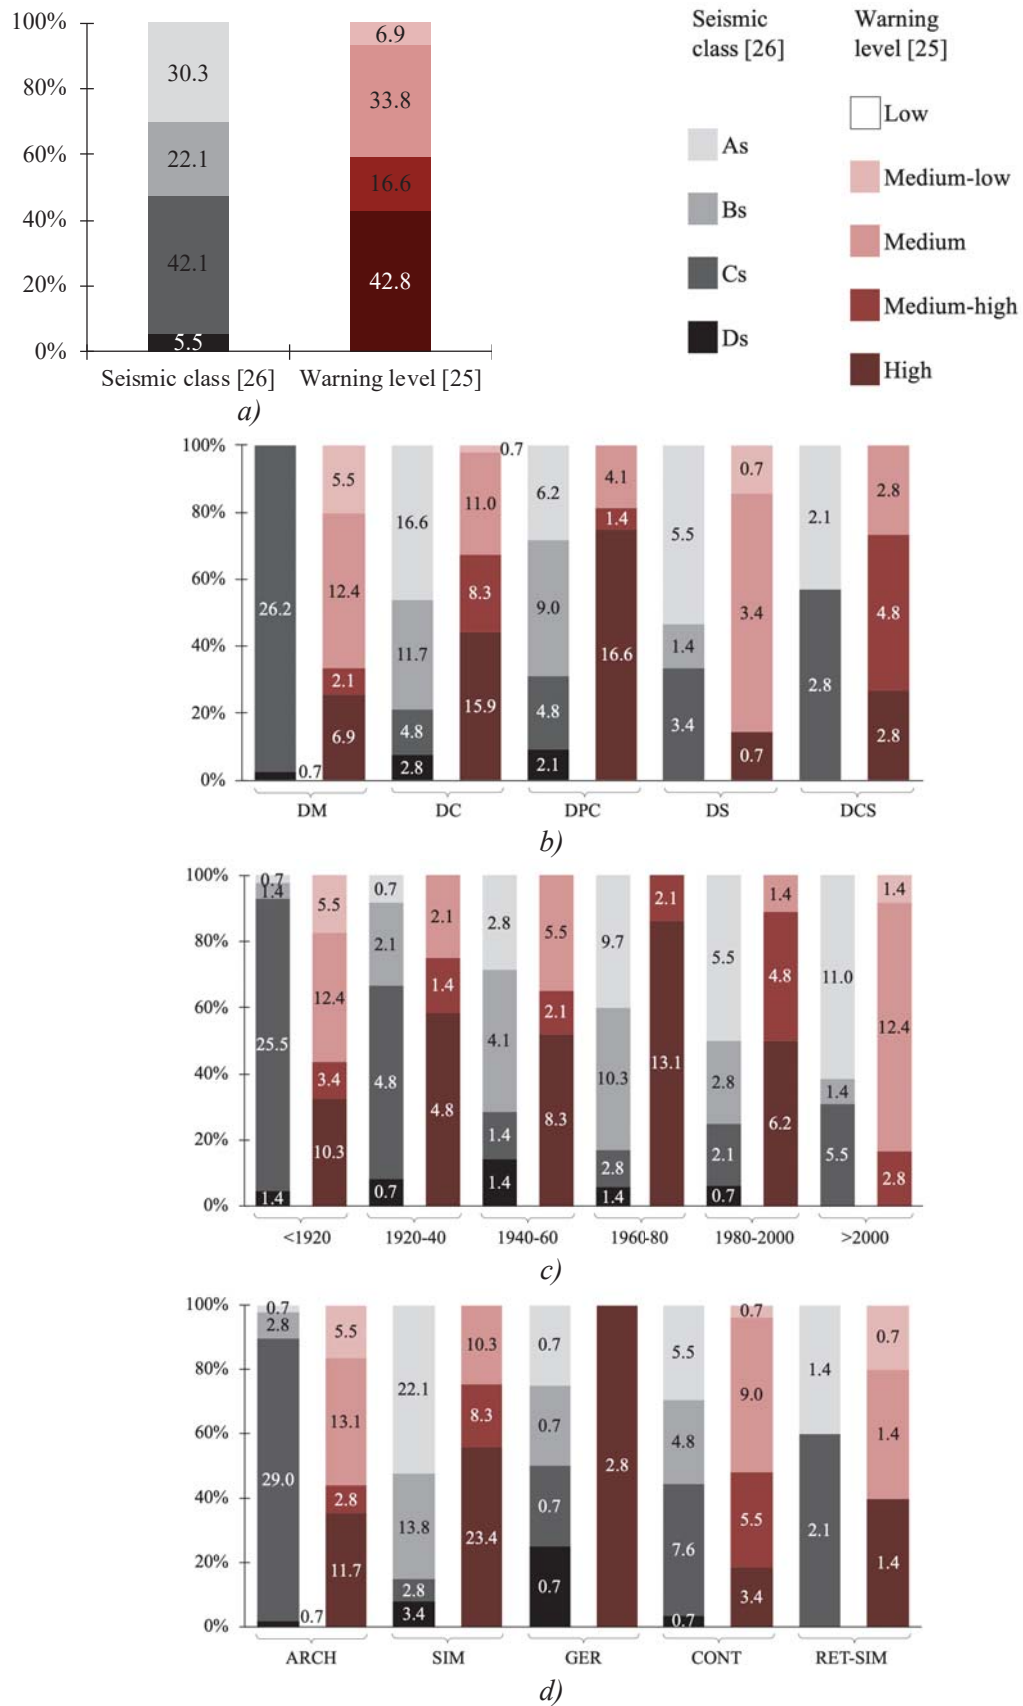

Figure 6: Comparison of seismic class [26] and warning level [25] distributions: a) general; b) based on deck material; c) based on construction age; and d) based on static scheme.

- The evaluation of seismic warning levels according to novel Italian Guidelines on existing bridges [25] was carried out for the bridge inventory of Padova. Italian Guidelines group structures in warning levels (homogeneous risk), while the proposed approach rates each structure, allowing bridges to be sorted according to their vulnerability.
- Results from the applied procedures have been compared. Guidelines resulted to be more conservative, with most bridges presenting a high or medium-high warning level, and no structure with low warning level. However, similar results might be difficult to be managed by local administrations in charge, for the high number of bridges requiring urgent verifications to be urgently planned.

## ACKNOWLEDGEMENTS

Special thanks are due to the Municipality of Padova which partly funded this work.

### Abstract

*The seismic resilience is becoming an important indicator for the performance assessment of structures and infrastructure systems. This paper proposes a probabilistic approach based on seismic fragility analysis to assess the seismic resilience of steel-concrete composite bridges. By considering the structural and seismic uncertainties in different analysis steps of this approach, the sample generation process for probabilistic demand models is simplified, which largely reduced the computational burden. To deeper understand the seismic resilience and better describe the uncertainties, the estimation interval of the expected resilience is given, while the uncertainties are considered in fragility and propagated to the resilience. This approach is applied to a new typology of steel-concrete composite bridge endowed with concrete cross beams, which has been analyzed within the European Research Project SEQBRI. The results show that this probabilistic approach can largely speed up the process of seismic resilience assessment, while both the aleatory and epistemic uncertainties are considered. Meanwhile, the resilience of the bridge is assessed under both the near-fault and the far-field ground motions which aim to study the influence of near-fault earthquakes on the seismic resilience.*

