Based on the insights obtained from the mentioned experimental program, Grilli and Kanvinde [7] presented a strength method to characterize the flexural capacity of EmBCs. Key aspects of this method are detailed here. The applied Moment is resisted by a combination of horizontal bearing stresses developed by the contact between the column flange and the concrete foundation and vertical bearing stresses at the bottom base plate. Shear forces in the panel zone complement the horizontal bearing stresses. Thus, the Moment is resisted by these two mechanisms, i.e., horizontal and vertical stresses, with the implication that a fraction of the total applied Moment is distributed to each mechanism. This idealization entails an indeterminate problem, which is solved by the introduction of an empirically calibrated equation that considers the relative stiffness of the embedded column and the surrounding media.

In this manner, the connection strength may be calculated based on the associated limit states to each force transfer mechanism. For the horizontal bearing stresses, two limit states can take place 1) concrete bearing failure and 2) joint shear failure. On the other hand, in the vertical bearing mechanisms, four possible modes of failure are identified 1) base plate yielding, 2) concrete breakout under the base plate, 3) concrete breakout above the base plate, and 4) bearing failure of the concrete around the base plate. The connection strength is calculated by combining the Moment capacity associated with both mechanisms ( $M_{HB}^{capacity}$  and  $M_{VB}^{capacity}$ ). Grilli and Kanvinde [7] concluded that the capacity estimated with the preceding procedure must be reduced by 30% for design purposes.

### 3 FINITE ELEMENT MODELS

A total of four FE models have been developed to study the seismic behavior of EmBCs using the ABAQUS [16] simulation platform. Figure 3 illustrates a representative model built in this investigation. The models are composed of 3D Hex-structured elements. The meshes were refined in places where concentrations of stress are anticipated. As described in the previous section, the strength of the connection may be explained due to the contacts between the column flange and the base plate with the concrete foundation. Thus, the contacts are an essential feature of these models. These contacts are simulated with a finite sliding formulation with Normal and Tangential interaction properties. The former property was defined as hard contact, while the latter with a frictional formulation following the penalty method. A friction coefficient of 0.45 is adopted as recommended by Gomez et al. [11]. In contrast, welded elements inside the connection are assigned the tie constraint (i.e., steel column and base plate, steel column, and stiffeners) since welds are detailed to resist fracture even at large deformations.

Geometric nonlinearities, including large deformations formulations, are included in the models. The steel column and base plate are modeled with the Von-Mises surface with isotropic hardening. On the other hand, for concrete modeling, it is common to assume that this material behaves as an elastoplastic material in compression and brittle in tension. In this investigation, the concrete damaged constitutive plasticity (CDP) model was employed since it provides a general capability for modeling concrete and other quasi-brittle materials. Some of the details of this constitutive model provided by [16] are discussed. The CDP model uses concepts of isotropic damaged elasticity in combination with isotropic tensile and compressive plasticity to represent the inelastic behavior of concrete. It assumes that the main two failure mechanisms are tensile cracking and compressive crushing of the concrete material. Two hardening parameters control the evolution of the yield surface,  $\epsilon_t^{-pl}$  and  $\epsilon_c^{-pl}$  associated to failure mechanisms under tension and compression loading, respectively [16]. The material properties are obtained from the ancillary tests from [7], and true stresses and strains were assumed in the material formulation.

The FE models were subjected to the SAC load protocol [15] in the Axial Load presence. In order to avoid the interference of P-delta effects in the connection response, the Axial Load was

applied strategically at the bottom of the base plate. Thus, the Moment-Rotation response was recorded from the simulations and compared to validate the models with the associate experimental test. Figure 4 illustrates the results of the simulations and the corresponding validation against the experimental data. As per this Figure, the essential aspects of the hysteretic response are capture by the numerical results. Specifically, the simulations are able to capture the pinching behavior observed in the tests. Cyclic deterioration of the strength and the unloading stiffness are identified in these connections and well-represented in the simulations. The parameters that define the response's backbone curve are the Moment at First Yield, the Initial Rotational Stiffness, the Peak Moment Strength, and the Rotation Associate to the Peak Strength. A visual inspection of Figure 4 indicates that the differences between the simulations' parameters to the experimental tests' corresponding values are neglectable. Consequently, in the authors' opinion, the FE models are able to capture the key features of the connection response and are appropriate to investigate the behavior of EmBCs.

#### 4 DISCUSSION OF THE RESULTS

This section discusses the key findings from the FE simulations. Referring to Figure 4, all simulations show a well-defined linear-elastic branch up to the point where nonlinear behavior starts, which corresponds to rotations close to 0.005rad. This observation is consistent with the experimental evidence reported by [7] that indicates that after 0.005rads, small cracks on the tension column flange start to open, entailing a gradual nonlinear response. These small cracks are accompanied by diagonal cracks, which start to grow near the steel column corners. Figure 5 shows a schematic representation of the crack propagation obtained from the simulation of test 1 once the deformation progresses.

As deformation progresses in all simulations, an appreciable loss of stiffness is observed because the concrete reaches its peak strength. At this point, the gap formed in the foundation in the tension flange side grows, which is consistent with the experimental tests [7]. This gap entails the pinching behavior observed in all the tests since it causes a relatively unconstrained rotation of the steel column as it moves back to the vertical position and goes in the reverse direction (following the cyclic loading protocol). A closer inspection of Figure 4 reveals that tests with higher embedment depths (760mm) present a more gradual stiffness decrease. This phenomenon may be attributed to the fact that higher embedment lengths imply a great fraction of the total Moment carried by the horizontal bearing stresses. Thus, when this latter mechanism starts to deteriorate, the force transfer to the vertical stresses seems to be more gradual.

Finally, in this section, the distribution of the horizontal bearing stresses is discussed. Figure 6 shows the stress distribution along the steel column flange of test 1 in two stages of the response, i.e., at the Moment associated with the First Yield and Peak Strength. As per Figure 6, for the first condition (i.e.,  $M_y$ ), the "real" stress distribution is closer to a triangular shape. This observation is not surprising since at this level of deformation, the connection starts to incursion in the nonlinear regime, and a triangular shape is consistent with an elastic behavior. In contrast, once the connection has reached its peak, it is observed in the simulations a more uniform stress distribution along a certain length of the flange. This finding is consistent with the rectangular stress block assumed by Grilli and Kanvinde [7] in their strength method. Although these findings may be used in the future to refine the strength, this topic deserves further scrutiny.

## 5 SUMMARY, LIMITATIONS, AND RECOMMENDATIONS

This paper presents a numerical study conducted on a critical component of SMFs such as EmBCs. A total of four FE models were developed in the ABAQUS platform [16] to explore the seismic behavior of these connections. Specifically, in this study, the internal force distribution and the patterns of deformation were identified from the simulations with the intention to gain insights aimed to improve the current design methods (e.g., [7]). All the models were validated against the experimental program conducted by Grilli and Kanvinde [7]. The goodness of the fit (i.e., the difference between the experimental and the numerical results) was considered an indicator of the reliability of the models.

The simulations indicate that at rotation levels close to the "first" yield of the connection, the stresses are not uniform along the column flange; instead, a triangular shape can be assumed. In contrast, at higher rotations, the stresses tend to become relatively uniform. Thus, when the connection reaches its peak strength, it seems that the rectangular block assumption is appropriate. However, this issue deserves a further look.

The paper has several limitations that should be addressed in a new study in order to generalize the conclusions. For example, the number of simulations (four in total) is limited. Moreover, the experimental program by [7] is the only testbed used. It is recommended to build more FE models from other experimental programs available to assess different configurations' behavior (e.g., column size, embedment length, the influence of shear studs). Besides, this study does not address issues related to the seismic demands on the EmBCs, or a reliability analysis to assess if the strength resistance factors adopted are adequate or not. These topics have been addressed for exposed-based plates by [17,18,19] and should be conducted for EmBCs.

**Keywords:** Damping, Reinforced Concrete, Dynamic, Nonlinear Model, Energy Balances.

**Abstract.** Reinforced concrete (RC) structures dissipate energy when subjected to seismic excitations. Modeling seismic energy dissipations on a rational basis still represents challenging issues. At local scale, dissipative constitutive RC models are developed to take into consideration different phenomena, such as cracks opening, friction, plasticity, and their couplings or rebar bond slip. Practically some of those dissipative mechanisms are modeled by equivalent Rayleigh viscous damping at the global structural level. However, Rayleigh damping lacks a physical basis leading sometimes to an uncontrolled evolution of energy dissipation when non linearities occur [1]. This paper provides the basis of an updated local damping model based on parameters modeling concrete dissipative phenomenon, to reduce the need for arbitrary equivalent viscous damping as much as possible and thus better model energy dissipations on a rational physical basis. Using shake table experimental results on prismatic RC beams [2], a numerical study is presented to assess the performance of sixteen different global damping formulations to represent physical energy dissipation mechanisms. Energy balance analyses are used to evaluate dissipative phenomena at the local concrete level and to demonstrate that friction is the most significant local dissipative phenomenon. In addition, an equivalent viscous damping identification method is developed to determine transient damping ratio evolution during dynamic computations as a function of damage parameters, like stiffness degradation. An exponential function is found suitable to take into consideration global viscous damping adjustment as a function of local damage occurring during dynamic nonlinear analyses.

## 1 INTRODUCTION

Earthquake events in recent years lead to the need to evaluate structural vulnerability and to quantify related safety margins. Particularly, the combination of critical infrastructures presence on territories and more stringent seismic regulations represent a current challenge. Nuclear power plants are representing such critical structures. In the aim of increasing their lifespan, analyses are required to ensure their safety under current and evolving standards. For example, after a moderate earthquake excitation, the nuclear containment vessel still need to demonstrate airtightness. But, the difficulty with reinforced concrete structures is related to the lack of knowledge about concrete cracking damage and about the ability of the material to dissipate seismic energy.

To improve dynamic non-linear computations of complex structures under earthquake excitations, rational physical models need to be developed. To model dissipations during earthquake events, different scales are considered. First, at local scale, physical phenomena can be described through material constitutive laws. Then, at global scale, energy dissipations are also occurring because of the structure interaction with its environment. The impossibility to model all phenomena at local and structural scales leads to the use of equivalent viscous damping. Following Rayleigh's works [3], a large amount of viscous damping matrix formulations have been developed in the literature. However, those formulations still lack a sound physical basis.

Based on a shake table experimental campaign performed by Heitz [2] to characterize seismic energy dissipation in reinforced concrete beams, a numerical study is presented herein. It aims at evaluating the performances of existing local as well as global (Rayleigh) damping formulations in representing the experimental data. The focus is put in dissipative evolutions at local and global scales. An identification method is also developed to study evolution of the equivalent viscous damping ratio during non-linear computations.

## 2 REINFORCED CONCRETE BEAM UNDER EARTHQUAKE EXCITATION

The experimental campaign performed by [2] at the French Alternative Energies and Atomic Energy Commission (CEA) Saclay represents a huge amount of data that can be used as a reference to validate numerical analyses. Experiments were performed with different material properties, structural configurations and excitation characteristics on reinforced concrete beam. The main objective was to evaluate seismic energy dissipations mechanisms.

### 2.1 Beam model

Figure 1: Dynamic experimental setup

Based on information about the experimental setup (fig. 1), a numerical model of the tested reinforced concrete beams has been developed using Cast3m, a finite-element software. The main advantages of using a multi-fiber models are: (i) to avoid solid 3D models, limiting the number of degrees-of-freedom and so to save computational time, (ii) to consider 1D constitutive material models, which are easier to implement and unable to model local behaviors, and (iii) its usability for results interpretation [4, 5, 6]. Multi-fiber beam elements are based on Timoshenko beam the-

ory in Cast3m.

A typical model geometry is presented in figure 2. Along the beam, sections are considered at each Gauss point of the beam elements (fig. 2a). Then, each section is decomposed in fiber elements. Figure 2b shows the section model with concrete and steel elements. Those elements are 2D linear quadrangle elements.

Figure 2: Beam geometry and discretization

To match experimental boundary conditions and beam undamaged properties, spring elastic supports are considered. Spring rotational and translational stiffnesses are calibrated from modal analyses performed on undamaged beam, considering a global symmetrical problem. The aim is to match the two first numerical eigen-frequencies with those deduced from experimental hammer shock tests. Finally, additional masses are added at the quarter and three-quarter beam span, and vertical displacements are blocked at those nodes. For quasi-static analyses, displacements are imposed at additional masses positions, and for dynamic computations, a force equivalent loading is derived from measured table accelerations.

## 2.2 Material constitutive models

**Concrete model** Two hysteretic models developed in Cast3m are compared in numerical studies. First a simple model, named BARFRA, was proposed by Crambuer [7]: the only dissipative phenomena considered is concrete cracking. The second model, named RICBET and developed by Richard [8] is more complex because it considers four dissipative phenomena: (i) cracking and (ii) friction in tension, (iii) plasticity in compression, as well as (iv) the unilateral effect dissipating energy upon crack closing. Thermodynamic potentials of both models are respectively expressed in equations 1 and 2. Computations of energy dissipations in section 3.1 of the paper will be deduced from those equations.

$$\rho\psi = \frac{1}{2}(1 - d_+)\langle\varepsilon_{ij}\rangle_+ C_{ijkl} \langle\varepsilon_{kl}\rangle_+ + H_+(z_+) + \frac{1}{2}(1 - d_-)\langle\varepsilon_{ij}\rangle_- C_{ijkl} \langle\varepsilon_{kl}\rangle_- + H_-(z_-) \quad (1)$$

with  $\langle\varepsilon_{ij}\rangle_+$  and  $\langle\varepsilon_{ij}\rangle_-$  respectively the positive and negative parts of the strain tensor,  $C_{ijkl}$  the elastic tensor,  $d_+$  and  $d_-$  the damage index representing concrete cracking respectively for positive and negative strains and  $H_+(z_+)$  and  $H_-(z_-)$  the functions representing isotropic work

hardening respectively for positive and negative strains.

$$\begin{aligned} \rho\Psi = & \frac{1}{2} \left\{ (1 - D) (\varepsilon_{ij} - \varepsilon_{ij}^p) C_{ijkl} (\varepsilon_{kl} - \varepsilon_{kl}^p) \right\} + \frac{1}{2} \left\{ D (\varepsilon_{ij} - \eta \varepsilon_{ij}^\pi - \varepsilon_{ij}^p) C_{ijkl} (\varepsilon_{kl} - \eta \varepsilon_{kl}^\pi - \varepsilon_{kl}^p) \right\} \\ & + \frac{1}{2} \left\{ \gamma \alpha_{ij} \alpha_{ij} \right\} + H(z) + G(p) \end{aligned} \quad (2)$$

with  $D$  the damage index representing concrete tensile cracking,  $\varepsilon_{ij}^p$  the plastic strain tensor,  $\eta$  the variable associated to unilateral effect,  $\varepsilon_{ij}^\pi$  the strain tensor associated to friction,  $\gamma$  a parameter characterizing friction,  $\alpha_{ij}$  the tensor of kinematic work hardening (friction phenomenon) and  $H(z)$  and  $G(p)$  the functions representing isotropic work hardening (damage and plasticity phenomena).

Both models are calibrated on the experimental data obtained from quasi-static tests. The advantage of using the most complex model is to better represent hysteresis cycles.

**Steel model** For steel reinforcements a classical elastoplastic model is used. Typical parameter values are considered. Indeed, experimental tests were developed to avoid reaching nonlinearities in steel reinforcements, to represent what happens to structures subjected to moderate earthquake accelerations.

### 2.3 Dynamic problem

**General equation** After calibrating the model with quasi-static tests, non-linear dynamic computations can be performed. Dynamic equilibrium equation for a multi-degree-of-freedom (MDOF) nonlinear damped system is:

$$\mathbb{M} \cdot \ddot{\mathbf{U}} + \mathbb{C} \cdot \dot{\mathbf{U}} + \mathbf{f}_{int}(\mathbf{U}) = -\mathbb{M} \cdot \underline{\Gamma} \cdot \ddot{\mathbf{U}}_s \quad (3)$$

with  $\mathbb{M}$  the mass matrix,  $\mathbb{C}$  the damping matrix,  $\ddot{\mathbf{U}}$ ,  $\dot{\mathbf{U}}$  and  $\mathbf{U}$  respectively the acceleration, velocity and displacement of beam nodes,  $\mathbf{f}_{int}(\mathbf{U})$  the internal force characterizing the non-linear constitutive model,  $\ddot{\mathbf{U}}_s$  the seismic accelerations and  $\underline{\Gamma}$  is the influence vector given the direction of seismic excitation. So, only the damping matrix  $\mathbb{C}$  is unknown if  $\mathbf{f}_{int}$  can be assessed with confidence.

**Focus on damping matrix formulations** The most frequently used formulation for the damping matrix derived from Rayleigh's work [3]. It consists in a linear combination of mass and initial stiffness matrices. Mathematically, this model leads to a decoupled problem using the undamped modal basis enabling its solving. However, numerous papers present the limits of this damping model, synthesized by Hall [1]. That is why, the literature presents different alternative for Rayleigh damping formulation that improve computations by minimizing some Rayleigh damping limitations. Particularly, we can find the use of tangent or secant stiffness matrix instead of initial ones [9]. This requires recomputing the damping matrix several time during analysis, increasing computational time. But it is a way to consider non-linear behavior in Rayleigh damping. On the other hand, it was demonstrated that the mass proportional part leads to unrealistic damping forces because higher modes are very lightly undamped. So, some papers propose to remove the mass matrix to keep only the stiffness proportional part given a linear correlation between the damping ratio of each mode and its frequency [10].

In addition to Rayleigh-type formulations, modal damping formulations are often used in the literature. In those cases, the  $\mathbb{C}$  matrix is computed from modes determined from a modal analysis. For example, Wilson & Penzien [11] proposed such a formulation, as well as Chopra & McKenna [12] based on the choice of a damping ratio for  $N$  modes.

Herein, sixteen equivalent viscous damping formulations have been studied and compared in relation to each other, but also with different damping ratios, and with or without parameters updating. When parameters are updated during computation, modal analyses are performed at each time step and the new frequencies are considered to compute the damping matrix. Table 1 presents the classification and name of all studied Rayleigh type and modal damping formulations.

	Formulation	Modes*	Parameter updating		Formulation	Modes*	Parameter updating

### 3 THEORETICAL DEVELOPMENTS

Using the developed multi-fiber model, the aim of this section is to focus on seismic energy dissipation-computations and transient damping evolution.

#### 3.1 Energy analyses

**Structural level** Energy balance is deduced from the integration of dynamic equations (eq. 4) [13], corresponding to equation 5, in absolute formalism:

$$\frac{1}{2} (\mathbb{M} \cdot \dot{\mathbf{U}}_a) \cdot \dot{\mathbf{U}}_a + \int (\mathbb{C} \cdot \dot{\mathbf{U}}) \cdot \dot{\mathbf{U}} dt + \int \mathbf{f}_{int}(\mathbf{U}) \cdot d\mathbf{U} = \int (\mathbb{M} \cdot \ddot{\mathbf{U}}_a) \cdot d\mathbf{U}_s \quad (4)$$

$$E_{k,a} + E_d + E_a = E_{i,a} \quad (5)$$

where  $E_{k,a}$ ,  $E_d$ ,  $E_a$  and  $E_{i,a}$  are respectively the absolute kinematic energy, the viscous damping energy, the absorbed energy (or internal energy) and the absolute injected energy. In the case of a linear behavior, the three left terms are easily computed respectively from mass, damping and stiffness matrices. However, when a nonlinear constitutive model is considered, the absorbed energy is decomposed between the strain energy (corresponding to the elastic part) and the hysteretic energy deduced from thermodynamical approach. The right energy balance term, the injected energy, corresponds to the energy induced by the seismic acceleration.

**Local level** At material level, the hysteretic energy is now defined for both constitutive models in Table 2, with phenomenon and associated variables presented in Table 3 for BARFRA model and in Table 4 for RICBET model.

Name	Symbol	Equation	
		BARFRA	RICBET
<b>Hysteretic energy</b>	$E_h$	$\int_{\mathcal{V}} (Y.\dot{d}) d\mathcal{V}$	$\int_{\mathcal{V}} (\sigma_c.\dot{\varepsilon}_c^p + \sigma^\pi.\dot{\varepsilon}^\pi + Y.\dot{d} + \zeta.\dot{\eta}) d\mathcal{V}$
<b>Concrete strain energy</b> (elastic recoverable)	$E_{s,c}$	$\int_{\mathcal{V}} (\sigma_c.\dot{\varepsilon}_c - Y.\dot{d}) d\mathcal{V}$	$\int_{\mathcal{V}} (\sigma_c.\dot{\varepsilon}_c - \sigma_c.\dot{\varepsilon}_c^p - \sigma^\pi.\dot{\varepsilon}^\pi - Y.\dot{d} + \zeta.\dot{\eta}) d\mathcal{V}$
<b>Steel strain energy</b> (elastic recoverable)	$E_{s,s}$	$\int_{\mathcal{V}} (\sigma_s.\dot{\varepsilon}_s^e) d\mathcal{V}$	$\int_{\mathcal{V}} (\sigma_s.\dot{\varepsilon}_s^e) d\mathcal{V}$
<b>Work hardening</b>	$W_h$	$\int_{\mathcal{V}} (Z.\dot{z}) d\mathcal{V}$	$\int_{\mathcal{V}} (R.\dot{p} + X.\dot{\alpha} + Z.\dot{z}) d\mathcal{V}$
<b>Dissipated energy</b>	$E_{dis}$	$\int_{\mathcal{V}} (Y.\dot{d} - Z.\dot{z}) d\mathcal{V}$	$\int_{\mathcal{V}} (\sigma_c.\dot{\varepsilon}_c^p + \sigma^\pi.\dot{\varepsilon}^\pi + Y.\dot{d} + \zeta.\dot{\eta} - R.\dot{p} - X.\dot{\alpha} - Z.\dot{z}) d\mathcal{V}$

Table 2: Absorbed energy decomposition

Observable	Internal	Associated forces	Phenomena

### 3.2 Viscous damping identification method

To study the evolution of viscous damping during nonlinear dynamic computations, an identification method using a single degree-of-freedom model, equivalent to the global structural beam, is developed.

**Coupling of modes** When the projection on a modal basis is used to solve a dynamic problem, orthogonality of mode is implemented. But, if the damping matrix evolves during computation,

for example by considering the tangent stiffness matrix, the orthogonality can be altered. So, to evaluate the evolution of modes orthogonality along computation, the matrix  $\mathbb{C}^{mod}$  is computed at different time steps. This matrix is composed by the terms  $C_{ij}^{mod}$  in equation 6.

$$C_{ij}^{mod} = \underline{\phi}_i \cdot \mathbb{C} \cdot \underline{\phi}_j \quad \forall (i, j) \in \llbracket 1; N \rrbracket^2 \quad (6)$$

where  $\{\underline{\phi}_i\}_{i \in \llbracket 1; N \rrbracket}$  are the modes determined by a modal analysis on a linear system. So, only matrix  $\mathbb{C}$  is evolving during computation in equation 6. By computing  $\mathbb{C}^{mod}$  at different damage levels during dynamic computations, we did not observe significant coupling development. So the resolution of dynamic equation on modal basis remains herein acceptable, even when the tangent stiffness matrix is used.

**Modal basis projection** Equivalent model of structural element is obtained using a projection of dynamic equation (eq. 3) on modal basis  $\mathcal{B} = \{\underline{\phi}_i\}_{i \in \llbracket 1; N \rrbracket}$ . Displacement vector is defined as a linear combination of modes:  $\mathbf{U} = \sum_{i=1}^N a_i \cdot \underline{\phi}_i$  with orthogonal modes:  $\underline{\phi}_i \cdot \mathbb{M} \cdot \underline{\phi}_j = \delta_{ij} \cdot m_i$  and  $\underline{\phi}_i \cdot \mathbb{K} \cdot \underline{\phi}_j = \delta_{ij} \cdot k_i$  where  $\delta_{ij}$  is Kronecker index, and  $m_i$  and  $k_i$  are respectively the mass and the stiffness associated to mode  $i$ . Generally, the basis is mass-normalized, so  $m_i = 1$  and  $k_i = \omega_i^2$  where  $\omega_i = 2\pi f_i$  with  $f_i$  the frequency associated to mode  $i$ .

The first mode is representing more than 90% of modal mass, therefore the projection will be done on the first mode only. The displacement is expressed as  $\mathbf{U} = a_1 \cdot \underline{\phi}_1$  where  $a_1$  is time dependent. So, equation 3 in a linear case, and projected on the first mode, becomes equation 7, and then equation 8 on a normalized format:

$$\ddot{a}_1 \cdot \underline{\phi}_1 \cdot \mathbb{M} \cdot \underline{\phi}_1 + \dot{a}_1 \cdot \underline{\phi}_1 \cdot \mathbb{C} \cdot \underline{\phi}_1 + a_1 \cdot \underline{\phi}_1 \cdot \mathbb{K} \cdot \underline{\phi}_1 = -\underline{\phi}_1 \cdot \mathbb{M} \cdot \underline{\Gamma} \cdot \ddot{\mathbf{U}}_s \quad (7)$$

$$\ddot{a}_1 + 2\xi\omega_0 \cdot \dot{a}_1 + \omega_D^2 \cdot a_1 = -\frac{\kappa_1}{m_1} \cdot \ddot{u}_s \quad (8)$$

where  $\xi$  is the viscous damping ratio,  $\omega_0$  the initial eigen-frequency,  $\omega_D$  represents a "damaged" eigen-frequency,  $\kappa_1 = \underline{\phi}_1 \cdot \mathbb{M} \cdot \underline{\Gamma}$  is the projection coefficient and  $\ddot{u}_s$  is the seismic acceleration.

**Method presentation** Demarie & Sabia [15] proposed a non-linear and non-parametric method to identify non-linear damping and frequency of damaged reinforced concrete elements. The method developed herein is based on this approach. Despite the non-linearity in the studied time responses, we consider that it is possible to decompose the signal in  $n_w$  windows, such that in each time window the system response can be considered linear. That is to say that, in each window, we are able to evaluate a viscous damping ratio  $\xi_w$  and a damage eigen-frequency  $\omega_{D,w}$  from equation 8 reduced to the window  $w$ .

After having projected data on the modal basis, a function to identify  $f_{id}$  has to be defined, as well as windows characteristics. On each window, a minimization algorithm is performed to find the best pair of parameters  $(\xi_w, \omega_{D,w})$  using the objective function in equation 9:

$$\varepsilon_w = \frac{\int_{t=0}^{t_w} (f_{id,w} - f_{c,w})^2 dt}{\int_{t=0}^{t_w} (f_{id,w})^2 dt} \quad (9)$$

where  $f_{id,w}$  and  $f_{c,w}$  are, respectively, the function to identify and the computed function, reduced to the window  $w$ . Finally, by applying the minimization algorithm in all windows, we obtain the evolution of identified parameters all along the computation.

## 4 STUDIES ON DAMPING MODELS

### 4.1 Dynamic response of the beam

**Comparison of classical damping matrix** The first dynamic signal has a very low amplitude. Experimentally, this white-noise signal was performed to characterize the undamaged modal properties of the beam. Numerical responses are well matching experimental ones and we found a first mode eigen-frequency with less than 3% of error with almost all tested damping formulations. A damping ratio around 0.5% is required to compute Rayleigh-type matrices.

Then, non-linearities development is studied by applying a high amplitude decreasing sine sweep signal (fig. 3). Damping matrix formulations are compared with experimental data in terms of displacement, acceleration and from constitutive law responses. Viscous damping ratios varying between 0.5% and 5% have also been studied. On the contrary to the first linear test, viscous damping ratios around 2% are most appropriate. This value is smaller than the 5% often recommended in engineering codes because of the dissipative model used at local scale, the no-yielding of steel reinforcements and the modest strains and stresses responses. It appears that the viscous damping ratio is strongly dependent on input signal, damping formulations and levels of stress, strain and damage. So, it is impossible to propose a general viscous damping ratio working for all experimental vs numerical simulations. This represents a very significant limitation of viscous damping models computed from classical matrices.

To compare damping matrix formulations, figure 4 synthesizes different results as (i) the error between experimental and numerical data for displacements, accelerations and force responses and (ii) the error in the evolution of eigen-frequencies, and (iii) energy criteria. The best damping formulations are the one given the largest area in spider diagrams. Some formulations are better for some criteria than others. We are still able to say that the most appropriate damping formulations are Rayleigh damping (CRD) and stiffness proportional damping (CKPD) both with the use of tangent stiffness.

Figure 3: Decreasing sinus sweep - DSS85b

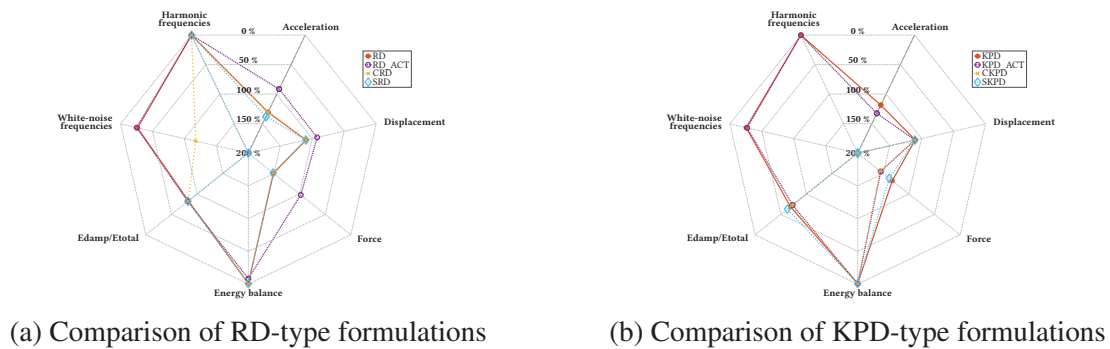

Figure 4: General comparison of damping formulations

**Energy dissipations** Energies presented in equation 5 are plotted in figure 5a for CKPD damping matrix formulation with a viscous damping ratio of 2% in case of a damageable (cracking) test (DSS) and with RICBET constitutive model. What is of interest, in this figure, is the distribution of energy between viscous damping and internal local material mechanisms. Indeed, kinematic energy represents a very small part of total energy and is recoverable, so it is null at the end. Generally, viscous damping energy dissipates the most energy. Only stiffness proportional damping matrix leads to a distribution almost 50%/50%. This demonstrates that even with a complex material model, a large amount of energy lacks to be dissipated at material level and has to be dissipated by equivalent viscous damping. Undoubtedly, decreasing the viscous damping ratio leads to a most equal distribution of the two dissipative energy but we saw in dynamic responses that a very small viscous damping ratio does not allow to match experimental data. Finally, to be able to reduce the requirement of viscous damping, we have to dissipate more energy at the material level.

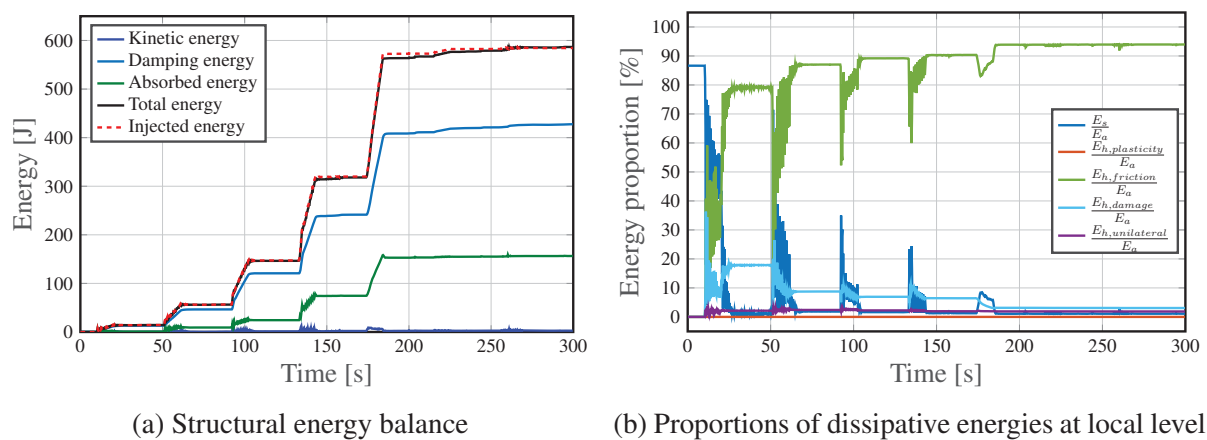

Figure 5: Energy analyses

The RICBET model takes into consideration four dissipative phenomena. Figure 5b focuses on hysteretic and strain energies, at local scale. In the beginning, the beam behaves linearly, so no dissipation occurs and strain energy is dominating. Then, cracks open and damage associated energy is dissipated. As soon as cracks open, because they are submitted to an oscillating signal, friction between crack lips develops. We observe that friction fast becomes dominating. When, a mono-harmonic signal segment excites the beams more strongly, cracks pattern evolves leading to an increase in the cracking associated energy proportion (crack propagation) at the expense of friction energy. Finally, plasticity is not dissipating energy because we do not reach concrete compressive non-linearities. Unilateral effect dissipates a small amount of energy during all computation after development of non-linearities.

As a conclusion, we can say that viscous energy is still representing a major part of all dissipative energies demonstrating again the lack of knowledge around the physical representation of local dissipative mechanisms. And, in the case of linear response of steel reinforcements, but nonlinear concrete behavior, the main concrete local dissipative phenomena is the friction, so works should focus on that phenomenon.

## 4.2 Damping coefficient evolution

Identification method can be applied on experimental or numerical data. Figure 6 particularly focuses on experimental data of two tests. Green data correspond to the lowest amplitude signal (with a maximum acceleration of  $1.25 \text{ m/s}^2$ ) while blue data correspond to the strongest signal (with a maximum acceleration of  $2.25 \text{ m/s}^2$ ). The first test leads to a maximal damage index (modelling the stiffness reduction due to cracking) around 0.6 what we also observed in identification of numerical data. But, in terms of viscous damping ratio, green data are staying around 5% experimentally while much stronger values are obtained with numerical identification. This demonstrates that the multi-fiber numerical model is not able to dissipate enough energy at the local scale and that a stronger influence has to be given to viscous damping in numerical computations. This is a huge limitation for the use of viscous damping in non-linear structural analyses.

To conclude on experimental data, the combination of the two more damageable tests shows that the viscous damping ratio can be defined as an exponential (eq. 10) or a polynomial (eq. 11) function of the cracking damage index.

$$\xi_{expon} = (2.96 \times 10^{-3}) \times \exp(4.75 \cdot d) \quad (10)$$

$$\xi_{ratio} = \frac{-62.1 \cdot d + 385}{d^2 - 1.36 \times 10^4 \cdot d + 1.41 \times 10^4} \quad (11)$$

Figure 6: Experimental evolution of identified damping coefficient

## 5 CONCLUSIONS

The modeling of damping in structural non-linear dynamic computations was discussed in this paper using different analyses. First, an exhaustive numerical campaign was performed to characterize dissipations in reinforced concrete elements submitted to earthquake excitations and tested on a shake table. Particularly, sixteen classical damping matrix formulations proposed in literature have been compared. Results demonstrate that it is difficult to determine one type of damping working for all signal intensities. The damping formulation has to be selected depending on input signal intensity. However, using tangent stiffness matrix in Rayleigh damping formulation with or without the mass proportional part appears the best choice herein to represent the dynamic experimental responses. Rayleigh damping matrix evaluation requires to impose damping ratios for some modes frequencies. Analyses performed on multi-fiber model as well as on identification studies with a 1D model show that a constant value of damping ratio all along computation does not give accurate results when non-linearities occur. Exponential evolutions of damping coefficient as a function of internal damage characterized by stiffness degradation due to concrete cracking seems to better model physical phenomena and so to improve correlation with experimental data.

The works to follow will propose a new formulation of damping matrix based on local variables. The aim is to increase physical basis of the damping matrix. Preliminary results are showing good accuracy in comparisons with experimental data. But some developments still remain to compare local variables associated to different phenomena, like friction, and determine predictive functions to compute damping matrix.

**Abstract.** Shock absorbers or hydraulic dampers are power dissipating devices. The fluid flow inside the damper is governed by predefined passages. The damping effect is accomplished by the resistance of oil to flow through the restrictions. The impact of the viscosity and the velocity of the oil determines the fluid flow behaviour and hence, the resulting damping effect. The piston inside the damper has various orifices or piston valves that cause different flow losses. These losses are observed during the extension and compression strokes of the damper. In the compression and extension strokes, rebound and compression pressures are developed at the damper orifice. In this work, Computational Fluid Dynamics (CFD) analysis is carried out on a rear side two-wheeler automobile mono tube damper to investigate the variation of the damping properties using viscous oils. Averaged Navier-Stokes equations are solved by the SIMPLE method and the RNG  $k-\epsilon$  is used to model turbulence. The piston contains eight orifices which separate the rebound and compression chambers of the damper. The numerical analysis used four values of velocity; 0.8, 1, 1.2, and 1.5 m/s. The viscous fluid model was SVI2.5, having viscosity value of 0.009 Pa.s. The damping coefficient values for rebound and compression sides were obtained based on their pressure values showed in the CFD contour plots. It was noticed that the increasing trend of damping coefficient is linearly for two velocity's intervals; (0.8-1) m/s and (1.2-1.5) m/s, and nonlinearly for velocity interval of (1-1.2) m/s.

**Keywords:** Hydraulic damper, viscosity, CFD, damping characteristics, orifice, and pressure contours.

## 1 INTRODUCTION

A shock absorber, or viscous damper, is mainly functioning to dampen body/suspension motions, control tire force variation, and dissipate impact energy. Hydraulic oil is passed between two chambers via a system of pressure sensitive flow restrictions. The damping effect is accomplished by the resistance of oil to flow through the restrictions. Most vehicular shock absorbers are either twin-tube or mono-tube types with some variations on these themes as shown in Fig. 1. Twin tube shock absorber consists of two nested cylindrical tubes, an inner tube that is called the "working tube" or the "pressure tube", and an outer tube called the "reserve tube". At the bottom of the device on the inside is a compression valve or base valve. When the piston is forced up or down, hydraulic fluid moves between different chambers via small holes or "orifices" in the piston and via the valve. The fluid movement converts the "shock" energy into heat which must then be dissipated. The mono-tube shock, which is a gas-pressurized shock and also comes in a coil over format, consists of only one tube, the pressure tube, though it has two pistons. The two pistons separate the shock's fluid and gas components. Mono tube shocks are typically found in trucks, vans, or vehicles used for hauling or transportation or driven in areas where harsh road conditions are common. While twin tube is found in cars and smaller SUVs, twin-tube shocks have a second cylinder specifically for internal fluid (Shams et al. [1]).

Fig. 1. Types of shock absorbers [1].

Generally, two main analytical models describe the viscous shock absorber behaviour; linear model, and generalized viscous damper model [2]. In linear model the damping force increases linearly as the velocity increases. On the other hand, generalized viscous model include the nonlinear behaviour of the damper force with respect to the change in velocity. The nonlinear behaviour provides a high damping force for the small vibration amplitudes (velocity). In viscous dampers, the linearity behaviour is governed by; orifice and damper geometry, fluid characteristics, and velocity of the vibrating structure. Many experimental studies were carried out to investigate the behaviour of fluid damper [3],[4]. For example, a recent experimental study conducted by Badri et al. [5] to investigate the effect of increasing velocity (increasing frequency) of mono tube damper in the damping coefficient value. In addition, numerical models are also used to characterize the viscous damper's damping effect. A physical model for a shock absorber was developed by Surace et al. [6]. This model provided a more realistic representation of the stiffness characteristics than previous simple models. Reybrouk et al. [7] presented a nonlinear physical model for predicting shock absorber performance. Dyum et al. [8] studied the mechanism of shock absorber rattling noise by valve behaviour analysis and CFD simulation. Herr et al. [9] identified valve parameters from several simple dynamometer tests and an additional incompressible model. These parameters

were then used to analytically determine valve flows for given pressure drops in the main model. Purdy et al. [10] evaluated the flow and performance of an automotive shock absorber by coupling a Computational Fluid Dynamics method with a dynamic modelling technique. They evaluated the pressure flow characteristics of the differing valve components using Computational Fluid Dynamics (CFD). Disk deformation information from finite element analysis simulations are incorporated into the calculation of blow-off valve opening. They obtained the damping force versus piston velocity curves. The radial flow of magnetic fluid under the piston of a magneto fluid shock absorber was studied by Tallec et al. [11]. Lee et al. [12] developed a non-linear model that includes the compressibility of the fluid, trapped gas and expansion of the cylinder. The performance of the shock absorber model was examined as the parameters were varied. Interaction of fluid and deformable structural parts in the shock absorber caused difficulties such as; compelling the kinematic compatibility at the fluid-structure interface and updating the geometry of the domain. Maikulal et al. [13] investigated the damping characteristics when the number of orifice holes changed using CFD. The numerical model results showed a nonlinear increase in the damping force with respect to the velocity increase.

In this paper, CFD simulations using ANSYS Fluent software is used to model a fluid flow inside the cylinder of a mono tube shock absorber. The damper's damping characteristics are investigated by changing the flow velocity using Rock Oil Rear shock fluid SVI2.5 oil as a viscous oil of the damper

This paper is outlined as follows; Section 1 introduces the topic and provides a literature review. Section 2 shows the methodology followed for the CFD starting from the governing equations and ending with the boundary conditions. Section 3 discusses the results and the main findings of this work. Finally, this paper ends at Section 4 which concludes and summarize the scope of this work as well as the main findings.

## **2 METHODOLOGY**

This work will follow a methodology used by Maikulal et al. [13], when a CFD model simulates the flow inside a viscous damper. Following the same approach, a mono tube damper with new orifice design will be characterized over different velocities. The model is characterizing the viscous damper by calculating the damping coefficient at compression and rebound side based on their damping forces. Damping forces when using SIV-2.5 oil is analysed for different velocities and the variation of damping coefficient value will be investigated. In this section, the internal damper's chambers will be discussed, followed by the equations used to obtain the damping forces regarding constant velocities.

### **2.1 Damping characteristics of a damper**

The scope of this work for the hydraulic damper is by identifying the damping action by allowing the hydraulic fluid (mainly a viscous fluid) to throttle through orifice in the piston (piston valve). The flow will be governed by the physical properties of the fluid such as viscosity and density, and the geometry of the piston valve (orifice). Mainly, the damper modelled for the CFD analysis is a piston cylinder system representing a mono tube shock absorber containing a hydraulic fluid as shown in Fig. 2 (a). The piston consists of; a rod and an orifice plate which connects two chambers (Chamber 1 and Chamber 2) showed in Fig. 2. The orifice plate has a small orifice which exposed to both piston sides and chambers of the

cylinder as shown in Fig. 2 (b). Chamber 1 represents the rebound piston side and chamber 2 represents the compression piston side.

Fig. 2. Hydraulic fluid flow through orifices [13].

The damping force is proportional to the velocity, as for a linear viscous damper, the damping force ( $F_d$ ) may be related to the piston velocity ( $v$ ) by Leea et al. [14]

$$F_d = c \times v \quad (1)$$

where  $F_d$  = damping Force (N),  $c$  = Damping Coefficient (N.s/m),  $v$  = velocity of the piston (m/s).

The force of the piston in the two chambers is found by obtaining the pressure and the area on each piston side (compression and rebound). The force of the compression piston side is expressed by Guan et al. [15]

$$F_c = P_c \times A_c \quad (2)$$

$$F_r = P_r \times A_r \quad (3)$$

where  $F_c$  and  $F_r$  are piston forces on compression and rebound side, respectively.  $P_c$  and  $P_r$  are the pressure on compression and rebound side (Pa),  $A_c$  and  $A_r$  are the area of piston on compression and rebound sides ( $m^2$ ).

### 3 NUMERICAL ANALYSIS

#### 3.1 3D CAD modeling

In this study the orifice geometry was reproduced from dimensions used in Maikulal et al. [13]. The orifices plate was redesigned by modifying the number, and location of the orifice holes. 8 orifice holes are placed near the edge of the plate separated by an angle ( $45^\circ$ ). Top view of the orifice plate is shown in Fig. 3 (a). Fig. 3 (b) shows the 3D CAD drawing of the plate.

**Fig. 3.** Orifice's geometry and orientation.

Fig. 4 shows the 3D drawing of the damper. The idea behind this model is that CFD simulation will be done inside the cylinder of the damper. This can be explained as the domain as shown in Fig. 4 (a); where the viscous oil will be moving through the orifice plate between the chambers at a specific velocity. Fig. 4 shows the 3D CAD model of the damper with 8 orifices in ANSYS.

**Fig. 4.** 3D CAD drawings of the damper.

The CFD analysis will be based on throttling the viscous oil through the orifice of the three different cases. This will require the drawing of the inside domain of the cylinder. The oil will be throttled between the two chambers. Therefore, the domain will appear as a solid, but it will be considered as fluid in the CFD simulations. The orifice plate is placed at the midpoint of the length of the cylinder which is 118 mm. The volume of the orifice plate and the rod

(piston) is subtracted so that the domain is only fluid throttling through the orifice for the different three cases.

### 3.2. Mesh generation and quality

Unstructured automatic fine meshing with 3D tetrahedral cells was used. The meshing smoothing chooses to be high, while having a normal curvature angle of  $15^\circ$ . The mesh responded to high gradient and curvature areas by providing more cells to those areas. By increasing the number of cells at the throttling area, while having fewer elements at areas near the inlet, and the outlet ensure accurate results with less computational time. The grid is then generated having 445076 elements with 87552 nodes, as shown in Fig. 5.

Fig. 5. Meshing.

### 3.3 CFD methodology, boundary conditions and simulation studies

The CFD modelling involves the numerical solution of the conservation equations in the laminar and turbulent fluid flow regimes. Therefore, the theoretical predictions were obtained by simultaneous solution of the continuity and the Reynolds averaged Navier-Stokes (RANS) equations. The governing equations for an incompressible flow are [16]

Conservation of mass:

$$\vec{\nabla} \cdot (\vec{v}) = 0 \quad (4)$$

Conservation of momentum:

$$\rho \left[ \frac{\partial(\vec{v})}{\partial t} + (\vec{v} \cdot \vec{\nabla}) \vec{v} \right] = \rho g - \nabla P + \mu \nabla^2 \vec{v} \quad (5)$$

Since the flow in the shock absorber is in a state of turbulent motion, it is important to use an appropriate turbulence model for evaluating the flow field. The standard  $k-\epsilon$  model is a semi-empirical model based on transport equations for the turbulent kinetic energy ( $k$ ) and its dissipation rate ( $\epsilon$ ). Improvements have been made to the model to improve its performance by the Realizable  $k-\epsilon$  model [20]. Realizable  $k-\epsilon$  model have shown substantial improvements over the standard  $k-\epsilon$  model where the flow features include strong streamline curvature, vortices and rotation. The flow governing equations are solved with ANSYS FLUENT 17R. A standard wall functions is used in order for wall treatment since the most focus is on

the orifice plate. The velocity and pressure coupling used the SIMPLE algorithm with a second order upwind spatial discretization for a pressure-based study.

#### 4. RESULTS AND DISCUSSION

Static pressure contours are required to identify the forces on the two orifice sides (rebound, compression). The pressure contours for the compression and rebound piston sides for one case are presented in Fig. 7 (velocity of 0.8 m/s and using SVI-25 oil; 0.009 Pa.s).

Fig. 6. Pressure contour for (a) rebound piston side, and (b) compression piston side.

The rebound-compression forces are calculated with respect to the maximum pressure value observed at the contour plot range. These forces are also related to the piston side surface areas. The compression side area is  $1.8569 \times 10^{-4} \text{ m}^2$ , and the rebound surface area is  $2.4649 \times 10^{-4} \text{ m}^2$ . The forces acting on small area (rebound) is greater than the forces acting on bigger area (compression) due to the pressure and area differences.

Fig. 7. Damping coefficient vs velocity (a) at the compression stroke (b) at the rebound stroke.

Damping values results are shown in Fig. 7 for the range of velocity of 0.8 m/s, 1 m/s, 1.2 m/s, and 1.5 m/s. Fig. 7 (a) shows the damping coefficient variation inside the compression chamber which was found to be; 1.59kN.s/m, 1.97kN.s/m, 2.15kN.s/m, 2.55kN.s/m, respectively. The damping coefficient inside the rebound chamber is shown in Fig. 7(b). The damping constant values with respect to the velocity range was found to be; 2.81kN.s/m, 3.5kN.s/m, 4.5kN.s/m, 5.6kN.s/m.

## 5 CONCLUSION

In this study, a CFD model was used to characterize a mono tube damper filled with SIV-2.5 oil over a range of velocity using Ansys 17 Fluent. The CFD model only takes into consideration the fluid chamber compressibility. However, the contribution of the internal friction in the damping force was omitted. Based on the obtained numerical damping coefficient values parametric the following was concluded:

- 1- Increasing the velocity tend to contribute in increasing the damping force, and hence the damping coefficient.
- 2- The damping values in both compression and rebound strokes are increasing linearly with the increase of velocity for two ranges; (0.8 - 1) m/s and (1.2 - 1.5) m/s. The damper is experiencing a nonlinear increase of the damping constant at the middle range of velocity of (1 - 1.3) m/s.
- 3- Using oil with low viscosity value (0.009 Pa.s) combines the linear-nonlinear behavior.

**Keywords:** energy harvesting, vibration energy harvester, stack harvester, ballasted track, passenger trains

**Abstract.** *The objective of this paper is to investigate energy harvesting of train-induced rail vibrations and to provide a comparison between various feasible harvesting locations based on the expected electrical power output. The vibrations of the railway track are modelled using the beam-on-elastic-foundation model under quasi-static loading. The loading applied is from a passenger train moving at a constant velocity. The vibrations of the railway track are then used to determine the energy harvested at each location using one-degree-of-freedom models. The numerical study concludes that the optimal configuration of the harvester is on the rail for the vibration harvester and as a harvesting rail pad between the sleeper and the rail for the compression harvester. The harvested energy with each configurations is  $\mathcal{O}(\sim 10^{-6})$  and  $\mathcal{O}(1)$  J/kg of harvester, respectively.*

## 1 Introduction

The use of energy harvesting systems has been explored in a wide array of systems ranging from biomedical application to condition monitoring systems. Zurbuchen et al. [1] developed a customized pacemaker which was tested to harvest energy from heartbeats while pacing the heart. Research in embedding piezoelectric harvesters into knee implants showed potential in improving patient experience and enhancing motion post-surgery [2]. Yip et al. [3] presented a fully-implantable cochlea for acoustic sensing of the middle ear. Akkaya and Özdemir [4] designed and tested a cost-effective piezoelectric energy harvester that converts wind energy into useful electric energy. Mekid et al. [5] even investigated the worthiness of energy harvesting from ambient radio frequency.

To optimize the operational life of a helicopter blade, Jong et al. [6] recommended a compression (stack-type) harvester designed to monitor blade health and transmit information to the aircraft using mechanical energy. A compression harvesting system under pavements was developed by Jiang et al. [7] to investigate the feasibility of powering transport infrastructure using traffic-induced vibrations. Zhang et al. [8] conducted comprehensive simulations of various bridge properties under different loading conditions and analysed their impact on vibration-based energy harvesting. Recently, Bendine et al. [9] proposed using a vibration energy harvester in the form of a cantilever beam to harvest vibration energy from a bridge subjected to time-dependent moving loads.

This paper targets promoting energy harvesters by proposing five suitable energy harvesting configurations using vibration and stack harvesting technologies. In this paper, energy harvesting from five locations on a ballasted track using two different harvesters is investigated. The two harvesters are: vibration harvesters and compression harvesters. The vibration harvester is studied at two locations: (a) attached to the rail and (b) attached to the sleeper. The compression harvester is studied at three locations: (a) between the rail and rail pad, (b) between the rail pad and sleeper and (c) as a rail pad.

The remainder of this paper is organized as follows. In Section 2, a numerical model for the vibration of the train loading, the vibration of the track and the dynamics of the energy harvesters are presented. The models adopted for describing rail vibration and energy harvesting are described in section 2 and section 3, respectively. Section 4 presents the simulation results and analyses the energy harvesting capability of each of the five configurations for various train speeds. Conclusions for this work are drawn in section 5.

## 2 Rail Vibration and Energy Harvesting

In this section, a model for the vibration of a railway track is presented. Then, approaches to harvest energy from rail vibration will be briefly reviewed.

### 2.1 Railway Track Model

The loading applied on the rail is determined based on a typical passenger train. This choice is arbitrary and is only used for the purpose of advocating the adoption of energy harvesting capabilities in the railway sector. The developed model allows for adjustments that can later be made to accommodate for any train type. For simplification, this study considers a train made of four passenger cars of equal geometry and weight.

To calculate the loading applied by each passenger car the following is assumed:

1. The maximum seating and standing capacity is 376 passengers and thus the total weight observed accounts for the difference in the tare weight of each car type.

2. The weight of the train is equally distributed between the cars and the weight of each car is equally distributed between eight wheels.
3. The load is transmitted to the rail as vertical point loads.

Four train speeds will be considered in the numerical simulations: 20, 40, 80 and 160 km/h. The mathematical model used to establish the train-induced vibrations of a ballasted track is the Winkler mathematical model. In order to conform to this model, the two rails in a typical track system are modelled as a single continuously-supported infinite elastic beam. The loading applied by two parallel wheels on the rail is combined to produce a single quasi-static, vertical load. Superposition is enforced to take into account the influence of successive wheels on an arbitrary location of the track, i.e., the harvester's location  $z$  as shown in Figure 1.

Figure 1: A beam on Elastic Foundation (Winkler model) subjected to a point load.

The vertical rail displacement  $u_r$  at any location  $z$  is given by:

$$u_r(t) = -\frac{P}{8EI\lambda^3}e^{-\lambda|z|}[\cos(\lambda|z|) + \sin(\lambda|z|)] \quad \text{with} \quad \lambda = \sqrt[4]{\frac{k}{4EI}} \quad (1)$$

where  $EI$  is the bending stiffness of the beam representing the two rails and  $k$  is the stiffness of foundation per unit length.

For a load  $P$  moving with a constant velocity  $v$  that is lower than the critical wave velocity of the track (i.e., quasi-static), and given that the load is at position  $x_0$  at time  $t = 0$  (see Figure 1), the response of the beam at point  $x$  and time  $t$  can be calculated by substituting  $z = x - x_0 - vt$  in Equation 1.

The direct differentiation of Equation 1, the velocity and acceleration of the rail are numerically evaluated in preparation for the dynamic analysis in Section 3. The velocity and acceleration of the track can be obtained as:

$$v_r(t) = \begin{cases} -\frac{Pv}{4EI\lambda^2}e^{-\lambda z}[\sin(\lambda z)] & \forall z \geq 0 \\ -\frac{Pv}{4EI\lambda^2}e^{\lambda z}[\sin(\lambda z)] & \forall z \leq 0 \end{cases} \quad (2)$$

$$a_r(t) = \begin{cases} \frac{Pv^2}{8EI\lambda}e^{-\lambda z}[\cos(\lambda z) - \sin(\lambda z)] & z \geq 0 \\ \frac{Pv^2}{8EI\lambda}e^{\lambda z}[\cos(\lambda z) + \sin(\lambda z)] & z \leq 0 \end{cases} \quad (3)$$

## 2.2 Rail Stiffness

Due to the variation in the components and their respective characteristics, in order to simulate the track as a whole system the stiffness of the various components were combined. In the simulated cases, the track components from top to bottom consist of the rail (denoted by

subscript  $r$ ), rail pads (denoted by subscript  $rp$ ), sleepers (denoted by subscript  $s$ ), ballast foundation (denoted by subscript  $b$ ) and the ground (denoted by subscript  $g$ ). As the rail displacement considered is at the web of the rail, the equivalent stiffness ( $k_e$ ) of the track system is determined using the stiffness of the components in series.

$$\frac{1}{k_e} = \frac{1}{k_{rp}} + \frac{1}{k_s} + \frac{1}{k_b} + \frac{1}{k_g} \approx \frac{1}{k_{rp}} + \frac{1}{k_b}$$

Since the stiffness of both the sleeper  $k_s$  and ground  $k_g$  are significantly larger than that of the ballast and rail pad, then

$$\frac{1}{k_e} \approx \frac{1}{k_{rp}} + \frac{1}{k_b}$$

In the following simulations, the following numerical values will be used: the bending stiffness  $EI$  is assumed to be  $2.52 \times 10^7 \text{ Nm}^2$  and the equivalent stiffness  $k_e$  is  $1.66 \times 10^8 \text{ N/m}$  as per the work of Cleante et al. [17].

### 2.3 Base-Excitation Energy Harvesters

The first systems that were developed to harvest energy from rail vibration were track-mounted [18]. Such harvesters rely on base-excitation ensuing from the track to convert the mechanical energy to electric energy. However, the base excitation of the track will depend on the exact mounting location (e.g. sleeper vs rail). With loading applied to the rails being directly transferred to the sleepers ( $k_s$ ), the following relationship can be used to represent the train-induced vibration of the sleeper as a factor of the rail vibration:

$$u_s(t) = \frac{k_s k_r}{k_s + k_g} u_r(t) \approx 0.53 u_r \quad (4)$$

where  $u_h$  is the displacement of the harvester  $m_h$ . From Equation 2 and 3 and the rail-sleeper relationship prescribed above, it is inferred that the sleeper velocity and acceleration can be determined as a fraction of the rail velocity and acceleration, respectively as

$$v_s(t) = \frac{d}{dt} \left[ \frac{k_s k_r}{k_s + k_g} u_r(t) \right] \approx 0.53 v_r \quad \text{and} \quad a_s(t) = \frac{d^2}{dt^2} \left[ \frac{k_s k_r}{k_s + k_g} u_r(t) \right] \approx 0.53 a_r \quad (5)$$

where  $v_r(t)$  and  $a_r(t)$  were obtained in Equations 2 and 3.

Previous literature utilized vibrations at the sleeper to produce energy rather than the rail due to ease of access. This energy harvesting configuration generated an optimal electrical output in the order of mW which is sufficient for low-power applications such as warning signals, switches and health monitoring sensors [19]. The linear power equation adopted in many energy harvesting works:

$$P_h = c_h v_h^2 \quad (6)$$

where subscript  $h$  denotes the harvester,  $P$  is the electrical energy harvested,  $c$  is the damping and  $v$  is the velocity induced by the mechanical vibrations of the rail.

### 2.4 Compression-Based Energy Harvester

Compression-based harvesters (also known as stack harvesters) are composed of two surface electrodes with opposing polarities inducing a voltage in the piezoelectric material sandwiched between them [20, 21]. Throughout this section it is assumed that the strains are uni-directional and in the direction of the applied loading only.

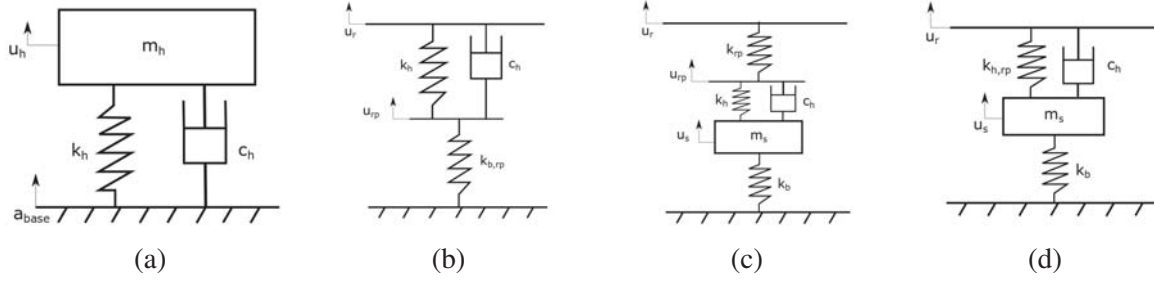

Figure 2: (a) SDOF harvester model mounted on rail (Configuration 1) or on sleeper (Configuration 2), (b) Stack harvester between the rail pad and the rail – Configuration 3, (c) Stack harvester between the rail pad and the sleeper – Configuration 4, (d) Stack harvester is used as rail pad – Configuration 5.

### 3 Harvester Models

In [10, 21], track-mounted harvesters were represented as single-degree-of-freedom (SDOF) systems. This methodology will be adopted here to study the performance of vibration energy harvesters and compression energy harvesters.

#### 3.1 Vibration Energy Harvesters

The model shown in Figure 2a is adopted herein in two configurations: (a) the SDOF harvester is mounted on the rail (Configuration 1) or (b) mounted on the sleeper (Configuration 2).

These models can be used to determine the optimal electrical power output at each train speed. It must be noted that the dynamic model applied to both configurations is identical, the only difference is the base excitation  $a_{base}$  applied to the system is dependent on the mounting location of the harvester. The governing equation of the harvester in this case is

$$m_h a_h + c_h v_h + k_h u_h = m_h a_{base} \quad (7)$$

where  $m$  is mass in kg,  $a$  is acceleration in  $m/s^2$ ,  $c$  is the damping constant,  $k$  is the stiffness in  $N/m$ ,  $v$  is the velocity in  $m/s$ ,  $u$  is the displacement and  $a_{base}$  is the base acceleration in  $m/s^2$ . In the forthcoming simulations, the following values will be used:  $m_h = 1$ ,  $k_h = 1.5$  and three values of the damping ratio will be used  $\zeta_h = c_h / \sqrt{k_h m_h} = 10^{-3}$ ,  $5.5 \times 10^{-3}$  and  $10^{-2}$ . The appropriate base acceleration  $a_{base}$  is obtained from the Winkler model.

#### 3.2 Compression Energy Harvesters

The compression harvester has three configurations: (a) the harvester is placed between the rail and the rail pad (Configuration 3 in Figure 2b), (b) the harvester is placed between the rail pad and the sleeper (Configuration 4 in Figure 2c) and (c) the rail pad itself is a compression harvester (Configuration 5 in Figure 2d). The mass of the compression harvester is assumed to be only 0.004% of the sleeper's mass; therefore, the harvester is presented as a point mass for the three aforementioned configurations. The governing equations of these three configurations are presented below:

The governing equations of Configuration 3 (Figure 2b) is

$$c_h(v_r - v_{rp}) + k_h(u_r - u_{rp}) - k_{b,rp}u_r = 0 \quad \text{with} \quad k_{b,rp} = \frac{k_b}{1 + \frac{k_b}{k_{rp}}} \quad (8)$$

Table 1: Modelled compression harvester parameters

Component	Mass, $m$ [kg]	Damping values $\zeta$ [dimensionless]	Stiffness $k$ [N/m]
Rail pad, $rp$	0	0	$2.1 \times 10^8$
Sleeper, $s$	192	0	$\infty$
Harvester, $h$	$7.5 \times 10^{-3}$	$10^{-3}, 5.5 \times 10^{-3}, 10^{-2}$	$7.8 \times 10^8$

Configuration 4 (Figure 2c) is governed by the following equation

$$m_s a_s - c_h(v_{rp} - v_s) - k_h(u_{rp} - u_s) + k_b u_s = 0 \quad (9)$$

The governing equation of Configuration 5 (Figure 2d) is

$$m_s a_s - c_h(v_r - v_s) - k_{h,rp}(u_r - u_s) + k_b u_s = 0 \quad \text{with} \quad k_{h,rp} = \frac{k_{rp}}{1 + \frac{k_h}{k_{rp}}} \quad (10)$$

where  $k_{h,rp}$  is equivalent stiffness of the the harvester and rail pad.

Numerical values for the parameters of Equation 8 through Equation 10 are provided in Table 1.

The stiffness of the rail pad and the sleeper are extracted from [20]. The sleepers are introduced into the model also undamped with negligible stiffness. As for the compression harvester, a cuboid structure of dimensions  $10^{-2} \times 10^{-2} \times 10^{-2} \text{ m}^3$  was adopted. The modelled stack harvester is purely made of piezoceramic material with a density of  $7500 \text{ kg/m}^3$ . Based on an averaged Young's modulus value for piezoceramic material and the set dimensions mentioned earlier, the axial stiffness of the harvester was obtained as listed in Table 1.

#### 4 Results and Discussion

The simulation was run for all velocities under consideration ( $v = 20, 40, 80, 160 \text{ km/h}$ ). Figure 3a and 3b shows the response of the rail under a moving passenger train at speeds 20, 40, 80 and 160 km/h. It can be noted that the sleeper displacement is 53% of the rail displacement as a result of the relationship employed in Section 2.2.

(a) Rail displacement,  $u_r(t)$ .

(b) Sleeper displacement,  $u_s(t)$ .

Figure 3: Vertical displacement for various train speeds,  $v$ , using the Winkler model.

Determining the vibration harvester velocity required the numerical integration of Equation 2a using simultaneously state representation of the 2<sup>nd</sup> order ODE. It can be observed from Figure 5a between 8 and 20 s that the vibration harvester is in a transient state. The transient

state in Figure 5b is between 1 and 3s, far shorter and much sooner than Figure 5a. It is evident from Figures 4a-4d that with increased harvester damping, the time it takes for the harvesting system to reach rest decreases. It must be noted from Figures 4a-4d that despite the train having passed, the harvester continues to oscillate and hence producing electrical output at both velocities for  $t \rightarrow \infty$ .

(a) Configuration 1,  $v = 20$  km/h.

(b) Configuration 1,  $v = 160$  km/h.

(c) Configuration 2,  $v = 20$  km/h.

(d) Configuration 1,  $v = 160$  km/h.

Figure 4: Vertical harvester velocity,  $v_h(t)$ , for different configurations and train speeds.

From Figures 5a-5d it is observed that the peaks of power generated by the harvester correspond with the peaks in velocity from Figures 4a-4d. Thus, the majority of the electrical energy provided by the harvester is extracted during the transient-state. For forcing frequencies not equal to the harvester natural frequency, a larger damping is beneficial. However, greater damping of the system does not necessarily guarantee optimal power generation. This is attributed to larger damping having a detrimental affect on the oscillations of the harvester when not under resonance [14]. Table 2 presents the results of the the five investigated configurations.

Table 2: Energy harvested  $E$  in J/kg

Configuration	Optimal Damping, $\zeta_h$	Train speed $v$ in km/h			
		20	40	80	160
1	$10^{-2}$	$2.85 \times 10^{-6}$	$5.15 \times 10^{-6}$	$9.92 \times 10^{-6}$	$2.00 \times 10^{-5}$
2	$10^{-2}$	$7.90 \times 10^{-7}$	$1.43 \times 10^{-8}$	$2.75 \times 10^{-6}$	$5.53 \times 10^{-6}$
3	$10^{-3}$	$1.45 \times 10^6$	$3.82 \times 10^5$	$1.84 \times 10^5$	$9.13 \times 10^4$
4	$10^{-3}$	$5.38 \times 10^4$	$1.45 \times 10^2$	$3.00 \times 10^1$	$3.93 \times 10^{10}$
5	$10^{-2}$	$7.18 \times 10^{-2}$	$1.36 \times 10^{-1}$	$2.71 \times 10^{-1}$	5.19

(a) Configuration 1,  $v = 20$  km/h.(b) Configuration 1,  $v = 160$  km/h.(c) Configuration 2,  $v = 20$  km/h.(d) Configuration 2,  $v = 160$  km/h.

## 5 Conclusions

To articulate the potential of harvester technology in providing reliable, safe and green energy to power and monitor appliances in industry, this paper proceeded in utilizing preliminary dynamic models and a typical passenger train to propose an optimal harvesting configuration for railway application. Current literature on railway harvesting are limited to vibration energy harvesting from sleepers due to ease of access and installation in comparison to alternative locations. This paper aspires to numerically model multiple harvesting configurations using MATLAB and determining an optimal harvesting location and corresponding harvester properties based on performance. Firstly the beam-on-elastic-foundation model for a continuously-supported infinite beam on ballast foundation was employed to determine the rail responses under train-induced quasi-static loading. The train modelled was a typical passenger train. Simplified mass-spring damper models were used to represent five different configurations of energy harvesters. The five configurations considered are labelled 1-5 are in the following order: Electromagnetic harvester placed on the rails, Electromagnetic harvester placed on the sleeper, Stack of harvesters above the rail pads, Stack of harvesters between rail pads and sleepers, Stack harvesting rail pad. The energy harvested at each configuration for a number of train speeds was evaluated. It was concluded that Configuration 1 is the most favourable for vibration harvester for all train speeds. As for the stack harvester, the more advantageous configuration is a variable of the train speed. Overall, Configuration 3 and 4 are better at generating electrical energy under the same conditions than Configuration 5.

## 6 Acknowledgment

This paper has been carried out under a research project entitled “Framework for Research on Railway Engineering” which is supported by a grant sponsored by Qatar Rail and managed by Qatar University under reference number: QUEx-CENG-Rail 17/18.

**Keywords:** Structural Dynamics, Moving Loads, Impact Factors, Continuous Beams.

**Abstract.** *The aim of this work is to analyse the impact factors in the Timoshenko beams response under moving loads in terms of both displacements and internal forces, particularly bending moments. The dynamic response is determined by modal analysis, which consist in representing the absolute displacement field by means of a weighted combination of the undamped system eigenfunctions. This paper presents a finite-element based approach that can be used to compute the dynamic internal forces, both in Bernoulli–Euler and Timoshenko beams models under moving loads. Firstly, this methodology has been validated against an analytical solution for a single-span bridge. Afterwards, the impact factors in a real four-span bridge are presented with a discussion of several issues which come up with the resolution of this kind of problems, such as the damping level and the difference between positive and negative bending moments. Finally, conclusions about the similarities in the dynamic amplification factors for different magnitudes are discussed, including one case of visible resonant behaviour.*

## 1 INTRODUCTION

The idea of substituting the dynamic analysis of structures under moving loads by static analyses where the results are amplified by an *impact factor* is as old as the moving load problem itself. Certainly, static analysis is more amenable to practical application by engineers who may be specialists in various aspects of structural analysis and design, but with no particular background in dynamics. Moreover, before the speeds of trains were high enough to raise concerns about resonance problems, carrying out full dynamic analyses with the sole purpose of obtaining a certain percentage of increase in structural displacements and internal forces was not justified: a simple amplification coefficient is generally perceived as sufficient in that case, also because vibrations levels (accelerations) are not of importance. With the advent of high-speeds railways, the perspective has changed noticeably.

Presently this issue is tackled in some building codes in a way that leaves margin for interpretation. We consider EN 1991-2 [1] as a reference standard for railway bridge design. Under certain conditions, an impact coefficient or *dynamic enhancement*  $\varphi'$  is to be calculated according to EN 1991-2, as a function of the “maximum dynamic response” and “maximum static response”, where the meaning of the term “response” is not unambiguous. If the designer is to provide a solution that complies with the standard employing the least effort, “response” can be interpreted as “displacement”—particularly, “vertical displacement” when the deformation is characterised by such type of motion, as it is the case during bending of beam-like structures.

Therefore, the question can be set forth as follows: is it possible to obtain a good approximation to the dynamic enhancement of internal forces (bending moments, shear force, etc.) by using the dynamic enhancement corresponding to displacements?

Since the computation of dynamic displacements is simpler than for internal forces, an affirmative answer to this question would have certain advantages: a coarser mesh could be used and, principally, less modes are needed for a good convergence to the dynamic displacements than to internal forces. The difficulties of convergence can be circumvented by using solution methods that combine *quasi-static* analysis plus a *dynamic increment* with respect to the quasi-static solution, as González *et al.* employed for the shear forces in [2]. However, this approach is not usually available in commercial Finite Element (FEM) codes. Additionally, less information is generated and manipulated if only displacements are postprocessed to obtain the impact factors, which results in faster analyses and reduced possibilities of unnoticed errors.

For these reasons, this paper explores the possibility of approximating impact coefficients for internal forces by means of displacement-based coefficients. The problem is addressed for bending moments in continuous beams, which is a structural type of great interest in bridge engineering. Timoshenko beam theory is used as a basis. While this theory is not expected to produce results significantly different from Bernoulli–Euler (B-E) theory for maximum resonant response of railway bridges—due to the usual slenderness of such structures—, there are other applications of interest where Timoshenko beam theory could be required, as for instance Hyperloop™ tubes of large diameter and small thickness, recently analysed by the authors under the main expected design loads [3].

The dynamic response of continuous beams is determined here by modal analysis. The paper presents a systematic, finite-element based approach to compute the dynamic internal forces, both in B-E and Timoshenko beams models under moving loads. In section 2 the closed-form solution is presented for the vertical displacements and rotations according to Timoshenko’s theory. Subsequently, the FEM approach is described in section 3. Section 4 presents a validation example of the FEM modal solution against the closed-form version. From there, obtaining

the internal forces is straightforward. Section 5 shows an application to the computation of impact factors in a real four-span continuous bridge; the results are presented with a discussion of several issues that come up with the resolution of this kind of problems, such as the poor convergence of some magnitudes and damping modelisation. Finally, conclusions about the similarities in the dynamic amplification factors for different magnitudes are discussed.

## 2 CLOSED-FORM SOLUTION

Analytical methods for dynamic response of one-span Bernoulli-Euler beam under concentrated moving loads has been extensively developed in the last few decades. Regarding the solution to this problem in the framework of Timoshenko's beam theory, current existing publications address the question employing several methods such as modal expansion, integral transforms or wave propagation functions to name just a few. A complete treatment is given in the work of Kim *et al.* [4].

For the sake of completeness, the essential aspects of the solution corresponding to Timoshenko's beam theory are summarised in this section. Classical modal expansion approach is adopted here, in which the complete displacement field is represented by means of a weighted combination of the undamped system eigenfunctions, typically truncated for computational efficiency.

Aside from the beam model selected, as is well known, a deflection function convergence is achieved with relatively low modes whereas bending moment and shear forces require far more terms to attain a reasonable accuracy. Since conventional methods are not able to capture well the discontinuities in shear diagram and bending moment slope generated at the concentrated moving load location, some attempts has been made to overcome this limitations, see [5]. For our purpose, the accuracy achieved with the modal superposition technique is enough to gain insight into the impact factor properties for the bending moments.

Consider the governing differential equations of a Timoshenko beam model:

$$\begin{aligned} m \frac{\partial^2 w}{\partial t^2} - k_s G A \left( \frac{\partial \theta_y}{\partial x} + \frac{\partial^2 w}{\partial x^2} \right) &= q_z \\ m r_y^2 \frac{\partial^2 \theta_y}{\partial t^2} + k_s G A \left( \theta_y + \frac{\partial w}{\partial x} \right) - E I_y \frac{\partial^2 \theta_y}{\partial x^2} &= m_y \end{aligned} \quad (1)$$

Once the separation of variables has been imposed  $w(x, t) = W(x)e^{i\omega t}$ ,  $\theta_y(x, t) = \Psi(x)e^{i\omega t}$  on the related homogeneous equation, the spatial displacement function  $W(x)$  will be the solution of the following compact equation,

$$W^{IV}(x) + \frac{m(\omega r)^2}{EI} \left( 1 + \frac{E}{k_s G} \right) W^{II}(x) - \frac{m\omega^2}{EI} \left( 1 - \frac{m(\omega r)^2}{k_s G A} \right) W(x) = 0 \quad (2)$$

being the roots of this spatial differential equation,

$$r_{1,2,3,4} = \pm \frac{\bar{\omega}}{\sqrt{2}\lambda} \sqrt{\sqrt{\left(1 - \frac{\eta}{12}\lambda^2\right)^2 + \left(\frac{2\lambda^2}{\bar{\omega}}\right)^2} \pm \left(1 + \frac{\eta}{12}\lambda^2\right)} \quad (3)$$

where the following dimensionless parameters has been defined,

$$\begin{aligned}\lambda &= \frac{L}{\sqrt{I/A}} && \text{slenderness ratio} \\ \bar{\omega} &= \omega \sqrt{m/EI} L^2 && \text{adimensional frequency} \\ \eta &= \frac{12EI}{k_s GAL^2} && \text{bending to shear stiffness ratio}\end{aligned}$$

Except for the critical frequency  $\bar{\omega}_c = \sqrt{12/\eta} \lambda$  the general solution is in the form,

$$W(x) = A_1 e^{r_1 x/L} + A_2 e^{r_2 x/L} + A_3 e^{r_3 x/L} + A_4 e^{r_4 x/L} \quad (4)$$

which in turn can be reformulated in terms of trigonometric and hyperbolic functions,

$$W(x) = C_1 \sin(ax) + C_2 \cos(ax) + C_3 \sinh(bx) + C_4 \cosh(ax) \quad (5)$$

being,

$$\begin{aligned}a &= \frac{\bar{\omega}}{\sqrt{2}\lambda L} \sqrt{\sqrt{\left(1 - \frac{\eta}{12}\lambda^2\right)^2 + \left(\frac{2\lambda^2}{\bar{\omega}}\right)^2} - \left(1 + \frac{\eta}{12}\lambda^2\right)} \\ b &= \frac{\bar{\omega}}{\sqrt{2}\lambda L} \sqrt{\sqrt{\left(1 - \frac{\eta}{12}\lambda^2\right)^2 + \left(\frac{2\lambda^2}{\bar{\omega}}\right)^2} + \left(1 + \frac{\eta}{12}\lambda^2\right)}\end{aligned}$$

Additionally, taking into account the boundary conditions of a simply supported beam, these coefficients  $C_i$  can be established as a function of  $\bar{\omega}$  except for a constant of proportionality. In order to let exist a non-trivial solution, the frequency equation for frequencies lower than  $\bar{\omega}_c$  is as follows,

$$\sin(aL) = 0 \quad \longrightarrow \quad aL = h_k \pi \quad (6)$$

Sorting the eigenvalues in increasing order ( $w_k$ ;  $k = 1, n$ ) and preserving the number of its spatial half-waves  $h_k$  (wave number), their associate eigenfuctions turn out to be,

$$\begin{aligned}W_k(x) &= \sin\left(h_k \pi \frac{x}{L}\right) \\ \Psi_k(x) &= \frac{-h_k \pi}{L} \left[1 - \frac{\eta}{12} \left(\frac{\bar{\omega}_k}{h_k \pi}\right)^2\right] \cos\left(h_k \pi \frac{x}{L}\right)\end{aligned} \quad (7)$$

in virtue of the orthogonality property of modes, the projection onto the modal space with the displacement vector  $N_k(x) = (W_k(x) \ \Psi_k(x))^T$  results in a set of independent non-homogeneous second order differential equation.

$$\ddot{q}_k(t) + 2\zeta_k \omega_k \dot{q}_k(t) + \omega_k^2 q_k(t) = \frac{P \sin\left(h_k \pi \frac{x}{L}\right)}{\frac{mL}{2} M_{eq_k}} \quad (8)$$

with the equivalent modal mass

$$M_{eq_k} = m \int_0^L N_k^T \begin{pmatrix} 1 & 0 \\ 0 & \left(\frac{L}{\lambda}\right)^2 \end{pmatrix} N_k dx \quad (9)$$

its solution for an underdamped system will be,

$$q_k(t) = \begin{cases} \frac{1}{\omega_{d_k}} \int_0^t e^{-\omega_k \zeta_k (t-\tilde{t})} \sin(\omega_{d_k} (t-\tilde{t})) \frac{P \sin(h_k \pi \frac{v \tilde{t}}{L})}{\frac{mL}{2} M e q_k} d\tilde{t}, & \text{if } t \leq t_e \\ e^{-\omega_k \zeta_k (t-t_e)} \left( \frac{\dot{q}_k(t_e) + \omega_k \zeta_k q_k(t_e)}{\omega_{d_k}} \sin(\omega_{d_k} (t-t_e)) + q_k(t_e) \cos(\omega_{d_k} (t-t_e)) \right), & \text{otherwise.} \end{cases} \quad (10)$$

where,

$$\begin{aligned} \omega_{d_k} &= \omega_k \sqrt{1 - \zeta^2} && \text{damped angular frequency} \\ v &&& \text{load constant velocity} \\ t_e &= L/v && \text{time when the load leaves the bridge} \end{aligned}$$

Adding up the contribution of all retained modes, the displacement and rotation response will be respectively,

$$\begin{aligned} w(x, t) &= \sum_{k=1}^n q_k(t) W_k(x) \\ \theta_y(x, t) &= \sum_{k=1}^n q_k(t) \Psi_k(x) \end{aligned} \quad (11)$$

### 3 FINITE ELEMENT IMPLEMENTATION

An analytical formulation for a one-span simple supported beam has been presented in previous section. However, analytical solution for multiple-span bridges with general boundary conditions is so arduous and cumbersome to obtain analytically that it is of common use to employ numerical methods like, in most cases, the Finite Element Method [6]. The FEM permits a systematic implementation to solve general problems, so the implementation to solve the moving load problem is particularly presented here in this section.

A Timoshenko beam element has been adopted to model the bridge behaviour, as well as the Bernoulli-Euler to allow a comparison of results. Element mass and stiffness matrices follow the formulation in [7], while the concentrated moving loads are assembled as equivalent nodal loads to obtain the global matrices. The equation of motion of the bridge is given in terms of the displacement vector  $\mathbf{x}$ , and its derivatives  $\dot{\mathbf{x}}$ ,  $\ddot{\mathbf{x}}$ , the force vector  $\mathbf{f}$ , mass matrix  $\mathbf{M}$  and stiffness matrix  $\mathbf{K}$  as

$$\mathbf{M} \ddot{\mathbf{x}} + \mathbf{K} \mathbf{x} = \mathbf{f} \quad (12)$$

As well as in the analytical formulation, displacements are represented by a truncated base of eigenvectors  $\Phi_k$ , previously determined by a modal analysis.

$$\mathbf{x}(t) = \sum_{k=1}^k q_k(t) \Phi_k \quad \begin{cases} |\omega^2 \mathbf{M} - \mathbf{K}| = 0 \\ [\omega_k^2 \mathbf{M} - \mathbf{K}] \Phi_k = \mathbf{0} \end{cases} \quad (13)$$

The orthogonality property of the undamped eigenvectors permit the projection of the global matrix equation onto the modal space turning into a set of independent second order differential equations in which viscous modal damping  $\zeta_k$  is then assigned.

$$\ddot{q}_k(t) + 2 \zeta_k \omega_k \dot{q}_k(t) + \omega_k^2 q_k(t) = \frac{\Phi_k^T \mathbf{f}}{\Phi_k^T \mathbf{M} \Phi_k} \quad (14)$$

After each mode coordinate  $q_k(t)$  is obtained, the displacements are expanded as previously stated 13. Internal forces, namely bending moment and shear force, are afterwards recovered by means of the element stiffness matrices  $\mathbf{K}^e$  and the displacement vector  $\mathbf{u}^e$  of their related nodes.

$$\mathbf{F}^e = \mathbf{K}^e \mathbf{u}^e \quad (15)$$

Actually, element nodal loads consist of a contribution of stiffness, damping and inertial forces. Inertial loads at nodes are a result of the space discretization and tends to vanish with the mesh refinement. Internal damping forces depends on the physical phenomena from which they are originated. Introducing modal damping leaves the distribution of that forces undetermined and a hypothesis on how they are generated is required to define damping forces. In any case, for a conventional structure damping  $\zeta$  is usually below 3%, which would represent a negligible contribution to the total internal force. Thus, if the mesh is refined enough, the stiffness part

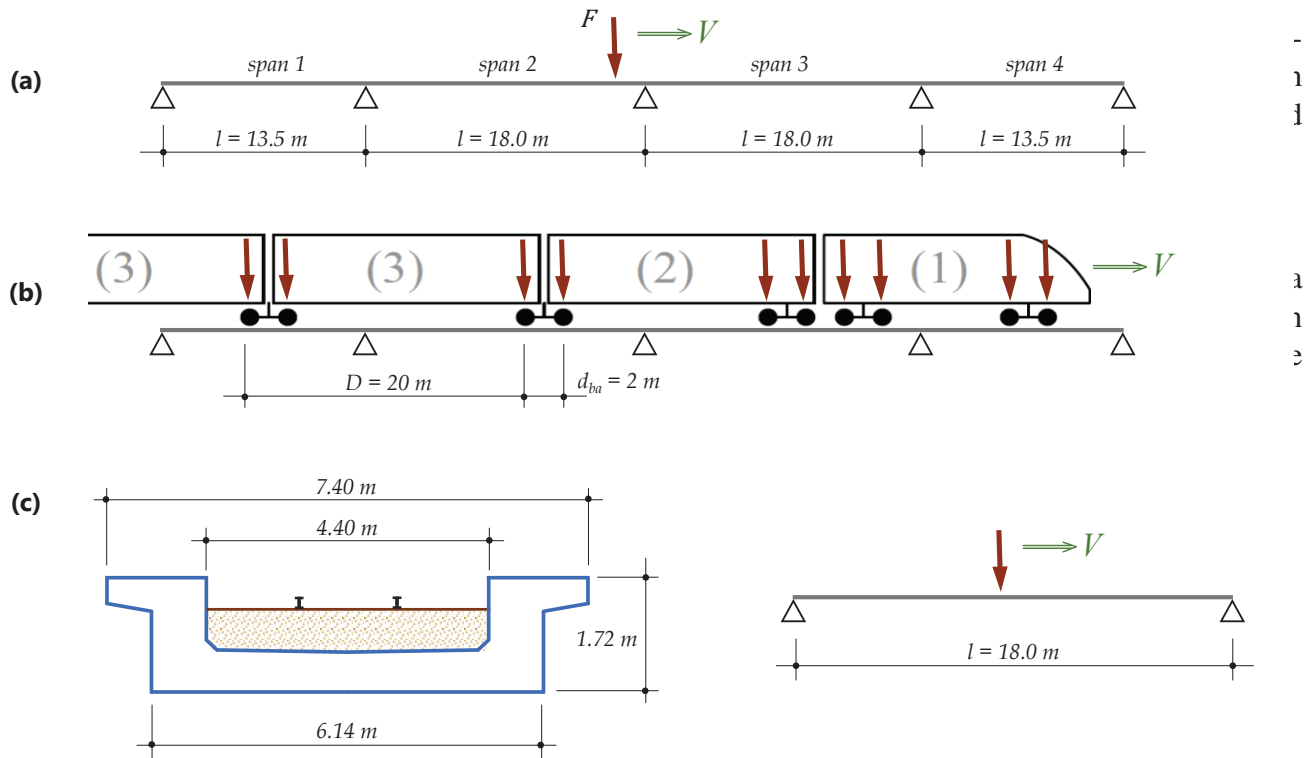

Figure 1: Bridge Section and one-span moving load model.

Section properties are as follows: cross-section area  $A = 6.46 \text{ m}^2$ , second moment of area about an horizontal axis passing through the c.o.g.  $I = 1.69 \text{ m}^4$  with a linear mass density  $m = 21400 \text{ kg/m}$  including self and dead weight. Flexural to shear stiffness factor is estimated in  $k_s = 0.461$  to be used in the Timoshenko beam model. Material properties are  $E = 36.0 \text{ GPa}$ ,  $\nu = 0.3$  with a viscous critical damping ratio of  $\zeta = 1.14\%$  for prestressed structures according to [1].

## 4.2 FEM RESULTS vs. CLOSED-FORM SOLUTION

In a single-span SS beam the firsts few lower modes are the major contributors to the displacement response, with a fast convergence to the complete solution. Therefore, in this section both analytical and FEM displacement variables are expanded with the contribution of the first five modes.

As can be seen in Table 1, with a mesh of 100 elements, relative error of FEM compared to the analytical solution is negligible. Even with 0.75m element length (24 elem) is enough to accurately capture up to 5 modes with a relative error less than 1.0%.

An interesting fact is that the first two eigenfrequencies from B-E theory are quite similar to that of Timoshenko theory, while higher modes are appreciably stiffer with the B-E modelisation.

Mode no.	Timoshenko			Bernoulli-Euler		
	Analytic	FEM	$\epsilon_r(\%)$	Analytic <sup>1</sup>	FEM	$\epsilon_r(\%)$
1	7.968	7.968	0.000%	$\pi^2 k$	8.175	0.000%
2	29.76	29.76	0.000%	$(2\pi)^2 k$	32.70	0.000%
3	60.97	60.97	0.000%	$(3\pi)^2 k$	73.57	0.000%
4	97.62	97.62	0.001%	$(4\pi)^2 k$	130.8	0.000%
5	137.1	137.1	0.002%	$(5\pi)^2 k$	204.4	0.000%

<sup>1</sup> Conversion factor from dimensionless frequency to the angular frequency  $k = \sqrt{EI/m}/(2\pi L^2)=0.828\text{Hz}$

Table 1: Timoshenko vs Bernoulli-Euler eigenvalues.

Figure 2 illustrates the displacement transient response of the mid-span section when the beam is traversed by a concentrated load of 100 kN. An excellent agreement of the FEM solutions compared with the analytical one is obtained with a 100 elements mesh for two different load velocities in a one-span simple supported bridge. Changes to the spatial discretisation show that even with a coarse mesh of 4 elements reasonable accuracy is achieved. The use of different beam models arise some perceivable differences in the transient response, but the maximum response is quite similar in this example.

Figure 2: Analytical and FEM displacements (TSK - Timoshenko; BNU - Bernoulli-Euler beam model).

## 5 REAL CASE STUDY. FOUR-SPAN BRIDGE

As mentioned before, one four-span continuous bridge from the Swedish railway network has been selected as a real case study. Figure 3 shows the spans length and Figure 1 depicts the beam section dimensions whose properties has been described in Section 4.1

### 5.1 LOAD CASES

Two cases of constant velocity moving loads are considered, and presented in Figure 3. Case (a) is a single concentrated moving load 100 kN, while (b) is an articulated train (HSLM-A Train A-3, as defined in [1]) comprising a series of coaches with axle loads of 180 kN.

Figure 3: Bridge dimensions, support conditions and load set (a) single load, (b) HSLM-A3 trainset.

### 5.2 IMPACT FACTORS

In order to compare the impact factors (IF) of displacements and bending moments, both are evaluated at the mid-span sections. The IF is defined simply as the ratio between the maximum dynamic effect divided by the maximum static effect. First, positive bending moments at mid-span are compared with downward displacements in order to analyse possible similarities. Later, negative bending moments will be also discussed. A 0.75m mesh element length has been used and response variables are expanded with the contribution of 5 clusters of modes. A cluster is considered as group of (similar) frequencies equal to the number of spans, which is typical in continuous beams.

IFs for a single load, Figure 4, does not display too prominent peaks, and values remain lower than 1.2 in the analysed velocity range. Its aspect reminds of the classical dynamic influence lines, obtained for one load in a single span [8]. While for central spans maximum value appears at 300-350 km/h, outer spans seems to increase their level at velocities higher than 400 km/h. Also, the curves for spans 1-2 are smoother than for spans 3-4. Of great interest is that IFs for positive bending moment follow in general the same tendency than the displacement ones for each span, with somewhat lower values.

When a train of loads is considered, the system can be expected to develop resonance at certain speeds. Figure 5 presents a noticeable peak around 340 km/h that is more prominent in spans 1-2-3. Interestingly, as it happened for the single concentrated load, positive bending moment IFs follow the same tendency than the displacement ones, being slightly lower.

Figure 4: IF for a single concentrated moving load,  $\zeta = 1.14\%$ , outer spans (left) and inner spans (right).

Figure 5: IF for HSLM-A3 train,  $\zeta = 1.14\%$ , outer spans (left) and inner spans (right).

As it was expected, a decrement in the damping factor produce a higher amplification of the IF as can be seen in Figure 6. All the conclusions from the previous analyses are applicable to this case as well.

In this case, the fact that IFs for positive bending moment follow the trends of the displacement IF, being slightly lower, is in accordance with the usual procedure followed in many technical offices, in which the displacement IF is also applied for the strength verification at ULS, as it was mentioned in the introductory section.

Figure 6: IF for HSLM-A3 train,  $\zeta = 0.50\%$ , outer spans (left) and inner spans (right).

However, the situation is not so clear when negative bending moments at the supports are analysed. Figures 7 to 9 show the IF for the negative moment in all three supports, along with the IFs corresponding, in each case, to the mid-span sections of both adjacent spans, as well

as the average displacement IF of both mid spans. We designate *support 2* the one located at the left end of *span 2*, according to Figure 3, and similarly for supports 3 and 4. Focussing on the resonant speed determinant for the bridge design, one first conclusion is that IFs for negative bending moments are lower compared to positive bending moments. Moreover, the approximation via displacement IFs is not satisfactory: in supports 2 and 3 the displacement coefficients overestimate the negative bending moment impact, see Figures 7 and 8; besides, in support 4 the correlation of the peak is good with the average of the displacements, but the curves are irregular in that speed range and no clear trend can be established (Figure 9).

Figure 7: IF for HSLM-A3 train,  $\zeta = 1.14\%$ , support 2.

Figure 8: IF for HSLM-A3 train,  $\zeta = 1.14\%$ , support 3.

Figure 9: IF for HSLM-A3 train,  $\zeta = 1.14\%$ , support 4.

These findings suggest that using displacement-based impact factors to amplify static negative bending moments may be less accurate than for positive bending moments. Nevertheless,

such conclusion is based in the analysis of one representative example and needs further verification.

## 6 CONCLUSIONS

In this paper a Finite Element approach based on Timoshenko beam theory for the calculation of dynamic impact factors in continuous beams has been presented. The time-varying amplitudes of the modal coordinates have been validated against a closed-form solution of the equations of motion. The influence of mesh refinement has been discussed.

Subsequently, the impact factors for positive bending moments at mid-span have been compared with those of downwards displacements. Impact factors for negative bending moments have been scrutinised as well. First, a single travelling load has been considered; secondly, the effects of a high-speed train capable of producing resonance have been analysed for an actual four-span, single-track, continuous railway bridge. In light of the outcomes of these analyses it can be concluded that:

- Though it is sometimes believed that continuous bridges are largely immune to resonance, results for the four-span bridge studied here under the HSLM-A3 train display a prominent peak around 340 km/h, with impact factors as high as 1.6 (for damping  $\zeta = 1.14\%$ ), or 2.1 (for damping  $\zeta = 0.5\%$ ).
- Inner spans present higher resonant peaks than the end spans.
- Impact factors for positive bending moment follow the same tendencies of the displacement ones for each span, with slightly lower values.
- The preceding conclusions related to the impact factors are valid for different levels of structural damping.
- The use of displacement-based impact factors to amplify static negative bending moments may be less accurate than for positive bending moments.
- As it is known, Bernoulli-Euler beam theory overestimates natural frequencies with respect to the Timoshenko beam model. Particularly, the first two natural frequencies of a single-span railway bridge have been found to be quite similar—specially the first one. The difference increases noticeably for the higher modes.

**Keywords:** SPH, Euler-Bernoulli, Linear Elasticity, FSI, CFD, DualSPHysics, Project Chrono.

**Abstract.** *This work presents a novel numerical framework for dynamic analyses of structure systems within the meshless approach Smoothed Particle Hydrodynamics (SPH) method. The Lagrangian solver DualSPHysics presents several advantages over the widely used Eulerian solvers, dealing with nonlinearities and multiphase phenomena with reasonable numerical stability and reliability. The proposed procedure exploits the mechanical features provided by the Project Chrono library to simulate elastic beams. The modelling procedure is of interest for studying complex soil-, solid-, fluid-structure interactions, involving a system that includes all of the aforementioned phases in a unitary context. The analytical formulation to pass information over to the SPH solver for generating a sub-assembly of rigid stubs and elastic hinges, that will mimic the behavior of a Euler-Bernoulli flexible beam, is presented. The approach is validated against theoretical Euler-Bernoulli solutions: the agreement between the theoretical solutions for the behavior of the flexible beams and the presented model is very good and increases when the number of elements that make up the beam,  $N$ , increases. In addition, the behavior of the flexible beam thus created in the SPH environment is validated considering a sensitivity analysis based on several parameters, such as the model resolution (initial interparticle distance) and the number of elements.*

## 1 INTRODUCTION

The Meshfree Particle Methods (MPMs) present several advantages over mesh-based methods, like the natural ability to solve multi-mechanics problems: the Lagrangian nature of this family of numerical methods allows to compute, with relative ease, multi-mechanics problems involving complex interfaces and moving boundaries. In particular, the Smoothed Particle Hydrodynamics (SPH) method, is, by now, well established in the Computational Fluid Dynamics (CFD) discipline, and its effectiveness has been proven in several works, especially when dealing with free-surfaces flows and large deformations [1].

The DualSPHysics code has been applied to several multiphysics phenomena, for example in coastal engineering simulations: to compute forces exerted by large waves on the urban furniture of a realistic promenade [2], to study the run-up on a real armour block coastal breakwater [3, 4] and to simulate large waves generated by land-slide events [5]. Other successful applications of DualSPHysics are performed in the field of renewable energies, for example the simulation of Wave Energy Converters (WECs) in several contexts: from the study of the moorings and floatings dynamics [6, 7, 8, 9], to the efficiency [10] and survivability [11] analysis when combined with closed loops [12, 13], PTO systems [4, 14] or non linear mechanical constraints [15]. These works present first attempts of reproducing the effects of power take-off systems through simplified, although reliable, approaches. Specific validation of Fluid Structure Interactions (FSI) in DualSPHysics are provided by [16]. However, an option to model flexible objects is not yet available.

In this work, the potentiality of an SPH-based solver, DualSPHysics [17], augmented with the Project Chrono library [18], developed as a general purpose simulation framework for multi-body problems, are utilized to simulate the flexural behavior of one-dimensional beams. Other approaches to this issue, with the SPH formulation, can be found in several works (for example, [19, 20, 21, 22]). Rigid bodies and mutual constraints allow developing an alternative framework for the dynamics analysis of structural systems, able to reproduce extremely high deformations of flexible elements, under complex and time-variant load conditions, or impacts - useful for simulating the response of engineered structures under the menaces of hazardous natural events. The aforementioned numerical architecture, in fact, provides a robust and reliable framework for studying fluid-solid interaction, handling arbitrarily defined fluid-structure-structure coupled systems, consenting to specify mutual and/or absolute constraints, such as joints and sliders. SPH is a suitable method for modelling water-related natural hazards due to its characteristics [23, 24].

The proposed beam model relies on a lumped elasticity formulation, in which the only deformation allowed is represented by the relative rotation between consecutive trunks. A similar representation can be found in [25], while a valid application of this formulation to structure collapse is presented in [26]. To improve this work, following [25] and [26], the interactions between the rigid bodies, modelled as mutual constraints, can be characterized by elastic, then plastic behavior, up to a threshold value of stress that determines the collapse. For the peculiarities of the Lagrangian-based method here presented, the latter situation is reproducible with relative ease, encouraging further investigations. In the SPH-based framework, the dynamics of the trunks, and so of the beam as a whole, depends on the Newton's equations for rigid bodies, computed taking into account the mutual constraints and the interaction with external forces. A numerical algorithm developed from classical static theories is here proposed (i.e. Euler-Bernoulli (EB) beam theory), and implemented in DualSPHysics to simulate linear elasticity, using the features provided by the coupling with Project Chrono. In the following, after the

presentation of the SPH formulation implemented in the DualSPHysics code, and its coupling with Project Chrono, the theoretical approach is formulated and validated against EB solutions. Then, the proposed approach is reproduced in DualSPHysics by combining hinges and rigid bodies and their response in investigated.

## 2 SPH FORMULATION

MPMs in general refers to the class of meshfree methods that employ a set of finite number of discrete particles to represent the state of a system and to record its movement. Each particle can either be directly associated with one discrete physical object, or be generated to represent a part of the continuum problem domain. For CFD problems, each particle possesses a set of field variables such as mass, momentum, energy, positions etc., and other variables (vorticity, etc.) related to the specific problem. The advantages of the MPMs methods over conventional grid-based numerical methods can be roughly summarized as follows:

- the problem domain is discretized with particles without a fixed connectivity, so treatment of large deformation is relatively easier;
- discretization of complex geometry is simpler as only an initial discretization is required;
- it is easy to obtain the features of the entire physical system through tracing the motion of the particles, therefore, identifying free surfaces, moving interfaces and deformable boundaries, is no longer a tough task.

Among the MPMs, the Smoothed Particle Hydrodynamics (SPH) method is employed in the present work.

### 2.1 Principles of the SPH method

The strategy in SPH is to discretize the physical domain (fluid and/or solid objects) into a set of particles, where the physical quantities (position, velocity, density and pressure) are obtained as an interpolation of the corresponding quantities of the surrounding particles. The contribution of those particles is weighted using a kernel function, with an area of influence that is defined using a characteristic smoothing length. This discretization process is divided into two key steps [27].

The first step is the integral representation or the so-called kernel approximation of field functions, consisting in the integration of a multiplication of an arbitrary function and a smoothing kernel function. The integral representation of a generic spatial function  $f(\mathbf{r})$  within an integral volume  $\Omega$ , is given by:

$$\langle f(\mathbf{r}) \rangle = \int_{\Omega} f(\mathbf{r}') W(\mathbf{r} - \mathbf{r}', h) d\mathbf{r}' \quad (1)$$

where  $W$  is the so-called smoothing kernel function or kernel. In the smoothing function,  $h$  is the smoothing length defining the influence area of  $W$  (Figure 1).

The second step is the particle approximation. The integral representation is approximated by summing up the values of the nearest neighbor particles, which yields the particle approximation of the function at a discrete point (particle). The position  $\mathbf{r}_b$  is defined as the position of a particle having a fixed mass  $m_b$  and a finite volume  $V_b$ , related by

$$V_b = \frac{m_b}{\rho_b} \quad (2)$$

where  $\rho_b$  is the density of particle  $b = 1, \dots, N_p$  in which  $N_p$  is the number of particles within the support domain of particle  $a$ . The integral representation can be written in a discrete form for a particle  $a$ ,  $b$  being part of its support domain:

$$\langle f(\mathbf{r}_a) \rangle = \sum_{b=1}^{N_p} \frac{m_b}{\rho_b} f(\mathbf{r}_b) W_{ab} \quad (3)$$

where:

$$W_{ab} = W(\mathbf{r}_a - \mathbf{r}_b, h) \quad (4)$$

The kernel function, hence, plays a fundamental role in the SPH method. In DualSPHysics the Wendland [28] quintic kernel function is utilized:

$$W(r, h) = \alpha_{D,n} \begin{cases} \left(1 - \frac{q}{2}\right)^4 (1 + 2q) & 0 \leq q \leq 2 \\ 0 & 2 < q \end{cases} \quad (5)$$

where:

$$q = \frac{r}{h} = \frac{|\mathbf{r} - \mathbf{r}'|}{h} \quad (6)$$

and  $\alpha_{D,n}$  is a constant depending on the dimension of the problem.

Figure 1: Smoothing kernel function.

## 2.2 Governing equations for rigid bodies

Rigid bodies are sub-sets of SPH particles, the variables of which are integrated in time with the Newton's equations for rigid body dynamics, in the domain frame reference.

The equations of motion are:

$$\begin{aligned} M \frac{d\mathbf{V}}{dt} &= \mathbf{F}_\Omega \\ \mathbf{J} \frac{d\boldsymbol{\Omega}}{dt} &= \mathbf{F}_\Omega \end{aligned} \quad (7)$$

where  $\mathbf{F}_\Omega$  is the *total moment* with respect to the center of mass, and they assume the following aspect in particle approximation:

$$\begin{aligned} M_I \frac{d\mathbf{V}_I}{dt} &= \sum_{k \in I} m_k \frac{d\mathbf{u}_k}{dt} \\ \mathbf{J}_I \frac{d\boldsymbol{\Omega}_I}{dt} &= \sum_{k \in I} m_k (\mathbf{r}_k - \mathbf{R}_I) \times \frac{d\mathbf{u}_k}{dt} \end{aligned} \quad (8)$$

where the body  $I$  posses a mass  $M_I$ , velocity  $\mathbf{V}_I$ , inertia tensor  $\mathbf{J}_I$ , angular velocity  $\boldsymbol{\Omega}_I$  and center of gravity  $\mathbf{R}_I$ . The vectorial quantities are computed at every time step (discretizing the temporal derivative  $\frac{d}{dt}$ ). The force by unit mass applied to the particle  $k$  belonging to  $I$  is expressed as  $m_k \frac{d\mathbf{u}_k}{dt}$ , encompassing body forces (gravity) and external loads resultants. The net force on each boundary particle is computed according to the sum of the contributions of all surrounding fluid particles according to the designated kernel function and smoothing length. It is clear that every particle within the body has a velocity given by:

$$\mathbf{u}_k = \mathbf{V} + \boldsymbol{\Omega}_I \times (\mathbf{r}_k - \mathbf{R}_I) \quad (9)$$

These equations are integrated in times over a staggered interval, in DualSPHysics, using a computationally simple Verlet based scheme that guarantees a second order spatial accuracy. For more details about rigid bodies in DualSPHysics, [29] is suggested.

### 2.3 Coupling scheme

Mechanisms involving contacts and impacts between parts can be modeled in terms of multi-body systems with unilateral constraints. Considering the success of SPH for fluid descriptions and non-smooth multi-body solvers for mechanical systems, attempting to couple both under a generalized framework should provide new simulation possibilities, by leveraging the strengths of both methods. Project Chrono is able to simulate a wide range of physical problems, but at the moment, DualSPHysics uses the rigid body, constraints and collision detection parts of the library. This allows to use a set of bodies described in meshes, define restrictions applied to the bodies (from the implemented list of joints, hinges and springs) and compute interactions between bodies, in a similar fashion of the DEM implementation, but in a more stable manner.

The implementation strategy is to couple both models with a message passing interface. Once quantities from the rigid bodies are computed by DualSPHysics (Equation (8)), the time step, along with the linear and angular accelerations from each body, are sent to the Project Chrono module [16]. For that time step, Chrono returns the linear and angular velocities, as well as centres of mass position, computed by integrating the fluid contributions with the dynamic or kinematic restrictions of the system, including collisions.

## 3 LUMPED ELASTICITY FORMULATION

The developed approach is based on the discretization of a one-dimensional element (Figure 2) defined under the assumptions of the EB theory, which are here briefly recalled. Being  $x$  the abscissa that identifies the beam axis:

- the longitudinal axis of the unloaded, undeformed beam, is rectilinear;
- small shifts;
- inalterability of the cross section, i.e. always planar;
- the generic cross section  $\Sigma(x)$  is always orthogonal to the axis, also in the deformed configuration;
- isotropic elastic material;
- $x$  dimension predominant with respect to  $y, z$ .

As a consequence of these assumptions, considering the behavior of the beam to be only flexural, the function which uniquely describes its deformation is the *vertical displacement function*  $v = v(z)$ , namely the *elastic line equation* (Figure 2). Furthermore, every cross section is characterized by infinitesimal rigid displacements, expressible as a summation of a translation ( $v$ ) and a rotation ( $\vartheta$ ) around its centre of mass  $G$ .

Figure 2: Representation of a beam with rectilinear axis (a), and relative kinematic parameters (b).

Following these considerations, it is possible to reproduce the displacement function with the finite element representation, in which the elements assume a physical dimension, and thus the latter are governed by the rigid body kinematics. In fact, a generic derivable function, in this case  $v = v(x)$ , can be replaced with a series of local defined low-order functions  $\psi_i$ , which interpolate between the  $v(x_i) = v_i$  values:

$$v(z) \approx \sum_i \psi_i v_i \quad (10)$$

In case  $\psi_i$  is a first order polynomial, the approximation is linear, which can be materially represented by rigid elements, from now on *trunks*. The numerical properties of the interpolation polynomials are physically the positions and the lengths of the trunks, whose ending cross section are equipped with rotational hinges. The hinge positions, related to a generic trunk, identified respectively as  $i$  and  $i + 1$ , are expressible with a single rotational parameter, namely  $\vartheta_i$  (Figure 3). The displacement of the point  $i + 1$  is known, once the the angle  $\vartheta_i$  (rotation in  $i$ ) is note; from the Equation (9) we have:

$$\mathbf{u}_{i+1} = \mathbf{\Omega}_i \times \mathbf{r}_{i,i+1} \quad (11)$$

which becomes in a two-dimensional EB framework, being  $r_{i,i+1} = r_{i+1} - r_i \doteq \Delta x$ , and assuming  $\mathbf{\Omega} = \{0, 0, \vartheta_i\}$ :

$$v_{i+1} = \sin \vartheta_i \Delta x \quad (12)$$

The proposed numerical model is elaborated for a cantilever, but its approximations can be extended to any kind of Boundary Conditions (BC). This particular static scheme was chosen because several FSI problems present models akin to this one, and also various validation processes are based on cantilevers (see [30, 31]). The cantilever, hence, is discretized as a set of rigid trunks and rotational hinges [25]. The hinge is characterized by a proper value of *rotational stiffness*  $K_{\vartheta,i}$ , constant with the length of the trunk  $\Delta x$ , that is deduced from the geometrical e mechanical properties of the section.

Figure 3: Vertical displacement of the end of a rigid trunk (a), and discretization scheme (b).

### 3.1 Numerical discretization

Let us consider the cantilever section in the plane  $\{x, y\}$ , of length  $L_s$  and thickness  $h_b$ , the beam axis being axis of symmetry and coincident with  $x$ . Let  $A_s = h_s b_s$  be the area of the cross section, assumed rectangular and constant,  $b_s$  being the base, aligned with  $x$ ,  $I_s$  the moment of inertia,  $E_s$  and  $\rho_s$  respectively the Young's modulus and density of the material. The beam is arbitrarily divided in  $N$  (identified with the subscript  $j$ ) trunks  $\Delta x$ , linked with  $N$  (identified with the subscript  $i$ ) hinges (Figure 5). In case of constant spatial discretization, we can define:

$$\Delta x = \frac{L_s}{N} \quad (13)$$

and the generic abscissa is  $x(i) \doteq x_i$ . Within this framework, following the assumption that the behavior of the beam is only flexural, as visible in the elastic line equation:

$$\frac{d^2 v(x)}{dx^2} = -\frac{M(x)}{E_s I_s} \quad (14)$$

the moment is the only components of tension to be dealt with. The *moment*  $M_{ij}$  is defined as the moment created by the  $j$ -th resultant with respect to the  $i$ -th hinge:

$$M_{ij} = d_{ij} F_j \quad (15)$$

where  $d_{ij}$  is the *lever arm* of the force  $F_j$ , applied in the center of mass  $G_j$  of the trunk, with  $G_j > x_i$ . The *total moment* referred to the  $i$ -th hinge is:

$$M_i \doteq \sum_{k=j}^N M_{ik} = \sum_{k=j}^N d_{ik} F_k \quad (16)$$

The *local rotation*  $\bar{\vartheta}_i$  of the  $i$ -th hinge is proportional to the total moment calculated in the section  $x_i$ , by the rotational stiffness, following the theory of linear elasticity:

$$\bar{\vartheta}_i = \frac{M_i}{K_{\vartheta,i}} \quad (17)$$

This value, which characterizes the flexural behavior of each trunk, can be computed once the external load is known. To secure a correct numerical result for a cantilever scheme, the rotational stiffness of the bearing (first section) has to be doubled with respect to the generic stiffness value, since the first trunk can be considered semi-fixed. Thanks to rigid body kinematics is possible, then, to obtain the complete displacement function of the beam; let

$$\vartheta_i = \sum_{k=1}^i \bar{\vartheta}_k \quad (18)$$

be the *total rotation* of the  $i - th$  hinge;

$$\bar{v}_{i+1} = \Delta x_{j=i} \sin \vartheta_i \quad (19)$$

is, hence, the *local vertical displacement* of the section  $x_{i+1}$ , and

$$v_i = \sum_{k=1}^i \bar{v}_k \quad (20)$$

is the *total vertical displacement*.

This numerical approach, being based on an equilibrium (Equation (17)), can be naturally extended in the dynamic framework of DualSPHysics and Project Chrono, once defined the governing parameters to be transmitted: number and dimensions of the trunks and the stiffness related to each hinge. To complete the implementation of the one-dimensional elastic element in DualSPHysics, the resolution parameter  $dp$  has to be defined, namely the initial inter-particle distance, as function of the beam thickness  $h_s$ :

$$dp \doteq \frac{h_s}{pp(h_s)} \quad (21)$$

where  $pp(h_s)$  is the number of particles per straight section.

#### 4 Validation

The use of the SPH formulation to discretize one-dimensional flexible elements has two main, and consequential, objectives:

1. demonstrate that a fixed set of particles is able to reproduce, properly, the behavior of a rigid element, subject to active (force  $\frac{d\mathbf{u}_k}{dt}$  applied to the  $k - th$  particle, computed with Equation (8) by DualSPHysics) and reactive (forces exerted by the mutual and absolute constraints, computed by the Project Chrono module) forces, and that several rigid elements and links can be combined to mimic one-dimensional flexible beams;
2. proved the first statement, the potentialities of the SPH method can be exploited: due to the use of rigid body dynamics, high order elasticity formulations are not required to compute extremely high deformations; the natural ability to reproduce free-surface flows, impacts, complex interfaces, can be used, then, to investigate fluid elastic-structure interactions (for example [20, 32, 33]).

The validation is based on a static comparison between the analytical and numerical displacement function of a cantilever: being the DualSPHysics framework dynamic, the results of

a static case can be generalized with ease to a wide field of dynamic conditions. The potentialities of this approach in the SPH framework are, then, shown in several works, which represent various possible physical contests, like interaction with free-surfaces flows or dynamics impacts with fluid mass (reproducing a dambreak flow impacting a flexible obstacle [31, 33]).

#### 4.1 Cantilever test case: static validation

Here the graphics of the statical deflection of the beam, compared against the EB solution, are exposed. The elastic line equation for a cantilever gives:

$$v_{an}(x) = \frac{q_s L_s^2 x^2}{4E_s I_s} - \frac{q_s L_s x^3}{6E_s I_s} + \frac{q_s x^4}{24E_s I_s} \quad (22)$$

where  $q_s = q_s(x)$  is the *vertical load* (only gravitational load, in this case).

The sensitivity analysis on the model is conducted with variable number of trunks ( $N$ ) and with different values of resolution. The displacement function in the DualSPHysics dynamic framework is obtained by adding a linear spring element at the free end of the cantilever, as schematized in Figure 4. The circles in Figure 4(b) represent the hinges, that mutually link the trunks, identified with the color bar and a number  $mk$ .

Figure 4: Simulation set-up (a) and relative SPH model (b).

The ulterior constraint works uniquely as a liner damper, being the stiffness value set to zero, thus affecting only the velocity of the oscillation and yielding to the steady state for the system. In the two-dimensional  $\{O, x, z\}$  space of our simulations, the force exerted by the additional constraint is:

$$F_{ls} = cu_{v,z} \quad (23)$$

where  $c$  is the damping, considering the cantilever axis parallel to  $x$  axis.

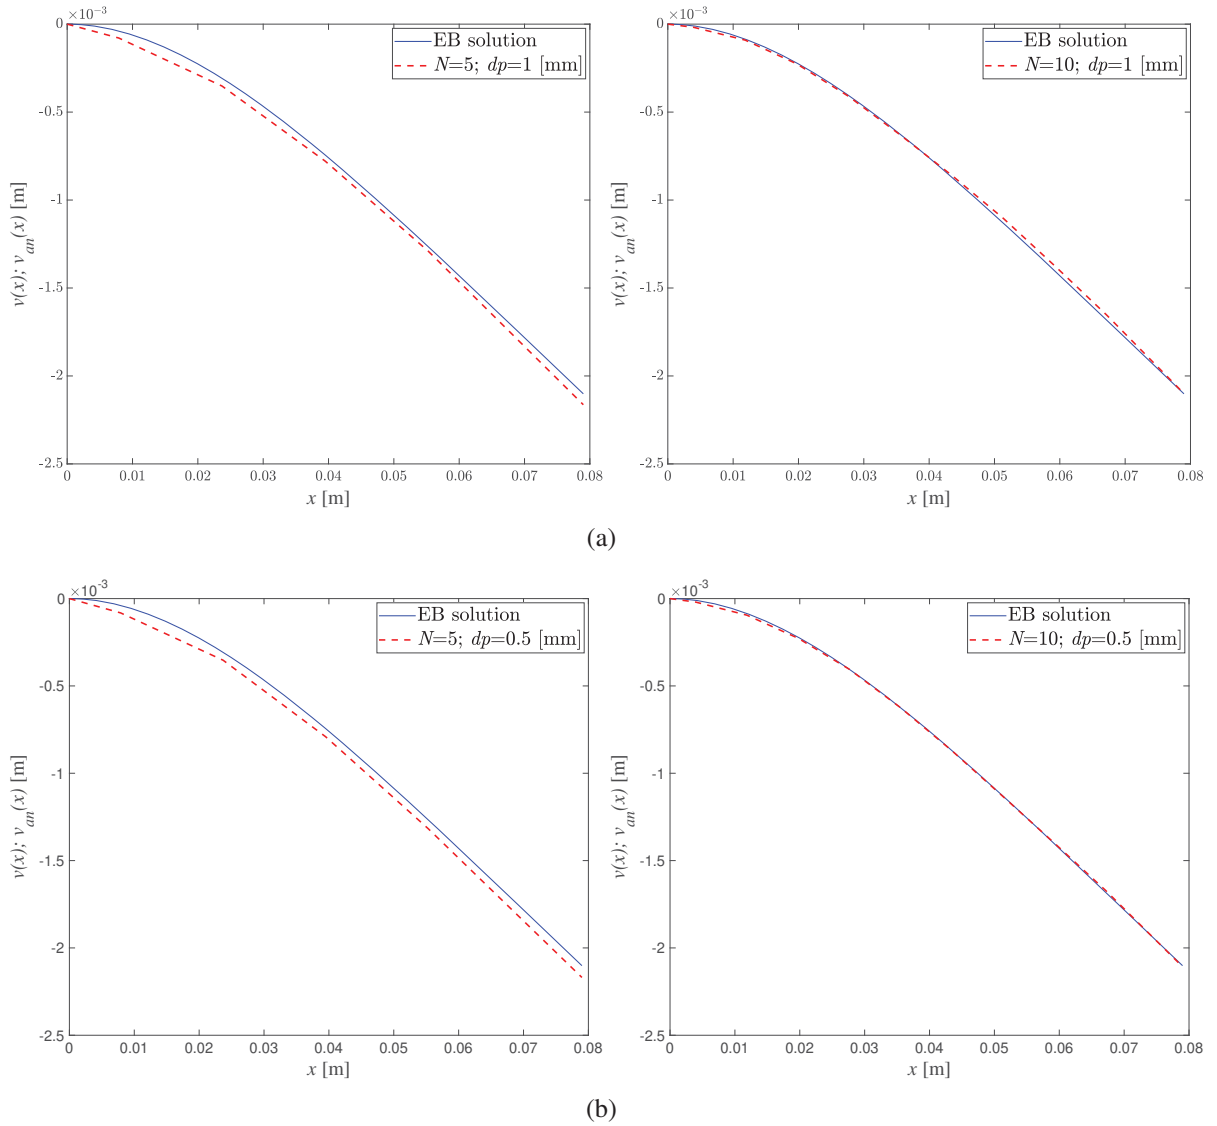

In the Table 4.1, the model information necessary for the DualSPHysics simulations is recalled, with clear significance of the nomenclature. The simulation shows the rising agreement, in the SPH framework, depending on the number of trunks. The agreement is good, and the model can be considered effective with the first value of resolution,

$$dp = \frac{0.005}{5} = 0.001 \text{ [m]} \quad (24)$$

the displacement function being properly fitted (Figure 5(a)), despite a small deviation around the centerline, regardless of the number of trunks. This is highlighted in the zoom (Figure 6(a)). By doubling the resolution, instead, the numerical solution is perfectly reproduced (Figure 5(b)).

Dimensions	
$L_s$ [m]	0.079
$b_s$ [m]	0.005
$h_s$ [m]	0.005
Physical characteristics	
$\rho_s$ [kg/m <sup>3</sup> ]	1100
$E_s$ [N/m <sup>2</sup> ]	1.2E+7
$g$ [m/s <sup>2</sup> ]	9.81
$c$ [Ns/m]	0.08

Table 1: Dimension and physical characteristics of the cantilever.

Figure 5: Comparison between the DualSPHysics results and the analytic solution: first value of resolution ( $dp = 1$  [mm]) (a), and second value of resolution ( $dp = 0.5$  [mm]) (b).

It is safe to say, after this test, that the software is able to simulate the static displacement function of an EB cantilever, and the model converges with the analytical solution as the number

of trunks increases, as visible in Figure 6. With a higher number of particles the precision is very high (Figure 6(b)), but more costly in terms of computation, since the resolution value is unique for all the simulated domain. The particle analysis on the beam model shows that beyond a certain value of particles per cross section, the agreement remains unchanged. These two values, the number of trunks and the number of particles, influence the computational effort: the former by increasing the number of interactions to be computed by the Project Chrono module, the latter by increasing the number of discrete entities where the field variables have to be calculated by DualSPHysics, with more neighbors within each support domain. With  $N = 10$ , as seen in Figure 5, the model is already effective in simulating one-dimensional beams; for what concerns the resolution value, an adequate value of  $pp(h_s)$  is enough to guarantee the numerical stability. It means that, in complex simulation involving fluid domains, the resolution needed for the beam constitutes the lower limit, which could be increased if required by other relevant conditions, just as the number of trunks, which can be raised if there are particular situations or a very high precision is required.

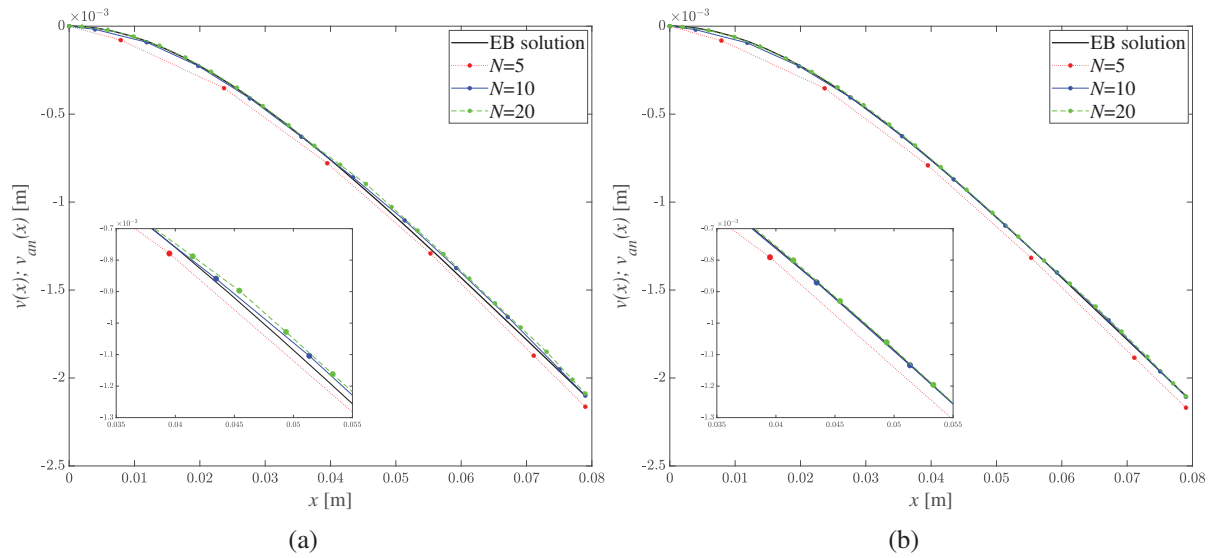

Figure 6: Convergence analysis of DualSPHysics results: first value of resolution ( $dp = 1$  [mm]) (a), and second value of resolution ( $dp = 0.5$  [mm]) (b).

## 5 CONCLUSIONS AND FUTURE WORK

The results show very good agreement between the analytic solutions and the presented model, highlighting its applicability to elastic cantilevers, or comparable static schemes, interacting with fluid or, in general, subject to dynamic impacts, time-variant load conditions, causing extreme deformations and high order effects. The numerous advantages of the SPH formulation, hence, allow thorough investigation of structure models, based on the proposed lumped elasticity discretization.

The solid framework of DualSPHysics and Project Chrono, moreover, offers the possibility to simulate complex multiphysics problems, making it suit to real-world engineering problems. Possible application fields are:

- flow-structure interactions of coastal vegetation;
- swinging of wind turbine columns subject to waves or seismic action;

- modelling of vibrations of one-dimensional structures interacting with Newtonian or non-Newtonian fluids; and
- structure collapse.

In conclusion, the simplicity, the effectiveness and the wide possibilities of implementation, in several fields, make this model a valuable starting point to investigate fluid elastic-structure interactions, or, more widely, elastic structure dynamics.

### Abstract

*Mullions are important structural windows elements that provide their resistance to wind forces. These elements are of fundamental importance for the energy balance of the building since their structural behavior deeply affects its energy losses. A proper structural design of the windows mullions is therefore important for evaluating a suitable stiffness indicator of the mullions to avoid energy losses. In the present paper, a parametric study aiming to investigate the wind-induced displacements of the window mullions and their compatibility with their thermal barrier has been conducted. The proposed study aims to evaluate a proper moment of inertia of the aluminum profiles forming the mullions as a function of the windows exposition for different wind forces depending on the elevation of the building in which the window has been installed.*

**Keywords:** wind induced effects, window mullions, stiffness indicators.

---

## 1 INTRODUCTION

The This paper discusses the turbulent wind effects on the window mullions for different wind window expositions and different wind velocities. A proper design of the window mullions is of paramount importance for the energy balance of the building since their structural behavior deeply affects the energy losses of the building [1].

At present, it is always a big challenge for architects and planning engineers to design new buildings with different shapes with respect to the fact that the wind load is an important input parameter in the design of the windows. Wind forces acting on windows are strongly dependent on the building shape, on the environment and by the orographic in which the building has been built, such forces are usually determined by using Computational Fluid Dynamics (CFD) techniques or wind tunnel experiments [2].

In the present paper, a parametric study aimed to investigate the wind-induced displacements of the mullions and their compatibility with the energy losses of the building has been conducted, the study aims to assess a proper stiffness indicator of the mullions as a function of the window elevation.

## 2 DIGITAL SIMULATION OF WIND FIELD VELOCITY

Wind load simulation has been studied acting on the mullions through spatial discretization of the wind field using an idealized grid. At each node of the grid partially correlated wind turbulence time histories of the along-wind field (primary) load component are synthetically generated by the standard wave superposition method [2, 3]. The turbulent wind load, generated by assuming the validity of the quasi-steady formulation for pressures and equivalent forces (based on tributary areas), has been imposed for a duration equal to 600s, with a time step  $\Delta t = 0.01$ s and evaluated for elevation of the idealized grid (Fig.1).

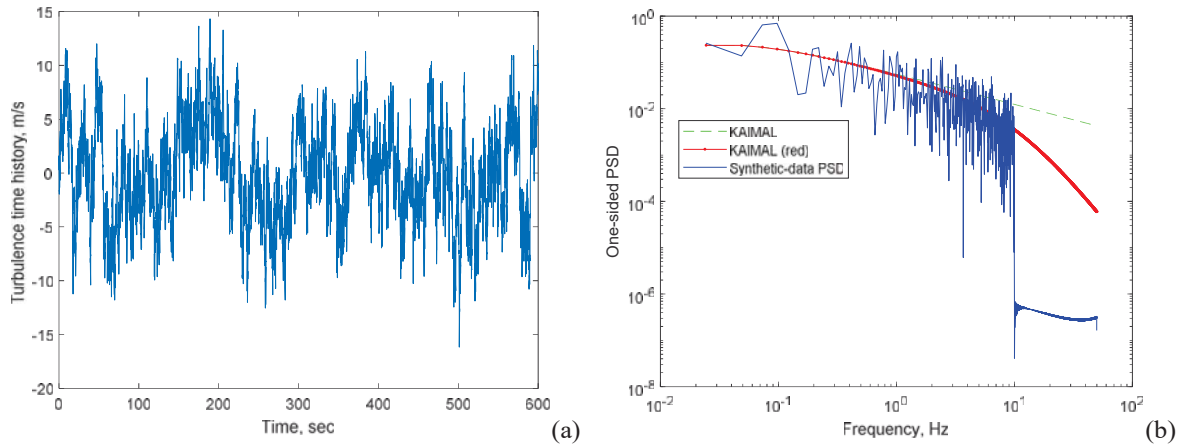

The pressure coefficients of the surface window  $C_p$  have been obtained and adapted from the results by Hubova et al. [4] in the present case has been prudentially taken  $C_p=1$ . Mean wind velocity  $\bar{U}(H)$  can be found through the following relation according to the reference wind speed  $U_{ref}$ , and the constants  $k_T$  and  $z_0$  provided by the Eurocode 1 [5]:

$$\bar{U}(H) = U_{ref} k_T \ln \frac{H}{z_0} \quad (1)$$

Accounting on the turbulent component of  $V_{turb}$  of the wind, the time varying wind speed at the altitude  $H$  can be expressed as:

$$V(t) = \bar{U}(H) + V_{turb}(t) \quad (2)$$

Figure 1 shows an example of the wind velocity simulated time history and its spectral compatibility.

**Figure 1.** Wind speed simulation for elevation  $H=30\text{m}$ ,  $U_{bar}=28\text{m/s}$  at  $H_{ref}=10\text{m}$ ; (a) Turbulent wind speed time history in one point of the idealized; (b) comparison between the employed synthetic data, Kaimal reduced and Kaimal power spectral density function.

According to the above formulated hypothesis, dynamic force  $F_i(t)$  acting on the mullion can be written as:

$$F_i(t) = \frac{1}{2} C_p A_p V^2(t) \quad (3)$$

Wind force simulation has been performed through a concentrated load force acting on the center of the span of the elements accounting of an aerodynamic admittance function of rectangular plates, with “projected area”  $A_p$  (Fig. 2) orthogonal to the flow direction [6]. The loads have been evaluated for different “elevation”  $H$  and for a constant width  $B$  (mullion distance) of the idealized grid.

### 3 BACKGROUND MATHEMATICAL MODELS AND BENCHMARK SYSTEM

The present approach is based on the dynamic equilibrium equations of a discretized uncoupled Single Degree of Freedom (SDOF) lumped masse system [1] comparable to the one described by Giaccu in [7], in this treatment, structural interaction between mullion and glass has been conservatively neglected, it must be noted that this interaction is not often fully defined because of the uncertainties due to the assembly of the glass window. Geometrical properties of the glass window are described in Table 1.

**Figure 2.** Benchmark model employed for the simulations of wind forces on facade.

Structural properties of the dynamic system have been calculated accounting of the geometrical features of the glass window illustrated in Fig.2 and in Table 1, which include the mass per unit area of the glass  $\rho_{glass}$ , the mullion span  $h$ , the modulus of elasticity of the aluminum  $E$  and its specific mass  $\rho_{al}$ , the a cross section area of the mullion  $A_{mul}$  and the mass of unit of length of the mullion  $\rho_{mul}$ .

$h$ (m)	$B$ (m)	$A_p$ (m <sup>2</sup> )	$E$ (MPa)	$A_{mul}$ (m <sup>2</sup> )	$\rho_{glass}$ (kg/ m <sup>2</sup> )	$\rho_{al}$ (kg/m <sup>3</sup> )	$\rho_{mul}$ (kg/m)	$M$ (kg)	$\zeta_s$ (%)	$E$ (MPa)
3.00	1.50	4.5	$6.9 \times 10^{10}$	$2.24 \times 10^{-3}$	20.00	2699	6.05	98.60	5.0	$6.9 \times 10^{10}$

Table 1: Geometrical and Mechanical properties of the glass window and of the lumped mass model.

Tributary area of the window can be therefore found as  $A_p = Bh/2$ , mechanical properties of the lumped mass model can be obtained, accounting of the halved mass of the mullion, as  $M = \rho_{wind} A_p + \rho_{al} h/2$  and the stiffness of the spring which can be obtained as  $k_s = 48EI/h^3$ .

The moment of inertia of the profile can be written, accounting of the the radius of gyration of the mullion  $r_G$ , as  $I = A_{mul} r_G^2$  and damping constant can be written as  $c = 2\zeta_s(kM)^{0.5}$ , considering a conventional structural damping  $\zeta_s = 5\%$ .

**Figure 3.** Schematic representation of the mathematical model employed for the simulations.

#### 4 PARAMETRIC STUDY

The parametric study has been conducted according to Eq. 1 for the mean wind speed  $U_{ref}=28\text{m/s}$  at reference altitude  $H_{ref}=10\text{m}$ , with  $k_T=0.17$  and for a roughness length  $z_0=0.03$  (m). The maximum displacement for different elevation  $H$  of the glass window has been detected.

For simplicity, the considered moments of inertia correspond to the same cross section  $A_{mul}$  for different slenderness  $\lambda$  of the mullion. Moment of inertia  $I$  of the mullion, can be therefore obtained as function of the slenderness  $\lambda$  through the following relation:

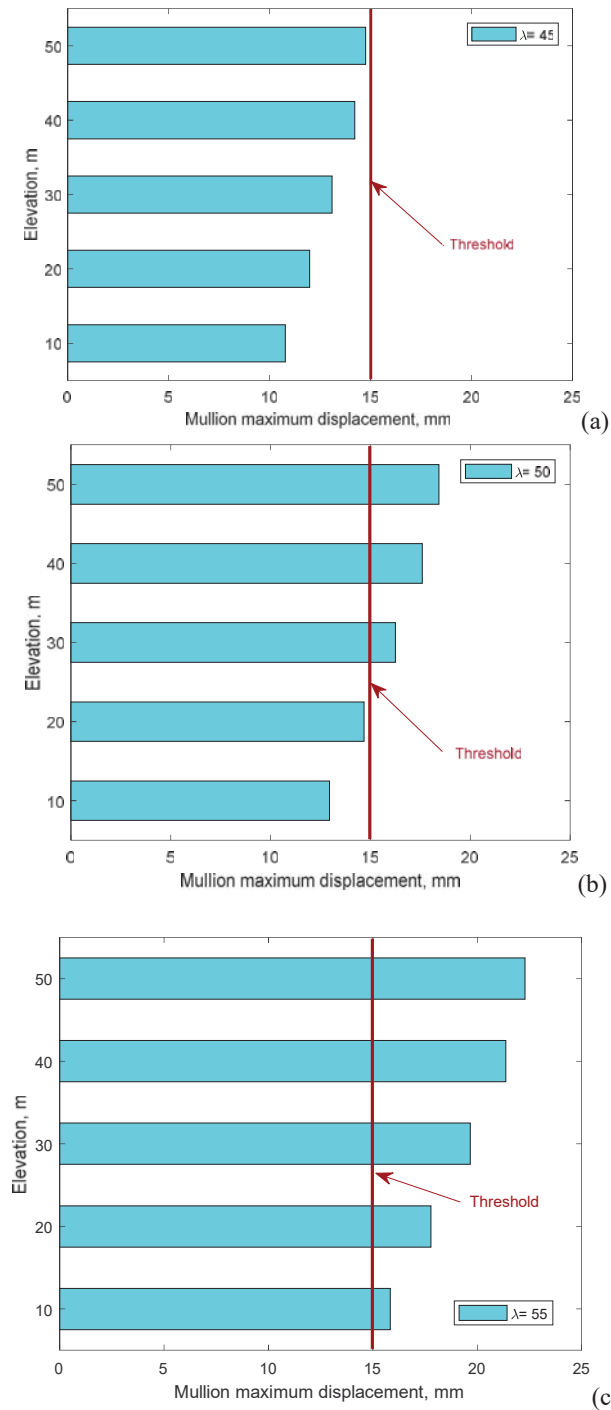

$$I = A_{mul} \left( \frac{h}{\lambda} \right)^2 \quad (4)$$

Deflections of the aluminum profiles have been compared with the conventional limit deflection indicator discussed in [1] ( $1/200$  of the span  $h$ ) which indicates the threshold beyond which the thermal barrier rigidity is necessary. The number of mullions considered in the idealized grid is  $n=6$ .

**Figure 4.** Displacement time history for  $H=40\text{m}$ ,  $U_{ref}=28\text{m/s}$  at  $H_{ref}=10\text{m}$  and  $\lambda=45$  in comparison with the displacement threshold  $h/200$ .

Results have been illustrated in Fig.5 as function of the elevation  $H$  of the window for different slenderness  $\lambda$ . Three different slenderness have been considered for the proposed simulation  $\lambda=45, 50$  and  $55$ .

**Figure 5.** Maximum displacement of the mullion in case of  $U_{bar}=28\text{m/s}$  at  $H_{ref}=10\text{m}$  for different elevation  $H$ , in comparison with the displacement threshold  $h/200$  for different slenderness  $\lambda$  of the mullion cross section: (a)  $\lambda=45$ , (b)  $\lambda=50$  and (c)  $\lambda=55$ .

From an examination of the results illustrated in Fig.5, it can be inferred that, slenderness of the mullion plays an important role in the wind induced deflections, in particular, for the considered case, a slenderness of the aluminum profile  $\lambda>55$  leads to crossing the

threshold limit ( $1/200$  of the span  $h$ ) for all the considered altitudes, whereas profile with slenderness  $\lambda=50$  can be utilized up to heights of 30 m, finally the slenderness  $\lambda=45$  can be utilized up to heights of 50 m without crossing the threshold.

## 5 CONCLUSIONS

The comparison of the data obtained during the performed simulations allowed to study different cases of buildings accounting of different expositions and different wind loading, a parametric study has been conducted for the considered cases assessing proper stiffness indicators of the mullions for different window properties and for different window expositions. A parametric study aimed to investigate the wind-induced displacements and of their compatibility with the windows' thermal barrier has been conducted. Results indicate that slenderness of the mullions plays an important role in limiting the wind-induced displacements in the mullion of the window since displacements are in turn directly related to the energy losses of the building. Suitable stiffness indicators of the mullions were indicated for all considered cases.

## Abstract

*In this work the problem of the dynamic response of a flexural elastic plate on a continuously non-homogeneous viscoelastic cross-anisotropic half-plane or half-space soil medium to a line or rectangular load moving with constant speed is determined analytically/numerically. Soil non-homogeneity is associated with elastic moduli increasing with depth. Plate viscous damping is considered, and the viscoelastic effects of the soil are introduced via hysteric damping. The solution of the problem is obtained with the aid of the complex Fourier series method involving the horizontal coordinates and the time. Employment of this method reduces the partial differential equations of motion for the soil and the plate to ordinary differential equations with variable coefficients and an algebraic equation, respectively. Those ordinary differential equations are solved by the method of Frobenius. Verification of the solutions is done by means of comparisons with known existing analytical solutions for the special cases of isotropy and homogeneity with or without the plate.*

**Keywords:** Moving loads, dynamic response, elastic plate, soil non-homogeneity, Soil cross-anisotropy.

---

## 1 INTRODUCTION

In this work, the dynamic response of a flexural elastic plate to a distributed load moving with constant speed is determined analytically. The plate is supported by a cross-anisotropic, non-homogeneous, viscoelastic half-plane or half-space soil medium. Soil viscoelasticity is considered in order to take into account dissipation of energy [1]. In the context of linear dynamic analysis, viscoelastic material behavior is usually modeled in the frequency domain by replacing the elastic moduli by their complex counterparts, which are functions of hysteretic damping [2]. Soil anisotropy is considered in order to take into account different moduli values along different directions. In soils, the simple but realistic model of transverse isotropy (or cross-anisotropy) is considered with elastic moduli being different in horizontal and vertical planes due to the soil layers deposition process [3-5]. Soil nonhomogeneity is characterized by different physical properties (density, elastic moduli) at different depths because of the soil overburden. It can be modeled in a discrete manner by layers or in a continuous manner by assuming density and/or elastic moduli to vary continuously with depth. In the latter case, it is usually assumed that density is constant and the elastic moduli vary non-linearly with depth [6-12].

Use is made of the complex Fourier series method involving the horizontal coordinate and the time to reduce the governing equations of motion of the plate-soil system to algebraic and ordinary differential equations, respectively. The latter equations because they have variable coefficients are solved by the method of Frobenius.

The following literature review is restricted to analytical works closely related to the present work. One can place those works in the following categories:

- 1) Works associated with a homogeneous or layered, isotropic elastic half-space under point or distributed, constant or time harmonic loads moving with constant speed, e.g., [13-22].
- 2) Works associated with elastic beams or plates on a homogeneous or layered, isotropic half-space under point or distributed, constant or time harmonic loads moving with constants speed, e.g., [23-26].
- 3) Works associated with or without plates on a homogeneous or layered, transversely isotropic (or cross-anisotropic) elastic half-spaces under point or distributed, constant or time harmonic loads moving with constant speed, e.g., [27-28].
- 4) Works associated with homogeneous, transversely isotropic (or cross-anisotropic) elastic half-spaces under dynamic but stationary loads, e.g. [29-31].
- 5) Works associated with an isotropic, continuously non-homogeneous elastic half-space or half-plane under dynamic stationary or moving with constant speed [32-34].
- 6) Works associated with a transversely isotropic (or cross-anisotropic), continuously non-homogeneous, viscoelastic half-space [35,36] under stationary dynamic.

From the above, one can easily conclude that the only works dealing with all three features of soil behavior (viscoelasticity, anisotropy and continuous nonhomogeneity) are [35, 36] and the present work. However, works [35, 36] are associated with stationary and not moving loads as it is the case with the present work. In addition, no plate effect is considered in [35, 36] as in the present work. Furthermore, use is made here of the complex Fourier series method, which is able, because the load speed is constant, to handle both the horizontal coordinate and the time using a single summation and provide a closed form solution in series form. Most of all the other methods used in the aforementioned works employ integral transform methods (mainly Fourier and Hankel transforms) and this requires numerical integration or complicated analytical inversion techniques instead of simple series evaluation in the present case. This complex Fourier series method has

been successfully used by Siddharthan et al [37] and Theodorakopoulos [38] in connection with moving loads on poroelastic half-planes and Beskou et al [39] and Muho and Beskou [40] in connection with moving loads on anisotropic homogeneous half-plane and isotropic nonhomogeneous half-plane, respectively.

The obtained analytical solution of the problem considered here is first verified against other existing analytical solutions pertaining to simpler special cases.

## 2 PROBLEM DESCRIPTION

Consider a homogeneous isotropic, elastic, thin flexural plate, supported by a cross-anisotropic (or transversely isotropic) nonhomogeneous viscoelastic half-plane or half-space soil medium under conditions of plane strain, as depicted in Fig. 1 in the framework of a Cartesian system  $x$  and  $z$  or  $x, y, z$ , respectively. On the surface of the plate, a uniformly distributed load of intensity  $F$  over a rectangle with sides  $2l_1$  along the  $x$  direction or  $2l_1$  and  $2l_2$  along the  $x$  and  $y$  directions, respectively, is assumed to move with constant velocity  $V$  along the  $x$ -direction, as shown in Fig. 1.

Figure 1: A rectangular distributed load moving with constant speed  $V$  on a plate resting on a transversely isotropic viscoelastic (a) half-plane or (b) half-space with variable with depth moduli.

The equations of motion of the half-plane soil medium read as [41]

$$\frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{xz}}{\partial z} = \rho \ddot{u} \quad (1)$$

$$\frac{\partial \sigma_{xz}}{\partial x} + \frac{\partial \sigma_{zz}}{\partial z} = \rho \ddot{w} \quad (2)$$

and for the half-space as [34]

$$\frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{xy}}{\partial y} + \frac{\partial \sigma_{xz}}{\partial z} = \rho \ddot{u} \quad (3)$$

$$\frac{\partial \sigma_{yy}}{\partial y} + \frac{\partial \sigma_{yx}}{\partial x} + \frac{\partial \sigma_{yz}}{\partial z} = \rho \ddot{v} \quad (4)$$

$$\frac{\partial \sigma_{zz}}{\partial z} + \frac{\partial \sigma_{zx}}{\partial x} + \frac{\partial \sigma_{zy}}{\partial y} = \rho \ddot{w} \quad (5)$$

where,  $\rho$  is the soil mass density,  $u = u(x, y, z, t)$ ,  $v = v(x, y, z, t)$  and  $w = w(x, y, z, t)$  are the soil displacements along the  $x$ ,  $y$  and  $z$  directions, respectively, and overdots denote differentiation with respect to time  $t$ .

The equation of lateral motion of the plate for the half-plane case has the form [42]

$$D \frac{\partial^4 w_p}{\partial x^4} + m_p \frac{\partial^2 w_p}{\partial t^2} + c_p \frac{\partial w_p}{\partial t} = f(x, t) - q(x, t) \quad (6)$$

where  $w_p = w_p(x, t)$  is the lateral plate deflection,  $m_p$  is the mass per unit length of the plate,  $c_p$  is the viscous damping coefficient of the plate,  $q(x, t)$  is the interaction of the soil on the plate and  $D$  is the flexural rigidity of the plate defined as

$$D = E_p h_p^3 / 12(1 - \nu_p^2) \quad (7)$$

with  $h_p$  being the thickness of the plate and  $E_p$  and  $\nu_p$  the modulus of elasticity and Poisson's ratio of the plate, respectively. For the half-space case Eq. (6) is replaced by

$$D \nabla^4 w_p + m_p \ddot{w}_p + c_p \dot{w}_p = f(x, y, t) - q(x, y, t) \quad (8)$$

where,  $\nabla^4 = \frac{\partial^4}{\partial x^4} + \frac{2 \partial^4}{\partial x^2 \partial y^2} + \frac{\partial^4}{\partial y^4}$  is the biharmonic differential operator.

The soil stresses are expressible in terms of displacements for the present anisotropic and nonhomogeneous half-plane case as [41]

$$\sigma_{xx} = c_{11}(z) \frac{\partial u}{\partial x} + c_{13}(z) \frac{\partial w}{\partial z} \quad (9)$$

$$\sigma_{zz} = c_{13}(z) \frac{\partial u}{\partial x} + c_{33}(z) \frac{\partial w}{\partial z} \quad (10)$$

$$\sigma_{xz} = c_{44}(z) \left( \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right) \quad (11)$$

and for the half-space as [34]

$$\sigma_{xx} = c_{11} \frac{\partial u}{\partial x} + c_{12} \frac{\partial v}{\partial y} + c_{13} \frac{\partial w}{\partial z} \quad (12)$$

$$\sigma_{yy} = c_{12} \frac{\partial u}{\partial x} + c_{11} \frac{\partial v}{\partial y} + c_{13} \frac{\partial w}{\partial z} \quad (13)$$

$$\sigma_{zz} = c_{13} \frac{\partial u}{\partial x} + c_{13} \frac{\partial v}{\partial y} + c_{33} \frac{\partial w}{\partial z} \quad (14)$$

$$\sigma_{yz} = c_{44} \left( \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} \right) \quad (15)$$

$$\sigma_{xz} = c_{44} \left( \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right) \quad (16)$$

$$\sigma_{xy} = c_{66} \left( \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right) \quad (17)$$

for the half-space soil medium [34].

In the above equations,  $c_{11}$ ,  $c_{12}$ ,  $c_{13}$ ,  $c_{33}$ ,  $c_{44}$  and  $c_{66}$  are elastic constants which are expressible in terms of the engineering constants as [34]

$$c_{11} = \frac{E(E' - E'v'^2)}{(1 + v)(E' - E'v - 2Ev'^2)} \quad (18)$$

$$c_{12} = \frac{E(E'v + Ev'^2)}{(1 + v)(E' - E'v - 2Ev'^2)} \quad (19)$$

$$c_{13} = \frac{EE'v'}{E' - E'v - 2Ev'^2} \quad (20)$$

$$c_{33} = \frac{E'^2(1 - v)}{E' - E'v - 2Ev'^2} \quad (21)$$

$$c_{44} = G' \quad (22)$$

$$c_{66} = G = \frac{c_{11} - c_{12}}{2} = \frac{E}{2(1 + v)} \quad (23)$$

where,  $E$ ,  $G$ , and  $v$  denote elastic modulus, shear modulus, and Poisson's ratio, respectively and the primes refer to the vertical axis of rotational material symmetry, which coincides with the  $z$ -axis of Fig.1. Those  $E$  and  $G$  without prime refer to the horizontal ( $x$ ,  $y$ ) plane of isotropy, while it has been assumed here that the value of the Poisson's ratio is the same along the vertical and horizontal direction.

Substitution of Eqs. (9)-(11) into Eqs. (1) and (2) for the half-plane model or Eqs. (12)-(17) into (3) and (4) for the half-space model, results in the governing equations of motion of the soil medium in terms of displacements of the form

$$c_{11} \frac{\partial^2 u}{\partial x^2} + c_{44} \frac{\partial^2 u}{\partial z^2} + c'_{44} \frac{\partial u}{\partial z} + (c_{13} + c_{44}) \frac{\partial^2 w}{\partial x \partial z} + c'_{44} \frac{\partial w}{\partial x} = \rho \ddot{u} \quad (24)$$

$$c_{33} \frac{\partial^2 w}{\partial z^2} + c_{44} \frac{\partial^2 w}{\partial x^2} + c'_{33} \frac{\partial w}{\partial z} + (c_{13} + c_{44}) \frac{\partial^2 u}{\partial x \partial z} + c'_{13} \frac{\partial u}{\partial x} = \rho \ddot{w} \quad (25)$$

for the half-plane and

$$c_{11} \frac{\partial^2 u}{\partial x^2} + c_{66} \frac{\partial^2 u}{\partial y^2} + c_{44} \frac{\partial^2 u}{\partial z^2} + c'_{44} \frac{\partial u}{\partial z} + (c_{12} + c_{66}) \frac{\partial^2 v}{\partial x \partial y} + (c_{13} + c_{44}) \frac{\partial^2 w}{\partial x \partial z} + c'_{44} \frac{\partial w}{\partial x} = \rho \ddot{u} \quad (26)$$

$$c_{66} \frac{\partial^2 v}{\partial x^2} + c_{11} \frac{\partial^2 v}{\partial y^2} + c_{44} \frac{\partial^2 v}{\partial z^2} + c'_{44} \frac{\partial v}{\partial z} + (c_{12} + c_{66}) \frac{\partial^2 u}{\partial x \partial y} + (c_{13} + c_{44}) \frac{\partial^2 w}{\partial y \partial z} + c'_{44} \frac{\partial w}{\partial y} = \rho \ddot{v} \quad (27)$$

$$c_{44} \frac{\partial^2 w}{\partial x^2} + c_{44} \frac{\partial^2 w}{\partial y^2} + c_{33} \frac{\partial^2 w}{\partial z^2} + c'_{33} \frac{\partial w}{\partial z} + (c_{13} + c_{44}) \frac{\partial^2 u}{\partial x \partial z} + (c_{13} + c_{44}) \frac{\partial^2 v}{\partial y \partial z} + c'_{13} \frac{\partial u}{\partial x} + c'_{13} \frac{\partial v}{\partial y} = \rho \ddot{w} \quad (28)$$

for the half-space, respectively, where primes on  $c_{ij} = c_{ij}(z)$  denote differentiation with respect to the depth  $z$ .

The boundary conditions of the half-plane case consist of dynamic equilibrium and compatibility at the plate-soil interface (where smooth contact is assumed) of the form

$$\sigma_{xz}(x, 0, t) = 0 \quad (29)$$

$$\sigma_{zz}(x, 0, t) = -q(x, t) \quad (30)$$

$$w(x, 0, t) = w_p(x, t) \quad (31)$$

The corresponding boundary conditions for the half-space case have the form

$$\sigma_{xz}(x, y, 0, t) = 0 \quad (32)$$

$$\sigma_{yz}(x, y, 0, t) = 0 \quad (33)$$

$$\sigma_{zz}(x, y, 0, t) = -q(x, y, t) \quad (34)$$

$$w(x, y, 0, t) = w_p(x, y, t) \quad (35)$$

Finally, at a depth  $z = H$  approaching infinity, all soil displacements become zero due to the radiation conditions at infinity and one has

$$u(x, H, t) = 0 \text{ for half-plane or } u(x, y, H, t) = 0 \text{ for half-space} \quad (36)$$

$$v(x, y, H, t) = 0 \text{ for half-space} \quad (37)$$

$$w(x, H, t) = 0 \text{ for half-plane or } w(x, y, H, t) = 0 \text{ for half-space} \quad (38)$$

Viscoelasticity in the soil medium is considered in the frequency domain, utilized during the solution procedure of the next section, by replacing the elastic constants  $c_{ij}$  by their complex counterparts  $c_{ij}^*$  according to the relation [2]

$$c_{ij}^* = c_{ij}(1 + 2i\xi) \quad (39)$$

resulting from the correspondence principle, where  $\xi$  is the hysteretic damping coefficient and  $i = \sqrt{-1}$ .

 Figure 2: Soil elastic constants  $c_{ij}$  increasing with depth  $z$ 

The nonhomogeneity of the soil is associated here only with a variability of the elastic constants with depth, i.e.,  $c_{ij} = c_{ij}(z)$ . It is assumed here that these constants increase with depth  $z$  in accordance with the relation

$$c_{ij}(z) = c_{0ij} + (c_{\infty ij} - c_{0ij})(1 - e^{-\alpha z}) \quad (40)$$

due to Vrettos [7, 8] as shown in Fig. 2, which is based on tests and provides bounded values of  $c_{ij}$  at infinity. In the above,  $c_{0ij}$ ,  $c_{\infty ij}$  and  $c_{ij}(z)$  are elastic constants at the soil surface, at an infinite depth and at depth  $z$  from the soil surface, respectively, and  $\alpha$  is a constant with dimensions of inverse length.

### 3 SOLUTION PROCEDURE

The problem to be solved consists of the governing partial differential equation of motion of the plate (Eq. (6) or Eq. (8)) and the governing partial differential equations of motion of the soil (Eqs. (24), (25) or (26)-(28)) subject to the boundary conditions (29)-(31) or (32)-(35). The solution procedure consists of two major steps: i) reduction of the partial differential equations of the plate-soil system to an algebraic and ordinary differential equations, respectively, by using the complex Fourier series approach [37-40] and ii) solution of the ordinary differential equations with variable coefficients for the soil by the method of Frobenius [43] and employment of the boundary conditions to obtain the final response of the plate-soil system to the moving load.

Thus, using the method of complex Fourier series, the load  $f(x,t)=f(x-Vt)$  is expanded in series of the form [39, 40]

$$f(x - Vt) = \text{Re} \sum_{n=0}^N F_n e^{i\lambda_n(x-Vt)} \quad (41)$$

where the load amplitude  $F_n$  is given by

$$F_n = \begin{cases} \frac{Fl}{L}, & \text{for } n = 0 \\ 2 \frac{F}{n\pi} \sin\left(\frac{n\pi l}{L}\right), & \text{for } n = 1, 2, \dots, N \rightarrow \infty \end{cases} \quad (42a)$$

for the half-plane model or

$$F_{nm} = \begin{cases} F \frac{l_1 l_2}{L_1 L_2} & \text{for } n = m = 0 \\ 2F \frac{l_2}{n\pi L_2} \sin \frac{n\pi l_1}{L_1} & \text{for } m = 0, n = 1, 2, \dots, N \\ 2F \frac{l_1}{m\pi L_1} \sin \frac{m\pi l_2}{L_2} & \text{for } n = 0, m = 1, 2, \dots, M \\ 4F \frac{1}{nm\pi^2} \sin \frac{n\pi l_1}{L_1} \sin \frac{m\pi l_2}{L_2} & \text{for } n = 1, 2, \dots, N, m = 1, 2, \dots, M \end{cases} \quad (42b)$$

for the half-space model, respectively.

In Eqs. (41) and (42) and with reference Fig.1,  $\lambda_n = n\pi/L$  are the wavenumber parameters,  $2l$  is the length of the distributed load,  $2L$  is the wavelength of the system,  $Re$  denotes the real part and  $i = \sqrt{-1}$ . Because the plate-soil system is linear, its response to the moving load  $f(x, t)$  will be of the form

$$w_p(w, t) = Re \sum_{n=0}^N W_{pn} e^{i\lambda_n(x-Vt)} \quad (43a)$$

$$u(x, z, t) = Re \sum_{n=0}^N U_n(z) e^{i\lambda_n(x-Vt)} \quad (44a)$$

$$w(x, z, t) = Re \sum_{n=0}^N W_n(z) e^{i\lambda_n(x-Vt)} \quad (45a)$$

$$q(x, z, t) = Re \sum_{n=0}^N Q_n e^{i\lambda_n(x-Vt)} \quad (46a)$$

for the half-plane model or

$$w_p(w, t) = Re \sum_{n=0}^N \sum_{m=0}^M W_{pnm} e^{i\lambda_n(x-Vt)} e^{i\mu_m y} \quad (43b)$$

$$u(x, z, t) = Re \sum_{n=0}^N \sum_{m=0}^M U_{nm} e^{i\lambda_n(x-Vt)} e^{i\mu_m y} \quad (44b)$$

$$v(x, z, t) = Re \sum_{n=0}^N \sum_{m=0}^M V_{nm} e^{i\lambda_n(x-Vt)} e^{i\mu_m y} \quad (44c)$$

$$w(x, z, t) = Re \sum_{n=0}^N \sum_{m=0}^M W_{nm} e^{i\lambda_n(x-Vt)} e^{i\mu_m y} \quad (45b)$$

$$q(x, z, t) = Re \sum_{n=0}^N \sum_{m=0}^M Q_{nm} e^{i\lambda_n(x-Vt)} e^{i\mu_m y} \quad (46b)$$

for the half-space model, respectively, where  $W_p$ ,  $U$ ,  $V$ ,  $W$  and  $Q$  denote response amplitudes to be determined and  $n, m=1, 2, \dots, N, M \rightarrow \infty$ .

In order to avoid numerical problems associated with  $n=0$  or  $m=0$  implying  $\lambda_n=0$  or  $\mu_m=0$ , respectively, solutions can be derived for each of the following four cases of the load amplitudes of Eq. (42), i.e., i)  $n=m=0$ , ii)  $m=0, n>0$ , iii)  $n=0, m>0$  and iv)  $n>0, m>0$ . Only the solution for  $n>0, m>0$  will be derived here. Solutions for the other three cases can be very easily determined following the same procedure.

Substituting Eqs. (43)-(46) in Eqs. (6), (24), (25) or (26)-(28), omitting the summation symbol and the common factors  $e^{i\lambda_n(x-Vt)}$  and introducing the proposed by Vrettos [7, 8] dimensionless parameters

$$\begin{aligned} \frac{\lambda_n^2}{a^2} &= \beta, \quad \frac{\lambda_n}{a} = -\gamma, \quad \frac{\lambda_n^2 \rho V^2}{a^2 c_{\infty 44}} = \theta \\ \frac{c_{\infty 11}}{c_{\infty 44}} &= \delta_1, \quad \frac{c_{\infty 13}}{c_{\infty 44}} = \delta_2, \quad \frac{c_{\infty 33}}{c_{\infty 44}} = \delta_3, \end{aligned} \quad (47)$$

for the half-plane or

$$\begin{aligned} \frac{\lambda_n^2}{\alpha^2} &= \beta_1, \quad \frac{\mu_m}{\alpha^2} = \beta_2, \quad \frac{\lambda_n}{\alpha} = -\gamma_1, \quad \frac{\mu_m}{\alpha} = \gamma_2 \\ \frac{\rho \lambda_n^2 V^2}{\alpha^2 c_{\infty 44}} &= \theta, \quad \frac{c_{\infty 11}}{c_{\infty 44}} = \delta_1, \quad \frac{c_{\infty 13}}{c_{\infty 44}} = \delta_2, \quad \frac{c_{\infty 33}}{c_{\infty 44}} = \delta_3, \quad \frac{c_{\infty 12}}{c_{\infty 44}} = \delta_4, \quad \frac{c_{\infty 66}}{c_{\infty 44}} = \delta_5 \end{aligned} \quad (48)$$

for the half space model, respectively, one finally receives the form

$$\zeta^2(1-\zeta)U_n'' + \zeta(1-2\zeta)U_n' + [\theta - \beta\delta_1(1-\zeta)]U_n + i\gamma\zeta(1-\zeta)(1+\delta_2)W_n' - i\gamma\zeta W_n = 0 \quad (49)$$

$$\delta_3\zeta^2(1-\zeta)W_n'' + \delta_3\zeta(1-2\zeta)W_n' + [\theta - \beta(1-\zeta)]W_n + i\gamma\zeta(1-\zeta)(1+\delta_2)U_n' - i\gamma\zeta\delta_2 U_n = 0 \quad (50)$$

for the half-plane or

$$\begin{aligned} (1-\zeta)\zeta^2 U_{nm}'' + \zeta(1-2\zeta)U_{nm}' + [\theta - (1-\zeta)(\beta_1\delta_1 + \beta_2\delta_5)]U_{nm} \\ - (\delta_4 + \delta_5)\gamma_1\gamma_2(1-\zeta)V_{nm} + (1+\delta_2)i\gamma_1\zeta(1-\zeta)W_{nm}' - i\gamma_1\zeta W_{nm} = 0 \end{aligned} \quad (51)$$

$$\begin{aligned} (1-\zeta)\zeta^2 V_{nm}'' + \zeta(1-2\zeta)V_{nm}' + [\theta - (1-\zeta)(\beta_1\delta_5 + \beta_2\delta_1)]V_{nm} \\ - (\delta_4 + \delta_5)\gamma_1\gamma_2(1-\zeta)U_{nm} + (1+\delta_2)i\gamma_2\zeta(1-\zeta)W_{nm}' - i\gamma_2\zeta W_{nm} = 0 \end{aligned} \quad (52)$$

$$\begin{aligned} \delta_3(1-\zeta)\zeta^2 W_{nm}'' + \delta_3\zeta(1-2\zeta)W_{nm}' + [\theta - (1-\zeta)(\beta_1 + \beta_2)]W_{nm} \\ + (1+\delta_5)i\gamma_1\zeta(1-\zeta)U_{nm}' - \delta_2 i\gamma_1\zeta U_{nm} + (1+\delta_2)i\gamma_2\zeta(1-\zeta)V_{nm}' \\ - \delta_2 i\gamma_2\zeta V_{nm} = 0 \end{aligned} \quad (53)$$

for the half-space model, respectively, where primes indicate differentiation with respect to  $\zeta$ .

The above system of two or three coupled ordinary differential equations with variable coefficients is solved by the method of Frobenius [43].

A power series solution is assumed of the form

$$U_n(\zeta) = \sum_{r=0}^R a_r \zeta^{r+m} \quad (54)$$

$$W_n(\zeta) = \sum_{r=0}^R b_r \zeta^{r+m} \quad (55)$$

for the half-plane or

$$U_{nm} = \sum_{r=0}^{\infty} a_r \zeta^{r+k} \quad (56)$$

$$V_{nm} = \sum_{r=0}^{\infty} b_r \zeta^{r+k} \quad (57)$$

$$W_{nm} = \sum_{r=0}^{\infty} c_r \zeta^{r+k} \quad (58)$$

for the half-space model, respectively, where  $\alpha_r$ ,  $b_r$  and  $m$  or  $a_r$ ,  $b_r$ ,  $c_r$  and  $k$  are constants to be determined and  $r=0,1,2,\dots,R \rightarrow \infty$ . Substitution of the expressions (54) and (55) for  $U_n$  and  $W_n$  or (56)-(58) for  $U_{nm}$ ,  $V_{nm}$  and  $W_{nm}$ , respectively, into Eqs. (49) and (50) or (51)-(53) after some manipulations results in the equations

$$\begin{aligned} & ([m^2 + (\theta - \beta\delta_1)]\alpha_0 + [i\gamma(1 + \delta_2)m]b_0)\zeta^m + \sum_{r=1}^R [(r+m)^2 + (\theta - \beta\delta_1)]\alpha_r \zeta^{r+m} \\ & + \sum_{r=1}^R [i\gamma(1 + \delta_2)(r+m)]b_r \zeta^{r+m} \\ & - \sum_{r=1}^R [(r+m)(r+m-1) - \beta\delta_1]\alpha_{r-1} \zeta^{r+m} \\ & - \sum_{r=1}^R [i\gamma(1 + \delta_2)(r+m-1) + i\gamma]b_{r-1} \zeta^{r+m} = 0 \end{aligned} \quad (59)$$

$$\begin{aligned}
 & ([\delta_3 m^2 + (\theta - \beta)]b_0 + [i\gamma(1 + \delta_2)m]a_0)\zeta^m + \sum_{r=1}^R [\delta_3(r + m)^2 + (\theta - \beta)]b_r \zeta^{r+m} \\
 & + \sum_{r=1}^R [i\gamma(1 + \delta_2)(r + m)]a_r \zeta^{r+m} \\
 & - \sum_{r=1}^R [\delta_3(r + m)(r + m - 1) - \beta]b_{r-1} \zeta^{r+m} \\
 & - \sum_{r=1}^R [i\gamma(1 + \delta_2)(r + m - 1) + i\gamma\delta_2]a_{r-1} \zeta^{r+m} = 0
 \end{aligned} \tag{60}$$

for the half-plane or

$$\begin{aligned}
 & ([k^2 + \theta - (\beta_1\delta_1 + \beta_2\delta_5)]a_0 - [(\delta_4 + \delta_5)\gamma_1\gamma_2]b_0 + [(1 + \delta_2)i\gamma_1k]c_0)\zeta^k \\
 & + \left( \sum_{r=1}^{\infty} [(r + k)^2 + \theta - (\beta_1\delta_1 + \beta_2\delta_5)]a_r - \sum_{r=1}^{\infty} [(\delta_4 + \delta_5)\gamma_1\gamma_2]b_r \right. \\
 & + \left. \sum_{r=1}^{\infty} [(1 + \delta_2)i\gamma_1(r + k)]c_r \right) \zeta^{r+k} \\
 & - \left( \sum_{r=1}^{\infty} [(r + k - 1)(r + k) - (\beta_1\delta_1 + \beta_2\delta_5)]a_{r-1} \right. \\
 & - \sum_{r=1}^{\infty} [(\delta_4 + \delta_5)\gamma_1\gamma_2]b_{r-1} \\
 & + \left. \sum_{r=1}^{\infty} [(1 + \delta_2)i\gamma_1(r + k - 1) + i\gamma_1]c_{r-1} \right) \zeta^{r+k} = 0
 \end{aligned} \tag{61}$$

$$\begin{aligned}
 & ([k^2 + \theta - (\beta_1\delta_5 + \beta_2\delta_1)]b_0 - [(\delta_4 + \delta_5)\gamma_1\gamma_2]a_0 + [(1 + \delta_2)i\gamma_2k]c_0)\zeta^k \\
 & + \left( \sum_{r=1}^{\infty} [(r + k)^2 + \theta - (\beta_1\delta_5 + \beta_2\delta_1)]b_r - \sum_{r=1}^{\infty} [(\delta_4 + \delta_5)\gamma_1\gamma_2]a_r \right. \\
 & + \left. \sum_{r=1}^{\infty} [(1 + \delta_2)i\gamma_2(r + k)]c_r \right) \zeta^{r+k} \\
 & - \left( \sum_{r=1}^{\infty} [(r + k - 1)(r + k) - (\beta_1\delta_5 + \beta_2\delta_1)]b_{r-1} \right. \\
 & - \sum_{r=1}^{\infty} [(\delta_4 + \delta_5)\gamma_1\gamma_2]a_{r-1} \\
 & + \left. \sum_{r=1}^{\infty} [(1 + \delta_2)i\gamma_2(r + k - 1) + i\gamma_2]c_{r-1} \right) \zeta^{r+k} = 0
 \end{aligned} \tag{62}$$

$$\begin{aligned}
 & ([\delta_3 k^2 + \theta - (\beta_1 + \beta_2)]c_0 - [(1 + \delta_2)i\gamma_1 k]a_0 + [(1 + \delta_2)i\gamma_2 k]b_0)\zeta^k \\
 & + \left( \sum_{r=1}^{\infty} [\delta_3(r+k)^2 + \theta - (\beta_1 + \beta_2)]c_r + \sum_{r=1}^{\infty} [(1 + \delta_2)i\gamma_1(r+k)]a_r \right. \\
 & \left. + \sum_{r=1}^{\infty} [(1 + \delta_2)i\gamma_2(r+k)]b_r \right) \zeta^{r+k} \\
 & - \left( \sum_{r=1}^{\infty} [\delta_3(r+k-1)(r+k) - (\beta_1 + \beta_2)]c_{r-1} \right. \\
 & - \sum_{r=1}^{\infty} i\gamma_1[(r+k)(1 + \delta_2) - 1]a_{r-1} \\
 & \left. + \sum_{r=1}^{\infty} i\gamma_2[(r+k)(1 + \delta_2) - 1]b_{r-1} \right) \zeta^{r+k} = 0
 \end{aligned} \tag{63}$$

for the half-space model, respectively.

For the case of the half-plane model, equations (59) and (60) are satisfied for all powers of  $\zeta$  and hence one obtains a system to determine  $\alpha_0$  and  $b_0$  of the form

$$[m^2 + (\theta - \beta\delta_1)]\alpha_0 + [i\gamma(1 + \delta_2)m]b_0 = 0 \tag{64}$$

$$[i\gamma(1 + \delta_2)m]\alpha_0 + [\delta_3 m^2 + (\theta - \beta)]b_0 = 0 \tag{65}$$

and a system of recursive relations to determine  $\alpha_r$  and  $b_r$  in terms of  $\alpha_{r-1}$  and  $b_{r-1}$  ( $r > 0$ ) of the form

$$[(r+m)^2 + (\theta - \beta\delta_1)]\alpha_r + [i\gamma(1 + \delta_2)(r+m)]b_r = F_1 \tag{66}$$

$$[i\gamma(1 + \delta_2)(r+m)]\alpha_r + [\delta_3(r+m)^2 + (\theta - \beta)]b_r = F_2 \tag{67}$$

where

$$F_1 = [(r+m)(r+m-1) - \beta\delta_1]\alpha_{r-1} + [i\gamma(1 + \delta_2)(r+m-1) + 1]b_{r-1} \tag{68}$$

$$F_2 = i\gamma[(1 + \delta_2)(r+m-1) + \delta_2]\alpha_{r-1} + [\delta_3(r+m)(r+m-1) - \beta]b_{r-1} \tag{69}$$

For the case of half-space model, equations (61)-(63) are satisfied for all powers of  $\zeta$  and hence one obtains a system to determine  $\alpha_0$  and  $b_0$  of the form

$$[k^2 + \theta - (\beta_1\delta_1 + \beta_2\delta_5)]a_0 - [(\delta_4 + \delta_5)\gamma_1\gamma_2]b_0 + [(1 + \delta_2)i\gamma_1 k]c_0 = 0 \tag{70}$$

$$-[(\delta_4 + \delta_5)\gamma_1\gamma_2]a_0 + [k^2 + \theta - (\beta_1\delta_5 + \beta_2\delta_1)]b_0 + [(1 + \delta_2)i\gamma_2 k]c_0 = 0 \tag{71}$$

$$[(1 + \delta_2)i\gamma_1 k]a_0 + [(1 + \delta_2)i\gamma_2 k]b_0 + [\delta_3 k^2 + \theta - (\beta_1 + \beta_2)]c_0 = 0 \tag{72}$$

and system of recursive relations to determine  $a_r$ ,  $b_r$  and  $c_r$  in terms of  $a_{r-1}$ ,  $b_{r-1}$  and  $c_{r-1}$  of the form

$$\begin{aligned}
 & [(r+k)^2 + \theta - (\beta_1\delta_1 + \beta_2\delta_5)]a_r - [(\delta_4 + \delta_5)\gamma_1\gamma_2]b_r + [(1 + \delta_2)i\gamma_1(r+k)]c_r \\
 & = F_1
 \end{aligned} \tag{73}$$

$$-[(\delta_4 + \delta_5)\gamma_1\gamma_2]a_r + [(r+k)^2 + \theta - (\beta_1\delta_5 + \beta_2\delta_1)]b_r + [(1 + \delta_2)i\gamma_2(r+k)]c_r = F_2 \quad (74)$$

$$[(1 + \delta_2)i\gamma_1k]a_r + [(1 + \delta_2)i\gamma_2(r+k)]b_r + [\delta_3(r+k)^2 + \theta - (\beta_1 + \beta_2)]c_r = F_3 \quad (75)$$

where

$$F_1 = [(r+k-1)(r+k) - (\beta_1\delta_1 + \beta_2\delta_5)]a_{r-1} - [(\delta_4 + \delta_5)\gamma_1\gamma_2]b_{r-1} + i\gamma_1[(1 + \delta_2)(r+k-1) + 1]c_{r-1} \quad (76)$$

$$F_2 = -[(\delta_4 + \delta_5)\gamma_1\gamma_2]a_{r-1} + [(r+k-1)(r+k) - (\beta_1\delta_5 + \beta_2\delta_1)]b_{r-1} + i\gamma_2[(1 + \delta_2)(r+k-1) - 1]c_{r-1} \quad (77)$$

$$F_3 = i\gamma_1[(r+k)(1 + \delta_2) - 1]a_{r-1} + i\gamma_2[(r+k)(1 + \delta_2) - 1]b_{r-1} + [\delta_3(r+k-1)(r+k) - (\beta_1 + \beta_2)]c_{r-1} \quad (78)$$

In order for the system of Eqs. (64) and (65) or (70)-(72) to have nonzero solutions, one should have

$$Am^4 + Bm^2 + C = 0 \quad (79)$$

for the half-plane or

$$A k^6 + B k^4 + C k^2 + J = 0 \quad (80)$$

for the half-space model, respectively, where A, B, C, and J are functions of the dimensionless parameters of Eq. (47) or (48). One can observe that out of the four or six roots of Eq. (79) or (80), respectively, only the two or the three positive ones are acceptable.

Thus, in view of Eqs. (54), (55) or (56)-(58), the complete solution of Eqs. (49) and (50) or Eqs. (51) – (53) has the form

$$U_n(\zeta) = A_1 U_n^{(1)}(\zeta) + A_2 U_n^{(2)}(\zeta) \quad (81)$$

$$W_n(\zeta) = A_1 W_n^{(1)}(\zeta) + A_2 W_n^{(2)}(\zeta) \quad (82)$$

for the half-plane or

$$U_{nm}(\zeta) = A_1 U_{nm}^{(1)}(\zeta) + A_2 U_{nm}^{(2)}(\zeta) + A_3 U_{nm}^{(3)}(\zeta) \quad (83)$$

$$V_{nm}(\zeta) = A_1 V_{nm}^{(1)}(\zeta) + A_2 V_{nm}^{(2)}(\zeta) + A_3 V_{nm}^{(3)}(\zeta) \quad (84)$$

$$W_{nm}(\zeta) = A_1 W_{nm}^{(1)}(\zeta) + A_2 W_{nm}^{(2)}(\zeta) + A_3 W_{nm}^{(3)}(\zeta) \quad (85)$$

for the half-space model, respectively, where  $A_1$ ,  $A_2$  and  $A_3$  are constants of integration to be determined by the boundary conditions (29)-(31) and (32)-(35) where

$$U_n^{(i)}(\zeta) = \sum_{r=0}^R a_r \zeta^{r+m_i} \quad (86)$$

$$W_n^{(i)}(\zeta) = \sum_{r=0}^R b_r \zeta^{r+m_i} \quad (87)$$

$$U_{nm}^{(i)}(\zeta) = \sum_{r=0}^{\infty} a_r \zeta^{r+k_i} \quad (88)$$

$$V_{nm}^{(i)}(\zeta) = \sum_{r=0}^{\infty} b_r \zeta^{r+k_i} \quad (89)$$

$$W_{nm}^{(i)}(\zeta) = \sum_{r=0}^{\infty} c_r \zeta^{r+k_i} \quad (90)$$

with  $i=1,2$ , (or  $i=1,2,3$ ) for the two (or three) roots of  $m$  (or  $k$ ) given by Eq. (79) or Eq. (80), the  $a_r$  and  $b_r$  and  $c_r$  given recursively from the solution of Eqs. (66) and (67) or respectively (73) – (75) and  $\alpha_0$  and  $b_0$  and  $c_0$  obtained by assuming  $\alpha_0=1$  and solving Eq. (64) for  $b_0$  or respectively the system of Eqs. (70) and (71) for  $b_0$  and  $c_0$ .

Thus, the soil response solution is given by Eqs. (44) and (45) and the plate response solution is by Eq. (43) for both the half-plane and half-space cases. Once the plate deflection  $w_p$  is known, one can obtain the plate bending moment  $M_{xx}$  and shear force  $Q_x$  from [42]

$$M_{xx} = -D \frac{\partial^2 w_p}{\partial x^2} \quad (91)$$

$$Q_x = -D \frac{\partial^3 w_p}{\partial x^3} \quad (92)$$

for the half-plane or

$$M_{xx} = -D \left( \frac{\partial^2 w_p}{\partial x^2} + \nu_p \frac{\partial^2 w_p}{\partial y^2} \right) \quad (93)$$

$$M_{yy} = -D \left( \frac{\partial^2 w_p}{\partial y^2} + \nu_p \frac{\partial^2 w_p}{\partial x^2} \right) \quad (94)$$

$$Q_x = -D \frac{\partial}{\partial x} \left( \frac{\partial^2 w_p}{\partial x^2} + \frac{\partial^2 w_p}{\partial y^2} \right) \quad (95)$$

$$Q_y = -D \frac{\partial}{\partial y} \left( \frac{\partial^2 w_p}{\partial x^2} + \frac{\partial^2 w_p}{\partial y^2} \right) \quad (96)$$

for the half-space model, respectively.

#### 4 VERIFICATION AND CONVERGENCE STUDIES

In this final section, the accuracy of the proposed method is validated through comparison with two special cases for which there exist solutions in the literature involving homogeneous soil with and without a plate on its surface. The homogeneous soil is approximated by the proposed method by assigning a very small value to  $\Xi$ , e.g.,  $\Xi = 10^{-4}$ .

For the first verification it is assumed a load  $P=80$  kN distributed on a line-length  $l=0.15$  m, which implies a value of  $F=266.66$  kN/m, moving with constant speed  $V=40$  m/s on the surface of

a half-plane isotropic soil medium. For this soil medium one has mass density  $\rho = 1816 \text{ kg/m}^3$ , Poisson's ratio  $\nu = 0.35$  and shear modulus varying with depth according to Eq. (40) with  $G_0 = 0.077 \text{ GPa}$  (or  $E_0 = 2G_0(1 + \nu)$ ) with parameters  $\Xi = 0.5$  and  $\alpha = 1 \text{ m}^{-1}$ . The absence of the plate was simulated by giving very small values to the plate parameters. Other parameters used here are  $L = 80 \text{ m}$  and  $x = L/3$ . Using the present solution, the soil surface vertical displacement  $w$  versus time  $t$  was calculated and the results are given in Fig. 3a together with those from [34]. One can clearly see in that figure that the two solutions coincide.

For the second verification, the problem of a load moving on the surface of a homogeneous cross-anisotropic half-space medium is solved by the proposed method and compared with the solution of Ba et al [27]. Thus, assuming the same values with Ba et al [27], i.e.,  $E = 5 \text{ GPa}$ ,  $E' = 2E$ ,  $\nu = \nu' = 0.25$ ,  $G = E/2(1 + \nu)$ ,  $G' = 0.3 E'$  and  $\rho = 2000 \text{ kg/m}^3$ , one can obtain the normalized vertical displacement  $\bar{w} = G_1 z / P$  at a depth  $z = 10 \text{ m}$  as a function of the normalized load speed  $\bar{V} = V / \sqrt{G' / \rho}$  as shown in Fig. 3b. The concentrated load  $P$  was modeled by the proposed method assuming a very small rectangular area of  $l_1 = l_2 = 0.015 \text{ m}$ , while the absence of the plate is approximated by the proposed method by assigning a very small value to  $h_p$ , e.g.,  $h_p = 10^{-4} \text{ m}$ . Finally, the solution is obtained assuming  $L_1 = L_2 = 75 \text{ m}$ ,  $N = M = 512$ , and  $r = 5$ . One can observe in Fig. 3b (a) that the response obtained by the proposed method coincides with the solution of Ba et al [24].

Next, a convergence study with respect to the required values of  $N$  and  $R$  in Eqs. (43a) and (55), respectively, or  $N$ ,  $M$ , and  $r$  in Eqs. (43b) and (58), respectively, is presented, where the maximum vertical displacement of the plate at the center of the load versus  $N$ ,  $M$ , and  $r$  is shown, respectively. One can observe from Figs. 4 and 5 that values of  $N$ ,  $M > 400$  are sufficient to obtain solutions with high accuracy. As far as the required maximum value of  $r$  is concerned, it should be noted here that this value depends on the non-homogeneity index  $\Xi$ . Thus, for higher values of  $\Xi$ , higher values of  $r$  are required. It has been observed that for very small values of  $\Xi$ , e.g., homogeneous soil, a value of  $r \geq 5$  is sufficient. In order to determine the highest possible required value of  $r$  in this convergence study, a very high value of non-homogeneity index is assumed, i.e.,  $\Xi = 0.99$  and as it is shown in Figs. 4b and 5c, values of  $r \geq 250$  are sufficient to obtain results of high accuracy.

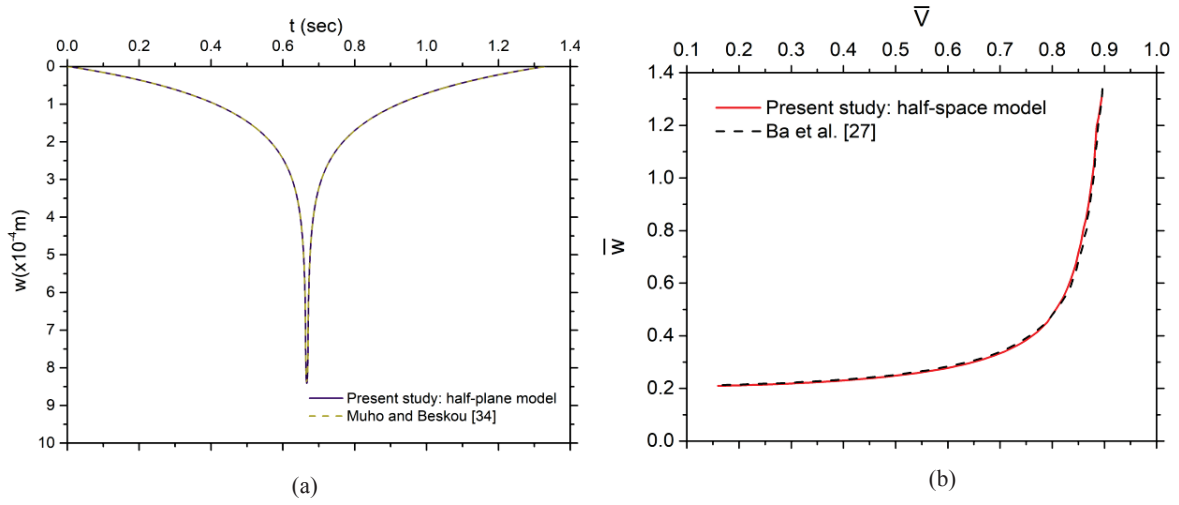

Figure 3: Use of the present solution for the special cases of (a) a nonhomogeneous isotropic half-plane without plate of [34] and (b) the homogeneous and cross-anisotropic soil of Ba et al [27].

Figure 4: Convergence analysis: Maximum plate vertical displacement  $w_p$  versus (a) the number  $N$  in Eq. (43a) and (b) the number  $R$  in Eq. (55).

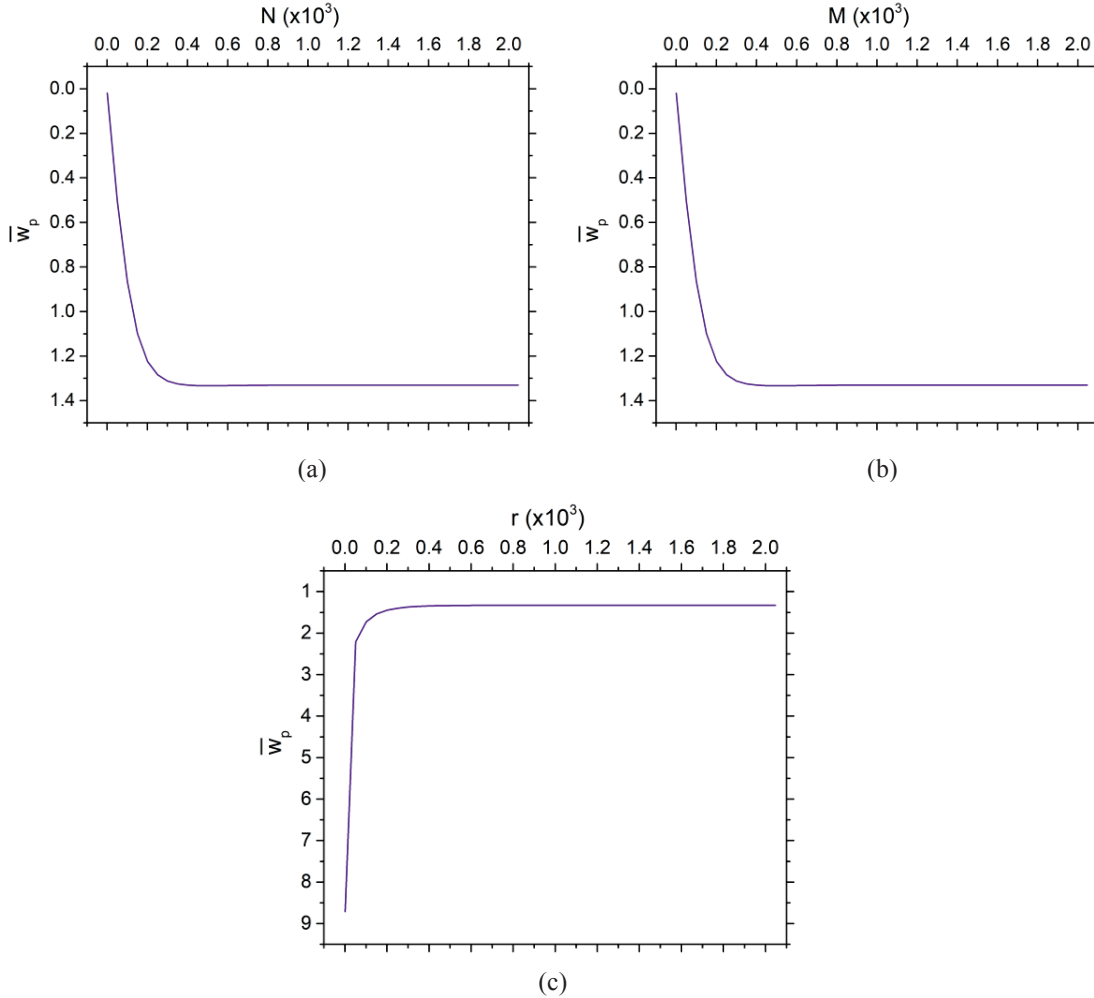

Figure 5: Convergence analysis: Maximum plate vertical displacement  $w_p$  versus (a) the number  $N$ , (b) the number  $M$  in Eq. (43b) and (c) the number  $r$  in Eq. (58).

Finally, a comparison of the results produced by the half-plane and half-space models is presented. Both models share the same material properties for the soil ( $E=0.2$  GPa,  $E'=E$ ,  $\nu=\nu'=0.35$ ,  $G'=0.30 E'$ ,  $\rho=2100$  kg/m<sup>3</sup> and  $\Xi=0.01$ ) and the plate ( $E_p=30$  GPa,  $\rho_p=2300$  kg/m<sup>3</sup>,  $\nu_p=0.2$  and  $h_p=0.2$  m) and are associated with the same data for the moving load ( $P=80$  kN,  $l_1=l_2=0.15$  m and  $V=80$  m/s). One can observe in Fig. 6 (a) that the half-space model with the plate results in much smaller maximum vertical displacement at the surface ( $z=0$  m) compared to that of the half-plane model with the plate. The same above problem is solved again assuming very small values for the plate parameters in order to model the absence of the plate and the response is shown in Fig. 6 (b). One can observe that in this case, both models provide similar maximum vertical displacement with the half-plane model resulting in a slightly higher displacement. Furthermore, it is interesting to observe that in both cases the half-plane model results in a much wider displacement-time response shape than the half-space one and clearly provides higher displacement values than those from the half-space model away from the area of the load application.

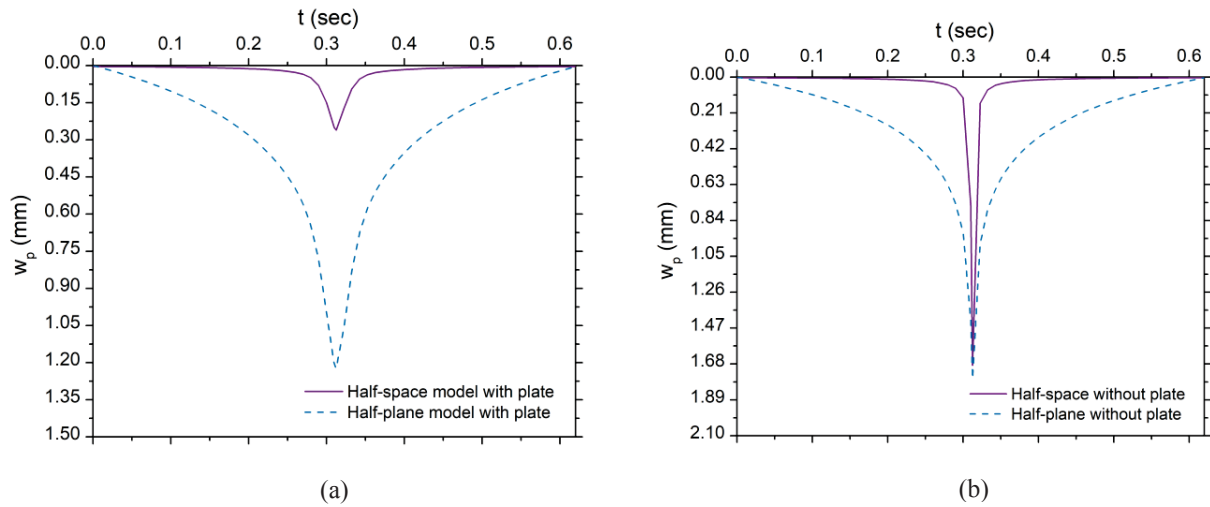

Figure 6: Comparison of the present half-space with the half-plane (a) considering the plate and (b) without the plate.

## 5 CONCLUSIONS

1. The problem of a distributed load moving with constant speed on the surface of an elastic plate resting on a non-homogeneous and cross-anisotropic viscoelastic half-plane or half-space has been analytically treated by using the complex Fourier series method.
2. The proposed solutions were verified for the two special cases of a load acting on a homogeneous cross-anisotropic elastic half-plane or half-plane.
3. A comparison of the proposed half-space and half-plane models has shown that both models result in a similar maximum vertical displacement only for the case of the half-plane model without the plate and under the load where the half-plane displacement has a slightly higher value. However, the half-plane model without the plate clearly shows higher displacements than those of the half-space far from the area of the load application. On the other hand, in case there is a plate, the half-space model results in a much lower vertical response compared to that of the half-plane one.

### Abstract

*Controlling wind-induced vibrations as well as aerodynamic forces is an essential part of the structural design of tall buildings in order to guarantee the serviceability limit state of the structure. This paper presents a numerical investigation focused on finding the optimal design parameters of a Tuned Inerter Damper (TID) based system for the control of wind-induced vibration in tall buildings. The control system is based on the conventional TID, with the main difference that its location is changed from the ground level to the last two story-levels of the structural system. The TID tuning procedure is based on an evolutionary cultural algorithm in which the optimum design variables defined as the frequency and damping ratios are searched according to the optimization criteria of minimizing the root mean square (RMS) response of displacements at the  $n$ th story of the structure. A Monte Carlo simulation is used to represent the dynamic action of the wind in the time domain in which a time-series derived from the Davenport spectrum using eleven harmonic functions with randomly chosen phase angles was reproduced. The above-mentioned methodology is then applied on a case-study derived from a 37-story prestressed concrete building with 144 m height, in which the wind action overcomes the seismic action. The results showed that the optimally TID is effective to reduce the RMS response of displacements up to 37.12% which demonstrates the feasibility of the system for the control of wind-induced vibrations in tall buildings.*

## 1 INTRODUCTION

In recent years, the construction of high-rise buildings has increased, using lightweight and high-strength materials. Those structures are typically more flexible and exhibit lower damping values, making them more vulnerable to vibration problems induced by wind loads [12]. Consequently, interest in the field of vibration control has increased, leading to the extensive application of passive control for wind loads. According to Kwok and Samali [1], for several decades, classic devices such as Tuned Mass Damper (TMD) have been implemented, which are composed of a mass attached to the building with a system of springs and dashpots that dissipates energy as a relative movement develops between the mass and structure. In that sense, Lazar [5] proposed a novel passive control system which is called Tuned Inerter Damper (TID), similar to the TMD but with the attached mass being replaced by the inerter device. This inerter is a negligible mass device proposed by Smith [2] that induces an equivalent mass amplification effect called inertance with a 1/200 ratio between the actual mass and the inertances, as demonstrated in laboratory investigations carried out by Papageorgiou & Smith [3].

It has been shown that the use of inerter devices in control systems provides considerable improvements in controlling mechanical vibrations [7]. Different authors [14, 17, 18] have adapted the inerter device in classic TMDs, obtaining significant enhancements in the dynamic response of buildings under wind-induced vibrations. Subsequently, various authors have achieved large reductions in the vibrations of a building by applying TID as well as TMDI systems, overcoming the limitations of the large amounts of mass that have to be implemented in conventional TMDs [15, 26, 27].

This paper presents a numerical investigation focused on finding the optimal design parameters of a Tuned Inerter Damper (TID) based system for the control of wind-induced vibration in tall buildings. The control system is based on the conventional TID, with the main difference that its location is changed from the ground level to the last two story-levels of the structural system according to the recommendations provided in [15]. The TID tuning procedure is based on an evolutionary cultural algorithm in which the optimum design variables defined as the frequency and damping ratios were searched according to the optimization criteria of minimizing the root mean square (RMS) response of displacements at the  $n$ th story of the structure. A Monte Carlo simulation is used to represent the dynamic action of the wind in the time domain in which a time series derived from the Davenport spectrum is reproduced using eleven harmonic functions with randomly chosen phase angles. Effective results are expected with the implementation of optimized TID to reduce the RMS response of displacements.

## 2 MATHEMATICAL MODELS OF A MDOF STRUCTURE EQUIPPED WITH TID-BASED SYSTEM

The inerter is a two-terminal-one-port mechanical device proposed by Smith [2] with the property that the equal and opposite force applied at the terminals is proportional to the relative acceleration between the terminals.

Figure 1: The symbol of inerter.

The mathematical notation corresponding to Figure 1 is:

$$F = b(\ddot{u}_2 - \ddot{u}_1) \quad (1)$$

Where  $\ddot{u}_1$  and  $\ddot{u}_2$  represents the relative acceleration between its nodes and the constant  $b$  is called the *inertance*.

The main focus of this work is to apply the variant of the TID proposed by Caicedo in [15]. Figure 2 presents a 2D shear frame with  $n$  horizontal DOF at each level of the building and wind loads applied at each level. It is observed that the TID is positioned in the last two levels with  $m_i$ ,  $k_i$  and  $c_i$  as the mass, lateral stiffness and damping coefficients of each story level ( $i = 1, 2, \dots, n$ ). Additionally,  $k_d$  and  $c_d$  are the stiffness and damping that define the behavior of the TID. These two last variables can be rewritten as:

$$k_d = \omega_s^2 f^2 b \quad (2)$$

$$c_d = 2f\xi_d\omega_sb \quad (3)$$

In equations (2) and (3),  $\omega_s$ ,  $f$  and  $\xi_d$  are the fundamental circular frequency of the structural system, the frequency and damping ratios between the structure and the TID.

The design procedure to be carried out in this work consists of finding the optimal frequency ratio and damping ratio to minimize the dynamic response of the structure.

Figure 2: 2D frame equipped with a TID in the last two levels.

The following dynamic equilibrium equations describe the behavior of the  $n$  degrees of freedom of each level of the structural system, and the additional degree of freedom ( $n + 1$ ) given the possibility of horizontal movement of the TID.

$$m_1 \ddot{u}_1 + (c_1 + c_2) \dot{u}_1 - c_2 \dot{u}_2 + (k_1 + k_2) u_1 - k_2 u_2 = F_1(t) \quad (4)$$

$$m_2 \ddot{u}_2 - c_2 \dot{u}_1 + (c_2 + c_3) \dot{u}_2 - c_3 \dot{u}_3 - k_2 u_1 + (k_2 + k_3) u_2 - k_3 u_3 = F_2(t) \quad (5)$$

$$m_{n-1} \ddot{u}_{n-1} - c_{n-1} \dot{u}_{n-2} + (c_{n-1} + c_n + c_d) \dot{u}_{n-1} - c_n \dot{u}_n - c_d \dot{u}_{n+1} - k_{n-1} \dot{u}_{n-2} + (k_{n-1} + k_n + k_d) u_{n-1} - k_n u_n - k_d u_{n+1} = F_{n-1}(t) \quad (6)$$

$$m_n \ddot{u}_n - c_n \dot{u}_{n-1} + (c_n + c_d) \dot{u}_n - c_d \dot{u}_{n+1} - k_n u_{n-1} + (k_n + k_d) u_n - k_d u_{n+1} = F_n(t) \quad (7)$$

$$b \ddot{u}_{n+1} - c_d \dot{u}_{n-1} - c_d \dot{u}_n + c_d \dot{u}_{n+1} - k_d u_{n-1} - k_d u_n + k_d u_{n+1} = \frac{1}{200} b F_{n+1}(t) \quad (8)$$

Where the constant  $1/200$  denotes the ratio between the physical mass of the TID and the inertance ( $b$ ). The ratio is assumed according to Papageorgiou and Smith [3] and Papageorgiou et al. [26].

Therefore, the System of Equations can be written in matrix form, corresponding to the general equation of motion:

$$\mathbf{M} \ddot{\mathbf{U}}(t) + \mathbf{C} \dot{\mathbf{U}}(t) + \mathbf{K} \mathbf{U}(t) = \mathbf{F}(t) \quad (9)$$

$$\mathbf{M} = \begin{bmatrix} m_1 & 0 & \cdots & 0 & 0 & 0 \\ 0 & m_2 & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & m_{n-1} & 0 & 0 \\ 0 & 0 & \cdots & 0 & m_n & 0 \\ 0 & 0 & \cdots & 0 & 0 & b \end{bmatrix} \quad (10)$$

$$\mathbf{C} = \begin{bmatrix} c_1 + c_2 & -c_2 & \cdots & 0 & 0 & 0 \\ -c_2 & c_2 + c_3 & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & c_{n-1} + c_n + c_d & -c_n & -c_d \\ 0 & 0 & \cdots & -c_n & c_n + c_d & -c_d \\ 0 & 0 & \cdots & -c_d & -c_d & c_d \end{bmatrix} \quad (11)$$

$$\mathbf{K} = \begin{bmatrix} k_1 + k_2 & -k_2 & \cdots & 0 & 0 & 0 \\ -k_2 & k_2 + k_3 & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & k_{n-1} + k_n + k_d & -k_n & -k_d \\ 0 & 0 & \cdots & -k_n & k_n + k_d & -k_d \\ 0 & 0 & \cdots & -k_d & -k_d & k_d \end{bmatrix} \quad (12)$$

$$\mathbf{U} = \{u_1 \quad u_2 \quad \cdots \quad u_{n-1} \quad u_n \quad u_{n+1}\}^T \quad (13)$$

$$\boldsymbol{\delta} = \{1 \quad 1 \quad \cdots \quad 1 \quad 1 \quad 1/200\}^T \quad (14)$$

Where  $\mathbf{M}$ ,  $\mathbf{C}$  and  $\mathbf{K}$  are the mass, stiffness and damping matrices, and  $\mathbf{U}$  is defined as the structure displacement response.

### 3 TID DESIGN AND OPTIMIZACIÓN PROCEDURE THROUGH CULTURAL ALGORITHM

This work intends to implement a cultural algorithm for the optimal design of a TID. The cultural algorithm was first presented by Reynolds in [9] as a complementary algorithm to the evolutionary computation and natural selection algorithms. Cultural algorithms have been used for the solution and optimization of multiple engineering problems, such as the vibration control of vehicles or the design of stabilizers for power systems [10,11].

Figure 3, shows of the three components of the cultural algorithm. The first of the three components are the population space, which includes the population to be developed and the evaluation, reproduction, and modification mechanism. The second component is the belief space, representing the direction in which the population has to seek solutions. Finally, the third component of the cultural algorithm is made up of the communication protocol, through which the population and beliefs interact [9]. The functions in Figure 3 are defined as follows:

- Acceptance function: transfers individual knowledge that satisfies the aptitude value to belief space.
- Update function: adjusts the knowledge of the belief space according to the individual knowledge transferred.
- Influence function: adjusts the individual knowledge of the population space according to the knowledge of the belief space.
- Fitness function: produces the individual knowledge of the next generation according to certain rules.

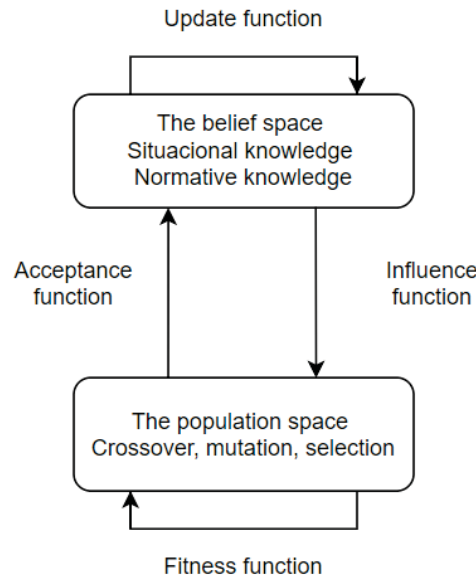

Figure 3: Framework of cultural algorithms.

The objective function defined in Eq. 15 will assess the performance of the control system applied to the case-study structure. This will be determined by means of the dynamic root mean square (RMS) response of displacements of the last floor of the structure.

$$F_{obj} = \frac{\text{RMS of the } n^{th} \text{ DOF controlled response}}{\text{RMS of the } n^{th} \text{ DOF uncontrolled response}} \quad (15)$$

#### 4 WIND EXCITATION MODEL AND FREQUENCY DOMAIN ANALYSIS FOR THE TID-EQUIPPED SYSTEM

To model the dynamic wind action, a computational simulation based on the Monte Carlo method is carried out, following the recommendations provided by Franco [21]. The procedure is based on the wind power spectrum developed by Davenport [23] through which it is possible to separate fluctuating pressure into  $m$  harmonic functions (at least 11), one of which will be resonant. The Monte Carlo method and the Fourier transform are used to reproduce the fluctuating pressures of the wind.

The building is used as case-study in this investigation. The building, which is the tallest residential tower in Medellín, with 144 m in height, distributed over 37 floors. The location and topographical characteristics of the building are used to obtain the basic parameters to be used in the Synthetic Wind Method. These parameters were taken from the Colombian code, *Reglamento Colombiano de Construcción Sismo Resistente* (NSR-10) [24]

#### 5 NUMERICAL RESULTS AND DISCUSSION

Following the procedure exposed previously and the mathematical formulation described in [19-22], it is possible to obtain the fluctuating pressures as shown in Figure 4.

Figure 4: Fluctuating Pressure.

Now, the fluctuating forces over 600 seconds are computed from the fluctuating pressures [25]. It is worth noting that twenty simulations of fluctuating forces were performed to determine the highest displacements achieved at each simulation. Then, a unique fluctuating force is selected to generate a maximum displacement with a 95% probability of occurrence, following a Gumbel extreme value distribution. Figure 5 shows the time histories of wind loads on the 37th floor of the building.

Figure 5: Time histories of wind loads on the 37<sup>th</sup> floor of the building.

Table 1 reports the design parameters optimized with the Cultural Algorithm. The optimization was carried out considering fixed  $b$  values, which represent 2%, 5% and 20% of in-ertance ratios.

$b$	$f$	$\zeta_d$	$F_{obj}$
2%	0.9882680	0.0000000	0.62616
5%	0.5000000	0.5000000	0.68861
20%	0.5000000	0.0219307	0.73547

Table 1: Optimal design parameter for the TID.

On the other hand, Table 2 reports the RMS values of the displacements for the uncontrolled and controlled structure. Furthermore, the percentage of reduction of the RMS is presented as well.

	$b$	Uncontrolled Response [m]	Controlled response [m]	% Reduction
37th RMS [m]	2%	0.17363	0.10914	37.12%
	5%	0.17363	0.11954	31.15%
	20%	0.17363	0.12770	26.45%

Table 2: Maximum RMS response of displacements of 37th story

Figure 6 shows the variation of the RMS values of the displacements of each degree of freedom considered. With these results, the efficiency of the TID is demonstrated.

Figure 6: RMS displacement at each story level.

The maximum uncontrolled RMS response of displacement at the 37th story level in Figure 6 is 0.173 m. The reductions achieved using the optimized TID decrease between 37.12% and 26.45%, as inertance values increase. Using the  $b=2\%$  TID, the maximum RMS displacement value is 0.109 m (37.12% reduction); with  $b=5\%$ , the maximum RMS value diminish to 0.119 m (31.15% reduction); finally, with the  $b=20\%$  TID, the RMS value of displacement reduce hardly to 0.128 m (26.45% reduction). Thus, it is clear that the best reductions in the dynamic response, under wind excitations, are attained using the TID with the lowest inertance value ( $b=2\%$ ).

Figure 7: Time histories of controlled displacement on the 37<sup>th</sup> floor of the building.

Finally, Figure 7 shows a comparison between the uncontrolled and controlled history of displacements on the 37th floor of the structure. The peak displacement in Figure 7 was reduced from 0.463 m to 0.345 m using the  $b=2\%$  TID, which represents a 25.48% overall reduction.

## 6 CONCLUSIONS

- A numerical investigation on the optimal design parameters of a Tuned Inerter Damper (TID) based system for the control of wind-induced vibration in tall buildings was presented in this paper. The control system was inspired by the conventional TID, with the main difference that its location was changed from ground level to the last two levels of the structural system. To represent the dynamic action of the wind in the time domain, a Monte Carlo simulation was used in which a time series derived from the Davenport spectrum was re-produced using eleven harmonic functions with randomly chosen phase angles.
- The obtained results shows that TIDs with lower inertance values installed at the last floors of the building are useful to reduce the dynamic response of the structure under wind loads. Reductions up to 37.12% were achieved for RMS values of displacement us-

ing  $b=2\%$  TID. Moreover, the cultural algorithm proved to be an efficient and useful tool for determining the optimal TID de-sign parameters, and the effectiveness of modified TID systems on mitigating wind-induced vibrations in high-rise buildings was demonstrated.

### Abstract

*The present investigation examines how the properties of the double concave friction pendulum (DCFP) devices influence the seismic performance of isolated multi-span continuous deck bridges. The numerical simulations are carried out using an eight-degree-of-freedom model to reproduce the elastic behavior of the pier, associated to the assumption of both rigid abutment and rigid deck, and the non-linear velocity-dependent behavior of the two surfaces of the double concave friction pendulum isolators, under a set of natural records with different characteristics. The results in terms of the statistics related to the relevant response parameters are computed in non-dimensional form with respect to the seismic intensity considering different properties of both DCFP isolators and bridge.*

**Keywords:** Seismic isolation, Double concave friction pendulum isolators, Multi-span continuous deck bridges, Performance-based engineering, Non-dimensional form.

---

## 1 INTRODUCTION

The seismic isolation is one of the most used and efficient techniques able to improve seismic performance of both new or existing buildings [1]-[2] and infrastructures [3]. With reference to bridges, the seismic isolation allows to uncouple the super-structure represented by the deck and the sub-structure represented by the system piers/abutments/foundations. The main benefit to the structural system relates to significant reduction of forces transmitted from the deck to the piers under seismic event.

In particular, the quantification of safety level of structures [5] and road infrastructures [6]-[8] is a relevant topic for research with special reference to areas subjected to high seismicity. In such areas, the non-linear behaviour of RC members [9]-[11] has a significant influence on structural response when structures are not provided of appropriate isolation systems. For instance, different investigations focused on the analysis of seismic response of bridges equipped with isolator devices have been performed over the years [12].

In literature, several studies have been carried out concerning seismic isolation of bridges through friction pendulum devices (FPS) [13]-[15]. The FPS bearings are able to make the natural period of the isolated bridge independent from the mass of the deck and allows significant energy dissipation under seismic motion thanks to friction on sliding surfaces [16]. The FPS bearings can be realized with single (SCFP) or multiple concave sliding surfaces [17]-[18]. In particular, the use of double concave sliding surface friction pendulum devices (DCFP) have positive influence on the seismic response of isolated bridges as demonstrated by [19].

The present study investigates the effectiveness of the use of DCFP to improve the seismic response of multi-span continuous bridges considering the interaction between piers, abutments and deck [20]. The structural response of the system under seismic excitation is analysed by means of an eight-degree-of-freedom (8-dof) model accounting for the reinforced concrete (RC) pier stiffness, the DCFP behaviour and the rigid RC abutment.

The seismic action and related uncertainties are reproduced adopting a set of natural records having different spectral characteristics. In detail, a non-dimensional parametric study is developed for several geometric configurations of the pier and of the DCFP isolators. The responses of the deck, of the pier and of each surface of the DCFP isolators are monitored to determine effectiveness of the isolation system.

## 2 DESCRIPTION OF DYNAMIC BEHAVIOUR OF DECK-ABUTMENT-PIER STRUCTURAL SYSTEM

The structural behavior of the multi-span continuous deck bridge (e.g., isolated three-span continuous deck bridge) isolated with DPCF is reproduced by means of an 8-degree-of-freedom (8-dof) system as shown by Figure 1.

In detail, 5 degrees of freedom relate to the lumped masses associated to the RC bridge pier (supposed to be elastic), 2 degrees of freedom correspond to the two sliders of the DPCF bearings and, finally, 1 degree of freedom concerns the mass of the rigid RC deck [14].

The governing equations of motion of the system can be expressed in terms of relative horizontal displacements with respect to the ground (Figure 1(a)) along the longitudinal direction as follows:

$$\begin{aligned}
 m_d [\ddot{u}_d(t) + \ddot{u}_g(t)] + F_{1a}(t) + F_{1p}(t) &= 0 \\
 m_{sa} [\ddot{u}_{sa}(t) + \ddot{u}_g(t)] - F_{1a}(t) + F_{2a}(t) &= 0 \\
 m_{sp} [\ddot{u}_{sp}(t) + \ddot{u}_g(t)] - F_{1p}(t) + F_{2p}(t) &= 0 \quad (1 \text{ a,b,c,d,e}) \\
 m_{p5} [\ddot{u}_{p5}(t) + \ddot{u}_g(t)] + c_{p5} [\dot{u}_{p5}(t) - \dot{u}_{p4}(t)] + k_{p5} [u_{p5}(t) - u_{p4}(t)] - F_{2p}(t) &= 0 \\
 m_{pi} [\ddot{u}_{pi}(t) + \ddot{u}_g(t)] + c_{pi} [\dot{u}_{pi}(t) - \dot{u}_{pi-1}(t)] + k_{pi} [u_{pi}(t) - u_{pi-1}(t)] + \\
 - c_{pi+1} [\dot{u}_{pi+1}(t) - \dot{u}_{pi}(t)] - k_{pi+1} [u_{pi+1}(t) - u_{pi}(t)] &= 0 \quad \text{for } i=1, \dots, 4
 \end{aligned}$$

where  $u_d$  denotes the displacement of the deck relative to the ground;  $u_{sp}$  is the displacement of the slider of the DCFP device located on the pier with respect to the ground;  $u_{sa}$  is the displacement of the slider of the DCFP device located on the abutment with respect to the ground,  $u_{pi}$  ( $i=1, \dots, 4, 5$ ) is the displacement relative to the ground of pier  $i$ -th mass;  $m_d$ ,  $m_{sp}$  and  $m_{sa}$  are the masses of the deck and of the two DCFP devices installed on the pier and on the abutment;  $m_{pi}$  ( $i=1, \dots, 4, 5$ ) is the  $i$ -th lumped mass of the pier segment;  $k_{pi}$  and  $c_{pi}$  ( $i=1, \dots, 5$ ) are the stiffness and associated viscous damping constant for each dof associated to the pier segments;  $t$  is the time instant;  $F_{ja}(t)$  and  $F_{jp}(t)$  denote the reaction forces of the DCFP bearings on the abutment and on the pier, respectively, for the upper ( $j=1$ ) and lower sliding surface ( $j=2$ ). With reference to the modelling of behavior of the DCFP, the device can be modelled as a serial combination of two single FPS isolators. Then, according to [17]-[18], the reaction forces at the upper ( $j=1$ ) and lower ( $j=2$ ) surface (i.e.,  $F_1$  and  $F_2$ ) are identical and can be obtained according to the following expression:

$$F = F_1 = F_2 = \frac{m_d g}{R_1 + R_2} (u) + \frac{m_d g (R_1 \mu_1 (\dot{u}_1) \text{sgn}(\dot{u}_1) + R_2 \mu_2 (\dot{u}_2) \text{sgn}(\dot{u}_2))}{R_1 + R_2} \quad (2)$$

where  $u$  is the global horizontal displacement of the DCFP isolator;  $u_1$  represents the horizontal displacement of the upper surface ( $j=1$ );  $u_2$  is the horizontal displacement of the lower surface ( $j=2$ ). The first part of Eq. (2) represents the equivalent restoring stiffness ( $k_{comb}$ ) of the DCFP device expressed as:

$$k_{comb} = \frac{m_d g}{R_1 + R_2} \quad (3)$$

from which the restoring natural period can be derived as follows:

$$T_d = 2\pi \sqrt{(R_1 + R_2) / g} = 2\pi / \omega_d \quad (4)$$

where  $g$  is the gravity constant;  $R_1$  and  $R_2$  denote the upper and lower radius of curvature of the DCFP bearing. In Eq.(2),  $\mu_j(\dot{u}_j(t))$  (with  $j=1,2$ ) represents the sliding friction coefficient, which depends on the slider slip velocity  $\dot{u}_j(t)$  along one of the two sliding surfaces and on its sign,  $\text{sgn}(\dot{u}_j)$  (for  $j=1,2$ ). The second part of Eq.(2) represents the equivalent friction coefficient of the DCFP device [17]:

$$\mu_{eqv} = \frac{\mu_1 R_1 + \mu_2 R_2}{R_1 + R_2} \quad (5)$$

Eq.(5) is valid under the assumption that the sliding occurs on the both surfaces of the device and in the same direction.

Figure 1: Representation of the 8-dof model of the bridge. Relative displacements with respect to the ground (a) and drifts between the different lumped masses (b).

The experimental investigations of [21]-[23] demonstrate that, the coefficient of friction on sliding surfaces of DCFP can be estimated according to the following expression:

$$\mu_j(\dot{u}_j) = \mu_{j,\max} - (\mu_{j,\max} - \mu_{j,\min}) \cdot \exp(-\alpha |\dot{u}_j|) \quad \text{for } j = 1, 2 \quad (6)$$

where,  $\mu_{j,\max}$  denotes the maximum value of friction coefficient at high sliding velocities;  $\mu_{j,\min}$  represents the value at near-zero sliding velocity. In the present investigation, it is assumed that  $\mu_{j,\max} = 3\mu_{j,\min}$  and  $\alpha = 30$  according to the researches of [21]-[23].