**Keywords:** Seismic resilience; seismic fragility; steel-concrete composite bridges; near-fault earthquakes.

---

## 1 INTRODUCTION

The concept of seismic resilience has been fast developing in recent years, which plays an important role in performance assessment especially for infrastructure systems. The structural condition of bridges is one of the key aspects of the functionality of transportation networks, which must correspond to an acceptable resilience level to guarantee the efficient flow of people and services (Deco et al. 2013). However, the approach on seismic resilience assessment for bridges has not been yet adequately investigated, being in general difficult to be performed especially for near-fault earthquakes.

Deterministic approaches for seismic resilience evaluation have been developed in the past by many researches. Bruneau et al. (2003) proposed the preliminary framework of seismic resilience assessment. Xu et al. (2007), Frangopol and Bocchini (2011) were interested in the recovery scheduling optimization, while Cimellaro et al. (2010) developed the recovery functions based on empirical formulas. Further developments proposed a probabilistic treatment of the seismic resilience. For example, Deco et al. (2013) suggested a probabilistic approach for resilience prediction based on fragility analysis, while Karamlou and Bocchini (2015) assessed the accuracy of traditional fragility methods for resilience prediction.

The performance-based earthquake engineering (PBEE) approach has been broadly proposed to assess the seismic performance of structures and supporting decision-makers in disaster management. The probabilistic approach adopted by PBEE allows considering the intrinsic randomness related to earthquakes and structures. In this respect, a seminal work concerning the probabilistic seismic demand analysis (PSDA) was performed by Shome (1999), in which the uncertainty of the seismic demand was accounted for. Cornell et al. (2002) derived the demand fragility functions to combine the inherent uncertainties of seismic hazard and structural response. Deco and Frangopol (2013) proposed a method for resilience calculation of bridges in seismic prone-areas including structural uncertainties and variability in the restoration process and rehabilitation costs.

It is worth mentioning that the epistemic uncertainties, which derive mainly from the inadequacy of FE models, cannot be totally neglected (Ellingwood et al. 2009). However, in the previous analyzed works, the epistemic uncertainty for resilience analysis has not been correctly accounted for, which should instead be quantitatively calculated for improving the accuracy of probability models. Therefore, an advancement towards this direction appears necessary.

According to the above-depicted framework, this paper presents a probabilistic approach to estimate the seismic resilience for bridges. For this purpose, analytical seismic fragility functions are used, accounting for both aleatory and epistemic uncertainty associated with earthquake event, structural response and expected damage (Lu et al. 2014). The point and interval estimation methods are firstly used for the expected recovery curves, which allow to easily estimate the seismic resilience and help decision-makers in predicting the seismic performance of bridges. The procedure is then applied to a short-span steel-concrete composite (SCC) bridge which has been analyzed within the Project SEQBRI. In order to estimate the seismic performance of bridges under an extreme event, the effect of near-fault earthquakes is considered. Finally, simplified seismic fragility analysis and seismic resilience estimation of the case study are performed.

## 2 ASSESSMENT METHODOLOGY

In this section, a simplified method to assess the seismic resilience of bridges is presented, which consists of four steps as illustrated in Fig. 1:

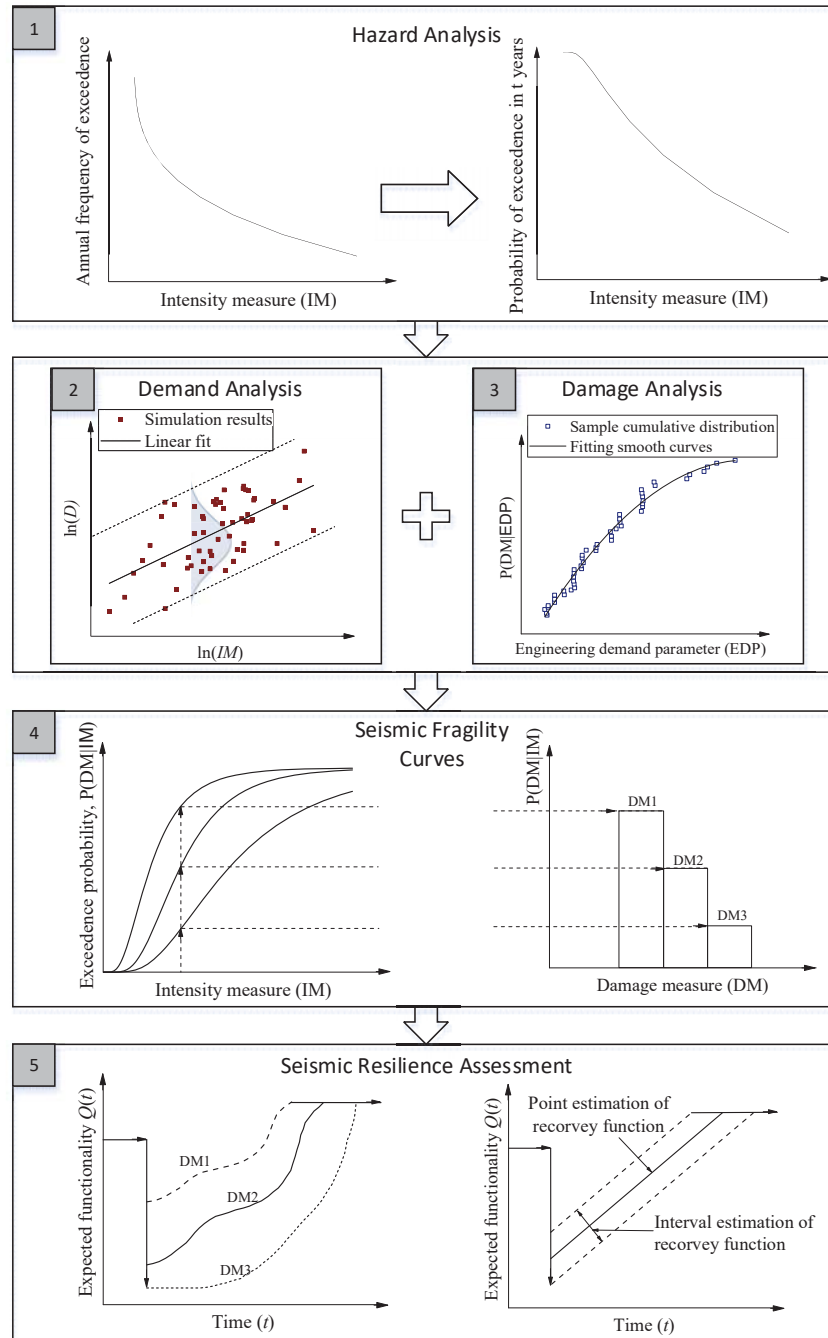

Fig. 1 Analysis stages of assessment methodology

1. **Seismic hazard analysis.** The classical Probabilistic Seismic Hazard Analysis (PSHA) is here in adopted, which provides the mean annual frequency (MAF) of exceedance of a selected intensity measure (IM) for all possible sources generating an earthquake (Cornell 1968);
2. **Seismic demand analysis.** Among different nonlinear demand estimation methods for the PSDA, the Cloud Analysis (CA) certainly is the commonly used. This method consists in

generating cloud of Engineering Demand Parameter (EDP) values for a set of earthquake ground motion records characterized by a hazard-consistent IM. Basic and improved versions of CA have been proposed to account for the inherent randomness of the seismic action in the form of record-to-record variability only or also the epistemic uncertainty, related to the modelling (Bazzurro 1998; Cornell et al. 2002; Ellingwood et al. 2009). In this work only the basic version has been implemented to evaluate the probability of exceedance (POE) of a given demand level.