### 3 NON-DIMENSIONAL SYSTEM OF EQUATIONS

The analysis of the seismic behavior of the bridge under seismic action is performed according to non-dimensional form of the system of equations of motion, in line with previous applications [24]. In order to obtain the response of the DCFP devices along each sliding surface, Eq.(1) can be expressed in terms of drifts between the lumped masses of the structural system (Fig.1(b)), according to the following relationships:

$$\begin{aligned} & m_d \ddot{x}_7(t) + m_d \ddot{x}_6(t) + m_d \ddot{x}_{p5}(t) + m_d \ddot{x}_{p4}(t) + m_d \ddot{x}_{p3}(t) + m_d \ddot{x}_{p2}(t) + m_d \ddot{x}_{p1}(t) + \\ & + c_d \dot{x}_d(t) + F_{1a}(t) + F_{1p}(t) = -m_d \ddot{u}_g(t) \\ & m_{sp} \ddot{x}_6(t) + m_{sp} \ddot{x}_{p5}(t) + m_{sp} \ddot{x}_{p4}(t) + m_{sp} \ddot{x}_{p3}(t) + m_{sp} \ddot{x}_{p2}(t) + m_{sp} \ddot{x}_{p1}(t) - F_{1p}(t) + F_{2p}(t) = -m_{sp} \ddot{u}_g(t) \\ & m_{sa} \ddot{x}_8(t) - F_{1a}(t) + F_{2a}(t) = -m_{sa} \ddot{u}_g(t) \\ & m_{p5} \ddot{x}_{p5}(t) + m_{p5} \ddot{x}_{p4}(t) + m_{p5} \ddot{x}_{p3}(t) + m_{p5} \ddot{x}_{p2}(t) + m_{p5} \ddot{x}_{p1}(t) - c_d \dot{x}_d(t) + c_{p5} \dot{x}_{p5}(t) + \\ & + k_{p5} x_{p5}(t) - F_{2p}(t) = -m_{p5} \ddot{u}_g(t) \\ & m_{p4} \ddot{x}_{p4}(t) + m_{p4} \ddot{x}_{p3}(t) + m_{p4} \ddot{x}_{p2}(t) + m_{p4} \ddot{x}_{p1}(t) - c_{p5} \dot{x}_{p5}(t) - k_{p5} x_{p5}(t) + c_{p4} \dot{x}_{p4}(t) + k_{p4} x_{p4}(t) = -m_{p4} \ddot{u}_g(t) \\ & m_{p3} \ddot{x}_{p3}(t) + m_{p3} \ddot{x}_{p2}(t) + m_{p3} \ddot{x}_{p1}(t) - c_{p4} \dot{x}_{p4}(t) - k_{p4} x_{p4}(t) + c_{p3} \dot{x}_{p3}(t) + k_{p3} x_{p3}(t) = -m_{p3} \ddot{u}_g(t) \\ & m_{p2} \ddot{x}_{p2}(t) + m_{p2} \ddot{x}_{p1}(t) - c_{p3} \dot{x}_{p3}(t) - k_{p3} x_{p3}(t) + c_{p2} \dot{x}_{p2}(t) + k_{p2} x_{p2}(t) = -m_{p2} \ddot{u}_g(t) \\ & m_{p1} \ddot{x}_{p1}(t) - c_{p2} \dot{x}_{p2}(t) - k_{p2} x_{p2}(t) + c_{p1} \dot{x}_{p1}(t) + k_{p1} x_{p1}(t) = -m_{p1} \ddot{u}_g(t) \end{aligned} \quad (7a,b,c,d,e,f,g,h)$$

where, in line to Eq.s(2)-(6), the reactions of the DCFP bearings on the sliding surfaces are:

$$\begin{aligned}
 F_{1a} &= \frac{m_d g}{2} \left[ \frac{1}{R_{1a}} \left( \sum_{i=1}^5 x_{pi} + x_6 + x_7 - x_8 \right) + \mu_{1a}(\dot{x}_9) (\text{sgn}(\dot{x}_9)) \right] \\
 F_{2a} &= \left( \frac{m_d}{2} + m_{sa} \right) g \left[ \frac{1}{R_{2a}} (x_8) + (\mu_{2a}(\dot{x}_8)) (\text{sgn}(\dot{x}_8)) \right] \\
 F_{1p} &= \left( \frac{m_d g}{2} \right) \left[ \frac{1}{R_{1p}} (x_7) + (\mu_{1p}(\dot{x}_7)) (\text{sgn}(\dot{x}_7)) \right] \\
 F_{2p} &= \left( \frac{m_d}{2} + m_{sp} \right) g \left[ \frac{1}{R_{2p}} (x_6) + (\mu_{2p}(\dot{x}_6)) (\text{sgn}(\dot{x}_6)) \right]
 \end{aligned} \tag{8 a,b,c,d}$$

where, in detail,  $x_9 = u_d - x_8 = \sum_{i=1}^5 x_{pi} + x_6 + x_7 - x_8$ . Next, dividing all the equations by the mass  $m_d$ , the system of equation of Eq.(7) becomes:

$$\begin{aligned}
 &\ddot{x}_7(t) + \ddot{x}_6(t) + \ddot{x}_{p5}(t) + \ddot{x}_{p4}(t) + \ddot{x}_{p3}(t) + \ddot{x}_{p2}(t) + \ddot{x}_{p1}(t) + 2\xi_d \omega_d \dot{x}_d(t) + \\
 &+ \frac{g}{2} \left[ \frac{1}{R_{1a}} \left( \sum_{i=1}^5 x_{pi} + x_6 + x_7 - x_8 \right) + \mu_{1a}(v) \left( \text{sgn} \left( \sum_{i=1}^5 \dot{x}_{pi} + \dot{x}_6 + \dot{x}_7 - \dot{x}_8 = v \right) \right) \right] + \\
 &+ \frac{g}{2} \left[ \frac{1}{R_{1p}} (x_7) + (\mu_{1p}(\dot{x}_7)) (\text{sgn}(\dot{x}_7)) \right] = \ddot{u}_g(t) \\
 &\lambda_{sp} (\ddot{x}_6(t) + \ddot{x}_{p5}(t) + \ddot{x}_{p4}(t) + \ddot{x}_{p3}(t) + \ddot{x}_{p2}(t) + \ddot{x}_{p1}(t)) + \\
 &- \frac{g}{2} \left[ \frac{1}{R_{1p}} (x_7) + (\mu_{1p}(\dot{x}_7)) (\text{sgn}(\dot{x}_7)) \right] + \left( \frac{1}{2} + \lambda_{sp} \right) g \left[ \frac{1}{R_{2p}} (x_6) + (\mu_{2p}(\dot{x}_6)) (\text{sgn}(\dot{x}_6)) \right] = -\lambda_{sp} \ddot{u}_g(t) \\
 &\lambda_{sa} \ddot{x}_8(t) - \frac{g}{2} \left[ \frac{1}{R_{1a}} \left( \sum_{i=1}^5 x_{pi} + x_6 + x_7 - x_8 \right) + \mu_{1a}(v) \left( \text{sgn} \left( \sum_{i=1}^5 \dot{x}_{pi} + \dot{x}_6 + \dot{x}_7 - \dot{x}_8 = v \right) \right) \right] + \\
 &+ \left( \frac{1}{2} + \lambda_{sa} \right) g \left[ \frac{1}{R_{2a}} (x_8) + (\mu_{2a}(\dot{x}_8)) (\text{sgn}(\dot{x}_8)) \right] = -\lambda_{sa} \ddot{u}_g(t) \\
 &\lambda_{p5} (\ddot{x}_{p5}(t) + \ddot{x}_{p4}(t) + \ddot{x}_{p3}(t) + \ddot{x}_{p2}(t) + \ddot{x}_{p1}(t)) - 2\xi_d \omega_d \dot{x}_d(t) + 2\xi_{p5} \omega_{p5} \lambda_{p5} \dot{x}_{p5}(t) + \omega_{p5}^2 \lambda_{p5} x_{p5}(t) + \\
 &- \left( \frac{1}{2} + \lambda_{sp} \right) g \left[ \frac{1}{R_{2p}} (x_6) + (\mu_{2p}(\dot{x}_6)) (\text{sgn}(\dot{x}_6)) \right] = -\lambda_{p5} \ddot{u}_g(t) \\
 &\lambda_{p4} (\ddot{x}_{p4}(t) + \ddot{x}_{p3}(t) + \ddot{x}_{p2}(t) + \ddot{x}_{p1}(t)) - 2\xi_{p5} \omega_{p5} \lambda_{p5} \dot{x}_{p5}(t) - \omega_{p5}^2 \lambda_{p5} x_{p5}(t) + \\
 &+ 2\xi_{p4} \omega_{p4} \lambda_{p4} \dot{x}_{p4}(t) + \omega_{p4}^2 \lambda_{p4} x_{p4}(t) = -\lambda_{p4} \ddot{u}_g(t) \\
 &\lambda_{p3} (\ddot{x}_{p3}(t) + \ddot{x}_{p2}(t) + \ddot{x}_{p1}(t)) - 2\xi_{p4} \omega_{p4} \lambda_{p4} \dot{x}_{p4}(t) - \omega_{p4}^2 \lambda_{p4} x_{p4}(t) + 2\xi_{p3} \omega_{p3} \lambda_{p3} \dot{x}_{p3}(t) + \omega_{p3}^2 \lambda_{p3} x_{p3}(t) = -\lambda_{p3} \ddot{u}_g(t) \\
 &\lambda_{p2} (\ddot{x}_{p2}(t) + \ddot{x}_{p1}(t)) - 2\xi_{p3} \omega_{p3} \lambda_{p3} \dot{x}_{p3}(t) - \omega_{p3}^2 \lambda_{p3} x_{p3}(t) + 2\xi_{p2} \omega_{p2} \lambda_{p2} \dot{x}_{p2}(t) + \omega_{p2}^2 \lambda_{p2} x_{p2}(t) = -\lambda_{p2} \ddot{u}_g(t) \\
 &\lambda_{p1} \ddot{x}_{p1}(t) - 2\xi_{p2} \omega_{p2} \lambda_{p2} \dot{x}_{p2}(t) - \omega_{p2}^2 \lambda_{p2} x_{p2}(t) + 2\xi_{p1} \omega_{p1} \lambda_{p1} \dot{x}_{p1}(t) + \omega_{p1}^2 \lambda_{p1} x_{p1}(t) = -\lambda_{p1} \ddot{u}_g(t)
 \end{aligned} \tag{9a,b,c,d,e,f,g,h}$$

introducing the mass ratios; the circular frequency of vibration of the isolated deck and of the  $i$ -th dof of the pier; the damping coefficient of the  $i$ -th dof of the pier, as expressed in the following:

$$\lambda_{pi} = \frac{m_{pi}}{m_d}, \quad \lambda_{sa} = \frac{m_{sa}}{m_d}, \quad \lambda_{sp} = \frac{m_{sp}}{m_d}, \quad \omega_d = \sqrt{\frac{k_{comb}}{m_d}}, \quad \omega_{pi} = \sqrt{\frac{k_{pi}}{m_{pi}}}, \quad \xi_{pi} = \frac{c_{pi}}{2m_{pi}\omega_{pi}} \tag{10 a,b,c,d,e,f}$$

In line to [24], the time scale  $\tau = t\omega_d$  can be introduced together with the seismic intensity scale factor  $a_0$ , expressed as  $\ddot{u}_g(t) = a_0 \ell(\tau)$ . The function  $\ell(\tau)$  is a non-dimensional function of

time describing the time history of the seismic input. Finally, the non-dimensional system equations can be expressed as follows:

$$\begin{aligned}
 & \ddot{\psi}_7(\tau) + \ddot{\psi}_6(\tau) + \ddot{\psi}_{p5}(\tau) + \ddot{\psi}_{p4}(\tau) + \ddot{\psi}_{p3}(\tau) + \ddot{\psi}_{p2}(\tau) + \ddot{\psi}_{p1}(\tau) + 2\xi_d \dot{\psi}_7(\tau) + \frac{g}{2} \left[ \frac{1}{R_{1p}} \frac{1}{\omega_d^2} \psi_7(\tau) + \frac{\mu_{1p}(\dot{\psi}_7)}{a_0} \text{sgn}(\dot{\psi}_7) \right] + \\
 & + \frac{g}{2} \left[ \frac{1}{R_{1a}} \frac{1}{\omega_d^2} \left( \sum_{i=1}^5 \psi_{pi}(\tau) + \psi_6(\tau) + \psi_7(\tau) - \psi_8(\tau) \right) + \left( \frac{\mu_{1a}(\dot{\psi}_9)}{a_0} \right) \left( \text{sgn} \left( \sum_{i=1}^5 \dot{\psi}_{pi}(\tau) + \dot{\psi}_6(\tau) + \dot{\psi}_7(\tau) - \dot{\psi}_8(\tau) \right) \right) \right] = -\ell(\tau) \\
 \\
 & \lambda_{sp} \left[ \ddot{\psi}_6(\tau) + \ddot{\psi}_{p5}(\tau) + \ddot{\psi}_{p4}(\tau) + \ddot{\psi}_{p3}(\tau) + \ddot{\psi}_{p2}(\tau) + \ddot{\psi}_{p1}(\tau) \right] - \frac{g}{2} \left[ \frac{1}{R_{1p}} \frac{1}{\omega_d^2} \psi_7(\tau) + \frac{\mu_{1p}(\dot{\psi}_7)}{a_0} \text{sgn}(\dot{\psi}_7) \right] + \\
 & + \left( \frac{1}{2} + \lambda_{sp} \right) g \left[ \frac{1}{R_{2p}} \frac{1}{\omega_d^2} \psi_6(\tau) + \frac{\mu_{2p}(\dot{\psi}_6)}{a_0} \text{sgn}(\dot{\psi}_6) \right] = -\lambda_{sp} \ell(\tau) \\
 \\
 & \lambda_{sa} \ddot{\psi}_8(\tau) - \frac{g}{2} \left[ \frac{1}{R_{1a}} \frac{1}{\omega_d^2} \left( \sum_{i=1}^5 \psi_{pi}(\tau) + \psi_6(\tau) + \psi_7(\tau) - \psi_8(\tau) \right) + \left( \frac{\mu_{1a}(\dot{\psi}_9)}{a_0} \right) \left( \text{sgn} \left( \sum_{i=1}^5 \dot{\psi}_{pi}(\tau) + \dot{\psi}_6(\tau) + \dot{\psi}_7(\tau) - \dot{\psi}_8(\tau) \right) \right) \right] + \\
 & + \left( \frac{1}{2} + \lambda_{sa} \right) g \left[ \frac{1}{R_{2a}} \frac{1}{\omega_d^2} \psi_8(\tau) + \frac{\mu_{2a}(\dot{\psi}_8)}{a_0} \text{sgn}(\dot{\psi}_8) \right] = -\lambda_{sa} \ell(\tau) \\
 \\
 & \lambda_{p5} \left[ \ddot{\psi}_{p5}(\tau) + \ddot{\psi}_{p4}(\tau) + \ddot{\psi}_{p3}(\tau) + \ddot{\psi}_{p2}(\tau) + \ddot{\psi}_{p1}(\tau) \right] - 2\xi_d \dot{\psi}_d(\tau) + 2\xi_{p5} \lambda_{p5} \frac{\omega_{p5}}{\omega_d} \dot{\psi}_{p5}(\tau) + \frac{\lambda_{p5} \omega_{p5}^2}{\omega_d^2} \psi_{p5}(\tau) + \\
 & - \left( \frac{1}{2} + \lambda_{p5} \right) g \left[ \frac{1}{R_{2p}} \frac{1}{\omega_d^2} \psi_6(\tau) + \frac{\mu_{2p}(\dot{\psi}_6)}{a_0} \text{sgn}(\dot{\psi}_6) \right] = -\lambda_{p5} \ell(\tau) \\
 \\
 & \lambda_{p4} \left[ \ddot{\psi}_{p4}(\tau) + \ddot{\psi}_{p3}(\tau) + \ddot{\psi}_{p2}(\tau) + \ddot{\psi}_{p1}(\tau) \right] - 2\xi_{p5} \lambda_{p5} \frac{\omega_{p5}}{\omega_d} \dot{\psi}_{p5}(\tau) + \\
 & + 2\xi_{p4} \lambda_{p4} \frac{\omega_{p4}}{\omega_d} \dot{\psi}_{p4}(\tau) - \lambda_{p5} \frac{\omega_{p5}^2}{\omega_d^2} \psi_{p5}(\tau) + \lambda_{p4} \frac{\omega_{p4}^2}{\omega_d^2} \psi_{p4}(\tau) = -\lambda_{p4} \ell(\tau) \\
 \\
 & \lambda_{p3} \left[ \ddot{\psi}_{p3}(\tau) + \ddot{\psi}_{p2}(\tau) + \ddot{\psi}_{p1}(\tau) \right] - 2\xi_{p4} \lambda_{p4} \frac{\omega_{p4}}{\omega_d} \dot{\psi}_{p4}(\tau) + \\
 & + 2\xi_{p3} \lambda_{p3} \frac{\omega_{p3}}{\omega_d} \dot{\psi}_{p3}(\tau) - \lambda_{p4} \frac{\omega_{p4}^2}{\omega_d^2} \psi_{p4}(\tau) + \lambda_{p3} \frac{\omega_{p3}^2}{\omega_d^2} \psi_{p3}(\tau) = -\lambda_{p3} \ell(\tau) \\
 \\
 & \lambda_{p2} \left[ \ddot{\psi}_{p2}(\tau) + \ddot{\psi}_{p1}(\tau) \right] - 2\xi_{p3} \lambda_{p3} \frac{\omega_{p3}}{\omega_d} \dot{\psi}_{p3}(\tau) + 2\xi_{p2} \lambda_{p2} \frac{\omega_{p2}}{\omega_d} \dot{\psi}_{p2}(\tau) - \lambda_{p3} \frac{\omega_{p3}^2}{\omega_d^2} \psi_{p3}(\tau) + \\
 & + \lambda_{p2} \frac{\omega_{p2}^2}{\omega_d^2} \psi_{p2}(\tau) = -\lambda_{p2} \ell(\tau) \\
 \\
 & \lambda_{p1} \ddot{\psi}_{p1}(\tau) - 2\xi_{p2} \lambda_{p2} \frac{\omega_{p2}}{\omega_d} \dot{\psi}_{p2}(\tau) + 2\xi_{p1} \lambda_{p1} \frac{\omega_{p1}}{\omega_d} \dot{\psi}_{p1}(\tau) - \lambda_{p2} \frac{\omega_{p2}^2}{\omega_d^2} \psi_{p2}(\tau) + \lambda_{p1} \frac{\omega_{p1}^2}{\omega_d^2} \psi_{p1}(\tau) = -\lambda_{p1} \ell(\tau)
 \end{aligned}
 \tag{11 a,b,c,d,e,f,g,h}$$

with the following non-dimensional parameters:

$$\begin{aligned}
 \Pi_{oi} &= \frac{\omega_{pi}}{\omega_d} \quad , \quad \Pi_{\lambda i} = \lambda_{pi} = \frac{m_{pi}}{m_d} \quad , \quad \Pi_{\lambda sa} = \lambda_{sa} \quad , \\
 \Pi_{\lambda sp} &= \lambda_{sp} \quad , \quad \Pi_{\mu 1a}(\dot{\psi}_9) = \frac{\mu_{1a}(\dot{\psi}_9) g}{a_0} \quad , \\
 \Pi_{\mu 1p}(\dot{\psi}_7) &= \frac{\mu_{1p}(\dot{\psi}_7) g}{a_0} \quad , \quad \Pi_{\mu 2a}(\dot{\psi}_8) = \frac{\mu_{2a}(\dot{\psi}_8) g}{a_0} \quad , \\
 \Pi_{\mu 2p}(\dot{\psi}_6) &= \frac{\mu_{2p}(\dot{\psi}_6) g}{a_0} \quad , \quad \Pi_{\xi pi} = \xi_{pi}
 \end{aligned}
 \tag{12 a,b,c,d,e,f,g,h,i}$$

The non-dimensional parameters  $\Pi_{\mu 1a}$ ,  $\Pi_{\mu 1p}$ ,  $\Pi_{\mu 2a}$ ,  $\Pi_{\mu 2p}$  depend from the velocities and are used as follows:

$$\Pi_{\mu 1a}^* = \frac{\mu_{1,\max,a} g}{a_0}, \quad \Pi_{\mu 1p}^* = \frac{\mu_{1,\max,p} g}{a_0}, \quad \Pi_{\mu 2a}^* = \frac{\mu_{2,\max,a} g}{a_0}, \quad \Pi_{\mu 2p}^* = \frac{\mu_{2,\max,p} g}{a_0} \quad (13 \text{ a,b,c,d})$$

With reference to Figure 1, it can be recognized that the peak response in terms of non-dimensional parameters can be expressed as:

$$\psi_{u_d} = \frac{u_{d,\text{peak}} \omega_d^2}{a_0}, \quad \psi_{x_d} = \frac{x_{d,\text{peak}} \omega_d^2}{a_0} = \frac{(x_6 + x_7)_{\text{peak}} \omega_d^2}{a_0}, \quad \psi_{u_p} = \frac{u_{p,\text{peak}} \omega_d^2}{a_0} = \frac{\left( \sum_{i=1}^5 x_i \right)_{\text{peak}} \omega_d^2}{a_0} \quad (14 \text{ a,b,c})$$

#### 4 PARAMETRIC INVESTIGATION OF STRUCTURAL RESPONSE UNDER SEISMIC ACTIONS

Next, the results of parametric analysis of the bridge system isolated with DCFP bearings of Figure 1 are reported in non-dimensional terms. Firstly, the criteria for selection of earthquake events and the response parameters adopted to monitor the seismic performance are described.

##### 4.1 Selection of the seismic inputs

In line with the approach of performance-based earthquake engineering (PBEE) [25], the present investigation accounts for the uncertainties related to the seismic input intensity separately from the ones related to the characteristics of the record (i.e., record-to-record variability). This is possible to the introduction of an intensity measure (IM) that corresponds to the seismic intensity scale factor  $a_0$ . According to the criteria of efficiency, sufficiency and hazard compatibility [26], this study assumes that the spectral pseudo-acceleration,  $S_A$ , at the isolated period of the system,  $T_d = 2\pi / \omega_d$  (Eq.(4)), represents the adopted intensity measure IM. In the parametric analyses,  $\xi_d$  is taken equal to zero, in line to [24]. Then, the related  $IM = a_0$  is hereinafter denoted to as  $S_A(T_d)$ . The record-to-record variability is described through a set of 30 ground motion records with details in [27]-[30].

##### 4.2 Evaluation of the seismic response

In the present investigation, the peak response parameters considered are the following:

- the *peak deck response*  $u_{d,\text{peak}}$ , that corresponds to the peak isolator global response on the abutment;
- the *peak isolator global response* on the pier,  $x_{d,\text{peak}}$ ;
- the *peak displacement at the top of the pier*  $u_{p,\text{peak}}$  with respect to the ground.

According to the nondimensionalization previously introduced, the solution of Eq. (11) for the ground motions records allows to determine a set of samples of the mentioned above output variables. Next, the non-dimensional response parameters are assumed consistent with a lognormal probabilistic model as widely employed in PBEE [31] and in other studies [32]-[39]. The statistical parameters for lognormal distribution can be derived from generic response parameter  $D$  (i.e., the extreme values of  $\psi_{u_d}$ ,  $\psi_{x_p}$  and  $\psi_{u_p}$  of Eq.s (11) and (14)) by estimating the mean value  $GM(D)$  and the coefficient of variation  $\beta(D)$  of the observed samples as follows:

$$GM(D) = \sqrt[N]{d_1 \cdot \dots \cdot d_N} \quad (15)$$

$$\beta(D) = \sqrt{\frac{(\ln d_1 - \ln[GM(D)])^2 + \dots + (\ln d_N - \ln[GM(D)])^2}{N-1}} \quad (16)$$

where  $d_h$  represents the  $h$ -th sample value of  $D$  associated to the  $h$ -th accelerogram and  $N$  is the total number of samples equal to the total number of accelerograms herein adopted ( $h=1, \dots, N$ ). According to the lognormal distribution assumption, the  $k$ -th percentile of the generic response parameter  $D$  can be derived as follows:

$$d_k = GM(D) \exp[f(k)\beta(D)] \quad (17)$$

where  $f(k)$  assume the values of  $f(50) = 0$  for 50-th percentile and  $f(84) = 1$  for 84-percentile, respectively [40].

### 4.3 Outcomes from non-dimensional analyses

This section reports the results of the parametric investigation developed in line to the proposed criteria for nondimensionalization of the equations of motion. The influence of the properties of the DCFP isolators and bridge geometry on the seismic performance of the structural system under the ground motion records has been investigated. The following parametric analysis has been carried out:

- the parameters  $\Pi_{\xi_d} = \xi_d$  and  $\Pi_{\xi_p} = \xi_p$  are assumed equal to 0% and 5%;
- the isolated bridge period  $T_d$  has been assumed as 2s, 2.5s, 3s, 3.5s and 4s;
- the RC pier period  $T_p$  equal to 0.2s [19];
- the five pier lumped masses  $\Pi_{\lambda} = \lambda_p$  has been considered equal to 0.1, 0.15 and 0.2 [19];
- the two DCFP devices on the abutment and on the pier have identical properties (i.e., follows that  $\Pi_{\mu_{1a}}^* = \Pi_{\mu_{1p}}^* = \Pi_{\mu_1}^*$  as well as  $\Pi_{\lambda_{sa}} = \Pi_{\lambda_{sp}} = \Pi_{\lambda_s}$ ) and the mass ratio  $\Pi_{\lambda_s}$  is set equal to 0.005;  $R_1 / R_2$  equal to 2,  $\mu_{1,\max} / \mu_{2,\max}$  equal to 4,  $\mu_{j,\max} / \mu_{j,\min}$  (with  $j=1,2$ ) equal to 3;
- the parameter  $\Pi_{\mu_1}^*$  is assumed to vary in the range between 0 (no friction) and 2 (very high friction) (specifically, 95 values are considered).

Then, the non-dimensional parametric investigations have been carried out on 1425 different systems, defined by varying the main structural properties within the two bearing cases, assuming 30 different ground motions. For each value of the parameters of interest in the parametric study, the differential equations of motion, (i.e., Eq. (11)), have been solved for the 30 different ground motions. The Bogacki-Shampine integration algorithm available in Matlab-Simulink [41] has been adopted.

Figs 2-4 show the statistics ( $GM$  and  $\beta$  values) of the non-dimensional peak response parameters considered, obtained for different values of the system properties varying in the range of interest. Each figure contains three surface plots, corresponding to the different values of  $\Pi_{\lambda}$ .

Fig. 2 plots the results concerning the peak normalized displacement of pier top  $\psi_{u_p}$  with respect to the ground. It is noteworthy that for very low  $\Pi_{\mu_1}^*$  values,  $GM(\psi_{u_p})$  decreases by increasing  $\Pi_{\mu_1}^*$ , whereas it increases for high  $\Pi_{\mu_1}^*$  values. Thus, there exists an optimal value

of  $\Pi_{\mu 1}^*$  such that the peak displacement of pier top is minimized. This optimal value varies between 0 and 0.5 depending on the values of  $T_d$  and  $\Pi_\lambda$ . In addition,  $GM(\psi_{u_p})$  decreases significantly with increasing  $\Pi_\lambda$ . The parameter  $T_d$  has an influence on  $GM(\psi_{u_p})$  leading to a general decrease for an its increase thanks to the effectiveness of the seismic isolation. The dispersion  $\beta(\psi_{u_p})$  shows a maximum value approximatively at the same value of  $\Pi_{\mu 1}^*$  that gives the minimum  $GM(\psi_{u_p})$ . The response dispersion increases with increasing the mass ratio  $\Pi_\lambda$ . From low to high values of  $T_d$ ,  $\beta(\psi_{u_p})$  also increases.

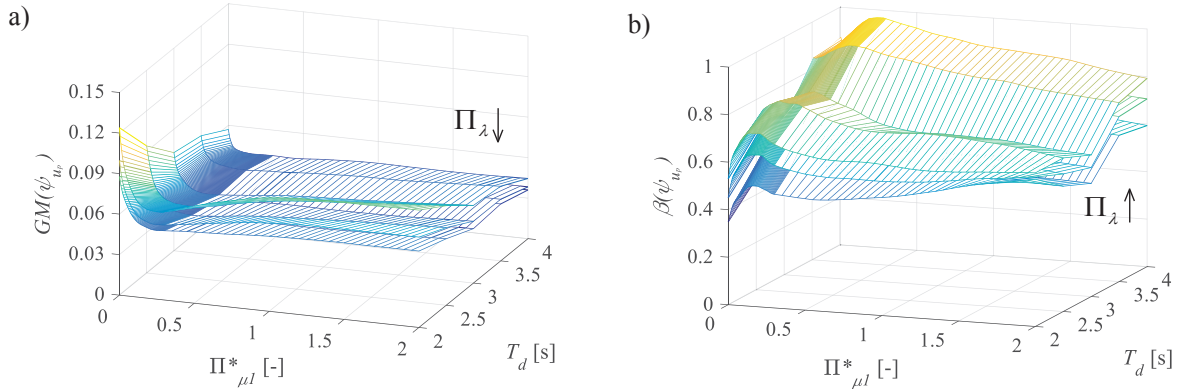

Figure 2: Normalized displacement of pier top vs.  $\Pi_{\mu 1}^*$  and  $T_d$ : median value and dispersion for  $T_p = 0.2s$  and for different values of  $\Pi_\lambda$ . The arrow denotes the increasing direction of  $\Pi_\lambda$ .

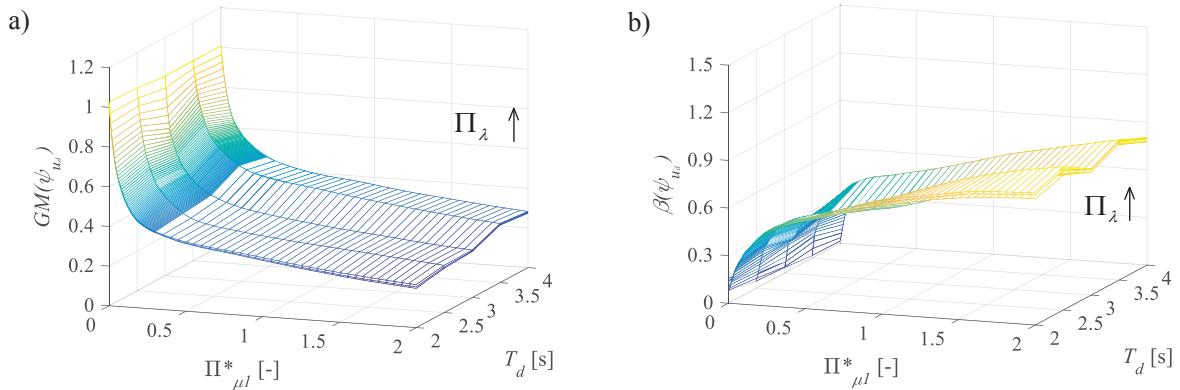

Figure 3: Normalized deck displacement vs.  $\Pi_{\mu 1}^*$  and  $T_d$ : median value and dispersion for  $T_p = 0.2s$  and for different values of  $\Pi_\lambda$ . The arrow denotes the increasing direction of  $\Pi_\lambda$ .

Fig. 3 shows the response statistics of the peak normalized deck displacement  $\psi_{u_d}$ , which also corresponds to the peak global response of the bearing placed on the abutment. Obviously,  $GM(\psi_{u_d})$  decreases significantly as  $\Pi_{\mu 1}^*$  increases. In general, the values of  $GM(\psi_{u_d})$  slightly increase for increasing values of both  $T_d$  and  $\Pi_\lambda$ . The values of the dispersion  $\beta(\psi_{u_d})$ , plotted in Fig. 3 (b), are very low for low  $\Pi_{\mu 1}^*$  values due to the high efficiency of the *IM*, and attain their maximum for high values of  $\Pi_{\mu 1}^*$ . The other system properties have a reduced influence on  $\beta(\psi_{u_d})$  compared to the influence of  $\Pi_{\mu 1}^*$ .

Fig. 4 shows the variation of the peak global response with regard to the bearing placed on the pier  $\psi_{x_d}$ . As already observed for  $GM(\psi_{u_d})$ , also  $GM(\psi_{x_d})$  tends to show a decrease

against increasing  $\Pi_{\mu 1}^*$  values. The dispersion is low in correspondence of low  $\Pi_{\mu 1}^*$  values due to the high efficiency of the *IM*, attaining its peak for high  $\Pi_{\mu 1}^*$  values. Note that the influence of  $\Pi_{\lambda}$  is slightly more marked for  $GM(\psi_{x_d})$  with respect to  $GM(\psi_{u_d})$  leading to lower values due to the flexibility of the pier.

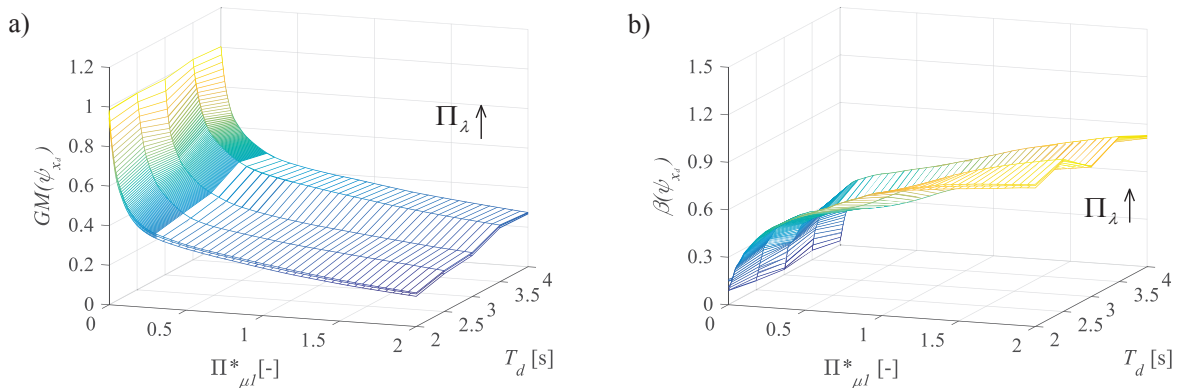

Figure 4. Normalized pier bearing global displacement vs.  $\Pi_{\mu 1}^*$  and  $T_d$ : median value and dispersion for  $T_p = 0.2s$  and for different values of  $\Pi_{\lambda}$ . The arrow denotes the increasing direction of  $\Pi_{\lambda}$ .

The existence of an optimal value of the normalised friction coefficient of the upper surface  $\Pi_{\mu 1}^*$  for the both DCFP devices able to minimize the displacement of pier top (Fig. 2) is the result of counteracting effects that occur for increasing values of the friction coefficient.

## 5 CONCLUSIONS

This paper analyzes the seismic performance of multi-span continuous deck bridges isolated with DCFP devices considering the pier-abutment-deck interaction. The results of an extensive non-dimensional parametric study encompassing a wide range of isolator and bridge properties have been illustrated monitoring various response parameters of interest related to both the isolators and the pier. Specifically, the RC pier is considered elastic, whereas the RC deck and RC abutment are assumed rigid. The results in terms of geometric mean and dispersion for each peak normalised response parameter are summarized as follows.

Regarding the pier performance, there exists an optimal value of sliding friction coefficient for each surface of the DCFP device able to minimize the pier response. This optimal value depends on the bridge and isolator properties.

Regarding the deck performance, which also corresponds to the peak global response of the bearing placed on the abutment, the response decreases significantly as the sliding friction coefficient increases. Slightly lower results are achieved for the global response of the bearing placed on the pier.

### Abstract

*The scope of the present study is focused on the evaluation of the seismic response of bridges isolated by single concave sliding pendulum isolators (FPS) for the different structural properties when the presence of the rigid abutment is considered or neglected (i.e., isolated viaducts). In this way, they have been defined two specific multi-degree-of-freedom (mdof) models to simulate the elastic behavior of the reinforced concrete pier in combination to the infinitely rigid presence of the deck and to the presence of the rigid abutment if considered. Both the numerical models also account for the non-linear velocity-dependent behavior of the FPS bearings. Considering the aleatory uncertainty in the seismic input by means of several natural records with different characteristics, a parametric analysis is developed for several structural properties. The relevant results expressed as the statistics in non-dimensional form with respect to the seismic intensity have permitted to study the differences between the two numerical models in relation to the effectiveness of the seismic isolation.*

## 1 INTRODUCTION

Seismically isolated bridges permit to obtain a substantial reduction of the deck acceleration and, as consequence, of the forces transmitted to the pier in comparison to non-isolated bridges as widely demonstrated in many studies focusing with both elastomeric (LRB) and frictional (FPS) isolators [2]-[8]. This topic is in line with the issue of the infrastructure safety [9]-[10]. Tongaonkar and Jangid [11] evaluated the effects of soil-structure interaction on the peak responses of a three-span continuous deck bridge isolated by the elastomeric bearings particularly, showing their influence to assess the bearing displacements at abutment locations. Contextually, friction pendulum system (FPS) devices have been widely used for their capability to provide an isolation period mass independent and to assure high dissipation and re-centering in addition to their longevity and durability properties [12]-[14]. Several experimental and numerical researches have explored the behavior of the FPS devices [15]-[23]. The seismic response of isolated multi-span continuous deck bridges is investigated in [24] confirming the effectiveness of simplified models in relation to the flexibility of the deck and of the piers. In [25]-[26], it was carried out a large parametric analysis demonstrating the influence of the design parameters on the response of a three-dimensional multi-span continuous steel girder bridge model seismically isolated by the FPS isolators. Moreover, other works have been more oriented to develop design approaches for the isolators. In this context, the seismic reliability-based design (SRBD) approach has been proposed and widely discussed in [27]-[34] as a new methodology mainly aim to provide design solutions for seismic devices taking into account the main uncertainties relevant to the problem itself.

The main goal of this work consists in evaluating the influence of the pier-abutment-deck interaction on the seismic response of bridges isolated by single concave sliding pendulum isolators (FPS) mainly comparing the results with those coming from the seismic response of isolated bridges without considering the presence of the rigid reinforced concrete (RC) abutment (i.e., isolated viaducts). With this aim, two different multi-degree-of-freedom (mdof) models representative, respectively, of a single-column bent viaduct [22] and a multi-span continuous deck bridge [7],[13] are defined. Specifically, a six-degree-of-freedom model is used to represent the dynamic behaviour of both the isolated bridge systems. In fact, in both the mdof models, five vibrational modes are considered to describe the elastic behavior of the RC pier and an additional degree of freedom represents the response of the infinitely rigid RC deck isolated by the FPS devices. If considered, the presence of the RC abutment is assumed rigid and so no degree of freedom is related to that. The FPS isolator behavior is described through a widespread velocity-dependent model. In order to obtain a system response independent from the specific seismic source, a non-dimensional formulation of the motion equations proposed in [20] and herein extended and, in addition, a parametric analysis considering several structural properties is performed with the aim to investigate the differences between the two mdof models in relation to the relevant response parameters. The uncertainty in the seismic input is taken into account by means of a set of natural records with different characteristics. Finally, the optimum values of the sliding friction coefficient able to minimize the pier displacements relative to the ground as a function of the structural properties and of the seismic input intensity considering or neglecting the rigid presence of the abutment (i.e., single-column bent viaduct and multi-span continuous deck bridge) have been derived.

## 2 NON-DIMENSIONAL MOTION EQUATIONS

The motion equations, in terms of drifts between the different degrees of freedom, governing the seismic response when the isolated system refers to a multi-span continuous deck bridge (e.g., three-span continuous deck bridge) [7],[13], and the presence of the rigid RC abutment is considered (Figure 1(b)), subjected to the seismic input along the longitudinal direction,  $\ddot{u}_g(t)$ , are:

$$\begin{aligned}
 m_d \ddot{u}_d(t) + m_d \ddot{u}_{p5}(t) + m_d \ddot{u}_{p4}(t) + m_d \ddot{u}_{p3}(t) + m_d \ddot{u}_{p2}(t) + m_d \ddot{u}_{p1}(t) + c_d \dot{u}_d(t) + F_p(t) + F_a(t) &= -m_d \ddot{u}_g(t) \\
 m_{p5} \ddot{u}_{p5}(t) + m_{p5} \ddot{u}_{p4}(t) + m_{p5} \ddot{u}_{p3}(t) + m_{p5} \ddot{u}_{p2}(t) + m_{p5} \ddot{u}_{p1}(t) - c_{p5} \dot{u}_d(t) + c_{p5} \dot{u}_{p5}(t) + k_{p5} u_{p5}(t) - F_p(t) &= -m_{p5} \ddot{u}_g(t) \\
 m_{p4} \ddot{u}_{p4}(t) + m_{p4} \ddot{u}_{p3}(t) + m_{p4} \ddot{u}_{p2}(t) + m_{p4} \ddot{u}_{p1}(t) - c_{p5} \dot{u}_{p5}(t) - k_{p5} u_{p5}(t) + c_{p4} \dot{u}_{p4}(t) + k_{p4} u_{p4}(t) &= -m_{p4} \ddot{u}_g(t) \\
 m_{p3} \ddot{u}_{p3}(t) + m_{p3} \ddot{u}_{p2}(t) + m_{p3} \ddot{u}_{p1}(t) - c_{p4} \dot{u}_{p4}(t) - k_{p4} u_{p4}(t) + c_{p3} \dot{u}_{p3}(t) + k_{p3} u_{p3}(t) &= -m_{p3} \ddot{u}_g(t) \\
 m_{p2} \ddot{u}_{p2}(t) + m_{p2} \ddot{u}_{p1}(t) - c_{p3} \dot{u}_{p3}(t) - k_{p3} u_{p3}(t) + c_{p2} \dot{u}_{p2}(t) + k_{p2} u_{p2}(t) &= -m_{p2} \ddot{u}_g(t) \\
 m_{p1} \ddot{u}_{p1}(t) - c_{p2} \dot{u}_{p2}(t) - k_{p2} u_{p2}(t) + c_{p1} \dot{u}_{p1}(t) + k_{p1} u_{p1}(t) &= -m_{p1} \ddot{u}_g(t)
 \end{aligned} \tag{1}$$

where  $u_d$  denotes the horizontal displacement of the deck relative to pier,  $u_{p1}, u_{p2}, u_{p3}, u_{p4}, u_{p5}$  are the pier displacements relative between two consecutive dof,  $m_d, m_{p1}, m_{p2}, m_{p3}, m_{p4}, m_{p5}$  respectively the mass of the deck and of each dof of the pier,  $k_{p1}, k_{p2}, k_{p3}, k_{p4}, k_{p5}$  and  $c_{p1}, c_{p2}, c_{p3}, c_{p4}, c_{p5}$  respectively the stiffness and inherent viscous damping coefficient of each dof of the pier,  $c_d$  the bearing viscous damping factor,  $t$  the time instant, the dot differentiation over time.

Figure 1: 6dof model of a bridge isolated by FPS bearings without pier-abutment-deck interaction (i.e., viaduct) (a); 6dof model of a bridge isolated by FPS bearings considering pier-abutment-deck interaction (b); FPS response (c).

The forces related to both the isolator device placed at the pier level  $F_p(t)$  and at the abutment level  $F_a(t)$  are the following:

$$F_p(t) = \frac{m_d g}{2} \left[ \frac{1}{R_p} u_d(t) + \mu_p (\dot{u}_d) \text{sgn}(\dot{u}_d) \right] \tag{2a}$$

$$F_a(t) = \frac{m_d g}{2} \left[ \frac{1}{R_a} \left( u_d(t) + \sum_{i=1}^5 u_{pi} \right) + \mu_a \left( \dot{u}_d(t) + \sum_{i=1}^5 \dot{u}_{pi} \right) \operatorname{sgn} \left( \dot{u}_d(t) + \sum_{i=1}^5 \dot{u}_{pi} \right) \right] \quad (2b)$$

where  $k_d = W / R = m_d g / R$ ,  $g$  is the gravity constant,  $R$  is the radius of curvature of the FPS device,  $\mu(\dot{u}_d(t))$  the sliding friction coefficient, which depends on the bearing slip horizontal velocity  $\dot{u}_d(t)$  [31], and  $\operatorname{sgn}(\cdot)$  denotes the sign function. As reported in [14], the fundamental vibration period of an isolated bridge,  $T_d = 2\pi\sqrt{R/g}$ , corresponding to the pendulum behaviour component, depends only on the radius of curvature  $R$ . According to [16]-[19], the sliding friction coefficient of teflon-steel interfaces can be expressed by the following equation:

$$\mu(\dot{u}_d) = \mu_{\max} - (\mu_{\max} - \mu_{\min}) \cdot \exp(-\alpha |\dot{u}_d|) \quad (3)$$

where  $\mu_{\max}$  and  $\mu_{\min}$  represent, respectively, the maximum value of sliding friction coefficient attained at large velocities and the value at zero velocity. In this study, it is considered that  $\mu_{\max} = 3\mu_{\min}$  with the exponent  $\alpha$  equal to 30 [20].

What is worth underlying is that, differently to the reaction force of the seismic device on the pier, the reaction force as well as the friction coefficient related to the abutment isolator depend on both the horizontal velocity and displacement [31] of the deck with respect to the ground.

By dividing Eq. (1) by the mass deck  $m_d$ , the following equation system is obtained:

$$\ddot{u}_d(t) + \ddot{u}_{p5}(t) + \ddot{u}_{p4}(t) + \ddot{u}_{p3}(t) + \ddot{u}_{p2}(t) + \ddot{u}_{p1}(t) + 2\xi_d \omega_d \dot{u}_d(t) + \frac{g}{2} \left[ \frac{1}{R_p} u_d(t) + \mu_p(\dot{u}_d) \operatorname{sgn}(\dot{u}_d) \right] + \frac{g}{2} \left[ \frac{1}{R_a} \left( u_d(t) + \sum_{i=1}^5 u_{pi} \right) + \mu_a \left( \dot{u}_d(t) + \sum_{i=1}^5 \dot{u}_{pi} \right) \operatorname{sgn} \left( \dot{u}_d(t) + \sum_{i=1}^5 \dot{u}_{pi} \right) \right] = -\ddot{u}_g(t) \quad (4a)$$

$$\lambda_{p5} [\ddot{u}_{p5}(t) + \ddot{u}_{p4}(t) + \ddot{u}_{p3}(t) + \ddot{u}_{p2}(t) + \ddot{u}_{p1}(t)] - 2\xi_d \omega_d \dot{u}_d(t) + 2\xi_{p5} \omega_{p5} \lambda_{p5} \dot{u}_{p5}(t) + \lambda_{p5} \omega_{p5}^2 u_{p5}(t) - \frac{g}{2} \left[ \frac{1}{R_p} u_d(t) + \mu_p(\dot{u}_d) \operatorname{sgn}(\dot{u}_d) \right] = -\lambda_{p5} \ddot{u}_g(t) \quad (4b)$$

$$\lambda_{p4} [\ddot{u}_{p4}(t) + \ddot{u}_{p3}(t) + \ddot{u}_{p2}(t) + \ddot{u}_{p1}(t)] - 2\xi_{p5} \omega_{p5} \lambda_{p5} \dot{u}_{p5}(t) - \lambda_{p5} \omega_{p5}^2 u_{p5}(t) + 2\xi_{p4} \omega_{p4} \lambda_{p4} \dot{u}_{p4}(t) + \lambda_{p4} \omega_{p4}^2 u_{p4}(t) = -\lambda_{p4} \ddot{u}_g(t) \quad (4c)$$

$$\lambda_{p3} [\ddot{u}_{p3}(t) + \ddot{u}_{p2}(t) + \ddot{u}_{p1}(t)] - 2\xi_{p4} \omega_{p4} \lambda_{p4} \dot{u}_{p4}(t) - \lambda_{p4} \omega_{p4}^2 u_{p4}(t) + 2\xi_{p3} \omega_{p3} \lambda_{p3} \dot{u}_{p3}(t) + \lambda_{p3} \omega_{p3}^2 u_{p3}(t) = -\lambda_{p3} \ddot{u}_g(t) \quad (4d)$$

$$\lambda_{p2} [\ddot{u}_{p2}(t) + \ddot{u}_{p1}(t)] - 2\xi_{p3} \omega_{p3} \lambda_{p3} \dot{u}_{p3}(t) - \lambda_{p3} \omega_{p3}^2 u_{p3}(t) + 2\xi_{p2} \omega_{p2} \lambda_{p2} \dot{u}_{p2}(t) + \lambda_{p2} \omega_{p2}^2 u_{p2}(t) = -\lambda_{p2} \ddot{u}_g(t) \quad (4e)$$

$$\lambda_{p1} \ddot{u}_{p1}(t) - 2\xi_{p2} \omega_{p2} \lambda_{p2} \dot{u}_{p2}(t) - \lambda_{p2} \omega_{p2}^2 u_{p2}(t) + 2\xi_{p1} \omega_{p1} \lambda_{p1} \dot{u}_{p1}(t) + \lambda_{p1} \omega_{p1}^2 u_{p1}(t) = -\lambda_{p1} \ddot{u}_g(t) \quad (4f)$$

and the following ratios are introduced:

$$\omega_d = \sqrt{\frac{k_d}{m_d}}, \quad \omega_{pi} = \sqrt{\frac{k_{pi}}{m_{pi}}}, \quad \xi_d = \frac{c_d}{2m_d \omega_d}, \quad \xi_{pi} = \frac{c_{pi}}{2m_{pi} \omega_{pi}}, \quad \lambda_{pi} = \frac{m_{pi}}{m_d} \quad \text{with } i=1, \dots, 5 \quad (5)$$

The first two terms denote, respectively, the circular frequency of vibration of the isolated deck and of the  $i$ -th lumped mass of the pier;  $\xi_d$  is the damping factor of the isolated deck,

$\xi_{pi}$  is the damping factor corresponding to the  $i$ -th dof in which the pier has been discretized. The last term represents the  $i$ -th mass ratio between the  $i$ -th lumped mass of the pier and the deck mass.

With the aim to extend the non-dimensionalization approach proposed by [20]-[21], let us introduce the time scale  $\tau = t\omega_d$ , in which  $\omega_d = \sqrt{k_d / m_d}$  is the fundamental circular frequency of the isolated system with infinitely rigid superstructure, and the seismic intensity scale  $a_0$ , so that  $\ddot{u}_g(t) = a_0 \ell(\tau)$ , where  $\ell(\tau)$  is a non-dimensional function of time describing the seismic input time-history, the following non-dimensional equations can be obtained:

$$\ddot{\psi}_d(\tau) + \ddot{\psi}_{p5}(\tau) + \ddot{\psi}_{p4}(\tau) + \ddot{\psi}_{p3}(\tau) + \ddot{\psi}_{p2}(\tau) + \ddot{\psi}_{p1}(\tau) + 2\xi_d \dot{\psi}_d(\tau) + \left[ \frac{1}{2} \psi_d(\tau) + \frac{\mu_p(\dot{\psi}_d)g}{2a_0} \text{sgn}(\dot{\psi}_d) \right] + \left[ \frac{1}{2} \left( \psi_d(\tau) + \sum_{i=1}^5 \psi_{pi}(\tau) \right) + \frac{g}{2a_0} \left( \mu_d \left( \dot{\psi}_d(\tau) + \sum_{i=1}^5 \dot{\psi}_{pi}(\tau) \right) \right) \left( \text{sgn} \left( \dot{\psi}_d(\tau) + \sum_{i=1}^5 \dot{\psi}_{pi}(\tau) \right) \right) \right] = -\ell(\tau) \quad (6a)$$

$$\lambda_{p5} \left[ \ddot{\psi}_{p5}(\tau) + \ddot{\psi}_{p4}(\tau) + \ddot{\psi}_{p3}(\tau) + \ddot{\psi}_{p2}(\tau) + \ddot{\psi}_{p1}(\tau) \right] - 2\xi_d \dot{\psi}_d(\tau) + 2\xi_{p5} \frac{\omega_{p5}^2}{\omega_d^2} \lambda_{p5} \dot{\psi}_{p5}(\tau) + \lambda_{p5} \frac{\omega_{p5}^2}{\omega_d^2} \psi_{p5}(\tau) - \left[ \frac{1}{2} \psi_d(\tau) + \frac{\mu_p(\dot{\psi}_d)g}{2a_0} \text{sgn}(\dot{\psi}_d) \right] = -\lambda_{p5} \ell(\tau) \quad (6b)$$

$$\lambda_{p4} \left[ \ddot{\psi}_{p4}(\tau) + \ddot{\psi}_{p3}(\tau) + \ddot{\psi}_{p2}(\tau) + \ddot{\psi}_{p1}(\tau) \right] - 2\xi_{p5} \frac{\omega_{p5}^2}{\omega_d^2} \lambda_{p5} \dot{\psi}_{p5}(\tau) + 2\xi_{p4} \frac{\omega_{p4}^2}{\omega_d^2} \lambda_{p4} \dot{\psi}_{p4}(\tau) - \lambda_{p5} \frac{\omega_{p5}^2}{\omega_d^2} \psi_{p5}(\tau) + \lambda_{p4} \frac{\omega_{p4}^2}{\omega_d^2} \psi_{p4}(\tau) = -\lambda_{p4} \ell(\tau) \quad (6c)$$

$$\lambda_{p3} \left[ \ddot{\psi}_{p3}(\tau) + \ddot{\psi}_{p2}(\tau) + \ddot{\psi}_{p1}(\tau) \right] - 2\xi_{p4} \frac{\omega_{p4}^2}{\omega_d^2} \lambda_{p4} \dot{\psi}_{p4}(\tau) + 2\xi_{p3} \frac{\omega_{p3}^2}{\omega_d^2} \lambda_{p3} \dot{\psi}_{p3}(\tau) - \lambda_{p4} \frac{\omega_{p4}^2}{\omega_d^2} \psi_{p4}(\tau) + \lambda_{p3} \frac{\omega_{p3}^2}{\omega_d^2} \psi_{p3}(\tau) = -\lambda_{p3} \ell(\tau) \quad (6d)$$

$$\lambda_{p2} \left[ \ddot{\psi}_{p2}(\tau) + \ddot{\psi}_{p1}(\tau) \right] - 2\xi_{p3} \frac{\omega_{p3}^2}{\omega_d^2} \lambda_{p3} \dot{\psi}_{p3}(\tau) + 2\xi_{p2} \frac{\omega_{p2}^2}{\omega_d^2} \lambda_{p2} \dot{\psi}_{p2}(\tau) - \lambda_{p3} \frac{\omega_{p3}^2}{\omega_d^2} \psi_{p3}(\tau) + \lambda_{p2} \frac{\omega_{p2}^2}{\omega_d^2} \psi_{p2}(\tau) = -\lambda_{p2} \ell(\tau) \quad (6e)$$

$$\lambda_{p1} \ddot{\psi}_{p1}(\tau) - 2\xi_{p2} \frac{\omega_{p2}^2}{\omega_d^2} \lambda_{p2} \dot{\psi}_{p2}(\tau) + 2\xi_{p1} \frac{\omega_{p1}^2}{\omega_d^2} \lambda_{p1} \dot{\psi}_{p1}(\tau) - \lambda_{p2} \frac{\omega_{p2}^2}{\omega_d^2} \psi_{p2}(\tau) + \lambda_{p1} \frac{\omega_{p1}^2}{\omega_d^2} \psi_{p1}(\tau) = -\lambda_{p1} \ell(\tau) \quad (6f)$$

The non-dimensional parameters  $\psi_{u_d} = \frac{u_{d,peak} \omega_d^2}{a_0}$  and  $\psi_{u_p} = \frac{u_{p,peak} \omega_d^2}{a_0} = \frac{\left( \sum_{i=1}^5 u_{pi} \right)_{peak} \omega_d^2}{a_0}$  describe the peak dynamic response of the deck and of pier, respectively. Moreover, from Eq.(5), it is possible to observe that the five non-dimensional  $\Pi$  terms [20]-[21],[35]-[36] that control the system non-dimensional response are:

$$\Pi_{\omega_i} = \frac{\omega_{pi}}{\omega_d}, \quad \Pi_{\lambda_{pi}} = \lambda_{pi} = \frac{m_{pi}}{m_d}, \quad \Pi_{\xi_d} = \xi_d, \quad \Pi_{\xi_{pi}} = \xi_{pi} \quad \text{with } i = 1, \dots, 5 \quad (7)$$

in particular,  $\Pi_{\omega_i}$  represents the  $i$ -th frequency ratio,  $\Pi_{\lambda_{pi}}$  is the  $i$ -th mass ratio as previously defined,  $\Pi_{\xi_{pi}}$  and  $\Pi_{\xi_d}$  are the inherent viscous damping related to the  $i$ -th dof of the pier and to the isolator/deck, respectively. Regarding the control parameters of the pier, indeed, the parameters  $\omega_{pi}$  are related to the fundamental vibration pulsation  $\omega_p$  (the first vibration mode)

as well as the sum of the mass ratios is related to the overall mass ratio  $\Pi_\lambda = \lambda_p = \sum_{i=1}^5 m_{pi} / m_d$  and, finally, all the damping factors are assumed equal to  $\Pi_{\xi_p} = \xi_p$ .

The normalized friction coefficients for the FPS devices on the pier and on the abutment are the derived, respectively:

$$\Pi_{\mu_p}(\dot{\psi}_d) = \frac{\mu_p(\dot{\psi}_d)g}{a_0}, \quad \Pi_{\mu_a}\left(\dot{\psi}_d + \sum_{i=1}^5 \dot{\psi}_{pi}\right) = \frac{\mu_a\left(\dot{\psi}_d + \sum_{i=1}^5 \dot{\psi}_{pi}\right)g}{a_0} \quad (8)$$

and since these parameters depend on the response through the corresponding velocities, each one is used in its stead as follows [20]:

$$\Pi_{\mu_p}^* = \frac{\mu_{p,\max}g}{a_0}, \quad \Pi_{\mu_a}^* = \frac{\mu_{a,\max}g}{a_0} \quad (9)$$

It is worth underlining that even if the two FPS devices are equal,  $\Pi_{\mu_p}^* = \Pi_{\mu_a}^*$ , during the dynamic response the terms of Eq.(8) depend on different velocities.

On the other hand, in the case of a single-column bent viaduct (or neglecting the presence of the abutment) [22],[37], the same 6-degree-of-freedom (dof) model presented above, having 5 degrees of freedom for the elastic RC pier and 1 degree of freedom for the rigid RC deck mass equipped with FPS devices is adopted and shown in Figure 1(a).

The main difference in the form of the equation of motion when the abutment is neglected consists in the absence of the term related to the isolator force placed on the abutment and at the beginning of the paragraph indicated as  $F_a(t)$ .

Note that cracking phenomena [38]-[42] of the RC deck are herein neglected.

### 3 GROUND MOTIONS AND INTENSITY MEASURE

#### 3.1 Seismic records

In this study, the record-to-record variability is considered using 30 seismic records selected from 19 seismic different events [43]-[45]. Table 1 reports the details of the earthquakes used for the study.

#	Year	Earthquake Name	Recording Name	Station	Vs <sub>30</sub> [m/sec]	Source (Fault Type)	M	R [km]	PGA <sub>max</sub> [g]

### 3.2 Intensity measure

The intensity scale factor,  $a_0$ , of Eq. (5) is the seismic intensity measure ( $IM$ ) used in this study coherently with the performance-based earthquake engineering (PBEE) [46],[47]. In this study, the abovementioned term coincides with to the spectral pseudo-acceleration,  $S_A(T_d, \xi_d)$ , corresponding to the isolated period of the bridge  $T_d = 2\pi / \omega_d$  with the damping ratio  $\Pi_{\xi_d} = \xi_d$ . As also observed in [20]-[22], since the spectral acceleration is related to the spectral displacement  $S_A(T_b, \xi_d) = \omega_d^2 S_d(T_d, \xi_d)$ , if all the records are normalized with respect to  $S_A(T_d, \xi_d)$ , the normalized displacement and force of the isolated bridge deck, in the hypothesis of both a rigid substructure (pier) and absence of the sliding friction, are equal to 1 for each record without any record-to-record variability. In the following analysis, the damping ratio  $\xi_d$  is set equal to zero [20],[34],[48] and the corresponding  $IM$  is hereinafter denoted to as  $IM=a_0=S_A(T_d)$ .

## 4 PARAMETRIC STUDY

In the analysis carried out in this study, the effects of higher order modes due to the flexibility of the elastic RC pier together with of the pier-abutment-deck interaction are investigated and the seismic performance of isolated bridges is assessed. This section describes the results of the parametric study carried out on the two systems of Figure 1 to evaluate the performance of bridge isolated with FPS bearings for different structural properties. The first subsection deals with the response parameters relevant to the seismic performance and the second subsection illustrates the parametric study results.

### 4.1 Non-dimensional response parameters examined

The following response parameters relevant to the seismic performance assessment of isolated bridges are considered: the peak deck displacement relative to the pier for the model of Figure 1(a) as well as the peak deck displacement relative to the pier or to the abutment for the model of Figure 1(b),  $u_{d,peak}$ , either important for the design of the FPS isolator and of

the seismic joint deck-abutment, the peak pier displacement  $u_{p, peak} = (\sum_{i=1}^5 u_{p_i})_{peak}$  (related to the internal forces in the bridge substructure) for the both models. All these relevant response parameters can be defined in non-dimensional form, in line with Eq.s (4) and (6), as follows:

$$\psi_{u_d} = \frac{u_{d, peak} \omega_d^2}{a_0}, \quad \psi_{u_p} = \frac{u_{p, peak} \omega_d^2}{a_0} = \frac{(\sum_{i=1}^5 u_{p_i})_{peak} \omega_d^2}{a_0} \quad (10)$$

Eq.s (4) and (6) are repeatedly and numerically solved in Matlab–Simulink [49] computing a set of samples for each response parameter for the two structural models. As also described in [20],[21],[48],[50], the response parameters are modeled in probabilistic terms [51]–[58]: the generic response parameter  $D$  (i.e., the extreme values  $\psi_{u_d}$ ,  $\psi_{u_p}$  of Eq. (10)) can be fitted by a lognormal distribution estimating the sample geometric mean,  $GM(D)$ , and dispersion,  $\beta(D)$ , defined, respectively:

$$GM(D) = \sqrt[N]{d_1 \cdot \dots \cdot d_N} \quad (11)$$

$$\beta(D) = \sigma_{\ln}(D) = \sqrt{\frac{(\ln d_1 - \ln[GM(D)])^2 + \dots + (\ln d_N - \ln[GM(D)])^2}{N-1}} \quad (12)$$

in which  $d_h$  is the  $h$ -th sample realization of  $D$ , and  $N$  represents the total number of samples (i.e., ground motions):  $h=1, \dots, N$ . The  $k$ th percentile of the response parameter  $D$  can be evaluated as:

$$d_k = GM(D) \exp[f(k)\beta(D)] \quad (13)$$

where  $f(k)$  is a function that assumes the following values  $f(50)=0$ ,  $f(84)=1$  and  $f(16)=-1$  [59], for the 50<sup>th</sup>, 16<sup>th</sup> and 84<sup>th</sup> percentile, respectively.

## 4.2 Non-dimensional results

In this section, the results of the parametric study for the two structural configurations developed on the equivalent 6dof systems, for the different structural properties and 30 ground motion records, are illustrated and commented. Specifically, in line with [2],[11],[13],[25],[60], the parameters  $\Pi_{\xi_d} = \xi_d$  and  $\Pi_{\xi_p} = \xi_p$  are assumed respectively equal to 0% and 5%, the isolation period  $T_d$  varies in the range between 2s, 2.5s, 3s, 3.5s and 4s, the elastic RC pier period  $T_p$  equal to 0.2s,  $\Pi_{\lambda} = \lambda$  between 0.1, 0.15 and 0.2,  $\Pi_{\mu}^*$  between 0 and 2. The latter one is related to the FPS device on the pier for the model without the abutment and to the FPS isolators, assumed equal, on the pier and on the abutment for the model of Figure 1(b):  $\Pi_{\mu p}^* = \Pi_{\mu a}^* = \Pi_{\mu}^*$ . For each parameter combination and for the two structural configurations, the differential motion equations (Eq.s (6) and (12)) have been repeatedly and numerically solved adopting the Bogacki-Shampine and Runge-Kutta-Fehlberg integration algorithm available in Matlab-Simulink [49]. After that, for each normalized response parameter, the geometric mean,  $GM$ , and the dispersion,  $\beta$ , have been evaluated by means of Eq.s (11) and (12) and are illustrated in Figures 2-3 for the both structural models. Each figure con-

tains different meshes as many as the values of  $\Pi_\lambda$ : the arrow indicates the increasing values of  $\Pi_\lambda$ . Note that for the configuration with the pier-abutment-deck interaction (i.e., multi-span continuous deck bridge), the peak normalized deck displacement, showed in Figures 2, has always been the one between the deck and the abutment. This is because of the elastic response of the pier that reduces the relative displacement between the deck and itself.

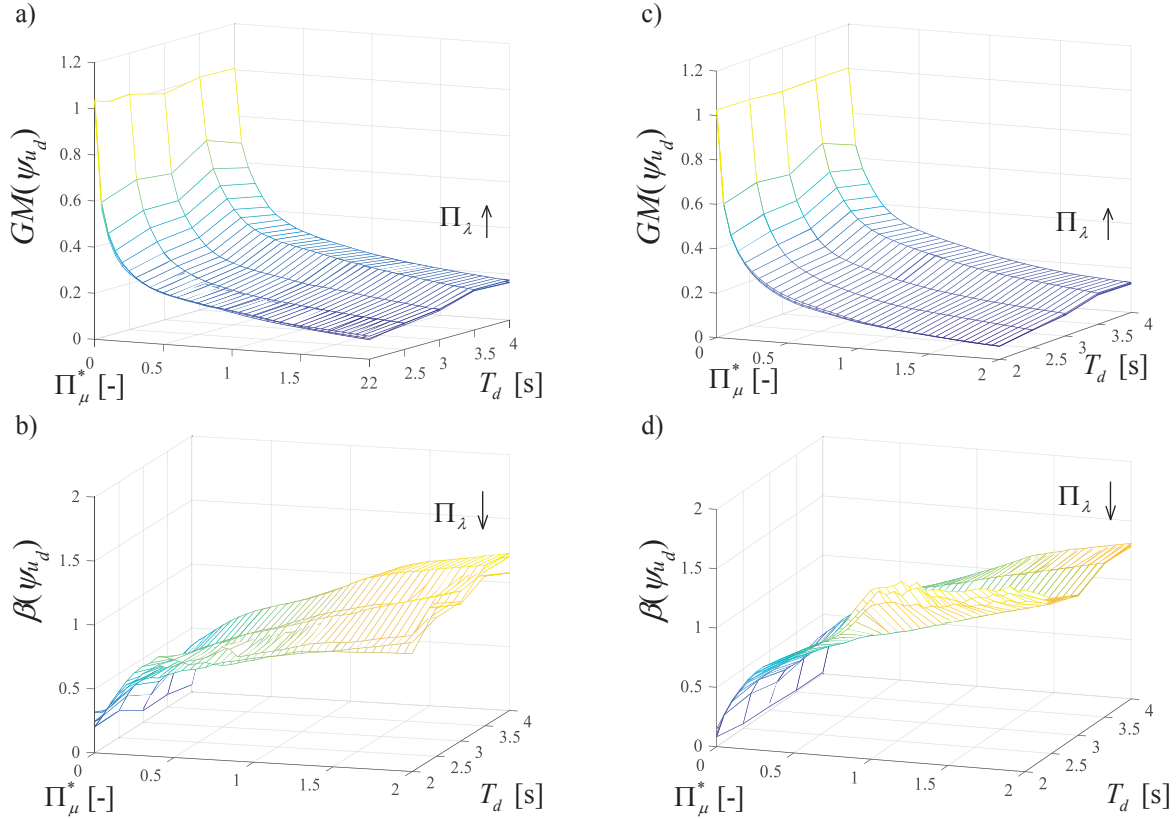

Figure 2: Normalized deck displacement vs.  $\Pi_\mu^*$  and  $T_d$ : median value ((a): analysis with only pier; (c): analysis with the pier-abutment-deck interaction) and dispersion ((b): analysis with only pier; (d): analysis with the pier-abutment-deck interaction) for  $T_p=0.2$ s and for different values of  $\Pi_\lambda$ .

In Figures 2,  $GM(\psi_{u_d})$  is quite equal to unit for  $\Pi_\mu^* = 0$ . For  $\Pi_\mu^* \neq 0$ ,  $GM(\psi_{u_d})$  increases slightly for increasing  $T_d$  because of the period elongation. Obviously,  $GM(\psi_{u_d})$  decreases significantly as  $\Pi_\mu^*$  increases showing an hyperbolic trend while it is not heavily influenced by  $\Pi_\lambda$ . The dispersion  $\beta(\psi_{u_d})$ , for high  $T_d$ , increases for increasing values of  $\Pi_\mu^*$ , as a result of the reduction of the efficiency of the IM. Obviously, in the situation corresponding to  $\Pi_\mu^* = 0$ , the dispersion is quite zero for all the values of  $T_d$  and of  $\Pi_\lambda$  considered. The mass ratio  $\Pi_\lambda$  does not affect significantly the response dispersion. Despite the trends of the both statistics are similar for the two configurations, it is possible to observe that the values of  $GM(\psi_{u_d})$  are larger in the case of the model without the pier-abutment-deck interaction. On the other hand, higher values of  $\beta(\psi_{u_d})$  are achieved for the model with the pier-abutment-deck interaction.

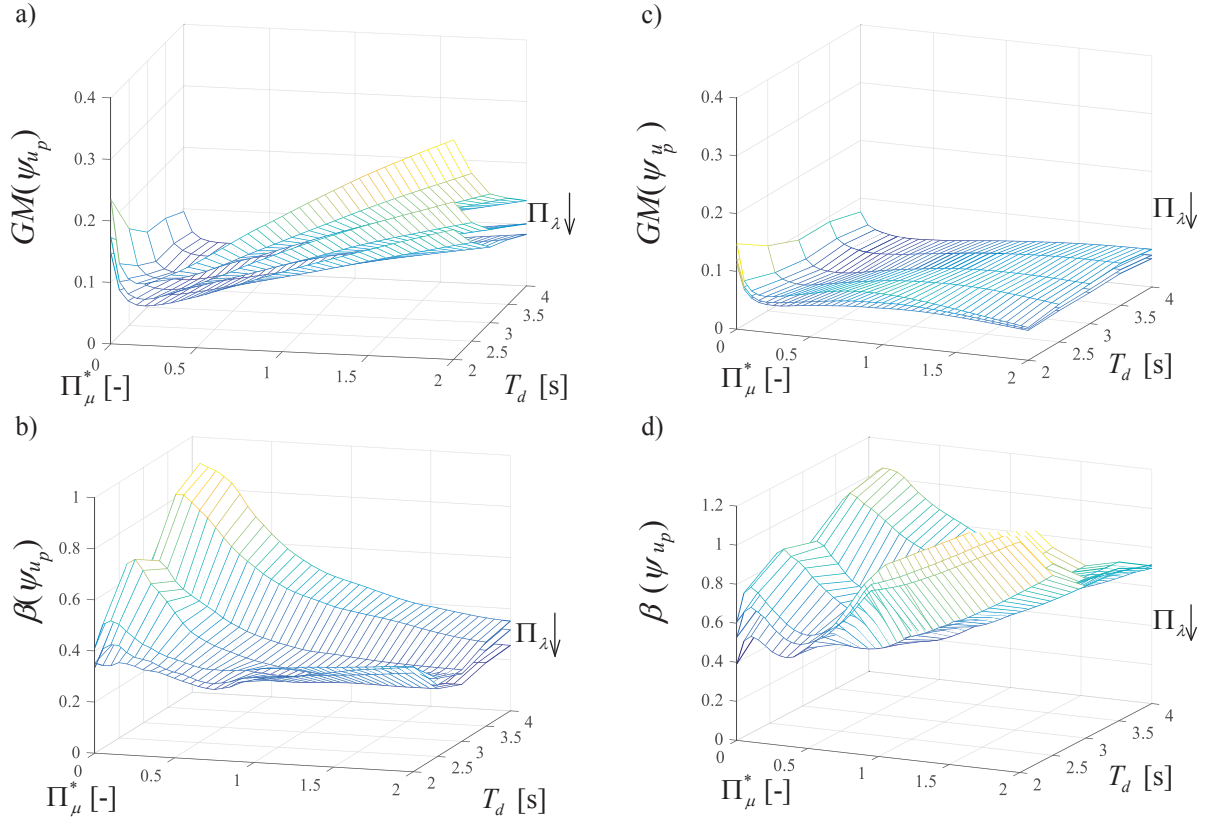

Figure 3: Normalized pier displacement vs.  $\Pi_\mu^*$  and  $T_d$ : median value ((a): analysis with only pier; (c): analysis with the pier-abutment-deck interaction) and dispersion ((b): analysis with only pier; (d): analysis with the pier-abutment-deck interaction) for  $T_p=0.2s$  and for different values of  $\Pi_\lambda$ .

Figure 3 represents the response statistics of the normalized pier displacement  $\psi_{u_p}$ . For the both structural configurations,  $GM(\psi_{u_p})$  decreases for higher values of  $T_d$  and of  $\Pi_\lambda$  as well as for decreasing values of  $T_p$ ; whereas it first decreases and then increases for increasing values of  $\Pi_\mu^*$ , meaning that there is an optimal value of  $\Pi_\mu^*$  able to minimize the geometric mean of the pier displacement. This optimal value varies in a range that depends on the values of  $T_d$  and  $\Pi_\lambda$  and on the structural configuration. Note also that for not optimal values of  $\Pi_\mu^*$ ,  $GM(\psi_{u_p})$  is not so high. Conversely,  $GM(\psi_{u_p})$  presents higher values for the structural configuration without the pier-abutment-deck interaction (i.e., single-column bent viaduct). The values of the dispersion  $\beta(\psi_{u_p})$  are very low for low  $\Pi_\mu^*$  values due to the high efficiency of the *IM* used in this work, and reach their peak for values of  $\Pi_\mu^*$  close to the optimal ones. The other system parameters have a reduced influence on  $\beta(\psi_{u_p})$  compared to the influence of  $\Pi_\mu^*$ . Higher values are achieved for the structural configuration with the pier-abutment-deck interaction (i.e., multi-span continuous deck bridge).

## 5 OPTIMAL VALUES OF THE SLIDING FRICTION COEFFICIENTS

Once the results from the analysis are obtained, for each parameter combination (i.e.,  $\Pi_\lambda$  and  $T_d$ ) and structural model (i.e., single-column bent viaduct and multi-span continuous deck bridge), the optimal values of the normalized sliding friction coefficient,  $\Pi_{\mu, \text{opt}}^*$ , that minimize the median (50<sup>th</sup> percentile) of the normalized pier displacements  $\psi_{u_p}$  have been assessed and are reported in Figure 4. Figure 4 reports the variation of  $\Pi_{\mu, \text{opt}}^*$  with  $\Pi_\lambda$  and  $T_d$  and in relation to the two structural models (Figure 4a,b). The optimal values of the sliding friction coefficient manifest a slightly increase as  $T_d$  decreases, and this is valid for the either the configurations. It is also observed that, especially for high  $T_d$  values,  $\Pi_{\mu, \text{opt}}^*$  increases by increasing  $\Pi_\lambda$  in order to dissipate more energy.

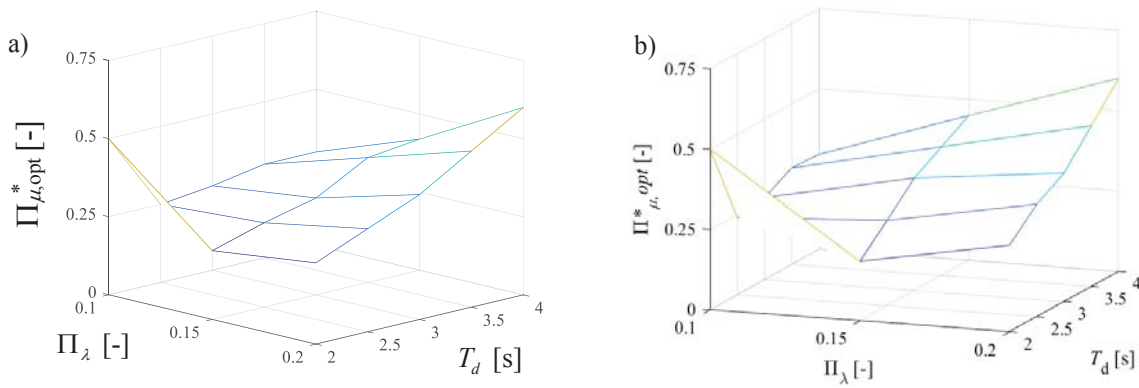

Figure 4: Optimal values of normalized friction that minimize the 50<sup>th</sup> percentile of the normalized pier displacements vs.  $\Pi_\lambda$  and  $T_d$ , for  $T_p=0.2\text{s}$ ; (a) with only pier; (b) with the pier-abutment-deck interaction.

## 6 CONCLUSIONS

This paper summarizes the seismic performance of bridges and viaducts isolated with single concave friction pendulum system bearings focusing on the influence of the pier-abutment-deck interaction on the seismic response. The analysis carried out aim to define the optimal isolator friction properties taking into account the uncertainty in the seismic input. Adopting the nondimensionalization of the motion equations, a wide parametric analysis considering several structural properties has been conducted by monitoring the response parameters of interest regarding both an isolated bridge where only the pier response is considered and an isolated bridge where the interaction between pier and abutment is taken into account (i.e., single-column bent viaduct and multi-span continuous deck bridge, respectively). The seismic response of these systems is modelled by employing a six-degree-of-freedom system mainly to capture the effects due to the higher modes of the elastic pier.

As far as the deck response is concerned, the geometric mean of the normalized deck displacement tends to slightly increase for increasing isolation period because of the period elongation and it decreases significantly as the normalized friction increases. It presents higher values in the case of the model with only pier (i.e., single-column bent viaduct). The dispersion increases for increasing both isolation period and normalised friction coefficient. It presents higher values in the case of the model with the pier-abutment-deck interaction.

With regards to the pier response, the geometric mean of the normalized displacement decreases for increasing values of isolation period and of mass ratio, whereas it first decreases

and then increases for increasing values of normalized friction. Assuming that, an optimal value of normalized friction coefficient such that the pier displacement is minimized does exist. Regarding the dispersion, higher values are observed for the pier-abutment-deck interaction model.

Finally, the optimal values of the normalized friction coefficient, able to minimize the 50<sup>th</sup> percentile of the pier response, as a function of the structural properties and for the both structural models, are estimated. Higher optimum friction coefficients are required, when the pier-abutment-deck interaction (i.e., multi-span continuous deck bridge) is taken into account.

### Abstract

*Cantilever walls are a popular type of retaining system. The slip mode of failure of these retaining systems under seismic loading has recently been studied. Cantilever walls must be designed in a manner such as to minimize the seismic displacement. The "conventional" sliding-block model is the most commonly used simplified model predicting the seismic displacement of slopes for given earthquake motions. However, in dynamic analyses, usually the seismic motion is applied at the underlying bedrock and the seismic displacement along a slip surfaces depends not only on the seismic response of the slip surface, but also on the dynamic characteristics of the soil profile both above and below the slip surface. The present work proposes a cost-effective method predicting the seismic displacement of cantilever walls, and applies it for their smart design. In order to achieve the paper first proposes a method predicting the critical acceleration value of cantilever walls retaining systems by application of equations predicting the critical acceleration value for gravity walls for the slip mode of failure of these retaining systems. Then the paper proposes a method predicting the seismic displacement of cantilever walls considering the dynamic response of the underlying soil profile by applying a recently developed 1-D 2-body dynamic stick-slip method at the particular geometry of cantilever walls. Finally, based on the above, the paper proposes a cost-effective method for smart design of cantilever walls, and presents a typical example. The work illustrated that the de-amplification effect of the seismic response can be crucial if the soil underlying the wall is soft and deep and in this case a wall with a looser backfill may be preferable.*

## 1 INTRODUCTION

Engineers usually assess the seismic safety of slopes and retaining structures using the dynamic factor of safety calculated from loads. However, evaluations based on the dynamic factor of safety have the serious drawback that they do not consider the seismic displacement, which is directly related to damage and recently design of retaining structures is based on prediction of the seismic displacement along its slip surface and its comparison with the tolerable displacement that this structure can sustain [1].

Cantilever walls of L or inverted T-shape are a popular type of retaining system. The design exploits the stabilizing action of soil weight over the footing slab against both sliding and overturning. It is widely considered as advantageous over conventional gravity walls for it combines economy and ease in construction and installation [2]. Design of cantilever walls depends on its dimensions, but also the soil type used in the backfill, as well as its compaction. Cantilever walls must be designed in a manner such as to minimize the seismic displacement. The slip mode of failure of these earth structures under seismic loading has been studied by Kloukinas et al. [3]. However, the seismic displacement along a slip surface and, additionally, its dependence on the dynamic characteristics of the backfill and the soil profile below has not been studied.

The "conventional" Newmark sliding-block model [4], illustrated in Fig. 1, is the most commonly used simplified model predicting the seismic displacement of natural slopes and retaining structures for given earthquake motion [1, 5, 6]. As illustrated in Fig. 1a, a rigid block rests on an inclined plane. The resistance along the block-inclined plane boundary follows the Mohr-Coulomb law. Critical acceleration is the minimum horizontal acceleration which causes movement of the block. Every time where the applied horizontal acceleration is larger than the critical acceleration, the block slides. The total displacement is obtained by the addition of the partial slips. This model is used for the prediction of permanent seismic movement of slopes and retaining structures along a predefined slip surface, by appropriately selecting the equivalent critical and applied acceleration values of the rigid block [5]. For gravity walls, according to the Monobe-Okabe theory [7, 8], methods have been developed to determine the critical acceleration value, both by iteration [9] and analytically by first indicating the appropriate slip surface [10, 11].

In dynamic analyses, usually the seismic motion is applied at the underlying bedrock and the seismic displacement along a slip surfaces depends not only on the seismic response of the slip surface, but also on the dynamic characteristics of the soil profile both above and below the slip surface [12-14]. Katsenis et al., [13, 14] simulated the effect of the soil profile on the seismic displacement along the slip surface using a 1-D dynamic system of 2 continuous bodies separated by a horizontal slip which simulates the seismic displacement of the conventional sliding-block model.

The present work proposes a method predicting the seismic displacement of cantilever walls, and applies it for its smart design. In particular, the simplified geometry of Fig. 2 and table 1 of a cantilever wall above a soil layer is considered. In order to achieve the paper first proposes a method predicting the critical acceleration value of cantilever walls by application of equations predicting the critical acceleration value for gravity walls given by [11] for the slip mode of failure of these retaining systems identified by [3]. Then the paper proposes a method predicting the seismic displacement of cantilever walls considering the dynamic response of the soil profile be first describing the Katsenis et al. [13] model and then applying it at the particular geometry of cantilever walls. Finally, the paper proposes smart design of cantilever walls by first presenting typical results of the Katsenis et al. [13, 14] model and then applying them for cantilever walls smart design.

## 2 PROPOSED METHOD PREDICTING THE CRITICAL ACCELERATION OF CANTILEVER WALLS

### 2.1 State of the art: The critical acceleration value for gravity walls

Gravity walls are relatively rigid structures walls used for supporting soil laterally so that it can be retained (Fig. 3a). The applied force in walls under a horizontal acceleration value is estimated by the Mononobe-Okabe equation [7, 8], and typically iteration is performed to estimate the estimate the critical acceleration causing failure, i.e. the value for limit equilibrium [9-11]. Furthermore, Stamatopoulos and Velgaki [10] observed that for failure of gravity walls, a wedge in the backfill behind the wall reaches an active state, and that the wall and the backfill slide outward, and thus the soil-wall system consists really of two bodies: (a) the active soil wedge that slides with the inclination of least resistance in the backfill, and (b) the wall that slides along the soil-wall boundary in the foundation (Fig. 3b).

Stamatopoulos et al. [11] developed an analytical equation predicting the critical acceleration value of the soil-wall system of Fig. 3a and table 2, by solving the force equilibrium equations assuming a geometry consisting of two rigid blocks [15]. For a horizontal wall and backfill with inclination  $\alpha_{B-i}$  and for only frictional resistance at both the backfill and the soil-wall boundaries, this equation gives

$$a_{c-i} = g AA_B / BB_B \quad (1a)$$

where  $g$  is the acceleration of gravity

$$AA_b = X G [(1 + A_i B)(1 + FD) - (B - A_i)(F - D)] - \frac{(DA_i - 1)(B - A_i)[(1 + FD) - G(F - D)]}{A_i} \quad (1b)$$

$$BB_b = X [(1 + A_i B)(1 + FD) - (B - A_i)(F - D)] - \frac{(DA_i - 1)(1 + A_i B)[(1 + FD) - G(F - D)]}{A_i} \quad (1c)$$

and

$$\begin{aligned} X &= 2 W_W / (\gamma H_o^2), & D &= \tan \delta, & B &= \tan \phi_B, \\ G &= \tan \phi_W, & F &= \tan \phi_i, & A_i &= \tan \alpha_{B-i} \end{aligned} \quad (1d)$$

where the parameters  $W_W$ ,  $\gamma$ ,  $H_o$ ,  $\delta$ , ( $\alpha_{Bcr-i}$ ) are illustrated in Fig. 3,  $\phi_B$  is the frictional resistance at the backfill,  $\phi_W$  is the frictional resistance at the foundation soil-wall boundary and  $\phi_i$  is the frictional resistance at the backfill soil-wall boundary.

The critical acceleration value  $a_c$  corresponds to the critical rupture angle  $\alpha_{Bcr-i}$  which is the value of  $\alpha_{B-i}$ , which minimizes  $a_{c-i}$  in Eq. (1). As illustrated by [10],  $a_{c-i}$  is a parabola in terms of ( $\alpha_{B-i}$ ), having a single well-defined minimum. It is inferred that estimating numerically  $A_i$ , and thus  $\alpha_{Bcr-i}$  also, is a simple matter using, for example, the bisection method [16].

Figure 3: (a) Wall- retained soil geometry considered by [11] and (b) its simulation with a two-body model [11]

	Parameter	Symbol	For Cantilever wall
Wall	Weight	$W$	$W=W_c + \gamma_b H_c [b + H_c \tan(\alpha_i - \phi_b)]/2$
	Friction angle at base	$\phi_w$	$\phi_c$
Backfill	Height	$H$	$H_c$
	Unit density	$\gamma$	$\gamma_s$
	Friction angle	$\phi_b$	$\phi_s$
Soil-wall interface	Friction angle	$\phi_i$	$\phi_s$
	Inclination	$\delta$ (Fig. 5)	$\alpha - \phi_b$

Table 2: Parameters which define the Stamatopoulos et al. [11] model considered in section 2.1 and the corresponding values for the cantilever wall of Fig. 2.

## 2.2 The critical acceleration value of cantilever walls

Figure 4 presents the mode of failure of cantilever walls proposed by Kloukinas et al. [3], where  $\theta_2$  is related to  $\theta_1$  and the frictional resistance of the backfill ( $\phi_b$ ) as

$$\theta_2 = \theta_1 - \phi_b \quad (2)$$

Based on this mode of failure, it can be inferred that the sliding mechanism of cantilever walls can be simulated as a wall-backfill 2-body system of Fig. 3, where the first body corresponds to the cantilever wall and part of the backfill to the left of the slip segment AA' of Fig. 4, and the second body corresponds to the backfill part to the right of the slip segment AA' of Fig. 4. Table 2 gives the equivalent values of the system of Fig. 3 solving the cantilever wall of Fig. 2. A condition needed for this solution, is that the slip surface passes through the ground surface of the backfill, or that

$$\tan(\alpha_{b-i} - \phi_b) < b/H_c \quad (3)$$

It is inferred that equations (1) and the procedure outlined in section 2.1 with the values given in table 2 and the condition of equation (3) can be applied to estimate the critical acceleration value for relative motion of cantilever walls of the geometry of Fig. 2. A microsoft excel worksheet was programmed to estimate the critical acceleration value of cantilever walls of the geometry of Fig. 2, based on the procedure described above.

Figure 4: The mode of failure of cantilever walls proposed by Kloukinas et al. [3], where  $\theta_2$  is related to  $\theta_1$  with equation (2)

### 3 PROPOSED METHOD PREDICTING THE SEISMIC DISPLACEMENT OF CANTILEVER WALLS CONSIDERING THE DYNAMIC RESPONSE OF THE SOIL PROFILE

#### 3.1 State of the art: The Katsenis et al., [13, 14] model

Katsenis et al. [13, 14] simulated the field configuration of a slope with a slip surface where seismic displacement may accumulate as a result of a horizontal shear wave of Fig. 5a with a 1-D dynamic system of 2 continuous bodies separated by a horizontal slip element. In particular, the Katsenis et al., [13, 14] model, illustrated in Fig. 5b and table 3, considers the 1-dimensional dynamic response of a horizontal soil profile of depth  $(h_1+h_2)$  with a slip element at depth  $h_1$ . Different shear wave velocities ( $V_{s-1}$ ,  $V_{s-2}$ ), densities ( $\rho_1$ ,  $\rho_2$ ) and damping ( $\lambda_1$ ,  $\lambda_2$ ) may exist above and below the slip element. The slip element simulates the seismic displacement of the conventional sliding-block model, where its resistance is defined by the critical horizontal value ( $a_c$ ), for which relative movement in only one direction occurs.

The numerical code associated with the numerical model above is derived by extending the derivation proposed by [17]. When seismic displacement accumulates along the slip surface, the method simulates the independent movement of the two bodies, and thus the solution is “coupled”. Additional options exist in the model where (a) the rotation of the slip surface with displacement is simulated by adjusting the critical acceleration value ( $a_c$ ) in terms of the accumulated seismic displacement and (b) the non-linear shear stress-strain response of the soil profile is simulated. However, these options are not applied in the present application.

When applying the model, if the soil profile of body  $i$  is non-uniform, the average properties may be used [14]. In this respect, in the case of stratified deposit with  $M_i$  sub-layers with height  $H_{k-i}$  and shear wave velocity  $VS_{k-i}$ , it is recommended to estimate  $VS_i$  based on an equation proposed by Vijayendra et al. [18] as:

$$VS_i = \frac{h_i}{\sum_{k=1}^{M_i} \frac{H_{k-i}}{VS_{k-i}}} \quad (4)$$

Figure 5: The Katsenis et al. [13, 14] model: (a) field configuration of a slope with a slip surface where seismic displacement may accumulate as a result of a horizontal shear wave, (b) simulation of (a) with a 1-D dynamic system of 2 continuous bodies separated by a horizontal slip element.

	Parameter	Symbol	For Cantilever wall
Upper (1) Body	Height	$h_1$	$H_b/2$
	Shear Wave velocity	$V_{s-1}$	$V_{s-b}$
	Density	$\rho_1$	$\rho_b$
Lower (2) Body	Height	$h_2$	$H_s + H_b/2$
	Shear Wave velocity	$V_{s-2}$	$(H_b/2 + H_s) / [H_b/(2 V_{s-b}) + H_s/V_{s-s}]$
	Density	$\rho_2$	$(H_b/2 + H_s) / [H_b/(2 \rho_b) + H_s/\rho_s]$
Slip surface	Critical acceleration for relative movement	$a_c$	Specified in section 2.2

Table 3: Parameters which define the Katsenis et al. [13, 14] model for the linear case. The corresponding values when this model is applied to simulate cantilever walls is also given.

### 3.2 Proposed method

In order to perform the numerical simulation of the seismic displacement of the cantilever wall of Fig. 2 considering the dynamic response of the soil profile both above and below the slip surface, we apply the 1-D coupled stick-slip dynamic model of Fig. 5b. The upper body of the dynamic system corresponds to the wall backfill above the slip plane. The lower body of the dynamic system corresponds to the wall backfill below the slip plane and the underlying soil profile. The critical acceleration of the stick-slip element for a cantilever wall was evaluated in section 3.

Based on the above, table 3 gives the corresponding when the Katsenis et al. [13, 14] model is applied to simulate the response of the cantilever wall of Fig. 2. As body 2 corresponds to both the wall backfill below the slip plane and the underlying soil profile, the average values are obtained using equation (3).

## 4 SMART DESIGN OF CANTILEVER WALLS

### 4.1 Results of the Katsenis et al. [14] model

Katsenis et al. [14] present the computed permanent seismic displacement ( $u_f$ ) for the Aegion 1995 seismic motion with  $a_c=0.5\text{m/s}^2$  and (ii) Mid-Niigata Prefecture 2004 seismic motion with

$a_c=3\text{m/s}^2$ . Table 4 gives the characteristics of the input motions considered and the critical acceleration  $a_c$  was selected as  $0.5\text{m/s}^2$  and  $3\text{m/s}^2$  for the input motions (i) and (ii) respectively, because they correspond to a rigid system having seismic displacement of about 5-10cm, which is the tolerable displacement value for typical structures.

In particular, they define

$$T_{s1}=4 h_1/V_{s-1} \quad (5a)$$

$$T_{s-ave} = 4 (h_1/V_{s-1} + h_2/V_{s-2}) \quad (5b)$$

and Fig. 6 presents the computed permanent seismic displacement ( $u_f$ ) versus (a)  $T_{s1}/T_m$  for  $h_1+h_2=30\text{m}$ ,  $\rho_1=\rho_2=2 \text{ Mg/m}^3$  and  $\lambda_1=\lambda_2=0.15$  (a) for the coupled case with  $V_{s-2}=V_{s-1}$ ,  $h_2=1\text{m}$ ,  $15\text{m}$ ,  $25\text{m}$ , (b)  $T_{s1}/T_m$  for  $h_2=15\text{m}$ ,  $V_{s-2}= 25, 75, 150, 300, 500, 5000\text{m/s}$  and (c)  $T_{s-ave}/T_m$  of the results of Figs (a), (b) for (i) the Aegion 1995 seismic motion with  $a_c=0.5\text{m/s}^2$  (ii) Mid-Niigata Prefecture 2004 seismic motion with  $a_c=3\text{m/s}^2$ . Table 4 gives the characteristics of the input motions considered.

It can be observed that if  $u_f$  is plotted in terms of the ratio  $T_{s-ave}/T_m$ , the scatter in results for different  $V_{s2}$  and  $h_2$  decreases considerably. It is inferred that the dynamic effect on  $u_f$  can partly be interpreted by relating  $u_f$  to  $T_{s-ave}$ . In particular, similarly to the response predicted by [16], but by replacing  $T_s$  with  $T_{s-ave}$ , it can be observed that the dynamic response (a) does not exist for  $T_{s-ave}=0$ , (b) as  $T_{s-ave}$  increases, it produces maximum response when  $T_{s-ave}$  approximately when  $T_{s-ave}=T_m$  and (c) as  $T_{s-ave}$  further increases, the dynamic response decreases towards zero.

#### 4.2 Indicative approximate criterion for de-amplification

According to Fig 6, the seismic displacement decreases and takes values less than  $0.05m$ , at large values of the ratio  $Ts\text{-ave}/T_m$ , and certainly when

$$Ts\text{-ave} / T_m > 4 \quad (6a)$$

According to Eurocode 8 [21] at rock site the dominant period is less than  $0.4 \text{ sec}$ . It is inferred that de-amplification of the seismic response occurs when

$$Ts\text{-ave} > 1.6s \quad (6b)$$

According to equations (4) and (5b), in the canteliver wall of Fig. 2,

$$T_{s-ave} = 4 (H_b/V_{s-b} + h_s/V_{s-s}) \quad (7)$$

Thus, according to eqs. (6b) and (7), for de-amplification of the seismic response

$$4 (H_b/V_{s-b} + h_s/V_{s-s}) > 1.6s \quad (8a)$$

or

$$H_b/V_{s-b} > 0.4s - H_s/V_s \quad (8c)$$

Fig. 7 presents the limit shear wave velocity of the backfill ( $V_{s-b}$ ) in terms of the height of the backfill ( $H_b$ ) and the ratio ( $H_s/V_{s-s}$ ) of the underlying soil satisfying equation (8c). Figure 7 illustrates that the de-amplification effect of the seismic response can be crucial for loose backfill and if the soil underlying the wall is soft and deep. On the other hand, for small ratios of ( $H_s/V_{s-s}$ ) of the underlying soil, smaller than 0.1, the de-amplification requires  $V_{s-b}$  values for the backfill, which are too small for practical application.

Figure 7: The limit shear wave velocity of the backfill ( $V_{s-b}$ ) in terms of the height of the backfill ( $H_b$ ) and the ratio ( $H_s/V_{s-s}$ ) of the underlying soil satisfying equation (8c).

### 4.3 Proposed smart design method

Typically, in cases where cantilever walls must be designed, the density of the backfill may be selected from loose to dense and this may affect the seismic displacement. Table 5 gives typical values of shear wave velocity [19], frictional resistance [20] and unit density in terms of soil density. Certainly dense construction is more costly and considering the soil strength along the slip surface produces less displacement. However, this may not hold in all cases: the previous section illustrated that considerable de-amplification may occur in softer layers.

The model proposed in section 3 above, which simulates in a cost-effective manner not only the mode of failure and corresponding displacement along the slip surface, but also the dynamic response of the backfill and underlying soil layer, allows the investigation and proposition of smart design of cantilever walls by performing relative parametric analyses. Such analyses are proposed to establish smart design of cantilever walls for given underlying soil conditions, and in particular the density of its backfill. Design seismic motions at the underlying bedrock, representative of the site under consideration, must be applied for this purpose.

	Loose (L)	Medium (M)	Dense (D)
$\phi$ (°)	25	35	40
$V_s$ (m/s)	100	150	350
$\gamma$ (kN/m)	18	20	22

Table 5: Typical values of shear wave velocity [19], frictional resistance [20] and unit density for loose, medium and dense sands used in the analyses.

#### 4.4 Typical example

In order to illustrate smart design of cantilever walls and its dependence to the underlying soil profile, we consider a cantilever wall with the typical properties given in table 6a above three different underlying soil profiles: C1, C1, C3 with properties given in table 6b. The backfill was considered to be in the loose, medium and dense states, with the corresponding properties of table 5. The seismic motion Mid-Niigata Prefecture 2004 was applied at the underlying rock.

##### (a) Wall

Parameter	Value
$W_c$ (kN/m)	112.5
$H_b$ (m)	6
$H_c$ (m)	5.5
$b$ (m)	3
$\phi_c$ (°)	25

##### (b) Underlying soil profile: C1, C1, C3 cases

Parameter	Value		
	C1	C2	C3
$H_s$ (m)	10	50	10
$V_{s-s}$ (m/s)	100	100	300
$\rho_s$ (T/m <sup>3</sup> )	2	2	2

Table 6: Parametric analyses: Model parameters used: (a) Wall and (b) Underlying soil profile: C1, C1, C3 cases

Table 7 presents the results of the parametric analyses and Figure 8 plots the computed ratio of the seismic displacement when the backfill is in the loose and dense states ( $u_{f-loose}/u_{f-dense}$ ), in terms of the ratio  $H_s/V_{s-s}$  of the underlying soil profile. It can be observed that if the ratio  $H_s/V_{s-s}$  is large, which corresponds to the case C2 where the soil underlying the wall is soft and deep, the loose backfill wall gives less seismic displacement and thus, for this case of seismic motion, it is recommended for optimum design.

Case	Loose	Medium	Dense
C1	0.88	0.7	0.61
C2	0.02	0.06	0.08
C3	0.7	0.65	0.36

Table 7: Results of the parametric analyses: The final seismic displacement (in m) in terms of the underlying soil type and the soil density of the backfill.

Figure 8: Results of the parametric analyses: The ratio of the seismic displacement when the backfill is in the dense and loose states in terms of the ratio  $H_s/V_{s-s}$

## 5 DISCUSSION

The analysis of the present paper are initial findings of on-going research regarding smart design of cantilever walls. The theoretical work predicting the critical acceleration of cantilever walls may be generalized considering walls of more general geometry and strength. The proposed method predicting the seismic displacement of cantilever walls considering the dynamic response of the soil profile may be (i) improved by considering the non-linear soil response [22] and (ii) verified by the comparison of predictions with results of relative elaborate numerical analyses [11]. Furthermore, smart design of cantilever walls recommendations may be established more adequately by performing extensive parametric analyses where different soil profiles are studied and more seismic motions are applied.

## 6 CONCLUSIONS

The paper considers the cantilever wall of the geometry of Fig. 2 and (a) proposes a method predicting the critical acceleration value in section 2, (b) proposes a method predicting the seismic displacement considering the dynamic response of the soil profile in section 3 and (c) studies the de-amplification effect and proposes a methodology for smart design in section 4. The work illustrated that the de-amplification effect of the seismic response may be crucial if the soil underlying the wall is soft and deep and in this case a wall with a looser backfill may be preferable.

### Abstract

*The structural control, basically, promotes a change in the damping and stiffness properties of the structure, either by the addition of external devices or by the action of external forces. It can be classified as: passive control, active control, hybrid control or semi-active control (Soong & Dargush, 1997). The hybrid mass damper (HMD) is a system that deals with the combination of a tuned mass damper (TMD) with an active control actuator. In addition to requiring lower control forces and maintaining its efficiency over a long range of frequencies, this system has a more robust and reliable control, when compared to active and passive alone (Collette & Chesné, 2016). Among the structures, the wind turbine stands out, which is supported by towers, which due to its geometry and height, are slender, flexible and can suffer excessive levels of vibration caused by the operation of the turbine, as well as by external forces (Woude & Narasimhan, 2014). In this work it is proposed the application of a structural control system, in the way of HMD, to protect a wind tower with theoretical dimensions and with a simplified as single degree of freedom model, submitted to wind and seismic loads that leads to levels of undesirable vibrations that may compromise the safety and integrity of the structure. In addition, it is proposed to compare the performances obtained from the system without control and by the Instantaneous Optimal Control (IOC), Proportional Integral Derivative (PID) and Linear Quadratic Regulator (LQR) controllers with numerical simulations performed using the MAPLESOFT, MATLAB and its Simulink control toolbox. The results obtained numerically were analyzed and compared with each other, and it was observed that HMD was efficient in reducing the dynamic response of the tower. Although it is a preliminary model, it is a basis for studies in this area to evolve into a more sophisticated model and full-scale applications.*

**Keywords:** Hybrid mass damper; Wind Turbine; Seismic; Instantaneous Optimal Control; Proportional Integral Derivative; Linear Quadratic Regulator.

## 1 INTRODUCTION

According to GWEC [1], despite being a pandemic year, 2020 was a record year of wind growth with an estimated 82.3 GW of new wind energy capacity globally, according to initial calculations by GWEC, which represents an increase of 36% in installations.

This expansive growth on energy generation is reflected to technological development, as well as in the development of increasingly tall and slender wind turbines, and as a consequence, these turbines can suffer severe dynamic excitations, thus reaching the service limit state for excessive vibrations [2, 3].

One way to reduce excessive vibration levels, maintain the stability and safety of systems and avoid collapse is to use the structural control solution, which can be classified into four categories, such as passive, active, hybrid and semi-active control. These four categories are based on applying external corrective forces or on the installation of external devices in order to reduce the levels of vibrations experienced by the structures and/or promoting variations in stiffness and damping properties of the main structure [4].

Each structural control category has a specific characteristic and can have more than one control method. The hybrid control has characteristics of passive control added to active control ones, always with the aim of increasing the performance of the system when compared, with a purely passive control. Making also the system less dependent on energy, when compared with the active control alone. The hybrid control uses actuators and energy dissipators [5].

According to Bhaiya [6] and Hu and He [7], the hybrid controller has a wider frequency range than the passive controller, making it more efficient and requiring less force than the active one, which reduces the cost of the system. In the case of a power failure or failure of the active control component, the passive component of the hybrid control still offers some level of protection. The hybrid mass damper (HMD) is the combination of a tuned mass damper (TMD) with an active control actuator [8, 9].

S. Xie, X. Jin, J. He et al. [10] developed a numerical model of a reduced-order offshore wind turbine, subjected to wind loads, sea waves and earthquakes for hybrid control. The authors found that the HMD system can better reduce the displacement from the top of the tower compared to the passive TMD system before and during earthquakes, although the need of high input control power and large displacements of the TMD.

D. Lima, P. López-Yáñez and M. Pereira [11] presented a vibration control device design for a 120-meter-high steel tubular tower for a wind turbine. Three types of absorbers were then studied comparatively: tuned mass damper (TMD), active mass damper (AMD) and hybrid mass damper (HMD). They used the Linear Quadratic Regulator (LQR) to obtain the optimal control variables introduced by the actuators hydraulic. It was found that the HMD achieves excellent levels of vibration reduction for the tower subjected to harmonic actions, in a transient and permanent (stationary) regime, resonant to the first mode of vibration of the structure without control.

M. Rahman, Z. Ong, Zhi Chao, W. Chong et al. [12] implements a proportional derivative integral controller (PID) designed and optimized to find the ideal required force for actuators and, therefore, reduce the vibration of the wind generator tower. The active vibration control system with an optimized PID controller in the wind turbine tower offered a higher rate of vibration reduction under different loads compared to the uncontrolled and passive control system.

Yanik [13] makes a comparison between the LQR controller and the Instantaneous Optimal Controller (IOC) using seismic forcing for a semi-active system applied in a 3-storey building and a 5-storey building.

In this work it is proposed the application of a structural control system, considering a HMD, to protect a wind tower with theoretical dimensions considering a simplified single degree of freedom model. It is submitted to wind and seismic loads that leads to levels of undesirable vibrations that may compromise the safety and reliability of the structure. In addition, it is proposed to compare the performances obtained from the system without control and with an HMD using different controllers: Instantaneous Optimal Control (IOC), Proportional Integral Derivative (PID) and Linear Quadratic Regulator (LQR) through numerical simulations.

## 2 MATHEMATICAL FORMULATION

The large wind turbine studied in this work is composed of a tall, slender and flexible tower that supports the blades and nacelle at the top. The system has infinite degrees of freedom, however, through a modal reduction technique, it is possible to model it as a discrete system with multiple degrees of freedom (MDOF) [14]. The effects of rotating the blades and their vibrations in the *flapwise* and *edgewise* directions are not considered in this preliminary model [2]. This structure can be modeled as a system having  $N$  degrees of freedom with a TMD device installed and subjected to external dynamic excitation [15]. Figure 1 represents the turbine and the system modelled as a cantilever beam with a tip mass.

Figure 1. (a) Tubular structures of steel tower of wind turbines; (b) Schematic description of a cantilever beam with a tip mass [2].

In systems with multiple degrees of freedom, it is possible to reduce the structural response to a single degree of freedom and obtain the structural response for structural systems that vibrate mainly on a single mode, usually the first [4, 8, 14].

Although the structural model of the wind turbine has multiple degrees of freedom, the system under study was reduced to a single degree of freedom [4] and a hybrid tuned mass damper was added to the top of the turbine, which is connected to the main system with the intention of decreasing the amplitude of the structure vibration [2, 4].

The main system representing a wind turbine, reduced to a single degree of freedom associated with an HMD, shown in Figure 2, has two degrees of freedom, where  $\mathbf{M}_1$  is the mass,  $\mathbf{K}_1$  is the stiffness and  $\mathbf{C}_1$  is the damping of the main system, while  $\mathbf{M}_2$  is the upper mass of HMD,  $\mathbf{K}_2$  is the stiffness of HMD and  $\mathbf{C}_2$  is the damping of HMD,  $\mathbf{F}(t)$  is the dynamic load applied on the structure,  $\mathbf{u}(t)$  is the control force, while  $\mathbf{y}(t)$  and  $\mathbf{z}(t)$

are the horizontal displacements of the main system and the HMD, respectively.

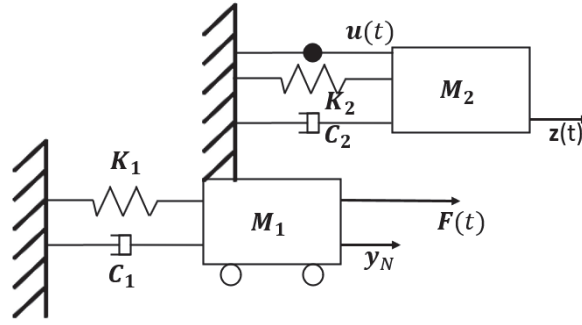

Figure 2. Two degrees of freedom model: main system + mass damper tuned with  $u(t)$  (HMD) actuator [16].

The equations of motion of the main system with a connected HMD, including the force applied to the base of the structure  $g(t)$ , and control force  $u(t)$  is given by (2):

$$M_1 \ddot{y}(t) + C_1 \dot{y}(t) + K_1 y(t) = F \quad (1)$$

$$M_2 \ddot{z}(t) + C_2 \dot{z}(t) + K_2 z(t) = -M_2 \ddot{y}(t) + g(t) + u(t) \quad (2)$$

Three control algorithms were used to calculate the control force  $u(t)$  in order to compare their performances: Linear Quadratic Regulator (LQR), Proportional, Integral, Derivative (PID) and Instantaneous Optimal Control (IOC). The Optimal Control aims to control the dynamic system at a minimum cost, the optimization process is performed through the Linear Quadratic Regulator (LQR). The LQR can be presented as a regulator that stabilizes the system's response. It is a controller capable of optimizing through control considering the constraints of a cost function and uses all states of the system for feedback, while the gain of control is selected in a way that the performance index subjected to the constraints of the system state equation is minimized [17, 18]. Although the LQR controller deals better with systems with multiple inputs and multiple outputs, on the other hand it has certain difficulties in defining the cost function and the weighting matrices [19, 20].

For modeling the LQR controller, it is necessary to represent the equations of motion of the system in state space form, according to the state equation (3) and the output equation (4) for  $n$  degrees of freedom.

Where  $A$  is the state matrix,  $B$  is the input matrix,  $C$  is the output matrix and  $D$  is the direct transmission matrix. Equations (5) and (6) represent the equations of motion of the system under study in this work in the state space.

$$\dot{x}(t) = Ax(t) + Bu(t) \quad (3)$$

$$y(t) = Cx(t) + Du(t) \quad (4)$$

$$\begin{bmatrix} \dot{X}_1 \\ \dot{X}_2 \end{bmatrix} = \begin{bmatrix} 0 & I \\ -M^{-1}K & -M^{-1}C \end{bmatrix} \begin{bmatrix} X_1 \\ X_2 \end{bmatrix} + \begin{bmatrix} 0 \\ M^{-1} \end{bmatrix} u \quad (5)$$

$$Y = [1 \quad 0 \quad 0 \quad 0] \begin{bmatrix} X_1 \\ X_2 \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad (6)$$

For structural control, the classical optimal control problem consists in finding the control vector  $\mathbf{u}(t)$  that minimizes the quadratic performance index [21]:

$$J = \int_{t_0}^{t_f} [\mathbf{x}^T(t) \mathbf{Q} \mathbf{x}(t) + \mathbf{u}^T(t) \mathbf{R} \mathbf{u}(t)] dt \quad (7)$$

where  $\mathbf{Q}$  is a real, symmetrical and positive semi-defined  $2n \times 2n$  real, matrix and  $\mathbf{R}$  is a real, symmetric and positive defined  $m \times m$  matrix. The matrices  $\mathbf{Q}$  and  $\mathbf{R}$  are weighting matrices, whose magnitudes are defined according to the relative importance given to the state variables and the control forces in the minimization process.

According to Meirovitch [21], in structural applications, the Riccati matrix,  $\mathbf{P}(t)$  can be approximated by a constant matrix  $\mathbf{P}$ . The minimization of the index falls on the solution of the Riccati equation.

$$\mathbf{P}\mathbf{A} - \frac{1}{2}\mathbf{P}\mathbf{B}\mathbf{R}^{-1}\mathbf{B}^T\mathbf{P} + \mathbf{A}^T\mathbf{P} + 2\mathbf{Q} = 0 \quad (8)$$

Having knowledge of the weighting matrices  $\mathbf{Q}$  and  $\mathbf{R}$ , it is possible to obtain the control gain, that is  $\mathbf{G}$  given by

$$\mathbf{G} = -\frac{1}{2}\mathbf{R}^{-1}\mathbf{B}^T\mathbf{P} \quad (9)$$

The optimal control law establishes a linear relationship of the control vector  $\mathbf{u}(t)$ .

$$\mathbf{u}(t) = \mathbf{G}\mathbf{x}(t) = -\frac{1}{2}\mathbf{R}^{-1}\mathbf{B}^T\mathbf{P}\mathbf{x}(t) \quad (10)$$

When  $\mathbf{x}(t)$  is known,  $\mathbf{u}(t)$  can be obtained through equation (10) generating a closed loop system.  $\mathbf{H}\mathbf{f}(t)$  is the portion related to external loading. The behavior of the optimally controlled structure is described by

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{u}(t) + \mathbf{H}\mathbf{f}(t) \quad (11)$$

$$\dot{\mathbf{x}}(t) = (\mathbf{A} + \mathbf{B}\mathbf{G})\mathbf{x}(t) + \mathbf{H}\mathbf{f}(t) \quad (12)$$

It can be seen that the effect of closed loop control is to change the state matrix of the system from  $\mathbf{A}$  (open loop system) to  $\mathbf{A} + \mathbf{B}\mathbf{G}$  (closed loop system).

Another controller used in the comparison of the present work was the Proportional Integral Derivative (PID), this controller features the use of closed loop control loop feedback to keep the actual output of a process as close as possible to the destination output or setpoint [19].

The MATLAB control system's *Simulink* toolbox provides algorithms and applications for systematically analyze, design and adjust linear control systems. It is possible to specify a system as a transfer function, status space, zero pole gain or frequency response model.

The response of the PID controller was calculated using *Simulink* using the closed loop block diagram with the insertion of external forces such as wind and earthquake.

The transfer function of the system in relation to the HMD installed on top of the wind turbine, presents the ratio between the displacement of the main system (output) and the control force (input). Figure 3 represents a block diagram of *Simulink* with PID control under the action of external forces.

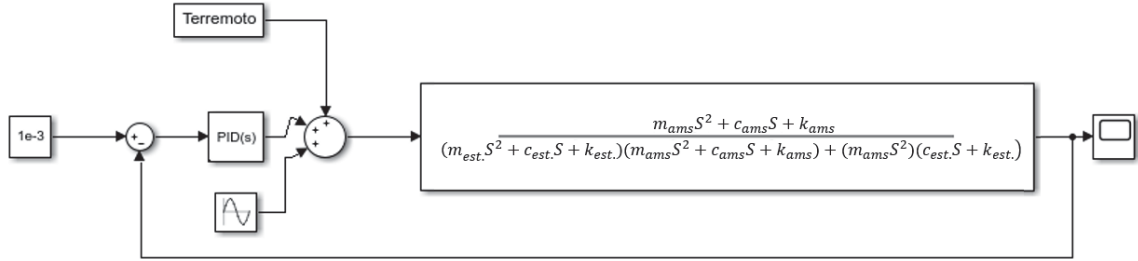

Figure 3. Closed loop block diagram with PID [16].

The instantaneous optimal control (IOC) is a variation of the classic optimal control aiming at computational cost savings since it does not require the solution of the Riccati equations [20]. For this controller, the same formulation of the equations of motion of the system was used in the form of state equations of state shown previously eq. (3) and eq. (4). This algorithm is easier to implement, since it is not necessary to calculate the Riccati matrix [8].

The quadratic performance index, represented by eq. (13), is minimized in each instant of time,

$$J(t) = \mathbf{x}^T(t) \mathbf{Q} \mathbf{x}(t) + \mathbf{u}^T(t) \mathbf{R} \mathbf{u}(t) \quad (13)$$

where  $\mathbf{T}$  is the modal matrix, whose columns are the eigenvectors of  $\mathbf{A}$ .

$$\mathbf{x}(t) = \mathbf{T} \mathbf{w}(t) \quad (14)$$

From the decoupled state equations, the diagonal matrix with the eigenvalues of  $\mathbf{A}$  is obtained.

$$\mathbf{\Lambda} = \mathbf{T}^{-1} \mathbf{A} \mathbf{T} \quad (15)$$

Over a short time step  $\Delta t$ , the modal state vector  $\mathbf{x}(t)$  can be expressed as

$$d(t - \Delta t) = \exp(\mathbf{\Lambda} \Delta t) \mathbf{T}^{-1} \left\{ \mathbf{x}(t - \Delta t) + \frac{\Delta t}{2} [\mathbf{B} \mathbf{u}(t - \Delta t) + \mathbf{H} \mathbf{f}(t - \Delta t)] \right\} \quad (16)$$

The weighting matrices  $\mathbf{Q}$  and  $\mathbf{R}$  are also arbitrarily defined in the IOC case, they influence the control force and the displacement suffered represented by equations (17) and (18), respectively.

$$\mathbf{u}(t) = -\frac{\Delta t}{2} \mathbf{R}^{-1} \mathbf{B}^T \mathbf{Q} \mathbf{x}(t) \quad (17)$$

$$\mathbf{x}(t) = \left[ \mathbf{I} + \frac{\Delta t^2}{4} \mathbf{B} \mathbf{R}^{-1} \mathbf{B}^T \mathbf{Q} \right]^{-1} \left[ \mathbf{T} d(t - \Delta t) + \frac{\Delta t}{2} \mathbf{H} \mathbf{f}(t) \right] \quad (18)$$

The optimized control force was calculated according to the procedures used by S.

Avila and P. Gonçalves [22].

### 3 RESULTS

In this, it is considered a wind turbine, previously studied by S. Avila, M. Shzu, M. Morais et al. [2]. The structure was reduced to a single degree of freedom model and subjected to the following loads: earthquake El Centro [23]; harmonic loading  $f(t) = 2500\sin(\omega t)$  applied at the top of the tower. The mass, damping and stiffness properties of the structure are, respectively,  $M_1 = 34,899,00$  kg,  $C_1 = 0,00$  Ns/m and  $K_1 = 463,671,00$  N/m. HMD properties were calculated using Den Hartog equations [24]:  $M_2 = 967,98$  kg,  $C_2 = 427,6724$  Ns/m and  $K_2 = 8,9096 \times 10^3$  N/m. The damping ratio,  $\zeta$ , is assumed to be 2% of the critical value.

Initially, the controller of the LQR type had the control force in the HMD actuator calculated and one of the factors that influence the achievement of good results through this algorithm is the choice of the weighting matrices  $Q$  and  $R$ . The values of the coefficients of the weighting matrices  $Q$  and  $R$  are defined according to the relative importance given to state variables and control forces in the minimization process [21, 22]. The weighting matrices used in the analysis were as follows:

$$Q = \begin{bmatrix} 10^{10} & 0 & 0 & 0 \\ 0 & 10^2 & 0 & 0 \\ 0 & 0 & 10^2 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (19)$$

$$R = [1] \quad (20)$$

The LQR was performed using a function from the MATLAB library and still using a closed-loop block diagram using the Matlab Simulink toolbox. Figure 4 represents the block diagram of the LQR controller for the hybrid mass damper under the action of wind force (represented by the sinusoidal excitation) and seismic excitation (represented by the El Centro earthquake), where  $A$  is the state matrix,  $B$  is the input matrix,  $C$  is the output matrix and  $G$  is the gain.

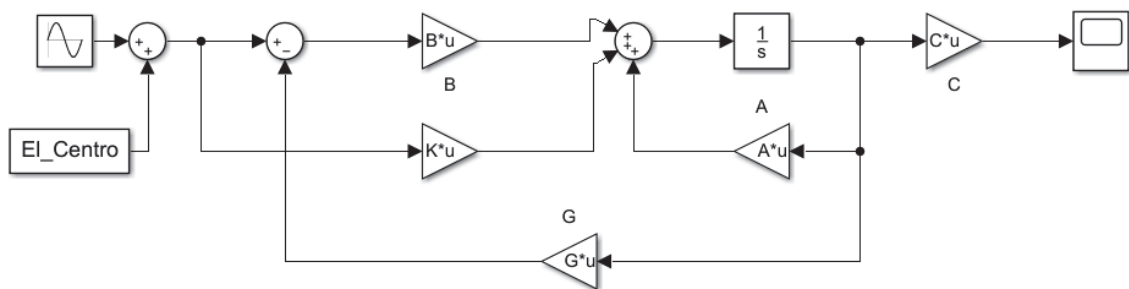

Figure 4. Block diagram of the LQR controller with HMD [16].

The displacement time history of the main structure is shown in Figure 5, comparing the use of a tuned mass damper (TMD) and an HMD, considering seismic and wind excitations with LQR controller. It can be seen that the HMD demonstrated an excellent performance, reducing, approximately, up to 6 times the amplitude of vibration presented with the passive control (TMD), when compared to the HMD.

Figure 5. Time history displacement of the main system (comparative AMS x HMD) [16].

Then, numerical simulations are performed using the PID controller to obtain the HMD control force and the displacement of the main system [16]. The gains of the PID controller were obtained through the MATLAB computer package tuning tools and the Simulink toolbox. Figure 6 presents the block diagram for system analysis with HMD using the PID controller to calculate the control force. The system is subjected to the same wind and earthquake excitations, through the PID block and the transfer function of the hybrid system.

Figure 6. Block diagram of the PID controller with HMD [16].

Figure 7 shows the comparison of the response, in terms of the evolution of displacement, for the HMD, of the main system using the system without control and the LQR and PID controllers. It is possible to observe that the LQR controller has a better performance than the PID controller, with a reduction, compared to the uncontrolled system response, of approximately 63% and 43%, respectively.

Figure 7. Time history displacement of the HMD using the LQR and PID controllers [16].

The *rms* displacement value, for the HMD, obtained for the system without control was 0.2098 m, while for the system with LQR controller, the displacement was 0.04506 m and for the PID it was 0.09592 m. For the LQR and PID controllers, there was a reduction in the *rms* response of approximately 78.5% and 54.2%, respectively.

Figure 8 presents the comparison of the evolution in time of the control force required in the LQR and PID controllers, where the maximum required force is 28030 N and 2735 N, respectively. It appears that the required control force, using the LQR, was approximately 10 times greater than the control force obtained with the PID controller.

Figure 8. Time evolution of the control force required in the LQR and PID [16].

The IOC also needs an adjustment in the weighting matrices, where equations (21) and (22) present the matrices  $\mathbf{Q}$  and  $\mathbf{R}$ , respectively.

$$\mathbf{Q} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 6.654 * 10^3 & 0 & 0 & 0 \\ 1 * 10^{-3} & 0 & 0 & 0 \end{bmatrix} \quad (21)$$

$$\mathbf{R} = [1000000] \quad (22)$$

For the IOC algorithm, the calculations were performed using MATLAB, where it was possible to obtain the answer in a time range of 600 s. Figure 9 shows the evolution in time of the displacement of the main structure controlled by an HMD with an IOC controller. It is possible to observe that the amplitude of the response has an order of magnitude ten times smaller than those obtained in the simulations with the LQR and PID controllers.

Figure 9. Time history displacement of the structure controlled by an HMD using the IOC controller.

Figure 10 represents the force response required by the IOC to control the dynamic response. It appears that the order of magnitude of the control force is a thousand times smaller compared to those corresponding to the LQR and PID controllers.

Figure 10. Time evolution of the control force required by the IOC controller.

## 4 CONCLUSION

In this work, the use of an hybrid mass damper for the analysis of the dynamic response and required control force of a wind tower model is studied. Three controllers are compared: LQR, PID and IOC. The analysis are performed using the wind turbine parameters model presented by S. Avila, M. Shzu, M. Morais et al. [2]. The results are obtained through numerical analysis considering dynamic excitations of wind and earthquake.

Although the LQR controller has a better response and a lower rms value than the PID, the two controllers reduce the system response satisfactorily. The IOC controller reduces the displacement of the system by up to 10 times and the force required to control the system is in the order of a thousand times less than the previous controllers.

It can be seen, therefore, that of the three controllers analyzed, the IOC was the one that presented the best performance, without adding computational effort. It even has the advantage of not relying on the solution of the Riccati problem, which can be computationally costly in the case of problems with a higher order. However, its efficiency is quite sensitive to the choice of suitable weighting matrices. For future work, it is interesting to carry out experimental studies using the Hardware in the Loop methodology to consolidate the comparative study.

### Abstract

*Modernity and advances in civil design are directed at increasingly tall and slender buildings, adding vibrations to structures that generate discomfort, being necessary to mitigate the amplitudes of vibrations produced by low-frequency excitations, characterized in these buildings. In this sense, for some time, experimental studies have been developed with the objective of investigating low-cost scale models, which allow a more detailed study of this type of phenomenon. In this paper, the experimental validation of a dynamic parameterization of low-frequency periodic base motion, considering one degree of freedom, with a synchronized electrodynamic system and controlled with Arduino microcontroller boards is presented. Developed using a small-scale homemade shake table, the system was applied to case studies as a control system using a simple pendulum. The necessary tools are presented to measure the system's responses over time; the dynamic response of the vibratory system can simulate several excitation frequencies. The results obtained in the proposed experimental tests are feasible, with satisfactory precision. The documented results can support an overview of the trend in the efficiency of vibrating table tests in the study of low-frequency vibration control.*

## 1 INTRODUCTION

Modernity and advances in civil engineering design are directed at increasingly tall and slender buildings, causing vibrations to structures that generate discomfort, being necessary to mitigate the amplitudes of vibrations produced by low-frequency excitations, characterized in these buildings. In this sense, experimental studies have been developed aiming to investigate low-cost scale models, which allow a more detailed study of this type of phenomenon.

Shaking tables are equipments widely used in engineering laboratories, in order to analyze the behavior of structures subjected to seismic actions [1,2]. Small-scale shake tables are widely used, due to its practicality and low-cost, to study the dynamic behavior of a dynamic system. You can find several manufacturers of this equipment for commercial purchase. Or you can also design a homemade one.

Experimental studies with pendulum elements are often used in literature for experimental studies of its nonlinear behavior, to identify oscillation frequency and damping properties, for example. As well, they are always present in basic physics disciplines, teaching science, engineering, and/or technology courses.

Huang [3] and Soeiro [4] define some types of dynamic actuators (known in laboratories as shakers) as a device used to induce vibration in a system, with controlled amplitude and frequency. It may be mechanical, electromagnetic, electrodynamic or hydraulic. Oliveira [5] stated that an electrodynamic actuator is the most common excitation mechanisms in vibration laboratories to simulate controlled excitation (sinusoidal, random and mechanical shock). The electrodynamic shakers can perform tests that identify important dynamic parameters such as: resonance frequencies, resistance to fatigue and product durability. The use of these actuators is very common due to the cost-benefit ratio and their load capacity of up to 30 kN with a frequency range of 5-20 kHz [6]. At this frequency range, it can be achieved displacements up to 25 mm [7]. But these industrial solutions can reach thousands of dollars.

Damci and Şekerçi [8] compared the results of a homemade shake table with commercial ones with similar characteristics. The shake table was excited using a small-scale structure excited by a step motor actioned by *Arduino* microcontrollers, to precisely achieve the imposed base-motion. The use of small-scale shake tables is the most common way to perform vibration tests for industrial applications [9]. Liu *et al.* [10] stated that the shake table test has been increasingly used to study the dynamic responses of structures in these decades. And this device is a powerful tool for researchers and designers to examine dynamic system performance.

In this paper, the experimental validation of a dynamic parameterization of low-frequency periodic base motion, considering one degree of freedom, with a synchronized electrodynamic system and controlled with *Arduino* microcontroller boards is presented. Developed using a small-scale homemade shake table, the system was used to case studies like a control system using a simple pendulum. The necessary tools to measure the system's responses along time are presented; the dynamic response of the vibratory system can simulate several excitation frequencies. The results obtained in the proposed experimental tests are feasible, with satisfactory precision.

## 2 SHAKE TABLE

The shake table is a type of electrodynamic actuator capable of carrying out controlled displacements on a sliding table with prescribed amplitude and frequency. A schematic drawing of the shake table used in this work is shown in Figure 1.

Figure 1 – Shaking Table Scheme

The shake table equipment, to generate and analyze electrodynamic excitation, is divided into two systems: movement of the mechanical system and data acquisition. For the mechanical system, a sliding platform is used to simulate the movement of seismic vibrations at low frequencies, a stepper motor as a source of mechanical force capable of generating potential energy, which allows the movement of the platform and a microcontrolled board that encodes the controlled movement to be transferred electronically to the stepper motor that transforms the force.

In this work, a handcrafted shaking table sampled was used (Figure 2). With base dimensions of 0.423 x 0.048 x 0.100 m, two axial axes (0.423 m) that serve as a guide and support, a trapezoidal spindle with 8 mm in diameter and an adaptation for the connection of the mechanical energy generator system, which is able to move the square iron base, with base dimensions of 0.100 x 0.100 m, that simulates a car.

Figure 2 – Eletro-mechanical devices of Shake Table

The electro-mechanical actuator is a bipolar stepper motor bipolar *Nema 17* to perform very precise angular movements, in discrete or fractional steps, controlled by A4988 driver module [11]. The stepper motor *Nema 17* is a high torque motor with dimensions 42 x 34 mm, the equivalent rotation angle of 1.8° for a complete lap (a spin of 360°). To know the steps taken to complete a lap or revolution, what is known as PPR (steps per revolution or pulses per revolution), the following calculation is performed:

$$PPR = \frac{360^\circ}{rotation\ angle} \quad (1)$$

$$PPR = \frac{360^\circ}{1.8^\circ} = 200 \text{ steps per revolution} \quad (2)$$

Stepper motors can be controlled in open loop, as they have a known position at all times [12] In this case the motor is connected to a microdevice controller, capable of controlling the interpolation of the flow current in stepper motors, controlling the size of the pulse. The slower the rotation, the larger the pulse size, smoothing the resulting movement of the motor. One of the main advantages of this device is being able to manually set the maximum output current, allowing the application of voltages above the motor's nominal value. The controller drive has a voltage regulator with an intelligent system that automatically adapts the decay mode, a thermal protector that shuts down allowing the temperature control and, a protection against cross currents that generates a reduced dissipation in the power and allows the immediacy in the precision.

To find the reduction in the size of the pulse, the complete cycles are divided into smaller steps, smoothing the movement of the motor, after all, the smaller the step, the greater the precision. The  $1.8^\circ$  angle can be divided up to 256 times, obtaining steps up to 0.007 degrees ( $1.8 \times 0.007$ ) or 51,200 micro steps. To establish communication with the engine it is using an Arduino Uno, which is the most popular microcontroller model and widely used for its simplicity, accessibility and low power consumption; the programming is done through the regular computer, connected by a USB port that establishes a communication link with the flash memory built into the Arduino, the USB socket also supplies power to the Arduino. The programming used is the C programming language and through execution in the integrated development environment (IDE) as explained by S. Monk [13] allowing one program to run at a time.

In Figure 3, the components of the mechanical system of the handmade vibrating table are sampled.

Figure 3 – Composition of the handmade shake table.

### 3 METHODOLOGY

Initially, the evaluation and behavior of the shaking table is carried out and then a simple pendulum excited by the table is analyzed.

For the movement of the vibrating table, energy is transformed using an electric motor, step-by-step, controlled by a potentiometer and a microcontroller, capable of directing the information from the programming code that allows excitation and rotation control to be carried out. Low frequencies in the range of 0.3 Hz and 2.1 Hz were considered, varying in steps of 0.2 Hz, verifying the limitations of displacement of the table in its maximum trajectory and minimum motor capacities. In order to guarantee greater reliability to the study [14], an ap-

appropriate number of repetitions were carried out for each study. In this sense, the number of repetitions of sixty-four (64) periods was considered for each operating mode of the engine in random order and in duplicate; also, it saves the life of the controller drive in function of thermodynamic capacity for the most rambling mode of the engine and the storage capacities of the data analysis program according to the resources available for the study.

The technique used in this study for data acquisition was video capture, performed using a Samsung-SM-G920A Smartphones camera, Android version 5.0.2, with resolution adapted to FHD (60fps) 1920x1080, and speed of 60 images for approximate seconds according to the instrument's specifications. Where the object of the center of analysis of differentiated color is identified that will facilitate and it was used a measuring tape that allows to carry out the necessary calibration on the screen in the data analysis software with the intention of guaranteeing the accuracy of the data under study. Figure 4 shows the image of the slide platform with the identification of the elements that allowed the object to be marked, calibrated, to locate the known points and the Cartesian axis, and to define the units considered.

Figure 4 – Detail of sliding platform with follower point.

In this work, the free software Tracker is used to analyze the results (Figure 5), which was also used by Bezerra Jr. et al. [15] for their analysis of the results, they specified the software's capacity to measure several quantities in two-dimensional space, based on a standard established by the user. The software identifies the number of frames per second of the video in analysis, presenting the data and graphics corresponding to the study of physical phenomena, automatically and in real time, such as: displacements, velocities, accelerations, time, angular frequencies, among others, making it possible to carry out various analysis, such as comparing results, identifying discrepancies in movement patterns and analyzing performances. Bonventi Jr. and Aranha [16] describes that the software also allows you to make adjustments to various functions and even to build your own mathematical models.

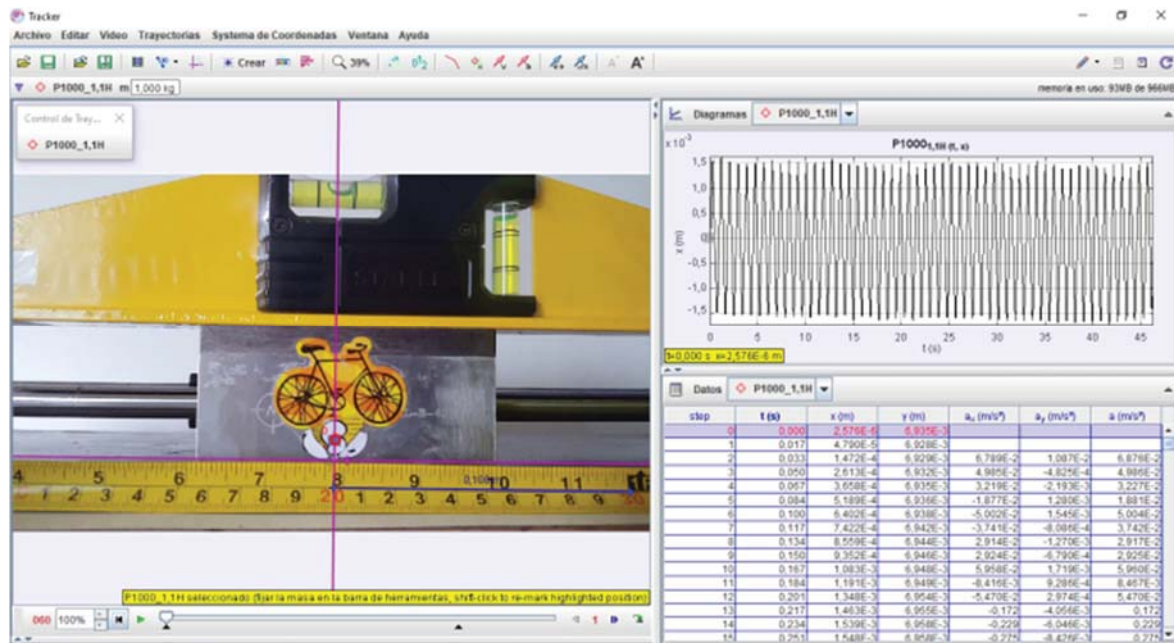

Figure 5 – Motion of sliding platform analyzed by Tracker software.

## 4 RESULTS

The results of the study consist of validating the movement of the vibratory table movement, and studying simple pendulum tests.

### 4.1 Validation of the Shake Table

The study of the motor oscillation movement for five (5) different configuration of the stepper motor + A4988 controller on the Arduino platform, Table 1, was performed.

Mode	Steps (PPRM)	Angular Speed ( $\omega$ )	Motor Deceleration (%)
Full	200	1,85	-
Half	400	1,49	(20)
1/4	800	1,07	(28)
1/8	1600	0,68	(36)
1/16	3200	0,39	(42)

Table 1 – Operating Parameters of the A4988 Controller on the NEMA motor rotational movement.

By enabling one of these operation modes of the stepper motor [11], the waveform obtained resembles the square wave, Figure 6. The precision of periodicity is observed. Figure 6 shows the experimental result of rotation of the stepper motor for modo mode, obtaining an oscillation frequency of 0.6 Hz and an average angular velocity amplitude of 2.62 rad / s, analogous to Brites, [17]. The experimental result was obtained through motion capture by video analyzed by the Tracker program.

Figure 6 – Angular rotation of the stepper motor for the operation mode  $\frac{1}{4}$ .

For the validation of the movement of the shake table, the acceleration time history of the sliding platform is shown in Figure 7 showing a triangular waveform. As expected, a triangular wave-type displacement has the following shape as a series of Fourier:

$$x(t) = x_o \cdot \frac{8}{\pi^2} \sum_{i=0}^N \frac{(-1)^i}{n^2} \sin(n \cdot 2\pi f t) \quad (3)$$

where,  $n = 2i + 1 = 1, 3, 5, \dots$ . Note that from the triangular wave, the square wave is obtained with the time derivative of the expression (3) referring to the velocity of movement of the platform and similar to the angular velocity of the stepper motor.

$$\dot{x}(t) = \dot{x}_o + \frac{8}{\pi^2} \sum_{i=0}^N (n \cdot 2\pi f)^2 \cdot \frac{A(-1)^i}{(2n)^2} \sin(n \cdot 2\pi f t) \quad (4)$$

Figure 7 compares the experimental results and the simulated theoretical model regarding the acceleration of the platform. There is a gap between the experimental results and the theoretical model due to inaccuracies in the excitation frequency.

Figure 7 – Comparison of experimental data and analytical waveform of sliding platform acceleration

When analyzing the time-history acceleration of the platform in different directions, the Figure 8 shows the acceleration of the platform in the x-direction (parallel to the movement of the platform) and the y-direction (perpendicular to the movement of the platform) measured by a smartphone *Samsung-SM-G920A*, Version of *Android 5.0.2* and by the program *Tracker*. As expected, the platform response (in the x-direction) presents the expected waveform for acceleration, as Figure 8. The acceleration in the x-direction is ten times greater than the acceleration in the y-direction (perpendicular) demonstrating a good relationship signal-to-noise ratio for this frequency 1,1 Hz. These parasitic accelerations are due to noise mainly due to small clearances in the linear platform mechanism.

Figure 8 – Time history acceleration of the platform to the excitation frequency **1,1 Hz**.  
(a) Steering acceleration-X (b) Steering acceleration -Y.

When analyzing the experimental results for other excitation frequencies, the shake table shows signs of acceleration with different magnitudes depending on the number of steps of the stepper motor. A series of experimental measurements of the acceleration of the platform for excitation frequencies between 0,3 Hz to 2,1 Hz for a range of 0,2Hz. Only the results are presented for the frequencies of 0,3Hz (Figure 9), 0,7Hz (Figure 10) e 1,7Hz (Figure 11). The results show good signal-to-noise ratios for frequencies above 0,5Hz. Due to mechanical gaps, failures in the platform support, and inaccuracies in the stepper motor action, the acceleration signal for low frequencies is less than the noise for low frequencies ( $f \leq 0,5\text{Hz}$ ).

Figure 9 – Time history acceleration in the X-direction for the excitation frequency 0.3 Hz.

Figure 10 - Time history of acceleration in the X-direction for the excitation frequency 0.7 Hz.

Figure 11 - Time history acceleration in the X-direction for the excitation frequency 1.7 Hz.

The analysis in the frequency domain of the temporal signals results in a spectrum of acceleration amplitudes for the excitation frequencies de 0,9 Hz (Figure 12), 1,2 Hz (Figure 13) e 2,1 Hz (Figure 14). The frequency peaks are observed for the respective fundamental frequencies  $f_n$  and its odd harmonics  $f_i = i f_n$  ( $i = 1, 3, 5, \dots$ ), accordingly the expression of the Fourier series (1).

$$f(t) = a_0 + \sum_{n=1}^{\infty} a_n \cdot \cos(n\omega_0 t) + b_n \cdot \sin(n\omega_0 t) \quad (5)$$

where, Fourier coefficients are obtained through the temporal expressions  $a_0 = \frac{1}{T_0} \int_{t_1}^{t_1+T_0} f(t) dt$ ,  $a_n = \frac{1}{T_0} \int_{t_1}^{t_1+T_0} f(t) \cdot \cos(q\omega_0 t) dt$ ,  $b_n = \frac{2}{T_0} \int_{t_1}^{t_1+T_0} f(t) \cdot \cos(q\omega_0 t) dt$ ;  $t_1$  is a temporal arbitrary instant [18]. The amplitude spectrum has even symmetry and the phase spectrum has unique symmetry. When evaluating the acceleration spectra, it is found discrete spectra containing a number of harmonics integer multiples of the signal fundamental frequency.

Figure 13 - Spectral response from acceleration to excitation frequency 1.5 Hz.

Figure 14 - Spectral response from acceleration to excitation frequency 2.1 Hz.

#### 4.2 Free Pendulum Vibration Test

In order to study a practical application of the platform, it was studied the dynamic behavior of a simple pendulum (Figure 15) with length  $l = 0,255 \text{ m}$  between the contact point and the mass center of the small sphere of mass  $m = 0,04101 \text{ g}$ , considering local gravity acceleration in Brasilia DF-Brazil ( $15^\circ 45' 43'' \text{S}$   $47^\circ 52' 25'' \text{W}$ )  $g = 9,7808439 \text{ m/s}^2$ . Using motion capture by video with the Tracker software, the dynamic behavior of the simple pendulum is studied.

Figure 15 – Simple Pendulum

At first, the preliminary results to determine the behavior of the pendulum's amortization are presented, varying the amplitude of the sphere's displacement in small angles and considering the approximation  $\sin \theta \cong \theta$  acceptable. The initial movement is generated carefully and searching that the effects of air displacement can be minimized.

The motion equation of the pendulum can be written as:

$$\ddot{\theta} + 2\xi\omega_n\dot{\theta} + \omega_n^2 \sin \theta = 0 \quad (5)$$

where  $\theta$  is the angle of the pendulum, the period of undamped linear oscillation is  $T_0 = 2\pi/\omega_n = 2\pi\sqrt{L/g}$ , it is function of local gravity acceleration  $g$  and pendulum length  $L$ , assuming that  $\sin \theta \approx \theta$ , and the exact oscillation period  $T$  It is given by [19]:

$$T = T(\theta) \approx T_0 \left[ 1 + \frac{1}{16} \theta^2 + \frac{11}{3072} \theta^4 + \frac{173}{737280} \theta^6 + \dots \right] \quad (6)$$

Providing an initial disturbance, Figure 16 presents the comparison of the experimental response of the simple pendulum obtained by motion capture in the *Tracker* and the result of the theoretical model obtained by numerical simulation with MatLab software. In this case, the amplitude of displacement of the pendulum mass is of  $0.2094 \text{ rad}$ . There is a certain similari-

ty in the temporal results of the angular position of the mass between the theoretical models and the experimental result. The damping model needs to be improved.

Figure 16 – Damped Response of the Simple Pendulum: Experimental results x numerical simulation.

The period of experimental oscillation is compared as a function of the angle of oscillation of the simple pendulum according to the expression (6). Figure 17 presents a comparison between the theoretical results with the experimental period extracted from the temporal response. The experimental results show an evolution close to the theoretical solution and an evolution dependent on the maximum period of oscillation angle.

Figure 17 - Period Relationship - Position of a Simple Pendulum

## 5 CONCLUSION

This work performs an experimental study of a low-frequency handcrafted electrodynamic shake table. Initially, the validation of the shake table dynamic is done using video motion capture through Tracker software for experimental frequencies between 0.3 and 2.1 Hz. The dynamic displacement, velocity, and acceleration of the shake table platform are compared to analytical solution achieving reasonable agreement. Finally, the free vibration of a simple pendulum motion is acquired through video motion capture. The experimental data is compared to theoretical models that show a good agreement with reasonable accuracy.

The authors suggest carrying out future work to verify and adapt the study, based on the results obtained in the validation of the shake table, the study of the dynamic response of a simple pendulum, or coupled pendulums, or of a tuned liquid column damper (TLCD).

### Abstract

*A new optimal damper design method, called ‘consecutive design generation method (CDGM)’, is presented for elastic-plastic multi-degree-of-freedom (MDOF) building structures under multiple-level earthquake ground motions (GMs). The procedure of the proposed method is as follows: (i) Set a variety of levels of input GMs  $\{IM_1, \dots, IM_L\}$  ( $IM_1 < \dots < IM_L$ ). (ii) Obtain the optimal design under GM with  $IM = IM_1$  using an optimization method. (iii) Obtain the optimal design under GM with  $IM = IM_2$  by a local search around the optimal design under GM with  $IM = IM_1$  as the initial design. (iv) Obtain the optimal design under GM with  $IM = IM_3$  by a local search around the optimal design under GM with  $IM = IM_2$  as the initial design, and the same procedure is repeated under GMs with other IMs. By using the proposed method, all the optimal designs can be obtained with much lower computational effort than the method repeating an ordinary optimization procedure under every-level GM. The proposed method helps to understand how the distribution of added damper damping coefficients changes as the level of GMs changes. Furthermore, a simple design guideline for the problem, which design to be chosen from various optimal designs, is presented based on the ‘ideal drift response curve’, which is also a new concept. Two representative recorded ground motions are employed as a set of GMs and the proposed method is applied to these GMs. The influence of the number of GMs and the level of GMs on the optimal damper design is clarified.*

## 1 INTRODUCTION

Problems of optimal design of passive dampers have been tackled by many researchers (for example see [6, 11]). Zhang and Soong [15] proposed a sequential procedure to obtain the optimal placement of viscoelastic dampers. Then this method was extended to a simpler method by Garcia [5]. Takewaki [10] developed an optimality criteria-based algorithm to minimize the sum of the amplitudes of the transfer functions at the fundamental natural frequency under a constraint on the sum of the additional damping coefficients. Silvestri and Trombetti [9] demonstrated the effectiveness of mass-proportional damping systems. Some researchers compared several methods for optimal damper placement ([2, 4, 14]).

In most researches on optimal damper placement, elastic frames are treated and a limited number of researches deal with optimal damper placement problems for inelastic frames (for example, [1, 7, 12]). In the presence of yielding in a frame, the setting of the level of input ground motions (GMs) used for the optimization affects the final design. However, even in these studies, a problem how to determine the level of input GMs has not been examined. An optimal damper distribution designed under a specified-level GM may not be necessarily effective for larger-level GMs. Especially, a model optimally designed in the elastic range exhibits a large plastic deformation concentration to specific stories for larger inputs [2, 3]. Therefore, a design effective for various levels of GMs is desirable.

In this paper, a new optimal damper design method, called a ‘consecutive design generation method (CDGM)’, is presented for elastic-plastic multi-degree-of-freedom (MDOF) building structures under multiple-level GMs. The procedure of the proposed method is as follows: (i) Set a variety of levels of input GMs  $\{IM_1, \dots, IM_L\}$  ( $IM_1 < \dots < IM_L$ ). (ii) Obtain the optimal design under GM with  $IM = IM_1$  using an optimization method. (iii) Obtain the optimal design under GM with  $IM = IM_2$  by a local search around the optimal design under GM with  $IM = IM_1$  as the initial design. (iv) Obtain the optimal design under GM with  $IM = IM_3$  by a local search around the optimal design under GM with  $IM = IM_2$  as the initial design, and the same procedure is repeated under GMs with other  $IM$ s. By using the proposed method, all the optimal designs can be obtained with much lower computational effort than the method repeating an ordinary optimization procedure under every-level GM. The proposed method helps to understand how the distribution of added damper damping coefficients changes as the level of GMs changes. Furthermore, a simple design guideline for the problem, which design to be chosen from various optimal designs, is presented based on the ‘ideal drift response curve’, which is also a new concept. Two representative recorded ground motions are employed as a set of GMs and the proposed method is applied to these GMs. The influence of the number of GMs and the level of GMs on the optimal damper design is clarified.

## 2 PROBLEM OF OPTIMAL DAMPER PLACEMENT

In this section, two kinds of problems of optimal damper placement are presented. An ordinary problem of optimal damper placement (OPODP) is stated as minimizing the maximum interstory drift under the condition on the specified total quantity of added viscous damping coefficients and the specified level of input GMs. Another problem is to find the problem of optimal damper placements under consecutive-level GMs (PODPCG). The problem PODPCG is mainly dealt with in this paper. Since elastic-plastic MDOF structures are dealt with, the setting of the level of input GMs affects the final design. Therefore, solving the problem PODPCG helps to understand how the distribution of added damper damping coefficients changes as the level of GMs increases. The relation of the problems OPODP and PODPCG will be explained, and a solution algorithm will be proposed for the problem PODPCG.

## 2.1 Problem of optimal damper placement for consecutive-level ground motions

Consider first the problem OPODP.

### [Ordinary Problem of Optimal Damper Placement (OPODP)]

Find  $\mathbf{c}_{add}$   
 so as to minimize  $d_{\max} = \max_i \{d_{\max,i}\}$   
 subject to  $\mathbf{c}_{add} \cdot \mathbf{1} = W_c$  (const.)

where  $\mathbf{c}_{add}$ ,  $d_{\max,i}$ ,  $W_c$  denote the added damping coefficient vector, the maximum interstory drift in the  $i$ -th story, the sum of the added damping coefficients, respectively.

Consider next the problem PODPCG.

### [Problem of Optimal Damper Placements for Consecutive-level GMs (PODPCG)]

Obtain the  $L$  sets of damper placements  $\mathbf{c}_{add}^{opt}(IM_1), \dots, \mathbf{c}_{add}^{opt}(IM_L)$  ( $IM_1 < \dots < IM_L$ )

where  $IM, L, \mathbf{c}_{add}^{opt}(IM_j)$  denote the level of input GMs, the number of  $IM$ s, the optimal damper placement under the GMs with  $IM = IM_j$ , respectively.

All the optimal designs  $\mathbf{c}_{add}^{opt}(IM_1), \dots, \mathbf{c}_{add}^{opt}(IM_L)$  are obtained by solving the problem OPODP  $L$  times for each level of the input GMs. However, it is preferable to avoid such iteration for lower computational effort. To overcome this difficulty, a simple and efficient approach including a local search is proposed.

## 2.2 Solution algorithm: consecutive design generation method

The solution algorithm for the problem PODPCG may be described as follows.

### [Algorithm: Consecutive Design Generation Method (CDGM)]

Step 1 Set a variety of levels of input GMs  $\{IM_1, \dots, IM_L\}$  ( $IM_1 < \dots < IM_L$ ).

Step 2 Obtain  $\mathbf{c}_{add}^{opt}(IM_1)$  using an optimization method. Put  $i \rightarrow 1$ .

Step 3 Obtain  $\mathbf{c}_{add}^{opt}(IM_{i+1})$  by a local search around  $\mathbf{c}_{add}^{opt}(IM_i)$  as the initial design.

3.1 Find the story  $j$  which exhibits the largest value of  $d_{\max,j}$ .

3.2 Select the stories in which dampers are installed (exclude the stories without damper). Then find the story  $k$  which exhibits the minimum value of  $d_{\max,k}$  from those stories.

3.3 Update the damping coefficients  $c_j \rightarrow c_j + \Delta c, c_k \rightarrow c_k - \Delta c$ .

3.4 Repeat 3.1-3.3  $n_{ls}$  times.

3.5 Select the design which exhibits the minimum value of  $d_{\max}$  from  $n_{ls}$  designs.

Step 4 Put  $i \rightarrow i+1$ . If  $i = L$  is satisfied, then finalize the process. If  $i < L$  is satisfied, return to Step 3.

The overview and the flow of this algorithm are shown in Figure 1. It is noted that the sensitivity-based approach [3, 8] is adopted to obtain  $\mathbf{c}_{add}^{opt}(IM_1)$  in this paper. It is also pointed out that the local search method used in Step 3, 4 is quite simple, but it works well so far as the value of  $\Delta IM (= IM_{i+1} - IM_i)$  is small (the effectiveness of the proposed local search method is demonstrated through the numerical examples in Section 3.1 and 3.2).

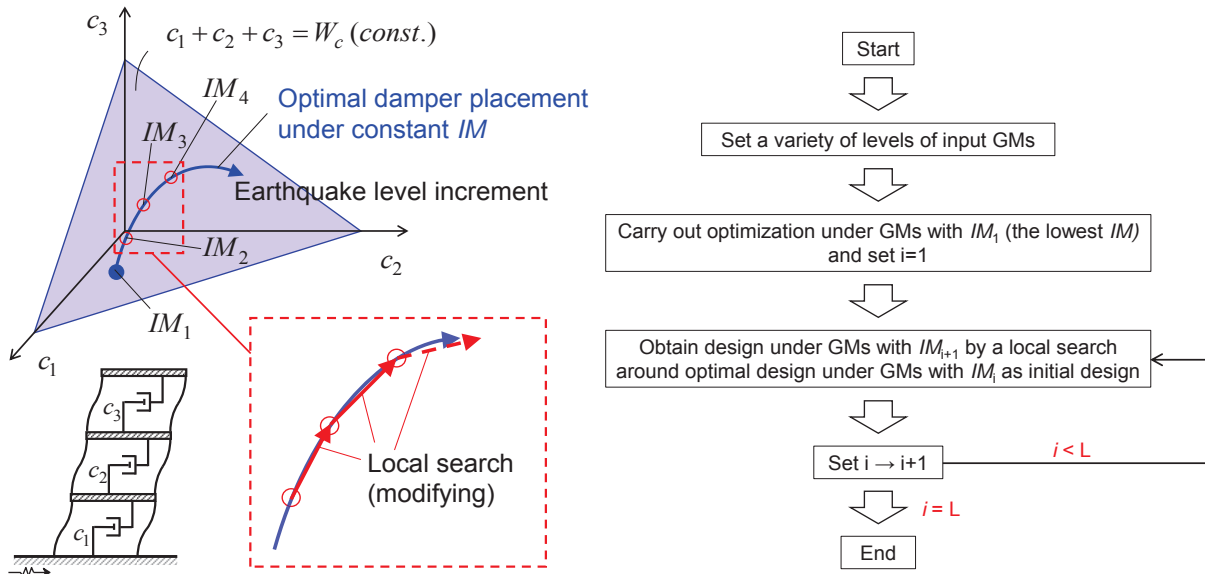

Figure 1: Overview and schematic diagram of proposed solution algorithm.

## NUMERICAL EXAMPLE

Consider two shear building models of 12 stories with different story stiffness distributions. Model 1 has a trapezoidal distribution of story stiffnesses ( $(k_1 / k_{12}) = 4$ ). Model 2 has a uniform distribution of story stiffnesses. The undamped fundamental natural period of these two models is 1.2[s] and the structural damping ratio is 0.01 (stiffness proportional type). All the floor masses have the same value. The common story height is 4[m] and the common yield interstory drift is 4/150[m]. The story shear-interstory drift relation obeys the elastic perfectly-plastic rule.

### 2.3 Influence of level of input ground motion

In this section, the influence of the level of input GMs on the final design is investigated. El Centro NS component during the Imperial Valley earthquake in 1940 is employed here. The level of the GM is adjusted by the peak ground velocities (PGV). 51 levels of the GM (from PGV = 0.5 [m/s] to PGV = 1.5 [m/s] by the increment 0.02 [m/s]) are used to obtain optimal designs. The sensitivity-based approach [3, 8] is adopted to obtain  $\mathbf{c}_{add}^{opt}$  (PGV=0.5) and the required number of time-history response analyses is about 6000 to obtain  $\mathbf{c}_{add}^{opt}$  (PGV=0.5). The targeted value of the sum of the added damping coefficients is set to  $W_c = 10 \times 10^7$  [Ns/m]. The value of  $W_c$  is given so that the final design has the fundamental-mode damping ratio of about 0.05.  $n_{ls} = 50$  and  $\Delta c = W_c / 240$  are employed for the local search. The total number of time-history response analyses is  $6000 + n_{ls} \times (51 - 1) = 8500$ .

Figures 2 and 3 show the optimal designs for Model 1 and 2. It can be observed that the proposed method certainly provides effective designs for various levels of GMs for both Model 1, 2. This means that the proposed local search method works well even though the local search method is quite simple. It can also be said that, as PGV used for the design becomes larger, the dampers concentrated to the specified stories spread around those stories and the distributions of added damping coefficients become smoother. This is because those surrounding stories without dampers tend to exhibit large deformation concentrations for larger levels of GMs. For Model 1, the added dampers are allocated only in the 6-10th stories in

the case of  $PGV < 0.7[m/s]$ . As PGV becomes larger, the dampers are allocated to the 4-5th stories. For Model 2, the dampers allocated only in the 1-3th stories for smaller PGV spread to the 4-6th stories as PGV becomes larger. Furthermore, the distribution of added damping coefficients shows a drastic change just after  $d_{\max}/d_y$  attains 1 as shown in Figures 2c and 3c. For larger levels of GMs, the distribution changes gently.

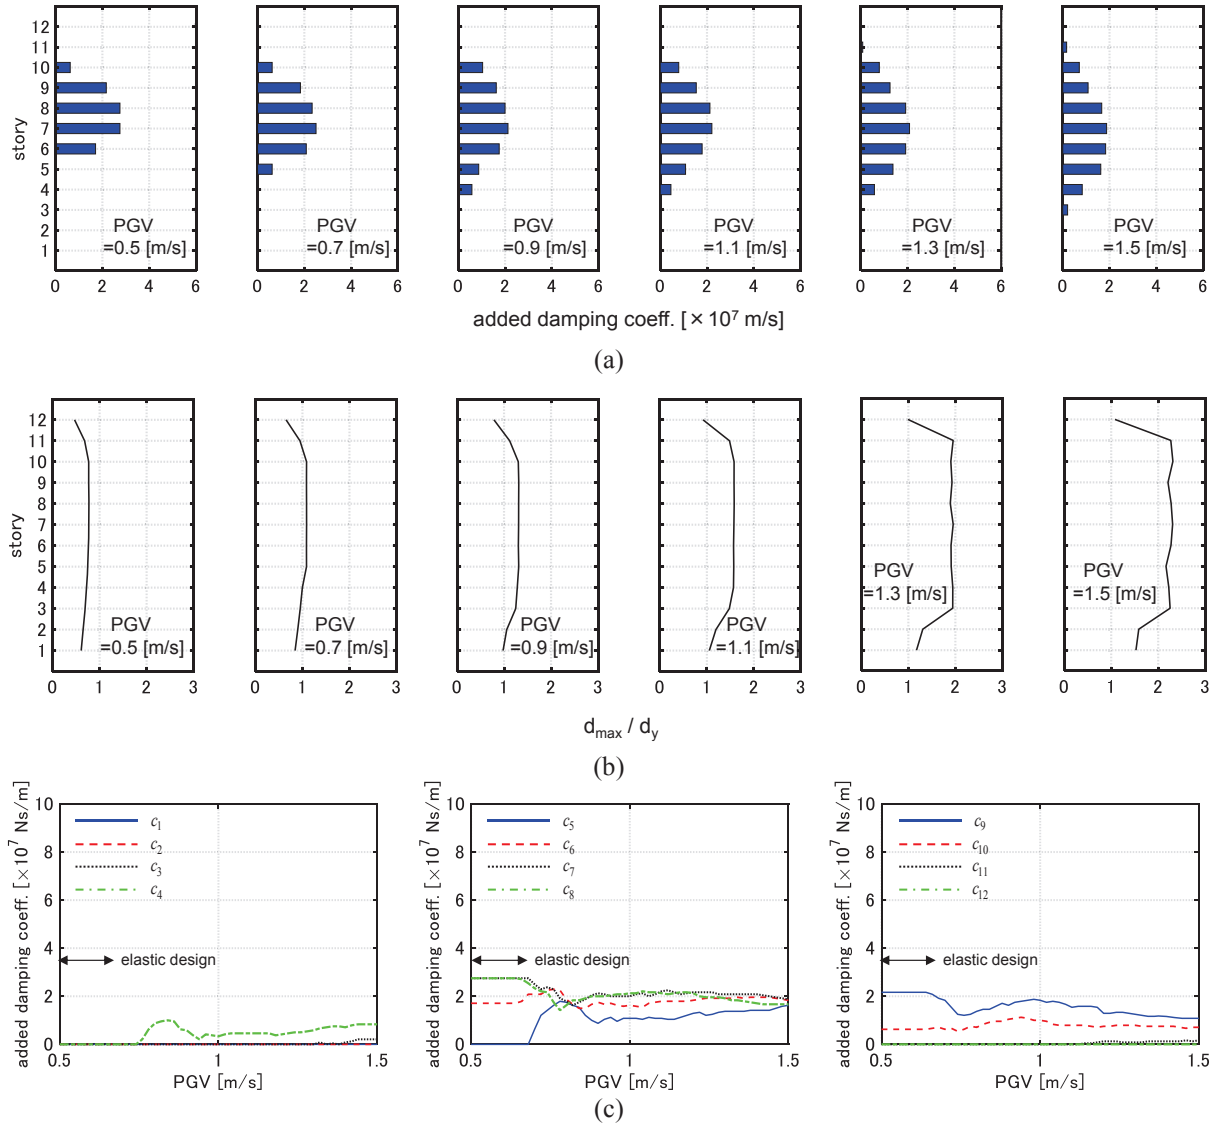

Figure 2: Optimal designs of added viscous damper for multiple-level GMs (Model 1), (a) distribution of added damping coefficient, (b) distribution of  $d_{\max,i}/d_y$ , (c) change of added damping coefficient of each story.

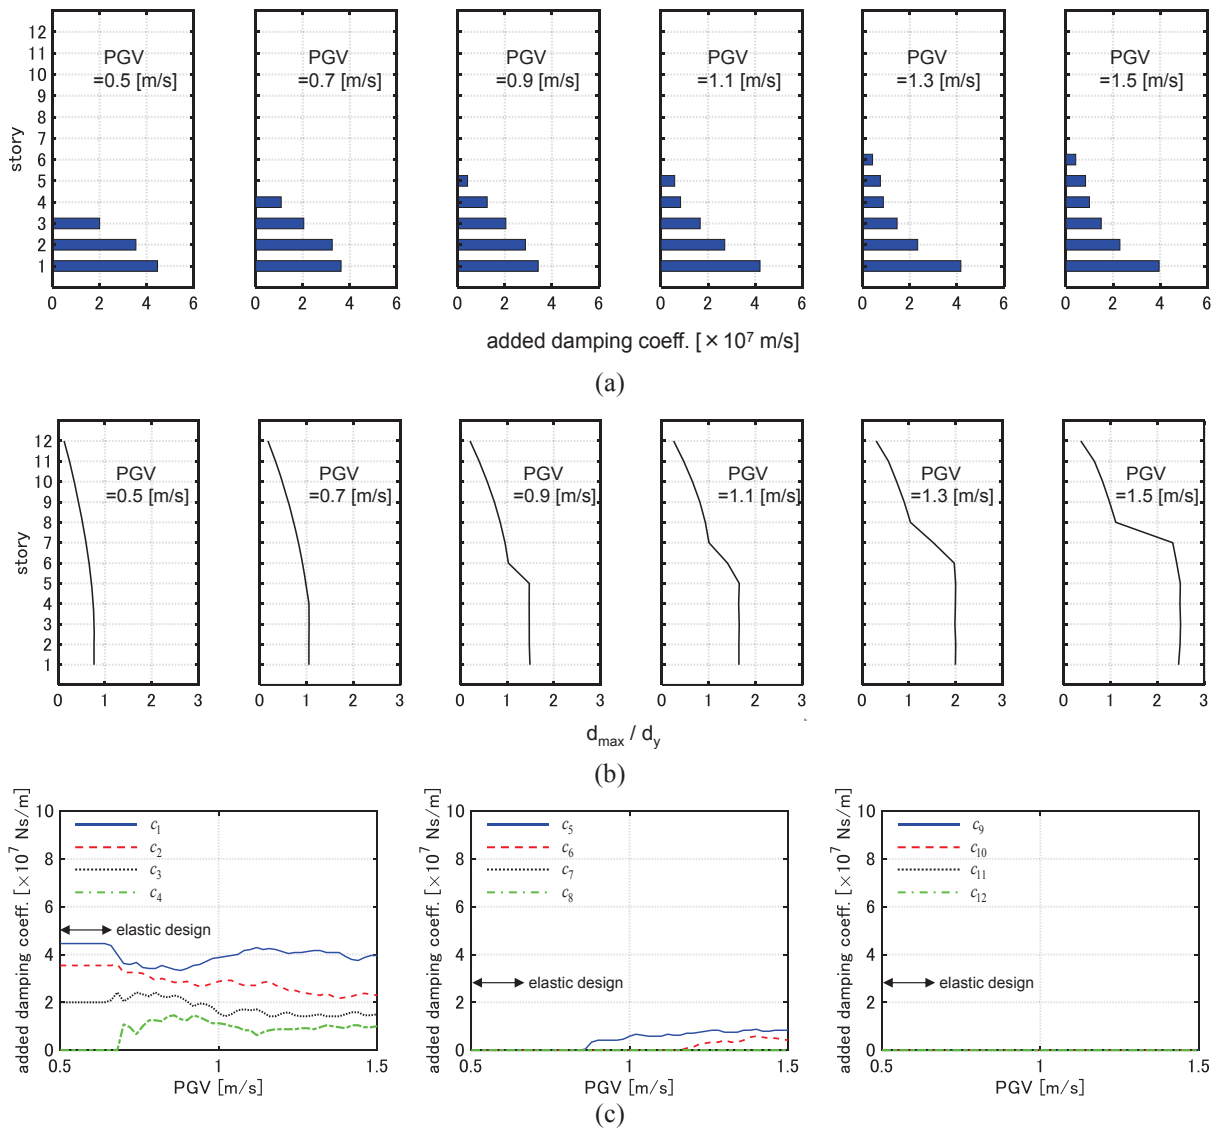

Figure 3: Optimal designs of added viscous damper for multiple-level GMs (Model 2), (a) distribution of added damping coefficient, (b) distribution of  $d_{\max,i} / d_y$ , (c) change of added damping coefficient of each story.

## 2.4 Influence of number of input ground motions

In this section, the influence of the number of input GMs on the final design is investigated. Hachinohe NS component during the Tokachi-oki earthquake in 1968 and El Centro NS component are employed. All the other parameters for the optimization are the same as those in Section 3.1. It should be noted that the predominant period of Hachinohe NS component is longer than that of El Centro NS component.

Figures 4 and 5 show the optimal designs for Model 1 and 2. It can be observed that, in the case of  $PGV \leq 0.9$  [m/s], the optimal distributions of added damping coefficients are the same as those in Section 3.1. This is because El Centro NS component provides the response envelopes. When PGV used for the design becomes larger, Hachinohe NS component is critical in the lower stories. This means that, as PGV becomes large and the plastic deformation level increases, the equivalent natural period is lengthened. For Model 1, the distributions of the

added damping coefficients are smoother than the optimal distributions designed only under El Centro NS component. For Model 2, similar to the case in Section 3.1, the added dampers are concentrated to the lower stories. This is because Model 2 has a uniform distribution of story stiffnesses and tends to exhibit plastic deformation concentration in the lower stories for large inputs. It can also be said that, while almost all the stories exhibit plastic deformations for large inputs in the case of Model 1, the upper stories remain elastic for large inputs in the case of Model 2. Therefore, the value of  $d_{\max} / d_y$  of Model 2 for larger inputs are larger than that of Model 1.

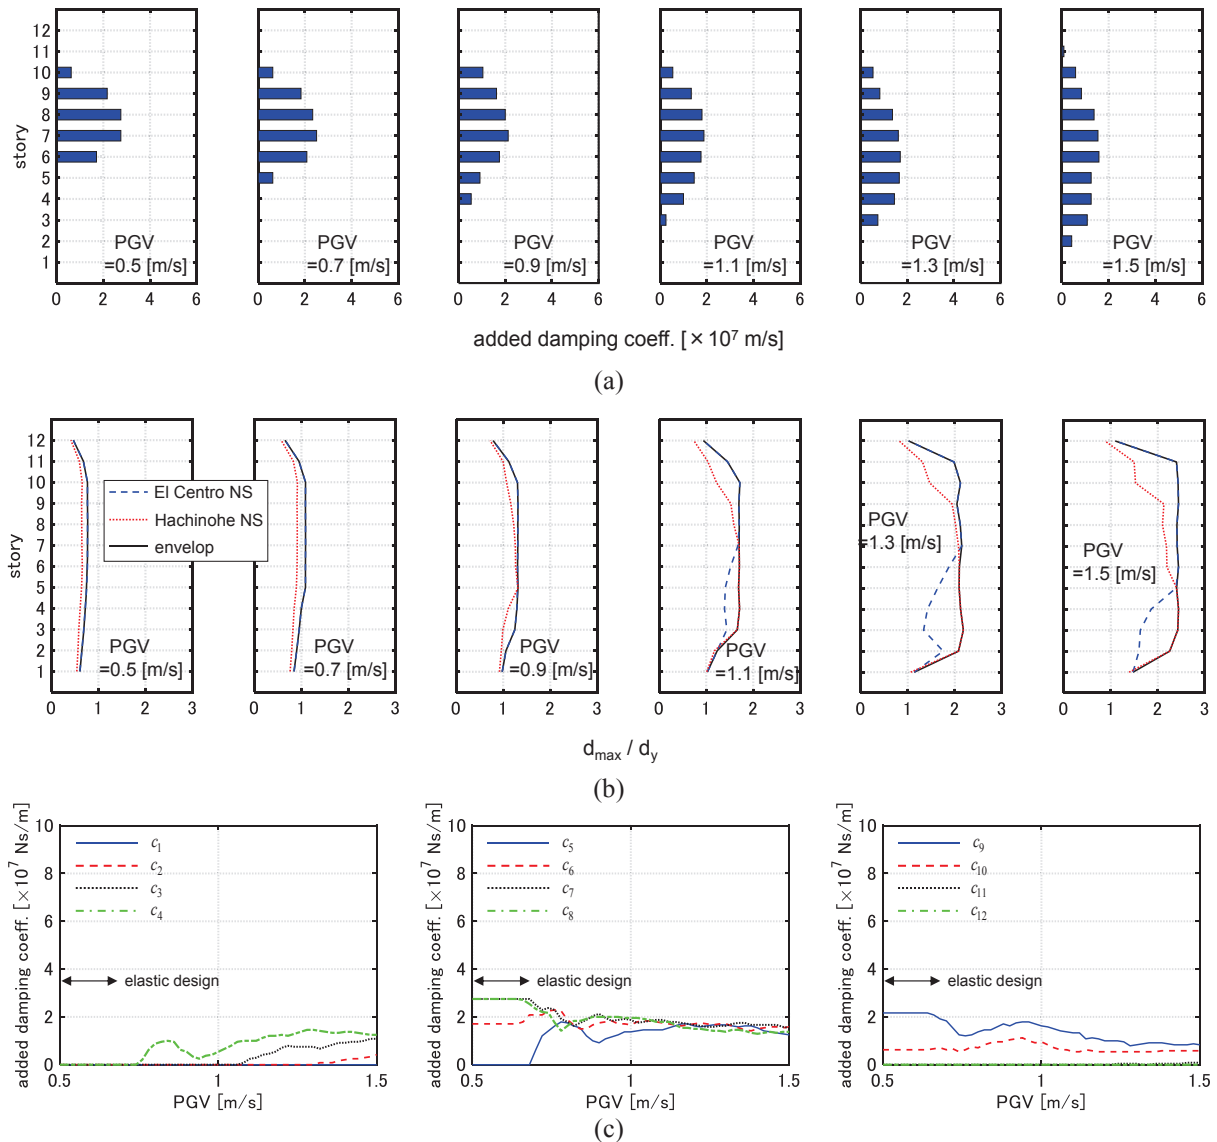

Figure 4: Optimal designs of added viscous damper for multiple-level two GMs (Model 1), (a) distribution of added damping coefficient, (b) distribution of  $d_{\max,i} / d_y$ , (c) change of added damping coefficient of each story.

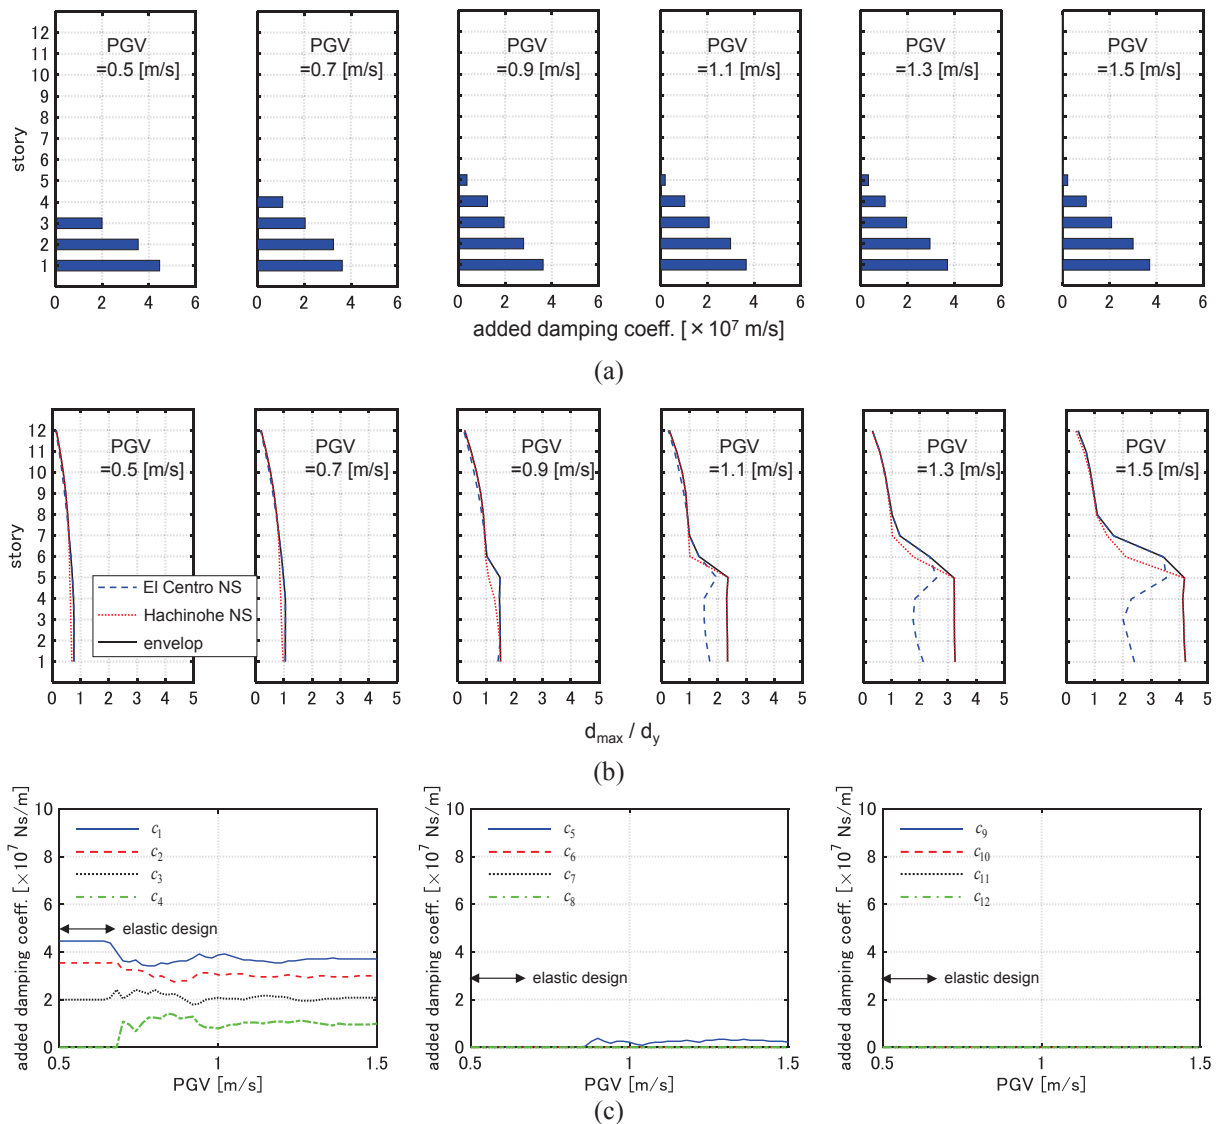

Figure 5: Optimal designs of added viscous damper for multiple-level two GMs (Model 2), (a) distribution of added damping coefficient, (b) distribution of  $d_{\max,i} / d_y$ , (c) change of added damping coefficient of each story.

## 2.5 IDA analysis and ideal drift response curve

In this section, IDA analysis [13] is conducted for the models obtained in Section 3.2. El Centro NS component and Hachinohe NS component are adopted for IDA. PGV is increased from 0.5 [m/s] to 1.5 [m/s] by 0.02 [m/s].

Figures 6a and 7a show the maximum interstory drift distributions by IDA analysis for the models designed under these two GMs with PGV=0.5, 1.0, 1.5 [m/s]. The input level PGV=0.5 corresponds to elastic design. It can be observed that the models designed for PGV=0.5, 1.0 [m/s] exhibits large deformation concentrations in specific stories for these two GMs with larger PGV. Figure 6c and 7c illustrate the critical earthquakes in the applications of IDA. El Centro NS component is critical in the lower range of PGV and Hachinohe NS component is critical in the upper range of PGV for all models since the predominant period of the latter is longer than that of the former as stated in Section 3.2.

Figures 6b and 7b show the IDA curves and the ideal drift response curves. An ideal drift response curve is a plot of the optimized maximum deformations versus design  $IM$ . The opti-

mal designs for various levels of GMs are obtained by conducting CDGM, and simultaneously the ideal drift response curve is provided. The IDA curves for all the optimal designs never cross the ideal drift response curve, and the IDA curve for each optimal design is tangent to the ideal drift response curve only at the point where  $IM$  corresponds to the design  $IM$ . It can be observed that the IDA curves for the models designed for  $PGV=1.5$  [m/s] run near the ideal drift response curves.

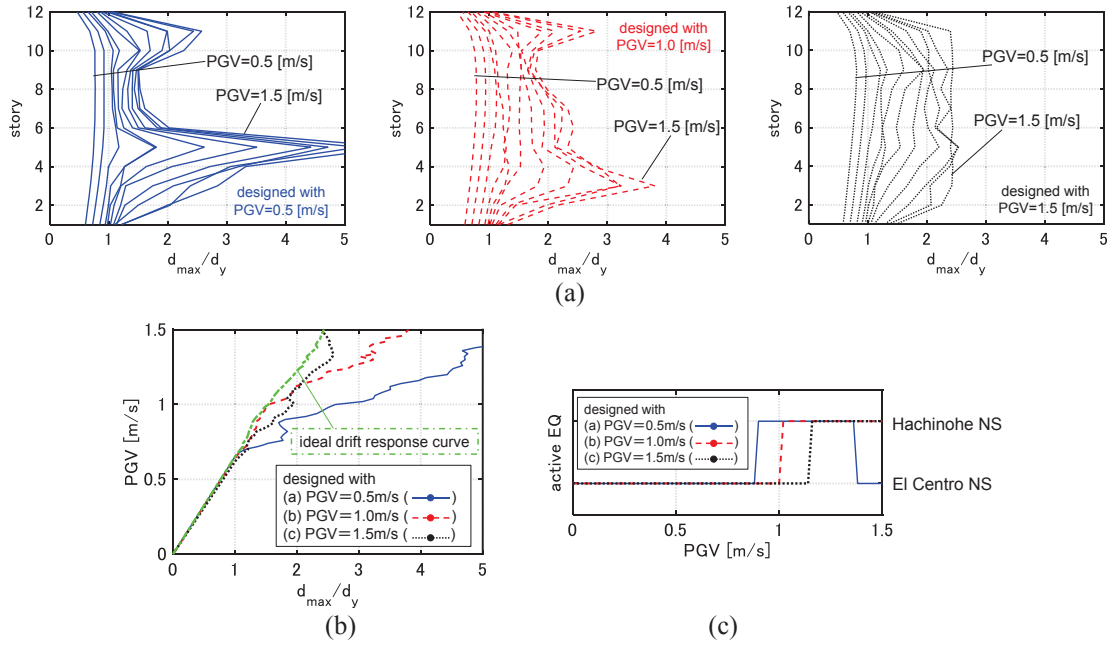

Figure 6: IDA analysis for 3 models designed under GMs with  $PGV=0.5, 1.0, 1.5$  [m/s] (Model 1), (a) distribution of  $d_{max,i} / d_y$ , (b) IDA curves and ideal drift response curve, (c) active EQ.

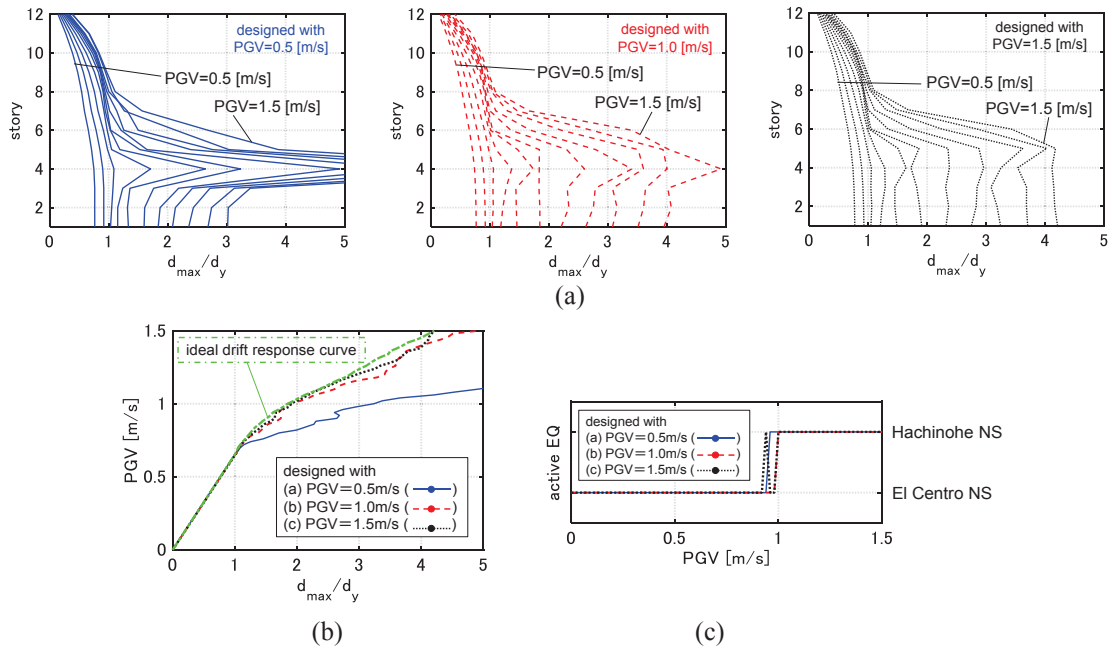

Figure 7: IDA analysis for 3 models designed under GMs with  $PGV=0.5, 1.0, 1.5$  [m/s] (Model 2), (a) distribution of  $d_{max,i} / d_y$ , (b) IDA curves and ideal drift response curve, (c) active EQ.

As shown in Figures 6 and 7, the model optimally designed for a specified-level GMs is not necessarily effective for other levels of GMs. Therefore, a design guideline for the problem, which design to be chosen from the various optimal designs, is needed. In this paper, a simple index for selection is introduced as follows,

$$\max_{IM} \{d_{\max}(IM) - \text{IDRC}(IM)\}$$

where IDRC denotes the value of the ideal drift response curve. It can be said that the design, which minimizes the proposed index, shows high robustness (effective for various levels of GMs). Figure 8 indicates the procedure for selecting such design.

Figures 9 and 10 show the values of the proposed index for the models obtained in Section 3.2 and the IDA curves for the models which minimize the proposed index. It can be observed that, as PGV used for the design becomes larger, the value of the proposed index generally decreases. It can also be said that the elastic designs provide the highest value of the index. For both Models 1 and 2, the designs, which minimize the index, are effective for various levels of the GMs. Especially for Model 2, the IDA curve for the selected design runs quite near the ideal drift response curve. This is because Model 2 tends to exhibit plastic deformation concentration in the lower stories for large inputs as stated in Section 3.2.

Figure 9: Proposed index and IDA curve for design with minimum index (Model 1).

Figure 10: Proposed index and IDA curve for design with minimum index (Model 2).

### 3 CONCLUSIONS

A new optimal damper design method is presented for elastic-plastic MDOF building structures under multiple-level earthquake ground motions (GMs). The main conclusions can be summarized as follows.

- A consecutive design generation method (CDGM) was proposed for the above-mentioned problem. By using CDGM, all the optimal designs can be obtained with much lower computational effort than the method repeating an ordinary optimization procedure under every-level GM. CDGM also helps to understand how the distribution of added damper damping coefficients changes as the level of GMs changes.
- As the level of input GMs used for the design becomes larger, dampers concentrated to the specified stories spread around those stories and the distribution of the added damping coefficients becomes smoother.
- As the number of input GMs used for the design increases, the distribution of the added damping coefficients becomes smoother.
- Models designed for lower-level GMs may exhibit large plastic deformation concentrations in specific stories for larger-level GMs.
- A new concept of ‘ideal drift response curve’ was presented for selecting a robust design for various levels of GMs. This is a plot of the optimized maximum deformation versus design  $IM$  (level of input GMs). The optimal designs for various levels of GMs were obtained by conducting CDGM, and simultaneously the ideal drift response curve was provided.

### Abstract

*Greece is divided into three seismic hazard zones ZI, ZII, ZIII. In the present research work, the same building in the three seismic zones of Greece is modeled, analysed and dimensioned and then the construction cost of its structural body is estimated. The building modeling was performed in SAP2000 using linear finite elements. The analysis of the building was performed by dynamic spectral analysis methods using the design spectrum of EC8. A fifteen-storey building with a standard floor plan per floor was used. The purpose of this research paper is to study the possible influence of seismicity, based on which the dimensioning takes place, on the construction cost of the load-bearing structure of a fifteen-storey building with a standard floor plan per floor. The degree of influence is studied by estimating the quantities of materials required depending on the seismic hazard zone. Interesting comparisons take place between the results for the three different seismic hazard zones. Useful conclusions are drawn regarding the influence of seismicity on the construction cost of the load-bearing structure of reinforced concrete buildings.*

**Keywords:** Seismic zone, Construction cost, Multi-storey building

---

## 1 INTRODUCTION

Greece ranks sixth in the world in the list of most seismic countries. Although it occupies 0.02 of the Earth's surface, it releases 2% of global seismic energy each year and more than 50% of the European. Therefore, Greece is challenged to face earthquake phenomenon by improving the construction of structures, taking under consideration the parameters of safety and cost. According to those factors, the earthquake resistant regulations have been evolved worldwide [1]–[3], facing with great effectiveness the safety of human life. In the seismic design of reinforced concrete structures, a key parameter is the seismic design actions, based on which the structures in each area are designed (Table 1).

The seismic design actions of the structures depend on the seismic hazard of each area and their values are determined in the Seismic Hazard Map, which is an integral part of the Earthquake Regulation [2], [3]. Seismic hazard is the maximum expected value of a seismic parameter for a given recurrence period or for a specific probability of non-overcoming and a specific period of time. The results of seismic hazard studies are given in the form of maps or curves that provide the distribution of the selected ground motion measure and the probability that it will be exceeded or not exceeded in a certain period of time (Figure 1). Usually, the probability of distribution is estimated by 10% of exceeding a defined value of land movement for the time period of 50 years or equal, an average repetition of 475 years.

The expected values of the ground acceleration are derived from seismic hazard studies, after statistical processing of seismic events that have occurred in the wider project area. Such studies are prepared for large and important projects, while for ordinary constructions the prices are given by the regulations, depending on the area in which the construction is going to take place. According to EC8 [2] and Greek Seismic Code [3], national areas are subdivided into seismic zones (Z1, Z2 and Z3) depending on the local hazard (Figure 1). By definition, it is assumed that within each zone the hazard is constant and is described by a single parameter, the value of the maximum reference ground acceleration  $\alpha_g R$ , which corresponds to soil category “A” and characterizes the seismic activity in each zone. Considering the above, the present work aims to investigate whether the design and study of a building in each seismic zone, can affect the cost of construction of its load-bearing structure. Several studies have been conducted regarding the cost, as far as various types of structures are concerned [4]–[10]. This study aims to investigate the cost in terms of the construction cost of load-bearing structure of multi-storey buildings and if and how it is affected by the seismicity of the area.

Zone of seismic risk	Ground acceleration values (g)
Z1	0,16
Z2	0,24
Z3	0,36

## 2 ANALYTICAL RESEARCH

### 2.1 Building data

The building under consideration is symmetrical, with a rectangular floor plan with dimensions of 25 x 25 m, slab thickness equal to 15 cm, total height 46.50 m (all floors are 3 m, except the 1<sup>st</sup> floor which has a height equal to 4.5 m) and will not include basement. The influence of the soil is neglected and rigid connections are used for the building's supports [11]–[16]. In the center of the floor plan, there are two symmetrical cores consisting of 8 walls with different dimensions (6 along the Y axis and 2 along the X axis), which are connected by three beams 1m long and 0.70 m high. Also, there are two walls in the perimeter of the floor plan along the Y axis, which have enlarged boundary edges at their both ends (Figure 2), in order for phenomena of lateral buckling at seismic walls to be avoided [17]–[31].

Regarding the dimensions of the cross-sections of the structural elements, the cross-sections of the columns of the building remain constant for the 1st floor (ground floor) and the 2nd, while the rest are reduced by 5 cm per floor. The cross-sections of the beams remain fixed on all floors, while the cross-sections of the walls vary in height and are reduced per 5 floors by 12.5 cm. The construction materials of the building are concrete C30/37 and steel B500C. The cross sections of the beams remain the same in every storey but the cross sections of the walls shift per floor and decrease per 5 storeys for 12.5 cm. The construction materials of the building, is C30/37 concrete and Steel B500C. Finally, below are presented the floor plan and the table of cross sections of the structural elements of the building.

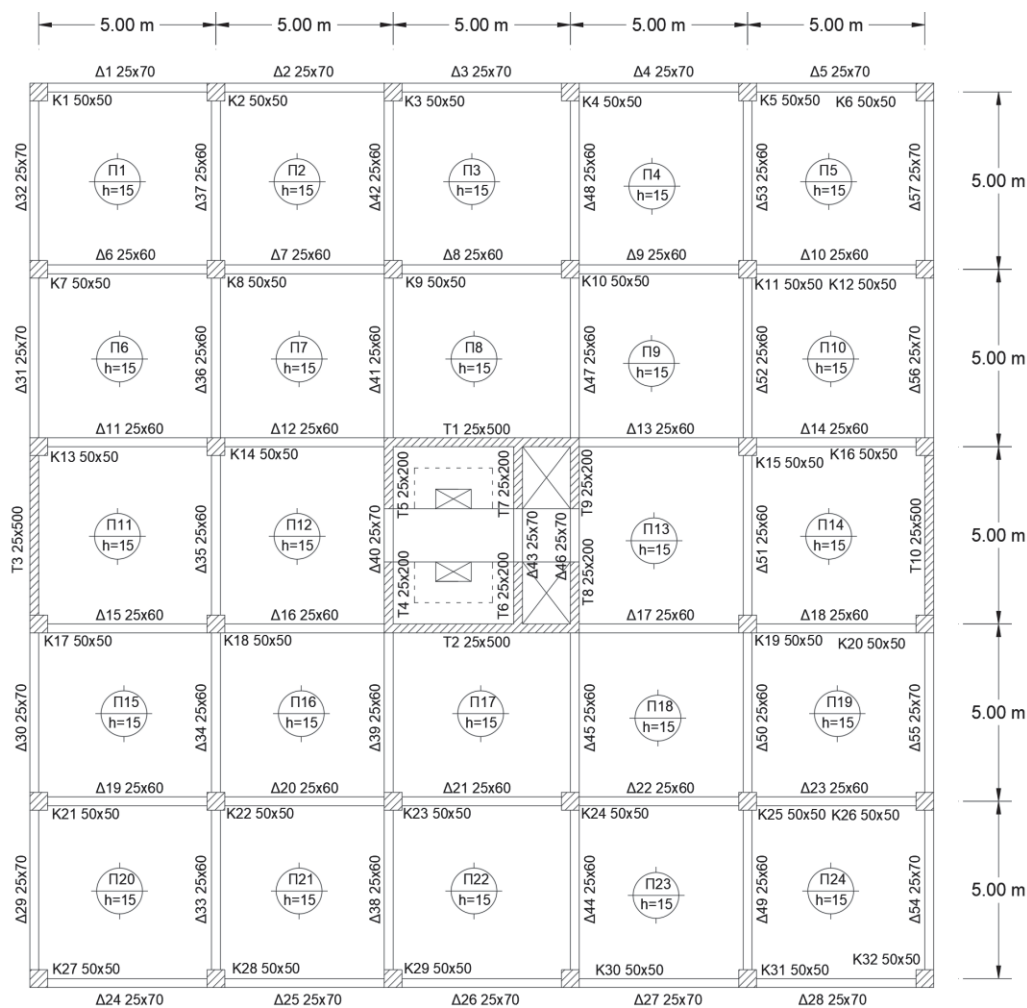

Figure 2: Typical floor plan.

Floor	Height (m)	Beam dimensions (cm)		Wall thickness (cm)	Column dimensions (cm)
		Perimetric	Internal		
<b>1<sup>st</sup> (Ground floor)</b>	4.50	25x70	25x60	50	100x100
<b>2</b>	3.00	25x70	25x60	50	100x100
<b>3</b>	3.00	25x70	25x60	50	95x95
<b>4</b>	3.00	25x70	25x60	50	90x90
<b>5</b>	3.00	25x70	25x60	50	85x85
<b>6</b>	3.00	25x70	25x60	37.5	80x80
<b>7</b>	3.00	25x70	25x60	37.5	75x75
<b>8</b>	3.00	25x70	25x60	37.5	70x70
<b>9</b>	3.00	25x70	25x60	37.5	65x65
<b>10</b>	3.00	25x70	25x60	37.5	60x60
<b>11</b>	3.00	25x70	25x60	25	55x55
<b>12</b>	3.00	25x70	25x60	25	50x50
<b>13</b>	3.00	25x70	25x60	25	45x45
<b>14</b>	3.00	25x70	25x60	25	40x40
<b>15</b>	3.00	25x70	25x60	25	35x35

Table 2: Dimensions of the structural elements.

## 2.2 Construction

The building, as a typical construction, is stressed by gravity loads which are the permanent loads (self-weight, etc.), the live loads (human load, etc.) and the seismic loads. For the building in question, the loads are shown in Table 3.

PERMANENT LOADS		
N/A	Type	Value
1	Flooring	1.40 kN/m <sup>2</sup>
2	Partition brick structures	1.00 kN/m <sup>2</sup>
3	Perimeter brick structures	8.00 kN/m
4	Roofing	3.50 kN/m <sup>2</sup>
5	Parapet roof load	3.60 kN/m <sup>2</sup>
LIVE LOADS		
N/A	Type	Value
1	Ground floor	2.00 kN/m <sup>2</sup>
2	Typical floors	2.00 kN/m <sup>2</sup>
3	Roof	2.00 kN/m <sup>2</sup>
SPECTRUM DATA EC8		
N/A	Type	Data
1	Spectrum type	Horizontal design spectrum type 1
2	Soil category	B
3	Factor $\beta$	0.20
4	Seismic acceleration factor $\alpha$	For the three categories: $\alpha = 0.16, 0.24, 0.36$
5	Gravity acceleration g	9.81 m/sec <sup>2</sup>
6	Coefficient behavior q	Calculation based on EC8

Table 3: Building loads.

## 2.3 Modelling

The modeling of the load-bearing structure of the building will be performed with the finite element software SAP2000. The individual structural elements that were modeled are the beams, the columns and the seismic walls of the building. Also, it is essential to simulate the diaphragm function of the slabs on each floor. The dynamic spectral method analysis according to the EC8 [2] will be applied for the seismic actions of the building.

In conclusion, through the simulation some results will be extracted according to which the building will be dimensioned for the three seismic hazard zones and these are the design moments of the beams, the values for N,  $M_{33}$ ,  $M_{22}$  of the vertical elements. Figure 3 presents the 3D model of the building.

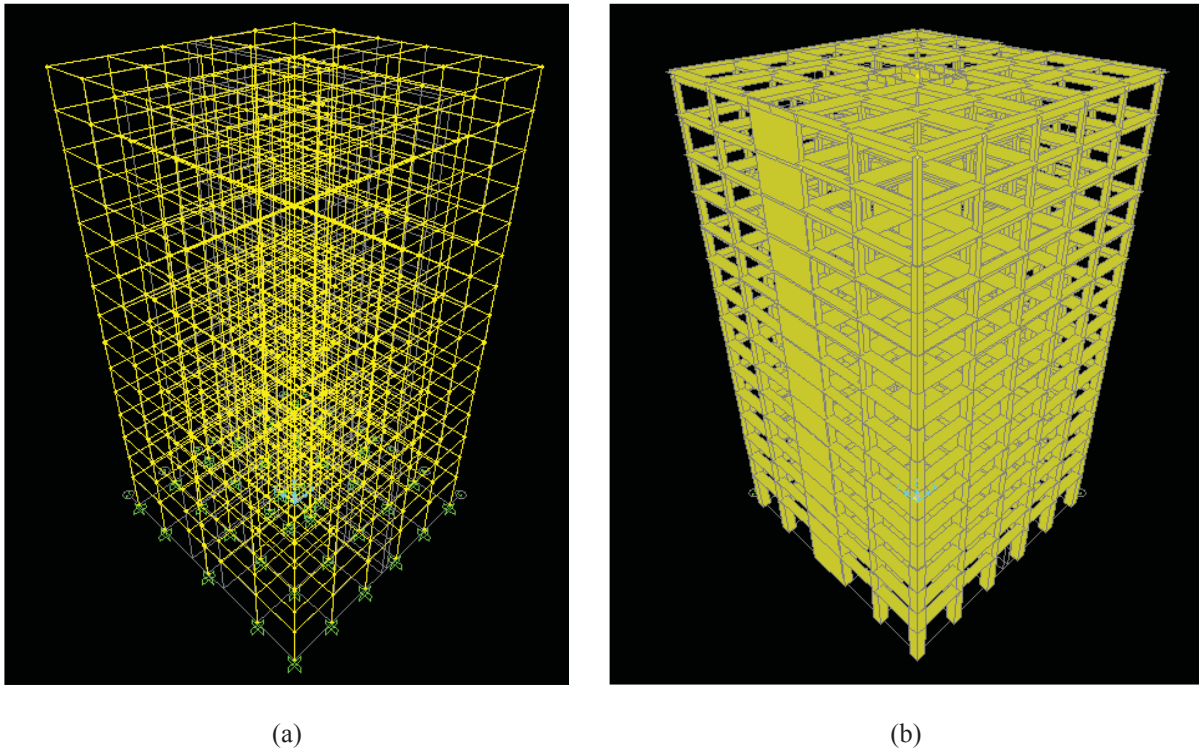

Figure 3: Views of the 3D building model: (a) Linear finite elements (b) Sections.

## 2.4 Dimensioning of the building

The dimensioning of the building will be based on EC8 [2] and EC2 [32], for each seismic hazard zone only for the 14<sup>th</sup> floor level. The horizontal structural members dimensioned are the slabs of the 14<sup>th</sup> floor and the beams of this level, while the vertical structural members are the columns and the structural walls. Figure 4 and Figure 5 present indicative reinforcement of the beam and the slab respectively resulted by the building design.

Figure 4: Beam reinforcement of the 14<sup>th</sup> floor.

Figure 5: Slab reinforcement of the 14<sup>th</sup> floor.

## 2.5 Measurements of building materials

The measurement of building materials used for the construction of the load-bearing structure (concrete and steel) for all three seismic zones will be calculated considering the results of the design. Table 4 displays the measurements for the concrete material, which remain the same for all three seismic zones. Similar calculations have taken place for the measurement of the steel material used for the concrete reinforcements.

CONCRETE MEASUREMENT					
STOREY	SLABS (m <sup>3</sup> )	BEAMS (m <sup>3</sup> )	COLUMNS (m <sup>3</sup> )	WALLS (m <sup>3</sup> )	TOTAL (STOREY) (m <sup>3</sup> )
1	90	33.08	139.2	63.08	325.36
2	90	33.08	91.20	41.33	255.61
3	90	33.92	82.31	41.61	247.84
4	90	34.72	73.87	41.90	240.49
5	90	35.55	65.89	42.18	233.62
6	90	36.35	58.37	31.85	216.57
7	90	37.19	51.30	32.06	210.55
8	90	37.99	44.69	32.28	204.96
9	90	38.82	38.53	32.49	199.84
10	90	39.62	32.83	32.70	195.15
11	90	40.46	27.59	21.95	180.00
12	90	41.26	22.80	22.09	176.15
13	90	42.09	18.47	22.23	172.79
14	90	42.89	14.59	22.37	169.85
15	90	43.69	11.17	22.52	167.38
				<b>TOTAL</b>	<b>3196.16</b>

Table 4: Concrete measurement.

### 3 RESULTS ANALYSIS

#### 3.1 Concrete measurements

Figure 6 shows the amount of concrete per floor and Figure 7 displays the amount of concrete occupied by the structural elements of the load-bearing structure.

Figure 6: Percentage of concrete per floor (%).

Figure 7: Percentage of structural elements in the total concrete (%).

From the previous diagrams, it is obvious that the 1<sup>st</sup> floor occupies the largest percentage of concrete in relation to the other floors, while at the same time the percentage of the other floors decreases from floor to floor. Also, the slabs occupy the largest percentage of the total concrete with 42.2%, followed by the columns with 24%, the beams with 18% and finally the walls with 16%.

### 3.2 Steel measurements

#### 3.2.1. Steel measurement per seismic zone

Table 5 presents the quantities of steel in kgr that result for the structural elements of the building, in each seismic zone. The same results are displayed in the form of a column graph in Figure 8.

REINFORCEMENT STEEL MEASUREMENT					
Seismic zone	Slabs	Beams	Columns	Walls	TOTAL
<b>I</b>	9214.32	6353.50	2615.83	2826.53	<b>21010.18</b>
<b>II</b>	9214.32	6416.78	2623.71	3019.44	<b>21274.25</b>
<b>III</b>	9214.32	6455.03	2631.59	3261.77	<b>21562.71</b>

Table 5: Structural element steel weight for the three seismic zones.

Figure 8: Total weight of reinforcement steel of structural elements of the 14<sup>th</sup> floor for each seismic zone.

### 3.2.2. Percentage change of steel weight between the seismic zones

Figure 9: Percentage change of weight of steel reinforcement of the 14<sup>th</sup> floor for each seismic zone concerning:  
(a) All structural elements, (b) Beams, (c) Columns, (d) Seismic walls

From Figure 9, it appears that:

- The transition from Zone I with seismic acceleration  $\alpha_g = 0.16g$ , to Zone II with seismic acceleration  $\alpha_g = 0.24g$  causes:
  - 1.24% increase of the total steel weight for all structural elements
  - 1.00% increase of the steel weight for the beams
  - 0.3% increase of the steel weight for the columns
  - 6.39% increase of the steel weight for the structural walls
- The transition from Zone II with seismic acceleration  $\alpha_g = 0.24g$ , to Zone III with seismic acceleration  $\alpha_g = 0.36g$  causes:
  - 1.34% increase of the total steel weight for all structural elements
  - 0.59% increase of the steel weight for the beams
  - 0.29% increase of the steel weight for the columns
  - 7.43% increase of the steel weight for the structural walls
- The transition from Zone I with seismic acceleration  $\alpha_g = 0.16g$ , to Zone II with seismic acceleration  $\alpha_g = 0.36g$  causes:
  - 2.56% increase of the total steel weight for all structural elements
  - 1.57% increase of the steel weight for the beams
  - 0.60% increase of the steel weight for the columns
  - 13.34% increase of the steel weight for the structural walls

Therefore, if the weight percentage of the individual structural elements of the structure (columns, beams and structural walls) increases from Zone I to Zone II and Zone III, except for the steel weight for the slabs that remains constant in the three seismic zones, that fact results to the increase of the total steel weight of the 14<sup>th</sup> floor.

### 3.2.3. Percentage of reinforcement steel per structural element for each seismic zone

Figure 10 shows the percentage of steel weight of each structural element in all three seismic zones. According to these figure, it is concluded that:

- Slabs occupy the largest percentage of steel in Zone I: 44%, while in Zone II: 43% and in Zone III: 42.7%.
- Beams occupy the second largest percentage of steel in Zone I: 30%, while in Zone II: 30% and in Zone III: 29%.
- Structural walls occupy the third largest percentage of steel in Zone I: 13%, while in Zone II: 14.2% and in Zone III: 15.1%.
- Columns occupy the smallest percentage of steel in Zone I: 12.5%, while in Zone II: 12.3% and in Zone III: 12.2%.

Furthermore, the design and detailing of the various structural elements has shown that during the transition from Zone I to Zone II and II:

- The beams maintain their longitudinal reinforcement constant, while the transverse reinforcement shows some increase.
- The columns also maintain their longitudinal reinforcement stable, while the transverse reinforcement shows some increase.
- Finally, the structural walls show an increase in their transverse reinforcement and the T3 and T10 structural walls (Figure 5) also show increases in their longitudinal reinforcement.

(a)

(b)

(c)

Figure 10: Percentage of steel weight per structural element for: (a) Zone I, (b) Zone II, (c) Zone III.

## 4 CONCLUSIONS

The structure studied in the present research is a fifteen-storey reinforced concrete building without a basement with rectangular conventional floor plan. It has been designed for all three seismic hazard zones Zone I, Zone II and Zone III. The resulting conclusions can be summarized as follows:

1. Walls show the largest percentage increase in steel weight with the increase of seismic acceleration.
2. At the beams, the steel weight increases much less than in seismic walls.
3. At the columns, the steel weight increases even less than the beams.
4. Therefore, the seismic walls are the dominant structural element in the building's system. Thus, it is a wall-governed system.
5. The increase of seismic acceleration  $\alpha_g$ :
  - From Zone I to Zone II is about 50%, while the percentage increase of the total amount of materials is only 1.24%.
  - From Zone II to Zone III is about 50%, while the percentage increase of the total amount of materials is only 1.34%.
  - From Zone I to Zone III is about 125%, while the percentage increase of the total amount of materials is only 2.56%.
6. Thus, the percentage increase in the total demand on steel is quite small.
7. So, we conclude that for a fifteen-storey reinforced concrete building, with a strong core wall arrangement, the influence of seismic hazard on the construction cost of the load-bearing system should not be significant because the percentage increase of materials required is much smaller than the large percentage increases of the respective seismic accelerations.

### Abstract

*In the present research work, an attempt is made to investigate the possible influence of the seismic acceleration on the construction cost of the load-bearing anti-seismic structure of reinforced concrete (R/C) buildings. It is not uncommon for the design engineer to be confronted with the question of dimensioning a building for seismicity greater than that provided by the relevant seismic regulations. More specifically, the Greek Seismic Code (EAK 2000) provides for three different seismic hazard zones. Will the choice of the engineer, then, affect the construction cost and if so, to what extent does it influence it? A fifteen-storey building with a standard floor plan per floor was used for this study. The building simulation took place using the SAP2000 analysis and dimensioning software. The seismic regulation used is Eurocode 8. The study of the influence of seismicity takes place by measuring the quantities of concrete and steel reinforcement construction materials. Analyses of the results and comparisons between them are made for all three seismic zones. Useful conclusions are drawn regarding the influence of seismicity on the construction cost of the load-bearing structure of R/C buildings.*

**Keywords:** Cost, Seismicity, Load-bearing structure

---

## 1 INTRODUCTION

Construction cost is an issue that has troubled engineers, consultants and contractors worldwide [1], [2]. The basic problem has to do in achieving the best technical solution in terms of safety along with the best solution possible in terms of economy; meaning a techno-economical best solution for the design of a structure that should take into account the influence of the soil properties, too [3], [4]. In simple words, the goal is to achieve both safety [5]–[14] and economy at the same time when the consultant engineers design a structure. This issue has troubled engineers for all types of structures: (a) Buildings [15]–[17], (b) bridges [18], [19], (c) other types of structures [20]–[22]. Thus, this analytical study investigates the influence of seismicity to the construction cost of the load-bearing structure of reinforced concrete (R/C) buildings.

## 2 CONSTRUCTION DESCRIPTION

In the present work, the study of a load-bearing structure of a R/C building in the three seismic hazard zones is carried out. This is a fifteen-storey building, double symmetrical that has a rectangular plan with dimensions of 25 x 25 m, which corresponds to a total area of  $E=625 \text{ m}^2$ , without a basement. In the center of the floor plan, there is a strong core consisting of 8 walls of different dimensions, 6 along the Y axis and 2 along the X axis. At the perimeter of the plan, there are two walls along the Y axis, which have enlarged boundary edges at their ends. The cross-sections of the columns of the building are the same for the 1<sup>st</sup> (ground floor) and 2<sup>nd</sup> floor, while after they are gradually reduced to the other floors, except for the walls T3 and T10, whose cross-sections are reduced as they depend on the enlarged boundary edges of their ends. Below is a summary table with the geometric elements of the floor plan (Table 1), as well as a top view of the floor plan of the building (Figure 1).

FLOOR	HEIGHT (m)	BEAM DIMENSIONS		WALL THICKNESS (cm)	COLUMNS (cm)
		PERIMETER	INTERIOR		
<b>1st (Ground)</b>	4.5	25x70	25x70	50	100x100
<b>2</b>	3	25x70	25x70	50	100x100
<b>3</b>	3	25x70	25x70	50	95x95
<b>4</b>	3	25x70	25x70	50	90x90
<b>5</b>	3	25x70	25x70	50	85x85
<b>6</b>	3	25x70	25x70	37.5	80x80
<b>7</b>	3	25x70	25x70	37.5	75x75
<b>8</b>	3	25x70	25x70	37.5	70x70
<b>9</b>	3	25x70	25x70	37.5	65x65
<b>10</b>	3	25x70	25x70	37.5	60x60
<b>11</b>	3	25x70	25x70	25	55x55
<b>12</b>	3	25x70	25x70	25	50x50
<b>13</b>	3	25x70	25x70	25	45x45
<b>14</b>	3	25x70	25x70	25	40x40
<b>15</b>	3	25x70	25x70	25	35x35

Table 1: Geometric plan elements

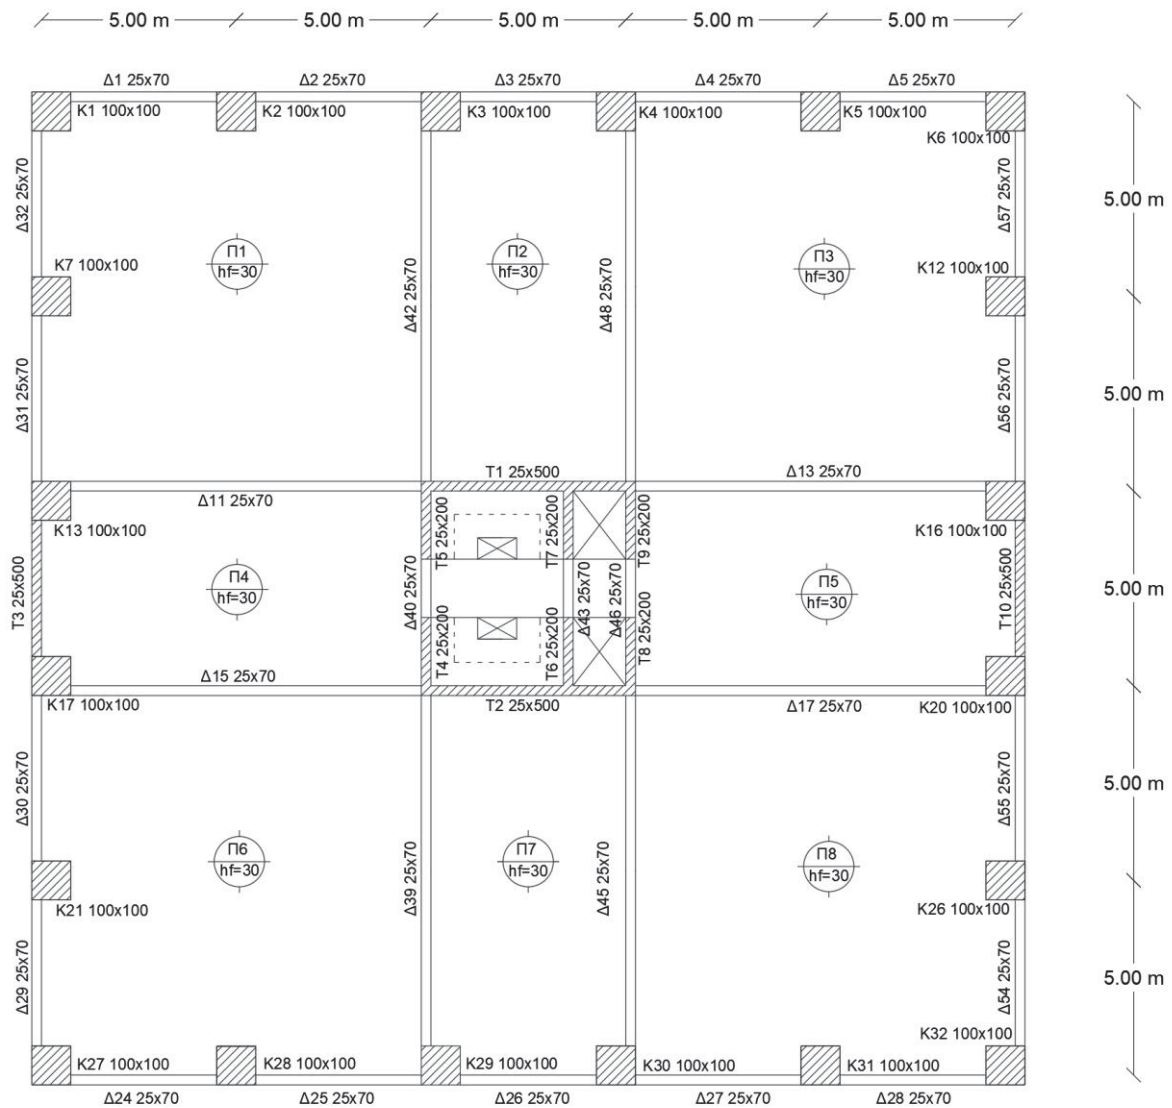

Figure 1: Floor plan of the building

### 3 BUILDING MODELING

The construction materials of the load-bearing body are:

- Concrete quality C30/37
- Steel quality B500C

According to Eurocode 2 [23] the measure of elasticity is equal to  $E_{cm} = 32$  GPa. The value of the Poisson ratio is considered to be zero, according to the specifications of the code for cracked concrete sections.

The beams are simulated using a linear finite element in space placed on the centripetal axis of the structural element. Due to the diaphragm action of the slabs, they are considered to have a T-type cross section. The columns are modeled in the same way as the beams, using linear finite elements and with reduction of their properties due to cracked concrete cross section (stage II). The modeling of the walls is done with the help of the “equivalent frame mod-

el". It has to do with the replacement at each level using a linear element that is placed on the center of gravity of the wall with reduced properties for cracked sections. The wall is connected to the neighboring beams by means of rigid bodies. The building 3D model is displayed on Figure 2.

Figure 2: 3D illustration of the building

#### 4 LOADS

The dead loads of the structure according to which the building is dimensioned, are presented below in Table 2:

DEAD LOADS		
N/A	Type	Value
1	Flooring	1.40 kN/m <sup>2</sup>
2	Partition brick walls	1.00 kN/m <sup>2</sup>
3	External brick walls	8.00 kN/m
4	Roofing	3.50 kN/m <sup>2</sup>
5	Parapet roof load	3.60 kN/m <sup>2</sup>

Table 2: Dead loads

- The load of the partition brick walls is considered to be evenly distributed over the entire surface of the floor plan.
- The load of the external brick walls is applied only on the perimeter beams and directly on them.
- On the roof of the top floor around the perimeter, it is considered that there is a parapet with a height equal to 0.90 m.

Table 3 shows the live loads of the construction.

LIVE LOADS		
N/A	Type	Value
1	Ground floor	2.00 kN/m <sup>2</sup>
2	Other floors	2.00 kN/m <sup>2</sup>
3	Top roof	2.00 kN/m <sup>2</sup>

Table 3: Live loads

The spectrum data used according to Eurocode 8 [24] are shown below in Table 4:

EC8 SPECTRUM DATA		
N/A	Type	Data
1	Spectrum	Type 1
2	Soil Category	B
3	$\beta$	0.20
4	Seismic acceleration factor $a$	For all three categories i.e., $a = 0.16, 0.24, 0.36$
5	Gravity acceleration $g$	9.81 m/sec <sup>2</sup>
6	Behavior factor $q$	Calculations based on EC8

Table 4: Spectrum data

Based on the results of the dynamic analysis of the building for each seismic zone, for the two seismic combinations along the X and Y axes, the percentage of the seismic force received from the walls was determined. In this way, it is proved that the static system under consideration is a wall system in every direction and for every seismic zone.

ZONE I		
	G+0.3Q+Ex+0.3Ey	G+0.3Q+0.3Ex+Ey
Base shear force	429.76	887.01
T1, T2 (X-axis)	379.75	
T3, T10 (Y-axis)		460.21
T4, T5, T6, T7, T8, T9 (Y-axis)		415.97
Percentage of shear force by walls	88.36% > 65%	99.91% > 65%

Table 5: Indicative percentages of seismic force carried by the structural walls (Zone I)

## 5 DYNAMIC ANALYSIS

Table 6 displays the sum of mass activated in each eigenmode. According to EC8 [24], dynamic spectral analysis requires activation of a mass percentage of at least 90% of the total mass of the building per direction.

Eigenmode	Participating mass			Eigenmode	Participating mass		
	SumUX	SumUY	SumRZ		SumUX	SumUY	SumRZ
1	0.679	0.000	0.000	24	0.998	0.992	0.989
2	0.679	0.690	0.000	25	0.998	0.995	0.989
3	0.679	0.690	0.712	26	0.998	0.995	0.989
4	0.877	0.690	0.712	27	0.998	0.995	0.993
5	0.877	0.865	0.713	28	0.999	0.995	0.993
6	0.877	0.867	0.852	29	0.999	0.997	0.993
7	0.942	0.867	0.852	30	0.999	0.997	0.993
8	0.942	0.922	0.860	31	0.999	0.997	0.995
9	0.942	0.929	0.917	32	0.999	0.998	0.995
10	0.969	0.929	0.917	33	1.000	0.998	0.995
11	0.969	0.959	0.918	34	1.000	0.998	0.997
12	0.969	0.960	0.951	35	1.000	0.999	0.997
13	0.982	0.960	0.951	36	1.000	0.999	0.997
14	0.982	0.977	0.951	37	1.000	0.999	0.997
15	0.989	0.977	0.951	38	1.000	0.999	0.997
16	0.989	0.977	0.971	39	1.000	0.999	0.998
17	0.993	0.977	0.971	40	1.000	0.999	0.998
18	0.993	0.987	0.971	41	1.000	1.000	0.998
19	0.993	0.987	0.982	42	1.000	1.000	0.999
20	0.995	0.987	0.982	43	1.000	1.000	0.999
21	0.995	0.992	0.982	44	1.000	1.000	1.000
22	0.997	0.992	0.982	45	1.000	1.000	1.000
23	0.997	0.992	0.989				

Table 6: Percentage of mass activated in each eigenmode

The results of Table 6 show that:

- In the first eigenmode, 68% of the mass is activated and is translational by X.
- In the second eigenmode, 69% of the mass is activated and is translational by Y.
- In the third eigenmode, 71% of the mass is activated and a torsional result is obtained.
- The requirement of the code for 90% of the mass to be activated for movements in X and Y directions arises in the ninth eigenmode.

## 6 DIMENSIONING OF BUILDING

Building has been dimensioned for all three seismic zones based on the reinforcement calculated for the ground floor slab. Figure 3 shows the plan view of the layout and the quantity of the reinforcement of the ground floor slab which resulted based on the necessary calculations for seismic zone I.

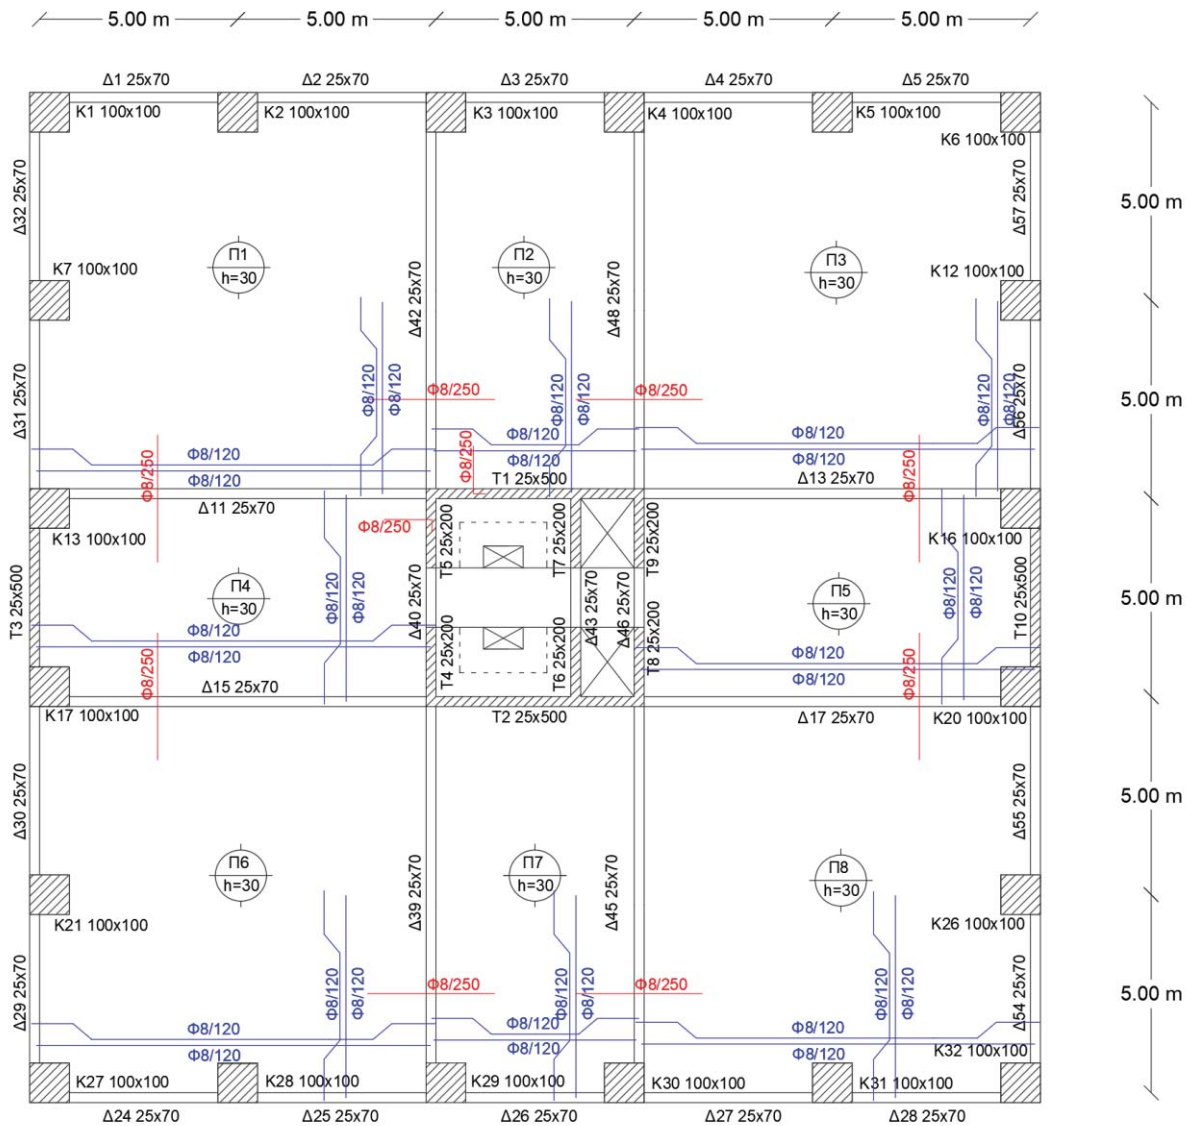

Figure 3: Ground floor slab reinforcement arrangement

## 7 CALCULATION RESULTS AND ANALYSIS

The engineering study of a building, in addition to the construction plans and the static calculations, also includes the pre-measurement of the project for the estimation of the construction costs. This section presents the measurements of the quantities of concrete and steel for the construction that has been studied, analyzed and dimensioned for all three seismic zones.

Figure 4: Percentage of concrete per floor

Figure 5: Percentage of total amount of concrete per structural element

It is therefore concluded that the first floor has the largest percentage of concrete while at the same time the percentage of the concrete is reduced from floor to floor (Figure 4). Also, the slabs occupy by far the largest percentage of the total amount of concrete with a percentage of 64.29%, followed by the seismic walls with 13.01%, the columns with 12.07% and finally the beams with 10.63% (Figure 5).

Figure 6: Percentage increase in total steel weight of ground floor seismic walls' steel (Zones I-III)

Figure 7: Percentage increase in total steel weight of ground floor beams' steel (Zones I-III)

Figure 8: Percentage increase in total steel weight of ground floor structural components (Zones I-III)

From the above diagrams that emerged from the measurements of the building materials for each seismic zone, it is observed that:

1. During the increase of the seismic acceleration in the building in question, it is observed that the steel of the seismic walls has the largest percentage increase of its weight.

Specifically, during the passage from (Figure 6):

- Zone I ( $a_g = 0.16g$ )  $\rightarrow$  Zone II ( $a_g = 0.24g$ ) percentage increase of 9.69%
- Zone II ( $a_g = 0.24g$ )  $\rightarrow$  Zone III ( $a_g = 0.36g$ ) percentage increase of 10.58%
- Zone I ( $a_g = 0.16g$ )  $\rightarrow$  Zone III ( $a_g = 0.36g$ ) percentage increase of 19.24%

The steel of the beams increases by much less (Figure 7):

- Zone I ( $a_g = 0.16g$ )  $\rightarrow$  Zone II ( $a_g = 0.24g$ ) percentage increase of 0.09%
- Zone II ( $a_g = 0.24g$ )  $\rightarrow$  Zone III ( $a_g = 0.36g$ ) percentage increase of 0.09%
- Zone I ( $a_g = 0.16g$ )  $\rightarrow$  Zone III ( $a_g = 0.36g$ ) percentage increase of 0.19%

Therefore, the walls have a dominant position in the load-bearing structure, as the static system is governed by the wall behavior.

2. The increase in seismic acceleration from (Figure 8):

- Zone I to Zone II is of the order of 50% while the percentage increase in the total amount of material is only 1.41%, i.e., many times smaller.
- Zone II to Zone III is of the order of 50% while the percentage increase in the total amount of material is only 1.61%, i.e., many times smaller.
- Zone I to Zone III is of the order of 125% while the percentage increase in the total amount of material is only 3.01%, i.e., many times smaller.

## 8 CONCLUSIONS

In conclusion, in a reinforced concrete building, with strong structural walls, designed and dimensioned according to modern seismic codes, the influence of seismic hazard on the construction cost of the building is not significant, due to the small percentage increase in total material costs in comparison to the drastic percentage increases of the respective seismic accelerations.

### Abstract

*Naturally Buckling Braces (NBBs) utilize a built-up dual material steel section given a parallel offset (i.e., eccentricity) from the normal working points of a conventional brace. NBB sections consists of a low-yield-point steel (LYS) channel and a high-strength steel (HSS) channel connected in parallel through steel battens. This new brace configuration provides a combined axial-flexural behavior that improves the buckling performance and post-yielding stiffness of braced framed structures. In this paper, on the basis of test results on a full-scale NBB specimen, a detailed computational study is performed with the aid of the finite element software ABAQUS. The specimen is subjected to a low-cycle fatigue protocol with increasing amplitudes and repeated inelastic loading cycles at the event of local buckling. The parametric study aims to evaluate partial strengthening methods for NBB sections that aim to delay local buckling initiation and local buckling growth. It was found that the energy dissipation capacity of NBBs can be enhanced up to 40% at a story drift ratio (SDR) of 2.0% by using transverse rib stiffeners at the central part of the LYS channel, while the use of thicker channel battens can provide further restrain to local buckling growth up to a 3.0% SDR.*

## 1. INTRODUCTION

Steel braces are often used as vertical and lateral load resistant systems in multi-story buildings for dissipating large amount of input energy under damaging dynamic loads, such as strong winds and earthquakes. While the most frequently used Concentrically Braced Frames (CBFs) consisting conventional steel braces increase the lateral stiffness of steel framed structures and decrease the lateral story drift, they exhibit a marked strength deterioration under large compression loads due to sudden geometric instabilities (global and local buckling) followed by fracture [1-4]. Buckling Restrained Braced Frames (BRBFs) have been proved as reliable, more ductile alternative to CBFs providing a relatively large strength and stiffness under both tension and compression loads. However, in both CBFs and BRBFs, residual story displacements, and in a worst-case loading scenario, a soft-story failure mechanism may occur under rare earthquake events, resulted by their inherent low post-yielding stiffness [5-7].

Recently, the authors and co-workers developed an alternative brace known as Naturally Bucking Brace (NBB) [8] aiming at enhancing the poor post-yielding or post-buckling behavior of current brace design. The main advantages of NBBs are the relatively high tensile post-yielding stiffness and the delay of mid-length local buckling, thereby fracture. NBB consists of a built-up dual-material steel section made of a low-yield-point steel (LYS) channel and a high-strength steel (HSS) channel arranged in parallel and joined together through a series of battens that secure compactness of the section. An intentional eccentricity is introduced along the brace length that inherently subjects the brace to bending loads in addition to axial loads [9]. The effective combination of the two steel grades (i.e., large material contrast) and eccentricity helps the brace to develop a stable and advantageous hysteretic behavior, a concept that was recently extended in uniform circular steel cross sections [10].

Local buckling can initiate at lower drift levels in full-scale specimens compared to small scale specimens and can suddenly reduce the load carrying capacity of the member. Various studies explored the use of stiffeners to resist local buckling and it was found to be an effective method. Mulligan and Pekoz [11] who investigated the effect of edge stiffeners in lipped channel sections found a significant improvement in the local-buckling resistance. Further works suggested enhancing local-buckling resistance through selecting optimum stiffener position and proportion for web stiffeners [12] and proper configuration and sectional sizes for longitudinal stiffeners in case of bolted side plated beams [13].

In this paper, based on the experimental test results on cyclic performance of full-scale NBBs, a finite element analysis study is performed to calibrate the computational model with the experimental results, which are found to be in a good agreement. Additional finite element models with rib stiffeners and stronger channel battens are developed to perform an elaborate parametric study focusing on the effectiveness of such strengthening methods in eliminating the local buckling related failures and thereby enhancing its energy dissipation capacity. Application of rib stiffeners seemed to be a candid way of strengthening open channel sections like NBB. The effect of several parameters, such as, the number and thickness of stiffening ribs as well as the thickness of channel battens is examined.

## 2. CONFIGURATION OF NBB

NBB consists of two cold-formed LYS and HSS channels connected along the brace length at multiple points. Steel battens are welded to each channel as shown in Fig. 1. The brace-ends are free to rotate about  $x$ -axis (in-plane buckling) while are fixed to rotate about  $y$ -axis (out-of-plane buckling). LYS exhibits a low yielding stress (120~220MPa) and a high inelastic deformation capacity (30~50%) which enhances the overall ductility of NBB. On the other hand, HSS exhibits

a high yielding stress (600~800MPa) which enhances the overall strength of NBB, but emphasis needs to be given in the lower ductility (10~15%) of HSS.

Figure 1: Overview of Naturally Buckling Brace.

The presence of eccentricity redistributes the internal stresses in a way that HSS remains elastic until very large inelastic deformations. At the same time, the very high ductility of LYS is efficiently and uniformly exhausted. This configuration and contrast of the material properties eventually contributes to the high post-yielding stiffness of NBBs. Under cyclic loading, unlike the unstable phenomenon of the axial buckling, NBB bends stably due to the combined axial-flexural behavior [8-10].

### 3. EXPERIMENTAL TEST ON NBB

#### 3.1. Overview of the test specimen

A full-scale NBB specimen denoted as SP1 was subjected to a quasi-static cyclic testing to evaluate its seismic performance. The design details of SP1 are summarized in Table 1. Japanese steels SM570 and LY225 are used for the fabrication of HSS and LYS channels, respectively. The channel battens are made of SS400 steel and are welded to the surface of each channel flanges through fillet welding.