3. **Damage Analysis.** The damage analysis aims at predicting the structural damage at component level as function of demand parameters. Any damage level, usually expressed in terms of Damage Measures (DM), presents variability with EDP due to the uncertainty of material properties and structural response history (Gardoni et al 2002).
4. **Fragility Analysis.** In this step, the POE of a given DM conditioned to a selected IM is determined by adopting an analytical approach. By assuming a lognormal distribution, a closed-form formulation of demand and capacity fragility curves is proposed, which accounts for epistemic uncertainty as well.
5. **Resilience estimation.** This is the last step that consists in the seismic resilience assessment for different structural damage level caused by the earthquake event, considering the uncertainty associated with the restoration process.

This paper focuses on the previous steps and proposes a methodology based on numerical simulation, which is described in the following sub-sections.

## 2.1 Probabilistic seismic demand models (PSDA)

The purpose of PSDA is to establish a probabilistic relationship between the selected EDP and IM (Tondini and Stojadinovic 2012).

It is assumed that the seismic demand  $D$  follows a lognormal distribution (Cornell et al. 2002). The probability of exceeding the demand level  $d$  conditioned on  $IM = x$  can be expressed as:

$$P[D \geq d | IM = x] = 1 - \Phi \left[ \frac{\ln(d) - \ln(m_D)}{\beta_{D|IM}} \right] = 1 - \Phi \left[ \frac{\ln\left(\frac{d}{m_D}\right)}{\beta_{D|IM}} \right] \quad (1)$$

where,  $m_D$  is the median of the demand parameter EDP,  $\beta_{D|IM}$  is the dispersion of the demand about its median value conditioned to  $IM$ , and  $\Phi(\cdot)$  is the standard normal cumulative distribution function. Additionally,  $m_D$  can be assumed linear in the log-log space (Cornell et al. 2002). Consequently, the probabilistic seismic demand model (PSDM) can be expressed as

$$\ln(m_D) = a + b \ln(IM) \quad (2)$$

in which,  $a$  and  $b$  are regression parameters, which could be assessed by a linear regression analysis on the logarithmic maximum response versus  $\ln IM$ . Accordingly, the logarithmic standard deviation could be estimated by the following formula:

$$\beta_{D|IM} = \sqrt{\frac{\sum_{i=1}^N [\ln(d_i) - \ln(m_D)]^2}{N-2}} \quad (3)$$

Previous studies on bridges clearly demonstrated that the uncertainty from earthquakes events is much bigger than that of structures (Wen et al. 2003; Padgett and Des-Roches 2007). For this reason, in the following only the randomness due to the earthquake is considered by selecting suites of ground motions and generating samples of EDPs. For this approach simplified, the computational burden is reduced several times in time-history analysis.