The gusset-plate connection that accommodates in-plane member buckling is designed based on the AISC design specifications [14, 15]. A clearance distance twice the gusset-plate thickness,  $t_p$  (56mm), is considered. Assuming that a pin is formed at the middle of clearance distance, the pin-to-pin length of NBB,  $L$  is equal to 2,825mm. The actual intentional eccentricity determined based on the center of gravity is  $e''$  (see Figure 1) but as the center of gravity has been moved towards the LYS channel due to asymmetrical sections about  $x$ -axis in NBB, the measured eccentricity is denoted as  $e^\#$ . The member slenderness about  $x$ -axis is denoted as  $\lambda_x$  and thickness of steel sections as  $t_{HS}$  and  $t_{LY}$  and that of battens as  $t_{Batten}$ . The quantities  $\sigma_{y,HS}$ ,  $\sigma_{u,HS}$  and  $\sigma_{y,LY}$ ,  $\sigma_{u,LY}$  refers to the yield stress and ultimate stress of HSS and LYS channel respectively.

Table 1: Dimensions and material properties of test specimens.

The loading protocol consists of two symmetric cycles laterally imposed at each load amplitude of 0.25, 0.5, 0.75, 1.0, 1.5, and 2.0% story drift ratio (SDR) except for the SDR at which local buckling occurs in compression. At this SDR, loading cycles are repeated five times

in order to evaluate the post-local buckling behavior of the brace to cumulative damage. In SP1, the local buckling initiated during 1.5% SDR. More details can be found elsewhere [16].

### 3.2. Cyclic behavior

Fig.2a shows the axial load – axial displacement relationship of SP1. A high energy dissipation capacity without any strength deterioration was observed until an axial displacement of 27.6 mm (i.e., 1.5% SDR). Fig. 2b depicts the overall deformation of brace specimen for an axial displacement of 27.6 mm (i.e., 1.5% SDR) under the 2<sup>nd</sup> compression cycle. The specimen deformed in-plane of the frame and no excessive concentration of local deformation was observed. Until 4<sup>th</sup> compression cycle of repeated loading at 1.5% SDR, a slight strength deterioration was observed. Although local buckling was more intense during the 5<sup>th</sup> repeated cycle of 1.5% SDR, the compressive strength maintained 79% of the strength that recorded in the 1<sup>st</sup> compressive cycle of this repeated loading. For an axial displacement of 36.7 mm (i.e., 2.0% SDR), local buckling increased and the compressive strength started to deteriorate but the tensile strength was further increased. During the 2<sup>nd</sup> cycle of the 2.0% SDR, the fillet welding around the steel battens was failed and battens were detached from the LYS channel during the compressive loading.

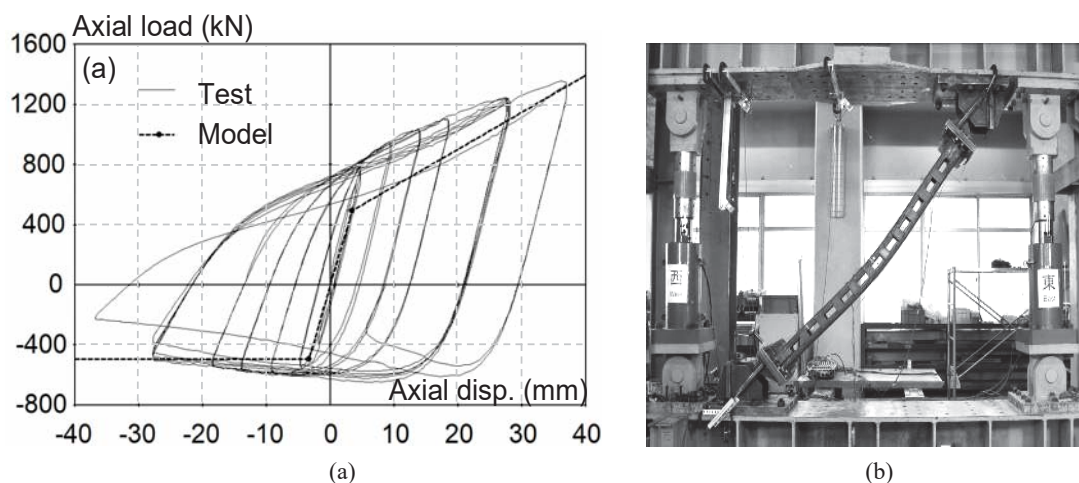

Figure 2: Test results; (a) Axial load – axial displacement relation, (b) Deformed shape at 1.5% SDR.

## 4. FINITE ELEMENT MODELING OF NBB AND PARAMETRIC STUDY

A computational study of the cyclic behavior of the NBB specimen was performed using the finite element (FE) simulation software ABAQUS [17]. To verify the reliability of the proposed detailed FE model, the computational simulation results were compared with the experimental results. The loading pattern followed for the finite element analysis is the same as the one used in experiment.

### 4.1. Finite Element Model

Fig. 3 illustrates the FE model of NBB with an HSS channel section and a LYS channel section connected through battens. The model was divided into 30 elements along the steel section and more than 100 elements along the length for each section. Fine rectangular mesh along with linear quadrilateral 4-noded S4R shell elements of reduced integration were used. Tie constraint was used to define the contact between battens and channel section surfaces. Both ends of the brace were provided with gusset plates having a  $2t_p$  clearance distance to act as

pinned connections at an eccentricity specified in Table 1. A multi-point constraint (MPC) was used to connect the gusset plates and the brace member. An incremental displacement-controlled analysis was performed to one brace end for simulation. The brace was arranged in the same angle as in the experiment.

Figure 3: Finite element modeling: (a) entire FE model with gusset plates; (b) Meshed view of the model.

The properties of specimen used for the computational study are summarized in Table 2. The comparison of results from experimental and FE analysis studies are shown in Fig. 4. From the figure, one can observe that the FE model was able to simulate the test with a good accuracy. The full details of the gusset-plate connections were not modelled as a choice to reduce the computational time and complexity of the model. The FE model meticulously captured local buckling at 2% SDR as observed in the experiment. Local buckling was induced during the 1<sup>st</sup> compression cycle of 1.5% SDR and became evident at a 2% SDR. The sudden drop in strength under compression can also be observed from the FE hysteretic loop similar to test results.

#### 4.2. Parametric study and performance evaluation indices

As local buckling was observed in LYS channel of NBB during the experimental study,

strengthening of NBB by utilizing stiffeners in the critical zones or by increasing the thickness of battens is explored through a parametric study. The use of stiffeners appears to be a straightforward strengthening approach as NBB consists of open channel sections. The stiffeners combined with the eccentricity distribute more evenly the local stresses in the middle area delaying the onset of local buckling. The parametric study investigated the influence of the number and thickness of stiffeners as well as the thickness of battens.

Using the hysteretic curves of each analysis model, the normalized dissipated energy is calculated to evaluate the hysteretic behavior and energy dissipation capacity of braces [18]. On the basis of this index, one can evaluate the influence local buckling has on the cyclic response and how the progress of local buckling affects the dissipative capacity of the member. More specifically, a comparison is made according to the equivalent viscous damping ratio,  $\xi_{eq}$ , by adopting the relation [19]:

$$\xi_{eq} = \frac{E_d}{2\pi F_m \Delta_m} \quad (1)$$

where  $E_d$  is the energy dissipation in each complete cycle of the force-displacement curve;  $F_m$  is the maximum force in a given cycle and  $\Delta_m$  is the corresponding displacement. The results are calculated considering a symmetrical hysteretic  $F-\Delta$  relation as obtained for chevron brace configurations (i.e., both compression and tension cycles are considered). It should be noted that  $\xi_{eq}$  accounts for the energy dissipation by nonlinear  $F-\Delta$  relations as expected during strong earthquakes.

Moreover, equivalent plastic strain (PEEQ) curves are prepared as additional performance evaluation index to  $\xi_{eq}$ , in order to identify the best brace configuration in terms of ductility capacity. PEEQ is a scalar measure of the accumulated plastic strain. For loading with reversals like cyclic loading, PEEQ will continue to increase if the plastic strain rate is non-zero (regardless of sign) and is an important index to evaluate the cumulative damage of a structural member. Higher the plastic strain, lower will be the ductility performance of the model. Effect of each parameter is discussed in the following sections.

#### 4.2.1. Effect of number of stiffeners

In order to evaluate the effect of numbers of stiffening ribs on NBB's cyclic performance, four NBB models with different numbers of stiffening ribs were developed on the basis of design details of SP1. The model properties are shown in Table 3. Nomenclature of the specimens used for the study follows the order, SP1-nSTt\_Stiffener-Bt\_Batten where ST stands for stiffeners, B for battens, 'n' for number of stiffeners, t\_Stiffener for thickness of stiffeners and t\_Batten for thickness of battens. Fig. 5a-d shows the different specimen categories along with their stiffener and numbers. Transverse rib stiffeners were placed exactly along the position of the battens and in the clearance distance between them throughout the central part of the LYS channel. Fig. 6 shows the  $\xi_{eq}$  curves and PEEQ curves. PEEQ always refers to areas prone to local buckling (i.e., usually in the middle length of the brace). In addition, Fig. 6b plots the threshold for PEEQ ( $\approx 0.58$ ). This value corresponds to the PEEQ at which local buckling occurred in FE simulations of SP1 (Fig. 4: 1<sup>st</sup> compression cycle of 1.5% SDR). It should be noted that  $\xi_{eq}$  was computed considering the complete cycles of the response at each amplitude (i.e., compression and tension). In Fig. 6b, the horizontal axis refers to the 2<sup>nd</sup> tensile loading cycle of each SDR of the low-cycle fatigue protocol considered in this study.

SPECIMEN	$L$ (mm)	$e^{\#}$ (mm)	$t_{LY}$ (mm)	$t_{HS}$ (mm)	$\sigma_{y,LY}$ (MPa)	$\sigma_{y,HS}$ (MPa)	$t_{Batten}$ (mm)	$t_{Stiffener}$ (mm)	Stiffener No. ( $n$ )
SP1	2825	85	12	9	231	638	6	0	0
SP1-1ST9-B6	2825	85	12	9	231	638	6	9	1
SP1-5ST9-B6	2825	85	12	9	231	638	6	9	5
SP1-9ST9-B6	2825	85	12	9	231	638	6	9	9
SP1-12ST9-B6	2825	85	12	9	231	638	6	9	12

Table 3: Properties of SP1 specimens with varying number of stiffening ribs.

Figure 5: Specimen categories with varying specimen numbers.

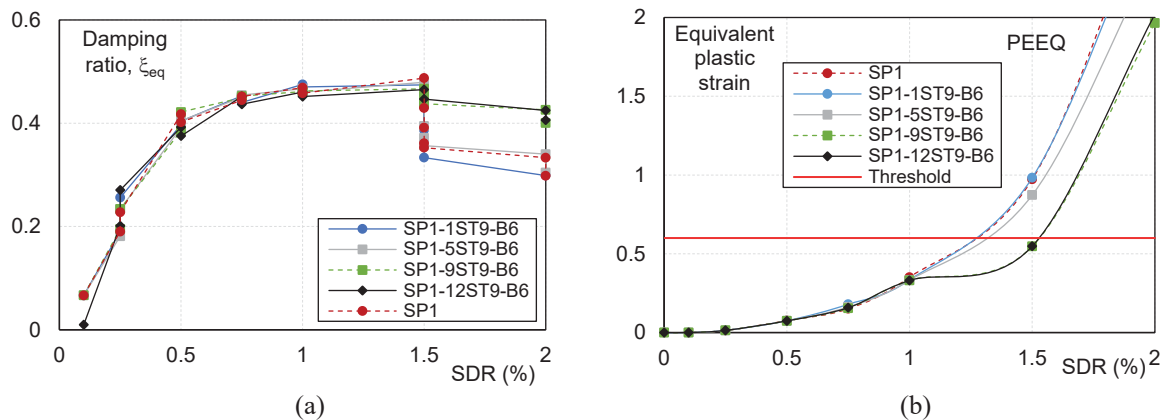

Figure 6: Relation of SDR with: (a) Equivalent damping ratio; (b) Equivalent plastic strain (PEEQ) for the FE models under the influence of varying stiffener number.

SP1 with stiffeners has an increase of 35% in its damping ratio at 2% SDR compared to SP1 without stiffeners (Fig. 6a), thereby strengthening it against local buckling. With the increase of the number of stiffening ribs in the model, its equivalent damping ratio value also increases

from 0.29 for non-strengthened model to 0.41 for model with stiffeners. It can be noted that when the number of stiffening ribs increases to 9 (SP1-9ST9-B6), the curve tends to be stable. However, when the number of stiffening ribs increases to 12 (SP1-12ST9-B6), the equivalent damping ratio curve at this point almost matches that SP1-9ST9-B6, indicating no further improvement, thus making SP1-9ST9-B6 the ideal configurations for this specimen.

In the effective strain curve of PEEQ (Fig. 6b), both SP1-9ST9-B6 and SP1-12ST9-B6 exhibit the lowest PEEQ value at 2% SDR. Moreover, for 1.5% SDR, PEEQ is lower than the threshold for both models. It should be noted that, once local buckling occurs, plastic strain accumulation takes place in the vicinity of damaged area resulting in very high values of PEEQ.

#### 4.2.2. Effect of stiffener thickness

To evaluate the effect of different thicknesses of stiffening ribs on NBB performance, three models with properties summarized in Table 4 were created. The  $\zeta_{eq}$  curves and PEEQ curves of the three models are shown in Fig. 7 in the same manner with Fig. 6.

SPECIMEN	$L$ (mm)	$e^{\#}$ (mm)	$t_{LY}$ (mm)	$t_{HS}$ (mm)	$\sigma_{y,LY}$ (MPa)	$\sigma_{y,HS}$ (MPa)	$t_{Batten}$ (mm)	$t_{Stiffener}$ (mm)	Stiffener No. ( $n$ )
SP1-9ST6-B6	2825	85	12	9	231	638	6	6	9
SP1-9ST9-B6	2825	85	12	9	231	638	6	9	9
SP1-9ST12-B6	2825	85	12	9	231	638	6	12	9

Table 4: Properties of specimens with varying stiffener thickness.

By observing Fig. 7a, the  $\zeta_{eq}$  for all FE models are not very different but takes the maximum value, i.e., 0.40 when the thickness of the rib stiffener is 12 mm (SP1-9ST12-B6) closely followed by stiffener thickness of 9 mm (SP1-9ST9-B6). On the contrary, the damping ratio is lowest, i.e., 0.37 when the rib thickness is 6 mm (SP1-9ST6-B6).

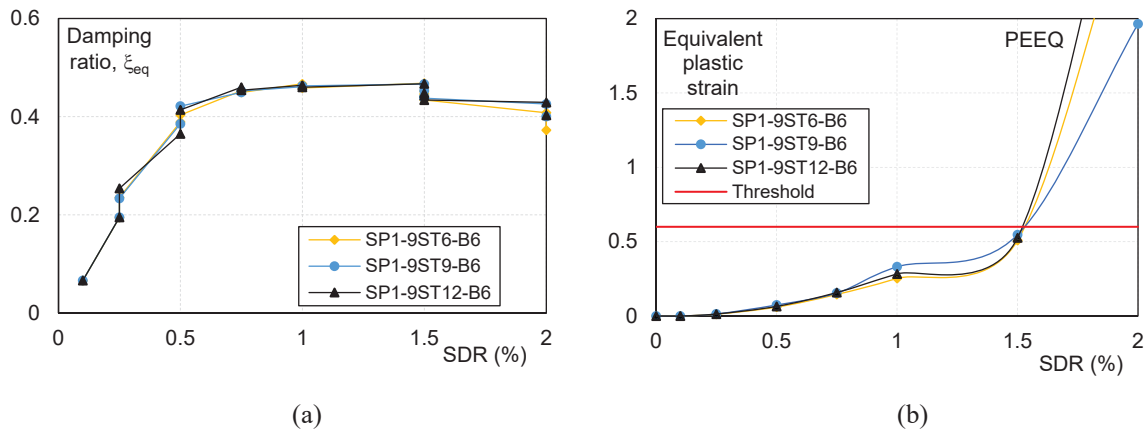

Figure 7: Relation of SDR with: (a) Equivalent damping ratio; (b) Equivalent plastic strain (PEEQ), for the FE models under the influence of varying stiffener thickness.

By observing the PEEQ curves, the model SP1-9ST9-B6 exhibits the lowest strain values indicating a higher reserved ductility capacity to tension loads. Moreover, for 1.5% SDR, PEEQ is lower than the threshold for all cases indicating that local buckling is likely to be prevented during the compression cycles of 1.5% SDR. Fig. 7b indicates that the thicker stiffeners are effective to restrain local buckling, but once local buckling occurs, they tend to increase plastic strain demands in the vicinity of damaged area more than the medium thickness ribs. As a result,

9mm stiffeners were found to be most efficient in reducing local buckling of SP1.

#### 4.2.3. Effect of batten thickness

Apart from unstiffened SP1, two models with batten thicknesses 9 mm and 12 mm were modelled without stiffeners to understand the effect of batten thickness alone. The use of thicker battens would be an alternative strengthening process to stiffening ribs. The properties of models are shown in Table 5. The  $\zeta_{eq}$  curves and PEEQ curves as obtained from the FEA are shown in Fig. 8a and b respectively.

SPECIMEN	$L$ (mm)	$e^{\#}$ (mm)	$t_{LY}$ (mm)	$t_{HS}$ (mm)	$\sigma_{y,LY}$ (MPa)	$\sigma_{y,HS}$ (MPa)	$t_{Batten}$ (mm)	$t_{Stiffener}$ (mm)	Stiffener No. ( $n$ )
SP1	2825	85	12	9	231	638	6	0	0
SP1 - B9	2825	85	12	9	231	638	9	0	0
SP1 - B12	2825	85	12	9	231	638	12	0	0

Table 5: Properties of specimens with varying batten thickness.

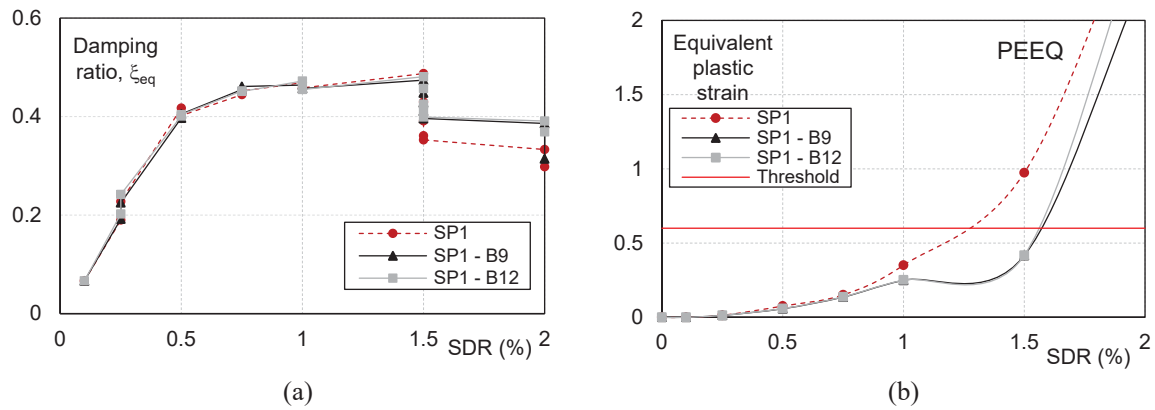

Figure 8: Relation of SDR with: (a) Equivalent damping ratio; (b) Equivalent plastic strain (PEEQ), for the FE models under the influence of varying batten thickness.

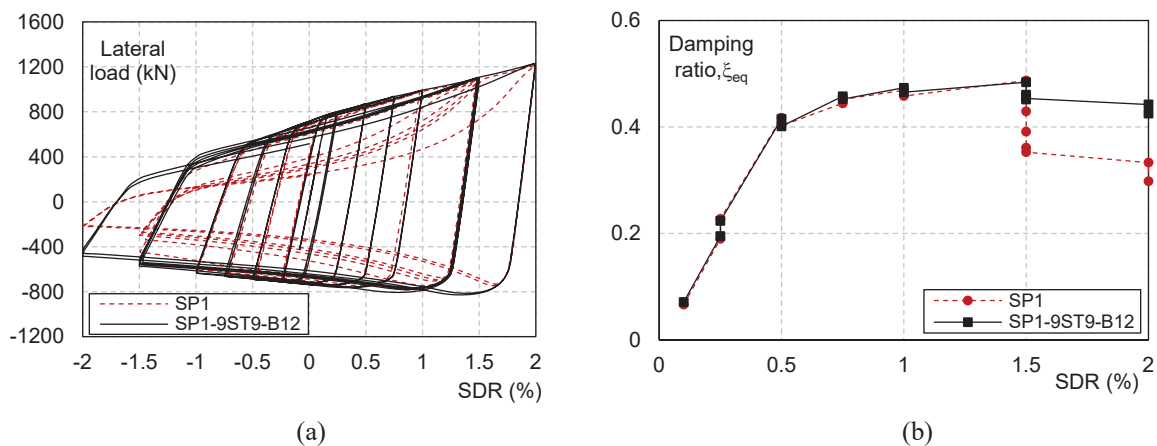

Figure 9: Comparison between SP1 and SP1-9ST9-B12 analysis results: (a) Lateral load – SDR relationship; (b) Damping ratios – SDR relation.

The difference between the  $\zeta_{eq}$  curves of the group of models in Table 5 is small, and almost coincide for models with batten thicknesses of 9 mm (SP1-B9) and 12 mm (SP1-B12),

respectively, as shown in Fig. 8a. However, for 2% SDR, the damping ratio of SP1-B9 is nearly 0.31 while that of SP1-B12 is higher and equals 0.37. This is because SP1-B9 exhibits greater strength degradation than SP1-B12 at 2% SDR but almost similar values of PEEQ at 1.5% SDR indicates a similar damage at this drift level. Based on these observations, both battens appear to be effective, but SP1-B12 can be considered as the one with the more stable cyclic behavior.

On the basis of the above parametric study, a better cyclic behavior was observed in the FE model designed to have 9 stiffeners with 9 mm thickness and channel battens with 12 mm thickness. This model is denoted as SP1-9ST9-B12 and is compared with the non-strengthened FE model SP1 in Fig. 9a and b. Overall, a 43% increase was observed in its  $\xi_{eq}$  compared to SP1 with no stiffeners at 2% SDR, while no sudden drop of compressive strength was observed until the very end of the damaging loading protocol. The use of sufficiently thick stiffeners and battens can strengthen NBB's energy dissipation capacity up to high inelastic levels. Future experimental works can validate these findings.

## 6. CONCLUSIONS

In this research, strengthening methods of Naturally Buckling Braces (NBB) against local buckling and cumulative damage were investigated through a parametric computational study using finite element (FE) analysis methods. The study proposes the use of sufficiently thick stiffeners and battens in order to enhance NBB's energy dissipation capacity up to high inelastic levels. Main conclusions are as follows:

- The application of transverse rib stiffeners in the LYS channel of NBB sections for a length equal to the two-third of the total length of the section was found to be beneficial to strengthen NBBs against local buckling failures.
- About 40% increase of the energy dissipating capacity at a 2% SDR was observed in the rib-strengthened NBBs compared to the non-strengthened NBBs. Specimen with a slenderness ratio equal to 44, requires at least 9 stiffeners and channel battens of 12 mm thickness.
- By comparing the equivalent damping ratio and the cumulative strain curves for the FE analysis models, it can be concluded that the number of rib stiffeners has the greatest impact to improve the cyclic behavior of NBB, followed by the thickness of battens. The thickness of rib stiffeners has the smallest influence on the energy dissipation capacity of NBB but rib stiffeners of at least 9 mm thickness shall be used for the NBB section with channel width-to-thickness ratio 13.6.
- Based on FE analysis results, local buckling can be reduced up to a SDR equal to 3% in strengthened full-scale NBBs.

### Abstract

*Yield penetration occurs from the critical section towards both the shear span and the support of reinforced concrete columns; physically it refers to the extent of the nonlinear region and determines the pullout slip measured at the critical section. Contrary to the fixed design values adopted by codes of assessment, the yield penetration length is actually the only consistent definition of the notion of the plastic hinge length, whereas the latter determines the contribution of pullout rotation to column drift and column stiffness. Yield penetration in the anchored reinforcing bar inside the shear span of the column where it occurs, destroys interfacial bond between bar and concrete and reduces the strain development capacity of the reinforcement. This affects the plastic rotation of the member by increasing the contribution of bar slippage. Results obtained from the analytical procedures introduced in this paper are compared with experimental evidence from tests conducted on circular reinforced concrete bridge piers under cyclic loading designed and detailed according with Eurocode 8-II (2005). It can be seen that the produced monotonic envelope for applied shear load versus the slip of the extreme tensile reinforcing bar of the circular section of the bridge piers under study is in good agreement with the experimental results.*

**Keywords:** yield penetration, bar slippage, circular bridge piers, pull-out rotation

## 1 INTRODUCTION

This paper presents a unidirectional bond model and its correlation with an experimental campaign of reinforced concrete bridge piers under cyclic excitation. The prototypes that were used in this study in order to determine the details of the specimens of the experimental study were monolithic concrete bridges located along the Egnatia highway [1] in Greece. The specimens (A1-A6) were designed to represent single column-to-superstructure connections. Four connection specimens (A1-A4) modeled at 1/5 scale the geometry and actions occurring in connections swaying in the direction perpendicular to the bridge axis (Fig. 1.a,b) whereas the remaining two specimens (A5,A6) modeled connections swaying in the direction parallel to the bridge axis (Fig.1c). In the remainder of this presentation these are denoted as group A specimens (A1-A6). All connections comprised a T-joint, but joint geometry and reinforcement arrangement were parameters of investigation (Fig. 2). Specimen A1 was designed and detailed according with EN 1998-2, 2005 [2] (Fig. 2). Specimen A2 was designed with the same geometry as A1, but with part of the required joint reinforcement placed in the primary beams adjacent to the joint. This alternative placement of joint shear reinforcement is allowed in EN 1998-2, 2005 [2] and CALTRANS (2004) [3] so as to avoid reinforcement congestion (Fig.2). Specimen A3 was designed with the same dimensions as A1, but with an inspection opening in the joint body in order to evaluate this construction practice in bridge monolithic joint connections (Fig. 2). Specimen A4 was designed with reduced cap beam width, in order to check whether the increased width for cap beams required by EN 1998-2, 2005 [2] is indeed an essential requirement (Fig.2). Specimen A5 was designed also according with EN 1998-2, 2005 [2], but it was tested for force and moment transfer acting in the direction of the bridge axis. This is the first reported beam-to-column specimen designed with a hollow section of beam (Fig. 2). Moreover, it has an opening for inspector passage in the joint panel (as in the case of specimen A3), in order to evaluate the influence of the openings when force transfer occurs in the longitudinal bridge axis (Fig. 2). Specimen A6 was designed with the same dimensions as A5, but without the opening for inspector passage in the joint panel.

All steel reinforcements used for the construction of the specimens were EN 1992, 2005 [4] compliant C500 deformed bars, with a nominal yield strength of  $f_y=500\text{MPa}$ , ratio of maximum strength to yield strength between 1.15 and 1.35 ( $1.15 \leq f_u/f_y \leq 1.35$ ) and tension strain ductility at failure in excess of 7.5 ( $\epsilon_u/\epsilon_y \geq 7.5$ ). Concrete material properties were determined from standard compression tests of 150x300 mm concrete cylinders that had been cast and cured along with the test specimens (Table 1, average values at time of component testing).

Table 1: Concrete material properties for all specimens [1].

Specimen	Days of test	$f_{cm}$ (MPa)	$E_{cm,o}$ (MPa)
A1	176	27.55	9910
A2	251	29.14	12445
A3	259	29.30	11725
A4	302	29.85	10705
A5 beam	30	26.00	9440
column	28	33.95	15595
A6 beam	88	26.30	5970
column	86	45.00	14645

## 2 PROPOSED ALGORITHM OF THE UNIDIRECTIONAL BOND MODEL

The deformation capacity of frame elements comprises contributions of flexural, shear and reinforcement pullout components. The estimation of the available deformation capacity of a column is linked to the length of plastic hinges. Following an implicit assumption that all terms are additive, the flexural component of lateral displacement is obtained from the sum of an elastic component, owing to the flexural deformation occurring along the length of the member, and a plastic component that is practically owing to the inelastic rotation that occurs in the small region near the face of the support where moments may exceed the yielding limit. When comparing these deformation estimates with the experimental evidence from predominantly flexural components, it is found that there is a great disparity between measured and estimated deformation capacities characterized by notable scatter [5], [6]. Several attempts to identify the source of inaccuracy have motivated the progress made in that field, not the least

Figure 2: Geometry and reinforcement arrangement for Group A specimens [1].

the empirical expressions for deformation capacity which are included in EN 1998-3, 2005 [7] that completely bypass the requirement of calculating the plastic hinge length. Another approach, initiated by Priestley et al. (1996) [8] and then followed by several other researchers, and the approach to deformability by EN 1998-1, 2004 [9] estimates the plastic hinge length including the length of yield penetration inside the anchorage (see, for example, the detailed analysis in [8]).

In new structural design with EN 1998-1 2004 [9], the plastic hinge length is also used in reinforced concrete (RC) seismic detailing in order to determine the region where additional confinement requirements apply, this is apart from its use in seismic assessment to estimate

the flexural deformation capacity. Due to its importance in these applications as the key to understanding deformability of members, the plastic hinge has been the subject of many experimental and analytical studies and the expressions derived have been quantified and calibrated against several hundreds of tests on isolated column specimens. Still, the disconnect between observation and theory persists, and is considered a major roadblock in establishing the performance criteria for many special categories of members (e.g. walls, columns carrying a high axial load, very slender columns, etc.).

In the typical test, a cantilever column fixed at the base and carrying a constant axial load is driven to a protocol of reversed cyclic lateral load displacement history at the top. Deformation capacity of such members is usually described by the chord rotation that may be sustained by the member prior to loss of its lateral load strength. Apart from the rotation due to flexural curvature that occurs along the length of the member, lumped rotation at the critical section resulting from inelastic strain penetration into the support (e.g. footing) as well as inside the shear span adds up in the reported drift ratios at different levels of performance. This share of deformation is attributed to reinforcement pullout due to the incompatible length change between the bar and the surrounding concrete.

In columns that do not fail by web crushing, pullout rotation increases gradually with imposed drift, claiming a predominant share of the members' deformation capacity near the ultimate limit state.

The following algorithm (Fig. 3) is established in order to define the locations of primary cracks and bar strain, slip and bond distribution along the shear span  $L_s$  of a laterally loaded reinforced concrete column as well as the yield penetration length (plastic hinge length). The equations of the proposed algorithm are given in Megalooikonomou et al. 2018 [10]:

**Initial Data:** Using standard section analysis obtain  $M-\phi$  (*Moment -curvature*) and  $M-\varepsilon$  (*Moment – Tensile Strain of Reinforcement*) diagrams (or better a unified diagram  $M-\phi-\varepsilon$ ) given the Axial Load  $N$  for the typical section of the reinforced concrete column studied:

**1<sup>st</sup> Step:** Select value of bar strain,  $\varepsilon_o^{(1)} = \varepsilon_o$ , after crack formation at the support (Fig. 3).

**2<sup>nd</sup> Step:** Find the corresponding moment,  $M_o$  at the support, from moment-bar strain diagram. Solve for the length of the disturbed region [10]  $\ell_{D1}$  emanating from the first crack.

**3<sup>rd</sup> Step:** Increase strain at critical section to  $\varepsilon_o^{(2)} = \varepsilon_o^{(1)} + \Delta\varepsilon_o$ . Find the location  $x_{cr,2}$  of the second crack. Check if second crack will occur: (a) inside  $\ell_{D1}$ , or (b) in the undisturbed region  $L_s - \ell_{D1}$ .

**4<sup>th</sup> Step:** (a) If next crack forms within  $\ell_{D1}$ , repeat Step 3 for  $\varepsilon_o^{(3)} = \varepsilon_o^{(2)} + \Delta\varepsilon_o$ . (b) Otherwise, find the new disturbed region  $\ell_{D2}$  that extends beyond  $x_{cr,2}$ .

**5<sup>th</sup> Step:** Find total disturbed length,  $\ell_{Do} = x_{cr,2} + \ell_{D2}$

**6<sup>th</sup> Step:** Solve for  $\varepsilon(x)$  (*strain*),  $s(x)$  (*slip*),  $f_b(x)$  (*bond stress*) for  $x_{cr,2} \leq x \leq \ell_{Do}$ . In this phase of the solution and up to stabilization of cracking elastic bond is assumed in  $\ell_{D2}$ .

**7<sup>th</sup> Step:** Repeat steps 2 to 6 for  $\varepsilon_o^{(i)} = \varepsilon_o^{(i-1)} + \Delta\varepsilon_o$  until stabilization of cracking (i.e., no more primary cracks can develop:  $\varepsilon_o^{stbl} = \varepsilon_o^{(i)}$ ). Final length of disturbed zone is obtained from the  $n^{th}$  increment using this procedure:  $\ell_{Do} = x_{cr,n} + \ell_{D,n}$ .

**8<sup>th</sup> Step:** Increase  $\varepsilon_o^{(i)} = \varepsilon_o^{(i-1)} + \Delta\varepsilon_o > \varepsilon_o^{stbl}$ . Solve for one continuous disturbed region  $\ell_{Do} \geq x_{cr,n} + \ell_{D,n}$  allowing for bond plastification and debonding as well as bar yielding (anchorage solution) up to either (a)  $\varepsilon_o$  exhausting the ultimate strain of the  $M-\varepsilon$  diagram, or (b)  $\ell_{Do}$  exceeding the available development length of the bar in the shear span, taken here as  $(L_s + h_{hook})$ , where  $h_{hook}$  refers to the bent length of a hooked anchorage (according with *fib* Model Code (2010) [11] the contribution of a hook to the strength of an anchored bar is  $50A_{bf}f_b^{max}$ , which corresponds to an additional anchored length,  $\Delta L_b = h_{hook} = 12.5D_b$ ). If (b) controls, continue

beyond that point for higher strains using the anchorage solution presented in [10] for the entire length  $\ell_{Do}$ .

**9<sup>th</sup> Step:** The last converged value of  $l_r$  in the shear span is added to the corresponding yield penetration length into the anchorage resulting in the definition of the total plastic hinge length  $\ell_{pl}$ .

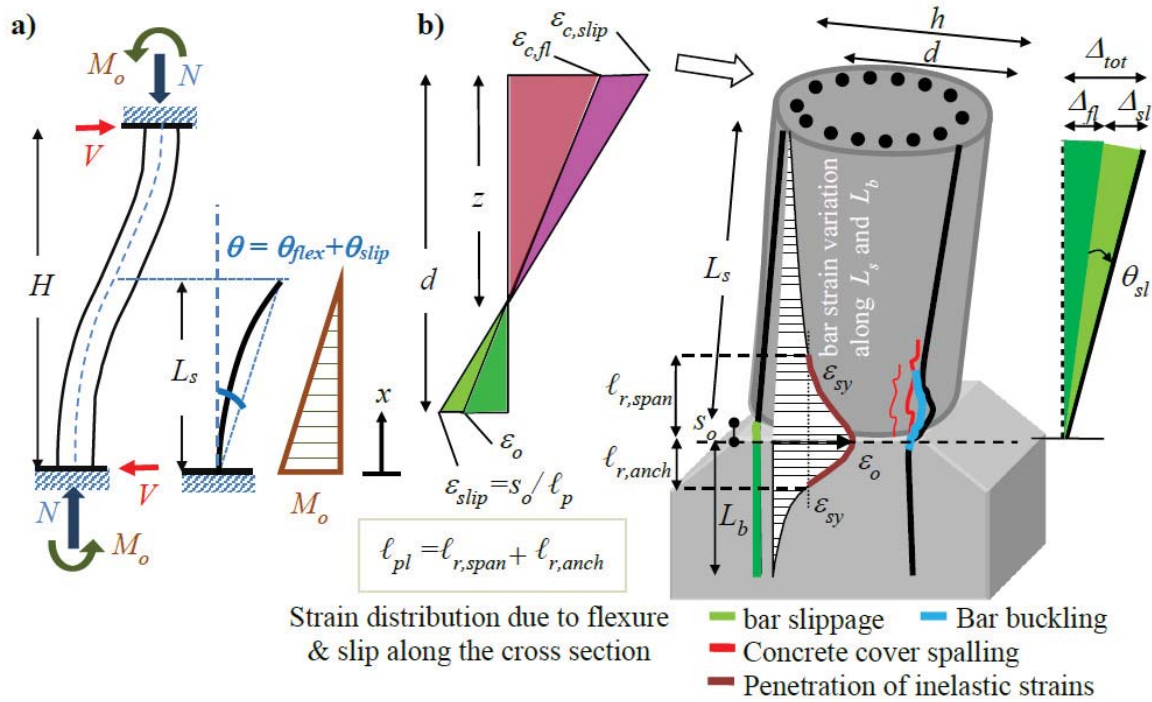

Figure 3: a) Column under lateral sway and b) cantilever model for its deformation analysis

### 3 CORRELATION WITH THE EXPERIMENTAL RESULTS

It is evident that yield penetration occurs from the critical section towards both the shear span and the support of columns; physically it refers to the extent of the nonlinear region and determines the pull-out slip measured at the critical section. Contrary to the fixed design values adopted by codes of assessment, the yield penetration length is actually the only consistent definition of the notion of the plastic hinge length, whereas the latter determines the contribution of pull-out rotation to column drift and column stiffness. When a reinforced concrete (RC) column is subjected to lateral sway as a result of earthquake action, the large strain demand in the end sections is supported by development of a strain distribution in the anchorage (Fig 3). This causes the bars to displace (or slip) relative to the anchoring concrete at the column fixed end(s). The lumped slip causes rigid-body rotation of the column, thereby alleviating partially the column deformation. This reinforcement slip is assumed to occur in the tension bars only and cause the rotation about the neutral axis. Development of flexural yielding and large rotation ductilities in the plastic hinge zones of frame members is synonymous with the spread of bar reinforcement yielding. Yield penetration in the anchored reinforcing bar inside the shear span of the column where it occurs, destroys interfacial bond between bar and concrete and reduces the strain development capacity of the reinforcement. This affects the plastic rotation of the member by increasing the contribution of bar slippage. Results obtained from the analytical procedures introduced in the previous section are compared here

with experimental evidence from the tests conducted on reinforced concrete bridge piers under cyclic loading reported previously.

In the following figures the aforementioned comparison is depicted and it can be seen that the produced monotonic envelope for applied shear load versus the slip of the extreme tensile reinforcing bar of the circular section of the bridge piers is in good agreement with the experimental evidence [1], [10].

#### 4 CONCLUSIONS

- The experimental study demonstrated that design and detailing of pier-superstructure monolithic connections according with the EN 1998-2 (2005) [2] leads to a satisfactory performance under earthquake loading. Based on the observed response it was concluded that special care ought to be provided for the design of the anchorages of the pier longitudinal reinforcement according with EN 1992-2 (2005) [4], in order to prevent joint failure due to anchorage pull-out. Placing a fraction of the necessary vertical joint reinforcement in the beams outside the joint, as suggested in EN 1998-2 (2005) [2] for congestion-free alternative detailing did not compromise the strength of the joint, whereas

this practice facilitates placement of the reinforcement during construction. In all cases discontinuities in the joint body such as openings for passage ought to be avoided.

- According to these experimental observations the analytical evidence showed that through the proposed algorithm, the bar strain distributions and the extent of yield penetration from the yielding cross section towards the shear span and towards the support were resolved and calculated analytically by reference to the state of reinforcement strain. The numerical results are well correlated with the experimental evidence and are consistent with the experimental trends described above confirming that the plastic hinge length is controlled by the residual bond that may be mobilized along the yielded reinforcement.

### Abstract

*Analytical fragility curves for structures used in chemical plants are not commonly derived because of the high computational cost. In contrast, empirical curves are utilized within a quantitative risk assessment framework given that they can be found easily and adopted for different structural configurations. Arguably, analytical fragility curves can account for dynamic idiosyncrasies due to the interaction of a supporting structure and equipment that diversify from one process unit to another. Additionally, the use of an efficient and sufficient earthquake intensity measure is essential for deriving robust fragility curves. Peak ground measures that are commonly adopted for risk assessment may not be efficient to describe more complex systems with higher mode effects.*

*Using time-efficient modelling, the present analytical study intends to evaluate the seismic risk to a hydrodesulphurization unit, a process used in modern refineries to remove sulphur from refined petroleum products. The 3D model of the unit consists of an irregular steel supporting structure, several vessels as well as a piping network. To attain a robust modelling, the effects of panel zone configuration is examined. Furthermore, the seismic response of steel structure and piping is seen through the lens of different intensity measures. In the end, the most efficient and sufficient intensity measure is considered to derive fragility functions and estimate the annual frequency of exceedance of two different limit states. The results show that the steel frame is more vulnerable than the piping due to pounding effects of a heavy vessel at high level. In addition, the results highlighted that the spectral acceleration is an efficient and sufficient intensity measure. However, the spectral acceleration should be used at different vibration periods due to higher mode effects of equipment, which cannot always be expressed as a percentage of fundamental period of the structure. Thus, the standard approach based on the average spectral acceleration, as proposed in the literature, may not apply for process units of this type.*

## 1 INTRODUCTION

In chemical plants, supporting structures are used to carry piping and equipment for mechanical, safety and maintenance reasons. Supporting structures can vary on purpose and configuration, but two main configurations can be described: 1) pipe racks are used to carry piping that transfers products from one process unit to another and 2) steel towers are constructed to support vessels and piping at different heights. In pipe racks, the supporting structures are quite regular and they are usually considered as cantilevers during design and assessment, because of the lack of diaphragmatic behaviour and because of the point forces of pipes at the top (Figure 1a). In steel towers, structures are more irregular, in terms of mass and stiffness, they present higher mode effects and can be high-rise to accommodate all the required equipment (Figure 1b). In both cases, however, the potential risk due to piping failure can be the reason for catastrophic cascading effects given the hazardous materials involved.

Earthquakes continue to expose European countries, particularly in the Mediterranean sea, to high risk where seismic events have triggered significant destruction over the last decades [1]. Additionally, numerous major accidents events have been triggered by the seismic hazard due to damage to piping and supporting structures, causing human losses, environmental contamination and financial losses ([2]–[4]). The life-saving issue of seismic integrity inside chemical plants was also illustrated by [5], who identified 78 Natech accidents triggered by earthquakes, involving 439 pipework components (directly or indirectly damaged).

Figure 1: Different types of supporting structures inside chemical plants: a) pipe rack, b) tower with process equipment.

Seismic assessment is essential for risk reduction inside chemical plants. One of the most decisive steps of the risk assessment of major accidents triggered by seismic events is the use of fragility functions [6], which express the conditional probability of reaching or surpassing a specific damage state given an Intensity Measure (IM) of earthquake shaking. Fragility functions can be utilized prior to an earthquake within a consequence-based analysis to design strengthening measures and devise emergency response plans as well as in the aftermath of an

earthquake to prioritize inspection and determine medium- and long-term response and recovery ([7], [8]). Although the robustness of analytical fragility curves for critical process units is crucial for risk reduction inside process plants, many researchers still adopt empirical ones e.g. from HAZUS [9], because they are easily available and have applicability to different process units. Other databases e.g. SYNER-G [10] include both empirical and analytical fragility curves, though they are not exhaustive in terms of the various process units that can be found in petrochemical plants and do not account for the fragility of equipment separately. At least to the Authors' knowledge, the literature on the fragility derivation of supporting structures that account for dynamic interaction with equipment is very scarce. Even though some studies have been conducted in the past, they mainly regarded the fragility assessment at the component level and usually neglected the dynamic coupling between the supporting structures and the equipment ([11]–[14]).

Apart from modelling uncertainties, robust fragility functions should be expressed by selecting seismic IM that are representative of the seismological properties of ground motion related to site and source (sufficiency) and which reduce the record-to-record randomness (efficiency). A sufficient IM is conditionally independent of magnitude,  $M$ , and Joyner-Boore distance,  $R_{jb}$ ; thus, these parameters have little effect on the resulting seismic demand model. Additionally, an efficient measure results in low variability of seismic demand and enables the evaluation of the demand with the least possible number of ground motions. The efficiency and sufficiency of different IMs have already been addressed for common civilian assets, bridges and transport pipelines ([15]–[18]). For example, [18] conducted a literature review on the existing fragility curves for the European building stock, and it was confirmed that typical ground measures, e.g. peak ground acceleration, velocity and displacement as well as spectral measures at the fundamental period of structures were considered efficient. When it comes to buildings with non-structural components, an average spectral acceleration based only on the fundamental period of a building was proposed by [18] and [19], so that it can be easily applied in a risk assessment procedure. However, whether this IM can be applied for high irregular and complex systems, like process units, or not is still an open question that will be discussed in the current work.

The present analytical study intends to: 1) examine the seismic response of a process unit, 2) compare the efficiency and the sufficiency of common and recently-proposed measures for which ground prediction models are easily available and which can be used within a quantitative risk assessment, and 3) estimate the seismic risk in terms of mean annual frequency of collapse for further decision making, e.g. retrofitting or response planning.

## 2 DERIVATION OF ANALYTICAL FRAGILITY

### 2.1 Methodology

Different fragility analysis methods can be adopted to derive the fragility of a structural system. The methods are generally categorized as narrow- and wide-range, depending on the range of IM values. Considering that process units are large in scale and complex, stick modelling should be used, accounting also for the analysis method with the least possible computational cost. In addition, when addressing the fragility of critical plants where high level of damage must be avoided or should occur at large seismic intensity only, it is prudent to localize the investigation of an industrial structure, at least preliminarily, at lower performance level e.g. serviceability or life safety.

To this effect, the so-called cloud analysis that belongs to narrow-range methods will be used for the present study. The probabilistic estimation of an engineering demand parameter

given an IM is attained through the least sum of the squares of the residuals method, as described in [21]. The logarithmic linear regression of seismic demand, EDP, as a function of IM is considered and described by Equation 1:

$$\begin{aligned} EDP &= (a \cdot IM^b) \cdot \varepsilon \\ \eta_\varepsilon &= 1 \text{ and } \sigma_{\ln \varepsilon} = \beta_{EDP|IM} \end{aligned} \quad (1)$$

where  $a$  is an intercept and  $b$  is the slope in log-space. The lognormal random variable  $\varepsilon$  has median,  $\eta_\varepsilon$ , equal to unity and its logarithmic standard deviation,  $\sigma_{\ln \varepsilon}$ , is equal to the standard deviation of the EDP for a given value of IM,  $\beta_{EDP|IM}$ . The latter constitutes a metric of the efficiency of the regression of tested IMs to describe the seismic response of a structure.

Assuming that the EDP follows a logarithmic standard distribution for a given IM, the logarithm of the median,  $\ln(\eta_{EDP|IM})$ , is equal to the mean of the logarithm of EDP,  $\mu_{\ln EDP|IM}$ . The standard deviation of the logarithm of EDP,  $\sigma_{\ln EDP|IM}$ , is equal to the dispersion of EDP,  $\beta_{\ln EDP|IM}$ . Therefore, the parameters of the linear regression,  $a$  and  $b$ , can be obtained by estimating the median using linear regression in the logarithmic space of “cloud” data. The cumulative lognormal distribution of the observed data is expressed by Equation 2:

$$\begin{aligned} P[EDP_D > EDP_C|IM] &= \Phi \left( \frac{\ln(a \cdot IM^b) - \ln \eta_{EDP|IM}}{\beta_{EDP|IM}} \right) \\ &= \Phi \left( \frac{\ln(IM) - \ln \eta_{IM|EDP}}{\beta_{IM|EDP,tot}} \right) \end{aligned} \quad (2)$$

The total dispersion  $\beta_{IM|EDP,tot}$  accounts for three types of uncertainty, namely seismic demand ( $\beta_{EDP|IM}$ ), capacity ( $\beta_C$ ) and limit state ( $\beta_{LS}$ ) definition. The first type of uncertainty will be evaluated via nonlinear dynamic analyses in Section 4. The second and third uncertainty types are set equal to 0.3 and 0.4, respectively, based on common values that can be found in [9]. A more rigorous definition of the last two types of uncertainty would require a further detailed examination, which is beyond the scope of the present study. Finally, the total dispersion is evaluated by Equation 3:

$$\beta_{IM|EDP,tot} = \frac{1}{b} \sqrt{(\beta_{EDP|IM}^2 + \beta_C^2 + \beta_{LS}^2)} \quad (3)$$

### 3 CASE-STUDY

The case-study deals with the seismic assessment of an existing desulphurization process unit that is made of steel (Figure 1b). It was originally designed according to [22] for a high seismicity region. By virtue of a recent update of seismic hazard maps in the region of interest ([23]), the seismic integrity of the process unit should be assessed. The new acceleration values,  $S_1=1.35g$  and  $S_8=0.38g$ , were used for selecting seismic records consistent with the seismic hazard. The system is divided into two parts in order to facilitate the assessment in the following; in particular, the first part regards the high-rise steel structure (S) with the vertical vessel at the top (Figure 2a&b), whilst the second part is composed of a low-rise steel structure with equipment (Eq) that consists of horizontal vessels and pipes (Figure 2b). In this respect, see also Figure 1b. The system was assessed in the nonlinear regime using [24] and [25] as reference codes.

#### 3.1 Modelling characteristics

The structural members are made of steel ASTM A36/A36M with expected yield ( $f_{yes}$ ) and ultimate strength ( $f_{ues}$ ) 372.32 MPa and 439.89 MPa, respectively, modulus of elasticity ( $E$ )

equal to 203 GPa, Poisson ratio ( $\nu$ ) equal to 0.3 and kinematic hysteretic behaviour. The lateral load resisting system is formed by ordinary braced frames in the X direction, and ordinary moment frames in the Y direction. Horizontal bracing is placed in the XY plane and some vertical cross-bracings can also be found in the Y direction.

Several process vessels e.g. heat exchanger, surge drum and steam generator are supported on the steel structure and are considered in the modelling. Also, there is a piping network that connects the vessels at different heights. Pipes have three different nominal diameters (DN), viz DN250 40S, DN500 and DN600 80S. More information about the geometrical properties of pipes can be found in [26]. The pipes are made of steel API 5L X42 with expected yielding ( $f_{yep}$ ) and ultimate strength ( $f_{uep}$ ) equal to 297.00 MPa and 335.50 MPa, respectively. The modulus of elasticity ( $E$ ) and Poisson ratio are equal to 203 GPa and 0.2, respectively. Anew, kinematic hardening is considered with rupture strain at 0.03. The piping is supported on the steel structure mainly with sliding and guided supports, so that pipes are free to move in the longitudinal direction; however, some fixed points are also used particularly at the connection of pipes with equipment at the base floor. The description of supports at different coordinates of the system is omitted for brevity.

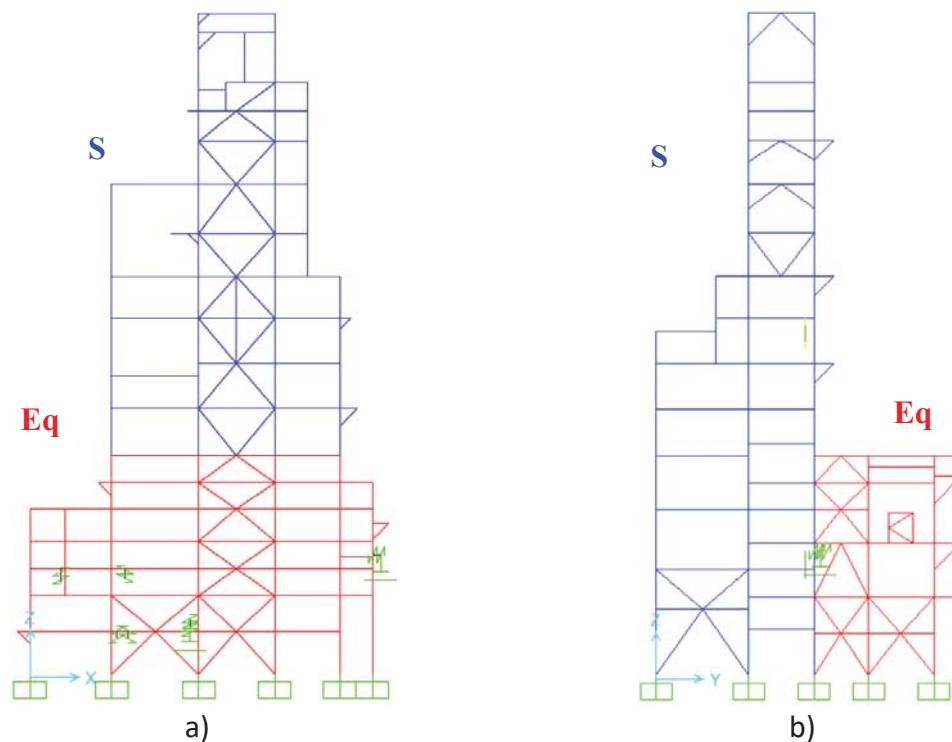

Figure 2: X-Z plane with part S (structure and vertical vessel) and Y-Z plane with part S and Eq (equipment)

Table 1: Impact of panel zone modelling on the first vibration period

Modal Analysis	Panel Zone	T(sec)	$\Delta T(\%)$	Mx/My (%)
X-direction	Centerline	1.084	N.A.	32/7
	Rigid offset	1.115	+2.95	22/18
	Scissor	1.073	-1.01	34/5
Y-direction	Centerline	1.175	N.A.	7/32
	Rigid offset	1.048	-10.71	18/22
	Scissor	1.172	-0.20	7/34

N.A.: Not Available

Before considering the assessment of the system in the nonlinear range using [27], it was necessary to examine a number of modelling aspects. First, three different configurations of panel zone were considered to examine the effects on vibration period of the structure, namely centerline without rigid offset, centerline with offset and scissor model as described in [28]. It can be seen in Table 1 that the maximum reduction of period between the centerline (most flexible) and rigid offset configuration was estimated roughly at 11% in the Y direction, whereas the difference with the scissor model did not exceed 3% in both directions. Furthermore, to examine the influence of flexibility of the beam-to-column connections, mainly in the X direction, two different lateral resisting systems were calibrated. In addition to the original system, a dual system was modelled with both directions being restricted. After comparing the vibration modes for the two different structural types, it was concluded that the maximum difference was 8% and 2% in the X direction and Y direction, respectively. Given that the rigid panel zone and the flexibility of connection did not influence considerably the response, the scissor model with the original configuration of frames was considered in the assessment. Finally, Table 2 quotes the first four vibration periods of the entire system, as inferred from modal analysis.

Table 2: The first four modes of vibration of the system

	Mode #	T(sec)	Mx/My (%)
Structural Part S	Mode 1	1.175	32/7
	Mode 2	1.084	7/32
Structural Part E	Mode 3	0.495	30/0
	Mode 4	0.450	0/17

The plastic deformation of structural members was described by concentrated hinge modeling. Although distributed plasticity formulations may capture the stress-strain behaviour along the structural member or local behaviour such as buckling of flanges, they require high computational effort, which becomes even more prohibitive for large scale models like the process unit under examination. On the other hand, point hinges can be more adequate to capturing the nonlinear degrading response [28]. In the framework of this study, concentrated plasticity was used, allowing for an analysis that is both time efficient and effective, under the condition that the response of the system is not investigated beyond the collapse prevention limit state. Concerning the plastic deformation on pipes, fiber sections with 8 integration points were used. More information about this method can be found in [27] and [28].

### 3.2 Selection of records

The selection of a sufficient number of records for seismic risk assessment is crucial for the accurate prediction of the system response. This comes as a function of the analysis method for deriving fragility functions. For example, the cloud analysis method that the present study employs requires a sufficient number of records with values close to, or larger than, the limit state of interest [29]. Additionally, the method for selecting a set of records consistent with the seismic hazard is equally important for improving the sufficiency and efficiency of the IMs. To this effect, a number of 40 far-field records from NGA West 2 database were selected with the conditional spectrum approach as described by [30]. The spectra of the selected records are shown in Figure 3. The moment magnitude of records,  $M_w$ , varies from 6 to 7.6, the Joyner-Boore distance,  $R_{jb}$ , spans from 22 to 92 km, approximately. Shorter distance was not considered to avoid including pulse-like records, which are being investigated by the Authors. Also, the average shear wave velocity of the upper 30 m of soil profile,  $V_{s30}$ , was found in the range

of 160 km to 360 km which refers to soil type D according to [31]. The records were shortened using the 5-95% significant duration rule and the maximum scale factor was set to 4. Finally, it should be emphasized that the records were conditioned at the first vibration period of the steel structure,  $T_1$ , in the weakest direction Y. This decision was made on the basis of the significant inter-storey drift ratio observed at the point where the vertical vessel is supported at the top of the steel structure. Additionally, [32] showed that risk-based assessments do not vary based on the choice of conditioning period given that hazard consistency is achieved.

Figure 3: Response spectra of the selected far-field records

## 4 SEISMIC RISK ASSESSMENT

### 4.1 Methodology for nonlinear analysis

Before running nonlinear analyses, the acceptance criteria should be defined. There are three main aspects that need to be accounted for when defining performance levels for irregular systems like the process unit. Firstly, the structural type should be considered. The unit is a concentrically braced frame in the X direction and ordinary moment frame with some bracing in the Y direction as well. Also, it lacks diaphragmatic behaviour, which can result in uneven deformation at the same height. Thus, acceptance criteria should not be the same as for common building structures considering also the higher risk that process plants pose to humans and environment. Secondly, the scale of the model necessitates the use of an engineering parameter that is able to describe the damage at global level and can be monitored easily. The shear or moment force of beams and columns as well as the axial force of braces can be suitable parameters for models with smaller scale. Finally, the selected parameter should be able to describe the damage to pipes. For the aforementioned reasons, the interstorey drift ratio (IDR) was selected as a global and generally recognized demand parameter by seismic codes ([24]) to describe the damage on the steel structure. The acceptance criteria for IDR are shown in Table 3 for two different limit states, namely serviceability (SLS) and safe life (SLLS) limit state. [33] investigated the seismic response of a 4-storey steel moment frame analytically and experimentally, indicating that the beginning of yielding and buckling of members occurs at IDR values equal to 1% and 2%, respectively. Given the higher risk, the presence of bracing and irregularity of the process unit, lower values than those indicated by [33] were set for the SLS and SLLS in Table 3. When it comes to piping, the yielding strain is commonly selected as the lower boundary of SLS both under tension and compression. More information about the limit states of piping can be found in [34] and [35].

Furthermore, preliminary time-history analyses were conducted using 11 unscaled records that examined the seismic response of the structure and defined the scaling factor that is required to equal or to exceed the SLLS, which was set as a performance objective. For the cloud

analysis method, there is a rule of thumb saying that 30% of selected records should exceed the desired limit state ([29]). To attain this goal, the records were initially scaled with a scaling factor that did not exceed 5, and then the factor was scaled down to reduce the bias due to some significant deformation that was observed both on steel structure and pipes.

#### 4.2 Efficiency and sufficiency of tested seismic IMs

The scope of the present study is to find an IM that is sufficient and efficient both for the structure and pipes, and which can be combined with a simple ground prediction model for risk assessment. Considering that the system includes structural and nonstructural components and the deficiency of the literature on the seismic response of petrochemical plants units, it was decided to compare measures of three different categories, namely duration-, amplitude- and period response-based. The first category consisted of Arias Intensity (AI, [36]) cumulative and standardized cumulative average velocity (CAV and SCAV, [28]&[29]) and the second one included the peak ground acceleration and velocity (PGA and PGV). Apart from the spectral acceleration at the first vibration period of both structural parts,  $S_a(T_s)$  and  $S_a(T_{Eq})$ , the effective peak acceleration (EPA, [39]) and the recently introduced equipment average spectral acceleration (E-ASA<sub>R</sub>, [19]) were also considered in the period response-based category.

Figure 4: Regression for structural part S using a. PGA in the Y direction, and b. 5%-damped  $S_a$  (design values  $PGA_d$  and  $Sa_d$  are equal to 0.37g and 0.35g, respectively)

Table 3: Median, dispersion and coefficient of determination for structural part S and SLLS

Intensity measure (IM)		$\mu_{\ln EDP IM}$	$\beta_{EDP IM}$	$R^2$
Duration-based	Aly (m/s)	22.77	0.43	0.10
	CAVy(g-s)	3.57	0.40	0.22
Amplitude-based	PGAy/PGA <sub>d</sub>	2.47	0.42	0.14
	PGVy (cm/s)	104.90	0.34	0.44
Period response-based	EPAy (g-s)	0.81	0.29	0.60
	<b>Sa(T<sub>s</sub>)/Sa<sub>d</sub></b>	<b>2.40</b>	<b>0.16</b>	<b>0.87</b>

The results from the linear regression analysis of IDR as a function of PGA and  $S_a$  for the structural part S in the Y direction are shown in Figure 4a&b, respectively. The most remarkable outcome regards the considerably lower dispersion of  $S_a$  compared to the PGA. This outcome stems from the fact that the concentrated mass of the vertical vessel at the top governs the response, resulting in the highest IDR at the same height. The low variability of the response is strengthened further by conditioning the records at the first fundamental mode that pertains mainly to the vibration of the vertical vessel. Obviously, the PGA that is proposed by HAZUS [9] is not efficient and should not be preferred over  $S_a$  for risk assessment of this process unit. Also, the rest of IMs were observed to be less efficient than  $S_a$  (Table 4). It is emphasized that

Table 4 quotes only the dispersion due to record-to-record randomness. The rest two types of uncertainty are not included to avoid blurring the comparison.

Figure 5: Regression for structural part Eq in terms of a. IDR of steel structure in the X direction and b. compression strain on pipe expressed as a function of 5%-damped  $Sa_{Eq}$  (design value,  $Sa_{Eqd}$ , equal to 0.94g)

Table 4: Median, dispersion and coefficient of determination for structural part Eq

Intensity measure (IM)		$\mu_{lnEDP IM}$	$\beta_{EDP IM}$	$R^2$
Duration-based	$A_{lx}$ (m/s)	6.48	0.54	0.31
	SCAVx (g-s)	1.85	0.59	0.15
Amplitude-based	$PGA_x/PGA_d$	1.48	0.36	0.69
	$PGV_x$ (cm/s)	118.90	0.63	0.05
Period response-based	E-ASA40x (g)	0.94	0.35	0.71
	EPAX (g-s)	0.75	0.44	0.53
	$Sa(T_{Eq})/Sa_{Eqd} _{ec}$	<b>1.29</b>	<b>0.31</b>	<b>0.77</b>
	$Sa(T_{Eq})/Sa_{Eqd} _{IDR}$	<b>3.12</b>	<b>0.22</b>	<b>0.83</b>

Furthermore, the regression for the structural part Eq, which refers to the steel structure out-fitted by the horizontal vessels and pipes, is expressed in terms of interstorey drift,  $IDR_{Eq}$ , and pipe strain due to compression,  $ec$ , as a function of spectral acceleration at the fundamental frequency of the equipment,  $Sa(T_{Eq})$  (mode 3 in Table 2). In this respect, see Figure 5a&b. It can be seen that the SLS for the structure occurred at 36% lower  $Sa$  compared to pipes. Additionally, the dispersion for the seismic response of the structure was lower than the pipe, which can be a clear indication that the vulnerability of the equipment should better be expressed in terms of steel structure deformation. It is reasonable that the response of pipes resulted in higher dispersion, since the dynamic interaction of structure, vessel and pipe can become complex, if the pipe is not rigidly supported on the rack. The rest of IMs that were examined resulted in higher dispersion than the above-mentioned measures (Table 5). It is emphasized herein that in contrast with [19] who formulated  $ESA_R$  ( $R$  means the percentage increase of vibration period) based on the fundamental period of a structure, in this case study, the fundamental period of the structure,  $Sa(T_s)$ , is much greater than the period of equipment,  $Sa(T_{Eq})$ , and thus it was decided to use the latter as a reference period and increase it by 40% in order to account for additional modes of vibration of equipment (not shown in Table 2). Nevertheless, it appeared that higher modes apart from  $T_{Eq}$  did not affect the response of equipment. Other researchers such as [20] have proposed similar IMs, which do not apply to our case due to the high irregularity of the process unit.

Furthermore, the dependency of IMs on magnitude,  $M$ , and Joyner-Boore distance,  $R_{jb}$ , was examined based on the p-value. A p-value greater than 0.05 is commonly accepted as a threshold for accepting the null hypothesis which states that the coefficient of regression is zero. As depicted in Table 6, some measures are sufficient for both parameters and others only for one

of them. It is emphasized that the  $Sa(T_S)$  proved to be sufficient for both seismological parameters, thus it meets the requirements to be used for risk assessment in the following. Even though the  $Sa(T_{Eq})$  was sufficient as a function of IDR, it was not evaluated as sufficient with respect to pipe strain,  $\epsilon_c$  (Table 7). Nevertheless, the dispersion of  $Sa(T_{Eq})|IDR$  is both efficient and sufficient, and thus it can be used as a proper IM for the risk assessment of the equipment. Finally, the PGA was also a sufficient IM, but lower efficiency was estimated compared to  $Sa(T_{Eq})$ .

### 4.3 Risk estimation

Based on the previous results, the fragility of the system was derived using the  $Sa$  as IM for both structural parts (Figure 6a&b). Also, for the structural part Eq, the fragility for the SLS of the most vulnerable pipe was depicted as well in Figure 6b for the sake of comparison. To derive the mean annual frequency of exceedance for each LS,  $\lambda$ , the fragility curves were integrated with the seismic hazard curves for both parts (Figure 7a&b). The hazard curve provides the mean annual frequency of exceedance, MAF, for each value of  $Sa$ . The values of  $\lambda$  for the SLS and SLLS are quoted in Table 8. For the part S, it can be seen that  $\lambda$  is equal to  $0.0021 \text{ yrs}^{-1}$  or, in other words, the mean return period of exceedance of the SLS is 476 years. Concerning the SLLS and structural part Eq, the mean return period is significantly higher. Based on the fragility analysis results, it can be mentioned that the performance objective of “control damage” on the structure, as stipulated in [24], is met; however, the estimated risk should further be assessed accounting for a greater number of records and soil deformability effects. In such case, the risk can be communicated to a stakeholder for further decision making.

Table 7: Annual frequency of exceedance and return period for the two limit states and structural parts

	PART S		PART Eq	
	$\lambda$ ( $\text{yrs}^{-1}$ )	Return period (yrs)	$\lambda$ ( $\text{yrs}^{-1}$ )	Return period (yrs)
SLS	0.0021	476	0.0014	716
SLLS	$1.32 \cdot 10^{-4}$	7,576	$4.67 \cdot 10^{-5}$	21,426

## CONCLUSIONS

The present analytical study evaluated the seismic risk of a chemical process unit accounting for dynamic interaction with equipment. The main considerations and outcomes can be summarized as follows:

- The system was separated into two different structural parts, part S and Eq. The part S included the high-rise steel structure, affected mainly by a heavy vertical vessel at the top, whilst the part Eq consisted of the low-rise steel structure and horizontal vessels. This separation was necessary, since the two parts exhibited considerably different vibration periods and the second part included the most vulnerable pipe;
- Using a set of far-field records, the steel structure was found to be more vulnerable than the piping network in both parts, S and Eq. This is because of the excessive concentrated mass of vessels that increased the deformation of steel members;
- Different IMs were considered. However, for both structural parts, S and Eq, the spectral acceleration, was evaluated as both the most efficient and sufficient IM to describe the seismic demand both on the steel structure and piping, although considering a different vibration period for each part.. This outcome brings into question the application of average spectral acceleration, as proposed in the literature, for chemical process units with numerous equipment.

- Finally, the seismic risk was derived for each part separately, and the mean period of exceedance was evaluated at 556 and 1011 years for the SLS. However, the soil deformability should also be considered to have a fully realistic estimation of global risk of the petrochemical plant facility.

Apart from far-field seismic motions, a near-field set of records will be used in the future to examine the seismic vulnerability of the system, accounting for soil-structure interaction. In the end, the results from the fragility analysis will be used for determining consequence scenarios.

### Abstract

*For super high-rise buildings, higher order modal shapes may have a significant impact on the structural response under seismic excitations. Since conventional pushover analysis procedure only includes the contribution from the first modal response, it is not able to accurately account for the varying dynamic characteristics of a super high-rise building. Based on mode superposition response spectrum method, modal pushover analysis (MPA) procedure is proposed to consider enough number of modes, which improves the conventional pushover analysis procedure to a certain extent. Based on a case-study super high-rise structure, this paper comparatively investigates the seismic responses of the structure using conventional pushover procedure and MPA procedure, and the accuracy of the results are validated through comparison with nonlinear time history analysis. The results show that the MPA procedure has a great improvement in accuracy as compared to the conventional pushover procedure. It is also demonstrated that the calculated structural response from MPA are in very good agreement with the results from nonlinear time history analysis, such as peak story displacements and story forces, while reducing computing time tremendously which improves the efficiency of seismic analysis of super high-rise buildings.*

## 1 INTRODUCTION

The philosophy of seismic design for building structures has been gradually evolved from force-based design to displacement-based and performance-based design during the past decades. Pushover analysis procedure, known as a nonlinear static analysis procedure which could be an alternative to nonlinear time history analysis (NTHA) procedure, has been widely used and adopted within the scope of performance-based design [1]. In spite that the Pushover analysis procedure has the benefits of simplicity and relative accuracy, the fundamental assumptions behind the procedure has limited its use to a certain extent, especially for high-rise structures, which are: 1) the response of the structure is related to a certain equivalent single degree of system (SDOF), and 2) the deformation envelop along the structure height is assumed to maintain constant throughout the entire seismic behavior evolution even for the nonlinear response stage. Obviously, these assumptions have excluded the higher mode responses which should be evident in high-rise and super high-rise structures. For this end, Chopra et al. [2] has proposed a new Pushover analysis procedure, i.e., Modal Pushover Analysis (MPA) procedure, which analyze a structure using Pushover analysis at several selected modes, and combines the modal responses using a certain combination rule to get the final response. Since this procedure is able to include the higher mode responses, it becomes more popular than conventional Pushover analysis for seismic performance assessment of high-rise buildings.

This paper comparatively investigates the seismic response of a case-study super high-rise structure using MPA procedure. Various numbers of modes are selected including only one mode (which becomes traditional Pushover analysis) in order to assess the accuracy of the procedure. The results from MPA are then compared with the results from NTHA to evaluate the accuracy of MPA procedure.

## 2 PROCEDURE OF MODAL PUSHOVER ANALYSIS

A brief introduction to the main process of MPA procedure used in the current study are presented in the following text. More details regarding the theory and any specific attentions that should be paid during analysis could be found in literature [3-6]. The step-by-step illustration of the MPA analysis process are:

- 1) Step 1: Calculate the structural vibration periods  $T_n$  and vibration modes  $\varphi_n$ ;
- 2) Step 2: For the  $n^{\text{th}}$  vibration mode, establish the base shear versus top displacement relationship (i.e., Pushover curve) based on a constant lateral force distribution  $s_n^* = m\varphi_n$ ;
- 3) Step 3: Transfer the analyzed Pushover curve to the idealized double broken Pushover curve for the  $n^{\text{th}}$  vibration mode, then transfer the idealized curve to the capacity curve (i.e., acceleration versus displacement relationship) for the  $n^{\text{th}}$  modal elasto-plastic SDOF system according to the following equations;

$$\frac{F_{sny}}{L_n} = \frac{V_{bny}}{M_n^*} \quad (1)$$

$$D_{ny} = \frac{u_{my}}{\Gamma_n \varphi_m} \quad (2)$$

where,  $M_n^*$  is the equivalent modal mass, and  $\Gamma_n$  is the modal contribution coefficient.

- 4) Step 4: Calculate the structural responses  $r_n$  of the  $n^{\text{th}}$  vibration mode using elasto-plastic response spectrum;

5) Step 5: Repeat the above Steps 3 and 4 for all the vibration modes determined to use in the MPA analysis;

6) Step 6: Obtain the total seismic demands based on a certain combination rule, such as the square root of sum of squares (SRSS) rule;

$$r = \sqrt{\sum r_n^2} \quad (3)$$

where,  $r_n$  is the  $n^{\text{th}}$  modal seismic demand, and  $r$  is total seismic demand.

### 3 THE CASE-STUDY SUPER HIGH-RISE BUILDING

#### 3.1 Description of the building

In this study, a super high-rise building is selected as the case-study structure for MPA analysis. Figure 1 shows the typical floor plan of the structure. As shown, the structural system of the building is frame-core wall system, which is the most commonly used system for super high-rise buildings in China. This system combines reinforced concrete (RC) wall cores (in the plan center) and columns (in the perimeter) to resist later loads, thus obtaining the balance between lateral resistance and stiffness along with architectural functions. The frame columns of the building are concrete filled steel tube (CFT) columns, and the frame beams are RC beams and steel beams. The coupling beams of core walls are steel-concrete coupling beams and RC coupling beams. In order to increase the lateral stiffness, outriggers and mega-braces are used at several stories along the building height. The total height of building is 400 m with 96 stories. Structural concrete strength is C60 based on Chinese design code [7] for columns and core walls, and C35 for floors. The structural steel is Q345, and reinforcing steel is HRB500 for force resisting bars and HRB400 for hoops and stirrups. According to Chinese seismic design code [8], the building is designed for a site of 8 degree representing high seismicity (the peak ground acceleration for design earthquake is 0.2g). The site class is III, and the seismicity group is I, resulting the site characteristic period of 0.45 sec. Dead and live loads for both floor and roof stories are 5 kN/m<sup>2</sup> and 2kN/m<sup>2</sup>, respectively. The design of the building is performed before the analysis of the study using the Chinese structural design software PKPM [9]. A list of the structural member sizes can be referred to as in Table 1 (for horizontal members) and Table 2 (for vertical members).

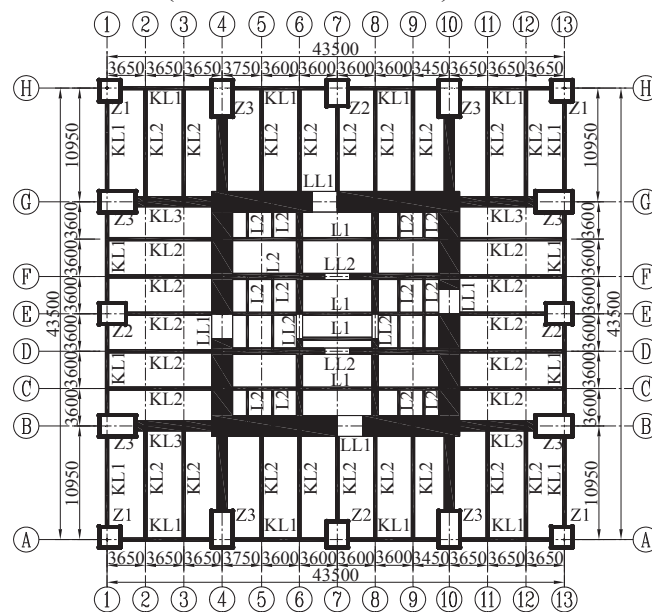

Figure 1: Typical floor plan layout (unit: mm).

90~95	500*500	500*800	650*1000		300	-	-
96						-	-

Note: 1) The meaning of section size of CFT column is height\*width\*thickness of steel plate in height direction\*thickness of steel plate in width direction. 2) The rectangular steel tube is used for truss and brace, and the meaning of section size is height\*width\*thickness of steel plate in height direction\*thickness of steel plate in width direction.

Table 2: Vertical members' section size (Unit: mm).

### 3.2 Numerical modeling

To conduct the MPA nonlinear static analysis, the numerical model of the case-study building is established using PERFORM-3D software [10]. The building core walls are modeled using General Wall element in PERFORM-3D, considering both the axial-flexural interaction as well as nonlinear shear behavior. The axial and flexural behavior of the core walls are modeled using fiber-section-based models, while the shear behavior is modeled by defining shear material in PERFORM-3D. The CFT columns are modeled using fiber section beam-column element, which similarly is capable to simulate the axial-flexural interaction

behavior of the columns. For simplicity, all the beams are modeled using concentrated plasticity beam-column element, and the moment-curvature constitutive relationship for the concentrated plastic hinge in the element could be determined based on the static elasto-plastic method. For coupling beams, it is critical to include shear effect in the element to model shear mechanism of coupling beams. All the material models are determined according to current design codes as well as several reference guidelines [7, 8, 11-14]. Figure 2 shows the elevation view of the considered super high-rise building model. Note that, this building model is analyzed only through only one of the horizontal directions (the X-direction) in the following text for simplicity. Table 3 shows the comparison of the first fifth modal period results (in X-direction) from both PERFORM-3D and PKPM, which indicates good agreement between different analytical software.

Figure 2: Elevation view of the building model.

Mode (X-direction)	PKPM	Perform-3D	Error
1	6.025	5.999	0.43%
4	1.615	1.569	2.85%
7	0.792	0.762	3.84%
10	0.518	0.493	4.73%
14	0.374	0.352	5.76%

Table 3: Modal analysis results in X-direction.

#### 4 GROUND MOTION DATA

For nonlinear time history analysis, a total of five ground motions are selected in the current study, including four recorded natural seismic excitations from PEER ground motion database, and one artificial ground motion. Table 4 presents the basic information for the five earthquake ground motions, including earthquake records' site station, year and duration time. Figure 3a shows the design spectrum with 5% damping ratio based on Chinese seismic design code [8] along with the individual ground motion spectrum. Figure 3b shows the comparison of the average ground motion spectrum with the design spectrum. It can be referred from the figure that the average spectrum of the ground motions matches well with the design spectrum in an overall sense.

Number	Station	Year	Duration Time (s)
User_1	-	-	43
RSN721	El Centro Imp. Co. Cent	1987	59
RSN728	Westmorland Fire Station	1987	52

Figure 3: Response spectrum of the ground motions.

## 5 SEISMIC RESPONSE RESULTS

### 5.1 Pushover curves

In this section, seismic analysis results for the case-study building from the MPA analysis and its comparison with traditional Pushover analysis (i.e., use the first mode for MPA only) are presented. As mentioned, the accuracy of the MPA results is assessed through comparison with results from nonlinear time history analysis. As per MPA process illustrated earlier, the building model is subjected to a specific lateral force distribution (i.e., modal force distribution) first, then the static pushover analysis is conducted for each mode, respectively. Since the aim of the current study is to demonstrate the accuracy of the MPA procedure rather than

seismic performance assessment, only the vibration modes in the X-direction are considered. The maximum number of modes in X-direction considered in the current MPA analysis is five. Figure 4 shows the Pushover curves, i.e., base shear versus roof displacement relationships for all the five modal responses. Since the equivalent SDOF system with larger vibration period has less lateral stiffness, the pushover curve tends to be more flexible (larger displacement). Each pushover curve is then transferred to the capacity curves and is used to compare with the demand curve (also transferred from response spectrum as in Section 2) in order to determine the “Performance point”. In this case, the seismic intensity is selected to be the design earthquake level, i.e., 8 degree seismicity ( $PGA = 0.2g$ ). Once the “Performance point” for each mode has been determined, the total response of the structure using MPA could be easily determined through SRSS combination rule.

(a) Mode 1 (mode 1 in X-direction) (b) Mode 4 (mode 2 in X-direction) (c) Mode 7 (mode 3 in X-direction)

(d) Mode 10 (mode 4 in X-direction) (e) Mode 14 (mode 5 in X-direction)

Figure 4: Pushover curves.

## 5.2 Story drifts and peak displacements

Figure 5 and Figure 6 show the story drift response and peak story response along the building height from both the MPA and NTHA analysis results. The relative error for each MPA results (including one mode to five modes) with NTHA results are also given. It can be seen clearly from the figure, with more modes considered in the MPA results, more accuracy results relative to NTHA response could be achieved. Moreover, for the case-study super high-rise building, all the MPA results show quite good results for those stories under 60. However, for those stories above 60, MPA results with more than three modes show evidently much better accuracy as compared with MPA results with only two or one (i.e., traditional Pushover analysis) modes considered. Noted that only the X-direction is considered in the analysis, and for the first three modes in X-direction, the total number of modes should be 11 when all the three directions are included.

### 5.3 Story shear forces and overturning moments

Similarly, Figure 7 and Figure 8 show the story shear force response and story overturning moment response from both the MPA and NTHA analysis results. The relative error for each MPA results (including one mode to five modes) with NTHA results are also given. Similar to the results of story drifts and story displacements presented above, it is referred from the figures that the MPA results with more modes included in the analysis, more accuracy of the results could be achieved relative to NTHA response. For the shear force response, MPA results with 5 modes (blue lines in the figure) shows better accuracy in an overall extent (Figure 7b). However, for overturning moment response, MPA results with 5 modes (blue lines) shows much better results for stories above 25 as compared to results from traditional pushover procedure (i.e., only one mode considered).

## 6 CONCLUSIONS

This study investigates the effects of the Modal Pushover Analysis (MPA) procedure for a case-study super high-rise building, and the accuracy of the MPA results is validated through comparison with NTHA responses. The following conclusions are drawn from the study.

1) Higher mode effects could be included in MPA procedure, which shows the advantage for MPA analysis over traditional Pushover analysis, especially for analyzing high-rise and super high-rise buildings. In this study, the accuracy of MPA is sufficient when more than three modes (in X-direction) are considered in MPA (corresponding to 11 modes when all the three directions are considered).

2) MPA procedure shows a great improvement in accuracy as compared to the conventional pushover procedure (MPA with only one mode considered). It is also demonstrated that the calculated structural response from MPA are in very good agreement with the results from NTHA, in terms of story displacements (and drifts) and story forces (shear force and overturning moment), while reducing computing time tremendously, which in turn improves the efficiency of seismic analysis for super high-rise buildings.

### Abstract

*Grille-type steel plate concrete composite shear wall (GSPCW) is an innovative shear wall system consisting of steel faceplates, steel tie plates and infilled concrete. Compared with traditional steel plate concrete composite shear wall, GSPCW has the following advantages: 1) high buckling resistance, and 2) simple structural measures and convenient construction. This paper presents a numerical study of the GSPCW using DIANA software and comprehensively investigates the influence of varying design parameters on the seismic performance. First, DIANA models are established for considered GSPCW specimens and validated through comparing numerical results with previous test data. The verified model is further used to perform a parametric study to understand the influence of several design variables on seismic behavior of GSPCW, including steel ratio, axial load ratio, height-width ratio, aspect ratio of grille as well as concrete compressive strength. Results indicate that the former four parameters have remarkable impacts on seismic behavior of GSPCW: 1) The load and deformation capacity of a GSPCW increase significantly as the steel ratio increase; 2) The load capacity and ductility increase to a certain degree with increase of axial load ratio, however excessively high axial load ratio may have a negative impact on ductility behavior; 3) The load capacity and stiffness of a GSPCW decrease with the increase of height-width ratio; 4) The aspect ratio of grille has a hooping effects on the infilled concrete, which should be reasonably considered during design; 5) Compared with other parameters, the influence of concrete compressive strength is negligible. The conclusion from the parametric study might be utilized for engineering practice of GSPCW in future.*

## 1 INTRODUCTION

Steel plate concrete composite shear wall is a shear wall formed by arranging steel plates on one or both sides or inside of the concrete slab, and combining the two materials through shear nails or bolt tie rods on the steel plate. According to the different steel layout of steel plate concrete composite shear wall, it can be roughly classified into three types, single-sided steel plate concrete composite shear wall, double-sided steel plate concrete composite shear wall and embedded steel plate concrete composite shear wall [1]. Domestic and foreign scholars currently have conducted many researches on various steel plate concrete composite shear walls. The previous researches indicate that steel plate concrete composite shear wall has higher load carrying capacity, larger stiffness, better ductility and energy dissipation capacity [3, 4, 5].

To further improve the seismic behavior of steel plate concrete composite shear wall, W. Xu [6] proposes grille-type steel plate concrete composite shear wall, which is consisted of steel faceplates, steel tie plates and infilled concrete. And W. Xu has conducted a series of researches in a certain degree.

The initial study about grille-type steel plate concrete composite shear wall is carried out by X. Guo [7]. He analyzes the influence of different factors on the seismic behavior of grille-type steel plate concrete composite shear wall with embedded corrugated steel plate through experimental research and numerical simulation. The results indicate that the out-of-plane deformation of steel plates on the both sides of the shear wall is restricted due to the existence of concrete slab and ties of corrugated steel plate, thereby improving the out-of-plane buckling resistance of steel plates in the shear wall. Then T. Xu [8] and S. Ye [9] further improve the structure of grille-type steel plate concrete composite shear wall to replace the embedded corrugated steel plate to single independent steel plate. They find the new type of the shear wall has good seismic performance.

The two-dimensional numerical model of the grille-type steel plate concrete composite shear wall (abbreviated as GSPCW) is established in DIANA based on the two shear walls in S. Ye [9]. And 18 GSPCW specimens with various design parameters are designed to systematically investigate the influence of design parameters on GSPCW, including steel ratio, axial load ratio, height-width ratio, aspect ratio of grille as well as concrete compressive strength. The conclusion will provide reference for engineering applications in future construction works.

## 2 BRIEF DISCRIPTION OF PREVIOUS TESTS

This paper selects two GSPCW specimens to verify the accuracy of the simulations. The details of the two walls and material properties are presented in S. Ye [9]. Figure 1 shows views of the shear wall and the material properties are listed in Table 1. The tests were conducted at the Civil Engineering and Transportation Building in Jiulonghu Campus of Southeast University. The two walls had the same height-width ratio of 2.0 and the axial load ratio is the main design variable considered in the experiments. The thickness of steel faceplates and steel tie plates is 4 millimeters. The concrete grade is C40 and the steel grade is Q235B. The loading beam and foundation beam are reinforcement concrete beams. And there is a H steel beam embedded in foundation beam, which is used to improve the stiffness of foundation beam.

As shown in Figure 2, the test setup consists of bottom fixing device, out-of-plane support, vertical and horizontal loading device, and loading method adopts force and displacement-controlled loading history. The vertical load is applied by a hydraulic jack, and a steel beam is placed on the top of loading beam to evenly distribute the vertical load. Before the formal ap-

plication of horizontal load, the pre-load of horizontal load needs to be carried out to determine whether the loading equipment, connected equipment and data acquisition system are normal. Then the single-stage horizontal load is applied until the specimen yields. After specimen yields, displacement controlled multi-stage loading is applied until the horizontal capacity of the specimen decreases to 85% of the peak horizontal load.

No.	Wall dimension W×T (mm×mm)	Steel plate thickness (mm)	Steel channel	Axial load ratio	Concrete strength (MPa)	Steel plate strength (MPa)
GSSW-1	1400×160	4	[16	0.1	26.6	263.2
GSSW-2	1400×160	4	[16	0.4	26.6	263.2

### 3 METHOD OF NUMERICAL SIMULATION

#### 3.1 Modeling assumption

Two-dimension simulation is adopted in this paper. Figure 3 presents the geometry of the GSPCW developed in DIANA. Eight-node quadrilateral isoparametric plane stress elements are used for the infilled concrete, steel faceplates, loading beam and foundation beam. Bar reinforcement elements are used for the steel tie plates. The size of all elements is 50 mm. The translation of the bottom of the foundation beam is constrained.

The FE models are loaded in two steps as the same as the experiments: 1) the vertical load is applied to the top of the loading beam in a manner of uniform pressure, and 2) cyclic lateral displacement is applied to the centroid of loading beam.

The modified Newton-Raphson method is used for incremental-iterative solution. The convergence criteria combine force norm and displacement norm. Both physical nonlinear analysis and geometrical nonlinear analysis are considered in the analysis procedure.

Figure 2: The loading process of GSSW-1.[9]

Figure 3: Model of GSPCW in DIANA.

#### 3.2 Material model

The total strain crack model available in DIANA [10] is used for the infilled concrete. The input parameters for this model include linear material properties, crack direction and uniaxial behavior of concrete in compression and tension. The crack direction is rotating direction.

The uniaxial behavior of concrete is represented by a stress-strain curve, see Figure 4. In this paper, the constitute model of concrete in compression adopts the model proposed by J. Mander et al. [11], which is applicable to both circular and rectangular shaped transverse reinforcement. The restraint effect of steel plates on concrete can be regarded as the restraint effect of many transverse reinforcements on concrete. The formula is as follows:

$$f_c = \frac{f'_{cc} x^r}{r - 1 + x^r} \quad (1)$$

$$x = \frac{\varepsilon_c}{\varepsilon_{cc}} \quad (2)$$

$$\varepsilon_{cc} = \varepsilon_{co} \left[ 1 + 5 \left( \frac{f'_{cc}}{f'_{co}} - 1 \right) \right] \quad (3)$$

$$r = \frac{E_c}{E_c - E_{\text{sec}}} \quad (4)$$

$$E_{\text{sec}} = \frac{f'_{cc}}{\varepsilon_{cc}} \quad (5)$$

Where  $f'_{cc}$  is compressive strength of confined concrete,  $\varepsilon_c$  is longitudinal compressive concrete strain,  $f'_{co}$  and  $\varepsilon'_{co}$  is the unconfined concrete strength and corresponding strain,  $\varepsilon'_{co}$  can be assumed as 0.002,  $E_c$  is the tangent modulus of elasticity of the concrete,  $E_c = 5000\sqrt{f'_{co}}$ . The compressive strength of confined concrete  $f'_{cc}$  is determined by the confinement effectiveness for sections confined by steel plates and calculated according to the proposal of J. Cai [12].

The constitute model of concrete in tension is calculated according to CEB-FIP Model 1990 [13], and the formula is given by

$$f_t = \begin{cases} 0.26f_{cu}^{2/3} & (f_{cu} \leq 50\text{MPa}) \\ 0.21f_{cu}^{2/3} & (f_{cu} > 50\text{MPa}) \end{cases} \quad (6)$$

Figure 4: Stress-strain relationship of concrete.

The constitute model of steel uses bilinear elastic hardening model. The elastic modulus, yield strength and ultimate strength are all base on the material properties tests. The Von Mises yield criterion is used to evaluate the yield status of steel.

#### 4 NUMERICAL RESULT AND VALIDATION

Figure 5 is the load-displacement hysteric curves of GSSW-1 and GSSW-2. The experiment data of the hysteric curves is available in S. Ye [9]. And according to the hysteric curves, it is easy to calculate the skeleton curves and the rest of the relevant data, see Figure 6~Figure 9 and Table 2. It can be seen from Figure 5 and Figure 6 that the hysteric curves obtained from the numerical simulation are in good agreement with the skeleton curves. The magnitude of the peak load of the numerical simulation is larger than that of the test result, because the test specimens in actual situation have initial defects in a certain degree, and the bottom restraints of the test specimens cannot achieve the perfect effect of complete fixing. From the Figure 7, the stiffness of the FE model at the beginning of loading is greater than that of the experiment result. But as the loading continues, the difference between the two is getting smaller and smaller, because the constraints of the specimens in experiment are not as ideal as the constraints of FE model, so a certain error will occur at the beginning of loading, but as the loading displacement increases, the error caused by the constraint becomes more and more

insignificant. From the perspective of energy consumption and equivalent viscous damping ratio, since the material in the finite element model is uniform and has no initial defects, the energy consumption capacity of the finite element model is stronger than that of the actual specimen.

Notes:  $F_y$  and  $F_p$  are respectively the horizontal capacity of specimen at yield point and peak point.  $D_y$ ,  $D_p$  and  $D_u$  are respectively the horizontal displacement of loading point of specimen at yield point, peak point and ultimate point. The ultimate point is the point at which the bearing capacity drops to 85% of the peak bearing capacity.

Table 2: Comparison of the features points of skeleton curves.

## 5 PARAMETRIC ANALYSIS

In this study, a total of 18 shear walls were simulated, as shown in Table 3. In the process of parametric analysis of numerical simulation, the values of material strength are taken in accordance with the "Code for Design of Concrete Structures" (GB50010-2010) [14] and "Code for Design of Steel Structures" (GB50017-2017) [15], and the rest of the parameter settings are shown in Section 3. The steel ratio is defined as the ratio of the cross-sectional area of the steel to that of the full cross-section of the specimen, and the steel ratio is reflected by the change of thickness of the steel faceplates and steel tie plates. The height-width ratio is defined as the ratio of the height from the top surface of the loading beam to the top surface of the ground beam to the section width of the member. The axial compression ratio is the ratio of the vertical load to the product of the axial compressive strength and the full cross-sectional area. The aspect ratio of the grille is the ratio of the spacing of the steel tie plates to the thickness of the wall.

No.	Wall dimension W×T (mm×mm)	Height- width ratio	Concrete grade	Aspect ratio of grille	Axial load ratio	Steel plate thickness	Steel ratio

GSPCW5-4	1400×160	2.0	C60	1.25	0.3	4	8.9%

Table 3: The main parameters of numerical models.

### 5.1 Steel ratio

In this study, the change in the steel ratio of the specimens is reflected by the thickness change of the steel plate: the thicker the steel plates, the greater the steel ratio of the specimens. When the thickness of the steel plate is 3 mm to 6 mm, the corresponding steel ratio of the specimen is 7.2% to 12.1%. According to Figure 10 and Table 4, the research results show that the increase of the steel ratio can improve the bearing capacity and lateral stiffness of the shear wall. The lateral stiffness is defined as the ratio of the bearing capacity to the displacement at the yield point. When the thickness of the steel plate is increased from 3 mm to 5 mm, the peak bearing capacity of the specimen is increased by 36.7%, and the lateral stiffness is increased by 14.4%. Because the axial load ratio of the model is relatively small, the lateral stiffness of the specimen is basically the full-section elastic stiffness, and the stiffness of the concrete section accounts for a relatively large amount. Therefore, the increase in the lateral stiffness of the specimen is smaller than the increase in the bearing capacity.

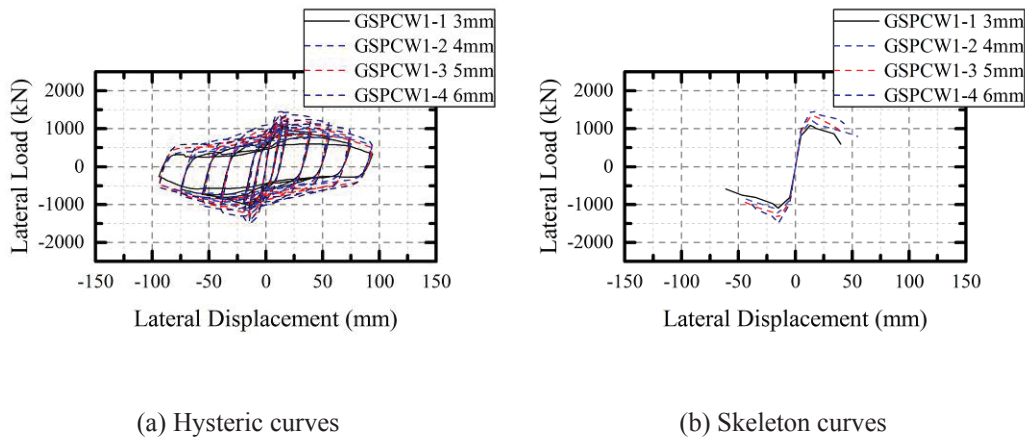

Figure 10: Influence of steel ratio on hysteric curves and skeleton curves.

Table 4: Influence of steel ratio on feature points of skeleton curves.

### 5.2 Axial load ratio

The variation range of the axial load ratio of the test specimens is 0.3 to 0.7. The hysteric curves, skeleton curves and feature points are shown in Figure 11 and Table 5. It can be seen from the calculation results that when the axial load ratio is in the range of 0.3 to 0.7, the horizontal bearing capacity estimated by finite element varies less, and the difference in the bearing capacity of the specimens is mainly due to the dispersion of material strength. It can also be seen from Table 5 that when the axial compression ratio is less than 0.5, the lateral stiff-

ness of the test specimen increases with the increase of the axial compression ratio. This is because the increase in axial load can delay the development of cracks, thereby improving the lateral stiffness of the specimen. However, when the axial compression ratio is greater than 0.5, due to the large axial load, the specimen enters the plastic development stage in advance, which reduces the lateral stiffness of the specimen. In general, it is recommended that in actual projects, the axial load ratio of the GSPCW should be controlled below 0.5 to ensure its good seismic performance.

### 5.3 Height-width ratio

The height-width ratio of the shear wall is one of the main factors that determines the failure type of shear wall and affects its seismic performance. The height-width ratio of the model studied in this paper ranges from 1.5 to 3.5. The hysteric curves, skeleton curves and characteristic points are shown in Figure 12 and Table 6. It can be seen from the calculation results that when the height-width ratio is increased from 1.5 to 3.5, its bearing capacity decreases by 58.3%, and its lateral stiffness decreases by 87.6%. The height-width ratio has a distinct effect on the bearing capacity and lateral stiffness of the shear wall. This is because as the height-width ratio increases, the failure mode of the specimen transitions from shear failure to bending failure, so the bearing capacity and lateral stiffness are reduced accordingly. When the height-width ratio is greater than 2.0, the bearing capacity and stiffness of the spec-

imens change slightly with the increase of the aspect ratio, and the descending segment of the skeleton curves of the specimens tends to be flat at the post-stage of loading, and the ultimate displacement gradually increases.

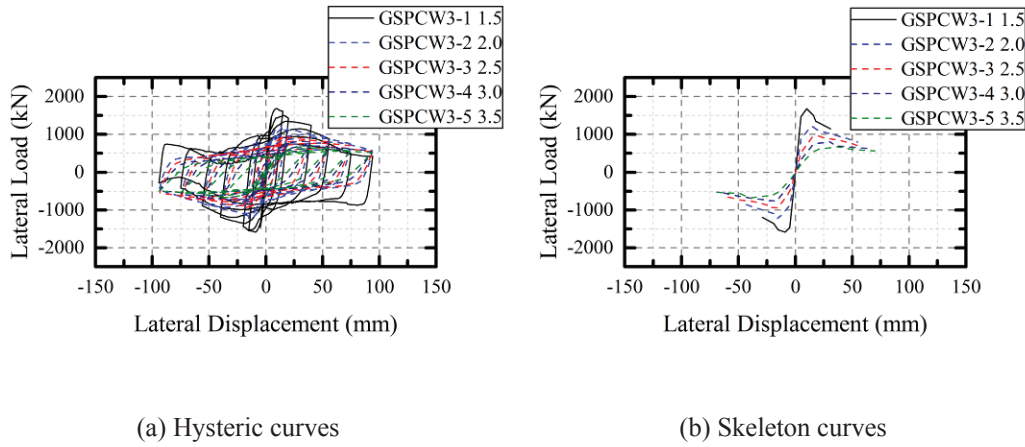

Figure 12: Influence of height-width ratio on hysteric curves and skeleton curves.

Table 6: Influence of height-width ratio on feature points of skeleton curves.

#### 5.4 Aspect ratio of grille

The aspect ratio of the grille refers to the ratio of the spacing of the steel tie plates to the thickness of the wall. It can be seen from Figure 13 and Table 7 that the aspect ratio of the grille has a certain influence on the seismic performance of the GSPCW. As the aspect ratio of the grille decreases, the horizontal bearing capacity of the specimens increases instead. This is because the steel faceplates and steel tie plates have a certain hoop effect on the filled concrete. When the aspect ratio of the grille increases, the bond between the steel faceplates and the inner concrete is weakened, which cannot effectively limit the out-of-plane deformation of the steel faceplate, so the hoop effect is relatively weakened. The displacements at yield points and ultimate points of the test specimens increase with the decrease of aspect ratio of grille, and the deformation performance of the test specimens have a certain improvement.

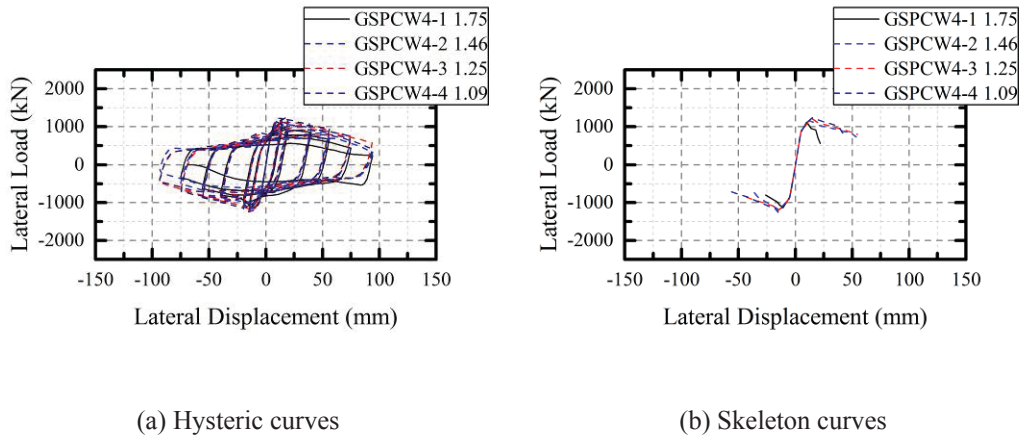

Figure 13: Influence of aspect ratio of grille on hysteric curves and skeleton curves.

	-	1049.23	9.40	111.58	1263.49	25.39

Table 7: Influence of aspect ratio of grille on feature points of skeleton curves.

### 5.5 Concrete compressive strength

In this study, the compressive strength of concrete was selected to be changed from 30MPa to 60MPa, and the calculation results are shown in Figure 14 and Table 8. The results show that with the increase of concrete strength, the horizontal bearing capacity and lateral stiffness of the specimens have a certain increase, but the growth rate is small. This is because high-strength concrete has a higher elastic modulus. Compared with other research variables, the compressive strength of concrete has less influence on the seismic behaviors of GSPCW.

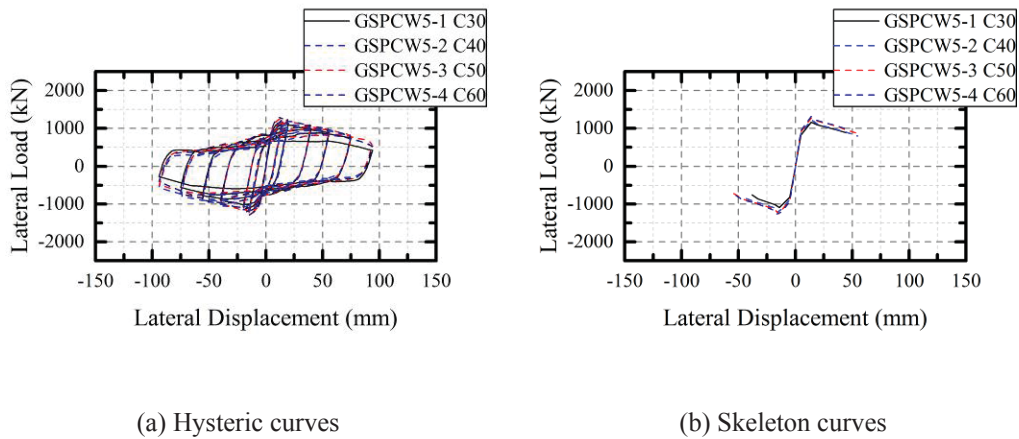

Figure 14: Influence of concrete compressive strength on hysteric curves and skeleton curves.

## 6 CONCLUSIONS

This paper mainly studies the influence of different design variables on the seismic behavior of GSPCW, including steel ratio, axial load ratio, height-width ratio, aspect ratio of grille as well as concrete compressive strength. The DIANA software was used to establish the finite element models of GSPCW, and the accuracy of the model was verified based on the previous test data. A total of eighteen shear wall models with different design parameters were further established. By comparing their hysteric curves, skeleton curves and feature points, the following conclusions were drawn:

1) To increase the steel ratio of the section can significantly increase the horizontal bearing capacity of the component, and increase the lateral stiffness of the component to a certain extent;

2) When the axial load ratio of the shear wall is less than 0.5, the bearing and deformation capacity will be improved with the increase of the axial load ratio. But when the axial load ratio is greater than 0.5, the increase in the axial compression ratio is more unfavorable to the seismic performance of the specimens. Therefore, the axial load ratio of this type of shear wall below 0.5 is expected in actual projects.

3) As the height-width ratio of the shear wall increases, the failure mode of the shear wall gradually develops from shear failure to bending failure, and the bearing capacity and lateral stiffness of the component decrease rapidly.

4) The aspect ratio of the grille is a meaningful design parameter to determine the hooping effect of the steel plate on the infilled concrete. The smaller the aspect ratio of the grille, the stronger the constraint on the infilled concrete, so the concrete compressive strength is higher, thereby the horizontal bearing capacity of the specimen is developed. In the actual practice, the influence of the aspect ratio of the grille on the seismic performance of the component should be reasonably considered.

5) Compared with other design parameters, concrete compressive strength has little-to-no effect on the seismic performance of GSPCW. The horizontal bearing capacity and lateral stiffness of specimens improve slightly with the increase of concrete strength.

### Abstract

*The present analysis deals with the seismic reliability of isolated multi-span continuous deck bridges considering as the main aleatory uncertainties relevant to the problem the sliding friction coefficient of the friction pendulum (FP) isolators together with the seismic records characteristics. A six-degree-of-freedom model is defined to simulate the elastic response of the reinforced concrete pier, the infinitely rigid response of the deck supported by the seismic devices and the non-linear velocity-dependent behavior of the FPS bearings. The reinforced concrete abutment is modelled as a rigid support above which a FPS device is located. A set of natural records with different characteristics is properly selected and scaled to increasing intensity levels. The randomness on the friction coefficient is described by an appropriate probability density function to sample. For different system and isolator properties, fragility curves of both the reinforced concrete pier and FP devices supporting the deck are estimated. In accordance with the hazard curve of the design site, the seismic reliability curves are derived by means of the convolution integral.*

## 1 INTRODUCTION

The aim of seismic isolation for bridges is to uncouple the deck from the horizontal components of the earthquake action, allowing a significant reduction of both acceleration and forces transmitted from the deck to the pier, compared to non-isolated bridges, as demonstrated in [1]-[3]. This topic is very crucial to the issue of the infrastructure safety [4]-[5]. Among the possible seismic retrofitting solutions, single concave friction pendulum system (FPS) devices have been often used because they imply a high dissipation capacity and determine an isolation period independent of the isolated mass as well as for their durability properties [6]-[10].

The use of both elastomeric and FPS bearings is studied in [11], where the efficacy of using simplified models in relation to the flexibility of the deck and of the piers is emphasized. Optimal values for the friction coefficient in seismic isolated bridges are proposed in [12], as function of the structural properties and of the soil condition. Furthermore, a three-dimensional multi-span continuous steel girder bridge, isolated by FPS isolators, is studied in [13], where the effect of modeling parameters and the influence of the design parameters on the response is investigated.

Seismic reliability-based design (SRBD) approach has been proposed in [14]-[18], in the context of investigating new design solutions for these seismic devices in relation to their main uncertainties. In [19] it is presented a probability-based reliability assessment method to consider the variations of the seismic isolation properties under different conditions, referring to a base-isolated two span reinforced concrete (RC) bridge. Seismic reliability analysis of a multi-span bridge pier developed through the response surface method-based metamodeling approach is described in [20]. Different methodologies to deal with seismic fragility assessment of highway bridges is presented in [21]. The research by [22] regards the efficiency of numerous seismic intensity measures to estimate the response of seismic-isolated bridges in relation to ordinary and pulse-like ground motions. Life-cycle reliability analyses of RC bridges are presented in [23]. In [24], the seismic design of RC bridge structures in relation to both ductile and brittle resisting mechanisms is evaluated, by proposing a reliability-based analysis with partial factors.

The present study regards the seismic reliability of multi-span continuous deck bridges isolated with FPS devices through the analysis of fragility curves related to a wide range of bridge properties as well as different seismic intensity levels. Five-degree-of-freedom (dof) models have been adopted, accounting for five vibrational modes representative of the elastic RC pier behaviour and another dof is added to analyze the response of the infinitely rigid RC deck isolated by the FPS devices. The pier-abutment-deck interaction is taken into account by modelling the RC abutment as a rigid support [2],[25],[26]. To model the behaviour of the FPS device the hypothesis of the friction coefficient varying with the velocity is adopted, as proposed by [7]. The friction coefficient has been described by means of an appropriate normal probability density function (PDF) and the Latin hypercube Sampling Method (LHS) [27], is employed as the random sampling technique to define the set of the input data. In addition, seismic uncertainty is accounted by considering 30 natural seismic records with different characteristics, scaled to different increasing intensity levels in line with the seismic hazard of the reference site (i.e., L'Aquila (Italy)). The relation between seismic demand and the capacity of the isolated bridge is analyzed through incremental dynamic analyses (IDAs) [28]. Thus, the response statistics related to both the superstructure (i.e., deck) and the pier have been evaluated. For the former in terms of peak deck displacement (with respect to the pier) and for the latter in terms of peak pier displacement (with respect to the ground). Furthermore, the results regarding the response statistics have been used to evaluate the seismic fragility curves

of both the rigid deck and the RC pier, assuming appropriate values of the corresponding limit state thresholds. The above-mentioned analyses (i.e., fragility curves) have been useful to assess the seismic reliability of bridges isolated with FPS bearings, according to the PEER-like modular approach [29], assuming the hazard curves of the site and a specific design life.

## 2 EQUATIONS OF MOTION

The structural system of an isolated multi-span continuous deck bridge is modelled, according to [2],[25],[26], as the sum of 5dof corresponding to the lumped masses of the RC pier and 1dof related to the rigid RC deck mass. The RC abutment is modeled as rigid and fixed.

The equations of motion of the response of an isolated bridge on FPS devices subjected to the seismic input along the longitudinal direction,  $\ddot{u}_g(t)$ , are:

$$\begin{aligned} m_d \ddot{u}_d(t) + m_d \ddot{u}_{p5}(t) + m_d \ddot{u}_{p4}(t) + m_d \ddot{u}_{p3}(t) + m_d \ddot{u}_{p2}(t) + m_d \ddot{u}_{p1}(t) + c_d \dot{u}_d(t) + f_b(t) + f_a(t) &= -m_d \ddot{u}_g(t) \\ m_{p5} \ddot{u}_{p5}(t) + m_{p5} \ddot{u}_{p4}(t) + m_{p5} \ddot{u}_{p3}(t) + m_{p5} \ddot{u}_{p2}(t) + m_{p5} \ddot{u}_{p1}(t) - c_d \dot{u}_d(t) + c_{p5} \dot{u}_{p5}(t) + k_{p5} u_{p5}(t) - f_b(t) &= -m_{p5} \ddot{u}_g(t) \\ m_{p4} \ddot{u}_{p4}(t) + m_{p4} \ddot{u}_{p3}(t) + m_{p4} \ddot{u}_{p2}(t) + m_{p4} \ddot{u}_{p1}(t) - c_{p5} \dot{u}_{p5}(t) - k_{p5} u_{p5}(t) + c_{p4} \dot{u}_{p4}(t) + k_{p4} u_{p4}(t) &= -m_{p4} \ddot{u}_g(t) \\ m_{p3} \ddot{u}_{p3}(t) + m_{p3} \ddot{u}_{p2}(t) + m_{p3} \ddot{u}_{p1}(t) - c_{p4} \dot{u}_{p4}(t) - k_{p4} u_{p4}(t) + c_{p3} \dot{u}_{p3}(t) + k_{p3} u_{p3}(t) &= -m_{p3} \ddot{u}_g(t) \\ m_{p2} \ddot{u}_{p2}(t) + m_{p2} \ddot{u}_{p1}(t) - c_{p3} \dot{u}_{p3}(t) - k_{p3} u_{p3}(t) + c_{p2} \dot{u}_{p2}(t) + k_{p2} u_{p2}(t) &= -m_{p2} \ddot{u}_g(t) \\ m_{p1} \ddot{u}_{p1}(t) - c_{p2} \dot{u}_{p2}(t) - k_{p2} u_{p2}(t) + c_{p1} \dot{u}_{p1}(t) + k_{p1} u_{p1}(t) &= -m_{p1} \ddot{u}_g(t) \end{aligned} \quad (1)$$

where  $u_d$  represents the horizontal displacement of the deck relative to the pier,  $u_{p,i}$  the displacement of the  $i$ -th ( $i = 1:5$ ) pier mass relative to the  $i$ -th-1 dof,  $m_d$  and  $m_{pi}$  are respectively the mass of the deck and of the  $i$ -th ( $i = 1:5$ ) lumped mass of the pier,  $c_d$  is the viscous damping constant of the isolated deck,  $k_{pi}$  and  $c_{pi}$  respectively the pier stiffness and inherent viscous damping constant of the  $i$ -th ( $i = 1:5$ ) dof of the pier,  $t$  the time instant,  $f_a(t)$  and  $f_p(t)$  are the reactions of the FP bearings, respectively on the abutment and on the pier, equal to:

$$f_a(t) = \frac{m_d g}{2R} \left( u_d(t) + \sum_{i=1}^5 u_{pi}(t) \right) + \frac{1}{2} \left( \mu_a \left( \dot{u}_d(t) + \sum_{i=1}^5 \dot{u}_{pi}(t) \right) \right) m_d g \left( \operatorname{sgn} \left( \dot{u}_d(t) + \sum_{i=1}^5 \dot{u}_{pi}(t) \right) \right) \quad (2)$$

$$f_p(t) = \frac{m_d g u_d(t)}{2R} + \frac{\mu_p(\dot{u}_d) m_d g \operatorname{sgn}(\dot{u}_d)}{2} \quad (3)$$

where  $g$  is the gravity constant,  $R$  is the radius of curvature of the two FPS isolators assumed equal,  $\mu(\dot{u}(t))$  represents the sliding friction coefficient of the isolator on the abutment (subscript  $a$ ) or of the isolator on the pier (subscript  $p$ ), which depends on the bearing slip velocity  $\dot{u}(t)$  (that is a relative velocity with respect to the ground for the isolator on the abutment or to the pier top for the isolator on the pier), and  $\operatorname{sgn}(\cdot)$  denotes the sign function.

Regarding Equations (2)-(3), the first addenda represent the elastic behaviour ( $k_d = m_d g / R$ ), associated to the pendulum motion with fundamental vibration period equal to  $T_d = 2\pi \sqrt{R / g}$  (i.e., only function of the radius of curvature  $R$ ), and the second is the frictional behaviour, related to the sliding friction coefficient of the teflon-steel interface [14]. Experimental results

[7]-[9] suggest adopting the following equation to model the sliding friction coefficient of teflon-steel interfaces:

$$\mu(\dot{u}) = f_{\max} - (f_{\max} - f_{\min}) \cdot \exp(-\alpha |\dot{u}|) \quad (4)$$

where  $f_{\max}$  is the maximum value of friction coefficient at large sliding velocities, and  $f_{\min}$  represents the value at zero velocity. Considering this, the hypothesis of continuous sliding in structures supported by teflon bearings is included by assuming, for simplicity, a ratio  $f_{\max} / f_{\min}$  equal to 3 and an exponent  $\alpha$  equal to 30, based on a regression of the experimental results of [7]-[9].

Note that cracking phenomena [30]-[34] of the RC deck are herein neglected.

### 3 ALEATORY UNCERTAINTIES AND DETERMINISTIC PARAMETERS

The relevant uncertainties assumed in the following parametric study are presented in this section. In particular, the seismic performance of multi-span continuous deck bridges isolated with FP bearings is evaluated for different structural properties, assumed as deterministic parameters.

#### 3.1 Seismic records

The uncertainties regarding the seismic input intensity are separated from the ones related to the characteristics of the record (i.e., record-to-record variability), according to the performance-based earthquake engineering (PBEE) approach [35],[36]. Specifically, a scale factor, i.e., an intensity measure ( $IM$ ), is considered such that the randomness in the seismic intensity is described by a hazard curve while the ground motion randomness for a fixed intensity level can be represented by a set of ground motions with a different duration and frequency content, scaled according to  $IM$ . A set of 30 natural ground motion records are considered in this work, selected from [37]-[39], in line with [40]. Particularly, these records derive from 19 different seismic events. The largest source-to-site distance is 98.2km, the moment magnitude ( $M$ ) varies between 6.0 and 7.6, the PGA between 0.13g and 0.94g. Table 1 illustrates the main properties of these earthquakes.

	Year	Earthquake Name	Recording Station Name	$V_{S30}$ [m/sec]	Source (Fault Type)	$M$ [-]	$R$ [km]	$PGA_{\max}$ [g]

### 3.2 Intensity measure in terms of spectral displacement

According to [41]-[44], the selection of the intensity measure should follow the criteria of efficiency, sufficiency and hazard compatibility. For the case of this work, the *IM* is chosen as the spectral-displacement  $S_D(T_d, \xi_d)$  which corresponds to the isolated period of the bridge system,  $T_d = 2\pi / \omega_d$ , and for the damping ratio  $\xi_d$ . As demonstrated in many studies, e.g., [41]-[43],[45], not only the spectral-displacement is more efficient than the peak ground acceleration, but also its use allows to obtain more reliable response estimates for a given number of records and to reduce the response dispersion [22].

In line with other studies [22], the damping ratio  $\xi_d$  is assumed equal to zero [46]. Therefore, in the following, the corresponding *IM* is indicated as  $S_D(T_d)$  and, to compute the IDAs, it is assumed varying from 0.10m to 0.45m (Table 2) in compliance with the seismic hazard of the reference site (L'Aquila (Italy)), from the operational to collapse limit state, as provided by [44].

<i>IM</i>	1	2	3	4	5	6	7	8
$S_D(T_d)$ [m]	0.10	0.15	0.20	0.25	0.30	0.35	0.40	0.45

Table 2: Selected values of the intensity measure  $S_D(T_d)$ .

### 3.3 Random variable of the friction coefficient

According to the experimental data on sheet-type teflon bearings [7]-[9], friction is not constant during sliding, as stated in the friction Coulomb law, but it is a much more complex phenomenon, governed by different mechanisms such as the sliding velocity, apparent pressure and temperature. Moreover, it has also been observed by [47] that the friction coefficient varies in space. That is why the sliding friction coefficient at large velocity  $f_{\max}$  is considered as a random variable described by a truncated normal PDF, with an average equal to 3%, a minimum value of 0.5% and a maximum of 5.5% as also studied in [14],[17],[18]. Furthermore, being valid the relation  $f_{\min} = f_{\max} / 3$ , the values of the friction coefficient at the low velocities,  $f_{\min}$ , have also been assumed as random variables. Finally,  $\alpha$  is considered equal to a deterministic value of 30 [17] (Equation (4)).

To deal with the abovementioned random variables, the LHS method [17] has been used to generate the input data samples starting from their PDFs, with a sample number of 15.

### 3.4 Deterministic structural properties

A parametric analysis has been conducted in this work, which has brought to a set of different isolated bridge models. Specifically, in compliance with [15],[25],[26],[46], the parameters  $\xi_d$  and  $\xi_{pi} = \xi_p$  are assumed respectively equal to 0% and 5%; the isolated deck period  $T_d$  is in the range between 1s and 4s; the RC pier period  $T_p$  equal to 0.2s; the overall mass ratio  $\lambda = \sum_{i=1,5} m_{pi} / m_d$  that is related to the sum of the  $i$ -th mass ratios (assumed equal), is in the range between 0.1, 0.15 and 0.2.

Combining these deterministic values with the above sampled values of the friction coefficient, 90 different types of isolated bridges are defined.

## 4 INCREMENTAL DYNAMIC ANALYSIS RESULTS FOR THE DIFFERENT STRUCTURAL PROPERTIES

The differential equations of motion (Equation (1)) have been solved for each of the 90 bridge models, combining the deterministic ( $T_d$ ,  $\lambda$  and  $T_p$ ) and aleatory parameters and for the 30 different ground motion records (Table 1), scaled to the increasing 8 values of  $S_D(T_d)$  (Table 2). Thus, IDAs [28] are performed in MATLAB-Simulink [48] employing the Runge-Kutta-Fehlberg integration algorithm. For each of the 90 deterministic combinations, a total number of 450 simulations has been carried out by pairing each one of the 30 seismic records with the sampled 15 friction coefficients. The IDAs have been obtained assuming the following engineering demand parameters (EDPs): the deck response with respect to the pier top  $u_d$

and the response of the pier top with respect to the ground  $u_p$ , computed as  $u_p = \sum_{i=1}^5 u_{pi}$ . For all the engineering demand parameters, the peak responses are determined:  $u_{d,max}$  and

$u_{p,max} = \left( \sum_{i=1}^5 u_{pi} \right)_{\max}$ . Following an assumption widely used in PBEE [36], each EDP output has been probabilistically [49]-[56] treated by means of a lognormal PDF: using the maximum likelihood technique [14]-[18], the sample lognormal mean  $\mu_{\ln}(EDP)$  and standard deviation  $\sigma_{\ln}(EDP)$  are computed for each EDP. In the end, the 50<sup>th</sup>, 84<sup>th</sup> and 16<sup>th</sup> percentiles of each lognormal PDF can be easily evaluated [17].

The following figures show the IDA curves for the peak deck displacement at the pier  $u_{d,max}$  (Figure 1) and for the peak pier displacement  $u_{p,max}$  (Figure 2). In particular, the EDPs values are plotted with respect to the  $IM$  and each curve corresponds to different percentiles and  $\lambda$  values.

The deck response (Figure 1) tends to decrease for lower values of  $\lambda$ . For the seismic device, the lognormal mean of the isolation system response increases with lower values of  $T_d$ , because the lower the period the larger the response, due to resonance phenomena occurring between deck and pier.

Regarding the IDA curves related to the pier response (Figure 2), the structural response generally decreases with increasing  $T_d$  due to the effectiveness of the isolation technique. The influence of  $\lambda$  decreases as  $T_d$  increases, while the opposite trend regards the dispersion.

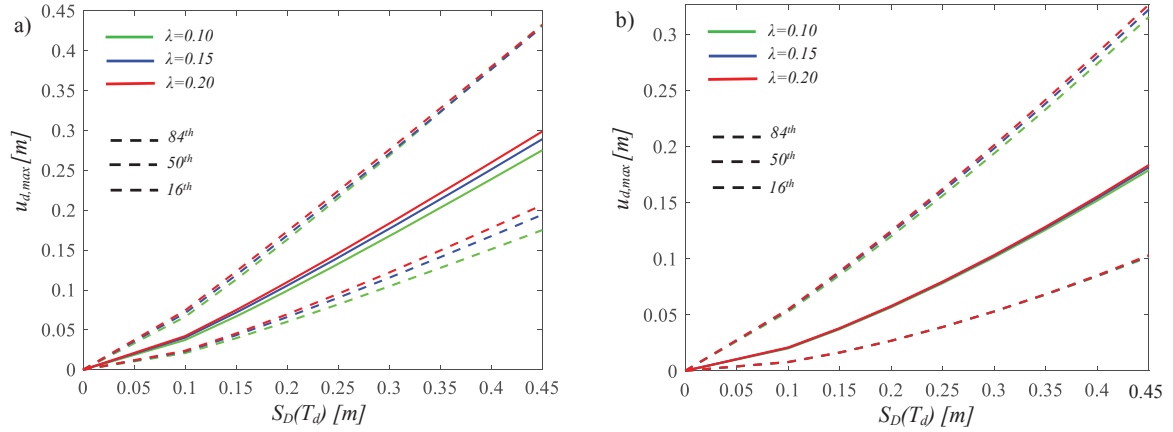

Figure 1: IDA curves of the deck response with respect to the pier, for  $T_p=0.20$ s and  $T_d=1$ s (a),  $T_d=4$ s (b).

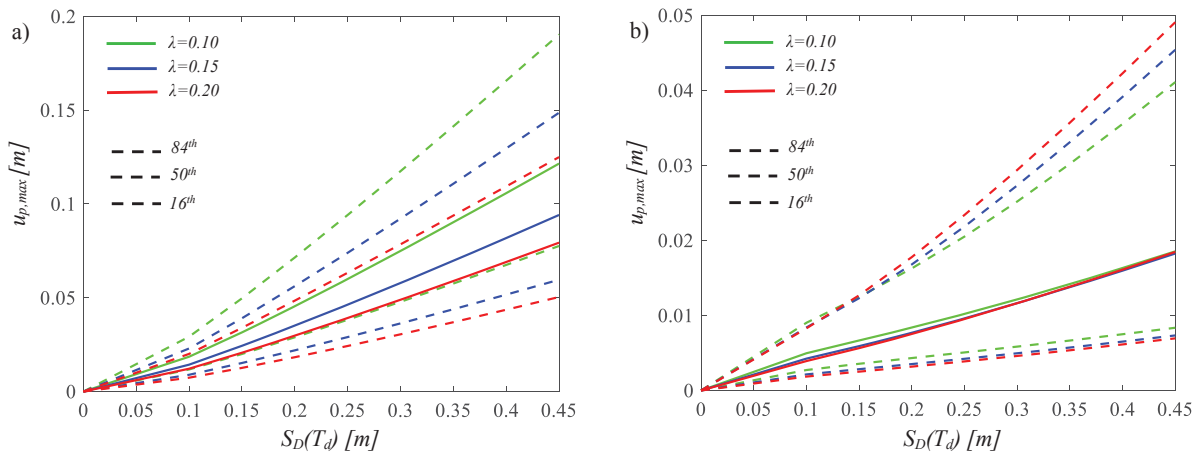

Figure 2: IDA curves of the pier, for  $T_p=0.20$ s and  $T_d=1$ s (a),  $T_d=4$ s (b).

## 5 SEISMIC FRAGILITY ASSESSMENT

The seismic fragility curves represent the probabilities  $P_f$  of exceeding different limit states ( $LS$ s) conditioned to each level of the  $IM$ . This implies the need of defining the  $LS$  threshold related to the isolation system. In particular, nine different values of the in-plan radius for the single concave surface have been assumed [14], herein summed in Table 3.

	1	2	3	4	5	6	7	8	9
$r$ [m]	0.10	0.15	0.20	0.25	0.30	0.35	0.40	0.45	0.50

Table 3: Limit State thresholds for the isolation system.

		PDI	PDI <sub>IB</sub>	$P_f$
$LS1$	Fully Operational	PDI=0.7%	PDI <sub>IB</sub> =0.23%	$5 \cdot 10^{-1}$
$LS2$	Operational	PDI=1.5%	PDI <sub>IB</sub> =0.5%	$1.6 \cdot 10^{-1}$
$LS3$	Life Safety	PDI=2.5%	PDI <sub>IB</sub> =0.83%	$2.2 \cdot 10^{-2}$
$LS4$	Near collapse	PDI=5%	PDI <sub>IB</sub> =1.67%	$1.5 \cdot 10^{-3}$

Table 4: Limit State thresholds for the pier [58].

Regarding the RC pier, four discrete performance levels or  $LS$ s ( $LS1$ ,  $LS2$ ,  $LS3$  and  $LS4$ ), corresponding respectively to “fully operational”, “operational”, “life safety” and “collapse prevention”, are suggested by Vision 2000 [57]. According to the displacement-based seismic

design, the pier drift index ( $PDI$ ), considered as the measurable structural response parameter, is adopted to define the specific  $LS$  threshold related to an acceptable probability of exceeding that  $LS$  [14]-[18], or failure probability, in the design/reference life of a structural system. In particular, the performance  $LS$ s for isolated bridges, in terms of  $PDI_{IB}$ , is defined as 1/3 of the  $PDI$  limit value of a comparable non-isolated bridge, in agreement with FEMA provisions [58]. In the following (Table 4), the  $LS$  thresholds are presented, together with the failure probabilities to respect in 50 years [14]-[18].

From the fundamental period of the RC pier,  $T_p$ , it is finally possible to compute its height [1], needed to assess the seismic fragility of the bridge, as follows:

$$T_p = \frac{2\pi}{(1.875)^2} \cdot \sqrt{\frac{\bar{m}_p h^4}{EI}} \quad (5)$$

where  $\bar{m}_p$  is the mass per unit length of the pier,  $h$  is its height and  $EI$  the flexural rigidity, having assumed a circular cross-section.

### 5.1 Seismic fragility curves

The probabilities  $P_f$  exceeding the  $LS$  thresholds have been numerically computed. Then, lognormal complementary cumulative distribution functions (CCDFs), representing the seismic fragility curves, have been fitted with R-square values higher than 0.8 [14],[17].

The results represented in Figure 3-Figure 4 show the fragility curves for  $T_p=0.2$ s and the different values assumed for  $T_d$ , for each  $LS$  and each value of  $\lambda$ , referring to the deck response with respect to the pier and to the RC pier. As a general behaviour, the seismic fragility decreases for larger values of  $LS$  thresholds. In addition, in compliance with the previous results (i.e., IDA curves), when the isolated vibration  $T_d$  increases, the seismic fragility decreases.

For what concerns the response of the isolation system (Figure 3), the variability of  $\lambda$  causes slight deviations, which are more relevant when  $T_d$  is low. In particular, an increase in  $\lambda$  determines an increase in the isolation response relative to the pier.

Regarding the seismic fragility curves for the pier (Figure 4) a larger influence of the  $\lambda$  variability is present, showing a lower fragility when  $\lambda$  increases.

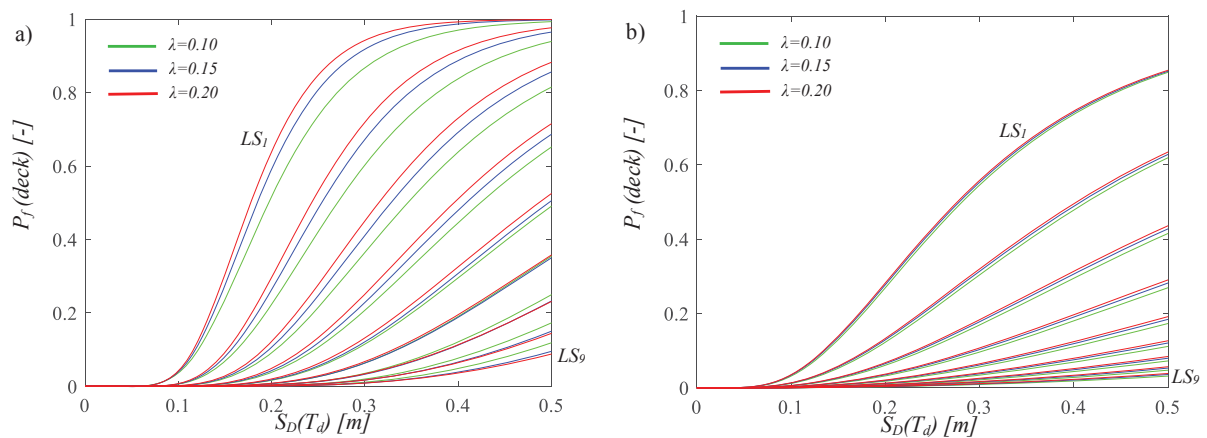

Figure 3: Seismic fragility curves of the deck response with respect to the pier for  $T_p=0.20$ s and  $T_d=1$ s (a),  $T_d=4$ s (b).

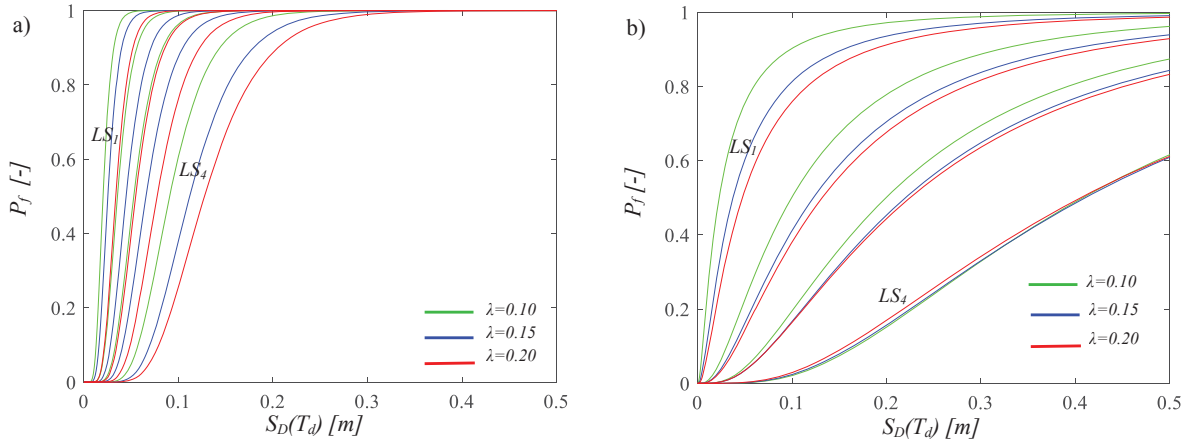

Figure 4: Seismic fragility curves of the pier for  $T_p=0.20s$  and  $T_d=1s$  (a),  $T_d=4s$  (d).

## 6 SEISMIC RELIABILITY OF ISOLATED BRIDGES WITH SINGLE CONCAVE FPS DEVICES

Adopting the Poisson model, the seismic reliability in 50 years can be computed by integrating the seismic fragility curves with the seismic hazard curves, evaluated for the same *IM* and related to the specific site (L'Aquila (Italy)). This allows to obtain the seismic reliability of the isolated multi-span continuous deck bridges, equipped with single concave FPS bearings.

### 6.1 Site seismic hazard

The seismic hazard curves (Figure 5) related to the site under analysis (L'Aquila (Italy)) are herein presented in terms of  $S_D(T_d)$ , as function of the fundamental periods. Each curve refers to the average values ( $50^{th}$  percentile) of the annual rate  $\bar{\lambda}_s$  exceeding the  $IM=S_D(T_d)$ . It is easy to observe that the seismic hazard increases with the increase of the isolated period.

Figure 5: Seismic hazard curves in terms of  $S_D(T_d)$  for the structural periods ( $T_d$ ) related to L'Aquila site.

### 6.2 Seismic reliability curves

In the following, the seismic reliability curves for the pier (Figure 6) are reported for the different thresholds of *LS* as seen in the above Table 4. The limit states *LS1* and *LS2* are always respected demonstrating the effectiveness of the seismic isolation technique.

In addition, the “life safety” *LS3* is not always respected because of the very stringent (equal to 1/3 of the standard ones) limit states for the pier. Moreover, the most flexible RC

piers, with medium-high  $T_p$  values, exceed this  $LS$  also due to the aleatory uncertainty of the sliding friction coefficient. On the other hand, an increase in the vibration period of the FPS devices leads to an increase in seismic demand to the pier also due to the high seismic hazard of the site. Lower is the influence of the mass ratio.

The seismic reliability curves related to for the isolation system with respected to the pier (Figure 7). These reliability curves are almost linear and reveal that the isolation system is seismically less reliable as its fundamental period,  $T_d$ , increases, since higher and higher failure probabilities correspond to the same  $LS$  due to the high seismic hazard of the site. The other structural parameters have a reduced influence.

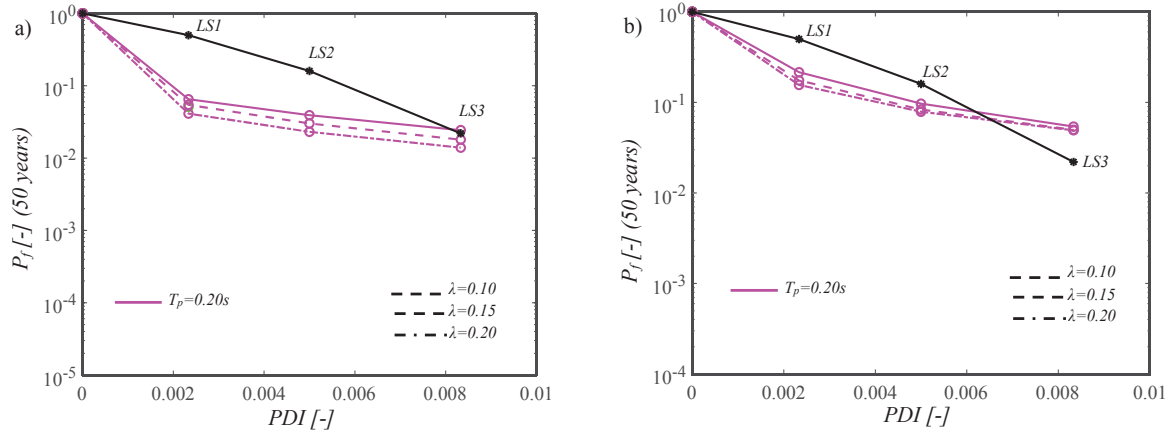

Figure 6: Seismic reliability curves of the pier for  $T_d=1s$  (a),  $T_d=4s$  (b).

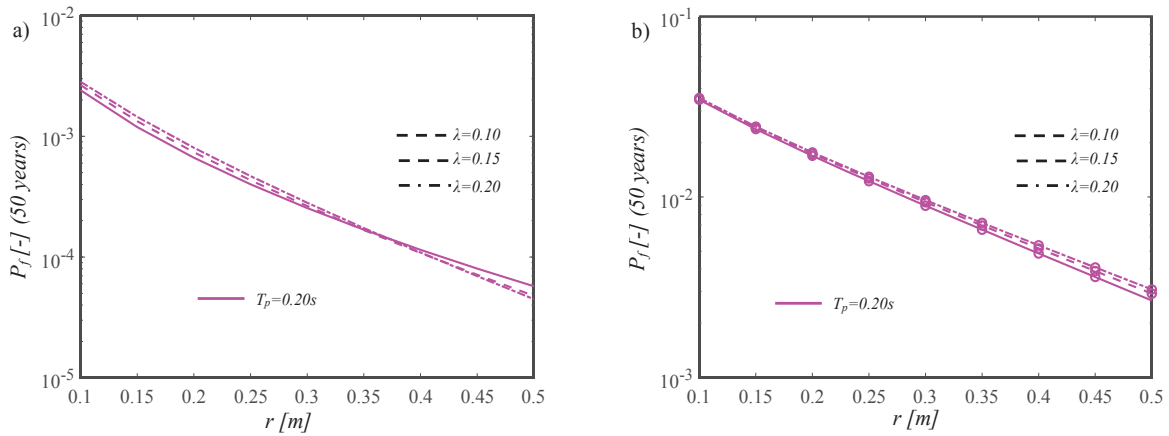

Figure 7: Seismic reliability curves of the deck response with respect to the pier for  $T_d=1s$  (a),  $T_d=4s$  (b).

## 7 CONCLUSIONS

This work regards the evaluation of the seismic reliability of multi-span continuous deck bridges isolated with single concave friction pendulum (FPS), accounting for a large range of isolator and bridge properties (i.e., the isolating system period, the vibration period of the elastic RC pier and the mass ratio, that is the ratio between the masses of the pier and the deck). A 6dof model is adopted, considering the RC pier flexibility, and both the RC abutment and RC deck infinitely rigid on the devices. The FP isolator is described by a wide-spread model, assuming that the friction coefficient varies with the velocity. The record-to-record is considered by defining a set of 30 ground motions, by scaling them to increasing seismic intensity levels. The fragility curves, referred both to the isolation system and the RC substructure/pier, have been computed for each limit state within the parametric analysis.

Then, the failure probabilities are evaluated considering the seismic hazard curves of the site (L'Aquila (Italy)), in a time interval of 50 years. This has resulted in the seismic reliability curves.

The seismic fragility of the seismic device decreases for lower values of the pier period and for increasing values of the isolated period, while the mass ratio has a reduced influence. For the pier, the fragility decreases for low pier periods, for increasing values of the mass ratio and for medium-high isolated periods.

The seismic reliability curves have shown that: it decreases for both higher pier periods and higher isolated periods due to the aleatory uncertainty of the sliding friction coefficient and to the high seismic hazard of the site, for the deck it decreases with the increase of the curvature radius of the isolator. For the pier, the fully operational and operational limit states are always respected demonstrating the effectiveness of the seismic isolation technique.

**Keywords:** Earthquake induced Building-Pounding, Intensity Measures, Non-Smooth Contact Dynamics, Efficiency-Sufficiency properties

**Abstract.** *This study aims at selecting the best suited Intensity Measures (IMs) in the case of earthquake-induced building pounding to plot fragility functions of civil engineering structures. IMs are indicators representative of the seism "intensity" (e.g. the magnitude, the Peak Ground Acceleration (PGA)) that are intended to be correlated with Engineering Demand Parameters (EDPs) of interest (e.g., interstory drift, shear force). Desirable properties of IMs are efficiency (i.e., the predictability of the EDP for a given IM), and sufficiency (i.e., the independence of the prediction regarding Ground Motions Parameters (GMPs)) on magnitude and source-to-site distance). The study is achieved by means of 1677 Ground Motions (GMs) computed on two Single Degrees Of Freedom (SDOFs) whose modal characteristics are fitted with real-size structures. The numerical treatment of the contact is achieved with the Non-Smooth Contact Dynamics (NSCD) method which showed very good capabilities of reproducing the expected occurrence and number of impacts. Once one or several IMs are considered both efficient and sufficient enough, a future work will compute fragility and risk curves of these adjacent pounding SDOF with various separation distances.*

## 1 INTRODUCTION

Earthquake-induced building pounding occurs typically in denser urban areas where low to mid-height buildings are more likely to be adjacent. Field reports, experimental campaigns, and numerical analysis, have shown and demonstrated the potential negative effects of impact between structures, ranging from minor architectural damages [1, 2], to significant increases in interstory drifts [3, 4] and ductility demand [5, 6], to, in rare occasions, collapse [7]. Figures 1a and 1b illustrate respectively the aftermaths of building pounding in Mexico and Turkey.

(a) Mid-story floor collapse of Hotel de Carlo in Mexico City (Mw 8.1 earthquake) [8]

(b) Pounding damage (Mw 7.4, Izmit earthquake, Turkey, 1999) [9]

Figure 1: Building pounding damage during earthquakes

Building codes such as Eurocode 8 [10] give recommendations on separation distance between adjacent buildings, but they are either too conservative leading to unused land space, or contact occurs due to both large ground motions and buildings uncertainties. Considering the increasing world urban densification, it is acceptable to say that building pounding will continue happening.

Predicting the effects of such phenomenon in engineering design is of importance, especially throughout the lifetime of a given building in a precise geographical and urbanized environment. The purpose of the PBEE (Performance-Based Earthquake Engineering) framework [11] is to assess numerically the IMs correlations with some EDPs of interest. Most often, the IMs chosen are hazard curves of pseudo-acceleration at the structure fundamental period [12]. Probabilities and return periods of critical events are then computed from the statistical data from the studied region. To a further length, damage measures (service state, close to collapse, necessary repairs,...) and decision variables (cost, life,...) can be successively evaluated. Such information is of importance during new phases of life of a project (*e.g.* building design, renovation and expansion) to help decision-makers. To do so, IMs and EDPs are to be correlated for the chief executives to trust the predictions. A trusted IM should then properly reproduce with a reduced variability the EDP value and be conditionally independent on GMPs such as source-to-site distance and magnitude. An efficient and sufficient IM also requires reliable attenuation relationships, or Ground Motion Prediction Equations (GMPEs) to produce trustworthy risk curves. IMs efficiency and sufficiency properties through earthquake and impact are investigated in this paper.

Today, fast (in terms of computational time), robust and ergonomic numerical tools are required in order to run these probabilistic seismic risk analysis. The contact formulation needs

appropriate treatment; classical penalty approaches might give scattered results due to the sensitivity of its parameters [13]. This study uses an alternative way by the use of the Non-Smooth Contact Dynamics (NSCD) method [14, 15]. First, its capabilities are introduced with an idealized test-case. Secondly, a comparison between the experimental and numerical displacements of colliding structures on a shaking table (scale 1:1, EMSI laboratory at CEA Saclay in the frame of national project ANR SINAPS [4, 16]) allows validating the efficiency and robustness of the NSCD method and its use in the efficiency-sufficiency analysis. To the knowledge of the authors, no NSCD-based risk analysis has been carried out in the literature.

## 2 CAPABILITIES OF THE NSCD METHOD

The works by Moreau [17], Jean [14], and Acary [15, 18] have proven the energy conservation, the accuracy, and the application of the NSCD method in finite elements methods. It uses a Moreau-Jean integration scheme associated with a Newton impact law. It allows to apply an instantaneous change in velocities of the nodes in contact. This method has the advantage to depend only on the sole coefficient of restitution  $e$  taken between 0 and 1; it represents the system energy dissipation upon contact.

### 2.1 Test case : two impacting structures with no energy loss

To illustrate NSCD capabilities, a test case involving impact is presented. Two similar SD-OFs named Structure 1 and Structure 2 with fundamental periods  $T_1$  and  $T_2$  both equal to 1s are set adjacent to one another with a null separation distance. They are both subjected to an initial velocity  $V_1$  and  $V_2$  of 1m/s shoving them away in opposite senses before going backwards and impact. Figure 2 presents the set-up. No damping is considered, and the coefficient of restitution equals 1. This way, structures are meant to collide perpetually every 0.5s.

Figure 2: Structures 1 and 2 at initial state for test case

Figure 3 presents the displacements (upper figure) and velocities (lower figure) of the system. The kinematics behaves exactly as expected with a instantaneous change in velocities upon contact, no damping is observed, and collisions are indefinitely perpetuated.

### 2.2 Scale 1:1 reinforced concrete impacting slabs

Ph.D work of Crozet [16] involved the study of scale 1:1 structures colliding both in free motion or subjected to a seismic solicitation. Two instrumented reinforced concrete slabs of 4.6

Figure 3: Impacting structures : test case with no damping

tons and 3.5 tons were mounted respectively on four 2.5m high steel HE100AA and HE140AA columns and set a few centimeters next to each other on a shaking table. Additional elements can be added to these single-story structures to make them two-story high, as shown by Figures 4a and 4b. Nevertheless, it is not the case of the present work where only the single-story set-up is considered because behaving like SDOFs. Structures are named 1 and 2, behave in linear elastic fashion, and have respectively their fundamental period equal to 0.28s (heavier, more flexible) and 0.15s (lighter, stiffer).

(a)

(b)

Figure 4: Structure 1 and Structure 2 set on the shaking table [16, 4]

Figure 5 presents the comparison of the experimental outcomes with the numerical model. The coefficient of restitution  $e$  equals 0.6. The comparison shows excellent agreement between the expected and numerical displacements, both in terms of kinematics, and time occurrence of impacts. Only one impact is not reproduced at 9.5s. Even if structures visually seem to collide more, especially between 11s and 14s, the accelerometers set up on the slabs did not detect more contacts.

Figure 5: Cadarache 0.25g : Numerical versus Experimental comparison

Additional kinematic and spectral analysis produced very good results that confirmed  $e = 0.6$  is a value of interest in the frame of parallel colliding reinforced concrete slabs, but are not presented in the current work. To reduce the computation cost, the efficiency and sufficiency analysis are run with the structures modelled as SDOFs calibrated on the experimental data.

### 3 IMs EFFICIENCY AND SUFFICIENCY PROPERTIES

This section presents successively the list of IMs that are studied, the GM database, the coefficients used to assess the efficient and sufficient properties, and a discussion on the various gaps studied. Henceforth, the EDP chosen to deduce IM properties is the interstory drift  $\delta$ .

#### 3.1 List of IMs

Six IMs are investigated, the pseudo-acceleration at the fundamental period  $T_f$  of the structure  $S_a(T_f)$ , the *PGA*, the Arias Intensity (*AI*), the Cumulative Absolute Velocity (*CAV*) and Standard CAV (*SCAV*), and the averaged pseudo-acceleration  $S_{avg}(T_f)$ . Considering that earthquake-induced building pounding necessarily involves two buildings,  $S_a(T_f)$  and  $S_{avg}(T_f)$  are studied for  $T_f$  equal both to  $T_1$  and  $T_2$ , the respective fundamental periods of the Structure 1 and 2. Table 1 lists the six IMs studied throughout this work.

#### 3.2 Ground Motion set: Siber-Risk database

The 1677 GM extracted from the Siber-Risk database [19] comply with the properties presented by Table 2. This selection is consistent with the geographic location of the Valparaíso city in Chile. Interface types earthquakes (rupture zone located above 60km under the earth surface) are the most frequent, and the shear velocity in 30 meters below the ground surface  $V_{s30}$  is a class C type soil (very dense). Only ground motions of magnitude greater than five are selected, the authors considering that no significant damages are produced with smaller magnitudes.

$IM$	Formulation	Notes
$S_a(T_f)$	pseudo-spectral acceleration at $T_f$	$T_f$ : fundamental period
$PGA$	$\max( a(t) )$	$a(t)$ : acceleration time history
$AI$	$\frac{\pi}{2g} \int_0^{t_f} a(t)^2 dt$	$g = 9.81 \text{ m/s}^2$ $t_f$ : seism time duration
$CAV$	$\int_0^{t_f}  a(t)  dt$	$t_f$ : seism time duration
$SCAV$	$SCAV = CAV_i + \int_{t_{i-1}}^{t_i}  a(t)  dt$	$a(t)$ : acceleration in one-second interval where at least one value is greater than $0.025g$ $i = 1, \dots, N_r$ with $N_r$ the record length in seconds
$S_{avg}(T_f)$	$(\prod_{i=1}^N S_a(c_i T_f))^{1/N}$	$T_f$ : fundamental period Scalars $c_i$ : $c_1 = 0.5 \leq \dots \leq 1 \leq \dots \leq c_N = 2$ $N$ : length of $[c_1 T_f, \dots, T_f, \dots, c_N T_f]$

Table 1: List of IMs studied

GMP	Min. Value	Max. Value
Magnitude	5	8.8
Vs30	360	800
Type	Interface	

Table 2: GM selection for the Valparaiso region (Chile)

### 3.3 Efficiency

The efficiency of an IM regarding a peculiar EDP is assessed with both the Coefficient Of Variation ( $COV$ ) and the regression coefficient ( $R^2$ ). The first represents the variability around the mean value of the distribution (*i.e.* Eq.(1) where  $\sigma$  is the standard deviation, and  $\mu$  the mean value of the distribution). Unlike  $\sigma$ ,  $COV$  has no dimension which is useful when comparing the efficiency property between EDPs of different natures.

$$COV = \frac{\sigma}{\mu} \quad (1)$$

$R^2$  represents how much the logarithmic EDP-IM correlation is linear, and is calculated directly from a software. A  $R^2 = 1$  value indicates a perfect linear relationship. Henceforth, an IM is arbitrary considered "efficient enough" if  $COV \leq 0.10$  and  $R^2 \geq 0.90$ .

### 3.4 Sufficiency

The sufficiency of IMs is commonly calculated regarding the source-to-site distance (*i.e.*, herein, the distance to the rupture fault) and the magnitude of the GM. The results of the present study are independent of the soil conditions (see Vs30 range in Table 2) and the earthquakes nature (Interface type) accordingly to the selected dataset. Non-exhaustively, the fault rupture mechanism, the directivity of the earthquakes, and the  $\epsilon$  coefficient [12] representing the ran-

domness of the GM are not considered in this study.

Two ways of assessing the sufficiency to magnitude and distance are studied. The p-value "p" (statistical F-test) delivers a binary assessment of the IM, considering it either sufficient if  $p \geq 0.05$  or not sufficient if  $p \leq 0.05$ . This parameter has been notably used by Luco and Cornell [20], and Eads and Miranda [21, 22] in the civil engineering field. This parameter is calculated through a calculation software. The second sufficiency coefficient is the Spearman rank coefficient  $\rho$  presented by Eq.(2).

$$\rho = 1 - \frac{6 \sum_{i=1}^N D^2}{N(N^2 - 1)} \quad (2)$$

With  $D$  the differences between the ranks of the  $N$  dataset values.  $\rho$  measures how much the data fits with a monotonic relationship.  $\rho$  is between -1 and 1, representing respectively a perfect negative linear dependency, and a perfect positive linear dependency. A  $|\rho|$  close to zero denotes the IM is independent from the GMP.

Unlike the p-test, the Spearman coefficient does not produce a binary evaluation of the sufficiency, but it allows a relative comparison of this property, enabling a classification of IMs. To the knowledge of the authors, no risk analysis of building pounding has been carried out with both p-value and Spearman coefficients.  $p(M)$ ,  $p(D)$ ,  $\rho(M)$ , and  $\rho(D)$  are respectively the p-value and Spearman coefficients calculated for magnitude and distance for a given couple of EDP and IM. Henceforth, an IM is considered sufficient if  $p(M)$  and  $p(D)$  are, by definition, greater than 0.05 and if  $|\rho(M)|$  and  $|\rho(D)|$  are arbitrary less than 0.10 (De Biasio [23] considered the IM sufficient if  $|\rho| \leq 0.20$ ).

## 4 RESULTS

One important issue of the building pounding study is the gap separation. Each gap separation chosen consists in itself in a whole single system. For instance, if 11 gaps are studied, then the outcomes to analyse are multiplied by 11 ; *i.e.*, it means first computing 11 times 1677 GM on the structures, retrieving 11 times 1677 EDPs, and inferring 11 times the efficient-sufficient coefficients. The analysis of six coefficients of eight IMs for two structures separated by 11 different gaps is important in terms of computation time. In this work, authors decided to rather obtain a general overlook by averaging the efficient-sufficient coefficients over all the gaps. Thus, the amount of data to analyse is reduced by a factor 11. First, an example is given with the coefficients  $R^2$  and  $COV$  of  $S_a(T_1)$  for Structure 1. Secondly, all efficiency-sufficiency coefficients for both structures are presented.

### 4.1 Example of the average of $R^2$ and $COV$ coefficients $S_a(T_1)$ relationship

Figure 6b presents the interstory drift  $\delta_1$  plots against the  $S_a(T_1)$  of Structure 1, in logarithmic scale, and for both a 5mm and infinite (no-collision case) separation distance. Only the ground motions that actually produced collision in the five millimeters case are plotted.

As expected without contact in a elastic linear structure, a perfect linear fit links the interstory-drift with  $S_a(T_1)$  (*i.e.*, magenta dots and green line are superposed),  $R^2$  and  $COV$  are respectively equal to 1 and 0. On the contrary, the efficiency properties are lesser when impact is

Figure 6: (a) Selected Database : 1677 GM (b) Outcomes of Structure 1 with gap = 5mm

involved with gap=5mm. At this distance, 227 out of the 1677 GM produced impact, resulting in  $R^2$  and  $COV$  respectively equal to 0.89 and 0.03 (*i.e.*, blue dots are scattered around the red linear curve). Thus, for each gap studied,  $R^2$  and  $COV$  will have different values.

As an example, Table 3 presents the  $COV$  results for  $S_a(T_1)$  for  $N=11$  separation distances.  $N_g^{GM}$  corresponds to the number of GM inducing collision for the gap indexed  $g$ .

Gaps (mm)	0	1	2	3	4	5	6	7	8	9	10
Index $g=1,...,N=11$	1	2	3	4	5	6	7	8	9	10	11
$N_g^{GM}$	1677	1020	575	395	297	227	182	148	128	113	106
$S_a(T_1): R_g^2$	0.90	0.91	0.91	0.91	0.91	0.89	0.88	0.85	0.82	0.79	0.82
$S_a(T_1): COV_g$	0.06	0.04	0.04	0.03	0.03	0.03	0.03	0.04	0.04	0.04	0.03

Table 3:  $S_a(T_1)$  :  $R^2$  and  $COV$  values of Structure 1

As expected for a gap null, all 1677 simulations induce impact and the number decreases as the gap increases. At 10mm the number drops to 106 which was decided to be the larger and last gap computed since (i) it is almost the same number (113) as for gap=9mm (ii) it is less than 10% of the totality of the database. In this study case,  $R^2$  decreases from 0.90 to 0.82 (important loss of efficiency) while  $COV$  decreases from 0.06 to [0.03;0.04] (small gain of efficiency) when the gap increases from zero to 10mm.

Let's now note  $R_g^2$  and  $COV_g$  respectively the regression coefficient and coefficient of variation for the  $g$  identified gap (Table 3). All  $R_g^2$  and  $COV_g$  are then averaged and weighted by  $N_g^{GM}$ , the number of ground motions that actually induced collision for the gap number  $g$ ; let's note the results respectively  $R_{avg}^2$  and  $COV_{avg}$ . Eq.(3) presents the formulation used with  $R_{avg}^2$ . Eq.(4) and Eq.(5) respectively present the numerical application for  $R^2$  and  $COV_{avg}$  for  $S_a(T_1)$ . These values can be found in the third column, at the third and fourth lines of Table 4.

$$R_{avg}^2 = \frac{\sum_{g=1}^{N=11} R_g^2 N_g^{GM}}{\sum_{g=1}^{N=11} N_g^{GM}} \quad (3)$$

$$R_{avg}^2 = \frac{0.90 * 1677 + 0.91 * 1020 + \dots + 0.82 * 106}{1677 + 1020 + \dots + 106} = 0.90 \quad (4)$$

$$COV_{avg} = \frac{0.06 * 1677 + 0.04 * 1020 + \dots + 0.03 * 106}{1677 + 1020 + \dots + 106} = 0.043 \quad (5)$$

## 4.2 Identification of the most efficient-sufficient IMs

Tables 4 and 5 present respectively for Structure 1 and Structure 2, the averaged values of the efficiency-sufficiency coefficients. The values are bold if the IM complies with the criterion of validity.

	Validity Criterion	$S_a(T_1)$	$PGA$	$AI$	$CAV$	$SCAV$	$S_{avg}(T_1)$
$R^2$	$\geq 0.90$	<b>0.90</b>	0.87	0.89	0.82	0.82	<b>0.92</b>
$COV$	$\leq 0.05$	<b>0.043</b>	<b>0.046</b>	<b>0.043</b>	0.055	0.054	<b>0.036</b>
$p(M)$	$\geq 0.05$	<b>0.37</b>	6e-6	<b>0.208</b>	<b>0.074</b>	<b>0.211</b>	0.044
$ \rho(M) $	$\leq 0.10$	<b>0.042</b>	<b>0.049</b>	<b>0.046</b>	<b>0.028</b>	<b>0.041</b>	<b>0.024</b>
$p(D)$	$\geq 0.05$	<b>0.66</b>	<b>0.13</b>	<b>0.41</b>	0.002	0.002	<b>0.13</b>
$ \rho(D) $	$\leq 0.10$	<b>0.048</b>	<b>0.037</b>	<b>0.029</b>	<b>0.041</b>	<b>0.039</b>	<b>0.030</b>

Table 4: Structure 1 : Averaged IMs coefficients of Efficiency-Sufficiency

**Efficiency:** For both structures,  $S_{avg}(T_f)$  is the most efficient IM, their respective  $R^2$  and  $COV$  respectively plainly greater and smaller than all the other IMs coefficients.  $S_a(T_f)$ ,  $PGA$ , and  $AI$  show good efficiency properties although closer to the validity criterion than  $S_{avg}(T_f)$ , or even not compliant with the criterion for Structure 2.  $CAV$  and  $SCAV$  are clearly not efficient enough in the regard of that study case.

**Sufficiency:**  $S_a(T_f)$ ,  $AI$ , and  $S_{avg}(T_f)$  are conditionally independent on magnitude and distance parameters for Structure 1, it is validated by both the p-value and Spearman ranking coefficients.  $PGA$  only misses the  $p(M)$  to have also a complete sufficiency validation. The Spearman coefficients of  $S_{avg}(T_f)$  are overall smaller than  $S_a(T_f)$ , implying a better sufficiency.

	Validity Criterion	$S_a(T_2)$	$PGA$	$AI$	$CAV$	$SCAV$	$S_{avg}(T_2)$
$R^2$	$\geq 0.90$	0.88	<b>0.91</b>	<b>0.90</b>	0.82	0.82	<b>0.94</b>
$COV$	$\leq 0.05$	<b>0.048</b>	<b>0.042</b>	<b>0.044</b>	0.06	0.057	<b>0.034</b>
$p(M)$	$\geq 0.05$	<b>0.459</b>	0.011	7e-5	2e-4	2e-4	<b>0.087</b>
$ \rho(M) $	$\leq 0.10$	<b>0.069</b>	<b>0.036</b>	0.054	<b>0.036</b>	<b>0.025</b>	<b>0.028</b>
$p(D)$	$\geq 0.05$	<b>0.77</b>	<b>0.29</b>	0.001	5e-5	4e-5	<b>0.32</b>
$ \rho(D) $	$\leq 0.10$	<b>0.046</b>	<b>0.029</b>	<b>0.040</b>	<b>0.044</b>	<b>0.027</b>	<b>0.051</b>

Table 5: Structure 2 : Averaged IMs coefficients of Efficiency-Sufficiency

## 5 CONCLUSIONS

This article presents the methodology for evaluating the properties of efficiency (predictability of the EDP for a given value of IM) and sufficiency (conditional independence of the IM regarding chosen GMP, herein magnitude and distance) of six IMs in the building pounding framework. It aims to select the best suited IM among  $S_a(T_f)$ ,  $PGA$ ,  $AI$ ,  $CAV$ ,  $SCAV$ , and  $S_{avg}(T_f)$  in the case of risk-assessment studies on elastic buildings colliding at their slab levels. Two different tests, p-value's and Spearman rank's, are used to enforce the conclusions.

The NSCD method used for contact detection and treatment on two SDOFs has produced excellent agreement with both an idealized test case (Figures 2 and 3), and the experimental data extracted from real size colliding structures (Figure 4). These tests validated the NSCD method use in the 1677 GM from the Siber-Risk database are computed on the numerical model for six different gaps as displayed by Table 3. The efficiency-sufficiency coefficients inferred from each gap study are then averaged and weighted (Eq.(3)) to obtain an overview of the IMs properties in this system configuration (two parallel colliding reinforced concrete slabs).

$S_{avg}(T_f)$  is the most efficient IM for the two structures and shows very good sufficiency properties relatively to the other IMs. Although with less interesting grades than  $S_{avg}(T_f)$ , the IMs  $S_a(T_f)$ ,  $PGA$  follow close behind.  $AI$  checks all the cases for Structure 1, but falls short on the p-value test of magnitude and distance for Structure 2. Finally,  $CAV$  and  $SCAV$  are discarded for far behind all the aforementioned IMs.

The continuation of this work is the computation of fragility and risk curves; the first giving the probability of exceeding an EDP value of interest for a given value of IM, the second being the convolution of the first with hazard curves [12].  $S_{avg}(T_f)$  is then the best candidate for fragility curves. For risk curves on the other hand, the more widely known the IM is, the larger the number of existing GMPEs is, and the more accurate and consensual the hazard curves are. In this regard, scientists have more experience using  $S_a(T_f)$  and  $PGA$  rather than  $S_{avg}(T_f)$  whose GMPEs are smaller in number.

## ACKNOWLEDGEMENTS

This work is partly founded by a CDSN Grant (Contrat Doctoral Spécifiques aux Normaliens) and the ECOS-Sud Grant for international collaboration CONICYT-ECOS170044. The authors deeply thanks V. Crozet of the French CEA for the provisioning of the experimental data [13]. Many thanks are also addressed to V. Acary and F. Bourrier respectively of the INRIA (Institut National de la Recherche en sciences et technologies du numérique) and INRAE (Institut National de la Recherche pour l’Agriculture, l’alimentation et l’Environnement) for their guidance into the NSCD method use. In addition, this work has been partially developed within the framework of the federative project I-RISK (L’offre de solutions au traitement des risques naturels) co-funded by the European Union (FEDER) and ”La région Auvergne-Rhône-Alpes” which aims at proposing innovative solutions for natural hazards mitigation. Dr. Candia received support from Facultad de Ingenieria Civil at Universidad del Desarrollo - Chile, FONDECYT Grant 11180937 “Seismic Risk of Mined Tunnels”, the National Research Center for Integrated Natural Disaster Management FONDAP/CIGIDEN 15110017, and FONDECYT Grant Number 1170836, “SIBER-RISK: SIMulation Based Earthquake Risk and Resilience of Interdependent Systems and NetworKs.” The authors are grateful for this support.

### Abstract

*Ductility demands observed in asymmetric plan structures due to earthquake excitations are investigated in this study. Torsional Ductility Spectra are utilized to estimate the maximum ductility response of such systems. Dynamic response of these systems are dominated by the lower vibration modes and observed seismic behavior is in conformance with the capacity design principles. In order to utilize the Torsional Ductility Spectra, five parameters of the asymmetric plan systems, namely, first mode period, uncoupled frequency ratio, stiffness eccentricity, stiff-to-flexible edge strength ratio and ductility reduction factor are estimated through a novel procedure. Simple formulations for representing the dynamic properties of shear frame systems in terms of described structural parameters are developed. Parametric equivalents of shear frame structures are obtained. Estimated ductilities from the developed charts are compared with those obtained from dynamic response analyses of shear frame asymmetric-plan systems.*

*The observed results indicate that developed spectra are able to estimate the ductility demands at both stiff and flexible side frames of actual asymmetric-plan systems with reasonable accuracy. Based on the conclusions, Torsional Ductility Spectra charts are considered practical tools for estimating the ductility demands of asymmetric plan structures.*

## 1 INTRODUCTION

Modern seismic design codes employ response reduction factors in design of structural members using linear elastic analysis [1, 2]. The capacity design methodology employing the response reduction factors may result in poor estimation of seismic performance in the case of irregular structures such as asymmetric-plan systems where torsionally coupled behaviour is observed. The resulting poor seismic performance, in turn, yields uneven ductility distribution among plan of asymmetric structures. Hence, varying degrees of inelastic behaviour is observed.

The discussed problem is a well-known issue and in the past it has been addressed in many studies. Comprehensive reviews of these studies has been made by various authors previously [3, 4, 5, 6]. Early research regarding the subject was performed using simple single-story models. Later more advanced studies based in multi-story asymmetric systems have also emerged. In one of the early studies, the reducing effect of torsional coupling with increasing inelastic deformations was observed [7]. An effective eccentricity and associated design torque was introduced to estimate the inelastic deformations of torsionally-coupled systems [8]. Peak ductility demands at the edges of asymmetric systems are determined to be not larger than those of symmetric systems [9, 10]. Moreover, it was proposed that, the inelastic displacements of asymmetric systems can be reduced by modifying the strength distribution along plan by changing the location of center of strength ( $CV$ ). In separate other studies, strength eccentricity has been determined to be more effective than stiffness eccentricity to control inelastic deformations [11, 12, 13]. A displacement-based design approach has also been proposed as an alternative to strength-based approach to limit and make ductility distribution among structural members in asymmetric systems more uniform [14]. A balanced distribution of center of strength and center of stiffness was proposed in order to minimize the edge displacements of torsionally coupled systems [15]. Contribution of load resisting frames that are perpendicular to the direction of earthquake loading to the torsional response was also investigated [16, 17].

The overstrength that is inherent in members of the torsionally coupled systems which are designed with force-based approaches has also been studied. It has been noted that accidental eccentricity formulations in seismic codes does not usually compensate the inelastic deformation demands, rather they increase the overstrength [18, 19]. The explicit inclusion of overstrength in the design of asymmetric systems was suggested in a study regarding the uneven distribution of overstrength in torsionally coupled multistory buildings [20]. Further studying the overstrength in asymmetric systems, uniform ductility spectra which has been proposed by the authors to estimate the optimum strength ratio of stiff and flexible sides of asymmetric systems for achieving balanced ductility demands [21].

The observations and suggestions regarding the torsional response of asymmetric systems vary dramatically among the vast research conducted in the past. Although this is the case for many of the deductions, it has been generally agreed by the researchers that the modification of strength eccentricity is closely related with controlling the inelastic torsional response. The work presented within this study is formulated upon this observation. The inelastic displacements of asymmetric systems are estimated with respect to strength distribution of these simple structures. Seismic response of shear frame systems is represented by simple models using basic dynamic properties.

## 2 TORSIONAL DUCTILITY SPECTRA

A simple tool to assess the ductility demands in simple asymmetric-plan multi degree of freedom systems is proposed. Basic vibration and strength parameters of a simple single story, two degree of freedom asymmetric shear frame are determined as the basic variables for a rigorous parametric study. A shear frame having a stiffness eccentricity ratio of  $e$  is constructed.

It is composed of a stiff side and flexible side structural member, both of which are connected a rigid slab. The system in question is designed under a typical design spectrum by employing the ductility reduction factor  $R\mu$ .

Another parameter that is taken into account is the uncoupled frequency ratio ( $\Omega_r$ ) of the parametric system. A variation for  $\Omega_r$  is introduced so that the variation in seismic response of a torsionally stiff ( $\Omega_r = 1.25$ ), torsionally equally stiff ( $\Omega_r = 1.0$ ) and torsionally flexible ( $\Omega_r = 0.8$ ) systems are investigated. The different parameters considered in this simple, single story shear frames are summarized in Table 1.

$e$	$R\mu$	$\Omega_r$
0.1	3	1.25
0.2	4	1.0
0.3	5	0.8

Table 1: System parameters used in single-story simple structures

The stiffnesses of flexible and stiff side members of the linear elastic system ( $k_F$  and  $k_S$ ) are selected such that the target stiffness eccentricity value is satisfied for each parametric system (Equation 1).

$$e = \frac{k_F - k_S}{2(k_F + k_S)} \quad (1)$$

The uncoupled frequency ratio can also be computed from Equation 2.  $L$  in Equation 2 is the distance between to structural members and  $r$  is the radius of gyration of the system (Equation 3.)

$$\Omega_r = \frac{L}{2r} \quad (2)$$

$$r = \sqrt{\frac{I_{CM}}{m}} \quad (3)$$

The terms  $m$  and  $I_{CM}$  in Equation 3 are the mass and the mass moment inertia of the parametric systems, respectively. Throughout the parametric study,  $L$  and  $m$  are utilized as unity. Solution of Equation 3 for each  $\Omega_r$  value yields the  $L$  parameter which, in turn, used to compute mass moment of inertia and create the mass matrix of the system. In addition, Equation 1 is used to determine  $k_F$  and  $k_S$  for every parametric system having  $e = 0.1, 0.2$ , or  $0.3$ . Upon using the determined stiffness values and  $L$ , the stiffness matrix for each unique system can also be obtained. Consequently, the relationship between modal vibration frequency  $\omega_n$ , stiffnesses  $k_F$  and  $k_S$ , and the inertial properties  $m$  and  $I_{CM}$  of the parametric system can be obtained from the solution of the eigenvalue problem in Equation 4:

$$\det(\underline{k} - \omega_n^2 \underline{m}) = 0 \quad (4)$$

Hence, upon solution of Equation 4, the linear elastic properties of the systems can be obtained for a range of different translational periods ( $T_1$ ). They are designed under the design response spectrum for obtaining the stiff side and flexible side strength demands for selected ductility reduction factors of  $R\mu$ . The schematic representation of the parametric systems and

the distribution of displacements computed under response spectrum analysis is shown in Figure 1. It should be noted here that accidental eccentricity is not included in the design.

Figure 1: Schematic distribution of displacements for a 2DOF parametric system.

At this stage, another parameter variation is introduced to the parametric systems. The assigned flexible side strength ( $F_F$ ) is kept fixed at its nominal value (i.e. the strength demand); whereas overstrength is introduced to the stiff side members in an incremental manner (Figure 2). Hence, the parameter stiff to flexible edge strength ratio ( $SFSR$ ) is defined (Equation 5).

$$SFSR = \frac{F_S}{F_F} \quad (5)$$

Figure 2: The flexible ( $F_F$ ) and stiff edge ( $F_S$ ) strengths of the parametric systems and variation of  $F_S$ .

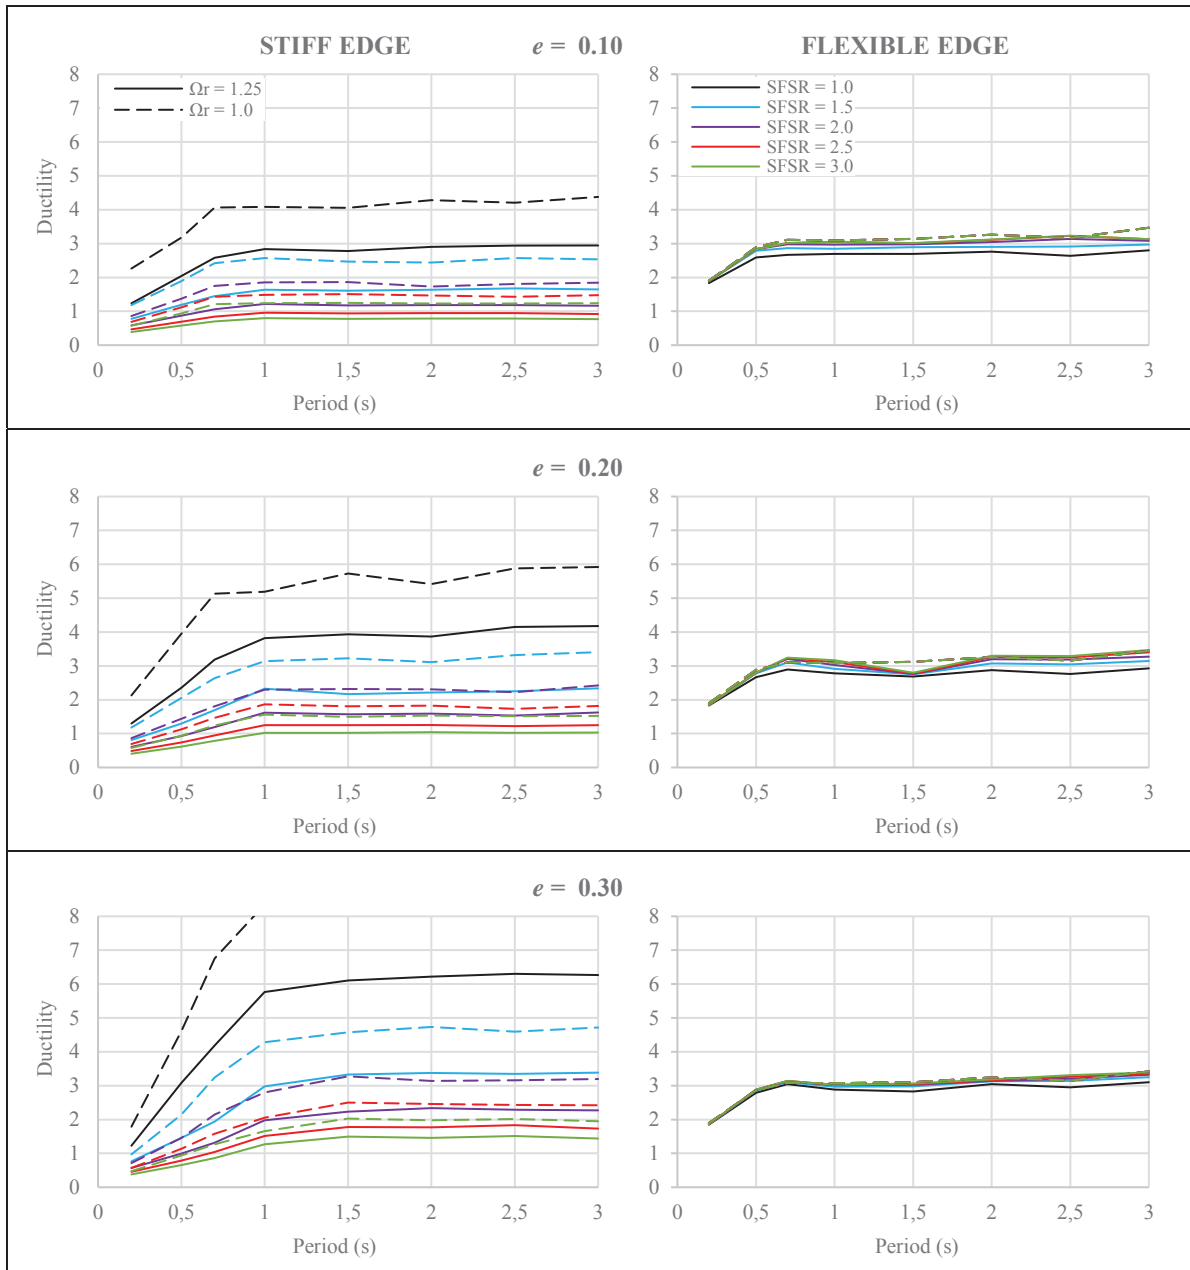

By utilizing this procedure, a family of parametric, two degree of system parametric systems are obtained. Each system is identified by a unique set of parameters ( $T_1$ ,  $\Omega_r$ ,  $e$ ,  $R_\mu$ ,  $SFSR$ ). Nonlinear dynamic response of these systems are then computed under a set of 30 spectrum matched [22] ground motions selected from PEER NGA Database [23]. The unscaled ground motion list and their characteristics are given in Table 2. Generally, they are all recorded in soft soil, at near fault regions. Linear elastic target spectrum is constructed per ASCE 7-16 [1] based on an imaginary location in downtown San Francisco. The site class is assumed as C.

Nonlinear models of the parametric systems have been prepared in OpenSees Platform [24] and elastic-perfectly plastic hysteresis models are employed in numerical representations of load resisting members.

Table 2: Strong ground motions used in the dynamic analyses.

Results obtained from nonlinear dynamic analysis of each parametric system having a distinct  $T_1$  are compiled in a spectrum format to create the Torsional Ductility Spectra. The main response parameter in this spectra set is selected as the mean maximum ductility of the systems. Ductility is a normalized indication of the inelastic response; therefore, it provides an objective response comparison for all parametric systems. Torsional Ductility Spectra produced for  $R_\mu = 3, 4$ , and  $5$  are presented in Figures 3, 4, and 5 respectively. The spectra compiled only for torsionally stiff and torsionally equally flexible systems are displayed in these figures in order to not to make the graphical view too complicated.

Figure 3: Torsional ductility spectra ( $R\mu = 3$ ).

## 2.1 Observations from Torsional Ductility Spectra

As can be seen in Figures 3, 4 and 5 the ductility trends of stiff and flexible side members vary considerably. Flexible side ductilities are invariant of  $SFSR$  and almost equal to  $R\mu$  in each chart. Stiff side ductilities, however, are quite sensitive to  $SFSR$ . It should be noted here that the variation in  $SFSR$  corresponds to the proportional variation of stiff side strength since the flexible side strength is held fixed at its nominal value among designs.

An important observation could be made from Figures 3, 4 and 5. The ductilities observed in flexible edge members are consistent with the ductility reduction factors employed in the design. Therefore, it could be concluded that energy is dissipated mainly through flexible side member. Stiff side member may also experience some inelastic response especially when  $SFSR$

is close to unity (stiff and flexible sides have similar strengths). Although in practice, this observation is not common. Due to relationship between strength and stiffness, the ratio of stiff side to flexible side strength (*SFSR*) is proportional to the ratio of stiff side to flexible side stiffness in most of the cases. This issue, in turn, is the cause of torsional behaviour and the cause of inherent overstrength located in stiff side members. Therefore, it can be deduced that the stiff side members in actual systems behave in a force-controlled manner with fairly small ductility demands. This is visualized in Figures 3, 4 and 5 especially when *SFSR* > 2. It is also well known that ductile seismic detailing supplied to structural members further increase the overstrength for stiff side, hence making the behaviour more unfavorable.

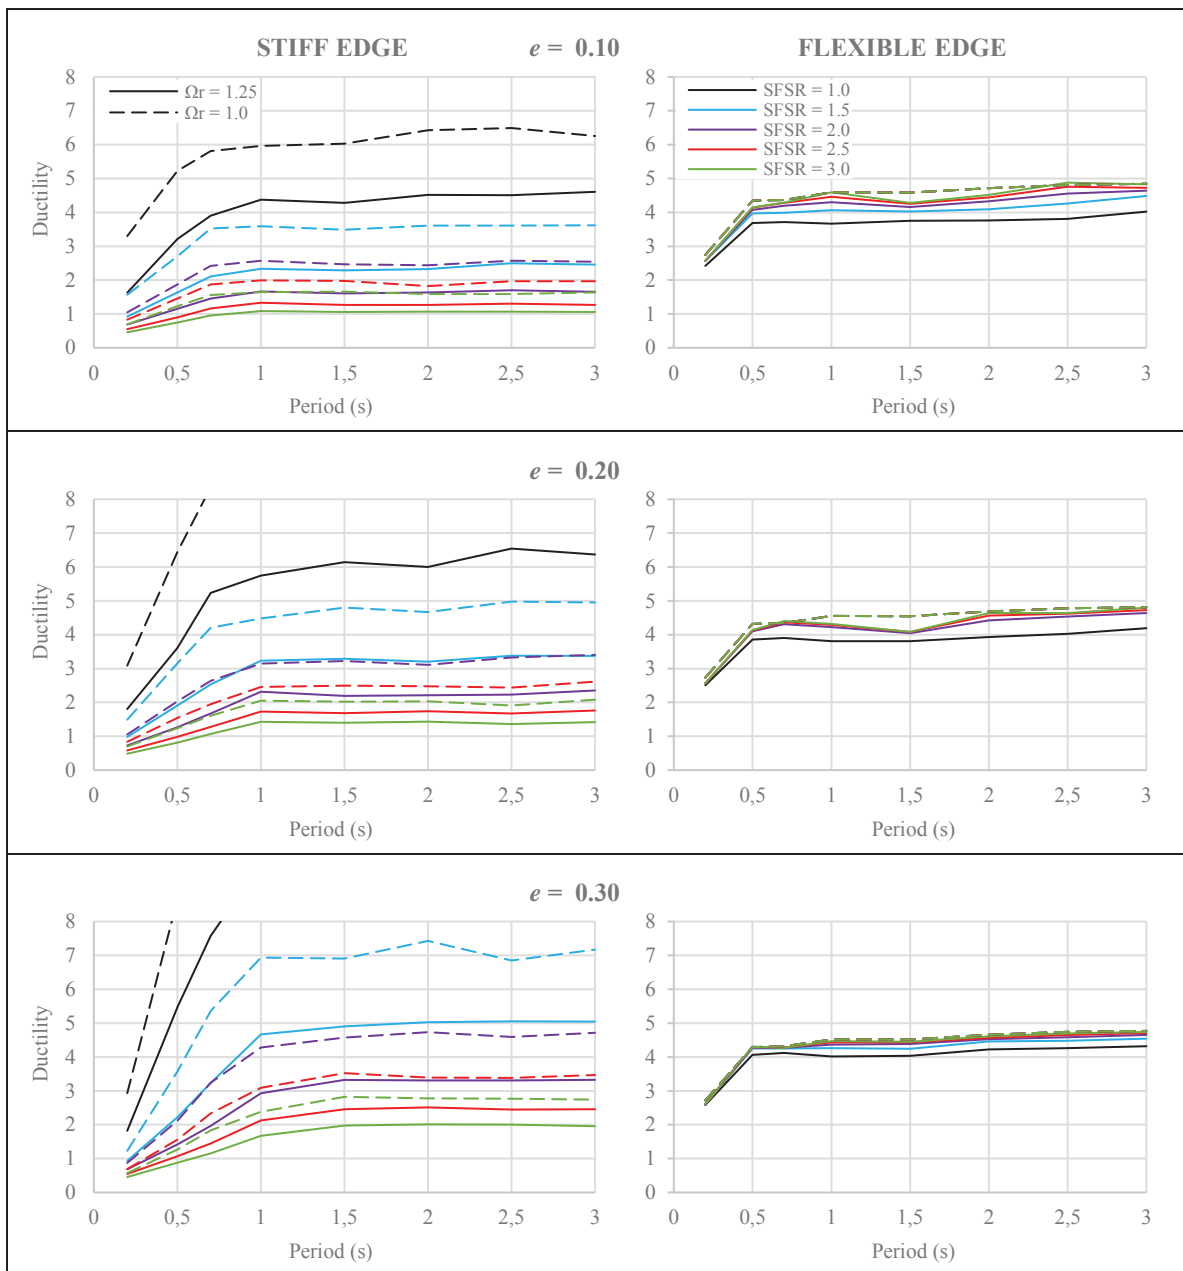

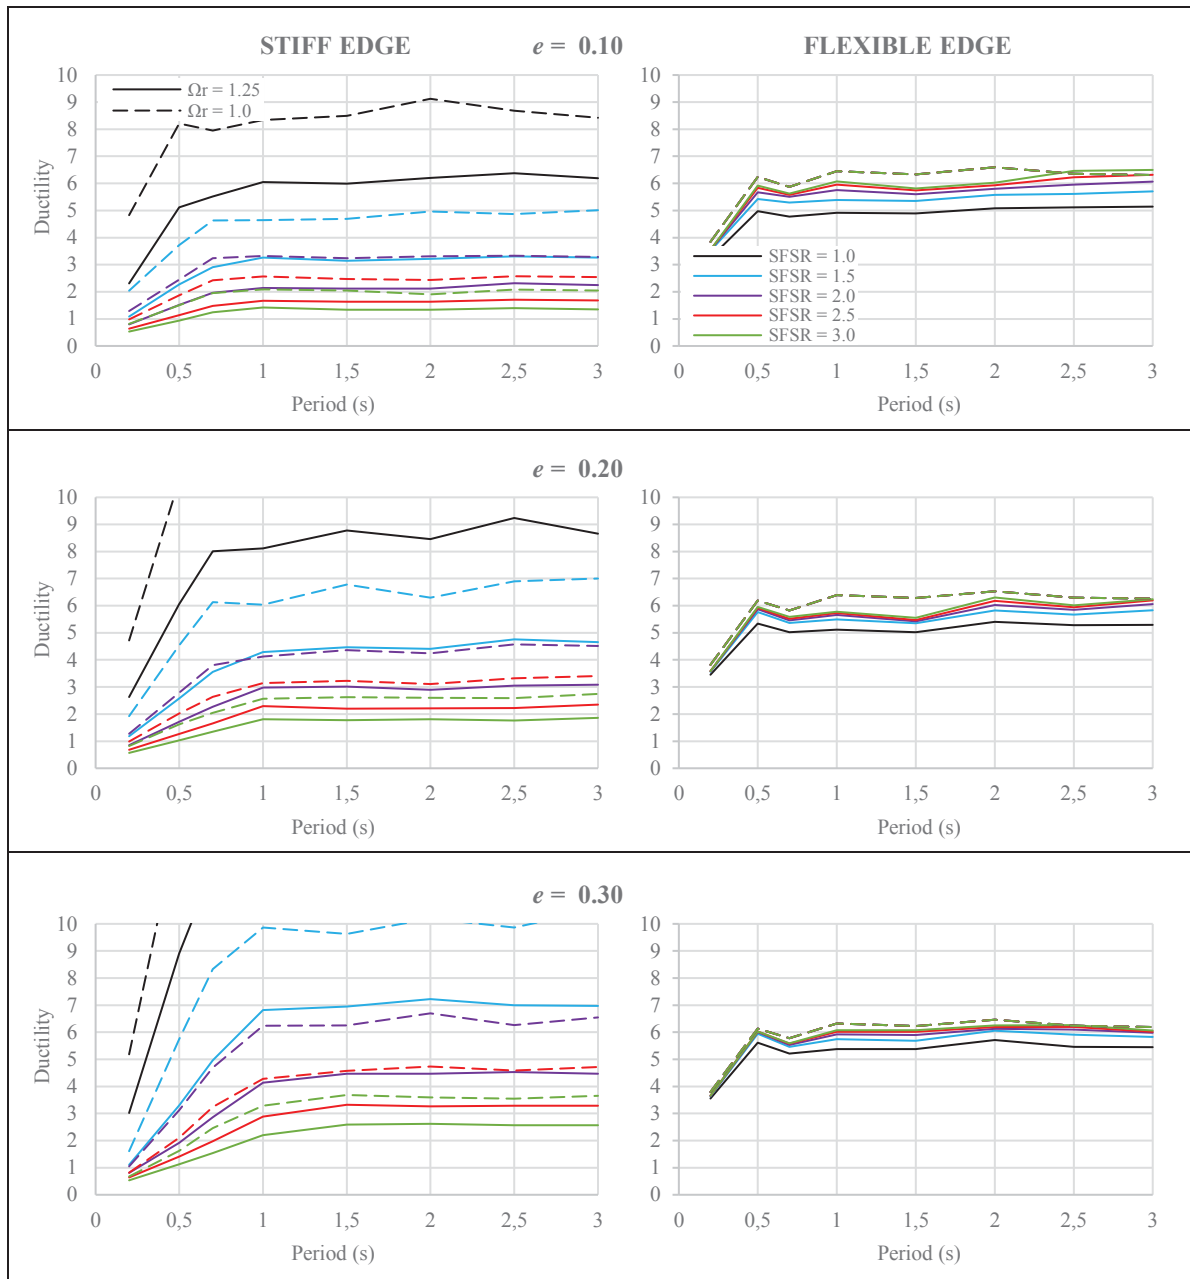

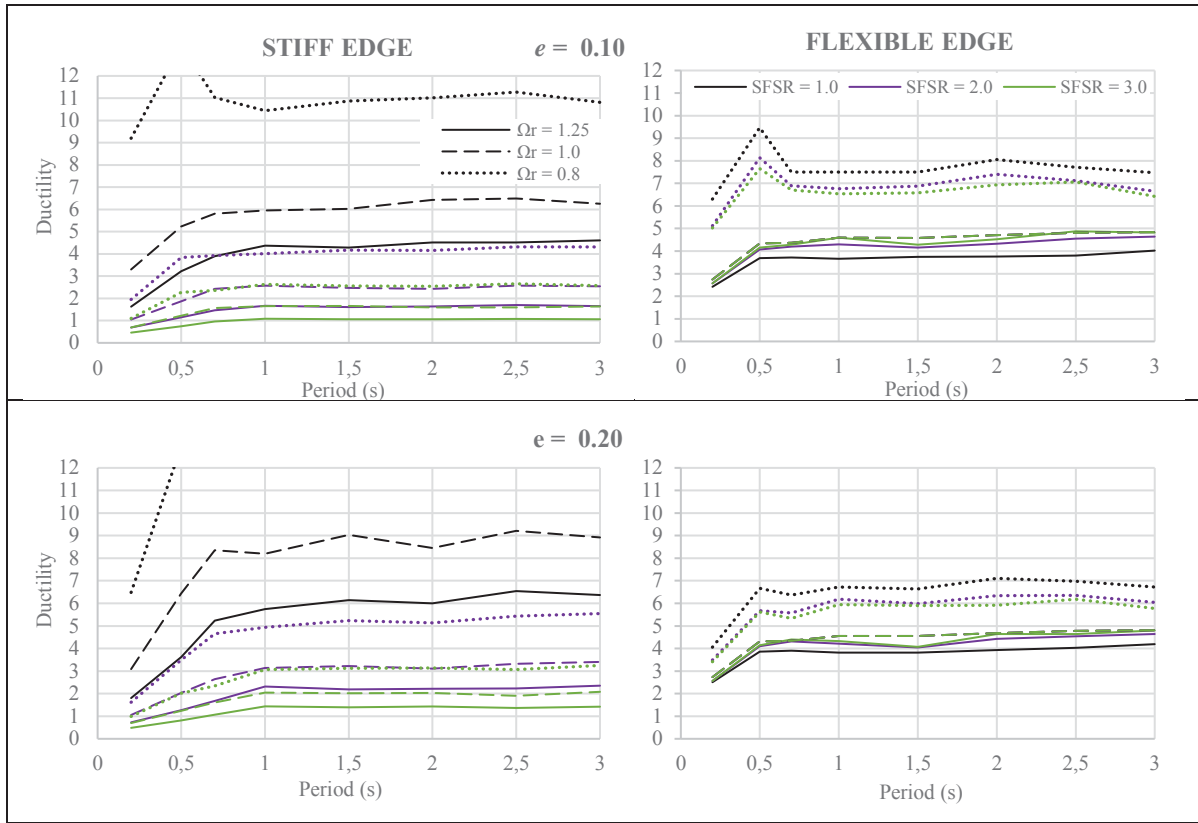

Figure 4: Torsional ductility spectra ( $R\mu = 4$ ).

Figure 5: Torsional ductility spectra ( $R\mu = 5$ ).

The effect of uncoupled frequency ratio is assessed comparatively for uncoupled rotational-to-translational frequency ratios of 1.25, 1.0 and 0.8. The results are presented in a separate figure (Figure 6) for  $R\mu = 4$ ,  $SFSR = 1.0, 2.0, 3.0$  and  $e = 0.1, 0.2$  combinations. It can be seen from Figure 6 that stiff edge ductilities are quite sensitive to increasing values of torsional flexibility whereas flexible edge ductilities are not affected considerably. As a general trend, stiff side ductility demands exhibit an increasing trend with decreasing frequency ratio. Hence, it could be concluded that the torsionally flexible systems display more non-uniform ductility distribution. This observation is consistent with the fact that modern earthquake codes which discourage or penalizes the design of torsionally flexible systems.

Figure 6: Sensitivity of the compiled spectra to uncoupled frequency ratio ( $R\mu = 4$ ).

### 3 ESTIMATION OF DUCTILITIES VIA TORSIONAL DUCTILITY SPECTRA

The torsional ductility spectra presented herein is a tool for estimating the ductility distribution of a 2DOF, 2-member system. In order to utilize the spectra set in performance assessment, more realistic structural systems having varying number of load resisting frames must be “transformed” to the schematic 2DOF system. In this section, a single-story shear frame having four load resisting members is investigated.

Figure 7: 4-member shear frame system.

The plan view of the 4-member shear frame is shown in Figure 7. The dimensions and related geometric properties of the system are selected such that they represent an actual structure. The rigid slab dimensions are 18 m by 11.5 meters, with a mass of 340 tons. Member 1 is 3.7 times more stiff than members 2, 3, and 4. Consequently, the system has  $e = 0.2$  static eccentricity towards member 1. The lateral stiffness values to the load resisting members are given such that modal vibration periods of  $T_1 = 0.7$  s,  $T_2 = 0.4$  s and uncoupled frequency ratio  $\Omega_r = 1.25$ . The system is designed under the same ASCE 7-16 [1] design spectrum used in parametric study with  $R \equiv R_\mu = 4$ . Since  $R \equiv R_\mu$ , no overstrength is considered for all members. The resulting strengths determined from design and corresponding force-deformation relationships of 4 members are given in Figure 8.

Figure 8: Force-deformation relationships of load resisting members.

All values related with the parametric systems  $[T_1, \Omega_r, e, R_\mu]$  except  $SFSR$  are obtained. Since  $SFSR$  defined within this study depends on single values of  $F_S$  and  $F_F$ , strength capacities of four members should be transformed. This could easily be achieved by satisfying the two equations of force equilibrium in Equation 6.  $x_i$  in Equation 6 is the location of frame  $i$  in the 4-Member system.

$$F_F = \frac{\sum_i (F_i \cdot x_i)}{L}; \quad F_S = (\sum_i F_i) - F_F \quad (6)$$

Using frame strengths and their respective locations in Equation 6,  $F_F = 340$  kN and  $F_S = 678$  kN. Therefore,  $SFSR$  is calculated as 2.0. Since all parameters of the structural system is now known, corresponding Torsional Ductility Spectra given in Figure 4 with associated parameters of  $T_1 = 0.7$  s,  $\Omega_r = 1.25$ ,  $e = 0.2$ ,  $R_\mu = 4$  and  $SFSR = 2.0$  can be used to obtain the estimated ductilities. From the related chart, stiff edge ductility is read as  $\mu_S = 1.7$ , whereas flexible edge ductility is read as  $\mu_F = 4.3$ .

In order to verify the accuracy of this estimation, actual nonlinear performance of the shear frame should be determined. Nonlinear response history analyses (NRHA) are performed on the shear frame system using the ground motion set given in Table 2. Load resisting members are defined with elastic-perfectly plastic hysteretic relationships in OpenSees Platform [24] using the yield force and deformation parameters given in Figure 8. Mean maximum inelastic member displacements are obtained from the dynamic analyses under the ground motion set and corresponding member ductility ratios are computed. Mean member displacements, member yield deformations shown in Figure 8 and corresponding member ductility ratios are given in Equation 7.

$$\begin{array}{l}
\text{Member 1:} \\
\text{Member 2:} \\
\text{Member 3:} \\
\text{Member 4:}
\end{array}
\quad \underline{\mu}_{NRHA} = \begin{Bmatrix} 0.039 \\ 0.055 \\ 0.096 \\ 0.145 \end{Bmatrix} \quad \underline{\mu}_y = \begin{Bmatrix} 0.0241 \\ 0.0129 \\ 0.0224 \\ 0.0331 \end{Bmatrix} \quad \mu_{NRHA} = \begin{Bmatrix} 1.6 \\ 4.3 \\ 4.3 \\ 4.4 \end{Bmatrix} \quad (6)$$

In order to compare the computed ductility ratios with estimations from the Torsional Ductility Spectra, members located at stiff and flexible sides of the shear frame system should be determined. This can be done by inspecting Figure 7 in a fairly straightforward manner. Member 1 is at the stiff side of the shear frame structure with respect to center of rigidity (*CR*); whereas members 2-4 are at the flexible side. Hence, comparison of ductilities estimated from Torsional Ductility Spectra and dynamic analyses can be made accordingly.

Upon comparing the estimation with the dynamic response, a close match can be seen. Mean member ductility ratios obtained from NRHA are seemingly close to the ductility estimations for both sides given by the associated spectrum. It should be noted here that ductility ratios of flexible side members are determined to be close to the imposed value of  $R_\mu = 4$ . On the other hand, mean ductility ratio of the stiff side member is considerably smaller than other members as well as imposed  $R_\mu$ . In practice, significant overstrength is expected to be present in the stiff side member due to factors such as seismic detailing and relationship between strength and stiffness. Therefore, the ductility imbalance shown here is expected to further increase in the case of a more realistic case study structure.

#### 4 SUMMARY AND CONCLUSIONS

Torsional Ductility Spectra as a tool for estimating ductilities and their distribution among asymmetric-plan systems are presented in this study. Basic 2DOF 2-member parametric systems are utilized and through a parametric study considering stiffness eccentricity, frequency ratio, ductility reduction factor, fundamental period and strength ratio, system ductilities are compiled in a spectrum format. Last parameter in question, stiff to flexible strength ratio (*SFSR*) is introduced to the systems such that flexible side members are kept at their nominal strengths whereas overstrength is introduced in stiff side members. By doing so, effect of inherent overstrength present in stiff structural elements to ductility distribution is clearly visualized in charts.

The ductility estimation performance of the spectra set is assessed by utilizing a 4-member shear frame system. Upon designing the system and performing inelastic dynamic analyses, computed mean ductilities are compared with chart estimations. In general, the Torsional Ductility Spectra estimates the expected ductilities of the shear frame members fairly well.

Some observations are also performed on the spectra trends. While flexible side members attain ductilities around imposed ductility reduction factors, this may not be the case for stiff side members especially when overstrength is present. Moreover, it is determined that increasing amount of torsional flexibility have a negative effect in ductility distribution of asymmetric-plan systems.

The proof of concept presented herein and the simple verification with respect to shear frame behaviour are considered as the first phase of the study. As part of the ongoing research, the spectra set defined in this study is to be verified further by computing the ductility distribution of a multi-story, actual asymmetric-plan systems and assessing the estimation performance of Torsional Ductility Spectra.

**Keywords:** RC Framed Buildings, Dual Hysteretic-Viscous Damped Braces, Dual Hysteretic-Hysteretic Damped Braces, Two-Level Displacement-Based Design Procedure.

**Abstract.** *The use of hysteretic damped braces (HYDBs) is an effective and low-cost solution for the seismic retrofitting of reinforced concrete (RC) framed structures. However, notable damage to nonstructural elements can be observed at the serviceability design earthquake (SDE), when too high activation forces of the HYDBs are designed in order to attain structural safety (SS) performance level at the basic (BDE) and/or maximum considered (MCE) earthquakes. On the other hand, HYDBs designed at the immediate occupancy (IO) performance level prevent nonstructural damage of MIs under SDE but may collapse and/or induce structural damage for high intensity seismic loads, due to their early activation which renders them unable to develop large energy dissipation. Aim of this work is the proposal of a multi-objective displacement-based design procedure, where viscous damped braces (VDBs) and HYDBs calculated for IO at the SDE are combined with HYDBs ensuring SS at the MCE. A six-storey RC framed structure, representative of the residential building stock in Italy prior to the 2008-2018 code changes, is to be retrofitted in a high risk-seismic region supposing that is preliminarily designed in L'Aquila (Italy) for moderate seismic loads. The OpenSEES platform is considered for the nonlinear dynamic analysis of the original and retrofitted structures. RC frame members are modelled with lumped plasticity elements while the shear behaviour of the beam-column joints is modelled by means of a scissor model. Masonry infills uniformly distributed in elevation are modelled with a simplified diagonal pin-jointed strut model taking into account the in-plane failure modes. HYDBs are modelled with truss elements characterized by a bilinear force-displacement law, without considering the flexibility of the supports, while nonlinear force-velocity law is considered for VDBs. Nonlinear dynamic analysis is carried out considering three stripes of real records, corresponding to the SDE, BDE and MCE seismic levels assumed in the current Italian code.*

## 1 INTRODUCTION

The use of hysteretic damped braces (HYDBs), based on a plastic deformation mechanism (e.g. axial, bending, shear, torsion) or a combination of some of them, represents an effective and low-cost solution for the seismic retrofitting of reinforced concrete (RC) framed structures [1]. However, notable damage to non-structural elements (e.g. masonry infills, false ceilings and suspended piping) can be observed at the serviceability design earthquake (SDE), when too high activation forces of the HYDBs are considered in order to improve structural performance level at the basic (BDE) and maximum considered (MCE) earthquakes [2, 3]. To overcome this problem, dampers working as fuses can be inserted as sacrificial elements in order to prevent damage of non-structural elements [4], by means of an in-parallel combination of different typologies of dampers [5, 6], or alternatively damping and stiffness properties of dampers arranging in-series minor and major cores can be modulated to different seismic intensity levels [7]. A multi-objective design procedure is proposed in the present work, where viscous (VDBs) and hysteretic (HYDBs) damped braces calculated for immediate occupancy (IO), at SDE, are combined with HYDBs ensuring structural safety (SS), at MCE. To this end, a displacement-based design procedure already proposed in previous works [8-10] is applied, also including the loss of capacity of the existing structure due to previous seismic damage [11-12].

A six-storey RC framed building, representative of the Italian residential housing stock during the 1990s in a medium-risk seismic zone, is assumed as test structure for the numerical investigation [13]. This structure is supposed to be retrofitted by inserting HYDBs and VDBs to attain IO (e.g. no damage to masonry infills, MIs, at SDE) and SS (e.g. limited damage to structural elements at BDE and collapse prevention of HYDBs at MCE) performance levels imposed by current Italian seismic code (NTC18) in a high-risk seismic zone [14]. Specifically, five structural arrangements of damped braces are compared: only HYDBs designed at MCE; in-parallel combination of VDBs and HYDBs designed at SDE and MCE, respectively, possibly with gap-hook elements acting in series with the HYDBs so as to delay their activation at SDE; in-parallel and in-series combinations of small and large HYDBs designed at SDE and MCE, respectively, without and with a gap-hook element positioned in parallel with the small HYDBs, so as to stop their deformation at MCE. Nonlinear dynamic multi-stripe analyses of the original and retrofitted structures are carried out with the OpenSees code [15], considering three different set of records selected and scaled in line with SDE, BDE and MCE intensity levels provided by NTC18 [16]. Brittle and failure mechanisms of the original structure are modelled, considering: a lumped plasticity model for RC frame members, with flexure- or shear-controlled moment-chord rotation at the critical end sections; a scissor model with rigid offsets for shear behaviour of the beam-column joints; a diagonal pin-jointed strut model for MIs, taking into account their in-plane failure modes.

## 2 DISPLACEMENT-BASED DESIGN PROCEDURE OF DAMPED BRACES

A multistep iterative Displacement-Based Design (DBD) procedure of HYDBs, proposed in previous works [8-10], is extended for the seismic retrofitting of RC framed structures with dual hysteretic-viscous and hysteretic-hysteretic damped braces designed at both SDE and MCE, with or without a gap-hook element to avoid activation of small and large dampers at MCE and SDE, respectively.

As first step, the pushover curve of the original structure ( $V-d$ ) is converted to that of an equivalent SDOF system ( $V^*-d^*$ ) and a piecewise linear fit of the initial backbone curve is determined by an ensemble of  $N$  pairs of bilinear elastic-perfectly plastic and elastic-softening damage laws [12]. Then, the damaged backbone curve that envelopes the hysteretic behaviour

of the equivalent SDOF system subjected to seismic loads is evaluated from nonlinear dynamic analysis of the combined plastic-damage hysteretic model. The monotonic and cyclic deterioration of plastic and damage mechanisms is described by a damage loading index  $\Psi$  [11], expressed as function of an ever-increasing curve whose shape depends on a degradation rate parameter (e.g.  $\varepsilon=0.5$ ). A weighting coefficient (e.g.  $C_{wc}=0.25$ ) distinguishes the effect of displacements less or greater than the previous maximum values ( $d_{max}^*$ ) in the same loading direction, while a damage coupling parameter (e.g.  $C_{cd}=0.5$ ) accounts for the influence of the energy dissipation under positive and negative forces on negative and positive values of the loading variable. Finally, the hysteretic energy dissipation of the degraded frame ( $\xi_{h,F}$ ) and the effective stiffness ( $K_{e,F}$ ) related to the performance displacement ( $d_p^*$ ) can be evaluated, while elastic viscous damping of the framed structure (e.g.  $\xi_{v,F}=5\%$ ) can be assigned (Figure 1a).

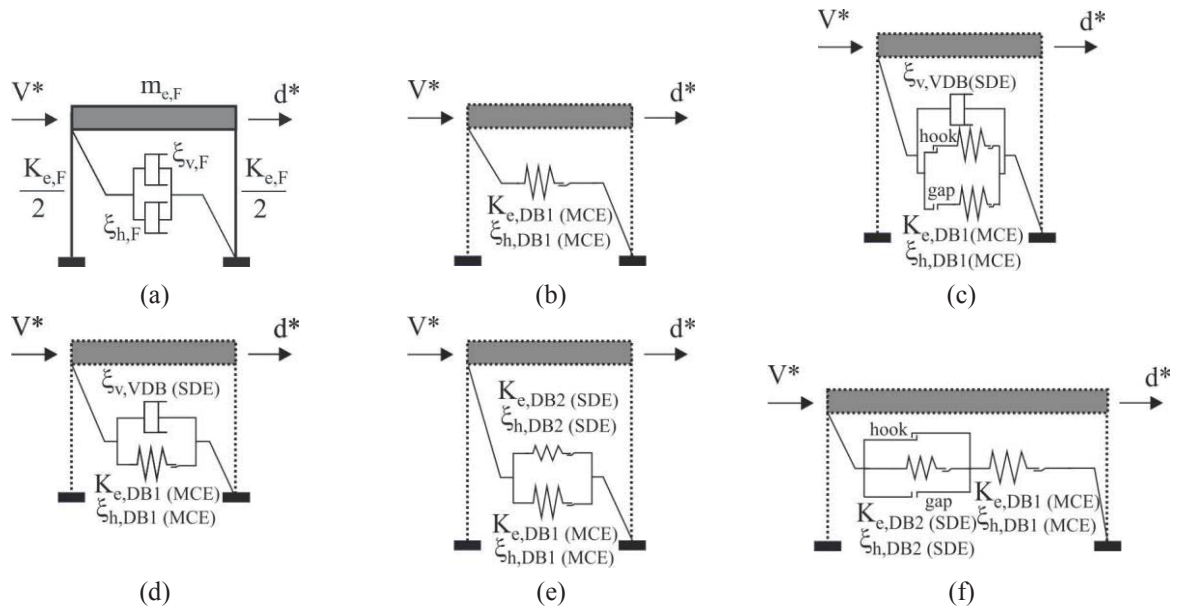

Figure 1. SDOF systems equivalent to the original structure (a), hysteretic (b) and dual hysteretic-viscous (c, d) and hysteretic-hysteretic (e, f) damped braces.

In order to design hysteretic (Figure 1b) and dual hysteretic-viscous (Figures 1c,d) and hysteretic-hysteretic (Figures 1e,f) damped braces at MCE, an iterative procedure is implemented in the acceleration-displacement response spectrum (ADRS) shown in Figure 2, where the bilinear capacity curve of the original structure is represented with a solid blue line. An initial value of the equivalent viscous damping ratio of the damped braced frame (i.e.  $\xi_{e,DBF} > \xi_{v,F} + \xi_{h,F}$ ) is tentatively assumed at the selected performance displacement ( $d_p^*$ ) corresponding to MCE, starting from 5% damped spectrum (solid black line). Then, effective vibration period ( $T_{e,DBF,MCE}$ ) of the retrofitted structure is determined on the reduced ADRS spectrum (dashed black line), starting from the trial performance point corresponding to the target displacement value, so allowing the calculation of effective stiffness  $K_{e,DB}(=K_{e,DBF}-K_{e,F})$  of the equivalent DB at MCE (i.e. DB1). Once ductility demand ( $\mu_{DB1}$ ) and hardening ratio ( $r_{DB1}$ ) of DB1 are assigned, it is possible to calculate the bilinear capacity curve of the damped brace (solid red line in Figure 2) and its viscous damping ( $\xi_{h,DB1}$ ) equivalent to the hysteretic energy dissipation:

$$\xi_{h,DB1}^{(MCE)} (\%) = 63.7 \frac{(\mu_{DB1} - 1) \cdot (1 - r_{DB1})}{\mu_{DB1} [1 + r_{DB1} \cdot (\mu_{DB1} - 1)]} \quad (1)$$

Finally, an updated value of the equivalent viscous damping of the retrofitted structure can be evaluated, being  $V_{p,F}^*$  and  $V_{p,DB1}^*$  strength values of the original frame and damped brace at  $d_p^*$ , respectively:

$$\zeta_{e,DBF}^{(MCE)}(\%) = \zeta_{v,F} + \frac{\zeta_{h,F}^{(MCE)} \cdot V_{p,F}^{*(MCE)} + \zeta_{h,DB1}^{(MCE)} \cdot V_{p,DB1}^{*(MCE)}}{V_{p,F}^{*(MCE)} + V_{p,DB1}^{*(MCE)}} \quad (2)$$

Figure 2. Design procedure of the hysteretic and dual hysteretic-viscous and hysteretic-hysteretic damped braces in the acceleration-displacement response spectrum at MCE.

In a similar way, viscous (Figures 1c,d) and hysteretic (Figure 1e) dampers at SDE, in parallel with the hysteretic damped brace previously designed at MCE (DB1), may be evaluated with an iterative process in the ADRS corresponding to SDE (Figure 3). At this point, the admitted target displacement ( $d_{p,SDE}^*$ ) and first equivalent viscous damping ratio ( $\zeta_{e,DBF,SDE}$ ) of the retrofitted structure will be considered in the evaluation of effective vibration period ( $T_{e,DBF,SDE}$ ) corresponding to dashed black line in Figure 3. Keeping in mind that the effective stiffness of DB1 is already known from the bilinear capacity curve corresponding to  $d_{p,SDE}^*$ , the effective stiffness ( $K_{e,DB1}$ ) of the additional damper (e.g. hysteretic in Figure 1e) for small deformation (DB2) can be determined by a simple subtraction ( $K_{e,DB2} = K_{e,DBF} - K_{e,DB1} - K_{e,F}$ ). It is worth highlighting that contribution of DB1 disappears when it is attached in series to a gap-hook element (Figure 1c), so avoiding its action at SDE.

Figure 3. Design procedure of the in-parallel hysteretic-viscous and hysteretic-hysteretic damped braces in the acceleration-displacement response spectrum at SDE.

Once viscous damping equivalent to the hysteretic energy dissipation of DB2 is evaluated ( $\zeta_{h,DB2}$ ) as function of the assigned values of  $\mu_{DB2}$  and  $r_{DB2}$  (see Equation (1)), an updated val-

ue of the equivalent viscous damping can be obtained for the retrofitted structure

$$\zeta_{e,DBF}^{(SDE)}(\%) = \zeta_{v,F} + \frac{\zeta_{h,F}^{(SDE)} \cdot V_{p,F}^{*(SDE)} + \zeta_{h,DB1}^{(SDE)} \cdot V_{p,DB1}^{*(SDE)} + \zeta_{h,DB2}^{(SDE)} \cdot V_{p,DB2}^{*(SDE)}}{V_{p,F}^{*(SDE)} + V_{p,DB1}^{*(SDE)} + V_{p,DB2}^{*(SDE)}} \quad (3)$$

depending on strength values, at the performance displacement  $d_{p,SDE}^*$ , for the original frame ( $V_{p,F}^*$ ) and hysteretic DB1 ( $V_{p,DB1}^*$ ) and DB2 ( $V_{p,DB2}^*$ ). Moreover, the expression

$$\zeta_{e,DBF}^{(SDE)}(\%) = \zeta_{v,F} + \zeta_{VDB}^{(SDE)} + \frac{\zeta_{h,F}^{(SDE)} \cdot V_{p,F}^{*(SDE)} + \zeta_{h,DB1}^{(SDE)} \cdot V_{p,DB1}^{*(SDE)}}{V_{p,F}^{*(SDE)} + V_{p,DB1}^{*(SDE)}} \quad (4)$$

corresponds to viscous damped brace (VDB) at small deformation combined with DB1 at large deformation (Figure 1d), with the further simplification

$$\zeta_{e,DBF}^{(SDE)}(\%) = \zeta_{v,F} + \zeta_{VDB}^{(SDE)} + \zeta_{h,F}^{(SDE)} \quad (5)$$

when DB1 is also combined with a gap-hook mechanism (Figure 1c).

As an alternative, in-series combination of hysteretic-hysteretic dampers (Figure 1f) may be considered adopting the iterative design process described in the ADRS corresponding to SDE (Figure 4), where the gap-hook mechanism acts as a very stiff end-stroke stopper that limits deformations of DB2 at the SDE threshold while ensuring that the energy dissipation at MCE is entrusted to DB1. This time, a starting value of the displacement of DB1 ( $d_{p,DB1}^*$ ) is tentatively assumed at the selected performance displacement ( $d_p^*$ ) at SDE, such to obtain as difference the displacement of DB2 ( $d_{p,DB2}^* = d_p^* - d_{p,DB1}^*$ ). Effective stiffness of both dampers (DB1+DB2) can be evaluated as function of the strength  $V_{p,DB1}^* (= V_{p,DB2}^*)$  corresponding to  $d_{p,DB1}^*$

$$K_{e,DB1}^{(SDE)} = \frac{V_{p,DB1}^{*(SDE)}}{d_{p,DB1}^{*(SDE)}}, K_{e,DB2}^{(SDE)} = \frac{V_{p,DB1}^{*(SDE)}}{d_{p,DB2}^{*(SDE)}} \quad (6a,b)$$

and from these ones the total stiffness

$$K_{e,DBF}^{(SDE)} = K_{e,F}^{(SDE)} + \frac{K_{e,DB1}^{(SDE)} \cdot K_{e,DB2}^{(SDE)}}{K_{e,DB1}^{(SDE)} + K_{e,DB2}^{(SDE)}} \quad (7)$$

and effective period ( $T_{e,DBF,SDE}$ ) of the retrofitted structure are derived. In order to determine the corresponding equivalent viscous damping ratio  $\xi_{e,DBF,SDE}$ , curve passing through the trial performance point is drawn in Figure 4 (solid green line).

Figure 4. Design procedure of the in-series hysteretic-hysteretic damped braces in the acceleration-displacement response spectrum at SDE.

On the other hand, equivalent viscous damping ratio is analytically evaluated with the expression

$$\zeta_{e,DBF}^{(SDE)}(\%) = \zeta_{v,F} + \frac{\zeta_{h,F}^{(SDE)} \cdot V_{p,F}^{*(SDE)} + \frac{(\zeta_{h,DB1}^{(SDE)} \cdot d_{p,DB1}^{*(SDE)} + \zeta_{h,DB2}^{(SDE)} \cdot d_{p,DB2}^{*(SDE)}) \cdot V_{p,DB1}^{*(SDE)}}{d_{p,DB1}^{*(SDE)} + d_{p,DB2}^{*(SDE)}}}{V_{p,F}^{*(SDE)} + V_{p,DB1}^{*(SDE)}} \quad (8)$$

and an iterative process is triggered until graphical and analytical values are the same.

Finally, vertical distributions of the (elastic) lateral stiffness of the HYDBs and damping coefficients of the nonlinear VDBs are evaluated proportionally to the interstorey drift and design storey shear of the original structure, respectively. Further information is contained in previous papers [8, 17], which complete the necessary detailing of the work.

### 3 ORIGINAL AND RETROFITTED TEST STRUCTURES

A six-storey RC framed structure (Figure 5a), representative of the residential buildings constructed in Italy during the 1990s, is selected from the RINTC project [13]. It is located in L'Aquila and designed as bare frame for a medium-risk zone, in line with provisions of the Italian code DM86 [18], assuming concrete with cylindrical compressive strength of 25 MPa and steel reinforcement with yield strength of 430 MPa. Columns with rectangular cross-section, oriented as shown in Figure 5b, are tapered along the height, considering:  $0,3 \times 0,6 \text{ m}^2$  at the first two levels;  $0,30 \times 0,5 \text{ m}^2$  at the third and fourth levels;  $0,3 \times 0,4 \text{ m}^2$  at the fifth and roof levels. The structure has deep beams along the perimeter and in the knee configuration of the staircase, with cross section  $0,3 \times 0,6 \text{ m}^2$  at the first two levels and  $0,3 \times 0,5 \text{ m}^2$  at the other four levels, while flat beams are considered for all internal frames, with cross-section  $0,6 \times 0,25 \text{ m}^2$  and  $0,8 \times 0,25 \text{ m}^2$  (the latest marked with an asterisk in Figure 5b). Masonry infills with a double leaf (0,08 m, external layer, and 0,12 m, internal layer) of hollow clay bricks are uniformly distributed along the height, with a percentage of openings depending on the in-plan architectural layout: i.e. 0%, MI.B in brown; 22%, MI.Y in yellow; 40%, MI.O in orange; 100%, MI.G in green. Further details can be found in [13].

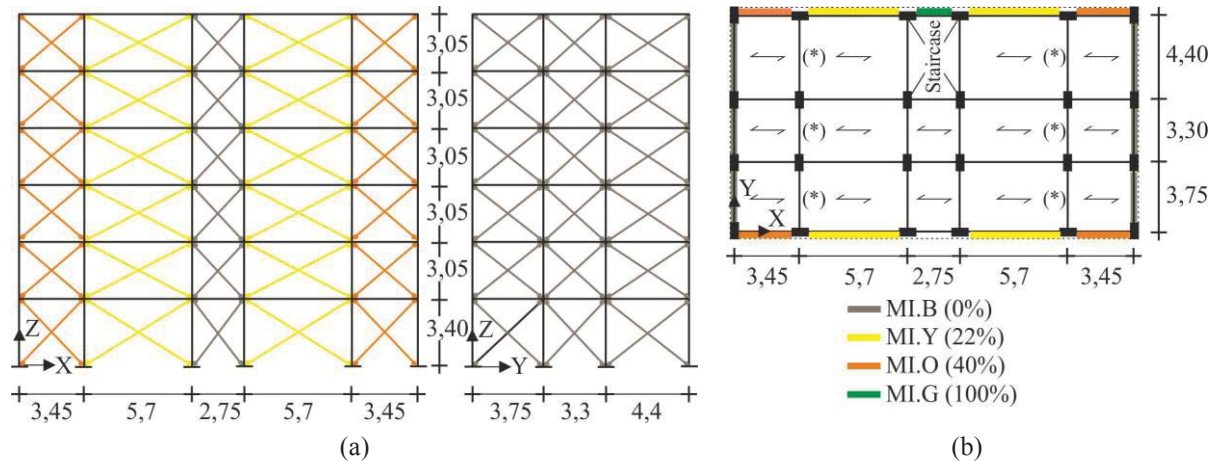

Figure 5. Original test structure (unit in m).

The seismic retrofitting of the original test structure is carried out by the insertion of chevron damped braces, with vertical distribution and in-plan arrangement shown in Figures 6a and 6b, respectively. Five structural configurations of damped braces are compared: i.e. HYDBs designed at MCE (Figure 6b); two in-parallel combinations of VDBs and HYDBs

designed at SDE and MCE, respectively, with (Figure 6c) and without (Figure 6d) gap-hook elements attached in series with HYDBs; in-parallel and in-series combinations of small and large HYDBs designed at SDE and MCE, respectively, without (Figure 6e) and with (Figure 6f) gap-hook elements attached in parallel with the small HYDBs. The deformability of the supporting chevron steel braces is not considered (i.e.  $K_B \rightarrow \infty$ ), so that lateral stiffnesses of the HYDB ( $K_{DB}$ ) and HYD ( $K_D$ ) are assumed equal; this is also for the corresponding stiffness hardening ratios (i.e.  $r_{DB}=r_D$ ). With regard to the VDB, the force developed in the damper is function of a damping exponent  $\beta=0.7$ , which corresponds to nonlinear viscous property.

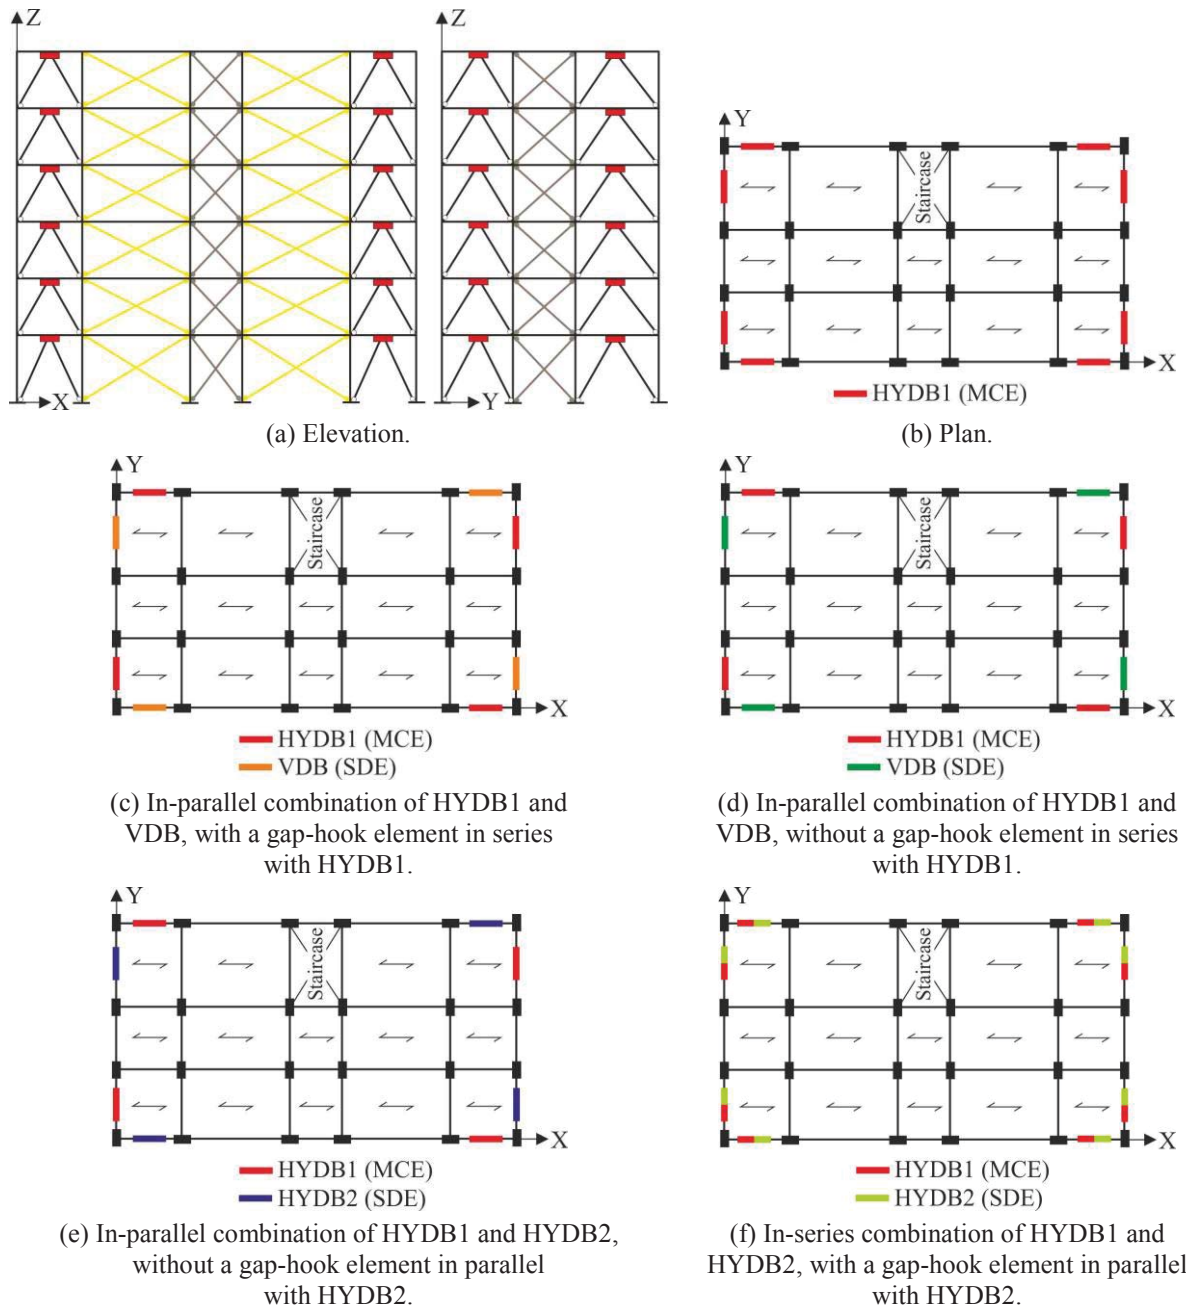

Figure 6. Retrofitted test structures.

Thirteen structural layouts are obtained combining above described five configurations of damped braces with: three ultimate performance levels in terms of top displacement (i.e.

$d_{p,X,MCE}=0,093$  m, 0,14 m and 0.184 m and  $d_{p,Y,MCE}=0,093$  m and 0,14 m), associated with different structural damage scenarios in terms of inter-storey drift ratio (i.e.  $\Delta_X/h=0.5\%$ ,  $0.75\%$  and  $1\%$  and  $\Delta_Y/h=0.5\%$  and  $0.75\%$ ); one serviceability target displacement (i.e.  $d_{p,X,SDE}=0,019$  m and  $d_{p,Y,SDE}=0,042$  m), corresponding to the attainment of the minimum value of peak lateral strength in the masonry infills of each storey, so preventing non-structural damage. Constant design values of damper ductility (i.e.  $\mu_D=5$ ) and hardening ratios (i.e.  $r_F=0\%$  and  $r_D=3\%$ ) are also assumed, except for the in-series arrangement of HYDBs. Main parameters of the equivalent damped braces along the in-plan principal directions are reported in Tables 1-5, with reference to: HYDB1 at MCE (Table 1); in-parallel combination of HYDB1 and VDB at SDE (Table 2); VDB at SDE (Table 3); in-parallel combination of HYDB1 and HYDB2 at SDE (Table 4); in-series combination of HYDB1 and HYDB2 at SDE (Table 5).

Table 5. Properties of the SDOF system equivalent to the DBF at SDE: in series combination of HYDB1 and HYDB2 (units in m, kN and s).

#### 4 NUMERICAL RESULTS

In this section, the effectiveness of the proposed multi-objective design procedure and the limitation of use of HYDBs, designed at MCE, in combination with HYDBs and VDBs, designed at SDE, are investigated on the five-storey RC building described in Section 2. Five structural arrangements of damped braces are considered in order to modulate effective damping and stiffness properties to assigned performance targets at the serviceability (e.g. protection of non-structural elements) and ultimate (e.g. upgrading up to full retrofitting of structural parts and collapse prevention of damped braces) limit states. Nonlinear seismic analyses of the original (IF) and retrofitted (DBIF) infilled structures are carried out using the OpenSEES platform [15]. Zero-length flexural- and shear-controlled elements are used to describe the inelastic response at the end-sections of RC frame members, with the internal part modelled with an elastic element, while a zero-length rotational spring is adopted for the beam-columns joints, reproducing shear failure prior to or after the achievement of yielding of the adjacent beams and columns [13]. An equivalent strut acting only in compression represents the in-plane behaviour of masonry infills, where the peak response is evaluated as minimum prediction between diagonal compression, corner crushing, sliding shear and diagonal tension failure mechanisms [19, 20]. Inherent damping equal to  $\xi_{v,F}=5\%$  is assumed for the RC framed structure, using mass and tangent stiffness proportional Rayleigh approach. Nonlinear fluid VDBs are modelled as nonlinear dashpots and linear springs [17], while truss elements with bilinear force-displacement law are considered for the HYDBs, with and without an in-parallel or in-series combination with a gap-link working in parallel to a hook-link. Then, three sets of biaxial accelerograms, each consisting of seven earthquakes, are selected from the PEER database and scaled to three different intensity levels [16]. At the site of L'Aquila (13.40° longitude and 42.35° latitude), design response spectra of acceleration provided by NTC18 are evaluated for moderately-soft subsoil, considering a nominal life  $V_N=50$  years and a functional class II (amplification factor,  $C_U=1.0$ ) resulting in a reference period  $V_R=50$  years. These spectra are matched on average in a suitable range of vibration periods, with reference to SDE (PGA= 0.156 g), BDE (PGA= 0.347 g) and MCE (PGA= 0.407 g).

The beneficial effects offered by the combination of HYDB1, ensuring structural safety (SS) at MCE, and VDB or HYDB2, calculated for immediate occupancy (IO) at SDE, are firstly investigated in Figures 7-9 with reference to the seismic performance of nonstructural elements. Specifically, maximum drift ratio of masonry infills  $\alpha_{\Delta I,max}(=\Delta_{I,max}/\Delta_{I,p}$ , being  $\Delta_{I,max}$  the mean of maximum drift demand at SDE and  $\Delta_{I,p}$  the value corresponding to full cracking)

is evaluated along the building height. As can be observed, the absence of openings in the infill walls along the Y direction (see Figure 5b) results in a significant reduction of  $\alpha_{\Delta I, \max}$ , whose values are less than those corresponding to the attainment of the peak lateral strength (i.e.  $\alpha_{\Delta I}=1$ ) for the IF structure, with a further slight improvement when DBIF structures are considered (Figures 7b, 8b,d and 9b).

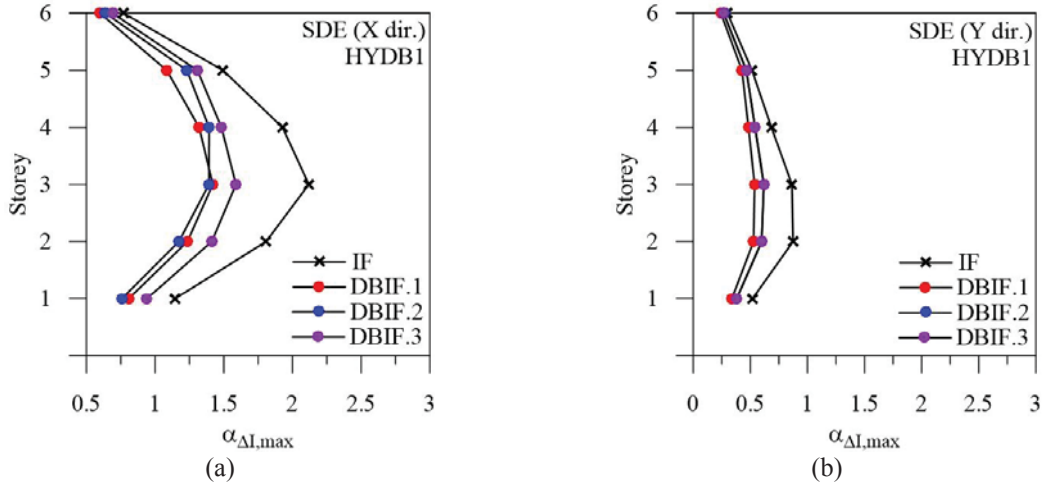

Figure 7. Maximum drift ratio of masonry infills for the original and retrofitted structures, at BDE: HYDB1.

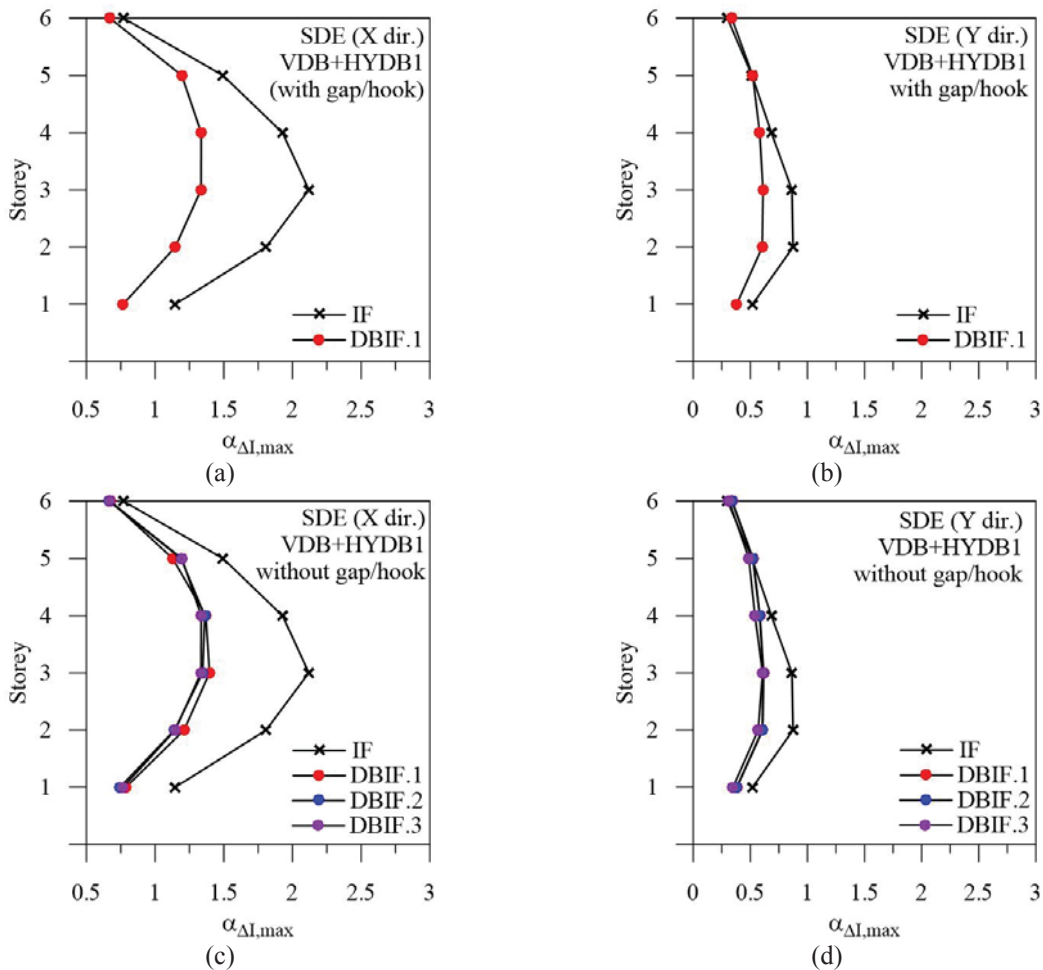

Figure 8. Maximum drift ratio of masonry infills for the original and retrofitted structures, at BDE: in-parallel HYDB1+VDB, with (a, b) and without (c, d) a gap-hook element in series with HYDB1.

On the other hand, extensive damage of masonry infills is resulted for the original structure along the X direction, characterized by infill walls with different percentage of openings, attaining strength reduction at all levels the only exception being the roof (Figure 7a). With regard to the retrofitted structures, the IO condition at SDE is not reached at intermediate storeys for the HYDB1 solution (Figure 7a), where only target performance levels at MCE are checked. The in-parallel combination of HYDB1 and VDB, with (Figure 8a) and without (Figure 8c) a gap-hook element in series with HYDB1, has not produced a marked improvement of the response that has practically unchanged for all examined cases and beyond the damage threshold at the intermediate levels. On the other hand, a significant reduction of  $\alpha_{\Delta I, \max}$  is attained when the in-parallel combination of HYDB1 and HYDB2 is considered, with fulfilment of the IO condition for all values of  $\Delta_x/h$  at MCE (Figure 9a). Finally, results corresponding to the in-series combination of the HYDB1 and HYDB2 are plotted in Figures 9c,d. It should be noted that HYDBs deriving from the in-parallel combination (see Table 4) are adopted when in-series arrangement of HYDBs is considered along X (see Table 5). As can be observed, a different arrangement of the HYDBs impairs their performance, resulting in non-operational condition of the retrofitted structure at SDE (Figure 9c), while the response is essentially the same as that obtained for the in parallel arrangement when Y direction is considered (Figure 9d).

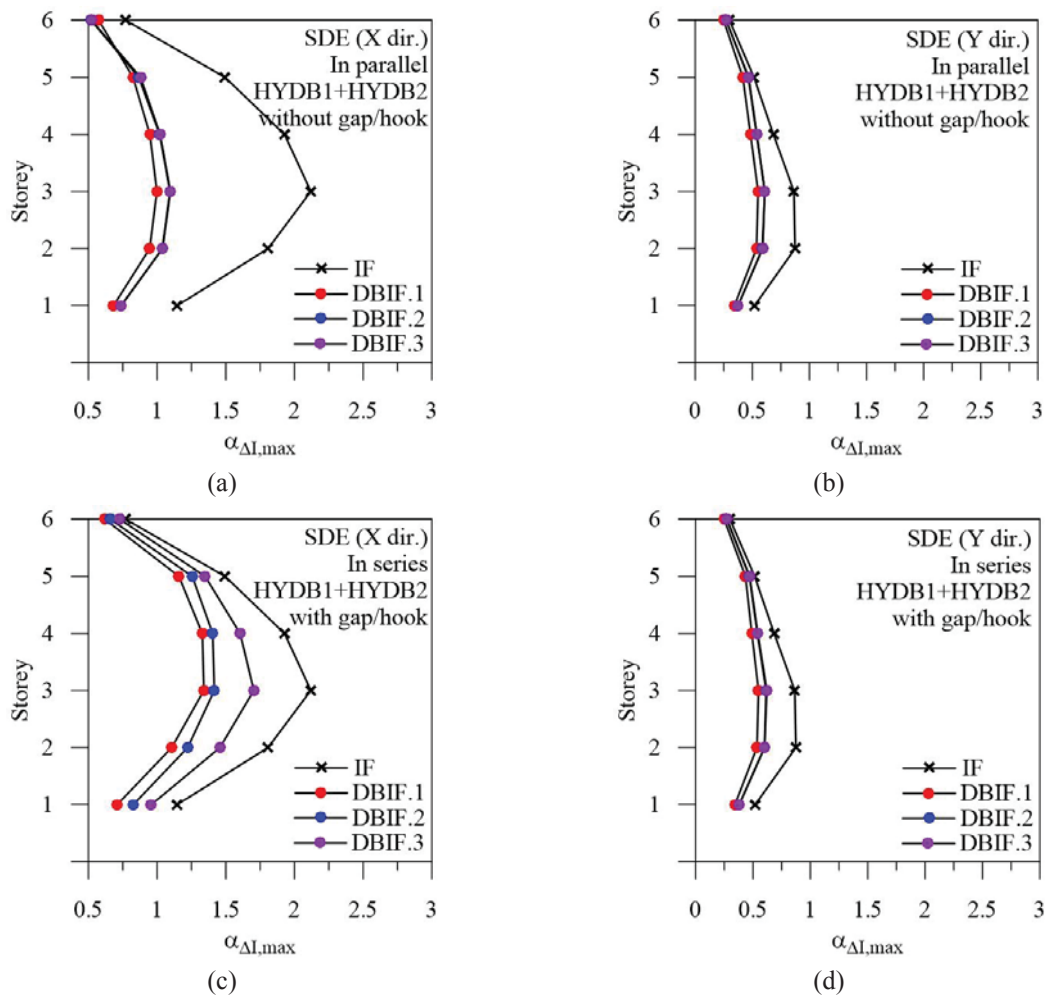

Figure 9. Maximum drift ratio of masonry infills for the original and retrofitted structures, at BDE: in-parallel (a, b) and in-series (c, d) HYDB1+HYDB2.

Afterwards, maximum drift ratio demand  $((\Delta/h)_{\max})$ , with inter-storey displacement  $\Delta_{\max}$  divided by the storey height  $h$  at BDE is shown in Figure 10, only considering HYDB1 since results corresponding to the other four arrangements are practically identical to those obtained for this solution. The effectiveness of the HYDBs is confirmed in both directions, with similar response for all performance levels in the Y direction (Figure 10b). Moreover, target displacements (see dashed lines) are never exceeded in the Y direction, while DBIF.i structures ( $i=1-3$ ) are resulted more flexible compared to the design thresholds in the X direction.

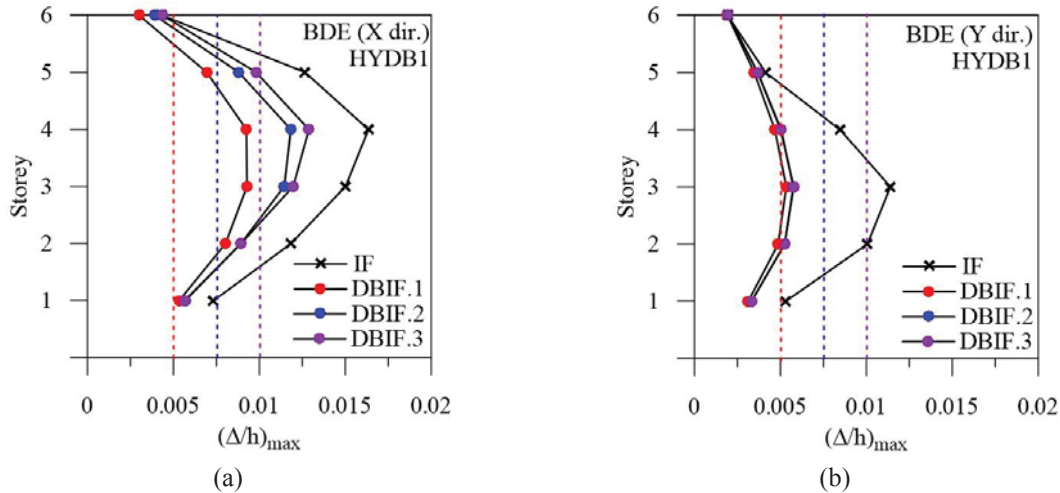

Figure 10. Maximum drift ratio for the original and retrofitted structures, at BDE: HYDB1.

Finally, maximum ductility demand  $(\mu_{D,\max})$  of the HYDBs at MCE are plotted in Figure 11, referring to the in-elevation and in-plan distributions. For all performance levels, the ultimate value ( $\mu_{D,u}=20$ ) is never reached, so avoiding collapse of the dissipative devices, and a rather uniform demand is resulted along Y (Figure 11b). As a confirmation, decreasing values of  $\mu_{D,\max}$  are obtained for increasing values of target displacement.

Figure 11. Maximum ductility demand of damped braces for the retrofitted structures, at MCE: HYDB1.

## CONCLUSIONS

A displacement-based design procedure of damped braces is proposed for optimizing the seismic performance of buildings, by minimizing damage of both non-structural and structural

elements at SDE and MCE, respectively. In order to quantify the enhanced seismic protection offered by the combination of HYDBs, designed at MCE, and HYDBs or VDBs, designed at SDE, comparison is made with a traditional solution consisting of HYDBs designed to guarantee the structural safety for severe ultimate limit state seismic events. Four alternative configurations are chosen for retrofitting the original building: in-parallel combination of HYDBs, at MCE, and VDBs, at SDE, with and without a gap-hook element in series with HYDBs; in-parallel and in-series combinations of HYDBs, with and without a gap-hook element in parallel with HYDBs at SDE. The procedure is applied for the seismic retrofitting of an RC framed structure, located in L'Aquila and designed for a medium-risk seismic zone, representative of the residential housing stock built in Italy during the 1990s. By carrying out nonlinear dynamic multi-stripe analysis of the original and retrofitted infilled structures, under three intensity levels provided by Italian seismic code, the following conclusions can be drawn.

The absence of openings along the Y direction results in a significant reduction of damage in the infill walls of the original structure at SDE, differently from strength reduction affecting many infill walls, with different percentage of openings, along the X direction. As expected, HYDBs designed at MCE are not able to ensure the IO condition of the retrofitted structure because too high yielding forces do not allow their activation at SDE. The in-parallel combinations of the HYDBs and VDBs does not produce a marked reduction of damage at SDE for masonry infills at the intermediate storeys, whose drift remains beyond the damage threshold. The in-parallel combination of HYDBs, half designed at SDE and half at MCE, allows the fulfilment of the IO condition; the same HYDBs with an in-series arrangement impairs seismic response of masonry infills at SDE. The effectiveness of the HYDBs is confirmed in both directions at BDE, with target displacements not exceeded in the Y direction, while more flexibility compared to the design thresholds is highlighted in the X direction. Finally, maximum ductility demand of the HYDBs at MCE confirm that their ultimate value is never reached, so avoiding collapse of the dissipative devices.

### Abstract

*To investigate the effect of damping ratio of non-structural components on floor acceleration demands in torsionally irregular buildings, reinforced-concrete moment-resisting frame buildings resting on flat ground (regular), and on hill slopes (irregular) are analyzed. Bi-directional linear dynamic analyses are conducted, by applying a suite of far-field ground motions, along two orthogonal axes, to obtain the floor response of the investigated frames. From the obtained floor acceleration response of the investigated buildings, the elastic floor response spectra are derived at two different floor levels: (i) the floor with maximum eccentricity in the irregular building, and the corresponding floor in the reference regular building; and (ii) at the roof levels, for both the regular and irregular buildings, for NSC's damping ratios of 1%, 2%, 5%, and 10%. The effect of damping ratio of the NSCs is studied in terms of damping modification factors, at three different locations on each of the considered floor levels, i.e. (i) at the flexible edge, (ii) at the center of rigidity, and (iii) at the stiff edge. The derived median damping modification factors, as obtained from the time-history analyses are compared with the recommendations of EC 8 and other existing models available in the literature. It is observed that the recommendations of EC 8 underpredict damping modification factors significantly, for non-structural components, tuned to structural modes of vibration, especially, for low damping ratios of the non-structural components, and also for relatively flexible non-structural components, for high damping ratio of the non-structural components.*

## 1 INTRODUCTION

Components and systems which are neither a part of the gravity load-resisting system nor a part of the lateral load-resisting system, but offer functionality to the buildings are termed as '*non-structural components*' (NSCs) or '*secondary systems*'. The typical examples of these NSCs in a building include electrical and mechanical equipments, architectural elements, bookshelves, suspended ceilings, furniture, and elevators. Typically, NSCs in buildings are either sensitive to the inertia forces, or to the inter-story drifts, or sometimes to both. Thus, based on sensitivity of their response, these NSCs are sub-categorized as: (i) acceleration-sensitive NSCs, (ii) displacement-sensitive NSCs, and (iii) combined acceleration- and displacement-sensitive NSCs. Seismic safety of NSCs is not only crucial due to their higher contributions to the total cost of the buildings (e.g. 70-80% of the total cost of the structure, especially in commercial buildings [1]), but, inoperability of these NSCs due to damage during earthquakes (specifically in lifelines buildings, e.g. hospitals) could lead to increased casualties, and delayed post-earthquake recovery operations. As a result, assessing the adequacy of the existing provisions, and developing new provisions, for ensuring seismic safety of NSCs is considered as an essential step in performance-based earthquake engineering.

It is a well-established fact in the literature [2-8] that dynamic response of the acceleration-sensitive NSCs is affected by the characteristics of both the structure and NSC itself. The typical structural characteristics which affects seismic response of NSCs include e.g. modal periods, height of the structure, stiffness distribution along the height of structure, strength of the structure, and its lateral-load resisting system [2-5]. On the other hand, the NSC's characteristics which affects their seismic response include the location of NSCs in the building, period of the NSCs, and the damping ratio of the NSCs [2-5]. A critical review of the existing literature suggests that most of the NSCs exhibit a low damping ratio, which typically ranges between 1-2% [9-12]. However, the various national building codes [13, 14], as well as most of the past studies [6-8] considered the NSC damping ratio equal to 5%.

Few studies conducted so far [2-5] identified the influence of damping ratio of the NSCs, on their floor acceleration demands. Medina *et al.* [2] conducted a study on the elastic and inelastic regular moment-resisting frame buildings, and observed that a lower damping ratio of the NSCs leads to amplification of the acceleration response, and a reduction in the NSC damping ratio from 5% to 2%, can result approximately 50% amplification in the acceleration demands on NSCs. Anajafi and Medina [4] conducted investigations on code designed structures to study the influence of the damping ratio of the NSC on the floor acceleration demands, and identified that the amplification/de-amplification in the floor accelerations, due to a decrease or increase in the damping ratio of the NSC, is a function of the tuning ratio (defined as the ratio of between the period of the NSC,  $T_s$ , to the fundamental period of the building,  $T_1$ ). Further, the effect of damping ratio of the NSCs was observed to be more pronounced, when NSCs are tuned to any structural modes of vibration, and less pronounced (minimal) for the non-tuned conditions. These findings of the investigations by Anajafi and Medina [4] were further supported by the recorded floor motions in 47 instrumented buildings, located in California [5]. Based on these findings, Anajafi and Medina [4] proposed a simplified tuning ratio dependent model to estimate damping modification factors (DMFs) to scale up or down the ordinates of the 5%-damped elastic floor response spectra, to account for the actual damping ratio of the NSCs.

The studies conducted so far to evaluate the influence of damping ratio of the NSCs on estimated floor acceleration demands are mostly based on NSCs mounted on regular buildings. The dynamic behaviour of the buildings is significantly altered by presence of torsion in the buildings, resulting coupling between translational and torsional motions. Thus, the present

study aims to investigate the influence of the damping ratio of NSCs on the floor acceleration demands, in torsionally irregular buildings. Accordingly, two different buildings, i.e. the reference regular building, and the irregular step-back building are considered for assessments in the present study. Bi-directional linear time-history analyses are conducted using a suite of recorded far-field ground motions. The elastic floor response spectra are obtained at two different floor levels, i.e. (i) at the floor with maximum eccentricity between centre of mass (CM) and centre of rigidity (CR) in the irregular building, and at the corresponding floor in the reference regular building; and (ii) at the roof levels, for both regular and irregular buildings, for NSC's damping ratios of 1%, 2%, 5%, and 10%. From the obtained floor response spectra, DMFs are derived at the CR in the reference regular building, and at CR, flexible edge (FE) and stiff edge (SE) in the irregular step-back building. The derived DMFs from time-history analyses are compared with the recommendations of EC 8 [14] and other models [4] in the existing literature, and the influence of the damping ratio of the NSCs on floor acceleration demands in torsionally irregular buildings is discussed and quantified.

## 2 NUMERICAL STUDY

### 2.1 Details of the investigated buildings

In the present study, two different 4-storied reinforced-concrete (RC) moment-resisting frame buildings, i.e. the reference regular building resting on plain ground, and the step-back irregular building on sloping ground are considered. The plan and elevations of the considered buildings are shown in Fig. 1. The step-back building considered in the assessments rest on a ground, having a slope of 2:1 (H:V), resulting a moderate slope angle of 27.3 degrees. In both, the regular and irregular buildings, the floor-to-floor height is considered as 3.3 m and set constant for all floors. In the irregular building, the ground supported short columns are of two different heights, i.e. 1.1 m and 2.75 m, in the successive storeys. Three-dimensional numerical models of the regular and irregular buildings are developed in OpenSees [15]. The structural elements, i.e. beams and columns are modelled as *ForceBeamColumn* elements, and floor slabs are defined as rigid diaphragms. The effective stiffness of RC beams and columns is modelled as per the recommendations of ASCE 41-17 [13]. Gravity loads (dead and live loads) on the considered buildings are applied as per the relevant Indian Standards [16, 17]. The investigated set of buildings are designed as the Special Moment Resisting Frame (SMRF) buildings, following the provisions of the Indian Standards [18-20], at the rock/stiff site, for the highest seismic zone (Zone V) in India. The member sizes are proportioned to result the longitudinal reinforcement in beams between 0.75-1.5 %, and in columns between 2-4 %, consistent with the typical design practice adopted in North India.

### 2.2 Dynamic characteristics and torsion in the investigated buildings

As highlighted in the past research [2-8], the floor response is significantly affected by the dynamic characteristics of the building, therefore, the dynamic characteristics of the investigated buildings are summarized in Table 1. Past investigations [21] on irregular step-back buildings suggest that in such buildings, the period corresponding to the fundamental mode of vibration is usually controlled by the number of storeys measured on the uphill side (Fig. 1(d)), irrespective of the direction under consideration. The very same effect is evident in the obtained periods of vibration in the present study (Table 1), where the first mode periods for the reference regular and irregular step-back buildings are in close agreements. In addition, the irregular step-back buildings are subjected to torsion, due to non-coincident locations of CM and CR (Fig. 1(b)). In the present study, CR is obtained considering the definition of the

single floor eccentricity. The additional details about estimation of CR in the investigated step-back building is available elsewhere [21]. Based on the obtained estimates of the eccentricity between CM and CR, it is observed that in the investigated irregular step-back building, the maximum torsional effects exist at the base floor (Fig. 1(b)), which further reduces while moving upwards, from base floor to the roof level (Fig. 1(a)). Accordingly, in the present study, the detailed results are reported for these two floor levels only.

Figure 1: Typical plan and elevation layouts: (a) floor plan of the step-back building, at the roof level, (b) floor plan of the step-back building, at the base foundation level, (c) elevation of the reference regular building, and (d) elevation of the step-back building, in the direction along the slope. The dashed lines define the boundary of the floor slab. CM and CR denotes the locations of the center of mass and center of rigidity in the floor plan. All dimensions are in meters.

### 2.3 Ground motions and linear dynamic time-history analyses

In the present study, the suite of 22 pairs of far-field recorded earthquake ground motions (having moment magnitudes varying between  $M_w$  6.5 to  $M_w$  7.6, with an average value of  $M_w$  7.0, as specified in the FEMA P695 [22]) are considered. For performing the bi-directional time-history analyses, both the horizontal components of seismic ground-motion records are

applied simultaneously, along the two orthogonal axes of the investigated buildings. A total of 44 linear time history analyses have been performed for each of the investigated buildings, by interchanging the two horizontal components of seismic ground-motions, along the two principal axes of the buildings. The viscous damping in the considered buildings is modelled as Rayleigh damping of 2.5% [23], and it is defined corresponding to the periods equal to 1.5 times the fundamental mode period ( $1.5T_1$ ), and the period resulting in a total of 95% cumulative mass participation, in both directions.

Building Type	Mode of Vibration	$T_{ALS}$	$T_{ACS}$	$\alpha_{mx}$ (%)	$\alpha_{my}$ (%)
Regular	First mode	1.23	1.73	72.00	71.00
	Second mode	0.40	0.53	08.07	09.28
	Third mode	0.24	0.28	02.50	03.52
Irregular	First mode	1.21	1.74	52.00	51.00
	Second mode	0.39	0.53	05.78	07.29
	Third mode	0.23	0.29	01.72	14.00

$T_{ALS}$  and  $T_{ACS}$  are the modal periods of vibration in the along and the across-slope directions of excitations, respectively, whereas,  $\alpha_{mx}$  and  $\alpha_{my}$  are the modal mass participation ratios in the along and across-slope directions of excitations, respectively.

Table 1: Dynamic characteristics of the investigated regular and irregular buildings.

### 3 RESULTS AND DISCUSSIONS: DMFS FOR FLOOR RESPONSE SPECTRA

In the present study, a total of 5,104 elastic floor acceleration response spectra are computed at different floor levels, along the height of both the regular and irregular buildings. These floor response spectra are computed at the CR in the regular building, and at the CR, the FE and the SE in the irregular building, for NSC's damping ratios of 1%, 2%, 5% and 10%. The obtained floor acceleration response spectra are used to estimate DMFs, i.e. the ratio between the floor spectral acceleration ordinate at any given period, corresponding to a NSC's viscous damping ratio,  $\xi_s$ , to the floor spectral acceleration ordinate at the same period, corresponding to NSC's viscous damping ratio of 5%, as defined through Eq. 1

$$DMF(T_s, \xi_s) = \frac{S_a(T_s, \xi_s)}{S_a(T_s, 5\%)} \quad (1)$$

where,  $DMF(T_s, \xi_s)$  is the damping modification factor corresponding to NSCs period of vibration,  $T_s$ , and damping ratio,  $\xi_s$ ,  $S_a(T_s, \xi_s)$  is the floor spectral acceleration corresponding to NSCs period of vibration,  $T_s$ , and damping ratio,  $\xi_s$ , and  $S_a(T_s, 5\%)$  is the floor spectral acceleration corresponding to NSCs period of vibration,  $T_s$ , and damping ratio of 5%. These DMFs are derived at all the floors, for both the regular and the irregular building, however, the results at the base floor and at the roof level are reported herein, for the sake of brevity.

Figure 2 presents the variations of DMFs in the across-slope direction (in which the torsional effects are present in case of the irregular step-back building), for the investigated regular and irregular buildings, at the base floor. It is to be noted that at the base floor, the CR and the SE are in close proximity to each other (Fig. 1(b)), and thus, the median floor response spectra at the CR and the SE overlaps with each other, in case of the irregular building. It can be observed that at the base floor level, the median DMFs estimated from the elastic floor re-

sponse spectra (derived from the floor motions) at CR are in close agreement with those recommended in EC 8, for non-tuned response of the NSCs, whereas, non-conservative for the tuned response of the NSCs, especially, when NSCs are tuned to higher modes of vibration. These observations can be attributed to the fact that the NSCs are subjected to limited filtering effects by the structure, due to insignificant contributions of the different modes of vibration at the base floor level.

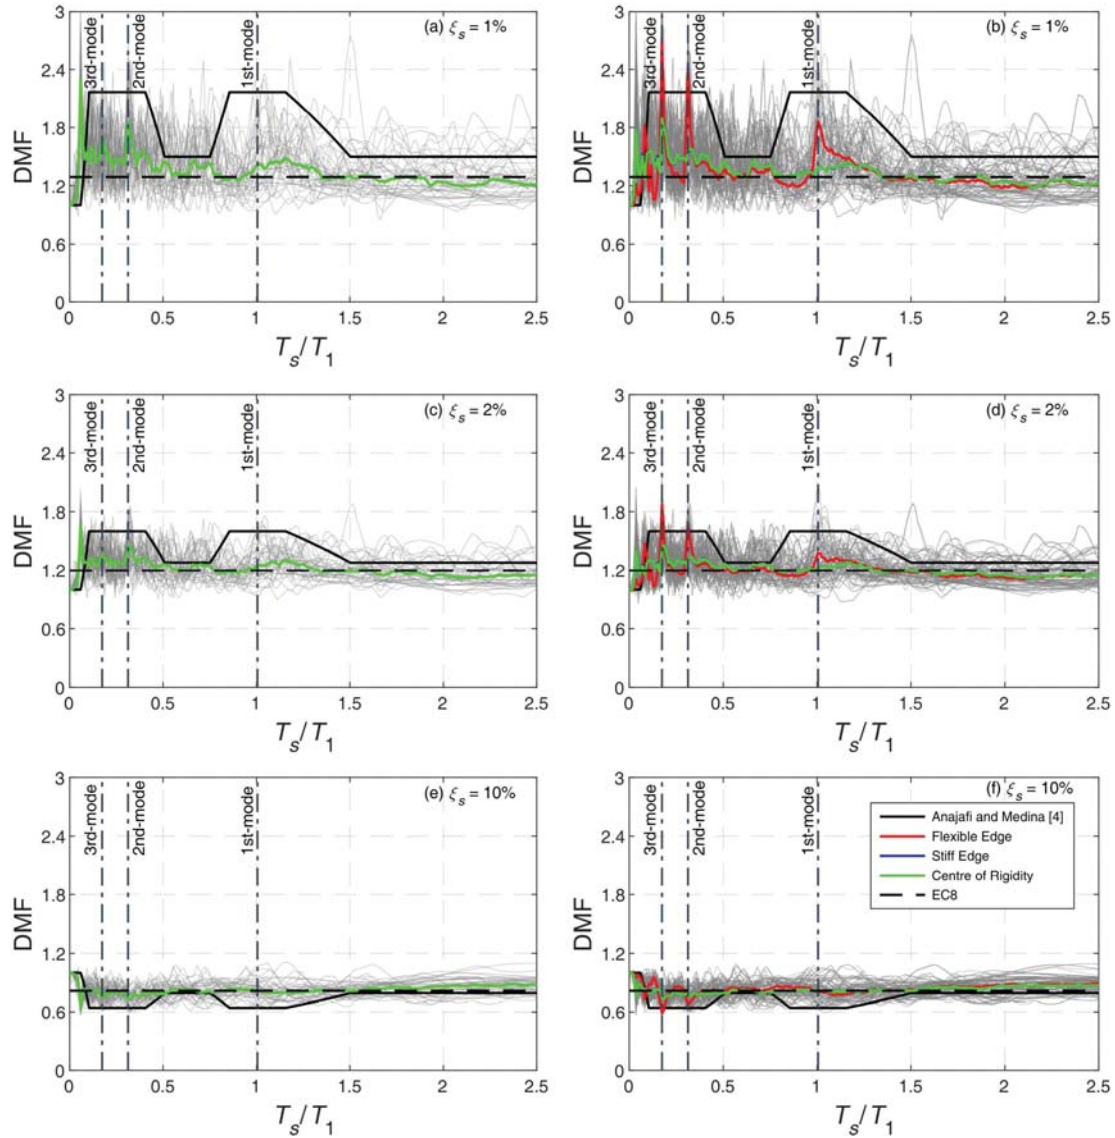

Figure 2: Comparisons of DMFs at the base floor (computed using linear dynamic analyses), with the available model in literature and EC 8. The first column in the plots corresponds to the derived DMFs for the regular building, whereas, the second column corresponds to the derived DMFs for the irregular building.

In case of irregular building, when NSCs are tuned to higher modes of vibration, the estimated DMFs at FE from EC 8 are underestimated by a factor of 2.12 and 1.56 (Fig. 2(b) and 2(d)), for NSC's damping ratios of 1% and 2%, respectively. On the other hand, at the base floor level, the DMF model proposed by Anajafi and Medina [4] provided significantly conservative estimates of the DMFs at the CR (Fig. 2(a)-(d)), for low damping ratios of the NSCs (i.e. 1% and 2%). However, this conservatism vanished at the FE, especially under the tuned response of the NSCs corresponding to higher modes (Fig. 2(b) and 2(d)). Further, the DMFs

obtained from EC 8 (at the CR and the FE), corresponding to NSC's damping ratio of 10% are observed to be reasonable at the base floor, upto tuning ratios of 1.50 (Fig. 2(e)-(f)), for both the regular and irregular buildings. Contrarily, at the base floor, for NSC's damping ratio of 10%, the DMF model proposed by Anajafi and Medina [4] provided non-conservative estimates of the DMFs under tuned response of NSCs (Fig. 2(e)-(f)), at the CR and the FE.

Figure 3 presents similar results at the roof level of regular and irregular buildings investigated in the present study. It is to be noted that at the roof level, only minor eccentricity exist in between CM and CR (Fig. 1(a)), thus, at the roof level, torsional effects are minimal. This effect is manifested in the form of almost overlapping median floor response spectra, for a given damping ratio of interest, at the CR, the FE and the SE (Fig. 3(b), 3(d), and 3(f)).

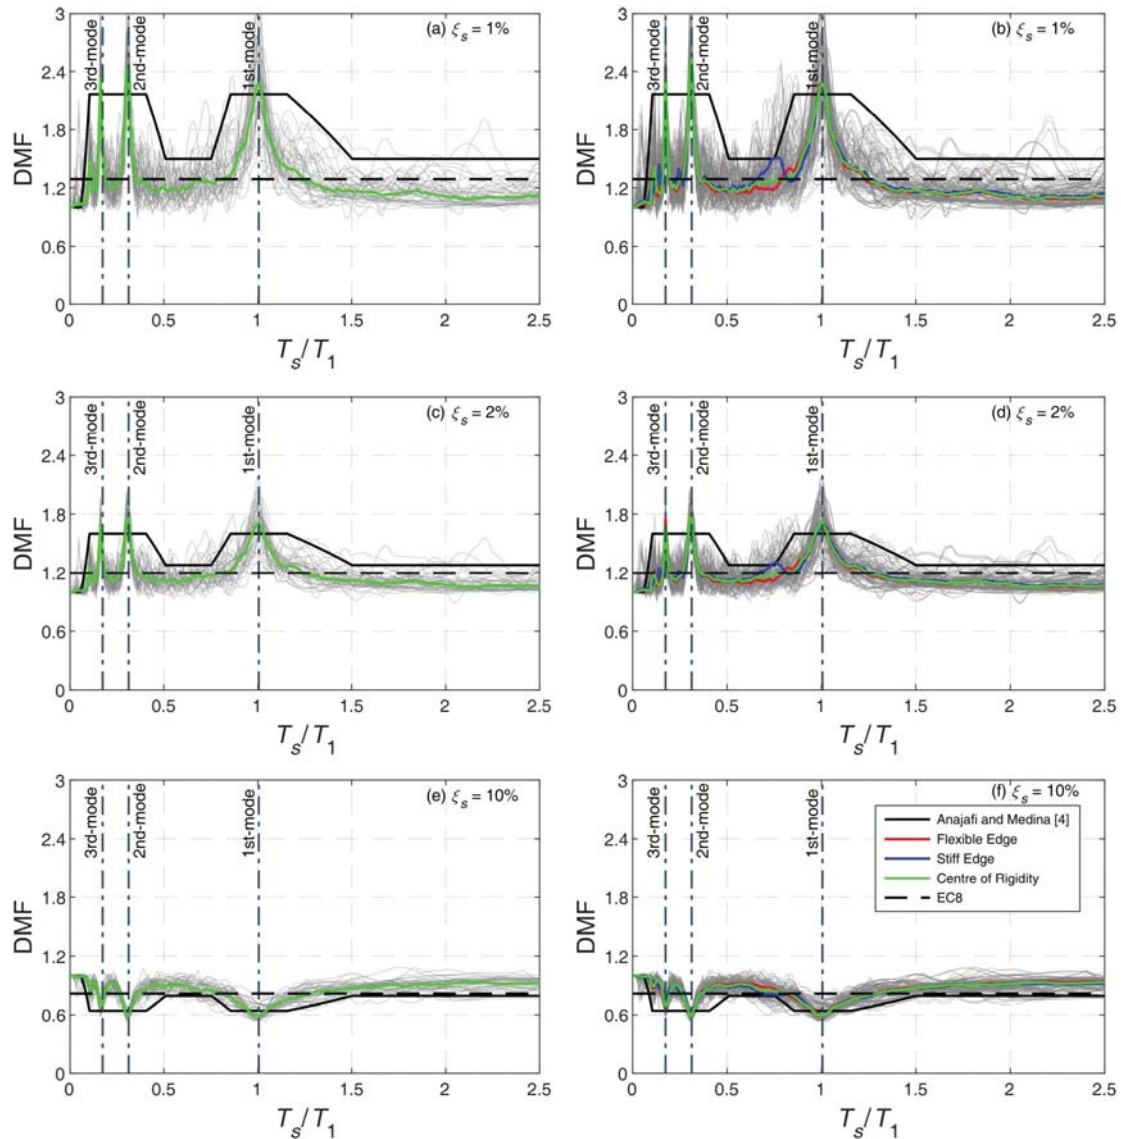

Figure 3: Comparisons of DMFs at the roof level (computed using linear dynamic analyses), with the available model in literature and EC 8. The first column in the plots corresponds to the derived DMFs for the regular building, whereas, the second column corresponds to the derived DMFs for the irregular building.

From Fig. 3, it is further evident that DMFs are tuning ratio dependent, and sharp peaks are observed in DMFs corresponding to the structural modes of vibration. As a result, the DMF model recommended in EC 8 underestimated median DMFs (obtained from floor response

spectra) by a factor of 1.94 and 1.50 (Fig. 3(a)-(d)), for NSC's damping ratios of 1% and 2%, respectively, when NSCs are tuned to the structural modes of vibration. For the non-tuned response of the NSCs having low damping ratios (i.e. 1% and 2%), the DMF model recommended in EC 8 is observed to be reasonable, at the roof level (Fig. 3(a)-(d)). Contrarily, the model proposed by Anajafi and Medina [4] provided slightly non-conservative estimates of DMFs for tuned response of the NSCs to the structural modes of vibration, for both regular and irregular buildings ((Fig. 3(a)-(d))). For high damping ratio of NSCs (i.e. 10%), at the base floor level as well as at the roof level, both the models, i.e. EC 8 and the one proposed by Anajafi and Medina [4] provided slightly non-conservative estimates of DMFs, for tuning ratios more than 1.50 (Fig. 2(e)-(f) and Fig. 3(e)-(f)), at both locations on the floor plan, i.e. at the CR and at the FE.

The observations presented in the study highlighted some of the shortcomings of the existing models in the literature and building codes to account for the actual damping ratio of NSCs in its seismic design and warrants a need for more reliable estimation of DMFs, for seismic design of NSCs.

#### 4 CONCLUSIONS

This study investigated the effects of damping ratio of non-structural components on floor acceleration demands for the reference regular and irregular step-back buildings. A total of 88 bi-directional linear time history analyses were conducted, and 5,104 floor response spectra were evaluated at different floor levels of the investigated buildings. DMFs were computed for the NSC damping ratios of 1%, 2%, 5%, and 10% and compared with the existing DMF prediction model available in the literature as well as in EC 8. The following major conclusions are drawn from this study:

- Consistent with the observations of the earlier studies [4-5], DMFs are observed to be tuning ratio dependent. This observation is found to be valid for both regular and torsionally irregular step-back building, investigated in the present study.
- Due to the presence of severe torsion at the base floor level, the estimated (median) values of DMFs, at the CR and the FE differs significantly, for the irregular step-back building. This effect was observed to be more pronounced for low damping ratio of the NSCs (i.e. 1% and 2%), especially, when NSCs are tuned to structural modes of vibration.
- For the range of damping ratios investigated in the present study, the DMF model recommended in EC 8 under predicted the median DMFs for the floor response spectra upto a factor of 2.12, when NSCs were tuned to structural modes of vibration.
- For higher damping ratio of NSCs (i.e. 10%), due to limited filtering effects at the base floor, the model proposed by Anajafi and Medina [4], provided non-conservative estimates of DMFs, for NSCs tuned to structural modes of vibration. Further, both the investigated models, i.e. the existing DMF prediction model [4] as well as EC 8 were found to be non-conservative, for relatively flexible NSCs ( $T_s/T_1 > 1.50$ ).

The present study was conducted considering mid-rise regular and irregular step-back buildings, exhibiting their elastic response. Further the study used ground motions recorded in far-field. Separate studies are recommended to further examine DMFs for other buildings types, for ground motions having different characteristics, and also considering the inelastic response of the buildings.

## 5 ACKNOWLEDGEMENTS

The first author's fellowship is granted by the Ministry of Education (MoE), Government of India (GoI). The investigations reported in this paper were conducted under the ISIRD project grant (F.No. 9-385/2019/IITRPR/3220) of the second author. The financial support received from both MoE and ISIRD Project Grant of IIT Ropar is gratefully acknowledged. The seismic ground-motion records used in this study were obtained from PEER NGA WEST 2 database.

### Abstract

*The severe socio-economic impact of recent earthquakes has further highlighted the existing mismatch between societal expectations and reality of seismic performance of modern buildings. Targeting the traditional Life-Safety level is not enough when dealing with new building design, thus the seismic scientific community is currently aiming to raise the bar in terms of seismic/structural safety. To achieve this goal, different strategies might be adopted, as implementing more advanced design methodologies, increasing the seismic demand (design) level and/or switching from a traditional/monolithic building system to an innovative high performance low-damage structure, capable to withstand high levels of shaking without being (significantly) damaged. Based on this motivation, the paper aims at comparing – through a parametric study – the cost/performance of Reinforced Concrete case-study buildings designed for increasing level of seismic intensity (low-to-high) according to: a) alternative design approaches (force-based vs displacement-based) and b) different earthquake-resisting technologies (monolithic vs low-damage). Thirty-seven parametric configurations are investigated. Analytical/numerical investigations are carried out to determine the building capacity curves and loss assessment investigations are performed to compute the Expected Annual Losses (EAL). Results highlight the convenience of a displacement-based design approach, allowing for a better control of the building performance in the plastic domain, as well as of the adoption of a low-damage technology, leading to a very high performance and significantly reduced economic losses for a small increase of the initial investment costs.*

---

# 1 INTRODUCTION

The current performance-based seismic design of new buildings is based on the acceptance of severe level of damage in buildings after major (design level) earthquakes. When subjected to seismic shakings, multi-story structures are expected to concentrate the inelastic demand (therefore damage for traditional technology) in plastic hinges zones located at the end sections of the structural members, according to the hierarchy of strengths or capacity design principles (Figure 1a). Furthermore, according to a Life Safety design approach, attention is typically given to the structural skeleton only, whilst non-structural elements can be very vulnerable and consequently susceptible to high level of damage under low-to-moderate intensity earthquakes. Recent seismic events, in particular the Christchurch earthquake 2011 [1], have further highlighted the limits of this traditional design approach. Although modern buildings behaved as expected, resisting to even higher than code design-level earthquakes, with no collapse and safeguarding humane life, severely damaged buildings were often deemed too expensive to be repaired and were demolished. Targeting the Life-Safety objective is thus not enough when dealing with new building design. As a matter of fact, in recent years research is raising the bar in seismic design aiming at enhanced structural/seismic safety levels for our modern structures in order to fulfil the society demand in terms of seismic resilience, avoiding massive consequences in terms of socio-economic losses.

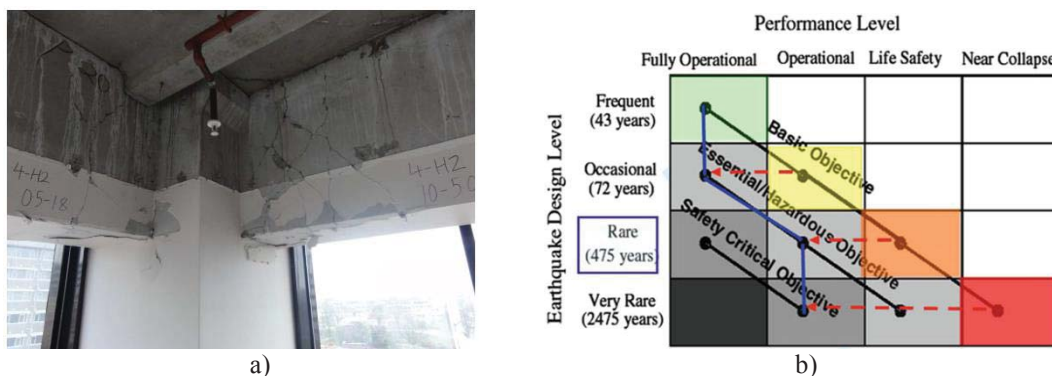

Figure 1. a) Example of beam plastic hinge from a 22 story RC Building [1]; b) Seismic performance design objective matrix [2] modified to emphasise a damage-control objective and design philosophy [3,4].

To reach this aim, different strategies might be adopted to improve the seismic safety and economic resilience of buildings (and communities) as 1) implementing more appropriate and advanced design methodologies and/or 2) increasing the seismic demand design level and/or 3) adopting high-performance earthquake-resistant solutions. In such context, growing attention has been recently dedicated to the development of innovative damage-mitigation technologies, aiming at the control and reduction of the post-earthquake damage. Apart from well-known advanced technologies such as base isolation and supplemental dissipative braces, particular interest is being received by more recently developed “low-damage” systems, based on post-tensioned rocking mechanisms, the so-called PRESSS technology (PREcast Seismic Structural System) for concrete structures [5,6,7,8]. This moment-resisting system combines self-centering capacity, through post-tensioned bars/tendons in the structural elements, and dissipating capabilities, provided either by internally located mild steel bars - as per the first generation of this technology - or using externally replaceable dissipaters, more recently developed [9]. The system behavior results in a dissipative and re-centering Flag-Shape hysteresis cycle [10] allowing for negligible permanent deformations after earthquakes.

Nevertheless, a common obstacle to the wider application of advanced seismic design methodologies and innovative low-damage technologies is often the uninformed perception/prejudice that such approaches would lead to substantially higher and unaffordable costs. Furthermore, rarely the economic benefits associated to a significantly reduced level of damage and thus direct and indirect losses, are computed. This paper intends to shed a light on this important topic, providing robust evidences for informed decision-making on the opportunity (and associated solutions) to raise the bar towards more resilient communities.

## 2 RESEARCH OUTLINE

Based on the above discussion, this work fits into the context of society's growing need for safer and more economically resilient buildings and aims to prove the beneficial effects of designing in a more conscious and controlled way. These objectives are pursued through a parametric study intended to compare the cost/performance of different case-study buildings with different design parameters, design methods, and/or construction technologies. A summary of all the resilient-enhanced strategies and cases investigated within this paper are summarized in the following Figure 2.

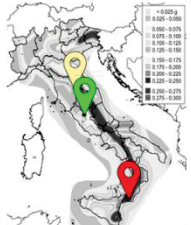

Design methodology		Seismic demand	
Force-Based Design	<div>Drift target</div> <div>1.0%</div> <div>1.5%</div> <div>2.0%</div>	Importance Class → Importance Coeff.	
		II	1.0
Displacement-Based Design		III	1.5
		IV	2.0
Technology		Seismicity area	
Monolithic cast-in situ connections		Low seismicity	
Hybrid low-damage connections		Moderate seismicity	
		High seismicity	

Figure 2: Summary of resilient-enhanced strategies and cases involved in the study.

Alternative design methods are adopted, namely the traditional Force-Based Design (FBD) and the more recently developed and advanced Direct Displacement-Based Design (DDBD), in order to highlight that a design based on (targeting and thus controlling/limiting) displacements rather than forces allows to better control the performance of buildings in the plastic domain. The FBD is implemented following the prescriptions of the Italian code, NTC 2018 [11], thus the method is based on the calculation of the natural period of the structure by alternative formulations and on the choice of the behavior factor,  $q$ , depending on the structural typology, its statically indeterminate level and the design criteria (ductility class). These assumptions do not allow to properly control the building structural behavior. On the other hand, the DDBD method [12] is based on the initial choice of a target drift, thus the seismic behavior/performance of the structure is controlled upfront by the designer and his design choice.

In addition to the two different design methodologies, the increase of seismic safety is studied through the variation of the Importance Level or Class (II, III, IV, i.e. from ordinary/residential buildings to strategic buildings), leading to a consequent increase of the seismic demand (design) level. This means that the buildings are firstly designed as ordinary residential structures, then as strategic structures such as hospitals, firefighter station, police station, etc. According to NTC 2018 [11], the variation of the Importance Class involves a different coefficient, indicated as  $C_u$ , on which the value of the Reference Period ( $V_R$ ) of the building, and consequently of the Return Period ( $T_R$ ) of the seismic demand at different limit states, depends. Thus, in practical terms, this coefficient modifies the design response spectra.

Then, in terms of technology, two different types of structural connections are studied: 1) the traditional/monolithic cast-in-situ system and 2) the hybrid low-damage PRESSS solution. The monolithic connections consist of steel reinforcement (steel B450C) within the structural members (concrete C 45/55) and are designed according to the NTC 2018 [11], while the hybrid connections comprise mild steel bars (dissipation) and unbonded post-tensioning tendons (self-centering).

Furthermore, the case-study buildings are designed referring to three different seismic zones located in Italy: Fabbrica di Roma (low seismicity,  $PGA = 0.15\text{ g}$ ), Subbiano (moderate seismicity,  $PGA = 0.25\text{ g}$ ) and Reggio Calabria (high seismicity,  $PGA = 0.35\text{ g}$ ), selected according to their PGA at the Ultimate Limit State (ULS). Moreover, when the DDBD is adopted, three alternative levels of target drift ratios, namely 1%, 1.5%, 2%, are identified to analyze the structural behavior and the economic losses when targeting different level of drift.

Therefore, a total of 37 parametric building configurations are employed. Analytical/numerical investigations are developed to analyze the building performance of all case-studies. Then, for each configuration, construction costs (material and labour costs) are computed to determine the short-term cost of the alternative technological solutions. Finally, loss assessment analyses are performed to obtain the Expected Annual Losses (EAL) following two alternative procedures [13, 14]. Results are finally compared for all the configurations under consideration in terms of seismic costs at the end of the building service life (50 years). This represents an interesting data for the purpose of the economic comparison, proving that designing for higher levels of safety and resilience is cost-effective, not only beneficial from a seismic performance point of view. In fact, this research will impact with the evidence that the choice of a building system/design strategy should be addressed by its long-term economic convenience. Consequently, highlighting that an improved design approach costs less, would hopefully trigger a step-change in the near future and thus represent a major step forward for the overall society and its well-being.

### 3 COST/PERFORMANCE PARAMETRIC STUDY

#### 3.1 Case-study buildings

The case-study is a 5-story Reinforced Concrete building with geometrical configuration as indicated in Figure 3. This structure has been selected from a previous study developed by *Bianchi et al.* [15]. The first two floors have residential use, while the other two are offices. The structural skeleton consists of seismic resistant four-bay frames in one direction and shear walls in the perpendicular direction.

Figure 3: Multi-story case-study RC building (modified after Bianchi et al. 2021).

In this paper, the study is implemented focusing on the frame direction only. As described in the previous section, 37 different combinations of the frame system are considered to develop the proposed investigation. A summary of all the considered frame systems is presented in Table 1. It can be highlighted from this table that the structural cases increase when moving towards a higher seismicity level and importance class. In fact, in these cases the seismic design through the DDBD methodology (the sole to be herein used in case of PRESSS-technology solution) can be developed referring to different (and higher) drift targets.

Seismicity level	Importance Class					
	II		III		IV	
Low	Monolithic	FBD	Monolithic	FBD	Monolithic	FBD
		DDBD (0.8%)		DDBD (0.8%)		DDBD (0.8%)
	PRESSS	DDBD (0.8%)	PRESSS	DDBD (0.8%)	PRESSS	DDBD (0.8%)
Moderate	Monolithic	FBD	Monolithic	FBD	Monolithic	FBD
		DDBD (1.0%)		DDBD (1.0%)		DDBD (1.0%)
	PRESSS	DDBD (1.0%)	PRESSS	DDBD (1.0%)	PRESSS	DDBD (1.0%)
High	Monolithic	FBD	Monolithic	FBD	Monolithic	FBD
		DDBD (1.0%)		DDBD (1.0%)		DDBD (1.0%)
		DDBD (1.5%)		DDBD (1.5%)		DDBD (1.5%)
		DDBD (2.0%)		DDBD (2.0%)		DDBD (2.0%)
	PRESSS	DDBD (1.0%)	PRESSS	DDBD (1.0%)	PRESSS	DDBD (1.0%)
		DDBD (1.5%)		DDBD (1.5%)		DDBD (1.5%)
		DDBD (2.0%)		DDBD (2.0%)		DDBD (2.0%)

Table 1: Selected frame configurations.

### 3.2 Design methodology

The case-study structures are designed at ULS level following two different methodologies: Force-Based Design (FBD) and Displacement-Based Design (DDBD). Taking into account the three different low-to-high seismicity zones (Figure 4a) as well as the three Importance Classes (II, III, IV) described in NTC 2018 [11], accounting for the importance of the building and providing a coefficient (1.0, 1.5, 2.0) which increases/decreases the seismic action, 9 alternative configurations are designed in case of FBD. As an example, Figure 4b presents the response spectra obtained for the case of high seismicity zone and varying the Importance Class.

Figure 4: a) Elastic (5% damped) acceleration and displacement response spectra for the three different seismic zones; b) design acceleration response spectra for the case of high seismicity and varying the Importance Class.

Following the NTC 2018 [11] procedure, the design acceleration response spectra at ULS are obtained from the 5% elastic spectra properly scaled by the behaviour factor (i.e.  $q = 3.9$ , for multi-storey frame reinforced concrete structures with regular height and plan, ductility class B). Thus, the base-shear is calculated by multiplying the spectral acceleration at the first natural period of the structure ( $T_1 = 0.68s$ , function of the building height  $H$  and a coefficient  $C$  based on the structural typology) and the building mass (1, 2). Table 2 summaries the seismic response of the case-studies (monolithic) designed following the codified FBD approach.

$$T_1 = C \cdot H^{3/4} \quad (1)$$

$$V_b = S_a(T_1) \cdot m \quad (2)$$

Seismicity level	Importance Class	Base Shear [kN]
Low	II	1206
	III	1391
	IV	1523
Moderate	II	1705
	III	1925
	IV	2122
High	II	2826
	III	3397
	IV	3785

Table 2: Configurations designed by the FBD approach.

Concerning the DDBD, the procedure consists in the evaluation of the equivalent building Single Degree of Freedom (SDoF) system with effective elastic stiffness ( $K_{eff}$ ), effective mass ( $m_{eff}$ ), effective height ( $H_{eff}$ ) and equivalent viscous damping related to the target displacement ( $\Delta_d$ ). Appropriate design inter-story drift limits are selected based on design code, good practice and/or material strain limits. Table 3 summarizes the various configurations designed following the DDBD approach, by reporting the design drift level, the effective period as well as the base shear, calculated as per (3, 4).

$$K_{eff} = (2\pi/T_{eff})^2 \cdot m_{eff} \quad (3)$$

$$V_b = \Delta_d \cdot K_{eff} \quad (4)$$

Seismicity level	Importance Class	Monolithic		PRESSS	
		Design Drift [%]	Base Shear [kN]	Design Drift [%]	Base Shear [kN]
Low	II	0.8	1797	0.8	1865
	III	0.8	1867	0.8	1977
	IV	0.8	1903	0.8	2161
Moderate	II	1.0	2004	1.0	2101
	III	1.0	2006	1.0	2111
	IV	1.0	2269	1.0	2505
High	II	1.0	2415	1.0	3264
	II	1.5	2274	1.5	3008
	III	1.0	3281	1.0	4468
	III	1.5	2874	1.5	3763
	III	1.8	2218	1.8	2989
	IV	1.0	3660	1.0	5822
	IV	1.5	3340	1.5	4614
	IV	2.0	2583	2.0	3041

Table 3: Configurations designed by the DDBD approach.

### 3.3 Numerical investigation

Numerical non-linear static (push-over, push-pull) analyses are carried out in SAP2000 software following a lumped-plasticity approach. The monolithic buildings are modelled by mono-dimensional elastic elements with plastic hinges at the end sections, where the inelasticity is represented by appropriate moment-curvature relationships and stiffness-degrading hysteresis rules (Takeda). The PRESSS connections are modelled using elastic members with two rotational springs working in parallel at the connection interfaces; 1) one simulating the re-centering contribution from the unbonded post-tensioning tendons (non-linear elastic hysteresis), 2) the other one representing the energy dissipation contribution from the mild steel dissipaters (elasto-plastic or bilinear hysteresis).

Non-linear static (pushover) analyses are performed to determine the building capacity curves, then converted into acceleration-displacement functions within an Acceleration Displacement Response Spectra (ADRS) domain. Introducing in the same graphs the code-design spectra and applying the Capacity Spectrum Method (CSM) [16, 17], with the building equivalent viscous damping being derived from push-pull analyses, the maximum expected seismic displacements and accelerations (performance) at each intensity level (namely SLO, SLD, SLV, SLC, or, Immediate Operational, Damage Control, Life Safety and Collapse Prevention, as indicated in the NTC 2018 [11]) can be identified. As an example, Figure 5 shows the acceleration-displacement performance points for the case of SLV, high seismicity and Importance Class IV.

Figure 5: Capacity curves in the Acceleration-Displacement Response Spectrum (ADRS) for both a) Monolithic and b) Low-damage skeletons, high seismicity level (PGA=0.35g), SLV limit state, Importance Class IV.

By comparing the results in terms of base shear for all the case-studies, important considerations supporting the thesis of this paper can be found. Specifically, as presented in Figure 6, ally, the base shear obtained by the FBD has a linear dependence with the Peak Ground Acceleration (PGA) for each seismic zone, however in high seismic zone its value tends to grow faster than the acceleration value. For the cases designed by DDBD, it can be highlighted that the base shear decreases as the design drift increases, due to a greater (accepted) target displacement and thus a lower stiffness, and no direct proportionality between base shear and Peak Ground Acceleration can be found. Furthermore, when considering the hybrid low damage skeleton, a slightly higher base shear – due to the lower hysteretic damping value – is obtained when compared to the traditional solution. This is due to the resisting moment capacity, which is distributed between dissipative and recentring systems, consequently the dissipation is lower when compared to the case of monolithic connections.

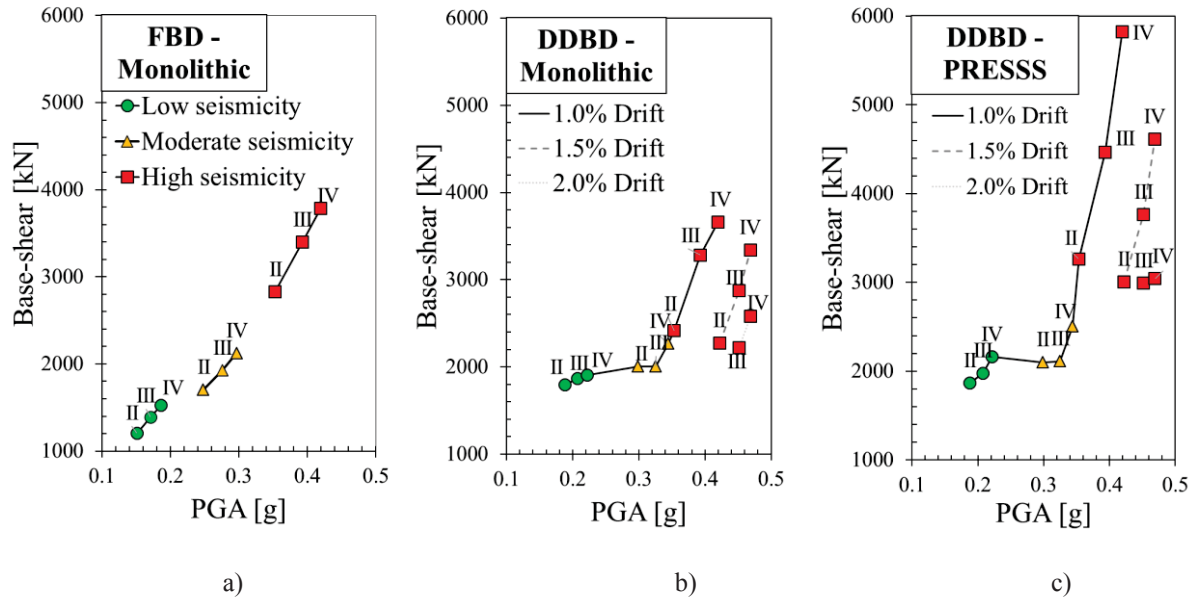

Figure 6: Base shear/PGA curves for: the monolithic structures designed by a) FBD and b) DDBD; c) the low-damage PRESSS structures designed by DDBD (II, III, IV refer to the Importance Class).

Referring to the same seismicity zone, results are also compared by varying the design methodology and type of connection system (Figure 7). Focusing on the monolithic structures, it can be noticed that the FBD underestimates the building base shear in case of low and moderate seismicity zones while overestimate its value in case of high seismicity zone, when compared to the DDBD results, assumed to provide a more reliable (“correct”) structural response. This highlights that the FBD method does not allow to have a proper control on the nonlinear behavior of the structure, due to a design procedure based on the selection of a behavior factor,  $q$ , representing the dissipation capability of the building under consideration.

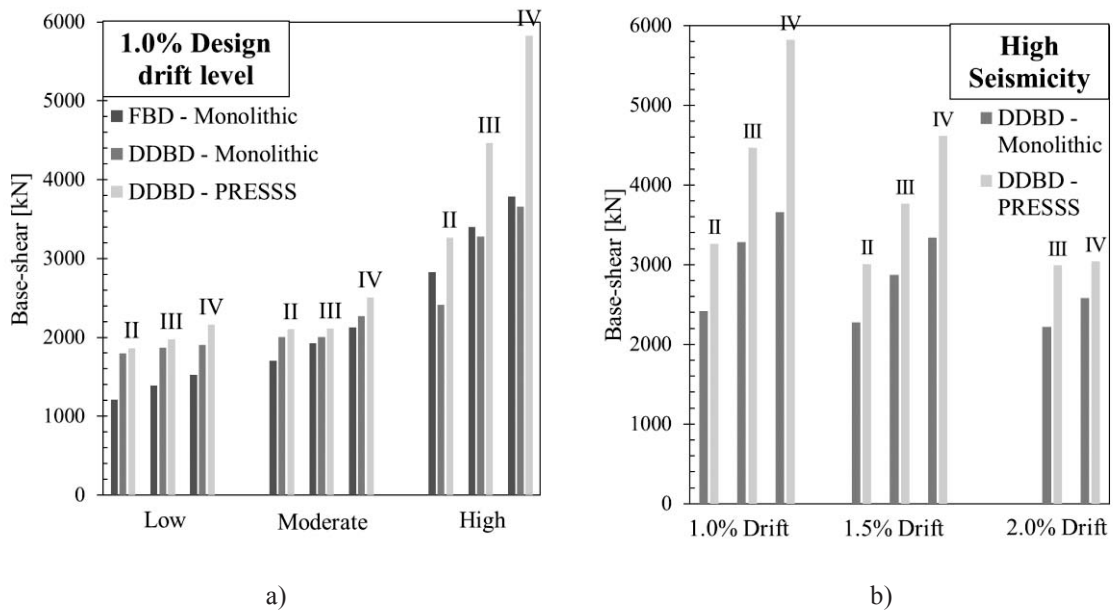

Figure 7: Comparison in terms of Base Shear for: a) alternative design methodologies (at the same design drift level for DDBD) and all the seismicity zones; b) different technological solutions at the same seismicity level, in case of DDBD and various design drift levels.

### 3.4 Construction costs

For each structural configuration involved, construction costs are computed based on the Regional Public Works Price List of the Friuli-Venezia Giulia region (IT), where the cost of each material already account for the specific labour cost. The cost of the monolithic structure is calculated taking into account the quantities of concrete and steel needed for the structural elements, as well as the cost of formworks, safety, excavation, foundations and geotechnical surveys. For the PRESSS structures, the cost of the tendons and their post-tensioning, the corrugated tube and the crane rental are added to the above items (apart from the cost of in-situ formworks, not needed for the precast elements). In order to define an overall cost of the multi-story building, since the seismic-resistant frames have only been designed for the purpose of this study, the other beams, columns and walls have been calculated taking into account code prescriptions and considering standard geometrical dimensions for each element.

A comparison in terms of construction cost for the alternative case-study configurations is reported in the following Figure 8 and Table 4. It can be noticed that the FBD provides costs equal to, or higher than, the DDBD for the same seismicity zone. Moreover, as far as a comparison between technologies is concerned, it can be highlighted that the PRESSS technology leads to an increase of 6.7-8.5% in low and moderate high seismic regions with peaks at 12.5-20.20% in high seismic region, for the construction cost when compared to the monolithic system, due to the presence of tendons/cables and their post-tensioning. In particular, the most expensive cases are those with 1.0 % design drift level in high seismic zone, as confirmed by the results obtained in the previous paragraph in terms of base shear.

Overall for a given seismicity the increase of direct costs associated with a significant raise for the bar, moving from Importance Class II to III and IV, is counter-intuitively rather moderate, ranging between 0.8-2.2%, 0.6-3.8%, 6%-13.3% in low seismic, moderate seismic and high seismic. Thus arguably, a significant level of higher safety of new construction can be achieved with minimal-moderate investment. In the next paragraph the tangible life-span economic benefits of such approach are investigated.

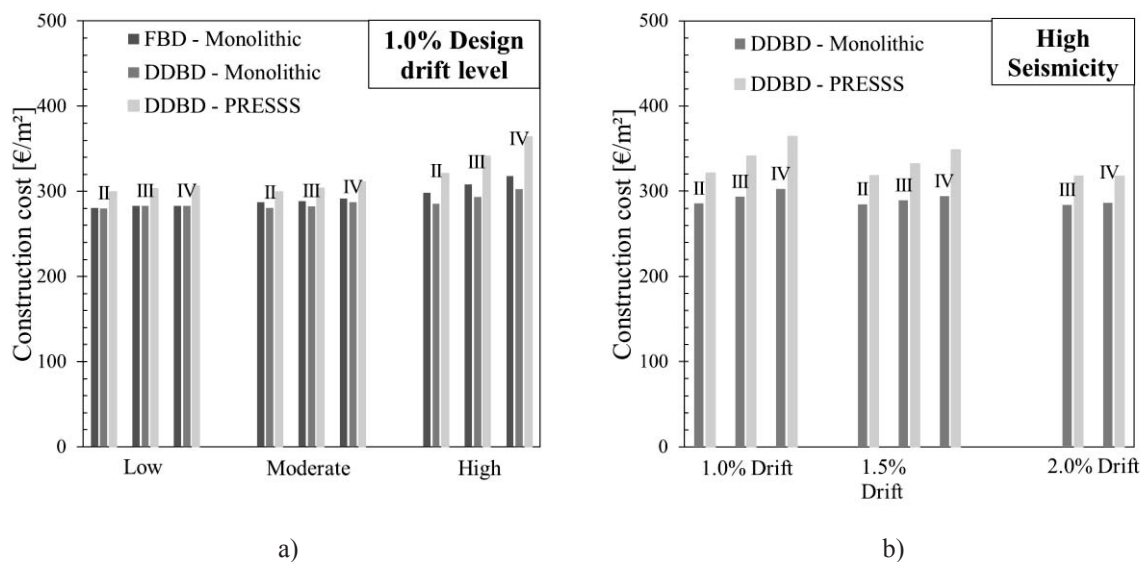

Figure 8: Comparison in terms of Construction Cost for: a) alternative design methodologies (at the same design drift level for DDBD) and all the seismicity zones; b) different technological solutions at the same seismicity level, in case of DDBD and various design drift levels.

Seismicity level	Importance Class	Construction Cost [€/m <sup>2</sup> ]			Cost Difference [%]	
		FBD Monolithic	DDBD Monolithic	DDBD PRESSS	DDBD vs FBD Monolithic	DDBD Monolithic vs PRESSS
Low	II	280.7	280.0	299.8	0.25	7.06
	III	282.9	282.7	303.0	0.07	7.19
	IV	282.9	282.8	306.4	0.04	8.34
Moderate	II	287.0	280.8	299.6	2.21	6.68
	III	288.6	282.6	303.7	2.12	7.45
	IV	291.8	287.3	311.5	1.57	8.44
High (1.0% drift)	II	298.4	285.5	321.2	4.52	12.50
	III	308.3	293.4	341.1	5.08	16.27
	IV	318.2	302.8	364.1	5.09	20.26

#### 4 LOSS ASSESSMENT ANALYSIS

The estimation of seismic economic losses is fundamental to evaluate the actual long-term (structure life-span) convenience of a design strategy when compared to another. As mentioned above, the economic aspect is certainly crucial when a project is carried out, and represents the factor mainly addressing the choice of a technological solution. Proving that a safer solution is also the least expensive (when considering the life-span of the building, not only the initial costs) is therefore essential to spread the idea that current traditional performance-based design approach (limited to Life Safety) is not enough to meet the seismic demands of our modern society.

From a procedural point of view, two assessment approaches are herein involved to evaluate the seismic losses and, specifically, to calculate the Expected Annual Losses (EAL), namely: 1) the simplified procedure by D.M. 65 2017 [13]; 2) the rigorous procedure by FEMA P-58 2012 [14]. The first procedure takes into account the direct losses only and is actually developed for, and calibrated on, existing buildings. On the other hand, the probabilistic FEMA P-58 methodology account for both direct and indirect economic losses, providing an accurate loss estimation if all the building component fragilities (and related fragility curves/consequence functions) are known.

##### 4.1 Simplified methodology

The procedure described in the “Seismic Bonus” guidelines - D.M. 65 2017 [13] - is herein implemented. From the building capacity curves, the capacity Mean Annual Frequencies (MAF) are computed at various seismic intensity levels (SLDI, SLO, SLD, SLV, SLC, SLR, or, respectively Non-structural Damage, Immediate Operational, Damage Control, Life Safety, Collapse Prevention, Demolition and Reconstruction). A Reconstruction Cost is associated with each intensity level and expressed as a percentage of the total building cost. This allows to build the cost/frequency curves and, thus, to determine the EAL value and related class. Since the case-studies are new buildings, the ratio of capacity to demand is equal to (or more than) 1, meaning that the Capacity Return Period is equal to (or more than) the Demand Return Period. The difference between the case-studies is therefore related to the different Importance Class only; as the Importance Class varies, the Return Period associated with each limit state varies. Consequently, only three EAL curves corresponding to the three Importance Classes are obtained for all the 37 cases employed (Figure 9).

Importance Class	EAL [% RC]
II	0.98
III	0.77
IV	0.66

b)

Figure 9: EAL curves and values obtained from the simplified loss assessment analysis.

In all cases, the building systems result in A class ( $0.5 \leq \text{EAL} \leq 1.0$ ) and it can be noted that losses are higher when an Importance Class II is assumed, representing the lower safety-resilience level for the building. Therefore, the implemented procedure highlights that the simplified approach, developed for existing structures, is not applicable for new buildings. In fact, it does not allow to account for between different construction methods as well as technologies.

#### 4.2 Probabilistic-based methodology

The refined loss assessment investigation is implemented using the PACT (Performance Assessment Calculation Tool) provided by the FEMA P-58 [14]. This practical tool allows to calculate the direct and indirect economic losses of a structure. In order to implement the analysis, input data describing the building (geometry, use, components) and hazard are required. Fragility curves and consequence functions need also to be defined for both structural and non-structural elements. Concerning the monolithic cast-in-situ connections, the fragility specifications are selected from the ones available in the FEMA P-58 database considering components with similar geometry to the case-study structure. In the case of PRESSS connections, section-analysis results are elaborated to build up specific fragility functions describing the connection behavior (i.e. fracture of the mild steel bars and yielding of post-tensioned tendons). Then, the seismic demand for each limit state in terms of inter-story drift ratios and floor accelerations, calculated through the pushover-based capacity spectrum method, are considered as additional input data. Moreover, the analysis is carried out including the contribution of residual drift ratios for the monolithic structures (negligible residual displacements characterize the hybrid system due to its self-centering behavior). The loss assessment analysis thus provides a more accurate estimation of the annualized expected repair costs (EAL values). Figure 10 and Table 5 present the results obtained from this probabilistic-based procedure.

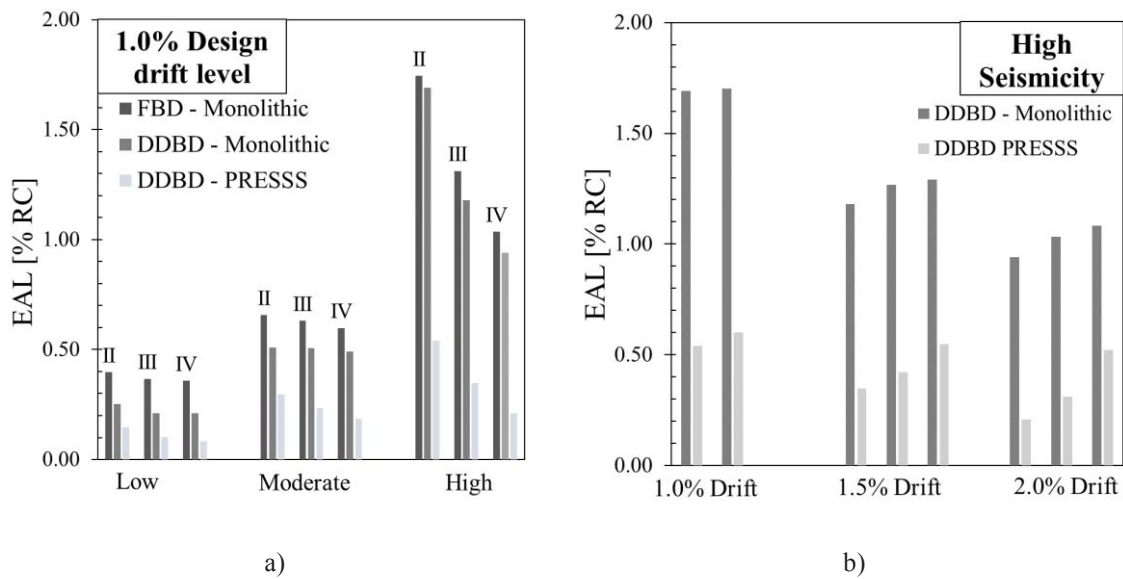

Figure 10: Comparison in terms of Expected Annual Losses for: a) alternative design methodologies (at the same design drift level for DDBD) and all the seismicity zones; b) different technological solutions at the same seismicity level, in case of DDBD and various design drift levels.

Seismicity level	Importance Class	Design Drift [%]	EAL [% Replacement Cost]		
			FBD Monolithic	DDBD Monolithic	DDBD PRESS
Low	II	0.76	0.40	0.25	0.14
	III	0.77	0.37	0.21	0.10
	IV	0.81	0.36	0.21	0.08
Moderate	II	1.0	0.66	0.51	0.30
	III	1.0	0.63	0.51	0.23
	IV	1.0	0.60	0.49	0.18
High	II	1.0	1.74	1.69	0.54
	II	1.5	-	1.70	0.60
	III	1.0	1.31	1.18	0.35
	III	1.5	-	1.27	0.42
	III	1.8	-	1.29	0.55
	IV	1.0	1.04	0.94	0.21
	IV	1.5	-	1.03	0.31
	IV	2.0	-	1.08	0.52

Table 5: Comparison in terms of Expected Annual Loss.

Results in terms of EAL highlight that: 1) as the service class increases, the losses decrease, due to the increased level of safety consequently leading to reduced seismic losses; 2) as the design drift level increases, the value of EAL parameter also increases; this is related to a seismic design for higher levels of displacement which brings to consequent higher damages. When comparing the results obtained for the same construction technology whilst varying the design method, FBD produces greater losses than the DDBD, confirming the disadvantage of applying such traditional design methodology. Moreover, looking at the different types of skeleton systems, PRESS structures lead to significantly lower losses when compared to monolithic structures, due to its inherent low-damage nature.

Referring to the repair costs of each limit state as well as to their Mean Annual Frequency of exceedance, EAL curves are built. These curves provide more reliable loss values when compared to the previous simplified results not accounting for the real repair costs associated with each limit state. The overall repair cost is now properly computed for the various intensity levels and this allows to appreciate the advantages and disadvantages of design methods and technologies. Comparisons in terms of EAL curves are thus carried out for the different seismicity levels as presented in Figure 11 (e.g. different seismicity areas, service class IV, 1.0% design drift level for DDBD). In the same graph a reparability threshold of 65%, i.e. value above which is no longer considered convenient to repair the building, is also included. It is noted that in low seismicity areas this threshold value is never reached.

Figure 11: Comparison of design strategies in terms of EAL curves (for different seismic zones: a) low; b) moderate; c) high, an Importance Class IV, 1.0% design drift level for DDBD).

## 5 SEISMIC COSTS IN THE BUILDING LIFE

In order to better appreciate the advantages of a design based on the control of damage and on increased safety levels, the seismic costs of all case-studies are compared at the end of the service life, that is, for example, 50 years after the building construction. This comparison can be carried out by considering the annualized losses (the EAL parameter) distributed along 50 years in order to evaluate the percentage of construction cost which would be lost at the end of the building life. As shown in Figure 13a, the cumulative seismic cost is described by a linear trend going from the initial cost at the time of construction to the cost at the end of the building service life. The intersection between the different lines, representing different design strategies, identify the break-even time at which the initial (if any) difference in the initial construction costs is balanced; therefore, although at the time of initial construction the PRESS technology might be slightly more expensive than the traditional one (notably the implementation of actual buildings have proven to be no more expensive), from the year corresponding to the intersection of their cost lines onward, the trend is completely reversed. For example, it can be noticed that in high seismicity and design drift of 1.0% for DDBD, the difference in the initial cost of 12% (monolithic vs. low damage) at the time of construction can be fully recovered in just ten years. In order to highlight the advantages obtained by switching from FBD to DDBD as well as from monolithic to hybrid connections, the savings after 50 years from the time of construction and for each seismicity area are shown and compared in Figure 12 (b, c) and Table 6.

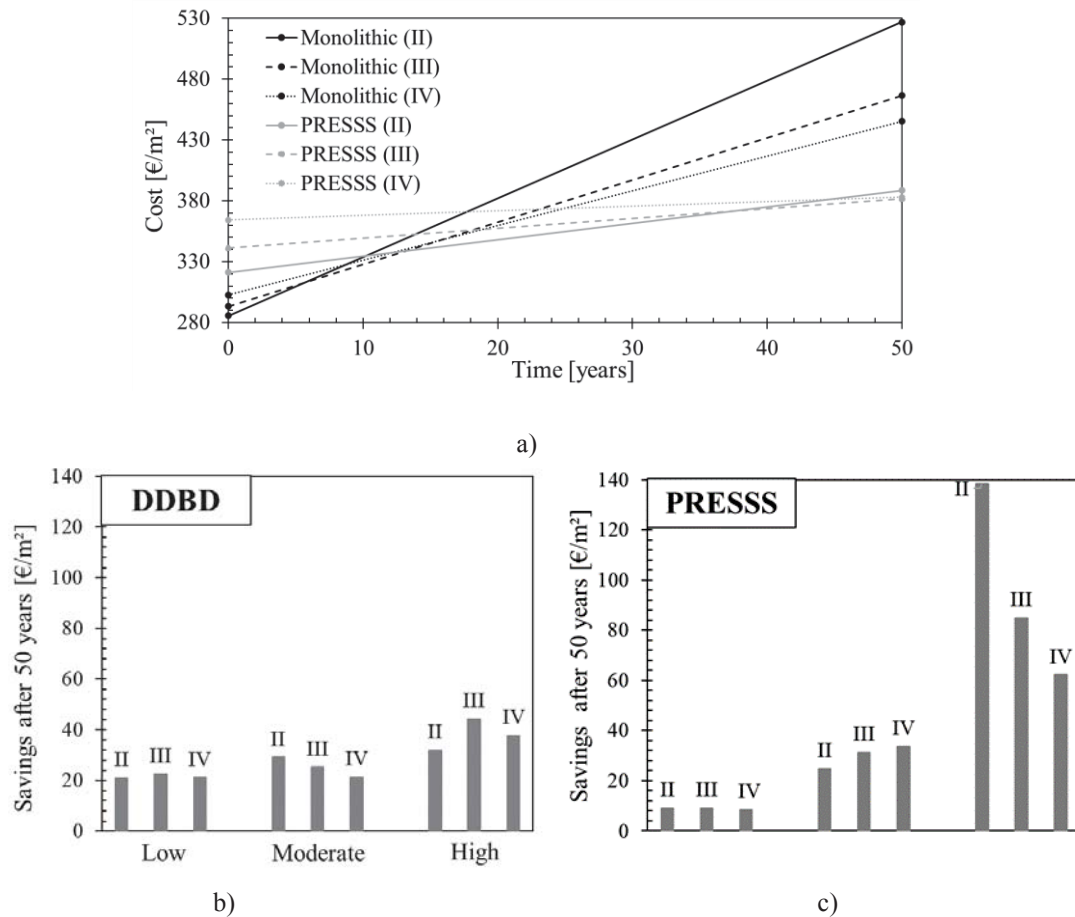

Figure 12: a) Cost/time curves in case of High Seismicity zone; Average savings at the end of the building life for different seismicity zones and due to: b) DDBD method; c) PRESSS technology.

Seismicity level	Importance Class	Savings at 50 years [€/m²]			Savings [€/m²]	
		FBD Monolithic	DDBD Monolithic	DDBD PRESSS	DDBD vs FBD Monolithic	DDBD Monolithic vs PRESSS
Low	II	336.3	315.2	306.1	21.1	9.1
	III	334.8	312.3	303.3	22.5	9.1
	IV	333.5	312.4	304.0	21.1	8.5
Moderate	II	381.3	352.3	327.6	29.0	24.7
	III	379.5	354.2	323.0	25.2	31.2
	IV	379.1	357.7	324.0	21.3	33.7
High (1.0% drift)	II	558.8	527.0	388.5	31.7	138.5
	III	510.6	466.4	381.5	44.1	84.9
	IV	483.0	445.3	383.1	37.7	62.2

Table 6: Comparison in terms of savings at the end of the building life.

The savings are clearly more consistent in high seismicity areas and consequently the advantages of a low-damage technology are more evident. The previous graphs are particularly relevant, as it presents in absolute terms the significant amount of (tax-payers) money that can be saved in 50 years. Cost of construction is correlated with losses over time and money savings are evident. Finally, it is observed that the convenience of implementing low-damage technologies is substantial for the case of high seismicity area and Importance Class II.

## 6 CONCLUSIONS

This paper has focused on the cost/performance-based study and comparison of alternative design strategies which might be adopted to enhance the seismic safety of new buildings. Focusing on Reinforced Concrete structures and considering increasingly levels of seismic intensity (representing either a higher seismic zone or a higher service class or Importance Level), different design methodologies (force-based vs displacement-based) or technologies (monolithic vs low-damage) have been adopted to develop the proposed parametric study.

Results of this research allows for greater awareness of the proper design method/strategy to be used according to the seismic area and the Importance Class of a specific building. In particular, the developed study highlights that the force-based design brings to different (yet not necessarily conservative) results when compared to the displacement-based design. Specifically, the parametric study on alternative structural configurations highlights that the building response in terms of base shear is generally overestimated. However, this does not mean that the force-based design is a more conservative method than the displacement-based approach (as it could in turn underestimate the displacement-ductility demand), while it highlights that this approach does not allow to have a proper control of the real structural behavior, and in general on the obtained seismic results. Furthermore, the parametric study shows that the base-shear, that is a fundamental parameter for the seismic design since it allows to determine the demand moment/shear values on the structural elements, does not necessary nor directly increase with the assumed level of seismic intensity, expressed in terms of Peak Ground Acceleration (PGA). Specifically, looking at the same design displacement, the base shear increases with the acceleration, whilst if the acceleration doubles, the base shear does not. This last consideration proves that designing for higher Importance Classes, and therefore with greater safety and resilience, does not necessarily lead to an equally higher cost. Minor but appropriately focused investments can instead lead to greater safety, resilience and long-term savings.

Taking into account the results in terms of initial construction cost and focusing on high seismicity area, (worst case scenario) it can be noticed that moving from Importance Class II to IV with the same design drift level (e.g. 1%), although the required base shear should be 50% higher, an initial cost increase of only 6% is expected. More importantly, when considering the cumulative seismic cost over time, the slight cost distance is completely recovered in less than 10 years, and at the end of the service life of the structure (50 years) a saving of about 15% is obtained, leading to an increased safety for the building as well as reduced losses over time.

Furthermore, the advantage related to the implementation of a low-damage technology such as the rocking-dissipative PRESSS system is evident, especially for the case-studies where post-earthquake damage causes very high repair costs. In fact, the computed savings at 50 years (service life) after the time of construction show that the greatest savings refer to Importance Class II, design drift of 1% and high seismicity zone. Importance Class II is, in general, the level with the highest losses over time (lower safety), while a design drift of 1% presents the most expensive case in terms of construction cost. However, this consideration does not lead to the conclusion that in areas with a low seismicity, low-damage connections are not convenient; savings are obtained for all seismic-prone areas and Importance Classes, so it is clear that designing better, that means for better performance and greater safety, is always also economically convenient leading to a more resilient community.

Despite this research work represents an initial study aiming to prove the convenience of implementing enhanced-safety design strategies, further investigations are needed to compare alternative design methods and technologies. In particular, more refined numerical studies are required, involving time-history analyses and performing a probabilistic-based approach, looking at the influence of the design approach on the building probability of collapse.

### Abstract

*This paper deals with the design of a transparent pavilion (museum) made of structural glass. The fundamental concepts of structural glass are described and its application in public buildings. The work is focused on the seismic analysis of the glass structural members in regions with high seismicity. Particularly in these regions the basic principles of seismic isolation are taken into account and applied in the model building in order to avoid brittle failures. Analytical results show that the elastic behavior of structural glass doesn't affect the overall response of the building in seismic events if it is properly isolated. Especially, glass structural members with pseudo-ductile behavior have favorable effect on the seismic response and contribute towards accomplishing the codes' safety for public buildings.*

## 1 INTRODUCTION

Glass has been one of the most well known structural materials since it was discovered back into the 1500 B.C. in Egypt and Mesopotamia and further developed in Rome during the 1<sup>st</sup> century [1]. Lately in 1950, its use in structure become very popular by Alastair Pilkington who developed the process of the float glass production (1,2). Due to its transparency and its high compressive and tensile strength, it was and remains the perfect material for the facades. As the years passed, the material affected the architectural rhythm and lately glass becomes the dominant material of the design [2]. Nowadays, after the progressive development of the material's properties and the new types of structural glass [1,2,3], the modern architecture trend to designing transparent buildings.

Apart from the esthetical value that the structural glass adds to the transparent buildings, it also shifts the negative impact on nature, since it is a full recyclable material [4]. The existing guidelines cover extensively the design of secondary structural elements [5,6] and only lately there is an effort to develop codes for all the structural members. As such, buildings of this kind are rarely met, especially in Northern Europe and US [1], and the vast majority is museums or public buildings. However, there are a few if any examples of transparent buildings in high seismicity regions. For this reason, this paper deals with the investigation of the response of a transparent public building (pavilion) made of structural glass in regions with high probability of severe seismic events.

## 2 STRUCTURAL GLASS

### 2.1 Mechanical properties

The high strength and the glass resistance to acids and salt corrosion, makes glass suitable to be used as a structural material. Especially, due to the lack of porous it is not affected by the climatic conditions and the environmental exposure. This contributes to the durability of the material and hence the structural members.

Glass is an isotropic (density  $\rho=2500\text{Kg/m}^3$ ), elastic material with a modulus of elasticity approximately equal to 70GPa, poisson ratio ranging from 0.2 to 0.3 and a compressive strength more than 500MPa [6]. The tensile strength depends on the chemical process of the production and varies from 45MPa to 120MPa [5,6].

It is worth noticing that, glass is considered a green material since it is fully recyclable and the energy need it for each production is considerably lower than that needed for compatible materials such as concrete and steel [7]. The use of glass needs special attention in order to provide energetically efficient buildings [1,2,3].

### 2.2 Types

The glass when imposed on tensile loads, cracks initiate and propagate. With further chemical process new types of glass are developed with higher tensile strength and more resistant surface on the whole. Consequently, this shift of the tensile strength, leads to different failure modes and patterns. As such there are numerous types of glass e.g. annealed, full tempered, chemically and heat strengthened or composite forms such as laminated and reinforced glass. All these categories have brittle failure mode with large and sharp or round fragments after cracking whereas composite forms present a pseudo-plastic behavior with a combination of the above maintained failure modes.

### 3 DESIGN

#### 3.1 Conceptual design of pavilion

The glass pavilion of this study is orientated to be part of an internal part of an existing museum. The pavilion is considered as a unit which can be an interior or exterior extension and can form various configurations in any natural environment.

The pavilion is a one storey building ( $H_{lev}=3.00\text{m}$ ) and has a total area equal to  $53.00\text{m}^2$  for hosting approximately 20 visitors. It consists of the exhibition room, the meeting room, reception, WC and traffic spaces as they are shown in the function diagram in Figure 1. The use of the spaces can differ according to the pavilion's demands and use. The basic conceptual design idea of the pavilion takes into consideration the proper ventilation and openings of the spaces, as well as the privacy and transparency. In case that there is a requirement for visual isolation, structural glass with controlled transparency can be used [1].

A main issue of the design with structural glass is the energy performance of the building [1,2,3]. Modern technology has lead to the development of various types of glasses e.g. reflective glass, insulating glass units, mirror glass and smart glasses [1,8] that enhance the energy efficiency. It's worth mentioning that in the present work, the energy evaluation and the use of different energy glasses has not been examined and it is a task of future work.

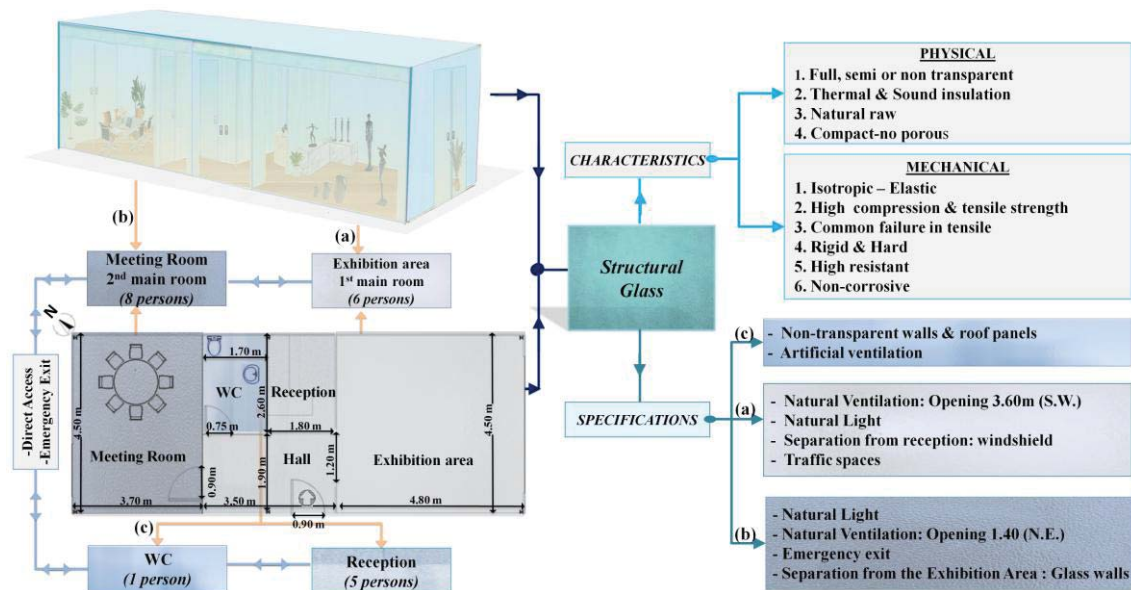

Figure 1: Function diagram of the glass pavilion

#### 3.2 Selection of structural members

Structural glass is mainly a brittle material. Alternative types such as laminated or reinforced glass present a quasi pseudo-plastic behavior [9]. This response is favorable to the overall performance of buildings in high seismicity zones, offering the desirable safety level. As such, safety glass type is preferred to form the structural body of the current study.

The glass moment frame consists of **H** shaped columns ( $250 \times 250 \text{ mm}^2$ ) and rectangular beams ( $66 \times 322 \text{ mm}^2$ ). The cross-section size is chosen so that the frame is resistant to gravity loads. Roof panels are designed to bear wind and snow loads. They are made of four sheets of full tempered laminated glass and they have total thickness equal to 40mm. The exterior glasses have 8.0mm thickness each, in order to protect the middle glasses. The infill panels, which are designed to resist in wind load, are made from triplex laminated glass and each glass panel has 15mm thickness. Columns are made of triplex laminated glass formed by three-layers of tempered glass of 22mm thickness each, assembled with a transparent sentry glass interlayer (SG). This interlayer helps to keep together the fragments in case of failure in tension. Beams contain also a steel rebar ( $22 \times 22 \text{ mm}^2$ ,  $\rho_s = 2.33\%$ ) mounted at the bottom part of the middle glass sheet which is heat-strengthened. The reinforcement is activated after the tensile failure of the cross section's glasses (heat-strengthened and tempered) and bears the tensile stresses developed without affecting significantly the transparency. Beams sheets are also kept together with a glass interlayer. The crack pattern of the fragments and the polymer defines the residual tensile strength of the member as it is shown in Figure 2. The steel reinforcement is also activated once the compressive loads exceed the compressive strength of the glass. Then fragments are created and kept in place by the SG interlayer.

Structural Member	Profile	Dimensions (mm)		Cross Section

Table 1: Cross section's geometry

### 3.1 Seismic design of the pavilion

The pavilion's demands for seismic resistance are quantified with response spectra analysis (RSA) according to Eurocode (EC8/EN1998-1) [10] considering the seismic action as an elastic response spectrum. A preliminary modal analysis is performed in order to obtain the modal expansion (shapes).

The dynamic analysis is performed with the elastic response spectrum for the ground accelerations horizontal directions. The seismic action is represented by the elastic response spectrum, Type 1 ( $M_s > 5.5$ ) and the elastic response of the structural glass denotes that the factor  $q$  is equal to 1.00.

According to EC8, the main factors that determine the elastic response spectrum are chosen. That is, soil conditions of type B, brittle type material and importance class of the building III. As such, the reference peak ground acceleration ( $a_{gR}$ ) for soil type B is equal to  $0.36g$  and the values of the characteristics periods ( $T_B$ ,  $T_C$ ,  $T_D$ ) and the soil factor ( $S$ ), are  $0.15\text{sec}$ ,  $0.50\text{sec}$ ,  $2.00\text{sec}$  and  $1.20$  respectively. The building seismic resistance is of importance in view of the consequences associated with a collapse (e.g. schools, museums etc) and thus is classified as importance class III with a corresponding importance factor ( $\gamma_I$ ) equal to  $1.20$ . Therefore the peak ground acceleration is equal to the reference peak ground acceleration ( $a_g = \gamma_I \cdot a_{gR}$ )  $0.43g$  and the damping factor ( $\eta$ ) of the material is equal to  $2\%$ , given the nature of the material [13].

Figure 2: M-φ diagram

### 3.2 Base isolation system

Due to the high importance of the museum demands safety is increased. Especially in high seismicity zones according to EC8 the design should ensure that no collapse occurs. The glass pavilion's response of this study is mainly defined by the elastic nature and brittle failure of glass, which happens in small ranges of deformations. In order to limit them and to prevent failures from extreme earthquake events, the drift of the single degree of freedom (SDOF) pavilion should be reduced.

The glass pavilion is designed to be properly based in separate reinforced concrete foundations. In this paper a solution of base isolation system is chosen in order to decrease the maximum relative displacement of the foundation and the upper level of the structure ( $H_{lev}$ ). Various types of base isolation systems exist e.g. roller and ball bearings, sliding bearings, springs and elastomeric rubber bearings [11], with the most common in use the elastomeric rubber bearings (Low or High Damping Rubber Bearing LDRB/HDRB, Lead Rubber Bearing LRB and Friction Pendulous Systems FPS) [11]. The chosen base isolation system is one LDRB at the base of each column, made of natural rubber (NR) with a rectangular shape ( $250 \times 350 \text{mm}^2$ ) and a total height equal to  $63 \text{mm}$ . The bearing, is also reinforced with steel plates between the elastomer layers which provide high vertical stiffness ( $K_v=418.90 \text{kN/mm}$ ),

considerably higher than the horizontal one ( $K_h=1.50\text{kN/mm}$ ). This type of bearing is chosen since practically vertically it is restricted and incapable to deform. At the same time, it is flexible to withstand horizontal seismic displacements and rotations.

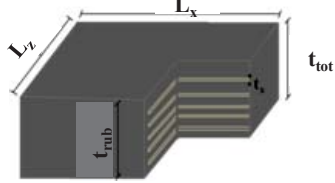

Seismic Isolation	Profile & Cross Section	Dimensions (mm)		Mechanical Characteristics		
<i>Elastomeric Bearing</i>		$L_z$	250	A	$75 \cdot 10^3$	$\text{mm}^2$
		$L_x$	300	$K_z$	$1.5 \cdot 10^3$	$\text{kN/m}$
		$t_{\text{tot}}$	63	$K_x$

#### 4 SIMULATION

The model building was numerically investigated using ANSYS software. The glass structural members (columns and beams) were simulated using a three-dimensional Finite Element Model (FEM). The roof of the building is considered as diaphragm, at the height of 3.0m. Proper finite element types were chosen for the simulation of glass columns (BEAM188), glass beams reinforced with steel rebars (REINF264) and the base isolation system (COMBIN14). Each bearing of the isolation system chosen is simulated with one spring for each direction with suitable stiffness, mechanical properties and stress strain laws, integrating the desired features of a certain base isolation system reducing the acceleration transmitted to the superstructure.

The two scenarios studied in this paper are a) a 3-D model of the glass pavilion without base isolation and b) a 3-D model of the glass pavilion based on elastomeric bearings (Figure 3).

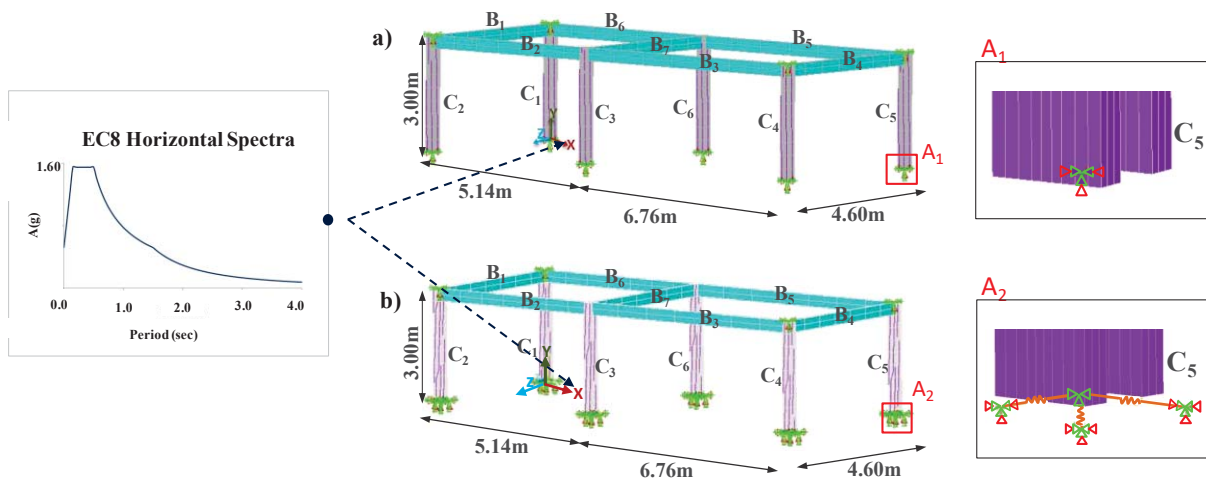

Figure 3: Two scenarios of study a) 3-D model without base isolation and b) 3-D model with base isolation

The seismic design of the pavilion is performed according to the regulations of EC8. An elastic acceleration spectrum is applied representing the seismic load, which is excited in the horizontal plane (directions  $x$  and  $z$ ), neglecting the vertical seismic component (direction  $y$ ). The spectrum's excitation point coincides with the center of the global coordinate system, as shown in Figure 3. For the proper distribution of the pavilion's mass and the calculation of the mode shapes due to gravity, a modal analysis is performed followed by the spectrum analysis. After both the modal and spectrum analysis, the significant modes of the pavilion are combined. The solution in terms of displacement is extracted by using the square route of the sum of squares mode combination method (SRSS). [10,12]

The solution for both models a) without seismic base isolation system or b) isolated with elastomeric bearings, is extracted in terms of the relative displacement of the upper and lower nodes of the columns of each frame.

## 5 RESULTS

The response diagrams of the two different described models are presented. First of the reference model which represents the initial design's performance without base isolation system (circled shaped red dot line) and for the second model which represents the target design performance of the base isolated model (square shaped green dot line). The results are presented in terms of drift ratio of the storey (Figure 4a), maximum displacement vs. the amplitude of the natural frequency of the structure (Figure 4b) and of the maximum acceleration at the base vs. amplitude natural period (Figure 4c).

There is a significant reduction in structure's drift as it is illustrated in Figure 4a corresponding to 83% lower values in respect to the reference model. This reduction of drift expresses the capacity of the bearings to absorb the seismic displacements. Also, the significant decrease of the relative displacement in terms of absolute values is depicted in Figure 4b, where it is shown that the maximum relative displacement of the isolated model happens when the elastomeric bearing reaches its maximum shear capacity (22.5mm), exhibiting also a larger cut off frequency. The cut off frequency of the initial design performance practically coincides with the natural frequency ( $f_n$ ) of the SDOF structure, which is reduced for the isolated model (65%) and exhibiting a sharp increase at the ultimate design state of the elastomeric bearing. The Figure 4c shows the shift of the natural period and response with which the SDOF structure oscillates in the two different models at the ultimate state. Especially, the target design performance has a value of period 2.9 times greater than the initial. This elongation of the period is beneficial as the reference model oscillates with a maximum acceleration of 0.266g, whereas the base isolation decreases the maximum acceleration of the upper structure to 0.014g.

The base isolation system has an overall remarkable effect by favoring glass columns' deformation, eliminating brittle failures. Not only columns, but also beams do not have significant deformation as it shown in Figure 5 in terms of elastic strain. The value range of elastic strains of the isolated structure is between  $\pm 0.10$  (Figure 5b), meaning 85% difference lower than the reference model (Figure 5a). These values of strains in all structural members corresponds to a curvature's value of stage I (Figure 2), which corresponds to non-cracked stage for all type of glasses both in tension and compression.

Figure 4: Results of the initial and target design performance in terms of: (a) Drift; (b) Relative displacement-Freq/ $f_n$  and (c)  $S_a(g)$ - $T/T_n$  diagrams

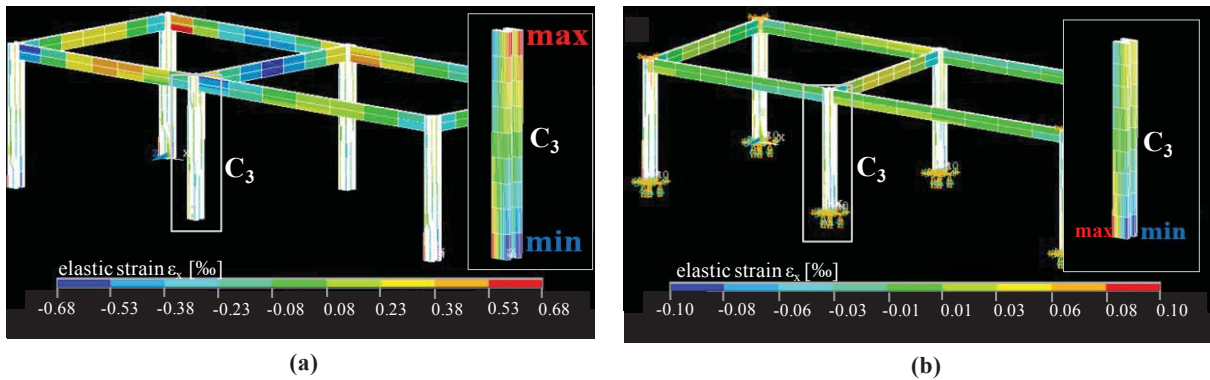

Figure 5: Elastic strain results for (a) non-isolated and (b) base isolated structure

## 6 CONCLUSIONS

- The isolated model exhibits a shift in the SDOF natural period and the significant reduction of the storey drift and the base acceleration, as well as the strains at the critical cross-sections of the structure. As such, glass exhibits no significant fracture or damage, even though is a brittle material. The proper design of the pavilion is proven to exhibit a high ratio of safety.
- A detailed selection of the structural glass type and in addition a proper layering of those types, in combination with structural steel, can lead in avoidance of brittle failures. Even though in the cases of columns the structural glass is proven to have enough resistance to deformations, the base isolation system enhances the overall performance.
- Further research is needed in order to study the connection assemblies between the structural members in order to assure that the abovementioned failure mode is achieved.
- The total displacement provoked from the seismic excitation can be dramatically reduced. Further investigation applying different isolation systems or a combination of them can result to the elimination of the displacement values, especially for different configurations of the unit model either vertically or horizontally.

### Abstract

*The current seismic design and assessment procedures describe the seismic demand in terms of elastic spectral accelerations, which may not be adequate to capture the destructive effects of near-fault ground motions. The relevant characteristics of near-fault records, such as the presence of a velocity pulse, the pulse amplitude, and the pulse period ( $T_p$ ), make the record selection and modification task more challenging. A newly proposed intensity measure, called Instantaneous Power ( $IP(T_1)$ ), takes into account the effects of velocity pulses on structural response. It has been shown that vector IM including  $IP(T_1)$  and elastic spectral acceleration at the first mode period of structure  $Sa(T_1)$  results in more reliable and accurate structural responses compared to the traditional IM,  $Sa(T_1)$ . A new matching method is developed to incorporate the effects of IP into the record modification process. The procedure combines a widely used time-domain spectral matching algorithm, *RspMatch*, and a velocity adjustment approach to simultaneously match the target response spectrum and IP spectrum. We investigate the extent to which controlling the IP parameter in the modification process affects the nonlinear structural response by comparing the results of single-degree-of-freedom (SDOF) systems and multi-degree-of-freedom (MDOF) system, under the sets of *Sa*-only matched and *Sa*- and *IP*- matched records. Our findings show that the consideration of IP in the record matching can help prevent potential bias in structural response.*

## 1 INTRODUCTION

Developing robust approaches for selecting and modifying records that can represent the critical aspects of the design motions is crucial to obtaining reliable and accurate structural response estimates. In current practice, the records having similar implicit causal parameters (e.g., magnitude, distance, site condition) with the scenario earthquake are typically scaled or modified such that their median response spectrum matches the target spectrum within the period range of interest [1]. However, selecting the records on the basis of spectral accelerations may not fully represent the damaging potential of near-fault records containing directivity pulses. For instance, characterization of the near-fault ground motions including velocity pulses requires the determination of the probability of the presence of a pulse, the period of the pulse, as well as the amplitude of the pulse. The recent study showed that the vector IM consisting of  $Sa(T_1)$  and Instantaneous Power ( $IP(T_1)$ ) sufficiently and efficiently captures the destructive impact of the near-fault ground motions on structural response [2]. In order to capture the damaging characteristics of these motions, it is necessary to consider the combined effects of relevant IMs, i.e.  $Sa$  and  $IP$ , in the seismic design and assessment procedures.

One of the most widely used approaches to obtain appropriate input motions for use in response history analysis is the time-domain response spectrum matching procedure, which is also known as RspMatch [3]. This technique adds wavelet function to accelerogram so as to ensure compatibility between record spectrum and target spectrum over a specified period interval. This study presents an  $IP$  matching approach that performs modification on velocity time series to match the target  $IP$  values. The proposed matching algorithm enables near-fault records to match both the target response ( $Sa$ ) spectrum and  $IP$  spectrum. The non-degrading bilinear SDOF systems of varying periods and nonlinearity levels as well as a 2-story steel frame that accounts for stiffness and strength degradation are used as case studies to evaluate the performance of the proposed matching procedure for predicting response of structures to  $Sa$ -only matched records and to  $Sa$ - and  $IP$ -matched records.

## 2 INSTANTANEOUS POWER

The  $IP(T_1)$  is defined as the maximum energy rate of the bandpass-filtered velocity time series over a short time interval given by half of the structural period (i.e.  $0.5T_1$ ) :

$$IP(T_1) = \max\left(\frac{1}{0.5T_1} \int_{t_0}^{t_0+0.5T_1} V_{filtered}^2(t) dt\right) \quad (1)$$

where the  $IP$  is in units of  $\text{cm}^2/\text{s}^2$ ,  $V_{filtered}$  is the bandpass-filtered velocity of the record in  $\text{cm/s}$ . A Butterworth bandpass filter with bandpass period between  $0.2T_1$  and  $3T_1$  is applied to a velocity time series. Figure 1 illustrates the original and filtered velocity time series of the 1979 Imperial Valley-06 earthquake (Agrarias station) record. Figure 1 also shows the variation of  $IP(T_1)$  level over the selected time interval ( $0.5T_1$ ) and the Cumulative Squared Velocity (CSV) of the filtered velocity. It can be seen that the maximum  $IP$  occurs at around 10 seconds, which corresponds to the steepest slope of the CSV. The previous findings showed that the  $IP$  has a significant influence on the structural response after eliminating the effects of spectral shape and amplitude of the ground motions [2-4].

Figure 1. The original and filtered velocity time series of the 1979 Imperial Valley-06 earthquake (Agrarias station) pulse record, and the variation of  $IP(T_1)$  over the selected time interval ( $0.5T_1$ ) and the Cumulative Squared Velocity (CSV) of the filtered velocity.

### 3 CONSTRUCTION OF TARGET SPECTRA FOR MATCHING

Matching of an individual component to a target median can lead to artificial suppression of the spectral variability as the target spectrum generated using geometric-mean or RotD50 (i.e., the median single-component horizontal ground motion across all nonredundant azimuth) of the ground motion does not include the peaks and troughs of the arbitrary component. To maintain the variability of the individual component of the record about the target, we construct a component-specific target spectrum, which is obtained using the Component-Variability Ratio (CVR) given by:

$$CVR_{ij} = \frac{Sa_i^{H_{j,record}}}{Sa_i^{RotD50,record}} \quad (2)$$

where  $Sa^{RotD50,record}$  is the RotD50 spectrum of the record, and  $Sa_i^{H_{j,record}}$  corresponds to the spectral acceleration of the  $j$  component of the record at the  $i$  period. The component-specific target spectrum  $Sa_i^{H_{j,target}}$  is then computed as follows:

$$Sa_i^{H_{j,target}} = CVR_{ij} \times Sa_i^{target} \quad (3)$$

where  $Sa_i^{target}$  is the target spectral accelerations. In computing the CVR for component-specific IP target, we employ geometric-mean IP values of the record instead of the RotD50 because the conditional GMM for the IP is developed based on the geometric-mean horizontal component of ground motion [5]. A conditional ground-motion model (GMM) for  $\sqrt{IP(T)}$  is given by;

$$\ln(\sqrt{IP(T)}) = a_1 + a_2 \ln(Sa(T)) + a_3(M - 6) + a_4 \ln(R_{rup} + 5 \exp(0.4(M - 6))) + \delta B_e + \delta W_{es} \quad (4)$$

in which  $M$  is the moment magnitude,  $R_{rup}$  is the rupture distance in kilometers, and the 5%-damped  $S_a$  in g. The subscripts  $e$  and  $s$  correspond to the indexes of the earthquake and the site, respectively. A more detailed description of the model can be found in [5].

Figure 2 illustrates 50<sup>th</sup> percentile (median) of the target scenario spectrum generated using the Abrahamson et. al. GMM [6], for an earthquake scenario with Magnitude=7,  $R_{rup}$ =3 km, and site condition  $V_{S30}$ = 400m/s, target IP spectrum, as well as component-specific  $S_a$ - and IP- spectra of the selected pulse record that are used as targets in the matching.

Figure 2. Comparisons of median target spectrum for an earthquake scenario with Magnitude=7,  $R_{rup}$ =3 km, and site condition  $V_{S30}$ = 400m/s, target IP spectrum, and component-specific  $S_a$ - and IP- spectra of the selected pulse record.

#### 4 IP ADJUSTMENT

In this section, we briefly mention about the IP adjustment approach that adds a Ricker wavelet to the velocity time series so as to match the target IP values [7]. The Ricker wavelet has good time localization and a broader frequency spectrum compared to the tapered cosine function, which is added to acceleration time history in response-spectrum matching. This adjustment function is centered at the time of IP occurs ( $tIP_j$ ), for the spectral period  $T_j$ , and is given by

$$h_j(t) = (1 - 2\pi^2 f^2 (t - tIP_j)^2) \exp(-\pi^2 f^2 (t - tIP_j)^2) \quad (5)$$

The adjusted velocity is defined as:

$$V_1(t) = V_o(t) + \gamma_{vel} \delta V_1(t) = V_o(t) + \sum_{j=1}^N b_j h_j(t) \quad (6)$$

where  $\delta V_1(t)$  is the adjustment velocity time history and  $\gamma_{vel}$  is a relaxation factor for the velocity adjustment, where  $b_j$  is a vector of amplitudes of a set of adjustment functions, and  $N$  is the total number of spectral periods. The objective is to equate the change in the IP due to the adjustment to the misfit between target IP and record IP. We refer the reader to the paper by Zengin and Abrahamson [8] for more details.

## 5 MAIN STEPS OF THE SIMULTANEOUS SA- AND IP-MATCHING

The proposed approach sequentially modifies time series to have a close match between records' spectra and target spectra. The flowchart of the proposed algorithm is shown in Figure 3. The required user inputs are target response spectrum, two horizontal components of the ground motion, time step, damping ratio, target peak ground acceleration (PGA). In the first step, the original acceleration time history is initially scaled to the target PGA of the record so as to preserve the shape of the envelope of the time series at high frequencies. The component-specific Sa- and IP- target spectra are then constructed using Equation 3. We subdivide the target periods into smaller subgroups to increase the stability of the matrix inversion as well as to avoid numerical convergence problems. In that regard, we divide Sa- and IP- periods into  $k$  subgroups and select every  $k^{\text{th}}$  element using the equation  $k=(N/n)$ , where  $N$  is the total population size, and  $n$  is the sample size. The maximum sample size is set to 20 because it yields optimum convergence. Moreover, we improve the stability of the matrix inversion by using a Tikhonov regularization method, which is also known as ridge regression [9].

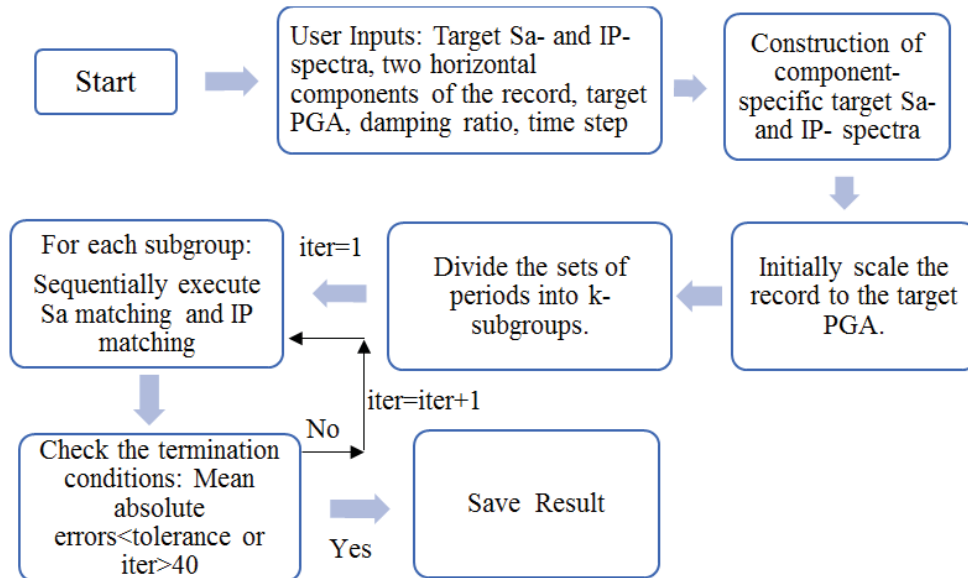

Figure 3. Flowchart of the Sa- and IP-matching algorithm.

Each iteration sequentially performs Sa matching and IP matching stages for each subset. In other words, the accelerogram adjusted using Sa-matching phase is integrated to obtain the velocity time history, which is then used as an input for IP matching. We note that the relaxation factors used to damp the total acceleration and velocity adjustments affect the convergence. Thus, after several trials, we select acceleration relaxation factor of 0.50 and velocity relaxation factor of 0.10. The iterations continue until the desired tolerance levels are achieved, or the maximum number of iterations is reached. Mean Absolute Error (MAE) of the misfit between target spectrum and record spectrum over  $N$  periods is calculated using the following formula:

$$MAE = \frac{1}{N} \sum_{i=0}^N |\ln(y_i) - \ln(x_i)| \quad (7)$$

where  $y$  denotes the target value and  $x$  is the current value of the reference time series. The tolerance levels for the Sa- and the IP- matching are 0.05 and 0.10, respectively. The maximum allowable number of iterations is selected as 40.

## 6 CASE STUDY FOR RECORD MATCHING

Figure 4 shows the acceleration, velocity, and displacement time histories of H2 horizontal component of the pulse record (1979 Imperial Valley-06 earthquake Agrarias station) before and after Sa- and IP- matching. The left panel of the figure illustrates the time histories of the original record, whereas the right panel shows the adjusted time series. It is seen that the addition of wavelets results in some changes in the amplitude and waveforms of the records. However, we assess the suitability of the records for nonlinear response history analysis based on Sa and IP IMs, which are pertinent to the structural response. It should be noted that the consideration of IP in the matching process alleviates the need to preserve the pulse characteristics (i.e., pulse amplitude and pulse period) in the matched record as the IP accounts for the destructive effects of the near-fault ground motion with or without velocity pulses. Thus, we do not check whether the resulting record exhibits velocity pulse.

Figure 5 compares the Sa- and IP spectra of the record and target spectra. Also plotted are the linearly scaled spectra of the record. These results indicate that the proposed matching algorithm performs well in the simultaneous matching of the Sa and IP.

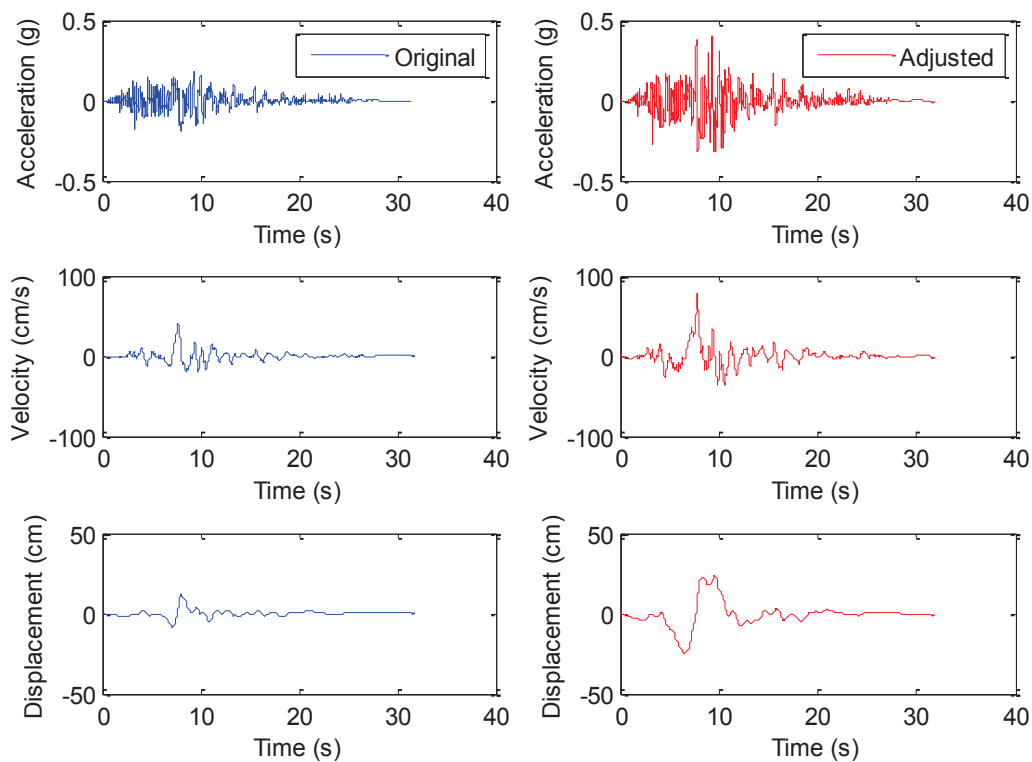

Figure 4. Acceleration, velocity, and displacement time histories of H2 component of the pulse record (1979 Imperial Valley-06 earthquake Agrarias station record) before and after Sa- and IP- matching.

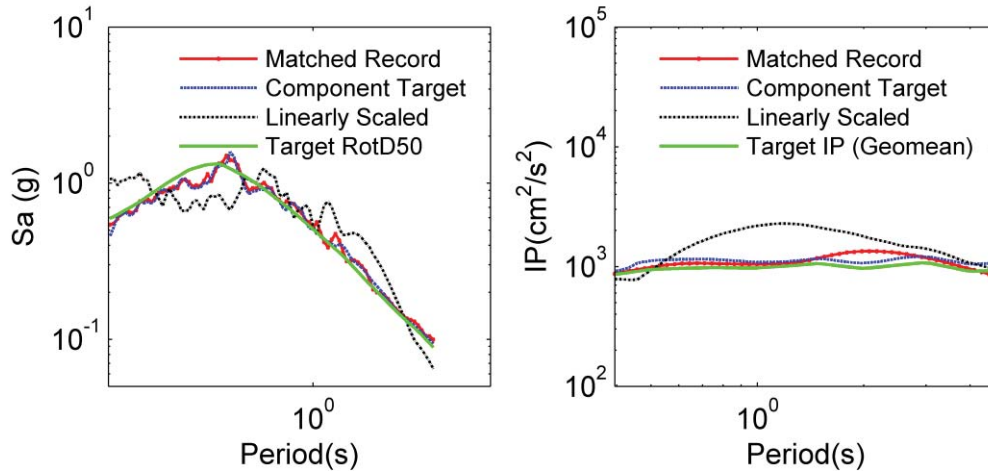

Figure 5. Comparisons of record Sa- and IP- spectra and target spectra

## 7 NONLINEAR STRUCTURAL RESPONSES

Using the proposed matching algorithm, we match 11 near-fault records to the target median scenario spectrum for an earthquake scenario with Magnitude=7,  $R_{rup}=3$  km and site condition  $V_{s,30}=400$  m/s. In our analysis, we utilize both Sa- matched and Sa- and IP-matched records. The records are randomly selected in the magnitude range 6.5-7.5,  $R_{rup}$  range 0-20 km, and  $V_{s,30}$  range 180-760 m/s. We perform nonlinear dynamic analyses of bilinear SDOF systems having five different structural periods between 0.6 and 3.0 seconds and two different inelasticity levels defined by strength reduction factors of  $R=2$  (nearly elastic) and  $R=6$  (highly inelastic). Damping ratio and strain hardening ratio are taken as 5% and  $\alpha=0.10$ , respectively. We also consider a 2-story moment-resisting frame that includes the Modified Ibarra Krawinkler stiffness and strength degradation material model [10][11]. The analytical model also takes into account the P-delta effects. The fundamental period of the frame structure is found to be 0.82 sec. The detail information about this structure can be found in [12]. In this case, the selected records are matched to the 84<sup>th</sup> percentile of the target spectrum to obtain post-elastic maximum interstory drift ratios (MIDRs) of the structure.

Figure 6 plots the mean ratio of the IPs obtained from Sa-matched records to the IPs obtained from Sa- and IP-matched records versus period. It is seen that the mean IP value of the Sa- matched records is lower than that of the Sa- and IP-matched records. Because there is almost no difference between the Sa-values of both record sets, we may attribute the differences observed in structural response to differences in IPs.

Figure 7 shows the results of inelastic displacements of SDOF systems having various periods for  $R=2$  and  $R=6$ . We see that the Sa-only matched records produce a lower mean structural response compared to the Sa- and IP-matched records, suggesting that the effects of IP on structural response are more pronounced for the highly inelastic case. We also observe that, in most cases, the Sa- and IP-matched records produce lower levels of dispersion compared to Sa-only matched records. Figure 8 shows the MIDRs of a 2-story steel frame structure obtained using Sa- matched and Sa- and IP-matched records, where dashed lines show the median results of the record sets. As seen, the MIDRs of Sa-matched records are, on average, lower than that of Sa- and IP -matched records. This indicates that the records having lower IP values than the target IP can produce biased-low responses, relative to the Sa- and IP-matched

record, highlighting the importance of considering the IP parameter in the record modification process.

Figure 6. Mean ratio of the IPs obtained from Sa-matched records to the IPs obtained from Sa- and IP-matched records.

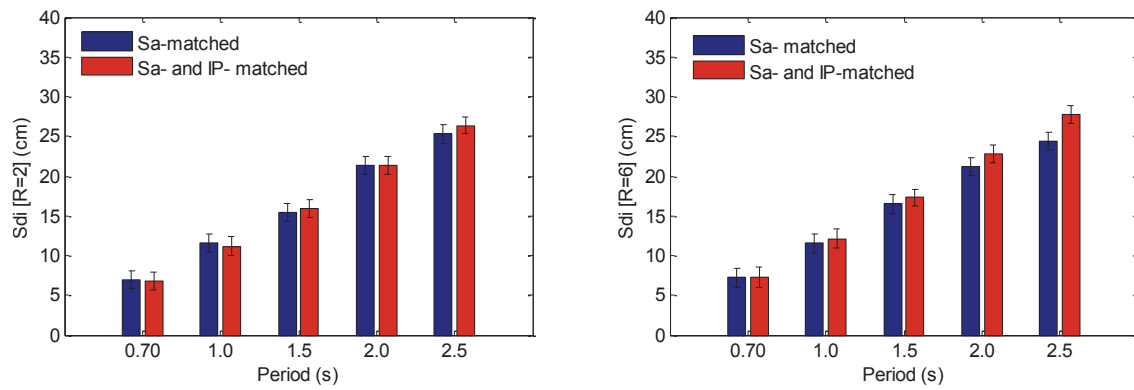

Figure 7. Inelastic displacements of SDOF systems having various periods for R=2 and R=6.

Figure 8. MIDRs of 2-story steel frame ( $T_1=0.82$  s) obtained using Sa- matched and Sa- and IP-matched records.

## 8 CONCLUSIONS

This paper proposes a ground-motion matching procedure that adjusts the near-fault records to simultaneously match target Sa- and IP- spectra. The algorithm builds upon the existing technique, RspMatch, for spectral matching and extends the time-domain modification for IP matching. The case study results show that our algorithm can effectively match the target values over a range of periods. One advantage of considering IP IM is that there is no need to preserve the pulse characteristics in the matching process because IP takes into account the effects of velocity pulses (i.e., pulse amplitude and pulse period). The results of this study indicate that the proposed matching approach can prevent potential bias in nonlinear structural response.

The Matlab source code and the documentation for the Sa- and IP- matching procedure are available at ([https://github.com/zenginesra/Sa\\_IPmatch](https://github.com/zenginesra/Sa_IPmatch)).

---

### Abstract

*Using induction heat treatment to increase the yield stress of one half of a steel brace section as well as inducing intentional eccentricity along the brace length has been experimentally proven to increase the limited post-yielding stiffness exhibited by concentrically braced steel structures. The high-post yielding stiffness and controllability of the brace response through the two material components and eccentricity provides the brace the capability of satisfying multiple displacement performance objectives offering a reduced section size. Design expressions that describe the mechanical behaviour of the bracing system are developed. The seismic performance of steel braced frames using the two-component composite steel braces with intentional eccentricity is investigated and a direct displacement-based design method (DDBD) is proposed in order to support their implementation to building structures. The design method is validated through a verification study performed on the theoretical design of a 4-storey office building and seismic performance is assessed through dynamic non-linear time history analysis (NTHA). Time-history analysis results demonstrate that a better control is achieved with the proposed bracing system for achieving drift and ductility limitations.*

## 1 INTRODUCTION

A new focus on reducing post-hazard financial losses and recovery time, alongside advances in computational methods, has culminated in the emergence of Performance Based Seismic Design (PBSD). Within PBSD, buildings are designed to respond to seismic loading predictably and reliably to various levels of structural performance, increasing hazard resilience [1]. This provides the ability to optimise structures to reduce total life cycle cost and increase sustainability [2]. The poor inelastic behaviour of certain conventional structures has provided difficulties in the reliable prediction of the non-linear response for these structure types [3]. New systems are under development with better controlled inelastic behaviour, providing satisfaction of PBSD with multi-level performance objectives.

In concentric braced frames (CBFs), the poor inelastic behaviour and early buckling of conventional steel braces (CBBs) leads to rapid loss of storey stiffness, large axial deformations, premature brace fracture and deflection of the brace intercepted beam [4, 5]. The localised inelastic deformations at the plastic hinge leads to a low tangential post-yielding stiffness, resulting in the concentration of residual and maximum drifts. A soft-storey mechanism may be produced, leading to structural instability and collapse in multi-storey buildings [6], observed in the aftermath of large earthquakes, notably the 1989 Loma Prieta [7], Northridge 1994 [8] and Kobe 1995 [9] events. The unfavourable inelastic behaviour of CBBs provides challenges for the application of PBSD with multi-level objectives.

The zero or negative post-yielding stiffness in CBBs leads to the design dominated by the more strenuous objective, leading to an increase in strength demand and larger brace sections [10]. Brace systems that possess and provide control of a large positive post-yielding stiffness will result in improved control of structural performance, a reduction in residual deformations and provide more economical structures through application of PBSD [3]. Several methods have been suggested to increase post-yielding stiffness, such as using reinforcement materials with improved strain hardening behaviour or introducing a secondary parallel inelastic system such as a moment resisting frame in parallel with a CBF [11].

In consideration of the need for alternative brace types, Skalomenos *et al.* [12] propose a brace with intentional eccentricity (BIE). The steel brace is arranged with end plate connections that provide an intentional eccentricity, producing a trilinear curve in tensile loading with a large post-yielding stiffness. Further to this concept, Skalomenos *et al.* [13] investigated applying induction-heating (IH) to the BIEs, increasing post-yielding stiffness and ultimate tensile strength, but decreasing ductility. When cyclic loading is applied, Induction-Heated BIEs (IH-BIEs) exhibit large increases in post-yielding stiffness and ultimate tensile strength. By specifying material properties and eccentricity, combinations of the backbone trilinear curves, with differing strengths and post-yielding stiffness can be specified against multi-level seismic design.

In this paper, a force-deformation model of IH-BIEs and the effect of the material properties and eccentric steel section is discussed. A Direct Displacement Based Design (DDBD) method is then proposed for a steel braced frame with IH-BIEs (FIHB) that satisfies multiple performance objectives, each relating to different level of seismic intensity. For validation, a 4-storey building is designed using the proposed method and non-linear time history analysis is performed. The results are compared against those of the same frame designed using conventional steel braces to Eurocode 8 [14].

## 2 INTENTIONALLY ECCENTRIC INDUCTION HEAT TREATED BRACES

### 2.1 Force-Deformation Behaviour

IH-BIEs comprise a conventional steel hollow member that is induction heated on one half and given a parallel offset from the normal working points of a conventional brace. A rigid brace-to-end gusset plate connection transfers the axial loads from the bracing member to the frame [13]. Figure 1a shows the force-deformation behaviour of a single IH-BIE in tension. A ‘first yield’ and ‘second yield’ point, denoted by  $P_{y1}$  and  $P_{y2}$ , are observed, corresponding to full yielding of the conventional steel and induction-heat treated steel, respectively. In compression, the brace is assumed to act elastic-plastically, and the compressive strength is taken as  $P_{y1}$ . Skalomenos *et al.* [13] found that the induction-heated steel has a fracture ductility 3 times lower than conventional steel and as a result, yielding of the IH-steel may lead to fracture before  $P_{y2}$  is reached. Therefore, in design, it is proposed that a safety factor is applied to give a lower ultimate tensile strength,  $P_u$ , preventing premature fracture of the brace. Figure 1a demonstrates the safety factor,  $\gamma$ , defined by relating the point at which the IH-steel yields to the portion of the section remaining elastic. A value of  $\gamma$  equal to 0.6 was found sufficient to limit the IH-steel from yielding for an IH-ratio, defined as  $F_{y,IH}/F_{y,CS}$ , equal to 4 and a value of 0.5 for all values of an IH-ratio below 4, although this requires verification. The value of this factored ultimate tensile strength is given in terms of  $\gamma$ ,  $P_{y1}$  and  $P_{y2}$  in Equation 1.

$$P_u = (1 - \gamma)P_{y1} + \gamma P_{y2} \quad (1)$$

The design method considers IH-BIEs in a brace pairing, with the maximum storey shear resistance of the brace pair in an inverted- ‘V’ configuration given by the sum of compressive strength,  $P_{y1}$ , and ultimate tensile strength,  $P_u$ .

Figure 1: a) Design quantities of a general IH-BIE Member b) Tensile force-deformation behavior of a 244.5 mm x 8 mm CHS IH-BIE member at differing eccentricities and IH-ratios

### 2.2 Effect of eccentricity and induction-heating

Figure 1b shows the effect of the eccentricity and IH-ratio on the idealised behaviour of an 244.5 mm x 8 mm circular hollow section IH-BIE brace member. As eccentricity increases the brace yields earlier, and  $P_{y1}$ , the elastic stiffness,  $K_e$  and post-yielding stiffness,  $K_{in}$  all decrease, increasing deformation for a given force.  $P_{y2}$  is constant as it is not a function of

eccentricity. For a constant eccentricity at increasing IH ratios,  $P_{y1}$  and  $K_e$  are constant, and post-yielding stiffness increases as the induction heat-treated steel remains elastic at greater forces and provides a restoring force to the brace. When combined with the effect of eccentricity, the strain demand on the conventional steel is uniform, preventing a strain concentration that produces local buckling [13]. By varying geometry and material properties a certain controllability of yield points and post-yielding stiffness is afforded, allowing IH-BIEs to be adjustable to satisfy several strength or deformation requirements.

### 3 PROPOSED MULTI-LEVEL DIRECT DISPLACEMENT BASED DESIGN METHOD

The Direct Displacement-Based Design method was selected for the PBSDB of FIHBs, since it has been validated for many cyclic force-deformation behaviours [1] and for application in CBFs [15]. DDBD involves the substitution of the MDOF model for an equivalent SDOF system with a secant stiffness and viscous damping that correspond to that of the real structure at maximum displacement response. In the proposed method, the traditional DDBD method is altered so that the satisfaction of two interstorey drift targets relating to different performance levels are achieved by a singular FIHB design, with no significant iterations.

#### 3.1 Selection of performance objectives

Two performance objectives relating to the interstorey drift, are first selected by the designer for a ‘design’ and a ‘maximum’ performance objective. For the purposes of validating the method, a design interstorey drift limit of 1% associated with life safety and a maximum interstorey drift limit of 2% associated with collapse prevention are later assumed and are comparable with drift limits and performance objectives provided by the SEAOC Blue Book [16] and ASCE 41-13 [17] for steel CBFs. The life safety objective is related to the EC8 design seismic action, 10% probability of exceedance in 50 years (a return period of 475 years), with the collapse prevention objective related to a 2% probability of exceedance in 50 years seismic action (a return period of 2475 years). In addition, the structure will be checked against a 0.5% limit for the damage limitation, ‘frequent’, seismic action, with a 10% probability exceedance in 10 years (a return period of 95 years).

#### 3.2 Design and yield displacement profiles

The selection of a suitable target displacement profile is a key design assumption for translating a MDOF system to a SDOF system and in DDBD methods is generally taken as the first mode inelastic shape of a structure. The high post-yielding stiffness of the FIHB is expected to produce a first mode inelastic displacement profile similar to an MRF due to the prevention of the column-sway inelastic displacement profile that is produced in CBFs. In this method, the equation empirically formulated by Priestley *et al.* [1] for the normalised first mode inelastic shape of moment-resisting frames is used, given in Equation 2. Further research is required to determine the first mode inelastic shape for FIHBs, but this profile provides a good approximation for FIHBs in preliminary analysis. Two design displacement profiles are calculated, one each for the design objective and maximum objective. The first floor is taken as the critical storey, as it is expected to obtain the highest interstorey drift concentration. The design displacement for the  $i^{\text{th}}$  storey,  $\Delta_i$ , can be found by scaling the first-floor design displacement and is given by Equation 3. This step is undertaken twice, using the interstorey drift once for the design event, giving  $\Delta_{i,d}$ , and once for the maximum event, giving  $\Delta_{i,u}$ .

$$n \leq 4 : \delta_i = \frac{H_i}{H_n} \quad (2)$$

$$n > 4 : \delta_i = \frac{4H_i}{3H_n} \left( 1 - \frac{H_i}{4H_n} \right) \quad (3)$$

$$\Delta_i = \delta_i \left( \frac{\Delta_1}{\delta_1} \right)$$

Where  $n$  is the number of storeys,  $\delta_i$  is the normalised lateral displacement of the  $i^{\text{th}}$  storey,  $H_i$  is the elevation of the  $i^{\text{th}}$  storey and  $H_n$  is the elevation of the top storey,  $\Delta_1$  is design displacement of the first storey and  $\delta_1$  is the inelastic mode shape of the first storey.

IH-BIEs exhibits the ‘first yield’ point when the conventional steel is fully yielded and can be considered to occur at the same time in compression and tension. The axial deformation of an IH-BIE brace cannot be determined without knowing section properties or eccentricity. Therefore, to avoid incurring a significant number of iterations in the design procedure, the inter-storey drift at yield is assumed to be 0.2%. In the existing experimental tests, IH-BIEs all yielded at approximately 0.2% interstorey drift [13]. For the purposes of validating the multi-level design method, the braces use the same procedure for the design and maximum displacements, given by Equation 2 and Equation 3, giving  $\Delta_{i,y}$ .

The design, maximum and yield displacement of the SDOF system and equivalent mass can then be determined by Equations 4-7, using mass and displacement of the  $i^{\text{th}}$  storey,  $m_i$  and  $\Delta_i$ . In order to calculate the equivalent viscous damping, the displacement ductility of the equivalent system at both the design event and maximum event is found by Equation 8.

$$\Delta_y = \frac{\sum_{i=1}^n (m_i \cdot \Delta_{i,y}^2)}{\sum_{i=1}^n (m_i \cdot \Delta_{i,y})} \quad (4)$$

$$\Delta_d = \frac{\sum_{i=1}^n (m_i \cdot \Delta_{i,d}^2)}{\sum_{i=1}^n (m_i \cdot \Delta_{i,d})} \quad (5)$$

$$\Delta_u = \frac{\sum_{i=1}^n (m_i \cdot \Delta_{i,u}^2)}{\sum_{i=1}^n (m_i \cdot \Delta_{i,u})} \quad (6)$$

$$M_{eff} = \frac{\sum_{i=1}^n (m_i \cdot \Delta_{i,d})}{\Delta_d} \quad (7)$$

$$\mu_d = \frac{\Delta_d}{\Delta_y}$$

$$\mu_u = \frac{\Delta_u}{\Delta_y} \quad (8)$$

### 3.3 Equivalent viscous damping and calculation of base shear

Priestley *et al.* [1] give an equivalent viscous damping expression for ductile steel frames based on the Ramberg-Osgood hysteretic shape which provides a close fit to that exhibited by FIHBs, given in Equation 9. For the purposes of verifying this method, EVD is not considered critical, and the chosen expression yields satisfactory results. The EVD expression assumes 5% elastic damping, although steel structures feature a lower level, of 2%. Thus, the expression is calibrated with a correction coefficient based on a numerical study by Grant *et al.* [18]. Equation

10 gives equivalent viscous damping using the correction factor  $k$ , provided by Equation 11. A correction coefficient,  $\lambda$ , of -0.617 is taken for tangent stiffness damping [1]. The equivalent viscous damping is found using the displacement ductility between yield and design level,  $\mu_d$ , since  $\xi_{eq}$  is used to reduce the displacement spectrum related to the design seismic action of 10% probability of exceedance in 50 years. Once  $\xi_{eq}$  is obtained, the damping correction factor is found by the expression recommended by Eurocode 8 [14] given in Equation 12.

$$\xi_{steelframe} = 0.05 + 0.577 \left( \frac{\mu - 1}{\mu\pi} \right) \quad (9)$$

$$\xi_{eq} = \xi_{steelframe} - k\Delta\xi_{elastic} \quad (10)$$

$$k = \mu^\lambda \quad (11)$$

$$\eta = \sqrt{\frac{0.1}{0.05 + \xi_{eq}}} \quad (12)$$

The target period,  $T_{eff}$  can be obtained using the reduced damped displacement spectrum by reading the spectral ordinate at  $\Delta_d$ . The secant stiffness is then calculated with Equation 13, and subsequently the base shear for the design objective using  $\Delta_d$  in Equation 14 and storey forces using Equation 15.

$$K_{eff} = 4\pi \frac{M_{eff}}{T_{eff}^2} \quad (13)$$

$$F_b = \Delta_d \cdot K_{eff} \quad (14)$$

$$F_i = \frac{F_b \cdot m_i \cdot \Delta_i}{\sum_{i=1}^n (m_i \cdot \Delta_i)} \quad (15)$$

### 3.4 Brace design

To satisfy both performance objectives, once the design level storey shear is found from the DDBD procedure, the values of displacement ductility at the design and maximum objective, and an assumed value of post-yielding stiffness ratio is used to find a brace section with an eccentricity that satisfies both drift targets. For this procedure, brace sections are considered in terms of brace pairs of an inverted- 'V' configuration. The ratio of storey shear resistance between that at yield and design or maximum level is related in Equation 16 to the corresponding displacement ductility,  $\mu_d$  or  $\mu_u$ , and the post-yielding stiffness ratio,  $\alpha$ . Figure 2 shows the relationships developed by Equation 16, which allows selection of a suitable brace section.

$$\Omega_d = \alpha(\mu_d - 1) + 1 = \frac{P_d + P_{y1}}{2 \cdot P_{y1}} \quad (16)$$

$$\Omega_u = \alpha(\mu_u - 1) + 1 = \frac{P_u + P_{y1}}{2 \cdot P_{y1}}$$

$$\Omega_u = 1 - \frac{\gamma_u}{2} \cdot \left( 1 - \frac{P_{y2}}{P_{y1}} \right) \quad (17)$$

Figure 2: Graph showing the proposed multi-level seismic design and the relationships developed in the proposed design procedure

By using an assumed value for  $\alpha$  and the design displacement ductility,  $\mu_u$ , the ratio  $\Omega_u$  is found using Equation 16. Then, the ratio  $P_{y2}/P_{y1}$ , is calculated using the relationship given in Equation 17, between  $\Omega_u$  and the parameter limiting maximum tensile strength  $\gamma_u$ . After  $P_{y2}/P_{y1}$  is obtained, the dimensionless ratio of eccentricity and radius of gyration is then calculated using Equation 18, considering the level of induction heating on the section. Finally, the brace area is calculated using Equation 19 for a given storey shear,  $V_i$ , the calculated  $e/r$  ratio and the ratio  $\Omega_d$ , given by Equation 18. Eccentricity can be determined from radius of gyration in the ratio  $e/r$ , after brace area has been selected. At this stage, the brace design is checked so that the post-yielding stiffness,  $\alpha$ , is within 5% of the assumed value, assuring the required resistance of the brace pair.

$$\frac{P_{y2}}{P_{y1}} = \frac{1}{2} \cdot \left(1 + \sqrt{2} \frac{e}{r}\right) \cdot \left[ \left( \frac{F_{u,CS}}{F_{y,CS}} \right) + \left( \frac{F_{y,IH}}{F_{y,CS}} \right) \right] \quad (18)$$

$$A_{req} = \left(1 + \sqrt{2} \frac{e}{r}\right) \frac{V_i}{2 \cdot \Omega_d} \cdot \frac{1}{F_{y,CS}} \quad (19)$$

For homogenous dissipative behaviour, the maximum value of storey overstrength at the design level, given by Equation 20, was checked to not differ from the minimum value by more than 25%, to avoid excessive storey shear demand, and the formation of a soft storey mechanism.

$$\Omega_i = \frac{P_d + P_{y1}}{V_i} \quad (20)$$

### 3.5 Capacity design rules

To avoid non-linearity in non-dissipative members, such as beams and columns, capacity design criteria adapted from Eurocode 8 [14] is applied using storey overstrength. The brace-intercepted beams are designed for both the gravity loads not considering the diagonals and the unbalanced force,  $P_{ub}$ , transmitted by the IH-BIE brace pair in an inverted- 'V' configuration at the design event seismic action. This is due to the difference in forces transmitted in tension and compression, given by Equation 21. In conventional braces, the effects of flexural yielding and vertical beam deflection from the unbalanced force leads to the prevention of yielding in tension, an increase in ductility demand, and an impairing of the deformation capacity of braces [5, 19]. To preserve the favourable response of the IH-BIEs in an inverted- 'V' configuration, the beam to vertical brace stiffness ratio is limited to a minimum of 0.2, given by Equation 22.

$$P_{ub} = (P_d - P_{y1})\sin\theta \quad (21)$$

$$K_F = \frac{k_b}{k_{br}} = \frac{48EI_b/L_b^3}{2K_e \sin^2 \theta} \geq 0.2 \quad (22)$$

Where  $P_{ub}$  is the unbalanced force,  $P_{y1}$  is the compressive strength, and  $P_d$  is the design tensile strength,  $k_b$  is the flexural stiffness of the beam, given by  $E$ , the elastic modulus of steel,  $I_b$ , the second moment of area of the beam, and  $L_b$ , the length of the beam span and  $k_{br}$  is the vertical stiffness of the brace pair given by  $K_e$ , elastic stiffness of the IH-BIEs.

### 3.6 Proposed design method flowchart

Figure 3 shows the design flowchart of the proposed method, showing how the direct displacement-based design and brace design produce an FIHB that satisfies two selected performance objectives.

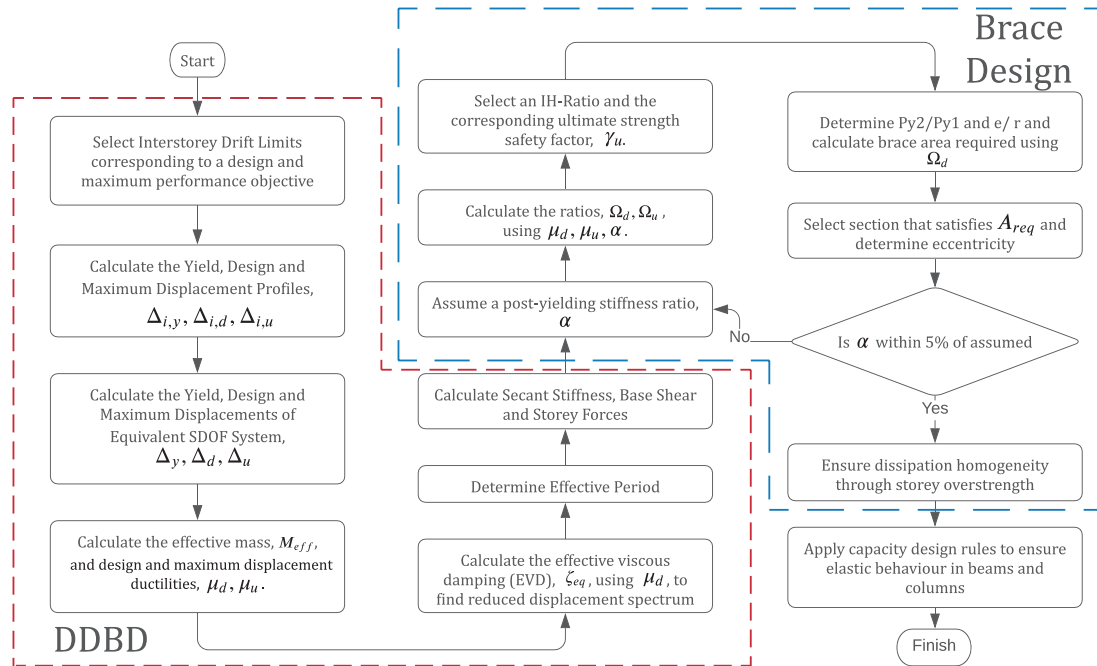

Figure 3: Flowchart of the proposed design method for FIHBs

## 4 VERIFICATION STUDY

### 4.1 Verification case study building

Figure 4: Diagram of a) Floor plan, b) Model elevation plan of the verification study building

A 4-storey mid-rise office building was investigated to verify the proposed design procedure. Figure 4 shows the plans of the 2D frame extracted at the location of the seismic resisting braces in the X-direction, consisting of 2 equally spaced braced bays of 6 metres. An inverted- ‘V’ configuration of the braces was chosen. A constant interstorey height is taken as 4.2 metres and torsional effects are neglected. The frame was designed with conventional braces to EC8 design rules and to the proposed procedure for IH-BIEs, giving two frames in total. The structural design for gravity loads was compliant to EN 1993-1-1 [20]. Permanent and live loads were assumed equal to  $5 \text{ kN/m}^2$  and  $3 \text{ kN/m}^2$  at each storey respectively and the cross sections of all members were selected to satisfy Class 1 requirements. All frames were designed for a ground motion with a probability of exceedance of 10% in 50 years, corresponding to a return period of 475 years, using the 5% damped acceleration spectrum defined by EC8. A peak ground acceleration equal to  $a_{gR} = 0.35g$ , a type B soil, and a Type 1 spectral shape, was assumed. The importance factor,  $\gamma_I$ , was taken as 1, according to EC8 for an ordinary building. The design displacement spectrum was obtained by multiplying the 5% damped acceleration spectral ordinates by the damping correction factor obtained in Equation 12. Non-linear time history analysis

To perform NTHA, the finite element software framework *OpenSees* [21] was used to develop a 2D mixed fibre-distributed frame model of the building. The braces were modelled with the induction heating properties on one half, and with a constant eccentricity. Whilst a 2D frame model, both conventional and IH-BIE braces are modelled in 3D to permit buckling out of plane. To account for second order effects, non-tributary loads were assigned a zero-stiffness leaning column, connected by pinned rigid links. All beam-to-column and columns of the frame are considered pinned, but the braces are fixed, so that only their contribution in resisting the seismic action is considered. The model uses mass-proportional Rayleigh damping, with a damping ratio of 2%, a typical value for steel buildings, and a Newmark acceleration time integration scheme with  $\beta = 0.25$  and  $\gamma = 0.5$ . A suite of 8 semi-artificial ground motions was considered to perform the NTHA, produced by the *Seismic Record Processing program* [22]. Existing ground motion histories were modified to fit the targeted EC8 design elastic response spectrum used in the procedure, so the DDBD method could be validated. For the frequent event and maximum event, the ground motions are scaled by a factor of 0.3 and 1.73, respectively.

## 5 RESULTS

### 5.1 Design summary

Table 1 gives a brief design summary of the FIHB, giving members at each storey of the braced bay. Brace members were selected to meet the slenderness and material properties of the IH-BIEs experimentally validated against the *OpenSees* model, to give confidence in the NTHA. The yield strength of the conventional steel is taken as  $F_{y,cs} = 235 \text{ MPa}$ , and an IH-ratio of 4 was selected, giving  $F_{u,cs} = 940 \text{ MPa}$ . The post-yielding stiffness of the brace pair was assumed to be  $\alpha = 0.16$ , which was later verified, giving the design ratios of  $\Omega_d = 1.64$  and  $\Omega_u = 2.44$ . An  $e/r$  ratio of 0.73 was found and circular hollow sections (CHS) with an area exceeding the calculated value was selected from the Steel Construction Institute Blue Book [23]. Capacity design was then applied to select the frame members.

Storey	IH-BIE Braces						Columns	Beams
	$V_i$ (kN)	D (mm)	t (mm)	e (mm)	$V_r$ (kN)	$\Omega_i$	S355	S355
1	1063.5	244.5	8	60	1303.2	1.23	350 x 10 SHS	HEB 500
2	957.2	244.5	7.1	60	1163.3	1.22	350 x 10 SHS	HEB 500
3	744.5	219.1	6.3	55	919.8	1.24	350 x 10 SHS	HEB 450
4	425.4	168	5.6	40	631.3	1.48	350 x 10 SHS	HEB 400

Table 1: Design summary of the FIHB at the braced bay

### 5.2 Non-linear time history analysis results

Figure 5: Mean maximum interstorey drift profiles of the FIHB using the proposed method and the CBF designed to EC8

To assess whether the design procedure controlled the response of the FIHB to the chosen interstorey drifts and to compare to a conventionally designed CBF, the mean maximum interstorey drift profiles for both braced frames are given in Figure 5. Both frames compare well against the 0.5% limit for the frequent event, with each experiencing drift concentration at the top storey. At the design and maximum event, the FIHB exhibits a response typical of a shear building, close to the 1% and 2% drift targets, in contrast to the severe cantilever type-response observed for the reference CBF. The response of the CBF designed to EC8 matches existing research [24, 25]. The results show excellent plastic engagement of the IH-BIE braces,

with a uniform drift demand, indicating the favourable characteristic of uniform damage distribution, unlike the conventionally designed CBF. The multi-level design method adequately predicts the storey drift demand at both performance objectives, representing excellent performance and satisfaction of the target drifts.

Figure 6: Maximum Displacement Profiles of the FIHBs

The mean and individual NTHA displacement profiles for the FIHB are plotted in Figure 6 against the design displacement profile. The appropriateness of the design displacement profile given in Equation 2 is demonstrated at both the design and maximum event, with only a small difference to the mean displacement profile for both FIHBs. Assumptions made in the DDBD method that the FIHBs provide a similar inelastic first mode shape to steel MRFs are well founded, hence providing an accurate prediction of their behaviour. Further investigation is required to validate Equation 2 for taller FIHBs, with more complex mode effects.

Figure 7: Force-Deformation behaviour of the conventional steel brace pair and the IH-BIE brace pair at the fourth storey at the design seismic action for all ground motions

Figure 7 show the lateral forces in the brace against storey shear drift of the conventional steel braces and the IH-BIEs respectively at the fourth storey, providing the force-deformation behaviour of both conventional steel brace pair and the IH-BIE brace pair system. Compared to a conventional steel brace, which stay elastic at low drifts, the IH-BIE yields earlier at a low

interstorey drift, as predicted, and dissipates energy. This is congruent with the results of Skalomenos *et al.* [13], with a more stable hysteretic behaviour found at low seismic intensities. The brace pairing exhibits a stable, and symmetrical response with a large post-yielding stiffness. The hysteretic shape is similar to that based on the Ramberg-Osgood model used in the assumed expression for equivalent viscous damping. Despite the derivation of Equation 9 relating to ductile steel frames, it provides a suitable translation of the energy dissipation between the IH-BIE system in the MDOF structure to that of the equivalent SDOF system.

## 6 CONCLUSION

In this paper, the performance and a new multi-level direct displacement-based design method has been presented for steel braced frames utilising IH-BIEs (FIHBs). The procedure assumes a displacement profile and equivalent viscous damping ratio developed for steel MRFs. Brace design is achieved by relating displacement ductility and a post-yielding stiffness ratio to the storey shears at a design and maximum performance objective, to find a single brace section with a given induction-heating ratio and eccentricity that can satisfy multiple drift targets corresponding to different levels of seismic intensity. To validate the design method, non-linear time history analysis at three different seismic intensities was performed on a 4-storey FIHB analytical model using *OpenSees*. The results indicate that:

- The design method adequately controls the drift demand of the FIHB
- The FIHB satisfies both the 1% interstorey drift limit at the design performance objective and a 2% interstorey drift limit at the maximum performance objective, without a design change or significant iteration
- FIHBs exhibit a shear building response and produce a hysteretic shape like that of an MRF, indicating the satisfaction of the assumption of a linear displacement profile and the chosen equivalent viscous damping expression
- The FIHB avoids concentration of drifts compared to a reference concentrically braced frame (CBF) designed to Eurocode 8 and promotes reliable and symmetric dissipation of seismic energy

---

### Abstract

*The paper shows, that especially for pulse-like ground motions, it is possible to truncate pulse-like signals using a novel wavelet-based definition that identifies the duration of the predominant velocity pulse. The truncated time history can efficiently reproduce the increased seismic demand that near-field records typically produce. Substituting the original ground motion with the truncated signal, significantly accelerates structural analysis and design. The truncated signal is the part of the original accelerogram that coincides with the duration of the predominant pulse, which is identified using a wavelet-based procedure, previously proposed by the authors.*

**Keywords:** Record truncation, effective duration, predominant pulse, pulse-like, pulse index, near-field.

---

## 1 INTRODUCTION

Replacing an acceleration time history with an equivalent, “truncated”, signal has many benefits in terms of accelerating the seismic performance assessment and for understanding structural response. Although this is a very appealing approach, experience has shown that there is no silver bullet to the problem. It is practically impossible to have a record truncation algorithm that is efficient and accurate for all ground motions and all structural systems possible. However, if the problem is narrowed down to the case of pulse-like ground motions, it is possible to achieve an efficient truncation using a novel wavelet-based definition for the record effective duration. The effective duration is calculated first fitting a wavelet on the ground motion and then truncating the record to the time interval that corresponds to the fitted wavelet.

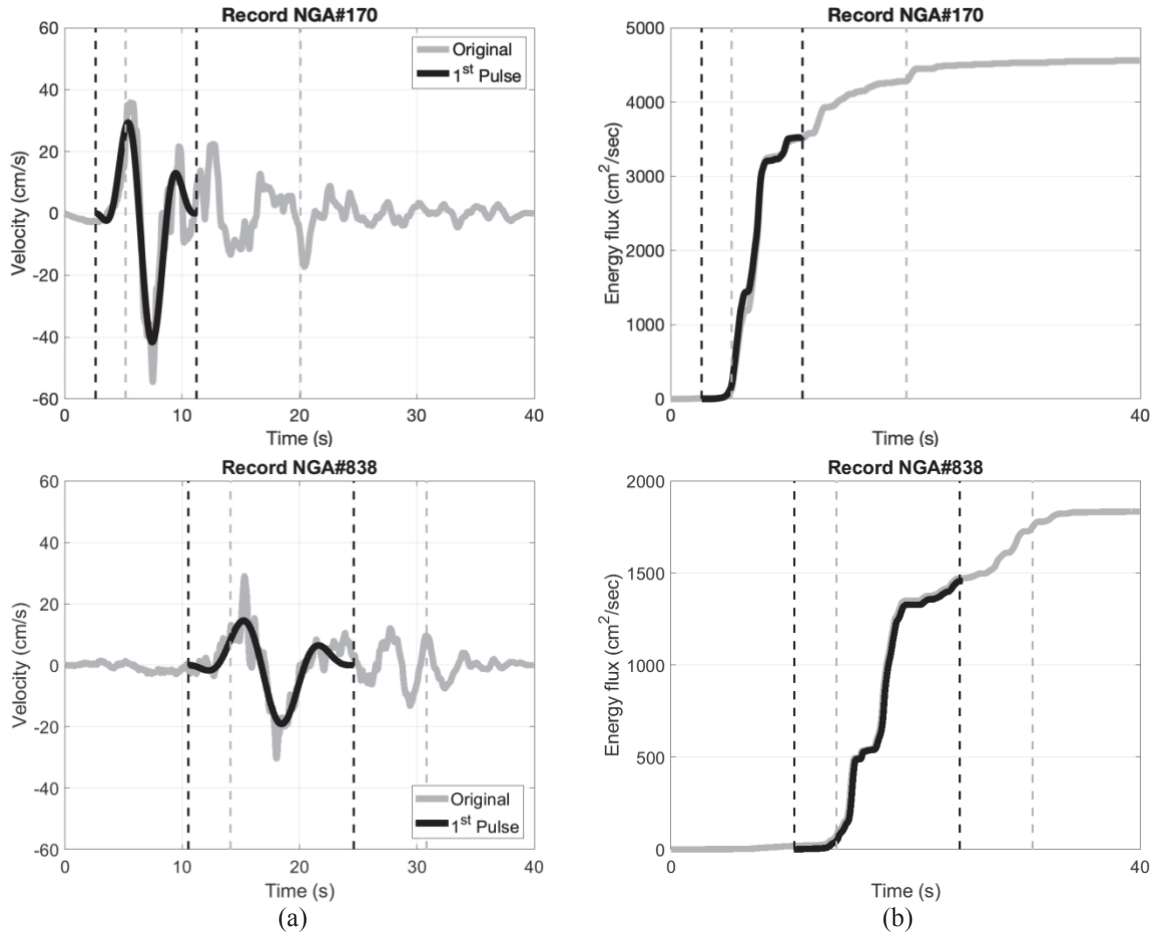

One of the early efforts for record truncation was that of Srivastav and Nau [1] who studied the influence of truncated earthquake records on the response of long-period structures. They recommend truncating the earthquake record at a small value of acceleration in order to reduce the error. However, most efforts are based on Arias intensity [2]. For example, Jin et al. [3] proposed the use of Arias intensity in order to study arch dams, while artificial intelligence approaches have been also proposed [4].

The scope of this study is to adopt the wavelet-based duration definition proposed by Repapis et al. [5] in order to truncate the acceleration time history and obtain a simpler and shorter signal. The paper shows that this practice can efficiently accelerate the simulation time with minor loss of accuracy. The efficiency of the proposed truncation approach depends on the pulse content of the record, which can be quantified with the aid of a pulse index. The approach proposed is quite efficient in the case of pulse-like records, such as those recorded in the case of near-field ground motions with forward directivity. These signals are characterized by strong, coherent, long period pulses that are found mainly in the strike normal direction. The effect of significant velocity pulse on the structural response has been highlighted by several studies, e.g. [6], [7], [8].

## 2 METHODOLOGY

Figure 1 shows two characteristic pulse-like ground motion records and the corresponding significant pulses. The pulses have been identified using the methodology proposed by Mimoglou et al. [9], i.e., appropriately fitting a wavelet on the signal. The plot on the right shows the cumulative energy flux and the time limits that correspond to the proposed “wavelet-based duration” (black dashed lines). The plots also show the 5% and the 95% of the record energy flux (dashed grey lines), which was proposed by Trifunac and Bray [10] as a measure of the record “significant duration”. Clearly, the two definitions of record duration differ considerably (Figure 1a).

In order to calculate the record duration, we first extract the predominant pulse. According to [9] the extraction is based on optimally fitting the Mavroeidis and Papageorgiou wavelet [11] on the signal. This is a versatile wavelet, suitable to represent different duration levels, since it includes a parameter that is explicitly associated with the number of pulse cycles. A further advantage of this wavelet is that it is defined as the product of a sinusoidal periodic function and a bell-shaped envelope.

**Figure 1: (a) Velocity time history showing the total, the proposed wavelet-based and the significant duration definition, (b) Energy flux (records NGA #170 and NGA #838).**

The Mavroeidis and Papageorgiou wavelet [11] depends on four parameters that control the frequency ( $T_p$ ), the amplitude ( $A$ ), the number of cycles ( $\gamma$ ) and the polarity ( $\phi$ ) of the signal. The frequency is obtained as the period value that the product of velocity and displacement spectra becomes maximum. An exhaustive search algorithm is then adopted in order to identify the other three parameters; the search is narrowed to two parameters since the amplitude and the number of cycles are related by the expression proposed by Taflampas *et al.* [12]:

$$CAD = \frac{\gamma A T_p}{\pi} \quad (1)$$

where CAD is the cumulative absolute displacement, obtained as the integral of the absolute value of ground velocity. The wavelet parameters that have the best cross-correlation value with the original signal define the most suitable wavelet model of the record predominant pulse. Once the wavelet is fitted on the ground motion, e.g., see Figure 1a, the wavelet-based effective duration of the signal is defined by the time boundaries of the fitted pulse.

The truncated signal is the part of the original record contained in the time boundaries of the wavelet that represents the predominant pulse (Figure 1a black vertical lines). Therefore, the truncated signal contains all the information, including the high frequency information, of the original ground motion. Moreover, according to Figure 1b, the ends of the proposed duration definition appear at points where the graph of the energy flux shows a horizontal step with zero first gradient. Therefore, there is no significant baseline offset at the beginning and the end of the truncated duration. This is not the case with other duration definitions, e.g. the “significant

duration” definition that use the arbitrary limits of 5 to 95% of the total energy flux in order to truncate the ground motion.

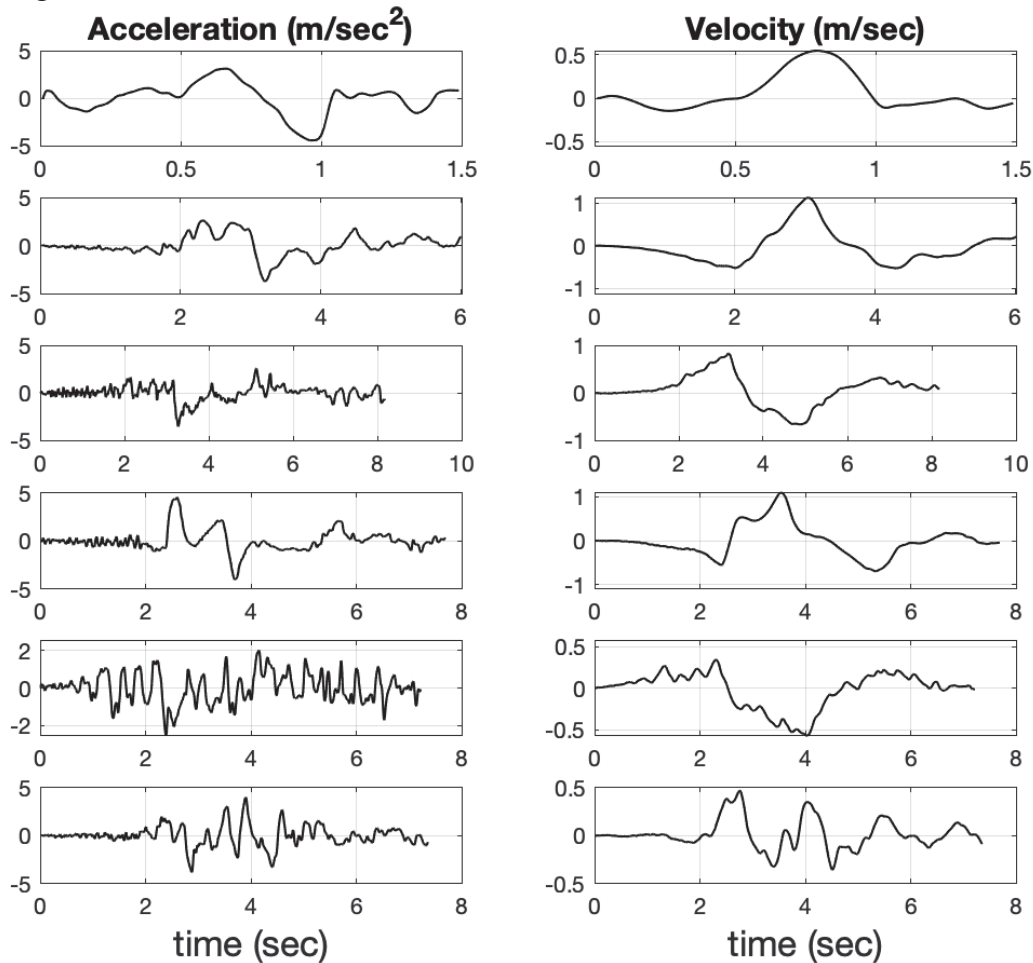

Figure 2: Acceleration and velocity time histories of truncated signals.

Thanks to the proposed wavelet fitting, the time boundaries identified, ensure that the truncated signal starts and ends at an acceleration value close to zero, similarly to the case of recorded acceleration time histories. Therefore, the limits of the envelope can be considered as boundary tapers that attenuate the harmonic function and smooth the baseline of the cut-off instants. This can be better understood looking at Figure 2, where the acceleration and velocity of six truncated signals are shown. The time histories smoothly converge to zero acceleration and velocity line which allows to use them for structural response history simulations without the need for further processing.

### 3 GROUND MOTION RECORDS

A set of 48 pulse-like ground motion records, included in the PEER-NGA2-West database [13], have been selected for our work. The excitations were recorded on different soil types and distances from the rupture plane and have different values of predominant pulse periods. Moreover, the selected ground motion sample contains records with strong directivity, mainly in the fault-normal direction (e.g., Loma Prieta), or records where both the fault-normal and the fault-parallel components show prominent directivity effects (e.g., Erzincan-Turkey).

#### 4 NUMERICAL INVESTIGATION

The efficiency of the proposed record truncation approach is studied using a nine-storey steel moment-resisting frame. The well-know LA9 frame is used as a testbed multi-degree-of-freedom (MDOF) structure. The building consists of five bays and a hinge-storey basement. The gravity loads and the mass of the internal gravity-resisting frames are placed on a leaning column, which does not contribute to the lateral stiffness. The fundamental period of the frame was found equal to  $T_1=2.35$  sec and the mass modal participation of the first mode amounts to 84% of the total mass. Thus, the frame is essentially dominated by the first mode, while higher modes may also contribute to the response. The cross-sections and more details about the building design can be found in [14]. A centreline model is adopted using the OpenSees platform [15]. The model account explicitly for the geometric nonlinearities in the form of  $P-\Delta$  effects. The columns are assumed linear-elastic, while a quadrilinear model is adopted for the beam-column connections. More specifically, the moment-rotation relationship of all beam-column connections have degrading properties equal to:  $a_h=10\%$ ,  $a_c=-50\%$ ,  $\mu_c=3$  and  $r=50\%$ .

**Figure 3: Ratio of the maximum interstorey drift for the 9-storey steel moment frame versus the calculated cross correlation.**

Primarily, the correlation with a pulse index is studied. Since the proposed wavelet-based truncation, in principle, applies to pulse-like ground motions, the seismic demand obtained with the truncated and the original ground motions is expected to be close. However, often the proposed approach gives sufficiently accurate results also for records that have been a priori classified as non pulse-like. It is, therefore, very useful to have a metric that can be used to determine, prior analysis, if the proposed truncation can be used to substitute the original signal. An obvious metric suitable for this purpose is a “pulse index” such as the one proposed by Kardoutsou *et al.* [16], which is defined as the cross-correlation of the original signal and the extracted wavelet and adopted in our work. This study is also based on fitting the Mavroeidis and Papageorgiou wavelet, as discussed in [9]. The authors recommend that records with  $PI$  less than 0.55 are non-pulse like, while when  $PI > 0.65$  the record is definitely pulse-like. Records with intermediate values, i.e.,  $0.55 < PI < 0.65$ , are characterized as ambiguous.

Figure 3 compares the ratio of peak interstorey drift of the original and the wavelet-based truncated time-history versus the Pulse Index ( $PI$ ). The comparison is based on the record set of FEMA P-695 [17]. A different and well-known record database is adopted in order to use ground motions that are completely different from those used in their previous studies of the authors, [9], [16]. Moreover, the ground motion set of [17] consists of 44 far-field records, 28 near-field records characterized as “pulse-type” and 26 near-field records characterized as “non pulse-type”. The far-field set includes earthquakes of large magnitude ( $M_w > 6.5$ ), recorded on

soil types C and D according to the NEHRP classification. The pulse-type set contains records, with varying pulse periods, corresponding to events of magnitude between 6.5 and 7.6. These records present strong directivity effects in the fault-normal/and or the fault parallel direction.

According to Figure 3, the difference in the maximum peak interstorey drift demand between the original and the truncated records is small for ground motions with a pulse indicator  $PI$  above the 0.65 threshold. This observation holds even for records that belong to the far-field set. The largest differences are again found for the far-field records (red crosses), but even for  $PI < 0.55$  the differences do not seem to exceed on average 18%. Overall, for the building examined, the scatter in the computed drift values is significantly decreased as  $PI$  increases, regardless of the classification of the ground motion record. This indicates the efficiency of the proposed wavelet-based approach for truncating a ground motion record and also the potential on the proposed pulse index  $PI$  metric to quickly assess using the efficiency of the proposed wavelet-based truncation.

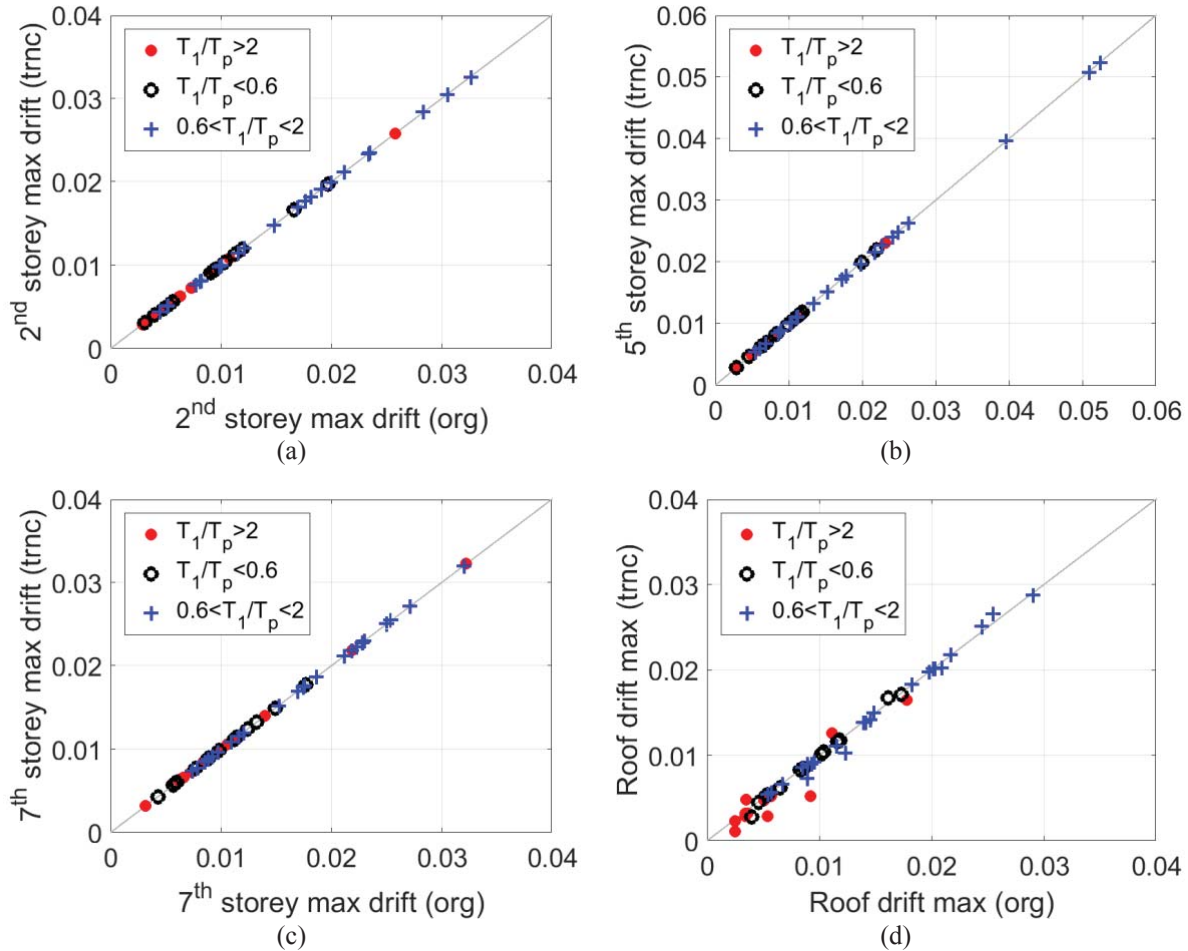

**Figure 4: (a) Profile of the median and the 16 and 84% percentiles drift demand for the 48 pulse-type ground motions; (b) Maximum interstorey drift obtained using the original and the truncated records versus the  $T_1/T_p$  ratio.**

In the following, the LA9 steel frame is subjected to the 48 near-field ground motions with forward directivity. Figure 4a presents the median peak interstorey drift demand and the corresponding 16% and 84% percentile curves of the interstorey drift demand. Excellent agreement for all the stories has been achieved along the height of the frame. Furthermore, the effect of record-to-record variability on the maximum interstorey drift demand is studied in Figure 4b. Although minor differences are seen for individual records, for the majority of ground motions the drift estimates of the original and the truncated signal practically coincide. Figure 4b deserves further attention. A different marker colour has been adopted depending on the storey that the maximum interstorey drift occurred. Overall, the seismic response computed for the truncated signals, follows the same pattern observed for the original records while for most cases the maximum drift demand occurs at the same level. Since the structure studied is sensitive to the first mode, the larger demand is due to records with  $T_1/T_p \leq 1$ . Furthermore, for these records, the peak drift appears at the middle stories (stories 4, 5 and 6).

Our findings are in agreement with Baker and Cornel [18] who discuss the effect of pulse period on the seismic behaviour of MDOF systems. They investigated the effect of the pulse on the higher modes of excitation through MDOF structures sensitive to second mode excitation and suggested that the ratio  $T_1/T_p$  is indicative of the level at which the peak displacement occurs; short period records excite higher modes, while for records with long period pulses the maximum response is expected at the low stories, indicating that first mode response governs

the peak displacements of the building. They proposed the thresholds,  $T_1/T_p < 0.5$  and  $T_1/T_p > 2$  that are also shown as vertical dashed lines in Figure 4b. According to Figure 4, for records with short period pulses,  $T_1/T_p > 2$  the higher modes of vibration are excited and the maximum interstorey drift is located at the upper stories (stories 7, 8 and 9). On the other hand, for records with  $T_1/T_p < 1$ , the maximum drift demand is observed at lower stories, indicating that the response is first mode dominated.

**Figure 5: Maximum interstorey drift at different stories of the building, (a) 2<sup>nd</sup> storey, (b) 5<sup>th</sup> storey, (c) 7<sup>th</sup> storey and (d) 9<sup>th</sup> storey (roof).**

Figure 5 shows the maximum drift demand for the 2<sup>nd</sup>, the 5<sup>th</sup>, the 7<sup>th</sup> and the 9<sup>th</sup> (top) storey. The agreement is practically perfect for all stories with the exception of the top storey where some minor errors appear for ground motions with  $T_1/T_p > 2$ . The maximum interstorey drifts occur mainly for records with  $T_1/T_p$  between 0.6 and 2, and in some cases for  $T_1/T_p > 2$ , while for the structure considered, the peak values appear at the middle stories of the building. Figure 6a shows the profiles of the median shear forces along the height of the building and the corresponding 16% and 84% percentiles. Very good agreement is again obtained, since the damage patterns are very close. Some minor differences are observed with respect to the demand in stories 3, 4 and 5. Furthermore, Figure 6b compares the base shear demand for the original and the truncated signal. It should be pointed out that the maximum values of the base shear are computed in the period range  $0.5 < T_1/T_p < 1$ , while (although not shown) most differences appear at the 1<sup>st</sup> and 5<sup>th</sup> storey, as also applies for the interstorey drifts (Figure 5).

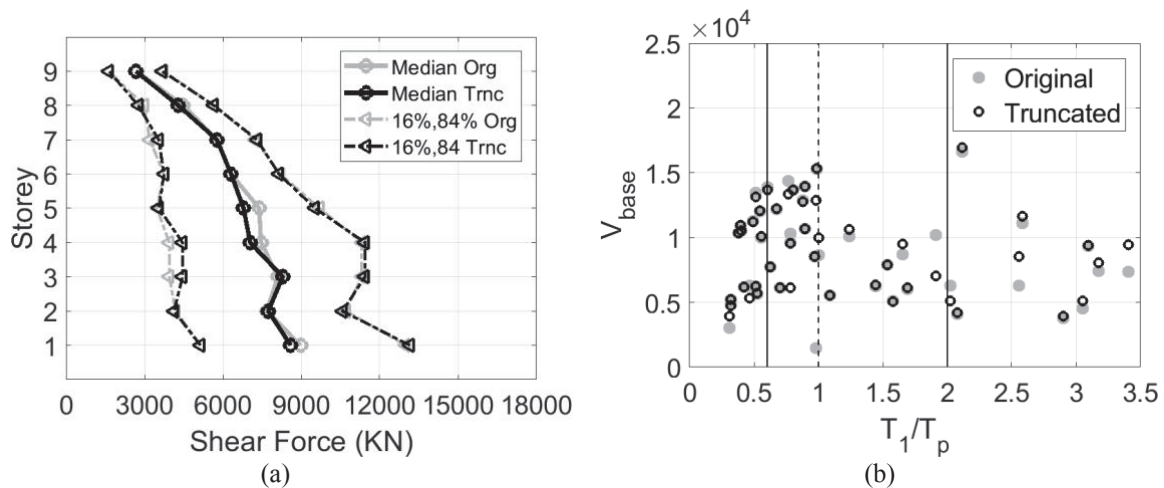

Figure 6: (a) Profiles of the maximum median storey shear force along with the standard deviation of storey shears. (b) Dispersion of the maximum base shear for original and truncated records versus  $T_1/T_p$ .

## 5 CONCLUSIONS

A novel record truncation approach has been presented. The proposed approach simplifies the input signal and accelerates the seismic performance assessment, especially in the case of pulse-like ground motions. The truncation does not require baseline correction and thus it can be integrated to give truncated realistic velocity and displacement time histories. The proposed approach has been validated through the study of a nine-storey steel building. Almost in all cases, the seismic demand, measured in terms of displacement, drift and shear forces, obtained using the truncated signal will produce close estimates. The computational process is performed within a fraction of the CPU time required when the original complete record is used, since the duration reduction lies on average around 80%.

### Abstract

*Masonry existing structures are prone to significant structural damages when subjected to seismic actions. Over the last decades, innovative techniques emerged as attractive solutions for repair and retrofit of structures. In particular, composite materials with inorganic matrix (FRCMs-CRMs) have emerged as an alternative to fiber reinforced polymers for their better compatibility with masonry substrates. The effectiveness of the strengthening relies on the FRCM-substrate bond behavior, which needs to be characterized for the design of the reinforcement elements. Shear bond tests are able to determine the stress–slip law and the failure mode that rules the FRCM-substrate stress transfer capacity. In the last years, several experimental investigations on shear bond tests of strengthened masonry prisms were performed even if the knowledge about the influence of each variable parameter is not fully known. In this context, the numerical simulation may be a rapid and economic tool to study the incidence of the most relevant parameters in the bond mechanism.*

*In this paper, a numerical study aimed at simulating the fiber-mortar bond behavior and at calibrating a shear stress ( $\tau$ )–slip ( $s$ ) constitutive bond law, is presented. Advanced 2D numerical models, able to simulate the most probable failure mode occurring in shear bond tests, have been developed. The results of the numerical simulations have been compared with the experimental results of a large database of tests on FRCM/CRM strengthened masonry prisms. An inverse analysis procedure has been used to fit the experimental bond stress versus slip curves and to predict the failure modes.*

## 1 INTRODUCTION

The structural deficiencies of existing masonry structures, in case of horizontal loading, are well-known in the literature. Generally, the strengthening of masonry walls is performed by means of retrofitting techniques which also implies the use of organic-based composite materials. In order to follow the code requirements in terms of lateral load capacity, and to guaranty the chemical compatibility between the substrate and the adopted strengthening solution, the use of the Fabric Reinforced Cementitious Matrix (FRCM) or Composite Reinforced Mortar (CRM) is nowadays considered a suitable solution.

In a large number of structural applications, including the strengthening of masonry walls, the effectiveness of the strengthening is strongly related on the FRCM-substrate bond behavior, which needs to be characterized for the design of the reinforcement and for the assessment of the retrofitted structural members. Experimental investigations have shown that, differently from FRPs, the FRCM-substrate bond failure may take place both within the substrate and within the thickness of the composite. The FRCM-substrate load transfer mechanism may be affected by the textile architecture, the coating or pre-impregnation of the fibers, the mechanical properties and the thickness of the matrix, the mechanical properties of the substrate, as well as by the quality of the application and the curing conditions [1].

In this paper, advanced finite-element 2D models, simulating the failure modes occurred in single-lap shear bond tests, have been developed. The results of the numerical simulations have been compared with the experimental results of a large database of tests on FRCM/CRM strengthened masonry prisms [2-9]. In particular, the database has been divided into two parts: the first one has been used to calibrate a  $\tau$ - $s$  fiber-mortar law, while the second one to validate the proposed  $\tau$ - $s$  fiber-mortar law. An inverse analysis procedure has been used to fit the experimental curve and to obtain the actual failure modes. Both a quantitative and a qualitative method have been used to evaluate the goodness of the fitting. Finally, the influence of some important parameters, such as bond length, grid spacing and grid coating on the shear stress-slip law results has been discussed.

## 2 A DATABASE OF SINGLE-LAP SHEAR BOND TESTS

In the last years, several experimental investigations on shear bond tests of strengthened masonry specimens were performed. A database collecting the results of the main studies available in the literature involving single-lap shear bond tests has been taken into account aiming to collect all the data required for the numerical simulations. In particular, eight different experimental campaigns were analyzed in the database [2-9].

A single-lap shear bond test allows to characterize the FRCM/CRM-substrate bond behavior by providing the following main information: (i) the peak axial stress ( $f_b$ ), referred to the cross-sectional area of the longitudinal fibers of the textile ( $A_f$ ); (ii) the axial stress ( $f$ ) – slip ( $s^*$ ) relationship (Fig. 1a), the slip  $s^*$  being the relative displacement between the substrate and the textile at the loaded end of the bonded area; and (iii) the failure mode that controls the FRCM-substrate load transfer capacity. Analyzing the data available in the literature, six failure modes can be observed (Fig. 1b):

- (a) Debonding with cohesive failure of the substrate;
- (b) Debonding at the matrix-substrate interface;
- (c) Debonding at the textile-matrix interface;
- (d) Textile slippage within the mortar matrix;
- (e) Textile slippage within the matrix with cracking of the outer layer of mortar;
- (f) Tensile rupture of the textile (out of the bonded area) [1].

As reported in Figure 1a, the FRCM-substrate response generally exhibits an initial linear phase, followed by a nonlinear phase up to the attainment of the peak stress value, and a post-peak phase in which the increase of slip is associated to a decrease of the stress.

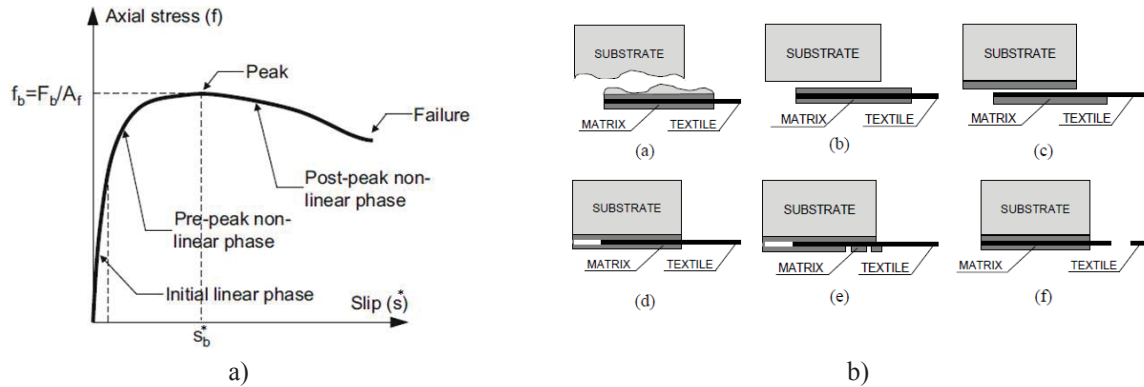

Figure 1: a) axial stress-slip law, b) failure modes [1].

Figure 2 reports both the typical specimen and set-up of a single-lap shear bond test. The grip system is designed “ad hoc” and it is constituted by a steel frame. The tensile force is applied at the specimens through the fabric strengthened at the end. During the tests, the slip between substrate and fiber grid and the slip between substrate and mortar matrix can be recorded [2].

Figure 2: Single lap shear test – a) specimen, b) set-up [2].

Tables 1 and 2 report all the properties of the specimens taken into account to create the database. In particular, Table 1 reports the characteristics of the considered FRCM specimens, while Table 2 reports the properties of the analyzed CRM specimens.

In Lignola et al. [3] the experimental results of bond test between basalt FRCM and masonry, showed that, when the fiber failure is observed, the bond peak stress is similar to the tensile peak stress of the fiber grid; while, when other failure modes occur, the bond peak stress is smaller than the tensile peak stress of the fiber grid. Carozzi et al. [4] observed different failure modes testing carbon FRCM bonded on masonry, the most common being the slippage of the textile within the matrix and the rupture of the textile. Specimens' geometry and curing time of the mortar largely affected the results. The bond tests between glass FRCM and masonry discussed in Bilotta et al. [5] did not underline relevant influence of the mechanical properties of the masonry substrate for the specimens bonded with 1 or 2 grid layers; while this influence is evident for the specimens bonded with 4 grid layers, where the debond-

ing of the reinforcement from the substrate occurred. Leone et al. [6] observed different failure modes performing single face shear test between glass FRCM and masonry: the most common type was the mortar cracking and tensile failure of glass fiber while cohesive failure of the reinforcement from the substrate never occurred. In D'Antino et al. [7] the failure mode of debonding of the PBO fibers at the matrix–fiber interface always occurred except for four specimens where the detachment of the entire composite from the concrete substrate was observed due to the lack of a surface preparation. The experimental results provided by Carloni et al. [8] on concrete specimens reinforced with PBO FRCM indicated that the values of bond peak load are influenced by the adopted test rate of the slip  $s^*$ . In detail, considering  $1V = 0.00084 \text{ mm/s}$ , the peak load increases as the rate increases from 0.5V to 3V; the maximum peak load is achieved for a rate between 3V and 5V; while for rate 5V or greater, it decreases with increasing rate.

Regarding the CRM reinforcement system, Rizzo [2] and Gattesco et al. [9] investigated the bond behavior between glass CRM and clay masonry substrates. In both studies three different bond lengths were considered: 120, 180 and 240 mm. In [2], for each bond length, the failure occurred by tensile rupture of fibers and the mortar layer was undamaged. In [9], caused by the poorer mechanical properties of the mortar, the failure for longitudinal wires rupture was obtained only for 240 mm, while in the other cases, textile slippage within the matrix with cracking of mortar occurred.

For each experimental campaign, the following information are recorded in the database (Tables 1-2) according to the following labels:

- ID = specimen name;
- N = number of specimens;

### 3 NUMERICAL MODELLING

In this study, 2D finite-element models, simulating FRCM/CRM-masonry bond tests, have been developed using Midas FEA [10].

The adopted two-dimensional model, schematized in Figure 3, is able to simulate the main failure modes occurring in a single-lap shear bond test, except for the A and/or B mode that involved the substrate (Fig. 1b). These failure modes were excluded because were not observed in the collected database. This assumption allowed to simplify the numerical model because the masonry substrate was not modelled, and it was replaced by fixed boundaries assigned to the mortar. This assumption is also feasible because the masonry prism is constrained to the steel supporting frame of the test set-up (Fig. 2). In detail, the adopted numerical models are similar to that developed in [11], and composed of:

- Mortar (two layers): it is modelled through four-node plane-stress 2D elements ( $A = 5 \times 5 \text{ mm}^2$ ) with a linear elastic behavior. The behavior was characterized using the elastic modulus and tensile strength provided in the experimental campaigns. The thickness is equal to the mortar width;
- Fiber grid: it is modelled through two-node truss 1D elements ( $l = 5 \text{ mm}$ ), with a linear elastic behavior. The behavior was characterized using the elastic modulus and tensile strength provided in the experimental campaigns. The cross-sectional area ( $A_f$ ) is equal to the sum of transversal areas of each yarn;
- Fiber-mortar interface (two layers): it is modelled through line interface zero-thickness elements, characterized from a nonlinear bond-slip  $\tau$ -s mechanical law. The thickness is equal to the sum of wet perimeters of each yarn;
- Upper-lower mortar interface: it is modelled through point interface zero-thickness elements, characterized from an infinitely rigid behavior.

In this study, a specific cracking modelling of the mortar was not introduced, for this reason is not possible to monitor the cracking development within the mortar. However, it is worth mentioning that this is out of the scope of this work.

The analyses have been conducted in displacement control using the Newton Raphson convergence method. The horizontal maximum displacement is assigned at the loaded end of the equivalent yarn and divided into 50 incremental steps.

Figure 3: Adopted 2D modelling.

The most critical point in the adopted modelling approach consists in the definition of the nonlinear bond-slip ( $\tau$ - $s$ ) mechanical law. This law will be calibrated for each specimen available in the database in order to find a correlation between the different involved parameters. As a starting point, the shape of the curve has been defined considering some studies available in the literature. In [12], shear bond tests on SRG systems were simulated introducing a steel-mortar nonlinear interface, whose fundamental parameters influence the eventual failure mechanism of the specimen for slippage of the steel cords from the grout.

In particular, with the aim to numerically define this interface, the authors chose a tri-linear constitutive law, taking into account the experimentally observed friction phenomena between textile and matrix (Fig. 4). The same bond stress-slip law form was introduced in [13], where a cohesive interface crack model for the matrix-textile debonding in FRCM composites was developed.

Following a similar approach, in this work, the fundamental values of the adopted bond  $\tau$ - $s$  law are (Fig. 4):  $\tau_m$  (bond strength),  $\tau_r$  (residual bond stress),  $s_0$  (slip corresponding to  $\tau_m$ ),  $s_1$  (slip at the end of softening branch) and  $s_2$  (ultimate slip). All the parameters have been defined through the calibration of the model using the experimental results. The simplified bond stress-slip law of the interface implies a first linear elastic behavior as the pre-peak branch (until the maximum stress  $\tau_m$ ), followed by a linear softening part representing loss of cohesion between the two materials in the interface. The third branch with the constant bond stress of  $\tau_r$  represents the frictional resistance of the interface, this branch is only necessary for convergence reasons.

 Figure 4: Adopted bond  $\tau$ - $s$  law.

To demonstrate the effectiveness of the numerical model, a preliminary parametric analysis has been conducted to check the physical robustness of the obtained results. In detail, the ratio between the fiber elastic modulus and the mortar elastic modulus ( $E_f/E_m$ ) and the interface stiffness ( $k_1 = \tau_m/s_0$  – slope of the bond stress versus slip curves) were varied respect to the ratio between the fiber stress and the mortar stress ( $\sigma_f/\sigma_m$ ) at the loaded end.

As expected,  $\sigma_f/\sigma_m$  increases as  $E_f/E_m$  increases (Fig. 5a) while  $\sigma_f/\sigma_m$  decreases as  $k_1$  increases (Fig. 5b). This last is related to the fact that as increasing  $k_1$ , the behavior is closer to the perfect bond behavior and the stresses in the two materials are similar.

Furthermore, with the same purpose to check the robustness of the model, the trend of shear bond stress  $\tau$  in the fiber-mortar interface, along the specimen, respectively for the case of mortar cracking and interface debonding, has been monitored (Fig. 6). The numerical analyses have showed that, if the crisis affects the mortar, the bond stress level in the interface is such that  $\tau$  falls in the first linear elastic phase of the  $\tau$ - $s$  curve (Fig. 4); while when the interface debonding occurs,  $\tau$  falls in the second linear softening phase of the  $\tau$ - $s$  curve. So, it is noticeable that the bond stress trend is opposite between these two cases: in case of mortar cracking,  $\tau$  decreases from loaded end (with higher value of slip) to free end (with lower value of slip); in case of interface debonding  $\tau$  increases from loaded end to free end.

#### 4 CALIBRATION OF BOND-SLIP INTERFACE LAW

The finite-element model described in Section 3 has been developed to simulate all the results collected in the FRCM/CRM-masonry single-lap shear bond tests database presented in Section 2. The database has been divided into two homogeneous parts: i) the first part has been used to calibrate the fiber-mortar interface laws (76% of the specimens); ii) the second part has been used for validation purpose (24% of the specimens).

The percentage assigned to the calibration and validation part was selected referring to similar studies available in the literature [14].

For each specimen, an inverse analysis has been made, looking for the best fitting between the experimental and numerical axial stress ( $f$ ) - slip ( $s^*$ ) curve to obtain the fiber-mortar  $\tau$ - $s$  interface law. For example, in Figure 7 and Figure 8, the experimental-numerical best fitting with the corresponding  $\tau$ - $s$  output related to the FRCM specimen “FRCM2-01” (Tab. 1) and to the CRM specimen “G66-120-01” (Tab. 2), respectively, are reported.

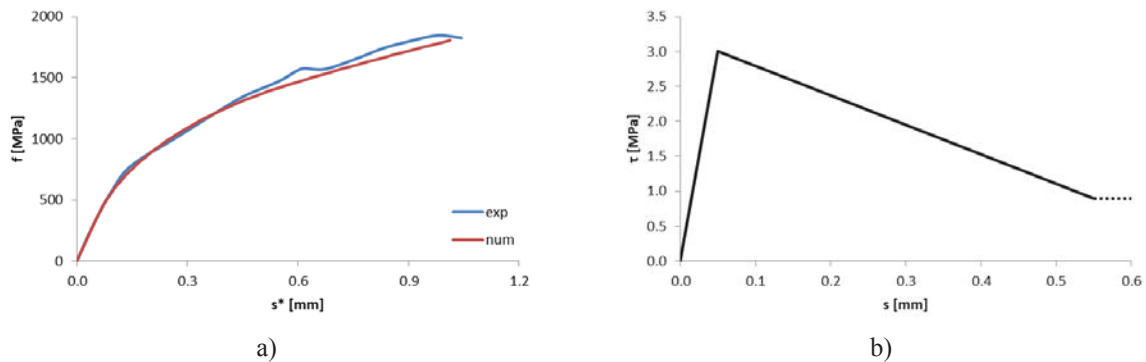

Figure 7: FRCM specimen – a) experimental-numerical best fitting, b) bond interface law.

Figure 8: CRM specimen – a) experimental-numerical best fitting, b) bond interface law.

For each inverse analysis, the goodness of the experimental-numerical fitting has been assessed through both qualitative and quantitative methods. The quantitative control has been made comparing the experimental and numerical peak axial stress ( $f_{bexp}$ ,  $f_{bnum}$ ) and corresponding slip ( $s_{bexp}^*$ ,  $s_{bnum}^*$ ).

In Figure 9, each doth represent a different specimen. It can be observed that the correlation in terms of stress is better than slip; in fact, the average value of  $f_{bexp}/f_{bnum}$  is equal to 1.00 (COV=7.4%), while the average value of  $s_{bexp}^*/s_{bnum}^*$  is equal to 1.13 (COV=27.8%).

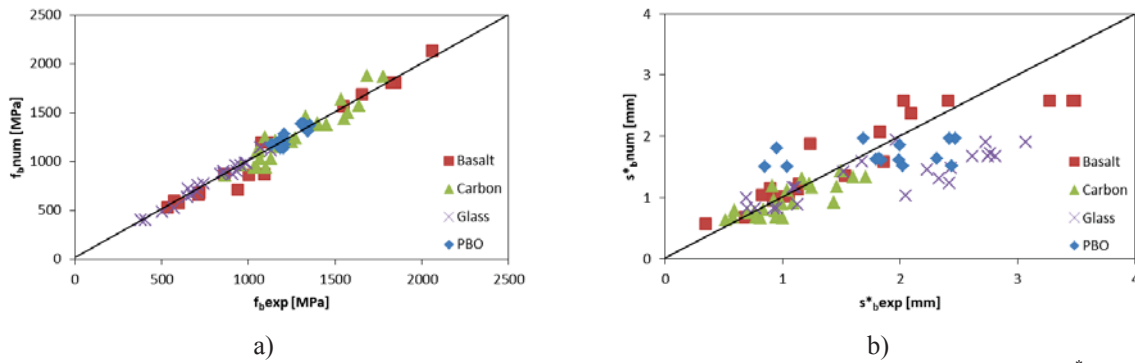

Figure 9: a) experimental-numerical dispersion for  $f_b$ , b) experimental-numerical dispersion for  $s_b^*$ .

In Figure 10 the comparisons between average  $\tau$ - $s$  curves varying  $E_f \cdot t_f$  [kN/mm] and  $f_{tm}$  [MPa], only related to FRCM specimens, are reported. A correlation between the stiffness of the reinforcement and the interface behavior is not completely clear as well as a trend between the tensile strength of the mortar and the peak of the bond-slip curve cannot be defined. Probably other parameters (for example grid coating and spacing), that have been neglected, might affect the obtained results.

Figure 10:  $\tau$ - $s$  average curves varying a)  $E_f \cdot t_f$  and b)  $f_{tm}$ .

#### 4.1 Discussion

In order to investigate the influence of other parameters that could affect the interface behavior, the superficial grid coating and the grid spacing ( $s_f$ ) have been analyzed. In particular, the incidence of these two parameters on the bond law has been investigated considering two representative specimen groups, extracted from the FRCM database (Tab. 1), composed of specimens characterized by similar properties in terms of mortar and fibers:

- Group 1 ( $E_f = 50$ -80 GPa,  $f_{cm} = 12$ -17 MPa), composed of 13 specimens;
- Group 2 ( $E_f = 80$ -110 GPa,  $f_{cm} = 12$ -17 MPa), composed of 10 specimens.

Each of these two groups is divided into two parts:

- Part a), characterized by a higher spaced grid ( $s_f = 25$  mm);
- Part b), characterized by a lower spaced grid ( $s_f = 10$  mm).

In Figure 11, the blue and the red columns indicates the average value of  $\tau_m$  (Fig. 11a) and  $k_1$  (Fig. 11b), respectively, for the part a) and the part b) of each group. It is expected that the presence of more transversal wires, in case of lower spaced grids, should cause a more significant increment of  $\tau_m$  and  $k_1$  than in higher spaced grids [2]. However, in the analyzed case, as evidenced in Figure 11, this trend is confirmed only for the Group 1 and it's completely opposite for the Group 2.

In fact, while all the specimens belonging to the Group 1 are characterized by the presence of a superficial grid coating; in the Group 2, only the specimens with higher spaced grids are characterized by the coating. So, this opposite trend could be justified by the fact that the presence (or absence) of the coating could have a greater influence than the grid spacing.

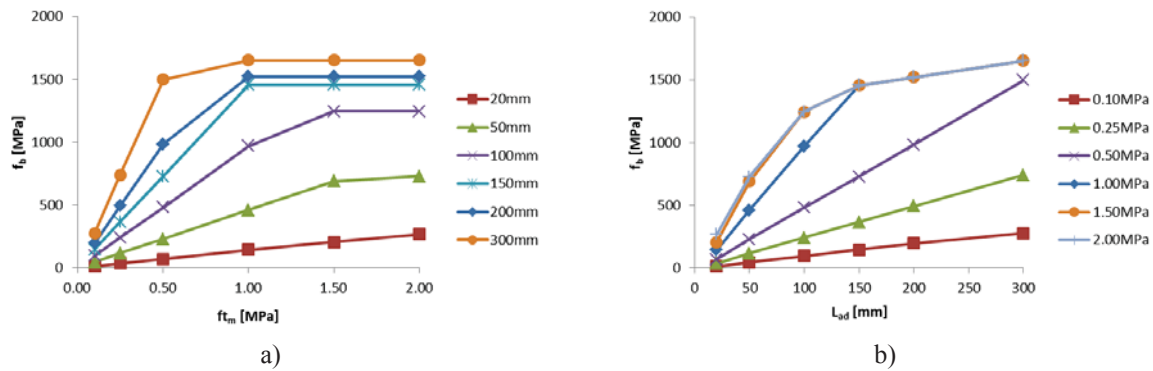

Figure 11: Grid coating and spacing effect in terms of: a)  $\tau_m$  and b)  $k_1$ .

The campaign on shear bond tests between GCRM and masonry, conducted by Rizzo [2] (explained in Section 2), was also used to individuate the effective bond length ( $L_{eff}$ ), beyond which there are no more significant increases in terms of peak axial stress  $f_b$ . The authors observed that  $f_b$  seems to be growing up from 120 mm until 180 mm, after that it remains almost constant at 240 mm. So, the effective bonded length could be estimated equal to 180 mm. From the numerical simulation of these bond tests, the same value of  $L_{eff}$  has been obtained (Fig. 12).

This analysis, with the aim to evaluate an effective bond length, has been extended to FRCM-masonry specimens with different mechanical properties. In detail, the numerical analysis has been made varying the mortar tensile strength  $f_{tm}$  (from 0.10 to 2.00 MPa) and the bond length  $L_{ad}$  (from 20 to 300 mm); while the grid properties have been kept constant:  $E_f = 300$  GPa and  $f_{tf} = 3000$  MPa.

Figure 13 reports the variation of  $f_b$  as a function of  $f_{tm}$  (Fig. 13a) and  $L_{ad}$  (Fig. 13b). In Figure 13a, the constant branch of each curve begins when the failure mode changes from mortar cracking to interface debonding without more increments in terms of  $f_b$ . It is noticeable that increasing the bond length the mode of failure changes for low value of the mortar tensile strength.

From Figure 13b, it is evident that for lower values of  $f_{tm}$ ,  $f_b$  increases as  $L_{ad}$  increases; however, for mortar tensile strength greater than 1.00 MPa and for  $L_{ad}$  values greater than 150 mm, the slope of the curve rapidly decreases and there are no more important increments in terms of  $f_b$ . In conclusion,  $L_{ad}$  equal to 150 mm seems to be the effective bond length ( $L_{eff}$ ) for specimens characterized by  $E_f = 300$  GPa and  $f_{tf} = 3000$  MPa.

## 5 CONCLUSIONS

The effectiveness of the FRCM/CRM strengthening techniques relies on the composite-substrate bond behavior. In this study, numerical simulations aimed to study the interface behavior have been carried out. The obtained results that represent the first part of a wider study are able to furnish the following conclusions:

- A simplified finite-element 2D model, able to simulate the main failure modes occurring in a single-lap shear bond test between FRCM/CRM and masonry, has been developed.
- An inverse numerical analysis has been used to calibrate the  $\tau$ -s law between fiber and mortar and to simulate the results of single-lap shear bond tests. The comparison between the numerical and experimental results demonstrated the effectiveness of the proposed numerical modelling approach.
- The influence of some important parameters, such as grid spacing and grid coating on the  $\tau$ -s law results has been investigated. For the analyzed cases, it has been observed that for masonry reinforced with coated FRCM, lower spaced grids give higher values of both maximum bond stress ( $\tau_m$ ) and slope of the bond stress versus slip curves ( $k_1$ ).
- The performed numerical analysis seems to be able to estimate the transfer length of the reinforcement.
- At the date, numerical simulations are still in progress with particular reference to shear bond tests between CRM and masonry. In the future, is in the authors' intent to carry out pull-out tests on FRCM and CRM specimens [15] in order to experimentally obtain  $\tau$ -s fiber-mortar relationships for comparison with the numerically obtained laws.

**Keywords:** RC Framed Buildings, Dissipative Steel Exoskeletons, Nonlinear Fluid Viscous Dampers, Seismic Retrofitting, Design Procedure.

**Abstract.** *The dissipative exoskeleton (DEX), an external framed structure equipped with a damped bracing system and rigidly coupled to the existing building is to be retrofitted, may be more convenient than a dissipative endoskeleton (DEN), constituted of braces connecting adjacent storeys and equipped with dissipative devices. Aim of the present work is the proposal of a displacement-based design procedure of the DEX based on the use of overdamped elastic response spectra, which could prove a valuable tool for practitioners. The DEX includes concentrically braced chevron frames, with pinned joints, and damped bracing systems, incorporating fluid viscous dampers (FVDs). Elastic-linear behaviour of steel frame members and nonlinear pure viscous dashpot for FVDs are hypothesized. A six-storey archetype located in L'Aquila (Italy), representative of many reinforced concrete (RC) framed buildings designed for moderate seismic loads, is to be retrofitted in a high risk-seismic region. The building is regular in plan, with five longitudinal bays (main fronts corresponding to the north- and south-facing façades) and three bays in the transversal one (east- and west-facing façades without apertures). Nonlinear static analysis using the software OpenSEES is preliminarily carried out, to investigate the seismic vulnerability of the existing building. RC frame members are modelled with lumped plasticity elements, with flexure- or shear-controlled moment-chord rotation at critical end sections, while the shear behaviour of the beam-column joints is modelled by means of a scissor model. Interventions with DEXs are designed at the life-safety (LS) limit state, considering parallel (DEX.Pa) and perpendicular (DEX.Pe) dispositions, running around all four façades, and mixed disposition (DEX.Mi), as an enlargement on the eastern and western sides only. In order to demonstrate effectiveness of the retrofitting interventions, nonlinear dynamic analyses of the bare (F) and coupled (DEXF) structures are carried out considering records scaled in line with a high-risk seismic region.*

## 1 INTRODUCTION

The dissipative endoskeleton (DEN) constituted of steel braces supporting devices dissipating energy by means of different mechanisms (metallic yielding, friction sliding, fluid orificing, viscoelastic deformation, phase transformation of metals) offers certain advantages (e.g. ease of inspection and replacement, low maintenance costs) in comparison to traditional retrofitting solutions [1, 2], but it can also induce downsides: e.g. notable increase in the axial load transmitted to columns and foundations; indirect costs associated with the temporary relocation of residents; service interruption during installation. On the other hand, the dissipative exoskeleton (DEX), an external steel framed structure equipped with a damped bracing system, rigidly coupled to the existing building but with an own foundation, exhibits many advantages [3]: the indirect costs associated with downtime during retrofitting are eliminated; the creation of new housing space and the opportunity for an energetic retrofit of the building envelope are possible; the complete reversibility is guaranteed.

Three typological choices are possible depending on the distributive (e.g. available space) and energetic (e.g. thermal loss) features along the perimeter [4-6]: a partial or uniform dissipative exoskeleton, parallel (DEX.Pa) and perpendicular (DEX.Pe) positioned to the façades to which it is connected through standard shear and axial links, respectively; a mixed DEX (DEX.Mi), where DEX.Pa and DEX.Pe are placed on the same façade. It should be noted that DEX.Pa always provides additional torsional stiffness to the original scheme, while the added spatiality in the façades resulting from DEX.Pe allows the creation of new housing space, partially or totally covering the retrofitting costs by means of the increased real estate value, upgrades vertical accessibility (e.g. stairwells and lifts) as well as horizontal private or collective circulation (e.g. balconies and living spaces). However, the increased useful space provided by DEX.Pe corresponds to a non-negligible additional mass of the exoskeleton structure compared to the total mass of the building, thereby inducing seismic loads higher than those corresponding to the DEX.Pa arrangement. As this last solution supports gravity loads due to their self-weight only, large overturning moments induced by the horizontal seismic loads may lead to tensile axial force in its foundation. Both solutions provide the opportunity for an energetic retrofit of the building envelope, but compared to the DEN not only the dissipative bracing system but also the new steel exoskeleton needs to be designed.

A design procedure of DEXs incorporating nonlinear fluid viscous dampers (FVDs) is implemented in this study, which focuses on displacement as the key sizing parameter and employs overdamped elastic response spectra. The procedure is a reformulated version of an approach recently derived for DEN systems [7-11], conceived in such way as to make a clear distinction between the design of a steel exoskeleton (i.e. mass, stiffness and strength) and a dissipative bracing system (i.e. added damping), and an extension including nonlinear FVDs. In the subsequent sections the proposed design procedure is applied for the seismic retrofitting of a six-storey reinforced concrete (RC) archetype in L'Aquila (Italy), representative of many buildings designed for moderate seismic loads prior to the 2008-2018 code changes [12]. Interventions with DEXs are designed at the life-safety (LS) limit state, considering three alternatives: i) parallel disposition running around all four façades (DEX.Pa), with a distance from the existing structure set to suit the new foundation and to allow the opening of windows; ii) perpendicular disposition running around all four façades (DEX.Pe), with a floor slab defining new spaces increasing the wellbeing of the inhabitants along main fronts with north and south exposure; iii) parallel-perpendicular mixed disposition (DEX.Mi), as an enlargement on the eastern and western transversal sides only where energy saving measures could be added. Nonlinear analyses are carried out using the software OpenSEES [13], in order to provide insights into the strength and weaknesses of the examined configurations.

## 2 DISPLACEMENT-BASED-DESIGN PROCEDURE OF THE VISCOUS DAMPED DISSIPATIVE EXOSKELETON

A four-step double-iteration design procedure of the DEX is proposed, whose design parameters are: target performance displacement evaluated through nonlinear static analysis of the existing structure; properties of the nonlinear fluid viscous dampers (FVDs), in terms of maximum equivalent viscous damping ratio ( $\xi_{v,DB0}$ ) and velocity exponent ( $\beta$ ); seismic loads. On the other hand, final unknown parameters are mass, stiffness and strength properties of the steel exoskeleton and damping constant of the FVDs.

By referring to two coupled equivalent single-degree-of-freedom (SDOF) systems shown in Figure 1, representing the original frame (F, black line) with an infinitely rigid but non-dissipative connection to a DEX (blue line), relevant design parameters are mass and stiffness ratios

$$\alpha_m = m_{e,DEX} / m_{e,F}; \quad \alpha_K = K_{e,DEX} / K_{e,F} \quad (1)$$

and uncoupled equivalent damping ratios  $\xi_F$  and  $\xi_{DEX}$ . Equivalent mass of the SDOF system representing the original frame can be evaluated by multiplying the first-mode (horizontal) components ( $\phi_1, \phi_2, \dots, \phi_n$ ) by the corresponding floor masses ( $m_{1,F}, m_{2,F}, \dots, m_{n,F}$ )

$$m_{e,F} = \sum_{i=1}^n (m_{i,F} \cdot \phi_i), \quad (\phi_n = 1) \quad (2)$$

while equivalent (secant) stiffness depends on base shear ( $V_{p,F}^*$ ) at the performance displacement ( $d_p^*$ )

$$K_{e,F} = V_{p,F}^* / d_p^* \quad (3)$$

resulting from the nonlinear static analysis of the original structure. A double iteration process is required because for an assigned value of  $\xi_{DEX}$  and known value of  $\xi_F$ , both corresponding to the assigned displacement demand  $d_p^*$ , the corresponding coupled total damping ( $\xi_{DEXF}$ ) is function of  $\alpha_K$  which in turns depends on the unknown  $\alpha_m$ .

Figure 1. DEXF system as coupling of two equivalent SDOF systems.

The four steps of the proposed design procedure are discussed below. It should be noted that the design procedure requires internal (step 3) and external (steps 3-4) iteration loops related to the stiffness ( $\alpha_K^{(\cdot)}$ ) and mass ( $\alpha_m^{(\cdot)}$ ) ratios, respectively. An initial approximation of these ratios is assigned in step 2 (i.e.  $\alpha_K^{(0)}$  and  $\alpha_m^{(0)}$ ), and then a sequence of iteration loops is performed until convergence to the correct values is attained (i.e.  $\alpha_K^{(i)} \approx \alpha_K^{(i-1)}$  and  $\alpha_m^{(i)} \approx \alpha_m^{(i-1)}$ ).

### 2.1 Properties of the SDOF system equivalent to the original frame (F)

Once base shear ( $V_F$ ) versus roof-storey displacement ( $d$ ) capacity curve of the original framed structure is evaluated from pushover analysis and transformed into the capacity (bilinear) curve ( $V^*-d^*$ ) of an equivalent SDOF system [14], the equivalent viscous damping due to hysteresis  $\xi_{h,F}$  at the performance displacement ( $d_p^*$ ) can be calculated

$$\xi_{h,F}(\%) = \kappa \cdot \left( 63.7 \frac{(\mu_F - 1) \cdot (1 - r_F)}{\mu_F \cdot [1 + r_F \cdot (\mu_F - 1)]} \right) \quad (4)$$

as function of the following parameters (Figure 2b): ductility demand  $\mu_F (=d_p/d_{y,F}$ , being  $d_{y,F}$  the yield displacement); stiffness hardening ratio ( $r_F$ ); reduction factor ( $\kappa$ ), depending on the degrading response of RC frame members [10, 11]. An inherent elastic viscous damping of the framed structure (commonly,  $\xi_{v,F}=5\%$ ) can be also defined (Figure 2a).

Figure 2. SDOF system equivalent to the original structure (a) and its response (b) idealized as bilinear.

## 2.2 Properties of the SDOF system equivalent to the dissipative exoskeleton (DEX)

Starting from the assumption that the stiffness ( $K_B$ ) of the brace used to install the damper in the exoskeleton (EX) is large enough to eliminate the added stiffness of the FV damped brace (i.e.  $K_{e,DB}=0$ ), the effective (secant) stiffness of the DEX is equal only to the EX part (Figure 3)

$$K_{e,DEX} = K_{e,EX} \quad (5)$$

and its unknown value is assumed as the effective (secant) stiffness of the original frame multiplied by an initial value ( $\alpha_K^{(0)}$ ) of the stiffness ratio

$$K_{e,DEX}^{(0)} = \alpha_K^{(0)} \cdot K_{e,F} \quad (6)$$

Similarly, the effective mass of the equivalent DEX is obtained on the basis of an initial value ( $\alpha_m^{(0)}$ ) of the mass ratio

$$m_{e,DEX}^{(0)} = \alpha_m^{(0)} \cdot m_{e,F} \quad (7)$$

as function of the effective mass of the SDOF equivalent to the original frame (see Equation (2)).