## 2.2 Seismic fragility functions

The seismic fragility represents the probability of occurrence or exceeding specified levels of damage in the considered range of IMs. This can also be expressed in terms of probability of the seismic demand (D) exceeding the seismic capacity (C) at the component or system level, conditioned on  $IM=x$ :

$$F_R(x) = P(DM|IM = x) = P(D > C|IM = x) \quad (4)$$

Assuming that the capacity (C) obeys lognormal distribution, using Equations (1) and (2), the fragility function can be further derived as:

$$F_R(x) = \Phi \left[ \frac{\ln(m_{D|IM}) - \ln(m_C)}{\sqrt{\beta_{D|IM=x}^2 + \beta_C^2}} \right] = \Phi \left[ \frac{\ln(aIM^b) - \ln(m_C)}{\sqrt{\beta_{D|IM=x}^2 + \beta_C^2}} \right] \quad (5)$$

where,  $\mu_C$  and  $\beta_C$  are, respectively, the median and the dispersion of the capacity. These parameters can be evaluated performing the probabilistic damage analysis adopting either experimental or numerical approaches (Melchers 1999). The fragility function can be further derived as:

$$F_R(x) = \Phi \left[ \frac{\ln(aIM^b) - \ln(m_C)}{\sqrt{\beta_{D|IM=x}^2 + \beta_C^2}} \right] = \Phi \left[ \frac{\ln(m_{D|IM}) - \ln(m_C)}{\sqrt{\beta_{D|IM=x}^2 + \beta_C^2}} \right] = \Phi \left[ \frac{\ln(x/m_R)}{\beta_R} \right] \quad (6)$$

where,  $\mu_R$  and  $\beta_R$  are, respectively, the median and the dispersion of the fragility, obviously, the parameters of the fragility can be re-formulated as (Lu et al. 2014):

$$m_R = \left( \frac{m_C}{a} \right)^{\frac{1}{b}} \quad (7)$$

$$\beta_R = \left( \frac{1}{b} \right) \sqrt{\beta_{D|IM=x}^2 + \beta_C^2} \quad (8)$$

## 2.3 Probabilistic seismic resilience assessment

In the field of civil engineering, the seismic resilience is defined as the ability of structures to contain the effects of a seismic event adopting effective measures to recover functionality after disasters and mitigate the effects of the future seismic risk (Bruneau et al. 2003). However, resilience is a multi-faceted concept, which covers too broadly social and technical aspects to be defined with a single analytical function. In the present paper the following definition of resilience index R is adopted (Deco et al. 2013):

$$R = \frac{\int_{t_0}^{t_0+t_h} Q(t) dt}{t_h} \quad (9)$$

where  $Q(t)$  is the functionality of the structure, which depends on time  $t$ ,  $t_0$  is the occurrence time of the earthquake, and  $t_h$  is the investigated time horizon. Based on the total probability theorem, the estimation of structural functionality at any specific time  $t$  after an earthquake can be calculated. Assuming a limited range of earthquake intensity, the expected functionality (" $Q$ ") (" $t$ ") can be computed as following (Karamlou et al. 2015),

$$\bar{Q}(t) = \sum_i^{n_{IM}} P(IM = i) \sum_j^{n_{DS}} P(DS = j|IM = i) Q_j(t) \quad (10)$$

where, " $P(IM = i)$ " is the probability of occurrence of the earthquake while the intensity  $IM=i$ , computed by using PSHA for the bridge location site (FEMA445). The second item of the right hand of the equation, " $P(DS = j | IM = i)$ ," is the vulnerability expressed as the probability of being in the damage state  $j$  conditioned on " $IM = i$ ".  $Q_j(t)$  is the time-variant functionality of the structure in the case of initial damage state  $j$ . Being different from buildings, the functionality of highway facilities (e.g., bridges) is usually defined as the carrying capacity of traffic under normal situations (ATC13).

## 2.4 Quantification of uncertainties, point estimation and interval estimation

In the field of civil engineering, the seismic resilience is defined as the ability of structures to con

In order to develop reliable probabilistic models the various sources of uncertainties need to be quantified. Two broad types of uncertainties in probability models have to be dealt with: aleatory uncertainties and epistemic uncertainties. The formers are involved in the modeling and evaluation of low-probability, high-consequence events in nature, which are caused by the inherent variability and randomness in nature, and cannot be influenced by the observation. The epistemic uncertainties arise from our limited knowledge, imperfect modeling and simplifications (Ellingwood and Kinali 2009).

As shown in Equation (6), the two probabilistic models of demand and capacity can be integrated into a unitary probabilistic model of the fragility. Alternatively, the fragility model can be separated into a probabilistic demand and a capacity model.

Following the first approach, the uncertainty of the demand and the capacity are considered separately. Referring to the probabilistic seismic demand analysis (PSDA), the dispersion  $\square D|IM$  represents the aleatory uncertainty raised from the randomness of the earthquake records input. That can be directly calculated in the PSDA. The epistemic uncertainty of the demand is instead not included in this model. This approach has been justified by Karamlou and Bocchini (2015) that have evaluated the epistemic uncertainty arising from the different assumptions used to build the probabilistic seismic demand models (PSDM). The effect of this uncertainty on the fragility is limited, whose influence range is smaller than 10%. For this reason, in the following only the aleatory uncertainty  $\square D|IM$  will be accounted for.