With regard to the nonlinear FVD, the force developed in the damper is function of the damping exponent ( $\beta < 1$ , with  $\beta = 1$  corresponding to linear viscous property)

$$F_{VD} = C_{NL} \cdot \text{sign}(v) \cdot |v|^\beta = F_{VDB} \quad (8)$$

where  $C_{NL}$  is the nonlinear damping coefficient,  $v$  is the relative velocity between the end sections of the device and  $\text{sign}(v)$  is the sign function. Moreover, the equivalent viscous damping ratio for one cycle of harmonic vibration can be expressed as [1, 15]

$$\xi_{v,DB}(\%) = \frac{\lambda \cdot C_{NL} \cdot \omega_{e,DEX}^\beta \cdot d_p^{\beta-1}}{2\pi \cdot K_{DEX}} \quad (9)$$

being

$$\lambda = 2^{2+\beta} \cdot \frac{\Gamma^2 \cdot \left(1 + \frac{\beta}{2}\right)}{\Gamma \cdot (2 + \beta)} \quad (10)$$

and  $\Gamma$  the gamma function. It is easy to verify that the equivalent viscous damping ratio corresponding to  $d_p$  can be computed in terms of an assigned maximum value ( $\xi_{v,DB0}$ ) at the limit of elastic behaviour for the original frame:

$$\xi_{v,DB} (\%) = \xi_{v,DB0} (\%) \cdot (\mu_F)^{\beta-1} \quad (11)$$

For completeness, an inherent elastic damping of the exoskeleton (e.g.  $\xi_{v,EX}=2\%$  is generally used for steel structures) is also defined in Figure 3a.

Figure 3. SDOF system equivalent to the DEX (a) and its non-elliptic hysteresis curve (b).

### 2.3 Properties of the SDOF system equivalent to the frame with dissipative exoskeleton (DEXF)

The equivalent viscous damping of the in-parallel system constituted of frame (F) and dissipative exoskeleton (DEX) is function of the stiffness ratio  $\alpha_K^{(\cdot)} (= \alpha_K^{(0)}$  at the first iteration loop)

$$\xi_{DEXF}^{(\cdot)} (\%) = \xi_{v,F} + \xi_{v,E} + \frac{\xi_{h,F} + \xi_{v,DB} \cdot \alpha_K^{(\cdot)}}{1 + \alpha_K^{(\cdot)}} \quad (12)$$

where  $\xi_{h,F}$  and  $\xi_{v,DB}$  are calculated in steps 2.1 and 2.2, respectively. Then, the effective period of DEXF ( $T_{e,DEXF}^{(\cdot)}$ ) is evaluated with reference to the curve of the overdamped displacement-acceleration response spectra corresponding to  $\xi_{DEXF}^{(\cdot)}$  and the performance displacement  $d_p^*$  (Figure 4). Moreover, the acceleration design value ( $a_p^{*(\cdot)}$ ) can be determined as y-coordinate by the same curve.

Figure 4. Displacement-acceleration overdamped (elastic) response spectra.

Once the mass of the DEXF is calculated

$$m_{e,DEXF}^{(\cdot)} = m_{e,F} + m_{e,DEX}^{(\cdot)} = (1 + \alpha_m^{(\cdot)}) \cdot m_{e,F} \quad (13)$$

the effective stiffness can be obtained as

$$K_{e,DEXF}^{(\cdot)} = \frac{4 \cdot \pi^2 \cdot m_{e,DEXF}^{(\cdot)}}{(T_{e,DEXF}^{(\cdot)})^2} \quad (14)$$

Finally, an updated value of the stiffness ratio is determined

$$\alpha_K^{(\cdot)} = K_{e,DEX}^{(\cdot)} / K_{e,F} \quad (15)$$

where

$$K_{e,DEX}^{(\cdot)} = K_{e,DEXF}^{(\cdot)} - K_{e,F} \quad (16)$$

As a consequence, an iterative procedure internal to the current step is needed for the solution of Equations (12)-(16) until a final stiffness ratio value is attained.

## 2.4 Properties of the dissipative exoskeleton (DEXF) for the MDOF system

The proportional stiffness criterion [16] allows evaluation of the internal design forces of the steel EX considering the distribution of the lateral loads resulting from the first-mode shape (i.e.  $\phi_i = \phi_{i,F} = \phi_{i,EX}$ ,  $i=1, \dots, n$ ) that remains practically unchanged after the insertion of the EX (Figure 5)

$$F_{EX,i}^{(\cdot)} = \frac{m_{i,F} \cdot \phi_i}{\sum_{i=1}^n (m_{i,F} \cdot \phi_i)} V_{d,EX}^{(\cdot)} \quad (17)$$

where it is proved that the base-shear is equal to

$$V_{d,EX}^{(\cdot)} = \frac{V_{d,DEXF}^{(\cdot)} \cdot \alpha_K^{(\cdot)}}{1 + \alpha_K^{(\cdot)}} = (1 + \alpha_m^{(\cdot)}) \cdot m_{e,F} \cdot a_p^{(\cdot)} \cdot \frac{\alpha_K^{(\cdot)}}{1 + \alpha_K^{(\cdot)}} = V_{d,DEX}^{(\cdot)} \quad (18)$$

It is worth mentioning that base shear expressed by Equation (18) depends on the mass ratio  $\alpha_m^{(\cdot)}$  which is initially unknown. As a consequence, an external iterative procedure needs to be carried out on steps 2.3 and 2.4 for the solution of Equations (12)-(18), until a final mass ratio value is attained.

$$\alpha_m^{(\cdot)} = m_{e,DEX}^{(\cdot)} / m_{e,F} = \sum_{i=1}^n (m_{i,DEX}^{(\cdot)} \cdot \phi_i) / m_{e,F}, (\phi_n = 1) \quad (19)$$

Finally, the distribution of the damping coefficients for the nonlinear FVDs is assumed proportional to the design storey shear of DEX, on the assumption that reduced efficiency of the FVDs generally observed on the upper storeys is related to slower interstorey velocities than those in the lower storeys, through the following expression [17]

$$C_{NL,tot,j} = \frac{(2\pi)^{3-\beta} \cdot (d_p)^{1-\beta} \cdot \zeta_{v,DB}}{(T_{1,DEXF})^{2-\beta}} \cdot \frac{S_j \cdot \sum_{i=1}^n (m_{i,DEXF} \cdot \phi_i^2)}{\lambda \cdot \sum_{i=1}^n [S_i \cdot f_i^{1+\beta} \cdot (\phi_i - \phi_{i-1})^{1+\beta}]}, \quad j = 1, \dots, n \quad (20)$$

where  $f_i$  is the magnification factor of the dampers, depending on their configuration in each storey ( $f_i=1$  for chevron configuration of the FVDB), and  $T_{1,DEXF}$  is the fundamental vibration

period of DEXF. It is clear that, at each storey the shear force is proportional to parameter [18]

$$S_j = \sum_{i=j}^n (m_{i,DEXF} \cdot \phi_i) \quad (21)$$

Figure 5. MDOF system representing the original frame (F) combined with DEX.

### 3 LAYOUT AND RETROFITTING OF THE TEST STRUCTURE

An RC framed building located in L'Aquila, representative of the Italian residential housing stock constructed prior to the 2008-2018 code changes [12], is considered as test structure for the numerical investigation. The building is regular in elevation (Figure 6b), while torsion is moderate so the building can be considered also as regular in plan although the staircase is asymmetrically placed along the X direction and bays with different lengths are considered along the Y direction (Figure 6a).

Figure 6. Layout of the archetype (unit in cm).

Cross-section of columns, with the orientation shown in Figure 6a, and deep beams, for perimeter frames and knee configuration of the staircase, are tapered along the building height but constant at each storey (Figure 6b); on the contrary, all internal beams are flat with a constant cross-section at all storeys but this is not the same for different bays (Figure 6a). Masonry infills contribute to the dead load, with a weight of  $3.5 \text{ kN/m}^2$  along the perimeter façades reduced as function of the percentage of apertures. A simulated design of the test structure is

carried out in line with the Italian code DM86 [19], for the seismic loads at the time corresponding to the medium-risk seismic zone and typical subsoil class. Provisions of the Italian code DM92 [20] are also satisfied, assuming the following gravity loads: dead loads of  $4.8 \text{ kN/m}^2$ , on the roof, and  $6.3 \text{ kN/m}^2$ , on the other floors; live loads of  $2.2 \text{ kN/m}^2$ , on the roof (snow),  $2 \text{ kN/m}^2$ , on the other floors, and  $4 \text{ kN/m}^2$  for the staircase. Further details can be found in [12]. Mean compressive cylindrical strength of concrete and steel yield strength equal to  $25 \text{ MPa}$  and  $435 \text{ MPa}$  are assumed, respectively, in the design of the test structure.

Modal and uniform nonlinear static analyses of the original building are preliminarily performed by the OpenSEES platform [13]. A lumped plasticity model is considered for RC frame members, with a trilinear moment-chord rotation backbone curve modified on the basis of the ultimate shear capacity in the event of brittle failure [21, 22]. The shear behaviour of the exterior and interior beam-column joints is modelled by means of a scissor model, with rigid end offsets and double node, considering shear failure prior to or together with yielding of the longitudinal steel reinforcement of beams [23, 24]. Capacity curves reported in Figure 7 represent roof drift ratio (i.e.  $d_{\text{top}}/H_{\text{tot}}$ ,  $d_{\text{top}}$  and  $H_{\text{tot}}$  being the horizontal top displacement and total height) versus normalized base shear (i.e.  $V_{\text{base}}/W_{\text{tot}}$ ,  $W_{\text{tot}}$  being the total seismic weight). Note that pushover curves referring to the positive and negative loading directions are nearly identical, especially in the X direction (Figure 7a), due to the structural symmetry. Maximum strength is always achieved in the Y direction (Figure 7b), depending on the effects of the staircase and in-plan orientation of the cross-sections of all interior columns and most of the exterior ones (Figure 6a), while maximum deformability is attained in the X direction (Figure 7a), where flat interior beams with reduced section are placed. Attention will be focused on the modal capacity curves, that show a maximum  $V_{\text{base}}/W_{\text{tot}}$  ratio roughly between 0.15 (X direction) and 0.2 (Y direction) when one of the aforementioned failure mechanisms is attained for structural elements and joints.

Figure 7. Comparison of pushover curves for modal and uniform lateral load patterns.

Different dissipative exoskeletons are designed at the life-safety (LS) ultimate limit state provided by NTC18 [25] for a residential building (functional class II, coefficient of use  $C_U=1.0$  and expected life of 50 years) located in L'Aquila ( $13.40^\circ$  longitude and  $42.35^\circ$  latitude). Current high-risk seismic zone designation (peak ground acceleration on rock,  $a_g=0.261g$ ) and moderately-soft subsoil (class C, site amplification factor  $S=1.33$ ) are assumed. In particular, concentrically chevron braced frames (CBFs) and chevron braces with fluid viscous dampers (FVDBs) are arranged in three configurations: i) DEX.Pa (Figure 8), configured in adhesion (parallel) to all façades, considerably limiting the external dimensions in the case of urban planning restrictions; ii) DEX.Pe (Figure 9), as an enlargement of the entire building plan, creating additional (perpendicular) living space only along main fronts with

north and south exposure as these are the sides with apertures; iii) DEX.Mi (Figure 10), where DEX.Pa and DEX.Pe are placed as an enlargement on the eastern and western sides without apertures to satisfy both thermal and seismic requirements. The seismic demand for the design of the DEXs assumes as performance objective an elastic behaviour of the original structure (i.e.  $d_p=d_{y,F}$  and  $\xi_{h,F}=0$ ), while the amount of supplemental viscous damping required to limit maximum displacement within this target value is assumed equal to  $\xi_{v,DB0}=20\%$  and elastic viscous damping of the exoskeleton is omitted.

Figure 8. Dissipative exoskeleton parallel (DEX.Pa) to the original building (unit in cm):

■—■—■ chevron brace; ■—■—■ viscous damped chevron brace.

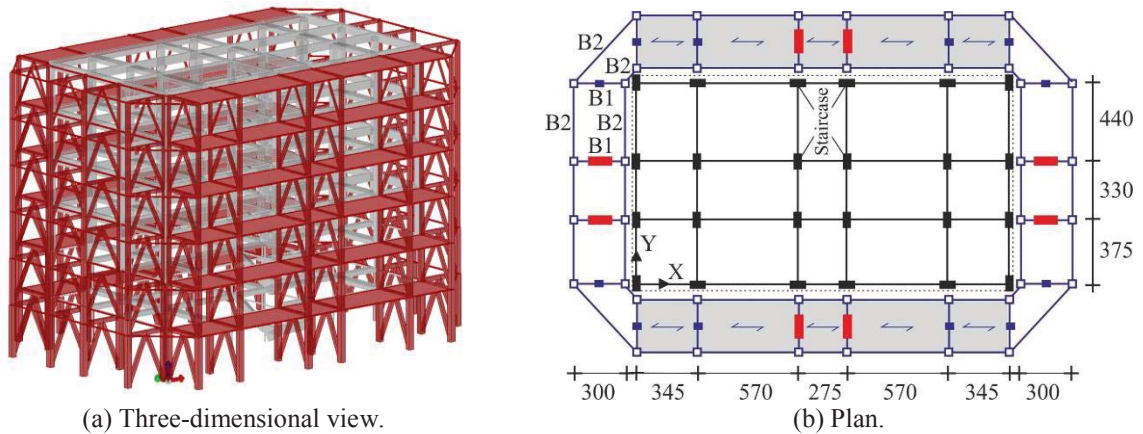

Figure 9. Dissipative exoskeleton perpendicular (DEX.Pe) to the original building (unit in cm):

■—■—■ chevron brace; ■—■—■ viscous damped chevron brace.

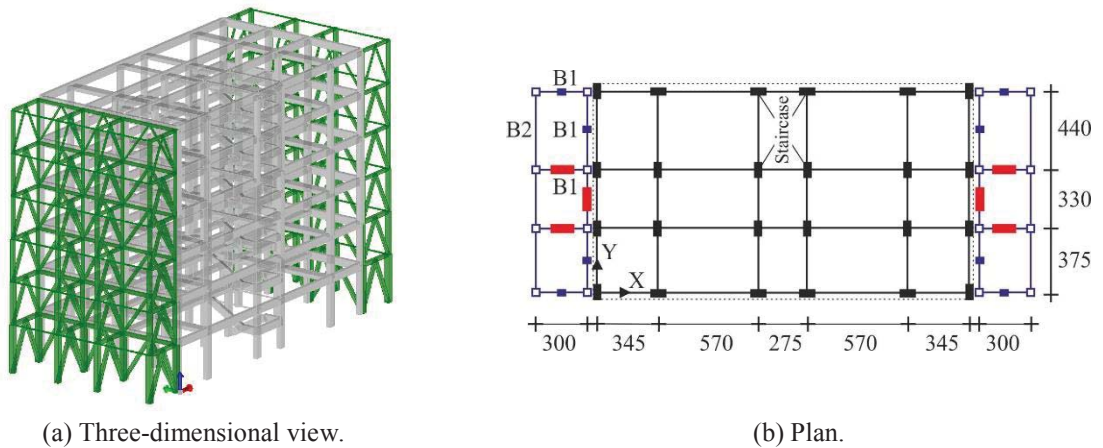

Figure 10. Dissipative exoskeleton with a mixed configuration (DEX.Mi) around the original building (unit in cm): ■—■—■ chevron brace; ■—■—■ viscous damped chevron brace.

The stiffening contribution of the chevron braces arranged in series with the FVDBs is not considered while nonlinear viscous behaviour, with an exponent  $\beta$  equal to 0.7, is assumed for the FVDs. The gravity loads considered for the composite deck with horizontal bracing of DEX.Pe, having a length of 3 metres (see grey areas in Figure 9b), are represented by a dead load of 3.73 kN/m<sup>2</sup> and a live load of 2 kN/m<sup>2</sup>. The design of DEXs is performed in accordance with the four-step procedure presented below, and main parameters of the equivalent SDOF systems are reported in Tables 1a and 1b with reference to the X and Y directions, respectively.

The tubular square cross-sections selected for primary beams (i.e. typology B1), columns and chevron braces of the CBFs are assumed ductile, in line with class 1 of NTC18. These elements satisfy the ultimate limit states for strength and buckling under the horizontal seismic loads evaluated through Equations (17) and (18). Moreover, secondary (i.e. typology B2) beams with circular (DEX.Pe) and square (DEX.Mi) cross sections are also considered in order to obtain a spatial truss exoskeleton, for which class 3 prevents local buckling until yield strength is reached in a compression fibre. The dimensions obtained for the member cross-sections, assuming yield strength equal to 275 MPa, and damping coefficients of nonlinear FVDs are reported in Table 2 (DEX.Pa), Table 3 (DEX.Pe) and Table 4 (DEX.Mi). It should be noted that FVDs are inserted on chevron braces with the same dimensions as those of the CBFs.

#### 4 NUMERICAL RESULTS

Nonlinear seismic analysis of the structure before (i.e. original, F) and after (i.e. retrofitted, DEX.Pa, DEX.Pe and DEX.Mi) the insertion of the dissipative exoskeleton is evaluated by the finite element code OpenSEES [13]. Nonlinear fluid viscous dampers are modelled as twoNodeLink elements, assuming nonlinear dashpot and linear spring acting in series without considering the combined flexibility of the supporting brace and FVD. An elastic linear behaviour, equal for tension and compression, is considered for all truss members of the concentrically steel braced frames. The exoskeleton is connected to the RC framed building at each floor level by means of shear and/or axial rigid steel links. Inherent damping  $\xi_{v,F}=5\%$  for the RC framed structure is modelled using mass and tangent stiffness proportional Rayleigh approach, while the contribution of steel exoskeleton is not considered ( $\xi_{v,EX}=0\%$ ). Seismic input selection for the bi-directional nonlinear dynamic analyses considers earthquakes taken from the Italian accelerometric archive [26] and NGAwest2 database [27], the latter when records reflecting the NTC18 provisions at the site in question were not available, and scaled to match the LS design response spectrum [28].

Mean values of the maximum base shear are reported in Figure 11 for the original (F) and retrofitted (DEX(F) and (DEX)F referring to parallel (Pa), perpendicular (Pe) and mixed (Mi) steel dissipative exoskeleton and RC frame, respectively) structures, which are labelled with letter A when resulting from nonlinear time-history analysis.

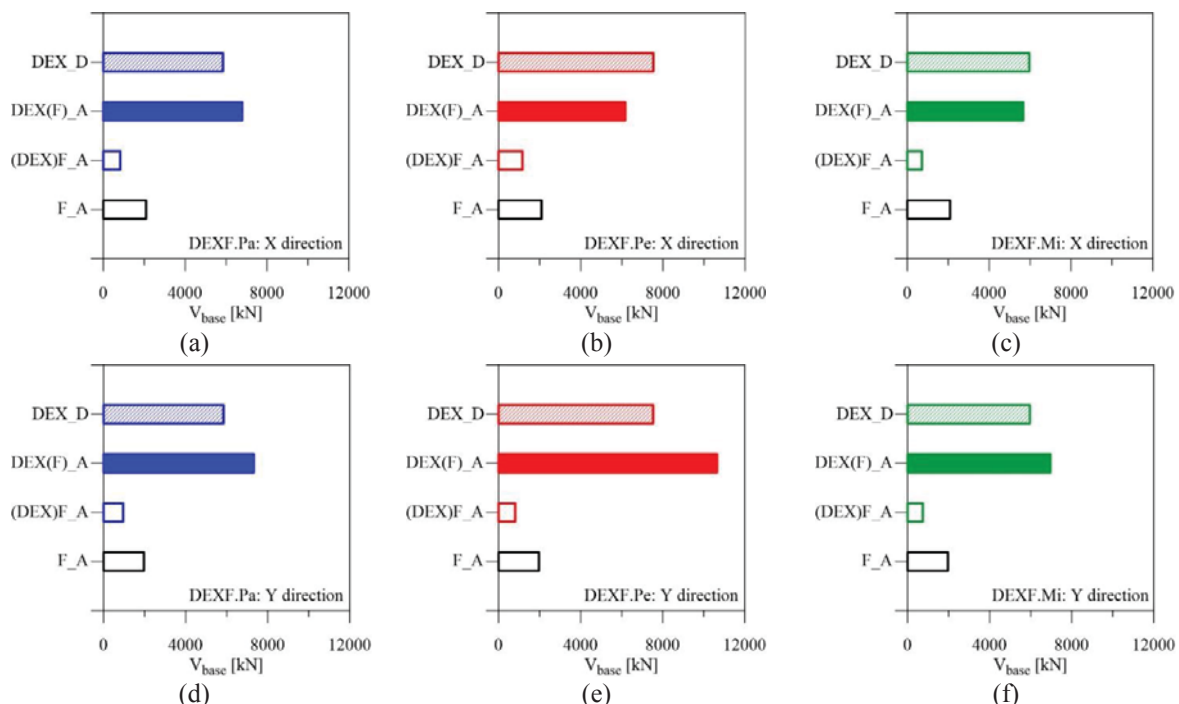

Figure 11. Seismic demand in terms of base shear for the original (F) and retrofitted (DEXF) structures.

As a comparison, design values (letter D) of the base shear obtained for DEXs are also reported with reference to DEXF.Pa (Figures 11a,d), DEXF.Pe (Figure 11b,e) and DEX.Mi (Figures 11c,f). The proportion between the base shear corresponding to DEX(F)\_A and (DEX)F\_A structural parts highlights a good fit with the design value of the stiffness ratio  $\alpha_K$  (see Tables 1a and 1b), thus confirming the reliability of the design procedure of DEXs. This is further demonstrated by the ratio between design (D) and analysis (A) base shear for DEX, whose value falls approximately into the range of -10% to +30%, which represent the lower and upper bound tolerances provided by NTC18 when recorded ground motions are scaled to a certain level of seismic intensity. Evidence of the effectiveness of the proposed retrofitting strategies also results from base shear related to (DEX)F\_A, whose value is between one half (Figure 11e) and one third (Figure 11c) of that given to the corresponding F\_A.

Afterwards, mean values of the storey drift ratio, defined as drift along the in-plan X ( $\Delta_X$ ) and Y ( $\Delta_Y$ ) directions normalized by the storey height (h), are shown in Figure 12. The original structure (F) exhibits an irregular distribution law of the drift ratio, with higher deformability in the X (Figure 12a) rather than in the Y (Figure 12d) direction. The insertion of DEXs generally ensures a reduction of at least half of the drift demand. The only exception is the top floor where an increase in drift demand referring to Y is observed for DEX.Pa and DEX.Pe (Figure 12d), though highlighting values less than 0.5%. Among the three viable retrofitting schemes, DEXF.Pa and DEX.Mi turn out to be the best choice parallel to X (Figure 12a) and Y (Figure 12d), respectively. Graphs of horizontal displacement at the floor levels (Figures 12b,e) confirm the effectiveness of all configurations of the DEX. The acceleration profiles over the elevation of the building, normalised by gravity acceleration g, are displayed in Figures 12c,f. Amplification of acceleration is found in all DEXF systems compared to the original frame, with values increasing towards the upper levels. Moreover, a clear worsening is observed in the Y direction (Figure 12f), where DEX.Pe is the worst solution inducing a threefold increase in top floor acceleration.

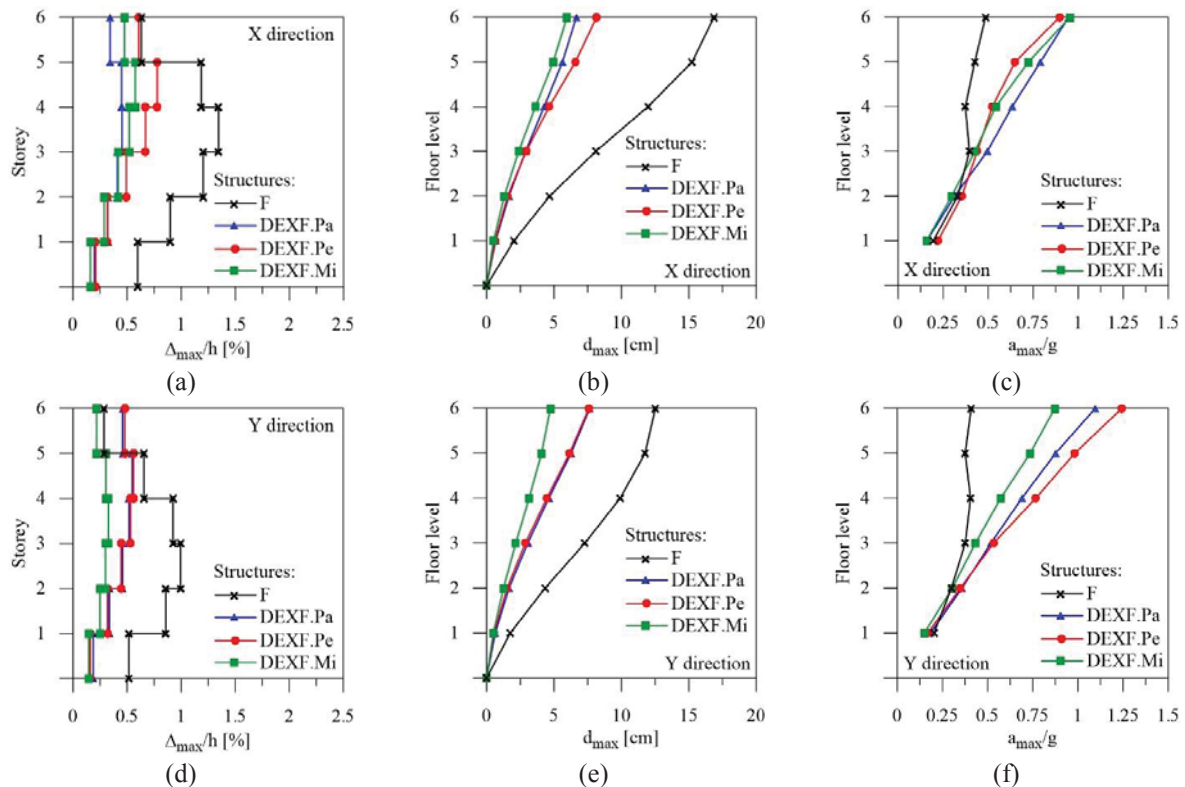

Figure 12. Global response parameters of the original (F) and retrofitted (DEXF) structures over the elevation.

With a view to analysing how different configurations of the exoskeleton (i.e. DEX.Pa, DEX.Pe and DEX.Mi) have an impact on the effectiveness of FVDs, the mean of the maximum values of the total damping force at different storeys are shown in Figure 13. As confirmed experimentally [17], the efficiency of the FVDs in the top storey is reduced by at least half of that at the intermediate levels where maximum values are attained, thereby highlighting that a distribution of damping constants proportional to the storey shear represents an efficient design criterion. The highest energy dissipation corresponds to DEX.Pa and DEX.Pe in the X (Figure 13a) and Y (Figure 13e) directions, respectively, but this does not correspond to significant advantages for the DEX.Pe characterized by the additional mass of balconies. It should be noted that total damping force is only divided between two FVDs for DEX.Pa (Figure 13d) and DEX.Mi (Figure 13f) along the Y direction, thus reducing structural redundancy, contrary to DEX.Pe which instead provides four FVDs at each level (Figure 13e), while all solutions ensure the same number of FVDs in the X direction.

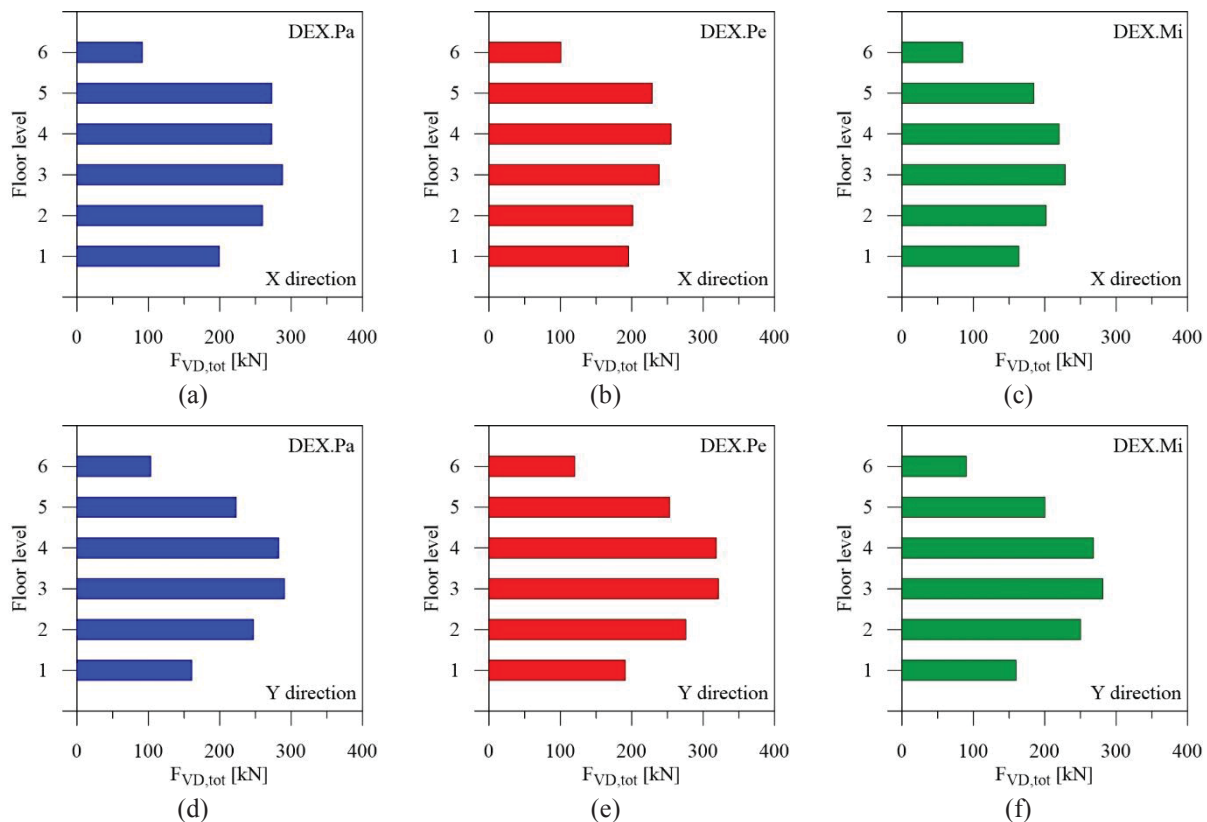

Figure 13. Distribution of the total damping force of FVDs over the elevation of the DEXs.

## 5 CONCLUSIONS

Pros and cons of the seismic retrofitting of RC buildings by means of dissipative exoskeletons is investigated. To this end, a practical procedure for the seismic design is proposed and developed, in such a way as to make a distinction between the steel exoskeleton and the dissipative bracing system. It is based on the rigid coupling of two SDOF systems equivalent to the original frame and dissipative exoskeleton, respectively, assuming elastic behaviour of steel exoskeleton and nonlinear FVDs. A six-storey RC framed structure located in L'Aquila is assumed as an archetype of the residential housing stock built in Italy during the 1990s, designed for medium-risk seismic zone. Three configurations of the DEX along the perimeter are chosen for retrofitting the original building, assuming elastic behaviour as performance

objective in a high risk-seismic zone: i.e. DEX.Pa, representing an envelope parallel to all façades; DEX.Pe, perpendicular to all façades; DEX.Mi, suggested as a compromise solution in which DEX.Pa and DEX.Pe are only placed on the sides without apertures. By carrying out nonlinear seismic analysis the following conclusions can be drawn.

The proportion between base shear demands corresponding to DEX(F) and (DEX)F structural parts matches well with the design value of the stiffness ratio, thus confirming the reliability of the proposed design procedure. Moreover, global and local confirmation of the effectiveness of the seismic retrofitting techniques can be drawn from the base shear and interstorey drift demands to (DEX)F, respectively, whose values are less than half of those corresponding to the original frame. The efficiency of the FVDs is confirmed at the lower and intermediate levels while it is reduced in the top storey, thereby highlighting that a distribution of damping constants proportional to the storey shear represents a good design criterion. DEXF.Pa and DEX.Mi appear the best choice parallel to X and Y, respectively, when drift ratios are considered. As expected, the top displacement target value is frequently exceeded by the building in its original condition, but it is sometimes exceeded when retrofitting with DEX.Pe, while DEXF.Pa and DEXF.Mi are always within the limits of this threshold. However, all DEXs induce amplification of the acceleration towards the upper levels of the original building and this may represent a potential risk in the case of acceleration-sensitive nonstructural components.

### Abstract

*Fiber Reinforced Cementitious Matrix (FRCM) materials are currently widely used for strengthening reinforced concrete (RC) structures and have assumed an important role in the seismic upgrading of these structures. The mechanical parameters for the evaluation of the capacity of strengthened structures, such as the tensile strength and the debonding load of the strengthening material, are determined through standards testing procedures that usually include tensile tests and bond tests. In this work the results of an experimental campaign of beam tests on RC elements strengthened with FRCM composites are presented. Different strengthening configurations and load rates are adopted. The experimental results are discussed and compared with the results available in literature to assess the influence of the testing procedure on the obtained mechanical parameters.*

**Keywords:** FRCM composites, RC structures, Experimental campaign, Beam test.

---

## 1 INTRODUCTION

Fiber reinforced polymers (FRP) [1, 2] and fiber reinforced cementitious matrix (FRCM) materials [3, 4] are widely used for strengthening and repairing masonry and reinforced concrete (RC) structures. The former are made of continuous fibers embedded in a polymeric matrix, while the latter consist of continuous fibers arranged in unidirectional or bidirectional textiles embedded in a cement based matrix. FRCM materials are effective in increasing the flexural [5, 6, 7, 8, 9, 10] and the shear [11, 12, 13] capacity of RC members.

Guidelines have recently been issued for the mechanical characterization and evaluation of the design parameters of FRCM materials [14, 15]. Italian guideline [14] provides for tensile tests both on textiles and on composites and direct shear tests, while US guideline [15] provides for tensile tests on composites and tests on structural elements.

The effectiveness of composite materials in increasing the capacity of concrete and masonry structural elements strongly depend on the bond properties between composite and substrate (FRP) [1, 16, 17] and between fibers and matrix (FRCM) [18, 19].

The shear stress transfer at the reinforcement-substrate interface is experimentally studied through direct shear tests in the single-lap configuration [20, 21, 22, 23, 24, 25, 26] (Figure 1a) or double-lap [27, 22] configuration (Figure 1b). These tests are performed to determine the debonding mechanism, i.e. the interface where debonding occurs, the maximum force transferable at the interface named joint capacity, the maximum force transferable when debonding initiates named debonding load [13, 26], and the minimum length of the interface surface to obtain the bond capacity named effective bond length. The tests performed so far have shown that for many FRCM materials the debonding occurs at the interface between fiber and matrix with significant relative displacements of the fibers with respect to the matrix and without debonding of the matrix from the support [28, 29].

The results of the single-lap or double-lap shear tests can be used to calibrate a cohesive material law (CML) [30, 24, 26], i.e. a relationship between the interfacial shear stress ( $\tau$ ) and the relative displacement or slip ( $s$ ) between the fibers and the substrate. In the case of FRCM materials that show a loss of bond at the interface between fibers and matrix, the CML allows to predict with reasonable accuracy the tensile response obtained through tensile tests [31] performed according to ACI 434 [15].

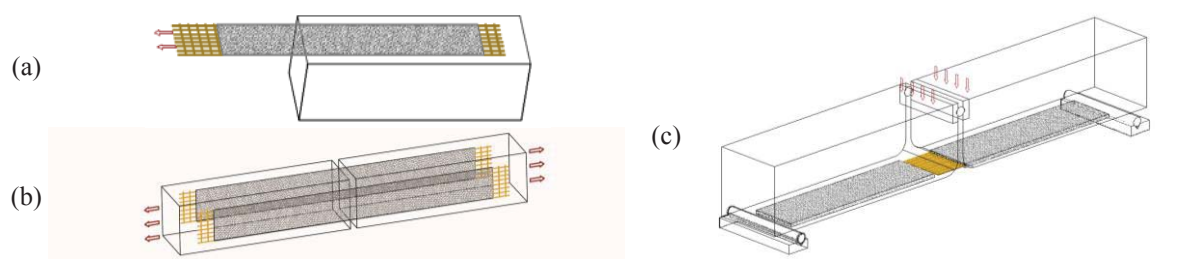

Figure 1. Typical test setup for (a) single-lap shear test, (b) double lap shear test, and (c) beam test.

An alternative to direct shear tests for the evaluation of the interfacial properties is the indirect shear test performed on specimens of the beam test type [32, 33, 34] (Figure 1c). The beams are made up of two concrete blocks connected by a hinge in the compression zone and by the reinforcement in the tensile zone and are subjected to bending test on 3 or 4 load points. The tensile force in the composite material is determined as a function of the applied force  $F$  through the equilibrium conditions.

In this work the results of an experimental campaign of beam tests on a FRCM material with poliparafenilenbenzobisoxazole (PBO) fibers are presented. With regard to the bond

properties of PBO-FRCM materials, many experimental results can be found in literature [13]. In particular the results of single-lap shear tests performed with different bond lengths are reported in [25]. In [26] the results presented in [25] are used to calibrate an interfacial CML based on the relationship between bond length and joint capacity. In [22, 33] the results of single-lap shear tests are compared with the results of double-lap shear tests. In [35] the dependence of the joint capacity evaluated with single-lap shear test on the loading rate is highlighted. Finally in [33] beam test results are compared with single-lap shear test results and it is observed that these two tests provide comparable results in terms of debonding load and joint capacity.

The experimental campaign presented in this paper includes beam tests on PBO-FRCM materials characterized by three different PBO textiles embedded in the same cement matrix. The tests were performed at different loading rates. The obtained experimental results are discussed and compared with the experimental results available in literature with the following aims: i) to compare the dependence of the joint capacity on the loading rate obtained with single-lap shear tests with the dependence of the joint capacity on the loading rate obtained with the beam test; ii) to assess the influence of the fiber arrangement in textiles on the fiber stress associated with the joint capacity; iii) to compare the results of single-lap shear tests with the results of beam tests in terms of joint capacity.

## 2 EXPERIMENTAL PROGRAM

### 2.1 Materials

Three different PBO textiles (Figure 2) embedded in the same cement matrix were used in the experimental campaign: i) bidirectional textile with 70 g/m<sup>2</sup> of fiber in the longitudinal direction (equivalent thickness of 0.046 mm) and 18 g/m<sup>2</sup> of fibers in the transversal direction (equivalent thickness of 0.012 mm); ii) unidirectional textile with 44 g/m<sup>2</sup> of fibers (equivalent thickness of 0.028 mm); iii) unidirectional textile with 105 g/m<sup>2</sup> of fibers (equivalent thickness of 0.067 mm).

Figure 2. PBO textiles used in the tested FRCM materials: (a) bidirectional textile with 70 g/m<sup>2</sup> of fibers in the longitudinal direction and 18 g/m<sup>2</sup> of fibers in the transversal direction; (b) and (c) unidirectional textiles with 44 g/m<sup>2</sup> and 105 g/m<sup>2</sup> of fibers in the longitudinal direction, respectively.

These PBO textiles are referred to as 70/18, 44, and 105, respectively. The main geometrical and mechanical properties of the PBO textiles are summarized in Table 1, where  $b^*$ ,  $t^*$  and  $i_f$  are the width, thickness and center-to-center distance of the longitudinal yarns, respectively, while  $t_f$  is the equivalent thickness defined as the cross section area per unit width, equal to  $t^*b^*/i_f = p/\gamma_f$ , where  $p=70, 44$ , or  $105$  g/m<sup>2</sup> is the weight of the longitudinal fibers per unit surface of the textile and  $\gamma_f = 1.56$  g/cm<sup>3</sup> is the unit weight of the PBO fibers.  $E_f$  is the elas-

tic modulus of the PBO fiber assumed equal to 206 GPa according to the tensile tests presented in [25], while  $f_t$  is the fiber tensile strength according to the manufacturer.

PBO textile	$p$ [g/m <sup>2</sup> ]	$b^*$ [mm]	$t^*$ [mm]	$i_f$ [mm]	$t_f$ [mm]	$E_f$ [GPa]	$f_t$ [GPa]
70/18	70	4	0.1081	9.5	0.046	206	5.8
44	44	4	0.1645	23.5	0.028		
105	105	4	0.1508	9	0.067		

Table 1. Geometrical and mechanical properties of the three different PBO textiles.

The cement based matrix was characterized through three-point bending tests and compression tests [36]. The performed tests provided an average compressive strength of 29.13 MPa and an average tensile strength of 6.40 MPa. The concrete blocks were casted with a commercial mix design (BIGMAT C25/30 concrete) with the addition of 20% river sand (grain size of 0.3÷1.25 mm) to obtain strength values close to those of existing concretes. Simultaneously to the block casting, 20 cubes with a side of 150 mm were casted. The compression tests of these cubes provided an average compressive strength [37] of 17 MPa (CoV 11%).

## 2.2 Test setup

The bond length  $L$  was the same for the two blocks and was equal to 363 mm while the width of the strip was equal to 94 mm (Figure 3).

Figure 3. Test setup: (a) front; (b) intrados (dimensions are in millimeters).

The bond length  $L$  was greater than the effective bond length  $L_{eff}$  which is approximately 250-280 mm according to [25, 26, 27, 30]. This allowed to reach the debonding load of the reinforcement and therefore to compare the obtained results with those of single-lap shear tests with  $L \geq L_{eff}$  in terms of debonding load. The edges of the concrete blocks were rounded at the intrados of the hinged cross sections to reduce the transverse compressive stresses at the interface associated with the relative rotation between the blocks during the test [13, 32].

The tests were performed with a servohydraulic universal testing machine (Instron) by controlling the displacement of the load application point at a constant rate. During the test the following response parameters were measured: i) the applied force  $F$  (Figure 3a); ii) the relative displacement between the blocks at the intrados (transducers T1 and T2 in Figure 3a); iii) the slip of the fibers at mid-span with respect to the two blocks (transducers T4 and T5). In particular transducers T4 and T5 measured the maximum relative displacements between the fibers and the concrete blocks (slips at points A and A'), which are referred to as global slips of the interface surfaces. The T1 and T2 transducers were of the CDP (LVDT) type with movable shaft, while the T4 and T5 transducers were of the CE cantilever type. Four displacement rates were used for the force application point: 0.17, 0.34, 0.51 and 0.68 mm/min.

Samples were named  $BT\_x\_yf\_z\_n$ , where  $x$  indicates the type of textile (70/18, 44, or 105),  $y$  the number of yarns,  $z$  the displacement rate, and  $n$  the number of the sample. The samples are listed in Table 2. At least three nominally equal specimens were tested for each textile and for each rate. Pictures of representative test samples are shown in Figure 4.

Figure 4. (a) Test set-up; (b) textile 44; (c) textile 105; (d) textile 70/18.

The adopted displacement rates correspond to nominal slip rates of 0.00085, 0.0017, 0.00255 and 0.0034 mm/s, respectively. The nominal slip rate associated with each displacement rate were evaluated neglecting the elastic deformation of the concrete blocks (i.e. rigid rotation of blocks was assumed) and assuming symmetric rotation of the two blocks. The lowest displacement rate was chosen to obtain a nominal slip rate similar to the slip rate adopted for the single-lap shear tests presented in [25]. Figure 5a shows the average of the global slips measured by the transducers T4 and T5 of four specimens with textile 74/18 as a function of time. Figure 5b shows the slip rate (obtained as the derivative of the corresponding curve of Figure 5a) as a function of time for one specimen. Figure 5 shows that after the initial branch the slip rate tends to be constant and proportional to the displacement rate. Nonetheless the slip rate is significantly different from the nominal value evaluated on the base of the rigid blocks assumption. Furthermore the slip rate is almost constant only at the end of the tests when the deboning has already initiated.

Figure 5. (a) Global slip as a function of time; (b) slip rate as a function of time for specimen BT\_70/18\_10f\_0.17\_1.

### 3 EXPERIMENTAL RESULTS AND DISCUSSION

All the specimens failed due to loss of bond at the fiber-matrix interface with high interfacial slip (Figure 4 (b)-(d)). Longitudinal cracks in a plane parallel to the intrados were observed in the matrix in many of the specimens with 10 yarns of textile 70/18, similar cracks were not observed neither in the specimens with 9 yarns of textile 70/18 nor in the specimens with textiles 44 and 105. With reference to textile 70/18 this is probably related to the ratio between the matrix surface and the textile surface, which is higher in the specimens with 9 yarns compared to the specimens with 10 yarns. With reference to textiles 44 and 105 the lack of longitudinal cracks is probably related to the lack of transverse yarns.

Figure 6 shows a typical experimental response in terms of fiber stress-global slips (transducers T4 and T5) and fiber stress-relative displacement of the blocks at the intrados (average of relative displacements measured by transducers T1 and T2).

Figure 6. Typical experimental response in terms of fiber stress-measured displacement.

The fiber stress was computed as the ratio between the axial force  $N$  in the fibers and the area  $A_f$  of the fiber cross section.  $N$  was computed as a function of the applied force  $F$  (Figure 3) via equilibrium equations. The global slips measured on the two blocks (points A and A', transducers T4 and T5 in Figure 3b) were similar in the first phase of the loading process, approximately up to a load equal to 50%-60% of the joint capacity. In the second phase of the loading process the global slip increased faster at the loaded end of one of the two interface surfaces (transducer T4 in the case shown in Figure 6) compared to the other interface surface due to the formation and propagation of a crack at the fiber-matrix interface. On this surface

complete debonding occurred at the end of the test. In this phase the global slip of the other interface surface (transducer T5 in the case shown in Figure 6) stopped or decreased. Figure 6 also shows that the global slips measured by the transducers T4 and T5 are consistent with the relative displacement of the blocks at the intrados, since the sum of these slips equals the average relative displacement measured by the transducers T1 and T2.

Table 2 summarizes the specimen characteristics and the experimental results in terms of peak load  $F_{\max}$ , corresponding tensile force in the fibers referred to as peak force  $N_{\max}$ , corresponding stress of the fiber referred to as peak stress  $\sigma_{\max}$ , and global slip of the surface where debonding occurs at the peak load  $g_{\max}$ .

Table 2. Peak load  $F_{\max}$  and corresponding axial force  $N_{\max}$ , axial stress  $\sigma_{\max}$ , and global slip  $g_{\max}$  of the tested specimens.

The average peak stress of textile 70/18 is between 1529 MPa (displacement rate 0.51 mm/min) and 2260 MPa (displacement rate 0.68 mm/min). The corresponding coefficients of variation (CoV) are equal to 18% and 6%, respectively. The slip at the peak load is between 1.57 mm (displacement rate 0.51 mm/min, CoV=27%) and 2.66 mm (rate 0.68 mm/min, CoV=14%). The average peak stress of textiles 44 and 105 are 2046 MPa (CoV=7%) and 2516 MPa (CoV=2%). The global slip at the peak load exceeds 3 mm for these textiles.

The  $\sigma$ - $g$  responses of the tested specimens are shown in Figure 7 where the fibers tensile stress  $\sigma$  is reported as a function of the global slip  $g$  of the interface surface on which the debonding occurs (maximum of the global slips measured by the transducers T4 and T5). The experimental  $\sigma$ - $g$  responses shown in Figure 7 are consistent with the idealized  $\sigma$ - $g$  response shown in Figure 8a, which is associated with the typical CML shown in Fig 8b [26] and with a bonded length equal to or longer than the effective bond length.

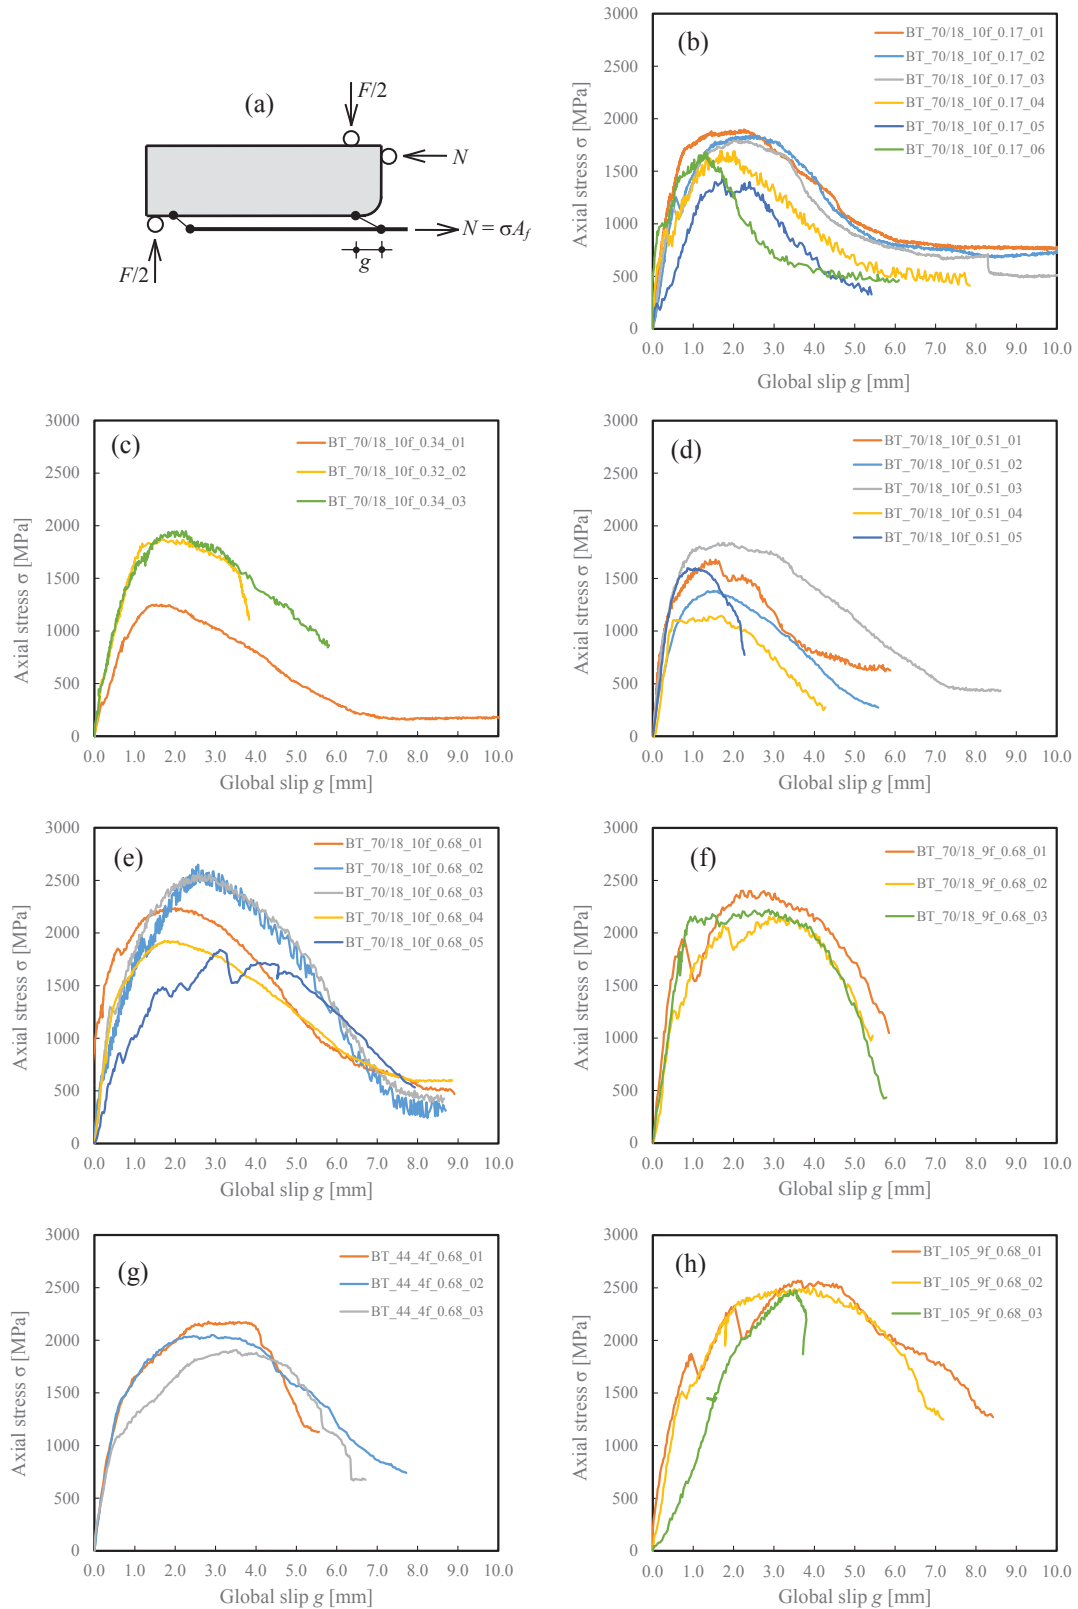

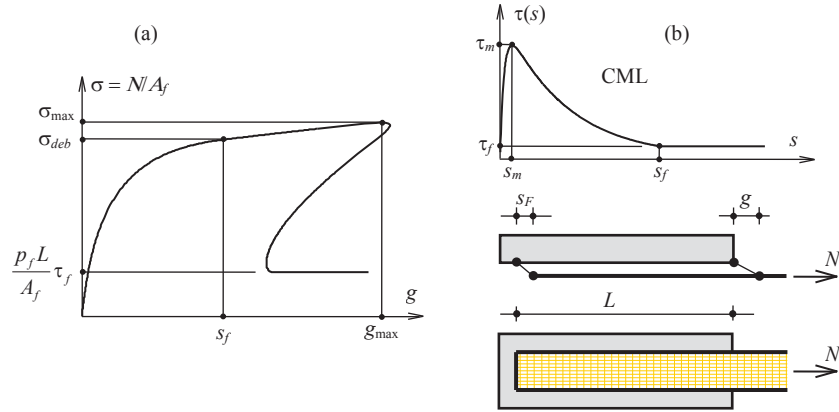

Figure 7. (a) Beam test; (b)-(h)  $\sigma$ - $g$  responses of the tested specimens.

Figure 8. (a) Idealized  $\sigma$ - $g$  response; (b) typical CML.

This response curve exhibits an ascending branch up to the debonding stress  $\sigma_{deb}$ , which correspond to the onset of the interfacial crack propagation that occurs for a global slip equal to  $s_f$  (Figure 8b). A further ascending branch, up to the peak stress  $\sigma_{max}$ , is exhibited if a constant friction branch follows the slip  $s_f$  in the CML and the bonded length is longer than the effective bond length. The slope of this branch is related to the friction shear stress  $\tau_f$  (Figure 8b). Once the peak stress is attained the applied stress decreases until it reaches a constant value due to friction only. The snap back phenomenon shown in Figure 8a, which is due to the elastic energy release associated with the decrease of the force  $N$ , is not experimentally caught by the performed beam tests since they are controlled by the displacement of the load application point.

An initial linear branch is exhibited by all the  $\sigma$ - $g$  responses shown in Figure 7 whose slope is related neither to the type of textile nor to the displacement rate. This branch is followed by an ascending branch with a smaller slope up to the onset of the debonding phenomenon. Once the debonding initiates the increase of the load up to the peak stress  $\sigma_{max}$  is associated with the development of friction shear stress [26] in the debonded region near to the loaded end. The descending branch is associated with the increase of the length of the debonded zone up to the complete debonding and the attainment of a constant stress associated with the interfacial friction shear stress  $\tau_f$  [25]. It should be noted that some beam tests were stopped before reaching the friction branch to save time.

Figure 9 compares the  $\sigma$ - $g$  responses of beam test on textile 70/18, characterized by a nominal slip rate equal to 0.00085 mm/s, with the  $\sigma$ - $g$  responses obtained by D'Antino et al. [25] on the same composite through single-lap shear tests at the slip rate of 0.00084 mm/s with a bonded length equal to 330 mm. Similar responses are obtained with the single-lap and beam tests. In particular the performed beam tests provided a slightly lower peak stress and corresponding global slip and a slightly higher friction stress compared to the values of the corresponding parameters provided by single-lap shear tests. The mentioned differences between the results of these tests are not fully consistent with the experimental results presented by Calabrese et al. [33]. In [33] it is observed that beam tests and single-lap shear tests provide similar peak stress, while beam tests provide friction stress that are roughly the double of those provided by single-lap shear test.

Figure 9. Comparison between the  $\sigma$ - $g$  responses obtained with beam tests and the  $\sigma$ - $g$  responses obtained by D'Antino et al. [25] through single-lap shear tests.

The higher friction stress obtained with beam tests is attributed by the authors of [33] to the transversal compressive stress on the textile at the edge of the blocks (at the mid-span of the specimen) associated with their rotation. The edges of the concrete blocks were rounded at the intrados of the hinged cross sections to reduce the transversal stress on the textile when the blocks rotate. This could explain the difference between the results presented in [33] and the results presented in this paper.

The influence of the displacement rate is shown in Figure 10 in which the peak stress (Figure 10a) and the corresponding global slip (Figure 10b) are reported as a function of the nominal slip rate.

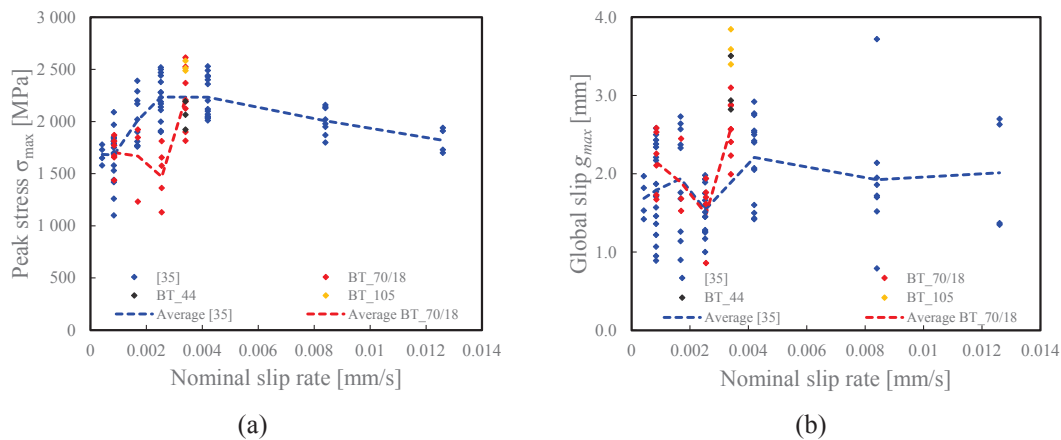

Figure 10. Influence of the slip rate: (a) peak stress vs. slip rate; (b) global slip at peak load vs. slip rate.

In Figure 10 the experimental results are also compared with those obtained by Carloni et al. [35] with single-lap shear tests. Experimental peak stress of single-lap shear tests presented in [35] refer to bonded length equal to 330 mm and 430 mm. It can be observed that the dependencies of the peak stress and corresponding global slip on the slip rate are different from those presented in [35], even if the peak stress corresponding to the slip rate 0.0025 mm/s is similar. The difference between the results of beam tests and the results reported in [35] is probably due to the different test procedure adopted. Indeed the single-lap shear tests presented in [35] are performed imposing a constant rate of the global slip, while the beam tests are performed imposing a constant rate of the load application point. As discussed in section 2.2 the slip rate approaches to a constant value only at an advanced stage of the test (Figure 3). This makes the beam test configuration unsuitable for investigating the influence of the load-

ing rate on the interfacial stress transfer phenomenon, unless the tests are controlled by the global slip measured through the transducers T4 and T5.

Figure 11 shows the comparison among the  $\sigma$ - $g$  responses of the three utilized textiles. It can be observed that the response curves of textiles 44 and 105 are similar to those of textile 70/18. Textile 105 is characterized by slightly higher slip at peak load than those of 70/18.

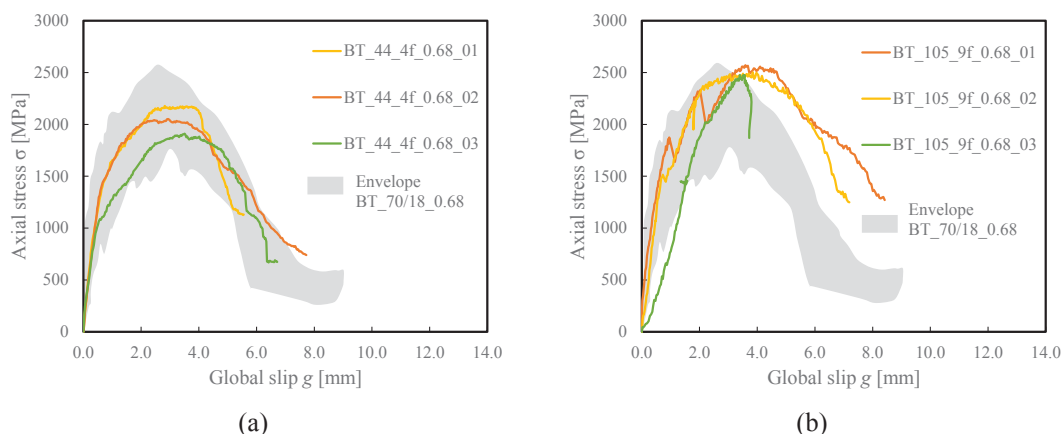

Figure 11. Effect of the fiber arrangement on the  $\sigma$ - $g$  responses: (a) textile 44 vs. textile 70/18; (b) textile 105 vs. textile 70/18.

#### 4 CONCLUSIONS

This paper presents the results of the first step of an experimental campaign for the characterization of the bond between PBO-FRCM materials and concrete by means of beam tests. Three composite materials made of the same matrix and different PBO textiles were tested. The tests were performed with different loading rates. The following conclusions can be drawn.

1. Beam tests provided experimental responses similar to those obtained by several authors through single-lap shear tests.
2. The fiber stress associated with the friction at the fiber-matrix interface was lower than that obtained by other authors with similar tests. This difference can be ascribed to the geometrical characteristics of the employed specimen.
3. It was not possible to observe a clear dependence of the joint capacity and the corresponding global slip on the loading rate. Therefore beam test does not appear suitable for evaluating the effect of the loading rate on the bond properties of PBO-FRCM materials, unless they are performed controlling the relative displacement between the concrete blocks or the interfacial slip at the mid-span of the specimen.
4. Textiles of PBO fibers with different fiber amounts have comparable responses in terms of shear stress transfer mechanism in the investigated range.

The beam test appears to be an alternative to single-lap or double-lap shear tests to characterize the interface between FRCM materials and the substrate. However further investigations are needed to determine the influence of the geometry of the specimen and the test procedure on the measured parameters.

## ACKNOWLEDGMENTS

The authors greatly acknowledge Ruregold s.r.l. (Italy) for providing the composite materials used in this experimental work.

### Abstract

*The low seismic performance level of precast reinforced concrete (RC) structures mainly depends on inadequate connections between structural elements. Seismic capacity of precast RC structures can be improved inserting dissipative devices in the nodes between structural elements. With reference to a new conception dissipative device named Joint Torsional Dissipative Device (JTDD) design abaci that represent the main correlations between the geometric and mechanical characteristics of the device are proposed. The design abaci constitute an operative tool that can be used to rapidly determine the optimal dimensions of the individual device as functions of the main characteristics of the structural system, e.g. angular rotation at the elastic limit, torsional stiffness and torsional moment at the elastic limit. The construction of the proposed design abaci is performed for a wide range of possible combinations of geometrical quantities characterizing the shape of the nodal devices.*

## 1 INTRODUCTION

In new precast reinforced concrete (RC) structures if typical isostatic schemes are adopted the fulfillment of the capacity requirements provided by current Italian code [1] is obtained only adopting very large column sections. This leads to high construction costs and low market competitiveness [2, 3, 4]. An improvement of the seismic capacity of precast RC structures can be obtained inserting dissipative devices in structural nodes [5, 6]. Many research works are available in technical literature [7], however the scarce application of the results to real precast RC structures suggests a necessary deepening of the constructive and economic aspects in order to ordinarily use these dissipative devices [2]. The research aim is that of defining the characteristics of a specific nodal device able to satisfy the requirements of energy dissipation, of adaptability to the current precast constructive systems and of cost containment. With reference to a device of new conception, described in the following paragraphs, the research activity has been focused on the definition of a design tool that allows to associate the nodal device mechanical characteristics to the geometric and dynamic characteristics of the precast system [8]. Indeed in previously performed studies [9, 10] it has been observed that a nodal dissipative device modifies the degree of constraint among the connected structural elements, producing a stress redistribution and a change of the dynamic characteristics of the precast system. Therefore in order to ensure that the device itself is effective in terms of dissipated energy and does not produce negative effects in terms of stresses, it must be designed appropriately for the specific precast structural system. In particular design abaci that represent the main correlations between the geometric and the mechanical characteristics of the device have been defined. The design abaci constitute an operative tool that can be used to rapidly determine the optimal geometric dimensions of the individual device as a functions of the demand parameters requested by the structural system (e.g.: angular rotation at the elastic limit, torsional stiffness and torsional moment at the elastic limit). The design abaci have been defined for a wide range of possible combinations of geometrical quantities characterizing the shape of the nodal devices.

## 2 DISSIPATIVE DEVICE DESCRIPTION

### 2.1 Operating principles

The JTDD are activated by the relative rotations that occur among the precast structural members (vertical and horizontal) following the system lateral deformation. The device allows horizontal and vertical displacements and restrains the nodal rotations through a hollow cylinder of steel or of a similar material that deforms in torsion in the elasto-plastic range. The amount of dissipated energy is therefore closely related to the extent of rotations and therefore to the floor drifts. This implies that the optimal working conditions of the device are those associated with structures undergoing large horizontal displacements under earthquakes. However the insertion of the JTDD modifies the degree of rotational constraint in the nodes among the structural elements with a consequent stress redistribution on them, that has to be accounted for in the verification of strength. A fundamental condition for a proper functioning of the devices is that the rotation at the elastic limit is larger than the nodal rotation induced by the vertical and horizontal service loads. For rotations lower than the elastic rotation the stress distribution on structural elements is a function of the device elastic stiffness. Therefore as the device constitutive law varies, stress distributions different from those associated to a scheme of isostatic columns and simply supported beams are obtained. In particular a constitutive law characterized by high values of elastic stiffness and plastic threshold leads to a late activation

of the devices in the plastic field, transforming the devices in fixed support constraints and impeding them to dissipate the energy necessary to reduce the seismic action effects. Low values of elastic stiffness and plastic threshold allow an early activation of the device with hysteretic cycles characterized by a small dissipation. In the case of an early device activation a significant part of the seismic action would still affect the columns only. The device calibration is closely related to the geometric and dynamic characteristics of the structure, therefore the present study has the aim of defining design abaci that correlate the geometrical and the mechanical characteristics of the devices. Indeed an incorrect calibration of the devices can compromise the benefits resulting from their insertion in the structural system.

## 2.2 Possible applications

In the last years numerous dissipative or isolation devices able to increase the energy dissipation of a structural system and to reduce the damage have been developed [7]. This approach allows to increase the performance level of precast structures keeping the construction cost at acceptable levels. The possible applications of the JTDD mainly concern new precast RC structures having a static scheme with isostatic columns and simply supported beams. Seismic protection devices can also be installed in existing structures for their seismic retrofitting. As already mentioned in previous paragraphs the proposed dissipative device works as a rotational constraint. Therefore with reference to precast structural system with isostatic columns and simply supported beams the natural positioning of the device is at the beam extrados in correspondence of the beam-column joint and laterally to the columns at the column-foundation joint (Figure 1). In this last case the device can be installed when columns are inserted into sleeve plinths and the internal hollow space between the column and the plinth is constituted by deformable material.

Figure 1: Installation example of the JTDD in the beam-column joint and in the column-plinth joint.

## 2.3 Geometrical and rheological characteristics

All elements constituting the proposed JTDD are made of steel type S275 (Table 1). It has been also studied the possibility of making the hollow cylinder, that is subjected to torsion, with different steel types or different materials characterized by a low elastic modulus and a low plastic threshold as the lead or the aluminum. The use of materials different from the steel type S275 allows to produce devices with lower stiffness and plastic threshold but with a larger dissipative capacity in the plastic field.

Material	E (N/mm <sup>2</sup> )	G (N/mm <sup>2</sup> )	f <sub>yk</sub> (N/mm <sup>2</sup> )	ε <sub>y</sub> (%)
Steel S275	210000	80000	275	0.13
Aluminium	70000	26000	150	0.21
Lead	5000	1785	25	0.50

Table 1: Material mechanical characteristics.

The device is constituted by a hollow section cylinder arranged with the longitudinal axis in the horizontal direction. The cylinder is constrained to a central plate connected to the vertical structural element and to two lateral plates connected to the horizontal structural element. The central plate has a vertical slotted hole, while the lateral plates have horizontal slotted holes. The presence of the slotted holes in the plates allows the structural elements connected by the device of sliding in the horizontal and vertical direction without inducing shear stresses in the hollow cylinder. The steel plates are connected to the structural elements through suitably dimensioned mechanical or chemical anchors (Figure 2). The length, the outer diameter and the internal thickness of the hollow cylinder vary as a function of the geometrical and dynamic characteristics of the precast structure. Indeed the geometrical parameters of the hollow cylinder together with the utilized material type determine the elastic stiffness, the plastic threshold and the ultimate angular strain of the torsional device.

Figure 2: 3D views of the JTDD.

### 3 NONLINEAR BEHAVIOUR

The linear and nonlinear behavior of the device is assimilable to the elastic-plastic behavior of the hollow cylinder subjected to torsional strains. The equations governing the device elastic behavior are those of the torsion classic theory for circular hollow section reported in the following. With reference to Figure 3 the following equations can be defined:

Figure 3: Infinitesimal cylindrical element subjected to torsion.

torsion angle per length unit

$$\vartheta = \frac{d\phi}{dx} \quad (1)$$

outer fiber slip

$$\gamma_{\max} = a \tan\left(\frac{\overline{bb'}}{\overline{aa'}}\right) \approx \frac{Rd\phi}{dx} = R\vartheta \quad (2)$$

linear variation of the distortion  $\gamma$  as a function of  $r$ . In the section the torsion angle is independent of  $r$ , therefore

$$\gamma(r) = r\vartheta = \frac{r}{R}\gamma_{\max} \quad (3)$$

The JTDD has a hollow circular section therefore with reference to Figure 4 the following equations are defined:

Figure 4: Section of hollow cylindrical element.

polar torsional inertia

$$I_{pol} = \frac{\pi}{2} (r_2^4 - r_1^4) \quad (4)$$

unit torsion angle

$$\vartheta = \frac{\gamma_{\max}}{r_2} \rightarrow \vartheta = \frac{M_t}{GI_{pol}} \quad (5)$$

where  $M_t$  = torsional moment and  $G$  = shear modulus;

total torsion angle between two section placed at a distance  $L$

$$\phi(L) = \frac{M_t L}{GI_{pol}} \quad (6)$$

Assuming the  $\tau_{\max}$  of the outer fiber equal to  $\frac{f_{yk}}{\sqrt{3}}$  the torsional moment at the elastic limit can be evaluated with the following relation:

$$M_{ty} = \frac{\tau_{\max}}{r_2} I_{pol} \quad (7)$$

In order to develop a design procedure for the selection of the device type to install in the precast structural system, the study of the JTDD plastic behavior has been performed in the first instance with a simplified analytical method. The evaluation of the device ultimate angular rotation is based on the maximum axial deformation of the diagonal of the unit element of the hollow cylinder outer fiber (Figure 5).

The element  $abcd$  in Figure 5 is considered deformed in torsion

Figure 5: Unit plane element deformed in torsion.

With reference to Figure 5 it is obtained:

$$L_{bd} = \sqrt{2h(1 + \epsilon_{\max})} \quad (8)$$

the same length can be determined with the cosine theorem applied to the  $abd$  triangle:

$$L_{bd}^2 = h^2 + h^2 - 2h^2 \cos\left(\frac{\pi}{2} + \gamma\right) \quad (9)$$

Using both relations it is obtained:

$$(1 + \epsilon_{\max})^2 = 1 - \cos\left(\frac{\pi}{2} + \gamma\right) \rightarrow 1 + 2\epsilon_{\max} + \epsilon_{\max}^2 = 1 + \sin \gamma \quad (10)$$

With this last equation it is possible to relate the ultimate axial deformation of the material  $\epsilon_{\max}$  with the ultimate slip  $\gamma_{\max}$ . Being linear the slip pattern with the radius, in that it derives from the congruence and is independent of the material behavior, it is possible to find the ultimate angular rotation associated to the ultimate slip.

#### 4 DEVICE PROPERTIES

As already introduced in the previous paragraphs the JTDD mechanical characteristics are directly relatable to the elastic stiffness, the plastic threshold and the ultimate rotation of the hollow cylinder subjected to torsional strains. In order to provide an operative tool design abaci for different material types have been defined. They graphically reproduce the analytical relations among the length, the outer radius and the thickness of the hollow cylinder and the mechanical parameters describing the device operation. For this purpose two shape factors, named S1 and S2 respectively, that represent the ratios of the geometric quantities defining the hollow cylinder have been defined. In particular  $S1 = rm/S$  and  $S2 = rm/L$  where  $rm$  is the average radius,  $S$  is the thickness and  $L$  is the length (Figure 6). Relating the shape factors S1 and S2 with the elastic stiffness, the angular rotation at the elastic limit, the plastic threshold and the ultimate angular rotation of the hollow cylinder it has been possible to define the above mentioned abaci. The material constitutive law has been assumed elastic-perfectly plastic. To determine the plastic torsional moment a tangential stress uniform distribution within the thickness of the hollow cylinder has been assumed. This last hypothesis implies that also the moment-angular rotation diagram of the hollow cylinder will show an horizontal plastic branch.

Figure 6: Geometrical quantities of the hollow cylinder.

Different types of JTDD have been designed parametrizing some geometrical quantities of the hollow cylinder to the varying of the utilized materials. The main results obtained with the performed analyses are reported in the following. In particular for different device types Figures 7, 8 and 9 report the torsional moment-total angular rotation diagrams while Figures 10, 11, 12 and 13 report the abaci relating the yielding torsional moment  $M_{ty}$  and the elastic stiffness  $K_t$  with the shape factors  $S_1$  and  $S_2$ .

Figure 7: Torsional moment - total angular rotation diagram of steel devices.

Figure 8: Torsional moment - total angular rotation diagram of aluminum devices.

Figure 9: Torsional moment - total angular rotation diagram of lead devices.

Figure 10: Torsional stiffness  $K_t$  - shape factor  $S_1$  abacus for steel devices.

Figure 11: Torsional stiffness  $K_t$  - shape factor  $S_2$  abacus for steel devices.

Figure 12: Yielding torsional moment - shape factor  $S_1$  abacus for aluminum devices.

Figure 13: Yielding torsional moment - shape factor  $S_2$  abacus for aluminum devices.

Where the symbols used in the figure legend have the following meaning:  
 $D_e$  = outer diameter,  $S$  = thickness and  $L$  = cylinder length.

In the diagrams reported in Figures 10, 11, 12 and 13 the quantity parametrized to define the devices is  $D_e$ .

Therefore the abaci relating the device mechanical characteristics to the  $S1$  and  $S2$  shape factors and the moment-total angular rotation diagrams constitute an operative tool to design the JTDD. Indeed once defined the device geometry through the  $S1$  and  $S2$  shape factors it is possible to determine the corresponding mechanical characteristics as elastic stiffness and yielding moment. For each device characterized by specific  $S1$  and  $S2$  shape factors it is moreover possible to determine the constitutive law in terms of torsional moment and total angular rotation.

## 5 CONCLUSIONS

- Aim of the present work is the definition of abaci for designing rotational dissipative devices to be placed in the nodes of precast reinforced concrete (RC) structures.
- The insertion in the structure of dissipative devices also at the column base leads to an increase of displacements under seismic action and although the natural consequence is the increase of energy dissipated by the devices, to contain the floor drifts below the thresholds allowed by code it is necessary to calibrate the device cycles also as a function of this last parameter.
- Moreover it has to be noticed that the insertion of these rotational devices produces a benefit in terms of reduction of retrofitting costs and unused costs of the structure subsequent to a seismic event.
- For what concerns the construction costs of a new structure, the proposed device has a low cost, their operation is of mechanical type and their installation and maintenance do not request particular precautions.
- Quick comparison calculations have been performed to evaluate the reduction of the construction costs after the insertion of the dissipative devices. The comparison of the construction costs, relative to the columns only, has shown a savings of about 35%.

### Abstract:

*This paper studies the behavior of enhanced strengthening Carbon Fiber Reinforced Polymer (CFRP) strengthening schemes. The CFRP systems are bonded to concrete substrates using toughened adhesive layers to limit the failure propagation in the interface and its brittle nature. Due to the importance of the integrity of the substrate two different scenarios are examined experimentally and analytically: healthy concrete and with corrosion products leached by the corroded reinforcement. The modified shear behavior (stress, slip) of the interfaces between concrete and CFRPs was investigated with a double shear test configuration. The corrosion products leached on the external layers of the substrate affected the interface response of the strengthening scheme, resulting in lower rates of shear stresses corresponding to lower slip ratios. The analysis of the sliding and shear stress distribution along the interface has also been investigated locally by finite elements using a cohesive model (CM) to examine the propagation of failure at the interface length. Toughened adhesives limit the substrate's dislocations and shift the response of the interface from pure elastic to pseudo-ductile in distinct stages. The debonding mode (brittle or pseudo-ductile) depends heavily on the toughness of the adhesive and its tensile modulus, since the higher the modulus is, the more brittle the response becomes.*

**Keywords:** CFRPs, corrosion, strengthening schemes, adhesive layers, toughness, efficiency

## 1 INTRODUCTION

In the past few decades, there is a boost in the technological advancement of structural solutions with various strengthening schemes developed for reinforced concrete (RC) members. Bonded composites, that is Fiber Reinforced Polymers (FRPs) made of glass, carbon or other kinds of fibers is a commonly used type. It is commonly accepted that the efficiency of the retrofitting measures is mainly based on the connection of the concrete substrate and the composite [1]. As such, the integrity of the substrate and the connection layer of the strengthening measure are the key elements to a successful intervention.

The use of FRPs orientates towards enhancing the deformability of the strengthened structural members since this type of retrofitting measures are not used to increase the stiffness of a structural member. They are applied on an adhesive layer, which fulfils the requirements of international standards, e.g. EN 1504-4 [2]. Standard epoxy adhesives normally show high tensile modulus and result in brittle fracture of the matrix. The main goal of this research paper is the explanation of the interfacial response of FRP and concrete substrate. FRP measures investigated are enhanced using toughened adhesive layers, which have a lower stiffness matrix and permit higher fracture energy.

This research examines, experimentally and analytically with finite element models (FEM), the use of toughened epoxy adhesive layers as part of strengthening schemes for RC members and has a focus on the examination of the limitation of the substrate's failure propagation due to the use of enhanced retrofitting systems. The toughened adhesives are expected to absorb more energy before debonding, especially under dynamic loads [3], [4]. The interaction with the concrete substrate to the dislocations imposed is examined with double-lap shear tests in carbon FRP (CFRPs) applied to concrete prisms.

Finally, the effectiveness of the bond behavior of these layers is also dependent on the concrete substrate integrity. As structures are exposed to various and at times extreme environmental conditions, the corrosion effect is usually met and has a tremendous impact on the structural integrity of the existing structures. As such, strengthening such members is challenging. A commonly accepted practice in these cases is, first, to define the corrosion rate and then to substitute the concrete substrate with a new one. In cases that the corrosion rate is low, and the bond behavior of concrete is within acceptable limits, strengthening measures can be directly applied. This paper also examines the influence of the corrosion products on the interface response of CFRP measures applied with toughened adhesive layers.

## 2 EXPERIMENTAL INVESTIGATION

For the purposes of the study, an experimental campaign has been designed. The campaign has two phases: a) accelerated corrosion procedure and b) double lap testing. The wider experimental campaign includes three different commercialized FRP systems (fabrics, laminates, Near Surface Mounted bars-NSM) applied in a healthy and corroded concrete substrate using three different adhesive layers, two of which are toughened. In this paper, the specimens including FRP fabrics are presented.

### 2.1 Materials

Nine concrete blocks with dimensions 150x150x250mm were prepared according to [5], [6], [7] with 28-day compressive strength of 37.5MPa corresponding to a tensile strength of 3MPa. All blocks contained steel rebar ( $f_{sy}=500$  MPa) of 18mm diameter in the middle of the cross-section placed longitudinally to the concrete block. CFRP sheets (SikaWrap: density  $\rho=1.8$  kg/L, tensile strength  $\sigma_u=4900$  MPa, modulus of elasticity  $E_{0.05-0.25\%}=230$  GPa, tensile strain  $\varepsilon_{EAB}=1.7\%$ ) were bonded symmetrically on opposite sides of the concrete blocks at a bond

length of 200m. The fibre orientation was  $0^\circ$  along the longitudinal direction of concrete blocks. The systems were applied with a dry lay-up process and according to the technical specification of the manufacturer. The interfaces were treated properly to have a laitance contaminant-free, open-textured surface and were cleaned with air pressure to remove loose material, dust and rust. The two components' epoxy adhesives (Table 1) were mixed according to the manufacturer's recommended ratio and time (4:1 for Sikadur 330 and 100:74 for Sikadur 370). The composites are left to cure at ambient conditions ( $20^\circ\text{C}$ , 50% relative humidity-RH) for at least a week before testing.

type	density $\rho$ [kg/L]	tensile strength $\sigma_u$ [MPa]	E-modulus (0.05-0.25%) [GPa]	tensile strain $\varepsilon$ (EAB) [%]
Sikadur 330	~1.4	29	4000	1
Sikadur 370	~1.7	30	5000	2.5

Table 1: Mechanical properties of epoxy adhesive layers.

## 2.2 Accelerated corrosion

The concrete prisms were exposed to wet conditions in a tank. They were bathed in a 3.5-5% weight NaCl-water solution (Figure 1a), which covered one third of the cross-section size of the concrete blocks [8], [9]. A low ratio of corrosion of the steel rebar cross-section is created almost equal to 6% with a continuous power supply ( $\approx 1\text{mA}$ ) [9] wired in the steel rebars for about three weeks.

## 2.3 Experimental configuration

Various experimental setups of double lap tests exist in the international literature [10]. These configurations permit the direct examination of the shear stresses of the interface. This study adopts a modified double lap shear test (Figure 1b). The concrete block lays on hollow support that permits slip and is hanged from the gripped ends of the FRPs that are fixed to a rigid steel frame. This alteration of the classic setup with two concrete blocks limits the relative slips of the interfaces of the different blocks, eliminates slips at the gripped ends of the FRP and at the same time permits direct shear stress measurement. The tests were performed on a compression machine at a speed of 1mm/min at room temperature ( $20^\circ\text{C}$ ). The measurements of the deformation of the central part of the CFRP were recorded using a high accuracy laser sensor. Also, two Linear Displacement Transducers (LDVT) with a maximum capacity of 100mm, were used to measure the displacement of the upper level of the concrete block and the grips.

(a)

(b)

Figure 1: Experimental campaign: a) accelerated corrosion, b) double lap (DL) setup.

### 3 FINITE ELEMENT SIMULATION

Except for the experimental investigation, a numerical study was conducted in order to study locally the overloading, the response, initiation and propagation of failure of the interface. The debonding of FRP composites applied to the concrete substrate was simulated with a numerical model developed using the commercial software ANSYS. For the realistic representation and simulation of the failure modes of CFRP strengthened concrete substrates a bilinear cohesion zone model (CZM) fracture model was used and calibrated from the experimental results [11]. Concrete and CFRPS were treated as homogeneous isotropic linear-elastic materials and were connected through zero thickness interfaces. Concrete and composites were simulated using a 3d solid element, defined by eight nodes having three degrees of freedom at each node (translations in the nodal x, y, and z directions).

## 4 RESULTS

### 4.1 Experimental results

The results are presented in shear stress- shear deformation diagrams of the average curves for the two categories of specimens, healthy and corroded, with both adhesive layers. Table 2 contains the characteristic values of the experimental results and the average curves.

Specimens wrapped with fabrics (HI330\_1-3, Cr330\_1-3) of unidirectional carbon fibers applied with the epoxy adhesive layer 330 present a response in three distinct stages, shown in Figure 2a. The toughened epoxy layers limit the substrate's failure propagation, allow the fracture to happen in stages and absorb more energy before debonding.

In the first stage the fabric is tensed (Stage I: linear elastic) at a linear rate. The fibers' configuration of the sheets is unidirectional and in parallel to the loading direction. This prevents bridging the crack propagation. In the second stage, there is a progressive crack initiation of the epoxy layer leading to crack opening, followed by a non-linear elastic yielding branch up to the transition point (Stage II: non-linear elastic yielding). The transition point ( $\tau^{\text{trans}}$ ,  $\gamma^{\text{trans}}$ ) practically corresponds to the further propagation of the crack pattern from the resin to the substrate and the overall connection of the two materials. The third stage is characterized by major cracking both at the adhesive layer and the substrate. Plastic regions are created at the concrete, and especially at the initial debonding area at a distance of 5 cm from the loading end. At the ultimate point of this stage (Stage III: major cracking), the specimens exhibit debonding of the FRP ( $\tau^u$ ,  $\gamma^u$ ). The failure mode is mainly caused due to the spalling of concrete at the delamination propagation area after the 5 cm and no FRP rupture is met (Figure 2c).

Figure 2b also shows the effect of corroded steel rebars on the interface response. The green dashed line represents the average curve of specimens with corroded steel rebar with fabrics applied on the concrete substrate with epoxy adhesive layer 330, whereas the red solid line represents the average curve of the healthy specimens containing the same epoxy. There is a clear difference in the response in both cases. The interface of the corroded substrate (330\_corroded\_ave) containing corrosion products presents a 20% decrease in shear strength ( $\tau^u$ ) and 24% lower shear deformation ( $\gamma^u$ ) at the ultimate point (Table 2). Also, the transition point is shifted to lower values of deformations (52%) and strength (18%). The leached corrosion products laying on the sides of the concrete substrate and the minor strains due to the initiation of corrosion are practically mass disturbance creating regions of altered consistency and resistance. Also, even in such low percentages of corrosion, which corresponds to corrosion initiation and to allowable bond values of the substrate, the crack initiation in the concrete mass in

combination with the rust laying on the interface, makes the connection with the FRP strengthening scheme weaker and results in lower values of slip and shear strength.

A higher stiffness matrix corresponding to the specimens with sheets applied with epoxy adhesive layer 370 (Sikadur370) presents a different response (HI370\_1-3, Table 2). Figure 2b shows that the tougher the epoxy resin matrix is, the stages II and III coincide. This means that even though there is a distinct transition point in almost the same levels of shear deformations but in higher values of shear stresses, the crack pattern both in the substrate and in the adhesive layer propagates simultaneously up to the debonding point of the strengthening system. The intrinsic toughened adhesive layer 370 is designed for steel substrates and especially suitable for fatigue cracking applications [4]. The crack width in the cases of concrete substrates is bigger than fatigue cracking in steel substrates. In combination with the stiffness of the matrix, the response alters from pseudo-plastic (case of Sikadur 330) to brittle.

#### 4.2 Finite element results

The finite element simulations' results were calibrated with the corresponding tests. Figure 3a shows the total stresses concentrated at the interface area between the concrete substrate and the FRP sheet. The stresses present a similar value in both cases, that is healthy and corroded substrates. Both cases, have a concentration of stresses near the loading end, presenting similar failure modes. Figure 2c show the differences of the failures and agree with the plastification mechanism of concrete and the sliding distance of the interface, of the FEM simulations' results presented in Figure 3a&b. It is also remarkable that the active length of the interface, meaning the length which concentrates the highest ratios of stresses, is 5% lower in the case of the corroded specimen.

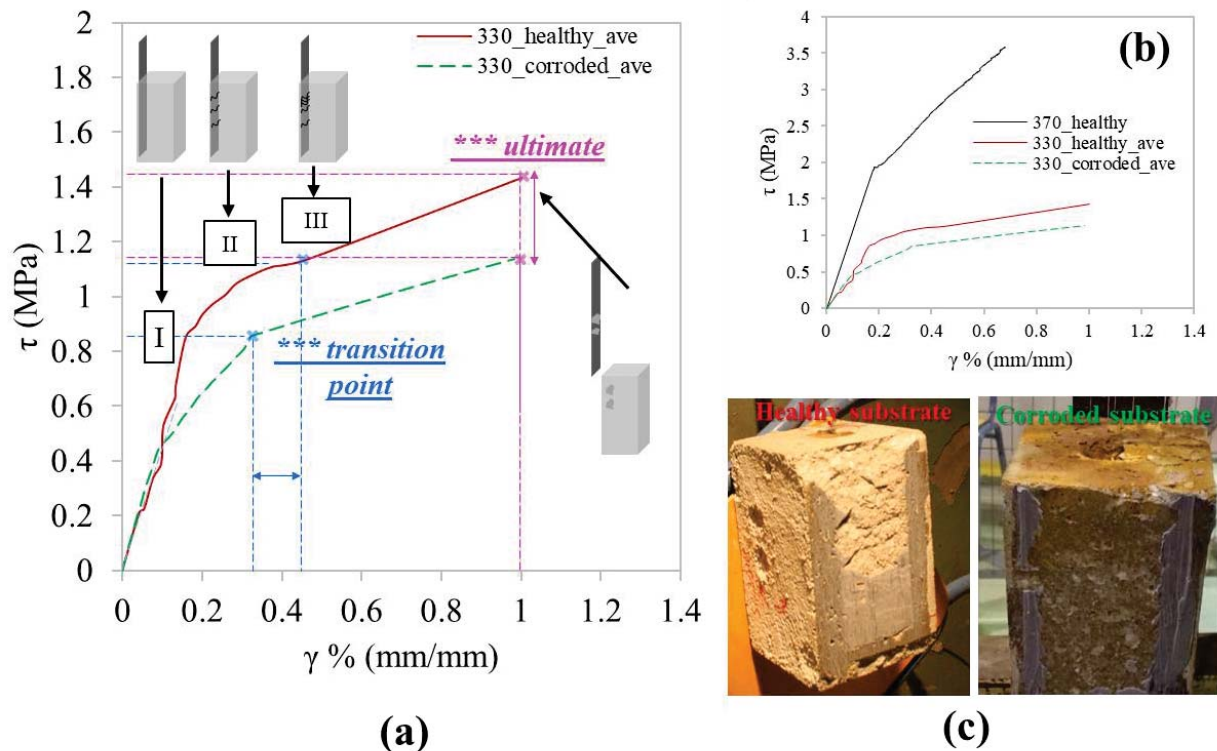

Figure 2: Experimental results of the DL tests: a), b) shear stress vs shear deformation curve, c) failure mode.

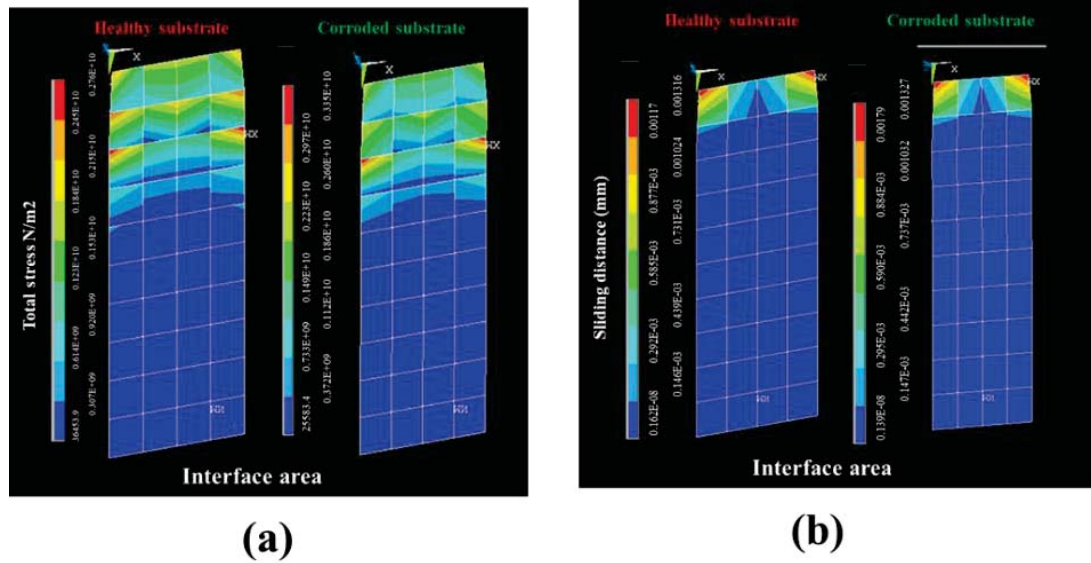

Figure 3: Contour plots of the interface a) total stresses, b) sliding distance.

Table 2: Experimental results.

## 5 CONCLUSIONS

- Toughened adhesive layers shift the interface response in comparison with the standard epoxy commonly used, from brittle to pseudo-ductile in distinct stages. The more tough the adhesive layer is, the shorter are the stages before the failure of the wrapped CFRPs.
- The distinct stages of the response of interfaces denote a progressive failure and correspond to the crack propagating stages up to failure.
- The corrosion products affect the interface response. They provoke a decrease of approximately 20% of the ultimate shear strength and corresponding shear deformation, whereas the transition point is met in almost half the shear deformation.
- The length of the CFRP which is overloaded and hence activated, is almost 40% of the total length, whereas, in the case of leached corrosion at the interface, the active length is 5% lower. The majority of stresses are concentrated at a distance of 5 cm of the loading end provoking spalling of the concrete's substrate.

## ACKNOWLEDGEMENTS

This study has received funding from the European Union H2020-Marie Skłodowska-Curie Research Grants Scheme MSCA-IF-2018 (grant agreement no 845549: BRIFACE-Novel assessment of bridge retrofitting measures through Interface Efficiency Indices (InterFeis) using a Guided Wave-based monitoring method).

The authors would like to thank Sika AG, one of the industrial partners of the project, for their contribution to the realization of the experimental program.

Special thanks to the Democritus University of Thrace and the laboratory of Reinforced Concrete and Seismic Design of Structures for collaborating on the experimental campaign.

### Abstract

*Structural joints are generally the most critical parts of RC precast structures in terms of seismic assessment, especially in existing buildings, where friction connections can be often found. This issue, widely highlighted in the aftermath of recent earthquakes in Europe, have brought the scientific community to develop retrofitting techniques improving the seismic performance of the connections. The presented work deals with a dissipative hysteretic device, made of two steel rods, arranged as a three-hinged arch, and provided with moon sickle shaped items. It is applied at the beam-to-column connection level and it is intended for both restraining the relative displacements between the joined structural elements and dissipating energy coming from the earthquake. In the presented study, the innovative device is described in detail along with its numerical model, as applied to an existing single-story RC precast structure with beam-to-column friction connections. The results of preliminary numerical analysis showing its efficiency are also reported.*

---

## 1 INTRODUCTION

Premature failure of structural joints is the main issue detected for the existing RC precast buildings during earthquakes. As demonstrated by recent seismic events in all Europe [1-7], this is caused by either the absence of a mechanical device, i.e., horizontal load transfer relying only on friction, or the inappropriate connection design, both resulting in inadequate seismic performance. Local collapse of structural joints often involves disastrous structural breakdown, due to the loads transfer inability and the loss of support phenomena. For this reason, together with retrofitting techniques at the structure and the element levels, some solutions aiming at improving connection seismic response are developed in last years. The simplest and most obvious intervention consists in the introduction of devices able to reproduce a hinged restrain at the joints level, thus reducing the deformation demand. However, a significant shortcoming for this solution is detected. Indeed, the stresses transmitted to the base of the columns are significantly higher than the ones recorded for the un-retrofitted structure, leading to a greater involvement of plastic hinges and, hence, a higher level of structural damage. Therefore, the state-of-the-art devices are able to both strengthen structural joints, limiting the relative displacement between the connected elements, and dissipate a portion of the seismic energy coming from the ground motion, avoiding high damage. Passive energy dissipation devices represent the easiest and most economical solution in the world of structural control systems, since they do not require any external energy power or electronic hardware and their functioning is simply activated by structural displacements. Martinelli and Mulas [8] investigated the potential application of a connection retrofitting device, already used for cast in situ reinforced concrete and steel buildings, to an RC precast industrial structure. The proposed system is able to both restrain the relative displacement between principal beams and columns and dissipate energy thanks to the friction developed during the rotation of an annular brass plate, inserted between steel components. Two UPN200 channel sections are connected to the beam and the column end respectively, creating the dissipative hinge at their intersection. The provided configuration allows a quick re-centering after the seismic event. Nonlinear dynamic analyses on a structural model are performed, comparing the seismic response of the bare building with the one equipped with rotational friction devices. Outcomes from this assessment show the good behavior of the analyzed retrofitting technique, able to enhance the damping of the structure reducing significantly the hysteretic energy ascribable to plastic hinges at the columns base, despite a moderate increase of the overall stiffness and, thus, of the seismic base shear. Pollini et al. 2018 [9] proposed an innovative connection retrofitting system, combining the deformability of steel with the high strength of composite materials. Carbon-wrapped steel tubes can be connected to the structural elements (beams and columns) thanks to a threaded bar passing through circular holes on the tube basis. Each tube works in compression, dissipating seismic input energy and, thus, limiting the transmission of the stresses to the base; so, for each connection two devices have to be provided. Quasi-static monotonic and cyclic experimental tests were performed on the proposed system in order to assess the energy dissipation capacity, recording very stable hysteretic cycles. A numerical validation was also performed, even if considering a simple structural model, demonstrating the expected beneficial impact of the proposed device on the seismic structural response. Soydan et al. [10] dealt with a new lead extrusion damper (LED), usable in retrofitting interventions for precast structures joints. It is constituted by a cylinder full of lead, a shaft and a cap. Lead is a relatively flexible metallic material, able to dissipate a considerable amount of energy when it is forced to deform. In order to dissipate seismic energy, the cap and the shaft have to be connected to different structural elements (i.e., columns and beams), where relative displacements are expected. A numerical model of an existing RC pre-

cast structure is developed in SeismoStruct [11] and dynamic analyses are performed with ten historical ground motions. The outcomes from the seismic assessment of the bare structure are then compared with the response of the same structure retrofitted with lead extrusion dampers. Even if the recorded acceleration increases for the retrofitted structure, due to the increase in lateral stiffness, shear resistance in the columns is not exceeded and benefits from the application of the LEDs are clear: beam-column relative displacements are strongly reduced, as well as the bending moment at the base. In this way, the plasticization of the structure is limited and the damage level results to be lower.

The present work shows an innovative hysteretic device for the retrofitting of RC precast structural joints. The efficiency of the system is assessed evaluating the seismic response of an existing RC precast structure with beam-to-column friction connections, before and after the application of the hysteretic device. To reach this goal seven nonlinear dynamic analyses are performed, together with an energy balance estimation, demonstrating the ability of the proposed system in both preventing the relative displacements at the connection level and reducing the rotational demand at the base.

## 2 DESCRIPTION OF THE RETROFITTING SYSTEM

The proposed device represents an upgrading of an already patented system for the retrofitting of structural elements connections in precast buildings [12, 13], which consists of two hinged steel profiles, linked through horizontal dowels to the connected elements, i.e., beams and columns. A 2 mm rubber layer surrounds the dowels, since it is demonstrated [13] that this expedient is able to reduce the concrete cracking at the rods connection location, thus improving the device functioning. This arrangement allows turning the horizontal shear forces acting on the connection in axial forces in the rods, thanks to a three hinged-arch behavior. Therefore, it is able to significantly limit, or even prevent, relative displacement between beams and columns. It is possible to take advantage of the device in both existing buildings, often provided with friction connections, and current code-conforming buildings, as a valid alternative to the conventional dowel connection. In the herein presented version (Figure 1), the hysteretic properties are given by some special gadgets, moon sickle shaped, mounted on each profile, which yield under the axial load in the rods and dissipate seismic energy undergoing plastic deformations.

Figure 1: Metallic hysteretic device configuration

The device acts like a structural fuse, in which the seismic damage is concentrated, decreasing the ductility demand at the plastic hinges location. At the end of the ground motion striking the building, these gadgets can be easily replaced, without interrupting the productive activi-

ties. The force-displacement backbone (Figure 2) can be represented as an elastic-hardening curve, characterized by a yielding point ( $d_1, F_1$ ) and a post yielding stiffness, defined thanks to the second point coordinates ( $d_2, F_2$ ). In Table 1, standard mechanical properties for the rods are reported, provided by the manufacturing company. The proposed types underwent qualification tests according to the European code UNI EN 15129 [14], governing the seismic devices design. In the present study, rod type is chosen among the presented ones considering the shear associated to the yielding moment at the columns base, and applying a capacity design safety factor, so as to allow the plasticization of steel gadgets before the yielding of the plastic hinges. However, this is a preliminary study, conducted only to understand how the device works under seismic actions; a proper calibration should be performed, in order to maximize its performance.

Figure 2: Monotonic force-displacement response

Type	$d_1$ [mm]	$F_1$ [kN]	$d_2$ [mm]	$F_2$ [kN]
1	3.9	34.5	20.0	40.0
2	3.7	43.5	20.0	50.0
3	3.0	52.0	15.0	60.0
4	2.8	75.0	15.0	86.0

### 3 CASE STUDY

An existing single-story RC precast structure, dated back to the Seventies, is considered in order to assess the effect of the proposed retrofitting device. The construction is configured with a single bay, 15 m long, in x direction and four bays, each of them 6 m long, in z direction. Columns' total height is equal to 9 m; furthermore, since this kind of buildings are usually intended for industrial activities, design procedure and modeling take into account the presence of a crane and the relative brackets supporting the crane, placed at 7.5 m from the columns' base. Structural layout is presented in Figure 3. A design simulating the elements dimensioning process is performed taking into account codes and regulations of the Seventies, i.e. DM 3/05/1974 [15] and CNR 10012/1967 [16]. The building is located in Catania, an Italian city with a high seismic hazard; nevertheless, at the time of construction, it was not considered as a seismic-prone area, so the design procedure ignored seismic actions. Roof

covering consists of prestressed double T elements, with equivalent section of  $0.40 \times 1.60$  m, placed one near the other on the top of the principal beams and linked together by a 5 cm thick concrete slab. The slope of the covering is assumed to be 10%. The presence of the topping slab involves a rigid diaphragm behavior, i.e. a rigid behavior of the floor in its own plane.

Figure 3: Structural configuration: plan view and transversal view

Roof elements are jointed to the principal beams through steel plates and bolts, ensuring in this way a hinge constrain. Principal beams in transversal direction (x direction) present a variable height and a variable section (T-shaped at the extremities and, after a tapering zone, I-shaped in the middle). However, an equivalent rectangular area ( $0.17 \times 1.14$  m) is assumed, since beams section shape does not affect the results. In z direction, instead, secondary beams are provided in order to both collect rainwater and connect structural frames in longitudinal direction. They usually have a U section, but an equivalent rectangular one is considered, with dimensions  $30 \times 50$  cm. Unlike roof elements and beams, which are dimensioned only for vertical loads (permanent and variable actions), columns are also designed for horizontal (wind) forces acting on the structure. They consist in precast monolithic elements with a square section, whose dimensions and reinforcement are shown in Figure 4a. The presence of socket foundations allows considering the columns fixed at their base. Principal beams are simply supported on columns' head through a neoprene pad, with dimensions  $0.25 \times 0.25 \times 0.01$  meters, generating a friction connection; secondary beams are hinged to the columns' head through steel angles and bolts. Indeed, according to the design practice of the time, the higher value of axial load provided by principal beams on the top of the columns was deemed sufficient to ensure a proper strength to the friction connection. From this assumption follows the most important weakness detected for existing RC precast structures.

#### 4 NONLINEAR MODEL

A nonlinear numerical model is created in OpenSees [17] in order to perform a seismic assessment of the un-retrofitted and the retrofitted structure. Columns and beams are represented as elastic elements through their longitudinal axis; the eccentricities generated at the connection level, typical of precast structures, are modelled thanks to rigid brackets. Roof elements are taken into account only as vertical load and mass, but they are not explicitly modelled since they do not affect the seismic response. Cladding panels are not modelled, only their mass contribution is considered. Even if the cladding affects the seismic behavior of the building, making it stiffer, it should be noted that, in existing structures, panels connections were not provided with earthquake resistance, so panels collapse at very low seismic intensi-

ties, i.e., in the early stages of a ground motion, leaving the structure bare. Therefore, the assumption of neglecting cladding panels in the modelling is reasonable. A lumped plasticity approach is followed, concentrating the nonlinear behaviour at the columns base. Moment-rotation curves are detected performing a fiber analysis of the columns cross section and applying Fardis formulations [18] for the yielding and the ultimate chord rotations. Different backbones are obtained for the two horizontal directions and for corner and lateral columns. These differences are due to the different longitudinal reinforcement provided in the two orthogonal sides of the columns cross-section and to the different value of axial loads on the top of the columns. Figure 4b illustrates the moment-rotation curves. Each column and the corresponding plastic hinge constitute a system working in series, so their stiffness are calibrated in order to return the overall nonlinear stiffness.

Particular attention is paid to the friction connection modelling, since the great impact of its seismic response on the structural global collapse condition. A zero-length element is inserted at the principal beam-to-column intersection, and proper materials are assigned for each degree of freedom. The horizontal translations in x and in z directions (Figure 3) are characterized by a frictional behavior, with an elastic perfectly plastic response; the elastic branch is defined by the lateral stiffness of the neoprene pad, whilst the flat branch is attained in correspondence of the friction force. In the vertical direction an elastic material, identified by the axial stiffness of the pad, is considered as acting only in compression, given that the pad does not react in tension. Rotation around the z axis (in the xy plan) is left free, whereas rotations around x and y axes are constrained.

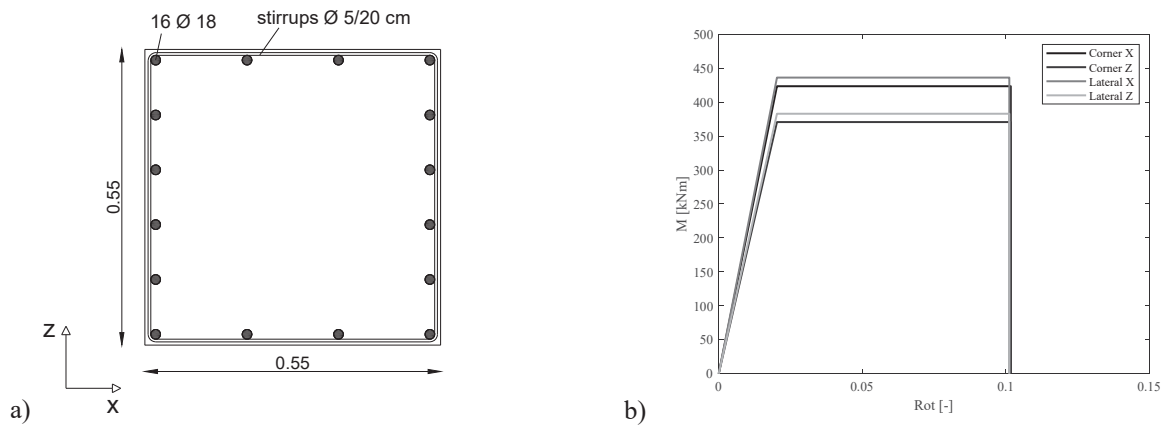

Figure 4: a) Column cross section and b) Moment-rotation backbones at the column plastic hinge

Finally, steel profiles constituting the retrofitting device are modelled thanks to truss elements, i.e., elements absorbing only axial loads. To define the constitutive law, the assigned material is a series of an elastic perfectly plastic gap material, in order to simulate the rubber layer around the dowels, and a hardening material, considering a kinematic hardening response. Parameters to be assigned are calibrated in order to reproduce a Type 1 rod response, according to the design procedure illustrated in Section 2. Following the recommendations provided by the manufacturer company, the device configuration is chosen so as to maintain a difference in the rods length equal to 0.4 m. Rigid brackets are inserted in the model in order to connect the rods to the beam and the column, representing the distance between the longitudinal axis of the structural elements and the connection provided by the device. Retrofitting is performed only in the transverse (x) direction. Figure 5 shows the schematic representation of a typical frame of the retrofitted structure in the x direction.

Figure 5: Retrofitted frame layout

## 5 ANALYSES OUTCOMES

In order to demonstrate the functioning of the proposed system, seven ground motions (GM) are selected and applied, first, to the un-retrofitted structure and, then, to the retrofitted one. For the records selection, Conditional Spectrum Method [19, 20] is implemented, according to [21]. All the spectrum coordinates are conditioned to the one corresponding to the fundamental structural period. A soil type C is considered to determine the elastic spectrum. The chosen intensity level refers to a return period,  $T_R$ , equal to 2500 years, i.e., a 2% in 50-years exceedance rate. Seismic records, taken from database of the Italian accelerometric archive (Itaca) [22] and from the database NGwest [23], are properly scaled in order to match the obtained target spectrum. As concern the un-retrofitted structure, outcomes show that the friction connections activate in the very first stages of the ground motions and significant relative displacement between principal beams and columns are recorded. Since, as expected, the sliding begins before the activation of the plastic hinges at the columns base, the structure shows an elastic response until the collapse, due to the loss of support of the beams. Applying the retrofitting device to the structure at each connection location (Figure 5), the first detected benefit is the strong reduction in beam-to-column relative displacements. In Figure 6, the recorded deformations of a friction connection element, corresponding to the relative displacements of the jointed members, is reported in both the case of the un-retrofitted and the retrofitted structure for a single ground motion.

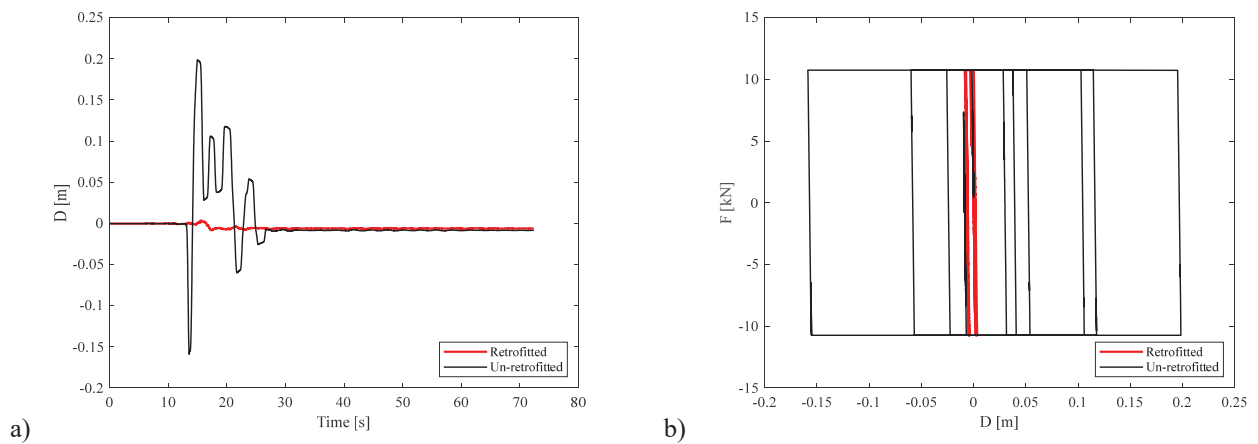

Figure 6: a) Comparison between the relative beam-to-column displacement for the un-retrofitted and the retrofitted structure for GM1, b) comparison between the force-displacement response for the un-retrofitted and the retrofitted structure for GM1

For the same connection and the same seismic input, force-displacement response of the retrofitting device, i.e. of the pair of rods, is reported in Figure 7, confirming the correspondence to the assigned behavior.

Figure 7: Force-displacement response of a pair of rods, in particular for a) an inferior profile and for b) a superior profile.

The inferior rod shows always a higher engagement, with larger and more numerous hysteretic cycles. It is worth to remember that each rod is provided with a 2 mm gap, simulating the rubber layer around the dowel: it is partially visible only in the superior rod response, represented by the flat branch at force equal to zero. In order to highlight the beneficial effect of the dissipative device on the hysteretic seismic response of the structure, the same set of ground motions is applied to the same structure retrofitted with an identical device but indefinitely elastic. For both the retrofitted systems, the elastic and the hysteretic one, the limitation of the displacements at the connection level is achieved, but in the first case the only source of hysteretic dissipation is provided by the plastic hinges at the columns base. From the comparison between these two solutions, it is possible to understand how much the proposed hysteretic device is able to reduce the plastic rotational demand at the base and, therefore, the structural damage. An energy balance analysis is performed on both the structures, allowing a rapid and synthetic evaluation. The input energy, transferred to the structure by the ground motion, is absorbed and dissipated thanks to energy contributions related to the structural response. In particular: kinetic energy, that is originated by the motion of the building; elastic strain energy, which depends on the level of strain recorded for the structural elements; hysteretic energy, given by the moment-rotation cycles of the plastic hinges at the base, i.e., by the nonlinear response of the structure; frictional energy, provided by the force-displacement cycles generated by the friction connection; viscous damping energy representing the contribution of the damping of the structure (Rayleigh damping is considered). Finally, there is the contribution of the retrofitting devices, which is recoverable for the elastic system and unrecoverable for the hysteretic device, thanks to its dissipative properties. Figure 8 shows the outcomes of the energy balance analysis for both the structures for a single ground motion.

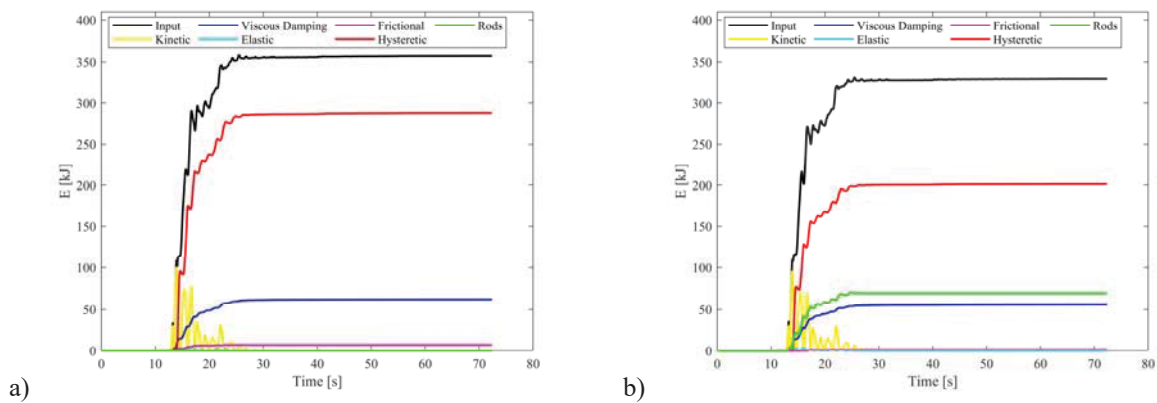

Figure 8: Energy balance for GM1 for a) the structure with an elastic retrofitting device and b) a structure with a hysteretic retrofitting device.

The beneficial effect of the hysteretic device in reducing the dissipated energy of the plastic hinges at the base is evident. The other energetic contributions seem not to be affected by the dissipative behavior of the device. This trend is observed for each of the considered seven ground motions, even if not to the same extent. In Figure 9 the plastic hinges hysteretic energy for both the systems is charted, expressed as a percentage of the total input energy. For some earthquakes, the proposed device slightly reduces the plastic involvement of the structure, and, in any case, it is not able to prevent the yielding of the hinges at the columns base. As already observed, a proper calibration is needed for the hysteretic device and a sensitivity analysis on the parameters conditioning its response should be performed.

Figure 9: Plastic hinges hysteretic energy in the case of an elastic retrofitting device and a hysteretic retrofitting device for all the ground motions.

## 6 CONCLUSIONS

This paper presents a novel metallic hysteretic device, intended for the seismic retrofitting of beam-to-column connections in RC precast buildings. The proposed system, applied at the joint level, is designed to both restrain the relative displacement between the connected elements, working as a three-hinged arch, and dissipate the ground motion input energy, thanks to special gadgets with hysteretic response. A nonlinear model of a RC precast industrial structure with friction connections is implemented in OpenSees [17], and seven nonlinear dynamic analyses are performed, highlighting the weakness of the structural joints. Indeed, the detected global collapse is due to the beams loss of support, when the structure is still in the

elastic field. Then, hysteretic devices are inserted in the structural model, at the connection levels along the transversal direction, and the same seismic inputs are applied on the retrofitted building. The comparison between the response of the un-retrofitted and the retrofitted structure leads to the following findings.

- i) The proposed device is able to strongly limit the relative displacements between beams and columns, avoiding structural collapse due to loss of support phenomena.
- ii) The seismic demand at the base increases when the device is inserted, resulting in the yielding of the plastic hinges. However, it is demonstrated that the recorded level of damage is lower than the one corresponding to the application of a traditional device, with an elastic behavior.
- iii) The hysteretic properties showed by the metallic device are not sufficient to reduce significantly the plastic deformations at the columns base for all the applied ground motions; indeed, in all the cases, yielding is never prevented. A proper calibration is needed to optimize the retrofitting performance.

### Abstract

*Engineering modeling and analysis of historical structures include various uncertainties and related difficulties. The most important difficulty is to obtain consistent data of structural materials without damaging historical texture as much as possible. The aim of this study is to determine the average compressive strength of the minarets of the Blue Mosque by means of ultrasonic testing. In the scope of the study, cube samples were collected from the unusable stones that were remained from restoration works carried out in the mosque. Compressive strength tests were performed following ultrasonic tests and a highly correlated relation was obtained. This relation was used in a detailed ultrasonic test study carried out in the minarets of the Blue Mosque and afterward, the mean compressive strength distributions for each minaret were estimated. It is thought that the results of the compressive strength test applied for the first time on the Blue Mosque stones as well as the detailed results for each minaret will make a significant contribution to the literature for future restoration studies and analyses.*

## 1 ULTRASOUND TESTING

Ultrasound testing is a nondestructive method that uses high frequency sound wave to determine the material properties. It is based on evaluation of the velocities of P and S waves which are transmitted and reflected back through the material. This study covers the application of ultrasound testing method on Blue Mosque Minarets in İstanbul, Turkey. The equipment utilized for the application is Proceq Pundit Lab Plus. It consists two probes that transmit and receive the sound waves and a device that displays the obtained value. In this study, two probes are used: 250 kHz probe and 54 kHz probe. The 54 kHz probe only generates P waves, whereas the 250 kHz can generate both P and S waves. As can be seen in Figure 1, there are three types of measurement techniques: direct, semi-direct and indirect. The most reliable one is the direct measurement technique, however it is only applicable when the material thickness is appropriate to transfer the waves through the probes which are located reciprocal.

Figure 1. The three types of measurement regarding the arrangement of the probes (Pundit Lab Operating Instructions)

## 2 EXPERIMENTAL STUDIES

Blue Mosque is constructed in between 1609-1616, with its 6 minarets. The laboratory experiments are applied on the stones of the minaret which is under restoration whereas the site investigation is carried on the other 5 minarets of the mosque. The two of those five minarets (M1 and M6) have a height of 57 meters with two balconies; whereas the other three ones (M2, M4, M5) are 66 meter tall with 3 balconies. The minarets are stone masonry constructions. Figure 2 illustrates the settlement of the minarets of the Blue Mosque. While this study is being carried, the honeycomb part of the minaret M3 is removed due to the restoration work. The ultrasound, Schmitt and the compressive strength tests are carried on the stones removed from the honeycomb and will not be reused after the restoration. Besides, ultrasound testing is done on the other five minarets on the site.

Figure 2. Blue Mosque and the settlement of its minaret

Figure 3. The debris removed from the minaret M3 and the cubic specimens obtained by cutting them

Figure 3 shows the debris removed from the minaret M3 and cut to the appropriate shape for the compressive strength test. The 7x7x7 cm and 5x5x5 cm cubic pieces, which are referred as “the large samples” and “the small samples” respectively in this paper, are obtained. First the large ones are worked. Five measurements are done for the each three pair of opposing surfaces to evaluate the P and S wave velocities, not only the numerical value but also with the wave forms. The 54 kHz probes are used for the P waves and the 250 kHz ones for the S waves. When it is completed, P wave velocity values are found to be reliable. However the 250 kHz probes generate the P and S waves together, therefore the velocity value shown on the screen is not respectable and the wave forms are required to be inspected. Nevertheless it should be a detailed observation, since the P and S waves are not clearly detectable due to the limited dimension of the specimens. After the ultrasonic test, the Schmitt Hammer test is carried and then the density of each cubic piece is determined.

Figure 4. The ultrasound and Schmitt Hammer tests application

Figure 5. The samples cracked while the Schmitt Hammer test application

The Schmitt Hammer test is applied on each three non-reciprocal surfaces. After the ultrasonic test, Schmitt Hammer test and the density evaluation, compressive strength test is applied. The small samples are cracked during the Schmitt Hammer test, due to their dimensions, hence it is decided not to apply the test on them. Besides, the test applied on the large samples

is not concluded in reliable correlation with the compressive strength test. Therefore, the Schmitt Hammer test results are not regarded in this study.

It is observed on the cracked specimens that, despite their soft surfaces they have quite stiff cores inside. This fact is considered as one of the reasons for not yielding reliable correlation between Schmitt Hammer test and compressive strength test results.

There are several ultrasound test measurements that resulted in remarkably different outcomes for each surface pairs of the same sample. Besides, it is thought that the compressive strength result is effected by the other two directions that the compression is not applied. Regarding these observations, three different methods are asserted in order to inspect the correlation between the P wave velocity and the compressive strength value.

### 3 THE ANALYSES

The analyses are launched after collecting the data from the previously mentioned tests. The S wave velocities are determined by observing the wave forms, then the regression analysis is carried to evaluate the correlation of the data. First, the correlation between the P wave velocity and the compressive strength is inspected. Concerning the readings on different surfaces of the samples, the correlations between the compressive strength and the following three measurements are regarded respectively: P wave velocity related to the compressed surface; the mean value of the P wave velocity related to each surface; the minimum P wave velocity obtained from each surface.

As can be seen in Figure 6 and 7, the correlations are found to be 66%, 77% and 79% respectively.

Figure 6. The correlation between the compressive strength and P wave velocity related to the compressed surface

Figure 7. The correlation between the compressive strength and (a) The mean value of the P wave velocity related to each surface (b) the minimum P wave velocity obtained from each surface

Then, the correlation between the minimum P wave velocity obtained from each surface and the compressive strength is observed for the samples having 40MPa and below compressive strength. As Figure 8(a) points, the correlation increases up to 81% in that case. Consequently, the same analysis is carried for the samples with a compressive strength of 35 MPa and below; 30 MPa and below. The correlations are found to be 81% and 85% respectively (Figure 8(b), 8(c)). It is clear that the correlation is the same for the samples with a compressive strength of 40 MPa and below and 35 MPa and below; whereas it increases for the ones with 30 MPa and below. However, there are 55 samples with 40 MPa and below compressive strength out of 61 total samples; whereas only 32 of them have 30 MPa and below compressive strength. It implies that, when only the samples with 30 MPa and below compressive strength are considered, almost the half of the specimens are disregarded.

Figure 8(d) represents that when the samples with a compressive strength of 25 MPa and below are considered, the correlation decreases to 77% and there are only 18 samples tested.

Respecting the previously mentioned results, when the correlation and the number of the tested samples are regarded, the correlation between the compressive strength and the P wave velocity for the specimens with a compressive strength of 40 MPa and below is found to be more reliable among the carried regression analyses.

Furthermore, the correlation between the P and S wave velocities is examined. As explained earlier, the S waves require a detailed eye observation on the waveforms. The observation declines that detecting the S wave velocity on a large cubic is easier and more reliable than that on a small one; since the wave path is longer. Therefore, the correlation between P and S waves is examined regarding the results obtained from the large samples. When the P wave velocity is considered, the mean value of the three surface readings is taken and as can be seen in Figure 9(a), it is found to be 86% correlated to the S wave velocity.

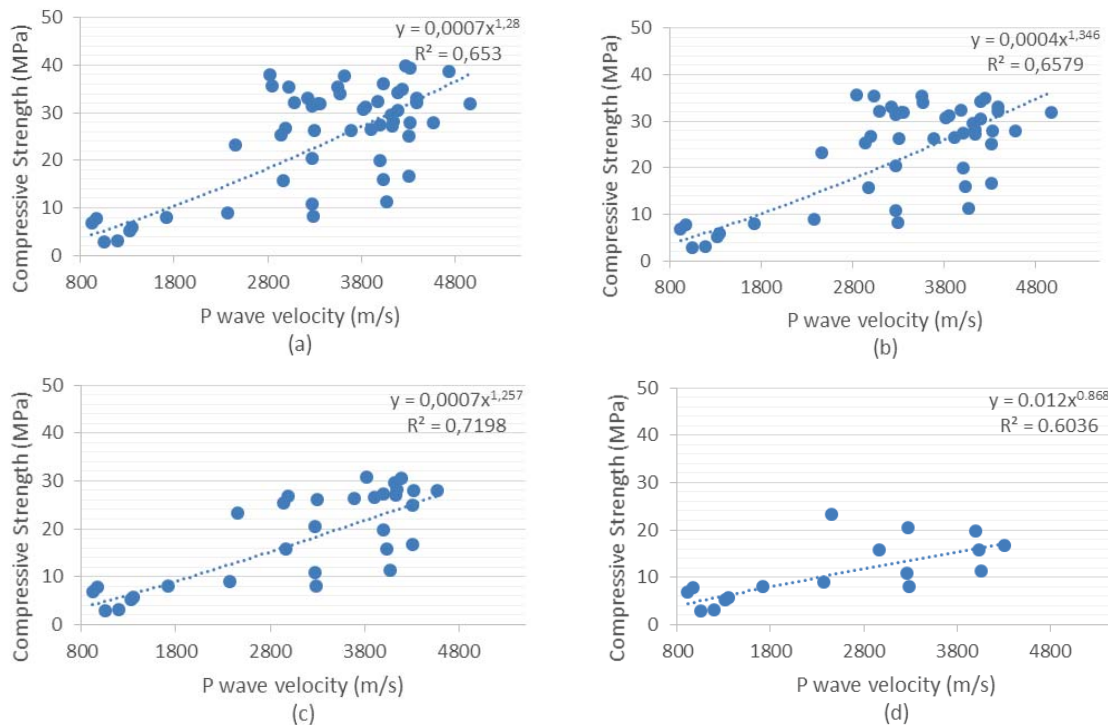

Figure 8. Correlation between the minimum P wave velocity from each surface and the compressive strength for the samples having 40 MPa and below (a), 35 MPa and below (b), 30 MPa and below (c), 25 MPa and below (d)

Figure 9. The correlation between (a) Vs and Vp (b) Density and Vp regarding three surfaces of the samples

Furthermore, the correlation between the density and the P wave velocity is examined. The minimum value of the P wave velocity readings from the three surfaces is regarded. First, the analysis is carried concerning the results taken from the samples with a compressive strength of 40 MPa and below; however it is revealed that the correlation and its equation does not change significantly when all the samples are considered. Therefore, the equation found when all samples are analyzed is respected (Figure 9(b)).

The other five minarets M1, M2, M4, M5, M6 are observed by ultrasound testing equipment on site and the results are assessed regarding the laboratory test results mentioned above. The 54 kHz and 250 kHz probes are used for the site survey. Besides, the circular column at the core of the minarets where the stairs are rising, is measured by direct method using 54 kHz probes.

#### 4 RESULTS

First, the equations obtained from the laboratory tests are applied on the site survey results. The regression equation of the P wave velocity and compression strength correlation is adopted on the P wave velocity reading taken from the minarets on site to reveal the compressive strength of the material. The mean compressive strength values of each stone in a minaret is evaluated as following: 28 MPa for M1, 10 MPa for M2, 31 MPa for M4, 10 MPa for M5, 10 MPa for M6. Besides, the samples tested in the laboratory result in 28 MPa of mean compressive strength. The compressive strength of different parts of each minaret is indicated in Figure 11, by a color scale. The color scale is illustrated in Figure 10.

Figure 10. Color scale

#### 5 DISCUSSIONS

This study offers the first application of compressive strength test on Blue Mosque stones, therefore it provides notable contribution to the literature when the future restoration works are considered. The samples tested in the laboratory result in 28 MPa of a mean compressive strength and the compressive strength of the other five minarets on the site is detected part by part for each one.

It is found to have a correlation of 81% between P wave velocity and the compressive strength of the material. Besides, it is assumed that the nonhomogeneous structure has an effect on the compressive strength of the stones.

Figure 11. The compressive strength of different parts of each minaret shown by a color scale

Moreover, a number of stones with tough inner cores despite of their soft surfaces are blamed for the unreliable Schmitt Hammer test results. Additionally, the Schmitt Hammer test is observed to damage the samples.

The samples tested in the laboratory reveal that the P wave velocity obtained from different directions of the same cubic is significantly variable and the compressive strength result is highly effected by this diversity. The most reasonable outcome is obtained when the correlation between the minimum of the P wave velocity readings taken from 3 different surfaces of the sample and the compressive strength. However, it must be regarded that, the five minarets on site are not appropriate for taking the readings from all directions of the material.

When the P wave velocity that appears on the screen during the reading and the S wave velocity that obtained by an eye observation on the wave form are compared, the former one is found to be more respectable. Therefore, especially for the site surveys, the limitations of reading the S wave velocity should be concerned. This study offers the idea to determine the material property using the P wave velocity, neglecting the S wave velocity.

When the larger samples are considered higher level of correlation is found between the P and S wave velocities and the correlation between the P wave velocity and the density. This relationship may lead to the evaluation of S wave velocity and the density; therefore the shear and the elasticity modulus, employing the measured P wave velocity. This concept is left for a further study.

### Abstract

*This study is part of an experimental program on full-scale strengthened Un-Reinforced Masonry (URM) walls with Textile reinforced mortars (TRM). Four solid brick walls (one control and three strengthened specimens with central opening), were tested under the diagonal tension (shear) test method in order to investigate the effectiveness of the strengthening system on the in-plane behavior of the walls. All the URM panels consist of solid bricks and a high strength binder mortar. Both of them have increased mechanical properties leading to improved shear behavior of the masonry walls. Several parameters pertaining to the in-plane shear behavior of the retrofitted panels were investigated, including shear capacity, failure modes, the number of layers of the external TRM jacket and the existence of the central opening of the wall. The experimental work allowed an evaluation of the shear behavior in the case of the bidirectional textile (TRM) system applied on URM walls. The experimental results of URM and retrofitted walls with different layers are compared with each other. The purpose is to investigate in depth and to draw conclusions about the in-plane shear behavior.*

**Keywords:** TRM, solid brick URM, in-plane performance, seismic strengthening, diagonal compression test, wall's opening.

## 1 INTRODUCTION

The existence of the doors and/or windows openings of the Unreinforced masonry (URM) walls significantly affects the shear behavior of the structure. Hence, there is an urgent need to investigate the influence of the retrofitting technique on URM walls with openings. In the field of rehabilitation and strengthening of the existing masonry buildings, Textile Reinforced Mortar (TRM) has attracted considerable research interest as an alternative to the traditional strengthening methods due to its better compatibility with the URM substrate, fire resistance, excellent mechanical strength and stiffness in the direction of the fibers, while it improves the seismic capacity of URM walls (Thomoglou et al 2020). Nevertheless, there is limited experimental research on full-scale walls.

The existence of openings in masonry walls is often responsible for in-plane collapse mechanism creation, leading to the entire building collapse (Chalioris et al. 2013, Chalioris et al. 2015). Considering this critical parameter, there is a limited experimental study on retrofitting masonry walls with openings. Several works on infill masonry walls with openings were carried out by Kakaletsis and Karayannis (2008), Kakaletsis and Karayannis (2009), Decanini et al. (2014), Mansouri et al. (2014), Sigmund and Penava (2014), Tasnimi and Mohebkah (2011), or without openings by Lee et al. (2010), Rousakis (2017) and Rousakis (2020). From the abovementioned research, it is concluded that openings have a significant effect on the characteristics of masonry infill walls, such as failure mode and lateral strength, and ductility reducing shear strength, stiffness, and energy dissipation capacity.

The work concerns diagonal compression tests on solid brick URM and retrofitted walls with TRM jacket on both sides of the walls. The TRM reinforcement system comprises one, two, or three plies of glass fiber mesh in a cement mortar matrix. This strengthening method has an advantage over other traditional solutions in easy application, excellent adhesion of the mortar to the brick substrate, high tensile strength, and low elasticity increasing compatibility with masonry. The purpose is to investigate and to draw conclusions about the shear behavior of strengthened full-scale brick URM walls with a central opening.

## 2 EXPERIMENTAL PROGRAMM

This experimental study deals with full-scale URM walls comprising solid bricks and a high strength binder mortar (Durostick D-31). The TRM strengthening system consist of one, two or three layers of glass mesh in a cementitious matrix applied to both of the specimen with central opening. The strengthening concept is based on the observation that the strengthening mortar matrix plays a key role to the contribution of the total shear capacity (Thomoglou et al. 2020). All the experiments were conducted at the Laboratory of Reinforced Concrete and Seismic Design of Structures of the Department of Civil Engineering of the Democritus University of Thrace.

## 3 MECHANICAL PROPERTIES OF MATERIALS

### 3.1 Mechanical properties of bricks and mortar and exterior strengthening

The nominal dimensions of the solid bricks were 200 mm (Length) x 100 mm (Width) x 50 mm (Height) (Figure 1a). The compressive behavior of brick units is determined in two load directions: perpendicular and parallel to the bed joints. Six units were tested in total under an axial load after grinding of their loading surfaces according to procedures established in the European standard EN 772-1 (2000). Two displacement transducers (LVDTs) and a laser meter were used to measure the vertical and horizontal deformations,  $\Delta v$  and  $\Delta h$  (Thomoglou et al. 2018). The compressive strength of the bricks equals to 116.17 MPa. A render mortar of

20M class was used to construct all the walls, with a nominal mortar thickness of about 10 mm. The 28-day compressive strength of the Durostick D-31 mortar obtained by testing 40 mm × 40 mm × 160 mm mortar prisms according to EN 1015-11 (1993) with an average value of 38.15 MPa, while the tensile strength is 15.76 MPa (Figure 1b).

Prior to the application of the TRM jacket, the masonry specimen was coated with light-heavy, reinforced cementitious mortar (SikaRep®-200 Multi) in order to smooth the protrusions and to get a flat layer on the external surface. The exterior strengthening system consisted of 1, 2 or 3 plies of glass grid embedded into a cementitious matrix. The glass fibers were arranged along two rectangular directions with axial spacing of 18.1 mm in the longitudinal and 14.2 mm in the lateral direction, respectively, as shown in Figure 1c, while its mass was 360 g/m<sup>2</sup> per unit area. The modulus of elasticity in the longitudinal direction was 80 GPa. Fiber reinforced cementitious mortar with pozzolanic admixtures had a 28-day compressive and flexural strength of 28.85 MPa (based on EN 1015-11) and 6.78 MPa, respectively, while the Modulus of elasticity was 8.03 GPa (according to the manufacturer) (Thomoglou et al. 2019b).

Figure 1 a) Dimensions of solid brick, b) Maturing mortar prisms and test pieces after a three-point bending test, c) Dimensions of fiberglass grid SikaWrap®-350GGrid.

## 4 TEST SET-UP AND LOADING

### 4.1 Main headings

In order to investigate the shear behavior of the strengthened walls under lateral loading, the diagonal compression test, was standardized by ASTM E 519-07 (ASTM 2010) to determine the shear capacity of 1200 mm x 1200 mm masonry panels. The specimens were loaded in compression along one diagonal to cause tension failure, with the specimens splitting apart parallel to the direction of loading. For this study, four specimens were constructed in full scale and the thickness for all panels was 210 mm. All specimens were with central opening (one control and three strengthened walls with 1-ply, 2-ply or, 3-ply glass TRM, respectively). The dimensions of the opening are 450 mm (length) and 300 mm (height) (see Figure 2a). The layers of the glass TRM were applied over each side of the panel.

The in-plane test setup comprises of two steel loading shoes, according to ASTM E519, placed diagonally opposite to the corners of the specimen, while they attached the upper shoe to the MTS servo-hydraulic piston (Figure 2b). Diagonal compression was applied via a 450 kN MTS servo-hydraulic piston. High-performance shrinkage compensated a cementitious,

free-flowing mortar SikaGrout-312 HP which was used to fill the two shoes (capping), maturing for at least 24 hours.

The compressive load applied uniaxially and monotonically to the failure point at a rate of 0.01 mm/s. The diagonal compression test was widely used to broaden the knowledge on masonry subjected to in-plane behavior. Although diagonal compression does not reproduce a field condition behavior of the masonry field, however, it is more conservative because of the limited value of the vertical load and is standardized according to ASTM 2010, (Thomoglou et al. 2019a).

## 5 RESULTS-DISCUSSION

### 5.1 Displacement Force Diagram

The mechanical parameters of the tested specimens are presented in Table 1. The results of the experimental tests on the maximum applied load, the ultimate shear stress, the ultimate displacement, the ultimate shear strain, and the failure mode for each specimen are presented in columns (2)-(6) of Table 1, respectively. The production of the reinforcement is defined as the ratio between the maximum load applied to each strengthened panel to the unreinforced control wall. It can be observed that there is an increase in shear capacity and therefore an improvement in the production of external strengthening amounting to 339%, 470%, and 701% for 1, 2, and 3-ply TRM jacket, respectively, compared to the value of 61.49 kN of the control wall. Besides, the displacement of the retrofitted specimen shows 2.31, 2.71 and 3.04 times the value of 4.19 mm of the control one, for 1, 2, and 3-ply TRM jacket, respectively.

The results from those masonry specimens with a central opening retrofitted with 1 to 3-ply TRM jacket are summarized in the response curves of Figure 3 and compared with each other. In the load-displacement diagram, the strengthened masonry specimen with central opening and 3-ply of fiberglass mesh (SS-O-UMG3), presenting more plastic behavior and

showing the best shear response from all the strengthened walls. An important observation is that as the shear capacity so the ultimate displacement of retrofitted masonry walls increases proportionally to the amount of TRM for 1 and 3 plies.

Figure 3 Experimental set up of solid brick URM wall with central opening.

Specimen Codes	Plies of TRM textiles	Maximum applied failure load $P_u$ (kN)	Ultimate Shear stress $\tau_u$ (Mpa)	Displacement $\delta_u$ (mm)	Ultimate Shear strain $\gamma_u$ (mm/mm)	Failure Mode
(1)	(2)	(3)	(4)	(5)	(6)	(7)
SS-O-UM1	Control	61.49	0.17	4.19	0.0028	SF
SS-O-UMG1	1 ply	208.19	0.59	9.67	0.0051	TRM failure-DT
SS-O-UMG2	2 plies	289.23	0.82	11.35	0.0068	TRM failure-DT
SS-O-UMG3	3 plies	431.20	1.22	12.72	0.0091	TRM failure-DT

DT: Diagonal Tension, SF: Shear Friction

Table 1: Experimental results.

## 5.2 URM Failure Modes

The typical crack patterns of the four masonry walls after shear failure are illustrated in Figure 4. The control wall with central opening showed a brittle failure caused by the loss of the bond between the mortar and the bricks, as well as a diagonal tensile stress with a simultaneous fracture of the mortar and bricks, which caused a stair-step cracking and shear friction (Thomoglou et al. 2019a). Hence, the failure mode of the control wall with central opening (SS-O-UM1) is a shear friction. The failure mode of the strengthened wall with 1-ply (SS-O-

UMG1) is diagonal tension, which appears with a thorough crack along the entire length of the diagonal parallel to the direction of the load and across the width of the panel. The evolution of the diagonal crack started from the point where the maximum concentrated tensile stresses appear. This point is the two opposite corners of the hole in the vertical direction, while at the two opposite corners of the other direction maximum compressive stresses develop. Also, two cracks are developed from the external side of the panel and end at the two opposite corners of the opening, which are located almost perpendicular to the load direction (Figure 4a)-b).

Figure 4 Failure mode of a) control brick URM wall (SS-O-UM1), b), c), d) strengthened wall with 1-ply (SS-O-UMG1), 2-ply (SS-O-UMG2) and 3-ply (SS-O-UMG3) glass textile, respectively.

The failure mode of the retrofitted solid brick URM (SS-O-UMG3) with 3 plies of glass textile and a central opening is similar to the specimens with 1 and 2 plies of TRM jacket (see Table 1 and Figure 4 b)-d)). Nevertheless, a wider vertical crack is observed and parts of the strengthening mortar of the TRM jacket are effectively detached. The glass textile failure is observed here as well as in the case with 1 and 2 plies (SS-O-UMG2, SS-O-UMG3), respectively (Figure 4b)-d)). Finally, the effectiveness of this significant strengthening technical is highlighted, if we include the fact of preventing the final collapse of the masonry, which is very important for the safety of human and material resources.

## 6 ACKNOWLEDGMENTS

We acknowledge KEVE. SA for the supply of Orthoblock K300 bricks and building masonry specimens, as well as Sika Hellas SA for providing all masonry strengthened materials and for our excellent cooperation.

## 7 CONCLUSIONS

A full-scale experimental investigation was aimed to assess the effectiveness of the TRM external jacket in order to improve the in-plane behavior of the four solid brick specimens with a central opening. The masonry panels were retrofitted using three different configurations (with 1, 2, 3 plies of a both-sided TRM application) and were tested under monotonic diagonal tension (shear) test. From the aforementioned results, the following concluding observations arise:

- The TRM jacket has improved the shear capacity and deformation capacity, which caused the failure of the strengthened walls in a more plastic way.
- There is an increase in shear capacity and therefore an improvement in the production of external strengthening amounting to 339%, 470%, and 701% for 1, 2, and 3-ply TRM jacket, respectively, compared to the value of 61.49 kN of the control wall.
- The displacement of the retrofitted specimens shows 2.31, 2.71 and 3.04 times for 1, 2, and 3-ply TRM jacket, respectively, compared to the value of 4.19 mm of the control wall.
- The best shear behavior was demonstrated by the masonry specimen with 3-ply of TRM and a central opening of solid bricks compared to all masonry walls.
- The failure mode of the control wall with central opening is shear friction, while the strengthened masonry specimens exhibited TRM failure and diagonal tension.
- The tests results demonstrated that the glass TRM jacket plays an important role in retaining and protecting the solid brick masonry wall. The strengthening system prevents the abrupt reduction of the resistance and significantly reduces the brittle behavior, avoiding an explosive collapse.

### Abstract

*Metamaterials for seismic protection are engineered to filter the low frequency component of seismic waves. In this study, we investigate the performance of a metastructure focusing on the improvement that the concept design of metamaterials can bring in the field of seismic isolation. The metastructure is realized as composite foundation built as a stack of concrete plates having internal resonant elements. The feasibility of the composite foundation is investigated by performing simulations in which at the base of each column of the building a composite metastructure replaces elastomeric isolator. Dynamic linear analyses are set for concrete multi-story frame buildings by using spectrum-compatible accelerograms for the horizontal components of the ground motion. The main result is the achievement of a reduction in the total displacement of the upper structure with respect a classical base isolation system. This work is a step forward in the understanding of the properties and performance of composite foundations as innovative base isolation system.*

**Keywords:** Metamaterials, Seismic isolation.

---

## 1 INTRODUCTION

Research and applications in earthquake engineering are focused on seismic protection methodologies for infrastructures and buildings since a lot of decades. Despite the great developments in geophysics seismic monitoring, the incoming earthquake is a dreadful natural event with a significant impact on the structures and people. The reduction of the buildings seismic vulnerability is an important research field in which two main approaches merge; from one side the design capacity strategies based on exploitation of the ductility resources of the building by preserving global safety condition are widely applied in common design activity; from the other side, seismic protection techniques are explored and improved in order to get the best safety condition for the structures when earthquakes occur. Nowadays, seismic protection system is often designed by combining more than one technology, such as elastomeric and damper elements. Within this context, concepts for seismic protection, related to metamaterials, are introduced by researchers as innovative approaches useful at developing technologies for seismic protection.

## 2 SEISMIC METAMATERIAL

Metamaterials attracted interest from the field of physics, where structures that shown negative refraction and permittivity were realized. From the end of the last century research on metamaterials in optical and electromagnetic field exploded [1]. They can be defined as artificial structures with periodic architecture, not available in nature, designed to produce an optimized response to specific excitation. The most interesting property for the development of seismic metamaterials is the chance to exploit the frequency bandgap in which propagation of seismic wave is attenuated [2]. From this starting point a lot of searches in earthquake engineering started and proposed new approach in seismic protection: seismic cloaks and metabarriers as large-scale protection system of large built areas (and ground volume) and metafoundations, as improvement of seismic protection for the single building by including metamaterial design in the foundation structure [3-9]. The main evidence in all the applications is the low frequency working range (0.1-20 Hz), because both earthquakes frequency content and natural frequencies of most of the building in civil engineering are low. For this reason, seismic metamaterials involve large mass and size.

## 3 STANDARD BASE ISOLATION SYSTEM

Base isolation systems are widely used for seismic protection of concrete multi-story frame buildings. The most popular devices are the elastomeric isolators in which layers of rubber and vulcanized reinforcement steel plates are alternated. Rubber compound guarantees high damping action or other elements with high damping capacity increase this property: the first are called High Damper Rubber Bearings (HDRB), the second Lead Rubber Bearings (LRB). The main features of elastomeric devices are the horizontal low stiffness and vertical load capacity need to transfer the entire dead and live load to the foundation. When this devices are installed at the base of the building, mechanical decoupling between superstructure and ground is achieved and, the vibration period of the structure shifts to higher period and the total acceleration of structural mass is reduced. Their effectiveness is tested by massive experimental tests and, by now, thousands of isolated buildings with this system demonstrate good performance when seismic event occurs.

#### 4 METASTRUCTURE

From analytical point of view, the study of seismic metamaterials is mainly based on the theory of phononic crystals and periodic chains of mass-in-mass system. The bandgap computed with the dispersion relation defines the attenuation regions of metamaterial in the space frequency-wavenumber [10]. Metastructure is proposed in this work, to replace elastomeric devices in standard base isolation system. In this study metamaterial is characterized by external element with inclusions therefore simplified lumped model is a bi-atomic chain or mass-in-mass chain. The parameters of the model are: mass of external element ( $m_1$ ), mass of internal element ( $m_2$ ), stiffness connection between consecutive external elements ( $k_1$ ) and stiffness connection between internal and external elements ( $k_2$ ). The dispersion relation of the periodic chain of the mass-in-mass system is given by:

$$m_1 m_2 \omega^4 - (k_2(m_1 + m_2) + 2m_2 k_1(1 - \cos(kL)))\omega^2 + 2k_2 k_1(1 - \cos(kL)) = 0 \quad (1)$$

Starting point of this study are the results obtained by experimental tests on a demonstrator built of four stacked concrete square plate in each of which five cylindric steel resonators are allocated [11]. Connections was realized by rubber elements excited in tension-compression regime. The demonstrator was tested under dynamic loading with sinusoidal input, from 1 to 8 Hz, applied at the bottom plate. Measurements of displacements confirm a bandgap near 5 Hz. From the bottom to the top, input signal is trapped, and the top plate does not move. Demonstrator was designed with external mass ( $m_1$ ) equal to 317 kg, total internal mass ( $m_2$ ) equal to 245 kg, external stiffness connection ( $k_1$ ) equal to 155e3 N/m and internal stiffness ( $k_2$ ) connection equal to 1080e3 N/m. These values are used in the following, as reference in design of metastructure simulated in this work.

Figure 1: (a) geometry of one plate of the metastructure designed in this work with values shown in Tab 1. (b) details about rubber connection between resonators and concrete plate.

#### 5 NUMERICAL INVESTIGATION

In this part, seismic performance of a square plan concrete four-story frame building is studied. An artificial seismic signal is applied and the results between the performance of the proposed metafoundation and the standard base isolation are compared. The building has a symmetrical geometry, with side equal to 6 m, height of each story equal to 3.5 m, section column of 0.5x0.5m, section beam of 0.4x0.6 m. Concrete floors have thickness equal to 0.2

m and base floor, that ensure rigid motion of the isolated structure, 0.35 m. The dead load is estimated at 7 kN/mq while live load is set at 2 kN/mq.

The design of metastructure is performed in order to define the lower branch of the bandgap by keeping appropriate horizontal stiffness and by limiting structural mass. Reference design is the experimental device [11] whose plate can be used as modular element and in this work by considering six plate in 2x3 array. Fig.1 shows sketch of one plate of the metastructure while Tab. 1 collects geometrical and mechanical data:  $m_1$  is the concrete plate mass,  $m_2$  is the total mass of resonators,  $k_2$  is the liner compression/traction stiffness of rubber elements that connect resonators with concrete plate, while  $k_1$  is the horizontal stiffness between overlapped plates that is realized by appropriate connection elements. Theoretical expected dispersion relation obtained by using this design is shown in Fig.2.

$m_1$	$k_1$	$m_2$	$k_2$
1902 kg	0.31e6 kN/mm	1470 kg	1.08e6 kN/mm

Table 1: Mechanical lumped parameters of metastructure.

Figure 3: Dispersion curves of mass-in-mass chain with lumped parameters equal to data in Table 1. Theoretical expected bandgap starting at 2.70 Hz.

In order to compare the behavior of metastructure and standard base isolation with elastic devices (named BI in the following for brevity), equivalent linear stiffness for BI is assumed equal to  $k_2$ .

### 5.1 Artificial seismic input

Dynamic loading applied at the building is a set of artificial ground acceleration time-history computed through the software SIMKE\_GR (SIMulation of earthQuaKE ground motions) [12]. Indeed, in compliance with construction standards in design of structures for earthquake resistance (European codes and Italian national codes), seismic analyses can be performed by using a set of spectrum-compatible artificial accelerograms at elastic response spectra with a viscous damping equal to 5%. The source data of artificial earthquakes generation are collected in Table 2 and one of the accelerograms is shown in Figure 3. Accelerograms concern horizontal component of the ground motion while vertical one is neglected.

site	design life	ground type	ag/g	viscous damping

## 5.2 Dynamic analysis: model

The building is modeled by using the structural software SAP2000 [13]. A diaphragm constraint is applied at each story to model high stiffness of the concrete floor. Metastructure is modeled by using a simplified configuration of points (one for each plate) connected by mechanical link with linear force-displacement law. Damping in metastructure is neglected in order to observe mechanical response associated with the design configuration of mass and stiffness. Linear dynamic analysis is performed by using direct integration method on Eq. 2 that represents the linear system of equations of motion of the building and metastructure (coupled) in which  $M$  is the stiffness matrix,  $C$  the viscous damping matrix,  $K$  the stiffness matrix,  $\ddot{u}$ ,  $\dot{u}$  and  $u$  are acceleration, velocity and displacement fields and  $\ddot{u}_g$  is the ground acceleration. Vertical motion is neglected in metastructure. Viscous proportional damping is set equal to 5% at 1 and 10 Hz.

$$M (\ddot{u} + \ddot{u}_g) + C \dot{u} + Ku = 0 \quad (2)$$

In addition to artificial earthquake, a sweep signal, modulated between 0.1 and 10 Hz, is applied at the base of the structure to check working frequency range of metastructure and frequency response function is evaluated as ratio between power spectral density of displacement field of the check point and that of input as shown in Eq.3.

$$FRF = 20 \cdot \log_{10} \frac{PSD(u_T)}{PSD(u_g)} \quad (3)$$

Results show comparison between response of structure with fix base, standard elastomeric devices and metastructures.

### 5.3 Results

The total displacement at the top of the building is shown in Fig. 4. Total displacement for isolated structures is almost entirely a rigid motion of the whole structure respect to the plane of the isolation system because bending modes are attenuated. Reduction of displacement when metastructure is set (red line) can be observed in the most time of structural response, in some points is closed at 50% compared to the BI case. This result improves performance in seismic protection because amplitude and number of oscillations of the superstructure is reduced. Fig. 5 shows the frequency response function of metastructures and highlights reduction at lower frequency compared to BI while peaks between 1 and 3 Hz concern local modes of the metastructure (motion in-phase and out-phase between plate and resonators).

Figure 4: Time-history total displacement at the top of the building ( $u_T$ ) with fix base (black line), BI (blue line), metastructure (red line) by applying artificial earthquake ( $u_g$ ) .

Figure 5: Frequency Response Function evaluated as ratio between power spectral density of total displacement at the top of the building ( $u_T$ ), with fix base (black line), BI (blue line), metastructure (red line), and ground motion ( $u_g$ ) set as modulated sweep signal.

## 6 CONCLUSIONS

- One metastructure characterized by four overlapped plates with inside resonators is proposed as innovative system of base isolation, by starting from good results in experimental investigation;
- The goal of metastructures would be the total isolation of the structure during earthquake but tuning bandgap at very low frequencies is very hard because requires lower stiffness and higher masses;
- By setting appropriate configuration of metastructure bandgap closed to 2 Hz is obtained and filter effect is enforced compared to standard BI system;
- Good reduction in oscillations and amplitude total displacements of four-story frame building under seismic dynamic loading is provided. This can have important benefits for the occupant because perception of earthquake is reduced.

### Abstract

*In this study the effect of ground motion characteristics on the response of an isolated base using double friction pendulum bearings (DFPBs) is presented. Planar nonlinear time history analyses are performed considering one horizontal and the corresponding vertical component of natural ground motion records. Both far-fault and near-fault ground motion records are considered. In order to focus on the effect of the ground motion intensity measures on the DFPBs response, without taking into account the effect of any other structural characteristics, an analysis model comprised of two DFPBs coupled with a rigid beam is assumed. For this reason, a finite element modeling that can capture the kinematic behavior of the isolation bearing parts is adopted. In order to investigate the effect of the vertical seismic component on the response of the isolated base results in terms of peak developed displacements are presented. Moreover, the performance of ground motion intensity measures for use in probabilistic seismic demand models for isolated base under horizontal and vertical seismic component is assessed.*

**Keywords:** Seismic Isolation, Double Friction Pendulum Bearings, Vertical Ground Motion, Optimal Intensity Measures.

---

## 1 INTRODUCTION

Base isolation consist a seismic protection technique which may applied in both new and existing structures [1]. Two main categories of base isolation devices are in use, the rubber bearings and the friction pendulum ones. The single friction pendulum (SFP) bearings have been studied since 1990 [2-4]. Subsequently, bearings composed by multiple concave spherical surfaces, such as double friction pendulums (DFPs), have been also examined [5].

Isolation devices are principally described by low lateral stiffness. Due to this fact, the superstructure is decoupled from the ground by implementing isolators at a certain level. Thus, the seismic demands of the superstructure are significantly reduced, while large displacements are introduced at the isolators [1]. However, under near-fault ground motions, which are characterized by large amplitude, low frequency, and pulse type of excitation, the performance of the base isolation tends to be reduced [6].

Another feature of near-fault ground motions is the intense vertical component [7, 8]. The detrimental effect of the strong vertical excitation is examined in reinforced concrete buildings, bridges and isolated structures [9-16]. The performance of friction pendulum bearings is strongly affected by the axial load variation during the sliding phase [17, 18]. As such, the effect of vertical ground motions on the response of seismically isolated structures should be studied using more sophisticated models. Given that, in order to assess the seismic response under a probabilistic framework, and set the probabilistic seismic demand model (PSDM), the uncertainties introduced by the ground motions should be examined [19-21]. By this, the efficiency of several intensity measures (IMs) in predicting the seismic response of base isolated structures, under horizontal and vertical ground motions, is investigated.

In the present study the effect of seismic excitation characteristics on the response of an isolated base, formed using DFP bearings, is assessed. Specifically, 21 IMs are examined in order to conclude to the most optimal one upon which the PSDM should be conditioned. Near-fault, as well as far-fault natural ground motion records are considered. Moreover, both horizontal and vertical seismic excitation are assumed, in order to highlight the contribution of the vertical component on the seismic response, examining also the variation of the performance of the IMs in estimating the response of the isolated base.

## 2 OPTIMAL INTENSITY MEASURES

In recent years, probabilistic analysis has become widely used for structural engineering purposes and PSDMs have been developed aiming to predict the response of a structure under earthquakes of certain intensities. The most common tool for this assessment is to develop fragility curves of structures. Specifically, fragility expresses the probability ( $P$ ) that the capacity ( $C$ ) of a specifically measured engineering demand parameter (EDP) of a structure will exceed a certain level of demand ( $D$ ), for a specific ground motion IM, as defined by the following equation [22]:

$$P(D > C | IM) = \Phi \left( \frac{\ln(S_d / S_c)}{\sqrt{\beta_{D|IM}^2}} \right) \quad (1)$$

where  $\Phi$  is the standard normal cumulative distribution function,  $S_c$  is the median value of the capacity which is estimated through the adopted limit states and  $\beta_{D|IM}$  is the dispersion or logarithmic standard deviation for the demand conditioned the IM.

The median seismic demand  $S_d$  is related to an examined IM with the following expression:

$$S_d = a(IM)^b \quad (2)$$

where  $a$  and  $b$  are the linear regression coefficients for the logarithmic expression of the assumed scale law.

The linear regression analysis is performed between the engineering demand parameter calculated via the time history analyses and the corresponding IM values. The dispersion of the median demand is reported by the logarithmic standard deviation of the linear regression analysis (Eq. (3)). This parameter constitutes the demand uncertainty introduced in the probabilistic model.

$$\beta_{D|IM} \cong \sqrt{\frac{\sum (\ln(d_i) - \ln(a(IM)^b))^2}{N - 2}} \quad (3)$$

where  $N$  is the total number of the data.

The appropriate selection of an IM plays an important role in the accuracy of a probabilistic seismic demand analysis (PSDA) for structures. As such, the choice must be made based on criteria, presented in the literature, which help to distinguish the accuracy of the seismic assessment. An optimal IM is defined by primary factors such as efficiency, practicality, proficiency and sufficiency [22-25].

Efficient IMs are the ones that eliminate the dispersion of the results about the median, which means a decrease in the uncertainties introduced to the PSDM, resulting in superior fragility curves during the vulnerability assessment. A distinguished IM according to its efficiency is represented by a lower logarithmic standard deviation  $\beta_{D|IM}$  (Eq. (3)). Moreover, the coefficient of determination of the linear regression analysis ( $R^2$ ) could represent a parameter that denotes the performance of an IM regarding its appropriateness in predicting the structural damage [26]. Practicality refers to whether or not there is any direct correlation between an IM and the demand placed on the structure and is measured by the regression parameter  $b$  in the PSDM. Proficiency is a composite measure that assesses the effect of both efficiency and practicality as follows [25]:

$$\zeta = \frac{\beta_{D|IM}}{b} \quad (4)$$

### 3 EXAMINED GROUND MOTION RECORDS AND IMS

In order to examine the effect of the ground motion characteristics on the response of the isolated base a cloud analysis is performed using the natural ground motions proposed by FEMA P695 [27] are considered. The specific data set is comprised of both far-field and near-field ground motion records. The whole set consists 50 pairs of ground motions. However, due to the fact that vertical excitations records are not provided for 4 seismic events (i.e. RSN725, RSN496, RSN723, RSN1048), 46 pairs of ground motions are used. From those, 21 pairs are far-field records, while 25 are near-fault ones.

In order to designate the earthquake intensity measures (IMs) that affect the seismic response, a large number of seismic parameters is considered in the present study. Specifically, 20 IMs, of the horizontal seismic excitation, are taken into account which can be classified into amplitude, energy, spectral, and frequency parameters [28]. Amplitude parameters include peak ground acceleration (PGA), peak ground velocity (PGV), and peak ground displacement (PGD). The root mean square of acceleration ( $A_{RMS}$ ), of velocity ( $V_{RMS}$ ), and of displacement ( $D_{RMS}$ ), the characteristic intensity [29] ( $I_C$ ), the Arias intensity [30] ( $I_A$ ), the cumulative absolute velocity (CAV), the specific energy density (SED), the strong motion duration [31] ( $t_D$ ), the index proposed by Fajfar-Vidic-Fischinger [32] ( $I_{FVF}$ ) and the characteristic length scale [33, 34] ( $L_m$ ), fall into the class of energy ground motion parameters. Re-

garding the spectrum intensity measures, the acceleration spectrum intensity [35] (ASI), the velocity spectrum intensity [35] (VSI), the Housner spectral intensity [36] ( $SI_H$ ), and the spectral acceleration ( $Sa(T_i)$ ) that correspond to the fundamental vibration period of the superstructure ( $T_i$ ) are considered. The mean period [37] ( $T_m$ ), the ratio PGV/PGA, and the period ( $T_{pred}$ ) corresponding to the peak acceleration of the elastic response spectrum are assumed as frequency parameters.

#### 4 EXAMINED MODEL

Scope of this study is to examine the effect of the ground motion IMs on the response of a seismic isolated base using DFPBs, under horizontal and vertical excitation. As such, the DFPBs are simulated with a full three dimensional continuum modelling using the finite elements method. The analytical presentation of the adopted modelling approach, as well as its validation has been presented by Kavvadias et al. [38]. The detailed model of the bearing's geometry allows a complete description of its kinematic behavior, accounting the restoring forces, the variation of axial forces among the contact surfaces as a consequence of vertical acceleration or overturning moments, and uplift [39]. In order not to count the effect of any structural feature on the dynamic response, a simplified analysis model is examined. The analysis model consists of two identical isolation bearings connected with a rigid and massless beam. The gravity loads  $W$  are considered at the top of the isolators, while the ground motion excitation is applied at the base in terms of seismic acceleration. The schematic of the model, as well as the DFPB properties are presented in Figure 1.

Figure 1: Schematic of the examined numerical model.

#### 5 RESULTS

Planar nonlinear time history analyses are performed using each horizontal component individually. Additionally, in order to examine the effect of the vertical ground motion, time history analyses are conducted assuming also the vertical excitation along with each horizontal one. The data are classified also according to the seismic record type to far-fault and near-fault. In order to evaluate the seismic response of the isolated structural system, the maximum bearing displacement (MBD) is considered as EDP.

In Figure 2 two representative force-displacements loops of the DFPBs are presented. It is obvious that vertical excitation causes an intense variation of the shear forces which can be justified by the variation of the axial forces due to the vertical acceleration. However, in both loops can be observed that the maximum developed displacements do not present a noticeable variation.

Figure 2: Force-Displacement hysteretic loops of the DFPBs.

In Figure 3 the MBDs for each analysis type is presented. Figure 3(a) depicted the results under far-field seismic records, while in Figure 3(b) the results under the near-fault records are illustrated. It can be observed that the maximum seismic demands are higher under near-fault records. However, regardless the ground motion record type, the maximum response seems not to be affected by the vertical excitation, as the maximum displacements considering only the horizontal component ( $MBD^H$ ) are fairly equal to the displacements assuming also the vertical component of the ground motion ( $MBD^{H+V}$ ). Although the detailed FEA modelling of the DFPBs, the effect of the vertical ground motion component on the MBD is negligible.

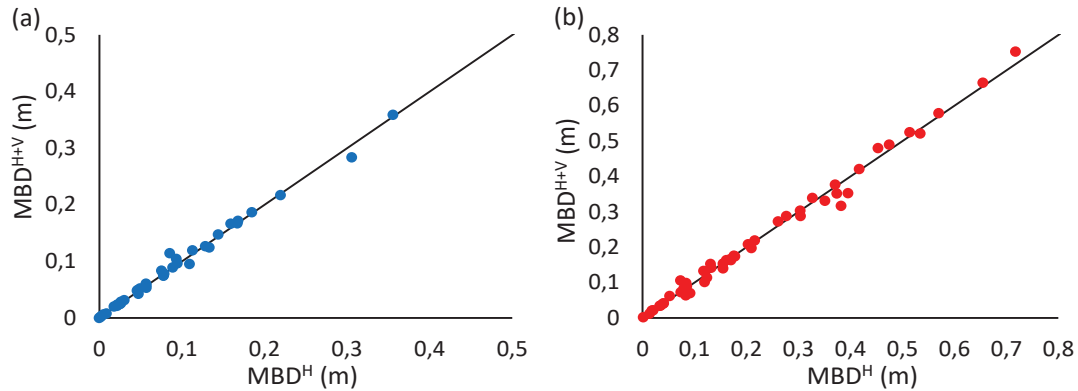

Figure 3: Comparison of the MBDs considering horizontal and horizontal along with vertical seismic excitation under (a) far-fault and (b) near-fault ground motion records.

As indicated above, the identification of an optimal IM in estimating the seismic demands, is based on criteria such as efficiency, practicality and proficiency. In Figure 4 the values of the coefficient of determination ( $R^2$ ), the standard deviation ( $\beta_{D|IM}$ ), the slope of the linear regression ( $b$ ) and the proficiency value ( $\zeta$ ) are presented. The IMs criteria values are presented comparatively regarding the ground motion record type and the consideration of the vertical ground motion on the analysis.

It is obvious that the presence of the vertical component do not affect the performance of the horizontal seismic excitation IMs. Therefore, there is no need to examine the effect of the characteristics of the vertical acceleration signal on the seismic demands, as it should be negligible.

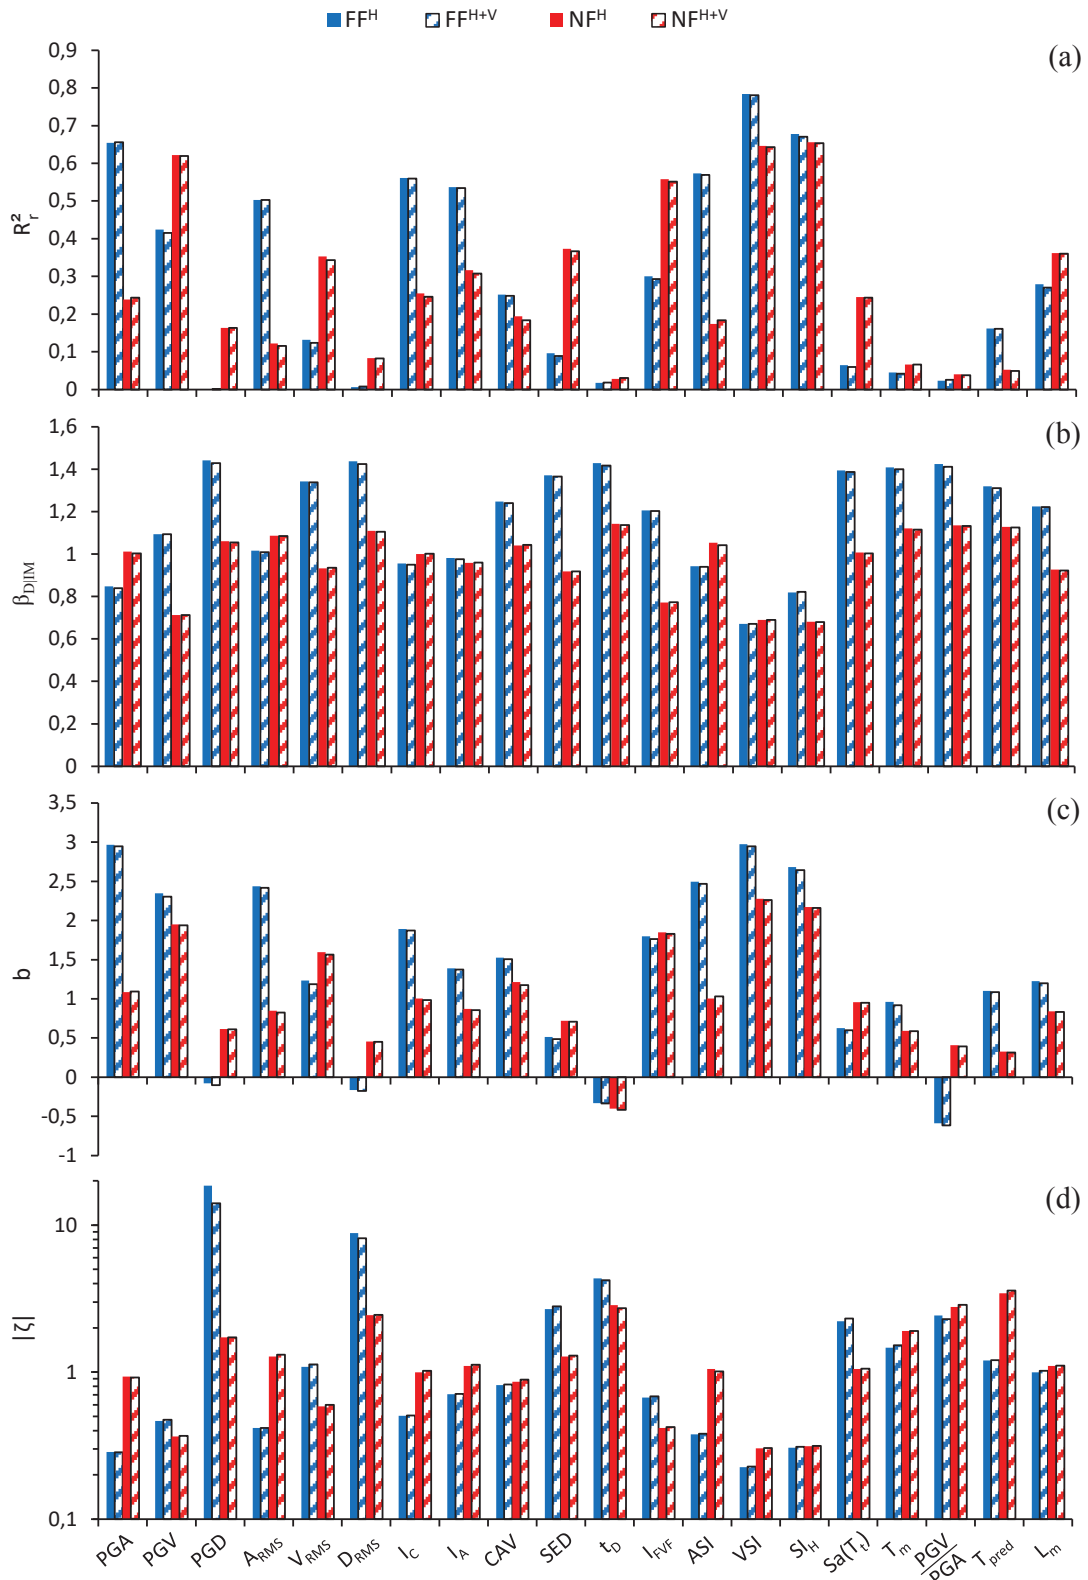

Figure 4: Values of (a) coefficient of determination  $R_r^2$ , (b) standard deviation  $\beta_{D|IM}$ , (c) slope of the linear regression  $b$  and (d) proficiency value  $\zeta$ .

In general the most optimal IMs are the parameters VSI and SI<sub>H</sub>. These two velocity based spectral parameters present at the same time the higher values of  $R_r^2$  and  $b$ , and the lower values of  $\beta_{D|IM}$  and  $\zeta$ . As such these parameters rank as the most optimal ones regardless the as-

assessment criteria. The performance level of the two aforementioned most optimal IMs are almost identical regardless the ground motion record type. Under far-fault excitations, acceleration based parameters such as PGA and ASI demonstrate high enough performance in predicting the seismic response with low uncertainties. Moreover, they present high level of practicality. That can be justified due to the fact that the acceleration level defines the initiation of sliding, given that a vast majority of the far-fault ground motions barely initiates the isolator's sliding. On the other hand, under near-fault excitations these parameters present poor performance. Furthermore, velocity based parameters such as PGV and  $I_{FVF}$  performs quite well in case of near-fault records. Finally, ground motion parameters such as PGD,  $\tau_D$  and frequency based ones are found to be the less optimal IMs to generate PSDMs for seismic isolated structures.

## 6 CONCLUSIONS

In the present study the effect of the ground motion intensity measures on the seismic response of a base isolated with double friction pendulum bearings is investigated. Moreover, the effect of the vertical ground motions is examined. Thus a finite element analysis modeling is adopted that can capture in high accuracy the kinematic response of the bearings. The main concluding remarks can be summarized as follows:

1. Vertical ground motion component may affect the shear forces of the bearings due to the variation of the axial forces, however does not significantly affect the developed maximum displacements.
2. Near-fault seismic records result to higher seismic demands.
3. The characteristics of the vertical excitations does not affect, in a systematic way, the developed maximum displacements of the isolation bearing. Therefore, the performance of the horizontal seismic component IMs presents identical performance regardless the consideration of the vertical seismic component.
4. The velocity spectrum intensity (VSI) and the Housner's spectral intensity ( $SI_H$ ) are identified as the most optimal IMs for use in probabilistic seismic demand models for the examined structural system under both far-fault and near-fault ground motion records.
5. Under far-fault records, peak ground acceleration (PGA) and acceleration spectrum intensity (ASI) follows, while under near-fault records peak ground velocity (PGV) and the intensity proposed by Fajfar-Vidic-Fischinger ( $I_{FVF}$ ) present also a high performance.

**Keywords:** Steel Structures, Adjustable Pallet Racks, Seismic Standards, Eurocode

**Abstract.** *The importance of the logistics sector has increased even more in the last year, due to the Pandemic event which lead to an increasing of the online purchases. Goods and products are generally located in steel frames known as steel racks or simply racks. Consequently also the safe design of these structures, i.e. preserve their fully functionality and avoid their collapse, is becoming of paramount importance, especially when they are located in strong and moderate seismic zones. Despite pallet rack provisions for seismic loads have been significantly improved in the recent years, only two classic ways to enhance the seismic performance are considered: rack netting and structural strengthening. Both of these suggested solutions are not fully effective to preserve the integrity of the stored products that, when subjected to strong accelerations, can topple and fall down. The only reliable and effective systems seem to be the introduction of seismic devices, such as base-isolation and energy dissipation systems. Since no indications about these techniques are reported in the standards, many researches worldwide are trying to fill this gap. Unfortunately, up to now, just theoretical studies and very limited applications are available in literature. In the present paper a short overview on the base isolation systems available on the market for different steel storage rack typologies is presented highlighting main advantages and defects of each solution.*

## 1 SEISMIC FEATURES OF PALLET RACKING SYSTEMS

Storage racking systems are engineered structures which are designed to withstand high loads during their life. In many countries all over the world, performance requirements and compliant criteria are established either by law or by technical recommendations, which often regard seismic actions as well. Typical rack frames (Figure 1) are made by open cold-formed thin-walled steel members, which lead to significant and non-negligible torsional effects. In fact, designers must be able to account for the calculation of *bimoment distribution* along the members and the associated tangential and normal warping stress during the design of rack frames [1]. In addition, these members are often prone to local and/or distortional buckling phenomena, which largely precede the attainment of the yielding capacity. These profiles do not guarantee the exploitation of the plastic capacities of the cross sections [2]. For this reason, designers cannot rely on the capacity design principles [3] enforced by the mainstream codes worldwide [4, 5]. For the plastic design of such structures, it is important to rely exclusively on the post-yielding capacity of connections. The cyclic response of standard beam-to-column rack joints is remarked by a strong pinched behaviour. The typical relationship between the bending moment and the relative upright-beam rotation shows a considerable loss of stiffness after the first cycle [6, 7, 8]. Also the connections between uprights and building slab are characterised by a very limited degree of flexural stiffness and bending resistance. In most of the cases, when the cross-aisle direction is considered, the seismic action can pose a risk for the overturning, which becomes the most dangerous limit state. Nevertheless, as happened for the beam-to-column connections, the nonlinear cyclic behaviour can provide a non-negligible ductility to the structure. The main peculiarity of these structures is the quite limited self-weight, which is generally not greater than 5% of the payload. This characteristic brings to periods of vibration which are greatly dependent on the considered level of occupancy, affecting hence either the seismic effects and the structural responses. The design is governed by different load conditions: i) the fully loaded rack (100% occupancy); ii) only the top storage level fully occupied and iii) occupancy levels from 50% to 70% of the total load. These conditions are prescribed in both the static (EN15512:2021 [9]) and the seismic (EN16681 [10]) design codes.

For seismic design purposes, racks are often broken down into two planar lateral resisting sub-systems, which can be used to assess the overall performance of the structure. The down-aisle structural scheme can be studied as a moment-resisting frames; they are made up of uprights (vertical elements) that are connected to pallet-beams (horizontal elements) by means of special beam-end connectors. A great body of research focused on studying its performance by exploiting the analogues techniques used for standard buildings [12]. Down-aisle frames have fundamental periods usually longer than 2.00 seconds (see, [11]), which entails a higher demand in terms of displacement.

The cross-aisle structural scheme is often truss-like and tends to have fewer internal degrees of freedom, thus making fragile collapse modes most likely. Hence, as also shown by many works [13, 14, 15]. Hence, its lateral resistance is promoted by the flexural behaviour of the base-plate connections and the stiffness of the braces. Nevertheless, this scheme gives to the upright frames a high degree of stiffness, which may cause excessive accelerations at decks level. This last circumstance sets the stage for the sliding of pallets on the supporting beams, which can lead to shedding of goods, endangering the health of workers/customers or damage some structural parts and thus likely triggering cascading effects. In the cross-aisle direction, the fundamental period is generally short, comprised between 0.5s and 1.0s [16, 17], placing the structure in the most energetic part of the commonly defined design spectra.

Figure 1: Typical steel storage pallet rack and its main components [11]

Despite the great efforts made to develop more safe and update standards [10], there are issues which still remain not solved. In particular, during a seismic events pallets can overturn and impact against the steel structural skeleton frame causing the well-known *domino effects*, i.e. the progressive collapse of the entire structural system, as showed in 2. An adequate isolation system could be useful to prevent also this phenomena.

Figure 2: Collapse of a warehouse after an earthquake in Italy [18]

## 2 SEISMIC ISOLATION AND ENERGY DISSIPATION DEVICES

Nowadays, a large variety of devices and techniques are available for seismic isolation of structures, often increasing in its use in highly exposed seismic areas [19], where seismic design of structures can be challenging when post-earthquake functionality is considered [20]. Base isolation systems (BIS) are known to be the most cost-effective and efficient devices for earthquake mitigation [21]. In general, BIS introduces a layer between structures and foundations (or bases) consisting of suitable devices with low lateral stiffness, which almost completely retain the previous vertical stiffness. The main effect of inserting the isolation system is a major shift in the fundamental vibration period of the structure that can be selected to be quite distinct from the energy contents of most predicted seismic events.

Similar benefits are demonstrated when the BIS technique is applied to racking systems. The research proposed by [22, 23] shows that if a warehouse is treated as a standard building, several advantages can be obtained when the seismic performance is evaluated. In particular, the proposed solution concerned the application of elastomeric seismic isolators at the base of the huge warehouse, under the concrete slab, as can be done in traditional buildings. Authors demonstrated a non-negligible benefits especially in terms of reduction of relative displacements and torsional effects. However, despite this approach is promising, it is not always applicable, and its convenience may stuck to only one structural direction due to a quite remarkable difference in periods. For this reason some pieces of research focused on proposing purposely developed hardware to be used for rack systems.

### 2.1 Seismic isolators for cross-aisle direction

#### 2.1.1 Pellegrino® isolation system

The trademark Pellegrino® identifies a system that provides seismic isolation along the cross-aisle direction alone to pallet type steel storage racks, by incorporating high damped elastomeric bearings and friction plates (Figure 3). Filiatrault et al. (2008) [24] presents a summary of the experimental results of isolated pallet racking tests performed on the triaxial shake table at the University of Buffalo (USA). The proposed Pellegrino® isolation system works in the cross-aisle direction and can cut down the amount of energy that is transmitted to the superstructure, thus reducing the likelihood of content spillage. Figure 3 shows a detailed view of the system, which consists of a *U-shape* plate (*Horizontal Support*), inserted inside a steel box (*Box Fabrication*) which is welded on the base plate (*Base Plate*). For the sake of brevity more details are not reported here. The base plate must be anchored to a rigid slab by means of anchor bolts. The results obtained from full-scale experimental tests [24] showed: i) the system reduce greatly the top accelerations in the cross-aisle direction but it has also some beneficial effects in reducing the accelerations in the down-aisle direction. The efficiency of the base isolation system in reducing the cross- and down-aisle accelerations increases with the weight of the merchandise. This beneficial effect is directly related to the changing in the fundamental period of vibration which increase in both directions with respect to the natural period of the racks with fixed bases; ii) damage on the uprights and merchandised overturning, which characterised the fixed base tests, have never observed in the base isolated cases; iv) the system brings to a great reduction of the interstorey drifts.

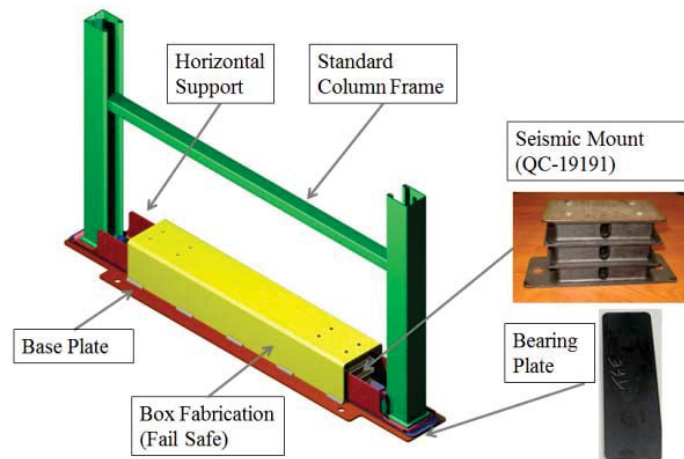

Figure 3: device installed under a single-entry pallet rack, render of Pellegrino® system (font <https://www.ridgurak.com/>)

### 2.1.2 IsolGOODS® isolation system

FIP MEC has developed a quite novel device (Figure 4) that is an unidirectional seismic isolation device that provides seismic isolation to the rack in the cross-aisle direction only. This solution is effective because the fundamental period of racks in the cross-aisle direction is usually short, and thus the isolation system can provide a greater shift in period while keeping a small footprint. This allows to use the pallet slots at ground level, as in a conventional pallet rack, while part of said pallet slots is lost when using multi-directional isolators. Additionally, the system is able to prevent the up-lift of the rack, that could happen in particular load cases under high seismicity actions, in particular in single-entry pallet racks. IsolGOODS® is classified as a pendulum isolator or Curved Surface Slider (CSS), as defined in [25], with a single surface of sliding. Low-lateral flexibility is guaranteed by a low-friction material, and FIP MEC uses a particular material for this device, i.e. FIP friction material (FFM), which ensures very high load-bearing capacity and wear resistance [26]. The performance of the IsolGOODS® device has been assessed by means of shake table test performed at the FIP Laboratory Tests (Italy). A one-bay four-storey pallet rack was equipped with the presented isolation system and its dynamic behaviour was studied under a set of ground motions, as discussed in Tagliaferro et al. (2021) [17].

Figure 4: device installed under a single-entry pallet rack: render view of IsolGOODS® solutions [11]

Together with the two presented solutions, other special devices have been developed by dif-

ferent company during the last years for storage racks, like the LOKI system one (<http://www.lokibase.com>, accessed 2021). However, up to now, there are no scientific results published on international journals for this or other systems.

## 2.2 Energy dissipation

For the points introduced in the previous section, the common procedures enforced by many codes for the seismic design of structures associate a certain structure ductility to a certain degree of energy dissipation. The most common approach foresees the use of a factor used to scale down the seismic demand, by inherently assuming that part of the energy that an earthquake can possibly transmit to a structure is partially dissipated/avoided. In general, a dissipative structure can be designed by either locating ductile zones or adding extra devices to perform that duty. The latter represents the approach that should be followed for inherently fragile structures.

### 2.2.1 Uplifting and sliding friction base-plates

The considered device was proposed as a friction-based devices and can provide energy-dissipation by means of wide and stable loops, with a negligible hardening phenomenon and experiencing no damage. For seismic resistant structures, purposely designed devices are commonly embedded into braces [27], beam-to-column joints, and into column-base joints [28], whereas it is always important to guarantee an even distribution of inter-storey drifts to exploit the displacement-dependent energy dissipation of these devices [29]. A novel dissipation joint was studied by Tang et al. (2017) [30] for adjustable pallet racking systems. It was developed for low and medium-rise racks, and the method consists of inserting a steel sliding friction base-plate connected to all the uprights (Figure 5(a)). The device, presented for the first time in Clifton (2005) [31] (Figure 5(d)), can dissipate energy thanks to a friction-based mechanism rather than forming yielding zones at the base connections. On top of this, this device promotes a rocking behaviour, so that, when the device is activated, the structure benefits from a further shift in period.

## 2.3 Seismic performance of Grana cheese steel racks

As it is well-known, Grana is a type of Italian cheese proposed in the form of large wheels. Generally Parmigiano cheese is stored in structures made by composed steel tubular columns (two tubes of  $50 \times 50$  mm with thickness of 3 or 4 mm and a global height from 7 to 9 m) having 1.5 m of span (Figure 6). Along the cross-aisle direction, each bay is connected by means of wooden panels, on which the cheese wheels rely, and via a continuous tubular steel on the top. Global length can vary from 18 to 40 m. When the steel rack is connected to the concrete wall (case S2 of Figure 6), it is simply supported on the floor, i.e. no anchors are present. On the other hand, when it is anchored to the floor, it is not connected to counter walls (case S1 of 6). Bracings are always present only in the down-aisle direction. A great number of these structures have been designed more than 20 years ago, considering only vertical forces (with no seismic actions) and, therefore, they are generally in an unsafe condition. For this reason, earthquakes occurred in May 2012 in Emilia Romagna (Italy) caused causes severe damages to grana warehouses, that progressively collapsed causing a domino effect leading to the loss/depreciation of several thousands of tons of grana cheese.

After this catastrophic event more attention has been paid to the seismic behaviour of these structures. Franco et al. [32] proposed a complete study on the dynamic behaviour of these racks, focusing the attention on the seismic improvement techniques. A solution proposed

Figure 5: (a) Test setup of the fully loaded frame [30]; sketches of the three connections compared: (b) rigid base-plate, (c) yielding base-plate and (d) friction base-plate

by the Authors is to use a passive-control system: viscous dampers are directly connect to the surrounding concrete structures (see, S3 of Figure 6). The time-history analyses of the proposed configurations have shown that the use of dampers presents noteworthy advantages for all cases in which the constraint degree of the racks is augmented and, consequently, their stiffness is increased. The advantages are in terms of stress reduction in the rack elements, and of reaction forces transmitted to the surrounding support structures.

Figure 6: Three structural configurations that can be considered to simulate the *scalere* in the cross-aisle direction (after Franco et al [32]).

Furthermore, as discussed in [33], some producers, instead of performing specific seismic study on their warehouse, decided to renew completely the steel structures by changing com-

pletely the structural system. The brand new structures that store Grana cheese consist of cold-formed columns; the components of the bracing system are made using structural bolts, instead of welding. Boxed composite columns (different from producer to producer) are realised by coupling two open cold-formed mono-symmetric channels or sigma members. Along the columns height (in general about 7-9 m), horizontal L-profiles (angles) are connected, vertically spaced at about 330 mm and protrude beyond the central column as cantilever beams supporting the wooden boards (with 30 mm thickness), on which cheese wheels are directly located. In the longitudinal (down-aisle) direction, the geometry of the oldest and new type cheese rack is the same, differing only for the structural components and for the connection system between columns. This new frames are never connected to the surrounding concrete structure and in seismic areas, rely completely on the hysteric behaviour of the base-plate.

### 3 FINAL REMARKS

The deep understanding of the seismic performance of steel structures used to store good and products, known as steel storage pallet racks, is becoming of a paramount importance. In the specific standards only the classic techniques to improve structural behaviour of racks in seismic zones are provided, with no indications about the seismic isolation or energy dissipation devices. If overturning of stored goods is of concern, there are only two ways reported for the improvement of the safety of racks in seismic zones: rack netting and structural strengthening. The rack netting is a steel netting installed on all sides of the rack, covering the bay openings from top to bottom. It can be noted that if netting is installed, it then needs to be removed and reinstalled every time a storage slot is accessed. As regards the latter provision, it can be noted that it allows the structure to meet the code requirements, but increases the stiffness of the structure at the same time, adding rigidity and introducing higher accelerations throughout the system. The two approaches can be used together, but neither rack netting nor structural strengthening protect the rack and prevent adequately the product shedding.

The product shedding prevention must be always considered in the design process, being the total cost of stored goods generally much higher than the cost of the structural components. Seismic isolation seems to be a very useful and effective solution, and a number of investigations are nowadays in progress in many parts of the world. The paper has shortly discussed the main characteristics of several devices applied to different typologies of steel storage racks, by reporting studies taken from the available literature. The two innovative systems called RIGID-U-RAK system (Pellegrino®) and FIP MEC System (IsolGOODS®) are reported showing main characteristic and advantages of each solution. The results show that the application of a seismic isolation system can reduce accelerations on both cross- and down-aisle directions, and avoid the overturning of the stored goods and damage on the uprights. Finally, the use of dissipative devices is discussed. It can be an effective and low-cost solution as demonstrated by Tang et al. (2017) and Franco et al. (2015). Devices of such kinds can provide rack structures with more resilience, for the design and retrofit of structures, as it is shown in the collected research.

### 4 ACKNOWLEDGEMENTS

The second author's Ph.D. scholarship is granted by the Italian Ministry for Education, University and Research (MIUR) as part of the program "Dottorati Innovativi a caratterizzazione industriale", ID DOT 1328490-3, funded by the European Union (Structural Funding ERDF-ESF for "Research and Innovation" 2014-2020). The authors are grateful for the support.

### Abstract

*This paper presents the research on recycled rubber material design, made from vehicle tires, to be used as a matrix of low-cost seismic isolators' prototypes for risk mitigation in South America buildings. Four mixes were contrasting to determine the influence of the particle size distribution on the recycled rubber characteristics, three of them with different size particle composition and the last one with a non-control distribution. Mechanical properties such as density, hardness, and tensile stress, were studied, and stereoscopic images were taken. In the controlled size distribution case, the experimental results showed an improvement in the packing capacity of the particles with a better consolidation of the material under the same processing conditions as a consequence. Regarding the tension stress, the controlled mixes achieved a maximum strength higher than the non-controlled mix (up to 70%), and their spectroscopy images show consolidated materials without voids or pores. All the samples presented a similar hardness with values higher than the natural rubber one (60). Therefore, the development of recycled rubber material with a control size distribution allowed to improve the material behavior without changes in the manufactured process.*

**Keywords:** Seismic Isolation, Low-Cost Seismic Isolators, Recycled Rubber, Particle Size Distribution.

---

## 1 INTRODUCTION

Seismic isolators are proposed as technologies for the mitigation of seismic risk to be applied in various structures and are currently accepted by several countries [1]. Current efforts are mainly directed towards reducing manufacturing costs and reducing the weight of devices, exploring variations in the matrix material [2], [3], and the reinforcement material [4]–[6]. Studies focused on the matrix of the devices offer interesting environmental benefits when using recycled rubber for their manufacture. The consolidation of the material from recycled rubber can be with additives such as binders or without using them [7].

The recycled rubber as a raw material of the seismic isolators has been studied by several authors [8 – 12] to gain insight into the possible parameters and their influence on the material performance and presented the viability to use it for commercial production [11]. These studies employed a manufactured molding process to consolidate the material, with additives [12] or without it [8-11]. They also studied the influence of the manufactured process parameter such as molding time and pressure time.

The tensile strength increases with higher pressure and more extensive molding time, which means the cohesion between particles improves to obtain density with values higher than 1.18 g/cm<sup>3</sup>, as shown at the diagram at figure 1 [8]. A relation between the size distribution on the particle rubber and the behavior of the final material was proved.

Higher results in tension were obtained for tertiary distributions with 25% of medium particles and 25% of large particles, in contrast to the distribution composed for 100% of fine material that presented comparable tension values but 62% of maximum elongation [9, 10]. The designed material from the studies mentioned previously were used to produce commercial devices such as anti-vibration tiles and tiles [11].

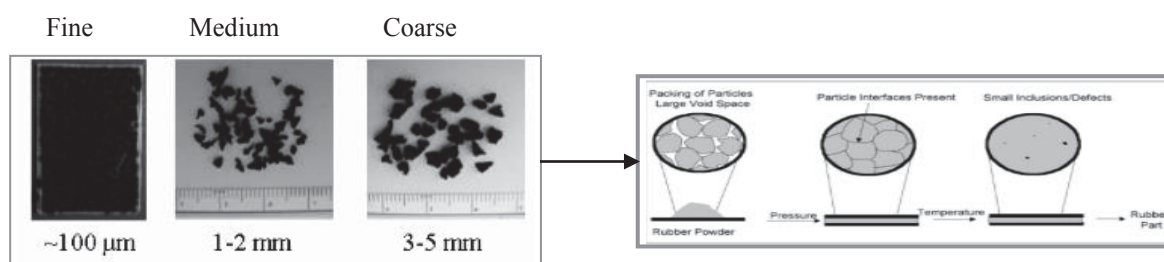

Figure 1: Work diagram of Guglielmotti [8].

According to the studies previously mentioned, the results obtained evidenced the influence of the particle distribution on the material properties for the same processing conditions. The current study proposes the design of a recycled rubber matrix by evaluating different particle size distributions to improve the performance of the recycled rubber material.

## 2 EXPERIMENTAL PROCEDURE

The samples were made with rubber particles recycled from tire used coming from the productive process of a Colombian Company (Occidental de cauchos). This company is dedicated to recycling and reusing tires used to produce simple components, like car mats and others. To obtain the particles of rubber, the tires were classified, separated, adequate, shredder, sieved, and packed; the process uses particles with a primary diameter higher than 2.00mm, which correspond to the material retention of 10 mesh sieves [13]. To consolidate the matrix, the particles were agglomerated with a polyurethane binder manufactured by molding compression.

The design of the rubber matrix was made to obtain insight into the effect of the size distribution in the performance of the rubber matrix, an additional separation after the recycle tyre process mentioned in the raw material section was made with mesh sieves. Table 1 shows the classification of the rubber particles used to design the rubber material.

Size (mesh sieve)	Diameter (mm)	Classification
5-200	0.074-0.297	Fine
10-30	0.595-2.00	Medium
10	>2.00	Coarse

Table 1: Particles classification.

Three size particle distributions were designed using the particle classification presented in Table 1. The denomination letter and composition in weight percentage of each mixer is show at the Table 2. These mixes were evaluated in contrast with a non-control distribution (NC) obtained from the separation process that the company currently uses at their productive process, using sizes of particles of 2.00 mm and less.

Mix	Fine (%)	Medium (%)	Coarse (%)
A	50	25	25
B	50	50	0
C	75	25	0

Table 2: Mixer composition.

The characterization techniques were tensile strength (ASTM D412-06, ASTM D3039), and hardness (ASTM D2240-05) [14]. Due to the dependence of the compression time by the sample size, each test requires different amounts of time to be manufactured. Table 3 shows compression times and molding temperature.

Test	Shear	Tensile	Hardness
Compression time (min)	15, 20	3, 5, 7	10
Compression temperature (°C)	140	140	140

Table 3: Fabrication process of sample rubber matrix.

To evaluate the matrix's conformability regardless of its compatibility and presences of porous, stereoscopic images were taken with a Stereoscopic Stereo Discovery V8 of Carl Zeiss with an AxioCam ERc5s camera in the facilities of the Pontificia Javeriana University.

### 3 RESULTS AND ANALYSIS

#### 3.1 Tensile test

The samples are denominated by letter and compression time, the first one was indicated at Table 2, and the last one was indicated at Table 3. For example, the A3 denomination is for mix A compressed for 3 minutes. Figure 2 shows the experimental results of the tensile test for each Mix and compression time. Results include the samples of non-control distribution made at this study and the results obtained in other studies [15].

Figure 2: Experimental results for tensile test.

The tension test provides information about the adhesion between the rubber particles; therefore, the material's behavior will depend on its consolidation. Figure 2 shows a proportional relationship between maximum stress and deformation, where the highest values of maximum stress correspond to the largest deformations. The dispersion founded in the results may be due to purely procedural conditions, such as the heat transfer that produced a loss of mold temperature.

In general, all the proposed mixtures (A, B, and C) reached values greater than 6 MPa with deformations greater than 100%. It was found that mixture A showed the highest value of maximum tensile stress, with 6.53 MPa for 109.7 % deformation, with differences of 7.2% and 2.8% compared to the maximum values of maximum stress of mixtures B and C, respectively. The synergy between particle sizes led to improved packing capacity in the material, increasing the contact surface area between them, and the density obtained from these samples was 0.94 g/cm<sup>3</sup>.

### 3.2 Hardness

The hardness samples were denominated similar to the tensile test. The three mixes are indicated by the letter (A, B, C), and the number 1 and 3 indicated 10 and 15 minutes of compression, respectively. Figure 3 shows the results of hardness for the different mixtures.

Figure 3: Shore A hardness of the samples.

Hardness is a surface property; it provides an idea of the surface resistance of the samples and the state of consolidation in this area. The hardness results show that mixture C presented the best performance for the shortest molding time evaluated, with 71.67 for 10 minutes, in contrast to 70 and 67.7 for the same molding time of mixtures B and A, respectively.

Similarly, the recycled rubber agglomerate material with the composition of the mixture C presented the highest hardness values, with 73.3 shore A for 15 minutes of molding time. In general, there is an increase in hardness with increasing molding time, although the values are very close to each other. These results are higher than those obtained from materials made from natural rubber, for which 50 Shore A is reported [16], but it is an acceptable difference for use in seismic isolators.

### 3.3 Stereoscopic Images

The stereoscopic images were used to evaluate the sample's failure zone to define the material behavior in the test. Figure 4 shows the 3 mixes (A, B y C) and the non-controlled sizes distribution sample. Each mix exhibits their own and particular surface provided by the compactibility due to different particle sizes where the fine particles fill the voids between the coarser particles.

Figure 4: Stereoscopic images of failure zone of the samples.

As shown in figure 4, the material failure occurred in the interface between the rubber particles and through some rubber granules, preserving the integrity of the adhesive and rubber adhesive interfaces. The tensile test proves the relation between compactability and material behavior. The adhesion between rubber particles grows as the compactability increases, producing higher tensile strength and percentage strain due to the bigger superficial area. The hardness does not exhibit a relation with the particle's sizes distribution. That fact could be related to the superficially feature of the property, which shows the adhesion between particle in a superficial way but does not reflect the property across the material.

#### 4 CONCLUSIONS

From the results obtained in this study, it can be concluded that the design of the matrix material made from recycled rubber particles, having the granulometric distribution as a control parameter, allows obtaining materials with good mechanical performance. This happens when 50% of its composition are fine grains, and the remaining percentage is distributed evenly between coarse and medium particles, producing synergy of sizes that increases the compaction capacity.

The stereoscopic images show the effects of different particle size distributions designed to provide synergy between sizes to increase the effective superficial area. These changes in the arrangement of the rubber particles produce a variety of mechanical behavior, affecting properties like tensile strength, as was shown in the experimental results of the present study.

The hardness results for the different mixtures (A, B, and C) presented very similar values, with a small increase with increasing molding time for each mixture. On the other hand, it was found that an improved behavior of the material fabricated with the particle size distribution, where Mix A presented an increase of 71.8% of maximum stress in tension for similar values of deformation concerning the results obtained with granulated rubber matrices without control over the distribution of particle sizes.

### Abstract

*Ports play a crucial role in the world economy, as they represent critical nodes in regional and national transportation networks. They are usually located in areas prone to geohazards, such as earthquakes and soil liquefaction. Although warehouses constitute a port system's key components, the published literature in the evaluation of their seismic vulnerability considering the effect of soil liquefaction and soil-structure interaction (SSI) is generally inadequate. To bridge this gap, this study's objective is to implement a numerical investigation of the influence of both liquefaction and SSI on the seismic vulnerability of typical port steel light-frame warehouses. The following numerical modelling approaches are applied: i) a 2D fixed-base structure subjected to outcrop bedrock seismic motion neglecting SSI and liquefaction; ii) ) a 2D flexible-base model, considering both SSI and liquefaction; iii) a 3D fixed-base model which is subjected to outcrop bedrock seismic motion and thus neglecting both SSI and liquefaction; iv) a 3D fixed-base model subjected to a free-field motion that considers liquefaction. We conduct nonlinear incremental dynamic analysis for the above numerical approaches to derive seismic fragility and vulnerability curves considering (or not) SSI and/or liquefaction. The earthquake demand is determined based on the selection of actual earthquake records covering a wide range of seismic input motions in terms of amplitude, frequency content, and significant duration. The comparative results show the considerable role of liquefaction and SSI in altering the seismic fragility and port warehouses' vulnerability.*

**Keywords:** Fragility, SSI, liquefaction, steel light-frame warehouse, numerical modelling.

---

## 1 INTRODUCTION

Ports represent critical nodes in regional and national transportation networks, having an important impact on the world economy. Thus, resilience and continuous operation of port structures are interrelated with international, national, and regional growth and development. However, ports are usually located in areas prone to geohazards, such as earthquakes and soil liquefaction. Although warehouses, which are large space steel light-frame buildings (with or without masonry infills), constitute key components of a port system, the published literature in the evaluation of their induced physical damages due to the effect of ground shaking and soil liquefaction is generally inadequate. Also, soil-structure interaction (SSI) may play a significant role in the seismic performance of port structures, modifying their dynamic characteristics, as well as the seismic response at the foundation level. According to PIANC [1], most damage to coastal structures is the result of SSI; thus, design and analysis procedures should include both geotechnical conditions and structural conditions of coastal structures.

Usually, the seismic response of buildings is estimated assuming fixed-base conditions, which is reasonable solely for structures on stiff or rock-type soils. Nevertheless, the seismic response of a structure on soft soil may considerably differ compared to the fixed-base assumption [2]. In general, nonlinear soil behaviour and SSI effects on structures, either beneficial or detrimental, are well-studied [3-5]. Geometrical and material nonlinearities in the soil-foundation-structure system may detrimentally affect the dynamic behaviour of the structure, with respect to the soil characteristics and the intensity of the ground motion [6]. The problem is expected to be even more complicated when soil liquefaction phenomena are present.

Although some progress has already been made on the influence of ground shaking and soil liquefaction on the structural response and vulnerability of steel frame buildings [7-9], studies coupling both phenomena are limited. To estimate the seismic response of buildings, also considering liquefaction, more sophisticated methods can be used [10-11]. Within an effective stress site response concept, a "fully coupled approach" can be adopted that uses a plasticity-based constitutive model to predict both the pore pressure and the stress-strain response of the soil [12]. For estimating seismic performance and damages, the "coupled approach" has already been used for bridge systems [13-15], quay walls [16-17] and other simplified soil-structure systems [18-19]. However, its application to steel frame buildings on soils considering both liquefaction and SSI effects so as to estimate their physical seismic damages, needs further investigation.

To bridge this gap, we implement a numerical investigation of the influence of both SSI and liquefaction on the seismic vulnerability of typical port steel light-frame warehouses. The numerical modelling approaches used for the investigation are a 2D fixed-base structure neglecting SSI and liquefaction, a 2D flexible-base model considering both SSI and liquefaction, a 3D fixed-base model neglecting both SSI and liquefaction as well as a 3D fixed-base model subjected to a free-field motion that considers liquefaction. We conduct nonlinear incremental dynamic analysis for the above numerical approaches to derive seismic fragility and vulnerability curves considering (or not) SSI and/or liquefaction. Comparative results are presented showing the significant role of liquefaction and SSI in altering the seismic fragility and vulnerability of port warehouses.

## 2 CONCEPTUAL MODELLING APPROACHES

We developed four modelling approaches to produce fragility curves considering (or not) SSI and soil liquefaction:

- i. a 2D fixed-base structure subjected to outcrop bedrock seismic motion neglecting SSI and soil liquefaction;

- ii. a 2D flexible-base model, considering both SSI and soil liquefaction. SSI is modelled by applying the direct approach. The soil and the structure are analysed as a single system, while liquefaction is considered by employing a fully coupled (u-P) formulation. Such a formulation is capable of simulating permanent shear-strain accumulation in clean medium-dense cohesionless soils during liquefaction and appropriate constitutive model for the examined soil profiles;
- iii. a 3D fixed-base model which is subjected to outcrop bedrock seismic motion and thus neglecting both SSI and liquefaction and
- iv. a 3D fixed-base model subjected to a free-field motion that considers liquefaction. This two-step uncoupled approach considers the liquefaction effects on the free-field response using the above described u-P formulation and appropriate constitutive model for the examined soil profiles. The free-field response is then applied to the fixed-base structure neglecting, thus, the SSI effects.

### 3 NUMERICAL MODELLING

#### 3.1 Selection of the structural building typology and soil profiles

We study a typical steel light-frame warehouse, representative of Thessaloniki port critical buildings. Figure 1 and Figure 2 illustrate a representative cross-section and the floor plan respectively of the typical warehouse, as provided by Thessaloniki Port authorities and reproduced by the authors. The main characteristics of the building are set equal to total mass  $m=5.1\text{tn}$ , fundamental period  $T_0=0.30\text{s}$ , and yield strength  $f_{ym}=235.0\text{ MPa}$ . Regarding the soil, we consider three representative soil profiles of the port area of Thessaloniki (Greece), simplified with respect to their total depth, denoted as SP1, SP2, and SP3 (Figure 3), based on the available geotechnical information of the port area and the available SPT and laboratory data [20-21]. The fundamental periods  $T_0$  of the three soil profiles are equal to 0.88 s, 0.73 s, and 0.64 s, respectively. Figure 3 presents for all three soil profiles the variation of the shear wave velocities  $V_S$  with depth together with a general geotechnical characterization according to the USCS soil classification scheme. The liquefaction potential of the subsoil layers of the selected soil profiles was quantitatively evaluated following the Eurocode 8 guidelines (EC8)- Part 5 (CEN 2004). For SP1, potentially liquefiable soil formations are found at depths  $z=-9\div-11\text{m}$ ,  $z=-14\div-20\text{m}$ , and  $z=-26.5\div-36\text{m}$ , for SP2 at depths  $z=-3\div-14\text{m}$ , while for SP3 at depths  $z=-4\div-20\text{m}$ , which are basically silty/clayey sands and non-plastic silts with low values of NSPT. Thus, knowing that the liquefaction susceptibility in the port area is rather high, these soil profiles refer to ground type S according to the EC8 soil classification scheme [22].

Figure 1: Cross-section of the typical warehouse.

Figure 2: Plan view of the typical warehouse.

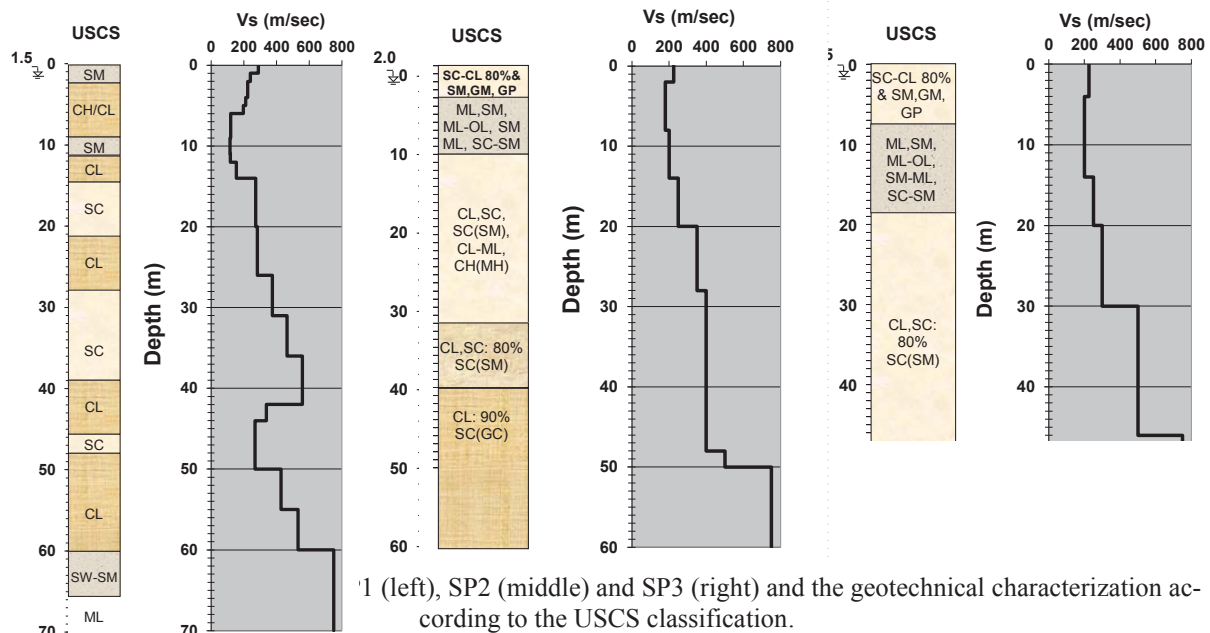

Figure 3: (left), SP2 (middle) and SP3 (right) and the geotechnical characterization according to the USCS classification.

### 3.2 Structural modelling

In the former two conceptual modelling approaches (i.e., i. and ii.), two-dimensional (2D) numerical simulation of the reference building, as shown in Figure 4 left, is conducted using the open-source computational platform OpenSees [23]. Inelastic force-based formulations are implemented for the 2D, three-degree of freedom nonlinear beam-column frame elements modelling, while the roof (trusses) of the building is modelled using "truss" elements (with two degrees of freedom). The uniaxial "Steel01" material is used to construct a uniaxial bilinear steel material object with kinematic hardening. The main parameters required, i.e., the yield strength ( $F_y$ ), the initial elastic tangent ( $E_0$ ), and the strain-hardening ratio ( $b$ ), which is the ratio between post-yield tangent and initial elastic tangent, are taken equal to  $F_y = 235.0$  MPa,  $E_0 = 2.1 \cdot 10^5$  MPa and  $b=0.01$ , respectively. The nonlinear beam-column frame elements are subjected to both axial compression and bending, considering five Gauss-Lobatto [24] integration points along each member's length. The applied formulations allow both geometric

nonlinearities (P-delta and large displacements/rotation effects) and material inelasticity to be captured. Distributed material inelasticity along the element is applied based on the fibre approach to represent the cross-sectional behaviour [25]. Each fibre is associated with a uniaxial stress-strain relationship; the sectional stress-strain state of the beam-column elements is obtained through the integration of the nonlinear uniaxial stress-strain response of the individual fibres in which the section is subdivided. The truss elements are subjected only to axial compression. As they are constructed with a uniaxial material object, they consider strain-rate effects. The masses are applied as distributed along columns and beams (by assigning the specific weight of steel material) plus concentrated vertical loads on joints due to the existence of trusses in the normal direction.

In the latter two conceptual modelling approaches (i.e., iii. and iv.), three-dimensional (3D) numerical simulation of the reference building, as shown in Figure 4 right, is conducted using the SAP2000 finite element program [26]. For all sections, the S235 built-in steel material with isotropic symmetry type is used with the yield stress defined equal to 235 MPa and the maximum tensile stress equal to 360 MPa. A parametric stress-strain curve is utilized to capture the nonlinear behaviour of the steel material comprising an initial linear region, a plastic plateau, a strain hardening region, and finally, a necking region leading to rupture. The main parameters required to construct the backbone stress-strain curve, i.e. the strain at yielding, the strain at the onset of strain hardening, the strain at maximum stress and the strain at rupture, are taken equal to 0.011 for yielding, 0.02 (end of the plateau), 0.14 and 0.20, respectively. The kinematic hardening model is also considered, which is based upon kinematic hardening behaviour that is commonly observed in metals. This model dissipated a significant amount of energy and is appropriate for ductile materials. Under the rules of kinematic hardening, plastic deformation in one direction "pulls" the curve for the other direction along with it. Matching pairs of points are linked. Upon unloading and reverse loading, the curve follows a path made of segments parallel to and of the same length as the previously loaded segments and their opposite-direction counterparts until it re-joins the backbone curve when loading in the opposite direction. We use the fibre approach to represent the cross-sectional behaviour of the beams and columns, while the built-in steel frame sections are utilized to model trusses and braces sections. To consider nonlinear element behaviour, SAP2000 offers various hinges, such as uncoupled moment (M2 or M3), axial force (P), or hinges with axial force and moment interaction. Herein, we consider nonlinear behaviour for beams and columns elements using fibre hinges P-M2-M3, where the hinge force-deformation relationship is input manually, determined from the cross-section fibre model, while for trusses and braces elements, concentrated plastic hinges calculated according to FEMA are used. Once hinges are assigned, material nonlinearity may then characterize the inelastic response of frame elements. For columns and beams, in that way, each point represents a tributary area, having its unique stress-strain law. The axial stresses are integrated over the section to estimate the values of P, M2, M3. Fibre hinges are adapted more effectively to reality, even though they demand a lot of computational workloads. When it comes to strength loss, this is orientated by stress-strain law. In a cross-section, all fibres do not fail at the same time, and, thus, the overall hinges lose their capacity at a steady pace. For trusses and braces, axial hinge type is used. Generally, these sections are not stressed by bending or shear force but only from axial compression load. In addition, the plasticity is distributed at the edges of each element. The hinges behave according to elastoplastic perfectly plastic law, with maximum stress defined by yield point stress. Strength loss is considered to be extrapolated, since sudden loss is often unrealistic and may cause difficulties to analysis, leading to time consuming.

Figure 4: 2D (left) and 3D (right) numerical model of the warehouse.

### 3.3 Soil modelling

Each soil profile comprises several layers of cohesive and cohesionless soil material. The groundwater table is located at a depth of 1.5m, 2.0m and 1.5m for the soil profiles SP1, SP2, and SP3, respectively (Figure 3). Saturated unit weights are used for the soil below this level and effective stress analysis is conducted using nine-node quadrilateral elements with both displacement and pore pressure degrees of freedom. Such elements are able to simulate fluid-solid coupling during the earthquake excitation, based on Biot's theory of porous medium [27]. To account for the finite rigidity of the underlying bedrock, a Lysmer-Kuhlemeyer [28] dashpot is incorporated at the base of the soil profile using a bedrock shear wave velocity of 627.0m/s, 750.0m/s and 750.0m/s for the soil profiles SP1, SP2 and SP3, respectively and a mass density of 2.2Mg/m<sup>3</sup>. The Lysmer-Kuhlemeyer dashpot is assigned based on the viscous uniaxial material model and the 'zeroLength' element formulation at the same location, to connect the two previously defined dashpot nodes. This material model requires a dashpot coefficient that is defined according to Joyner and Chen [29] as the product of the mass density and the shear wave velocity of the underlying bedrock also including the base area of the soil profile. To model the underlying elastic half-space necessitates that the nodes at the base of the soil model are free to displace in the horizontal direction, are all given the same horizontal displacements and finally are fixed against vertical translation only. Mass and stiffness proportional Rayleigh damping is assigned to account for energy dissipation during seismic loading with a damping ratio equal to 2.0%. Periodic boundary conditions are used to ensure that free-field conditions exist at the horizontal boundaries of the model. The displacement degrees of freedom for the nodes on either side of the soil model are tied together, imposing the same translational displacements in x and z directions, and rotation about the y-axis. Each soil profile is excited at the base by a horizontal force time history proportional to the known velocity of the ground motion [29]. Due to the consideration of an elastic half-space it was possible to directly apply the outcropping rock motion at the base of the soil model [30].

We employ a fully coupled (u-P) formulation, capable of simulating permanent shear-strain accumulation in clean medium-dense cohesionless soils during liquefaction and dilation due to increased cyclic shear stiffness and strength. The soil constitutive behaviour is based on the framework of multi-surface plasticity [31], with modifications by Yang [32]. The hardening law, the yield surface and the flow rule constitute the major components of the plasticity model. During the application of the gravity load, at first the material behaviour is linear elastic, while in the second part of the gravity analysis the constitutive behaviour of the soil elements is changed to elastoplastic. In the subsequent dynamic loading phase, the stress-strain response is elastic-plastic. To generate soil hysteretic response under cyclic loading, we adopt a purely deviatoric kinematic hardening rule [31]. This kinematic rule dictates that all

yield surfaces may translate in stress space within the failure envelope [32-33] and be consistent with the Masing unloading/reloading criteria [34]. For the cohesionless soil layers, an elastic-plastic material, namely "PressureDependMultiYield02", is used in Opensees, where the yield function is assumed to follow the Drucker-Prager shape and the yield surface is a function of friction angle and cohesion. Plasticity is formulated based on the multi-surface concept, with a non-associative flow rule [32] that handles the soil contractive/dilative behaviour during shear loading to achieve appropriate interaction between shear and volumetric responses. For the cohesive soil layers, an elastic-plastic material in which plasticity exhibits only in the deviatoric stress-strain response, namely "PressureIndependMultiYield", is used. The volumetric stress-strain response is linear-elastic and is independent of the deviatoric response. This material is implemented to simulate monotonic or cyclic response of materials whose shear behaviour is insensitive to the confinement change. The yield function is assumed to follow the Von Mises shape and the yield surface is a function solely of undrained shear strength. Plasticity is formulated based on the multi-surface concept, with an associative flow rule in which the incremental plastic strain vector is normal to the yield surface.

### 3.4 Soil-structure interaction modelling

For the 2D flexible-base model (modelling approach ii) the direct approach is applied, which accounts simultaneously inertial and kinematic interaction effects. Figure 5 represents the 2D coupled finite element (FE) soil-structure model for the warehouse resting on the liquefiable soil, which is subjected to combined ground shaking and liquefaction. The grids adapted for the different soils SP1, SP2, and SP3 have a total length three times their depth to avoid spurious wave reflections at the vertical boundaries. Their dimensions are defined equal to 60.0m x 180.0m, 50.0m x 150.0m and 46.0m x 138.0m, respectively. Dense discretization is achieved using quadrilateral elements of 0.5m x 2.0m, considering that the maximum frequency of interest is set to 10Hz. This mesh allows an adequate number of elements to fit within the shortest wavelength of the propagating shear wave.

Figure 5: Finite element 2D model for the typical steel light-frame warehouse on liquefiable soil.

A full bond is assumed between the structure's foundation and the soil nodes. The soil and the structure nodes at the level of foundation have appropriate constraints in order to ensure equal displacements. Shallow, relatively flexible foundations are considered, modelled as elastic beam-column elements of infinite rigidity, which allow columns to move differentially. In this case, it is furthermore assumed that no interface has been considered between the structure and the foundation and that failure will take place on the structural elements of the building, while the structural integrity of the foundation itself will not be affected by the liquefaction induced deformation.

## 4 NUMERICAL ANALYSIS

### 4.1 Seismic input motion

A representative set of fifteen real ground motion records (Table 1) is selected from the European Strong-Motion Database to perform nonlinear incremental dynamic analyses. They are all referring to rock type or stiff soils (ground types A and B according to EC8) with moment magnitude ( $M_w$ ) and epicentral distance  $R$  that range between  $5.5 < M_w < 6.5$  and  $0 < R < 45\text{km}$  respectively. The primary selection criterion is the average acceleration spectra of the set to match the corresponding 5% damped median plus 0.5 standard deviations spectrum defined based on the ground motion prediction equation (GMPE) proposed by Akkar and Bommer [35]. The optimization procedure is performed using REXEL software [36] that allows obtaining combinations of accelerograms, which on average are compatible to the reference spectrum. Figure 6 shows the mean elastic response spectrum of the records in comparison with the corresponding median plus 0.5 standard deviations Akkar and Bommer [35] spectrum. As shown in the figure, a good match between the two spectra is achieved.

Table 1: List of records used for the dynamic analyses.

These records are then filtered between 0.25 and 15.0 Hz, using a fourth-order bandpass Butterworth type filter. Baseline correction linear type is also applied. Table 1 also presents the values of  $PGA_{corrected}$  obtained from the corrected accelerograms used for the analyses.

Figure 6: Average elastic response spectrum of the input motions in comparison with the corresponding median plus 0.5 standard deviations Akkar and Bommer [35] spectrum.

## 4.2 Numerical analyses

To examine the effect of liquefaction on the seismic ground response, we initially perform a comparative dynamic analysis of the considered nonlinear soil profiles. In this respect, the utilized earthquake records are scaled at PGA values equal to 0.05g and 0.3g. For PGA equal to 0.05g, it seems that the soil responses are within the linear elastic range, since the effective confinement values with depth do not approach zero. On the contrary, for the dynamic analyses with input motions scaled at 0.30g, liquefaction is taking place. Layers of potential liquefaction may be identified by loss of effective confining stress at certain depths, which is verified by the relative stress-strain loops. Figure 7 shows representative results in terms of effective confinement with depth and stress-strain hysteretic loops at specific depth (i.e., 7 m below surface) indicatively for Soil profile SP2 and Montenegro (aftershock) input motion scaled at 0.05g and 0.3g.

Moreover, an initial elastic modal analysis of both the 2D and 3D fixed-base models is conducted to define the dynamic characteristics of the structure and increase the reliability of the proposed modelling approaches. The fundamental period of the studied structure is computed equal to 0.298 s for the 2D fixed-base model and 0.293 s for the corresponding 3D fixed-base model providing a first verification of their validity.

## 4.3 Incremental dynamic analysis

2D and 3D incremental dynamic analysis (IDA) is then conducted to estimate more thoroughly the seismic performance of the typical steel light-frame warehouse due to ground shaking and liquefaction. To express the scaling level an initial, temporary choice of an intensity measure (IM) is needed. Scaling can be re-expressed in any other scalable IM [37] after the runs are performed. In this study, the IM is initially described by the peak ground acceleration on rock outcropping conditions ( $PGA_{rock}$ ). This IM is considered more appropriate due to its simplicity. Hence, IDA for the fixed-base and the three SSI models is conducted by applying the 15 progressively scaled records, considering a first elastic run at 0.05g, an initial step of 0.1g and a step increment of 0.1 g. A sequence of at least ten runs is performed on

each record. The damage measure (DM) is expressed in terms of maximum inter-story drift (maxISD), which is known to relate well to dynamic instability and structural damage of frame buildings.

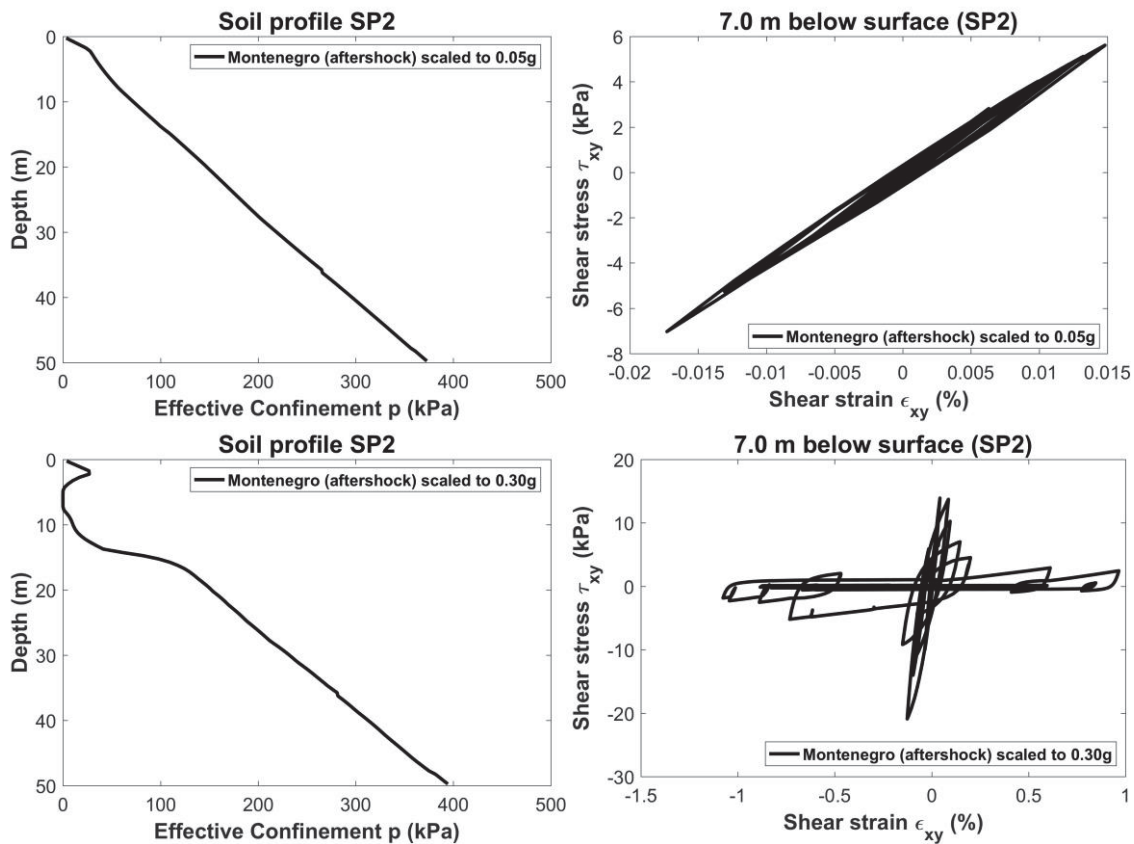

Figure 7: Variation of the effective confinement with depth and stress strain hysteretic loops at specific depth for SP2 and Montenegro (aftershock) input motion scaled at 0.05g (top) and 0.3g (bottom)

## 5 FRAGILITY AND VULNERABILITY CURVES

### 5.1 Definition of limit states

A key factor for the vulnerability assessment is the accurate definition of damage limit states as they directly influence the evaluation of the fragility function parameters. Four damage states are defined in terms of maxISD ratio, describing the exceedance of slight, moderate, extensive, and complete damage of light-weight steel warehouses. According to NIBS [38], "Steel Light Frames" structures are mostly single storey structures combining rod-braced frames in one direction and moment frames in the other. Due to the repetitive nature of the structural systems, the type of damage to structural members is expected to be rather uniform throughout the structure. Consequently, warehouses are considered as "Steel Light Frames" structures. The qualitative description of each damage state for steel light-frame structures adopted in this research work can be found in NIBS [38]. Usually, the damage limit states are defined on the IDA curves derived for the fixed-base building subjected to ground shaking, with the complete/collapse damage limit state placed at a point where the IDA curve is leaning towards the flatline. The damage limit states are selected based on the existing literature [7, 38] combined with the IDA analysis results and objective engineering criteria. The adopted damage limit state values are shown in Table 2.

Limit states	Steel light-frame warehouse
LS 1	0.50%
LS 2	1.00%
LS 3	2.00%
LS 4	3.30%

Table 2: Limit state values in terms of maxISD adopted for steel warehouse.

## 5.2 Development of fragility and vulnerability curves

A fragility curve describes the probability of exceeding a specific damage state under a seismic excitation of a given intensity. They can be produced taking advantage of the results of the nonlinear IDA in terms of PGA and maxISD ratio, as two parameters are required for the lognormal distribution functions given from the following equation:

$$P[LS_i/IM] = \Phi\left(\frac{\ln(IM) - \ln(\overline{IM}_i)}{\beta}\right) \quad (1)$$

where  $\Phi$  is the standard normal cumulative distribution function,  $LS_i$  is the damage limit state,  $IM$  is the intensity measure of the earthquake expressed both in terms of rock outcropping  $PGA_{rock}$  measure in g,  $\overline{IM}$  and  $\beta$  are the corresponding median values at which the building reaches each damage limit state,  $i$ , and log-standard deviations respectively. A linear regression fit of the logarithms of the  $PGA_{rock}$ -maxISD and data pairs which minimize the regression residuals is adopted. Three components of uncertainty are accounted for related to the definition of the limit state value  $\beta_{LS}$  (defined empirically as  $\beta_{LS} = 0.4$ ), the capacity of each structural type  $\beta_c$  (defined empirically as  $\beta_c = 0.30$ ), and the demand  $\beta_D$  [38]. The demand  $\beta_D$  is calculated conducting statistical processing of the numerical results (IM-DM data pairs). In particular, we estimate the dispersion of the logarithms of  $PGA_{rock}$ -maxISD obtained from the numerical analysis using the regression fit. The total parameter  $\beta$ , which represents the total dispersion related to each fragility curve, is finally evaluated as the root of the sum of the squares of the three variability dispersions assuming that they are statistically independent [38]. Figure 8 shows the derived fragility curves along with their fragility parameters (median  $\overline{IM}$  and log-standard deviation  $\beta$ ) in terms of  $PGA_{rock}$  for the steel light-frame warehouse subjected to ground shaking considering the different approaches.

From Figure 8 some interesting conclusions could be derived. First of all, it is noticed, that 2D and 3D configurations for the fixed-base structure, ignoring liquefaction and SSI effects, are generally correlated quite well with the 3D fixed-base model showing lower vulnerability values for all damage states. Secondly, it seems that the vulnerability of a steel light-frame warehouse, when considering liquefaction effects, is very low. More specifically, for  $PGA_{rock}$  values up to 2.0g, the 2D flexible-base and the 3D fixed-base models that consider liquefaction are almost no damaged. For  $PGA_{rock}$  higher than 2.0g, only the "Slight" damage state exists while fragility curves for the other damages are not proposed. A third important conclusion is that the effect of SSI is not significant for the 2D and 3D models which consider liquefaction. Thus, the proposed fragility curve for slight damage state is almost identical for the 2D flexible-base and the 3D fixed-base models implying that the influence of SSI is not of paramount importance for this specific structure.

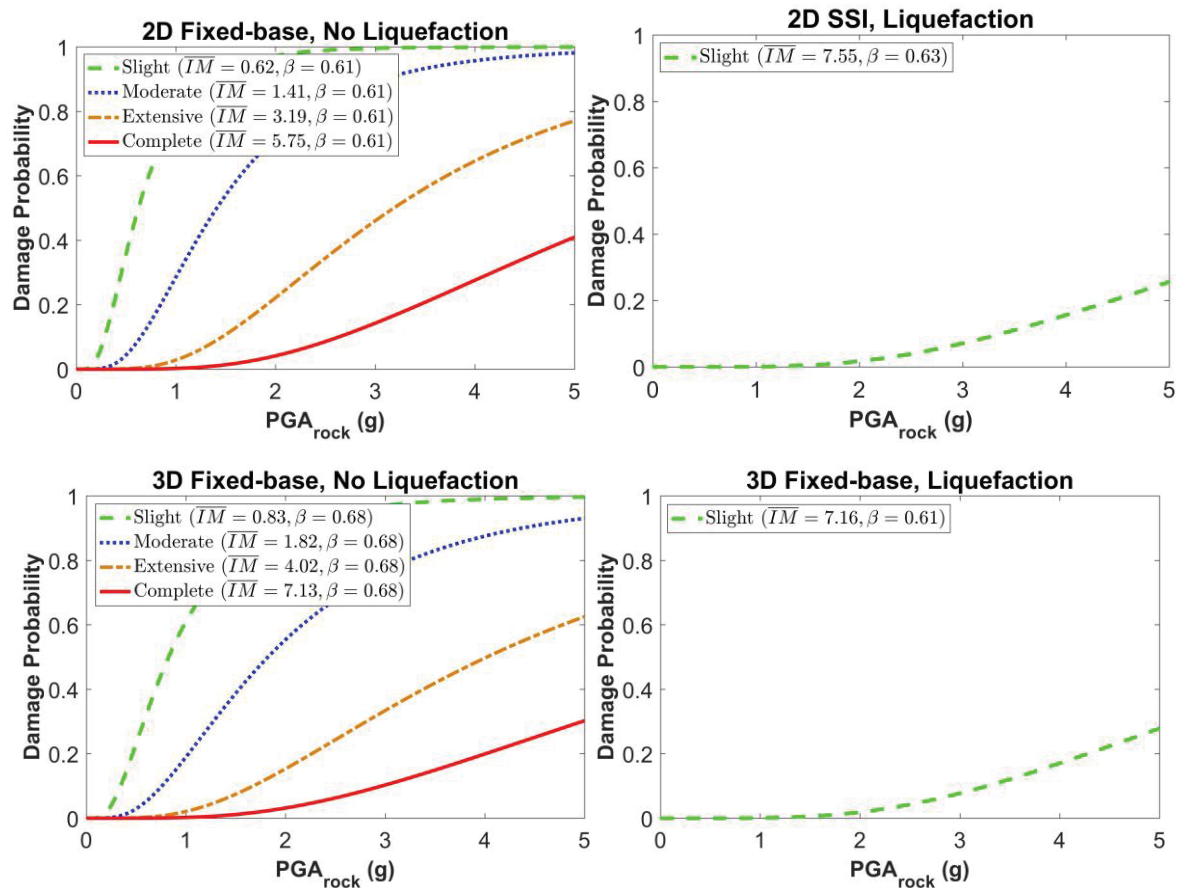

Figure 8: Fragility curves in terms of  $PGA_{rock}$  for the steel light-frame warehouse subjected to ground shaking considering the different approaches.

Next, for the 3D fixed-base approach neglecting liquefaction, we perform a comparison between the herein resulted fragility curves with the ones proposed by Nazri et al. [7] for similar structures (Figure 9). For the "slight" and "moderate" damage states fragility curves are in quite good agreement. For the rest two damage states the correlation between the two approaches is not that good. This is due among other factors to the differences on the structural characteristics and the definition of the complete damage limit state.

Figure 9: Comparison of the proposed fragility curves for the warehouse using the 3D fixed-base approach neglecting liquefaction with the corresponding analytical ones of Mohamed Nazri et al. [7].

Once the probabilities of exceeding the predefined damage limit states are calculated, the vulnerability (or damage) index  $d_m$  for each level of seismic intensity can be estimated according to the following expression:

$$d_{mj} = \sum_{i=1}^4 P_{ij} \cdot d_i \quad (2)$$

where  $d_{mj}$  is the damage index (taking values from 0: no damage to 1: complete damage) corresponding to each seismic intensity level  $j$ ,  $P_{ij}$  is the discrete damage probability for each damage limit state and  $d_i$  is the damage index at each damage limit state.

Following NIBS [38], we set the central value of the damage index at each damage limit state for the RC buildings equal to 0.10, 0.15, 0.40 and 0.80 for the LS1 (minor), LS2 (moderate), LS3 (extensive) and LS4 (complete), respectively. A vulnerability curve is then generated which provides a unique damage index for each level of seismic intensity.

Figure 10 shows the derived vulnerability curves in terms of  $PGA_{rock}$  for the warehouse subjected to ground shaking considering the different approaches. We observe that the vulnerability of the 2D and 3D fixed-base configurations is in good agreement. When liquefaction is considered, the vulnerability decreases. This is due to the increased nonlinear behaviour of the soil profile introduced by the liquefaction. The 3D fixed-base, and the 2D flexible models that consider soil liquefaction, give almost the same vulnerability curve, which shows that the consideration of SSI has no considerable effect on the vulnerability of the structure.

Figure 10: Vulnerability curves in terms of  $PGA_{rock}$  for the steel light-frame warehouse subjected to ground shaking considering the different approaches.

## 6 CONCLUSIONS

Within this study's framework, incremental dynamic analysis was performed for a typical port steel light-frame warehouse using a selected set of earthquake records considering four different modelling approaches. This study aimed to identify soil liquefaction and SSI's role in altering the seismic fragility and vulnerability of port warehouses.

1. We concluded that 2D and 3D configurations for the fixed-base structure, ignoring liquefaction and SSI effects, are generally correlated reasonably well with the 3D fixed-base model showing lower vulnerability values for all damage states.
2. Secondly, it seems that the vulnerability of a steel light-frame warehouse, when considering soil liquefaction effects, is very low, possibly due to the increased nonlinear behaviour of the soil profile introduced by the liquefaction.
3. A third important conclusion is that the impact of SSI is not significant for the 2D and 3D models which consider soil liquefaction. Thus, the proposed fragility curve

for slight damage state is almost identical for the 2D flexible-base and the 3D fixed-base models implying that the influence of SSI is not of paramount importance for this specific structure.

### ABSTRACT

*The assessment of the built heritage vulnerability is a needful task to mitigate the seismic risk. At this aim, fragility functions estimate the probability of exceedance of a structure at discrete levels of ground motion. The paper focuses on the estimation of seismic fragility of unreinforced masonry buildings typical of the inner Central Italy. Fragility assessments were performed for selected ordinary buildings representative of the urban fabric of the Central Italy, hit by the 2016 earthquake recently. The buildings' stock belongs to a macro-typology defined by structural features, easily available from visual inspections and geometric surveys. The structural performances of the buildings are assessed by means of empirical and numerical approaches, based on a large portfolio of information gathered after the 2016 earthquake swarm. Lastly, the fragility curves for the macro-typology have been derived referred to the attainment of four limit states of interest. A comparison between the obtained results in terms of probabilities of exceedance underlines the main advantages and limitations of each approach in the seismic vulnerability prediction on large scale applications.*

**Keywords:** Masonry un-reinforced buildings, fragility curves estimation, vulnerability assessment, damage scenarios.

## 1 INTRODUCTION

Recurring earthquakes in seismic prone areas represent a serious threat for the built environment due to structural vulnerabilities that affect the existing buildings. Particularly, masonry constructions suffer extended damage up to lose their structural stability under an earthquake action. Thus, in recent years, a growing attention has been reserved to the evaluation of the structural vulnerability of existing buildings, also deepened by fragility assessment, to mitigate the seismic risk. A fragility function specifies the probability of a structure of attainment or exceedance a limit states of interest, depending upon a certain ground motion intensity measure [1].

About the estimation of the fragility functions, a significant part of the scientific literature focuses on the derivation of fragility curves based on simplified analysis methods or alternative definition of the limit states [2, 3].

Several approaches are used to derive fragility curves: empirical, analytical and hybrid. Empirical fragility methods aim to predict damage for specific levels of ground motion intensity based on post-earthquake damage data of specific building typologies [4,5,6], through simplified assessment of seismic performance. Analytical methods, also called mechanics-based methods, define the fragility functions based on structural or analytical models that appraisal the seismic behaviour of the structure [7,8]. Limit state are defined in terms of quantitative measure of structural performance, like displacements and deformation indicators [9,10]. Hybrid methods derive fragility curves using features of empirical and mechanics-based methods.

The reliability of each method depends on the availability of data and its accuracy.

Empirical fragility assessment is calibrated on a specific area hit by an earthquake. In general, empirical fragility curves reflect uncertainties on structural data and ground shaking intensity. Analytical fragility assessment requires a numerical or mechanical model of the structure based on an in-depth knowledge of mechanical parameters and structural details, difficultly achievable at territorial scale application.

This paper aims to compare the empirical and numerical approaches to derive fragility curves for ordinary masonry buildings, located in the inner Central Italy, recently hit by a shattering seismic swarm. The investigation of the seismic behavior of these buildings attempts to mirror the entire class, representative of the local built-up.

The mean damage of the buildings' class was, in accordance with the European Macro seismic Scale classification, EMS-98, through an empirical approach proposed by the authors, to derive fragility curves for five damage states. After that, the fragility functions were estimated from the results of non-linear static analysis. A comparison between the typological empirical fragility curves and numerical ones reveals the main advantages and limitations in forecast damage scenarios and supporting resilience-enhancing strategies.

## 2 DESCRIPTION OF THE CASE STUDY

### 2.1 Characterization of the case study

The Italian built environment exhibits typical features for each region, in terms of materials and structural configurations, requiring a classification at local or regional scale [11]. This paper deserves attention to the seismic performance of the masonry ordinary buildings typical of the Central Italy, hit by the last seismic swarm occurred in the 2016. The proposed methodology can be addressed to any buildings' typology by considering structural features of the analyzed facilities, as done by other authors [12,13].

The prevalent typologies of the analyzed built-up consist of low-rise masonry buildings and reinforced-concrete frame buildings. Regarding the masonry facilities, two main typologies could be detected in the selected geographical area: (i) historical constructions and (ii) ordinary buildings. Buildings (i) are located in the historical centers, often built attached to each other up to compose masonry aggregates of structural units with different height, number of stories, structural types and materials heterogeneities [14,15]. In general, historical buildings are conceived to withstand only gravity loads: under an earthquake action, they suffer local mechanisms, like out-of-plane response of masonry walls. Buildings (ii), built in the last century to expand urban centers, follow the empirical rules and the code dispositions in force at the construction period. Most of them are endowed of connections wall-to-wall or anti-seismic devices, like iron ties, that ensure a global response of structures. Often though the poor mechanical properties of the masonry give rise to an unsatisfactory seismic performance.

Fifteen masonry buildings are selected as representative of the ordinary buildings' class of the area hit by the 2016 earthquake. Most of these buildings manifested an in-plane seismic response, with typical shear and bending failure modes. Some of them suffered local mechanisms due to the ineffectiveness of the connections wall to wall. The observed damage was estimated in agreement with the damage classification by Grünthal [16] that ranges from the Level 0 to the Level 5.

Buildings with a suffered damage grade  $D_{k2}$  consist of 13.33% of the sample; with a damage grade  $D_{k3}$  of 80 %, and with a damage grade  $D_{k4}$  of 6.67%.

## 2.2 The Central Italy seismic swarm

In 2016, the Central Italy was hit by a seismic swarm that started on 24 August. The first mainshock, with a magnitude  $M_w = 6.2$ , occurred with an epicenter located in Accumoli (Rieti). The second mainshock, with a magnitude  $M_w = 5.5$ , occurred with an epicenter in Norcia (Perugia). The seismic swarm continued up to 6500 aftershocks with a  $M_w$  until 5.5, affecting four regions: Lazio, Abruzzo, Marche and Umbria. The seismic genetic area concerns a complex structural configuration and different faults, see Fig.1 (INGV) [17]: the soil and topographic configurations drove strong local site effects.

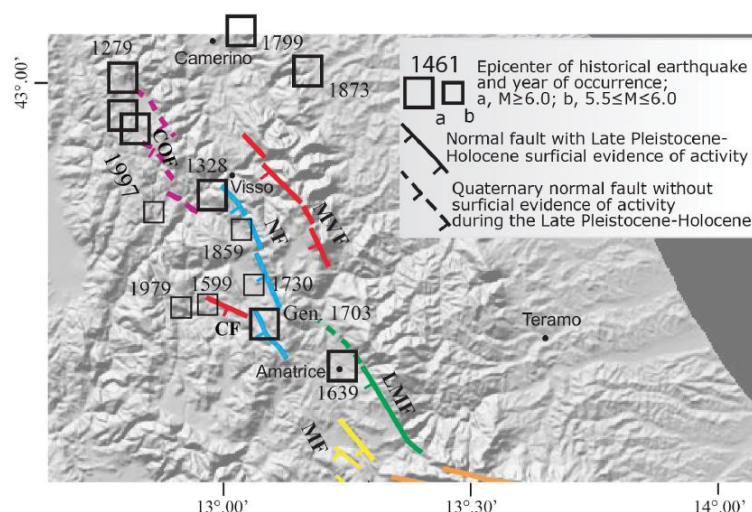

Fig. 1 Scheme of Quaternary and / or active faults in the area between the Monteverde basin (south) and the Colfiorito area (north): COF, Colfiorito fault; MVF, fault of the M. Vettore; NF, Norcia fault; CF, Cascia fault; LMF, Monti della Laga fault; MF, faults in the Monteverde basin (INGV)

Overall, the seismic swarm was shattering giving rise to hundreds of buildings damaged and un-safe.

### 3 SEISMIC VULNERABILITY ASSESSMENT

#### 3.1 Seismic assessment by means an empirical approach.

In the last decades, a significant part of the scientific literature focused on the simplified estimation of the seismic vulnerability of masonry buildings [18,19] to face the estimation of the seismic vulnerability at territorial level.

Empirical approaches attempt to overcome the effort of seismic vulnerability assessment on large-scale application resorting to few structural and mechanical parameters, known from visual inspections or geometric surveys.

The authors proposed a simplified method finalized to provide a vulnerability index (ranging from 0 to 100) for the in-plane seismic behavior, based on ten parameters evaluated through quick formulations, related to three classes of growing vulnerability (from A to C), with different scores associated, see Table 1.

	Parameter of the wall	Weight	
1	Quality of the masonry	1.00	
2	Amount of openings	0.5	
3	Behaviour in plan	0.8	Class A: score 0
4	Behaviour in elevation	0.75	
5	Typology of opening	0.20	Class B: score 50
6	Stiffness of the spandrel beams	0.40	
7	Tensional state in plan	0.8	Class C: score 100
8	Tensional state in elevation	0.8	
9	Position of the wall	1.25	
10	Site effects	1.05	

Table 1: Form of the proposed predictive method.

The method was applied to each building of the case study. The mean value of the vulnerability indices, representative of the entire buildings' sample, was equal to 43.88. The expected mean damage of the typological class  $\mu_D$  was estimated using the macro-seismic method [20], according to Equation 1:

$$\mu_D = 2.5 \left[ 1 + \tanh \left( \frac{(I+6.25V-13.1)}{Q} \right) \right] \quad (1)$$

Where  $I$  is the macro-seismic intensity,  $Q$  is a ductile factor set equal 2.3, and  $V$  is the normalized vulnerability index representative of the entire class. The average vulnerability curves and the confidence bounds associated are derived for different scenarios, expressed in terms of macro-seismic intensity, in Fig.2 (a), and in terms of peak ground acceleration in Fig.2 (b), evaluated according to Murphy O'Brien law correlation [21].

Fig. 2. Mean typological damage curves: in terms of Intensity Measure (a); in terms of  $a_g$  (b).

The probability of occurring the damage grade  $D_k$  is estimated as a function of the  $\mu_D$  according to the Eq. 2, [16]:

$$p_k = \frac{5!}{k!(5-k!)} \left( \frac{\mu_D}{5} \right)^k \left( 1 - \frac{\mu_D}{5} \right)^{5-k} \quad (2)$$

The typological fragility curves, derived by means the empirical method, are plotted in Fig.3: expressed in terms of macro-seismic intensity, in Fig.3 (a), in terms of peak ground acceleration in Fig.3 (b).

### 3.2 Seismic assessment by means mechanical approaches.

Mechanics-based approaches appraisal the seismic structural performance of buildings accurately based on a numerical or analytical modeling. The achievement of a reliable estimation of the seismic behavior of a structure requires a deep knowledge of the structural system,

detailed data, in-situ diagnostic tests, and a high computational effort. Therefore, the mechanical estimation of the seismic performance at territorial level represents a tricky application.

Nevertheless, the authors derived the fragility curves of the class through numerical analysis to compare the different approaches.

Static no linear analysis was performed using a commercial software package, 3Muri software [22], in which the equivalent frame modelling is implemented. The seismic action corresponds to the design response spectrum, defined to the spectral parameter  $a_g$  (max acceleration value),  $F_0$  (max value of the amplification factor for the horizontal acceleration response spectrum) and  $T_c^*$  (period of the horizontal onset for constant velocity), according to the Italian Seismic Code [23, 24]. The response spectrum is defined for a return period,  $T_r$ , of 30 years, for Operational Limit State, LS1; 50 years, for Damage Limit State, LS2; 475 years, for Significant Damage Limit State, LS3; 975 years, for Collapse Limit State, LS4. Non-linear static analyses were carried out along the longitudinal and transversal direction, by applying two different seismic loads, and an accidental eccentricity between the mass centroid and the stiffness centroid is considered, according to the Italian Design Code. The Acceleration Displacement Response Spectrum, ADRS, was assumed to evaluate the seismic capacity and demand of the structure [25]. Twenty-four pushover analyses were performed from each of the fifteen buildings, yielding 360 analysis.

Still, for each structure, the analysis representative of the lowest safety level.

The probability of collapse,  $P_c$ , descends from the estimation of the standard normal cumulative distribution function  $\Phi$ , as expressed in Equation (3):

$$P[d_s|S_d] = \Phi \left[ \frac{1}{\beta_s} \ln \left( \frac{S_d}{\bar{S}_{ds}} \right) \right] \quad (3)$$

Where  $d_s$  is the displacement of the threshold of damage state,  $S_{ds}$  is the median value of spectral displacement at  $d_s$ ,  $\beta_s$  is the standard deviation of the natural logarithm of spectral displacement of a damage state  $d_s$ . The limit damage thresholds are reported in Table 2:

Damage Limit State		Displacement Limit State
LS1	Operational Limit State	$0.7 \cdot d_y$
LS2	Damage Limit State	$0.8 \cdot d_y + 0.2 \cdot d_u$
LS3	Significant Damage Limit State	$0.5 \cdot (d_y + d_u)$
LS4	Collapse Limit State	$d_u$

Table 2: Damage thresholds definition.

The yielding and ultimate displacement,  $d_y$  and  $d_u$ , correspond to the average of the fifteen values, equal to 0.003 m and 0.011 m, respectively. The standard deviation is equal to 0.15 for the yielding displacement and 0.39 for the ultimate displacement. The typological fragility curves derived by means the numerical method are plotted in Fig. 4.

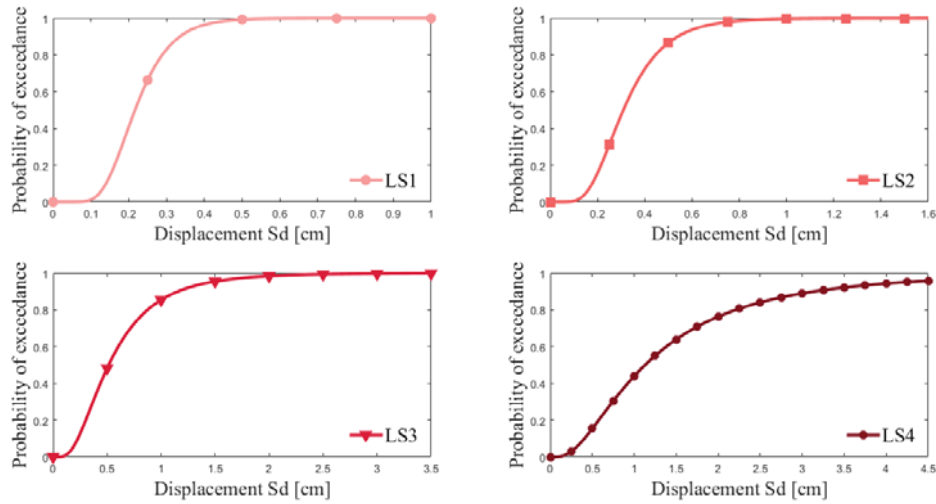

Fig. 4. Typical fragility numerical curves for different limit states.

#### 4 COMPARATIVE ASSESSMENT OF THE FRAGILITY CURVES

Fragility functions estimate the probability of a structure to attain or exceed limit states of interest, depending upon a certain ground motion Intensity Measure. In seismic risk assessment, probabilities of exceedance of limit states of interest are useful to predict the seismic behavior of the built environment before an earthquake occurs.

The authors performed seismic fragility assessment for the class of the ordinary masonry buildings based on the empirical and numerical probabilities of exceedance.

Furthermore, the large portfolio of the gathered information and data allows to estimate the real damage scenario occurred after the 2016 earthquake. The suffered damage of each building of the stock was correlated to the Intensity Measure experienced by the attenuation law proposed by Crespellani [26], see Eq. 4, to prove the reliability of the proposed empirical method in predicting seismic damage scenario:

$$I_{EMS-98} = 6.39 + 1.756M_w - 2.747\ln(R + 7) \quad (4)$$

Where  $M_w$  is the moment magnitude occurred, set equal 6.2, and  $R$  is the distance from the epicenter, equal to 21.5 km. The discrete damage distributions for each buildings of the sample, evaluated for an intensity measure equal to 8.07, is reported in Fig. 5.

Fig. 5. Discrete damage distributions for  $I=8.07$ .

The percentage of buildings of the sample with a damage grade  $D_{k2}$  was equal to 6.67; with a damage grade  $D_{k3}$  was equal to 86.67, and with a damage grade  $D_{k4}$  equal to 6.67.

The forecast damage shows a good agreement with the real suffered damage: the preponderant level of damage is  $D_{k3}$ , with a discrepancy equal to 6.97 % with the real damage.

Moreover, the correlation law neglects the influence of possible site effects on damage scenario.

The results discussed above prove the capability and reliability of the empirical method to forecast the expected damage of buildings' sample.

Whereupon a comparison in terms of typological fragility curves is performed to compare empirical and mechanics-based methods, see Fig. 6, expressed in terms of  $a_g$ .

Fig. 6. Fragility curves comparison.

For a seismic demand enclosed in the range 0-0.3 g, the discrepancy in terms of probability of exceedance for the LS1 reaches the value of 29.9 %; for the LS2 reaches the value of 47 %.

The comparison highlights a difference of fragility curves, more remarkable for the LS1 and LS2. Whereas the fragility curves referred to the attainment of the LS3 and LS4 shows a better agreement. For a seismic demand higher than 0.3 g, the discrepancy in terms of probability of exceedance for the LS3 reaches the value of 19 %; for the LS4 reaches the value of 25 %.

The empirical and numerical probability values of exceeding the limit state LS1 and LS2 may be regarded as too scattered to consider equivalently the two approaches.

Overall, the empirical curves overestimate the probabilities of the collapse, on the safe side in predicting the damage scenario.

## 5 CONCLUSIONS

The paper aims to derive fragility curves for masonry buildings' class, composed of fifteen selected buildings typical of the inner Central Italy, by empirical and numerical method. A simplified assessment of the seismic behavior of the buildings is performed, through an empirical method proposed by the authors, to provide a mean vulnerability index representative of the buildings' sample. Based on the empirical results, the mean damage was evaluated, according to the Macro Seismic Methodology to derive empirical fragility curves of the buildings' class. After that, fragility curves are derived from the results of non-linear static analysis. Based on a comparison between the different methodologies, the typological fragility curves show

different values of the expected damage, more scattered for the limit states LS1 and LS2. For a seismic demand enclosed in the range 0-0.3 g, the discrepancy in terms of probability of exceedance for the LS1 reaches the value of 29.9 %; for the LS2 reaches the value of 47 %. Whereas the fragility curves referred to the attainment of the LS3 and LS4 shows a better agreement. For a seismic demand higher than 0.3 g, the discrepancy in terms of probability of exceedance for the LS3 reaches the value of 19 %; for the LS4 reaches the value of 25 %. Thus, the current research results show that a typological approach fails for the LS1 and LS2 states of interest.

To improve the numerical fragility assessment of the buildings' typology, an investigation of the yielding displacements may be useful to propose an appropriate definition of the threshold for the slight and moderate damage states. The identification of suitable limit states for masonry buildings is still an open issue.

Similarly, to improve the empirical fragility assessment, the ductile factor of the masonry structures, set equal to 2.3 in the empirical formulation of the expected mean damage, could be deepened: even within the ordinary masonry class, buildings exhibit different ductile behaviour factors, showing the dispersion of the ductile parameter  $Q$ .

Therefore, the empirical typological fragility assessment ensures accurate and quick seismic vulnerability prediction on large scale, reducing computation time of seismic analysis of buildings' class. For the LS1 and LS2 limit states, the current research points out that a typological approach requires more accurate quantitative parameters to grasp the buildings' seismic behavior, with either approaches. To improve the fragility assessment of the buildings' typological class, an investigation of the onset of the damage may be useful to propose an appropriate definition of the threshold for the slight and moderate damage states. Thus, the limitations of each approach in forecasting damage scenarios and supporting resilience-enhancing strategies could be removed improving observational, experimental and numerical data to better deepen the seismic behavior of buildings under investigation.

### Abstract

*Seismic resilience is a modern approach that aims to return the community of damage to its natural condition in a shortest possible time. Seismic resilience could be interpreted as a structure's ability to maintain a degree of functionality over a particular period of time once it is exposed to seismic events. The research study aims to address with an approach of functionality and seismic resilience of a mid-rise Ordinary Moment Resisting Frame (OMRF) structure subjected to repeated earthquakes. Besides, as a vulnerability and functionality study for risk assessments, both the Seismic Resilience Index (SRI) and the fragility surface were used to determine the seismic resilience of the selected building. The fragility surfaces expressed the probability of damages with respect to intensity measure and seismic event period (T). The concept phases of this approach were as follows: (1): Select targeted buildings, (2): Select and scaled a set of repeated Seismic Ground Motion (SGM) records, (3): Generate an Incremental Dynamic Analysis (IDA), (4): Fragility surface and (5): Functionality curve, with seismic resilience index (RI). Eventually, after investigating the structure through the vulnerability assessment, initiating with IDA, and ending with the fragility surface, it is clearly established that the buildings do not have the capacity to withstand a 15 sec repetitive earthquake due to their ordinary structural design related to ductility demand. Meanwhile, with an increase in the possible seismic ground acceleration, the fluctuation in functionality, SRI, robustness, structural losses, and time recovery of distinct performance levels could be estimated.*

## 1 INTRODUCTION

In the last decades, the intensity and frequency of earthquakes has increased, causing severe destruction with enormous number of casualties, posing a main disruption and change in the economic, social, and technical conditions for specific communities. Due to this fact, ‘resilience’, ‘vulnerability’, ‘risk reduction’, and ‘recovery’ definitions are trending in research community. However, it is vital to conduct a quantitative procedure to evaluate these intuitive definitions [1].

All these lead to the development of a resilience assessment for earthquakes by using a specific index, which is considered an important factor for managing and planning natural disasters. The main idea of resilience at the beginning was developed by ecologists, however, it expanded to a wider range of fields i.e., social science, psychology, and engineering [2].

The Seismic Resilience Index (SRI) is considered a powerful tool to demonstrate the capability of a structure to sustain a particular standard of performance and usability across a span of time control ( $T_{LC}$ ) [3]. Bruneau et al. [4] introduced a very general definition for resilience, which covered all the precautions that should be taken to reduce the main losses resulting from hazards, and also the study covered the effects of mitigation and recovery. After this broad definition that was introduced by Bruneau and Reinhorn [5], many studies were produced tackling the development and assessment of resilience.

Samadian et al. [6] conducted a study in Iran to determine the seismic resilience of built and rehabilitated RC school buildings, whereby the study was assessed through utilising vulnerability and fragility curves. The main objective of this study is to implement a new approach which focuses on provincial economic conditions, through the use of vulnerability analysis to estimate earthquake-related losses. The results showed that when the magnitude of hazard levels was increased the SRI decreased functionally. The study concluded that retrofitted school buildings had a higher resiliency level. Furthermore, the comparative study between fragility and vulnerability curves showed that the vulnerability curve indicated more efficient results to evaluate the SRI.

Furthermore, Vona et al. [7] introduced a new resilience approach for communities based on numerical assessment and observed post-seismic restoration procedure. The study focused on the housing systems to develop SRI for the communities, by which it was expressed as a combination of SRIs for each building category. The proposed approach could help in assessing different scenarios with more precise results, which could be achieved with more potential choices.

Titi and Biondini [8] tested the reliability of concrete frame structural systems that were affected by corrosion. The results showed that the designed structures designated to have the same level of functionality could display different seismic resilience over a specific time span resulting from the surrounding environmental conditions. Other studies were established to assess resiliency and calculate the SRI for different type of structures. For instance, Alipour and Shafei [9] assessed the seismic resilience transport networks and Banerjee and Chandrasekaran studied the seismic resilience of bridges under the effect of multi-hazards [10].

In addition, Cimellaro et al. [1] introduced a framework for analytical quantification of disaster resilience. This research focused on integrating information from different fields, which were earthquake engineering, social sciences, and economics to develop a disaster resilience framework. The main outcome of this study was to build a decision-making tool that could help both the policy makers and the engineering professionals for better preparedness and restoration plans after disasters.

Various studies tackled the development and assessment of SRI and covered different categories and indicators [11-13], however, the studies that focus on the assessment and development of SRI under repeated earthquakes are limited.

Repeated earthquakes represented two or more incidents, which precisely hit the same fault area and slip, by which it generated the same waveform [14]. The repeated earthquakes could cause a significant deterioration and higher displacement demand for buildings. All these factors could directly impact the resiliency of these buildings [15-17]. Uchida [18] conducted a study to detect the repeated earthquakes and their application in characterising slow fault slip. The author concluded that by measuring the degree of waveform similarity and accurate hypocentre positions could help in recognising the repeated earthquakes and it could assist in evaluating the source-overlap ratio. The fragility curve or surface is considered as an efficient tool to study the effect of repeated earthquakes.

In seismic risk assessment, fragility curves are considered an essential element, which is defined by relating a given level of seismic intensity to the possibility of reaching or exceeding a certain degree of damage. To determine the performance limit states in relation to the Performance Based Seismic Design (PBSD) during earthquakes, structural damage was measured based on the Engineering Demand Parameters (EDP), i.e., vertical displacements, crack patterns or rotations. To establish fragility curves, which are empirical, theoretical, judgmental, and hybrid, different approaches could be used. [19, 20].

The fragility curve is usually defined by one parameter i.e., PGA, Sa, and Arias, but one distinct parameter is insufficient to study the effect of earthquakes on the buildings precisely. From here came the idea of developing fragility surface, by taking into consideration more than one parameter at the same time when studying the effect of the earthquake [21-23]. Many studies developed fragility surface to assess seismic risk on structures. For example, Ardebili and Saouma [24, 25] developed seismic fragility surfaces to study the effect of earthquakes on concrete dams, and Gehl et al. [26] developed fragility surfaces to evaluate the seismic vulnerability assessment for masonry buildings.

This leads to exploring the fact that lends the rise to the significance of seismic resilience and functionality, and the vulnerability risk assessment by using fragility surface. The aim of this paper is to shed the light on studying the seismic vulnerability assessment for an Ordinary Moment Resisting Frame (OMRF) structure that was designed away from any seismic attention under repeated earthquakes. This paper discusses the procedure for combining the vulnerability analysis to know the possibility of damages for four damage states, namely immediate occupancy (IO), damage control (DC), life safety (LS), and collapse prevention (CP), with the functionality of the structure post seismic event in respect to recovery time. Each damage states corresponds to an intensity measure to be determined by using the incremental dynamic analysis (IDA), and fragility surface. From the damaged states the preparedness of recovery procedure was adopted into three retrofitted actions. Firstly, no actions had been taken related to IO; secondly, the action was to apply a retrofitted application related to DC and LS; and thirdly, the action was at the replacement restoration process at CP level. Eventually, the SRI, functionality, loss of resilience and robustness were determined.

## 2 CONCEPTS OF SEISMIC RESILIENCE INDEX (SRI)

The Seismic Resilience Index (SRI) is considered as the main tool for studying the building ability to tolerate a particular standard of performance and reliability across a broad time control ( $T_{LC}$ ). In this paper, the SRI will be developed through applying different steps. Firstly, a model will be developed to the selected building by using finite element platform. Thereafter, ground motions for repeated earthquakes will be selected. Then, the IDA will be performed. This will all lead to the development of fragility surfaces and vulnerability curves. Finally, the functionality curve will be produced, which will help in estimating the SRI, Robustness (R), and Losses of Resilience (LOR). In order to develop the SRI and its functionality curve  $Q(t)$  the following steps should be tracked as shown and illustrated in Figure 1. Each step will be discussed in detail in the following section.

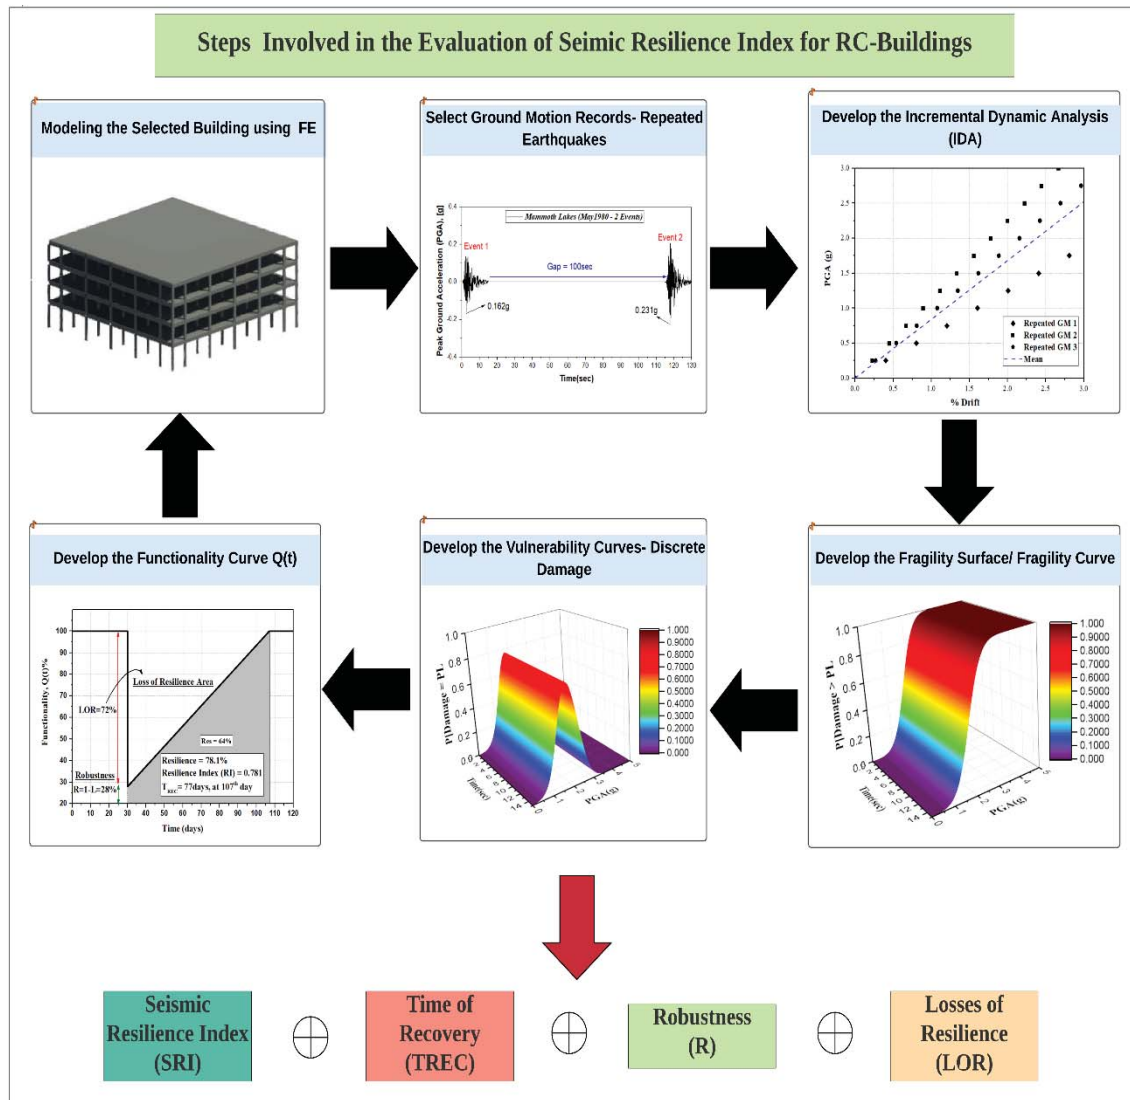

Figure 1: Framework steps for developing SRI.

## 2.1 Modelling structural configuration

A mid-rise model of a 4-storey reinforced concrete building with a total height of 12.0 m and with a common slab thickness of 200 mm was considered in this study. The structural system selected for lateral resistance is considered as Ordinary Moment Resisting Frame (OMRF). The model was designed according to the regulation of ACI318-14 code for gravity loads, and for UBC1997 as OMRF for seismic loads. With reference to the seismic code, the building was assumed to be in seismic zone 4, having soil profile SD, with  $C_a = 0.44$ , and  $C_v = 0.64$  seismic coefficients.

The building materials used were 35 MPa of concrete compressive strength ( $f'_c$ ), and yielding strength ( $f_y$ ) of 420 MPa for the reinforcing steel bars. The gravity loads consisted of dead load and live load which was taken as  $2\text{kN/m}^2$ , and  $4\text{kN/m}^2$ , respectively. The columns cross sections were selected with dimensions of 300 mm x 300 mm, with drop beams of 300 mm x 500 mm. The design calculations supported the use of minimum reinforcement ratio for column longitudinal rebars, which was 1%, whereby 8T12 was used for column reinforcements, with T8 spaced every 300 mm as transversal reinforcement. For the beams, the design expressed the use of 3T12 as bottom longitudinal reinforcement, and 2T12 as top reinforcement. Figure 2 shows the targeted selected building model in three-dimensional (3D) shape, and elevation views.

Figure 2: Selected targeted building model in 3D and elevation views.

## 2.2 Repeated ground motion selection

Many studies have considered the impact of repetitive earthquake-induced ground motions on the responsive behaviour of the structures. They found that both the inelastic displacement ratio and its inter-storey drift ratio were significantly influenced by the occurrence of frequent earthquakes. Therefore, in this study, the impact of repeated earthquakes is recognised.

Two real seismic sequences were allocated to each of the ground motion records, namely Chalfant Valley (July 1986 - two events), Imperial Valley (October 1979 - two events) and Mammoth Lakes (May 1980 - two events) from the same station with various record names. For each occurrence, each single ground motion record had a time interval of 15 sec. A gap time interval of 100 sec was added between the two consecutive seismic occurrences. As proposed by Hatzigeorgiou and Liolios [27], this gap had zero spite of potential acceleration values and was completely sufficient to reduce the displacement of any structure due to attenuating and returning to the remaining condition. The three repetitive events were selected from the Pacific Earthquake Engineering Research Center (PEER) database. The selected magnitude ( $M_w$ ) was between 5 and 7 Richter scale, and of intensity measure, PGA ranges between 0.113g, and 0.447g as shown in Figure 3.

Nevertheless, to perform the IDA and establish fragility surfaces or curves, the selection of appropriate ground motion records are very critical as recommended by international standard codes, such as FEMA356, UBC1997, IBC2000, and others [28-30]. These standard provisions also recommended to select a minimum of three ground motion records, or seven to develop a vulnerability assessment analysis. Finally, the selected earthquake events were scaled based on UBC97 target spectrum where the building was located.

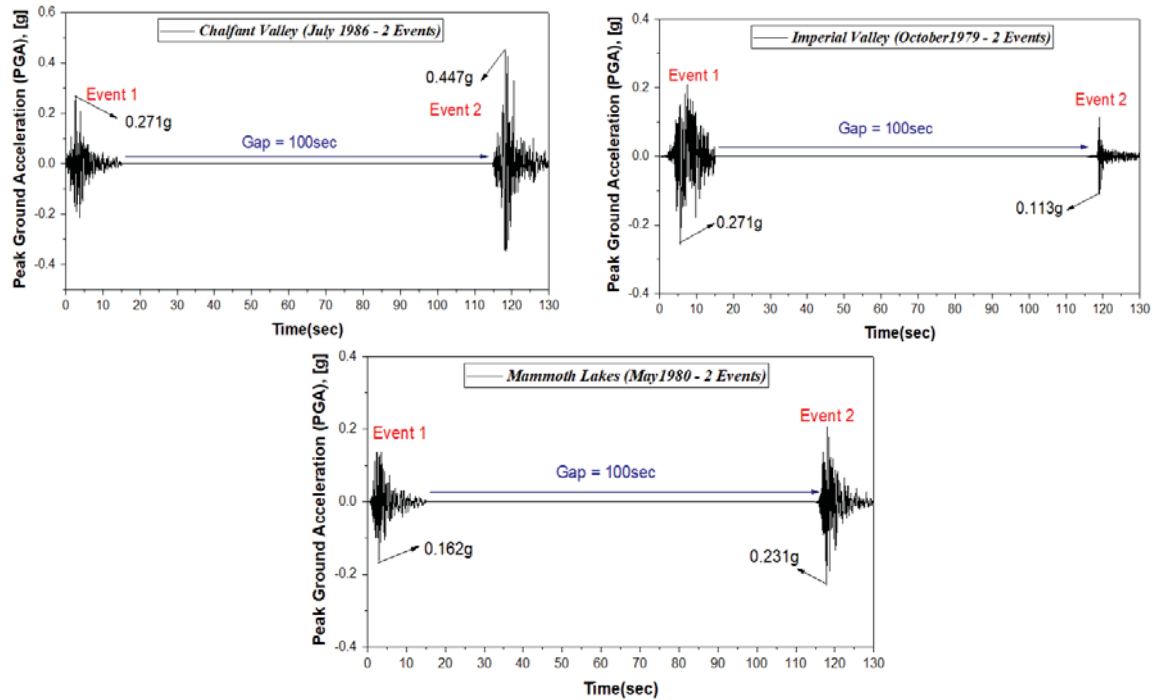

Figure 3: Selection of repeated ground motion seismic events.

### 2.3 Seismic resilience index functionality assessment procedure

Resilience is a specific consideration for evaluating the seismic resistance of the structures and infrastructures, as based on the Multidisciplinary Center for Earthquake Engineering Research (MCEER). Resilience is quantified ranging from 0% to 100% in terms of functionality to be normalised into 0 and 1 to develop its SRI, whereby 0% means spectacular failure and 100% reveals no structure deterioration. It is a wealth of information to develop the SRI as seismic indicator and a recovery application that can help to reduce direct and indirect losses caused by earthquakes.

The SRI is defined as the functionality of a structure after the recovery process or the ability of a structure to withstand earthquakes without any reduction in its functionality [31]. Also, the SRI can be treated as an alternative to deal with the problem of functionality which has been neglected in the seismic codes [32]. Therefore, the SRI is determined by referring to the functionality curves as shown in Figure 4. The area under the curve of functionality demonstrated the structure's resilience, whereby, the functionality of the structure was represented as  $Q(t)$ , as illustrated in Equation (1), and the resilience ( $R$ ) as a function of  $Q(t)$  and time of event ( $t_{OE}$ ) with recovery time ( $T_{REC}$ ) along the total control time ( $T_{LC}$ ), as shown in Equation (2).

Functionality :

$$Q(t) = 1 - \left\{ L(I, T_{REC}) \times [H(t - t_{OE}) - H(t - (t_{OE} + T_{REC}))] \times f_{REC}(t, t_{OE}, T_{REC}) \right\} \quad (1)$$

Resilience (R):

$$R = \int_{T_{OE}}^{T_{REC}} \frac{Q(t)}{T_{LC}} \quad (2)$$

Figure 4: Seismic Resilience with respect to time: Functionality curve.

## 2.4 Loss function evaluation

Losses are very unpredictable in an exceptional case, such as a terrorist attack, blast or other man-made catastrophe, and are different for any scenario discussed. The estimation of losses due to seismic activity is usually questionable and unpredictable. However, it is possible to make some common classifications and identify different types of losses.

Generally, the loss feature usually consists of two types of losses, such as direct losses and indirect losses. The direct loss is referred to structural damages and losses, whereas the indirect losses are referred to casualties, social and economic losses. Since the quantitative analysis of indirect financial damage and human casualties, losses is a complicated procedure, a lot of attention was given to the direct loss in this analysis, as it ultimately depends on the risk of the extensive structural damage.

The direct loss was calculated by using Equation (3) which was required to find the discrete damage probability of four damage states from the fragility surface as a vulnerability analysis. As per FEMA356, by taking into consideration the vertical and horizontal lateral-force resisting components, the state of structural damage during the earthquake determined the performance and output level of a building. These four-performance levels were classified and determined based on % Inter-Storey Drift Ratio (%ISDR) as an Engineering Demand Parameter (EDP). Table 1 describes performance levels of each damage state.

$$L_D = \sum P_E(DS = K) \times r_K \quad (3)$$

Where  $(L_D)$  is the direct loss,  $(K)$  represents the damage state of each performance level,  $P_E(DS = K)$  represents the discrete damage probability,  $(r_k)$  is the corresponding damage ratio for each limit state and damage state that was taken from HAZUS MR4 [33] technical manual, as shown in Table 2. The discrete damage was calculated from the difference between two cumulative distribution functions corresponded to develop fragility surface for each state, as shown from Equation (4) to Equation (8).

$$P[\text{Damage} > DS] = \phi\left(\frac{\ln(IM) - \lambda}{\varsigma}\right) \quad (4)$$

Where  $\phi$  is the cumulative distribution function, IM is an intensity measure,  $\lambda$  is the mean value, and  $\varsigma$  is the standard deviation.

$$P[DS = IO] = P[DS = IO] - P[DS = DC] \quad (5)$$

$$P[DS = DC] = P[DS = DC] - P[DS = LS] \quad (6)$$

$$P[DS = LS] = P[DS = LS] - P[DS = CP] \quad (7)$$

$$P[DS = CP] = P[DS = CP] \quad (8)$$

Damage State (DS)	Damage Description	% Inter-Storey Drift Ratio (%ISDR)
<b>Immediate Occupancy (IO)</b>	There is significant damage to the minor structural elements, but the building stability or lateral ability to resist prior and after the seismic is unaffected.	1.0%
<b>Damage Control (DC)</b>	A certain quantity of repairable damage is appropriate, but the repair cost should be substantially lower than the replacement value.	1.50%
<b>Life Safety (LS)</b>	Due to the higher damage, repair is feasible but economically inefficient and costly. The loss is moderate, but the structure stays stable.	2.0%
<b>Collapse Prevention (CP)</b>	The structure is on the threshold point of local or complete failure being experienced.	2.50%

Table 1: Damage state performance levels description and its damage measures

Damage State (DS)	Damage Ratio ( $r_k$ )
Immediate Occupancy (IO)	0.10
Damage Control (DC)	0.40
Life Safety (LS)	0.80
Collapse Prevention (CP)	1.0

Table 2: HAZUS MR4 technical manual for damage ratios of buildings

## 2.5 Recovery function and time

The progress and the pattern of the structure's post-seismic event rehabilitation will be represented through recovery functions and time. Therefore, for evaluating seismic resilience, recovery time and recovery function are crucial after a seismic event, hence, it should be precisely measured. There are different types of recovery function that could be selected depending on the system and society preparedness response, for example, three possible recovery functions are: linear, exponential, and trigonometric. Where the recovery improvements of the building vary according to the type of recovery functions, it is included to assess the building's functionality, since each function has its own path of restoration. In this study, the linear function is considered to evaluate the building functionality, whereby it is the simplest function commonly used when there is no information available about crisis management and resources. The equations (9, 10 and 11) show the different types of functions that may be used to develop the recovery time and its function path.

Linear function: 
$$f_{rec}(t, t_{OE}, T_{REC}) = \left(1 - \frac{t - t_{OE}}{T_{REC}}\right) \quad (9)$$

Exponential function: 
$$f_{rec}(t, t_{OE}, T_{REC}) = \exp\left(-\frac{(t - t_{OE})(\ln 200)}{T_{REC}}\right) \quad (10)$$

Trigonometric function: 
$$f_{rec}(t, t_{OE}, T_{REC}) = 0.5 \left\{ 1 + \cos \left[ \pi \frac{(t - t_{OE})}{T_{REC}} \right] \right\} \quad (11)$$

## 3 RESULTS AND DISCUSSION

The numerical model of the mid-rise building was developed by using the Finite Element (FE) platform, where the nonlinear time history analysis was generated to develop the incremental dynamic analysis curve. From the IDA curves, the relationship between %ISDR and spectral acceleration of first periodic mode  $S_a(T_1)$  could be determined, and thus, it determined the performance level of the structure based on 4-performance limit state as shown in Figure 5. Where the damage of measured  $S_a(T_1)$  of the repeated earthquakes were increasingly scaled by 0.05 g until it exceeds 2.0 g, the analysis was stopped due to the instability of the structure. The IDA curves are considered an important parametric tool, which evaluates the dynamic behaviour of the structures. This curve clarifies that the building performance is linearly in rapid changes between the damaged states, by which it tends to undergo into three restoration options that will be taken into consideration during post seismic events. The options are; no action at IO stage, restoration action at DC and LS stage, and replacement action at CP stage.

For example, in case of immediate occupancy, no retrofitting action is needed to be applied before exceeding 0.78 g. However, once it reaches the damage control and life safety stages at 1.24 g, and 1.54 g, respectively, it is recommended to apply a retrofitting action before it reaches the collapsed stage, whereby the replacement action is the only choice at 2.15 g and more. Table 3 summarises the structural performance levels, and types of preparedness actions.

Damage State	IM of each Damage State- $S_a(T_1)$ , [g]	Preparedness Action of each Stage
Immediate Occupancy	0.78g	No Action
Damage Control	1.24g	Restoration- repairing action
Life Safety	1.54g	Restoration- repairing action
Collapse Prevention	2.15g	Replacement action

Table 3: IM of each damage state and its preparedness actions.

Figure 5: Incremental dynamic analysis curve under repeated earthquakes.

After performing the IDA, the fragility surface and the fragility curve for each damaged state was developed to determine the probability of reaching or exceeding the damaged state at certain Intensity Measure (IM). In this research, the spectral acceleration  $S_a(T_1)$  was chosen as it was used to perform the nonlinear analysis of time history, as well as the seismic events periodic time was selected as another parameter to be used in developing the fragility surface in order to study the effect of 15 sec seismic events with 100 sec gap between two repetitive earthquakes. The mean and standard deviations are needed to establish the fragility surface assessment as shown in Table 4.

Damage State	IO		DC		LS		CP	
	$\lambda$	$\varsigma$	$\lambda$	$\varsigma$	$\lambda$	$\varsigma$	$\lambda$	$\varsigma$
Log-normal parameters for mid-rise building	0.899	0.249	1.333	0.386	1.794	0.517	2.22	0.631

Table 4: Log-normal distribution parameters for developing fragility surfaces for each damage state.

Figure 6 presents all set of fragility surface. The study focused on four intensity measures (1.0 g, 1.5 g, 2.0 g, and 2.5 g) for further applying the preparedness actions of recovery in respect to 15 sec of two repetitive seismic events without considering the 100 sec periodic gap. When 1.0 g ground motion intensity was applied, the building still behaved in the immediate occupancy level with a probability of reaching or exceeding damages of 66%, whereby the rest of the damaged states achieved 19%, 6%, and 2.5% for damage control, life safety, and collapse prevention states, respectively. However, when the structure was exposed to higher intensity measure of 1.50 g, the structure was between two damaged states of damage control and life safety. Whereas, a certain quantity of repairable action was appropriate to be applied with a probability of reaching or exceeding the states of 67%, and 28%, respectively, with slight increases for the collapse stage with 12% possibility of damage. Furthermore, at intensity measure of 2.0 g, the restoration process was mandatory where the loss was moderate, but the structure stays stable that could be classified at life safety stage with probability of reaching the damage of 65%, and 35% for collapse prevention state. Finally, with regard to the IDA curves, when the ground motion intensity surpasses 2.0 g, the structure would suffer from extensive damages and the structure would behave on the threshold point of local or complete experienced damage by achieving 100% probability of damages for the life safety stage. Furthermore, it started to

face a crucial damage by achieving probability of damages of 66% at 2.50 g. Therefore, after analysing the structure through the vulnerability examination, starting with IDA, and finishing with the fragility surface, it was clearly identified that due to its ordinary design moment frame system, the building did not have the ability to resist a 15 sec repetitive earthquake. In addition, the implementation of the resilience assessment was important to plan the recovery process for four different damage states by investigating the structure's functional resilience, degradation, robustness, and recovery time post-seismic events. Table 5 represents the percentage of cumulative damage probability of exceedance for the four damage states.

Figure 6: Fragility surfaces for each performance damage state.

Intensity Measure, $S_a(T1)$ , [g]	IO	DC	LS	CP
<b>1.00g</b>	66.00%	19.00%	6.00%	2.50%
<b>1.50g</b>	99.00%	66.00%	28.00%	12.00%
<b>2.00g</b>	100%	95.00%	65.00%	36.00%
<b>2.500g</b>	100%	100%	91.00%	66.00%

Table 5: Probability of damage using CDF for each damage state.

In order to find the SRI and its functionality, the discrete damage probability should be calculated by using Equations (5) to (8). The discrete damage probability was computed from the vulnerability analysis obtained from the fragility surface, known as cumulative distribution function. Table 6 presents the discrete damage probabilities due to post seismic events for each damage state. Subsequently, the direct damage loss ( $L_D$ ) ratio could be computed by the product of  $P_E(DS = K)$  with the damage ratio ( $r_K$ ) as illustrated in Table 7.

Intensity Measure, $S_a(T1)$ , [g]	IO	DC	LS	CP
<b>1.00g</b>	47%	16%	4%	3%
<b>1.50g</b>	32%	38%	16%	12%
<b>2.00g</b>	4%	30%	30%	36%
<b>2.500g</b>	0%	9%	25%	67%

Table 6: Discrete damage probability for different IMs and DS

Intensity Measure, $S_a(T1)$ , [g]	1.0g-IO	1.5g-DC	2.0g-LS	2.50g-CP
<b>Direct Loss (<math>L_D</math>)</b>	0.164	0.438	0.721	0.898

Table 7: Direct damage loss ratio for different IM and DS as a preparedness stages

For instance, the time needed for the recovery approach depends on the damage level of the structure. The time required for full recovery was deemed in this study between the time of occurrence ( $t_{OE}$ ) of seismic event as minimum period, and the control time ( $T_{LC}$ ) as the maximum period. In this study, the time occurrence was assumed to be taken at the 30<sup>th</sup> day of the 120 days of the total control period. This study focused on three types of preparedness actions for different retrofitting stages, which were IO, DC, LS, and CP with different intensity measures of 1.0 g, 1.50 g, 2.0 g, and 2.50 g. These preparedness actions were: No action, retrofitting action, and replacement action based on calculating the SRI and its functionality curve. At 1.0 g represented by IO retrofitting stage, the recovery time was set at 37<sup>th</sup> days which is seven days after earthquake time occurrence to return back to its functionality as before the earthquake. This means that no rehabilitation process needs to be performed. In terms of functionality, the building SRI at this stage was equal to 91.8% (0.918), with robustness of 83.6%. On the other hand, as the ground motion acceleration becomes higher reaching 1.50 g, which was represented by DC retrofitting stage, the recovery time was set to be at 54<sup>th</sup> days which was 24 days after seismic action occurrence, which means a simple retrofitting application is needed for restoration process. Whereas, at this stage the SRI decreased to 78.1% (0.781), with an approximate of 37% drop in its robustness to 56.2%.

Moreover, at the life safety retrofitting stage with 2.0 g, the recovery time was set at 107<sup>th</sup> days from total time control which equals to 77 days after the seismic time occurrence. The building requires a quick retrofitting action to be taken before it reaches the collapse stage, with losses of more than 72% from its robustness, with SRI equals to 64% (0.64) where the robustness equals to 28%.

Furthermore, at the collapse stage the retrofitting actions was not applicable, because the structure resilience loss exceeded 90%, where the structure robustness equals to 11%. Besides, the recovery time was set at 200<sup>th</sup> days which was 170 days after time occurrence, which means it exceeded the total time control, and it was beyond control to apply any of the rehabilitation process. In this stage, at 2.50 g the replacement action was the only option that could be applied, where the building SRI and its functionality equals to 55% (0.55). Although, during the total

time control of 120 days, the functionality of the structure equals to 33% (0.33). Figure 7 shows the variation of functionality curve with respect to time by using the linear function. Furthermore, the shaded area below the functionality curve represented the seismic resilience of the structural system. Table 8 summarises the resilience index, robustness, and losses for each damaged state.

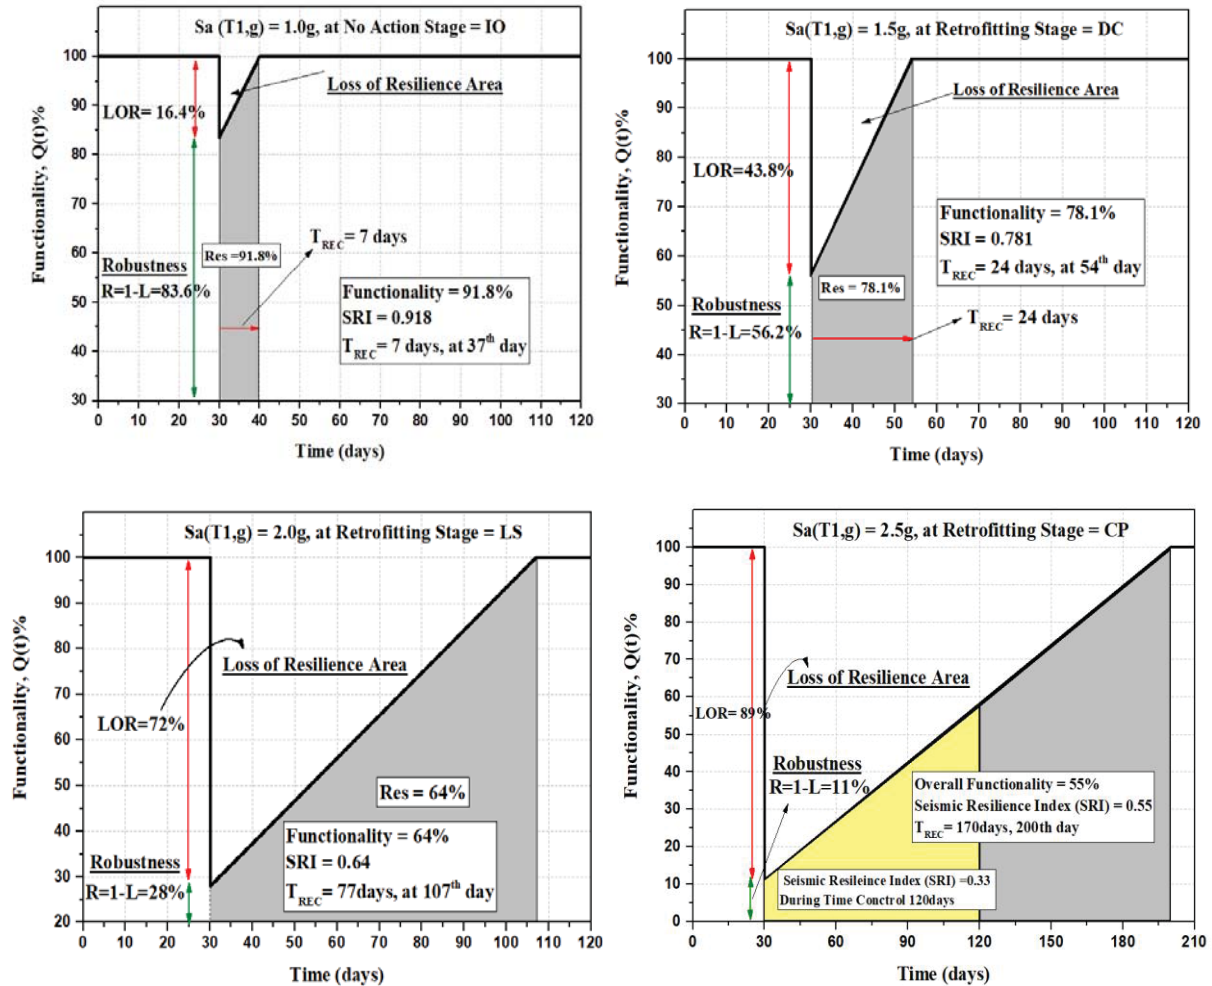

Figure 7: Functionality resilience curves for different preparedness stages.

Seismic Resilience Outcomes	IO	DC	LS	CP
Seismic Resilience Index (SRI)	0.918	0.781	0.64	0.55
Robustness (R)	83.6%	56.2%	28%	11%
Loss of Resilience (LOR)	16.4%	43.8%	72%	89%
Time Recovery ( $T_{REC}$ )	7 days	24 days	77 days	170 days

Table 8: Seismic resilience output results for the targeted building

## 4 CONCLUSION

The aim of the analysis was to determine the impact of the proposed repetitive seismic acceleration on the seismic resilience capability of the Ordinary Moment Resisting Frame (OMRF) building by applying a set of vulnerability assessment.

- From this analysis, the fluctuation in functionality, resilience index, robustness, structural losses, and time recovery of different performance levels could be predicted with an increase in the potential seismic ground acceleration (1.0 g, 1.50 g, 2.0 g, and 2.50 g), which was needed for the post-seismic event strategic recovery planning.
- It could be shown that the increase from 1.0 g to a maximum of 2.50 g as a seismic intensity measure for different damaged states resulted in a substantial increasing trend in the damage loss ratio that further influenced the structure's functionality. As well as it increases the time recovery for the structure to compensate its strength as before the seismic event.
- The disparity in seismic resilience demonstrated the effect of ductility capability and demand ductility of the OMRF structure at the post-seismic event for the various ground accelerations.
- The outcomes showed that despite the performance level, the seismic resilience for different damaged states had to be taken into consideration to assess the seismic vulnerability and functionality of the structural behaviour.

### Abstract

*Several European countries are likely to experience extensive damage following major earthquakes due to high vulnerability and exposure, associated with the age of the built environment and the presence of densely populated areas, respectively. For these reasons, large-scale seismic risk assessment has a pivotal role. Given the large number of buildings to be assessed, indirect methods are usually the preferred option. However, simplified methodologies for reinforced concrete buildings have been recently developed, predominantly using non-linear time history analyses, and have shown to be a suitable alternative to indirect approaches. Simplified methodologies represent buildings as multi-degrees-of-freedom “stick-like” models, with the inter-storey behaviour modelled through an equivalent spring. These methodologies considerably reduce the computational effort yet achieving comparable accuracy with rigorous analyses. A major limitation of these methodologies is that they are applicable only to shear-type buildings, regular both in plan and in elevation. Aimed at overcoming this gap, the present work proposes a simplified method applicable to both regular and irregular reinforced concrete buildings. More specifically, each column is modelled separately with two uncoupled springs, one in each principal direction, to capture the torsional behaviour while retaining high computational efficiency. The proposed method is applied to a case study to demonstrate its capabilities.*

## 1 INTRODUCTION

Cities are densely populated areas that may experience extensive damage and casualties in the occurrence of major earthquakes. Hence, large-scale seismic risk assessment is of paramount importance to assess expected damage and plan mitigation strategies. Given the high number of buildings to be assessed, indirect methods have been preferred to methods based on detailed structural analyses that use Finite Element (FE) modelling. More specifically, models based on vulnerability indices [1], or on the classification of buildings into typological classes (e.g. [2] and [3]) have been developed. More recently, Polese et al. [4] proposed an innovative method based on buildings inventory (combining Census-based data and interview-based CARTIS approach) and seismic damage assessment. Indirect methods have demonstrated to provide acceptable results in a general framework. However, their reliability is strictly dependent upon the amount and quality of data and they are drastically simplified with respect to a detailed modelling approach. Direct methods include the capacity spectrum method [5], which adopts Single-Degree-Of-Freedom (SDOF) building models and pushover (PO) analysis to predict damage. Lu, Xinzhen et al. [6] showed that the method provides a good estimation of global building behaviour (in terms of strength and ductility), with moderate computational effort but it has important limitations, e.g., it cannot represent concentration of damage at the different storeys.

Recently, as the computational power increases and becomes more easily available, direct Non-Linear History Analysis (NLHA)-based methodologies have become increasingly popular (e.g., [7], [8] and [9]). In this way, it is possible to fully describe the characteristics of the soil on which buildings are based (in time and frequency domain) through suitable ground motion selection, or more sophisticated approaches, along with the non-linear characteristics of the buildings [6]. These methodologies require a direct simplified model for buildings, to compute the Engineering Demand Parameters (EDP) (e.g., inter-storey drift, peak floor acceleration) needed to predict damage. Typically, buildings are directly implemented, usually as Multiple-Degree-Of-Freedom (MDOF) shear systems. More specifically, each storey is represented by a concentrated mass and a non-linear spring, thus considerably reducing the computational effort compared to refined models, yet increasing the accuracy compared to the indirect procedures. Backbone curves of springs are calibrated based on simulated design procedure [7] or adopting a multi-objective Genetic Algorithm (GA) procedure that employs the results of non-linear cyclic pushover analyses done on refined non-linear models (e.g., [9]).

A drawback of the simplified models developed to date is that they are applicable only to shear-type buildings, regular both in plan and in elevation. This drawback is relevant for two main reasons:

- structural irregularities, due to non-symmetric distribution of load resisting elements (stiffness and strength eccentricity) and non-symmetric distribution of masses are particularly common in old buildings;
- torsion can adversely affect the seismic performance of buildings with any type of eccentricity [10], [11] and [12].

For these reasons, a simplified model capable of capturing the torsional behaviour of buildings is needed for NLHA-based methodologies. In this work, a model is proposed which aims to represent the flexural and torsional behaviour of Reinforced Concrete (RC) frame structures in a simplified and light-computational manner. The applicability of the model is general since it is suitable for different structure configurations, not necessary shear-type. It can reproduce the behaviour not only of regular buildings, but also of irregular buildings with torsional behaviour, that have not been considered before. The main software used is OpenSees

along with STKO [13], a Graphical User Interface (GUI) with a pre and post processor for OpenSees.

## 2 METHODOLOGY

In the proposed simplified model, the building is represented by a three-dimensional (3D) MDOF model, fully described by the columns. The non-shear-type behaviour of the building is achieved by adopting calibrated shear-inter storey drift (V-ID) curves for each column. At the local level, each column is represented by two uncoupled translational springs in the two main horizontal directions. If the centre of mass and the centre of stiffness of the building do not coincide, coupling is automatically achieved at the global level, see Figure 1, thus capturing the torsional behaviour.

Each column is modelled in OpenSees as a *zeroLength* element with two nodes. A rigid material is assigned to all the Degrees Of Freedom (DOFs), except for the translations along the local axis (2) and (3) (assuming the local axis (1) always directed along the axis of the column) and for the rotation against the local axis (1) (torsion), which is kept released. Calibrated backbone curves are assigned to the two translational DOFs (see Figure 1).

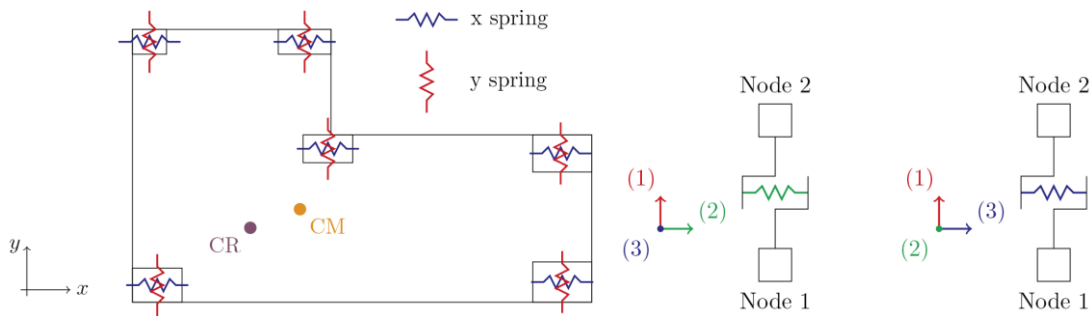

Figure 1. (left) Scheme of the general idea for the storey model (CR: Centre of Stiffness, CM: Centre of Mass); (right) model of the springs, in local axes (2) and (3).

Each spring is defined by an appropriate V-ID backbone curve, that represents the column behaviour in the considered direction. First, an analytical parameter-dependent V-ID curve is defined. A trilinear curve is adopted, and no refined models are needed for this first step. In a second phase, the parameters are calibrated to represent the behaviour of the column in its configuration (e.g., boundary conditions), accounting implicitly for beams flexibility. To derive the analytical parameter-dependent V-ID curve, the method stems from the definition of a trilinear sectional moment-chord rotation ( $M-\theta$ ) curve, which can be simply defined independently from column boundary conditions. The model proposed by Ibarra [14] is used in this work. Using basic structural mechanics relationships and assuming a shear-type configuration for the column, the  $M-\theta$  curve is used to find the corresponding analytical shear-type V-ID curve, which maintains the same shape of the  $M-\theta$  curve, see Figure 2.

Figure 2. (left) column model with two end rotational springs; (centre) moment-rotation ( $M-\theta$ ) curve by [14]; (right) V-ID curve for the column under the shear-type assumption.

The expressions for the points defining the shear-type V-ID relationship are then modified through a set of five parameters and are presented in Eq. 1 (for details on moment/rotation calculation see [14] and [15]).

$$\begin{aligned}
 V_{40} &= 2 M_{40}/L \cdot \mu & ID_{40} &= \theta_{40} \cdot L/\alpha \\
 V_Y &= 2 M_Y/L \cdot \mu & ID_Y &= \theta_{40} \cdot L/\alpha + (\theta_Y - \theta_{40}) \cdot L/\beta \\
 V_U &= 2 M_U/L \cdot \kappa & ID_U &= \theta_{40} \cdot L/\alpha + (\theta_U - \theta_{40}) \cdot L/\beta \\
 V_C &= 0 & ID_C &= \theta_C \cdot L/\gamma
 \end{aligned} \tag{1}$$

Changes in the values of the parameters (i.e.,  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\mu$ ,  $\kappa$ ) modify, in turn, the shape of the V-ID curve. The value of each parameter can be adjusted to represent the realistic behaviour of the column. Indeed, the analytical curves were purposely defined such that the values of the parameters could be directly retrieved making use of some data-driven techniques (e.g., machine learning) that, once developed, would make the definition of the final curve a rapid process. However, the development of this algorithm is beyond the scope of this paper and will be addressed in future works.

Refined reference curves are used in this work. In this perspective, parameters are found by comparison between the analytical and the numerical curves, either by trial-and-error process (i.e., manually changing the values until the approximation is acceptable) or making use of more automatised and accurate procedures. The latter approach is adopted herein, more specifically the parameters values are evaluated using a GA procedure, with the objective of finding the parameters for which the error between the numerical and analytical curves, see Eq. 2, is minimized. More insights about the proposed methodology can be found in [16].

$$\sqrt{\sum_i (V_{numerical,i} - V_{analytical,i})^2} \tag{2}$$

### 3 CASE STUDY

The building considered as case study is adapted from a structure dating back to the 1970s [17], whose characteristics have been slightly modified for the purpose of the current work. The building has three storeys, the first storey is 3.4 m high, the second and third storeys are 3.05 m high. The length of all spans is 3.75 m. Column sections may be divided into three groups, indicated in the following as CA, CB, and CC, see Figure 3. Within each group, columns have also different sections for each floor. Moreover, columns at the first, second and third storey are subject to an axial load of  $0.1 P_{cu}$ ,  $0.2 P_{cu}$  and  $0.3 P_{cu}$ , respectively, where  $P_{cu}$  is the ultimate axial compressive bearing capacity of the column. Beams are all deep with section 30 cm x 50 cm. The concrete and steel reinforcement properties are  $f_c = 23.5$  MPa,  $f_y = 440$  MPa. They are taken from [17] and represent mean values.

A detailed model is considered as benchmark for the simplified model. Both the columns and the beams are modelled as lumped plasticity elements. The model is fixed at the base and a rigid diaphragm is implemented at each storey level. The axial loads are applied as concentrated forces and the masses are added as nodal masses, equal in the three translational DOFs. A Rayleigh damping of 5% is applied, taking as reference the first and second frequencies of vibration of the structure, as derived from the modal analysis.

The simplified model is built as described in Section 2. Figure 4 shows the calibration of the V-ID curves for the frame 2Y of Figure 3. A set of all five coefficients equal to 1 would mean that the shear-type model perfectly captures the behaviour of the specific column.

Figure 3. Plan view of the case study building; identification of frame 2Y.

Figure 4. Comparison of analytical (shear-type), numerical and analytical (calibrated) V-ID curves for frame 2Y.

### 3.1 Pushover analysis

A pushover analysis is performed on both detailed and simplified models along both x and y axes of the model (see Figure 1). The pushover load is applied by following a uniform distribution along the height, hence the same load is applied at each storey, at its centre of mass (CM). The load is applied with 2,000 increments through the *DisplacementControl* static integrator in OpenSees, setting the top CM as control node and a target displacement of 0.2 m (corresponding to an average roof drift ratio of  $\sim 2\%$ ). The analysis is repeated in both global horizontal directions, x and y, and results are investigated in the direction of loading.

Results are compared by plotting the total base shear-top displacement curve and the Interstorey Drift Ratio (IDR) values along the height. Figure 5 and Figure 6 show results for the analysis in the x and y directions, respectively. Results show good correspondence between the two models, with the larger differences found in the analysis performed in the global y

direction. Yet, the simplified model underestimates the maximum base shear by only 2.3%. A final comparison is shown in Figure 7, where the deformed shape of the structure at a fixed time instant (step 1,000) is plotted. Both figures refer to the pushover in y, where the torsional behaviour is more evident, and show that the torsional behaviour of the building is perfectly captured by the simplified model.

Figure 5. Results from the pushover in x, base shear-top displacement and height-IDR plots.

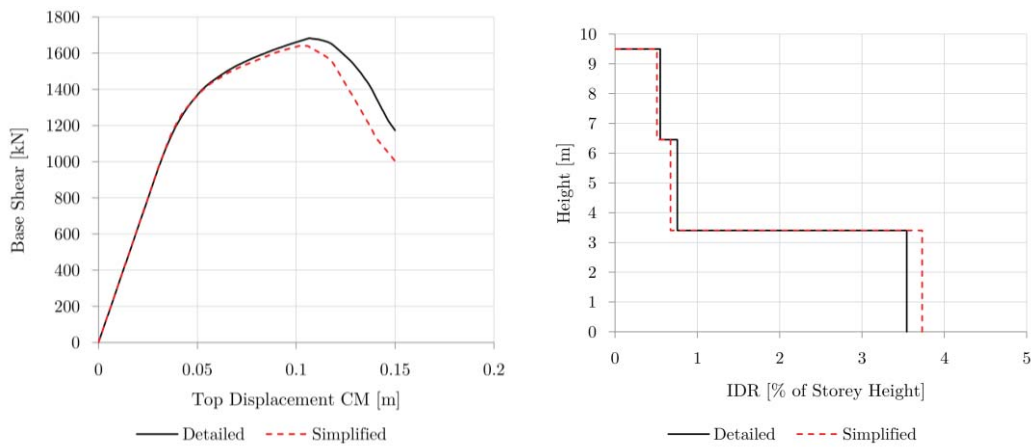

Figure 6. Results from the pushover in y, base shear-top displacement and height-IDR plots.

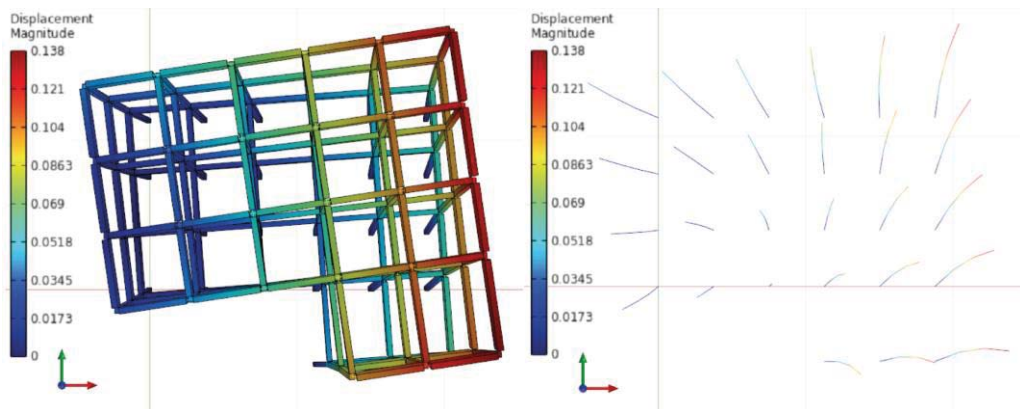

Figure 7. Results from the pushover in y, deformed shape at step 1000 for the (left) benchmark detailed model and (right) simplified model; colours represent the displacement in y (units: m).

### 3.2 Non-Linear History Analysis

A non-linear history analysis is performed on both the detailed and simplified models. The signal is a natural accelerogram selected from the PEER NGA database, related to the Imperial Valley earthquake of 1979, see Figure 8. The PGA is 0.24 g, and the total duration of the signal is 50 s.

Figure 8. Imperial Valley accelerogram used to perform NLHA.

The acceleration history is defined in STKO as a path time series and is applied through the *UniformExcitation* command. The analysis is performed using the Newmark transient integrator with parameters  $\beta = 0.25$  and  $\gamma = 0.5$ . The time step is 0.01 s and is taken also as time step for the analyses, deriving consequently the initial total number of steps. The adaptive time step is used in the detailed model to achieve convergence. The analysis is first performed separately in the global x and y directions. Then, a last analysis in which the seismic load is applied to both the global directions, x and y, is performed. Due to the non regularity of the building, the results are investigated in both directions. For brevity, only the analysis with the load applied in both directions and the results in the y direction are shown herein. Results from other analyses indicate very similar behaviour, for more details, see [16].

Results in terms of maximum base shear as absolute value show differences lower than 0.5 %, see Table 1 and Figure 9. The negligible difference is further confirmed by the total base shear-top CM displacement plots, see Figure 10. In terms of EDP, the IDR is the parameter that is best represented by the simplified model, with very small differences. The Peak Floor Acceleration (PFA) results show a very good correspondence between the two models too, see Figure 11.

The simplified model presents significant advantages in terms of computational efficiency reaching convergence much faster, with an overall shorter analysis duration. The gain in computational efficiency is more evident when NLHA are performed. More specifically, in the non-linear dynamic case, the simplified model shows a reduced analyses duration to approximately 1/4 of the computational time necessary to bring the detailed model to convergence in a case where no convergence issues arise, and up to approximately 1/100 when convergence problems in the detailed model arise, thus the time step needs to be reduced. The latter case is the one experienced in most of the analyses performed.

Table 1. NLHA - Imperial Valley signal, analysis in x+y, results in terms of maximum base shear.

		Simplified	Benchmark	Relative Difference
Max Base Shear [kN]	x	1513.0	1516.5	0.2 %
	y	1791.7	1786.0	0.3 %

#### 4 SUMMARY AND CONCLUSIONS

In this paper, a simplified model for reinforced concrete buildings that is suitable for large scale non-linear history analysis-based seismic assessment was proposed. The novelty of the proposed model is the applicability also to non-shear-type configurations and the ability to capture the torsional behaviour of irregular buildings. Both aspects are very common when

dealing with an existing building stock. The proposed model is a three-dimensional multiple degree of freedom column-based model, in which each column is represented by two uncoupled translational springs. In this way, coupling at the global level can be automatically obtained, making the model able to represent torsion. The non-shear-type behaviour is instead achieved by specific calibration of the shear-inter-storey drift relationships for the column backbone curves. Refined analyses on two-dimensional sub-frames together with a genetic algorithm are used in this work, however the analytical expressions developed to describe the shear-inter-storey drift curves are suitable for employment in a more efficient data-driven procedure that will be addressed in future research.

The benchmark analyses showed a very good correspondence between the refined and simplified results, both in terms of non-linear static and non-linear dynamic analyses. As for non-linear history analyses, the simplified model is perfectly suitable to represent the base shear history with negligible difference in terms of maximum base shear results. The investigated engineering demand parameters (i.e., inter-storey drift ratio and peak floor acceleration) are correctly captured by the simplified model, too. The model is accurately able to represent the torsional behaviour of the building. In terms of efficiency, the proposed model led to faster convergence and considerable decrease in computational times, making it a competitive option for large-scale assessment applications.

### Abstract

*The demand for a reliable modelling of steel structures introduces the need for the implementation of advanced techniques. Due to the shape and the properties of steel members, as well as the connections among them, the performance of materially and geometrically non-linear analyses are required in order to approach effectively the actual behavior of the steel structures. To this end, special calculation tools must be available in the software which is used for analysis and design. More specifically, phenomena such as the bending, the torsional and the torsional-flexural buckling as regards the geometric non-linear effects, and the elasto-plastic behavior of steel in critical cross-sections, as regards the materially non-linear effects, require the implementation of appropriate stiffness matrices and load vectors. These calculation tools are available in the literature. However, the inclusion of all required features in a finite element demands a specific formulation. Therefore, the purpose of the present paper is to propose the formulation of a two-noded macroelement with seven degrees of freedom per node, which possesses abilities to model effectively the above-mentioned phenomena in practice. On the basis of a two-stage static condensation technique, the proposed finite element includes features appropriate for the modelling of material non-linearity effects and the semi-rigid connections (through non-linear rotational springs), as well as the modelling of the geometric non-linear effects (using appropriate finite element formulation), and the influence of the rigid joints (through rigid offsets). The proposed macroelement was successfully added to the finite elements' library of an existing professional software for the analysis and design of steel structures. The reliability of the proposed element is tested in the current paper using the solutions of well-known problems selected from the literature.*

## 1 INTRODUCTION

The analysis and design of members of steel structures require the implementation of specific modelling techniques (see e.g. [1-3]). The requirement of these techniques arises from the fact that the shape and the load conditions of steel beams and columns make them sensitive to the consequences of phenomena which are related with geometric and material nonlinearities. Such phenomena are, for example the bending buckling, the torsional and torsional-flexural buckling as regards the geometric non-linear effects, and the elasto-plastic behavior of steel in critical cross-sections, as regards the materially non-linear effects. The existence of these unfavorable influences on the steel members has been recognized by the former, as well as by the modern, seismic codes, e.g. [4, 5]. Thus, the problem of the effective design of steel structures against static or dynamic (e.g. seismic) loads is treated in the cross-section and member levels. For this reason, specific recommendations are proposed which, however, require the appropriate (and most accurate possible) modelling. A significant number of research studies (e.g. [6-10]) and scientific books (e.g. [11-13]) focused on the effective modelling of steel members have been published. The existing theories regarding the elasto-plastic behavior of steel, as well as the continuous improvement of finite element formulation in combination with the computational abilities of the modern hardware, offer the possibility of a more effective approach to the behavior of steel structural members.

In the current paper, the formulation of a new two-noded macroelement with seven degrees of freedom per node, which can effectively model steel structures members in practice, is presented. Based on a two-stage static condensation technique, the proposed formulation includes features appropriate for the modelling of material non-linearity effects and the semi-rigid connections (through non-linear rotational springs), the modelling of the geometric non-linear effects (using appropriate finite element formulation), and the influence of the rigid joints (through rigid offsets). Using the static condensation method, the proposed element, with 14 degrees of freedom, can be compatible with the classic two-noded elements (with 12 degrees of freedom) and co-exist with them in structures' models. Thus, the problem of the design of steel members in the cross-section and member levels can be handled practically using a compact formulation. The reliability of the proposed element is tested using the solutions of well-known problems selected from the literature.

## 2 FORMULATION OF THE PROPOSED MACROELEMENT

### 2.1 General description of the element

The proposed macroelement consists of three segments, as shown in Figure 1. More specifically:

- the end segment between the external node 1 and the internal (virtual) node 2, and the corresponding end segment between the internal (virtual) node 3 and the external node 4. In each one of these segments, three absolutely rigid rod elements (perpendicular between them) are defined. These elements are the three spatial components of the end rigid offsets (in the local coordinate system of the macroelement) which model the bodies of beam-to-column joints.
- the median segment between the internal nodes 2 and 3. This segment models the flexible part of the macroelement. The type of finite element which is used in this segment can be selected on the basis of the considered problem. For example, Bernoulli or Timoshenko beam elements can be used (see eg. [14]). In the present paper, the formulation which is used for the modelling of the median segment will be described in the following sections.

The connection of the median segment to the rigid offsets is achieved by means of rotational springs. These springs can be considered either as linear for (1<sup>st</sup> or 2<sup>nd</sup> order) elastic analyses, or as nonlinear (in conjunction with  $M-\phi$  diagrams) for materially non-linear analyses in the framework of the concentrated plasticity model.

Figure 1: General description of the proposed macroelement

In Figure 1, the degrees of freedom (d.o.f.) of the proposed macroelement are also illustrated. It can be seen that they are 12 in number, as in case of the classic beam/column elements. The 7<sup>th</sup> d.o.f., which is required for the modelling of the effect of warping, is considered only in the median segment. Thus, the median segment can be an element with 14 d.o.f. The procedure of the transformation of the 14 d.o.f. of the median segment to the 12 d.o.f. of the whole macroelement will be described in sections 2.2 and 2.3.

## 2.2 Stiffness matrix derivation

The stiffness matrix of the macroelement is derived in two steps. In the first step, the stiffness matrix of the median segment's element is formed. In the second step, the matrix relation between the stiffness matrix of the median segment and the stiffness matrix of the macroelement is formulated. This relation demonstrates the effect of the rotational springs and the rigid offsets on the stiffness matrix of the macroelement.

### A) Step 1: Derivation of the stiffness matrix for the median segment

The method for the derivation of the stiffness matrix of the median segment's element is based on the static condensation procedure (e.g. [15,16]). In general, static condensation is used in order to reduce the number of the equations which constitute the system of equations of equilibrium. In the present case, static condensation is necessary due to the fact that the stiffness matrix of the median segment is based on the approach of the displacement field through algebraic interpolation functions. These functions are used when the 7<sup>th</sup> d.o.f. must be considered for the modelling of the warping effect, because, in this case, the exact solution of the corresponding differential equations of equilibrium is not available. Thus, the discretization of the median segment is necessary. This discretization causes the increase of the nodes and, consequently, the increase of the d.o.f. of the macroelement. Moreover, when the 7<sup>th</sup> d.o.f.

is considered, the corresponding elements' stiffness matrices are 14x14 matrices, not compatible with the classic 12x12 stiffness matrices which are mainly used in practice.

For this reason, in the present paper, the implementation of the static condensation procedure in two stages is proposed (Figure 2). In the first stage, all the internal d.o.f., which arise from the discretization of the median segment's element, are condensed. Thus, if the number of the sub-elements in which the median segment is discretized is  $n$  (using  $n+1$  nodes:  $n-1$  internal and 2 external), then the corresponding stiffness matrix is a  $[7(n+1)] \times [7(n+1)]$  matrix.

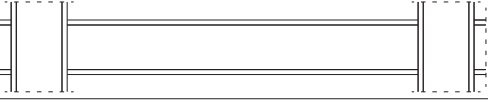

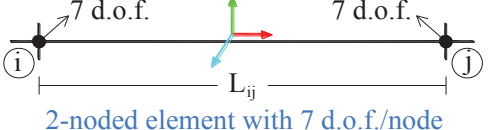

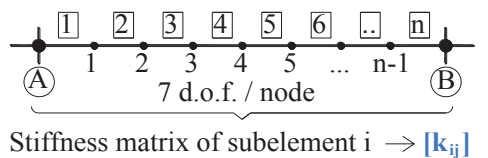

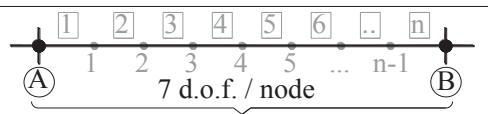

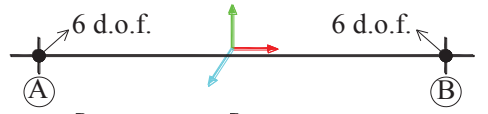

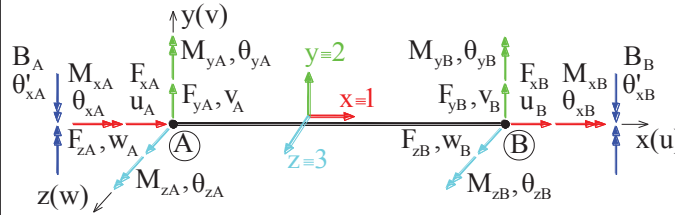

STEP	DESCRIPTION	COMMENTS
Actual member		Beam, member of a steel structure (e.g. steel frame)
<b>First step:</b> Definition of the stiffness matrix for the subelements of the median segment		Stiffness matrix: $[k_{ij}]$ (14x14)
<b>Second step:</b> Discretization of the median segment in $n$ subelements ( $n-1$ internal nodes, 2 external nodes: A,B)	 Stiffness matrix of subelement $i \rightarrow [k_{ij}]$	Formation of a "sub-structure" consisting of $n$ subelements: → Stiffness matrix: $[k_{sub}]$ $[7(n+1) \times 7(n+1)]$ → Load matrix: $[p_{sub}]$ $[7(n+1) \times 1]$
<b>Third step:</b> First stage of static condensation → Condensation of d.o.f. of the internal nodes ↓ Generation of 2-noded macroelement with 7 d.o.f. / node	 $[k_{sub}] = \begin{bmatrix} [k_{sub}^{(AB-AB)}] & [k_{sub}^{(AB-int)}] \\ [k_{sub}^{(int-AB)}] & [k_{sub}^{(int-int)}] \end{bmatrix}$ d.o.f. of the nodes A, B d.o.f. of the internal nodes $[p_{sub}]^T = \begin{bmatrix} [p_{sub}^{(AB-AB)}] & [p_{sub}^{(int-AB)}] \end{bmatrix}$ 14x1      7(n-1)x1	Generation of: Stiffness matrix $[k_{s.c.1}]$ (14x14) Load matrix $[p_{s.c.1}]$ (14x1) → Equation of Equilibrium: $[k_{s.c.1}] \{u_{s.c.1}\} + [p_{s.c.1}] = [F_{s.c.1}]$ $\{u_{s.c.1}\}$ = the (14x1) vector of the displacements of nodes A,B (includes and the warping d.o.f.) $[F_{s.c.1}]$ = the (14x1) vector of the forces of nodes A, B
<b>Fourth step:</b> Second stage of static condensation → Condensation of the warping d.o.f. in nodes A, B ↓ Generation of 2-noded macroelement with the conventional 6 d.o.f. in each of nodes A, B	 $[k_{s.c.1}] = \begin{bmatrix} [k_{s.c.1}^{(cc)}] & [k_{s.c.1}^{(cn)}] \\ [k_{s.c.1}^{(nc)}] & [k_{s.c.1}^{(nn)}] \end{bmatrix}$ conventional d.o.f. of the nodes A, B warping d.o.f. of the nodes A, B $[p_{s.c.1}]^T = \begin{bmatrix} [p_{s.c.1}^{(cc)}] & [p_{s.c.1}^{(nc)}] \end{bmatrix}$ $[F_{s.c.1}]^T = \begin{bmatrix} [F_{s.c.1}^{(cc)}] & [F_{s.c.1}^{(nc)}] \end{bmatrix}$ 12x1      2x1      12x1      2x1	Generation of matrices for the median segment $[k_{ms}]$ (12x12) and $[p_{ms}]$ (12x1) → Equation of Equilibrium of the median segment: $[k_{ms}] \{u_{ms}\} + [p_{ms}] = [F_{ms}]$ $\{u_{ms}\}$ = the (12x1) vector of the displacements of nodes A, B $[F_{ms}]$ = the (12x1) vector of the forces of nodes A, B
		$[u_{s.c.1}]^T = [u_A \ v_A \ w_A \ \theta_{xA} \ \theta_{yA} \ \theta_{zA} \ u_B \ v_B \ w_B \ \theta_{xB} \ \theta_{yB} \ \theta_{zB} \ u'_A \ v'_A \ w'_A \ \theta'_{xA} \ \theta'_{yA} \ \theta'_{zA}]$ $[F_{s.c.1}]^T = [F_{xA} \ F_{yA} \ F_{zA} \ M_{xA} \ M_{yA} \ M_{zA} \ F_{xB} \ F_{yB} \ F_{zB} \ M_{xB} \ M_{yB} \ M_{zB} \ B_A \ B_B]$ $[p_{s.c.1}]^T = [p_{xA} \ p_{yA} \ p_{zA} \ m_{xA} \ m_{yA} \ m_{zA} \ p_{xB} \ p_{yB} \ p_{zB} \ m_{xB} \ m_{yB} \ m_{zB} \ b_A \ b_B]$

Figure 2: The steps of the two-stage static condensation procedure

Eliminating all the internal nodes at the first stage of the procedure, the  $[7(n+1)] \times [7(n+1)]$  stiffness matrix is transformed to a  $14 \times 14$  matrix. Then, at the second stage of the procedure, the 7<sup>th</sup> d.o.f. which corresponds to warping is condensed, transforming the  $14 \times 14$  stiffness matrix  $[k_{s.c.1}]$  to a  $12 \times 12$  stiffness matrix  $[k_{ms}]$  for the median segment (Figure 2).

As regards the matrix transformations which are required for the static condensation in each one of the two stages, it must be noted that, whereas the first one of them is always performed using a specific procedure, the second one depends on the boundary conditions which concern the warping effects in the end nodes of the median segment. Thus, the stiffness matrix  $[k_{s.c.1}]$  and the load matrix  $[p_{s.c.1}]$  of the median segment after the first stage of the static condensation (Figure 2) are given by Eq. (1), (e.g. [17]):

$$\begin{aligned} [k_{s.c.1}] &= [k_{sub}^{(AB-AB)}] - [k_{sub}^{(AB-int)}] \cdot [k_{sub}^{(int-int)}]^{-1} \cdot [k_{sub}^{(int-AB)}] \\ [p_{s.c.1}] &= [p_{sub}^{(AB-AB)}] - [k_{sub}^{(AB-int)}] \cdot [k_{sub}^{(int-int)}]^{-1} \cdot [p_{sub}^{(int-AB)}] \end{aligned} \quad (1)$$

The required matrix transformations for the second stage of the static condensation are summarized in Table 1.

Case	Boundary condition in node A	Boundary condition in node B	Condensed stiffness matrix $[k_{ms}]$	Condensed load matrix $[p_{ms}]$
1	Bimoment $B_A=0$	Bimoment $B_B=0$	$[k_{s.c.1}^{(cc)}] - [k_{s.c.1}^{(cn)}] \cdot [k_{s.c.1}^{(nn)}]^{-1} \cdot [k_{s.c.1}^{(nc)}]$	$[p_{s.c.1}^{(cc)}] - [k_{s.c.1}^{(cn)}] \cdot [k_{s.c.1}^{(nn)}]^{-1} \cdot [p_{s.c.1}^{(nc)}]$
2	$\theta'_{XA}=0$	$\theta'_{XB}=0$	$[k_{s.c.1}^{(cc)}]$	$[p_{s.c.1}^{(cc)}]$
3	Bimoment $B_A=-S_A\theta'_{XA}$	Bimoment $B_B=-S_B\theta'_{XB}$	As in case 1, with: $[\bar{k}_{s.c.1}^{(nn)}] = [k_{s.c.1}^{(nn)}] + \begin{bmatrix} S_A & 0 \\ 0 & S_B \end{bmatrix}$	
4	$B_A=0$	$B_B=-S_B\theta'_{XB}$	As in case 3, with: $[\bar{k}_{s.c.1}^{(nn)}] = [k_{s.c.1}^{(nn)}] + \begin{bmatrix} 0 & 0 \\ 0 & S_B \end{bmatrix}$	
5	Bimoment $B_A=0$	Warping $\theta'_{XB}=0$	$[k_{s.c.1}^{(cc)}] - \frac{1}{k_{s.c.1}^{(nnAA)}} \cdot [k_{s.c.1}^{(cnA)}] \cdot [k_{s.c.1}^{(ncA)}]$	$[p_{s.c.1}^{(cc)}] - \frac{1}{k_{s.c.1}^{(nnAA)}} \cdot [k_{s.c.1}^{(cnA)}] \cdot b_A$
6	$\theta'_{XA}=0$	$B_B=-S_B\theta'_{XB}$	$[k_{s.c.1}^{(cc)}] - \frac{1}{k_{s.c.1}^{(nnBB)} + S_B} \cdot [k_{s.c.1}^{(cnB)}] \cdot [k_{s.c.1}^{(ncB)}]$	$[p_{s.c.1}^{(cc)}] - \frac{b_B}{k_{s.c.1}^{(nnBB)} + S_B} \cdot [k_{s.c.1}^{(cnB)}]$

Table 1: Summary of matrix transformations in the second stage of the static condensation

Where:

$[k_{s.c.1}^{(cc)}], [k_{s.c.1}^{(cn)}], [k_{s.c.1}^{(nn)}], [k_{s.c.1}^{(nc)}]$  are sub-matrices of  $[k_{s.c.1}]$  after the first stage of the static condensation (Figure 2),

$[p_{s.c.1}^{(cc)}], [p_{s.c.1}^{(nc)}]$  are sub-matrices of  $[p_{s.c.1}]$  after the first stage of the static condensation (Figure 2),

$[k_{s.c.1}^{(cnA)}], [k_{s.c.1}^{(ncA)}], [k_{s.c.1}^{(cnB)}], [k_{s.c.1}^{(ncB)}]$  are sub-matrices and  $k_{s.c.1}^{(nnAA)}, k_{s.c.1}^{(nnBB)}$  are elements of  $[k_{s.c.1}]$ , if this matrix is written in the following expanded form:

$$[k_{s.c.1}] = \begin{bmatrix} [k_{s.c.1}^{(cc)}] & [k_{s.c.1}^{(cnA)}] & [k_{s.c.1}^{(cnB)}] \\ [k_{s.c.1}^{(ncA)}] & k_{s.c.1}^{(nnAA)} & k_{s.c.1}^{(nnAB)} \\ [k_{s.c.1}^{(ncB)}] & k_{s.c.1}^{(nnBA)} & k_{s.c.1}^{(nnBB)} \end{bmatrix}$$

It must be noted that cases 3 and 4 in Table 1 correspond to the partial restraint of warping in end nodes A, B (for details see e.g. [18]). Thus,  $s_A$ ,  $s_B$  are the constants of the warping spring elements which partially restrain the warping. Finally, the terms  $b_A$ ,  $b_B$  (see Figure 2) are elements of the median segment's load matrix  $[p_{s.c.1}]$ , which correspond to the warping d.o.f. in the end nodes A, B.

The procedure described in Figure 2 is based on the derivation of the stiffness matrices  $[k_{ij}]$  for the sub-elements (ij) which are the basic components of the macroelement (see the first step of the procedure in Figure 2). The stiffness matrices for these sub-elements are available in the literature (see e.g. [6, 7]). Their formulation is based on the linearized updated Lagrangian formulation of the equation of the incremental virtual work for a beam/column element which possesses 7 d.o.f. in the end nodes (Eq. (2)):

$$\begin{aligned} & \frac{1}{2} \int_0^{L_{ij}} \left[ EA \delta \left( \frac{du}{dx} \right)^2 + EI_{yy} \delta \left( \frac{d^2 w}{dx^2} \right)^2 + EI_{zz} \delta \left( \frac{d^2 v}{dx^2} \right)^2 + EC_\omega \delta \left( \frac{d^2 \theta_x}{dx^2} \right)^2 + GJ \left( \frac{d\theta_x}{dx} \right)^2 \right] dx + \\ & + \frac{1}{2} \int_0^{L_{ij}} F_x \delta \left[ \left( \frac{dv}{dx} \right)^2 + \left( \frac{dw}{dx} \right)^2 \right] dx + \int_0^{L_{ij}} \frac{K_w}{2} \delta \left( \frac{d\theta_x}{dx} \right)^2 dx - \int_0^{L_{ij}} \left[ V_y \delta \left( \frac{du}{dx} \frac{dv}{dx} \right) + V_z \delta \left( \frac{du}{dx} \frac{dw}{dx} \right) \right] dx - \\ & - \int_0^{L_{ij}} M_y \delta \left( \frac{dv}{dx} \frac{d\theta_x}{dx} \right) dx - \int_0^{L_{ij}} M_z \delta \left( \frac{dw}{dx} \frac{d\theta_x}{dx} \right) dx - \frac{1}{2} \int_0^{L_{ij}} M_x \left[ \delta \left( \frac{dv}{dx} \frac{d^2 w}{dx^2} \right) - \delta \left( \frac{d^2 v}{dx^2} \frac{dw}{dx} \right) \right] dx + \\ & + \int_0^{L_{ij}} V_y \delta \left( \frac{dw}{dx} \theta_x \right) dx - \int_0^{L_{ij}} V_z \delta \left( \frac{dv}{dx} \theta_x \right) dx = \{\delta u\}^T (\{^2 f\} - \{^1 f\}) \end{aligned} \quad (2)$$

Where:  $E$  is the modulus of elasticity;  $G$  is the shear modulus;  $A$  is the area of the beam/column's cross-section;  $I_{yy}$ ,  $I_{zz}$  are the moments of inertia of the beam/column's cross-section with respect to local axes  $y$ ,  $z$  (Figure 2);  $J$  is the torsional constant;  $C_\omega$  is the warping constant;  $L_{ij}$  is the length of the element;  $\{du\}$  is the vector of the displacements of nodes  $i$  and  $j$  (Figure 2);  $\{f\}$  is the vector of forces of nodes  $i$  and  $j$  (Figure 2) and  $K_w = [F_x(I_{yy} + I_{zz})]/A$  is the Wagner coefficient. It must also be noted that the right superscripts 1 and 2 of vector  $\{f\}$  refer to the deformed configurations  $C_1$  (the last known state) and  $C_2$  (current deformed state). Both of these configurations are defined in the framework of the updated Lagrangian approach, as the start and the end of each incremental step of external loading (see e.g. [11]).

In order to derive the stiffness matrix  $[k_{ij}]$  starting from Eq. (2), the displacement field of the element (ij) must be defined. For this reason, the following shape functions are used:

$$\begin{aligned} N_1 &= N_1(x) = 1 - (x/L_{ij}) & N_2 &= N_2(x) = (x/L_{ij}) \\ N_3 &= N_3(x) = 1 - 3 \cdot (x/L_{ij})^2 + 2 \cdot (x/L_{ij})^3 & N_4 &= N_4(x) = x - 2 \cdot (x^2/L_{ij}) + (x^3/L_{ij}^2) \\ N_5 &= N_5(x) = 3 \cdot (x/L_{ij})^2 - 2 \cdot (x/L_{ij})^3 & N_6 &= N_6(x) = -(x^2/L_{ij}) + (x^3/L_{ij}^2) \end{aligned} \quad (3)$$

The corresponding matrices of these functions are:

$$\begin{aligned} [N_u] &= [N_1 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0 \quad N_2 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0 \quad \dots \quad 0 \quad 0] \\ [N_v] &= [0 \quad N_3 \quad 0 \quad 0 \quad 0 \quad N_4 \quad 0 \quad N_5 \quad 0 \quad 0 \quad 0 \quad N_6 \quad \dots \quad 0 \quad 0] \\ [N_w] &= [0 \quad 0 \quad N_3 \quad 0 \quad -N_4 \quad 0 \quad 0 \quad 0 \quad N_5 \quad 0 \quad -N_6 \quad 0 \quad \dots \quad 0 \quad 0] \\ [N_\theta] &= [0 \quad 0 \quad 0 \quad N_3 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0 \quad N_5 \quad 0 \quad 0 \quad \dots \quad N_4 \quad N_6] \end{aligned} \quad (4)$$

Thus, the displacement in any point inside the element can be expressed in terms of its end nodes displacements using Eq. (5):

$$\begin{aligned} \mathbf{u} &= [\mathbf{N}_u] \{\mathbf{u}\} \quad \mathbf{v} = [\mathbf{N}_v] \{\mathbf{u}\} \quad \mathbf{w} = [\mathbf{N}_w] \{\mathbf{u}\} \quad \boldsymbol{\theta}_x = [\mathbf{N}_\theta] \{\mathbf{u}\} \\ \{\mathbf{u}\} &= \left[ u_i \quad v_i \quad w_i \quad \theta_{xi} \quad \theta_{yi} \quad \theta_{zi} \quad u_j \quad v_j \quad w_j \quad \theta_{xj} \quad \theta_{yj} \quad \theta_{zj} \quad \theta'_{xj} \quad \theta'_{yj} \right]^T \end{aligned} \quad (5)$$

Eq. (2) also introduces the internal forces of the element (ij):  $F_x$ ,  $V_y$ ,  $V_z$ ,  $M_x$ ,  $M_y$  and  $M_z$ . Assuming that no loads act on the element, these forces can be expressed in terms of the corresponding forces in the element's ends i and j, using the relations of Eq. (6):

$$\begin{aligned} F_x &= F_{xj}, \quad V_y = -\frac{M_{zi} + M_{zj}}{L_{ij}}, \quad V_z = \frac{M_{yi} + M_{yj}}{L_{ij}} \\ M_x &= M_{xj}, \quad M_y = -M_{yi} \left( 1 - \frac{x}{L_{ij}} \right) + M_{yj} \left( \frac{x}{L_{ij}} \right), \quad M_z = -M_{zi} \left( 1 - \frac{x}{L_{ij}} \right) + M_{zj} \left( \frac{x}{L_{ij}} \right) \end{aligned} \quad (6)$$

Inserting Eqs. (5), (6) into Eq. (2), and after a specific transformation (e.g. [6, 8, 19]), the stiffness matrix of the element (ij) can be expressed as follows:

$$\begin{aligned} [k_{ij}] &= EA [k_{uu}^{110}] + EI_{zz} [k_{vv}^{220}] + EI_{yy} [k_{ww}^{220}] + GJ [k_{\theta\theta}^{110}] \\ &\quad + F_{xj} [k_{vv}^{110}] + F_{xj} [k_{ww}^{110}] + V_y [k_{uv}^{110}] + V_y [k_{vu}^{110}] \\ &\quad - V_z [k_{uw}^{110}] - V_z [k_{wu}^{110}] + K_w [k_{\theta\theta}^{110}] - \frac{M_{yi} + M_{yj}}{L_{ij}} ([k_{v\theta}^{100}] + [k_{\theta v}^{010}] + [k_{v\theta}^{111}] + [k_{\theta v}^{111}]) \\ &\quad + M_{yi} [k_{v\theta}^{110}] + M_{yi} [k_{\theta v}^{110}] + M_{zi} [k_{w\theta}^{110}] + M_{zi} [k_{\theta w}^{110}] \\ &\quad - \frac{M_{xj}}{2} [k_{vv}^{120}] - \frac{M_{xj}}{2} [k_{ww}^{120}] + \frac{M_{xj}}{2} [k_{vw}^{210}] + \frac{M_{xj}}{2} [k_{wv}^{120}] \\ &\quad - \frac{M_{zi} + M_{zj}}{L_{ij}} ([k_{w\theta}^{100}] + [k_{\theta w}^{010}] + [k_{w\theta}^{111}] + [k_{\theta w}^{111}]) + EC_\omega [k_{\theta\theta}^{220}] \end{aligned} \quad (7)$$

Where:

$$[k_{gh}^{stv}] = \int_0^{L_{ij}} \frac{d^s [N_g]^T}{dx^s} \cdot \frac{d^t [N_h]}{dx^t} \cdot x^v dx \quad (8)$$

$g = u, v, w \quad h = u, v, w$

$s, t = \text{order of differentiation}$

$v = \text{order of exponent of } x$

From the study of Eq. (7), it can be concluded that the stiffness matrix  $[k_{ij}]$  (which can be used for geometric non-linear analysis, additionally including the influence of the warping effects) consists of 28 matrices. These matrices correspond to contribution of the element's elastic deformations and to the contribution of the element's end forces. On the basis of the above conclusion, the stiffness matrix can be expressed as the summation of two matrices: the linear elastic stiffness matrix  $[k_{ij,e}]$  and the geometric stiffness matrix  $[k_{ij,g}]$ :

$$[k_{ij}] = [k_{ij,e}] + [k_{ij,g}] \quad (9)$$

Where:

$$[k_{ij,e}] = EA[k_{uu}^{110}] + EI_{zz}[k_{vv}^{220}] + EI_{yy}[k_{ww}^{220}] + GJ[k_{\theta\theta}^{110}] + EC_{\omega}[k_{\theta\theta}^{220}] \quad (10a)$$

$$\begin{aligned} [k_{ij,g}] = & F_{xj}[k_{vv}^{110}] + F_{xj}[k_{ww}^{110}] + V_y[k_{uv}^{110}] + V_y[k_{vu}^{110}] \\ & - V_z[k_{uw}^{110}] - V_z[k_{wu}^{110}] + K_w[k_{\theta\theta}^{110}] - \frac{M_{yi} + M_{yj}}{L_{ij}}([k_{v\theta}^{100}] + [k_{\theta v}^{010}] + [k_{v\theta}^{111}] + [k_{\theta v}^{111}]) \\ & + M_{yi}[k_{v\theta}^{110}] + M_{yi}[k_{\theta v}^{110}] + M_{zi}[k_{w\theta}^{110}] + M_{zi}[k_{\theta w}^{110}] \\ & - \frac{M_{xj}}{2}[k_{vv}^{120}] - \frac{M_{xj}}{2}[k_{ww}^{210}] + \frac{M_{xj}}{2}[k_{vw}^{210}] + \frac{M_{xj}}{2}[k_{wv}^{120}] \\ & - \frac{M_{zi} + M_{zj}}{L_{ij}}([k_{w\theta}^{100}] + [k_{\theta w}^{010}] + [k_{w\theta}^{111}] + [k_{\theta w}^{111}]) \end{aligned} \quad (10b)$$

### B) Step 2: Derivation of the stiffness matrix $[k_{me}]$ for the macroelement

After the formulation of the stiffness matrix for the macroelement's median segment according to the procedure which is summarized in Figure 2, the corresponding stiffness matrix for the whole macroelement (Figure 1) can be derived.

At the beginning, the relationships between the displacements of internal nodes 2 and 3, with those of external nodes 1 and 4 (Figure 1) are established. To this end, two factors must be considered: (a) the fact that the rigid offsets are non-deformable elements and behave as absolutely rigid bodies in 3D-space, and (b) the existence of the rotational springs which are located in internal nodes 2, 3, where the median segment is connected to the rigid offsets (Figure 1).

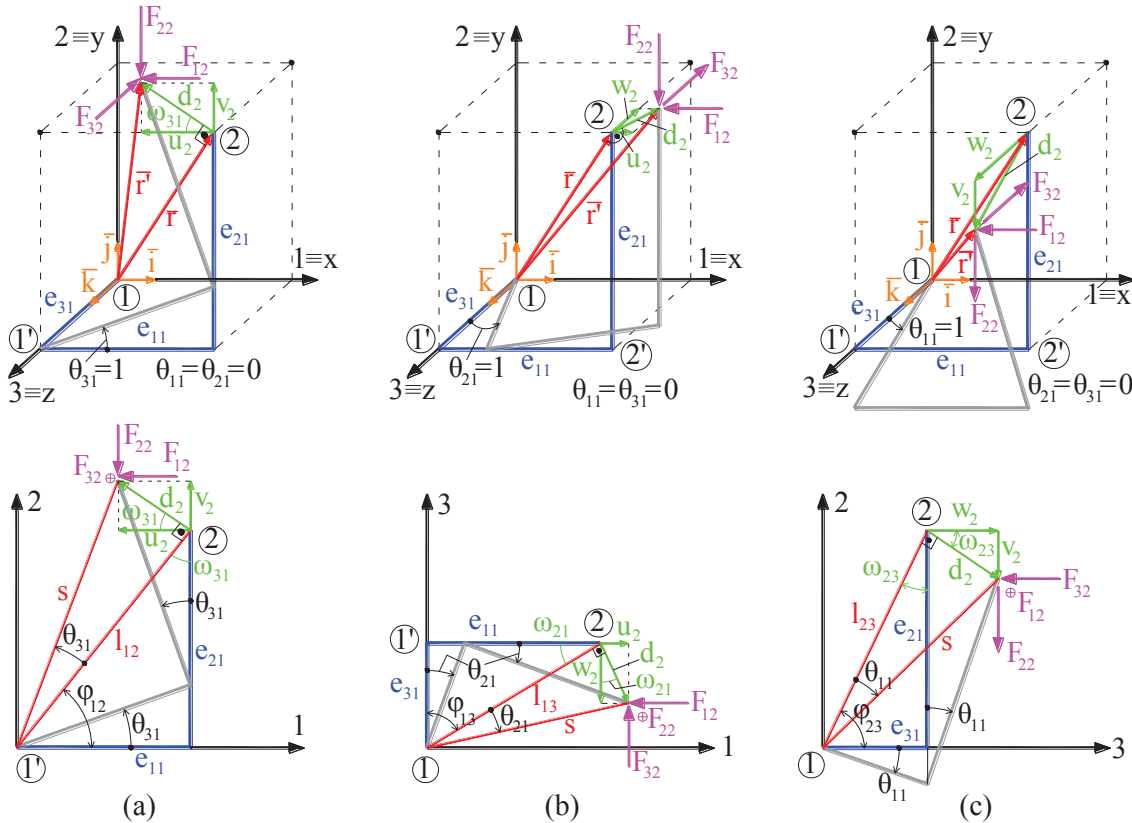

Figure 3: Kinematic conditions of the proposed macroelement's rigid offsets

Due to the fact that the rigid offsets move as rigid bodies in the 3D-space, the displacements of the internal nodes 2 ( $u_2, v_2, w_2$ ), 3 ( $u_3, v_3, w_3$ ) are equal to the displacements of the external nodes 1 ( $u_1, v_1, w_1$ ), 4 ( $u_4, v_4, w_4$ ) respectively, plus the displacements which are caused by the rotations of the rigid offsets about the local axes 1, 2 and 3 (Figure 3). These additional displacements can be calculated on the basis of Figure 3, with the assumption that the displacements are infinitesimal. Moreover, the behavior of the rigid offsets as absolutely rigid bodies leads to the conclusion that the rotations of the internal nodes 2 ( $\theta_{12}, \theta_{22}, \theta_{32}$ ), 3 ( $\theta_{13}, \theta_{23}, \theta_{33}$ ) about the local axes 1, 2 and 3 are equal to the corresponding rotations of the external nodes 1 ( $\theta_{11}, \theta_{21}, \theta_{31}$ ), 4 ( $\theta_{14}, \theta_{24}, \theta_{34}$ ). It can be proved, with the aid of the Figure 3, that (see also [20]):

$$[u_{int}] = [T] \cdot [u] = \begin{bmatrix} [I_3] & [t_{12}] & [0_3] & [0_3] \\ [0_3] & [I_3] & [0_3] & [0_3] \\ [0_3] & [0_3] & [I_3] & [t_{34}] \\ [0_3] & [0_3] & [0_3] & [I_3] \end{bmatrix} \cdot [u] \quad [t_{12}] = \begin{bmatrix} 0 & e_{31} & -e_{21} \\ -e_{31} & 0 & e_{11} \\ e_{21} & -e_{11} & 0 \end{bmatrix} \quad [t_{34}] = \begin{bmatrix} 0 & e_{32} & -e_{22} \\ -e_{32} & 0 & e_{12} \\ e_{22} & -e_{12} & 0 \end{bmatrix} \quad (11a)$$

$$[u_{int}]^T = [u_2 \ v_2 \ w_2 \ \theta_{12} \ \theta_{22} \ \theta_{32} \mid u_3 \ v_3 \ w_3 \ \theta_{13} \ \theta_{23} \ \theta_{33}] \quad (11b)$$

$$[u]^T = [u_1 \ v_1 \ w_1 \ \theta_{11} \ \theta_{21} \ \theta_{31} \mid u_4 \ v_4 \ w_4 \ \theta_{14} \ \theta_{24} \ \theta_{34}]$$

Where  $[I_3]$  is the 3x3 identity matrix and  $[0_3]$  is the 3x3 zero matrix.

The existence of the rotational springs in the internal nodes 2, 3 causes discontinuity of the rotations about the local axes 2 and 3 in these points. This is expressed through the parameter  $\Delta\theta$  and illustrated in Figure 4 for the case of bending of the macroelement in the local plane 1-2, where the rotational springs  $K_{r32}$  and  $K_{r33}$  are activated.

Figure 4: Modelling of semi-rigid connections through the rotational springs in the element's internal nodes

If the rotational springs behave elastically or in the case of inelastic analysis (where, during every incremental step of loading, the tangent stiffness of the rotational springs is used), the equation which gives the value of the discontinuity  $\Delta\theta$  is:

$$\Delta\theta_{2i} = M_{2i}/K_{r2i}, \quad \Delta\theta_{3i} = M_{3i}/K_{r3i} \quad (i = 2, 3) \quad (12)$$

Thus:

$$\begin{aligned} \theta_{22} &= \theta_{21} - (M_{22}/K_{r22}) = \theta_{21} + (-K_{r22}^{-1}) \cdot M_{22} \\ \theta_{23} &= \theta_{24} - (M_{23}/K_{r23}) = \theta_{24} + (-K_{r23}^{-1}) \cdot M_{23} \\ \theta_{32} &= \theta_{31} - (M_{32}/K_{r32}) = \theta_{31} + (-K_{r32}^{-1}) \cdot M_{32} \\ \theta_{33} &= \theta_{34} - (M_{33}/K_{r33}) = \theta_{34} + (-K_{r33}^{-1}) \cdot M_{33} \end{aligned} \quad (13)$$

Taking into consideration Eq. (13), Eq. (11a) is modified as follows:

$$[u_{int}] = [T] \cdot [u] + \underbrace{\begin{bmatrix} [0_3] & [0_3] & [0_3] & [0_3] \\ [0_3] & [K_{R2}] & [0_3] & [0_3] \\ [0_3] & [0_3] & [0_3] & [0_3] \\ [0_3] & [0_3] & [0_3] & [K_{R3}] \end{bmatrix}}_{[T_{KR}]} \cdot [S_{int}] \quad [K_{Ri}] = \begin{bmatrix} 0 & 0 & 0 \\ 0 & -K_{r2i}^{-1} & 0 \\ 0 & 0 & -K_{r3i}^{-1} \end{bmatrix} \quad (i = 2, 3) \quad (14a)$$

$$[S_{int}]^T = [F_{12} \ F_{22} \ F_{32} \ M_{12} \ M_{22} \ M_{32} \ F_{13} \ F_{23} \ F_{33} \ M_{13} \ M_{23} \ M_{33}] \quad (14b)$$

Thus, the matrix equation which relates the displacements of internal nodes 2 and 3 with those of external nodes 1 and 4 is:

$$[u_{int}] = [T] \cdot [u] + [T_{KR}] \cdot [S_{int}] \quad (15)$$

It is also necessary to relate the forces of internal nodes 2 and 3 with those of the external nodes 1 and 4. To this end, the six equations of equilibrium for each one of the two rigid off-sets must be formed. These equations state the equilibrium of the three forces and the three moments which act in each one of the two edges of the rigid off-sets (nodes 1,2 and nodes 3,4). Obviously, the forces which act at the edges of the rigid off-sets are the elements of the vectors  $[S_{int}]$  (Eq. (14b)) and  $[S]$ , which is the vector of the forces of the external nodes 1, 4:

$$[S]^T = [F_{11} \ F_{21} \ F_{31} \ M_{11} \ M_{21} \ M_{31} \ F_{14} \ F_{24} \ F_{34} \ M_{14} \ M_{24} \ M_{34}] \quad (16)$$

It can be proved [20] that the required relation of the forces of the internal nodes 2 and 3 with those of the external nodes 1 and 4 can be expressed in the following matrix form:

$$[S] = [T]^T \cdot [S_{int}] \quad (17)$$

Eq. (17) arises from the rigid off-sets' equilibrium in the undeformed condition of the macroelement. However, in the framework of the geometric non-linear analyses, the equations of equilibrium must be formulated in the element's deformed condition. For this reason, Eq. (17) must be modified. This modification concerns the introduction of the additional moments which are produced when the forces in internal nodes 2, 3 are applied in the deformed state of the element (Figure 3). It can be proved [14] that the modified form of Eq. (17) is:

$$[S] = [T]^T \cdot [S_{int}] + [T_g] \cdot [u] \quad (18)$$

where  $[u]$  is the vector of the displacements of the external nodes 1, 4 (Eq. 11(b)) and the matrix  $[T_g]$  is calculated by means of the following equation:

$$[T_g] = \begin{bmatrix} [0_3] & [0_3] & [0_3] & [0_3] \\ [0_3] & [K_{s12}] & [0_3] & [0_3] \\ [0_3] & [0_3] & [0_3] & [0_3] \\ [0_3] & [0_3] & [0_3] & [K_{s23}] \end{bmatrix} \quad [K_{sij}] = - \begin{bmatrix} F_{3j}e_{3i} + F_{2j}e_{2i} & 0 & 0 \\ 0 & F_{3j}e_{3i} + F_{1j}e_{1i} & 0 \\ 0 & 0 & F_{2j}e_{2i} + F_{1j}e_{1i} \end{bmatrix} \quad (i,j) = \begin{cases} (1,2) \\ (2,3) \end{cases} \quad (19)$$

The relation between the displacements of the internal nodes 2,3 and the external nodes 1,4 (Eq. (15)), as well as the corresponding relation between the forces (Eq. (18)), constitute the basis for the derivation of the stiffness matrix of the macroelement  $[k_{me}]$  as a matrix function of the stiffness matrix of the macroelement's median segment  $[k_{ms}]$  (Table 1). It can be

proved (e.g. [14]) that, after a sequence of matrix transformations using Eqs. (15), (18), the stiffness matrix  $[k_{me}]$  arises from the following equation:

$$[k_{me}] = [T]^T \cdot \{[I_{12}] - [k_{ms}] \cdot [T_{KR}]\}^{-1} \cdot [k_{ms}] \cdot [T] + [T_g] \quad (20)$$

where the  $[I_{12}]$  is the 12x2 identity matrix.

### 2.3 Load matrix derivation

The load matrices for the macroelement are formed using the basic principles of the two-step procedure which is used for the derivation of the stiffness matrix. This procedure was described in Section 2.2. The current section focuses on the points of difference between the procedure for the derivation of the load matrices and the corresponding procedure for the derivation of the stiffness matrix.

#### A) Step 1: Derivation of the load matrix for the median segment

As in case of the derivation of the median segment's stiffness matrix, the corresponding procedure for the formulation of the load matrix is based on the performance of static condensation in two stages (Figure 2). The load matrix of the median segment obviously depends on the shape of the external loading. However, due to the fact that the median segment is discretized in sub-elements, any shape of continuously distributed load can be replaced by concentrated forces which are applied on the generated  $(n-1)$  nodes and the two external nodes A, B (see Second step in Figure 2). As an example, this procedure for the case of a trapezoidal load on a random part of the median segment is illustrated in Figure 5.

Figure 5: Modelling of distributed load in the median segment through concentrated forces in the generated nodes

Thus, the procedure for the derivation of the load matrix (as is the case with the procedure for the derivation of the stiffness matrix) is based on the consideration of the median segment as a sub-structure which is loaded only by concentrated forces in its nodes. This procedure can generally be programmed, provided that the concentrated forces which replace the actual external load are known. Using this approach, the load matrix  $[p_{sub}]$  (Figure 2) is derived. Then, the next steps of the procedure which is illustrated in Figure 2 (third and fourth step) lead to the generation of the 12x1 load matrix  $[p_{ms}]$  for the macroelement's median segment.

#### B) Step 2: Derivation of the load matrix $[p_{me}]$ for the macroelement

The relation between the displacements and forces of internal nodes 2, 3, considering the external loading of the median segment, is:

$$[S_{int}] = [k_{ms}] \cdot [u_{int}] + [p_{ms}] \quad (21)$$

The corresponding relation for the external nodes 1, 4 is:

$$[S] = [k_{me}] \cdot [u] + [p_{me}] \quad (22)$$

By combining Eqs. (15) and (21), we obtain:

$$[S_{int}] = \{[I_{12}] - [k_{ms}] \cdot [T_{KR}]\}^{-1} \cdot [K_{ms}] \cdot [T] \cdot [u] + \{[I_{12}] - [K_{ms}] \cdot [T_{KR}]\}^{-1} \cdot [p_{ms}] \quad (23)$$

The combination of Eq. (23) and Eq. (18) leads to the following equation:

$$[S] = \{[T]^T \cdot \{[I] - [k_{ms}] \cdot [T_{KR}]\}^{-1} \cdot [k_{ms}] \cdot [T] + [T_g]\} \cdot [u] + \{[T]^T \cdot \{[I] - [k_{ms}] \cdot [T_{KR}]\}^{-1} \cdot [p_{ms}]\} \quad (24)$$

Finally, by comparing Eqs. (22) and (24), the load matrix of the macroelement  $[p_{me}]$  as a function of the stiffness matrix  $[k_{ms}]$  and the load matrix  $[p_{ms}]$  of the median segment is extracted:

$$[p_{me}] = [T]^T \cdot \{[I_{12}] - [k_{ms}] \cdot [T_{KR}]\}^{-1} \cdot [p_{ms}] \quad (25)$$

### 3 NUMERICAL EXAMPLES

In order to check the efficiency of the proposed macroelement in the geometrically non-linear analyses of framed structures, the solution of a set of numerical examples is presented in the current section. A computer program in Fortran was developed for the implementation of the proposed macroelement in these numerical examples.

#### 3.1 Calculation of the critical load of beam/columns

The ability of the proposed macroelement to accurately calculate the critical loads of beam/columns in lateral buckling was tested using a simply supported beam and a cantilever beam. The data and the boundary conditions of these beams are illustrated in Figure 6. It must be clarified that the ends of both beams are free to warp. Thus, the corresponding bimoments are equal to zero.

Figure 6: Simple beams for the study of the effectiveness of the new element in the calculation of buckling loads

For the modelling of beams, one macroelement with eight sub-elements was used. Thus, the length of each sub-element is equal to  $L_{se}=10/8=1.25$ m. The calculated critical load values were compared with the corresponding theoretical ones [21]. Three different load cases for the simply supported beam were considered: (a) pure bending i.e. external moments  $M_{ze}$  at its ends, (b) concentrated load  $F_{ye}$  at the middle, and (c) uniform load  $q_{ye}$ . It must be clarified that the force  $F_{ye}$  and the distributed load  $q_{ye}$  are applied at the shear center of the beam's cross section. The above load conditions can cause lateral buckling. In order to estimate the critical load in each load case, two different approaches were adopted. In the first approach, the problem was solved by the addition of a perturbation torsional moment  $M_{xe}$  at the middle of the beam. The value of this torsional moment was taken equal to 1/1000 of the value of each one

of the three considered external loads. In the framework of this approach, the external loads (and the perturbation torsional moment) were applied incrementally (i.e. step by step). In each load step, the solution was achieved through an iterative procedure. The displacements and the internal forces of the beam were stored after the convergence of each load step. The analyses were terminated when the convergence was impossible, after a pre-defined maximum number of iterations. The termination of analyses indicates the values of the critical loads. In the second approach, the calculation of the critical loads was achieved considering and solving the stability problem. Thus, in each load step (without the perturbation torsional moment  $M_x$ ), the value of the determinant  $\det K$  of the stiffness matrix of the restrained beam was calculated and stored. The value of the external load for which the condition  $\det K=0$  is fulfilled corresponds to the value of the critical load.

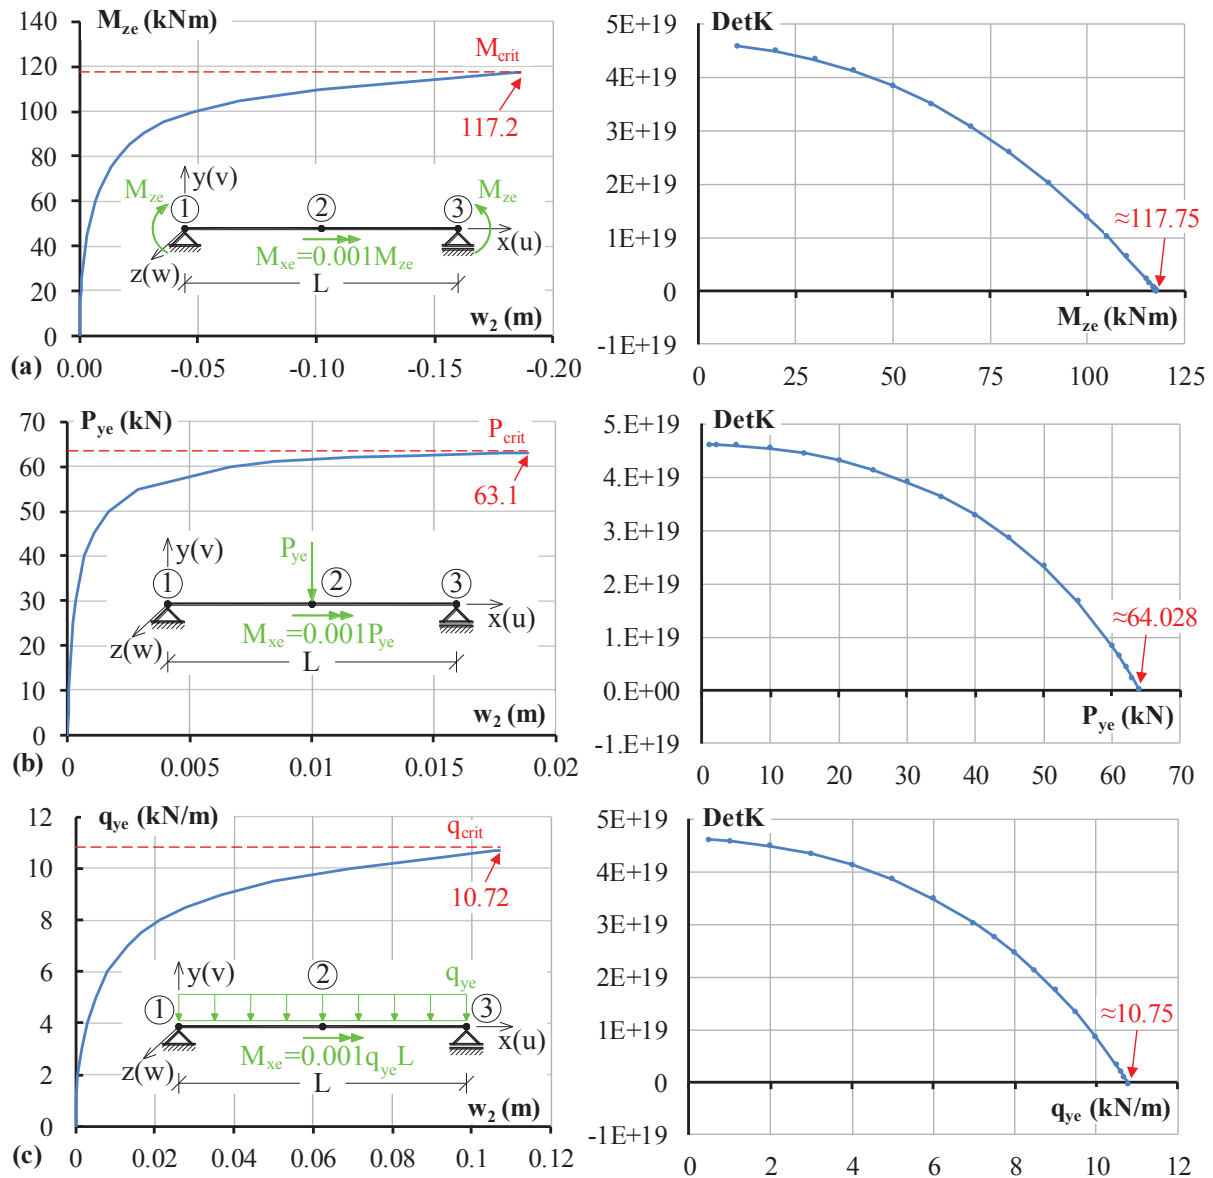

Figure 7: Calculation of critical loads in lateral buckling for a simply supported beam using the new element

Figure 7 illustrates the main results of the analyses described above. The main conclusion to be extracted from this figure is that the implementation of the proposed macroelement can effectively approach the theoretical values of the critical loads for the studied cases (Eqs. (26a)-(26c) [21]). More specifically, the differences of the calculated critical values from the

theoretical ones are 0.47% in the case of the pure bending (Figure 7a), 2.12% in the case of the concentrated load  $F_{ye}$  at the middle of the beam (Figure 7b), and 0.34% in the case of the uniform load  $q_{ye}$  (Figure 7c) when the first approach is adopted. The differences when the second approach is adopted are correspondingly: 0.01%, 0.68% and 0.06%.

$$M_{cr,L}^{s.s.} = \pi \cdot \sqrt{1 + \frac{EI_w}{GJ} \cdot \frac{\pi^2}{L^2}} \cdot \frac{\sqrt{EI_y GJ}}{L} = 117.76 \text{ kNm} \quad (26a)$$

$$P_{cr,L}^{s.s.} = 19.239 \cdot \frac{\sqrt{EI_y GJ}}{L^2} = 64.47 \text{ kN} \quad (26b)$$

$$q_{cr,L}^{s.s.} = 32.1 \cdot \frac{\sqrt{EI_y GJ}}{L^3} = 10.76 \text{ kN/m} \quad (26c)$$

$$P_{cr,L}^c = \frac{4.013}{\left[1 - \sqrt{EI_w / (L^2 GJ)}\right]^2} \cdot \frac{\sqrt{EI_y GJ}}{L^2} = 19.04 \text{ kN} \quad (26d)$$

Similar conclusions are extracted from the results of the solution of the cantilever beam, which are presented in Figure 8. The theoretical value of the critical load (Eq. (26d), [21]) is effectively approached using both types of analysis procedure. More specifically, the differences between the calculated and the theoretical value of the critical load are 0.72% according to the first approach and 0.59% according to the second one.

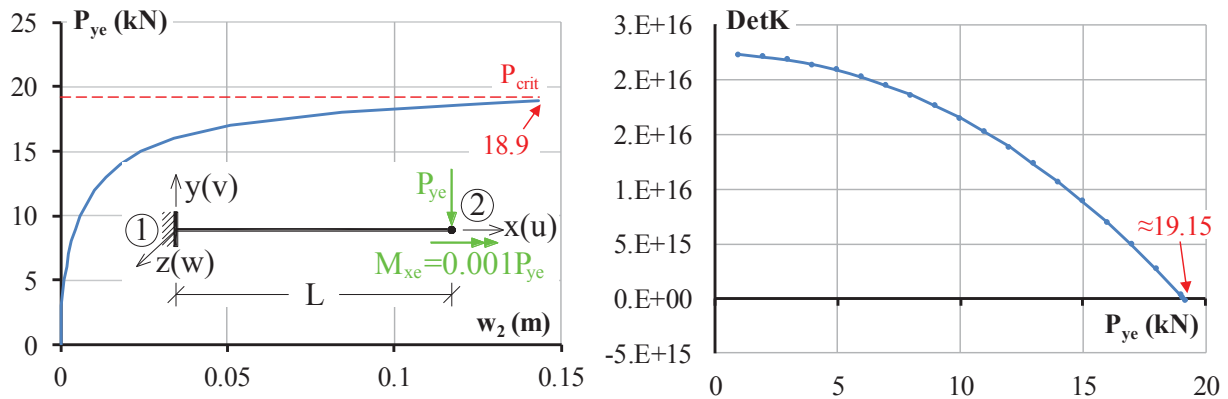

Figure 8: Calculation of the critical load in lateral buckling for cantilever beam using the new macroelement

The efficiency of the proposed macroelement was also studied in the case of an axially loaded column with a cruciform cross-section (Figure 9a). This example was also studied in [22]. The theoretical value of the critical load for pure torsional buckling is available in [21], whereas the corresponding critical value of the axial force for flexural buckling can be calculated by the classic Euler formula. Both of the above critical values of the axial force  $P_{xe}$  are given by Eqs. (27a), (27b).

$$P_{cr,t}^{s.s.} = \frac{A \cdot GJ}{I_y + I_z} = 195 \text{ kN} \quad (27a)$$

$$P_{cr,f}^{s.s.} = \frac{\pi^2 \cdot EI_z}{L^2} = 15791.4 \text{ kN} \quad (27b)$$

For the solution of the two problems, one macroelement with eight sub-elements was used. The procedure which was adopted for the estimation of the critical axial-torsional buckling load was based on the addition of a perturbation torsional moment  $M_{xe}$  equal to 1/1000 of the

applied compressive axial force  $P_{xe}$  at the middle of the column (Figure 9b). Correspondingly, a perturbation concentrated force  $P_{ye}$  was added for the estimation of the critical axial-flexural buckling load (Figure 9c). As in the case of the beam without an axial force, the external forces were applied progressively (step by step). However, in each one of the loading steps, an iteration procedure was adopted for the accomplishment of the equilibrium between the internal and the external forces. As can be seen in Figure 9, as the compressive axial force approaches the theoretical values of the critical load, the displacements and the rotations at the middle of the column are increased rapidly. In addition, the convergence to the solution became slow. Thus, the algorithm fails to converge after the pre-defined maximum number of iterative steps. The solution with the proposed macroelement gives a value for the critical axial-torsional buckling load that is equal to  $P_{cr,t}=194.85\text{kN}$  (0.08% difference from the theoretical value), whereas the corresponding value for the critical axial-flexural buckling load is  $15735\text{kN}$  (0.36% difference from the theoretical value).

Figure 9: Calculation of critical loads for an axially loaded simply supported column using the new macroelement

### 3.2 Calculation of the critical load of simple framed structures

The scope of the current section is the study of the performance of the proposed macroelement in the geometric nonlinear analysis of simple framed structures. The extracted results are compared with known solutions or with the corresponding results extracted from reliable software.

The first example of this category is a clamped right-angle frame under a load  $P$  at the free end, which was first solved by Argyris et al. [23], as well as by other researchers [22].

Figure 10: Calculation of the buckling load of a clamped right-angle frame using the new macroelement

The data of this frame are presented in Figure 10. Each one of the two members of the frame was modelled using one macroelement with eight sub-elements.

Following the procedures of the two approaches which were described in the previous section, the values of the frame's critical load were estimated. These values are  $P_{cr}=1.0875N$  (first approach) and  $P_{cr}=1.091N$  (second approach). The corresponding value which was calculated by Argyris et al. [23], using their formulation for the geometric stiffness matrix and 10 beam elements per member, is  $P_{cr}=1.088N$ .

The second example of this category concerns the one-storey steel space frame of Figure 11. This example was selected for the study of the performance of the proposed macroelement when its abilities for the modelling of rigid offsets and semi-rigid connections are activated.

Figure 11: One-storey steel space frame – data and modelling details

Two different types of analyses were performed. The first one concerns the flexural buckling analysis which leads to the calculation of the frame's critical loads. More specifically, the scope of this type of analysis is the calculation of the critical values (eigenvalues) of the load factor  $\lambda$  which correspond to the modes of the overall flexural buckling of the frame for the load pattern of Figure 12. The method which was adopted is based on the estimation of the roots of the equation:

$$\text{Det}[K(P \cdot \lambda)] = 0 \quad (28)$$

where  $K(P \cdot \lambda)$  is the global stiffness matrix of the restrained frame which depends on the external compressive forces  $P$ .

These roots were calculated using the Newton-Raphson algorithm. Details for the shape of the function which relates the  $\lambda$  values with the values of  $\text{det}[K(P \cdot \lambda)]$  for the examined frame are presented in Figure 12. The first five critical values of factor  $\lambda$  were estimated. Definitely, in practical applications only, the first (and smaller) critical value  $\lambda_1$  is useful for the design. However, the calculation of the first five critical values of factor  $\lambda$  was carried out for the further study of the effectiveness of the proposed macroelement.

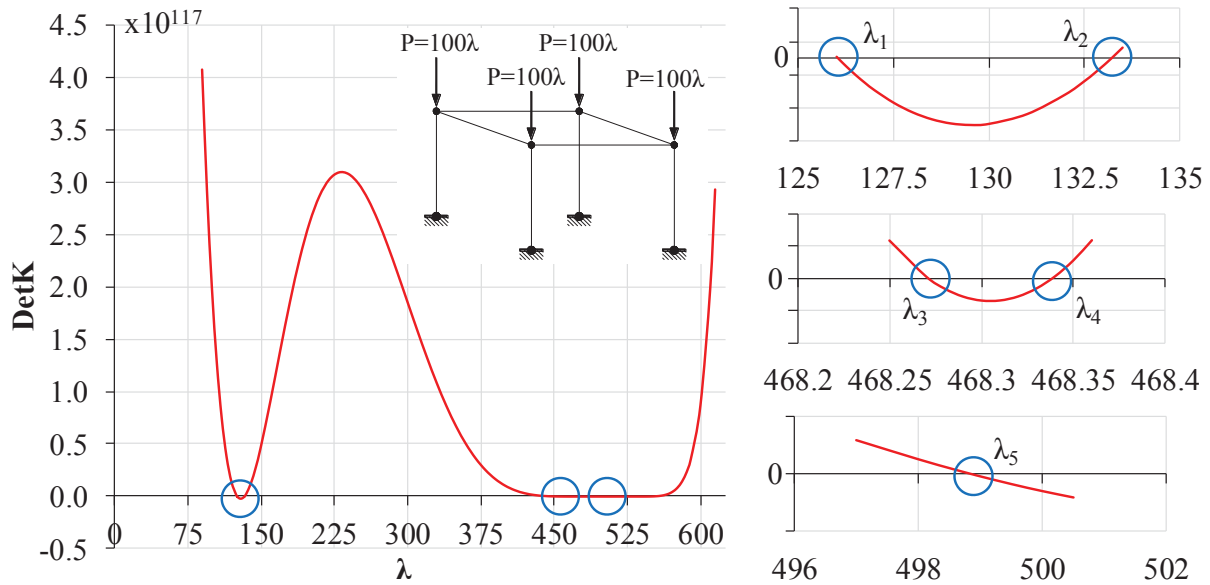

Figure 12: Calculation of the eigenvalues of the overall flexural buckling of the examined space frame using the proposed macroelement

The problem was also solved using the program SAP2000 [24]. Table 2 presents the slight differences of the first five critical  $\lambda$  values between the solution extracted by the SAP2000 program and the corresponding values extracted by the solution using the proposed macroelement.

$\lambda_i$	SAP2000	Proposed Macroelement	Difference (%)
$\lambda_1$	126.06	126.04	0.014%
$\lambda_2$	133.23	133.21	0.019%
$\lambda_3$	468.26	468.27	-0.002%
$\lambda_4$	468.32	468.34	-0.004%
$\lambda_5$	498.86	498.82	0.008%

Table 2: Comparison of the eigenvalues calculated using the new macroelement and the SAP2000 program

The second type of analysis concerns the geometric non-linear analysis of the frame for the vertical (distributed and concentrated) loads and the horizontal concentrated forces which are illustrated in Figure 13.

Figure 13: Load case for the geometric non-linear analysis of the space frame

The problem was also solved using the program SAP2000, activating the option for the consideration of the geometric non-linear effects. The comparison between the characteristic results (bending moments and shear forces) which were extracted by SAP2000 and the corresponding results which were extracted by the solution using the proposed macroelement are illustrated in Table 3. This comparison indicates that the proposed macroelement is capable of extracting results very similar to ones extracted by the well-documented SAP2000 program.

Element/Node	Internal Force	Proposed Macroelement	SAP2000	Differences (%)
1/1	$M_{2,1}$	-15.75	-15.72	0.17%
	$M_{3,1}$	178.46	178.37	0.05%
	$V_{2,1}$	-49.40	-49.39	0.02%
	$V_{3,1}$	25.84	25.85	-0.05%
2/3	$M_{2,3}$	-15.82	-15.79	0.22%
	$M_{3,3}$	254.82	254.76	0.02%
	$V_{2,3}$	-100.61	-100.61	0.00%
	$V_{3,3}$	25.85	25.86	-0.03%
5/5'	$M_{3,5'}$	74.33	74.38	-0.07%
	$V_{2,5'}$	78.80	78.75	0.06%
5/6'	$M_{3,6'}$	-190.80	-190.65	0.08%
	$V_{2,6'}$	-180.85	-180.8	0.03%

#### 4 CONCLUSIONS

In the current paper, the formulation and the study of the effectiveness of a proposed beam/column macroelement for non-linear analysis is presented. This macroelement is a two-noded element with seven degrees of freedom per node and possesses abilities to effectively model the members of steel structures. The inclusion of the seventh degree of freedom in each node permits the modelling of the warping effects which are significant in steel members with open thin-walled sections. The proposed formulation is based on a two-stage static condensation technique, which permits the connection of the new element with classic elements with six degrees of freedom per node. The formulation of the new macroelement also includes rotational springs and rigid offsets at ends. It is thus able to model steel members with semi-rigid connections, as well as the influence of the body of rigid joints.

The proposed macroelement was successfully tested using well-known theoretical solutions from the literature and well-documented software (program SAP2000). The macroelement was also inserted to an existing professional software for the analysis and design of steel structures.

### Abstract

*The wind-structure interaction for structures sensitive to the wind action is commonly investigated through experimental campaigns in wind tunnel. Aerodynamic tests on rigid body models are carried out to estimate pressure coefficients that in turn are used to estimate the wind action on the prototype surfaces. Pressure taps are located on the model surfaces and pressure scanners acquire pressure time histories. Pressure coefficients are calculated from pressure series, they are dimensionless values and they are nondimensionalized on the wind velocity. In the wind tunnel, the flow is assumed stationary and consequently the mean value of pressure coefficient time history is independent of the experiment time length. However, the acquisition time length affects peak values and in particular the peak factor. In addition, the most of processes acquired near edges and near the flow detachment zones are non-Gaussian, contrary to what codes and standard suggest. It was estimated that several processes on the surfaces of a rigid body are non-Gaussian and, in this case, the mean value is not significant. At contrary, the mean value is mostly assumed as representative value of a measurement and it is used to size the structure. It is true only for some specific zones. In addition, they depend on the wind angle of attack. The purpose of this study is to discuss the Gaussian and non-Gaussian processes localization for two examples of structure families, large span roofs and bridge closed box section using aerodynamic experiments given by literature. The geometries subject of this investigation are typical geometries of roofs and bridge sections sensitive to wind action as for example cable nets roofs and suspended bridges.*

**Keywords:** Wind tunnel, light structure, random processes, Gaussianity, stochastics.

## 1 INTRODUCTION

The wind tunnel experimental campaign is largely used to estimate the wind effects on structures sensitive to the wind. Structures very sensitive to the wind action are generally large span roofs [1-5] as for example tensile structures for which the permanent load is smaller than the wind action, suspended bridges [6] that differently than traditional bridges made of reinforced concrete that are sensitive to the seismic action [7] or steel corrosion [8] can be affected by the flutter instability and finally, high-rise buildings [9] that are slender.

The wind tunnel is used to investigate the aerodynamics and the aeroelastic behavior of structures. The aerodynamics is commonly investigated through rigid body models and the test purpose is to estimate pressures using tubes and pressure taps [1] or wind forces using beam balances. The aeroelastic behavior is investigated through dynamic models that reproduces the prototype masses and stiffness based on scaling laws [10-14].

Aerodynamic and aeroelastic wind tunnel tests are both carried out for structures very light and for which instability due to wind effects is expected. However, it is well known that the more common experiments in wind tunnel are intended to estimate the wind action on the structure surface through the pressure distribution. The pressure distributions across the test model have historically been measured by drilling small holes (i.e. pressure taps) along the airflow path and using multi-tube manometers to measure the pressure at each hole. Pressure distributions can more conveniently be measured using pressure-sensitive paint, in which higher local pressure is indicated by lowered fluorescence of the paint at that point. Pressure distributions can also be conveniently measured using pressure-sensitive pressure belts, a recent development in which multiple ultra-miniaturized pressure sensor modules are integrated into a flexible strip. The strip is attached to the aerodynamic surface with tape, and it sends signals depicting the pressure distribution along its surface, [15].

The main results obtained from pressure tests is the pressure coefficients that depend on the building shape and the turbulence flow. The experimental data are time histories and stationary processes. Many codes [16-17] suggest assuming the mean value of the pressure coefficient time history as a representative value for the wind action estimation. It is because codes assuming that the random processes acquired in wind tunnel are gaussian [18] and consequently, the distribution of values is centered around the mean value. However, several studies have shown that in many cases, processes acquired in wind tunnel are not Gaussian, [19-23] and the skewness and kurtosis of the process are not negligible [24]. For these cases the mean value can be not representative of the phenomenon. Another important statistic parameter of a random process is the absolute maximum that depends on the peak factor that in turn depends on the time length of the process. The peak factor can be predicted analytically through models that assume that the process is Gaussian [18] or not-Gaussian [25-31]. This is a hot topic in the scientific literature because codes suggest the common value of the peak factor of 3.5 that is commonly smaller than the experimental value.

This paper discusses the statistics of random processes acquired in wind tunnel during different experimental campaign on roofs and bridge sections. The pressure coefficients time histories peak factors are plotted comparing to the 95% level of confidence given by [18] and the number of Gaussian and non-Gaussian processes were compared.

## 2 RANDOM PROCESSES STATISTICS

In this paper two set of pressure coefficients time histories are discussed. The first one consists of pressure coefficients time histories acquired on hyperbolic paraboloid roofs given by [21] (Fig.1) and the second one consists of pressure coefficients time histories acquired on closed box section of suspended bridges (Fig.2).

The experimental campaign of hyperbolic paraboloid roofs discussed by [21] consists of sixteen different geometries of hyperbolic paraboloid roofs with different plan shape (i.e. square, rectangular, circular, and elliptical), two different curvature (i.e. more curved and flatter) and two different heights (i.e. tall and low). All geometries were tested in wind tunnel to acquire pressure coefficients subsequently published in [16]. Models were equipped with pressure taps (Fig.1) connected to pressure scanners.

Figure 1: Pressure taps tubes on a large span roof test model.

Pressure taps were located on the model external surfaces and more thickly along edges where the flow detachment occurs. In these zones the pressure coefficient is generally bigger than elsewhere for both values, the mean, and the peak value. In these zones the processes are generally non-Gaussian [19].

Figure 2: Test model setup for a closed box section model [6, 13].

The pressure coefficients time histories were analysed to estimate the Gaussianity observing the empirical cumulative density function (ECDF), the skewness and the excessive kurtosis of the processes.

If the ECDF of the local peaks of the random process is fitted by a Rayleigh distribution, the processes is Gaussian [18]. Otherwise, if the ECDF of the local peaks is fitted by a Weibull distribution it corresponds to a non-Gaussian condition.

According to [24] the roof regions where the pressure coefficient process is non-Gaussian are identified by the skewness bigger than 0.5 and/or the excessive kurtosis bigger than 0.5.

### 3 GAUSSIAN AND NON-GAUSSIAN PROCESSES

In this study the assumption given by [24] was assumed to select Gaussian and non-Gaussian processes. They were compared with the 95% level of confidence of the Davenport peak factor [18-19], for two set of data, pressure coefficients time history of hyperbolic paraboloid roofs [20] (Figs. 3-5) and of an example of closed box section for suspended pedestrian bridge [6, 13] (Fig.6). In Figs. 3-6, graphs show the peak factor  $g_p$  for each pressure taps #, gray continues line means the 95% Davenport level of confidence [18], green squared dot means non-Gaussian processes and finally red dot means Gaussian processes.

Figures 3 show a comparison between a flutter (Fig.3a) and a more curved (Fig.3b) roofs and it was observed that the curvature promotes the non-Gaussian processes decreasing.

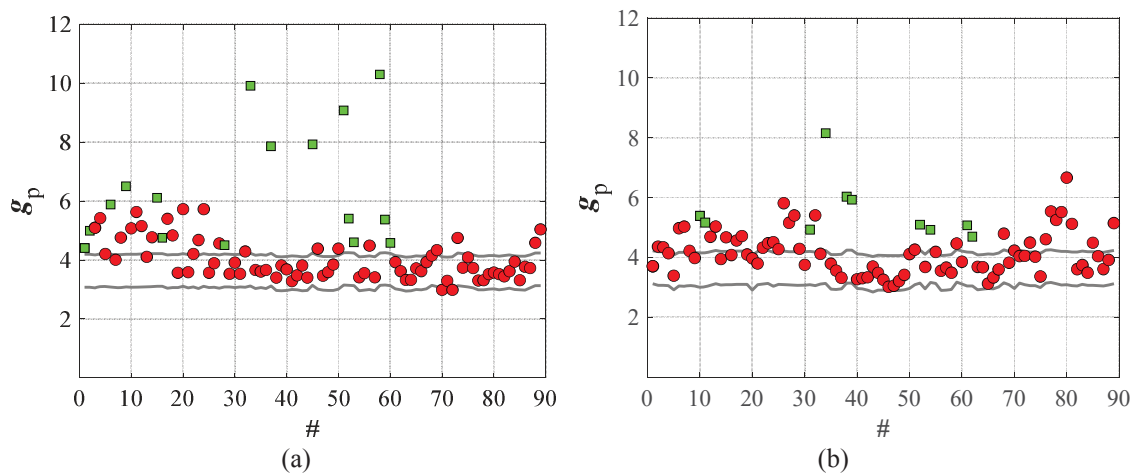

Figure 3: Gaussian and non-Gaussian processes for hyperbolic paraboloid roof: comparison between flatter (a) and more curved (b) roof.

Figure 4 shows a comparison between low (Fig.4a) and tall (Fig.4b) building covered with a hyperbolic paraboloid roof. It was observed that the building height slightly increase the number of non-Gaussian processes.

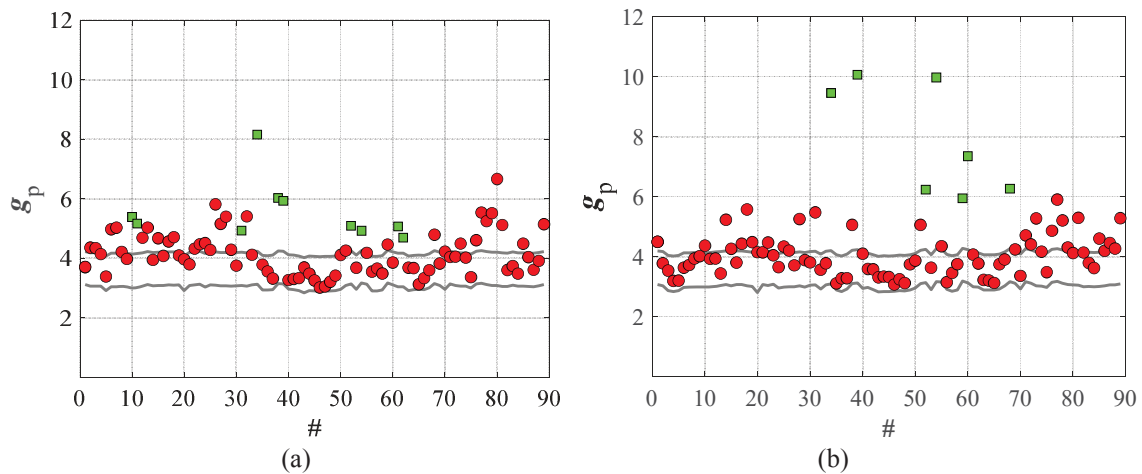

Figure 4: Gaussian and non-Gaussian processes for hyperbolic paraboloid roof: comparison between low (a) and tall (b) building.

Figure 5 shows a comparison between two wind angles,  $0^\circ$  (Fig.5a) and  $90^\circ$  (Fig.5b). For the wind angle equal to  $0^\circ$  the flow is parallel to cables with a downward curvature, for the wind angle equal to  $90^\circ$  the flow is parallel to cables with an upward curvature. It was observed that the wind direction closely affects the Gaussianity. Fig.5b shows that the number of non-Gaussian process for  $90^\circ$  is bigger than  $0^\circ$ .

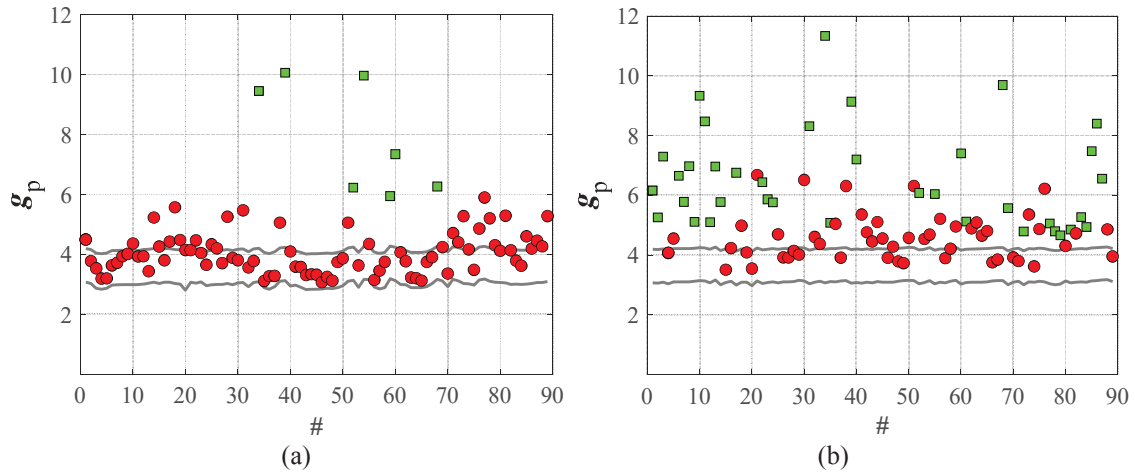

Figure 5: Gaussian and non-Gaussian processes for hyperbolic paraboloid roof: comparison between wind angle equal to  $0^\circ$  and  $90^\circ$ .

Figure 6 shows results for a closed box section (Fig.2) with two angles of attack,  $-10^\circ$  and  $0^\circ$ , respectively. Results show a very relevant difference between the two configurations (Fig.6a and Fig.6b). The number of Gaussian process decreases from  $-10^\circ$  to  $0^\circ$  due to the aerodynamics.

Figure 6: Gaussian and non-Gaussian processes for closed box bridge section: comparison between angle of attack equal to  $-10^\circ$  (a) and  $0^\circ$  (b).

## 4 CONCLUSIONS

The Gaussianity of random processes was investigated on different geometries of roofs and closed box section with different angle of attack. It was observed that:

- For roofs the curvature affects the number of Gaussian processes that increases for flatter roofs.

- The building height is not relevant in term of number of non-Gaussian processes for the geometry investigated.
- The wind direction closely affect the number of non-Gaussian processes for roofs with a double curvature (i.e. Hyperbolic paraboloid roofs) and during the oscillation of a closed box section for a suspended pedestrian bridge.

Data have shown that non-Gaussian processes are mostly located near edges and near the detachment zones. For these zones the davenport peak factor is not reliable because it underestimates the peaks of the random processes.

### Abstract

*The prediction of the maximum or minimum peaks of a random process in the fields of civil and mechanical engineering is a hot topic for the scientific literature. It is known that the maximum of a random process depends on the process length. For this reason, a probabilistic approach is necessary to estimate a reliable value from the process. Researchers for specific case of studies proposed several analytical models to predict maxima of a random process. Mostly, they are grouped on two families, models for Gaussian processes and models for non-Gaussian processes. Each model was computed and calibrated based on a specific experimental campaign for a specific case of study. This makes difficult to select the best model for every application. In addition, codes and standards neglect this topic and one might happen to make the error to assume the maximum value as the statistical maximum of the random process. Commonly, in the field of the structural engineering, peaks of a wind induced, or wind-induced flow acceleration time histories are estimated following the probabilistic approach of Cook and Mayne. However, from 1950 to today hundreds different probabilistic approach was given by literature. The purpose of this paper is to discuss an overview of models grouped by theoretical underlying assumptions.*

**Keywords:** Random processes, Gaussianity, stochastics, peak factors, wind tunnel.

---

## 1. INTRODUCTION

In the field of wind engineering the experimental tests in wind tunnel are the rule to investigate the building aerodynamics. In wind tunnel random processes of pressure are acquired through pressure taps and tubes located on the building surfaces. Generally, the main result that it is estimated is the pressure coefficient that is dimensionless respect to the wind tunnel velocity. In wind tunnel, processes generally are stationary, and the mean value does not depend on the history time length. However, the mean value of the pressure coefficient time history is not the only one parameter that is important for the building structural analyses. In many cases the most important magnitude is the maxima or minima peak of the random process that are closely important to design structure very sensitive to the wind action differently than structure sensitive to the seismic action [1]. This is a hot topic for the scientific literature in the fields of civil and mechanical engineering. Unfortunately, the absolute maximum (or minimum) of a random process depends on the process time length. Usually, a probabilistic approach is used to estimate a reliable maximum (or minimum) value from the process and several analytical models were proposed by the scientific literature. Mostly, they are grouped on two families, models for Gaussian processes and models for non-Gaussian processes. Each model was computed and calibrated based on a specific experimental campaign for a specific case of study and this makes difficult to select the best model for every application. The purpose of this paper is to discuss an overview of models grouped by theoretical underlying assumptions.

## 2. LITTERATURE OVERVIEW

### *2.1 From Cartwright and Longuet-Higgin, 1956 to Vanmarcke, 1975, through Davenport, 1964.*

One of the first analytical model computed to predict extreme peaks used the field of wind engineering is given by [2] (more recently developed by [3]) and it was computed to predict the peaks of the sea waves. It is based on the assumption that the process is stationery and Gaussian and that the maxima follow a Rayleigh distribution. Starting from this model, Davenport [4], developed the most used model to predict the peak factors of Gaussian processes. It was based on the assumption that largest extreme values of a Gaussian normalized and standardized process, asymptotically follow a Gumbel distribution. This model still today to be the base of all analytical models to predict extreme peaks. About ten year later, [5] accounting for the dependence among the crossing events through a shape factor calculated from the process spectral moments. Unlike Davenport's peak factor, Vanmarcke's [5], peak factor can be applicable to narrow-band response processes while taking consideration of the spectral bandwidth effects [6,7]. Several studies, also recently, have proposed method to extend the [4] and its subsequent updates to non-Gaussian processes, as for example [8] that proposed the extended Davenport peak factor (EDPF). This method relates the descriptors of the resultant, the parameters of the distribution function of the peaks, and the probability of not exceeding a given threshold, however the method seems to have be limited and poorly generalizable.

### *2.2 From Cook and Mayne 1979 to Harris, 2005*

From 1979 to today, the studies published by Cook are a milestone because they proposed a working approach based on a fully probabilistic assessment (i.e. the Gumbel distribution of extremes) to estimate wind loads for the equivalent static design of structures [9, 10]. This approach was born with the precise intent to fill a gap in codes and consequentially it is very

sample. This approach was proposed in [11] and refined in [12] in which the previous approach is extended from the original first-order form, to admit multiple-order corrections through a Monte-Carlo method that replaces the former integral method. This method is still very often used in the field of structural wind engineering [13]. The design fractile of extreme wind load coefficient distribution for a 50-year return period is recommended equal to 79%. According to [14] this value can be increased to 93% to estimate the extremes of the wind velocity, based on the multi-order technique applied by authors.

In Cook, 1982 [15], Cook proposed the peak-factor approach that aims to exceed the limits of the fully probabilistic approach, given by [11], for which fluctuations of load are due to corresponding gusts in the approach flow. These numerical approaches will feed in the designer's guide to wind loading of building structures, Parts 1 and 2 [16, 17]. These methods were based on the assumption that the process is stationary, and this hypothesis is one of the weaknesses on which [18] worked. It has given an extension of the methods given by Cook, to full-scale wind-load measurements where the flow is intrinsically non-stationary. Harris, 1982 [19] provides the [15] theoretical background fully probabilistic approach (i.e. based on the Gumbel distribution of the extremes). It proposed the elimination of the Monte-Carlo corrections, the will be widely used by researchers, as for example [20] that have used this method to estimates peak wind pressures on three-dimensional rectangular buildings with different aspect and side ratios in different atmospheric boundary layers.

Harris will develop the traditional Gumbel extreme value method in [21] through a fitting procedure using weighted least squares that improves set of plotting positions based on the mean values of the order statistics and subsequently, through a direct method given by [22]. This last method does not require Monte-Carlo simulations or the assumption that extreme pressures conform to the ultimate Fisher-Tippett Type I asymptote.

### *2.3 From Holmes and Moriarty, 1999 to Torrielli et al, 2016 through modification of the Cook and Mayne 1979 model*

Several approaches have discussed modification and updates of the [11, 12] approach focused on the probability trend of the extremes in a random process.

The important issue of the extreme peaks of the wind velocity discussed by [23] have inspired [24-26] that have applied the Annual Rate of Independent Events (ARIE) method values, though its modification, to estimate the extremes wind velocity, subsequently discussed for clarification by [27, 28] and [29]. The modification consists on using the Hybrid Weibull model given by [30], to describe the parent distribution of the wind velocity simulations.

Holmes and Moriarty, 1999 [31] proposed the generalized Pareto distribution (GPD) and its application to the statistical analysis of extreme wind speeds. It concluded that generalized extreme value distribution (GEVD) can be used to determine the appropriate value of shape factor,  $k$ , for use in the GEVD. In 2001, [32] and [33] not recommend this approach and discussed the conclusion given by [31], because this method is closely threshold dependent and so not applicable for a process with a Weibull parents. However, [34] confirm the goodness of this method using many and very long acquisitions of pressure series in wind tunnel experiments on a low-rise building as similarly it was done by [35].

Similarly, the Peaks-Over-Threshold (POT) is also affected by limits given by the practical applications of POT method as it was shown by [36]. An and Pandey, 2005 [36] shown that this model fail because the acute threshold sensitivity of wind speed estimates, which can be attributed to erratic variation of model and sampling errors with selected threshold values. In addition, [36], based on results given by [37], proposed a modification based on the assignment of an exponential prior on preconditioned data that is augmented with additional sample information in an optimal sense through the principle of Minimum Cross-Entropy (Cross-

Ent). An update of the POT method was proposed by [38] through a declustering of process to extract independent peaks over a given threshold. for POT method and [39].

#### *2.4 From Grigoriu 1984 to Kwon and Kareem, 2011, though Winterstein models.*

Meanwhile, [40] discussed the mean up-crossing rates for Gaussian and non-Gaussian processes, laying the groundwork for future analytical models that aim to predict extremes of non-Gaussian processes, as for example the analytical models given by [41, 42] and the chaos polynomial theory of which some applications are discussed by [43, 44]. This approach was largely used by researcher through application, as for example by [45, 46] or to develop new models. Winterstein proposed a nonlinear vibration approach using the Moment-based Hermite model to predict extremes of a random vibration, subsequently applied in [47] on a statistical analysis of tension-leg platforms. Kareem and Zhao 1994 [48] developed the model applied by [47]. The given improvement consists of an equivalent statistical quadratization method that permits to derive the response probability density function, crossing rates, and peak value distribution based on the first four cumulants. The method was known as revised Hermite model [49, 50].

This method was developed by [51] using a limited number of statistical moments. Subsequently the model given by [47] and based on the an equivalent statistical quadratization method was developed using a cubicization in [52]. Depending upon the nature of the nonlinearity, the quadratization and the cubicization method may be employed to approximate the process by a quadratic or cubic polynomial. It permits to preserve the nonlinearity using a Volterra functional series approach to attain the response transfer functions. The models is known as modified Hermite model [49]. The distribution of the largest peak values is assumed as a Gumbel distribution, which implies a Weibull distribution for the local peaks of the pressure coefficients.

Yang et al, 2013 [53] proposed a modification of modified Hermite model given by [52] and [54] has given an application. The modification proposed by [53] consists on a numerical inversion of the relationship between skewness, kurtosis and the Hermite model shape parameters and on an approximate solution to improve the accuracy of the Hermite model.

The peak factor for non-Gaussian processes given by [48], was used by [55] to simulate non-Gaussian processes in terms of correlation-distortion methods and application of higher-order spectral analysis. Similarly, the model given by [48] was used to Kareem et al 1998, that developed a technique to model the contribution of the quadratic drag term containing the square of the fluctuating velocity component through the development of a non-Gaussian gust loading factor via moment-based Hermite transformation. This model was based on the concept of a translation process given by [40], moment-based Hermite model given by [42], and the framework of Gaussian peak factor given by [4]. Thirteen years later, after [51] updates, [49] completed the model and it gives the variance of the estimates in standard deviation for the peak factor of non-Gaussian processes on the basis of a moment-based Hermite model [41, 42].

Later, [56] proposed the “L-Hermite” model, an alternative cubic transformation calibrated by the response “L-moments” rather than its ordinary statistical moments. However, this method seems valid only for specific cases of study as for example marine structures in shallow waters [57], because it cannot convey sufficient information to accurately estimate extreme response statistics. The Winterstein, 1988 [42] and 2000 [51] models were developed by [58] to improve their accuracy and simplify their application to measured data in the case of wind pressure data. In particular, [58] proposed a closed form approximate relationship between the skewness and kurtosis and the Hermite models shape

parameters. Based on its results, it suggests that the bandwidth parameter related to the 4th-order spectrum moment should not be introduced.

Several papers proposed new models based on the moment-based Hermite polynomial model as for example the model proposed by [59] that modify the Hermite polynomial method to obtain accurate approximation of extremes of processes with high skewness and Gaussian kurtosis. Many models promoted the Hermite polynomial model to transform non-Gaussian data into a Gaussian process. Huang et al 2016 [60, 61] results suggest that Hermite moment-based should be adopted in the peak value estimation for wind pressures only when the skewness and kurtosis of a process are sufficient to capture its non-Gaussian properties. However, Cook, 2016 [62] refuted these results applying the Bootstrapping methods (EVA ) [63].

Liu et al, 2016 and 2017 [64, 65] proposed a model that aims to solve the problem given by the positive and negative probability distribution tails that affect skewness and kurtosis are statistical moments. To improve the accuracy of the moment-based model approach, it derived a new moment-based translation model by defining a modified probability density function that is symmetric around the median of the original non-Gaussian process. Accordingly, the distributions of maximum and minimum are addressed separately using newly defined two sets of statistical moments with zero skewness. Rizzo et al, 2018 [50] have shown that for strongly non-Gaussian processes this method is not particularly accurate. Rizzo et al, 2018 [50] have given an application of the modified Hermite models on Hyperbolic paraboloid roofs [66-70].

### *2.5 From Sadek and Simiu, 2002 to Huang M. F. et al 2016*

The theory proposed by [71] was innovative because it proposed an automated mapping procedure to estimate the peak distribution of wind-induced non-Gaussian internal forces on low-rise buildings by using a database-assisted design software. This mapping procedure requires identifying an analytical marginal probability distribution for the time series of interest through numerical fitting of the distribution parameters. However, the Sadek and Simiu, 2002 [71] method has been applied only to non-Gaussian processes with an underlying marginal gamma distribution [50]. The result obtained is that a gamma distribution (i.e. three-parameter Gamma distribution) is appropriate for estimating the peaks corresponding to the longer tail of the time series' histograms and a normal distribution corresponding to the shorter tail of the time series' histograms, that are the same conclusions shown by [72]. The distribution of the peaks is then estimated by using the standard translation processes approach given by [40] and developed in [73]. It is found that the peak distribution can be represented by the Gumbel distribution. The estimation obtained through this approach is based on the entire time series and consequently it is more reliable than estimation based only on observed peaks. However, the three-parameter Gamma distribution specific relationship between skewness and kurtosis holds. Once the combinations of skewness and kurtosis of actual samples deviate far away from the relationship, remarkable fitting errors will be incurred [74]. Ma and Xu, 2017 [74], proposed an update of the Gamma method through the Johnson transformation to solve the fitting error. This method depends on the maximum likelihood (MML) [75] to estimate the Johnson transformation parameters.

Using the [71] procedure, [76, 77], estimated the extreme peak pressure distribution based on wind-induced time history pressure data recorded in a wind tunnel and determined the design pressure and load coefficients at any selected probability level of non-exceedance for reliability-based structural design. Recently, Yang et al, 2019 [75] proposed an update using a three-parameter Gamma distribution through formulations for estimating sampling errors of the first four statistical moments.

Based on the [71] results, [6] proposed the Gamma peak factor and it have applied this approach to estimate the wind-induced vibration on tall buildings. This study is one of the few studies that worked on accelerations, discussed in this paper, differently than pressure or wind velocity. For this reason, this contribute will be carefully discussed in the next sections.

From Sadek and Simiu, 2002 [71], Huang et al 2013 [78] and [79], gives an efficient model known as translated-peak-process method (TPP) for the estimation of the peak distribution, peak factor, and variability of extremes, based on the Weibull distribution and point-to-point mapping procedure. The innovation consists on a modification of the [71] from Gamma to Weibull distribution processes [50] and it is particularly efficient for non-Gaussian process. However, it needs to an elaboration of the measured data to fit a Weibull distribution that take only positive bigger than zero values.

### *2.6 Analytical models based on the ACER approach*

The univariate concept of average conditional exceedance rate (ACER) is a method for estimation of extreme wind speed statistics proposed by [80] and by [81] that have given an extension for estimation of extreme wind speed statistics to the case of bivariate wind speed time series based on the previous research on the Monte Carlo methods for estimating the extreme response of dynamic systems [82, 83]. Naess and Karpa, 2015 [81] calibrated and tested the bivariate method for simultaneous wind speed measurements from two separate locations. The univariate approach is based on two separate components: the first component has the capability to accurately capture and display the effect of statistical dependence in the data; the second component is then constructed so as to make it possible to incorporate to a certain extent also the subasymptotic part of the data into the estimation of extreme values [80]. The goodness of this analytical method was confirmed by [84] and it was used by the models developed by [85] and [86]. Finally, Chen, 2014 [87] proposed a model that, based on results given by [88], through the curve-fitting and extrapolation of crossing rate, permits the estimation of extreme values distribution using Poisson distribution of crossings.

## **3. CONCLUSIONS**

This paper discusses the most common analytical models to predict peaks (i.e. local and absolute) from random processes. Models are grouped based to milestones and specifically they are grouped in five families: (I) models for Gaussian process; (II) models from Cook school, (III) models based on Grigoriu studies; (IV) models based on the Sadek and Simiu studies and finally, (V) recent models based on the ACER approach. It is not possible to a priori estimate the best model for a specific case of study investigated and all models are valid until proven otherwise.

### Abstract

*In earthquake analyses, usually the seismic displacement is estimated by the sliding-block model, where a rigid block rests on an inclined plane and every time that the applied horizontal acceleration is larger than the critical horizontal acceleration value for relative motion, the block slides. This model is used for the prediction of permanent seismic movement of slopes along a predefined slip surface, by appropriately selecting the equivalent critical and applied acceleration values of the rigid block. However, the input seismic motion is usually specified at the underlying bedrock and the seismic displacement along a slip surface depends not only on the resistance along the slip surface, but also on the dynamic characteristics of the soil both above and below the slip surface. Based on the above, the present work investigates and proposes expressions relating the ratio of the seismic displacement of slopes along a slip surface and the corresponding displacement of the sliding-block model for similar applied acceleration and critical acceleration of the slip surface in terms of characteristics of the soil profile both above and below the slip surface. The proposed expressions were obtained based state-of-the-art description of the dynamic response and results of previous dynamic seismic sliding displacement analyses. Parametric analyses using a recently developed numerical code were performed to calibrate and validate the proposed expressions. In these analyses, different acceleration histories measured at rock sites are applied below soil layers with a slip surface with varying critical acceleration value and dynamic properties both above and below the slip surface.*

## 1 INTRODUCTION

The seismic displacement of slopes usually occurs along a slip surface [1]. Engineers usually assess the seismic safety of slopes using the dynamic factor of safety calculated from loads. However, evaluations based on the dynamic factor of safety have the serious drawback that they do not consider the seismic displacement, which is directly related to damage. In earthquake analyses, usually the seismic displacement is estimated by the sliding-block model [2], where a rigid block rests on an inclined plane and every time that the applied horizontal acceleration is larger than the critical horizontal acceleration value for relative motion ( $a_c$ ), the block slides. This model is used for the prediction of permanent seismic movement of slopes and retaining structures along a predefined slip surface, by appropriately selecting the equivalent critical and applied acceleration values of the rigid block [1, 3].

Different empirical expressions have been proposed predicting the seismic displacement of the sliding-block model, in terms, primarily, of the ratio of the maximum acceleration of the applied seismic motion by the critical horizontal acceleration for sliding [3]. In addition, some of these expressions use other than the maximum acceleration parameters of the seismic motion, such as the maximum velocity or the Arias Intensity, or parameters of the earthquake that produced the seismic motion, such as its earthquake magnitude or its earthquake fault distance [4,5]. Furthermore, region-specific empirical expressions have been proposed predicting the seismic displacement of the sliding-block model, as different regions have different earthquake faults and geological profiles conditions, and thus potentially different applied seismic motions characteristics [6].

However, the input seismic motion is usually specified at the underlying bedrock and the seismic displacement along a slip surface depends on both the dynamic characteristics of the sliding mass, and the soil profile below [8]. Based on the above, it is of interest for practicing engineers, to relate the seismic displacement along slip surfaces, not only on characteristics of the applied seismic motion and the critical horizontal acceleration for sliding of the slip surface, but also to the dynamic soil properties both above and below the slip surface. Expressions have been proposed predicting the seismic displacement of slopes in terms of not only characteristics of the applied seismic motion and the critical horizontal acceleration for sliding, but also on the dynamic characteristics of the sliding mass [7]. Furthermore, Katsenis et al [9] proposed empirical expressions relating the ratio of the seismic displacement of slopes along a slip surface and the corresponding displacement of the sliding-block model for similar applied acceleration and critical acceleration of the slip surface considering the dynamic soil profile characteristics both above and below the slip surface. Their relationships are in terms of the soil profile type of the slope according to Eurocode 8 [10] and the depth of the slip surface. Yet, the dynamic response of soil layers is related to its dominant period [7, 8], and Eurocode profile types provide only an approximate prediction of the actual dynamic response.

The present work extends the Katsenis et al. [9] work by proposing an empirical expression predicting the seismic displacement of slopes where the soil profile has any shear velocity value and depth both above and below the slip surface. In order to achieve this goal, below, first a critical literature review of the dynamic effect on the seismic displacement of slopes is pre-

sented. Then, based on this critical review, equations simulating the dynamic effect on the seismic displacement of slopes are proposed. Following, a data base of seismic motions measured at rock sites is obtained, mainly recorded in the European-Mediterranean regions and using this data base an evaluation of the model parameters of the proposed equations and an assessment of the accuracy of the model is performed. Finally, the paper discusses further validation and application of the proposed equation.

## 2 CRITICAL LITERATURE REVIEW OF THE DYNAMIC EFFECT ON THE SEISMIC DISPLACEMENT OF SLOPES

### 2.1 Eurocode

According to Eurocode 8 (European Standard, 2003), as illustrated in Fig. 1, the dynamic response of elastic systems ( $S$ ) depends on the critical period of the system ( $T_s$ ) according to the following equations:

$$T_s < T_a \quad S(T_s) = 1 + A T_s / T_a \quad (1)$$

$$T_a \geq T_s \geq T_b \quad S(T_s) = 1 + A$$

$$T_s > T_b \quad S(T_s) = (1 + A) (T_b / T_s)^B$$

Where the parameters  $A$  and  $B$  typically equal 0.25 and 2/3 respectively and the parameters  $T_a$  and  $T_b$  depend on the underlying soil type and for rock sites they equal  $T_a = 0.10s$   $T_b = 0.40s$ .

Figure 1: Seismic response in terms of  $T_s$  as predicted by Eurocode 8 (European Standard, 2003) for rock sites.

### 2.2 Work by Rathje and Bray [7] and Bray and Travarasrou [13]

The effect of the dynamic response of the sliding mass on the seismic displacement along slip surfaces has been modelled among others by Rathje and Bray [7]. They consider the 1-dimensional geometry of Fig. 2a where a horizontal shear wave propagates vertically above a

slip surface with critical acceleration  $a_c$  at a body with height  $h$  and shear wave velocity  $V_s$  and identify the critical period of the system, as

$$T_s = 4h / V_s \quad (2)$$

Fig. 2b presents typical predictions of their model: The variation of sliding displacement with  $T_s/T_m$ , where  $T_m$  is the mean period of the applied seismic motion, for the Aegion 1995 seismic motion with  $a_c=0.5\text{m/s}^2$ ,  $h= 15\text{m}$ ,  $\rho= 2 \text{ Mg/m}^3$  and damping  $\lambda=0.15$  is presented. In Fig. 2b it can be observed that, similarly to Fig. 1, the effect of dynamic response (a) does not exist for  $T_s=0$ , (b) as  $T_s$  increases, the dynamic effect increases and it produces maximum response approximately when  $T_s=T_m$  and (c) as  $T_s$  further increases beyond  $T_m$ , it decreases the final seismic displacement along the slip surface ( $u_f$ ) towards zero.

Consistently, Bray and Travasarou [13] proposed empirical expressions relating the seismic displacement, in addition to the critical acceleration  $a_c$  and characteristics of the applied seismic motion such as the earthquake magnitude  $u_f$ , to  $T_s$ .

Figure 2: (a) The Rathje and Bray [7] model and (b) typical predictions of the model: Variation of sliding displacement with  $T_s/T_m$  for rigid and dynamic analyses. The Aegion 1995 seismic motion with  $a_c=0.5\text{m/s}^2$ ,  $h= 15\text{m}$ ,  $\rho= 2 \text{ Mg/m}^3$  and  $\lambda=0.15$  is presented.

### 2.3 The Katsenis et al. [9, 11] model

In the analyses described above the effect of the soil profile below the slip surface on the seismic displacement has not been studied. The Katsenis et al [9, 11] model, is a cost-effective

model which can study it: As shown in Fig. 3b, it considers the 1-dimensional dynamic response of a horizontal soil profile of depth  $(h_1+h_2)$  with a slip element at depth  $h_1$ . Different shear wave velocities ( $V_{s-1}$ ,  $V_{s-2}$ ), densities ( $\rho_1$ ,  $\rho_2$ ) and damping ( $\lambda_1$ ,  $\lambda_2$ ) may exist above and below the slip element. The slip element simulates the seismic displacement of the conventional sliding-block model, where its resistance is defined by the critical horizontal value ( $a_c$ ), for which relative movement in only one direction occurs. The two bodies move a horizontal distance  $x_i$ , velocity  $\dot{x}_i$  and acceleration  $\ddot{x}_i$ , where  $i$  takes the values 1 and 2 for bodies 1 and 2 respectively. The corresponding field configuration is that of a slope with a slip surface where seismic displacement may accumulate as a result of a horizontal shear wave, illustrated in Fig. 3a

Figure 3: The Katsenis et al, (2020) model: (a) field configuration of a slope with a slip surface where seismic displacement may accumulate as a result of a horizontal shear wave, (b) simulation of (a) with a 1-D dynamic system of 2 continuous bodies separated by a horizontal slip element. In the dynamic system (b) slippage may occur along AA'.

#### 2.4 Results of the Katsenis et al. [11] model

Katsenis et al. [11] define

$$Ts1 = 4 h_1 / V_{s-1} \quad (3a)$$

$$Ts\text{-ave} = 4 (h_1 / V_{s-1} + h_2 / V_{s-2}) \quad (3b)$$

and Fig. 4 presents a typical computed permanent seismic displacement ( $u_f$ ) response of their model. In particular, the computed displacement ( $u_f$ ) for the Aegion 1995 seismic motion with  $a_c = 0.5 \text{ m/s}^2$ ,  $h_1 + h_2 = 30 \text{ m}$ ,  $\rho_1 = \rho_2 = 2 \text{ Mg/m}^3$  and  $\lambda_1 = \lambda_2 = 0.15$  (a) versus  $Ts1/T_m$  for  $V_{s-2} = V_{s-1}$ ,  $h_2 = 1 \text{ m}$ ,  $15 \text{ m}$ ,  $25 \text{ m}$ , (b) versus  $Ts1/T_m$  for  $h_2 = 15 \text{ m}$  and (c) versus  $Ts\text{-ave}/T_m$  for the cases (a) and (b) is presented.

It can be observed that the effect of the soil profile both above and below the slip surface on the seismic displacement is considerable and that if  $u_f$  is plotted in terms of the ratio  $Ts\text{-ave}/T_m$ , the scatter in results for different  $V_{s-2}$  and  $h_2$  values decreases considerably. It is inferred that the dynamic effect on  $u_f$  can partly be interpreted by relating  $u_f$  to  $Ts\text{-ave}$ . In particular, similarly

to the response of Figs. 1 and 2, but replacing  $T_s$  with  $T_{s-ave}$ , it can be observed that the dynamic response (a) does not exist for  $T_{s-ave}=0$ , (b) as  $T_{s-ave}$  increases, the dynamic effect increases and it produces maximum response approximately when  $T_{s-ave}=T_m$  and (c) as  $T_{s-ave}$  further increases beyond  $T_m$ , it decreases the final seismic displacement along the slip surface ( $u_f$ ) towards zero.

Furthermore, Katsenis et al. [11] illustrate that the dynamic response play an important role for small seismic displacement, but a smaller role for large seismic displacement ( $>0.5$  m). Typical results are given in Fig. 5, where the ratio of the rigid and dynamic  $u_f$  value tends to zero as  $a_c$  decreases. Indeed, as identified by previous researchers also [14], large seismic displacement corresponds to low critical acceleration value, which limits the seismic actions transmitted across the slip surface, and thus the dynamic effect.

Figure 4: The computed permanent seismic displacement ( $u_f$ ) for the Aegion 1995 seismic motion with  $a_c=0.5\text{m/s}^2$ ,  $h_1+h_2=30\text{m}$ ,  $\rho_1=\rho_2=2\text{ Mg/m}^3$  and  $\lambda_1=\lambda_2=0.15$  (a) versus  $T_{s1}/T_m$  for  $V_{s-2}=V_{s-1}$ ,  $h_2=1\text{m}$ ,  $15\text{m}$ ,  $25\text{m}$ , (b) versus  $T_{s1}/T_m$  for  $h_2=15\text{m}$  and  $V_{s-2}=75, 150, 300, 500\text{m/s}$  and (c) versus  $T_{s-ave}/T_m$  for the cases (a) and (b) [11].

Figure 5: Computed permanent seismic displacement ( $u_f$ ) by [11] for the elastic and rigid analyses in terms of  $a_c$  for the Aegion 1995 seismic motion,  $h_1=h_2=15\text{m}$ ,  $V_{s-1}=V_{s-2}=200\text{m/s}$ ,  $\rho_1=\rho_2=2\text{Mg/m}^3$ ,  $\lambda_1=\lambda_2=0.15$ .

## 2.5 Previous empirical equation

Different empirical expressions have been proposed predicting the seismic displacement of the conventional sliding-block model ( $u_{f-bl}$ ) in terms of  $a_c$  and characteristics of the seismic motion such as  $a_{max}$ , Arias intensity, earthquake magnitude etc. [2-6]. In addition, some of these

expressions are region-specific [7]. Katsenis et al. [9] in order, to separate the dynamic effect from the seismic displacement accumulating along the slip surface for rigid blocks, propose to relate  $u_f$  on the conventional sliding-block model ( $u_{f-bl}$ ) seismic displacement for the same applied seismic motion and critical acceleration value, as

$$u_f = R u_{f-bl} \quad (4)$$

where the factor  $R$  simulates the dynamic effect and depends on various factors such as  $u_{f-bl}$ , the soil profile type and the depth of the slip surface.

### 3 PROPOSED EQUATION PREDICTING THE DYNAMIC EFFECT ON THE SEISMIC DISPLACEMENT OF SLOPES

The problem considered is that of Fig. 3a where a seismic horizontal motion is applied at the bedrock underlying a soil profile where a potential slip surface exists at some depth, which is simulated with the system of Fig. 3b.

In order, to separate the dynamic effect from the seismic displacement accumulating along the slip surface for the same seismic motion, which has been predicted by previously proposed empirical equations, similarly to [9], we relate  $u_f$  on the conventional sliding-block model seismic displacement for the same applied seismic motion and critical acceleration value ( $u_{f-bl}$ ). More specifically, we propose the following equation to predict  $u_f$ :

$$u_f = u_{f-bl} K_{dyn} \quad (5a)$$

At this point it should be noted that  $u_{f-bl}$  equals to  $u_f$  in the case of a very stiff or of a very shallow soil profile, where  $Ts-ave$  tends to 0.

As described above, (i) the dynamic response can be simulated in terms of the critical period by an equation of the form of equation (1), (ii) the dynamic response of the problem considered depends on the value of  $Ts-ave$ , given by equation (3b), (iii) the response of Figs. 4 illustrate that the dynamic response (a) does not exist for  $Ts-ave=0$ , (b) as  $Ts-ave$  increases, the dynamic effect increases and it produces maximum response approximately when  $Ts-ave=T_m$  and (c) as  $Ts-ave$  further increases beyond  $T_m$ , it decreases the final seismic displacement along the slip surface ( $u_f$ ) towards zero and (iv) the dynamic effect is affected by the magnitude of the sliding seismic displacement. Thus, we apply equation (1) by assuming that  $T_a=T_b$  and replacing and  $T_s$  with  $Ts-ave$  and we obtain

$$\begin{aligned} Ts - ave &\leq T_a & K_{dyn}(Ts-ave) &= 1 + A Ts-ave/T_a \\ Ts - ave &> T_a & K_{dyn}(Ts-ave) &= 1 + (1+A) (T_a /Ts-ave)^B \end{aligned} \quad (5b)$$

where  $T_a$  is the  $Ts-ave$  value where  $K_{dyn}$  is maximum and the parameters  $A$ ,  $B$  determine the peak value and the post-peak rate of decrease of the dynamic effect, as illustrated in Fig. 6. Section 2.4 above, described that the dynamic effect diminishes as the seismic displacement increases, or, equivalently, as the critical acceleration value for relative motion increases. Indeed, at the time intervals where seismic displacement accumulates, the body above the slip surface is separated from and moves independently from the body below the slip surface, and thus the relationship between the dynamic effect and the factor  $Ts-ave$  ceases to exist.

We define as ( $R_t$ ) the ratio of the sum of times where the seismic displacement accumulates ( $t_s$ ) by the total duration time of the applied seismic motion:

$$R_t = t_s / t_t \quad (6a)$$

Based on the discussion above, it is inferred that as ( $R_t$ ) increases towards 1, the dynamic effect diminishes. Thus, as  $R_t$  increases, the factors A and B of equation (5b) decrease, and in particular for large values of  $R_t$ , A and B tend to zero.

Yet, the factors  $t_t$ ,  $t_s$  are not usually used or specified on earthquake engineering. On the other hand, the intensity of a seismic motion is best defined by the Arias Intensity measure ( $I_a$ ) [5, 6] and the corresponding magnitude of the relative slip which occurs can be identified by  $u_{f-bl}$ . Thus, we approximate the factor  $R_t$  of equation (6a) with the factor  $R'_t$  defined by commonly used and well defined parameters  $I_a$  and  $u_{f-bl}$  as

$$R'_t = (u_{f-bl} / I_a) \quad (6b)$$

As  $R'_t$  increases, the factors A and B of equation (5b) decrease towards zero and thus we can write

$$A = a_1 (I_a / u_{f-bl})^{a_2} \quad (5c)$$

$$B = b_1 (I_a / u_{f-bl})^{b_2} \quad (5d)$$

where  $a_1$ ,  $a_2$ ,  $b_1$ ,  $b_2$  are model parameters.

It can be noted that equations (5b) and (5d) predict that, similarly to the response described in section 2.4, (a) A and B decrease, and the dynamic response decreases, as  $A_r$  decreases and  $u_f$  increases and (b) A and B tend to zero and the dynamic response diminishes as  $A_r$  tends to zero and as  $u_f$  becomes very large.

Figure 6: The function  $K_{dyn}$  in terms of (a) A and (b) B. In (a)  $B=0.5$  and in (b)  $A=1$ .

#### 4 DATA BASE AND PARAMETRIC ANALYSES

A data base of seismic motions was obtained using the ESM site (the Engineering Strong-Motion Database), which contains waveforms with magnitude  $\geq 4.0$ , mainly recorded in the European-Mediterranean regions and the Middle-East and provides a set of facilities to search, select, download and analyze ground-motion data. It is obtained by selecting the Northern and Eastern components of seismic motions with the following restrictions: Soil type according to EC8 : A (Rock),  $\max(\text{PGA}) > 100 \text{ cm}^2/\text{s}$ ,  $M > 5$ . The reason of the selection described above is that (a) the Katsenis et al. [9, 11] model input motions must correspond to seismic motions at rock sites without the amplification and modification phenomena that seismic motions exhibit as they pass thru soil layers and (b) seismic motions with  $\max(\text{PGA}) < 100 \text{ cm}^2/\text{s}$  and  $M < 5$  typically do not cause intolerable seismic displacement along slip surfaces.

The data base included 56 cases, sorted in descending PGA order, given in Appendix A. For the present application four seismic motions were selected. In particular, as the seismic displacement greatly depends on PGA, the seismic motions were selected starting from the first and taking the next after passing 12. In this way, the seismic motions No1, 13, 25, 37 were selected, having a variety of PGA values, ranging from large to small PGA. Table 1 gives the main characteristics of these applied seismic motions.

Coupled linear dynamic parametric analyses were performed using the Katsenis et al. [9, 11] model, and more specifically the corresponding numerical code DIAS [11]. All the seismic motions described above were applied at the base of soil column with  $h_1=h_2=15\text{m}$ . The shear wave velocities of the two bodies considered are given in table 2. In each seismic motion, at the slip surface three  $a_c$  values were assumed, selected in such a way that  $u_{f-bl}$  equals 0.01, 0.1, 1m, which cover the range of typical values of typical field problems of instability interest. In addition,  $\lambda_1=\lambda_2=0.05$ ,  $\rho_1=\rho_2=2\text{t/m}^3$  were assumed.

No	Region	Date	ML	Epicentral Distance	PGA ( $\text{cm/s}^2$ )	Ia (cm/s)	Tcr (s)
1	Turkey, Düzce	11/12/1999	6.6	27.4	-1010	1331.53	0.25
2	Montenegro	15/04/1979	6.8	62.9	211	73.32	0.25
3	Turkey, Düzce	12/11/1999	6.6	30.3	-157	44.30	0.25

Table 1: The main characteristics of the applied seismic motions.

$V_{s-1}$ (m/s)	50	100	130	180	270	370	470	580	700	1000	2000
$V_{s-2}$ (m/s)	75	1500	300	500	750	5000					

Table 2: Shear wave velocities applied in the parametric analyses

#### 5 EVALUATION OF MODEL PARAMETERS

Fig. 7 gives the obtained results of the parametric analyses: The ratio  $u_f/u_{f-bl}$  in terms of  $T_{s-ave}$  in terms of applied seismic motion and  $u_{f-bl}$  is given for all seismic motions. Similarly to the theory described above, it can be observed that plotting the results for each case of seismic motion and  $u_{f-bl}$  values in terms of  $T_{ave}$  has small scatter and this is true especially for small

$u_{f-bl}$  values. It is also worth noting that in the results presented in Fig. 7,  $u_f/u_{f-bl}$  was plotted in terms of  $T_{s1}$  instead of  $T_{s-ave}$  also, and it was observed that the scatter was much larger.

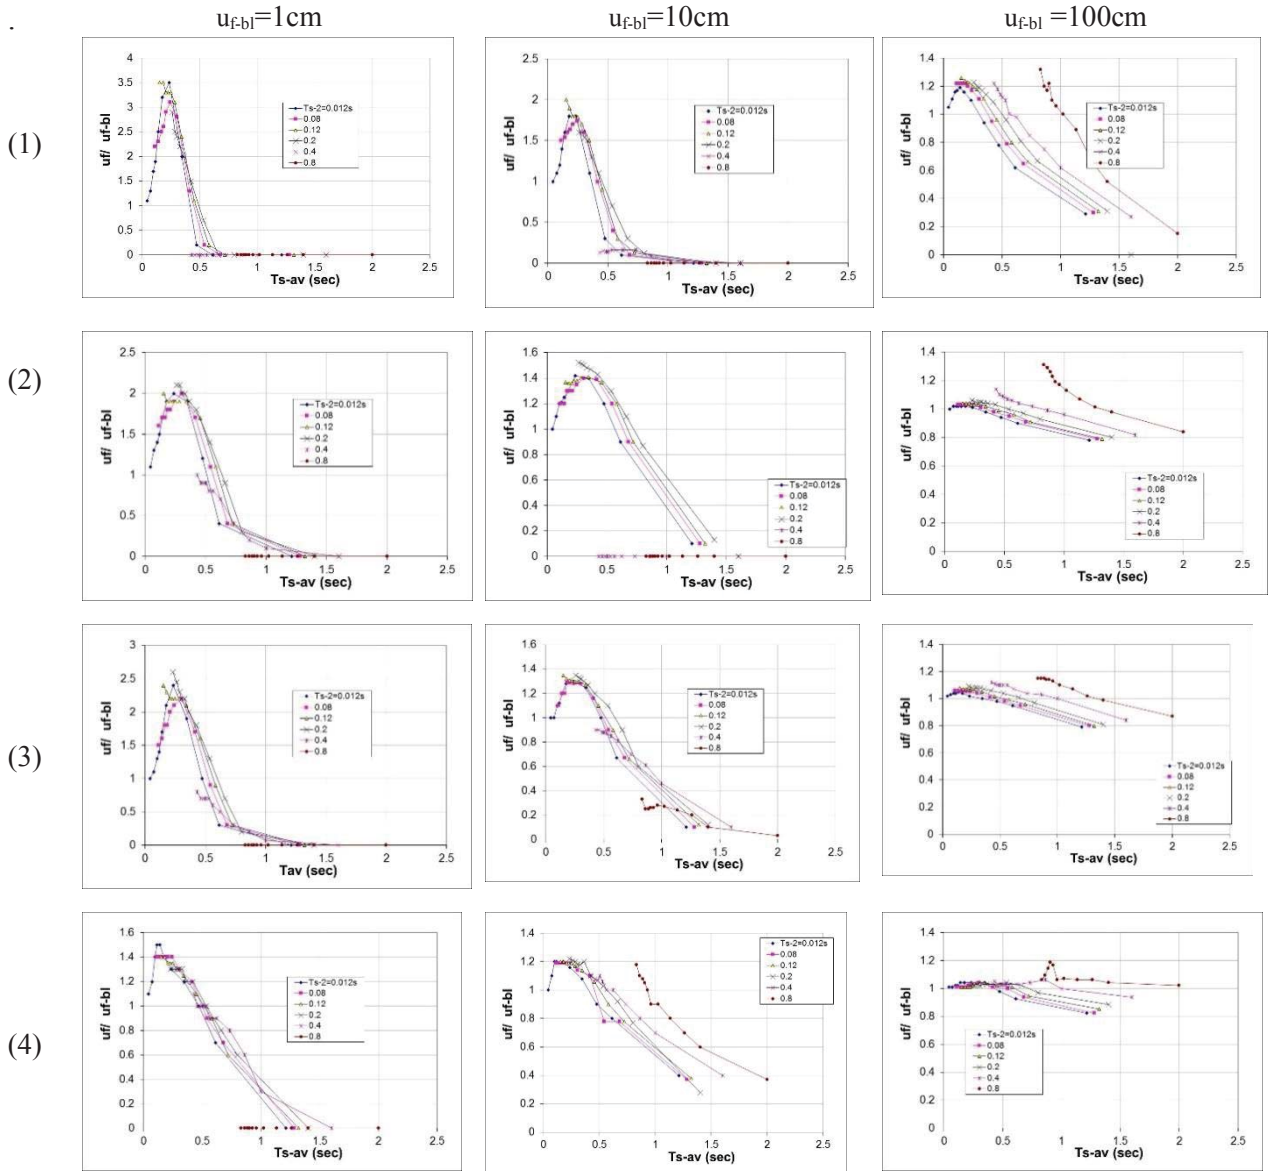

Figure 7: The function  $K_{dyn}$  for the seismic motions (1)-(4) in terms of  $u_{f-bl}$ .

For each case of seismic motion and  $u_{f-bl}$  value, the model parameters simulating the dynamic response according to equation (5) were obtained. In all cases, the seismic response was simulated well when

$$T_a = 0.3s \quad (5.e)$$

It can be noted that this value is consistent with section 2.1 statement that in rock sites  $T_m$  does not exceed 0.4s. With  $T_a = 0.3s$ , table 3 gives the obtained factors A and B. Fig. 8 presents the parameters of table 3: The factors A and B in terms of (a)  $(1/u_{f-bl})$ , (b)  $I_a$ , (c)  $(I_a/u_{f-bl})$  are given.

Strong correlations are observed in all cases and as illustrated in Fig 8c, the best-fit correlations of the relations (5c) and (5d), according to equation (5b), occur when,

$$a1=0.17, a2=0.39 \quad (5.f)$$

$$b1=0.20, b2=0.35 \quad (5.g)$$

As illustrated in Fig. 8c, the coefficient of determination is larger than 0.85 in all cases and as the coefficient of determination is close to unity, it is inferred that the proposed equation describes well the computed response

(a) Factor A

<i>Ia (cm/s):</i>	<i>u<sub>f-bl</sub>(cm): 1331.5</i>	<i>73.3</i>	<i>44.3</i>	<i>19.7</i>

## 6 DISCUSSION

### 6.1 Validation and Application

Partial validation of the proposed equation (5) is the fact that the coefficient of determination ( $R^2$ ) of the fitting parameters  $a_1$ ,  $a_2$  and  $b_1$ ,  $b_2$  of the proposed equation is near unity and certainly larger than 0.8. However, it is desirable to perform additional analyses to validate equation (5), especially as only four seismic motions were used to derive it. For this purpose, more parametric analysis to validate the proposed equation and analyze its error may be performed by applying all the seismic motions of table A1, as well as different soil profiles.

Furthermore, because deterministic methods obtaining empirical expressions predicting the seismic displacement of slopes do not rationally take into account the uncertainty of these expressions, researchers have recently turned to the probabilistic approach: (a) Creating probability curves of an annual exceedance of a specific value [15], or (b) fragility curves which give the possibility of exceeding a certain seismic displacement value in the design time depending on the properties of the seismic excitation and of the slope [16]. Thus, it is desirable

to extend and modify as necessary the proposed equation (5) by applying probabilistic methods.

### 6.2 Effect of non-linearity

Soil behaves linearly only at very small shear strains, well below the typical shear strains exerted in soil profiles near severe earthquakes [11]. It is inferred that for accurate predictions, the linear methods described above must be extended with constitutive equations simulating the non-linear soil response. Under dry conditions the degradation of the shear modulus with shear strain must be simulated. The Katsenis et al [11] model simulates this degradation in terms of the Plasticity Index of the Soil (PI), as proposed by the state-of-the-art model of Vucevic and Dobry [17], shown in Fig. 9a. Typical results of numerical simulations illustrating the profound effect of soil non-linearities on the seismic response are given in Fig. 9b. The case of the Aegion 1995 seismic motion with  $a_c=0.5\text{m/s}^2$ ,  $V_{s-2}=V_{s-1}$ ,  $h_1=h_2=15\text{m}$ ,  $\rho_1=\rho_2=2\text{Mg/m}^3$ ,  $\lambda_1=\lambda_2=0.15$ ,  $PI_1=PI_2=0$  is considered.

Katsenis et al. [11] observed that the effect of soil non-linearities can be simulated in linear analyses by reducing the shear wave velocity to the average value one during the non-linear dynamic simulation. Thus, it is inferred that equation (5) may potentially be extended to predict the non-linear soil response by proposing methods which adequately reduce the  $V_{s-1}$  and  $V_{s-2}$  values in terms of the intensity of the applied seismic motion and the soil stiffness.

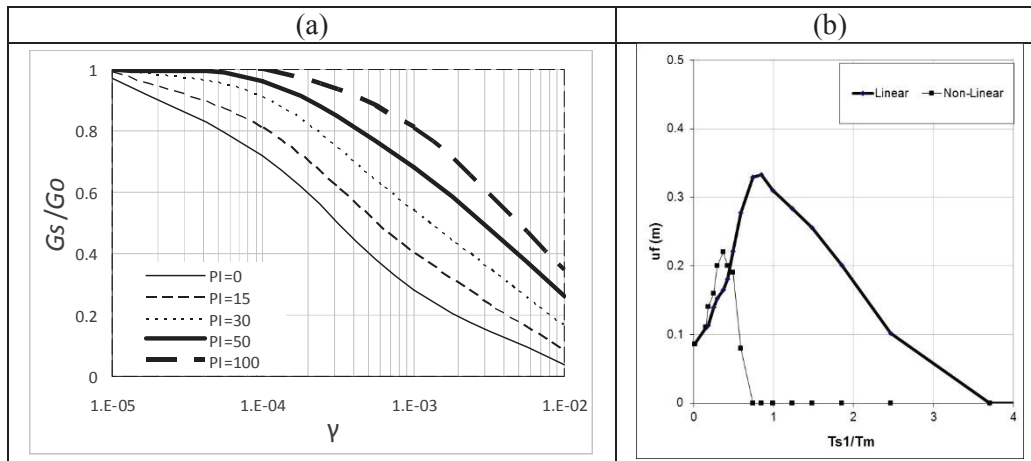

Figure 9: (a) Shear modulus degradation versus shear strain in terms of PI, as proposed by Vucevic and Dobry [17], (b) The computed displacement ( $u_f$ ) by Katsenis et al. [11] for the linear and nonlinear dynamic analyses versus  $Ts1/Tm$  for a specific case, described in the text.

## 7 CONCLUSIONS

- Expressions have been proposed predicting the seismic displacement of slopes in terms of characteristics of the applied seismic motion and the critical horizontal acceleration for sliding and only the dynamic characteristics of the sliding mass [7]. Only Katsenis et al. [9] proposed empirical expressions in terms of the soil profile both above and below the slip surface. Yet, their expressions are in terms of the soil profile type of the slope according to Eurocode 8 and not related to the dominant profile period.
- The present work proposes equation (5) simulating the effect of the dynamic response on the seismic displacement of slopes in terms of the dominant period of the soil profile both above and below the slip surface.
- This equation is based on state-of-the-art descriptions of the dynamic response, results of previous dynamic seismic sliding displacement analyses and numerical predictions of the model of Fig. 3b.
- It is desirable to perform more parametric analysis to validate the proposed equation and analyze its error.
- The proposed equation may be extended to predict the non-linear soil response.

### Abstract

*Urban development is increased and the construction of building on poor quality soils becomes non avoidable which increases the geotechnical risk. Below these circumstances, the probabilistic approaches to study the behavior of a soil profile in a given environment have been proposed in recent years. The purpose of this research work is to study the effect of vertical variability of soil shear modulus on soil seismic response using the probabilistic approach. Two types of heterogeneity are considered: (1) heterogeneity due to the random distribution of the shear modulus in a soil profile; (2) heterogeneity of soil layer with shear modulus increasing linearly with depth. The first heterogeneous soil models are generated by Monte Carlo simulation. The spatial variation of the shear modulus is controlled by the variation coefficient parameters. The second heterogeneous soil models are assumed to have shear modulus increasing linearly with depth. These heterogeneous soils are generated and then integrated into the computer program based on the one dimensional wave propagation, resulting in seismic responses at the 'free field' soil. To demonstrate and show the importance of considering heterogeneities in the model, the results are compared with examples of deterministic analysis by means of the experimental value of shear modulus obtained from a specific site in Algeria.*

## 1 INTRODUCTION

In geotechnical practice, the determination of soil properties is based on tests carried out on a limited number of samples in the laboratory or on site. Soil state variables in space and time are due to complex geological conditions. Their properties change from a point to another. Due to the uncertainty associated with their inherent spatial variability, and limited available information, soil properties can be considered as random variables. Moreover, poor soil sampling procedures, test procedures, characteristics of the test setup device and operator experience can have a large impact on the measured geotechnical properties. The probabilistic approach is often used in engineering sciences to represent and decrease these uncertainties. It attempts to take into account all the uncertainties affecting the properties of soils, and allow the engineer to make the decision that bringing more objectivity; it assumes that the characteristics are variables defined by a mean, a standard deviation and a distribution law. To consider these uncertainties using the probabilistic approach, soil properties are treated as random variables. These random variables are functions defined on a sample space to represent quantities that can change. In practice, a random variable is where the estimated value is uncertain, but a certain probability can be assigned to any specific value (take values from a finite or countable set) "for discrete random variables" or within any value from an interval on a real line "continuous random variables".

Several studies have been conducted taking into account uncertainty in geotechnical engineering, Tian and Jie [1] conducted a study of the uncertainty of soil parameters, regarding the shear wave velocity (VS), thickness (h), density and damping for the propagating of one-dimensional wave. Specific conclusions were drawn. Nour [2] studied, two-dimensional seismic response, using Monte Carlo simulations combined with the deterministic method of shear modulus, critical damping and Poisson's ratio of soil properties. The results showed a significant attenuation of the tendency of the acceleration at the ground surface compared to the homogeneous case. Dominic et al [3] carried out a study of the importance of the spatial variability of soil properties on the surface response spectrum using Monte Carlo simulation based on the Popescu methodology [4]. They concluded that local conditions are important according to the gradient of the stiffness of the profile and intensity of the movement and that further studies should be performed. Paolo and Cornell [5] presented a probabilistic work to study the effect of soil layers on the estimation of the nonlinear amplification function, AF (f) and the acceleration response spectrum for a frequency range of the oscillator of the structures. The results revealed that AF (f) depends strongly on the intensity of the input soil movement at the same oscillator frequency, for the two soil types studied (sand and clay). Andrade and Borja [6] performed a combined stochastic-deterministic analysis of the local site response. To compare the sensitivities of equivalent linear and non-linear analysis procedures, two computer codes SHAKE and SPECTRA were used. The soil variability as well as the frequency and duration of earthquakes were considered in this study. The results showed that SPECTRA has approximately the same sensitivity as SHAKE.

Other recent typical examples include the work of Li and Assimaki [7], Johari A. [8] and Menzer Pehlivan et al [9] examined the special variability of soil on the prediction of a strong soil motion, where the consequences of spatial variability on the seismic response are not well understood. The basic characteristics of any layer are the shear wave velocity, the thickness and the non-linear properties of soil. The values of these properties in nature through a site vary from one point to another and there is always uncertainty in their measurement, this is a major contributor to uncertainty in geotechnical engineering analyzes.

## 2 PROBABILISTIC METHOD OF INDIRECT SIMULATION OF NON-GAUSSIAN RANDOM FIELDS

The probabilistic method of indirect simulation of non-Gaussian random fields is based on the theory of random fields. This approach is based on the decomposition of random variables as described by Fenton [10].

The algorithm that allows the generation of  $\Delta f_p(z)$  is described as follows:

$$\Delta f_p(z) = \sum_{n=1}^{N_p} \Delta g_{pn}(z) \quad (1)$$

With  $N_p$  is the number of soil properties to be simulated. The Gaussian random field with  $N_p$  variables, one-dimensional, with zero mean and unity variance  $\Delta g_{pn}(z)$  can be simulated as follows [11, 16]:

$$\Delta g_{pn}(z) = \sqrt{2} \sum_{l=0}^N A_{l,pn} \cos(k_l z + \Omega_{l,pn}) \quad (2)$$

With

For multivariate fields

$$A_{l,pn} = H_{pn}(k_l) \sqrt{2\Delta k} \quad (3)$$

For uni-variate fields

$$A_l = \sqrt{2S(k_l)\Delta k} \quad (4)$$

Equation (3) also can ensures the inter-property correlation,  $\Omega_{l,pn}$  are random phases uniformly distributed in the interval  $[0, 2\pi]$ . The coefficients  $H_{pn}$  are obtained from the inter spectral density matrix in the wave number domain  $S(\mathcal{K})$ , the latter is a real, symmetrical matrix, and positive definite. The elements of the matrix  $H$  are obtained from the Cholesky decomposition of the symmetric matrix  $S$  which is defined by:

$$S(k) = \begin{bmatrix} S_{11}(k) & S_{12}(k) & \cdots & S_{1N_p}(k) \\ S_{21}(k) & S_{22}(k) & \cdots & S_{2N_p}(k) \\ \cdots & \cdots & S_{p_i p_i}(k) & \cdots \\ S_{N_p 1}(k) & S_{N_p 2}(k) & \cdots & S_{N_p N_p}(k) \end{bmatrix} \quad (5)$$

The matrix  $H_{pn}$  is assumed to be lower triangular:

$$H(k) = \begin{bmatrix} H_{11}(k) & 0 & \cdots & 0 \\ H_{21}(k) & H_{22}(k) & \cdots & 0 \\ \cdots & \cdots & \cdots & 0 \\ H_{N_p 1}(k) & H_{N_p 2}(k) & \cdots & H_{N_p N_p}(k) \end{bmatrix} \quad (6)$$

with  $\mathcal{K}$  is the number of waves which satisfies:

$$\begin{cases} k_l = l \cdot \Delta k \\ k_u = N \cdot \Delta k \end{cases} \quad (7)$$

The wavenumber step  $\Delta\mathcal{K}$  is evaluated from the representation of  $S\mathcal{K}$  and by evaluating the cut-off wavenumbers values  $\mathcal{K}u$  for  $N$  increments,  $\mathcal{K}u$  is defined by:

$$k_u = \frac{1}{a} \sqrt{\ln\left(\frac{1}{\lambda^4}\right)} ; \lambda = 0.001 \quad (8)$$

$a$  is a parameter statistic, which is obtained from a non-linear regression of experimental data.

In this study, we consider one-dimensional, univariate, homogeneous but non-Gaussian field with mean zero and spectral density function given by [2]:

$$S(k) = \frac{\sigma^2|_{\sigma=1} a}{2\sqrt{\pi}} \exp\left[-\left(\frac{ka}{2}\right)^2\right] \quad (9)$$

In order to considerably reduce the computing time, the digital generation of sample functions of equation (2) is easily calculated using the Fast Fourier Transform (FFT), developed by Yamazaki and Shinozuka [17] and modified by Zerva [18].

The analysis carried out in this paper considers  $\lambda$  (is a small real number close to zero) equal to 0.001.

### 3 SPATIAL VARIABILITY OF UNBOUNDED SOIL PROPERTIES

Soil properties such as elastic modulus  $E$ , shear modulus  $G$ , permeability  $k$ , etc., are assumed to be lognormally distributed. This choice is motivated by the fact that these properties are positive parameters, and that the lognormal distribution makes it possible to analyze their great variability. The expression of the shear modulus for example is given by [2,10]:

$$\lambda_G(z) = \exp[\lambda_{0G}(z) + \xi_G \Delta f_G(z)] \quad (10)$$

With:

$$\begin{cases} \xi_G^2 = Ln(1 + \frac{\sigma_G^2}{\lambda_{0,G}^2}) \\ \lambda_{0G}(z) = \ln(\lambda_{0,G}) - \frac{1}{2} \xi_G^2 \end{cases} \quad (11)$$

Where  $\lambda_{0,G}$  and  $\sigma_G^2$  are respectively stand for shear modulus means and variance.

CV<sub>G</sub>: Coefficient of variation: To provide a dimensionless expression of the uncertainty inherent in a random variable.

### 4 HETEROGENEITY OF SOIL LAYER WITH SHEAR MODULUS INCREASING LINEARLY WITH DEPTH

In this proposed approach the soil profile is assumed to have shear modulus increasing linearly with depth. In the upper layer, of thickness  $h_1$ , the shear modulus is supposed to vary according to [19]:

$$G_1(z) = G_0(z/h_1)^p \quad (12)$$

Where  $z$  is the depth counted positively downwards from ground surface,  $G_0$  is the shear modulus at depth  $h_1$ ,  $p$  is an arbitrary exponent, which takes values in range  $0 \leq p < 2$ . The

parameter  $p$  can be determined by a least square fit through the measured values of the shear wave velocity  $\hat{V}(z)$  and is given by Ref. [20]:

$$p = \ln V_{s1} \frac{1}{h_1} \int_0^{h_1} \ln \left( \frac{z}{h_1} \right) \ln \hat{V}(z) dz \quad (13)$$

Where  $V_{s1}$  is the shear wave velocity at depth  $h_1$

For the underlying layer the shear modulus is assumed to be:

$$G_2(z) = G_0 + G_1(z/h_2) \quad (14)$$

Where  $z$  is counted from the layers interface and  $h_2$  is the thickness of second layer and  $G_0+G_1$  is the shear modulus at depth  $h_2$ .

## 5 RESULTS OF THE DYNAMIC RESPONSE OF A HETEROGENOUS ONE-DIMENSIONAL SOIL PROFILE

### ▪ Site variability Effects (shear modulus): the case of Souidania

This example deals with the vulnerability of a site with an inclined topography, with a slope that varies from 4% to 5%, (figure 10). The site is located at Souidania, located in the southwestern suburbs of Algiers and occupies an area of around 6 ha [21].

**Fig. 1.** Location of the project (Google Earth, October 2016)

It is shown in figures 2 and 3 ten realizations of the shear modulus for different values of  $CVG$ . The effect of site variability is therefore an essential parameter in an urban environment which must be evaluated to better define the lateral variability of the seismic movement of the soil, with immediate consequences on the response of structures and their damage.