In the probabilistic capacity analysis, the capacity dispersion  $\square C$  generally contains two components of uncertainty (Wen et al. 2003), which is defined as:

$$\beta_C = \sqrt{\beta_{CR}^2 + \beta_{CU}^2} \quad (11)$$

where the dispersion  $\square CR$  is the aleatory uncertainty arising from the randomness of the structural capacity, which can be assessed based on some experimental studies. The dispersion  $\square CU$  presents the epistemic uncertainty of capacity, which depends on the effects of the different sample sizes selection in probabilistic capacity seismic analysis (Ellingwood 2001; Ellingwood and Kinali 2009). The substitution of Equation (11) into Equation (8) leads to the point estimation of the fragility function considering the epistemic uncertainty:

$$F_R(x) = \phi \left[ \frac{\ln(x/m_R)}{\beta_R} \right] = \phi \left[ \frac{\ln(ax^b) - \ln(m_C)}{\sqrt{\beta_{D|IM=x}^2 + \beta_{CU}^2 + \beta_{CR}^2}} \right] \quad (12)$$

where the epistemic uncertainty of the fragility is presented by the dispersion  $\square CU$  of the capacity.

In the second approach, the epistemic uncertainty in the fragility model is assumed unitary, which can be directly considered as the epistemic uncertainty of the median  $m_R$  of the fragility curve (Eq. (6)). Therefore, the median of the fragility can be expressed as

$$M_R = \varepsilon m_R \quad (13)$$

in which the  $\varepsilon$  is the random error of the median value.

It is assumed that the median of the fragility follows the lognormal distribution, whose median and dispersion are  $m_R$  and  $\square RU$  (Ellingwood and Kinali 2009; Lu et al. 2014). According to the definition of the confidence level  $C$ , we have:

$$\Phi \left[ \frac{\ln(m_{R,\alpha}/m_R)}{\beta_{RU}} \right] = 1 - \alpha \quad (14)$$

where,  $m_{R,\alpha}$  is the fractile of the median given the confidence level  $\alpha$ , which can be further derived as:

$$m_{R,\alpha} = m_R \exp[-\beta_{RU} \Phi^{-1}(\alpha)] = \left(\frac{m_C}{a}\right)^{\frac{1}{b}} \exp[-\beta_{RU} \Phi^{-1}(\alpha)] \quad (15)$$

Then, the interval estimation of the fragility function becomes:

$$F_R(x) = \Phi \left[ \frac{\ln(x/m_R)}{\beta_R} \right] = \Phi \left\{ \frac{\ln x / (m_C/a)^{\frac{1}{b}} \exp[-\beta_{RU} \Phi^{-1}(\alpha)]}{\sqrt{\beta_{D|IM=x}^2 + \beta_{CR}^2}} \right\} \quad (16)$$

where the dispersion of the fragility  $\square R$  just represents the aleatory uncertainty of the fragility, which can be calculated by the first method mentioned above. The belief interval is assumed to have lower and higher bounds equal respectively to 16% and 84%:

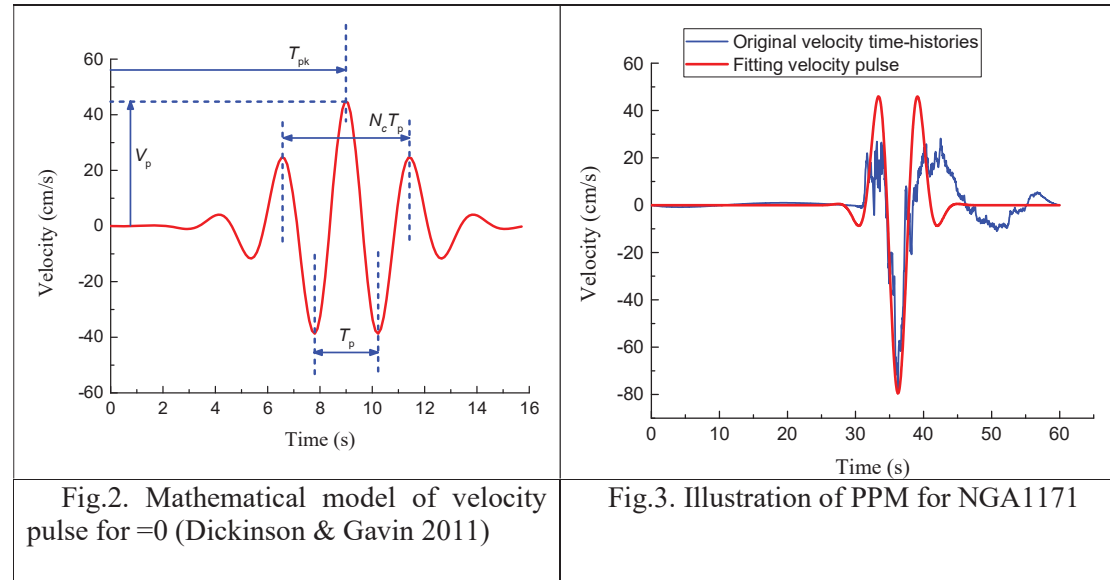

$$m_{R,16\%}(x) = m_{RR} \exp(-\beta_U), m_{R,84\%}(x) = m_{RR} \exp(\beta_U) \quad (17)$$

Equation 10 shows clearly the process of the uncertainty propagation from the hazard, the fragility and the recovery functionality to the expected recovery functionality. The uncertainty in  $Q$  consists of corresponding to the uncertainty in  $P(IM=i)$ ,  $P(DM=j|IM=i)$  and  $Q_j$ . The functionality restoration of bridges is affected by a large amount of uncertainties associated with the condition of the disaster area, the decisions of disaster relief, the support from surrounding areas, etc. (Frangopol et al. 2011). Given that the related research regarding to this uncertainty is limited in the literature, additional research is needed to address this shortcoming. For the sake of brevity, the uncertainty associated to the  $Q_j$  is here neglected in this content. It is assumed that all the uncertainty for the expected recovery functionality is derived from the occurrence of the earthquake and the damage. Then, the epistemic uncertainty in  $Q$  derived from decision making could be considered in the fragility analysis.

### 3 DETERMINATION OF PULSE-LIKE GROUND MOTIONS

It is well known that the near-fault (NF) earthquakes can induce significant seismic damages to the structures. The single or multiple pulses observed in their velocity time histories is the key characteristic for this type of ground motions. With respect to this feature, those ground motions can obviously induce higher seismic demands (Bertero et al. 1978; Hall et al. 1995; Chopra and Chintanapakdee 2001; Alavi and Krawinkler 2001, 2004). Consequently, it is strongly suggested to use this type of ground motions for the seismic assessment of bridges.

In the following, a method to quantify the strong velocity pulse that characterizes NF pulse-like ground motions is introduced (Zhai et al. 2013). The least-square fitting (LSF) technique is firstly used to find best matching with the main velocity pulse of the real ground motion of a simplified numerical model of the time history. Then, the parameters of the velocity pulse (e.g., period of pulse, peak velocity) are identified by using the peak-point method (PPM). Finally, the energy index ( $E_p$ ) is defined and calculated to determine, for the selected natural earthquake records, the pulse-like ground motions (Baker 2007; Zhai et al. 2013).

As shown in Fig.2, the pulse model is defined as (Dickinson & Gavin 2011):

$$v_p(t; V_p, T_p, N_c, T_{pk}, \varphi) = V_p \exp \left[ -\frac{\pi^2}{4} \left( \frac{t - T_{pk}}{N_c T_p} \right)^2 \right] \times \cos \left( 2\pi \frac{t - T_{pk}}{T_p} - \varphi \right) \quad (18)$$

in which  $v_p$  is the velocity pulse,  $V_p$  and  $T_p$  are respectively the amplitude and the period of the pulse,  $N_c$  and  $T_{pk}$  represent the number of cycles and the location in the pulse time-history,

and  $\phi$  is the phase of the pulse. The LSF algorithm is used to match the original velocity pulse and the simplified mathematical model, which is used to remove the high-frequency content of the real ground motions. Based on the PPM (Osaki 2008; Baker 2007), the peak velocity is extracted from the original velocity time histories to locate the velocity valley, and then the time interval of velocity valley is defined as the pulse period. Fig.3 illustrates the extracted velocity pulse for the NGA1171 ground motion.

With the aim to identify, among the selected natural records, the pulse-like ground motion, an energy-based method is used (Baker 2007). In this study, the determination indicator is defined as (Zhai et al. 2013):

$$\begin{cases} E_p = \int_{t_s}^{t_e} dE(t) = E(t_e) - E(t_s) \\ E(t) = \frac{\int_0^t v^2(\tau) d\tau}{\int_0^\infty v^2(\tau) d\tau} \end{cases} \quad (19)$$

in which  $E_p$  is the energy index,  $E(t)$  is the cumulative energy of the ground motion at time  $t$ ,  $t_s$  and  $t_e$  represent respectively the starting and ending time of the velocity pulse and  $v(\tau)$  is the velocity time-history.

According to the recent studies (Zhai et al. 2013), the ground motions are determined as the pulse-like ground motions when the value of  $E_p$  is greater than 0.3. While the peak ground velocity is greater than 30cm/s, the failure probability of this method is about 1.5%. That means some non-pulse-like ground motions may be determined as the pulse-like ground motions. Since the number of the pulse-like ground motions is limited, this standard with value 0.3 is used.

## 4 PROBABILISTIC RESILIENCE CALCULATION OF A SHORT-SPAN STEEL-CONCRETE COMPOSITE BRIDGE

### 4.1 Description of the bridge and its finite element model

The case study is a typical short span overpass with two lanes, currently under investigation within the European Project SEQBRI (Paolacci et al. 2016). The bridge is 40.00m long and consists of 2 spans of 20.00m each.

The bridge presents two spans of 20.0 m each for a total length of 40.0 m (Fig. 4). The roadway width of bridge is 10.6 m, including 6.5 m wide carriageway and two sidewalks of 2.05m wide each. Four HE600B steel girders of S460 steel grade are used, with 2.65 m in-between distance. The thickness of the concrete slab is 25cm. The steel girders are monolithically connected to the pier by a reinforced concrete crossbeam (CCB) 0.9 m wide, whereas they are simply supported on normal (low) damping bearings at the abutment through an additional CCB.

Details of the CCB configuration are shown in Fig. 5. The pier of wall type is 7.0 m height, 0.6 m thick and 7.0 m wide. The foundation soil is assumed to be categorized as type B according to EN1998 (BIBLIO) and the soil structure interaction effect is neglected.

Fig. 4. Longitudinal section and cross section at span

Fig. 5. CCB configuration

The 3D finite element (FE) model illustrated in Fig. 6 has been developed by using the OpenSees software (McKenna et al. 2007). In this model, the nonlinearities of materials are explicitly considered. In particular, the nonlinear beam elements with fiber cross-sections are used to model the single steel girder and the tributary concrete slab (Fig. 6 and 7). The Menegotto-Pinto model is adopted to simulate the mechanical behavior of steel girders and slab reinforcement, whereas the Kent and Park model is used to reproduce the mechanical behavior of concrete.

Nonlinear links with elasto-plastic behavior are used to model the vertical shear studs connecting the steel girders to the slab as well as the shear studs within the CCB. The strength of the shear studs has been evaluated in accordance with CEN (2006), while the stiffness has been evaluated by means of the load-slip curves experimentally defined by Gattesco and Giuriani (1996), even though different other recent proposal has been formulated (Shim et al. 2004; Lee et al. 2005).

Horizontal elasto-plastic links are also used to simulate the shear studs along the deck whereas the vertical direction and the rotation are constrained by rigid links between girders and slab.

Fig. 6. 3-D finite element model

Fig. 7. Fiber sections of the single composite beam

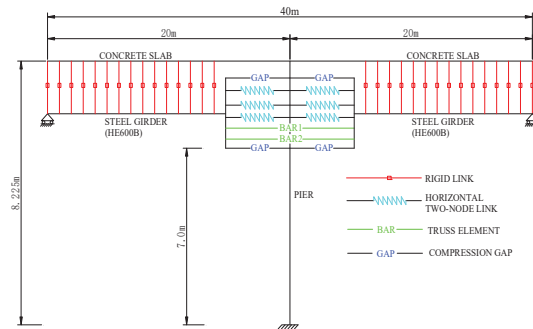

Fig. 8. 2D view of the model and details of the CCB modeling of the single composite beam

Fig. 9. 2D Component-based model of CCB joint

The behavior of the CCB joint is difficult to reproduce. For this reason, a component-based model has been recently proposed (Paolacci et al. 2014), which is currently under experimental investigation.

Rigid links are used to model the vertical head plates welded on the steel girders and directly in contact with the transverse concrete beam. Different non-linear links reproducing the behavior of the horizontal shear headed studs within the joint are connected to these rigid links according to the CCB configuration (Fig. 5). In order to reproduce the constraint in compression due to the presence of the CCB, gap elements are adopted at both left and right sides of the CCB joint at two different heights, as shown in Fig. 8. A simplified evaluation of the stiffness of the gap elements is performed, assuming that the compressive force transmitted by the girder would act uniformly on the contact area of the vertical head plate. The two groups of prestressing bars at the bottom area of the CCB, are modeled by two elastic truss elements. The 2-D FE model for concrete cross beam is shown in detail in Fig. 9.

#### 4.2 Selection of input ground motions