### First layer

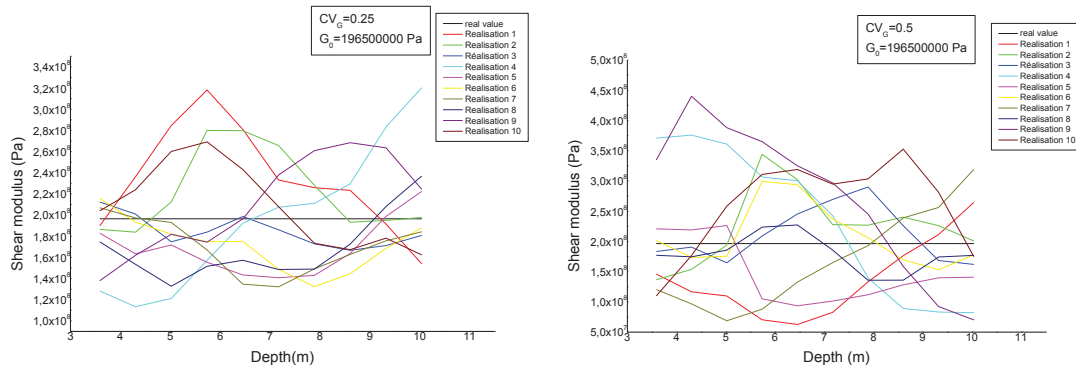

Fig. 2. Ten realizations of variations in shear modulus, first site layer, for different values of  $CV_G$ .

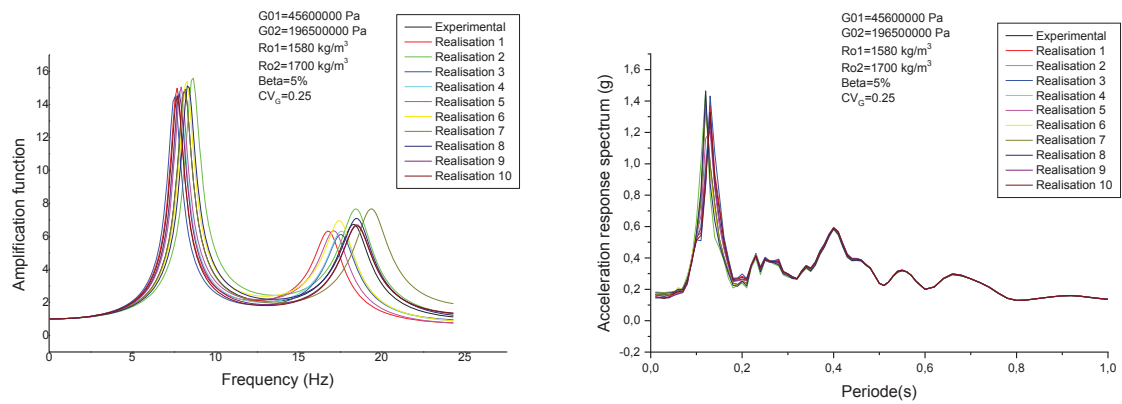

### Second layer

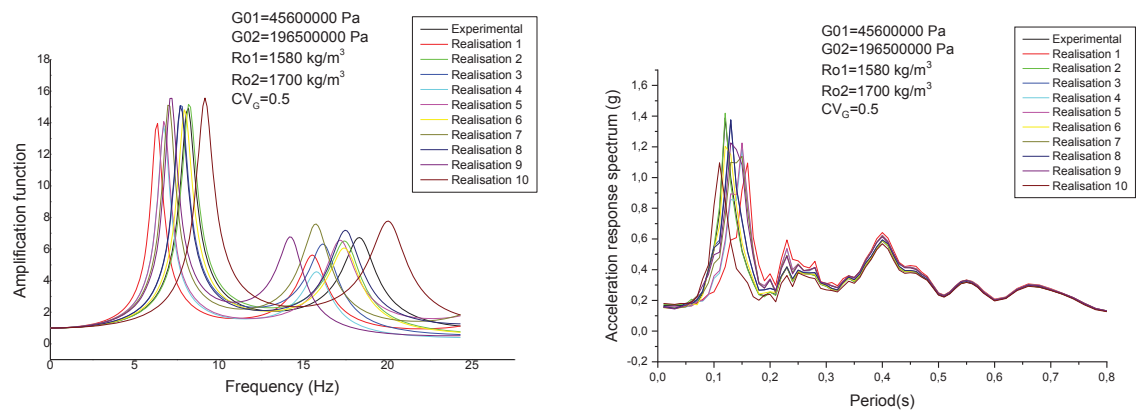

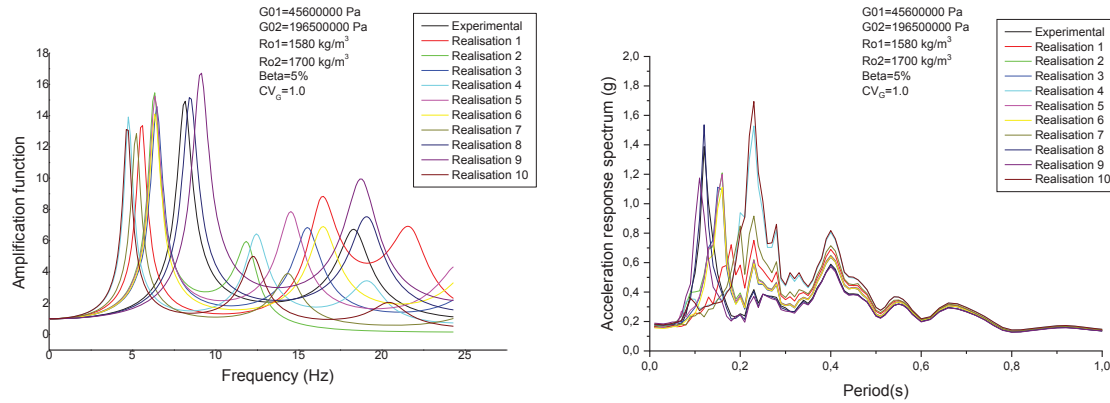

**Fig. 3. Ten realizations of shear modulus variations, second site layer, for different values of  $CV_G$ .**

**Fig. 4. Seismic amplification and the response spectrum in acceleration at the surface of the experimental case and of ten realizations according to the variability of the shear modulus  $G$  for a value of  $CV_G = 0.25$ .**

**Fig. 5. Seismic amplification and the response spectrum in surface acceleration of the experimental case and ten realizations according to the variability of the shear modulus  $G$  for a value of  $CV_G = 0.5$ .**

**Fig. 6. Seismic amplification and the response spectrum in acceleration at the surface of the experimental case and of ten realizations according to the variability of the shear modulus  $G$  for a value of  $CV_G = 1$**

From figures 4, 5 and 6, it is clearly seen that the variation of the shear modulus has great importance on the seismic amplification of the soil and this amplification varies according to the coefficient of variation  $CV_G$  where the value of the  $CV_G$  varies from 0.25 slightly heterogeneous to the value 1.00 strongly heterogeneous. Figure 7 shows a comparison between the case of heterogeneous experimental case, the cases of average of the ten realizations for each  $CV$  value and the case of shear modulus increasing linearly with depth.

**Fig.7. Surface acceleration response spectrum difference between the experimental case, the case of Monte Carlo as a function of the variability of the shear modulus  $G$  for different  $CV_G$  values and the case of shear modulus increasing linearly with depth.**

From the curves we can clearly see the differences between the studied cases, and that the probabilistic seismic response of heterogeneous soil profile via Monte Carlo simulations, for the value of  $CV = 0.25$ , is more equivalent to that of the seismic response of experimental case. On the other hand, we have observed an attenuation compared to the other cases of the value of  $CV = 0.5$  and  $CV = 1$ . Furthermore, For the case of the shear modulus increasing linearly with depth, the value of the response spectrum is identical to the probabilistic seismic response of heterogeneous soil profile via Monte Carlo simulations for the case of  $CV = 1$ .

## 6 DISCUSSION AND CONCLUSIONS

In this paper the acceleration response spectrum of the heterogeneous seismic amplification soils is analyzed. The random soil properties considered is the shear modulus, modeled by random spatial fields. The random field for the shear modulus is obtained by adopting the lognormal distribution, which allows its great variability to be analyzed.

As a summary of this article, we can recapitulate the following comments

- The increase in the coefficient of variation of the shear modulus induces a decrease in soil amplification and the peak acceleration response spectrum for the one-dimensional case. On the other hand, it is observed that increasing the coefficient of variation of the shear modulus also causes a filtering effect which slides the fundamental frequency of the system towards low frequencies, and causes attenuation of high frequencies. In this case, the simulated soil becomes softer compared to the homogeneous soil ( $CVG = 0$ ).
- For the case of shear modulus increasing linearly with depth, the value of the response spectrum is identical to the probabilistic seismic response of heterogeneous soil profile via Monte Carlo simulations for case of  $CV = 1$ .

The results obtained indicate that the seismic response is related to the shear modulus variability. In addition, it is observed that the increase in the coefficient of variation of the shear modulus induces a decrease in the peak value of the response spectrum in acceleration for the one-dimensional case. The method described in this paper, by analyzing several realizations, can reduce the geotechnical risk.

### Abstract

*The existence of a “weak” layer, of low relative density, within a liquefiable soil profile, may have a beneficial effect on the overall seismic response. The “weak” layer will liquefy earlier and may act as a “Natural Seismic Isolation” system, for the overlying, stronger, liquefiable layers, preventing thus the onset of liquefaction in them. In other words, it is possible that the liquefiable ground above the “weak” layer will not liquefy and may thus form a competent soil crust which will protect the integrity of infrastructure founded on it. The paper presents results of a parametric investigation of the “weak” layer effects on the overall seismic response of liquefiable soil profiles. It is based on nonlinear numerical analyses, performed with the Finite Difference method, and focuses on the effects of (i) soil properties (thickness and relative density) of the “weak” layer and the overlying liquefiable layers as well as (ii) the seismic motion characteristics on the extent of “weak” layer-induced natural seismic isolation.*

**Keywords:** Liquefaction, Numerical Analysis, Seismic Response, Natural Seismic Isolation.

---

## 1 INTRODUCTION

It is widely known that soil formations consisting of saturated, cohesionless soil layers are highly susceptible to earthquake induced excess pore pressure accumulation and liquefaction, with devastating results for infrastructures. However, it is possible that, under certain circumstances, the liquefaction of a soil layer prevents the propagation of seismic waves to the ground surface and leads to the drastic attenuation of seismic actions on infrastructures. Bouckovalas et al. [1] have shown that a uniform liquefiable layer, of adequate thickness and drastically reduced acoustic impedance, may indeed act as a “Natural Seismic Isolation” system for seismic ground motions.

The concept of “Natural Seismic Isolation” can be also generalized for non-uniform liquefiable layers which include an intermediate “weak” layer, with significantly degraded liquefaction resistance. In these soil profiles, the intermediate “weak” layer will liquefy first and will cause the attenuation of seismic motions, an effect which may prove beneficial for the overlying and more stiff sand layers. Hence, it will act as a “Natural Seismic Isolation” system, preventing liquefaction to extent up to the ground surface. In other words, the liquefiable ground above the “weak layer” will not liquefy and consequently it will maintain its strength and may thus act as a foundation bearing soil crust. To date, there are no research studies that systematically examine the above phenomena and suggest methods for their quantitative description. However, the few experimental and numerical studies that are found in the literature (e.g. [2,3]) confirm the abovementioned beneficial “weak” layer effect.

The scope of this paper is to investigate the seismic response and the liquefaction of non-uniform sand deposits, aiming to a qualitative evaluation of the “Natural Seismic Isolation” effect due to a “weak” soil layer embedded within the soil profile. For this purpose, a parametric investigation was performed focusing on the seismic response of non-uniform sand deposits. In total, approximately 100 nonlinear, fully coupled, one-dimensional effective stress numerical analyses aimed to examine the effect of various soil and seismic parameters on the seismic response of liquefiable sites with an intermediate “weak” layer.

## 2 NUMERICAL ANALYSES

All numerical analyses were conducted in the Finite Difference code FLAC [4], for the custom made soil profile depicted in Figure 1, which consists of five distinct soil layers under the groundwater table. The total thickness of the soil profile is 18 m, with the upper and the lower 2 m consisting of non-liquefiable medium plasticity clay with plasticity index  $PI=30$ . The shear wave velocity of the clay crust and the clay bed layers is equal to  $V_s=100$  and  $300$  m/s respectively. The rest 14 m consist of liquefiable sand of variable relative density  $D_{r,o}$ , with a “weak” layer of relative density  $D_r=30\%$  and variable thickness  $H_{weak}$  embedded in it.

The base of the soil column was shaken with a 15-cycle harmonic excitation, of peak acceleration  $a_{max}=0.25$  g and variable period  $T_{exc}$  (Figure 1). The values of: (i) the thickness of the “weak” layer  $H_{weak}$ , (ii) the total thickness of the overlying soil layers  $H_{crust}$  (soil crust), (iii) the period of the seismic excitation  $T_{exc}$  and (iv) the relative density  $D_{r,o}$  of the stiffer sand layers were varied parametrically to cover a wide range site and earthquake conditions encountered in practice. The baseline analysis was conducted for the following reference values of the basic parameters:  $H_{weak}=2$  m,  $H_{crust}=6$  m,  $D_{r,o}=60\%$  και  $T_{exc}=0.3$  sec.

The NTUA-SAND critical state plasticity constitutive model [5,6] was employed to simulate the response of the liquefiable sand, while the simpler Ramberg and Osgood [7] constitutive model was selected to simulate the nonlinear hysteretic response of clay layers. The NTUA-SAND model was calibrated against static and cyclic tests on saturated fine Nevada Sand [8], while the Ramberg and Osgood [7] model was calibrated against the experimental

modulus reduction and damping curves of Vucetic and Dobry [9] for low plasticity ( $PI=30$ ) clays. Free-field lateral boundaries were simulated with the “tied-node” technique, which imposes the same (horizontal and vertical) boundary displacements at grid-points of the same elevation. The “Selective Filtering Method” [10] was used in order to eliminate the numerical noise which is inherent to elastoplastic dynamic analyses with FLAC, while the overall accuracy of the numerical methodology has been successfully evaluated in similar studies in the past [e.g. 11,12].

### 3 MECHANISMS OF WEAK LAYER EFFECT

To identify the mechanisms which control “weak” layer effects, and demonstrate their consequences on the seismic response of non-uniform sand deposits, the results of a typical analysis with  $H_{weak}=2$  m,  $H_{crust}=8$  m,  $D_{r,o}=60\%$  and  $T_{exc}=0.3$  sec are first presented in more detail. For comparison purposes, the numerical analysis was repeated for the case of uniform sand of relative density  $D_{r,o}=60\%$  over the entire 2 - 16 m depth, namely without intermediate “weak” layer (i.e.  $H_{weak}=0$  m). Figures 2a and 2b compare the time-histories of the excess pore pressure ratio  $r_u$ , defined as the ratio of the excess pore pressures  $\Delta u$  over the initial effective vertical stress  $\sigma'_{v,o}$  (i.e.  $r_u=\Delta u/\sigma'_{v,o}$ ), in the middle of the top sand layer as well as in the middle of the “weak” layer, for the cases of uniform and non-uniform sand respectively. In addition, Figures 2c and 2d present the respective comparisons for the time-histories of the shear stress ratio  $CSR=\tau_d/\sigma'_{v,o}$  (where  $\tau_d$  is the seismic shear stress amplitude).

As depicted by the  $r_u$  time-histories of the non-uniform ground (Figures 2a and 2b), liquefaction occurs first in the “weak” layer at approximately  $t=0.8$  sec, and affects significantly the evolution of the excess pore pressures on the sandy layers above and below the “weak” one. Following the red lines in Figures 2a and 2b, it is observed that after the time instance  $t=0.8$  sec, the excess pore pressure ratio in the “weak” layer becomes almost unity ( $r_u\approx 0.8-1.0$ ) practically diminishing the shearing resistance of that layer. The result of this is to decelerate the excess pore pressure buildup in the overlying layer of relative density  $D_{r,o}=60\%$  and

prevent the onset of liquefaction that would have occurred in the absence of the “weak” layer (black line). The above observations are in total accordance with the respective  $CSR$  time-histories in Figures 2c and 2d, where it is observed that around  $t=1.0$  sec the amplitude of the  $\tau_d/\sigma'_{v,0}$  ratio above the “weak” layer drops to significantly lower levels. This observation, in combination with the small excess pore pressure ratios at these depths, leads to the conclusion that the liquefaction of the “weak” layer actually functions as a “Natural Seismic Isolation” system for the overlying sand layer.

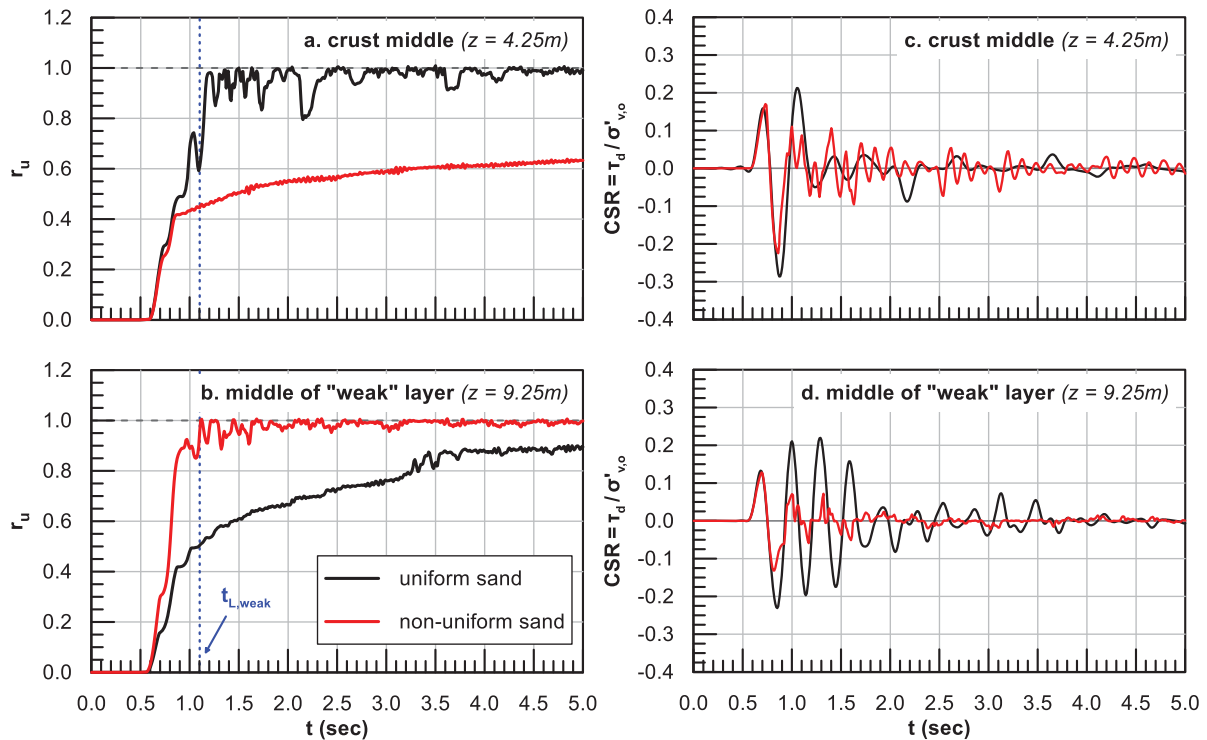

Figure 2: Typical time histories of excess pore pressure ratio  $r_u$  and shear stress ratio  $CSR$  at the middle of the “weak” layer and the overlying layer of sand.

For further insight, Figure 3a compares the variation with depth of the maximum excess pore pressure ratio  $r_{u,max}$  for both the non-uniform and the uniform soil profiles. It is observed that due to the existence of the “weak” layer, liquefaction has not occurred at any depth in the sand layer above it. In particular, the average value of the maximum excess pore pressure ratio above the “weak” layer  $r_u^{cr}$  has been reduced from  $r_u^{cr} \approx 1.0$  for the uniform sand deposit to the value  $r_u^{cr} = 0.65$  in the presence of the “weak” layer. It is also observed that the effect of the “weak” layer is also beneficial on the seismic response of the liquefiable sand layer below it, although less significant and consistent than for the overlying sand layer. For this reason, the following presentation will focus only upon results for the overlying sand layer.

The variation of the factor of safety against liquefaction  $FS_L$  with depth is depicted in Figures 3b and 3c for the case of non-uniform and uniform sand deposit respectively. In both cases, the values of the factor of safety were estimated following two different approaches. Initially,  $FS_L$  was estimated via the empirical methodologies that are commonly utilized in practice (e.g. [13]), based on the results of in-situ SPT or CPT tests. More specifically, it was assumed that the number of SPT blow counts is equal to  $N_{1,60} = 4.1$  and  $16.5$  for  $D_r = 30\%$  and  $D_{r,0} = 60\%$  respectively [14]. For the estimation of the seismic actions, the nonlinear numerical analyses were repeated under drained conditions, i.e. without excess pore pressures

buildup and liquefaction onset. In parallel, the values of  $FS_L$  which correspond to the actual response of each soil element during the numerical simulation were estimated, as follows:

$$FS_L = \left( \frac{N}{N_L} \right)^{-b} \quad (1)$$

where  $N$  is the applied number of cycles by the seismic motion and  $N_L$  the number of loading cycles required to cause liquefaction based on the numerical analysis results. Equation (1) is based on the mathematical expression of the liquefaction resistance curve, namely on the correlation between the cyclic stress ratio  $CSR$  and  $N_L$ :

$$CSR = a \cdot N_L^{-b} \quad (2)$$

where the values of coefficient  $a$  and of exponent  $b$  depend on soil type and loading conditions. For the NTUA-SAND constitutive model and for Nevada Sand, it was assumed that  $b=0.41-0.57$ , based on the previous work of Kalogeraki and Zontanou [15]. More information regarding the estimation of  $FS_L$  from the numerical analysis results can be found in [15-17].

Figure 3: Typical variation with depth of (a) maximum excess pore pressure ratio  $r_{u,max}$  and  $FS_L$  considering (b) non-uniform and (c) uniform sand deposit.

According to Figure 3b, the values of the factor of safety against liquefaction on the top sand layer, based on the numerical analysis results and Eq (1), vary in the range  $FS_L = 1.15 - 1.45$ , compared to the considerably smaller  $FS_L$  values ( $FS_L = 0.30 - 0.45$ ) which were computed for the "weak" layer. It is thus evident that due to the onset of liquefaction in the "weak" layer, the applied shear stress ratio  $CSR$  in more shallow depth is reduced, acting thus benefi-

cially for the overlying sand layers, which have not been already liquefied. As the applied seismic action is reduced, the factor of safety against liquefaction at these depths increases significantly to values larger than unity, implying that the onset of liquefaction has been prevented. On the contrary, it is shown that the empirical methodologies that are used in practice, which cannot take into account the presence of the “weak” layer, are entirely misleading as they predict that the top sand layer will also liquefy and exhibit  $FS_L \approx 0.30-0.40$ . For the “weak” layer, where the onset of liquefaction actually occurs, the two methodologies give compatible results.

Similar conclusions arise even in the case of a uniform sand deposit (Figure 3c). In particular, the empirical methodologies give compatible results with the numerical analyses only for the depths that liquefy first, while they predict considerably smaller  $FS_L$  values in all other depths. This means that the empirical methodologies for the estimation of  $FS_L$ , which are based on in-situ test results, are valid with acceptable accuracy only for the depths which correspond to the minimum factor of safety against liquefaction  $FS_{L,min}$ , as they do not take into account the drastic attenuation of the seismic actions in the soil deposits above the depth where liquefaction is first triggered (or equivalently the minimum  $FS_L$  value).

#### 4 PARAMETRIC INVESTIGATION

In total, about 100 numerical analyses were performed, to explore the effect of the following basic parameters: (i) the thickness of the “weak” layer  $H_{weak}$  ( $=0-11$  m, at 1 m increments), (ii) the thickness of the top sand layer  $H_{crust}$  ( $=5-10$  m, at 1 m increments), (iii) the excitation period  $T_{exc}$  ( $=0.2-0.5$  sec, at 0.1 sec increments) and, finally, (iv) the relative density of the stiffer sand layers  $D_{r,o}$  ( $=40-90\%$  at 10% increments).

Initially, the analysis of Section 3 was repeated for values of the “weak layer” thickness varying in the range  $H_{weak}=0-8$  m, while its top remained constant at  $z=8$  m (namely with constant  $H_{crust}=8$  m). Figure 4a depicts the variation of the average value (with depth) of the maximum excess pore pressure ratio in the top liquefiable sand layer  $r_u^{cr}$  with the thickness of the “weak” layer  $H_{weak}$ . In the same figure, the total range of  $r_{u,max}$  values in the liquefiable zones of the top sand layer is also presented. It is observed that the thickness of the “weak” layer  $H_{weak}$  is a basic parameter as it significantly affects the value of  $r_u^{cr}$ . It is noteworthy that even a very thin liquefiable “weak” layer with  $H_{weak}=1$  m can prevent the onset of liquefaction on the overlying sand layers. In addition, it is observed that for larger  $H_{weak}$  thickness values the  $r_u^{cr}$  diagrams tend to stabilize to a minimum value  $min(r_u^{cr})$ , which denotes the maximum possible reduction of excess pore pressures in the top sand layer, or else the maximum possible “Natural Seismic Isolation” that can be achieved. In the examined case, the increase of the thickness of the “weak” layer  $H_{weak}$  leads to a significant reduction on  $r_u^{cr}$  values until the minimum value  $min(r_u^{cr})=0.49$  is reached, which corresponds to the numerical analyses with thickness equal to  $H_{weak}=8$  m.

The format of Figure 4a was adopted for the presentation of the effect of all examined parameters in the present numerical investigation (i.e.  $H_{crust}$ ,  $T_{exc}$ ,  $D_{r,o}$ ). In particular, the diagrams of the  $r_u^{cr}$  variation with the thickness of the “weak” layer  $H_{weak}$  are depicted in Figure 4b for different top sand layer thicknesses  $H_{crust}$ , in Figure 4c for different excitation periods  $T_{exc}$  and in Figure 4d for different values of the relative density  $D_{r,o}$  of the stiffer sand layers. Figure 4b shows that not only the shape of the  $r_u^{cr}-H_{weak}$  diagrams but also the minimum values  $min(r_u^{cr})$  are similar in all numerical analyses with different thickness of the top sand layer  $H_{crust}$ . In other words, the thickness of the top sand layer, namely the depth where the “weak” layer is met, does not seem to have a significant effect on the values of  $r_u^{cr}$ .

On the other hand, Figure 4c shows that the shape of the diagram alters significantly based on the period  $T_{exc}$  of the seismic excitation. In particular, it is observed that the excitation pe-

riod has no effect on the values of the minimum  $r_u^{cr}$  ratio  $\min(r_u^{cr})$ , which in all cases is approximately equal to  $\min(r_u^{cr}) \approx 0.50$ , but affects the reduction rate of  $r_u^{cr}$  with  $H_{weak}$ , which decreases as the excitation period increases. This effect becomes more prominent for  $T_{exc} = 0.5$  sec. This practically means that for larger  $T_{exc}$  periods the  $H_{weak}$  thickness that is required in order to achieve the maximum possible reduction in the mean pore pressure ratio of the top sand layer increases. In more detail, for  $T_{exc} = 0.2$  sec the minimum ratio  $\min(r_u^{cr})$  is achieved for  $H_{weak} = 3$  m, while for  $T_{exc} = 0.5$  sec it is achieved for  $H_{weak} = 10$  m. It should be noted that this observation is in accordance with the findings of Bouckovalas et al. [1], who showed that the excitation period is one of the basic parameters which affect the minimum thickness of liquefied sand that is required for drastic attenuation of the seismic actions on the ground surface.

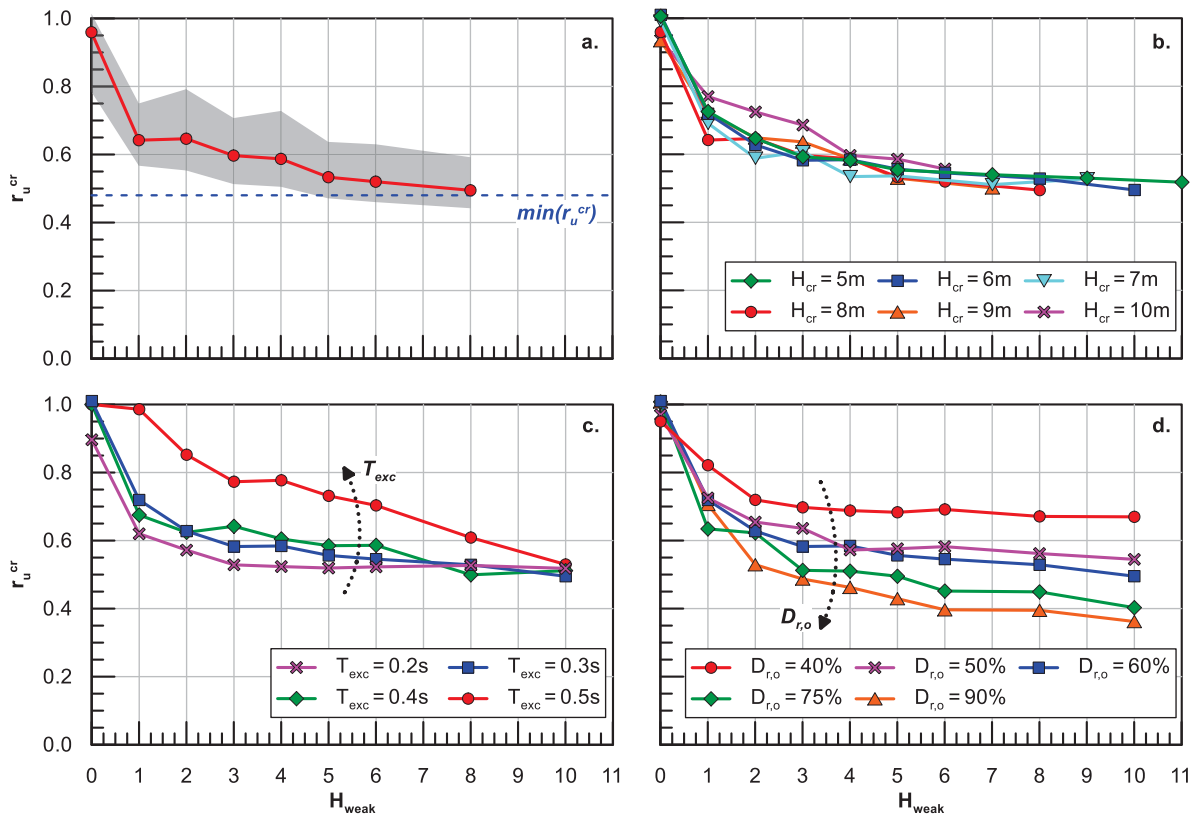

Figure 4: Effect of parameters: (a)  $H_{weak}$ , (b)  $H_{cr}$ , (c)  $T_{exc}$  and (d)  $D_{r,o}$  on the variation of the average pore pressure ratio in the top sand layer  $r_u^{cr}$ .

Finally, Figure 4d shows that the relative density  $D_{r,o}$  of the stiffer sand layers constitutes also a crucial parameter for the definition of the minimum  $r_u^{cr}$  value  $\min(r_u^{cr})$ , which reduces significantly with the increase of  $D_{r,o}$ . Apart from that, the shape of  $r_u^{cr}$ - $H_{weak}$  diagrams is similar for all different relative densities  $D_{r,o}$ . It is worth mentioning that even for relative density  $D_{r,o} = 40\%$ , i.e. slightly larger than that of the “weak” layer ( $D_r = 30\%$ ), a reduction in the values of  $r_u^{cr}$  is observed, which implies that even a small difference in the soil conditions of the “weak” layer, relative to the rest liquefiable ground, is adequate in order to achieve “Natural Seismic Isolation” conditions.

For a more detailed insight in the effect of the relative density of the stiffer layer  $D_{r,o}$  on the values of the minimum ratio  $\min(r_u^{cr})$ , Figure 5 shows the variation of  $\min(r_u^{cr})$  values with the relative density of the top sand layer  $D_{r,o}$ . It is thus observed that the minimum value of

$r_u^{cr}$  reduced from  $\min(r_u^{cr}) \approx 0.67$  for relative density  $D_{r,o} = 40\%$  to  $\min(r_u^{cr}) \approx 0.36$  for  $D_{r,o} = 90\%$ , while the reduction rate of  $\min(r_u^{cr})$  reduces with the increase of  $D_{r,o}$  value.

Figure 5: Variation of  $\min(r_u^{cr})$  with the relative density of the top sand layer  $D_{r,o}$ .

## 5 CONCLUSIONS

In the present study, the seismic response of non-uniform liquefiable sand deposits with an embedded “weak” sand layer of low relative density and significantly downgraded liquefaction resistance is examined. In such deposits, the “weak” layer liquefies earlier than the stiffer sand layers above and below it and forms a “Natural Seismic Isolation” system for the stiffer overlying layers, which are now protected and maintain low excess pore pressure ratio values, in the order of  $r_u = 0.40 - 0.70$ . The “weak” layer effect on the seismic response of the underlying liquefiable layer is also beneficial, but not as important and consistent as for the overlying layer.

The parametric analyses of this study revealed that the average values of the maximum excess pore pressure ratio that develop in the overlying sand layer  $r_u^{cr}$  depend on the following site and seismic excitation parameters: (i) the thickness of the “weak” layer  $H_{weak}$ , (ii) the excitation period  $T_{exc}$  and (iii) the relative density  $D_{r,o}$  of the stiffer layers. In particular, the increase of the thickness  $H_{weak}$  leads to reduction of  $r_u^{cr}$  values until a minimum value ( $0 < \min(r_u^{cr}) < 1$ ), the increase of the excitation period  $T_{exc}$  reduces the reduction rate of  $r_u^{cr}$  with the increase of  $H_{weak}$ , without however affecting the aforementioned  $\min(r_u^{cr})$  value, while the increase of  $D_{r,o}$  leads to a reduction of the  $\min(r_u^{cr})$  values. Finally, the depth of the “weak” layer surface ( $H_{crust}$ ) has no substantial effect on the seismic system response.

Furthermore, it has been shown that the empirical methodologies which are widely applied in practice for the estimation of  $FS_L$  based on in-situ test results (e.g. [13]) can be applied with satisfactory accuracy only for the depths corresponding to the minimum factor of safety against liquefaction  $FS_{L,min}$ , while they significantly underestimate the actual value of  $FS_L$  mainly for shallower depths.

It should be finally noted that the present research is currently in progress, aiming to study the effect of additional parameters, such as the relative density of the “weak” layer and the permeability of the liquefiable sand, as well as to propose an analytical methodology for the prediction of the average value (with depth) of the maximum excess pore pressure ratio  $r_u^{cr}$  and of the factor of safety against liquefaction in the top sand layers.

### Abstract

*The paper presents numerical analyses of a pile supported Tension Leg Platform wind turbine, during seismic loading and seabed liquefaction, taking consistently into account the pile-tendon-platform interaction. The emphasis is on the system response when liquefaction in the subsoil is extensive, leading to degradation of the pseudo-static factors of safety against pullout failure of the pile well below unity. It is shown that the pile resistance to pullout failure decreases drastically during shaking, but fully recovers during the following dissipation of earthquake-induced excess pore pressures and even exceeds the initial (pre-shaking) resistance value. Pile head displacements develop steadily during shaking and the following excess pore water pressure dissipation phase, but only during the limited time period when the static pullout factor of safety of the pile remains less than unity. Due to the very high tensional stiffness of the tendons, relative to the buoyancy stiffness of the platform considered in this study, the pile head pullout is mostly transmitted to the platform, with only a very small part corresponding to reduction of tendon elongation. As a result, the potential loss of buoy stability and tendon pretension may prove detrimental, but they are recoverable following a strong seismic event, as is unlikely to threaten the short-term safety of the platform.*

## 1 INTRODUCTION

Compared to bottom-fixed support platforms (e.g. gravity base, tripod, monopile and “jacket” supporting structures), the cost of Tension Leg Platforms (TLPs) depends on depth only for the station keeping component and becomes competitive for relatively large water depths, beyond about 80 m (e.g. Big Foot TLP, Magnolia TLP, Ursa TLP etc.). In addition to the lower construction cost, the TLP concept is also appealing for high seismicity areas (e.g. Italy, East Mediterranean, California, China, Japan), as it is rather insensitive to seismic actions, especially when the pile foundation response is considered along with the tendon-buoy dynamic model (e.g. [1-4]).

Nevertheless, it should be noted that the previous findings apply to seismically stable soil and foundation conditions, but they are still under consideration for liquefiable sand and silt seafloor soil profiles, where seismic shaking may lead to excess pore pressure buildup and partial or total loss of the pile foundation capacity to sustain the pretension of the tendons [5]. The static design of pile foundations is described with sufficient detail in a number of design guidelines [6-7]. However, available guidance on the seismic design of TLP foundations is limited and practically non-existent for earthquake-induced liquefaction in the foundation soil.

In view of the above objective limitations, the paper presents numerical analyses of a TLP supported wind turbine during seismic loading and seabed liquefaction, taking consistently into account the pile-tendon-platform interaction. The emphasis is on the system response when liquefaction in the subsoil is extensive, leading to degradation of the pseudo static factors of safety against pullout failure of the pile well below unity. For this purpose, it was assumed that the liquefiable soil deposit extends along the entire pile length, instead of forming one or more layers of limited thickness.

## 2 NUMERICAL MODELLING

### 2.1 The POSEIDON Model Floating Platform

The basic data for the numerical analyses are derived from the POSEIDON model TLP (Figure 1a), which was conceptually designed and analyzed for combined wind and wave energy exploitation in Mediterranean Sea conditions [8]. In particular, the system consists of a triangular platform supported by cylindrical floaters with a 5 MW wind turbine mounted at deck's center and three cylindrical oscillating water column (OWC) devices at its corners. The spacing between each OWC is 50 m. In the center of the platform, a cylindrical solid body is arranged to support the wind turbine. When positioned and stabilized, the draught of the platform is 20 m and the tower of the wind turbine is cantilevered at an elevation of 10 m above sea water level (SWL), at the top of the main column of the floating platform.

The floating structure is held in position by a Tension Leg Platform mooring system, which consists of three steel tendons, anchored at the seabed. The tendons are symmetrically placed and mounted at the base of the offset columns, i.e. at a depth of 20 m below the SWL. The diameter of each tendon is 0.130 m, while its length varies in each examined location. In all cases, the pretension load of each tendon is equal to  $F_0 = 10800$  kN. This load is transferred to the foundation system of the platform, which consists of a single driven open-ended steel pile under each tendon. The mass, including ballast, of the floating platform is 2183.6 t. The equivalent, in terms of buoyancy force, cross-section area of the platform is 298.53 m<sup>2</sup>.

The pilot foundation design of the POSEIDON platform was conducted parametrically for two installation locations in the Aegean Sea, assuming typical soil profiles that cover the basic soil types commonly encountered in offshore sites. Of interest for the present study is

the case of the non-cohesive seabed with medium density sand of relative density  $D_r=50\%$ , which is susceptible to earthquake-induced liquefaction.

The foundation piles were properly designed to withstand the combined static and cyclic axial loads applied during the normal and extreme environmental design conditions [9]. In more detail, the static loads come from the pretension of the steel tendons (i.e.  $F_o=10800$  kN), while the cyclic loads are due to sea waves during a storm. The geometry of the pile (length and diameter) was defined in order to ensure a that the factor of safety against static pullout of the pile is greater than 2.0 for normal environmental conditions and greater than 1.50 for extreme environmental conditions [6-7]. This led to the selection of a steel pipe pile of  $L=55$  m length and  $D=2.5$  m outer diameter.

Figure 1: (a) Illustrative presentation of the POSEIDON floating TLP [10], (b) The 3D numerical model of the pile-tendon-floater system.

## 2.2 The 3D Numerical Model

The problem is analyzed numerically by means of 3D coupled dynamic analyses with the finite difference code FLAC3D v6.0 [11]. The specific code employs an explicit scheme for the integration of the equations of motion which is more efficient for highly nonlinear problems like the one analyzed herein, while it allows for coupling between water flow and dynamic loading.

The 3D mesh built to simulate the problem is shown in Figure 1b. A pile of length  $L$  and diameter  $D$  is installed in a liquefiable uniform layer of Nevada Sand of relative density  $D_r$  and permeability  $k$ . As the OWCs are at large distance apart, i.e 50 m, each pile and tendon support is simulated independently. The liquefiable sand layer extends to the depth of the pile tip, followed in depth by a much denser non-liquefiable sand layer of thickness  $4D$ .

The pile supports a floater, defined in terms of its cross-sectional area  $A_f$ , through a pretensioned tendon of free length (before pretension)  $L_{free}$ , cross-sectional area  $A_t$  and Young's modulus  $E_t$ . The floater-tendon system can be adequately represented by two serially connect-

ed springs [12] which are simulated herein by two sets of cable elements. The properties of the cables (length, cross-sectional area and Young's modulus) are properly calibrated to provide the axial stiffness of the tendon  $K_t$  (i.e. the tendon's resistance against unit tensile displacement) and the axial stiffness of the floater  $K_f$  (i.e. the floater's resistance against unit downward displacement), computed as:

$$K_t = \frac{E_t A_t}{L_{\text{free}}} \quad (1)$$

and

$$K_f = A_f \cdot \gamma_w \quad (2)$$

During static uplift loading of the pile, the base of the model is fixed in all three directions and vertical hinges are applied on the vertical boundaries. During seismic shaking the hinges at the lateral boundaries are replaced with "tied-nodes" which impose the same boundary displacements at grid-points of the same elevation, replicating free field conditions, while a harmonic motion of amplitude  $a_{\text{max}}$ , period  $T$  and  $N$  cycles is directly applied at the base assuming rigid bedrock conditions. The in-plane and out-of-plane width of the mesh is 40D and 20D respectively. The thickness of each zone is 1.0m, while the width is approximately equal to 0.2D next to the pile and gradually increases to about 2.7D at the lateral boundaries.

The highly nonlinear response of the liquefiable sand is simulated with NTUA-Sand [13-14] implemented in FLAC3D as a C++ plug-in constitutive model. NTUA-Sand is also used to simulate the response of the dense sand layer below the pile tip, while the pile is simulated through elastic solid elements with the axial stiffness and the unit per length weight of a hollow steel pile with diameter  $D = 2.5$  m and wall thickness  $t = 31.35$  mm.

A key aspect of the numerical methodology is the accurate simulation of the pile-soil interface, as the pile-soil relative slip, as well as the pullout capacity of the pile are both related directly to the strength characteristics and the radial stresses of that interface. Following a trial-and-error approach [15], it was finally decided to install six sets of interface elements, one for each set of zones that encircle the pile. Large values are assigned to the elastic stiffnesses of the interface to ensure that no interface straining occurs before yield. The tensile strength and the shearing cohesion of the interface are set to zero, while an interface friction angle  $\delta$  is adopted and properly calibrated based on relevant guidelines

### 2.3 Numerical Solution Sequence

The seismic response analysis of the pile-tendon-floater system is performed in two stages. Initially, the pretension force  $F_0 = 10800$  kN is applied statically at the structural node corresponding to the top of the floater. In the sequel, the displacement of that node is constrained, and the input seismic motion is applied at the base of the model. The analysis continues beyond the end-of-shaking, until excess pore pressures are fully dissipated. During this second stage, the displacements of the pile head and the floater are continuously monitored, along with the loss of tendon pretension and floater buoyancy. Still, to shed light on the mechanisms that control the system response, it is also necessary to monitor the variation with time, during shaking and following excess pore water pressure dissipation, of the degraded pullout capacity of the pile.

When numerically performed, the latter may extend the computational effort enormously, as it is not part of the main seismic response analysis, but it has to be performed independently at regular time intervals, based on the ever current stress state around the pile. For this reason, the static pullout capacity of the pile was computed analytically, according to the API [7]

and DNV [6] recommendations in connection with the liquefaction-affected radial stresses at the pile-soil interface predicted during the second stage of the seismic response analyses. This semi-analytical methodology has been implemented in the numerical analysis through a user-defined subroutine, written in FLAC3D's inbuilt programming language FISH, to provide the continuous with time variation of the pile capacity to sustain the tendon pretension load.

### 3 LIQUEFACTION EFFECTS ON PILE-TENDON-FLOATER RESPONSE

#### 3.1 Input data and assumptions

The basic analysis presented herein is performed for 120 m water depth, assuming that the relative density of the liquefiable layer is  $D_r=50\%$  and that of the underlying non-liquefiable sand is  $D_r=90\%$ . The permeability is set equal to  $k=6.6 \times 10^{-4}$  m/s for both layers corresponding to a clean sand [16]. The single tendon-pile support considered in the analysis is attached to a floater with equivalent cross-section area  $A_f=99.51 \text{ m}^2$  (i.e. 1/3 of the total), while the free length of the tendon is  $L_{\text{free}}=100$  m, the associated cross section area is  $A_t=0.01327 \text{ m}^2$  and the modulus of elasticity is  $E_t=200 \text{ GPa}$ . According to Eqs. **Error! Reference source not found.** and **Error! Reference source not found.**, the preceding values lead to an axial stiffness  $K_t=62800 \text{ kN/m}$  and  $K_f=995 \text{ kN/m}$  for the tendon and the floater respectively. The input seismic motion consists of  $N=15$  uniform acceleration cycles (corresponding to an  $M_w=7.5$  earthquake) with amplitude  $a_{\text{max}}=0.24 \text{ g}$  and period  $T=0.5 \text{ sec}$ .

#### 3.2 Pile response

Figure 2 summarizes the response of the pile-tendon-floater system. More specifically, Figure 2a presents time-histories of the pile's pullout capacity  $Q_{\text{ult}}$  and the tendon's force  $F$  (black and red line respectively) both during and after the end of shaking until full excess pore pressure dissipation. Similarly, Figure 2b presents the factor of safety against pullout of the pile  $FS=Q_{\text{ult}}/F$  as well as the Stability Safety Factor  $FS_{\text{st}}=U/W_f$  ( $U$  is the total buoyancy force and  $W_f$  is the weight of the floater), while Figure 2c shows the uplift displacement of the pile head and the floater. To further verify the semi-analytical procedure for the estimation of  $Q_{\text{ult}}$ , during and after shaking, a set of undrained numerical analyses is performed at selected time instances in order to compute  $Q_{\text{ult}}$  and is compared with the analytical estimates. The results of these analyses are shown on Figure 2a with the cyan bullets.

Based on the above observations the following critical time instances can be identified:

- Point A ( $t_A=3.5 \text{ sec}$ ): The factor of safety drops below 1.0 for the first time.
- Point B ( $t_B=8.0 \text{ sec}$ ): At the end of shaking  $Q_{\text{ult}}$  reaches a local minimum practically equal to the buoyant weight of the pile.
- Point C ( $t_C=36.5 \text{ sec}$ ): The Factor of Safety becomes again larger than unity.
- Point D ( $t_D=250 \text{ sec}$ ): At the end of consolidation the post-shaking pullout capacity stabilizes to a value that is approximately 38% larger than the initial.

The evolution of the pullout factor of safety is the key factor determining the accumulation of pile displacements. More specifically, as shown on Figure 2c, pile displacements are limited as long as the factor of safety remains greater than 1.0 (up to Point A) and do not exceed 5-6 cm. However, as the  $FS$  becomes and remains lower than unity (between points A and C) the rate of displacement accumulation increases substantially leading to uplift displacements that increase linearly with time. It is noteworthy that at the end of shaking only a fraction of the total pullout displacement has accumulated. Namely, at the end of shaking (Point B) dis-

placements are approximately equal to 30 cm, and at the end of the failure stage (Point C) they are equal to 85 cm. Afterwards (between points C and D), as the factor of safety becomes again larger than unity, displacement accumulation practically ceases and the pile stabilizes. The above observations suggest that the accumulation of pile pullout displacements is primarily influenced by the duration of the failure stage ( $t_A - t_C$  in Figure 2b) and may thus increase considerably when the excess pore water pressure dissipation is delayed (e.g. for silty sand seabed with lower permeability coefficient).

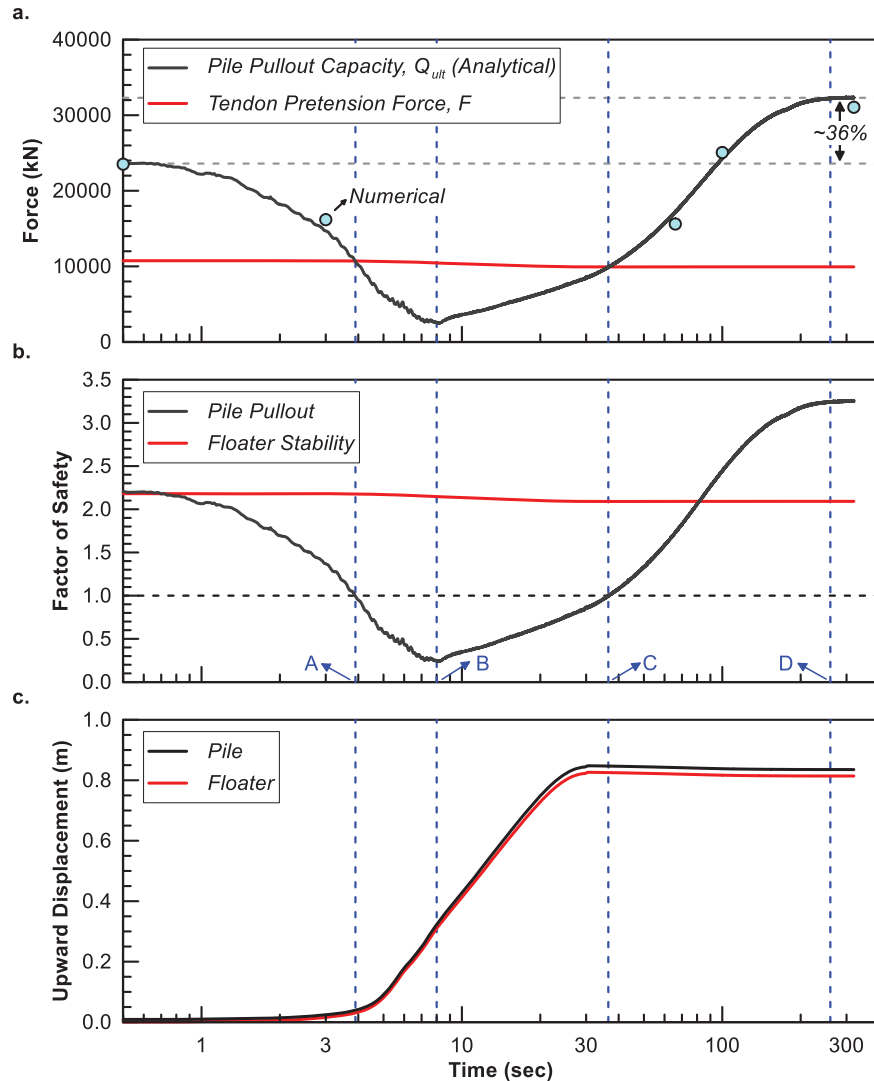

Figure 2: (a) Pile pullout capacity and tendon pretension force, (b) Pullout and Stability Factor of Safety ( $FS$  and  $FS_{st}$ ), (c) Pile head uplift time-histories.

### 3.3 Soil Response

The patterns described in the previous section regarding the pullout capacity of the pile are directly associated with excess pore pressure generation and soil liquefaction. Figure 3 presents time-histories of excess pore pressure ratio  $r_u$ , defined as the ratio of the excess pore pressures  $\Delta u$  over the initial effective vertical stress  $\sigma'_{v,0}$  (i.e.  $r_u = \Delta u / \sigma'_{v,0}$ ), at depths  $z = 1, 10$  and  $40$  m below ground surface both at the free field and next to the pile.

Focusing first on the co-seismic response ( $t = 0 - 8$  sec), the figure shows that complete liquefaction ( $r_u = 0.9 - 1.0$ ) takes place almost in the entire soil mass with the exception of the ar-

ea around the pile head where the excess pore pressure ratio stabilizes at a peak value of  $r_u \approx 0.5-0.6$  (Figure 3). This non-liquefied zone is more clearly illustrated on Figure 4a which shows contours of  $r_u$  at the end of shaking. It has an inverted-cone shape and extends to a depth of about 4-5 m (1.6-2.0 D). Post-seismically ( $t > 8$  sec), excess pore pressures dissipate primarily towards the ground surface as evidenced by the fact that excess pore pressures at large depths dissipate earlier. Furthermore, this upward flow towards areas of lower hydraulic head, causes the pore pressures near the pile head, where the soil hasn't fully liquefied, to notably increase before they also start to dissipate.

It is interesting to observe the correlation between the generation of excess pore pressures and the degradation of the pile's pullout capacity. Namely, as shown in Figure 2b, the factor of safety drops below unity at  $t \approx 3.5$  sec, which, according to Figure 3, coincides with the moment when significant excess pore pressures ( $r_u > 0.6$ ) have started to develop in the soil. Furthermore, the ultimate pullout capacity  $Q_{ult}$  and the factor of safety  $FS$  reach a local minimum at the end of shaking, when the majority of the soil is liquefied (Figure 4a). Finally, as shown on Figure 4b, at  $t \approx 36.5$  sec the dissipation process has progressed significantly, the soil has regained a considerable amount of its shear strength, and thus the factor of safety becomes again larger than unity.

Figure 3: Excess pore pressure ratio ( $r_u$ ) time-histories at the free field and next to the pile at various elevations.

### 3.4 Tendon & floater response

Pullout of the pile causes both the floater to move upwards as well as the tendon's elongation to decrease subsequently decreasing the pretension force. For the platform examined herein, Figure 2c presents the evolution with time of the upward displacement of the floater (red line) compared to that of the pile head (black line). As shown on this figure, the displacement of the floater resembles that of the pile head. Initially the displacement is very limited (up to Point A), while, afterwards, it increases linearly with time until the end of the failure phase (Point C). Finally, the floater stabilizes to an upward displacement of about

82 cm, approximately 3 cm less than that of the pile head. It is thus observed that the pile head displacement is almost entirely (by approximately 96-97%) transmitted to the floater, while only a small portion ( $\sim 3-4\%$ ) causes the length of the tendon to decrease.

As a result, the tension force of the tendon is only marginally reduced by 7.8%, from its initial value  $F_0 = 10800$  kN to approximately  $F = 9950$  kN (Figure 2c). Subsequently the stability safety factor of the floater decreases by 6.2%, from 2.25 to 2.11 (Figure 2b). It should be noted that the system studied herein employs a relatively short tendon (due to the shallow seabed) with high tensional stiffness. For larger water depths and less stiff tendons, the percentage of pile head pullout that is transferred to the floater will substantially decrease, leading to higher loss of pretension platform stability.

Figure 4: Excess pore pressure ratio  $r_u$  contours (a) at the end of shaking and (b) at  $t = t_c$  when FS becomes greater than 1.0 post-seismically.

#### 4 CONCLUSIONS

In summary, the following findings emerged from the study presented in this paper, with regard to seismic liquefaction effects on TLP foundation-tendon-buoy systems:

- (a) Upon complete free field liquefaction, the excess pore pressure ratio becomes approximately equal to unity ( $r_u = 0.9-1.0$ ) along almost the entire pile length. As a result, the skin friction resistance of the pile is drastically reduced during shaking and it is almost eliminated when free field liquefaction extends over the entire pile length. At that stage, the main force resisting the pretension of the tendons is the buoyant weight of the pile.
- (b) The pile resistance to pullout failure increases with dissipation of the excess pore pressures created during shaking, while the associated factor of safety becomes gradually larger than unity, mainly due to the increase of the total radial soil stresses at the pile-soil interface caused during shaking but also to the loss of tendon pretension. For the analyses of this study, the final value of the ultimate resistance exceeds the initial static design by about 38%, while the corresponding factors of safety increase by approximately 48%.
- (c) Pile head displacements develop essentially in the time period, during and after shaking, when the factor of safety against static pullout of the pile becomes less than unity (i.e. at failure conditions) and may thus increase considerably when the excess pore water pressure dissipation is delayed (e.g. for silty sand seabed with lower permeability coefficient). The displacements are insignificant before and after that time period, when the factor of safety remained larger than unity.

- (d) Due to the very high tensional stiffness of the tendons considered herein, relative to the buoyancy stiffness of the platform, the pile head pullout was almost entirely (96-97%) transmitted to the platform with only a very small percentage (3-4%) corresponding to the reduction of tendon elongation. For larger water depths and less stiff tendons, the percentage of pile head pullout that is transferred to the floater may decrease substantially, leading to higher loss of pretension and platform stability.
- (e) Despite the catastrophic per se effects of liquefaction (loss of pile capacity and large displacements), the overall stability of the floater is not jeopardized and the computed loss of the tendon's elongation and tension force is rather small to induce slackening. In addition, the above effects are potentially recoverable as the pretension force can be restored to its initial or to an even higher value, taking also into account that the post-shaking pullout capacity of the pile has considerably increased.

## 5 ACKNOWLEDGEMENTS

This research is carried out/funded in the context of the project “Seismic design of offshore wind turbines: Effect of pile foundation damping and soil liquefaction” (MIS 5049428) under the call for proposals “Researchers' support with an emphasis on young researchers- 2nd Cycle”. The project is co-financed by Greece and the European Union (European Social Fund-ESF) by the Operational Programme Human Resources Development, Education and Lifelong Learning 2014-2020.

### Abstract

*Investigating the dynamic response of wind turbine structures is of significant importance when it comes to better understanding how their behaviour is affected by different design considerations and their foundation's interaction with the soil. An extensive numerical investigation is presented herein that foresees the performance of modal and pushover analysis on a wind turbine structure that has an 80 m steel tower and is founded on different clay profiles. The 3D detailed models constructed in this research work consider the effect of soil-structure interaction by discretizing the pile foundation and soil domains through 8-noded hexahedral elements, achieving maximum modelling accuracy. An investigation was also performed on the optimum pile inclination, where based on the numerical findings, the optimum inclination of the battered piles was found to be that of 10 degrees.*

**Keywords:** Wind turbine structures, Battered piles, Push-over analysis, Modal analysis, Soil-structure interaction, Optimum design.

## 1 INTRODUCTION

The finite element method has become the most commonly used method to model large-scale reinforced concrete (RC) structures. It is of utmost importance for engineers to model large-scale designs to investigate the dynamic behaviour, understand the mechanical behaviour and to optimize their structural designs. It is evident that to capture the nonlinear dynamic behaviour of RC structures through the use of a 3D detailed modelling approach is very challenging [1-3], however, taking into account the soil-structure interaction (SSI) effect [4-6] is even more challenging due to the computational demand and numerical instabilities during nonlinear monotonic and cyclic analysis.

Due to the large size of wind turbine structures, it is not feasible to perform laboratory tests in the appropriate facilities, as this relates in a large cost for physical experiments. However, through time, to obtain more energy, wind turbines evolved rapidly in size. Therefore, this increase in size forced engineers to design larger towers that are founded on relatively large foundation systems, where the soil would have a larger influence on the overall dynamic response of these structures.

Several numerical methods were developed to investigate the dynamic response of wind turbine structures that account for the SSI effect and help in the better understanding of their mechanical behaviour. Some of these numerical methods are the spring and damper approach [7,8], which were also implemented in a pile foundation by Wang *et al.* [9]. Modelling and analysis of wind turbine structures were performed herein through a 3D detailed modelling approach [1-4], in order to investigate their dynamic response through implementing an accurate soil discretization through hexahedral finite elements (FEs). The soil parameters and wind turbine design were based on data provided by the Wind Africa research project [10].

Research on the SSI phenomenon was presented in [9] where they performed numerical and physical experiments on piled foundations. The spring and damper approach was used in [9] to model the SSI phenomenon. Wang *et al.* [9] based their soil parameters on research work performed by Blanco *et al.* [11]. The piles for the numerical experiment performed by [9] were modelled by using beam-column FEs and a pinned connection were assumed at the bottom of the piles to prevent any displacement or uplift during the numerical analysis. Other research was performed on wind turbine structures supported by monopiles in [12-16].

Prowell *et al.* [17] performed a numerical investigation on the influence of SSI on the dynamic response of wind turbine structure. Prowell *et al.* [17] used beam column FEs to discretize the wind turbine tower and solid FEs for the soil domain. The research work performed by [17] concluded an increase in the natural frequency as the soil became stiffer, however, there was a greater influence on the dynamic behaviour as the soil became softer. Guo *et al.* [18] also presented research work on wind turbine structures by account for the SSI where push over analyses were performed.

As discussed within [19], Reconan FEA [20] was used to reproduce experimental results of a foundation with piles embedded in sand [9] through the use of a push over analysis. The same software was also used [20] to perform modal and push over analyses on 80 m tall wind turbine steel towers founded on soft clay, where the soil domain was discretized through hexahedral FEs. The numerical results that derived from this research work are further discussed in this manuscript.

## 2 MODAL ANALYSIS OF LARGE-SCALE MODELS

Modal analysis was performed in order to get an overview of the expected structures' dynamic response. There are several solution methods for solving the eigenvalue problem that is described by the following equation:

$$\mathbf{K}\boldsymbol{\varphi}_i = \lambda_i \mathbf{M}\boldsymbol{\varphi}_i \quad (1)$$

where,  $\mathbf{K}$  is the stiffness matrix of the model,  $\mathbf{M}$  is the mass matrix of the model,  $\boldsymbol{\varphi}_i$  is a vector that contains the eigenvectors of the system and  $\lambda_i$  is the corresponding eigenvalue  $i$ . The solution method used in this research work is called the subspace iteration algorithm [21]. This solution technique is ideal when dealing with large-scale structures since it calculates few eigenvalues and eigenvectors of a large FE model.

This solution algorithm finds an orthogonal basis of vectors in  $\mathbf{E}_{K+1}$ , calculating in one step the required eigenvectors when  $\mathbf{E}_{K+1}$  converges to  $\mathbf{E}_\infty$ . The developed algorithm foresees the iteration used in the subspace iteration method, i.e., step 2 of the complete solution phase proposed in [21]. For  $k = 1, 2, \dots$ , iterate from  $\mathbf{E}_k$  to  $\mathbf{E}_{k+1}$ :

$$\mathbf{K}\mathbf{X}_{k+1} = \mathbf{M}\mathbf{x}_k \quad (2)$$

then, find the projections of matrices  $\mathbf{K}$  and  $\mathbf{M}$  onto  $\mathbf{E}_{k+1}$ :

$$\mathbf{K}_{k+1} = \mathbf{X}_{k+1}^T \mathbf{K} \mathbf{X}_{k+1} \quad (3)$$

$$\mathbf{M}_{k+1} = \mathbf{X}_{k+1}^T \mathbf{M} \mathbf{X}_{k+1} \quad (4)$$

and solve for the eigensystem of the projected matrices:

$$\mathbf{K}_{k+1} \mathbf{Q}_{k+1} = \mathbf{M}_{k+1} \mathbf{Q}_{k+1} \boldsymbol{\Lambda}_{k+1} \quad (5)$$

Thereafter, find an improved approximation to the eigenvectors:

$$\mathbf{x}_{k+1} = \mathbf{X}_{k+1} \mathbf{Q}_{k+1} \quad (6)$$

and then provided that the vectors  $\mathbf{x}_1$  are not orthogonal to one of the equilibrium eigenvectors,  $\boldsymbol{\Lambda}_{k+1} \rightarrow \boldsymbol{\Lambda}$  and  $\mathbf{X}_{k+1} \rightarrow \boldsymbol{\Phi}$  as  $k \rightarrow \infty$ .

It is important to note that the convergence of this method assumes that within the iteration procedure the vectors in  $\mathbf{X}_{k+1}$  are ordered in such a way that the  $i^{\text{th}}$  diagonal element in  $\boldsymbol{\Lambda}_{k+1}$  is always larger than the previous  $i-1$  element,  $i=2, \dots, p$ . This ensures that the  $i^{\text{th}}$  column in  $\mathbf{X}_{k+1}$  converges linearly to  $\boldsymbol{\Phi}_i$ . Although this is an asymptotic convergence rate, it was found that the smallest eigenvalues converge fastest [21], a finding confirmed by Markou *et al.* [22].

### 3 NUMERICAL MODELS OF WIND TURBINE STRUCTURES WITH SSI CONSIDERATIONS

Initially, two wind turbine geometries were developed, however, it was decided to consider only the first geometry (based on the needs of the project [10]), while it was also decided to remove the blades, nacelle and hub to reduce the computational demand of the model. The wind turbine in Fig. 1 (excluding the nacelle, hub and blades) was used during the parametric investigation that will be presented in this manuscript. It is important to note here that the mass of the nacelle, hub and blades was applied at the top of the tower during the analysis as dead load.

Several soil profiles were investigated that included soil geometries based on the Wind Africa project [10], whereas soil geometries where the piles are embedded in rock or situated on softer soil were analysed. The first soil geometry was the Equal Layer Geometry, which was refined into a model with piles embedded in a rock layer (Fig. 2a) and a model with extra soil underneath the piles Fig. 3a. The second soil geometry will be referred to as the Increasing

Layer Geometry. This geometry was also refined into a model with piles embedded in a rock layer (see Fig. 2b) and a model with extra soil underneath the piles (Fig. 3b). During the soil geometry investigation, the pile inclination was modified to determine the optimal foundation design for the under-study wind turbine structure.

Figure 1. Wind turbine geometry.

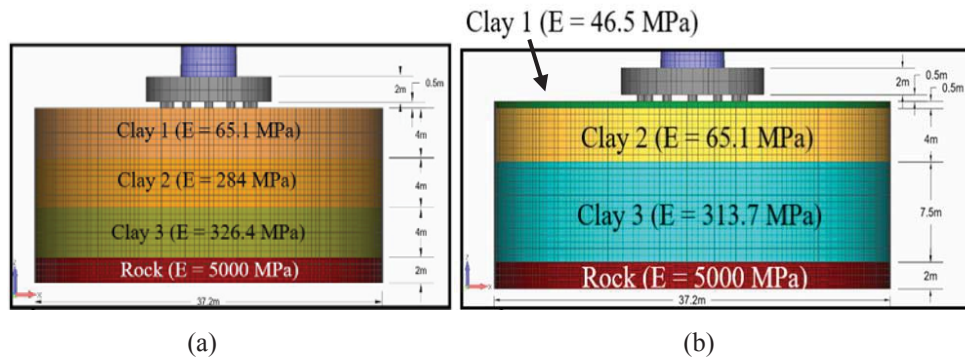

Figure 2. (a) Equal and (b) Increasing Layer Geometry with the piles embedded in a rock layer.

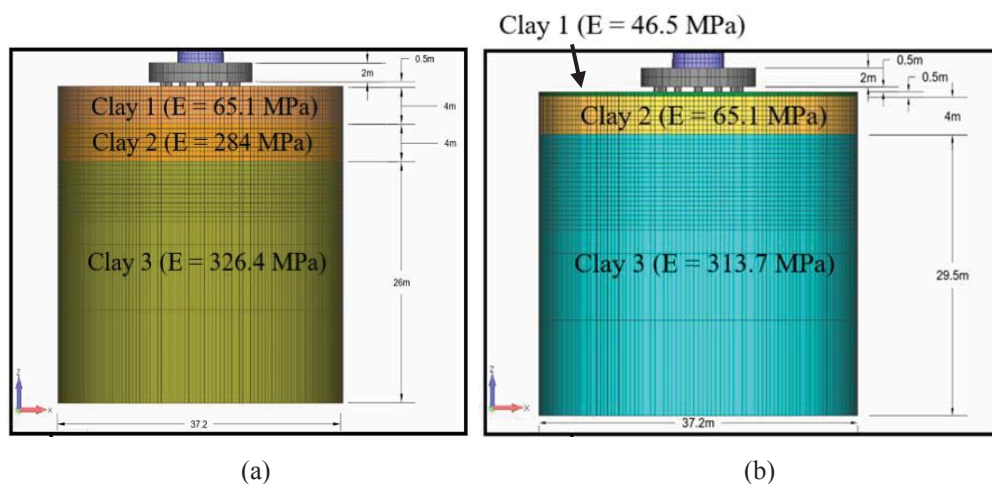

Figure 3. (a) Equal and (b) Increasing Layer Geometry with the piles embedded in extra soil.

The pile inclinations used with each soil geometry was 0-, 5-, 10- and 15-degree battered piles. The battered piles within the Increasing Layer Geometry can be seen in Fig. 4. For additional information on the material properties of soil domains please refer to [17]. It must be

noted at this point that, a mesh sensitivity was also performed by using 25, 50 and 100 cm elements for the discretization of the soil domains. This yielded an optimum mesh geometry when 50 cm hexahedral elements are used. Buckling was also considered during the performance of the pushover analyses.

Figure 4. Pile layout of the increasing geometry with extra soil. (a) 0, (b) 5, (c) 10 and (d) 15 degrees of pile inclination.

#### 4 MODAL ANALYSIS RESULTS

Modal analyses were performed for the first 24 modes, where the deformed shapes and the eigenfrequencies will be discussed herein. The eigenmode legend in each figure shows only the critical displacement, therefore, it has no physical meaning in terms of displacement. However, the periods and frequencies have a physical meaning and will be discussed in this section. Fig. 5 shows the fixed model (no SSI considerations), which had the same main eigenmodes as the corresponding eigenmodes of the different geometries with SSI considerations. The deformed shape of a fixed condition can be seen in Fig. 5.

The first three deformed shapes of the Equal Layer Geometry with 5- and 15-degree inclined piles situated on extra soil can be seen in Fig. 6 and 7. The deformed shapes for the other soil geometries can be found in [17].

The Equal Geometry and the Increasing Layer Geometry had the same eigenmodes during this numerical investigation, however, it was evident that the soil geometry has an influence on the stiffness of the Wind Turbine structure. As it can be seen in Fig. 8, the rock layer geometries had the lowest periods due to the hard rock that was practically acting as a fixed base to the piles. The numerical investigation of the 1<sup>st</sup> eigenmode yielded a minimum period value for the 10-degree pile inclination, which was then used to perform further investigations.

Figure 5: Deformed shapes of the first three eigenmodes with a fixed condition at the bottom of the pile cap. (a) 1st, (b) 2nd and (c) 3rd Mode [17].

Figure 8: Period comparison of the 1<sup>st</sup> eigenmode.

## 5 PUSHOVER ANALYSES

The pushover analyses were conducted by applying a horizontal force of 3 MN, where all dead loads were accounted for. The vertical and 10-degree inclination piles of the Equal and the Increasing Layer Geometry were analysed. The P- $\delta$  curves for the various models were compared, furthermore, the Load-Rotation relationship for the case of the pile cap was investigated.

The P- $\delta$  curves of the Equal Layer Geometry models can be seen in Fig. 9. It must be noted here that all the models derived a failure due to local buckling at the base of the steel tower. The Equal Layer Geometry with 10-degree inclined piles embedded in rock yielded the smallest displacement at failure. A mechanical behaviour attributed to the stiffness increase due to the rock layer combined with the pile inclination.

Figure 9: P- $\delta$  curves of the Equal Layer Geometry models [17].

The significance of SSI can yet again be observed when comparing the displacement at failure of the SSI models and the Fixed Geometry (Fig. 9). According to the numerical findings, the SSI can derive a total of 26.8 % increase in terms of horizontal displacement prior to failure for the case of the model with vertical piles founded on soft soil.

The rotation of the pile cap for the under-study models can be seen in Fig. 10. As expected, the foundation where the piles are situated on extra soil yielded a larger rotation than that of the

rock layer. The Equal Layer Geometry with 10-degree inclined piles embedded in rock had the lowest rotation of the different investigated foundation and soil profiles.

Figure 10: Rotation of the pile cap for the Equal Layer Geometry models [17].

The nonlinear increase in rotation of the pile cap for the Equal Geometry with vertical piles situated on extra soil (Fig. 10) is due to the yielding of the soil that occurred during the nonlinear analysis. The stress exceedance can be observed in Fig. 11, where the soil in the 1<sup>st</sup> layer yielded at 36 kPa (Fig. 11a). The Equal Geometry model with 10-degree inclined piles situated on extra soil had the same behaviour as previously discussed, but the observed level of plastification was less than that of the vertical piles.

The rotation of the pile cap for the optimum foundation design can be seen in Fig. 12. The von Mises stress distribution is also given, where it is easy to observe that the maximum developed stresses were found at the piles' heads.

Figure 11: Solid von Mises stress contours. Deformed shape of the tower for (a) Piles embedded in a rock layer and (b) Piles situated on extra soil.

Figure 12: Rotation of the pile cap of 10-degree inclined piles embedded in rock.

The SSI effect for the case of the models that foresee the Increasing Layer Geometry where the model founded on soft soil derived a 13.31% displacement increase prior to failure when compared to the fixed model. This verifies the more flexible behaviour of the SSI models, whereas it is evident that, when the second soil profile is adopted a stiffer behaviour derives when compared to the Equal Layer Geometry soil profile that derived a relevant 16% increase in-terms of horizontal displacements. This is a clear indication that the soil profile plays a significant role in the overall behaviour of the tower.

The 10-degree inclined and vertical piles embedded in rock have a small difference in terms of displacement at failure (see Fig. 13). The 10-degree inclined piles model embedded in rock and situated on extra soil yielded the lowest horizontal displacements.

The rotation of the pile cap for the under-study increasing layer models can be seen in Fig. 14. The Increasing Layer Geometry with 10-degree inclined piles embedded in rock had the lowest rotation out of the investigated increasing layer soil profile models. This verifies the previous finding that the 10-degree pile inclination stiffens the mechanical behaviour of the foundation.

Figure 13: P- $\delta$  curves of the Increasing Layer Geometry models [17].

Figure 14: Rotation of the pile cap for the Increasing Layer Geometry models [17].

## 6 CONCLUSIONS

Within this research work a numerical investigation was performed on the effect of the SSI phenomenon on wind turbine structures by using a 3D detailed modelling approach. The modelling approach foresaw the use of hexahedral element to discretize the soil domain as well as the wind turbine structure. Thereafter, modal and pushover analyses were performed.

In regards to the numerical investigation of wind turbine structures and their dynamic response, the numerical investigation of the modal analyses for the Equal Layer Geometry models with extra soil and a rock layer concluded that the optimum inclination of the piles is 10-degrees measured from the vertical. The results obtained within this research work can be used to optimally design the wind turbine foundation according to the relevant site conditions.

The pushover analyses further investigated the optimum foundation that derived from the modal analyses, where the Increasing Layer Geometry with 10-degree pile inclination situated on extra soil and embedded in rock were found to yield the lowest rotations and horizontal displacements prior to failure.

Soil-Structure Interaction has a significant effect on the outcome of an analysis and the mechanical response of the wind turbine structure, thus, the importance of a numerical investigation is crucial. It is essential to thoroughly investigate the effect of SSI on the superstructure prior to finalizing and optimally designing a wind turbine structure.

A future step is to optimize the proposed structural design presented in this research work, where a tower redesign is necessary to be performed so as to adjust the steel thicknesses based on the stress analysis that was performed, minimizing the required material to manufacture the tower. Furthermore, a full-scale nonlinear dynamic analysis will then be performed to further investigate the overall response of the proposed design and parametrically investigate the ability of the proposed design to minimize stress development at the soil, substructure and super-structure domains.

**Abstract.** *Increased demand for renewable energy production has stimulated interest in the offshore wind turbine (OWT) industry as a viable solution, and with OWTs growing larger in scale, further research is required into the dynamics of these newer structures. The majority of installed OWTs to date are built upon monopile foundations, and it is widely acknowledged that the current design methods for offshore piles are not appropriate for the large diameter piles required. This paper uses a novel pile-soil gapping algorithm to simulate the effects of degradation to the soil conditions in the sea bed. Using a 1D Winkler beam-spring approach, a dynamic model is validated for prediction of the natural frequencies of several OWT case studies, and the gapping algorithm is shown to reproduce well the reduction in natural frequency likely attributed to soil degradation measured from an OWT in Kentish Flats wind farm. It is found through the simulation of rotor-stop tests that the presence of gapping decreases the measured natural frequency, and this effect is greater for the monopile foundations with a smaller slenderness ratio.*

## 1 INTRODUCTION

The use of offshore wind power as a means of renewable electricity generation is becoming ever more popular, and is set to continue to grow as an industry. Offshore wind turbines (OWTs) can be mounted on a variety of foundations, including jacket structures, gravity bases, tripods and more recently floating foundation concepts. However, the most common choice is the monopile, due to its relatively simple and economical production. Monopiles are typically long and slender foundations that flex to accommodate the motion of the supported structure. But as energy demands grow, and the construction technology improves, OWTs are rapidly increasing in size, increasing their energy output, and requiring larger diameter and, therefore, more rigid foundations than previously detailed in design recommendations.

OWTs consist of a monopile foundation, a long flexible tower above the water line, and a substructure connecting the two. The nacelle, containing the generators and blade assembly, is affixed atop the tower. Due to the top-heavy nature of this arrangement, OWTs are dynamically sensitive structures, and as such due care must be taken to avoid unwanted resonances once operational. The OWT design paradigm can be described with three categories; stiff-stiff, soft-stiff, and soft-soft [1], referring to the flexibility of the support structure. Displayed in Figure 1, the OWT experiences four main driving frequencies. Wind and wave loading peaks at low frequencies around 0.1 Hz. The rotation of the rotor within the nacelle exerts an additional force on the system, at a frequency of  $1P$ , ranging from around 0.1 to 0.3 Hz. The  $3P$  loading arises from the blade shadowing force exerted on the OWT from the air deficiency created by the blades sweeping in front of the tower as they rotate, with a frequency of  $3 \times 1P$  for a three-bladed turbine, and  $2 \times 1P$  for a two-bladed turbine (i.e  $2P$  rather than  $3P$ ). In response to these driving forces, the soft-soft design regime places the natural frequency of the superstructure less than  $1P$ , the soft-stiff between  $1P$  and  $3P$  and the stiff-stiff above  $3P$ . Since the soft-soft is in danger of becoming excited by environmental loading, and the stiff-stiff requires too much steel to be economically viable, the soft-stiff approach is the most suitable. The bandwidth of non-resonant frequencies is narrow, so it is important to be aware of the the natural frequency of the structure upon installation, and also how it may vary during the operational lifetime.

Figure 1: Example power spectrum of an OWT, showing rotor frequency  $1P$ , blade passing frequency  $3P$ , and wind and wave spectra (Figure adapted from [1]).

OWTs experience cyclic loading in the lateral direction from wind and waves, and during its expected operational lifetime of 25-30 years may experience billions of cycles [2]. Currently, the design methods employ beam-on-nonlinear-Winkler-foundation (BNWF) models with prescribed soil reaction  $p$ - $y$  curves given by the DNV [3] and the American Petroleum Institute, or API [4]. They recommend the use of cyclic loading curves based on empirical tests performed on flexible piles under hundreds of loading cycles [5]. It is widely shown that long term cyclic loading has a considerable impact on the soil-structure interaction [6, 7, 8], including the effect of soil degradation and gap formation under cyclic loads. It is therefore important to include these mechanisms in models of OWT dynamics.

Gapping is the formation of a separation between the foundation and soil, causing unresisted lateral motion of the foundation, and a reduction in effective soil stiffness. It is affected by the soil condition, where different soil cohesiveness will affect the subsequent cave-in of a gap under cyclic load, but it has been shown that even cohesionless soils will not cave-in completely under continuous cyclic loading [9]. Changing the properties of the soil will have an impact on the natural frequency of the OWT, which is of specific importance for soft-stiff structures in danger of resonance if they experience drift of this natural frequency. Differences have been reported between the designed natural frequency and the measured value upon operation [10], with Damgaard et al. [11] recording reduction in natural frequency likely attributed to soil erosion in the upper layers around the foundation. It is important then to include in modelling efforts how this frequency may change with soil condition over long term cyclic loading.

In this paper, a simple gapping algorithm is applied to a dynamic BNWF model of several OWT case studies, and the effect of this gapping to the natural frequency is shown for different monopile geometries and levels of loading. The results of this study will have applications in the modelling and design of OWTs, and provide estimations for the condition of the soil after reasonable loading simulations are applied.

## 2 THE MODEL

A BNWF concept model is used with Euler-Bernoulli beams to model the structure, and soil springs with viscous dampers to model soil reaction, as displayed in Figure 2, with  $M_{RNA}$  representing the mass of the rotor-nacelle assembly, and  $F$  the externally applied force.

Soil reaction is modelled using the hyperbolic reaction curve of Duncan & Chang [12], defined as:

$$P = \frac{k_{max}y}{1 + y \frac{k_{max}}{P_{max}}} \quad (1)$$

where  $k_{max}$  is the initial spring stiffness in N/m,  $P_{max}$  is the ultimate capacity of the spring in N,  $y$  the horizontal displacement in m and  $P$  the force in N. Masing rules [13] are used to model the unloading response upon reversal. The value of the initial stiffness  $k_{max}$  used is that of Vesic [14], which is described by:

$$k_{max} = \frac{0.65 L_{EL} E_s}{(1 - \nu^2)} \left( \frac{E_s d_p^4}{E_p I_p} \right)^{\frac{1}{12}} \quad (2)$$

where  $L_{EL}$  is the elemental length in the BNWF model,  $E_s$  the Young's modulus of the soil,  $\nu$  the Poisson's ratio of the soil,  $d_p$  the diameter of the pile and  $I_p$  its second moment of area. The ultimate capacity of the pile is defined by the undrained shear strength of the soil, and given

Figure 2: The BNWF model of an OWT where the lateral soil reaction is modelled with  $p$ - $y$  springs and viscous dashpot dampers, and the vertical reaction with  $t$ - $z$  &  $Q$ - $z$  springs. The rotor-nacelle assembly is modelled as a point mass at the top node.

by [15]:

$$P_{max} = L_{EL} N_p S_u d_p \quad (3)$$

where  $N_p$  is a dimensionless coefficient increasing with depth, linearly from a value of 2 to a constant value of 11 from a depth of  $z/d_p = 3$ , and  $S_u$  is the undrained shear strength of the soil. Since the system is exclusively loaded laterally in this study, the axial component of the soil reaction springs can be neglected, as is commonly done for OWT analysis. A Newmark beta method [16] is used to solve the dynamic problem iteratively, with a beta value of 0.3025, and a gamma value of 0.6, in combination with a tangent stiffness method to model nonlinearity in the soil response.

## 2.1 Damping

Damping in the system consists of a superposition of structural, hysteretic and radiation damping. Aerodynamic and hydrodynamic damping sources are neglected for simplicity. Structural damping is modelled using the Rayleigh method, superposing contributions from the mass and stiffness matrices to form the damping matrix, and classical damping formulations for the coefficients. A damping percentage of 1% is used for structural contributions, as it is typically expected to be between 0.5% and 1.5% for OWTs [17]. Radiation damping is modelled with

the damping coefficient of Gazetas & Dobry [18], formulated as:

$$\frac{c_r}{2d_p\rho_s V_s} = \left[ 1 + \left( \frac{3.4}{\pi(1-v)} \right)^{5/4} \right] \left( \frac{\pi}{4} \right)^{3/4} a_0^{-1/4} \quad (4)$$

where  $V_s$  is the shear wave velocity in the soil,  $\rho_s$  is the mass density of the soil, and  $a_0 = 2\pi f d_p / V_s$  is the dimensionless frequency. This damping is tuned to achieve a contribution of 0.5%.

## 2.2 Gapping model

The gapping model is based on an entry condition defined by the soil reaction threshold, and an exit condition based on a displacement threshold. If a node enters a gap, it experiences soil resistance only from the side shear friction, modelled with a reduced stiffness value of 5% of  $k_{max}$ . If a node is no longer in, or has not entered the gap, it continues to move based on the Masing rules and hyperbolic curve.

The entry and exit conditions are modified using parameters  $\alpha_p$  and  $\alpha_y$ . A node enters the gap if its  $p$  value crosses the threshold defined by:

$$p_{pos} = \alpha_p(z) [p] \quad (5)$$

$$p_{neg} = \alpha_p(z) [p] \quad (6)$$

for  $p$  decreasing and increasing respectively, where  $[p]$  is the minimum and  $\lceil p \rceil$  the maximum  $p$  value for that degree-of-freedom over the time history of loading so far. The  $\alpha_p(z)$  value can be calibrated over depth  $z$ , to control the amount of gapping down the pile. Exit threshold values are based on displacement, and are defined by:

$$y_{neg}^N = \begin{cases} \alpha_y [y] & \text{if } y \leq 0 \text{ \& } N = 1 \\ \alpha_y y_{neg,entry}^{N-1} & \text{if } y \leq 0 \text{ \& } N > 1 \end{cases} \quad (7)$$

$$y_{pos}^N = \begin{cases} \alpha_y \lceil y \rceil & \text{if } y \geq 0 \text{ \& } N = 1 \\ \alpha_y y_{pos,entry}^{N-1} & \text{if } y \geq 0 \text{ \& } N > 1 \end{cases} \quad (8)$$

for  $p$  increasing and decreasing respectively, where  $[y]$  is the minimum and  $\lceil y \rceil$  the maximum  $y$  value for that degree-of-freedom over the time history of loading so far. The  $N$  value is the cycle number within the cyclic loading. After cycle 1, the  $y$  threshold values are derived from the displacement upon entry of the gap in the previous cycle. This means that different levels of cave-in can be modelled with the  $\alpha_y$  parameter, with a value of 1 meaning no cave-in occurs, and a value of 0 implying a fully caved-in gap upon exit. The above parameters are shown for reference over two example loading cycles in Figure 3.

## 3 RESULTS

The gapping model has been applied to four case study OWTs located in the UK and Netherlands. They have been selected for their availability of geometry and soil data. The data of these OWTs is summarized in Table 1.

Figure 3: A schematic of a  $p$ - $y$  curve for a node experiencing gapping behaviour. This figure demonstrates how the gapping parameters influence the  $p$ - $y$  curve.

Parameters	Unit	Irene Vorrink	Lely A2	North Hoyle	Walney 1
Tower height	[m]	45.8	37.9	67	67.3
Substructure height	[m]	5.2	12.1	7	37.3
RNA mass	[kg]	35,700	32,000	100,000	234,500
Pile length	[m]	19	13.5	33	23.5
Pile diameter	[m]	3.5	3.2	4	6
Pile wall thickness	[mm]	28	35	30-70	80
Rotor diameter	[m]	43	40.77	80	107
Soil shear modulus $G_s$	[MPa]	55	53	230	70
Eigenfrequency $f$	[Hz]	0.563	0.634	0.35	0.35

Table 1: Parameters defining the OWT case studies. OWT geometry and soil data from [19, 20, 21].

For all case studies, the soil was modelled for simplicity as a linearly increasing stiffness value such that the average over the pile length was equal to the given value in Table 1. Environmental loading is simulated with a sinusoidal load applied to the top node and lateral degree of freedom, with an amplitude given by [19]:

$$F_{ext} = 0.5\rho_a\pi R_T^2 V_w^2 C_T(\lambda_s) \quad (9)$$

where  $\rho_a$  is the density of air, taken to be  $1.25 \text{ kg/m}^3$ ,  $R_T$  is the radius of the turbine rotor blades in m,  $V_w$  the wind speed at the hub, assumed to be  $13.5 \text{ m/s}$ , and  $C_T$  is a dimensionless thrust coefficient due to the fact that the blades are rotating, dependent on the factor  $\lambda_s = \frac{V_{rot} R_T}{V_w}$ , where  $V_{rot}$  is the rotational speed (1P frequency) of the rotor in rad/s. The value of  $C_T$  can then be estimated from the function and graph given in [22].

The natural frequency is found by simulating a rotor-stop test, and then performing a fast Fourier transform (FFT) on the resulting period of free vibration. A rotor-stop test involves spontaneously feathering the OWT blades during operation, causing the turbine to stop spinning and the structure to freely vibrate. In this model, the OWTs are loaded with the force value given by Equation 9 sinusoidally, and then the load removed to simulate the feathering of the blades.

In this study, three rotor-stop tests are simulated; one without the gapping element, to validate

the structure geometries and soil conditions with natural frequency prediction, then two with the gapping enabled. The first is with loading equal to the value predicted in Equation 9, and a loading frequency equal to the 1P value of the OWT. The second normalises the force across all case studies, and they are loaded with a 100 kN force at 0.1 Hz to see the effect of gapping over different foundation geometries. For all tests the effect of gapping on the measured natural frequency is quantified. All the following tests were performed with representative gapping parameters of  $\alpha_y = 0.5$ , and  $\alpha_p = 0.15$  at the sea bed, reducing linearly with depth with a gradient of  $0.05 \text{ m}^{-1}$ .

### 3.1 Validation of the gapping model

In order to validate the use of the gapping model, the results of the natural frequency analysis for an OWT in Kentish Flats are compared to the results found in the study at this wind park by Damgaard et al. [11]. The OWT, with a total superstructure length of 105.56 m, and a 29.5 m monopile was modelled with an average soil shear modulus of 60 MPa. In the experimental results used for comparison, the OWT was monitored over time with accelerometers and a number of rotor-stop tests were performed, and its natural frequency was found to vary, likely attributed to soil erosion in the upper layers of the foundation.

This OWT was modelled, and a rotor-stop test performed with gapping parameters of  $\alpha_y = 0.65$ , and  $\alpha_p = 0.25$  to simulate the soil erosion. The magnitude of the force applied during the sinusoidal loading phase was selected to ensure the acceleration experienced at the top node of the OWT during free vibration aligned with the values measured during the experimental tests, for comparability. As is displayed in Figure 4, the plotted frequency spectrum found from the FFT of the free vibration, the natural frequency was predicted to vary from 0.338 Hz without gapping, to 0.327 Hz with gapping. This agrees well with the recorded data from Damgaard et al., who measured the value to vary between 0.340 Hz and approximately 0.327 Hz.

### 3.2 Calculated loads

Using the expression for expected external wind load in Equation 9, rotor stop tests were performed on the OWT case studies and the effect of gapping on the measured natural frequency tested. The OWTs were loaded for 20 cycles, in order to achieve steady state behaviour before the rotor-stop. Results for these tests are summarised in Table 2.

	Irene Vorrink	Lely A2	North Hoyle	Walney 1
Measured $f$	0.563	0.634	0.35	0.35
Modelled $f$ (no gapping)	0.588	0.647	0.349	0.333
Modelled $f$ (gapping)	0.572	0.596	0.329	0.129
$F_{ext}$ [kN]	99.25	103	343	460
Slenderness ratio $L_p/d_p$	5.43	4.22	8.25	3.92
Change with gapping	2.72%	8.31%	5.71%	61.25%

Table 2: Eigenfrequency results for the modelled rotor-stop tests using external load calculated from Equation 9.

The results in Table 2 show first a satisfactory prediction of the measured OWT eigenfrequency assuming soil condition without gapping, using the listed OWT geometries and soil parameters. Secondly, all four results show a decrease in predicted eigenfrequency value when

Figure 4: Frequency spectra of the Kentish Flats OWT model during the free vibration after a rotor stop test, with the gap algorithm enabled and disabled, as well as the reference 1P frequency of the OWT. The spectra resonant peaks are located at 0.338 Hz and 0.327 Hz.

the gapping is enabled. This is to be expected, since gapping essentially softens the soil response due to the transition portion of motion while in the gap which is unrestricted from soil reaction. The frequency reduction on the Walney 1 OWT is very large, due to the fact that the applied load was likely an overestimation, causing an exaggerated response.

### 3.3 Equal loads

The same test was then performed with the same load across all case studies, with  $F_{ext} = 100$  kN at a loading frequency of 0.1 Hz. The resulting frequencies identified in the rotor-stop tests are given in Table 3.

	Irene Vorrink	Lely A2	North Hoyle	Walney 1
Measured $f$	0.563	0.634	0.35	0.35
Modelled $f$ (no gapping)	0.588	0.647	0.356	0.338
Modelled $f$ (gapping)	0.575	0.602	0.348	0.302
Slenderness ratio $L_p/d_p$	5.43	4.22	8.25	3.92
Change with gapping	2.41%	6.95%	2.25%	10.65%

Table 3: Eigenfrequency results for the modelled rotor-stop tests using a 100 kN load for all tests.

It is noted that the change in external load and loading frequency has had a small effect on the predicted frequencies without gapping, highlighting the importance of considering a variety of expected loads when predicting the natural frequency, since the value is variable over

a small range once the structure is installed. Similarly to the previous results, the inclusion of gapping has introduced a reduction in the predicted eigenfrequency, but of lower magnitude than prior due to the reduced load magnitude and frequency. However, the results suggest that the size of the reduction may be attributed to the slenderness ratio of the monopile, with the smaller (and therefore more rigid) ratios experiencing a larger change in eigenfrequency. This could be attributed to the more rigid monopiles mobilizing the soil reaction further down the monopile's length, and therefore causing a gap response over a longer pile length. The flexible monopiles can be expected to behave as fixed below a certain critical depth, and therefore will not experience any gapping below that level.

#### 4 CONCLUSION

A simple gapping model was applied to a BNWF model of several offshore wind turbines, and the resulting effect on the natural frequency quantified. The natural frequency was identified with simulations of rotor-stop tests for OWTs of differing geometry and predicted external load. It was found that in all cases the natural frequency was reduced when the gapping effect was introduced, and that the effect appears more severe for the more rigid monopile foundations. The natural frequency is also slightly variable over different magnitudes of loading due to the nonlinear response of the soil, suggesting the importance of considering different weather and loading conditions for foundation design. With OWTs being designed with a natural frequency inside a narrow corridor of stability, it is important then to reliably predict by how much it is likely to drift throughout the operational lifetime. Including soil erosion effects like gapping may, then, assist in the design process and allow for reliable predictions. As well as application to the regular two-way dynamic loading used in this study, the model can be further included for use in stochastic loading simulations, such as more realistic wind and wave loads, and certainly has potential application to the impact of seismic loading on monopile foundations.

### Abstract

*Most seismic vulnerability analyses do not consider the Soil-Structure Interaction (SSI). However, it has been proved that SSI does not equally affect all types of structures and all types of soils. The analysis of the state of the art reveals that SSI especially affects the performance of mid/high-rise buildings under soft/inelastic soil conditions. This leads to overestimating the capacity of buildings and to obtaining unreliable results. This paper aims to assess the soil influence in the seismic vulnerability analysis of a reinforced concrete (RC) building. Three models of a real case study building have been determined (low-rise (real), mid-rise and high-rise). A pre-code 1970s case study building, located in Huelva, has been selected. This building shares typical constructive and structural characteristics with most RC buildings constructed during that period. The 3D continuum model of the soil has been carried out to simulate its nonlinear behaviour. The most probable soil profile has been defined, observing a clayey soil. Therefore, the analyses have been performed under undrained conditions. Nonlinear static analyses have been carried out to determine the seismic capacity of the models through the finite element method (FEM). The damage has been assessed by means of the local procedure, defined in the European seismic code, and the global fragility procedure. The results have shown that the soil does not significantly influence the behaviour of low-rise buildings. However, in the case of mid- and high-rise buildings, the maximum capacity can be reduced by up to 10% and 30%, respectively.*

## 1 INTRODUCTION

Most seismic vulnerability analyses of buildings are carried out without considering the soil-structure interaction effects (SSI). Despite these notable effects, their consideration in seismic analysis remains unclear. In fact, SSI was assumed to be beneficial in past research [1]. This benefit emerges from the reduction of the internal forces and the drifts due to the soil's increasing flexibility. Hence, the vast majority of seismic vulnerability analyses consider models with a fixed-based configuration to obtain more conservative results. However, recent studies on the influence of SSI in the capacity assessment of buildings has proved that it does not positively affect all types of structures and all types of soils [2]. They have concluded that structures are expected to experience different levels of damage when the soil's influence is taken into account [3]. In fact, the Eurocode-8 Part-1 (EC8-1) [4] establishes that the SSI effects must be born in mind when structures: i) present significant second order ( $p-\Delta$ ) effects; ii) are slender; or, iii) are medium/high-rise buildings. Moreover, it was proved that SSI might affect aspects related to the seismic performance of buildings such as the ductility and the strength [5] or the energy dissipation [6]. Studies have even shown that the SSI can greatly worsen the performance of buildings due to asymmetrical designs [7]. This suggests that further research is needed.

The SSI effects can be taken into account by simulating the flexibility of the soil. To do so, several approaches have been proposed over time. Among others, the most common approaches used in the behaviour assessment of buildings are the Nonlinear Beam on Winkler method (NBWM) and the continuum modelling of soil (in 3D). The first approach is mainly based on simulating the nonlinear behaviour of the soil by adding inelastic springs [8]. These springs present different characteristics which are applied in certain directions. The NBWM can simulate the SSI effects very easily and simply. In this way analyses do not become very tedious [9]. However, this approach presents certain drawbacks: it does not consider the complete behaviour of the soil, the frictional surface between the soil and the foundation and the effects of deeper soil layers. Therefore, this method might not be applicable for all soil and structural characteristics.

The continuum modelling of soils can exhaustively capture the soil constitutive behaviour, obtaining more realistic results [2]. Moreover, this type of analyses has been gaining importance over the past decade due to the availability of new methods and the increase of computational capacity [10]. Some related studies showed that the foundation characteristics and the soil modulus (shear and bulk) are the parameters that most affect the seismic response of buildings [2]. Others proved that the SSI are significant when both the structure and the soil are simulated as inelastic [6]. These parameters cannot be considered in SSI assessment via the NBWM.

Owing to the lack of studies and guidance, this paper aims to analyse the soil's influence in the seismic vulnerability analysis of a reinforced concrete (RC) building. To do so, different models of a real case study building have been simulated (low-rise (real), mid-rise and high-rise). The EC8-1 statement and past research have been proved. The 3D continuum modelling of the soil has been carried out to simulate its nonlinear behaviour. Furthermore, the characterisation of the most probable soil profile at the location has been done by considering different geotechnical studies. As a clayey soil has been observed, the analyses have been carried out under undrained conditions. Nonlinear static analyses have been performed to determine the seismic capacity of models by using the finite element method (FEM). The damage has been assessed by means of the local procedure established in Eurocode-8 Part-3 (EC8-3) [11] and the fragility procedure.

The case study building is a 1970s primary school building located in Huelva (southwestern Spain), which is an earthquake-prone area. This building shares typical constructive and structural characteristics with most RC buildings of the area. What is more, these buildings were constructed prior to the applications of seismic codes.

The key contributions of this paper are: i) the analysis of the soil influence in the seismic vulnerability analysis of RC buildings considering different geometrical characteristics; ii) the characterisation for the 3D continuum modelling of the most probable soil profile in Huelva; iii) 3D FEM models in OpenSees to realistically reproduce the entire system's behaviour (soil+foundation+structure); iv) the analysis of the seismic damage by means of both local and global procedures.

## 2 CASE STUDY

### 2.1 Building configuration

The case study building selected is a primary school building located in Huelva. It has been defined as an index-building of the typology of RC buildings [12]. This typology represents 27% (75 buildings) of the total (279) of the primary school buildings constructed in the province. As they were built during the 1970s, they share constructive and structural characteristics with a major part of the area's RC buildings: insufficient longitudinal and transversal rebar ratio, wide beams, short columns, very slender RC columns sections and low-quality structural materials. Moreover, these buildings have not been designed according to seismic criteria since they were constructed prior to restrictive seismic codes.

The case study building is a two-story RC frame building (Figure 1). Although it is regular in height, it presents short columns on the ground floor. This is a typical constructive configuration that can be commonly found in most RC buildings of the 1970s. Short columns are created due to the elevation of the ground floor from the soil surface to avoid humidity and water problems. This ground-floor construction often leads to isolated footings (superficial or deep). In this case, the building was constructed with isolated footings of a depth of 0.80 m. The structural characteristics of the building are listed in Table 1.

Figure 1: Case study building's configuration.

Characteristic	Columns	Load beams	Tie beams
Dimensions (cm)	30x40	60x30	30x30
Cross-section (cm <sup>2</sup> )	1,200	1,800	900
Longitudinal rebar (cm <sup>2</sup> )	1.572	Top: 0.786 Bottom: 3.495	Top: 0.786 Bottom: 0.786
Transversal rebar (cm <sup>2</sup> )	0.196	0.196	0.196
Spacing of stirrups (cm)	15	20	25

Table 1. Case-study's structural elements geometrical characteristics.

## 2.2 Soil characterisation

A characterisation of the soil under the building has been carried out to properly model its constitutive behaviour. The information has been compiled from 8 nearby geotechnical studies. These studies include information related to laboratory tests done with samples as well as in-situ geotechnical prospections. Based on the available information, an interpretation of the soil layering at the site has been performed. In this study, the most probable soil profile has been considered. To do so, the probability of each stratum according to its depth has been assessed. This determination has considered 17 boreholes. As shown in Figure 2a, four different geotechnical strata have been identified: tilled, grey clay, brown silt and clay loam. The laboratory tests have revealed a predominance of clay. Therefore, only the parameters to perform undrained analyses have been calculated.

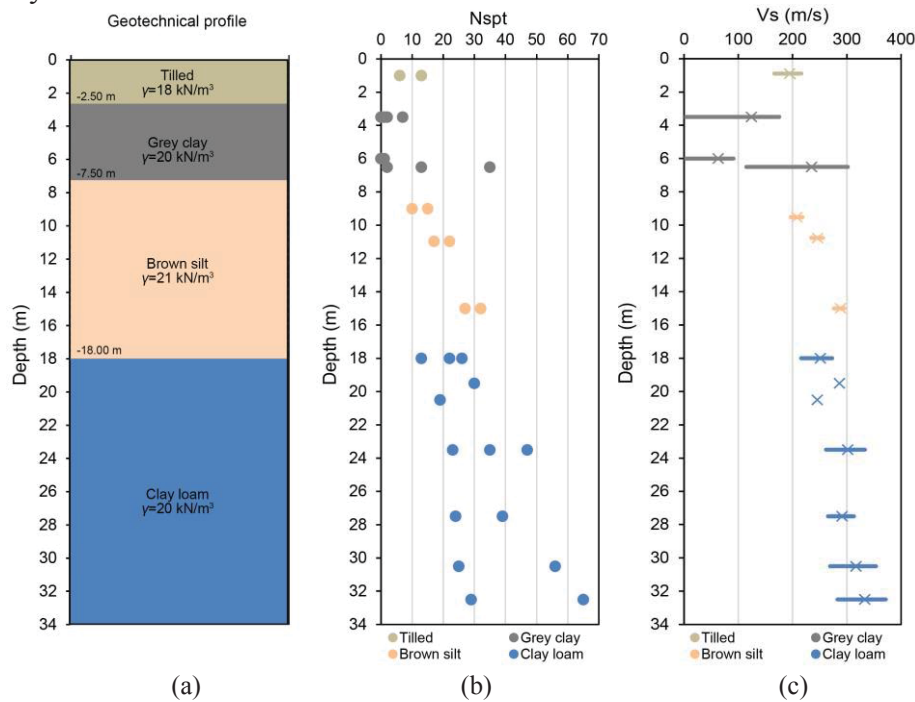

Figure 2: Soil characterization. (a) Soil profile (b)  $N_{spt}$  and  $V_s$  (c) according to depth.

Among other in-situ tests, standard penetration tests (SPT) were executed to determine the  $N_{spt}$ . In Figure 2b, the  $N_{spt}$  for each soil stratum has been plotted. According to [13], the shallow layers can be classified as low-dense soils ( $N_{spt} \approx 11-30$ ) while the deepest layers are dense ( $N_{spt} \approx 31-50$ ).

The shear wave velocity ( $V_s$ ) and the Poisson ratio ( $\nu$ ) are required to numerically model the soil in 3D. In [14], several correlations were defined to obtain  $V_s$ . However, in this work, only the Imai equation (Eq.(1)) has been used since it is widely accepted. In Figure 2c, the  $V_s$  values for each soil layer have been defined according to  $N_{spt}$  and depth. Since there are several values of  $V_s$  for each depth, the most probable value has been used to determine the parameters presented below.

$$V_s = 91 N_{spt}^{0.317} \quad (1)$$

The soil behaviour is defined according to three parameters: shear ( $G$ ), elastic ( $E$ ) and bulk ( $B$ ) modulus and the unit weight ( $\gamma$ ). The moduli have been calculated according to certain widely known geotechnical correlations (Eq.(2)(3)(4)).  $G$ ,  $E$  and  $B$  have been plotted in Figure 3 for each soil stratum. The soil constitutive behaviour has been plotted considering the

medium values of each modulus. As can be observed, the shallow layers are weaker than the deepest ones, which relates to  $N_{spt}$ . The soil stiffness increases at around 5 m depth. The clay loam's modulus rises slightly with depth. In order to take the variability of the modulus into account, four soil layers have been defined following the procedure established in Section 4.2.

$$G = \gamma V_s^2 \quad (2)$$

$$E = 2G(1 + \nu) \quad (3)$$

$$B = E/3(1 - 2\nu) \quad (4)$$

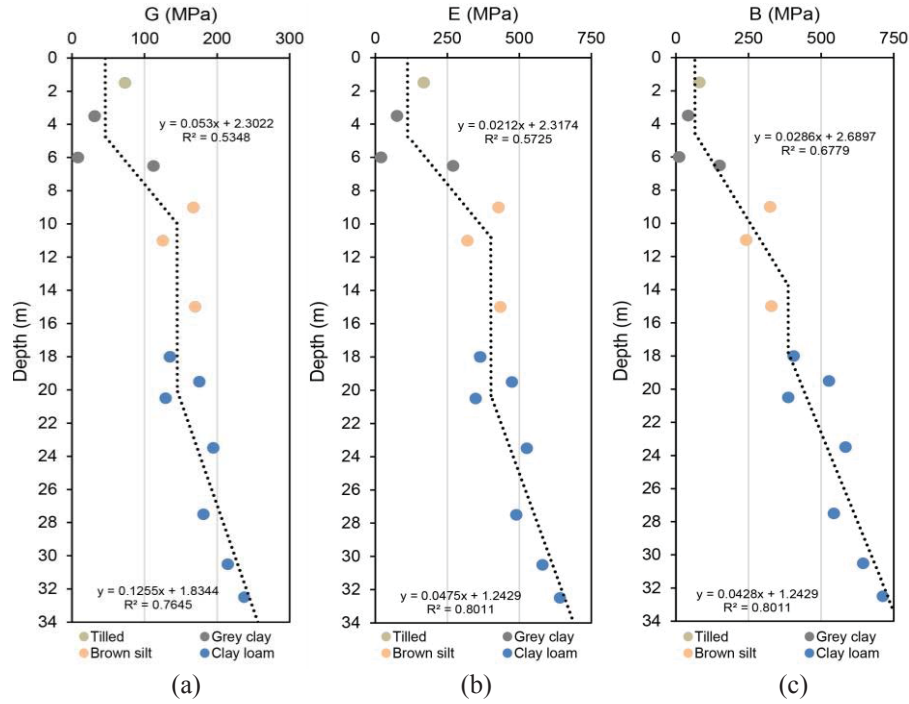

Figure 3:  $G$  (a),  $E$  (b) and  $B$  (c) values obtained from correlations according to geotechnical prospections.

### 3 NONLINEAR STATIC ANALYSES

#### 3.1 Models defined

The state of the art has revealed that SSI must be considered in the seismic analyses of mid- and high-rise buildings. Therefore, in order to better understand their influence, different configurations of the case study building have been determined by varying its height. As shown in Figure 4, three models have been defined: low-rise (real) (M1), mid-rise (M2) and high-rise (M3). The total mass and height of each model have been listed in Table 2. Fixed-base and solid models have been identified with “F” and “S”, respectively. The nodes at the base of the F-models have been fixed in the 6 degrees of freedom (DOF): X, Y, Z,  $R_x$ ,  $R_y$  and  $R_z$ . The modelling of the soil is presented in Section 4.2. It has also been checked that the foundations' dimensions are valid for the soil with each model's configuration.

Figure 4: Models' configuration.

Model	Nº of floors	Total mass (ton)	Total height (m)
M1	2	1,058	7.30
M2	4	1,952	13.90
M3	6	2,846	20.50

Table 2. Number of floors, total mass and height of the models analysed.

### 3.2 Analysis procedure

Nonlinear static analyses have been carried out to determine the capacity of the models by using the FEM OpenSees software [15]. Since the models are very large, the analyses have been done using the parallel option available in OpenSees by defying partitions. The outputs have been handled in PYTHON [16]. A load-control and displacement-control integrator have been used to perform the gravity and the pushover analyses, respectively. Only the modal load pattern results have been considered since this has been the most restrictive. Modal analyses have been carried out to define the load pattern. The *-genBandArpack* solver has been used due to the numerous constraints. As models have worked in Mode 1 and 2, torsional effects can be neglected.

### 3.3 Damage determination

The N2-method has been used to determine the single-degree-of-freedom (SDOF) idealised bilinear curves and the target displacement. Its extended version has also been used, which takes the infills' effects into account. A 0.1g PGA for *Huelva* has been used according to the Spanish updated seismic action values [17]. The response spectrum has been constructed using the EC8-1 procedure.

Two approaches have been considered to determine the damage: the local and the global. The first one has borne in mind the demand/capacity ratio (DCR) established in EC8-3 and the local damage of RC structural elements. Three damage states have been determined: damage limitation (DL), significant damage (SD) and near collapse (NC). The NC is calculated considering the ultimate chord rotation ( $\theta_{um}$ ). The SD is determined as  $3/4$  of  $\theta_{um}$ . The DL is worked out by means of the yielding chord rotation ( $\theta_y$ ). The formulae of each parameter are

established in the EC8-3. Each damage state has been calculated when the demand chord of one column reaches the capacity values of  $\theta_{um}$ ,  $\theta_{um}$  and  $\theta_y$ .

The second approach is based on the fragility curves assessment. These curves provide the probability of reaching or exceeding a certain damage state ( $d_s$ ), given a certain spectral displacement ( $S_d$ ). They are determined by the well-known lognormal cumulative distribution (Eq.(5)), where:  $\beta_{ds}$  is the dispersion at  $d_s$  and  $S_{d,ds}$  is the median value of the spectral displacement at which a building reaches the  $d_s$  threshold.

$$P[d_s|S_d]=\Phi[(1/\beta_{ds})\ln(S_d/S_{d,ds})] \quad (5)$$

Both  $\beta_{ds}$  and  $S_{d,ds}$  are statistical parameters that take into account different uncertainties. They should therefore be determined according to the models analysed. However, in this case they have not been studied since further research should be carried out considering many models and including the SSI effects. However, an exhaustive work carried out in [18] has been used to define these parameters. The authors performed the fragility assessment of typical Spanish RC buildings and determined the fragility parameters for low-, mid- and high-rise RC buildings. The values of  $\beta_{ds}$  for each building class are listed in Table 5. The values of  $S_{d,ds}$  have been determined for each of the models analysed and following the provisions established in [18], listed in Table 4. This procedure considers the parameters that characterise the idealised SDOF system curves:  $D_y$  and  $D_u$ , yielding and ultimate displacement.

Damage state/Class	Slight ( $\beta_1$ )	Moderate ( $\beta_2$ )	Severe ( $\beta_3$ )	Complete ( $\beta_4$ )
Low-rise	0.28	0.37	0.82	0.83
Mid-rise	0.28	0.36	0.50	0.61
High-rise	0.28	0.29	0.34	0.45

Table 3.  $\beta_{ds}$  for each RC building class.

Slight ( $S_{d1}$ )	Moderate ( $S_{d2}$ )	Severe ( $S_{d3}$ )	Complete ( $S_{d4}$ )
$0.7D_y$	$D_y$	$D_y+0.25(D_u-D_y)$	$D_u$

Table 4.  $S_{d,ds}$  determination for each damage state threshold.

## 4 NUMERICAL MODELLING

The different models considered in this study have been modelled with the STKO software [19], a Graphical User Interface (GUI) for OpenSees.

### 4.1 Superstructure

The nonlinear behaviour of the RC elements has been simulated through the distributed plasticity approach. This can automatically compute deformations and curvatures, reducing the modelling time. The RC beams and columns have been discretised into different fibres with the fibre section aggregator. In order to take  $p$ -delta ( $p$ - $\Delta$ ) effects into account, force-beams elements have been applied to the RC frames. “Concrete01” has been considered to simulate concrete. The concrete’s core has been defined by increasing its strength and strain according to [20]. “Steel02” has been used to model steel. In this case, the smooth rebars have been considered by decreasing the steel elastic modulus as in [21]. The effects of infills have been taken into account by means of the two-diagonal truss approach defined in [22]. Due to the rigidity of the concrete slabs, rigid diaphragm interactions have been applied to the nodes of each floor. Masses have been applied to each structural member considering the gravitational loads and the self-weights. Gravitational loads have also been applied to each structural element bearing in mind: dead (self- weight and the weight of constructive elements) and live

loads. The characteristics of the structural materials considered in this study are listed in Table 5.

Concrete		Steel		Infills	
$f_c$ (MPa)	28	$f_y$ (MPa)	370	$G_w$ (GPa)	1240
$f_{cu}$ (MPa)	4	$E_s$ (GPa)	310	$\alpha$	0.05
$\varepsilon_c$ (%)	0.002			$\tau_{cr}$ (MPa)	280
$\varepsilon_{cu}$ (%)	0.04			$E_w$ (GPa)	4092

Table 5. Values of the structural materials' parameters.

Where: concrete compressive ( $f_c$ ) and crushing strength ( $f_{cu}$ ); concrete strain at maximum ( $\varepsilon_c$ ) and ultimate strength ( $\varepsilon_{cu}$ ); steel yielding strength ( $f_y$ ); steel modulus of elasticity ( $E_s$ ); infills shear modulus ( $G_w$ ); post-capping degrading branch coefficient ( $\alpha$ ); shear cracking stress ( $\tau_{cr}$ ); masonry elasticity modulus ( $E_w$ ).

## 4.2 Continuum modelling of the soil

The underlying soil of the building has been modelled with a mesh of 125x40x21 m (X, Y and Z directions). The mesh has been defined according to the  $V_s$  and to the frequency ( $\omega$ ) of the models. "SSPbrick" brick elements have been applied to the solid elements to capture the soil small deformation (Figure 5). The mesh is characterised by 51,954 nodes and 120,040 brick elements. The lateral boundaries have been fixed in the corresponding direction and the base in all directions.

According to the different test results (Section 2.2), the soil beneath the building is clayey. Therefore, the analyses have been performed under undrained conditions since this is the most restrictive. Hence, the soil constitutive behaviour has been simulated by means of the "PressureIndependMultiYield" (PIMY) material. This has been implemented in OpenSees to model elasto-plastic undrained clay-type soils, which are independent from pressure. The soil's failure criterion is based on Von Mises' multi-surface plasticity theory (Figure 5) determined in [23]. "EqDOF" has been applied to the interaction between the soil's and the foundation's surfaces. Four soil layers have been defined according to the characterisation performed in Section 2.2, which can be observed in Figure 4.

Figure 5: "PressureIndependMultiYield" soil material's failure criterion.

## 5 RESULTS AND ANALYSIS

The results obtained from the analyses appear in this section. In Figure 6, the deformed shape of each model after the application of the gravity loads is shown. As can be observed, the settlement of the structure is higher when the height increases. The displacement in the Z

direction of the control node (in the rooftop) increases 220% and 323% when adding 2 floors (M2) and 4 floors (M3), respectively. Therefore, this increase is not linear.

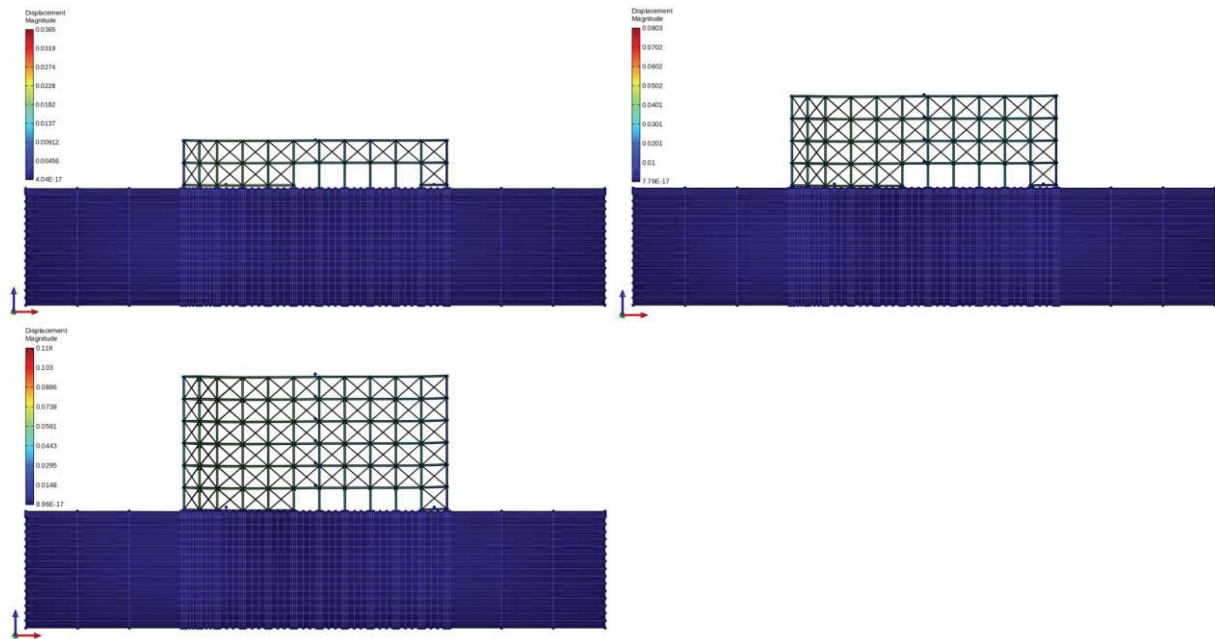

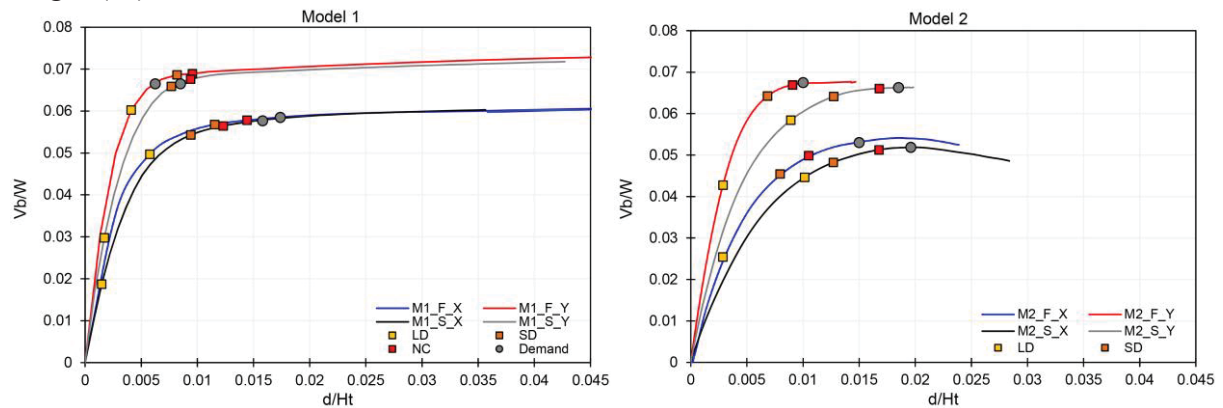

Figure 6: Deformed shape of models analysed after the application of gravity loads.

In Figure 7, the SDOF capacity curves for each of the models have been plotted. Also, the damage states (Section 3.3) and the target displacements (demand) have been determined. In order to compare the results, the multi-degree-of-freedom (MDOF) curves have been normalised by dividing the base shear ( $V_b$ ) by the weight ( $W$ ) and the displacement ( $d$ ) by the total height ( $H_t$ ).

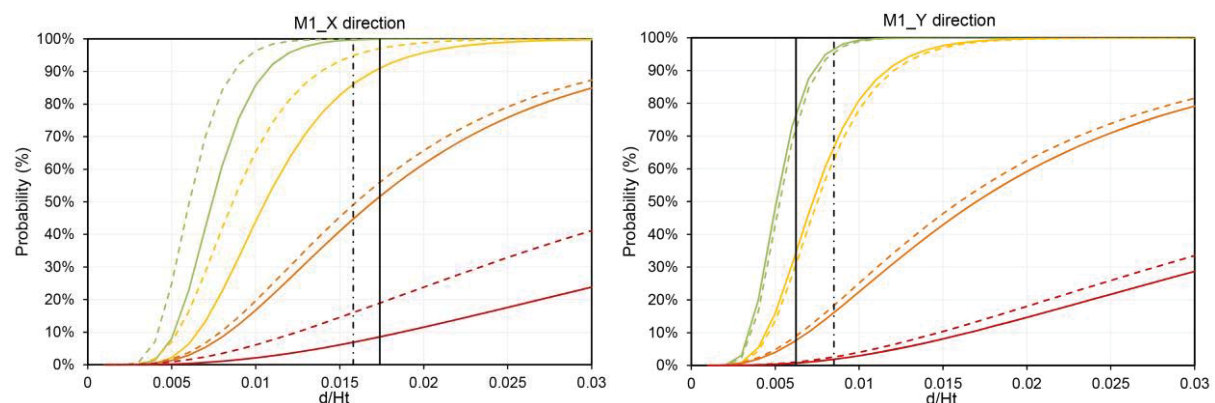

Figure 7: SDOF normalised capacity curves for each of the models assessed.

It can be observed that the higher the structures' height, the higher the soil effects. In the case of the low-rise model (M1), the SSI just decreases the initial stiffness of the systems. In the X direction, the difference between the demand and the NC displacement is higher for the S models. In the Y direction, for the F model, the demand is located between the LD and the SD. However, when considering the SSI, the demand is after the SD; therefore, it will not comply with the EC8 requirements like in the X direction. Mid-rise buildings are more affected by the SSI than low-rise buildings due to the considerable modification of the initial stiffness. The maximum capacity has been reduced by around 10%. In the Y direction, the demand displacement is considerably higher for the S model. High-rise models are the most affected by the SSI, the maximum capacity being reduced by up to 30%. In terms of damage, the models behave worse due to the failure of columns located in the irregularity of the ground floor.

In Figure 8, the fragility curves for each of the models analysed are plotted considering the demand displacement. It can be noted that the fragility curves for the models with SSI are worse than the F-model's curves. Therefore, the probability of reaching higher damage increases in models that bear the soil influence in mind. This probability also increases with the height. As can be seen, the S-model's fragility curves are worse than the F-model's curves when the height increases. This results in the high-rise models being the most affected. Moreover, the fragility curves of high-rise buildings are worse than the rest due to the statistical parameters' values.

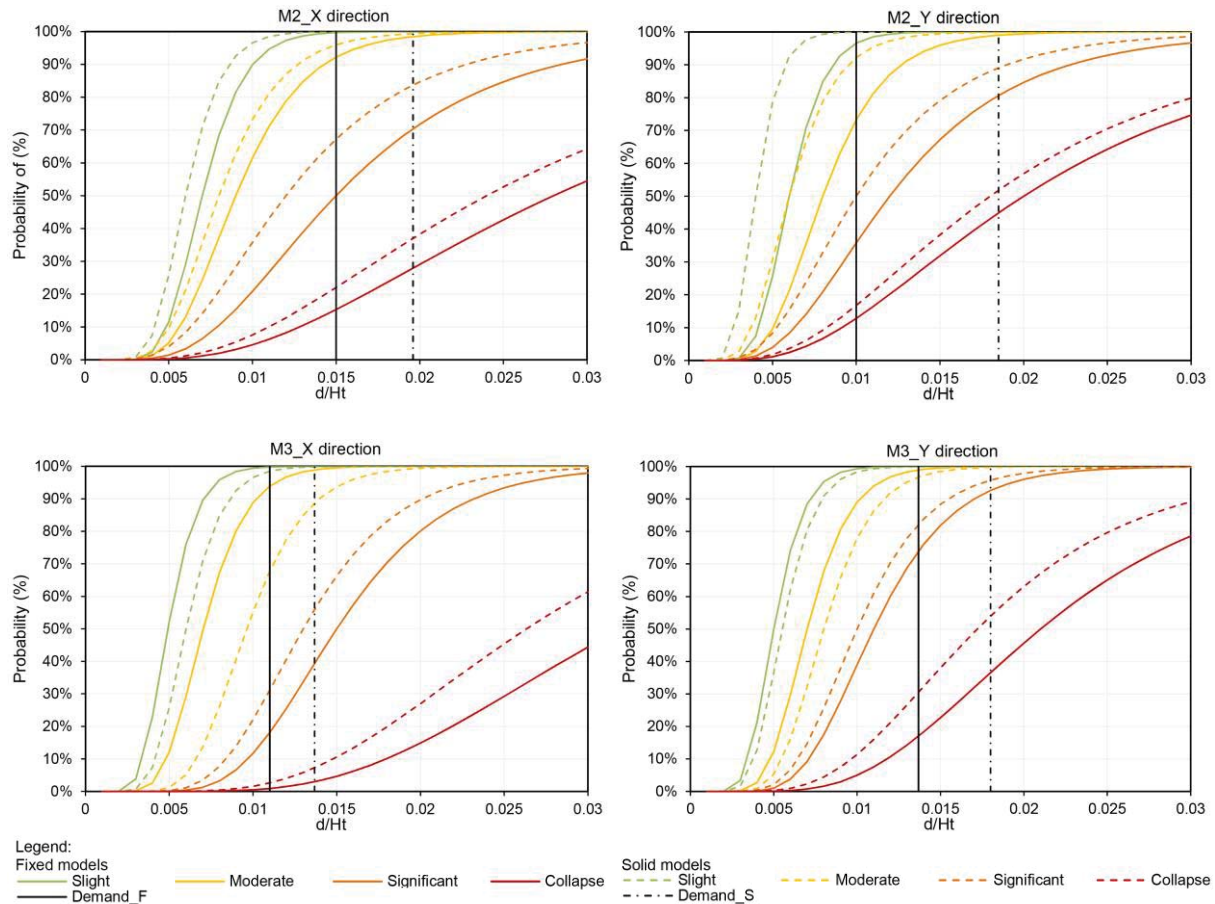

Figure 8: fragility curves considering fixed-based and solid models and low-, mid- and high-rise models.

## 6 CONCLUSIONS

This paper aims to analyse the SSI in the seismic vulnerability analysis of RC buildings. The state of the art has revealed that SSI must be considered in the seismic analyses of mid- and high-rise buildings. Therefore, different configurations of a case study RC building have been defined by varying the height: low- (real), mid- and high-rise. The characterisation of the location's soil profile has been carried out. This characterisation has revealed that the soil is clayey.

Nonlinear static analyses have been performed to assess the models' capacity. The seismic damage has been determined by means of the European seismic code (local damage of elements) and the fragility procedures (global damage). 3D nonlinear models considering the soil as a continuum have been modelled using the FEM to simulate the soil nonlinear behaviour.

The results have shown that the soil does not significantly influence the behaviour of low-rise buildings. However, in the case of mid- and high-rise buildings, the maximum capacity can be reduced by up to 10% and 30%, respectively. Moreover, according to the local damage assessment, structural elements might collapse due to considering the soil, even for low-rise buildings.

In the light of the fragility assessment results, it can be concluded that the probability of reaching higher seismic damage increases when considering the SSI. Moreover, this probability increases with the height.

This work has considered the most probable soil profile that can be found in the area. However, further research should be carried out in order to consider several soil profiles since softer layers could worsen the building's seismic capacity. This research has considered statis-

tical parameters from other works in the fragility assessment. Yet, further research should be assessed to properly determine these values according to the models' characteristics and the type of soil. This research has not considered the element contact between the soil and the foundation's surfaces, which can capture the soil behaviour better, leading to more accurate results.

**Keywords:** multi-span bridges, soil-structure interaction, modal analysis, piled foundation, periodic structure theory

**Abstract.** *This paper investigates the effect of soil-structure interaction (SSI) on the free vibration response of long multi-span bridges. A numerical case study of a continuous concrete box girder bridge is presented. For several bridge lengths, the influence of SSI on modal characteristics is studied. Furthermore, if the bridge is assumed to be infinitely long, periodic structure theory is used to compute the dispersion curves of the non-decaying waves that propagate through the bridge. The stop- and passbands are related to the natural frequencies of the bridges with finite length.*

## 1 INTRODUCTION

Road and railway bridges are frequently constructed in regions with changing topography or soft sub-soil conditions, and in dense urban areas due to space limitations. Often, these bridges consist of identical spans repeated over a long distance resulting in a convenient and cost-effective design. This paper investigates the effect of soil-structure interaction (SSI) on their free vibration response, which is important as the structure's modal characteristics (mode shapes, natural frequencies, modal damping ratios) are commonly used in structural health monitoring.

The influence of SSI on the modal characteristics of long multi-span bridges is often neglected in finite element model updating procedures [1, 2], as this significantly reduces the model complexity and is typically a valid simplification when the structure is founded on stiff soil. However, for short (single-span) bridges, many studies have highlighted the importance of SSI on modal characteristics. Romero et al. [3] studied the dynamic response of single-span, simply supported railway bridges under moving loads. They conclude that the resonant train speed is lower when dynamic SSI is accounted for, due to the lower natural frequency of the bridge. Furthermore, they report a substantial increase of the modal damping ratio if the soil stiffness is low, resulting in lower bridge deck acceleration at mid-span. Östlund et al. [4] investigate the effect of different foundation types and span lengths on the response and modal characteristics of a single-span railway bridge. They show that the modal damping ratio increases for shorter span lengths and that the bridge deck acceleration is generally higher in the case of fixed supports.

In this paper, a case study of a continuous concrete box girder bridge is presented in order to analyze the influence of SSI on the modal characteristics of long, repetitive bridges. Three cases are considered for the soil stiffness: a soft, medium, and stiff soil. Furthermore, the analysis is performed for a bridge with 5 spans, 15 spans, and an infinitely long bridge.

The paper is organized as follows. Section 2 introduces the numerical case study. Section 3 focuses on the influence of SSI and bridge length on the free vibration response of the bridge; the influence on modal characteristics is studied for the bridges with finite length, which are subsequently linked to dispersion curves of free waves propagating through the infinitely long bridge. Section 4 concludes the paper.

## 2 NUMERICAL CASE STUDY

This section presents a numerical case study of a continuous concrete box girder bridge founded on piled foundations. In the past decades, a large number of such bridges have been built in many European countries [5]. The advantage over simply supported box girder bridges, which remain the standard in China, is their greater slenderness (ranging between 12 and 14) and generally lower dynamic response. The geometry and material properties are based on a literature survey of existing box girder bridges presented by Kang et al. [5], Yan et al. [6], and Cascales Fernández et al. [7].

### 2.1 Bridge geometry

Figure 1a shows a single span of the railway bridge. The span length  $L$  equals 24 m. The bridge cross section is a concrete box girder with uniform height (Figure 1b). The bridge deck is periodically supported by 6 m high piers with a rectangular cross section of 5.5 m by 1 m. At each pier, the bridge deck rests on two bearings. The concrete has a Young's modulus  $E = 30$  GPa, a Poisson's ratio  $\nu = 0.25$ , and a density  $\rho = 2500$  kg/m<sup>3</sup>. Rate-independent hysteretic material damping in the frequency domain is modeled by introducing a complex

Figure 1: (a) Single bridge span and (b) cross section of the bridge deck. The red area indicates the area to which the load is applied.

Young's modulus  $E^* = E(1 + 2i\beta)$ , where a material damping ratio  $\beta$  of 0.02 is assumed.

The deck and piers are both modeled with 8-node quadratic shell elements based on Reissner-Mindlin plate theory. Figure 2 shows the FE model of the pier and bridge deck. The maximum element size equals 1 m for the deck and 0.5 m for the pier. Each bearing is represented by constraint equations between two nodes on the deck and two corresponding nodes on the pier. For the left bearing (in red), the vertical as well as the lateral displacement of the deck and pier are coupled. For the right bearing (in blue), only the vertical displacement is coupled. In the longitudinal direction, the displacement of the deck and pier is only coupled at one of the bridge piers.

Figure 2: Finite element model of a pier and part of the bridge deck. At the nodes representing the left bearing (in red), vertical and lateral displacements are coupled using constraint equations, while at the right bearing (in blue), only vertical displacements are coupled.

## 2.2 Bridge length

Three bridges are considered in this paper: a bridge with 5 spans, a bridge with 15 spans, and an infinitely long bridge. For the first two cases, the length of the end spans equals half the regular span length. At both bridge ends, constraint equations (as explained in Subsection 2.1) are used to account for the support conditions: the vertical displacements are prohibited by both supports, while lateral displacements are prohibited by the left support.

## 2.3 Piled foundation

Each pier is supported by a piled foundation that consists of eight piles connected to a pile cap with a thickness of 1 m. The pile cap is assumed to be rigid, as is the connection between the pier and the pile cap, and the pile cap and the piles. Figure 3b shows the geometry of the

piled foundation. The piles have a diameter of 0.4 m and a length of 10 m. The piles and pile cap are made of concrete with Young's modulus  $E = 35$  GPa, Poisson's ratio  $\nu = 0.25$ , and density  $\rho = 2500$  kg/m<sup>3</sup>. No material damping is considered for the piled foundation.

Each piled foundation is embedded in a horizontally layered soil (Figure 3a) consisting of a 9 m thick top layer on top of a halfspace. Three cases are considered for the top layer: a soft soil, a medium soil, and a stiff soil. The underlying halfspace consists of stiff soil. Hence, the stiff soil case corresponds to a homogeneous halfspace. The dynamic soil characteristics are specified in Table 1. The piles reach 1 m into the stiff halfspace.

Figure 3: (a) Piled foundation embedded in a horizontally layered halfspace and (b) geometry of the piled foundation.

Soil type	$C_s$ [m/s]	$C_p$ [m/s]	$\rho$ [kg/m <sup>3</sup> ]	$\beta_s$ [-]	$\beta_p$ [-]
Soft soil	100	200	1800	0.02	0.02
Medium soil	200	400	1800	0.02	0.02
Stiff soil	300	600	1800	0.02	0.02

Table 1: Dynamic soil characteristics: shear wave velocity  $C_s$ , dilatational wave velocity  $C_p$ , density  $\rho$ , and material damping ratio's  $\beta_s$  and  $\beta_p$  in shear and dilatational deformation.

The soil and the piles are both modeled with 10-node quadratic tetrahedral elements. A perfectly matched layer (PML) is used to absorb waves at the edges of the FE model [8, 9]. The element size  $l_e$  is chosen such that the distance between two nodes is always less than one-eighth of a shear wavelength for each frequency, both in the physical soil domain and the PML. The width of the physical soil domain between the PML and the foundation is chosen as one half shear wavelength at 50 Hz .

The FE-PML formulation used in this work is described in detail by Papadopoulos et al. [10], and based on the work of Chew and Qiu [8] and Basu and Chopra [9]. As explained in [10], the PML stretch functions consist of third-degree polynomial functions with  $\alpha_0 = \pi C_s / (l_e \omega) - 1$  and  $\alpha_1 = 20 C_s$ , controlling the attenuation of evanescent and propagating waves inside the PML domain, respectively. The FE-PML model of the piled foundation is validated using a finite element-boundary element model (FE-BE) model.

The dynamic stiffness of the piled foundation is defined as the forces or moments required to impose a unit displacement or rotation of the rigid pile cap. The real part determines the stiffness, while the imaginary part depends on the material and radiation damping in the soil.

Figure 4 shows the stiffness and damping coefficients of a single piled foundation modeled with a 3D FE-PML model and a 3D FE-BE model. The pile cap is assumed to be rigid and

massless. Figure 4a shows the vertical stiffness  $\text{Re}(k_{zz})$  of the piled foundation embedded in soft, medium, and stiff soil. The static stiffness increases with increasing soil stiffness. An increase in stiffness is observed for the soft soil around 22 Hz due to interaction between the individual piles. When the shear wavelength in the soil equals twice the pile spacing, the piles vibrate in anti-phase motion leading to a stiffer behavior of the piled foundation [11]. The pile-soil-pile interaction effect is observed around 45 Hz for the medium soil. For the stiff soil, a peak in the stiffness function is expected around 75 Hz. Figure 4b shows the vertical damping  $\text{Im}(k_{zz})$ . In the low frequency range it is observed that, as the soil stiffness of the top layer decreases, the damping decreases as well. This is explained by the fact that, for a soft layer on a stiffer halfspace, wave propagation in the soft top layer only occurs at frequencies above the cut-on frequency, activating radiation damping. This effect is more pronounced as the relative difference in stiffness between the top layer and the halfspace increases. Furthermore, the peaks due to pile-soil-pile interaction are also observed in the damping curves.

Figure 4c shows the rocking stiffness  $\text{Re}(k_{\varphi_x \varphi_x})$  around the  $x$ -axis, which is significantly lower than the rocking stiffness  $\text{Re}(k_{\varphi_y \varphi_y})$  around the  $y$ -axis shown in Figure 4e, due to the smaller eccentricity of the piles with respect to the center. Again, the effect of pile-soil-pile interaction is observed as peaks in the stiffness functions. Figures Figure 4d and Figure 4f show the corresponding damping values  $\text{Im}(k_{\varphi_x \varphi_x})$  and  $\text{Im}(k_{\varphi_y \varphi_y})$  for the rocking motion of the piled foundation around the  $x$ - and  $y$ -axis, respectively. Finally, the results obtained with the 3D FE-PML and 3D FE-BE model are in very good agreement across the entire frequency range. The slight discrepancy in the high frequency range is attributed to the FE discretization.

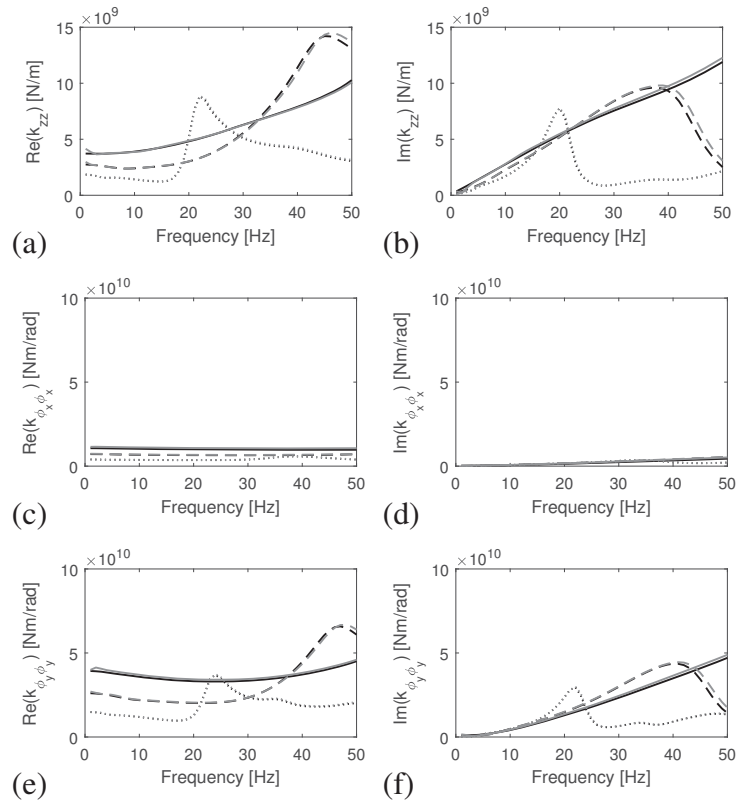

Figure 4: Vertical (a) stiffness  $\text{Re}(k_{zz})$  and (b) damping  $\text{Im}(k_{zz})$ , rocking (c) stiffness  $\text{Re}(k_{\varphi_x \varphi_x})$  and (d) damping  $\text{Im}(k_{\varphi_x \varphi_x})$ , and rocking (e) stiffness  $\text{Re}(k_{\varphi_y \varphi_y})$  and (f) damping  $\text{Im}(k_{\varphi_y \varphi_y})$  for the piled foundation embedded in stiff (solid line), medium (dashed line), and soft soil (dotted line). The black and gray lines correspond to the results obtained with the FE-BE and FE-PML model, respectively.

### 3 FREE VIBRATION RESPONSE

The effect of SSI and bridge length (number of spans) on the natural frequencies and mode shapes is investigated. Furthermore, the dispersion curves of the non-decaying waves propagating through an infinitely long bridge are computed and related to the modal characteristics of the bridges with finite length.

#### 3.1 Modal characteristics

A 3D FE model of the bridge with 5 spans (Figure 5) is constructed in order to compute its modal characteristics. First, SSI is neglected and the piers are assumed fixed at the bottom. Figure 6a shows the first five mode shapes and corresponding natural frequencies of the bridge.

Figure 5: Bridge with 5 spans. The support where longitudinal displacement of the bridge deck and pier are coupled is shown in red.

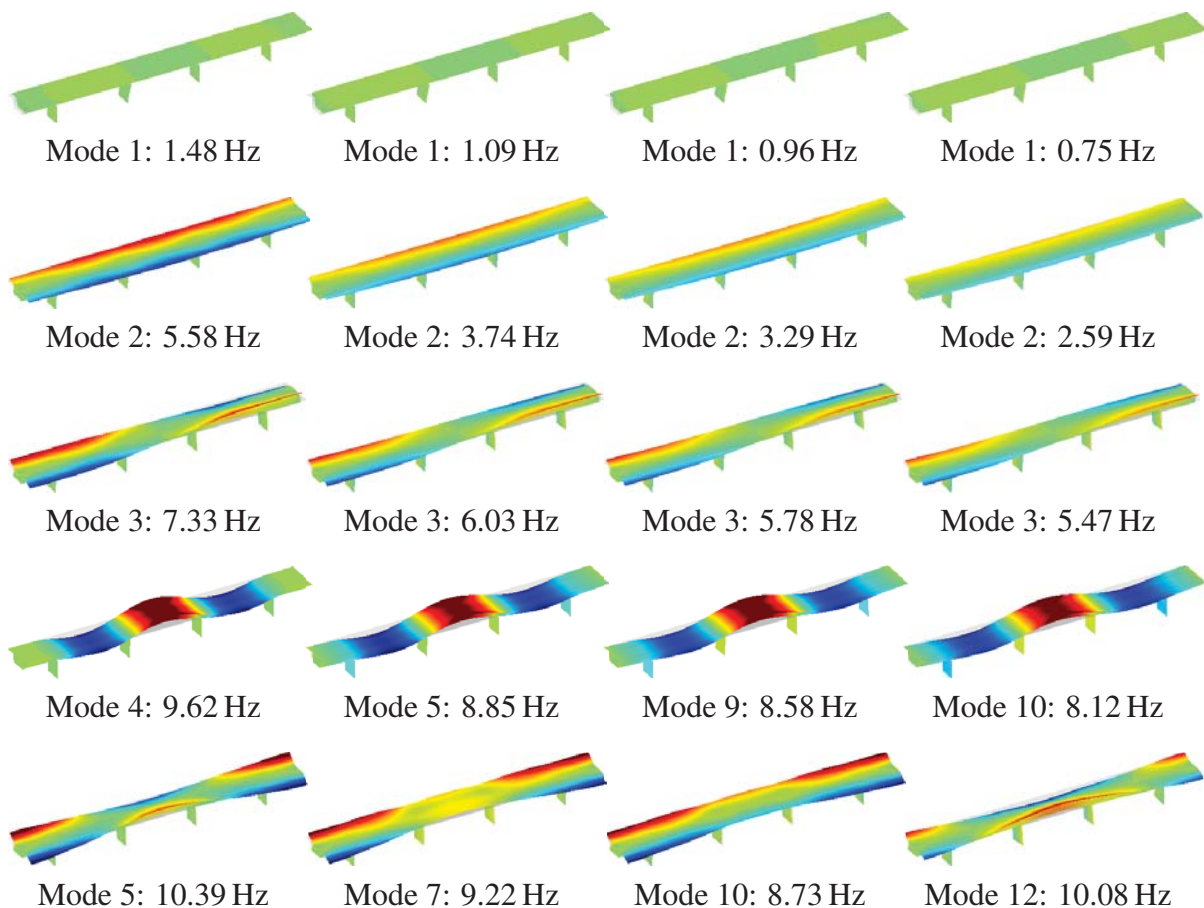

Figure 6: Mode shapes and natural frequencies of the bridge with 5 spans computed for (a) the case without SSI, (b) the stiff soil, (c) the medium soil, and (d) the soft soil. The color scheme indicates the magnitude of the vertical displacement while the undeformed structure is shown in light gray.

The first mode is a longitudinal translation mode of the bridge deck, which is not excited by a vertical load acting on the bridge. The top of the second pier translates with the bridge deck due to the fixed coupling at this support. Modes 2, 3, and 5 are torsional modes for which the dominant vertical displacement is situated in the flanges of the box girder. Mode 4 is a vertical bending modes of the bridge for which neighboring spans oscillate out-of-phase.

### 3.1.1 Influence of SSI

In order to assess the effect of SSI on the modal characteristics, the static foundation stiffness is added to each bridge pier (using springs) and the modal characteristics are recomputed. Alternatively, the dynamic stiffness at a resonance frequency of the bridge without SSI could be used [12]. Note that, in the present case, the dynamic stiffness does almost not depend on the frequency between 0 and 15 Hz (Figure 4), where the first bridge modes are situated, so that the outcome would be very similar.

In order to properly match the mode shapes and corresponding natural frequencies of the bridge with and without SSI, the Modal Assurance Criterion [13] is used. Whenever mode numbers are mentioned in the following, we refer to the modes without SSI. Figure 7a shows the MAC values computed for the first 20 mode shapes without SSI and with the stiff soil. The first 13 modes can be matched reasonably well to the mode shapes of the bridge without SSI. The order of the modes, however, changes when SSI is accounted for. In modes 8 to 10 (with SSI), the piers rotate around the  $x$ -axis and the bridge deck remains still as the piers can rotate freely with respect to the bridge deck. Figure 7b shows the MAC values computed for the medium soil. In this case, only the first five mode shapes can be matched accurately to the modes without SSI. For the soft soil case in Figure 7c, it is observed that only the first three modes are matched relatively well to the modes computed without SSI. Modes 4 to 6 (with SSI) are local rotation modes of the piers, which correspond to lower natural frequencies compared to the case with stiff soil. Mode 4, the first vertical bending mode, now corresponds to mode 7 with SSI.

Figure 7: MAC values between the mode shapes computed without and with SSI for the case of (a) stiff soil, (b) medium soil, and (c) soft soil.

Using the MAC values presented in Figure 7, the mode shapes of the bridge with and without SSI are matched. The mode shapes computed with the stiff soil are shown in Figure 6b. Overall, the mode shapes are very similar to those without SSI. For the torsional modes, rocking motion of the piers around the  $y$ -axis is observed due to the flexibility of the soil, resulting in significantly lower natural frequencies. Figure 6c shows the mode shapes computed with the medium soil. The natural frequencies are lower compared to those computed with the stiff soil, but the

mode shapes are very similar. Figure 6d shows the mode shapes computed with the soft soil. Compared to the case without SSI, a reduction of 53 % and 25.4 % on the natural frequency of the first and second torsional mode is predicted. The reduction of the natural frequency for the first vertical bending mode is 15.6 %. For mode 5, almost no decrease in natural frequency is observed, but the MAC value shows a poor agreement with the corresponding mode shape without SSI.

It can be concluded that, as the soil stiffness decreases, the effect of SSI on the modal characteristics of the bridge increases. Torsional modes in particular are significantly affected by SSI. Hence, when predicting the forced vibration response or performing structural health monitoring of multi-span bridges, it is important to account for SSI especially when soft soil conditions prevail.

### 3.1.2 Influence of the bridge length

Next, the influence of the bridge length (number of spans) on the natural frequencies is investigated. For periodic structures, natural frequencies tend to cluster in frequency bands corresponding to the pass-bands of the structure where non-decaying waves propagate. These frequency bands are characterized by a high modal density. This was already illustrated by Zhang et al. [14] for a periodic frame structure, who used free wave propagation constants for model updating purposes; however, the influence of SSI was not yet studied.

Figure 8 shows the natural frequencies of the bridge as a function of the number of spans. The computations are performed for the case without SSI and for the stiff, medium, and soft soil. Figure 8a presents the results for the case without SSI. As the number of spans increases, the natural frequencies tend to a limit value resulting in frequency bands with different modal density. Below 5 Hz, the longitudinal translation modes of the bridge deck are found. The natural frequencies between 5 Hz and 9 Hz correspond to torsional modes, while vertical bending modes as well as torsional modes are found between 9 Hz and 12.5 Hz. Above 12.5 Hz, only torsional modes are found. For the stiff soil, the natural frequencies are shown in Figure 8b. The decrease of the natural frequencies due to the flexibility of the soil is clearly observed. The frequency band of the vertical bending modes is very narrow between 8.5 Hz and 9 Hz, approximately. Furthermore, a narrow band around 10 Hz is observed corresponding to the rotation

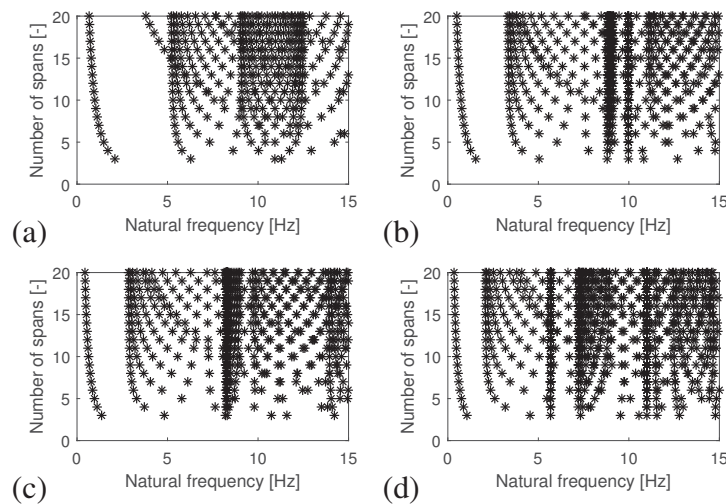

Figure 8: Natural frequencies of the bridge as a function of the number of spans computed for (a) the case without SSI, (b) the stiff soil, (c) the medium soil, and (d) the soft soil.

modes of the piers. This frequency band is also visible for the medium soil in Figure 8c around 8 Hz, nearly coinciding with the band where the vertical bending modes are situated. For the soft soil (Figure 8d), the narrow band around 5.7 Hz corresponds to the rotation modes of the piers, while the vertical bending modes are situated between 7 Hz and 9 Hz, approximately.

### 3.2 Dispersion curves

The dispersion curves of an infinitely long bridge in the wavenumber-frequency domain are presented in this subsection. As the bridge is periodic, the Floquet transform [15] is used to predict the forced vibration response of an infinitely long bridge due to a unit vertical eccentric load at mid-span (Figure 1a).

Figure 9 presents the vertical bridge mobility at mid-span in the wavenumber-frequency domain. Note that, in this model, the frequency dependent dynamic stiffness of the piled foundation is accounted for. The peaks observed in the forced vibration response correspond to the dispersion curves of the free waves propagating through the superstructure. These dispersion curves are obtained as the solution of an eigenvalue problem at each frequency; this originates from the condensation of the interior degrees of freedom of a reference cell and the application of Floquet theory [16, 17]. In order to reduce the computational effort, a methodology was proposed earlier [18] where advantage is taken from the fact that the bridge cross section does not vary between two piers so that the span can be subdivided in a finite number of identical cells. The dispersion curves that are superimposed on Figure 9 are: (1) the longitudinal translation mode, (2) the torsional mode, and (3) the vertical bending mode.

Figure 9a shows the dispersion curves for the case without SSI. The dispersion curves coincide with the peaks in the wavenumber-frequency domain response. The cut-on and cut-off frequencies of the dispersion curves correspond to the frequency bands observed in Figure 8a. The dispersion curve of the longitudinal translation mode does not appear as a peak in the wavenumber-frequency domain response because it is not excited by the applied load. Figure 9b shows the dispersion curves for the stiff soil. The dispersion curve of the vertical bending mode is nearly vertical, corresponding to the narrow frequency band in Figure 8b. For the medium soil, Figure 9c shows that the group velocity  $\partial\omega/\partial\kappa_y$  changes sign for the vertical bending

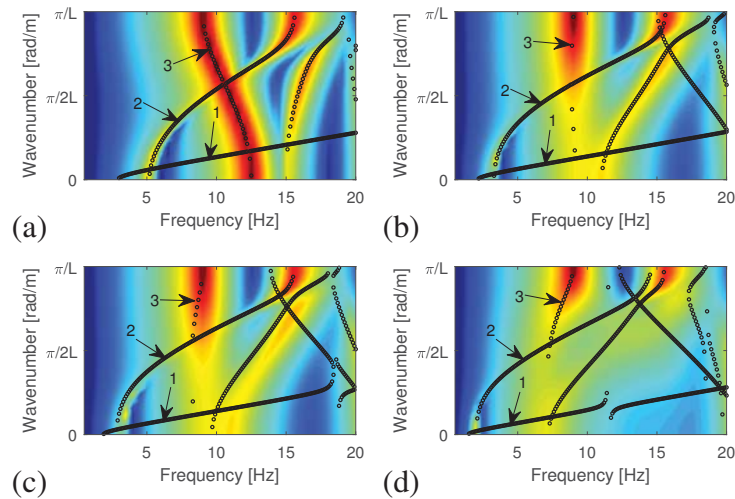

Figure 9: Logarithm of the amplitude of the vertical mobility at mid-span in the wavenumber-frequency domain. Superimposed are the dispersion curves of the non-decaying waves obtained with the WFEM: (1) the longitudinal translation mode, (2) the torsional mode, and (3) the vertical bending mode.

mode compared to the case without SSI. Figure 9d shows the dispersion curves for the soft soil. The cut-on frequency of the torsional mode equals 2 Hz, which is significantly lower than for the case without SSI (around 5 Hz). For the vertical bending mode, the cut-on frequency of the dispersion curve has decreased compared to the medium soil.

#### 4 CONCLUSIONS

A numerical case study of a continuous concrete box girder bridge is presented in this paper. It is shown that the natural frequencies of a bridge are significantly affected by SSI when the soil is soft, particularly for the torsional modes. The influence of SSI on the mode shapes is relatively small for the lower modes, but is important for the higher modes, especially when the soil is soft. Furthermore, it has been shown that as the number of bridge spans increases, the natural frequencies converge to a limit value. These values mark the boundaries of the stop- and passbands that were observed in the dispersion curves of an infinitely long bridge. Inside the passbands, high modal density is observed. As SSI results in shift of the natural frequencies, it also affects the boundaries of the stop- and passbands of the bridge.

**Keywords:** Soil Dynamics, Soil-Structure-Interaction (SSI), Integral-Transform-Method (ITM), Finite-Element-Method (FEM), Foundation-Soil-Foundation Interaction (FSFI), Vibration Mitigation, Wave Impeding Block (WIB)

**Abstract.** *The dynamic subsoil coupling for a finite number of adjacent foundations has a significant effect on the dynamic behaviour of the foundations involved and the structures based on them. As the mutual influence of the foundations on each other is decisively influenced by the properties and the composition of the subsoil, buried structures or inhomogeneities have to be included, in order to model the real soil conditions as exact as possible and to enable an accurate prediction of the interaction phenomena of adjacent foundations. In this contribution an efficient 2.5D coupled Integral Transform Method (ITM) – Finite Element Method (FEM) approach is used in conjunction with a conventional 3D FEM to compute the dynamic stiffness of foundations resting on the surface of a halfspace including a longitudinally invariant structure or inhomogeneity. Herein, the analytical ITM solutions of the dynamic wave equation allow to account for the infinite extension of the soil by satisfying the radiation condition. The 2.5D FEM formulation enables to model complex, spatially limited structures and a part of the surrounding soil within a cylindrical outer boundary, on which both methods are coupled. The finite foundations on the halfspace surface are modelled using 3D finite elements and are coupled to the soil substructure enforcing the compatibility conditions (full coupling or relaxed boundary conditions) at the common interface. The influence of the embedment depth, size and stiffness of the inclusion on the dynamic response of the foundations, taking into account the through soil coupling, is investigated for different configurations of the surface foundations (distance, width). Frequency dependent compliance functions at the soil-foundation interface are calculated for the different parameter settings and compared with existing solutions to verify the method as well as with the results for the homogeneous halfspace to illustrate the influence of an inclusion. Furthermore the displacement distribution over the total surface of a halfspace with a stiff inclusion due to a dynamic excitation of either one or both of the two considered adjacent rigid surface foundations obtained by a post-processing procedure is presented.*

## 1 INTRODUCTION

The dynamic interaction of structures based on a single foundation with the supporting homogeneous or stratified soil has been studied extensively in the past applying a variety of different methods as presented e.g. in [1–8]. However, in the dense urban areas buildings are often not well separated from each other and the dynamic foundation-soil-foundation interaction (FSFI) between the closely spaced structures has a significant effect on the dynamic behaviour of the foundations involved and the structures based on them. This mutual influence is decisively influenced by the properties and the composition of the subsoil.

In the literature, various approaches have been employed to investigate the interaction of foundations located on or embedded in a homogeneous or layered halfspace. Warburton et al. [9] were the first to study the dynamic FSFI of two neighbouring massive foundations resting on a homogeneous halfspace applying an approximate analytical method based on the Bycroft model. The cross interaction of multi-foundation systems located on a viscoelastic stratum due to different excitation types has been investigated by Kobori et al. [10]. Wong and Luco [11] analysed the effect of a layered halfspace on the interaction of two rigid, square surface foundations subjected to external forces by the boundary integral equation technique. Kausel et al. [12] and Lin et al. [13] used the Finite-Element-Method (FEM) together with consistent boundaries to examine the FSFI of rigid foundations resting on or embedded in a stratum over bedrock for harmonic force and moment excitation in all degrees of freedom. An analytical method addressing the dynamic subsoil coupling between a finite number of rigid, rectangular foundations solving the mixed boundary value problem by the Bubnov-Galerkin method has been presented by Triantafyllidis and Prange [14]. The Boundary Element Method (BEM) in the frequency domain has been employed to investigate the 3D FSFI of two adjacent rigid, surface foundations resting on a soil layer over bedrock by Karabalis and Beskos [15] and on a homogeneous halfspace due to seismic resp. harmonic excitation by Qian and Beskos [16] and Qian et al. [17]. Wang et al. [18] also used the BEM to investigate the cross interaction of flexible strip foundations embedded in a homogeneous halfspace. A coupled FEM-BEM approach for the 3D dynamic interaction of two surface foundations in the time domain was presented by Rizos and Wang [19]. More recently Chen et al. [20] employed a time domain Scaled-Boundary-Finite-Element-Method (SBFEM) to investigate the response of two strip foundations embedded in a layered soil. Sbartaï [21] coupled the BEM to the Thin-Layer-Method (TLM) to account for the interaction of two embedded, rigid 3D foundations within a layered soil over bedrock. A precise integration method (PIM) is used by Han et al. [22] to analyse the FSFI of a group of adjacent massless and massive 3D foundations on multilayered ground. Radisic [23] uses the Integral-Transform-Method (ITM) together with a kinematic conditions for the deformation of a rigid foundation to investigate the mutual influence of adjacent foundations.

In reality the ground often contains local inhomogeneities and structures, that have an effect on the wave propagation within the soil. Diffraction and scattering lead to an amplification of the initial vibrations and thus significantly influence both, the distribution and the amplitude of the stresses and displacements near the surface and within the surface foundations. Therefore, in order to model the real soil conditions as exact as possible and to enable an accurate prediction of the interaction phenomena of adjacent foundations, these buried structures or inhomogeneities have to be included in the model. The interaction of foundations on a soil including a spatially limited structure has been investigated in literature mainly in the context of Wave Impeding Blocks (WIB). Chouw et al. [24] used the BEM to analyse the vibration transmission in a soil layer over bedrock caused by a harmonic excitation of a rigid strip foundation and found,

that no wave propagation occurs in the layer, if the excitation frequency is lower than the first eigenfrequency ("cutoff frequency") of the stratum. This effect was used in Chouw and Schmid [25], where a spatially limited WIB was implemented into the soil in order to mitigate the low frequency vibration transmission, induced by the active of two foundations, and thus reduce the dynamic response of the passive foundation. Takemiya and Fujiwara [26] applied a 2D time domain BEM to examine the effect of a single or multiple WIBs located directly beneath or sideways under a rigid strip foundation on a homogeneous halfspace or soil stratum on the response of the system due to an excitation with an impulse load. A 3D BEM frequency domain approach was used by Antes and von Estorff [27] to study the influence of the stiffness of a finite block shaped elastic inclusion within a homogenous halfspace on the dynamic response of a elastic surface foundation. In Peplow and Finnveden [28] a 2D Spectral Finite Element Method (SFEM) is presented analysing the attenuation of surface vibrations by placing a WIB in the near field of the harmonic load applied at the surface of a layered soil stratum. Gao et al. [29] published a 3D BEM, based on Green's functions deduced with the TLM, which allows it to investigate the dynamic interaction of a surface foundation with a WIB located within a saturated, layered ground as well as to predict the vibration screening effectiveness of the WIB for different parameter settings.

In this study a coupled 2.5D ITM-FEM approach in conjunction with a conventional 3D FEM is presented to examine the influence of a local length invariant structure or inhomogeneity buried in the soil on the dynamic response of three dimensional, finite surface foundations. The 2.5D ITM-FEM approach is used to compute the dynamic stiffness at the discretization points within the interaction areas of the foundations with the soil substructure by evaluating its dynamic response due to concentrated harmonic loads. Therefore all interaction phenomena, including the interaction of the induced waves with the buried structure or inhomogeneity, are comprised. The analytical ITM solutions of the dynamic wave equation allow to account for the infinite extension of the soil by satisfying the radiation condition and thus avoid non-physical reflections at artificial boundaries. A 2.5D FEM formulation enables to model complex, spatially limited structures and a part of the surrounding soil within a cylindrical outer boundary, on which both methods are coupled. The foundations at the soil surface are modelled using common 3D finite elements and are coupled to the soil substructure enforcing the compatibility conditions at the common interface, whereby full coupling or relaxed boundary conditions can be applied.

The outline of the paper is as follows. In subsection 2.1 firstly the fundamental ITM solutions are introduced and superposed in order to obtain the stiffness matrix of a halfspace with cylindrical cavity. Subsequently in 2.2 the dynamic stiffness of the 2.5D FEM subsystem is used to model the embedded inclusion is presented, followed by the coupling of the substructures 2.3. In subsection 3.1 the dynamic stiffness of the soil substructure at the contact areas with the foundations is determined and coupled with the dynamic stiffness of the 3D FEM model of the foundations. A post processing procedure which allows to evaluate the displacement field over the total surface of a soil with inclusion due to a harmonic loading of the foundations is presented in subsection 3.3. The accuracy of the proposed method is demonstrated in subsection 4.1 by comparison with literature results for two benchmark examples. In subsection 4.2 the influence of the embedment depth, size and stiffness of the inclusion on the dynamic response of the foundations, also considering the through soil coupling, is investigated for different configurations of the surface foundations (distance, width). Frequency dependent compliance functions at the soil-foundation interface of a soil with inhomogeneity are presented and compared with the results for the homogeneous halfspace to illustrate the influence of the inclusion.

## 2 ITM-FEM FORMULATION FOR ELASTODYNAMICS

### 2.1 ITM Substructure

#### 2.1.1 Fundamental Solutions

The Lamé differential equation describes the dynamic behaviour of a linear elastic, homogeneous and isotropic continuum, which consists of three coupled partial differential equations

$$\mu u^i|_j^j + (\lambda + \mu) u^j|_j^i - \rho \ddot{u}^i = 0 \quad (1)$$

with the displacement field  $u^i$ , the Lamé constants  $\mu$  and  $\lambda$  and the density  $\rho$ . The differential equations are decoupled using a Helmholtz decomposition  $u^i = \Phi|_k^i + \Psi_l|_k \varepsilon^{ikl}$  and thereby expressing the displacement field by the sum of the gradient of a scalar field  $\Phi$  and the rotation of a vector field  $\Psi$ , resulting in an uncoupled system of three wave equations (setting  $\Psi_z = 0$  cp. [30]) only depending on the compressional and the shear wave velocities  $c_p$  and  $c_s$ .

$$\Phi|_j^j - \frac{1}{c_p^2} \ddot{\Phi} = 0 \quad \Psi_i|_j^j - \frac{1}{c_s^2} \ddot{\Psi} = 0 \quad (2)$$

The system halfspace is solved in Cartesian coordinates  $(x, y, z)$  and is derived from Eq. (2) applying a threefold Fourier transform into the wavenumber-frequency domain  $(k_x, k_y, z, \omega)$ . Thus the coupled partial differential equations turn into three decoupled ordinary differential equations that can be solved analytically with an exponential approach [31]:

$$\hat{\Phi} = A_1 e^{\lambda_1 z} + A_2 e^{-\lambda_1 z} \quad \hat{\Psi}_\alpha = B_{\alpha 1} e^{\lambda_2 z} + B_{\alpha 2} e^{-\lambda_2 z} \quad (3)$$

with  $\alpha = x, y$ ,  $\lambda_1 = (k_x^2 + k_y^2 - k_p^2)^{-2}$ ,  $\lambda_2 = (k_x^2 + k_y^2 - k_s^2)^{-2}$  and  $k_p = \frac{\omega}{c_p}$ ,  $k_s = \frac{\omega}{c_s}$ . The wavenumbers are given as  $k_x = o\Delta k_x$  with  $o = -N_x/2, \dots, (N_x/2-1)$  and  $k_y = s\Delta k_y$  with  $s = -N_y/2, \dots, (N_y/2-1)$ , where  $N_x, N_y$  is the number of Fourier series members or sample points in the original domain respectively. Applying the local boundary conditions on the halfspace surface  $\Lambda$  as well as the Sommerfeld radiation condition [32] the unknown coefficients can be determined and the stresses and displacements within the halfspace can be calculated by  $\hat{\sigma}_{hs} = \hat{K}_{hs} \hat{C}_{hs}$  and  $\hat{u}_{hs} = \hat{H}_{hs} \hat{C}_{hs}$  using the matrices given in [33], where  $\hat{K}_{hs}$  and  $\hat{H}_{hs}$  include the fundamental solutions, kinematic and material relations linking the unknowns with the stresses and the displacements. Quantities in the single, twofold resp. threefold Fourier transformed domain are marked with  $\hat{\phantom{x}}$ ,  $\sim$  and  $\wedge$ .

The system fullspace with cylindrical cavity is solved in cylindrical coordinates  $(x, r, \varphi)$  applying a Fourier transform with respect to  $x$  and  $t$  as well as performing a Fourier series expansion along the cylinder circumference  $\varphi \rightarrow n$ . Furthermore the vector field  $\Psi = \Psi g^1 + \chi|_j^j \varepsilon_{ij1} g^i$  is expressed by two independent scalar fields. The respective system of equations in the  $(k_x, r, n, \omega)$  domain is solved with Hankel functions of first and second kind [34]:

$$\hat{\Phi}(k_x, r, n, \omega) = C_{1n} H_n^{(1)}(k_1 r) + C_{4n} H_n^{(2)}(k_1 r) \quad (4)$$

$$\hat{\psi}(k_x, r, n, \omega) = C_{2n} H_n^{(1)}(k_2 r) + C_{5n} H_n^{(2)}(k_2 r) \quad (5)$$

$$\hat{\chi}(k_x, r, n, \omega) = C_{3n} H_n^{(1)}(k_2 r) + C_{6n} H_n^{(2)}(k_2 r) \quad (6)$$

with  $k_1^2 = k_p^2 - k_x^2$  respectively  $k_2^2 = k_s^2 - k_x^2$ . Applying the local boundary conditions at the cylinder surface  $\Gamma$  as well as the radiation condition the stresses and displacements can be determined as  $\hat{\sigma}_c = \hat{K}_c C_c$  and  $\hat{u}_c = \hat{H}_c C_c$  as given in [33].

For a more detailed derivation of the fundamental solutions the reader is referred to [33–36].

### 2.1.2 Superposition of Fundamental Systems

In order to obtain a stiffness matrix for the system halfspace with cylindrical cavity the fundamental solutions presented in 2.1.1 are now superposed in order to satisfy the boundary conditions of the final system on the surface of the halfspace  $\Lambda$  and the cylindrical cavity  $\Gamma$ . For this reason fictitious surfaces  $\delta\Lambda$  resp.  $\delta\Gamma$  are introduced into the fundamental systems allowing a superposition at the common surfaces as depicted in Figure 1. Thus, unit stress states  $\hat{\sigma}_\Lambda$  are

**Figure 1:** Fictitious surfaces and stresses in the fundamental systems halfspace and fullspace with cylindrical cavity for superposition to a halfspace with cylindrical cavity.

applied at  $\Lambda$  for each wavenumber combination  $(k_x, k_y)$  and the stresses  $\hat{\sigma}_{\delta\Gamma}^{(\Lambda)}$  at the fictitious surface  $\delta\Gamma$  are determined. Reciprocally, the stresses  $\hat{\sigma}_{\delta\Lambda}^{(\Gamma)}$  at  $\delta\Lambda$  due to unit stress states  $\hat{\sigma}_\Gamma$  at  $\Gamma$  for each series member  $n$  can be calculated. The sum of the stresses at  $\Lambda$  and  $\Gamma$  has then to coincide with the external loads  $\hat{p}_\Lambda$  and  $\hat{p}_\Gamma$  acting on the total system.

$$C_\Lambda \hat{\sigma}_\Lambda + C_\Gamma \hat{\sigma}_{\delta\Lambda}^{(\Gamma)} = \hat{p}_\Lambda \quad (7)$$

$$C_\Lambda \hat{\sigma}_{\delta\Gamma}^{(\Lambda)} + C_\Gamma \hat{\sigma}_\Gamma = \hat{p}_\Gamma \quad (8)$$

Thereafter it is possible to determine the amplitudes  $C_{ITM} = (C_\Lambda \ C_\Gamma)^T$  of the unit stresses and the stresses at the fictitious boundaries, gathered in  $\hat{S}_{ITM}$ , in dependency of the total external load  $\hat{P}_{ITM} = (\hat{p}_\Lambda \ \hat{p}_\Gamma)^T$  on  $\Lambda$  and  $\Gamma$  as:

$$C_{ITM} = \hat{S}_{ITM}^{-1} \hat{P}_{ITM} \quad (9)$$

Hereinafter, the amplitudes  $C_{ITM}$  are used to scale the displacements due the unit stresses, gathered in  $\hat{U}_{ITM}$ , finally resulting in the displacements  $\hat{u}_{ITM}$  of the halfspace with cylindrical cavity at  $\Lambda$  and  $\Gamma$ :

$$\hat{u}_{ITM} = \hat{U}_{ITM} C_{ITM} \quad (10)$$

Combining equations (9) and (10) the stiffness matrix  $\hat{K}_{ITM} = \hat{S}_{ITM} \hat{U}_{ITM}^{-1}$  of the ITM sub-system for a halfspace with cylindrical cavity is obtained, giving a direct relation between the displacements and the external loads:

$$\underbrace{\begin{bmatrix} \hat{K}_{\Lambda\Lambda ITM} & \hat{K}_{\Lambda\Gamma ITM} \\ \hat{K}_{\Gamma\Lambda ITM} & \hat{K}_{\Gamma\Gamma ITM} \end{bmatrix}}_{\hat{K}_{ITM}} \underbrace{\begin{pmatrix} \hat{u}_{\Lambda ITM} \\ \hat{u}_{\Gamma ITM} \end{pmatrix}}_{\hat{u}_{ITM}} = \underbrace{\begin{pmatrix} \hat{P}_{\Lambda ITM} \\ \hat{P}_{\Gamma ITM} \end{pmatrix}}_{\hat{P}_{ITM}} \quad (11)$$

## 2.2 2.5D FEM Substructure

In order to couple a finite element structure to the previously introduced ITM subsystem, both substructures need a matching outer boundary. Therefore the dynamic stiffness matrix of a finite element structure with equally distributed nodes on the cylindrical outer boundary, matching with the discretization points of the ITM on  $\Gamma$ , needs to be computed. The dynamic stiffness matrix of the halfspace with cylindrical cavity was computed in the transformed domain for each combination  $(k_x, \omega)$ . The length invariance of the system allows to reduce the originally 3D computations to a series of 2D calculations for each  $(k_x, \omega)$ , where the information of the third dimension is stored in  $k_x$ . This 2.5D approach allows to represent the cylindrical cavity in the original domain by a circular cavity in the transformed domain. Thus modified 2D quadrilateral finite elements with linear shape functions and an additional degree of freedom (DOF) in the length direction, adopted to the Fourier transformed domain  $(k_x, y, z, \omega)$  as presented in [34], can be used to discretize the cross section. The dynamic stiffness of the 2.5D FEM substructure (with the DOFs separated for the outer boundary  $\Gamma$  and the area inside  $\Omega$ ) can finally be computed as:

$$\begin{bmatrix} \tilde{\mathbf{K}}_{\Gamma\Gamma_{FE}} & \tilde{\mathbf{K}}_{\Gamma\Omega_{FE}} \\ \tilde{\mathbf{K}}_{\Omega\Gamma_{FE}} & \tilde{\mathbf{K}}_{\Omega\Omega_{FE}} \end{bmatrix} \begin{pmatrix} \tilde{\mathbf{u}}_{\Gamma_{FE}} \\ \tilde{\mathbf{u}}_{\Omega_{FE}} \end{pmatrix} = \begin{pmatrix} \tilde{\mathbf{P}}_{\Gamma_{FE}} \\ \tilde{\mathbf{P}}_{\Omega_{FE}} \end{pmatrix} \quad (12)$$

## 2.3 Coupling of Substructures

The coupling of the ITM and the FEM substructure is carried out at the two dimensional circular coupling surface  $\Gamma$  in the reference frame of the ITM. Therefore the dynamic stiffness matrix of the FEM subsystem on  $\Gamma$  needs to be transformed into the  $(k_x, r, n, \omega)$  domain by applying a transformation to a cylindrical reference frame as well as a Fourier series expansion along the circumference. The FEM formulation inside the structure  $\Omega$  is kept in the  $(k_x, y, z, \omega)$  domain (Figure 2).

**Figure 2:** (a) Displacements  $\hat{\mathbf{u}}_{\Lambda_{ITM}}(k_x, k_y, z, \omega)$  on  $\Lambda$  and  $\hat{\mathbf{u}}_{\Gamma_{ITM}}(k_x, r, n, \omega)$  on  $\Gamma$  of the ITM substructure, (b)  $\hat{\mathbf{u}}_{\Gamma_{FE}}(k_x, r, n, \omega)$  on  $\Gamma$  and  $\tilde{\mathbf{u}}_{\Omega_{FE}}(k_x, y, z, \omega)$  within  $\Omega$  of the FEM substructure in the respective reference systems for the coupling on the circular interaction surface  $\Gamma$ . (c) Halfspace with cylindrical inclusion modelled by the coupled 2.5D ITM-FEM approach.

Thereafter, the continuity of displacements as well as the equilibrium of forces are applied at the coupling surface, finally leading to the total dynamic stiffness matrix of the 2.5D ITM-FEM system of a halfspace with cylindrical cavity filled with finite elements.

$$\underbrace{\begin{bmatrix} \hat{\mathbf{K}}_{\Lambda\Lambda_{ITM}} & \hat{\mathbf{K}}_{\Lambda\Gamma_{ITM}} & 0 \\ \hat{\mathbf{K}}_{\Gamma\Lambda_{ITM}} & \hat{\mathbf{K}}_{\Gamma\Gamma_{ITM}} + \hat{\mathbf{K}}_{\Gamma\Gamma_{FE}} & \hat{\mathbf{K}}_{\Gamma\Omega_{FE}} \\ 0 & \hat{\mathbf{K}}_{\Omega\Gamma_{FE}} & \tilde{\mathbf{K}}_{\Omega\Omega_{FE}} \end{bmatrix}}_{\hat{\mathbf{K}}^{hc}} \underbrace{\begin{pmatrix} \hat{\mathbf{u}}_{\Lambda_{ITM}} \\ \hat{\mathbf{u}}_{\Gamma} \\ \tilde{\mathbf{u}}_{\Omega_{FE}} \end{pmatrix}}_{\hat{\mathbf{u}}^{hc}} = \underbrace{\begin{pmatrix} \hat{\mathbf{P}}_{\Lambda_{ITM}} \\ \hat{\mathbf{P}}_{\Gamma} \\ \tilde{\mathbf{P}}_{\Omega_{FE}} \end{pmatrix}}_{\hat{\mathbf{P}}^{hc}} \quad (13)$$

### 3 SOIL-FOUNDATION SYSTEM

#### 3.1 Dynamic Soil Flexibility and Stiffness

With the stiffness matrix  $\hat{\mathbf{K}}^{\text{hc}}$  it is possible to compute the displacements  $\hat{\mathbf{u}}_{\Lambda\text{ITM}}$  on the surface of a halfspace with length invariant FEM inclusion due to an external load  $\hat{\mathbf{P}}_{\Lambda\text{ITM}}$  on the ground surface. As the members  $\hat{F}_{mn}^{ij}$  with  $m, n = x, y, z$  of the complex, dynamic flexibility matrix at the ground surface correspond to the displacements  $\hat{u}_m^i$  at a discretization point  $i$  on  $\Lambda$  due to a concentrated unit load  $\hat{P}_n^j$  in direction  $n$  acting at a discretization point  $j$ , Eq. (13) can be used in the following to set up the flexibility matrix  $\hat{\mathbf{F}}_s^{ij}$  giving the force displacement relationship between a pair of discretization points:

$$\underbrace{\begin{pmatrix} \hat{u}_x^i \\ \hat{u}_y^i \\ \hat{u}_z^i \end{pmatrix}}_{\hat{\mathbf{u}}_s^i} = \underbrace{\begin{pmatrix} \hat{F}_{xx}^{ij} & \hat{F}_{xy}^{ij} & \hat{F}_{xz}^{ij} \\ \hat{F}_{yx}^{ij} & \hat{F}_{yy}^{ij} & \hat{F}_{yz}^{ij} \\ \hat{F}_{zx}^{ij} & \hat{F}_{zy}^{ij} & \hat{F}_{zz}^{ij} \end{pmatrix}}_{\hat{\mathbf{F}}_s^{ij}} \underbrace{\begin{pmatrix} \hat{P}_x^j \\ \hat{P}_y^j \\ \hat{P}_z^j \end{pmatrix}}_{\hat{\mathbf{P}}_s^j} \quad (14)$$

To avoid a singularity under the location of application of the unit load and to keep the numerical errors associated with the discrete calculations small, instead of an unit point force a load uniformly distributed over a small area with a unit resultant is used in the following and referred to as concentrated load [23].

For the later coupling with the finite foundations, modelled by a 3D FEM, the force displacement relationship is needed at the interaction areas of the foundations with the ground surface, as the nodal contact forces and displacements of both substructures must coincide there. Thus, it is necessary, that both substructures exhibit the same discretization at the interaction areas, so that the element nodes of the foundations match with the discretization points of the ITM-FEM soil substructure (Fig. 4), which was discretized on  $\Lambda$  with equidistant points in the original domain  $(x, y, z, \omega)$ . The coordinates of these can be obtained as  $x = o\Delta x$  with  $o = -N_x/2, \dots, (N_x/2 - 1)$  and  $y = s\Delta y$  with  $s = -N_y/2, \dots, (N_y/2 - 1)$ , where  $\Delta x, \Delta y$  are the incremental distances. Outside of the foundations a traction free surface is assumed.

In order to populate the overall flexibility matrix  $\bar{\mathbf{F}}_s$ , which fully represents the coupled 2.5D ITM-FEM system and specifies the force-displacement relationship

$$\bar{\mathbf{u}}_s(x, y, \omega) = \bar{\mathbf{F}}_s(x, y, \omega) \bar{\mathbf{P}}_s(x, y, \omega) \quad (15)$$

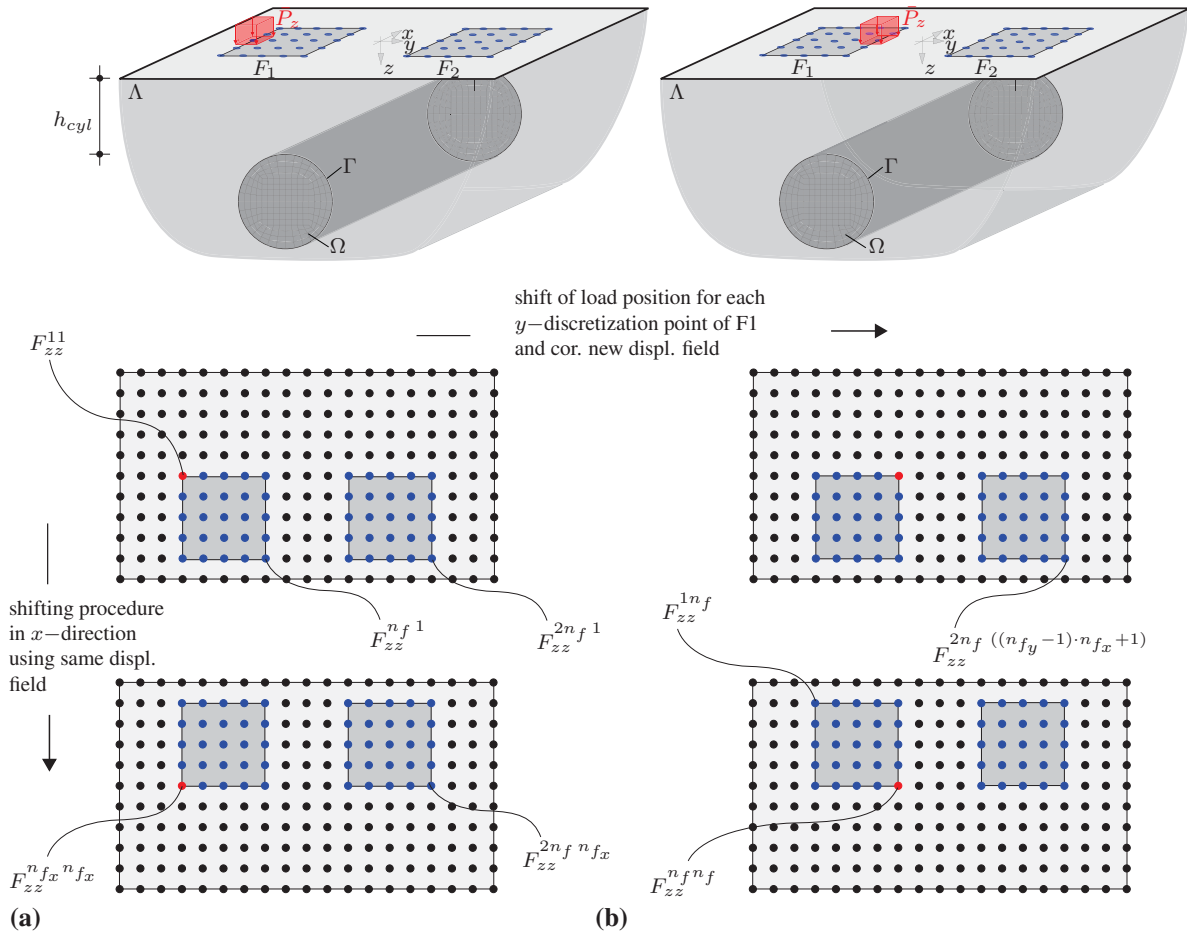

at all  $n_{f,\text{tot}} = N_f \cdot n_f$  discretization points within the soil-foundation coupling regions, the soil response  $\bar{\mathbf{u}}_s^i$  with  $i = 1 \dots n_{f,\text{tot}}$  in all directions at each of these points must be evaluated as a result of a harmonic excitation with concentrated unit loads  $\bar{\mathbf{P}}_s^j$  with  $j = 1 \dots n_{f,\text{tot}}$  in each spatial direction acting on each of these points in turn. Thereby  $N_f$  is the total number of foundations and  $n_f = n_{fx} \cdot n_{fy}$  is the number of discretization points of one foundation at the coupling surface with the soil and results from the product of the amount of discretization points of the foundation in  $x, y$ -direction  $n_{fx}, n_{fy}$ . Since all foundations possess the same size also the number of discretization points is equal. Thus the dimension of  $\bar{\mathbf{F}}_s$  yields to  $[3n_{f,\text{tot}} \times 3n_{f,\text{tot}}]$ .

The displacements and thus also the members of the flexibility matrix, resulting from the application of Eq. (13), are firstly obtained in the  $(k_x, k_y, z, \omega)$  domain. To enable a direct stiffness coupling by enforcing the compatibility conditions at the interaction areas of the soil with the 3D FEM foundations, it is necessary to have the soil stiffness matrix  $\bar{\mathbf{K}}_s = \bar{\mathbf{F}}_s^{-1}$  defined w.r.t. a Cartesian reference frame in the frequency domain  $(x, y, z, \omega)$  as it is the case for the dynamic stiffness of the foundations. Hence, a twofold inverse Fourier transform (IFFT)

is applied to finally attain the dynamic stiffness matrix  $\bar{\mathbf{K}}_s(x, y, z, \omega)$  of the 2.5D ITM-FEM system.

The computational effort to determine the soil flexibility resp. stiffness matrix can be reduced significantly by taking into account the symmetry conditions and in case of the halfspace with inclusion also the length invariance of the system. Instead of placing the concentrated load at each of the  $n_{f,\text{tot}}$  discretization points at the contact areas and evaluating the system response at all of them, the foundation areas can be shifted according to the discretization step size, such that every interaction node is positioned once under the unit concentrated load. In case of a homogeneous halfspace, due to the complete rotational symmetry, the position of the load on  $\Lambda$  is irrelevant and the displacement field only needs to be computed twice (once for the load acting in vertical direction and once for one of the horizontal directions, as the other can be determined via the symmetry conditions). In case of the halfspace with inclusion due to the inhomogeneity in the soil, the position of the concentrated load on  $\Lambda$  is no more irrelevant for the resulting displacement field. However, as the system is length invariant only a different position in  $y$ -direction causes a different system response. Consequently the concentrated load needs to be placed once at each  $y$ -discretization point of the foundations. For two foundations located symmetrically w.r.t. the  $x$ -axis, it is even sufficient to only consider the  $y$ -discretization points of one foundation for the load positions, as the results for the second foundation again can be gained by symmetry considerations. Nevertheless, all load directions have to be considered.

**Figure 3:** Shifting procedure and selection of displacements for (a) concentrated load at first and (b) last load position on discretization points of soil foundation interface in  $y$ -direction of foundation  $F_1$ .

Figure 3 illustrates the shifting procedure for the latter case. The load is positioned one after another on all  $y$ -discretization points of the first foundation  $F_1$  and the response at all interaction points of both foundations with the soil surface  $\Lambda$  is evaluated. A new displacement field is determined using Eq. (13) for each of this load positions. For the discretization points of the foundation  $F_1$  in  $x$ -direction the same system response is used and only the evaluation points are shifted under the point of load application. Thereby the displacements at all nodes of the soil foundation contact area due to a single load position in one direction are sorted into the respective column of  $\bar{\mathbf{F}}_s(x, y, z, \omega)$  after the IFFT. To avoid an ill conditioning of the flexibility matrix, which would result from a shift of the load position by only one discretization point in combination with the distributed uniform load (as then the adjacent columns of  $\bar{\mathbf{F}}_s$  contain very similar values), a coarser mesh is introduced for the shifting procedure as proposed by [23]. The displacements w.r.t. the coarse mesh are computed as the mean value of the displacements w.r.t. the fine mesh within an area  $A = n_\Delta dx n_\Delta dy$ . Thereby  $dx, dy$  are the discretization step sizes of the fine mesh and  $n_\Delta$  is the factor relating the old step size with the new one.

### 3.2 Dynamic Stiffness of Soil-Foundation-System

The three dimensional, finite surface foundations, that shall be coupled to the 2.5D ITM-FEM soil substructure, are modelled with conventional finite elements. Either 8-node solid elements or shell elements can be used for this objective. As in this work only foundations satisfying the thin plate assumptions are investigated, a shell element with six DOFs per node presented by Rojas et al. [37] is used due to reasons of computational efficiency. Assembling the element stiffnesses of all elements of one foundation  $n$ , the total dynamic stiffness matrix results as

$$\bar{\mathbf{K}}_{f_n}(\omega) = \mathbf{K}_{f_n} - \omega^2 \mathbf{M}_{f_n} \quad (16)$$

with  $\mathbf{K}_{f_n}$  and  $\mathbf{M}_{f_n}$  being the stiffness and the mass matrix of the respective foundation  $n$  and  $\omega$  as the excitation frequency.

The material properties of the foundations are fully described by the linear elastic parameters, i.e. the Young's Modulus  $E_f$ , the Poisson ratio  $\nu_f$  and the density  $\rho_f$ . For the following investigations only very stiff (subsequently termed as rigid), massless foundations are considered by assigning them a very high modulus of elasticity and close to zero density. However, it is easily possible with the presented approach, to also include elastic, hysteretically damped foundations with mass into the investigations.

For the coupling of the foundations and the soil substructure, the compatibility conditions need to be satisfied at the interaction nodes on the soil surface  $z = 0$  as illustrated in Fig. 4.

**Figure 4:** Coupling of FEM foundations  $F_1$  and  $F_2$  to the 2.5D ITM-FEM system of halfspace with stiff cylindrical inclusion at the common interaction surfaces.

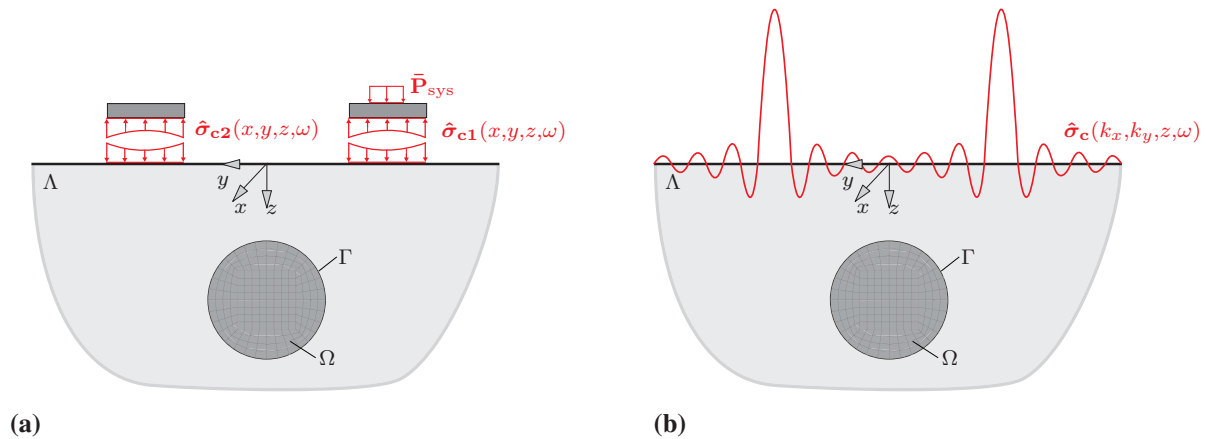

Thereby the soil substructure is fully represented by  $\bar{\mathbf{K}}_s(x, y, \omega)$ , which describes the cross interaction between the foundations under consideration of the interaction via the soil including the inhomogeneity. Since only translational DOFs exist at the discretization points of the soil substructure, the rotational DOFs of the shell elements of the foundations need to be condensed out, before assembling  $\bar{\mathbf{K}}_s(\omega)$  and  $\bar{\mathbf{K}}_{f_n}(\omega)$  into the total dynamic stiffness matrix

$$\bar{\mathbf{K}}_{\text{sys}} \bar{\mathbf{u}}_{\text{sys}} = \bar{\mathbf{P}}_{\text{sys}} \quad (17)$$

where  $\bar{\mathbf{u}}_{\text{sys}}$  is the vector of nodal displacements comprising the DOFs of the foundation nodes and the interface nodes with the soil and  $\bar{\mathbf{P}}_{\text{sys}}$  is the respective system load vector. Either full coupling of all DOFs or relaxed boundary conditions (frictionless contact) can be assumed at the interaction surfaces.

### 3.3 Postprocessing

Firstly the total system of equations in Eq. (17) is solved for the nodal displacements at the soil foundation interfaces  $\bar{\mathbf{u}}_c = \bar{\mathbf{u}}_{\text{sys}}(z = 0)$  due to a harmonic load on either one or both foundations. These displacements are used in the following to compute the nodal contact forces  $\bar{\mathbf{P}}_c = \bar{\mathbf{K}}_s \bar{\mathbf{u}}_c$  w.r.t. the  $(x, y, z, \omega)$  domain.  $\bar{\mathbf{P}}_c$  includes the components in all directions for the full coupling, whereas for relaxed boundary conditions only contact forces in the  $z$ -direction remain. Subsequently, these nodal contact forces are applied as external loads on the surface of the halfspace with inclusion, as depicted in Fig. 5a, in order to determine the displacements on the whole ground surface  $\Lambda$  by application of Eq. (13). Thereby the effects of the interaction of the foundations with the soil substructure are completely included. However, the members of the stiffness matrix  $\hat{\mathbf{K}}^{\text{hc}}$  and the load vector  $\hat{\mathbf{P}}^{\text{hc}}$  associated with  $\Lambda$  are given in the Fourier transformed domain. Furthermore, as  $\hat{\mathbf{P}}_{\Lambda\text{ITM}}$  in Eq. (13) consists of the stresses on the halfspace surface, the contact forces  $\bar{\mathbf{P}}_c$  need to be divided by the corresponding load influence area in a first step and have to be transformed into the  $(k_x, k_y, z, \omega)$  domain afterwards to obtain the contact stresses  $\hat{\sigma}_c(k_x, k_y, z, \omega)$ , depicted in Fig. 5b, that can then be sorted into  $\hat{\mathbf{P}}_{\Lambda\text{ITM}}$ . Therewith the displacements  $\hat{\mathbf{u}}_{\Lambda\text{ITM}}(k_x, k_y, z, \omega)$  and finally after a twofold IFFT  $\bar{\mathbf{u}}_{\Lambda}(x, y, z, \omega)$  over the total soil surface  $\Lambda$  can be computed.

**Figure 5:** Postprocessing procedure: Application of the contact stresses at the soil foundation interfaces as external load on the 2.5D ITM-FEM system halfspace with inclusion (a) in the original domain  $(x, y, z, \omega)$  and (b) in the transformed domain  $(k_x, k_y, z, \omega)$  to determine the displacements  $\bar{\mathbf{u}}_{\Lambda}(x, y, z, \omega)$  over the total ground surface.

#### 4 NUMERICAL RESULTS

In this section the above presented coupled ITM-FEM approach is applied to determine the dynamic response of a single or a group of two adjacent 3D square foundations with a side length  $B_f$ , a height  $h_f$  and a midpoint distance of  $d_{f1f2}$  resting on the surface of a halfspace with a length invariant, cylindrical inclusion of radius  $R$ , embedment depth  $H$  and a soil covering height  $h_{cyl}$ , as depicted in Fig. 6. The material properties of the linear elastic foundations, the soil and the inclusion are described by the Young's modulus  $E$ , the Poisson ratio  $\nu$  and the density  $\rho$ . For the soil substructure, whose properties as well as the corresponding wave speeds  $c_p$ ,  $c_s$  and  $c_r$  are listed in Tab. 1, additionally material damping was introduced by means of a complex Young's modulus  $\hat{E} = E(1 + i \text{sign}(\omega)\zeta)$  with the hysteric damping ratio  $\zeta$ .

**Figure 6:** Geometric parameters of the coupled 2.5D ITM-FEM system with two adjacent surface foundations.

For all subsequent calculations, full coupling of all DOFs between soil and foundations is assumed and only rigid, massless square foundations, modelled by choosing a large Young's Modulus  $E_f$ , are considered for reason of comparability with other results from literature. However, the limitation to this rather simple systems in this paper does not imply any confinement on the applicability of the proposed method for more complicated SSI and FSFI problems, including flexible and massive structures with rectangular contact area to the soil as well as more complex inclusion geometries inside the 2.5D FEM substructure with cylindrical outer boundary.

	$E$ (N m <sup>-2</sup> )	$\nu$ ( )	$\rho$ (kg m <sup>-3</sup> )	$\zeta$ (—)	$c_p$ (m s <sup>-1</sup> )	$c_s$ (m s <sup>-1</sup> )	$c_r$ (m s <sup>-1</sup> )

**Table 1:** Material parameters of soil, foundation and different inclusion infill materials.

Since only comparably very stiff foundations are considered, all elements of a foundation can be considered as constrained to move like a rigid body and the displacements of each point can be expressed by the displacements and the rotations at the center of the resp. foundation  $\bar{\mathbf{u}}_{c,r}^i = (u_x^i, u_y^i, u_z^i, \varphi_x^i, \varphi_y^i, \varphi_z^i)^T$  at the soil foundation interface  $z = 0$ . In case of two

adjacent foundations, the displacements  $\bar{\mathbf{u}}_{c,r}^i$  of foundation  $i$  due to an external load  $\bar{\mathbf{P}}_{c,r}^j = (P_x^j, P_y^j, P_z^j, M_x^j, M_y^j, M_z^j)^T$  on foundation  $j$  with  $i, j = 1, 2$  can be computed as

$$\begin{pmatrix} \bar{\mathbf{u}}_{c,r}^1 \\ \bar{\mathbf{u}}_{c,r}^2 \end{pmatrix} = \begin{pmatrix} \bar{\mathbf{F}}_{c,r}^{11} & \bar{\mathbf{F}}_{c,r}^{12} \\ \bar{\mathbf{F}}_{c,r}^{21} & \bar{\mathbf{F}}_{c,r}^{22} \end{pmatrix} \begin{pmatrix} \bar{\mathbf{P}}_{c,r}^1 \\ \bar{\mathbf{P}}_{c,r}^2 \end{pmatrix} \quad (18)$$

The main diagonal terms represent the compliance matrices of each rigid foundation itself in case it is loaded with an external load, whereas the off diagonal terms represent the coupling between the foundations. Thereby each member of the total flexibility/compliance matrix of the rigid foundations  $\bar{\mathbf{F}}_{c,r}^{ij}$  consists of

$$\bar{\mathbf{F}}_{c,r}^{ij} = \begin{pmatrix} \bar{F}_{xx}^{ij} & 0 & 0 & 0 & \bar{F}_{x,\varphi_y}^{ij} & 0 \\ 0 & \bar{F}_{yy}^{ij} & 0 & \bar{F}_{y,\varphi_x}^{ij} & 0 & 0 \\ 0 & 0 & \bar{F}_{zz}^{ij} & 0 & 0 & 0 \\ 0 & \bar{F}_{\varphi_x,y}^{ij} & 0 & \bar{F}_{\varphi_x,\varphi_x}^{ij} & 0 & 0 \\ \bar{F}_{\varphi_y,x}^{ij} & 0 & 0 & 0 & \bar{F}_{\varphi_y,\varphi_y}^{ij} & 0 \\ 0 & 0 & 0 & 0 & 0 & \bar{F}_{\varphi_z,\varphi_z}^{ij} \end{pmatrix} \quad (19)$$

In the entries  $\bar{F}_{rs}^{ij}$  the first subscript  $r$  indicates the mode of vibration and the second subscript  $s$  the direction of the force resp. moment.

For the subsequently presented dimensionless compliance functions, defined as

$$C_{rs}^{ij} = \frac{u_r^i G_s B_f / 2}{P_s^j} \quad (20)$$

the displacements  $u_r^i$  due to unit force  $|P_s^j| = 1$  with  $r, s = x, y, z, \varphi_x, \varphi_y, \varphi_z$  normalized with the shear modulus of the soil  $G_s$  and the foundation width are evaluated over the dimensionless frequency  $a_0 = \omega B_f / c_s$ , where  $c_s$  is the shear wave velocity of the soil. It is possible to determine the compliance functions for a load either on one or both foundations.

Concerning the dimensions and the discretization of the 2.5D ITM-FEM approach, used to model the soil subsystem, same parameters were chosen for all following computations. A total domain size of  $B_x = B_y = 64$  m with  $N_x = N_y = 2^9$  discretization points resp. Fourier members was chosen, resulting in a original step size of  $dx = dy = 0.125$  m at the halfspace surface. With a factor  $n_\Delta$ , relating the original and the coarse mesh, which is used for the determination of the flexibility, the contact area of each foundation with the soil is meshed with  $n_{\text{elem}} = (B_f / (n_\Delta dx))^2$  quadratic shell elements. The cylindrical 2.5D FEM inclusion was discretized with  $N_\varphi = 32$  equidistant nodes resp. Fourier series members along the circumference, leading to an element size between 0.25 and 0.375 m for the considered inclusion sizes  $R$  and thus ca. four elements per shear wave length  $\lambda_s$  of the soil at the highest regarded frequency.

#### 4.1 Validation

In literature numerous results applying a variety of different methods have been published, dealing with the interaction of surface foundations and a homogeneous halfspace. Therefore, the previously presented approach is used in the following to compute the flexibility resp. compliance functions of a single or two adjacent surface foundations resting on a halfspace with inclusion, whereby the material properties of the latter are chosen to be identical to those of the surrounding soil in order to reproduce a homogeneous halfspace. The obtained results are then compared to the literature results to validate the proposed method.

Fig. 7 shows the real and imaginary part of the vertical compliance  $C_{zz}^{11}$  of a single rigid, massless square foundation with  $B_f = 2$  m on a halfspace with cylindrical inclusion (soil material) with  $R = 3$  m and embedment depth  $H = 4$  m obtained with the presented 2.5D ITM-FEM approach. A point load with unit amplitude was applied at the midpoint of the foundation for excitation frequencies from 2 to 60 Hz.

**Figure 7:** Comparison of real and imaginary part of the vertical compliance functions  $C_{zz}^{11}(a_0)$  of a rigid, massless square foundation with  $B_f = 2$  m on a halfspace with cylindrical inclusion (Soil) with  $R = 3$  m and embedment depth  $H = 4$  m obtained with presented ITM-FEM approach with  $N_x = N_y = 2^9$  (—) to the results of the ITM-FEM approach on homogeneous halfspace with  $N_x = N_y = 2^{11}$  (—), Wong and Luco [1] (—), Hirschauer [38] (—) and Shahi and Noorzad [39] (—).

A good agreement of the results with those obtained by Wong and Luco [1], Hirschauer [38] and Shahi and Noorzad [39] can be observed. However, the compliances attained with the presented method show slightly lower values. One reason for that is the hysteretic material damping ( $\zeta = 0.05$ ), whereas the literature results were determined for zero material damping. In addition, the results for a rigid foundation, determined by enforcing the kinematics of a rigid plate as a displacement boundary condition at the soil-foundation interface of a homogeneous halfspace with lower material damping  $\zeta = 0.02$ , larger domain size  $B_x = B_y = 128$ , and larger sample number  $N_x = N_y = 2^{11}$  (possible as there the computational effort is much lower) are shown in Fig. 7, whose courses correspond even better with the literature solutions. However, for the halfspace with inclusion due to the rapidly raising computational effort, as the number of  $y$ -discretization points on the contact surface and thus the load positions, at which a new displacement field for the shifting procedure to populate the flexibility matrix needs to be computed, increases proportional to a decreasing incremental step width, this adaption of the discretization is not reasonable and the agreement of the results gained with the used parameters is considered as sufficient.

In Fig. 8 the absolute value of the vertical compliance of the active (loaded)  $|C_{zz}^{11}|$  and the passive (unloaded)  $|C_{zz}^{21}|$  of two adjacent surface foundations with distance  $d_{f1f2} = 4$  m due to a unit harmonic point load on foundation  $F_1$  are illustrated. The dimensions of the foundations

**Figure 8:** Comparison of absolute vertical compliance functions  $|C_{zz}^{ij}(a_0)|$  for (a) first (loaded) and (b) second of two adjacent rigid, massless square foundations with  $B_f = 2$  m and distance  $d_{f1f2} = 4$  m on a halfspace with cylindrical inclusion (Soil) with  $R = 3$  m and embedment depth  $H = 4$  m obtained with presented 2.5D ITM-FEM approach (—) to the results of the ITM approach on homogeneous halfspace, enforcing the kinematic of a rigid plate as displacement boundary condition (—), Radisic [23] (—) and Karabalis and Mohammadi [40] (—).

as well as the parameters of the halfspace with inclusion are chosen as before. A perfect match of the presented 2.5D ITM-FEM approach with the ITM approach with the kinematic condition can be observed, if same discretization parameters are chosen. Furthermore, the results show good agreement with those obtained by Radisic [23] and Karabalis and Mohammadi [40], who again obtained slightly larger compliances due to zero material damping. At higher frequencies, where mainly the geometrical damping dominates the system response, the deviations diminish.

Overall the comparison with literature results shows, that the proposed method delivers valid results and can further be applied to determine compliance functions of foundations resting on soils with embedded structures or inhomogeneities.

## 4.2 Parameter study

In this subsection the influence of the variation of the inclusion parameters such as embedment depth  $H$ , size  $R$  and stiffness  $E_{\text{cyl}}$  on the dynamic response of a single or two adjacent rigid, massless, square surface foundations, including their cross interaction, is investigated for different configurations of the surface foundations w.r.t. their midpoint distance  $d_{f1f2}$  and width  $B_f$ . The frequency dependent dimensionless compliance functions at the soil-foundation interface are presented for the different system designs and compared with the results for equivalent foundations resting on a homogeneous halfspace to illustrate the influence of the inclusion respectively the change in influence for varying configurations of inclusion and foundations. Furthermore the impact of a stiff, length invariant cylindrical confinement on the displacement distribution over the entire ground surface as a result of a simultaneous harmonic excitation of both foundations, determined by the post-processing method described above, is presented.

### Variation of embedment depth $H$ - single foundation

Firstly the influence of a variation of the embedment depth  $H$  of a stiff cylindrical inclusion (Infill D in Tab. 1) directly located beneath a single foundation on the compliance functions is investigated. All other parameters, such as the foundation width  $B_f = 2$  m, the inclusion radius  $R = 3$  m, as well as the soil and inclusion material are kept constant.

**Figure 9:** Absolute horizontal compliance functions  $|C_{xx}^{11}(a_0)|$  of a rigid, massless square foundation with  $B_f = 2$  m on a halfspace with cylindrical inclusion (Infill D) with  $R = 3$  m and varying embedment depth  $H = 4$  m (—),  $H = 6$  m (—),  $H = 8$  m (—),  $H = 12$  m (—) and on a homogeneous halfspace (—).

**Figure 10:** Absolute horizontal compliance functions  $|C_{yy}^{11}(a_0)|$  of a rigid, massless square foundation with  $B_f = 2$  m on a halfspace with cylindrical inclusion (Infill D) with  $R = 3$  m and varying embedment depth  $H = 4$  m (—),  $H = 6$  m (—),  $H = 8$  m (—),  $H = 12$  m (—) and on a homogeneous halfspace (—).

**Figure 11:** Absolute vertical compliance functions  $|C_{zz}^{11}(a_0)|$  of a rigid, massless square foundation with  $B_f = 2$  m on a halfspace with cylindrical inclusion (Infill D) with  $R = 3$  m and varying embedment depth  $H = 4$  m (—),  $H = 6$  m (—),  $H = 8$  m (—),  $H = 12$  m (—) and on a homogeneous halfspace (—).

Figs. 9 and 10 show the horizontal compliance functions due to a harmonic excitation with horizontal unit forces. In case of small embedment depths  $H$ , corresponding to a small thicknesses of the soil layer between the stiff inclusion and the bottom of the foundation  $h_{\text{cyl}}$ , large fluctuations of the flexibilities  $|C_{xx}^{11}|$  and  $|C_{yy}^{11}|$  can be observed. This large influence of the buried structure on the foundation flexibilities decreases with increasing  $H$ , for which the results converge to those obtained for a homogeneous halfspace. However, some waviness in the flexibilities is left, which can be attributed to waves reflected at the soil-inclusion interface and their superposition with the primary waves. The two rather distinct peaks for  $H = 4$  can be linked to the first and second horizontal eigenfrequencies of a soil layer over bedrock (defined equal to the natural frequencies of an equivalent one-dimensional rod featuring the same length as the thickness of the layer like proposed in [24] and also depicted in Figs. 9 and 10)

$$f_{\text{h,res}} = \frac{(2n-1)c_s}{4H_{\text{layer}}} \quad \text{with } n = 1, 2, \dots \quad (21)$$

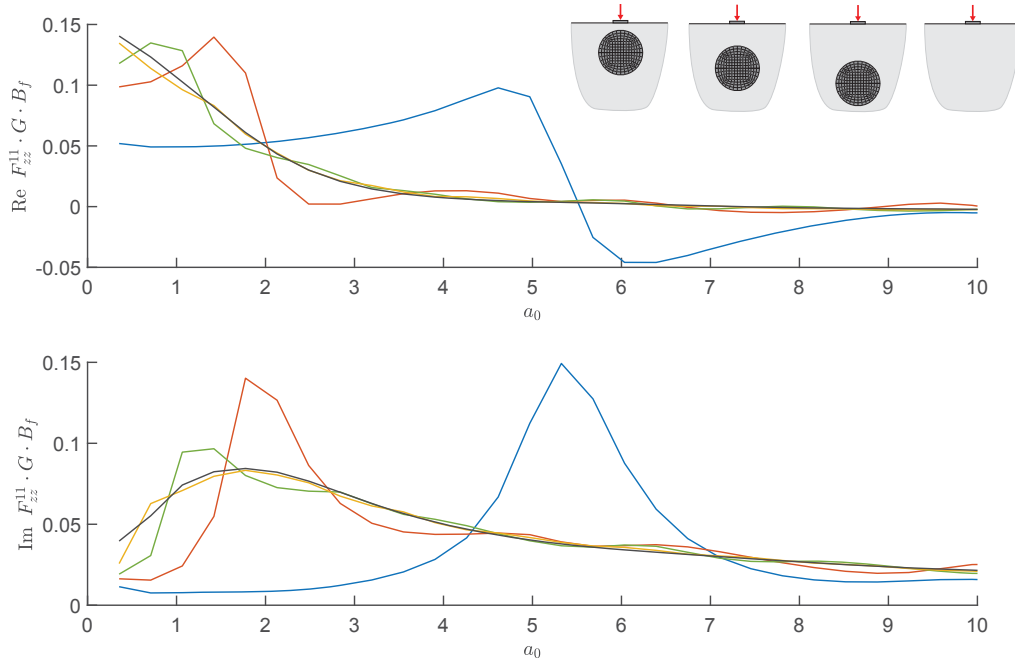

which here result with  $H_{\text{layer}} = h_{\text{cyl}} = 1$  to  $f_{\text{h,res}} = 17.7, 53.1$  Hz resp.  $a_{0,\text{h,res}} = 3.14, 9.42$ . The generally quite resembling qualitative course of  $|C_{xx}^{11}|$  and  $|C_{yy}^{11}|$  can be explained by the rather small foundation width  $B_f = 2$  m compared to the diameter of the inclusion with 6 m, which leads to a similar behaviour in the  $y$ - as in the  $x$ -direction of the fully length invariant inclusion. Nevertheless, the maxima of  $|C_{xx}^{11}|$  are slightly more peaked, show little higher amplitudes and fit better to the horizontal resonance frequencies of a soil layer in Eq. (21).

Also in the vertical compliances  $|C_{zz}^{11}|$  in Fig. 11 the existence of vertical resonances of the soil layer over the inclusion is clearly visible. Depending on the embedment depth  $H$ , distinct peaks occur in the vicinity of the vertical resonance frequencies of an elastic stratum also depicted in Fig. 11 by the vertical lines

$$f_{\text{v,res}} = \frac{(2n-1)c_p}{4H_{\text{layer}}} \quad \text{with } n = 1, 2, \dots \quad (22)$$

However, since the cylindrical inclusion is spatially limited in the  $y-z$ -plane, the behaviour only approximates that of a soil layer over bedrock. This also holds for the corresponding resonance frequencies and explains the shift of the smoother peaks towards lower frequencies. It was shown by Chouw et al. [24] and Kobori et al. [41], that in a perfectly elastic stratum with zero material damping, energy attenuation is only possible by free waves, i.e. Rayleigh and Love waves, travelling in radial direction away from the source and that for an excitation at the surface of the layer with a frequency below the first resonance frequency ("cutoff frequency") no such propagating waves can occur. The imaginary part of the flexibility at the soil foundation interface, associated with the system damping, in this case directly shows the amount of radiation damping due to propagating waves into the laterally infinite medium and is zero below the first natural frequency. In contrast, in a viscoelastic stratum with non zero material damping even in the low frequency range, below the first natural frequency, innumerable modes of the free propagating waves are possible. Consequently both attenuation mechanisms, material and radiation damping, are present in the whole frequency range. However, in the low frequency range each of these modes is highly damped, such that the dissipative attenuation predominates the radiative one greatly and the energy attenuation due to wave radiation is extremely small [41]. At resonance a significant amplification of the flexibility amplitudes can be observed, which decrease again and converge to the solution for the homogeneous halfspace with increasing frequency. This is because for larger layer thicknesses resp. higher excitation frequencies,

implying a larger ratio of  $H/\lambda_p$ , the waves introduced at the source at the ground surface almost attenuate before reaching the layer boundary resp. the stiff inclusion and only scarcely affect the dynamic response of the system. In this case approximately the same amount of energy is dissipated and dispersed as in case of the homogeneous halfspace. Also for the stiff cylindrical inclusion considered before, an imaginary part of the compliance  $C_{zz}^{11}$  in Fig. 12 close to zero can be observed for excitation frequencies below the first vertical resonance frequency. This small values of the imaginary part, which are linked to both, material and geometrical damping, can, according to the above explanations, be associated with an only small dissipative energy attenuation due to material damping in the low frequency range. At resonance, large values of the imaginary part are observed connected to a large amount of dissipated energy, which then is dominated by the energy dispersion of the freely propagating waves occurring from then on. For excitation frequencies, which are large in comparison to the first layer resonance, associated with the respective soil layer thickness  $h_{\text{cyl}}$ , the compliances converge to the halfspace solution.

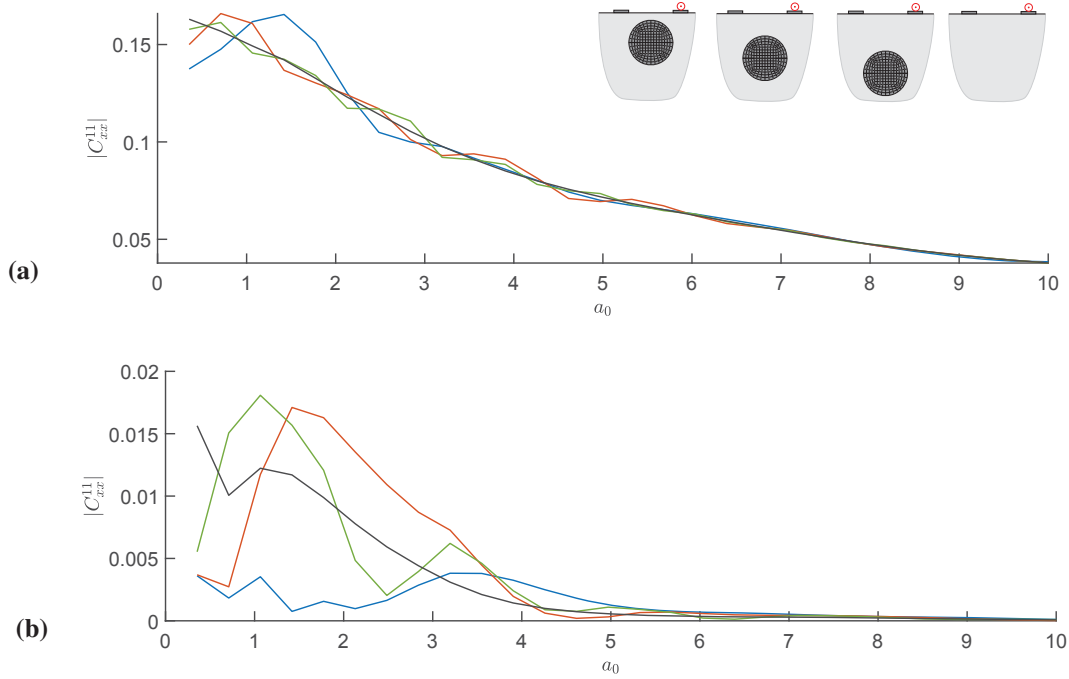

**Figure 12:** Real and imaginary part of vertical compliance functions  $C_{zz}^{11}(a_0)$  of a rigid, massless square foundation with  $B_f = 2$  m on a halfspace with cylindrical inclusion (Infill D) with  $R = 3$  m and varying embedment depth  $H = 4$  m (—),  $H = 6$  m (—),  $H = 8$  m (—),  $H = 12$  m (—) and on a homogeneous halfspace (—).

### Variation of embedment depth $H$ - two adjacent foundations

Now the compliance functions of two adjacent surface foundations with a width of  $B_f = 2$  m and a midpoint distance  $d_{f1f2} = 8$  m, again resting on a halfspace with a stiff cylindrical inclusion (Infill D) of radius  $R = 3$  m and varying embedment depth  $H$  are considered.

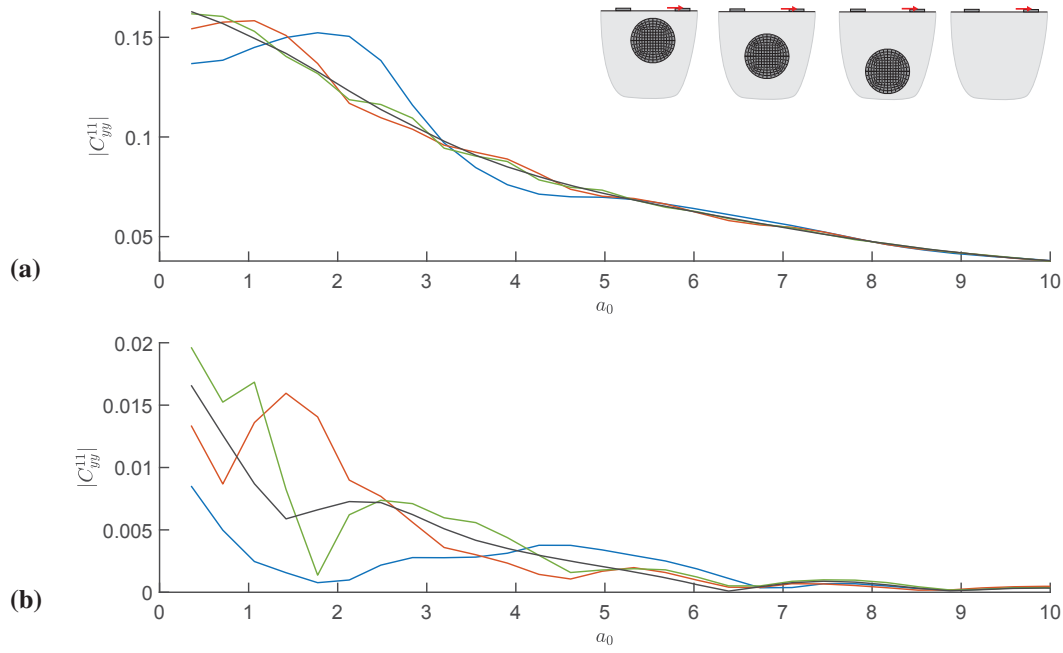

For the horizontal compliance  $|C_{xx}^{11}|$  of the loaded foundation in Fig. 13a, only relatively small deviations from those obtained for the homogeneous halfspace are visible in comparison to the case of the single foundation. This is because here the loaded foundation is located besides the stiff inclusion instead of directly over it. The largest deviations are observed for the smallest embedment depths and in the low frequency range. The then occurring amplification can be traced back to the effect of waves reflected at the inclusion. With increasing  $H$  and

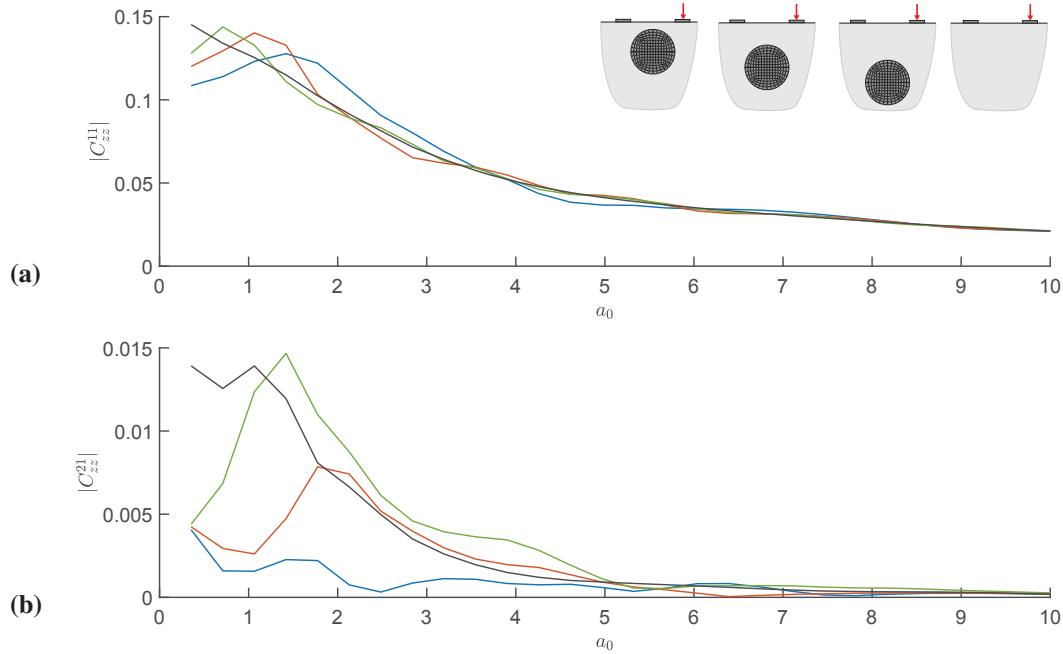

**Figure 13:** Absolute vertical compliance functions  $|C^{ij}_{xx}(a_0)|$  for (a) first (loaded) and (b) second of two adjacent rigid, massless square foundations with  $B_f = 2$  m and distance  $d_{f1f2} = 8$  m on halfspace with cylindrical inclusion (Infill D) with  $R = 3$  m for varying embedment depth  $H = 4$  m (—),  $H = 6$  m (—),  $H = 8$  m (—) and on a homogeneous halfspace (—).

increasing frequency  $|C^{11}_{xx}|$  converges to that for the homogeneous halfspace. The compliance of the passive foundation  $|C^{21}_{xx}|$  is very small for small  $H$ , as the main excitation takes place in the direction of the length invariant inclusion and a propagation of the elastic waves from the excited foundation  $F_1$  to the unloaded foundation  $F_2$  is disturbed by the cylindrical inclusion in the transmission path. Furthermore in the soil layer over the inclusion propagating waves can occur only above the first (here horizontal) layer resonance frequency, which can e.g. be observed by the increase of  $|C^{21}_{xx}|$  for  $H = 4$  at excitation frequencies  $a_0 > 3.14$ . With increasing  $H$  the amplitude of  $|C^{21}_{xx}|$  in the low frequency range increases due to a smaller shielding effect of the cylindrical inclusion. For intermediate values of  $H$ ,  $|C^{21}_{xx}|$  shows to be larger than in case of a homogeneous halfspace, probably due to reflected waves at the top of the inclusion, amplifying the response at  $F_2$ . In case of large  $H$  and with increasing frequencies, the compliance again converges to that obtained for the homogeneous halfspace, as with increasing ratio of the soil layer thickness to the elastic wave lengths the influence of the inclusion diminishes.

Comparing the results of for the compliances in  $x$ - and  $y$ -direction, it can be stated, that  $|C^{11}_{yy}|$  in Fig. 14 converges to the halfspace solution only at higher frequencies as  $|C^{11}_{xx}|$  and the deviations are larger, which is because the direction of excitation in this case directly points towards the inclusion located in the transmission path and thus a bigger portion of elastic waves is reflected as for the excitation in  $x$ -direction, especially as the foundation is located besides the inclusion. For very low frequencies the inclusion size is small compared to the wavelength, wherefore it has no big influence on the direct cross interaction of the adjacent foundations resulting in higher values of  $|C^{21}_{yy}|$ . Again a raise of amplitudes for  $a_0 > 3.14$  can be observed for  $|C^{21}_{yy}|$ .

**Figure 14:** Absolute vertical compliance functions  $|C_{yy}^{ij}(a_0)|$  for (a) first (loaded) and (b) second of two adjacent rigid, massless square foundations with  $B_f = 2$  m and distance  $d_{f1f2} = 8$  m on halfspace with cylindrical inclusion (Infill D) with  $R = 3$  m for varying embedment depth  $H = 4$  m (—),  $H = 6$  m (—),  $H = 8$  m (—) and on a homogeneous halfspace (—).

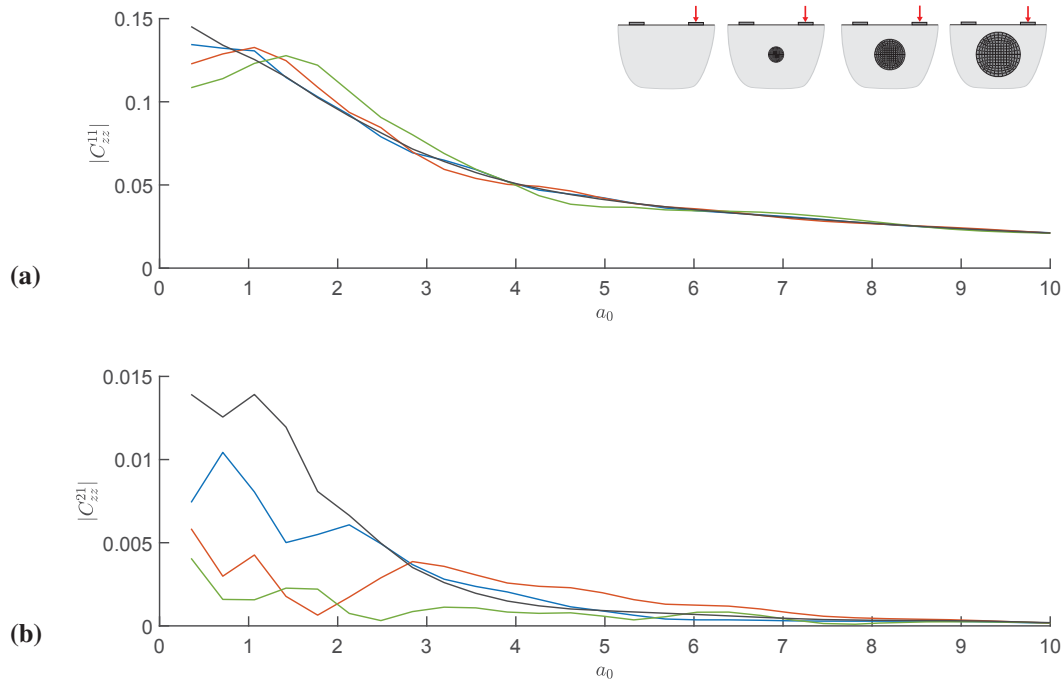

**Figure 15:** Absolute vertical compliance functions  $|C_{zz}^{ij}(a_0)|$  for (a) first (loaded) and (b) second of two adjacent rigid, massless square foundations with  $B_f = 2$  m and distance  $d_{f1f2} = 8$  m on halfspace with cylindrical inclusion (Infill D) with  $R = 3$  m for varying embedment depth  $H = 4$  m (—),  $H = 6$  m (—),  $H = 8$  m (—) and on a homogeneous halfspace (—).

Concerning the vertical compliances  $|C_{zz}^{11}|$  of the active foundation in Fig. 15 only small deviations occur as the foundation is located besides the inclusion and only a little part of the induced elastic waves interacts with it. In general small compliances  $|C_{zz}^{21}|$  are observed over the whole frequency range for small  $H$ . However, above the first vertical resonance frequency of the soil layer over the inclusion at  $a_0 = 5.87$  for  $H = 4$  a slight increase of  $|C_{zz}^{21}|$  can be observed. The overall trend of the compliances tending to those obtained for the homogeneous halfspace for increasing  $H$  and  $a_0$  is also found here.

Due to space limitation for all following cases only the vertical compliances are shown. However the computation of the compliances for any load direction and type is possible.

### Variation of the inclusion radius $R$

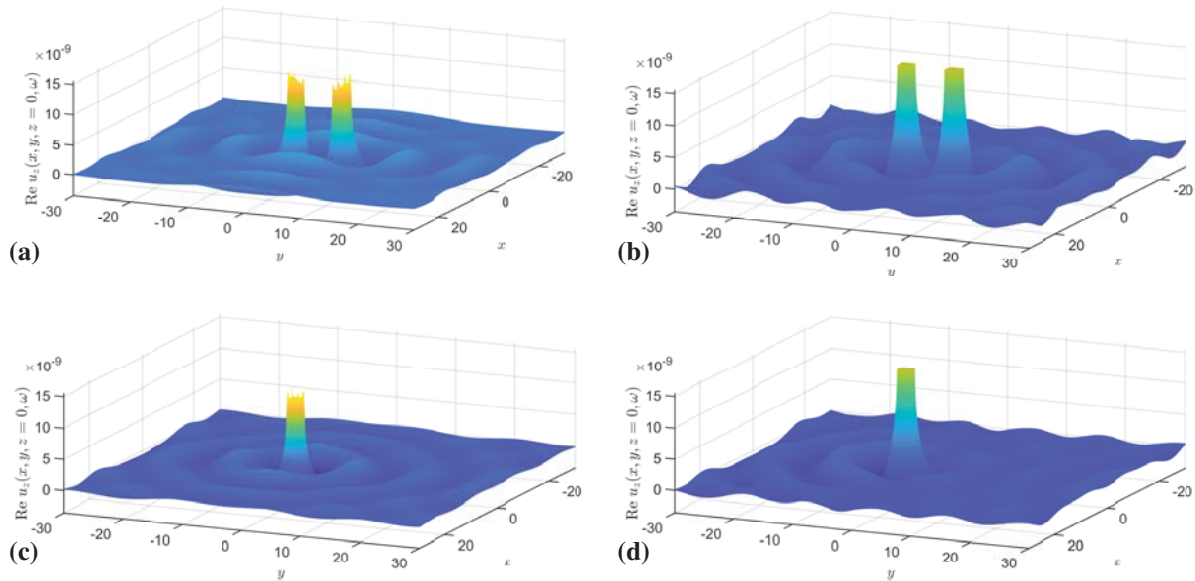

Hereinafter, the embedment depth  $H = 4$  m of the inclusion under two adjacent surface foundations with  $B_f = 2$  m and  $d_{f1f2} = 8$  m is fixed as well as the material properties and only its size  $R$  is varied. Fig. 16 shows, that the vertical compliances  $|C_{zz}^{11}|$  of the loaded foundation on the soil with the inclusion are very close to those for the homogeneous halfspace for small inclusion size  $R$ . Also for the largest considered radius  $R = 3$  m, only small deviations occur, as the foundation is located besides the inclusion and the share of waves travelling downwards or to the inclusion averted side (thus not affected by it) is quite large. The compliances  $|C_{zz}^{21}|$  of the passive foundation show low amplitudes for large  $R$  and converge, due to the effects already pointed out earlier, to those for the homogeneous halfspace with decreasing inclusion size.

**Figure 16:** Absolute vertical compliance functions  $|C_{zz}^{ij}(a_0)|$  for (a) first (loaded) and (b) second of two adjacent rigid, massless square foundations with  $B_f = 2$  m and distance  $d_{f1f2} = 8$  m on halfspace with cylindrical inclusion (Infill D) with embedment depth  $H = 4$  m for varying radius  $R = 1$  m (—),  $R = 2$  m (—),  $R = 3$  m (—) and on a homogeneous halfspace (—).

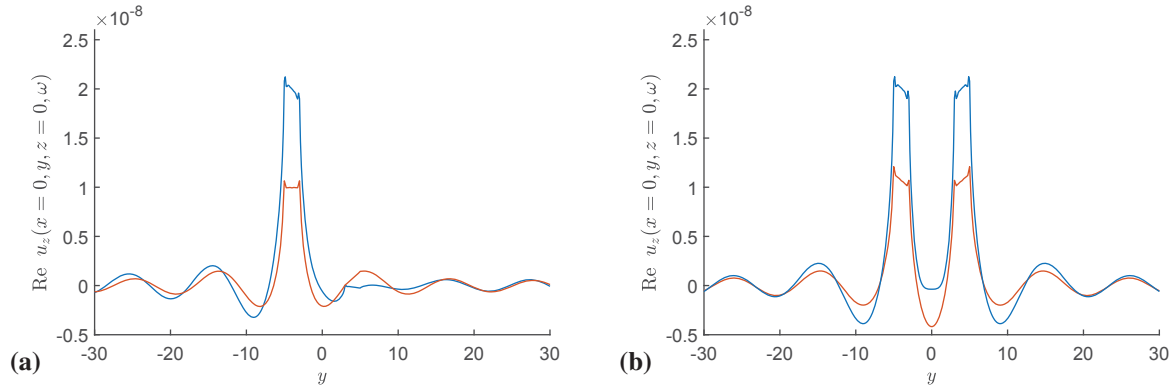

For the system configuration with the maximum inclusion size of  $R = 3$ , the displacements on the whole ground surface have been determined with the post processing procedure outlined in subsection 3.3 applying relaxed boundary conditions, i.e. frictionless contact at the soil foundation interfaces. The left column of Fig. 17 shows the results for the real part of the vertical displacements, obtained for a harmonic excitation with  $f = 6$  Hz of both resp. only one foundation, resting on a homogeneous halfspace. In Fig 17a, a wave propagation concentrated on the direction of the foundation alignment and perpendicular to it can be observed, whereas Fig 17c shows a nearly omnidirectional propagation of the surface waves. The second, unloaded foundation only hardly influences the displacement field on the ground surface, except the area directly under it, where a linear displacement course arises due to the rigidity of the foundation plate. In case of a massive foundation the inertia effects would lead to a much higher influence of the unloaded foundation on the system response. The right column of Fig. 17 shows the results for same foundation and load configuration, but on a halfspace with stiff inclusion. Fig. 17b shows a significant reduction of  $u_z(x, y, z = 0, \omega)$  in a limited area along the entire length of the stiff inclusion compared to the case of the homogeneous halfspace, in turn leading to an increase in amplitudes in the direction perpendicular to the inclusion on both sides. Furthermore, the behaviour of the stiff inclusion as wave barrier can clearly be observed in Fig. 17d, where a considerable reduction of  $u_z(x, y, z = 0, \omega)$  occurs on the load averted side of the inclusion. These effects gets even more obvious, when the displacements along the  $y$ -direction for  $x = 0$  are compared for both cases in Fig. 18.

**Figure 17:** Real part of vertical displacement  $u_z(x, y, z = 0, \omega)$  on whole ground surface due to harmonic loading ( $f = 6$  Hz) on (a),(b) both and (c),(d) only one of the adjacent rigid, massless foundations with  $B_f = 2$  m and  $d_{f1f2} = 8$  m resting on the surface of a (a),(c) homogeneous halfspace and (b),(d) halfspace with a stiff cylindrical inclusion (Infill D) with  $H = 4$  m and  $R = 3$  m, obtained with the post processing procedure.

### Variation of foundation size $B_f$

Now the width of the foundations is varied, while keeping the midpoint distance  $d_{f1f2} = 8$  m as well as all other parameters constant. Only relatively minor deviations of  $|C_{zz}^{11}|$  from the homogeneous halfspace response for  $B_f = 2$  and 4 m are observed in Fig. 19. This is

**Figure 18:** Real part of vertical displacement  $u_z(x=0, y, z=0, \omega)$  along  $y$ -direction for  $x=0$  due to harmonic loading with  $f = 6$  Hz on (a) only one and (b) both of the adjacent rigid, massless foundations with  $B_f = 2$  m and  $d_{f1f2} = 8$  m resting on the surface of a homogeneous halfspace (—) and a halfspace with a stiff cylindrical inclusion (Infill D) (—) with  $H = 4$  m and  $R = 3$  m, obtained with the post processing procedure.

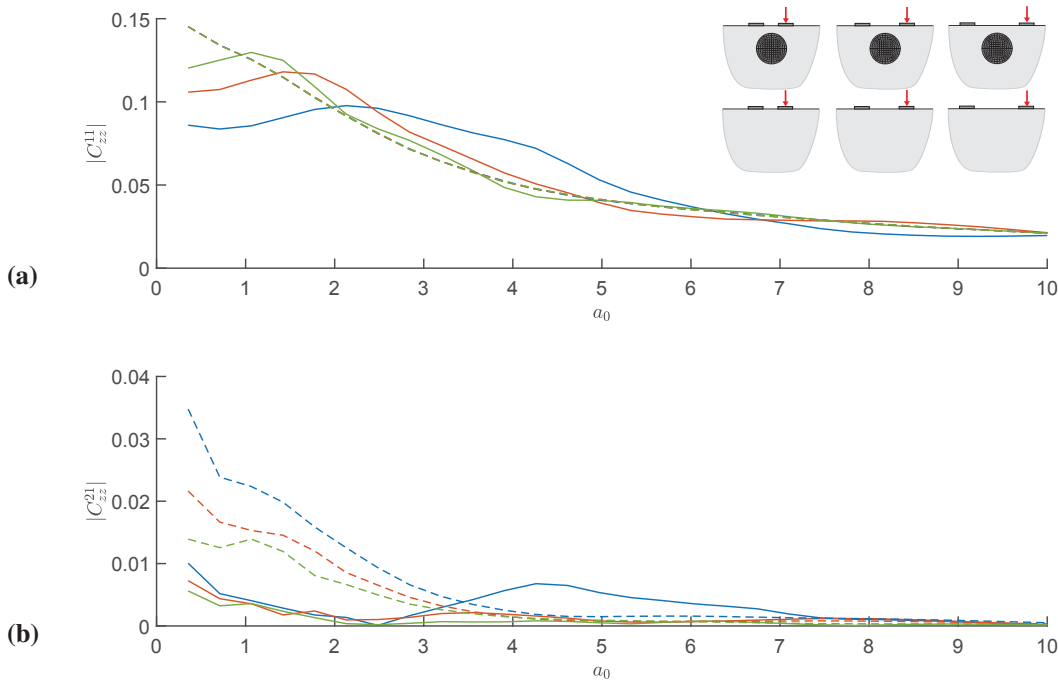

presumably because the center of the foundation is located besides the stiff inclusion. Especially in the high frequency range a comparably small influence of the inclusion turns out, whereas for low excitation frequencies some smaller oscillations of  $|C_{zz}^{11}|$  due to interaction effects with the inclusion are visible. Furthermore a considerably decreased compliance  $|C_{zz}^{21}|$  due to presence of the stiff inclusion, acting as wave barrier, is observed. In general larger  $|C_{zz}^{21}|$  occur in case of  $B_f = 4$ , as then distance of foundation edges is smaller and the mutual interaction effects are therefore stronger.

**Figure 19:** Absolute vertical compliance functions  $|C_{zz}^{ij}(a_0)|$  for (a) first (loaded) and (b) second of two adjacent rigid, massless square foundations with  $B_f = 2$  m (—),  $B_f = 4$  m (—) and distance  $d_{f1f2} = 8$  m on halfspace with cylindrical inclusion (Infill D) with embedment depth  $H = 3$  m and radius  $R = 2$  m (solid lines) and on a homogeneous halfspace (dashed lines).

### Variation of foundation distance $d_{f1f2}$

The variation of the midpoint distance  $d_{f1f2}$  in Fig. 20 for a constant foundation width as well as inclusion size, location and material shows, that the cross interaction between the foundations decreases with increasing distance regardless the underlying soil. For a homogeneous halfspace,  $|C_{zz}^{11}|$  of the loaded foundation is equal for all  $d_{f1f2}$ , whereas the influence of the inclusion is clearly visible for small distances of the foundations and decreases with increasing  $d_{f1f2}$ , thereby converging to the halfspace solution. In general larger  $|C_{zz}^{21}|$  are observed for the homogeneous halfspace, which also decrease with increasing  $d_{f1f2}$  and  $a_0$ . Due to the rather large inclusion located closely to the halfspace surface, only very low compliance values  $|C_{zz}^{21}|$  show up for larger foundations distances. For the likewise nearby foundations with  $d_{f1f2} = 4$  m, an increase of the compliance amplitude above the first horizontal resonance frequency of the soil layer at  $a_0 = 3.14$  can be observed and attributed to the then possible propagation of surface waves, passing through the soil over the inclusion and impinging at the second foundation.

**Figure 20:** Absolute vertical compliance functions  $|C_{zz}^{ij}(a_0)|$  for (a) first (loaded) and (b) second of two adjacent rigid, massless square foundations with  $B_f = 2$  m on halfspace with cylindrical inclusion (Infill D) with embedment depth  $H = 3$  m and radius  $R = 2$  m (solid lines) and on a homogeneous halfspace (dashed lines) for varying distance  $d_{f1f2} = 4$  m (—),  $d_{f1f2} = 6$  m (—) and  $d_{f1f2} = 8$  m (—).

### Variation of inclusion stiffness $E_{cyl}$

Finally, the effect of a varying stiffness of the inclusion is investigated. Therefore the Young's modulus  $E_{cyl}$  is adapted such that the ratio of the shear wave velocity of the infill material and the soil  $c_{s,cyl}/c_s$  takes values between 2 and 8, additionally to the very stiff inclusion with  $c_{s,cyl}/c_s = 37.6$  investigated in the previous cases.

The vertical compliance of the active foundation  $|C_{zz}^{11}|$  in Fig. 21a generally differs only slightly from the results for the homogeneous halfspace. However, an increase of the smooth peak in the low frequency range and an ascending waviness of the course of the compliance is observed for raising stiffness of the inclusion. The compliance of the passive foundation  $|C_{zz}^{21}|$

in Fig. 21b drastically reduces with increasing stiffness  $E_{\text{cyl}}$ . The oscillations in  $|C_{zz}^{21}|$  imply, that, in dependency of the frequency and with that the corresponding wavelengths, the elastic waves interact differently with the inclusion and the wave field resulting from the direct and reflected waves at the inclusion shows amplification and attenuation effects compared to the nearly monolithically decaying of the compliance  $|C_{zz}^{21}|$  in case of the homogeneous halfspace.

**Figure 21:** Absolute vertical compliance functions  $|C_{zz}^{ij}(a_0)|$  for (a) first (loaded) and (b) second of two adjacent rigid, massless square foundations with  $B_f = 2$  m and distance  $d_{f1f2} = 8$  m on halfspace with cylindrical inclusion with embedment depth  $H = 3$  m and radius  $R = 2$  m for varying stiffness of inclusion: Infill A  $c_{s,\text{cyl}} = 141.4 \text{ ms}^{-1}$  (—), Infill B  $c_{s,\text{cyl}} = 282.8 \text{ ms}^{-1}$  (—), Infill C  $c_{s,\text{cyl}} = 565.68 \text{ ms}^{-1}$  (—), Infill D  $c_{s,\text{cyl}} = 2661.45 \text{ ms}^{-1}$  (—) and on a homogeneous halfspace (—).

## 5 CONCLUSIONS

In this paper an efficient approach for the investigation of the dynamic interaction of finite, three dimensional foundations located on the surface of a soil with a buried local, length invariant structure or inhomogeneity is presented. A 2.5D ITM-FEM approach was used for the determination of the complex, dynamic stiffness matrix of the soil substructure, which is coupled to the dynamic stiffness of the foundations (modelled with conventional 3D finite elements), at the common interaction surfaces via the compatibility conditions. Frequency dependent, dimensionless compliance functions of rigid, massless surface foundations resting on a homogeneous halfspace, modelled with the presented approach by choosing the same material properties for the inclusion as for the surrounding soil, were computed and compared to literature results, showing very good agreement and thereby validating the proposed methodology.

The approach was applied to compute the dynamic response of a single or two adjacent surface foundations, taking into account the through soil coupling as well as the interaction with the inclusion inside the soil, for different system configurations. The influence of both, the embedment depth, size and stiffness of the inclusion and the width and distance of the foundations on the compliance functions at the soil foundation interface was investigated.

In general the impact of the inclusion on the response is larger, if it is located closely to the foundations and features a rather large size in comparison to the elastic wavelengths at the corresponding frequency. With increasing distance of the foundations, as well as for raising embedment depths, decreasing inclusion sizes or a reduced stiffness the compliance functions converge to the results for the case, where the foundations are resting on a homogeneous half-space. For the response at the unloaded foundation the resonance frequency of the soil layer over the inclusion showed to play a decisive role, as below this cut-off frequency a propagation of free waves through this soil layer in the transmission path between the two foundations is not possible. This effect, in combination with the behaviour of the inclusion as a wave barrier, leads to a very small reception at the passive foundation, if the excitation frequency is below this first critical frequency.

Furthermore, the displacement field resulting from the interaction of two adjacent surface foundations with a soil including a stiff cylindrical confinement, due to a dynamic excitation of either one or both, was presented. Thereby a significant reduction in displacement amplitudes at the surface was observed in a limited area along the entire length of the stiff inclusion compared to the case of a homogeneous soil, which in turn led to an increase in amplitudes in the direction perpendicular to the inclusion on both sides, in case both foundations are loaded. For a load only on one foundation, the stiff inclusion shows to act as a wave barrier, leading to significantly reduced displacement amplitudes on the opposite site of the confinement.

### Abstract

*The paper presents a numerical study aiming at establish the effects of removing the lateral ground connection between embedded shallow foundations and surrounding soil on dynamic soil-structure interaction. Series of two-dimensional finite element models were developed comparing the behaviour of two identical structures with just one difference: the embedment of their own foundations. In order to find the parameters that most influenced the effect of the lateral disconnection technique, the properties of the two structures (predominant period, aspect ratio, loading bearing, foundation embedment) as well as the ones of the soil were parametrically varied. From the results gathered in here, it was established the effectiveness of the proposed system to reduce the inter-story drifts demand on the structures and increase their predominant periods specially in case of high value of foundation embedment in a medium dense soil.*

## 1 INTRODUCTION

The geotechnical seismic isolation techniques transpose the effects of traditional isolation techniques, such as rubber or sliding bearing isolator, into the ground [1]. Several geotechnical seismic isolation strategies have been outlined over time. It has been shown experimentally and numerically that the creation of a surface with a low friction angle, immediately below the foundations, is able to dissipate the energy of earthquakes [2]. Similarly, the creation of an isolated volume of soil, through the use of vertical and horizontal soft barriers, is able to significantly reduce the accelerations in the volume itself [3]. Furthermore, the effectiveness of sand-rubber mixtures, in mitigating seismic accelerations, was demonstrated through numerical models and fields test [4]. All the procedures outlined have, as a common strategy, to increase the natural period or damping of the soil-structure system. An inexpensive and intuitive way to achieve this is to laterally disconnect the shallow foundations of a structure from the adjacent lateral soil as both the rotational and translational stiffness of soil-structure foundation decrease and, consequently, the equivalent natural period, computing the soil structure interaction, will increase [5]. The elongation of the natural period has as a direct consequence a different demand in terms of accelerations and displacement on the structure.

This article refers on a parametric analysis where the period elongation of the structure with the lateral disconnection is compared with the same structure laying on fully embedded foundation in the ground. Different parameters in the structure, such as the aspect ratio, the fixed base period, the embedded of the foundation, have been changed as well as the stiffness properties of the soil. Finally, a series of multiple real earthquakes have been applied to a single scenario with a specific seismic hazard to numerically highlight the potentiality of such G.S.I technique.

## 2 NUMERICAL ANALYSIS

### 2.1 Numerical model

The numerical analysis were carried out by the use of the software Plaxis 2D. The finite element model is presented in Figure 1.

Figure 1. Numerical model with the indication of width and depth of the soil domain and the mesh adopted.

The model has a width dimension of 60m and a total depth of 30meters. The width of the deformable soil is fixed at 20meters while 10 meters of bedrock are included in the model to ensure no significative interference between the bottom base and the soil layer. The ground water is absent. Standard boundary conditions were applied during the initial (static) stage, that

is zero horizontal displacements along the lateral boundaries and fixed nodes at the base of the grid. During the dynamic analysis, the seismic inputs were applied to the bottom nodes of the mesh. In order to take into account the finite stiffness of the underlying bedrock, and to reproduce the upward propagation of shear waves within a semi-infinite domain, the outcrop input accelerations were halved to compute the corresponding upward-propagating wave motion and applied to the bottom nodes together with adsorbing viscous dashpots. Free-field boundary conditions were applied along the lateral sides of the mesh. The element size of the soil has been taken always smaller than one-tenth of the wavelength associated with the highest frequency component of the input wave containing appreciable energy [6]. For this reason, the discretization was carried out using 7872 tetrahedral elements with 15 nodes each. Both the structures, with and without the lateral disconnection, have been studied in the same numerical model. The relative distance between the two structures (13meter) and between the structures and lateral boundaries of the models (16meters) ensures no significant interaction [7].

## 2.2 Static Force and Input Motion Applied

In order to evaluate the elongation of the natural period generated by the lateral disconnection, the Fourier Trasform of crossbeam free oscillation displacement was calculated for both structures. In particular an horizontal static force is applied on the structure crossbeam to impose an initial condition of motion and then the free oscillation was studied in a dynamic phase deactivating the force itself. The procedure was repeated for all the studied scenario.

Consequently, in order to evaluate the effectiveness of the lateral disconnection in terms of acceleration and Arias intensity reduction, a series of multiple earthquakes were selected and applied at the bedrock. The accelerograms were chosen and scaled by using the software Rexel [8] considering the Elastic Design Spectrum of L'Aquila centre (Italy) with a return period of 475 years, corresponding to the life safety limit states as defined by the Italian Code [9]. Since the earthquakes were selected on soil class A (rock) no deconvolution of the earthquakes is needed. Due to the fact that L'Aquila is one of the most affected Italian cities by the seismic events, the frequency content and intensity of L'Aquila hazard was considered a good reference to highlight the applicability of the proposed technique specially in a contest where the seismic hazard is particularly high. All the informations about the selected earthquakes are reported in Table 1 while Figure 1 shows the spectra compatibility of L'Aquila design spectrum with the selected scaled earthquakes.

Record (-)	Location (-)	Year (-)	M (-)	NERHP Site (-)	JB dist (km)	PGA (g)	Arias Intensity (m/s)
1	Campano Lucano	1980	6.9	A	25	0.06	0.06

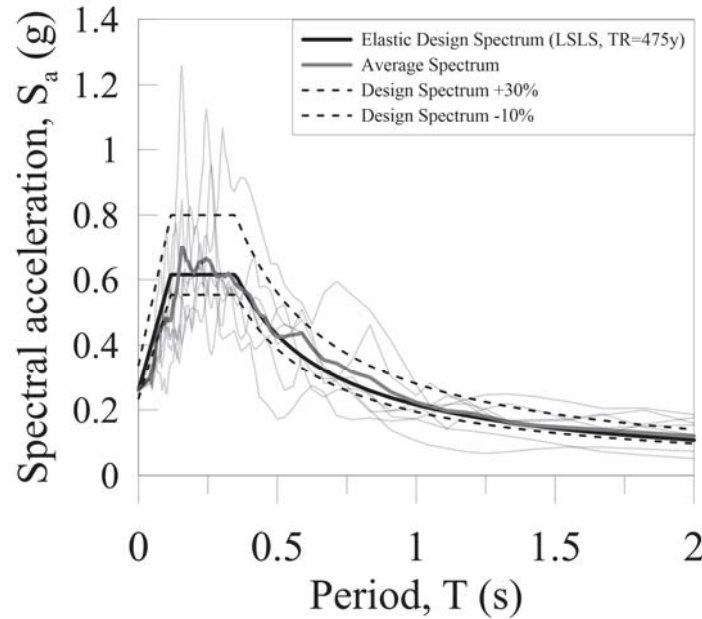

Figure 2. Spectro compatibility of the selected earthquakes with elastic design spectrum of Aquila centre at life safety limit state.

### 2.3 Structural models

The structural model is a linear elastic one bay one frame laying on shallow strip foundations. The foundations of the structures were modelled through the use of a non-porous linear elastic element volume with reinforced concrete properties ( $E=30000\text{Mpa}$ ,  $\nu=0.2$ ,  $\gamma=25\text{kN/m}^3$ ) while beam structural element were used to model the columns and crossbeams. The crossbeam length is equal to 5.00 meters while the distance between the strip shallow foundations ( $W$ ) is equal to 6.36 meters. The SDOF model would represent the main dynamic and static properties of masonry structures. In particular, in order to study the effect of the lateral disconnection on a structure with a different predominant period of vibration, the fixed base period of such structures was set at 0.3, 0.5, 0.8 and 1 sec, calibrating the stiffness of the columns beam and the mass of the crossbeam. Taking advantage of the Eurocode 8[10] formulation:

$$T_{\text{fixed\_base}} = C_t H^{0.75} \quad (1)$$

where  $T_{\text{fixed\_base}}$  is the fundamental period in seconds,  $H$  is the height of the building and  $C_t = 0.05$  is a constant depending on the type of earthquake resistant structural system, it is possible to estimate the total height of the prototype structure and, assuming an interfloors height equal to 3meter, estimate the specific number of floors associated at the fixed base period. Considering an unit load of 10kPa per floor it is possible to calculate the total mass to assign at the crossbeam and thus the stiffness of the column beam to ensure, respectively, the desired average bearing pressure on the soil and fixed base period.

In order to study the impact of the aspect ratio on the lateral disconnection technique, three different heights of the structures ( $H$ ), equal to 4.5, 5.8, 9.8 meters, has been considered. These heights correspond to the structure aspect ratio equal to 0.8-1-1.5.

The width of the strip footing shallow foundation ( $B$ ) was fixed at 1.4 meter while the embedment of the foundation ( $D$ ) was varied from 1.4 to 3.5 meters ( $D/B=1-2.5$ ).

In order to model correctly the contact between the foundation and the soil, interfaces along the foundation has been used assuming a reduction coefficient of 0.7 for the stiffness and strength properties at the interface. The stability of the small trenches, able to generate the lateral disconnection from the soil, is guaranteed by 4 cantilever walls. The viscous damping ratio of the structure is equal to 5% and was assigned to the columns beam with the double frequency approach. Table 2 summarize all the structural variable parameters considered to carry out the parametrical analysis and the fixed ones in the earthquake's analysis.

Type of analysis	Fixed Base period $T_{\text{fixed\_base}}$ (s)	Aspect Ratio $H/W$ (-)	Foundations Aspect Ratio $D/B$ (-)
Parametrical Analysis	0.3-0.5-0.8-1	0.8-1-1.5	1-1.5-2-2.5
Earthquakes Analysis	0.5	1.5	1.5

Table 2. Selected variable and fixed parameters for, respectively, the parametrical and earthquake analysis

## 2.4 Soil Material models

In order to evaluate the elongation of the natural period, the deformable soil was modelled as a homogeneous linear visco-elastic layer with different stiffness and damping properties (Table 3). The different stiffnesses of the soil analysed would represent a large spectrum of possible compliant base conditions for the structure. The bedrock has been modelled as visco-elastic half space with a damping ratio of 0.5%.

Soil type considered	Shear modulus $G$ (MN/m <sup>2</sup> )	Shear waves velocity $V_s$ (m/s)	Viscous Damping ratio (%)
Soil 1	200	350	1.42
Soil 2	141	300	1.60
Soil 3	94	250	2.00
Soil 4	58	200	2.5

Table 3. Different properties of the soil considered to carry out the parametrical analysis.

In order to evaluate the effectiveness of the lateral disconnection in the real earthquake's scenario, an equivalent visco-elastic model was used for the soil. In this case, the properties of Hostun Sand [11], at a relative density of 60%, was used (Table 4).

Maximum void ratio $e_{\max}$ (-)	Minimum void ratio $e_{\max}$ (-)	Specific gravity $G_s$ (-)	Relative Density RD (%)
1.01	0.555	2.65	60

Table 4. Properties of the Hostun Sand considered in the earthquake analysis.

To evaluate the increase of the shear modulus with depth the equation 1, by Hardin and Drenovich [12], was used with the specific parameter for Hostun Sand found by Hoque and Totquoka [13], (Table 5).

$$G_0 = A \cdot f(e) \cdot OCR^k \left( \frac{p'}{p_{ref}} \right)^m \quad (2)$$

Soil (-)	$A$ (-)	$f(e)$ (-)	$k$ (-)	$m$ (-)
Hostun Sand	80	$\frac{(2.17 - e)^2}{1 + e}$	0	0.47

Table 5. Specific parameters of Hostun Sand find by Hoque and Totquoka.

The different shear stiffness of the soil was assigned in the model considering different horizontal layers. In particular, 8 layers of 1 meter have been used for the first 8 meters while 6 layers of 2 meters have been used for the remaining 12 meters (Figure 3a). The mean curves of Seed and Idriss [14] has been selected to model the shear modulus reduction and the increase of damping with the shear strain (Figure 3b).

Figure 3. Properties of the sand used for earthquakes analysis: (a) Shear Modulus Profile with depth; (b) Shear modulus reduction and damping increase with shear strain by Seed and Idriss mean curves.

### 3 RESULT AND DISCUSSION

#### 3.1 Parametrical Analysis

Figure 4 summarize all the parametrical analysis carried out combining the different variable parameters.

Figure 4. Schematic representation of the parametrical analysis carried out.

From the 192 numerical analysis it was possible to understand the parameters that most influence the period elongation between the two structures. Figure 5 shows the period elongation ( $T_{Var} = (T_{disc} - T_{conn})/T_{conn}$ ) as function of the stiffness of the soil for different value of  $D/B$  with the aspect ratio ( $H/W$ ) equal to 0.7.

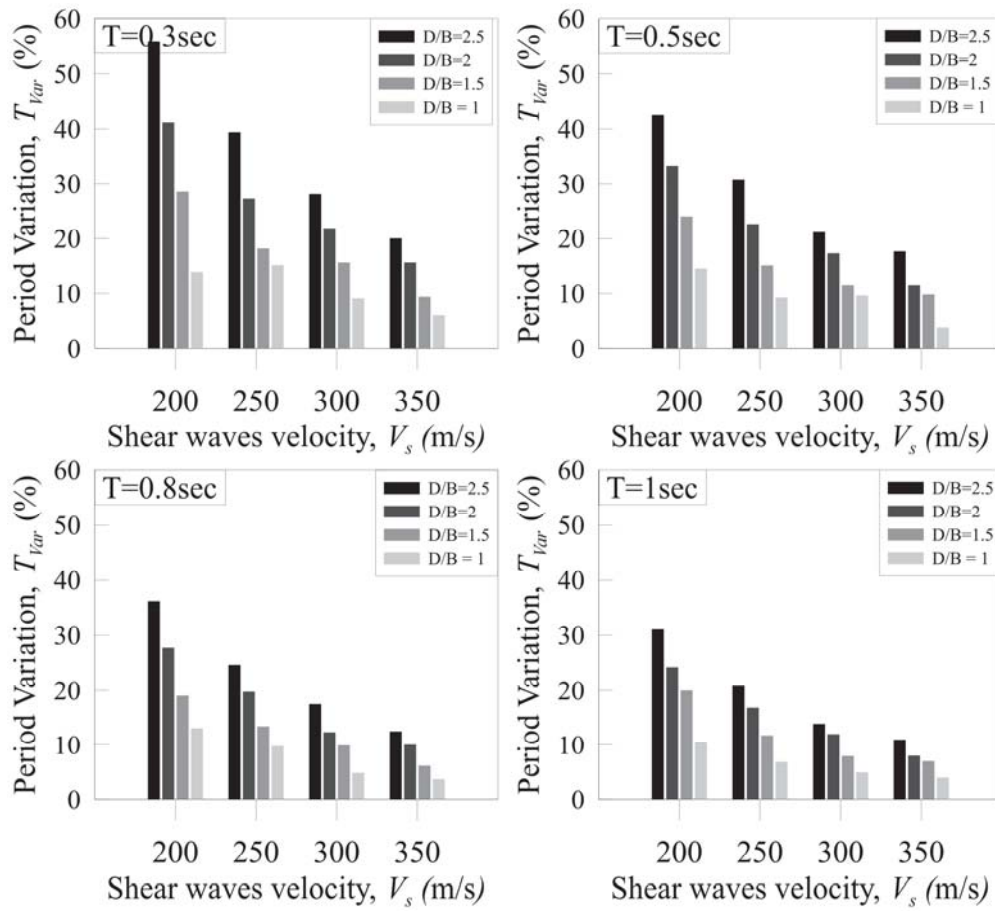

Figure 5. Period variation between the structures with and without lateral disconnection as function of the shear waves velocity and foundation aspect ratio.

It is clear that the period elongation is strictly depended on the value of the ratio  $D/B$ . In relative terms, scaling from  $D/B=1$  to  $D/B=2.5$  the period variation increases to 170% on average all scenarios. However, it is also possible to see, that the period elongation seems to increase as the stiffness of the subsoil decreased. In particular scaling from  $V_s=350$  m/s to  $V_s=200$  m/s the period elongation is increased by 160% on average. A possible explanation is that the high stiffness of the soil beneath the foundation inhibits the rotations more than the lateral soil and for this reason the two structures have almost the same natural period.

The results of the analysis also show that the period elongation seems to slightly reduce as the fixed base period increases. For this reason, the lateral disconnection technique could give more benefits, in terms of period elongation, especially for structures with low fixed base period.

All the results could be summarizing in Figure 7 where the relative soil-structure stiffness parameter,  $H/(V_s \cdot T_{Fixed Base})$ , is plotted against the elongation of period for different  $D/B$  values. Once again, as the stiffness of the structure increases related to the stiffness of the soil the predominant period of the lateral disconnected structure will increase up to 45-50% related to the no disconnected one.

Figure 7. Period variation generated by the lateral disconnection as function of the soil-structure stiffness parameter.

### 3.2 Earthquakes analysis

Two identical structures were modelled with and without the lateral disconnection with the properties reported in Table 2 and the soil properties of section 2.2. The numerical model was then subject to the earthquakes described in Section 2.1. Figure 8 shows the roof total acceleration for Campano Lucano and Friuli earthquakes.

Figure 8 Total crossbeam acceleration on the two-structure considered with and without lateral disconnection: (a) Campano Lucano Earthquake; (b) Friuli Earthquake

Due to the elongation of the predominant period generated by the lateral disconnection, the total roof accelerations are significantly different. Figure 9a shows the acceleration spectrum at the base of the structures with the indication of the elongated predominant periods.

Figure 9. Response spectrum acceleration with the indication of predominant period of the structures computing the S.S.I interaction.

The Arias Intensity variation ( $I.A. Var = I - I.A., LD / I.A., no LD$ ) and maximum total acceleration variation ( $a_{max Var} = I - a_{max, LD} / a_{max, no LD}$ ) provided by the lateral disconnection technique is shown in Table 6 for all earthquakes.

Record (-)	$I.A. Var$ (%)	$a_{max Var}$ (%)
Campano Lucano	80	62
Bingol	50	78
South Iceland	27	27
Mt. Vatnafjoll	64	29
Golbasi	11	0.3
Friuli	69	60
South Iceland(aftershock)	2	5

Table 6. Mitigation of the Arias Intensity and maximum total acceleration provided by the lateral disconnection.

Moreover, the beneficial effects of the lateral disconnection technique could be seen by comparing the structural drift (Figure 10). In fact, subtracting from the total horizontal displacement of the crossbeam the horizontal displacement of the foundations and the horizontal displacement generated by the rocking rigid movement of the structure, it is possible to calculate the structural drift.

Figure 10. Drift displacement with and without the lateral disconnection: (a) Campano Lucano earthquake; (b) Friuli earthquake.

#### 4 CONCLUSION

This paper has shown the potentiality of a new geo-technical seismic isolation technique called “Lateral Disconnection”. The reduction of the rotational and translational foundation-soil stiffness produced by the lateral disconnection leads to a period increase related to the classical embedment condition. This period lengthening was quantified through parametric analyses where the fixed-base period, the aspect ratio of the structure and foundations and the stiffness of the ground were varied. It was found that the aspect ratio of the foundations, as well as the stiffness of the ground, plays a key role on period lengthening. The more deformable the ground is and the more founded the foundation are, the greater will the period elongation produced by the lateral disconnection be. Under certain conditions the Lateral Disconnection technique can lead to an increase up to 45-50% of the predominant period of vibration related to the classical embedment foundations.

Following the parametric analyses, a series of compatible spectral earthquakes were used to show the effectiveness of such technique in terms of seismic actions (acceleration and drift) reduction. The maximum total acceleration reduction as well as the Arias Intensity reduction could be very high, up to 60%. Similar action reductions can be found if the maximum structural drift expected on the two structures is compared.

It is important to highlight that the lateral disconnection technique is not able to provide a total seismic isolation like rubber or sliding isolators but it can represent a valid seismic improvement strategy especially for its low cost and its low impact on the building. Like any anti-seismic strategy, its effectiveness must be studied in detail, on the basis of the local seismic

hazard and characteristics of the foundation, to predict, with a sufficient margin of reliability, the actions that will affect the modified structure.

### Abstract

*Essential facilities, such as hospitals, communication systems, highways, bridges, among others, play a significant role in a community. These facilities are vital, especially after being hit by a natural hazard. They must remain functional after a significant event to provide essential services to the community. The implementation of control systems during the structural design and rehabilitation stages enables an attractive manner for this type of structure to dissipate the dynamic response under major disturbance events. Typically, the design stage of structural control systems focuses its attention on the asset's structural configuration. Under seismic events, the structure's response can be altered by the interaction between the structure and the soil underneath. In this paper, the dynamic response's influence is evaluated through numerical simulation by including the effects of soil-structure interaction in a concrete moment resistant frame with viscous fluid-type energy dissipation systems. For this analysis, seven ground motion records were selected for the analysis, considering their frequency and source of content. These records are matched to the corresponding building code design response spectrum for areas prone to high seismicity. Similarly, the soil profiles used for the analysis correlates with the same seismic hazard zone. The analyzed structure corresponds to an essential facility of high importance modeled as a two-dimensional concrete moment resistant frame. The analysis is performed on a seven-story building implementing viscous dampers. Two cases are studied: implementing and neglecting the effects of the soil-structure interaction. The results for the case-study show a significant increase in the dynamic response in terms of displacement, inter-story drift, and base shear when considering soil-structure interaction.*

## 1 INTRODUCTION

For assets for the built environment, structural damage may occur due to medium to high-intensity seismic events. These effects can damage structural and non-structural elements, and on some unfortunate occasions, they have resulted in casualties. During the last decades, multiple researchers have focused their attention on alternatives for controlling the structure's response due to seismic loads in order to guarantee people's safety and to minimize the amount of inflicted damage into the buildings [1]. The seismic design aims to develop structural configurations to resist earthquake loads, providing reliability, durability, and, most importantly, minimizing casualties. Traditionally, the dissipation of energy has been considered by the deformation and damage of the building components. In the last decades, different methodologies have been developed for the design of structures (e.g., buildings, bridges, dams) with the objective of dissipating the energy while preserving the investment. For instance, displacement-based design and accounting for enough ductility into the structure are used alternatives for energy dissipation. The latter represents the basis of the current building design codes. Alternatively, there are other methods, such as the incorporation of energy dissipation systems, including base isolation, known as control systems. These systems are typically implemented on essential facilities to control the seismic response and remain functional during and after an earthquake [2-7]. Recently, it became evident that the traditional design of structures does not represent a sufficient solution to prevent the collapse of certain structures [8]. Rather, it is necessary to implement solutions that enable immediate occupancy while minimizing required repairs and functionality interruptions after medium to high-intensity earthquakes [8]. This can be achieved by incorporating control systems to reduce structure forces and displacements among seismic events. Incorporating control systems as an alternative for the design of new structures and the rehabilitation of existing structures is becoming more popular among building codes. Some examples of this implementation include the Colombian current code NSR-10 and the new one that is being developed AIS 700 (Asociación Colombiana de Ingeniería Sísmica), ASCE 7-16 (American Society of Civil Engineers), the Eurocode, and the Chilean Standard NCh. Additionally, previous studies have shown that the implementation of control systems may enable a life-time reduction of the structure's cost, in comparison with the cost associated with structures designed in a traditional manner, due to the capability to reach inelastic deformations during earthquakes, suffering minimal damage, providing post-earthquake operability, and reducing the need for repair [8]. Control systems have been implemented in multiple buildings around the world to reduce the dynamic behavior of the structure, for example: St. Francis Towers (Mandaluyong, Philippines), Churchill Hotel (San Diego, California, USA), King County Courthouse (Seattle, Washington, USA), Opera House (San Francisco, California, USA) and 3 Com (Foster City, California, USA) [9, 10].

However, these structures are typically designed neglecting any soil-structure interaction [11]. In structural dynamics, a structure's behavior is analyzed considering a set of discrete elements, modeled following a set of equations of motion to estimate displacements and stresses. For the case of soil dynamic analysis, the study is performed similarly while taking into account the effect of the soil, and therefore the resulting structure's displacements and stresses differ [12]. This effect is known as "Dynamic Soil-Structure Interaction" (DSSI). According to Kausel [13], the DSSI concept is hard to define completely. Still, in general terms, it refers to static and dynamic phenomena that occur between the ground and a much more rigid structure. For example, the seismic wave amplification in the ground and the dynamic interactions between different soil layers are factors to consider during a DSSI analysis. Other studies showed that DSSI consideration could significantly influence the dynamic response of structures [12-18]. This influence is mainly seen in three aspects: i) the change in the dynamic

characteristics of the soil-structure system such as frequencies and modes of vibration; ii) the increasing in damping within the system due to the transference of the structure's energy into the ground; and iii) the soil moving properties influence the analysis [11]. Recent studies have shown that the effects of the DSSI have a greater influence on the structural response in terms of base shear, performance level, and inter-story drifts when is supported on soft soils [17].

To evaluate the influence that the DSSI has on the response of concrete frames with viscous damper devices, we analyzed a seven-story concrete frame with and without implemented control systems. First, seven representative seismic records were selected, considering representative characteristics such as their frequency content. These records were matched to the corresponding response spectrum of a high seismic hazard zone, defined by the design codes. Subsequently, the matched records were filtered through a soil profile to obtain surface records. With the same profile data, the foundation stiffness was calculated at the surface level to perform a more accurate analysis of the structure and the soil at the transition zone between both systems. The soil stiffness and the earthquakes acting at the surface were considered during the analysis. For the seismic response analysis, the analytical model of the structure was done in the finite element software ETABS [21]. The analysis was performed for four cases: fixed and flexible base with and without viscous dampers. The results are presented in terms of the maximum inter-story drift, the base shear, and hysteretic curves for the viscous dampers. Although the complete analysis includes more models of structures with different characteristics (e.g., different number of bays, stories, dimensions) [22], only one structural model with seven stories and five bays are presented within this paper.

## 2 GROUND MOTIONS

### 2.1 Ground motion selection

For the dynamic analysis in the time domain, ground motion records must meet certain criteria [21, 22]: must be a minimum of three different acceleration records or the average value of seven acceleration records, all of them different and representative of the expected ground motions at that zone; they must be events with magnitude, distance to the seismic source and rupture mechanisms similar to the ones for the location of the case-study; and covering the broadest possible range of frequencies.

Following the guidelines outlined above, the seismic acceleration records were selected from the Pacific Earthquake Research Center (PEER), for the NGA-West2 database [25]. Ranges of magnitude and distance to the seismic source were established, according to the analysis of the disaggregation of the seismic threat of the seismic micro zoning project for the city of Cali, Colombia [26]. Two different searches were performed for the analysis: i) magnitude between 5.5 and 6.7 and a distance between 0 and 40 kilometers; ii) magnitude between 7.0 and 8.5 y distance between 110 and 180 kilometers. Also, an average shear wave velocity range of at least 500 m/s was required [27].

Table 1 shows the seven selected ground motion records and a summary of some of their most representative characteristics.

Event	Station	Year	Magnitude Mw	Distance to rupture sur- face (km)	Failure Mechanism	Vs30 (m/s)
ChiChi, Taiwan	TAP046	1999	7.62	118.34	Reverse Oblique	816.9
Kocaeli, Turkey	Eregli	1999	7.51	142.29	Strike Slip	585.09

Niigata	NIG023	2004	6.63	25.82	Reverse	654.76
Northridge-01	LA-Chalon Rd	1994	6.69	20.45	Reverse	740.05
Northridge-01	LA Dam	1994	6.69	5.92	Reverse	628.99
Northridge-01	Santa Susana Ground	1994	6.69	16.74	Reverse	715.12
San Fernando	Lake Hughes #12	1971	6.61	19.3	Reverse	602.1

Table 1: Selected ground motions.

## 2.2 Target response spectrum

The design elastic response spectrum was defined according to the Colombian NSR-10, whose parameters are shown in Table 2, taking into account an importance coefficient ( $I$ ) of 1.25. From this spectrum, the structure is designed without viscous dampers. For the structure with incorporated viscous dampers, a response spectrum of the maximum considered earthquake must be used. According to ASCE 7-16 [24], the response spectrum for the controlled structure must be determined using the code target spectrum amplified by 1.5. Figure 1 shows the two target spectra.

Ground seismicity	Soil Type	Importance Factor	$A_a$	$A_v$	$F_a$	$F_v$
High	D	III	0.25	0.25	1.30	1.90

Table 2: Parameters for the construction of the design spectrum according to Colombian design code NSR-10 [23].

Figure 1: Target response spectra.

## 2.3 Spectral matching

Considering that the acceleration records were selected from a location different than the one from the case-study, it is necessary to match these records according with the target spectrum. This matching process guarantees compatibility in terms of the frequency content and

tectonic regime between the acceleration records and the case-study location. Using the time domain matching methodology described in [28, 29], it is possible to modify the existing acceleration records while preserving the non-stationary character of the reference ground motion records. The methodology implements a tapered cosine wavelet for adjusting the acceleration records, resulting in records without drift in the corresponding displacements and velocities. This adjustment procedure ensures stability, efficiency, and speed in obtaining the numerical solution of the spectral match [29].

The acceleration records are matched to the target response spectrum employing the wavelet algorithm from SeismoMatch, a software by SeismoSoft [30]. Figure 2 shows the comparison between the original acceleration record for the 1971 San Fernando earthquake (recorded at the rock level), and the matched records with respect to the NSR-10 response spectrum and the maximum considered earthquake spectral response ( $MCE_R$ ).

Figure 2: Comparison of original and matched accelerogram records to the Colombian code NSR-10 and MCER target spectrum for 1971 San Fernando Earthquake.

Figure 3 shows the comparison of the mean matched spectrums to its respective target spectrum of the Colombian code NSR-10 (For the model without viscous dampers) and the  $MCE_R$  (For the model with viscous dampers).

Figure 3: Comparison of the Colombian NSR-10 and MCER target spectrum and their respective mean response spectrum for the original seismic records.

## 2.4 Non-linear properties of the soil

Generally, for stiff structural systems, foundation deformations can represent a significant component of system flexibility and ignoring it can result in bad characterization of properties as fundamental mode frequency and damping ratio [31]. Foundation damping results from the relative movements of the foundation and the supporting soil and these cause displacement and rotations of the structure relative to the free field. The difference between the foundation input motion and free-field motion gives rise to energy dissipation by radiation damping and hysteretic soil damping, and this affects the overall system damping [32].

Site effects are caused by the amplification of the seismic waves as they travel from the rock to the surface. This amplification is the result of the seismic wave traveling through the different layers from the soil profile. The most common physical properties used to characterize these soil layers include their thickness (H), the shear wave velocity ( $V_s$ ), the specific weight ( $\gamma$ ), the friction angle of the material ( $\Phi$ ), the modulus of elasticity (E), and the shear modulus (G) of the soil. Table 3 shows a summary of the soil layers implemented within this study and their representative characteristics.

Soil Layer	H [m]	$V_s$ [m/s]	$\gamma$ [kN/m <sup>3</sup> ]	$\Phi$ [°]	E [MPa]	G [MPa]
Surface Clay	4	157	18.5	25	123.11	46.28
Clay with lens	11	244	18.5	32	297.35	111.79
Hard Clay	7	570	20.0	33	1754.27	659.50
Peat Clay	8	736	21.8	42	3188.07	1198.52

Table 3: Soil profile data.

The implementation of the soil layers effects can be carried out using ProShake 2.0 [33], a software that finds the solution of ground response problem in the frequency domain, whose input acceleration records are represented as a sum of series of sine waves of different amplitudes, frequencies, and phase angles. Filtering the acceleration records using the transfer functions from the different soil layers, the response of the soil profile for each of the waves is obtained. Figure 4 and Figure 5 shows the rock records for the San Fernando earthquake and their comparison with the same record filtered through the soil profile.

Figure 4: Comparison of matched records to Colombian NSR-10 and the same records filtered through the soil profile for 1971 San Fernando earthquake.

Figure 5: Comparison of matched records to  $MCE_R$  spectrum and the same records filtered through the soil profile for 1971 San Fernando earthquake.

## 2.5 Soil structure interaction

Using the soil profile data shown in Table 3, the stiffnesses of the foundation are calculated at the surface level to posteriorly included in the flexible base model. This calculation is carried out using the following equations from [34]:

$$K_{x,sur} = \frac{GB}{2-\nu} \left[ 3.4 \left( \frac{L}{B} \right)^{0.65} + 1.2 \right] \quad (1)$$

$$K_{z,sur} = \frac{GB}{1-\nu} \left[ 1.55 \left( \frac{L}{B} \right)^{0.75} + 0.8 \right] \quad (2)$$

$$K_{yy,sur} = \frac{GB^3}{2-\nu} \left[ 0.47 \left( \frac{L}{B} \right)^{2.4} + 0.034 \right] \quad (3)$$

where,  $K_{x,sur}$ ,  $K_{z,sur}$ , and  $K_{yy,sur}$  are the stiffnesses for the translation along the X-axis, Z-axis, and the rocking effect about the Y-axis, respectively,  $G$  is the shear modulus,  $\nu$  is the Poisson ratio,  $B$  is the rectangular foundation width, and  $L$  is the rectangular foundation length.

For the flexible base model a foundation beam 0.60 meters wide and discretized in segments of 1.0 meters long, is implemented. Using equations 1 through 3, the following stiffness values are obtained:  $K_{x,sur} = 98752.0$  kN/m,  $K_{z,sur} = 127388.3$  kN/m, and  $K_{yy,sur} = 24402.8$  kN-m.

## 3 NUMERICAL MODEL

The seven-story frame is modeled in ETABS considering the geometry presented in Figure 6 for both cases with and without incorporating viscous dampers.

Figure 6: 7-story frame geometry for the case (a) without viscous dampers and (b) with viscous dampers. Dimensions in meters.

Structural elements are modeled using a value of concrete compressive strength of 28 MPa and reinforcing steel with yield strength of 420 MPa. The structural design of the case-study building is performed in accordance with the NSR-10 and performing a dynamic modal spectral analysis to determine that the maximum inter-story drift is less than established limit of one percent. Additionally, an adequate capacity of structural elements needs to be guaranteed with respect to the expected load demands that the structure is expected to withhold.

According to ASCE 7-16, the base shear used for the design of the main system for the structure with viscous dampers must not be less than 75 percent of the originally determined base shear. Consequently, the reduction in the lateral forces for the system results in a reduction on the transversal section of the structural elements from the main system.

Viscous dampers were incorporated into the model using link elements with a non-linear exponential damper. The non-linear properties were introduced considering a moderate damage level in a moderate-height building [35] and following the methodology presented in [36]:

Firstly, the response reduction factor  $B$  was calculated using the following equation:

$$B = \frac{D_{max}}{D_{obj}} \quad (4)$$

where  $D_{max}$  is the maximum drift obtained in the structural analysis and  $D_{obj}$  is the target drift, which in this case is 0.0051 for a moderate damage level according to [35]. A structure's effective damping of 35 percent is set as the target, meaning that viscous dampers must contribute to 30% of total structural damping. Then, the damping coefficient  $C$  was calculated for each floor using the equation below:

$$C = \zeta \frac{k_i}{\eta_i} * \frac{T}{\pi} * \frac{1}{\cos^2 \theta_j} \quad (5)$$

where  $\zeta$  is the damping ratio,  $k_i$  is the stiffness for the  $i$ -th story,  $\eta_i$  is the number of viscous dampers per story,  $T$  is the fundamental period of the structure, and  $\theta_j$  is the inclination angle for the viscous dampers.

The following non-linear properties for the viscous dampers were determined: damping coefficient  $C = 2553.59$  kN-seg/m, velocity exponent  $\alpha = 0.5$ , brace stiffness  $K = 202630.16$  kN/m, obtained by axial stiffness equation of a brace element using physical properties of a steel section HEB200. The maximum damper force can be obtained by using the equations shown on [36]:

$$F = C (V)^\alpha \quad (6)$$

$$V = \frac{2\pi}{T} 0.02xH_{story} \times \cos(\theta) \quad (7)$$

where  $F$  is the damping force,  $V$  is the velocity,  $T$  is the fundamental period,  $H_{story}$  is the height of the analyzed story, and  $\theta$  is the damper inclination angle.

### 3.1 Load considerations

A load assessment was carried out and summarized in Table 4Table 5.

Dead Loads	
Joist slab	3.00 kN/m <sup>2</sup>

Floor finishes	1.50 kN/m <sup>2</sup>
Facade and partition walls	3.00 kN/m <sup>2</sup>
Mechanical, electrical and plumbing systems (MEP)	0.55 kN/m <sup>2</sup>
Ceiling finishes	0.25 kN/m <sup>2</sup>
<b>SUM OF DEAD LOADS</b>	<b>8.30 kN/m<sup>2</sup></b>

Table 4: Dead loads included in the analysis of the seven-story frame building.

Live Loads	
Operating room	4.00 kN/m <sup>2</sup>
<b>SUM OF LIVE LOADS</b>	<b>4.00 kN/m<sup>2</sup></b>

Table 5: Live loads included in the analysis of the seven-story frame building.

## 4 RESULTS

Table 6 shows the Peak Ground Acceleration (PGA) values of the original, matched and filtered acceleration records and it shows that PGA for the matched records to  $MCE_R$  have an increase of approximately 50% comparing them to the matched records to the NSR-10.

Similarly, Table 7 shows the maximum Fourier amplitude for an analysis in the frequency domain. A graphic example of frequency content is shown for the San Fernando Earthquake on Figure 7. It is important to notice that the maximum Fourier amplitude has an average increase of 80% when the soil effects are considered.

Earthquake	Original Record	PGA			
		Matched NSR-10		Matched $MCE_R$	
		Rock	Surface	Rock	Surface
ChiChi	0.083	0.622	0.671	0.953	0.912
Kocaeli	0.087	0.404	0.623	0.596	0.998
Niigata	0.405	0.734	0.774	1.093	1.019
Northridge CHL	0.183	0.562	0.678	0.806	0.926
Northridge LDM	0.324	0.569	0.897	0.864	1.181
Northridge SSU	0.231	0.533	0.717	0.755	0.860
San Fernando	0.282	0.527	0.764	0.887	1.063

Table 6: PGA comparison between the different evaluated cases.

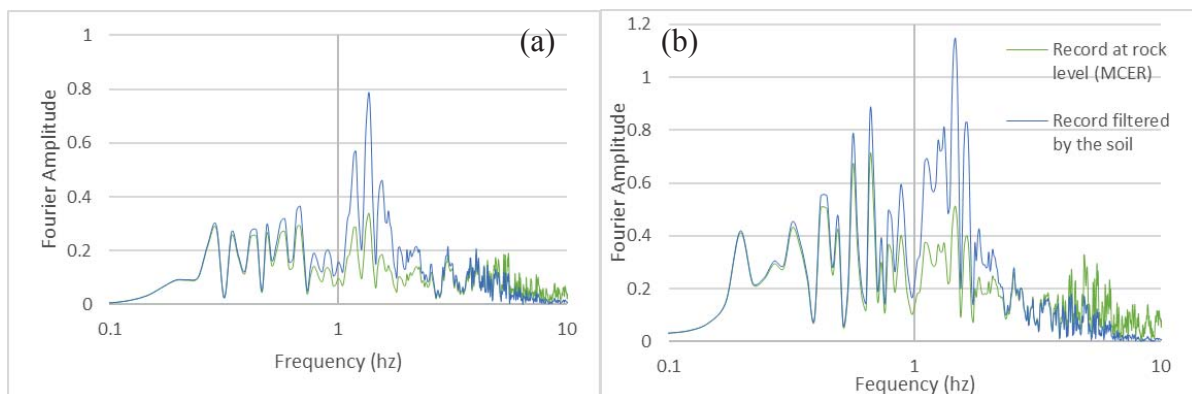

Figure 7: Frequencal content for matched record to the (a) Colombian Code NSR-and the same record filtered through the soil profile for San Fernando earthquake; (b) ASCE 7-16 Spectrum and the same record filtered through the soil profile for San Fernando earthquake.

Event	Original Record	Maximum Fourier Amplitude			
		Matched NSR-10		Matched MCE <sub>R</sub>	
		Rock	Surface	Rock	Surface
ChiChi	0.063	0.445	1.081	0.738	1.508
Kocaeli	0.102	0.613	1.192	0.873	1.390
Niigata	0.140	0.364	0.689	0.518	1.048
Northridge CHL	0.202	0.396	0.785	0.692	1.194
Northridge LDM	0.243	0.379	0.716	0.527	0.875
Northridge SSU	0.142	0.419	1.080	0.537	1.067
San Fernando	0.144	0.338	0.786	0.705	1.148

Table 7: Maximum Fourier amplitude comparison between the different evaluated cases.

For the structural model, the fundamental period for each case is shown in Table 8. The increment in the fundamental period for the structures with the viscous dampers results from the reduced section in structural elements (i.e., reduced stiffness).

Case	Fundamental period (s)
Fixed base without viscous dampers	0.354
Flexible base without viscous dampers	0.382
Fixed base with viscous dampers	0.450
Flexible base with viscous dampers	0.484

Table 8: Fundamental periods for studied cases.

Table 9 show the maximum displacement and acceleration values for response of the structure's top floor, showing values for all seven earthquake records for the 7-story frame building with viscous damper incorporation for the fixed base case and flexible base case, respectively.

Event	Maximum Displacement (mm)		Maximum Acceleration (m/s <sup>2</sup> )	
	Fixed Base	Flexible Base	Fixed Base	Flexible Base
ChiChi	23.7	50.4	10.3	7.7
Kocaeli	26.1	52.9	12.0	13.2
Niigata	38.1	62.2	14.3	11.9
Northridge CHL	23.3	52.7	10.4	8.3
Northridge LDM	24.0	66.1	12.4	13.3
Northridge SSU	24.7	51.6	13.0	10.9
San Fernando	25.0	64.2	11.9	10.8

Table 9: Maximum displacement and acceleration values for the seven records.

The inter-story drift response is also shown in Figure 8 for the fixed base model and the flexible base model incorporating viscous dampers.

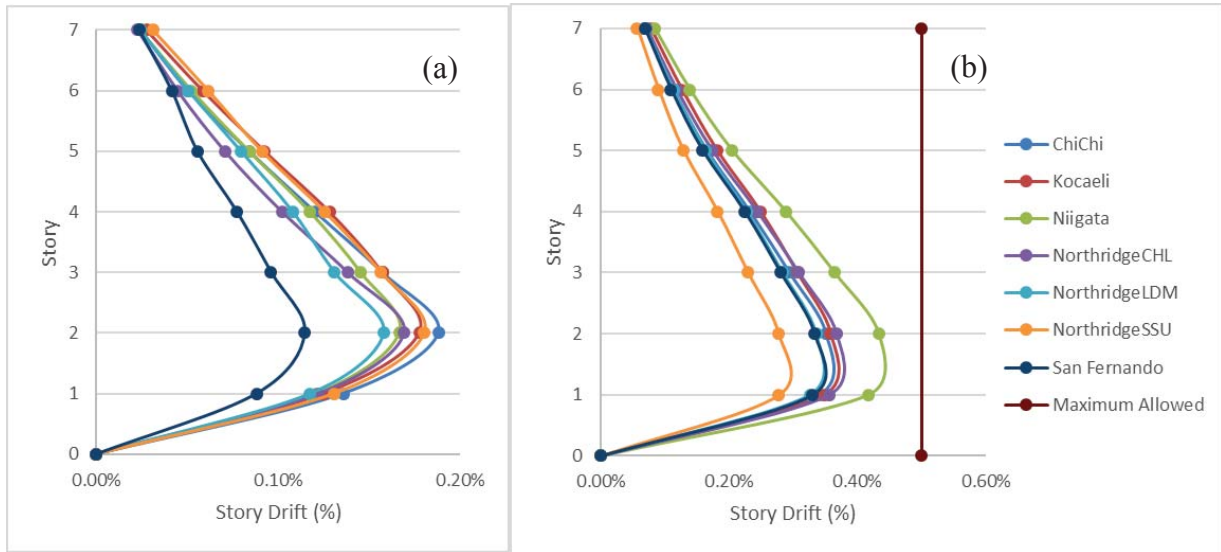

Figure 8: Maximum drift ratio for (a) fixed base model incorporating viscous dampers and (b) flexible base model incorporating viscous dampers.

The inter-story drift has an average increment of 117% for the flexible base than the fixed base case. But for both cases with viscous dampers, the maximum drift is below the limit for a moderate damage level (0.5 percent), according to Hazus [35].

The distribution of the story shear forces for both cases with viscous dampers are shown in Figure 9.

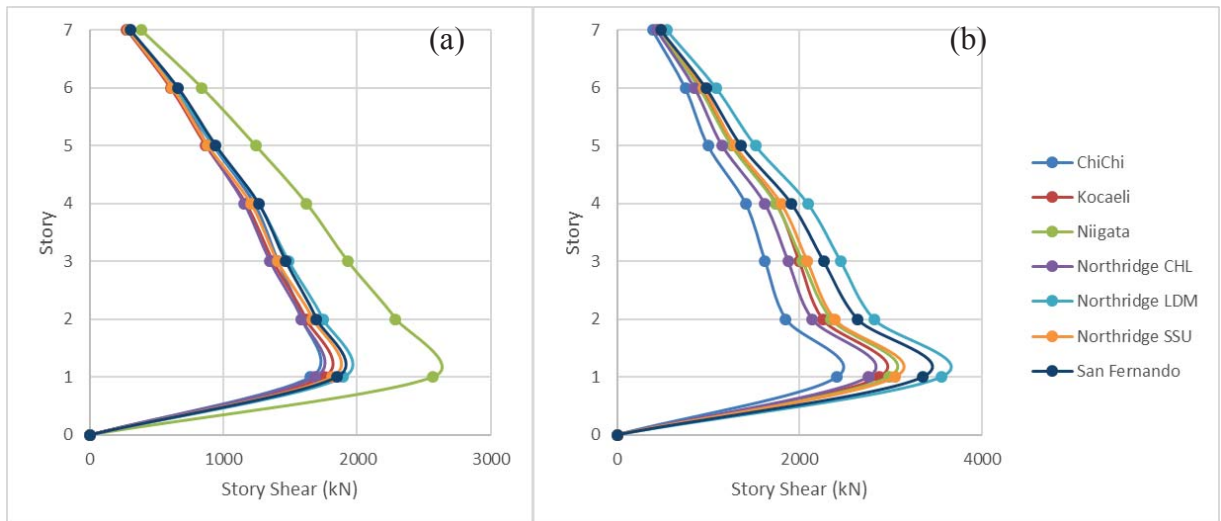

Figure 9: Shear distribution for (a) fixed base model incorporating viscous dampers and (b) flexible base model incorporating viscous dampers.

The maximum shear force increases on average 61% for the flexible base case with respect to the fixed base case.

The obtained results for the viscous dampers show stable hysteretic cycles. For space reasons, two hysteretic curves of the second-story viscous damper were presented for the Kocaeli earthquake for fixed-base and the flexible base cases (Figure 10).

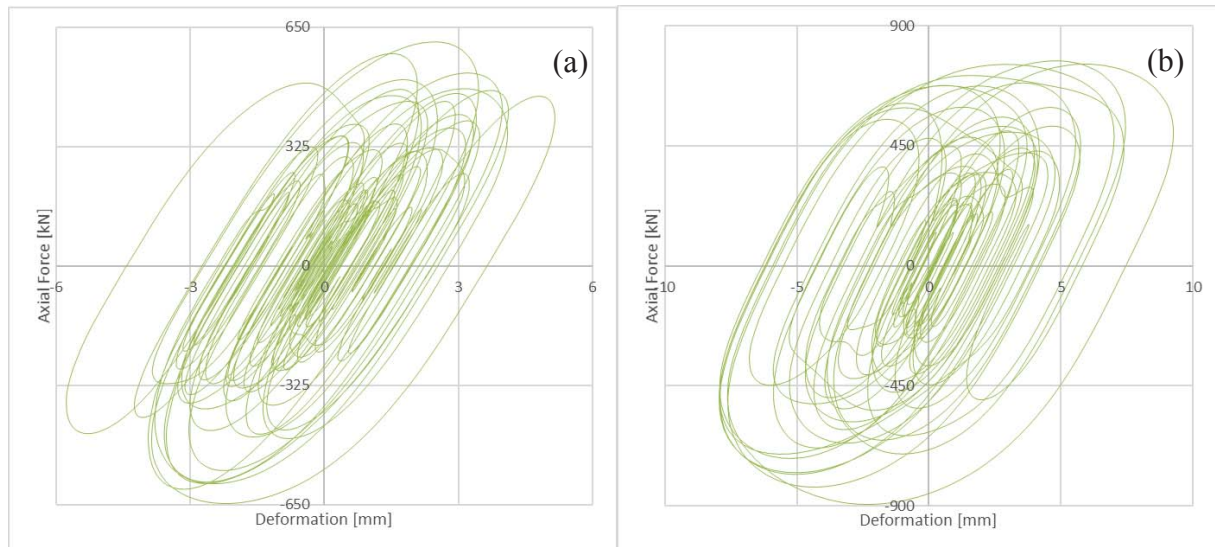

Figure 10: Hysteretic curve for K13 for Kocaeli earthquake of (a) fixed base model and (b) flexible base case.

The figures show that the dampers were successfully dissipating energy and reducing displacements of the structure. The maximum forces and deformations increased for the flexible base model, meaning that the viscous dampers have a wider working range when the soil effects are considered.

## 5 CONCLUSIONS

The SSI effects for concrete frame structures implementing viscous dampers have been investigated. The following conclusions were determined for the 7-story frame building used as case-study:

- In a comparison between the models with fixed and flexible base, the average inter-story drift increased by approximately 115 percent when the SSI is considered. Similarly, the maximum story shear force increased on average by approximately 60 percent for the model with flexible base.
- The results of the study show that the acceleration and displacement responses have inversely proportional effects when SSI is considered. Although the maximum displacement increased on average by approximately 120 percent, the acceleration response shows a slight noticeable reduction of less than 20 percent.
- For both cases implementing viscous dampers, the devices had a stable behavior and a good performance dissipating the energy. The use of viscous dampers enables the dynamic control during a seismic event, which may result in a reduction in the amount and the level of damage that both structural and non-structural elements can sustain. This is the result of the additional capacity to dissipate the energy provided by the control systems.
- There is a noticeable difference of the results when the SSI effects are considered in the analysis. For the case-study, the displacement and distribution of shear forces increases for the selected characteristics of the soil supporting the structure. Therefore, it is of high importance to consider the SSI effects when performing any type of global analysis of structures, and even more significant when the structure is categorized of high importance for a community.

### Abstract

Geotechnics and the study of the behavior of soil with the construction inserted in it is of extrema importance. This study aims at the computational analysis of a group of three reinforced concrete piles with axial and horizontal loads. The piles were inserted in non-cohesive soil (medium and dense sand). The geometric parameters of the piles (diameter, distance between them, and length) and physical parameters of the soil (stratification and angle of friction between them) were varied. The GEO5 "Pile Group" program, the NAVFAC DM 7.2 method was used to determine the bearing capacity. The Poulos & Davis (1980) and FEM methods for settlement, and the p-y method (FEM) to determine the internal forces distribution. The efficiency of the piles is more sensitive the more the distance between them varies. For settlement, Poulos & Davis values are sensitive to distance and diameter, and in FEM they are more sensitive to diameter and length variation.

**Keywords:** Pile group. Computational analysis. Axial load capacity. Horizontal load capacity. Settlement. Group efficiency. Horizontal displacements. Seismic activity.

---

## 1 INTRODUCTION

Knowing the soil and its movements is essential for structural design. Predicting soil behavior is a difficult task due to the heterogeneity of the rock or earth mass, which prevents precise and consistent characteristics. However, it must be ensured that there are no construction failures without over-design.

This study uses deep foundations, which dissipate the loads of the construction into deep soil beds. The objective is to determine the sensitivity of the bearing capacity (with the NAVFAC DM 7.2 method), settlement (Poulos & Davis (1980) and FEM methods), and group efficiency to variations in the piles and soil using the geotechnical analysis software GEO5 version 2020.

Soil has always occupied an important position in human evolution and engineering. The study of soil and its movement is known as geotechnics and dynamics. This knowledge helps to determine the physical and mechanical characteristics of soil, and thus to design its behavior under loads.

Usually, soil studies using empirical methods are found in the academy, which project local results for total volume. Even though they are close to the real ones, the results do not accurately describe soil behavior, which allows design errors. In deep foundations, the error can be even greater because they are inserted in numerous soil layers with different properties. Thus, the construction may encounter unexpected conditions and cause problems in the dispersion of loads.

Finally, studies such as this computer simulation are very important, enabling a range of information from different methods, soils, foundation solutions, and soil stratifications.

## 2 BIBLIOGRAPHIC REVIEW

Deep foundations are necessary when the uppermost soil layers are not strong enough for the building. Therefore, the foundation must reach deep into the soil. The pile group consists of elongated cylindrical or prismatic pieces, which can be precast or cast in the field, joined by a pile cap.

### 2.1 Load capacity

The distribution of structure loads through the piles is carried out in two components. The lateral frictional mobilization along the vertical axis, also called shear, is the  $R_{sk}$  component. The tip or base resistance is the  $R_{bk}$  component. All foundations use both components to transfer their loads. If more than 80% occurs through lateral resistance, the pile is called a floating pile. If 80% of the total occurs through tip resistance, the pile is called a tip pile. The sum of the two components results in the total load capacity of the pile ( $R_k$ ).

For non-cohesive soils, the method of foundation execution must be considered. This is done using the coefficient  $N_q$ , which depends on the angle of internal friction of the soil. For stratified soil, the value corresponding to the greatest angle of friction should be used. The equations determine how the forces are calculated, and the tables show the fixed values.

$$q_{bk} = \gamma D N_q = \sigma'_{vb} N_q \quad (1)$$

$$q_{sk} = \sigma'_n \tan \delta = K \sigma'_v \tan \delta \quad (2)$$

- Where:  $\sigma'_{vb}$ : Effective vertical stress at the base of the pile [kN/m<sup>2</sup>]  
 $\sigma'_v$ : Effective vertical stress in the pile vertical axis [kN/m<sup>2</sup>]  
 $K$ : Lateral thrust coefficient  
 $\delta$ : angle of friction between soil and pile ( $\frac{3}{4}$  of angle of internal friction)

For the bearing capacity it should also be said that the greater the depth in the soil, the greater the limit capacity of the pile. The critical depth is the quota that determines constant capacity values and is determined by the figure below [5].

Figure 1: Abacus used for the calculation of the critical depth. [5]

## 2.2 Group load capacity

For a group of piles, Prakash & Sharma (1989) determine that the minimum value of distance between elements should be three times the value of the diameter. If this heat is not placed, the group may behave as a single block.

When piles are placed in a group, there is an influence on the distribution of stresses and soil movement between them, called the group effect. This effect causes the piles not to perform at 100% of their capacity.

The expression that calculates the actual load capacity value is shown below.

$$R_{k;G} = \eta * n * R_k \quad (3)$$

- Where:  $R_{k;G}$ : Pile group load capacity [kN]  
 $\eta$ : Group Efficiency Factor [-]  
 $n$ : Number of piles in the group  
 $R_k$ : Pile load capacity [kN]

To calculate the efficiency factor, there are numerous methods. But none of them is completely reliable, the most widely used being that of Converse-LaBarré (1941), whose equation is shown below.

$$\eta_g = 1 - \psi \left[ \frac{(n_x-1)n_y + (n_y-1)n_x}{90n_xn_y} \right] \quad (4)$$

Where:  $\eta_g$ : Efficiency of the pile group

$\psi$ : Angle with tangent expressed in degrees  $\tan \psi = \frac{d}{s}$ , where s is the axial spacing between piles and d is the diameter of the piles.

$n_x$ : Number of piles in the x direction.

$n_y$ : Number of piles in the y direction.

## 2.3 Horizontal load capacity and displacements

Besides axial loads, structures can suffer horizontal loads, generating displacements, rotations, and bending moments. These loads can occur due to structural requests or, mainly, due to internal soil actions (seismic activities).

For the construction to be safe regarding these loads, it must present materials and strength that avoid rupture and control deformations along the pile [1].

There are many possible methods for structural behavior analysis, but the one that stands out as to its simplicity and coherence with reality is the p-y method, based on the finite element method and Winkler's model (spring method) [2].

### 2.3.1. Winkler Model (Spring Method)

This method was proposed in 1867, it considers the soil as a set of independent springs of elastic and linear behavior. The stiffness of these springs is numerically equal to the unit reaction coefficient of the soil ( $k_h$ ). These values vary with the soil composition and vary according to the following table [2].

Soil	$k$ [MN/m <sup>3</sup> ]
Dense sand	155 – 300
Medium Sand	110 – 280

Table 1: Unit reaction coefficient of soils according to Bowles [2] (adapted).

The final equation of the model follows Hooke's Law, and relates the modulus of elasticity of the pile and the moment of inertia with the soil and its respective displacement.

To determine the resulting values, the pile is considered as floating, in addition to considering the soil characteristics and the type of connection that the pile makes with the heading massif (fixed or with joints).

The GEO5 software determines that you should reduce the stiffness of a unit pile according to the position it is in the group. For horizontal stiffness, the value is reduced by 50% for external positions and 25% for internal ones. As for vertical springs, the reduction is 50% and 10% for exterior and interior positions.

### 2.3.1. P-y method

The p-y curve is a solution of the equation from the previous method. The vertical axis represents the applied load P and the horizontal axis represents the displacement y of the structure. This curve is a non-linear relationship, but it is common to consider it as linear for simplification of the calculations. [2]

The main advantage of this method is that it does not depend on the geometry nor the stiffness of the piles, and it can be used for numerous practical cases [11].

As a disadvantage, Budhu (2013) points out that the method does not consider the soil continuity effect and does not consider the shear strength of the soil, which can generate differences between the calculations and what happens. [10]

## 2.4 Settlement

The settlement of a structure is the displacement of the soil around it, causing vertical displacement. The values can vary for each element of the structure, with the total value being the sum of each. The total value for a group of piles is many times greater than that of an isolated pile, since one element generates the influence over the other as already explained in the group effect. [10]

There are many possible methods to use to estimate settlement, and it is necessary to analyze which one best suit the needs of the project in question. These values are difficult to estimate, they depend directly on the history of stresses over the years in the soil, the way the loads dissipate, the construction method used, among many other factors. [11]

The two types of methods used in this study are that of Poulos & Davis 1980 (theoretical analytical) and that in the finite element method (empirical).

### 2.4.1. Finite element method (FEM)

The finite element method subdivides the pile into small segments, thus determining the displacement for each of them. The total settlement value is the sum of these results. The method also takes into consideration analysis points at the interface between the pile and the soil, promoting values more consistent with reality.

This method also uses the endometric modulus, which determines the compression that occurs in the soil when the foundation is inserted. The equation that determines the settlement of each layer is presented below.

$$s_i = \sum \frac{\sigma_{z,i} h_i}{\frac{E_{def}}{\beta}} \quad (5)$$

Where:  $h_i$ : Layer thickness i.

$\sigma_{z,i}$ : Vertical component of the stress increase at the center of layer i.

$E_{def}$ : Soil deformation modulus.

$\beta$ : Ground scattering angle.

### 2.4.2. Poulos & Davis (1980)

This method is based on the theory of elasticity and considers the soil to have constant and unchanging characteristics, so the soil is homogeneous, isotropic, and elastic. In addition, the authors consider the distribution of stresses along the shaft to also be uniform, and that the resulting settlement values are proportionally linear to the requesting loads.

To determine the maximum settlement of a unit pile, the method uses the equation below.

$$S_{max} = \frac{R_{bk}}{\alpha d E_s} + \left[ R_{bk} - \frac{R_{sk}}{(1-\alpha)} \right] \frac{L}{A_p E_p} \quad (6)$$

Where:  $S_{max}$ : Maximum Pile Settlement.

$R_{bk}$ : Peak load capacity.

$R_{sk}$ : Lateral load capacity.

$E_s$ : Average soil modulus of elasticity.

$d$ : Pile diameter.

$\alpha$ : Proportion of applied load transferred by the base.

$A_p$ : Cross sectional area.

$E_p$ : Modulus of elasticity of the pile.

For group of piles, the study is an extension of the application for a single pile, with the total value multiplied by the group settlement factor. This factor depends on the distance between the elements of the group. The greater the distance, the lower the reduction factor, the inverse occurs for very close piles. The factor ranges from 1 (isolated piles) to values higher than 10 (piles working as a single block). Its use is presented by the equation below.

$$s_g = g_f \cdot s_0 \quad (7)$$

Where:  $s_g$ : Total settlement of the pile group.

$g_f$ : Pile Group Settlement Factor.

$s_0$ : Laying of an isolated pile.

$\beta$ : Ground scattering angle.

## 3 WORK PROGRAM

This paper analyzes a group of three axially and horizontally loaded piles using the geotechnical analysis software GEO5 version 2020. The foundation is inserted in a non-cohesive soil (medium and dense sand). It was verified the behavior of bearing capacity, settlement, and efficiency of the pile group with the variation of geometric parameters of the piles and soil parameters. The diameter, length and distance of the piles, and the internal friction angle of the medium sand were varied. The Spring (Winkler) method was used for determining the

displacements. For the load capacity study, the NAVFAC DM 7.2 method was used. Finally, for the settlement analysis was used the FEM and the method of Poulos & Davis (1980).

The following image represents the three-dimensional model, the stratification and the axes considered in the simulations.

Figure 2: Representation of soil stratification [First author].

Figure 3: Top view of the pile group and representation of the axes used [first author].

The following tables show the variables and properties of the pile materials and the two soil types.

Piles	
Number of piles	3
Length (L)	10, 15 e 20 m
Diameter (D)	0.4, 0.6 e 0.8 m
Ratio s/d (ratio between the distance and the diameter)	2, 3 e 4
Group efficiency $\eta_g$ (LáBarré)	0.66, 0.76 e 0.82
Axial loads	1980, 2280 e 2460 kN
Horizontal loads	396, 456 e 492 kN
Deformability modulus of concrete	$E_{def} = 29$ GPa
Poisson coefficient of concrete	$\Theta = 0.2$
Characteristic Strengths of concrete	$f_{ck} = 20$ MPa (compression) $f_{ct} = 2.2$ MPa (traction)
Concrete elasticity modulus	$E_{cm} = 29$ GPa
Tensile strength of steel	$f_{yk} = 500$ GPa
Modulus of elasticity of steel	$E = 200$ GPa

Table 2: Variables and properties of the pile materials [first author].

Soil		
Characteristic	Medium Sand	Dense sand
Soil Stratification (m)	L-L3	L3=3xD
Poisson coefficient	$\Theta = 0.35$	
Dry specific weight (kN/m <sup>3</sup> )	19	21
Saturated specific weight (kN/m <sup>3</sup> )	21	23
Soil modulus of deformability (MPa)	50	150
Unit reaction coefficient k (MN/m <sup>3</sup> )	113, 128 e 143	240
Internal friction angle $\Phi$ (°)	26, 28 e 30	40
Soil Cohesion (kPa)	0	
Critical depth	$k_{dc} = 12.5$	

Table 3: Variables and properties of the soils [first author].

## 4 RESULTS AND DISCUSSIONS

To generate the results, the load capacity coefficient  $N_q$  was considered equal to 72, because it corresponds to the value for the 40° internal friction angle of dense sand.

In total 81 simulations were carried out, and problems were observed in some of them. The models with pile lengths of 15 and 20 meters, diameter of 0.4 meters and s/d ratio of 2 and 3, presented excess reinforcement (ratio) with the necessary sizing. However, they will be considered to recognize the sensitivity of the factors.

### 4.1 Load capacity

The analysis is separated in three parameters: the normal end strength ( $q_b$ ), the shear strength ( $q_s$ ) and the pile efficiency  $\eta$ . In the examples of each parameter the intermediate case was sought, which represents the simulations in its great majority.

#### 4.1.1. Normal tip resistance ( $q_b$ )

The tip strength indicates the stress that is transferred to the soil through the cross-sectional area of the pile. It was observed that by increasing the length of the piles, there was an increase in resistance. As for example in the 0.6 meters diameter model with the values are 5,974.43 kPa, 8,710.44 kPa (+45.8%) and 11,446.42 kPa (+91.6%) respectively at 10, 15 and 20 m.

With increasing diameter, the resistance hardly changes. As for example in the model with length 15 m, ratio  $s/d=3$  and friction angle equal to  $28^\circ$  with strength of 8,650.72 kPa, 8,710.44 kPa (+0.7%) and 8,770.12 kPa (+1.4%) respectively at diameters of 0.4, 0.6 and 0.8 m.

As the distance between the piles increases, there is a considerable increase in resistance. This is what is seen in the example of length 15 m, diameter 0.6 m and internal friction angle  $28^\circ$ , with strength of 7,564.33 kPa, 8,710.44 kPa (+15.2%) and 9,398.10 kPa (+24.2%) respectively at  $s/d$  values of 2, 3 and 4.

With increasing the internal friction angle of the medium sand, no change in resistance occurs. As an example, the simulation of 15 m length, 0.6 m diameter and  $s/d=3$  ratio, the resistance value of 8,710.44 kPa is the same for the  $26^\circ$ ,  $28^\circ$  and  $30^\circ$  angles.

It was observed that what generates change in the ultimate strength is the variation in pile properties. The change in the soil friction angle does not affect the results.

#### 4.1.2. Shear or lateral resistance ( $q_s$ )

The lateral resistance indicates the dissipation of loads into the soil through the lateral area along the pile shaft. For the increase of the length of the pile, the lateral resistance hardly changes. As for example in the 0.6 meters diameter pile,  $s/d=3$  ratio and  $28^\circ$  internal friction angle, with values of 22.69 kPa, 22.35 kPa (-1.5%) and 22.18 kPa (-2.3%) respectively for lengths of 10, 15 and 20 m.

For the increase in diameter, there is also an increase in resistance values. This is visible with the model with a length of 15 m, ratio  $s/d=3$  and  $\Phi=28^\circ$ , and the values 15.17 kPa, 22.35 kPa (+47.3%) and 29.27 kPa (+92.9%) respectively for diameters of 0.4, 0.6 and 0.8 m.

When increasing the distance between the piles, an increase in resistance occurs. For example, the simulation of  $L=15$  m, 0.6 m diameter and  $28^\circ$  friction angle, with lateral strength of 19.41 kPa, 22.35 kPa (+15.2%) and 24.12 kPa (+24.2%) corresponding to  $s/d$  ratios of 2, 3 and 4 in order.

Finally, for the increase of the internal friction angle of the medium sand, the resistance also increases a little. This can be verified in the example of length 15 m, diameter 0.6 m and ratio  $s/d=3$ , being the strength 21.80 kPa, 22.35 kPa (+2.5%) and 22.99 kPa (+5.5%) respective to angles  $26^\circ$ ,  $28^\circ$  and  $30^\circ$ .

The following table summarizes the variations generally observed in the analyses and the sensitivity for each parameterization.

Parameter	$Q_b$	% medium	$Q_s$	% medium
increase of L	increases	50%	decreases and increases	2%
increase of D	increases	2%	increases	50%
increase of $s/d$	increases	15%	increases	15%
Increase of $\Phi$	equal	-	increases	2,5%

Table 4: Abstract of sensitivity of the strengths to the increase in the variables studied [first author].

### 4.1.3. Pile efficiency ( $\eta$ )

The pile efficiency is given by the ratio between the total capacity and the theoretical excavated volume ( $R_c/V$ ). As for increasing the length, diameter, and internal friction angle of the medium sand, one can notice derisory changes in efficiency (very low percentages).

The only parameter that generated significant changes in the load transmission efficiency was the increase in the distance between the piles. To exemplify, the simulation with 0.6 m diameter, 10 m length and internal friction angle of  $28^\circ$ , with efficiency of 650.23 kPa, 748.74 kPa (+15.2%) and 807.86 kPa (+24.2%) for s/d ratio of 2, 3 and 4 in order.

The most important thing to analyze in this topic are the values of the most and least efficient piles, which are represented by A and B in the following table.

L	D	s/d	$\Phi$ medium sand	$R_s$	$Q_s$	$R_b$	$Q_b$	$R_c$	$R_c/V$	$R_s/R_c$	$R_b/R_c$
(m)	(m)	-	( $^\circ$ )	(kN)	(kN/m <sup>2</sup> )	(kN)	(kN/m <sup>2</sup> )	(kN)	kPa	(%)	(%)
10	0.6	4	30	470.77	24.98	1822.59	6446.09	2293.36	<b>811.11</b>	20.5	79.5
20	0.4	2	26	316.73	12.60	1242.62	9888.47	1559.36	<b>620.45</b>	20.3	79.7

Table 5: Abstract of sensitivity of the strengths to the increase in the variables studied [first author].

With the previous table it is observed that the least efficient pile was characterized with the largest length, the smallest diameter, the smallest s/d ratio, and the smallest angle of internal friction of the medium sand. The best performing pile, on the other hand, was characterized by the shortest length, largest diameter, largest s/d ratio and largest angle of internal friction. In addition, it is observed that the percentage of load mobilization by lateral friction and by tip resistance in both cases are practically equal.

Finally, one should always remember that each project requires a thorough study of its needs, considering all available resources, material and financial.

## 4.2 Settlement

In this topic some simulations will be discarded. In the models with excess steel, the settlement by the Poulos & Davis method is not generated by the software. These are the simulations characterized by  $L=15$  m,  $d=0.4$  m and  $s/d=3$  and 4, and  $L=20$  m,  $d=0.4$  m and  $s/d=3$  and 4. Another group of simulations will not be used since, for no apparent reason, GEO5 also did not generate results, these are those for  $L=10$  m,  $d=0.4$  m and  $s/d=3$  and 4.

### 4.2.1. FEM

In this method all piles were considered as floating, with the value of the tip resistance equal to zero and the loads distributed only along the shaft.

For the increase in length, a decrease in settlement was observed. As for example the model with 0.6 m diameter, internal friction angle  $28^\circ$  and s/d ratio equal to 3, and maximum settlement values of 7.50 mm, 6.50 mm (-13.3%) and 6.00 mm (-20%) for the lengths 10, 15 and 20 m.

With the increase of the diameter, there was a reduction of the maximum settlement. This is exemplified by the model with length equal to 15 m, angle  $\Phi=28^\circ$  and distance ratio between piles equal to 3, with values of 11.00 mm, 6.50 mm (-40.9%) and 4.60 mm (-58.2%) of settlement, respective to diameters of 0.40 m, 0.60 m and 0.80 m.

The increase of the distance between the piles generated an increase in the final maximum settlement. As for example the model  $L=10$  m, diameter of 0.60 m and  $\Phi=28^\circ$  with values of 7.10 mm, 7.50 mm (+5.6%) and 8.10 mm (+14.1%) of maximum settlement for  $s/d$  ratios of 2, 3 and 4.

Finally, for the increase of the angle of internal friction, a decrease in the maximum settlement value is observed. Which can be verified with the example of  $L=15$  m,  $s/d=3$  and diameter  $d=0.6$  m, with values of 6.60 mm, 6.50 mm (-1.5%) and 6.40 mm (-3%), for  $\Phi$  of  $26^\circ$ ,  $28^\circ$  and  $30^\circ$  in order.

The above data is shown in the graphs below.

Figure 4: Finite element method settlement plotted A through D [first author].

#### 4.2.2. Poulos & Davis (1980)

In this method a limit settlement of 25 mm was pre-established if the value did not reach the critical settlement of the structure (foundation rupture).

As the length of the piles increased, a reduction in settlement was observed. As for example in the model with diameter 0.6 m, internal friction angle equal to  $28^\circ$  and  $s/d$  ratio equal to 3, the verified values are 8.50 mm, 4.10 mm (-51.8%) and 3.9 mm (-54.1%) for the lengths 10, 15 and 20 m.

For the increase in diameter, the settlement showed a reduction. This is observed with the example  $L=15$  m, angle  $\Phi=28^\circ$  and ratio  $s/d=3$ , the settlements are 22.70 mm, 3.10 mm (-86.3%) and 2.60 mm (-88.5%), respective to diameters of 0.40 m, 0.60 m and 0.80 m.

With the increase of the distance between the piles, the settlement values increased by approximately 35% in most cases. However, the most unfavorable case will be used as an example. In the model with  $d=0.60$  m,  $\Phi=28^\circ$  and  $L=10$  m, the values are 3.80 mm, 8.50 mm (+123.7%) and 13.00 mm (+242.1%) for  $s/d$  equal to 2, 3 and 4, in order.

Finally, for increasing the internal friction angle of the soil, no change was observed in the settlement values.

The above data is shown in the graphs below.

Figure 5: Poulos & Davis (1980) method settlement plotted A through D [first author].

### 4.3 Maximum rotation and displacement of the piles

In this topic it was observed that both increasing the geometric parameters (length, diameter, and distance between the piles) and increasing the angle of internal friction causes the rotation to decrease.

The following graphs show the variation of rotation at the pile head in degrees (y-axis) as a function of the change of parameters cited (x-axis).

The parameter that caused less change in the rotation of the piles was the increase of the internal friction angle of the medium sand, as shown in the images below.

Figure 6: Maximum rotation at the pile head plotted A through D [first author].

For the maximum displacement, an increase only occurs when the length of the pile is changed. For the other parameters there is a decrease in the final values. The following graphs illustrate the percentage of variation of the displacements.

It can be observed that the change that generated the greatest reduction in displacement was the increase in pile diameter.

Finally, it is important to say that all the values presented are negative due to the direction of the axis where the horizontal loads were applied. To facilitate the visualization of the variations, the values are presented as positive, being the y axis the displacement in millimeters and the x axis the variation of the parameters.

Figure 7: Maximum displacement at the pile head plotted A through D [first author].

## 5 CONCLUSIONS

From the 81 analytical models studied, it can be concluded that the ultimate strength of the piles increases according to the increase of the length and the distance between the group elements. As for increasing the diameter and the angle of internal friction of the medium sand, the change is insignificant. The shear strength shows increase when the values of distance between piles and diameter are increased. With the increase of pile length and angle of internal friction, the change is insignificant.

One of the most important parameters of this study is the efficiency of the cuttings. For this topic, it was observed that the only change that causes efficiency reduction is the increase in length. For alterations in the other parameters there is always an increase, with the distance between the piles being the variable that generates the highest percentage of increase. Furthermore, it can be observed that the most efficient pile has 31% higher results than the least efficient, shown in the item 4.1.3.

In the settlement through the method of Poulos & Davis (1980), the values increased only with the increase of the distance between piles. For the other variables, a decrease in the total values was observed. On the other hand, in the FEM analysis, the increase of all variables studied caused the decrease of the maximum settlement value.

The comparison of the settlement methods allows us to conclude that, in approximately 81% of the cases, the settlement results presented by FEM are higher than those presented by Poulos & Davis (1980) methods. This result was already expected, since the FEM considers analysis points at the soil-pile interfaces and express more faithfully the actual changes that

occurred. Moreover, the values obtained by the Poulos & Davis method presented a high percentage of variation between them, making it difficult to recognize a pattern of variation.

In the strain analysis, both the maximum rotation and the maximum displacement were identified in the pile head. In the rotation, there is a decrease in the results with the increase of all changed parameters. The increase in diameter was the one that generated the highest average percentage influence.

For the  $Y_x$  displacement, the only factor that increased the results was the increase of the length of the piles. Increasing the other variables generated decreases in considerably high percentages.

Finally, if the objective of the structural project is the reduction of the maximum rotation in case of higher horizontal loads, the increase of the pile's diameter would be the main factor for this correction. It is important to remember that any project alteration can imply in problems in the execution of the foundation or in the economics of the enterprise. It is indispensable that a thorough study be carried out, since it may require a larger excavation area or major changes in the reinforcement sizing. Besides, when resuming the previous conclusions, the increase of the pile diameter has almost no influence in the improvement of the pile efficiency.

e-mail: patorresr@usfq.edu.ec

---

### Abstract

Column Base Connections (CBCs) are one of the most important components of Steel Moment Frames (SMFs) since these connections transfer the loads (e.g., gravity, wind, or earthquake loads) from the superstructure to the foundation. Because of it, CBCs have been extensively studied over the last decade through large-scale experimental programs and computational models that have led to the development of well-developed design guides such as the Design Guide 1 (DG1). Early analytical models were developed to predict the strength of CBCs, while subsequent studies estimated their rotational Stiffness, as well as deformation capacity. Modern studies on the topic have been developed to explore their behavior further with sophisticated finite element simulations. Moreover, their high deformation capacity with desirable hysteretic properties has called the researcher's attention to incorporate CBCs as part of the energy dissipation system.

The broad research conducted on this area points to the importance of CBCs. Motivated by this issue, this paper summarizes the (*state of the art*) analytical and numerical models that characterize the behavior of CBCs. First, the different types of CBCs used in the industry are described. Next, the analytical models to predict their strength, rotational Stiffness, and hysteretic properties are summarized. Strategies for the development of finite element models, as well as results from simulations, are detailed. The influence of column base behavior on the global performance of SMFs (varying in height) is described. Finally, the author's essential results from ongoing research on ductile base plates are discussed, and lines for future investigations are recommended.

---

## 1 INTRODUCTION

Column Base Connections (CBCs) are, perhaps, the most important component of Steel Moment Frames (SMFs). These connections are designed to transfer the loads from the superstructure (Dead, Live, Wind, Earthquake) into the foundation, being an interface between them (i.e., superstructure and foundation). Depending on the loads that are going to be transferred and the type of building (low rise – high rise), CBCs might be classified into two categories: Exposed Base Plates (EBPs) and Embedded Base Connections (EmBCs). The former consists of a base plate welded to a steel column and anchored to the foundation through steel bolts (a grout pad typically levels the foundation), while the latter detail consists of a steel column with a base plate embedded into a concrete foundation. Typically EBPs are used for low to mid-rise buildings, while EmBCs are the norm for taller buildings. Figure 1 shows a schematic representation of both details.

Figure 1: a) EBP detail and the internal force distribution, b) EmBC configuration and the internal force distribution (from Torres-Rodas et al., 2018[12])

The EBPs resist the applied loads by a combination of the bearing stresses developed between the concrete foundation and the base plate and by the tensile forces in the anchor rods. Thus, the axially compressive force is resisted by the bearing stresses in the base plate's compression side, while the Moment is resisted by the couple formed by the resultant compressive force and the tensile force from the bolts (Figure 1a). The shear forces are carried by either friction forces developed between the base plate and the grout/foundation or with a shear key. These connections strongly rely on the level of axial Load applied, and consequently, the relation Moment/Axial Load significantly affects the connection response. Thus, the response of the connection (i.e., Strength, Rotational Stiffness, and Hysteretic characteristics) is defined by complex interactions between its components. Specifically, these interactions refer to the contact and gapping between the base plate and the foundation (or grout pad), and the contact between the top side of the base plate (tension side) and the bottom side of the nut-washers arrangement.

On the other hand, EmBCs resist the applied forces by the horizontal stresses developed between the column flange and the foundation and the vertical stresses in the interface between the embedded base plate and the concrete foundation (Figure 1b). Joint shear forces accompany the horizontal stresses. In contrast with EBPs, EmBCs are no dependent on the ratio of Moment/Axial Load applied. Instead, the experimental evidence [1] indicates that these

connections depend on the Moment/Shear Load's ratio. Thus, the response of EmBCs is dictated by the embedded depth as well as the cross-section of the steel column.

During the last years, CBCs have been extensively studied due to their importance. Early studies on EBPs focus on the development of strength methods based on the modes of failure [2-4]. These models have been validated in experimental programs [2] and further improved [5]. Subsequent studies focused on estimations of their rotational Stiffness [6] and investigation of their hysteretic characteristics [7]. Sophisticated Finite Element Models have been developed to explore the internal stress distribution further [8]. These studies ended up in notably guides for the design of EBPs, such as Design Guide 1 (DG1) [9]. Similarly, large-scale experimental tests have been conducted on EmBCs. These experimental programs lead to the development of methods to compute the strength [1], rotational Stiffness [10] and describe with computational models the hysteretic behavior of EmBCs [11]. Moreover, Torres-Rodas et al., 2018 [12] focus the attention on the seismic demands on these connections with recommendations for their design.

Recent studies on SMFs [13-18] have explored the consequences of weakening the strength of CBCs with the intention to leverage their high deformation capacities and desirable hysteretic properties. These studies show that similar performance (assessed in terms of collapse probability at MCE level) can be achieved in the SMF's behavior if CBCs are sized based on the overstrength seismic load combination rather than with the capacity design criteria. Thus, the idea of protecting the connection with the use of the capacity design criteria may be unnecessary.

Consequently, CBCs play an essential role in the behavior of SMFs. Motivated by this issue, this paper summarizes the main studies (in the author's judgment) about the behavior of both EBPs and EmBCs, describing the state of the art on CBC modeling, and presenting recommendations for new lines of research on the topic. The paper is divided into five sections, beginning with this introductory section, while section two presents models to characterize the Strength, Rotational Stiffness, and Hysteretic behavior of EBPs. Section three details the corresponding models for EmBCs, while section four discusses the findings of the effect of CBC's behavior on the performance of SMFs, finalizing the paper with the Conclusion section.

## **2 MODELS FOR EXPOSED BASE PLATES**

### **2.1 Strength Method**

The analytical methods that quantify the strength of EBPs may be classified into three categories: 1) models that assume a predefined stress distribution on the compression side of the base plate; 2) models that suppose that base plates are rigid and enforce the compatibility of deformation between the components; and 3) sophisticated models that consider the interaction between the modes of deformation of the components. In the context of U.S. construction practice (and in most of the European countries), the first approach is typically adopted for the design of EBPs. The main reason is due to its simplicity in contrast with the other methods. Elkyne and Drake [19] proposed a method that falls in this first category. This method assumes a predefined (either rectangular or triangular) bearing stress form in the connection's compression side. Thus, the Moment is carried by the force-couple developed by the tensile axial forces in the anchor rods and the resultant compressive force from the bearing stresses. The shear forces are taken by either the friction forces in the interface between the base plate and the grout pad/foundation or by a shear key (Figure 1a). On the other hand, the second approach assumes a rigid base plate

neglecting the base flexibility. The model proposed by Wald et al., [20] is an example of this category. However, studies such as Gomez et al., [5] and Kanvinde et al., [21] have indicated that this approach leads to inaccurate results (against test data) on the nonconservative side. Finally, the third method applies the principles of mechanics to propose a procedure to construct Moment – Curvature diagrams [22, 23] given the size of the base plate, anchor rods, their material properties, and the level of Axial Load. Although the results are accurate and based on fundamental principles, the procedure is relatively complex to be implemented in a design office.

In the context of US construction, the design of EBPs is carried out based on the recommendations of DG1 [9]. DG1 assumes a rectangular stress block on the compression side of the base connection. Depending on the level of Axial Compressive Force, the applied Moment is resisted by: 1) bearing stresses in the compressive side of the base plate (low-eccentricity condition), or 2) the force-couple developed between the tensile forces in the anchor bolts and the resultant compressive forces from the bearing stresses (high eccentricity condition). The critical eccentricity, which separates both conditions, may be calculated as:

$$e_{crit} = \frac{N}{2} - \frac{P}{2Bf_{max}} \quad (1)$$

In equation 1,  $N$ , and  $B$  are the length and width of the base plate, respectively.  $P$  is the Axial Load applied, while  $f_{max}$  is the maximum value assumed for the stress block. In the low-eccentricity condition (i.e.,  $e \leq e_{crit}$ ), the only limit state possible is base plate bending in the compressive side, while for the high eccentricity condition (i.e.,  $e \geq e_{crit}$ ), three limit states can occur: 1) fracture of the anchor bolts, 2) bending of the base plate in the tension side, 3) bending of the base plate in the compressive side. The equilibrium equations ( $\sum F_y = 0$ ,  $\sum M_z = 0$ ) are solved to determine the internal forces. For the low-eccentricity case, the unknowns are the magnitude of the bearing stresses ( $f < f_{max}$ ) and the length ( $y$ ) of the rectangular stress block. On the other hand, for the high eccentricity condition, the unknowns are the tensile forces in the anchor rods ( $T$ ) and the length ( $y$ ) of the rectangular stress block. The shear forces in these connections are taken by the friction forces in the interface base plate-grout pad or by a shear key designed for this purpose.

As per DG1, the attainment of one of the before-mentioned limit states represents the capacity of the connection. However, subsequent studies such as Gomez et al., 2010 [5] show that EBPs pose a higher strength capacity. In fact, the maximum capacity is reached once a second component of the connection yields. Thus, the first yield of a component is associated with the called Moment at First Yield of the connection, while the Peak Moment is associated with the formation of a mechanism.

DG1 only deals with the uniaxial bending problem. Hassan et al., 2021 [24] extended the concepts of DG1 to EBPs subjected to biaxial bending with Axial Loads to estimate the internal forces. This procedure implies solving the indeterminacies that take place due to the tensile forces in the anchor rods. The authors suggested a predetermined pattern of the anchor rods' forces based on an assumed Instantaneous Axis of Rotation in conjunction with the rectangular stress block assumption from DG1. An iterative process is required to define the position (inclined) of the Neutral Axis once the equilibrium equations are satisfied. The method was validated against a large set of FE simulations for different base plate configurations.

## 2.2 Rotational Stiffness

Several researchers have studied the flexibility of EBPs (e.g., [22]). Kanvinde et al. 2012 [25] provide a practical method to estimate these connections' rotational Stiffness by aggregating the deformations within its components. The details of this method (which has been validated by [26]) are explained next.

The method leverages the assumptions made by DG1 to characterize the internal force distribution (i.e., a rectangular bearing stress block). The next step is to estimate the Moment at the first yield of the connection, which is defined as the Moment corresponding to the first yield of one of the connection components, i.e., the anchor bolts, base plate at the tension side, or base plate at the compression side. Once this quantity is computed, it is compared with the critical Moment (related to  $e_{crit}$ ) to define if the connection is under high or low eccentricity. For the first case (i.e., high eccentricity), the internal forces are used to compute the deformations of the three sources of base flexibility: anchor rods elongation, base plate bending (in the tension and compression side), and the concrete foundation. For the low eccentricity case, the method considers the concrete foundation as the only source of flexibility since the base plate is not expected to uplift (and consequently, the anchor rods will not elongate). In this manner, the deformations of the components have been estimated. Thus, the rotation of the connection can be computed by dividing the total deformation of the components by the base plate length. Finally, the Rotational Stiffness is defined as the ratio between the Moment at the first yield and the base rotation. Figure 2 illustrates this definition.

Figure 2: Definition of Rotational Stiffness of EBPs (from [6])

## 2.3 Hysteretic Behavior

The hysteretic characteristics of EBPs have been studied by Torres-Rodas et al., 2016 [7]. These authors proposed a rotational hinge (EBC model) that captures the essential features of the hysteretic behavior of EBPs observed in experimental programs (e.g., [2], [3], [4], [5]). Specifically, this mathematical model consists of a tri-linear backbone curve, a set of hysteretic rules aimed to capture the characteristic shape of the M-Rot curves of EBPs, and rules to capture the modes of deterioration for these connections. Figure 3 illustrates the backbone curve of the model. As per this figure, the backbone curve captures the three initial stages of the connection response. The first stage refers to the linear elastic response. In this phase, the loads are taken by the combination of bearing stresses and tensile forces in the anchor bolts. This phase ends when one of the connection components yields (i.e., base plate or anchor bolts). The element that yielded continues to increase its deformations in the second stage of the response (i.e., strain hardening phase) with an increase in the connection strength. This strength reaches a peak (giving rise to the third phase) when a second component of the connection yields. In this

manner, a yield plateau is formed in the connection response. Thus, the backbone curve is defined by four parameters: 1) the Moment at First Yield ( $M_y$ ), 2) the Peak Moment ( $M_{peak}$ ), 3) the initial Rotational Stiffness ( $K_{init}$ ), and 4) the Rotation associate with the Peak Moment ( $\theta_{peak}$ ). Among these four parameters, the first three of them (i.e.,  $M_y$ ,  $M_{peak}$ ,  $K_{init}$ ) can be estimated by the analytical models described in the sub-sections 2.1 and 2.2, while the latter parameter ( $\theta_{peak}$ ) must be obtained experimentally.

In contrast with the monotonic response, the hysteretic rules from the EBC model capture the characteristic flag shape hysteresis and the related re-centering effect. Figure 3b shows the details of these hysteretic rules defined by four parameters. These parameters are the Initial Moment at the intermediate plateau, the end position of this intermediate plateau, and two parameters that define the pinching behavior. Only the Initial Moment at the intermediate plateau can be estimated from an analytical model, while the rest of the parameters are obtained by empirical calibrations. The Initial Moment at the intermediate plateau corresponds to the connection moment associate with the instant the anchor bolts start to carry axial forces. Finally, the EBC model captures four modes of cyclic deterioration observed in EBPs. These modes reflect the cycle to cycle decrease in 1) the unloading Stiffness, 2) Peak Strength, 3) Intermediate Plateau, and 4) deformation associated with the intermediate plateau. Four empirically calibrated parameters (two for each mode) are necessary to capture these modes of deterioration. EBC model uses the rule proposed by Rahnema and Krawinkler (1993) [27] to simulate the cyclic deterioration. The assumption of this rule is that deterioration depends on the energy dissipated.

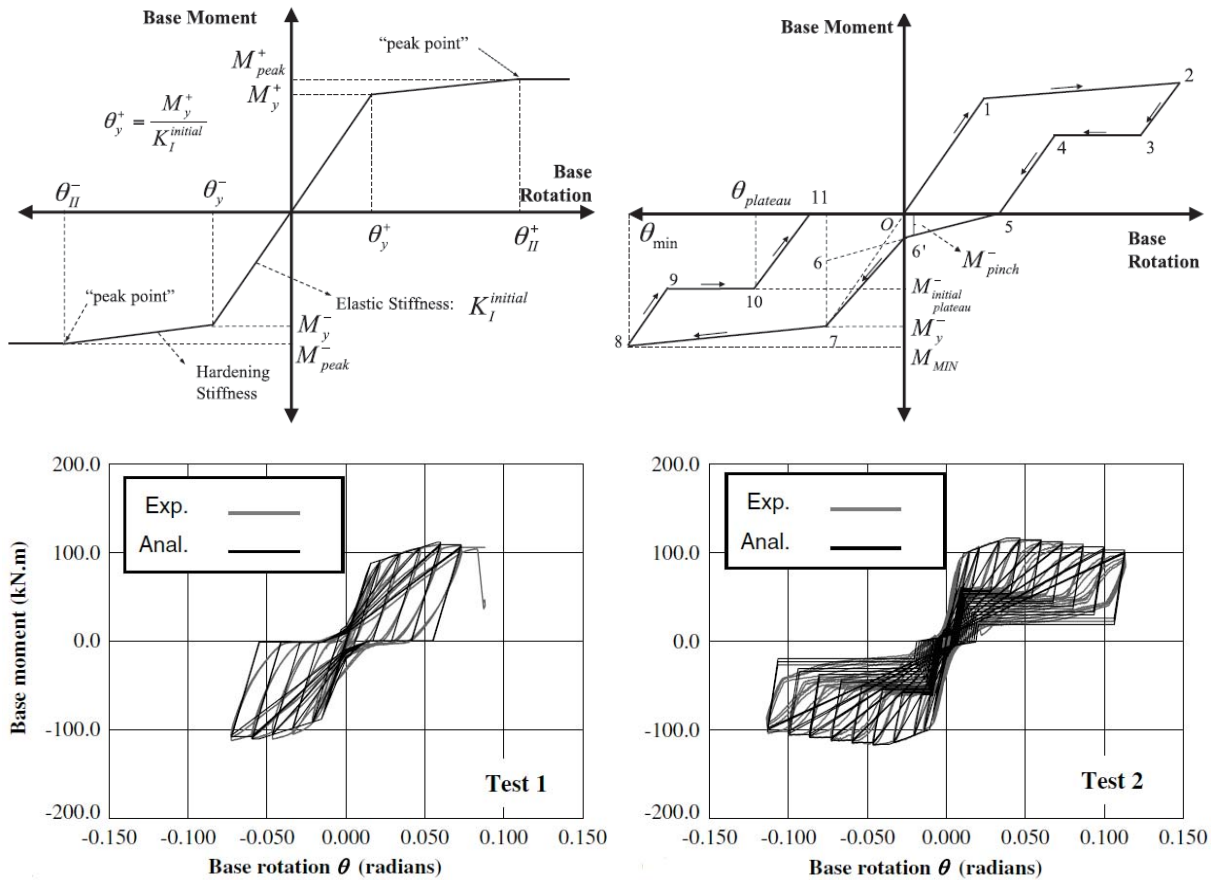

Figure 3: a) Backbone curve of ECB model, b) Hysteretic Rules, c) Calibration Test1, d) Calibration of test 2 (from [7])

Figure 3c,d shows the validation of the EBC model against the experimental test conducted by [5]. A visual inspection of Figure 3c indicates that the EBC captures the hysteretic response's essential features (i.e., the re-centering effect, the hysteretic shape, and the modes of deterioration). Thus, the EBC model is appropriate to capture the overall connection behavior in Non-linear Time History (NTH) frame simulations. However, it is important to detail its limitations. First, the EBC model (as all uniaxial plasticity models) cannot capture the Moment-Axial Load interaction. This problem may be treated in an approximate manner, assuming expected values of Axial Load. Second, the model has been validated against a limited number of tests (5 in total). Thus, it is difficult to generalize the EBC model's functionality for connections with significantly different configurations. Finally, the EBC model has not been validated against connections under tensile Axial Load or Biaxial Bending.

## 2.4 Finite Element Models

Several researchers have developed strategies to conduct Finite Element (FE) simulations on EBPs. Krishnamurty and Thambiratnam (1989) [28] presented one of the earliest FE studies conducted on EBPs to validate design methodologies based on the rigid base plate assumption. Stamapolous and Ermopoulos (2011) [29] conducted an experimental and analytical investigation on EBPs developing of 8 tests. These authors constructed 3D FE models to validate the mathematical formulation suggested in [22], and the results indicate a good agreement between the simulations, the experimental results, and the mathematical model suggested. As mentioned before in the paper, one of the drawbacks of this approach is that it is excessively complicated to be implemented in a design office.

Kanvinde et al., 2013 [8] examined the response of EBPs with sophisticated 3D FE simulations. This paper presents critics to the current assumptions regarding the internal stress distributions and suggests. The FE models include essential features of the connection behavior such as contact and gapping between the components (i.e., base plate and foundation/grout pad, nut-washer arrangement, and base plate) and the nonlinear multiaxial constitutive response of the materials. The models were validated against six large-scale tests conducted by Gomez et al., 2010 [5]. Results of this study indicate that the stress distribution in most of the cases is quite different from the assumed rectangular stress block at DG1. Thicker base plates tend to concentrate the stresses in the base plate's toe, while in thinner base plates, the stresses are concentrated under the compression flange of the column. In contrast to the drawbacks found in the internal stress assumption, the simulations indicate that the anchor bolt forces are well estimated by the equations given at DG1.

More recently, Trautner and Hutchinson 2018 [30] presented a procedure for parametric FE simulations of EBPs (with different details) subjected to combined Axial and Moment loads, validating the models against numerous experimental tests. Hassan et al., 2021 [24] studied with FE simulations the behavior (i.e., internal force distribution) of EBPs under combined Axial Compressive Force and Biaxial Bending. These simulations were validated against experimental test data and constituted the basis of the analytical method detailed in sub-section 2.1 for predicting internal forces in EBPs under Biaxial Bending in the presence of Axial Force. Torres-Rodas et al., 2020 [31] developed FE models to study the behavior of EBPs with extended anchor bolts. This configuration detail intends to concentrate all the inelastic action in the extended region of the anchor bolts, protecting the rest of the connection components.

## 2.5 Reliability Analysis of EBPs

Aviram et al. 2010 [32] carried out a system reliability analysis of the EBPs of a low-rise building located at Berkeley with the intention to evaluate the safety with respect to the different modes of failure reported in the literature. Results of this study indicate that the reliability index for these connections was below the value expected for connections [33]. Torres-Rodas et al., 2020 [34] studied this topic further. These authors evaluated the reliability of EBPs in SMFs designed based on DG1. A statistical approach was suggested to compute strength resistance factors for the modes of failure observed in connections (i.e., concrete bearing, base plate yielding, and anchor bolts failure) [5] to achieve a target reliability index of 4.5. Two buildings were analyzed (2-story and 4-story) using a suite of 120 ground motions from strike-slip and reverse faults. This paper presented a capacity limit state formulation for EBPs considering the M-P interaction, and the focus is on the seismic demands, which are explicitly treated as random variables. Results confirm the reliability index is below the target value. The reliability analysis of EBPs was also studied by Song et al., 2020 [35]. The analysis was conducted using Monte Carlo sampling for the uncertainties from the demands and capacity in this investigation. A total of 59 design scenarios was evaluated. Results confirm the findings from Aviram et al., 2010 and Torres-Rodas et al., 2010 with respect to the reliability index. This study's design recommendation is to eliminate the bearing resistance factor when the flexural demands on the base plate are calculated. Similar to Torres-Rodas et al., 2020, new load resistance factors (with values inferior to the suggested by DG1) are proposed.

## 3 MODELS FOR EMBEDDED BASE CONNECTIONS

### 3.1 Strength Method

Grilli and Kanvinde [1] conducted the first large-scale experimental program on EmBCs for seismic design purposes. The parameters investigated were the embedded length, the column size, and the level of Axial Load. From this experimental program, the modes of failure were identified, and the internal force distribution was postulated. Thus, it is assumed that the Axial Compressive force is resisted by the top stiffener plate as well as the bottom base plate. The applied Moment is resisted through the column flanges at the top of the connection. A fraction of this Moment is resisted by the horizontal stresses against the panel zone, whereas the remainder portion of the Moment is resisted by the vertical bearing stresses at the bottom base plate. The shear forces are resisted by a compression strut formed in the panel zone (Figure 1b).

Once the internal force mechanism is established, the capacities corresponding to each mode of failure can be characterized. Thus, for the horizontal bearing stresses developed in the interface between the column flanges and the concrete foundation, two modes of failure are identified 1) concrete bearing failure and 2) shear failure of the joint panel. On the other hand, the vertical bearing stresses in the bottom base plate entail four modes of failure 1) bearing failure of the concrete surrounding the base plate, 2) concrete breakout under the compression toe of the base plate, 3) concrete breakout above the base plate, and 4) base plate yielding. With these limit states, the Moment capacity associated with the horizontal bearing stresses (i.e.,  $M_{HB}^{capacity}$ ) and the Moment capacity associated with the vertical stresses (i.e.,  $M_{VB}^{capacity}$ ) might be calculated.

The capacity of the connection is determined by combining  $M_{HB}^{capacity}$  and  $M_{VB}^{capacity}$ . These mechanisms are constrained by deformation compatibility, implying that their moment

contributions are additive (i.e., system in parallel). The fraction of the total Moment to each mechanism is solved by the introduction of an empirical equation that relates the embedded length and the relative Stiffness of the column and the surrounding media. Thus, two scenarios can occur 1) failure due to vertical stresses takes place before failure due to horizontal stresses, 2) failure due to horizontal stresses occurs before failure due to vertical stresses. In the first scenario, the capacity of the connection is dictated by the precise mode of failure within the vertical bearing mechanism. In contrast, if the second scenario occurs, the capacity of the connection depends on which of the two modes of failure controls. If the concrete bearing failure controls, then  $M_{HB}^{capacity} = M_{HB}^{bearing}$  and the Moment carried by the horizontal stresses gradually decrease due to an increase in the deformations, and consequently, the vertical stresses will take a larger fraction of the total Moment. If shear failure controls, then no additional moment might be sustained.

### 3.2 Rotational Stiffness

The flexibility of EmBCs has been studied by Tryon 2016 [36] and Torres-Rodas et al., 2017 [10]. Tryon 2016 [36] studied the flexibility of base connections with an overtopping slab, which may be classified as shallowly embedded connections. In this detail, the Moment is carried primarily by the resistance to the uplift of the base plates due to the anchor bolts and by the overlying slab. Usually, the embedded length of these connections is less than 300mm. In contrast, in deeply embedded base connections, the loads are taken by (as described in the previous subsection) the bearing stresses in the column flanges (i.e., horizontal stresses) and the vertical stresses in the bottom base plate.

Torres-Rodas et al., 2017 [10] presented a method to characterize the rotational Stiffness of EmBcs. This method was developed based on the insights gained from the experimental program conducted by Grilli et al., 2018 [1], and consisted of calculating the components' deformations within the connection (i.e., embedded column and concrete foundation). The method was validated against a total of 9 large-scale tests from the programs conducted by [1] and [36]. The details of the method are explained next.

The method assumes from the experimental tests that the Moment at First Yield occurs at 0.7 of the Peak Moment. The latter parameter is obtained from the strength method earlier described. Thus, the connection stiffness is estimated as the ratio between the Moment at First Yield and the base rotation. Based on the internal force distribution postulated by Grilli and Kanvinde [1], the deformations of the embedded steel column and the surrounding foundation are calculated. Figure 4a illustrates the patterns of deformations assumed. Finally, the deformations are aggregated to determine the base flexibility (Figure 4b).

Figure 4: a) Patterns of deformation, b) Definition of Rotational Stiffness (from [10])

### 3.3 Hysteretic Behavior

The experimental studies conducted on EmBCs (e.g., [1],[36]) indicate that these connections are ductile with good hysteretic properties. This issue motivated the study by Torres-Rodas et al., 2018 [11] to formulate a mathematical model (EmBC model) to predict the essential characteristics of the behavior of EmBCs for Nonlinear Time History Simulations. The EmBC model is physically based and validated against Grilli and Kanvinde [1]. The details of this model are briefly explained next.

The EmBC model consists of two rotational springs arranged in parallel, where each spring is associated with the force transfer mechanism, i.e., horizontal bearing stress or vertical bearing stress. In this manner, the degradation of the capacity due to horizontal bearing stresses and the corresponding Moment transfer to the vertical bearing stresses is effectively simulated. Thus, the horizontal bearing mechanism is represented by a trilinear backbone curve defined by the well-known Ibarra-Medina-Krawinkler Pinching Model, while the elastic-perfectly plastic model simulates the vertical mechanism. Four parameters (i.e., Initial Elastic Stiffness, Moment at First Yield, Peak Strength, and Rotation Associate with Peak Strength) are necessary to define the spring that represents the horizontal stresses, while two parameters (i.e., Initial Elastic Stiffness, and Moment at First Yield) are required for the vertical bearing spring.

The cyclic response of these connections is described by the IMK Pinching Model's hysteretic rules detailed in Ibarra et al., 2006 [37]. These hysteretic rules capture two important aspects of the cyclic response: 1) pinching behavior, attributed to the closure of cracks or gaps between the column flange and the concrete foundation, 2) cyclic deterioration of two quantities, i.e., the strength plateau and unloading stiffness. The rules proposed by Rahnama and Krawinkler [27] were used to simulate cyclic deterioration and apply only to the horizontal spring since the experimental tests do not provide evidence of deterioration for the vertical spring. Besides, the vertical mechanism gains strength as the horizontal spring deteriorates.

Figure 5, illustrates the results of the validation of the EmBC model against two tests. Clearly, the essential aspects of the connection response are captured by the model formulation and can be easily implemented in NTH simulations. Although the results are promising, the EmBC model has several limitations that must be considered. The model is validated against a limit

(only five) number of tests. It implies that its results can not be extrapolated to connections with significantly different details. Moreover, it inherits the limitations of a uniaxial plasticity model, i.e., it can not capture the Moment-Axial Load interaction.

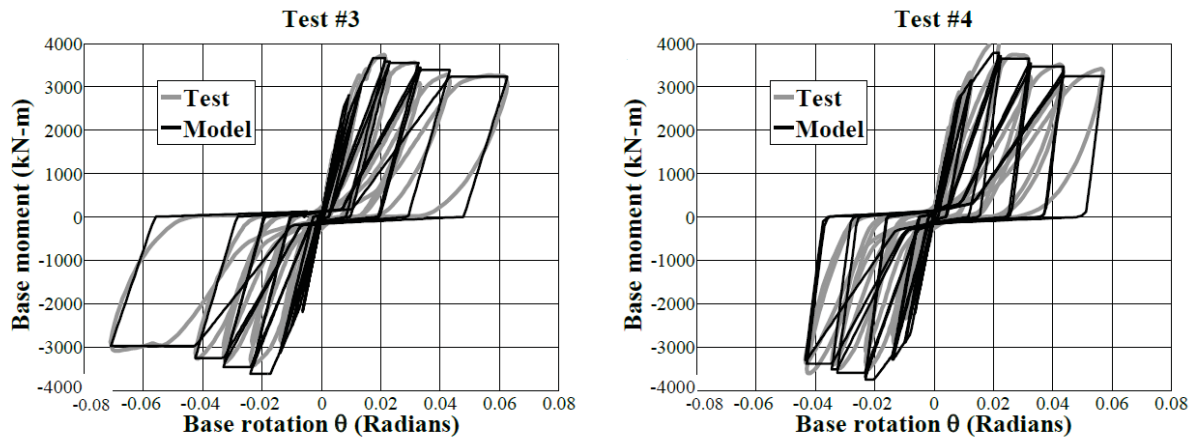

Figure 5: EmBC model validation (from [11])

### 3.4 Finite Element Models

Information about strategies to develop FE models for EmBCs is sparse. Jones 2016 [38] developed 3D FE models for the characterization of the Rotational Stiffness of shallowly embedded base connections. Inamasu et al. [39] studied the seismic design of EmBCs by FE simulations. In this study, the steel column was modeled with shell elements, and the base connection behavior was represented by a rotational spring at the bottom of the column. These models were validated against available tests (e.g., Grilli and Kanvinde [1]). The Finite element models feature the Voce-Chaboche multiaxial plasticity law. The constant parameters were obtained through an optimization process. Local buckling is triggered by considering local imperfections within a certain magnitude. The FE models simulate the response of a design example documented at the AISC Seismic Design Manual. Thus, the connection's response was studied parametrically, being the web local slenderness and the level of Axial Load the parameters investigated. Results indicate that the seismic demands on EmBCs are strongly influenced by the column position (i.e., interior or exterior) and by the cross-section geometry (i.e., local slenderness). Equations empirically calibrated are suggested to promote yielding in the column region above the concrete foundation. More recently, Mora-Bowen and Torres-Rodas [40] further explore the internal force distribution within the components and the patterns of deformation to provide improvements in the design of these connections. This topic is part of the ongoing research projects of the author.

## 4 EFFECT OF CBC'S BEHAVIOR ON THE PERFORMANCE OF SMFs

The effect of CBCs' behavior (i.e., ductility and flexibility) on the seismic response of SMFs has called the attention of researchers during the last years. The main reason is that experimental programs have shown that these connections pose excellent dissipative characteristics with high deformation capacities. Moreover, investigations such as Lignos and Krawinkler 2007 [41] indicate that the ductility of columns in the presence of Axial Compressive Forces might be compromised due to local buckling. Thus, the traditional concept of protecting the connection (remaining elastic) may be unnecessary. This idea may be attributed to the lack of analytical

models capable of predicting base connections' behavior. However, mathematical formulations such as [7, 11, and 16] have permitted to capture the overall connection response and incorporate it in NTH frame simulations.

Falborski et al., 2020 [14] studied the effect of Base Connection Strength, Rotational Stiffness, and Deformation Capacity on the Collapse Probability of four archetype frames parametrically. The authors considered four levels of base strength (and the associate Stiffness) and a range of deformation capacities (from 1% to 5%) to conduct the collapse assessment. Results indicate that if CBCs are detailed to hold rotations of 0.05rad, the seismic demands in the design can be reduced from the Capacity Design Criteria (1.1RyMp) to the Overstrength Seismic Load ( $\Omega=3$ ). This is supported by the similar performances (in terms of probability of collapse) achieved by the SMFs analyzed. The implication is that the strength of the connection is decreased by approximately 40%.

Base connections designed to promote anchor bolt yielding have been investigated by Trautner et al., 2016 [26] and Inamasu et al., 2020 [16]. Trautner et al., [26] conducted a series of large-scale tests to assess the effect of anchor bolt material type, anchor stretch length, column setting method, and base plate hole size on the behavior of the connection. Among these parameters, the setting method and the stretch length appear to be the most influential in the Moment-Rotation response. Moreover, Inamasu et al., 2020 [16] studied the influence of anchor-yield EBPs in the residual deformations of low-rise SMFs. Results from this study indicate that low-rise buildings with anchor-yield EBPs are less likely to experience residual drifts than buildings with EBPs designed based on the strong connection-weak column criteria. Besides, low-rise buildings with ductile EBPs, do not suffer an axial shortening which may significantly complicate the retrofit work.

More recently, Torres-Rodas et al., 2021 [18] studied the interactive effect of column base hysteretic behavior, continuity of gravity columns, and beam-column gravity connections strength on the seismic performance of SMFs. For each archetype frame, different levels of base connection strength, gravity columns rigidity, and beam-column gravity connections were assigned to assess their impact on the Collapse Probability at MCE level of 5 SMFs varying in height. A total of 80 mathematical models were developed, and NTH simulations were conducted as per FEMAp695 methodology. Results indicate that the presence of continuous gravity columns profoundly affects the archetype frames' behavior investigated by reducing their probability of collapse. In this manner, the desirable hysteretic characteristics of ductile CBCs can be incorporated safely as part of the energy dissipative mechanisms. The design implication is that seismic demands can be reduced (similar conclusion as Falborski et al., 2020) safely to the overstrength seismic loads if base connections can rotate up to 0.05rad.

## **5 CONCLUSIONS AND RECOMMENDATIONS FOR FUTURE WORK**

This paper presents a summary (based on the author's judgment) of the numerical and analytical models to characterize the column base connection behavior. Moreover, new findings on the influence of base connection behavior on the seismic performance of SMFs are detailed. The main intention is to synthesize current findings on the topic to highlight the importance of these connections in the overall frame behavior. Thus, the paper is divided into four sections. The first one introduces the topic, while the next two sections describe the main models to simulate

EBPs and EmBCs. A subsequent section is dedicated to examining the influence of the CBCs on building performance metrics (e.g., collapse probability at MCE level).

Traditionally, CBCs have been sized in order to promote plastic strains in the lower region of the column rather than in the connection itself. This approach may be attributed to 1) the intuitive idea that connections are less ductile than members and 2) the lack of available models to predict the behavior of base connections. However, in the last years, several studies have shown that perhaps this criterion is not appropriate for two main reasons 1) ductility in column members in the presence of Axial Load might be compromised due to local buckling, 2) column base connections pose high deformation capacities with desirable hysteretic properties.

Consequently, several researchers have explored the idea of moving from capacity design criteria to a weak base strong column concept. Results from studies such as [15-18] indicate that reducing the seismic design demands in ductile base connections would lead to similar performance to frames designed with stronger base plates. Moreover, column problems such as axial shortening may be eliminated if plastic strains are concentrated in ductile anchor bolts. This topic has called the attention of researchers and deserves further scrutiny. It is recommended to focus on experimental studies on ductile anchor bolt connections, especially with the intention to facilitate the retrofit work after an earthquake event.

### Abstract

Recent studies conducted on Steel Moment Frames (SMFs) highlight the importance of considering the effect of certain characteristics of earthquake ground motions (GMs) such as duration and spectral shape in their seismic response. Although their acceleration response spectra have mainly characterized ground motions in seismic standards, these studies indicate that the probability of collapse is sensitive to the GMs' duration. This represents a concern in areas with a different tectonic mechanism, such as South-America, and Pacific Northwest U.S., where subduction processes mainly generate GMs. It is well-known that the duration and spectral shape of subductions earthquakes are quite different from crustal earthquakes. Motivated by these issues, this research presents a parametric study to assess building height sensitivity to metrics such as inter-story drift ratios and floor accelerations, considering GMs records from subduction and crustal earthquakes carefully selected and scaled.

The scientific basis of this research is a series of nonlinear dynamic analyses conducted on SMFs (varying in height) at different seismic hazard levels. Two hazard levels are considered in this study: a) Life safety and b) Collapse prevention. The paper intends to understand the sensitivity of engineering demand parameters (i.e., drifts and floor accelerations) of SMFs to different earthquake mechanisms (i.e., crustal earthquakes vs. subduction earthquakes). The GMs records of subduction earthquakes consist of a set of GMs representative of South America and Japan's seismicity. The GMs records set of crustal earthquakes collects large magnitude-long distance events representative of Southern California.

## 1 INTRODUCTION

Steel Moment Frames (SMFs) are among the most popular systems to resist lateral forces, chiefly due to their architectural versatility. When appropriately designed and detailed, SMFs are among the most ductile available systems for seismic regions [1]. Because of these reasons, these systems have been extensively studied in the past. Early studies on the topic concentrated their attention on the response modes, ending up in the design philosophies [2]. After the 1994 Northridge and 1995 Kobe earthquakes, the focus was on the study of beam-column connections [3]. More recently, with the advances in computational capabilities, SMFs have been studied under the framework of Performance-Based Earthquake Engineering (PBEE). In this manner, extreme limit states such as the collapse probability have been introduced as performance metrics (e.g., [4,5]).

The PBEE approach has enabled researchers to explore profoundly different aspects of SMF response. For instance, the effect of column base behavior on the seismic performance of SMFs has been addressed by several studies (e.g., [6-9]). The influence of the gravity framing system on their collapse probability has been investigated by [10,11]. The soil-structure interaction effects on the response of buildings subjected to earthquakes were assessed by [12,13]. More recently, several researchers have focused on loss estimation after earthquake events [14,15]. Besides, different models have been proposed to predict the behavior of nonstructural elements [16-18]. The technological advances have permitted monitoring buildings entailing the development of new fields such as structural health monitoring [19,20].

The preceding discussion highlights the importance that SMFs have received during the last decades. Besides, it is worldwide accepted that ground motion (GM) parameters such as amplitude, duration, and frequent content, are the most influential on buildings' response. However, practitioner engineers typically carry out their structural designs based on the building codes (e.g., ASCE 7-16), which characterize GMs with the design spectrum. As per this concept, the design spectrum quantifies GMs' amplitude and frequency content, neglecting the influence of duration. Recent studies such as [21-24] have investigated the influence of duration on the collapse probability of buildings by subjecting archetype frames to short and long duration GMs. Results of these studies indicate that duration and spectral shape play a significant influence on the collapse probability of buildings.

Medalla et al. 2020 [25] studied the response of SMFs (i.e., 40 in total) subjected to megathrust earthquakes by performing a hazard-consistent analysis and a comparative collapse evaluation. The authors showed that the collapse probability of SMFs is higher when these systems are subjected to megathrust earthquakes rather than crustal earthquakes. Thus, the seismic demands for the design of buildings located in countries with high seismic activity (e.g., Ecuador) where the GMs are mainly caused by megathrust earthquakes and adopt the US steel design standards may be underestimated, resulting in potentially nonconservative designs.

Motivated by the preceding discussion, this paper presents an evaluation of the earthquake mechanisms' influence, i.e., crustal earthquakes vs. subduction earthquakes on Engineering Demand Parameters (EDPs) such as inter-story drift ratios (IDR) and floor accelerations (FA). For this purpose, a total of 5 archetype frames (varying in height) were subjected to two sets of GMs. The first set represents GMs associated with subductive mechanisms, while the second set contains GMs from crustal earthquakes. Those GMs were carefully selected and scaled to represent two hazard levels a) Life safety and b) Collapse prevention. Thus, the sensitivity of the SMFs to EDPs is assessed through this investigation. In this manner, new insights about SMFs behavior are given. The paper starts by describing the problem in this introductory section. Next, the details of the nonlinear models are described. Then, in a subsequent section of

the paper, the results are presented and discussed, and finally, conclusions, limitations of the current work, and lines for future work are provided.

## 2 METHODOLOGY OF THE PAPER

For the purposes of this paper, i.e., to assess the sensitivity of EDPs to earthquake mechanisms, a total of five archetype frames are developed. The difference among these frames lies in their height (varying from 8.50m to 79.85m). Thus, this investigation's scientific basis consists of a series of Nonlinear Time History (NTH) simulations conducted on the mathematical models developed herein. These archetype frames are part of the study by NIST [26], have been adopted in several studies about SMFs' behavior (e.g., [27-29]), and their salient features are described next.

### 2.1 Mathematical Models

Figure 1a illustrates the typical plan view of all buildings. The SMFs are located at the perimeter of the building, while the rest of the components are part of the gravity framing system. All SMFs are three-bay frames, with a width of 6.10m. The first story's height is 4.50m, while the rest of the stories are 3.90m. The buildings were designed as per ASCE 7-05. On all the floors it was applied a dead load of 4.78 kN/m<sup>2</sup>, and an unreduced live load of 2.38 kN/m<sup>2</sup>, with the exception of the roof, where a live load of 0.95 kN/m<sup>2</sup> was applied. The weight of the cladding was considered with a perimeter load of 1.20 kN/m<sup>2</sup>. For the seismic design of the SMFs it was assumed a Response Coefficient Factor  $R=C_d=8$ , and site class "D" conditions under the seismic design category  $D_{max}$ , which is consistent with the far-field conditions of Los Angeles. The beam-column connections are detailed as RBS connections based on ASIC 341 [30] and AISC 358 [x]. For more details about these SMFs, refer to [31].

Concentrated plasticity models have been adopted for this investigation since this approach has been broadly used for studies on SMFs (e.g., [27, 28, 29, 32, 33]). Thus, beams and columns are idealized as linear-elastic elements with rotational springs (hinges) at their ends. Beam members consist of three linear elastic elements with two hinges located each at the RBS, while column members consist of one linear elastic element with two rotational springs at the ends. These rotational springs are simulated with the well-known Ibarra-Medina-Krawinkler (IMK) bilinear model [34]. This model consists of a trilinear backbone curve with rules that capture cyclic strength and stiffness deterioration. These rules were initially proposed by Ibarra et al. [34] and then modified by Lignos and Krawinkler [35]. The spring properties were calculated by the methodology detailed at NIST [36].

The IMK bilinear models, as all uni-axial plasticity models, are not able to capture the Moment-Axial Load (M&P) interaction. For the springs located at the columns, this phenomenon is captured in an approximate manner. Thus, a reduced bending strength is calculated with the interactive equations from AISC [37] under the presence of an average gravity load (i.e.,  $1.05 P_D + 0.5 P_L$ ). This approach has been adopted in other studies related to the assessment of SMFs behavior (e.g., [27, 28, 29, 32, 33]) mainly because SMFs are drift-controlled rather than force-controlled, and consequently, the columns are lightly loaded. Moreover, studies such as [38] show good agreement between experimental results and this approach. Panel zones are modeled as a parallelogram assembly with rigid elements and with a nonlinear spring placed at one corner to simulate shear distortions in the parallelogram. Column bases were modeled with the rotational springs suggested by Torres-Rodas et al., 2016 [39] for the low-rise buildings (i.e., 2-, 4- story) and with the models by Torres-Rodas et al., 2018 [40] in the case of taller buildings

(i.e., 8-, 12-, 20- story). P-Delta effects were captured using a leaning column connected to the SMFs through rigid elements and loaded with the gravity load equivalent to half of the building at each floor plant.

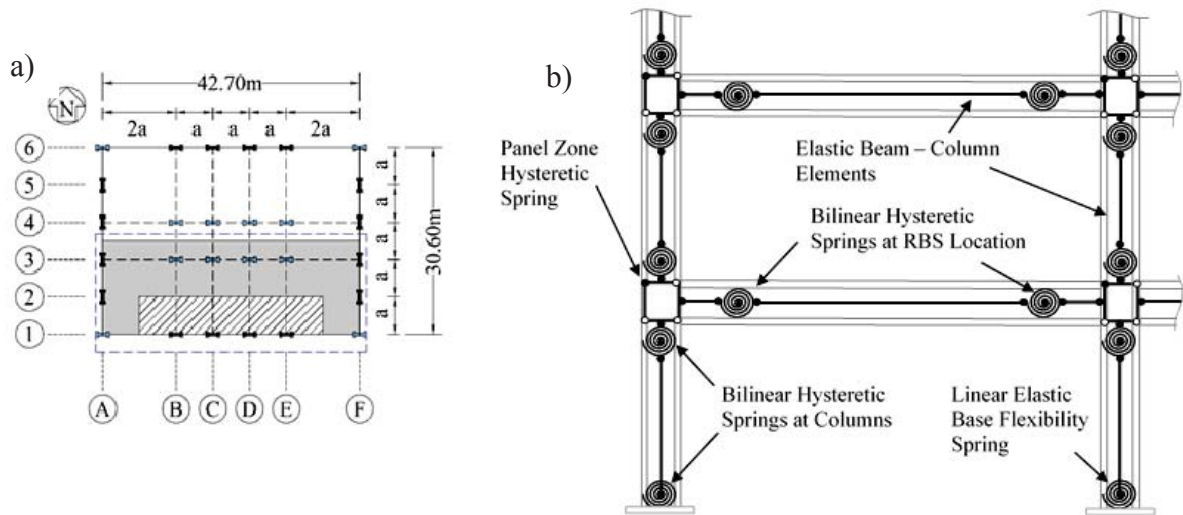

Figure 1: a) Typical plan view of all frames (from [9]), b) Mathematical models of the SMFs (from [32])

## 2.2 Ground Motions Selected

The seismic demands were analyzed using two criteria. On the one hand, several intense ground motions recorded worldwide were analyzed, including both subduction and crustal earthquakes. The earthquakes are shown in Table 1. These earthquakes were scaled linearly so that their intensities cover the accelerations reported in the MCE and DE spectrum of ASCE7-16 [41].

Table 1: Megathrust earthquakes used for seismic simulation

On the other hand, as mentioned within this research's objectives, the aim is to analyze records of subduction and crustal ground motions representing the tectonic behavior of South America. For this, subduction earthquakes in Chile and Ecuador and crustal earthquakes recorded in Colombia's central region were analyzed. In the seismic accelerometric network of the mentioned countries, there are few records generated during high-intensity ground motions associated with return periods of more than 250 years. Due to this lack of information, seismic simulation was used for analyzes carried out in this study.

The seismic simulations were carried out in two phases. On the one hand, seismological simulation techniques using Green's functions were applied. When it was not possible to reach the design intensities, linear scaling was used to reach the objective thresholds. Linear scaling factors were always lower than 1.8. The simulation technique used is proposed by Kohrs-Sansorny et al. [2005][42]. This methodology uses a two-stages stochastic summation of low-intensity motions (seed motions) that work as empirical Green's functions. Likewise, the simulation employed considers a seismic source point and requires the characterization of two parameters: a) the seismic moment ( $M_0$ ) and b) the stress drop ( $\Delta\sigma$ ). This methodology considers the variation of frequency and energy contents. This technique incorporates wave propagation and site effects in such a way as to eliminate geological uncertainties from the problem when using the same site where the record was obtained [43]. The seed motions for crustal earthquakes used in this paper were recorded during the events under consideration in Table 2 for the Colombian network.

Date	$M_w$	$M_0$ (dyne-cm)	$\Delta\sigma$
25/01/1999	6.3	2.54E+25	40
08/03/2005	5.2	7.94E+23	50
06/02/2017	5.4	1.58E+24	50

### 2.3 Nonlinear Time History Simulations

All the mathematical models developed herein were subjected to the two sets (i.e., crustal and megathrust) of GMs detailed in this paper's previous subsection. The software OpenSees is used for all the simulations since it has been extensively verified for NTH analysis [44], and all the modeling features earlier described can be applied. Moreover, several researchers have used this platform to study the behavior of SMFs with the use of NTH analysis [25-29]. Thus, the effect of the earthquake mechanisms (i.e., crustal vs. subductive) in the buildings' seismic performance (i.e., EDPs) is assessed. A total of five mathematical models representing the archetype frames (2-, 4-, 8-, 12- and 20- story) illustrated in Figure 1b have been developed for this investigation. Table 3 summarizes the fundamental periods of each frame. Two seismic hazard levels are considered in this study a) Life safety and b) Collapse prevention. For each simulation, two response metrics are recorded a) Maximum Floor Accelerations (FA) and b) Peak Interstory Drift Ratios (IDR). In this manner, the median values of the EDPs from each set (i.e., crustal vs. subduction) are compared.

Story Frame	First Period (s)
2-	0.69
4-	1.86
8-	2.42
12-	3.18
20-	4.44

Table 3: First Period of the frames

### 3 DISCUSSION OF RESULTS

The results from the NTH simulations of all the mathematical models are discussed in this section of the paper. Table 4 summarizes the results from the median IDR of all the SMFs at the two seismic hazard levels (i.e., DE and MCE level of shaking) analyzed herein, while Table 5 summarizes the results from the peak floor accelerations. As per Table 4, results from the simulations indicate that the IDRs of the low and mid-rise buildings (i.e., 2-, 4-, 8- and 12-stories) are relatively insensitive to the earthquake mechanism (i.e., crustal vs. subduction). The median values of the maximum IDRs associated with each earthquake mechanism are relatively similar, with the only exception in the tall building, i.e., the 20-story building. For this frame, the IDRs tend to be increased by 25% for the subductive earthquakes compared with the GMs' crustal set. This observation might indicate that the earthquake mechanism's influence is associated with the building height (and consequently the first vibration mode).

In contrast to IDRs, Table 5 indicates that the peak floor accelerations (FA) of all the frames are sensitive to the earthquake mechanism. As per Table 5, the subductive GMs entail higher FA than crustal earthquakes. At the Design seismic hazard level, the FA are amplified on average by 35% in the subductive earthquakes, while at MCE level of shaking, the FA are amplified (on average) by 50%. Results from the simulations indicate that the building height does not play an important role in the sensitivity of earthquake mechanisms to FA as apparently it does in IDRs.

Floor accelerations play an essential role in the behavior of nonstructural components. It is worldwide accepted that these components may be divided into two broad groups: the first one, sensitive to IDRs, while the second one, sensitive to floor accelerations [45,46]. Components such as masonry and partition walls fall in the first category, while ducts, parapets, or tanks are examples of the second group [46]. The components from this latter category must carry the forces coming from the building motion. Typically, the acceleration demands acting on these elements are evaluated from the floor response spectrum criteria, where the spectrum is calculated based on the floor accelerations at the desired level. Results from this investigation indicate that the earthquake mechanism (crustal vs. megathrust) profoundly influences the building response in terms of peak floor accelerations, which might affect the anchorage detailing of nonstructural components sensitive to this EDP.

Summary of Results median (I.D.R.) (%)					
Hazard Level	# Stories				
	2	4	8	12	20
M.C.E. with Crustal	3.00	3.12	3.44	3.37	3.46
M.C.E. with Megathrust	3.07	3.82	3.37	3.92	4.79
D.E. with Crustal	2.31	2.44	2.39	2.25	2.79

D.E. with Megathrust	1.97	2.80	2.48	2.48	3.75
----------------------	------	------	------	------	------

Table 4: Summary of Results median (I.D.R.) (%) including collapses.

Summary of Results median Floor Accelerations					
Hazard Level	# Stories				
	2	4	8	12	20
M.C.E. with Crustal	458.68	509.30	572.36	760.84	1018.11

#### 4 SUMMARY, CONCLUSIONS, AND LIMITATIONS

This paper presents the results from NTH simulations conducted on five archetype frames varying in height (i.e., 2-, 4-, 8-, 12- and 20-story) with the intention to evaluate the influence of the earthquake mechanisms (i.e., crustal vs. subduction) on building's metrics such as maximum IDRs and peak floor accelerations. For this purpose, ground motions from both mechanisms were carefully selected and scaled. Two criteria were used for the selecting and scaling process. The first one consists of a linear scaling to the GMs selected with the DE and MCE spectrums from ASCE 7-16 [41], while the second approach uses seismological techniques to simulate GMs.

The results from the NTH simulations conducted in this paper indicate that GMs (scaled at a defined intensity) from megathrust earthquakes cause higher peak floor accelerations than GMs (scaled at the same intensity as the megathrust ones) from crustal earthquakes. On average, the amplification is around 50% when the GMs are scaled to the MCE level of shaking, while it is close to 35% at DE level. This finding might be important in the context of detailing the anchorage of nonstructural components sensitive to accelerations. On the other hand, the IDRs seem to be less sensitive to the earthquake mechanism. Only the 20-story SMF shows an amplification due to the subductive process, which might indicate a potential influence of the building height.

The results of this paper are subjected to limitations that must be addressed appropriately to generalized the findings. First, a limited number of frames is considered (five in total); second, the bias due to ground motion effects, including the GMs' vertical component; third, the modeling assumptions might affect the results (e.g., concentrated plasticity models vs. distributed plasticity models). Finally, this research does not address the soil-structure interaction effects.

### Abstract

*The validity of the typical 100/30 combination rule for horizontal seismic action effects is investigated for the design of structures that are axially symmetric along the vertical direction. The 100/30 rule stipulates that one should combine 100% of the seismic action in one principal direction (as estimated by the design spectrum) with 30% of the action in the other principal direction, and vice-versa. Having been derived for azimuth-dependent structures, having e.g., a rectangular plan, it takes advantage of the fact that the two horizontal components of ground motion are only partially correlated, with peaks that in general do not happen simultaneously, to reduce the overall design loads. On the contrary, vertical liquid-storage tanks, silos and chimneys are examples of azimuth-independent structures, which by virtue of their symmetry will always experience the worst-possible incidence angle of a ground motion. To quantify the effect of axisymmetry we employed a database of 150 records with three components of ground motion. The results show that an 106/106 combination rule, or more accurately a 1.12 amplification factor on the design spectrum in a single direction, rather than the 1.04 implied by the 100/30, is adequate to account for the effects of axisymmetry. Still, this value depends on the definition of the underlying design spectrum, and whether, e.g., the maximum, arbitrary or geometric mean component is employed, which should be accounted for in all calculations.*

## 1 INTRODUCTION

In seismic design, engineers address the structure's seismic capacity by applying an acceleration, and therefore a seismic action to the structure, which corresponds to the site where the structure is going to be located. Those values are provided from hazard maps and are specified in the design code [1-3]. In typical structures, it is also the case that two orthogonal horizontal axes are defined, corresponding to the principal directions of the structure, along which the ground motion and therefore the acceleration is applied. As is often the case in modal response spectra analysis (MRSA) or equivalent lateral force (ELF), the response of the structure is calculated separately by applying the design spectra per each of the principal axes. After the response of the structure has been successfully calculated in each, specific combination rules are applied to combine the results of both directions in a singular peak response for designing the structure [4]. Many combination rules and methods have been described in the literature [5] and have been adopted by different design codes, for example the combination rules described in Eurocode 8 [1], for seismic design, proposes the 100+30% rule [6] that suggests that for a specific response we consider the following cases:

$$\begin{aligned} E_{Edx} "+" 0,30E_{Edy} \\ 0,30E_{Edx} "+" E_{Edy} \end{aligned} \quad (1)$$

where the "+" symbol typically signifies a square-root-sum-of-square (SRSS) combination of the effects of the two horizontal components, rather than an actual addition.

This whole process has been chosen after investigations suggesting that with the assumptions above we can safely combine the responses of a building in its principal axes X and Y, without being overly conservative. It would not be realistic to consider that in each direction the worst case values of acceleration would occur simultaneously [7]. This is of course an effective approach for the usual case of azimuth-dependent structures, but there is an obvious difference in case of structures that are fully symmetric with respect to a vertical axis and therefore have azimuth-independent properties, like cylindrical silos, spherical or vertical cylindrical liquid-storage tanks, circular pillars etc. In those structures the worst case scenario, considering the incidence angle of the ground motion, will always be in effect, as the structure has the same response and is equally vulnerable regardless of the axes defined.

In the following, a symmetrical three-dimensional elastic oscillator will be employed to examine its response after performing dynamic analysis using 150 pairs of strong ground motion records. The goal is to highlight the differences of such vertical axisymmetric structures when it comes to their response, ultimately calculating various amplification factors that allow combining the two horizontal components of motion when performing MRSA or ELF analysis for design purposes.

## 2 GROUND MOTION ACCELERATION DEFINITIONS

To properly clarify the process presented in the following paragraphs, in this segment some definitions [8] of how the ground motion acceleration parameters are usually defined in hazard maps provided by most design codes, are necessary. The following parameters represent the acceleration values calculated for a pair of records of the horizontal components derived for a specific earthquake:

- $Sa_{RotD100}$ : The maximum acceleration value from all possible orientations of the records for a specific response period T.
- $Sa_{RotD50}$ : The median value from all possible orientations for a specific period T.

- $Sa_{GMRotD100}$ : The maximum value of the geometric mean of the horizontal components from all possible orientations of the paired records for period  $T$ .
- $Sa_{GMRotD50}$ : The median value of the geometric mean of the horizontal components from all possible orientations for period  $T$ .
- $Sa_{arb}$ : An "arbitrary" horizontal component of the ground motion for a specific period  $T$ , as estimated by rotating the as-recorded components of the ground motion so that one coincides with a given axis
- $Sa_{GM}$ : Geometric Mean of as-recorded horizontal components for period  $T$ :

$$Sa_{GM}(T) = \sqrt{[Sa_x(T) \times Sa_y(T)]} \quad (2)$$

The above acceleration definitions are generally referring to acceleration values that are taking into account the incidence angle of the ground motion, meaning that for example for a value of  $Sa_{GMRotDXX}$  the response of the structure is calculated by rotating the ground motion records in all angles (for example with a suitable step of  $2^\circ$ ), and calculating the geometric mean value of the horizontal components, with the D50 or D100 value being chosen accordingly, in other words the median or maximum value could be adopted. In most codes the median values are adopted ( $Sa_{RotD50}$ ,  $Sa_{GMRotD50}$ ) taking into account that the principal axes of most structures, would not align to what the critical incidence angle of the ground motion would be, something though that as mentioned, is not true for azimuth independent structures. At this point it should be also clarified that in many cases in design codes the  $Sa_{RotI50}$  (period-independent-rotation-angle measure) is adopted, but according to available literature [9, 10], the differences are insignificant between the RotDXX or RotIXX definitions.

Figure 1: A perspective image of the 3 dimensional elastic and symmetrical oscillator's model, showing the common mass, stiffness and period in both horizontal axes.

Figure 2: Incident angle rotation of horizontal ground motion components.

### 3 OSCILLATOR MODEL AND DYNAMIC ANALYSIS PARAMETERS

To calculate the acceleration values mentioned above, a three-dimensional elastic and symmetrical oscillator will be used, having the same dynamic parameters in both its major directions X and Y. Using all the aforementioned 150 pairs of ground motion records, from earthquakes of various characteristics, dynamic analysis is performed in each case of record pairs, rotating the ground motion accelerations with an angle step of  $2^\circ$  through a complete circle, essentially altering in each case the incidence angle of the ground motion accelerations.

Through this process and by performing those calculations for all possible incidence angles starting from  $0^\circ$  to  $180^\circ$  (with the previously mentioned  $2^\circ$  step), the accelerations mentioned in the previous paragraph are easily defined, providing a range of responses that can be used to convert the GMRotD50 and RotD50 values in the more suitable D100 cases, that as mentioned before are more reasonable for axisymmetric structures. In Figures 3-4 the results for a specific case of an oscillator with an eigenperiod of  $T=1.0$  sec are presented to put into perspective the process in a more practical way.

Figure 3 : Results for each record pair, with diagrams for  $Sa_{arb}(\theta)/Sa_{RotD50}$  and the mean value for each rotation angle (arbitrary case).

Figure 4 : Results for each record pair, with diagrams for  $Sa_{GM}(\theta)/Sa_{GMRotD50}$  and the mean value for each rotation angle (geomean case).

It is very important to mention that to better identify the output of the results, each diagram for each record was plotted starting from the incidence angle where the maximum acceleration was found. Of course the results were also divided with the equivalent  $Sa_{RotD50}$  and  $Sa_{GMRotD50}$  values accordingly, for the results, concerning each pair of records, to be comparable to each other (in the second case where the geometric mean values are examined, after the  $90^\circ$  angle the diagrams repeat themselves).

#### 4 RESULTS

Using the process mentioned above for a wide spectrum of eigenperiods  $T(\text{sec})$  for the oscillator described, and by identifying the mean value for each of the factors, appearing in Figure 5, for every  $T$ , taking into account all 150 records, the more condensed diagrams were created. They of course provide a wider perspective of how the different definitions of ground motion acceleration relate to one another, examining not only the obvious cases of  $Sa_{RotD100}/Sa_{RotD50}$  and  $Sa_{GMRotD100}/Sa_{GMRotD50}$ , but also cases like  $Sa_{RotD100}/Sa_{GMRotD50}$  and  $Sa_{RotD50}/Sa_{GMRotD50}$ , in case a conversion of that kind could be useful.

According to the results of this investigation, it is obvious that if the peak horizontal acceleration value of a common structure according to the 100+30% rule, and combining the two horizontal components with the SRSS rule would be  $1.044 \cdot a_g$ . In a case where the hazard maps proposed are set up using the  $Sa_{GMRotD50}$  definition, which is expected to be the case of Eurocode, an amplification factor of  $1.117 \cdot a_g$  should be employed. A value between  $1.20 - 1.25 \cdot a_g$  is proper in case of a design spectrum definition based on  $Sa_{RotD50}$ . Those are significant differences that certainly should not be disregarded when axisymmetric structures are examined, as this could lead to non conservative results. At this point a reference of similar works can verify some of the results above especially in cases of the  $Sa_{RotD100}/Sa_{RotD50}$  diagrams for example, as similar results have appeared in the literature [9, 11].

Figure 5 : Aggregated results for various amplification factors for various eigenperiods  $T$ .

Figure 6 : Aggregated results for the  $Sa_{GMRotD100}/Sa_{GMRotD50}$  conversion factor for various eigenperiods  $T$ .

## 5 CONCLUSIONS

To conclude, the perspective of this article is to propose specific amplification factors in cases of azimuth-independent structures. Their symmetry suggests that the seismic accelerations that would affect them would act upon them in maximum effect, as the incidence angle of the ground motion will affect the structure regardless of the axis X and Y arbitrarily defined in the design process, always subjecting the structure in the peak acceleration produced by the earthquake. That is why we propose amplification factors for the horizontal acceleration component used in design, of 1.12 in a case of an acceleration definition of  $Sa_{GMRotD50}$  in the hazard maps and an amplification factor of 1.25 for the  $Sa_{RotD50}$  case accordingly. Specifically for Eurocode 8 the authors propose the 1.12 case, as an amplification factor for the design spectrum accelerations applied in a single direction to simultaneously account for the combined effect of both horizontal components in axisymmetric structures.

### Abstract

*Unanchored containers, e.g. for toxic waste, are required to be checked against overturning under seismic actions. Usually this is done by calculating static equilibrium, therewith ensuring stiction and avoiding overturning. When concepting seismic actions as displacement-controlled base excitation with reversals, it becomes obvious that neither the beginning of an overturning motion nor the loss of stiction necessarily causes the structure to fall over. Based on a simplified rigid body assumption for the unanchored container, analytical methods were used to describe the states of no-motion, sliding, overturning and restoring of the overturning motion by reversion of the base displacement in previous work presented by the authors of the current study. Depending on the aspect ratio and a variation of friction coefficients parameter, confidence boundaries were identified, within which the structure is safe against overturning. In the present study this analysis is extended by means of numerical simulation. Dynamic finite element analyses are carried out in order to validate and extend the analytical methods of the previous paper. Successful application of finite element models allows to drop of the rigid body assumption. Thus, deformations of the container, e.g. shell modes, can be considered in a next step. This can lead to more precise and less conservative results, as with the analytical methods dissipation of energy through transformation into deformation energy or damping is neglected.*

## 1 NOMENCLATURE

Symbol	Unit	Meaning
$t$	s	time
$F_F^s(t), F_F^d(t)$	N	static and dynamic (Coulomb) friction force
$\mu_s, \mu_d$	-	static and dynamic Coulomb friction coefficient
$G$	N	self-weight
$M_T(t)$	N·m	tilting moment
$m$	kg	mass
$a(t)$	m/s <sup>2</sup>	acceleration
$a, b, c$	m	dimensions of the body
$M_R$	N·m	restoring moment
$A$	m	amplitude of the ground motion
$\mathbf{c}$	N·s/m	damping matrix
$\mathbf{k}$	N/m	stiffness matrix
$p$	N	external load
$C$	-	decay constant with no physical meaning, set equal to 0
$v_{sliding}$	m/s	relative sliding velocity between the surfaces in contact
$\Delta A$	m	relative sliding between ground and base of the prism

## 2 INTRODUCTION

In the present study, the overturning stability of unanchored containers is investigated. A series of numerical investigations is presented, in order to validate and extend an analytical model previously proposed by the authors [1]. Although the nonlinear dynamics of rocking (tilting) and sliding oscillators have been described in the past, see [2], [3], [4] and [2], [5], [6], [7], [8] respectively, to the authors' knowledge no engineering approach existed for describing the behavior of rocking and sliding oscillators, till the recent introduction of the above-mentioned analytical model [1]. Therefore, the Lateral Force Method (LFM) suggested by Eurocode [9] (see also [10]) which leads to overconservative results for this case, had to be applied in practice until now.

Triggering point for the quasi-static analyses of [1] and the present investigations has been an industrial consulting project carried out by the second author regarding the tilting stability of unanchored steel boxes (Figure 1). These boxes are used for fire-proof storage of mercury and they are single-placed on the ground (e.g. on concrete surface) or stacked upon each other, up to three. Proof of the stacks' bearing capacity against earthquake and wind loads is required for receiving a General Type Approval by the German authorities [11]. Since the beginning of this consulting project, the over-conservatism of the LFM for the current case became apparent; loss of stiction or tilting had to be considered as loss of bearing capacity, while in reality these events can respectively lead to sliding, some bumping or even both. Therefore, the authors proposed an enhanced quasi-static solution in [1], based on the mechanical model of Figure 2, which still does not fully describe the physical reality i.e. the full dynamic response of the system, but nevertheless enabled a less conservative investigation of the problem. This was achieved by introducing four different modes for the oscillating system ground – stacked boxes, which are considered to behave as a rigid body<sup>1</sup>:

- The quasi-static or sticking mode with the limit conditions that the base shear does not exceed static friction (Eq. 1) and the tilting moment does not exceed the restoring moment from self-weight (Eq. 2). In this mode the stacked boxes stick to the ground and follow its displacement without any uplift or relative displacement between their base and the ground.

$$F_F^s(t) = m \cdot a(t) \leq F_{F,lim}^s = G \cdot \mu_s, \quad (1)$$

$$M_T(t) = m \cdot a(t) \cdot c/2 \leq M_R = -G \cdot a/2. \quad (2)$$

- The slipping mode, during which the stacked boxes slip on the oscillating ground surface due to loss of stiction. Therefore, there is relative displacement between the stack and the ground. For triggering this mode the base shear must exceed dynamic friction (Eq. 3),

$$F_F^d(t) = m \cdot a(t) \geq G \cdot \mu_d = F_{F,lim}^d, \quad (3)$$

while the tilting moment should not exceed the restoring moment from self-weight so that no uplift takes place (Eq. 2 still stands). When the system is in this mode, the accelerating base shear force is reduced during slipping compared to the stiction mode. Thus, the body is less accelerated, leading to a smaller rotation  $\varphi$  if it simultaneously tilts. Therefore, for same given displacement amplitude  $A$ , the motion of the body becomes less critical.

- The rocking mode, during which uplift of a stack's bottom corner occurs. The limit condition of the base shear not exceeding friction remains unchanged (equation 1 stands) but the tilting moment should exceed the restoring moment from self-weight. As in this mode  $\varphi \neq 0$ , the two moments are estimated as follows,

$$M_T(t) = m \cdot a(t) \cdot \frac{c}{2 \cdot \sin \alpha} \sin(\varphi + \alpha) > M_R = -G \cdot \frac{a}{2 \cdot \cos \alpha} \cos(\varphi + \alpha). \quad (4)$$

It is worth mentioning at this point that slipping, taking place simultaneous to rocking, during this mode cannot be excluded. Due to the uplift, slipping does not any longer refer to two surfaces sliding relative to each other. The Coulomb model theoretically would still stand, as it refers to acting forces and it can therefore, describe both the surface-on-surface and the edge-on-surface friction. Questions arise though, regarding its universal application due to its phenomenological nature. More complex analytical description of the limit conditions for the simultaneous initiation of slipping exceed the scope of the present study. Nonetheless, it is becoming evident from the above-presented argumentation regarding the reduced accelerating base shear during sliding, that neglecting of simultaneous sliding during rocking yields safe results.

Figure 1: Outer steel box of a double wall mercury container [11]

- Finally, overturning of the system takes place if rocking mode is initiated and the amplitude of the ground motion exceeds the half-length of the stack (we define as length the dimension of the specimen parallel to the ground motion)  $A > a/2$ . In a different case ( $A < a/2$ ), the overturning mode is not initiated and the previous rocking mode continues. In reality, this would lead to bumping due to consecutive ground motion reversals and loss of bearing capacity would be avoided.

It is becoming apparent from the above that the quasi-static model presented by the authors in [1] indeed describes more precisely the physical reality than the LFM, as loss of stiction leading to slipping or rocking without overturning is introduced and is not considered necessarily as loss of bearing capacity. Nonetheless, as the limit conditions of each mode are different from the rest due to changing conditions of friction and moment, the boundaries between the modes are not that discrete. Moreover, it is becoming evident that in reality two of the above-mentioned modes could as well coexist and the dynamic nature of the ground motion could further improve or deteriorate the rocking behavior, an effect that cannot be described by the quasi-static model considering a base shear. In order to enable a better understanding of the involved phenomena, introduce a first step for a future parametric analysis of the problem and extend the currently proposed model a series of full dynamic numerical analyses using the FEM is carried out in the present study.

### 3 NUMERICAL INVESTIGATIONS

#### 3.1 The finite element model

For the present analyses, a straightforward finite element model was developed with the ground being modelled as a „belt” of solid elements with thickness of 0.01 m and rigid material behavior. When a stack of more than one boxes was modelled, they were considered rigidly connected to each other as in [1] and they were therefore modelled as a single prismatic solid. A virtual density of  $2.066 \text{ kg/m}^3$  was assumed for the boxes considering the steel box structure and the stored material as a homogenous mass based on the suggestion of [1]. Assumption of a rigid body for the prism simulating the single box or the stack of boxes, hereinafter called simply prism, would still stand as for the analytical model. Nonetheless, due to numerical restrictions it was modelled as an elastic body with the mechanical properties of structural steel, which anyway stands closer to physical reality.

The FE Software ANSYS [12] was applied for creating the finite element model, while the explicit dynamic solver LS-Dyna [13] was used for its solution. Based on a convergence study, solid “brick” elements with uniform dimension of 0.05 m were applied (0.01 m in the height

direction for the elements modelling the ground). Linear dynamic analyses were carried out (Eq. 5),

$$m\ddot{u} + c\dot{u} + ku = p(t), \quad (5)$$

while the Coulomb friction model (Eq. 6) was applied for simulating the contact between the bottom surface of the prism and the upper surface of the ground,

$$F_F = \mu \cdot G. \quad (6)$$

LS-Dyna estimates the friction coefficient  $\mu$  by interpolating between the values of the static and dynamic friction coefficient based on the following equation (Eq. 7),

$$\mu = \mu_d + (\mu_s - \mu_d) \cdot e^{-C|v_{sliding}|}. \quad (7)$$

As for the present study  $C$  was set equal to zero,  $\mu = \mu_s$ .

Figure 3: The FE model

### 3.2 Investigated cases

Using the above described FE model, a series of numerical analyses was investigated in order to examine the influence of different input parameters to the rocking behavior of the prism. An overview of the investigated datasets is presented in Table 1, along with the resulting rocking behavior of the prism in each invested case. The geometry of the prism is differentiated, with the height gradually increasing from 1 m to 2 and 3 times respectively the length dimension of a single storage box (1.1 m x 1.1 m x 1 m), for which a fundamental period of 1.98 s is analytically calculated in [1]. For validating this result, prior to the rest of the numerical investigations a simulation was carried out, where the prism was uplifted from the ground around its corner and was left to bounce back to the ground with only gravitational forces acting on it. In all cases, the initial horizontal position of the prism's mass center coincided with the center of the modelled ground "belt" and the gravitational force was pointing the negative direction of the  $z$  axis (Figure 3). Degrees of freedom outside the XZ plane were restrained, as in different case irregular bumping and unexpected displacement out of this plane occurred. This was against initial expectations, as all applied loads were on the XZ plane and although the result is

closer to physical reality (for instance irregularities of real structures and ground can cause out of plane drift) in this case it was attributed to numerical effects and therefore, the additional restraints were imposed.

The seismic action was modelled in all cases as an ideal sinusoidal excitation of 5 periods in the length direction (x direction in Figure 3, the vertical component is neglected). Different values for seismic excitation were tested, with a peak ground acceleration of  $1.6 \text{ m/s}^2$  applied for all analyses, but with various values for the seismic period/frequency: initially, seismic period equal to the fundamental rocking period of the prism was considered and then it was respectively increased and decreased by 10 %. Moreover, as one of the limit conditions, which describe the physical reality, is the relationship between friction and base shear choosing a realistic value for the friction coefficient is crucial for the current problem. Nonetheless, previous experience shows that selection of appropriate values is challenging [14]. Selection of the appropriate friction coefficient  $\mu$  depends on the materials in contact, their roughness, their condition (dry or wet) etc. As a universal value cannot be proposed, two different values for the static friction coefficient 0.4 and 0.57 were tested in the current study, with the former one having been applied in [1] and the second one proposed in [15], for steel surfaces sliding on concrete. The dynamic coefficient in both cases was considered to be 50 % of the static one (see relevant discussion in [1]).

Case	Geometry a/b/c [m]	Seismic period [s]	Friction coefficients [-]	Activated mode of rocking behavior	maxA [mm]	maxΔA [mm]
A1	1.1/1.1/1	1.98	0.40/0.20	sliding - sticking	± 158	31
A2	1.1/1.1/1	2.18	0.40/0.20	sliding - sticking	± 193	37
A3	1.1/1.1/1	1.78	0.40/0.20	sliding - sticking	± 128	25
A4	1.1/1.1/1	1.98	0.57/0.29	sliding - sticking	± 159	14
A5	1.1/1.1/1	2.18	0.57/0.29	tilting & bumping - sticking	± 192	20
A6	1.1/1.1/1	1.78	0.57/0.29	tilting & bumping - sticking	± 128	13

## 4 RESULTS AND DISCUSSION

### 4.1 Presented results

For the shake of clarity, only selected results of the above-presented investigations are presented, as some models produced similar results with each other. At first the results of the fundamental period test and the models A2 and A5 regarding the case of a single box are presented. In the former case, the vertical displacement of the prism's upper left corner over time (Figure 5) along with contours of vertical displacement are presented. Tappauf and Taras [16], [17] found quite similar results when they investigated the partial uplift of big tanks. In that case though, a time offset between the bumps was documented due to the sloshing wave along the tanks diameter. For the models A2 and A5, both diagrams of horizontal displacement of the ground and the prism's bottom and top (right corner node for both, Figure 6, 7) and contours of

horizontal displacements at arbitrary but representative times of the simulation (Figure 8, 9) are presented. Later on, C1 and C2 referring to the case, where the height of the prism is three times its length and exhibiting respectively the modes of tilting and overturning are discussed. The results are presented in an analogous way as of those for the models A2 and A5, see Figure 10 – 13.

#### 4.2 Validation of analytically calculated fundamental period

The contours of vertical displacement at three different moments of the simulation, at time 0 s, 0.192 s and 0.360 s, are given in Figure 4. The results of the vertical displacement of the upper left corner over time are provided in Figure 5. During the simulation and after the first contact of the bottom left corner with the ground, the prism entered an irregular bumping sequence, which becomes obvious from the great number of hills and valleys in the diagram of Figure 5, including horizontal displacements as well (x axis). As a result, for the estimation of the fundamental rocking history, only the results up to this moment of first contact are considered. The time, until the initiation of this contact i.e. at 0.384 s constitutes a quarter-period, therefore a fundamental period of 1.536 s is estimated. A significant deviation of 20% with the analytically estimated fundamental period ( $T_{\text{analytical}} = 1.98$  s is given in [1], Eq. 19,  $T_{\text{num}} / T_{\text{analytical}} = 80\%$ ) is met.

#### 4.3 Models A1 – A6

For all the investigations with the prism geometry corresponding to the case of a single box, and despite any change in seismic action no overturning was documented. When the lower values of friction were considered (0.4-0.2 for models A1-A3) slight sliding during initiation of the seismic excitation was observed and the prism stuck to the ground for the rest of the reversals. It has to be highlighted, that after the end of the seismic action the prism slid back to its initial position. The diagram of the horizontal displacements over time presented in Figure 6 and the horizontal displacement contours from the first period of the seismic excitation presented in Figure 8 from the model A2, for which the most severe sliding of approximately 36 mm was observed, validate the above observations.

Nonetheless, when the friction coefficients were increased and for the models A5 and A6 with the lowest and highest seismic periods (A4 exhibited similar behavior with the previous), the prism during the initiation of the seismic action instead of sliding tilted with a slight uplift of the bottom corner on the side of displacement's direction being documented. At the same time the stiction between the left bottom corner and the ground led to a hopping of the prism towards the ground displacement direction, which introduced relative displacement between the ground and the prism. This could be mistakenly attributed to some sort of simultaneous sliding. Observing the diagram of horizontal displacements for the model A5 though, presented in Figure 7, it can be seen that in contrast to the case of A2 the prism exhibits higher horizontal displacement than the ground already from the first quarter of the first loading period. This is physically impossible to be caused by sliding. After the first hopping another uplift of lower magnitude is initiated, after the end of which the prism sticks to the ground for the rest of the excitation. The contours of Figure 9 offer a clearer overview of the above-described phenomenon. Once again after the end of the excitation, reversed uplift and hopping restores the prism to its original position.

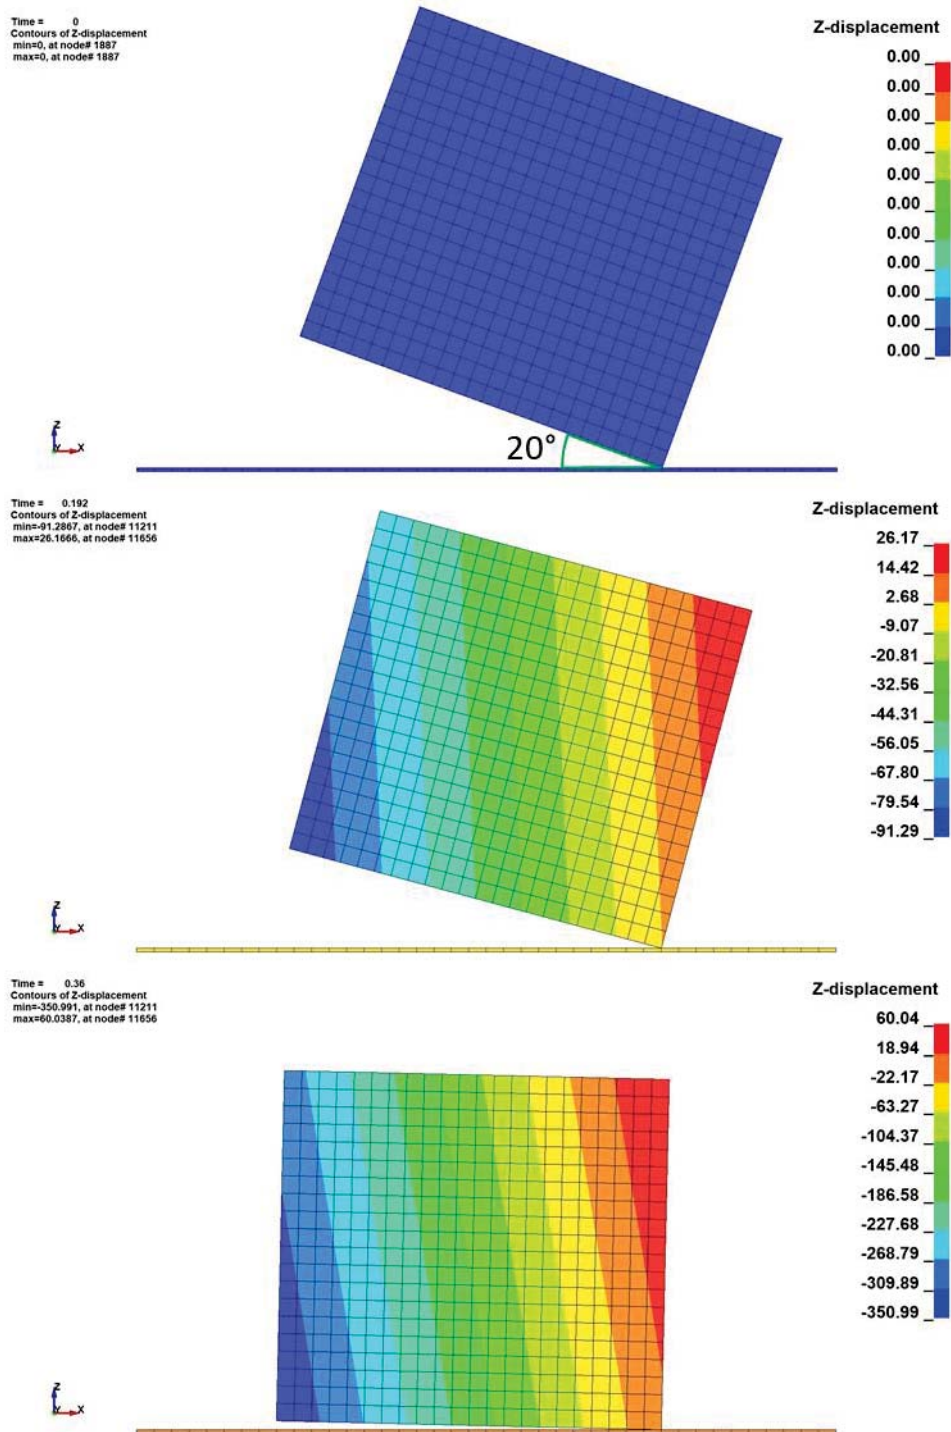

Figure 4: Checking the rocking fundamental period of the prism with dimensions 1.1 m x 1.1 m x 1 m – Contours of vertical displacement, given at mm, at time 0 s, 0.192 s and 0.360 s

Figure 5: Vertical displacement of the upper left corner over time

Figure 6: Horizontal displacement of the ground and the top and bottom surfaces of the prism for model A2

Figure 7: Horizontal displacement of the ground and the top and bottom surfaces of the prism for model A5

This effect of sliding back and forth at the beginning and at the end of the seismic motion is attributed to the simplified modelling of the ground motion. At the beginning and at the end of the loading, sinusoidal displacement is respectively abruptly initiated and changed back to no-motion. With a steady state harmonic oscillation, maximum speed is given at zero-crossing. Thus, in the present way of modelling the displacement, a very high acceleration is imposed onto the prism at these singular points. This in turn activates a very high impulse of inertia forces, which cause a short phase of sliding. This effect is a shortcoming when driving the model by displacements instead of prescribed accelerations. However, in previous work of the authors (e.g. [18], [19]) it was shown, that displacement drives make nonlinear systems with plasticity easier to handle. Note, that the simulations given in [14] are different: there, the displacements of the hammering pin are a priori unknown, and cannot be used to drive the system (see discussion in [14] chap. 5.1). In future simulations, a ramp-up as smooth transition between the states of motion and no-motion could be introduced.

#### **4.4 Models B2, C1, C2**

The increase of height in the model B2 being twice the length and width of the specimen led to qualitatively similar results to the models A5 and A6 with more severe tilting at the initiation of the excitation though, followed once again by a continuous stiction mode till the end of the excitation. Nonetheless, further increase of height in the model C1 led to significant tilting, taking place for more than the first 3 periods of seismic excitation as it is becoming obvious this time by both the horizontal displacement diagrams of Figure 9 and the horizontal displacement contours of Figure 12, but still without leading to overturning. As it can be seen in Figure 11 and Figure 13 though, this was the case for the analysis of model C2, for which the seismic frequency was doubled. Tilting initiated at the beginning of the seismic excitation caused uplift at first to the right side of the prism (direction of the seismic excitation at first quarter of the period), which was reversed after the reversal of the seismic displacement during the second quarter of the seismic period, which initiated at 0.389 s. This almost caused the overturning of the prism, which was nevertheless stalled due to the second reversal of the ground displacement. The prism remained at its uplifted position for the third quarter of the seismic period (0.778 s – 1.167 s) and finally after the third reversal and initiation of the fourth quarter of the 1<sup>st</sup> seismic period overturning was completed leading to loss of the bearing capacity. Once again, the prism carried out several consecutive hops, when in rocking position, during the second and third quarters.

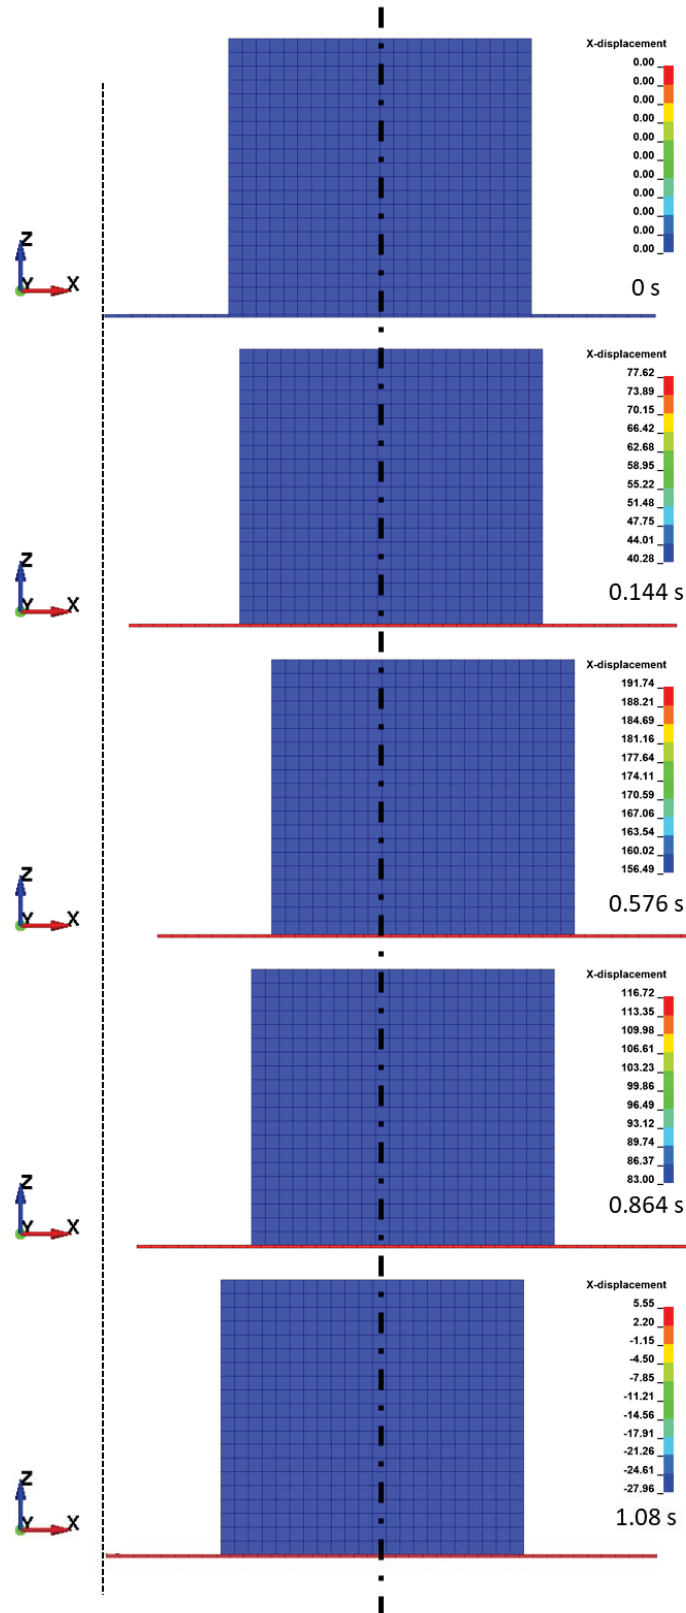

Figure 8: Horizontal displacement contours at arbitrary moments of the 1<sup>st</sup> period of the seismic loading for the model A2 – the broken and the dashed broken line show respectively the initial horizontal position of the ground belt's left edge and the prism's mass center

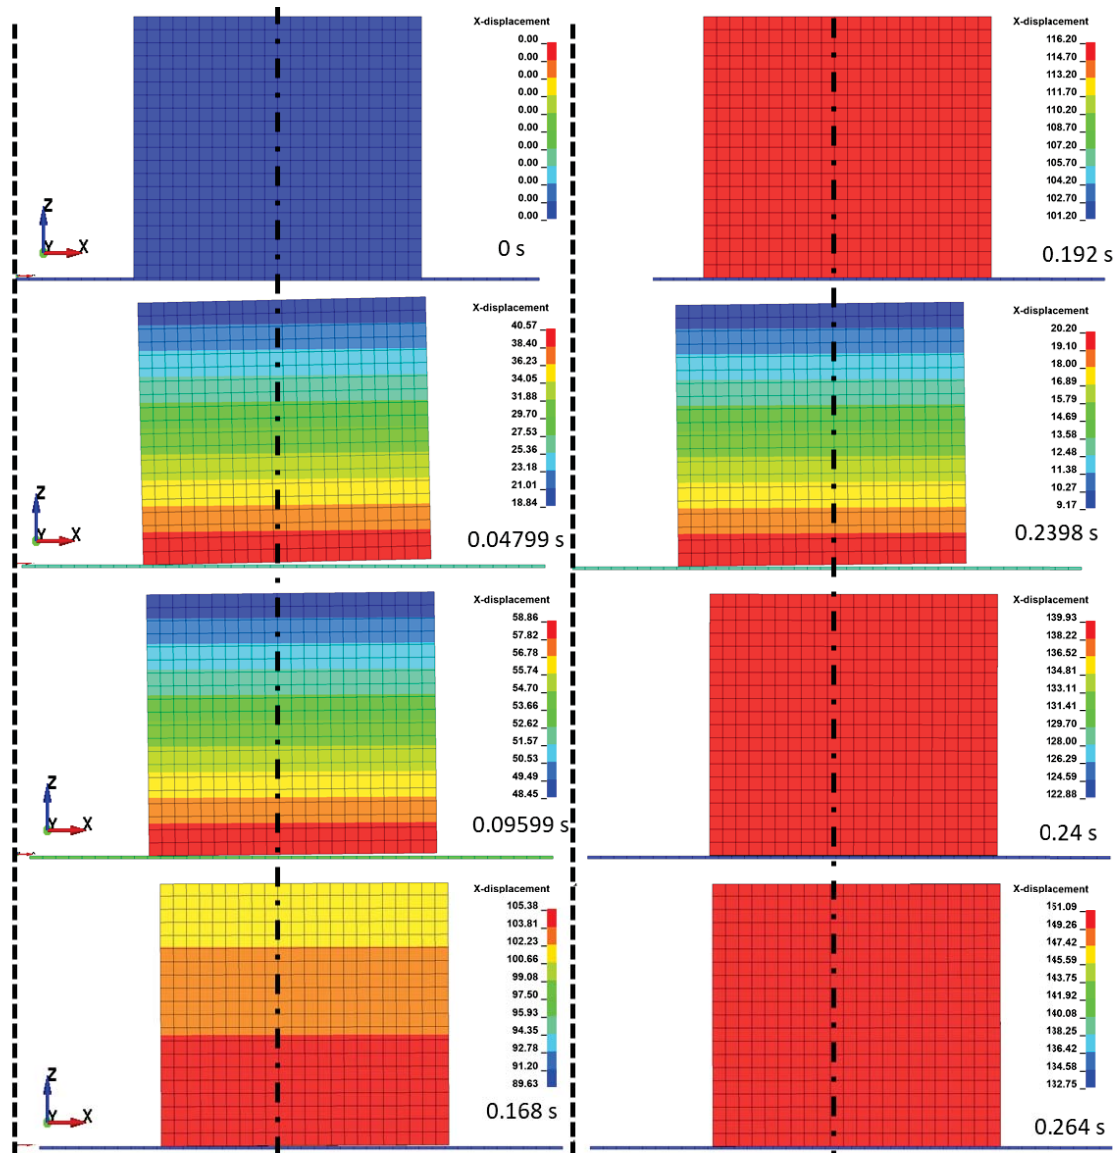

Figure 9: Horizontal displacement contours taken at arbitrary moments of the 1<sup>st</sup> period of the seismic loading for the model A5 - the broken and the dashed broken line show respectively the initial horizontal position of the ground belt's left edge and the prism's mass center

## 5 SUMMARY AND CONCLUSIONS

A series of numerical analyses was carried out in order to investigate the rocking behavior of a single or several steel boxes stacked upon each other, used for safe deposition of chemicals. Goal of the investigations was to test assumptions stated during the introduction of an analytical model in a previous study [1], prove the conservatism of this analytical model and act as a first-step towards the development of a numerical model, which will enable a parametric analysis of the investigated problem. The following conclusions were drawn:

- The numerically estimated rocking fundamental period of the investigated prism deviates significantly from the analytically calculated ( $\sim 20\%$ ). Further investigations are recommended in order to clarify the reasons for this discrepancy.
- The over-conservatism of the approach of the LFM is proven: It is shown that in many cases the loss of stiction does not lead to loss of bearing capacity.

Figure 10: Horizontal displacement of the ground and the top and bottom surfaces of the prism for model C1

Figure 11: Horizontal displacement of the ground and the top and bottom surfaces of the prism for model C2

- It is shown that the analytical model proposed by the authors is as well conservative, although less than the LMF method. For instance overturning of a structure, although initiated can be stalled due to the ground motion, an effect which cannot be described by the quasi-static model.
- The assumption stated above that different modes (sliding and sticking) can both be met during a seismic excitation is proven. This as well cannot be described by the quasi-static analytical model.
- The above-stated assumption that appropriate selection of friction coefficients is crucial is validated: for identical conditions increase of the static and dynamic friction coefficient from 0.4 to 0.57 and from 0.2 to 0.29 led to change of the rocking behaviour.
- Hopping due to bumping of the prism due to initial tilting of its front corner and action of horizontal stiction forces on its back corner, produces relative displacement between the prism and the ground. This as well cannot be described the quasi-static analytical model introduced by the authors.

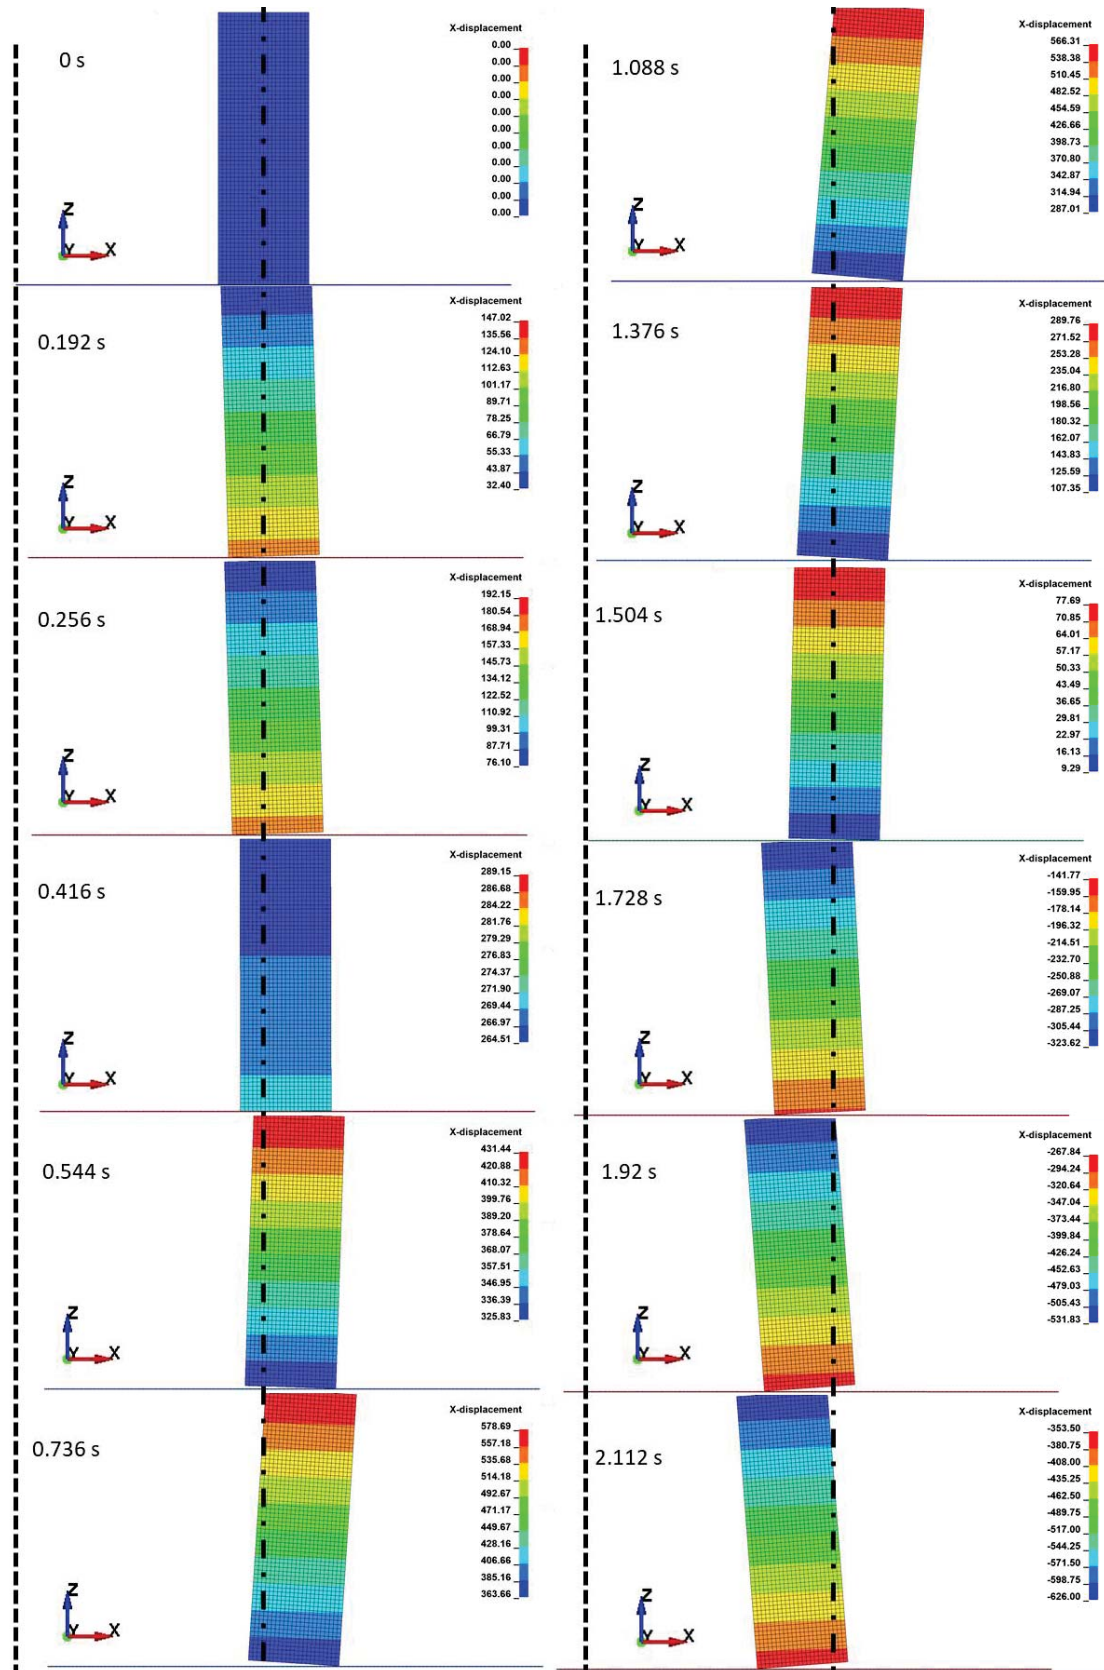

Figure 12: Horizontal displacement contours taken at arbitrary moments of the 1<sup>st</sup> period of the seismic loading for the model C1 – the broken and the dashed broken line show respectively the initial horizontal position of the ground belt's left edge and the prism's mass center

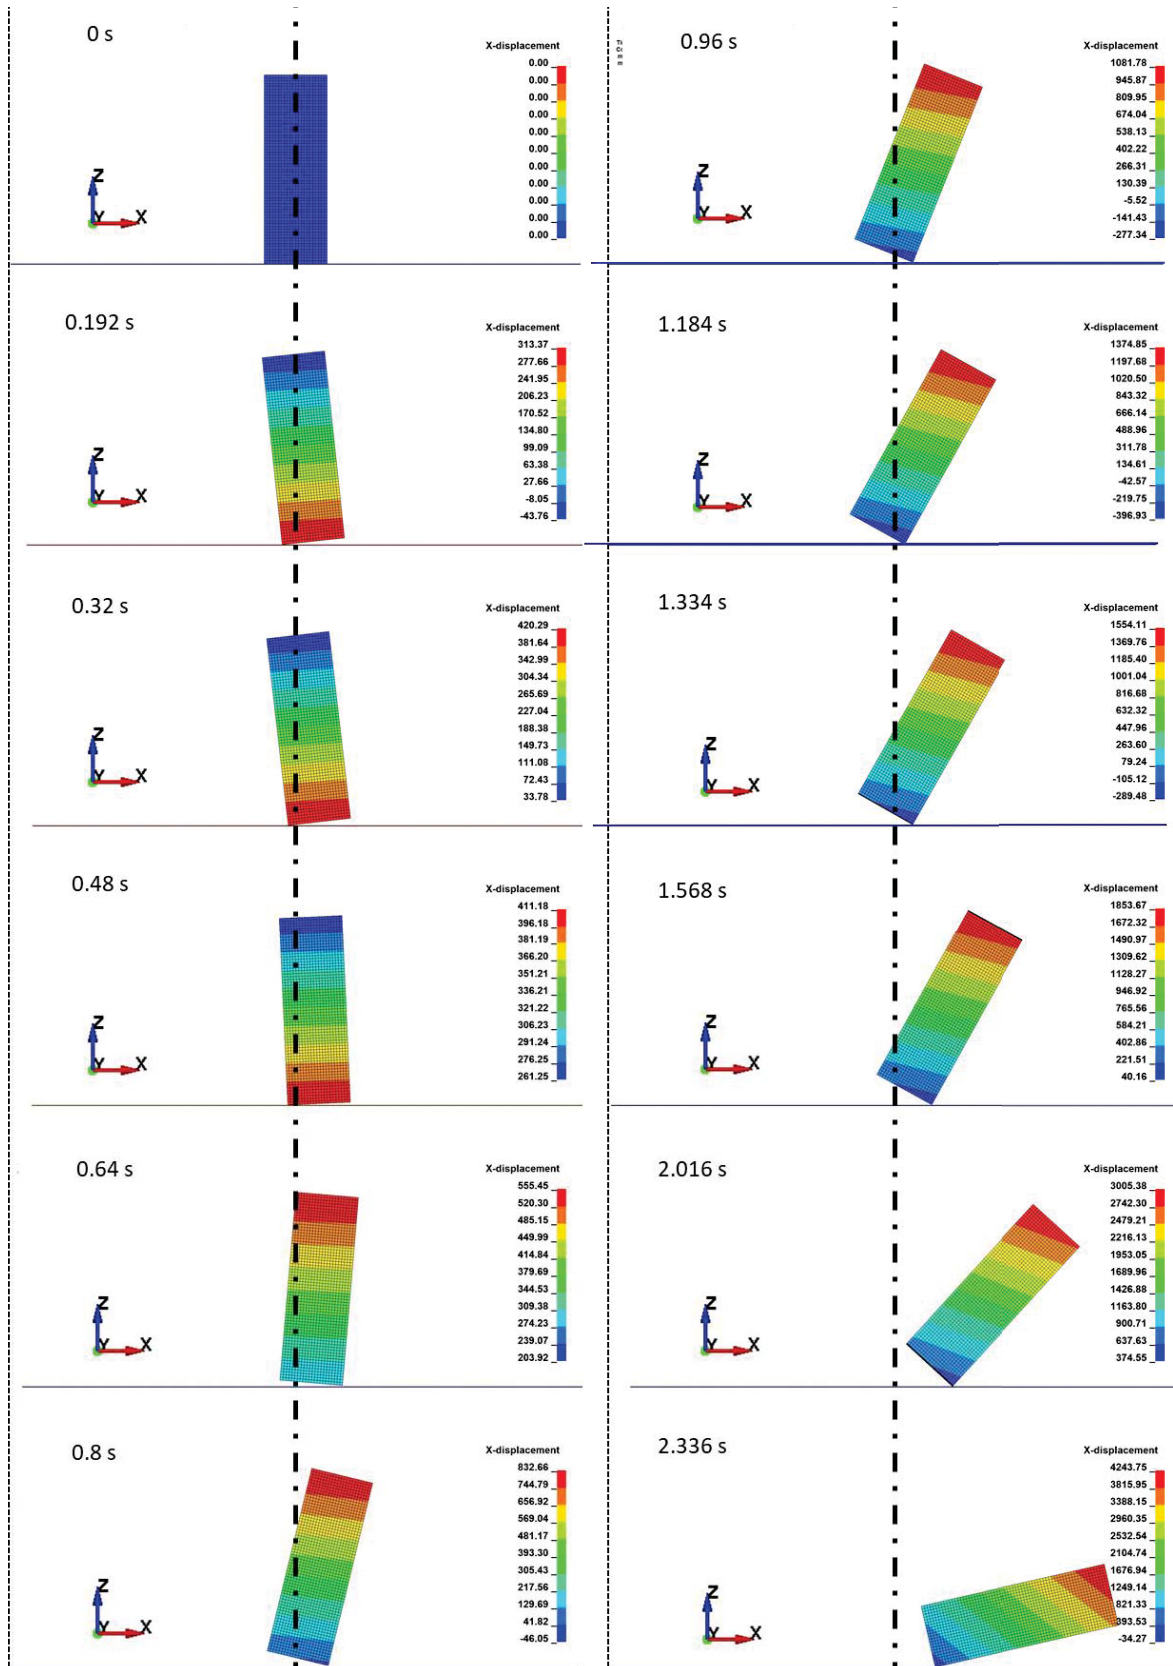

Figure 13: Horizontal displacement contours from the model C2 taken at arbitrary moments – the broken and the dashed broken line show respectively the initial horizontal position of the ground belt's left edge and the prism's mass center

In general, numerical investigations of the current problem show great potential for better understanding of the investigated systems behavior and for achieving less conservative results. A parametrization of the present model in future work in combination with varied and even real seismic excitation, could enable the estimation of the precise limits of transition from one mode of rocking behavior to another. It could be as well interesting to introduce a vertical seismic component, which assumingly could lead more easily to loss of stiction. Finally more detailed modelling of the structures geometry and physical properties could contribute to more accurate solutions.

## ACKNOWLEDGEMENT

The authors would like to thank the company *UTM Umwelt-Technik-Metallrecycling GmbH* for allowing the use of industrial data for the present academic project.

### Abstract

*Radio Telescopes have been widely used in deep-space exploration and satellite communications. High pointing accuracy is required to be high in these applications, since the beams involved in these measurements are narrow. However, pointing precision can be influenced by wind load effects, which represent a disturbance source for the support structures of the telescope, especially in the high-frequency range. This paper analyzes the wind load effects on the feed arm of the Green Bank Radio Telescope (GBO) for two different wind directions as a function of the wind speed. A Finite Element (FE) Model of the GBO has been assembled to evaluate the dynamic response of the structure against turbulent wind disturbances. The FE model has been updated according to results derived from previously developed models. The paper focuses the attention on the wind induced displacements of the feed arm, which is, for the examined structure, the main source of wind disturbances. The study shows that wind disturbances can deeply affect the pointing accuracy of GBO even at low wind speeds. Namely, for reference mean wind speed of 4 m/s the total along-wind lateral displacements of the feed arm can reach the maximum threshold associated with an acceptable Pointing Error (PE). Furthermore, displacements are larger for winds acting in the cross-elevation direction and can deeply affect pointing accuracy of the antenna measurements.*

## 1 INTRODUCTION

The Green Bank Radio Telescope is a large reflector antenna located in West Virginia, United States; it is a fully steerable, 100m diameter paraboloidal radio telescope capable of operating with high efficiency in a wide frequency range: from 0.1 to 116 GHz (wavelengths 3.0m – 2.6mm). The telescope is located near the heart of the United States National Radio Quiet Zone, a unique area in North America, close to the city of Green Bank, West Virginia, where authorities restrict all radio broadcasts to avoid emissions interfering with the GBT itself. The position of the telescope inside the zone of radio silence allows the detection of radio frequency signals, avoiding the interference of other weak signals emitted by other sources or human activities. The observatory is bordered by the National Forest and the Allegheny mountains, which shield it from further radio interference. As for the large antennas, which usually operate in open space without any protection from atmospheric loads, variable wind load effects can influence the accuracy of the pointing; in fact, the wind interference becomes one of the causes of PE that can induce structural resonance at low natural frequencies (close to 1Hz).

Figure 1. Picture of Green Bank Radio Telescope (reproduced from [www.skyandtelescope.com](http://www.skyandtelescope.com))

Pointing accuracy of large reflector antennas is influenced by few factors: deformation of the main reflector, lateral movement of the Feed-Arm, lateral displacement of the sub-reflector, rotation of the sub-reflector around the point of focus. Several types of orientation errors may be observed in large telescopes, requiring complex adjustment mechanisms to minimize the undesirable effects. These conditions can be, either integrally or in part, a consequence of the wind loads.

Pointing errors due to wind excitation have been often observed but rarely examined in the literature since the problem is particular to each structure (and telescope). For example, the first documented case of significant wind load effects on PE was documented by Ulich [1]. The current state-of-the-practice and analysis approach considers the combination of wind tunnel tests and computational fluid dynamics to simulate the wind loads [2-4]. Since each

structure is unique and effects are on occasion not fully predicted by simulations (i.e. during design), measurements of the flow field and wind loads around full-scale telescopes have also been considered [5]. In the case of flexible telescopes the issue of large deformation in the antenna may also affect the structural response [6]. Despite all these efforts, several problems are still unresolved and require careful consideration.

In this work the focus has been given to the lateral displacement of the sub-reflector, located at the top of the feed-arm, since it can be considered the largest source of wind induced PE in GBO. This work is part of ongoing research activity, which analyzes the wind-induced PE on large radio telescopes.

## 2 DESCRIPTION OF FINITE ELEMENT MODEL AND WIND LOAD SIMULATION

### 2.1 Finite Element (FE) model of GBO

For the purpose of studying wind effects on GBO, an FE model has been built, using *in Strand7* software package. The model consists of a total of 5702 nodes, 6133 beam elements, 2477 plate elements, 968 brick elements (Figure 2). Despite the geometric complexity of the model, the computational aspects do not require special efforts. Various models aimed to evaluate several load conditions, such as temperature gradient or gravitational effects, were previously built for similar structures [7].

The proposed analysis methodology is based on the application of wind loads on the structure through the FE model, after suitable discretization of the feed-arm in different sectors, each having different pressure distributions [8]. The discretization is schematically illustrated in Figures 2b, 2c. This approach aims to assess the wind load effects on the structure in terms of local displacements of the sub reflector, located at the top of the feed arm and the pointing error (PE), which represents the angle of rotation of the antenna compared to the non-deformed configuration [9-11].

Figure 2. (a) Finite element model of the Green Bank Radio Telescope, Schematic representation of the grid utilized for simulating wind forces on feed-arm, (b) elevation direction, (c) cross-elevation direction.

### 2.2 Application of the wind forces on the model of GBO

Wind load simulation has been studied on the GBO through spatial discretization of the wind field using a  $15 \times 15$  ( $6\text{m} \times 5\text{m}$ ) idealized grid in front of the telescope. At each node of the grid partially-correlated wind turbulence time histories of the along-wind field (primary)

load component are synthetically generated by standard wave superposition method [12]. The turbulent wind load, generated by assuming validity of the quasi-steady aerodynamic theory, which can be used to study a variety of structures (e.g. [13, 14]), has been imposed to simulate pressures and equivalent forces (based on tributary areas). The pressure coefficients of the telescope surface have been extracted and adapted from the results by Liu Yan [8]. The synthetically generated time histories of the loads have a duration equal to 60s, with a time step  $\Delta t = 0.01$ s. The loads have been evaluated for both “elevation” and “cross-elevation” mean wind directions, as shown in Figure 3.

Figure 3. Schematic representation of main, incident wind directions.

### 2.3 Linear dynamic integration approach

A linear, (step-by-step) dynamic integration approach has been applied for examining the wind load effects, described in the previous sections and acting on the feed arm, for the two examined mean wind directions (Figure 3). The Results of the dynamic integration approach of wind load simulation are illustrated in Figure 4 for a reference mean wind speed of 4 m/s at a reference elevation from ground  $z_{ref}=10$  m.

Figure 4. Time history of turbulent along-wind dynamic displacements of the top node of feed-arm, for wind acting in (a) elevation direction and (b) cross- elevation direction, at a reference ground speed of 4m/s.

Figure 4a presents typical along-wind displacements of the feed-arm top node for mean wind acting in the elevation direction; Figure 4b shows an example of along-wind displacements for mean wind acting in the cross-elevation direction.

### 3 CONCLUSIONS

This study discusses the turbulent wind effects on the GBO for two different wind directions: elevation and cross-elevation direction. Along-wind induced displacements of the feed-arm were examined for different ground wind speeds. Results shows that, even for low ground wind speed such as 4m/s, displacements of the-feed arm can approach the maximum threshold for pointing PE. In particular, displacements are greater for the wind acting in cross-elevation direction. Future studies will examine the validity of the quasi-steady aerodynamic theory for the estimation of wind loads, the relevance of transverse loads due to wake excitation along with potential flow-structure interaction.

### Abstract

*Column base plate connection is one of the most critical structural components of steel moment-resisting frames which acts as a transfer medium to transmit the reaction forces, shear and moments from the entire building into the foundation. Failure of these base plate connections is critical since it can result in the collapse of the entire structure. Very often these base plates experience bidirectional lateral loadings from natural events such as wind and earthquake. Previous studies considered uniaxial lateral loading combined with axial load but do not provide any guidelines for exposed column base plate connections under axial load and biaxial lateral loading. This study aims to develop an accurate nonlinear finite element (FE) model of exposed column-base connections under combined axial load and bi-axial lateral loading using general purpose finite element software ABAQUS. The developed model is validated against experimental results under monotonic and cyclic loading considering both geometric and material nonlinearities to check the accuracy of the model. After validation, a bidirectional symmetric lateral loading combined with constant axial compressive load is applied in the developed model to analyze the response of the column-base plate connections. Further, the effects of three different parameters of column base plate connection such as base plate thickness, base plate yield strength, and anchor rod diameter are investigated through parametric study. Results show that higher value of base plate thickness and anchor rod diameter significantly affect both the stiffness and strength of column base connections. It also demonstrates that base plate yield strength has no significant influence on column base connections.*

**Keywords:** Column Base Plate Connection, Bidirectional Lateral Loading, Finite Element Modeling, Parametric Study.

---

## 1 INTRODUCTION

In steel moment-resisting frames, column base plate (CBP) connection is one of the most critical structural components that transfer the forces and moments from the superstructure to the substructure. Under dynamic loadings, such as earthquake and wind, the dynamic effects are transferred to the structure through the base plate of this connection. Failure of the CBP connection can result in the collapse of the entire frame as the ductility demand and force distribution in the structure is directly affected [1]. Tremblay et al. [2] and Midorikawa et al. [3] outlined several issues with the exposed type CBP connections experienced during the past major seismic events (e.g. 2011 Tohoku, 1995 Kobe, 1994 Northridge). Exposed column base connections are mostly found in low-rise steel structures around the world. Over the past forty years, researchers have extensively investigated various parameters, both experimentally and numerically, affecting the design, behavior, and strength of CBP connections [4-7]. These research outcomes led to the publication of the AISC Design Guide 1 [8] for column base plate design, which is still widely used in the industry. Fahmy et al. [9] examined the base connection failure mechanisms and categorized them into three main groups as "weak column-strong connection", "balanced mechanism", and "strong column-weak connection". All of these previous studies and design guidelines focused on the base plate design under axial load and uniaxial bending moment although the base plates very often can experience bidirectional bending moment from lateral loads. Though the columns are designed and checked considering axial load and biaxial bending, when it comes to the base plate connection, only the axial load combined with major axis bending is considered.

Lee et al. [10, 11] experimentally and numerically investigated the response of CBP connections under weak axis moments. They concluded that the widely used Drake and Elkin's design method is inadequate for designing CBP connections under minor axis bending. Gomez et al. [12] formulated a new technique for characterizing the strength of the CBP connections by introducing a plastic mechanism through extensive experimental study. This study was further expanded by Kanvinde et al. [13] through finite element (FE) analysis to investigate the stress distribution in different components of CBP connections. Although very effective, both of them concluded that the recommended method is not applicable for designing CBP connections under biaxial bending. Fasaee et al. [14] conducted a numerical investigation to evaluate the capacity of flexible CBP connections under axial load and biaxial bending. They proposed an analytical model to determine the moment capacity along the major and minor axis considering the variation of applied axial load only. Recently, Song et al. [15] performed a reliability analysis of CBP connections under combined axial compression and flexure. They identified AISC Design Guide 1 [8] approach to be inconsistent which underestimated the flexural demand in the base plate and inapplicable for CBP connections under biaxial bending. Although they proposed two alternative design approaches for overcoming these limitations and improving the reliability, however, those are only applicable under uniaxial bending.

Currently, there exists a gap in the literature that comprehensively investigates the behavior of exposed CBP connections subjected to combined axial load and biaxial bending. Hence, this study aims to investigate the behavior of the W-shaped steel CBP connection under combined axial load and biaxial bending through parametric numerical analysis. This is achieved through the pursuit of considering different values for three parameters of CBP connections such as base plate thickness, base plate yield strength, and anchor rod diameter.

## 2 FINITE ELEMENT MODELING – METHODOLOGY AND VALIDATION

A detailed 3D nonlinear finite element (FE) model is developed using ABAQUS [16] simulation platform. FE model constructed for validation in this study considered the geometric

and material properties of CBP connections experimented by Gomez et al. [12]. The FE model is developed and validated in two phases where the model is constructed as a half model first due to the symmetric nature of the specimen under monotonic loading to reduce the simulation time for interpreting a suitable modeling strategy. Later, a full FE model is developed instead of the half-model to simulate the accurate behavior under combined axial load and lateral cyclic loading. A description of the overall methodology to develop the FE model followed by the validation of the developed models is presented in the subsequent sections.

## 2.1 Methodology

All the elements are modelled as 3D deformable solid elements except the column in the full model which is defined as shell elements for validating the complex cyclic simulation with the consideration of global and local buckling behavior [17]. The column is considered as a W200x71 section which reflects the typical members that are used as the first-story interior columns of steel moment resisting frames (SMRF). The length of the column is considered as 2350 mm from the top of the base plate. The cross-sectional dimension of the grout is considered the same as the base plate dimension (356mm x 356mm). A 1220x1220x610 mm concrete footing is considered for the foundation of the CBP connection. Figure 1 shows details of the geometry and dimensions of the specimens used to validate the FE model.

Figure 1: (a) Geometric details (b) Developed FE model

All the 3D solid elements of the developed model are meshed with hexahedral (C3D8R) element whereas the shell element of the column is meshed with quadratic 4-node doubly curved (S4R) shell elements accumulating a total number of 82000 elements. Geometric nonlinearity (NLGEOM) is considered due to the nonlinear effects of large displacement. Column is meshed by dividing its length into three equal parts for computational efficiency. The bottom part is meshed using the same element size as the base plate to neglect the convergence issue while the other parts are meshed using a coarser mesh size. Grout is also meshed by a size similar to the column bottom part and base plate. Anchor rods, nuts and washer are meshed using finer element size to accurately capture the stress behavior of these elements. Since the behavior of footing is not considered in this study, larger mesh size is considered for the footing. A mesh sensitivity study is conducted to accurately predict the results as well as to ensure the computational time efficiency of the developed FE models. For brevity, the details

of the mesh sensitivity study are omitted from this paper. It is very usual for steel structural elements to contain geometric imperfections as well as residual stresses due to the manufacturing and handling process. Geometric imperfection is introduced to capture the global out-of-straightness imperfections of the column. Separate linear perturbation buckling analysis is performed to obtain different buckling modes of the respective column. A global out-of-straightness limit equal to  $L/1500$  [17] is applied with the first buckling mode of the column during the construction of the full model under cyclic loading.

Explicit modeling of component interaction is critical as the contact and gapping of CBP connection components control the overall connection response [13]. Tie constraints are provided between the column and base plate, anchor rods, nuts, and washers, and between the grout and concrete because of their monolithic properties. Surface to surface contact interactions are defined between the interfaces of the base plate and grout, base plate and both the top and bottom washer, and anchor rod-base plate with the finite sliding formulation. Two different interaction properties are defined for these surface to surface interactions. A coefficient of friction of 0.45 is used for the base plate and grout whereas 0.80 is used for the other two interactions [18]. The pressure overclosure for normal behavior is considered as hard contact and separation after contact is allowed whereas the constraint enforcement method is set as default for both the interaction properties. No constraints or interactions are defined between the concrete footing and the anchor rods assuming their interfaces to be free as prescribed by Gomez et al. [12]. Figure 2 illustrates a schematic description of contact and interactions between different components of CBP connection.

Figure 2: Contact and interactions of different components of CBP connection

The bottom of the concrete footing is restrained in all six degrees of freedom to simulate a fixed-base condition. When the FE model is constructed as a half model under monotonic loading, a symmetric boundary condition is provided parallel to the center plane of the column web to simulate its full-scale behavior. On the other hand, to accurately capture the flexural yielding and geometric instabilities under cyclic loading with full model, a flexible boundary condition is considered at a reference point defined at the cross-section center of the top of the column.

## 2.2 Material modeling

**Steel Elements:** Von-Mises type of material with a nonlinear isotropic/kinematic hardening material model is used to define the column and base plate. In addition to the modulus of elasticity and yield stress, the nonlinear kinematic and isotropic hardening components ( $C$ ,  $\gamma$ ,  $Q^\infty$ ,  $b$ ) are considered for cyclic loading which are derived from the Chaboche [19] model. A

nonlinear monotonic isotropic hardening is modeled for anchor rod whereas nut and washer are modeled as elastic-perfectly plastic material. The hardening parameters used for these parts are from the results of the ancillary experiments conducted by Gomez et al. [12]. Table 1 and 2 provides the values used to define different steel materials for validation of developed FE model for monotonic and cyclic loadings, respectively.

	Yield Stress (MPa)	Modulus of Elasticity (GPa)	Poisson's ratio	Material type
Column	345	200	0.3	nonlinear isotropic hardening
Base Plate	280	200	0.3	nonlinear isotropic hardening
Anchor Rod	786	200	0.3	nonlinear isotropic hardening
Nut & Washer	345	200	0.3	elastic perfectly plastic

Table 1: Steel material for monotonic loading

	Yield Stress (MPa)	Modulus of Elasticity (GPa)	Poisson's ratio	C (MPa)	$\gamma$	$Q_{\infty}$ (MPa)	b
Column	380	200	0.3	3378	20	90	12
Base Plate	255	216	0.3	6895	25	172	2
Anchor Rod	790	200	0.3	nonlinear isotropic hardening			
Nut & Washer	345	200	0.3	elastic perfectly plastic			

Table 2: Steel material for cyclic loading

**Concrete Elements:** Concrete damage plasticity model is developed based on compressive strength for both grout and concrete pedestal. The compressive strengths used for developing concrete damage plasticity model are adopted from the ancillary test results by Gomez et al. [12] for both footing & grout. For monotonic loading phase, the compressive strength of grout and footing is considered as 51 and 27 MPa, respectively. Similarly, the compressive strength of grout and footing is considered as 64 and 30 MPa, respectively for the cyclic loading case. Default values were used for the other parameters to define the concrete damage plasticity model as provided in Table 3.

Parameters	Value
Dilation angle ( $\psi$ )	$36^{\circ}$
Eccentricity (e)	0.1
$f_{b0}/f_{c0}$	1.16
K	0.6667
Viscosity parameter	0.001

Table 3: Concrete damage plasticity parameters

### 2.3 Loading protocol

At first, monotonic loading in the form of lateral displacement (10.58% column drift) is applied along the major axis direction with no axial load. After validating under monotonic load, SAC cyclic loading protocol with a maximum drift of 10.6% is applied in the column major axis direction with a constant 410 KN axial compression at the top of the column to validate the model accuracy under combined axial load and uniaxial cyclic loading.

## 2.4 Validation of developed FE model

The developed FE model is validated against experimental results from Gomez et al. [12] under monotonic and cyclic loading for Test no. 1 and Test no. 5, respectively to check the accuracy of the adopted modeling approach. For monotonic loading, the developed half FE model is validated in terms of anchor rod force and base plate deformation profile as shown in Figure 3 and 4, respectively. From both the Figures, it can be seen that the developed FE model can very well predict the experimental results with reasonable accuracy signifying the suitability of the adopted modeling techniques and material models.

Figure 3: Comparison of experimental (Gomez et al. [12] Test no. 1) and numerical (FE) results

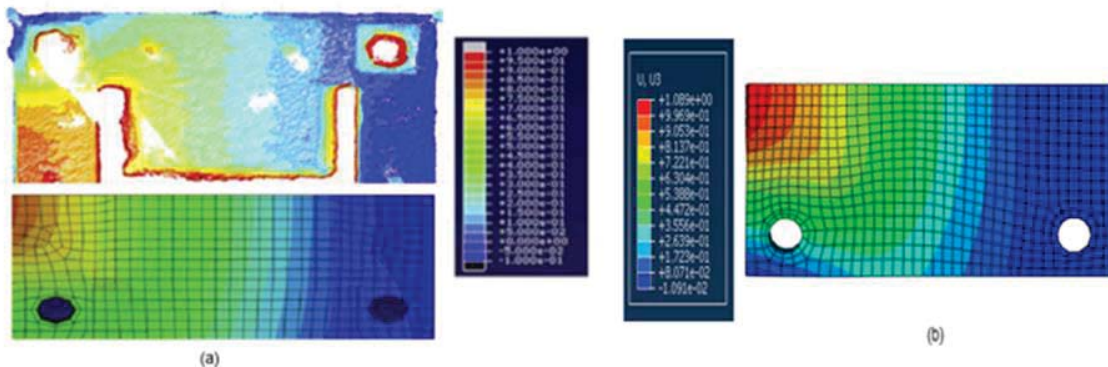

Figure 4: Base plate deformation behavior (a) Gomez et al. [12] Test no.1 (b) developed FE model

Further, the full FE model is validated under cyclic loading protocol in terms of the lateral load-displacement profile as shown in Figure 5. It is found that the variation of maximum lateral load is only 3% between the experimental (Test No. 5 of Gomez et al. [12]) and numerical results. Also, it is evident from Figure 5 that the hysteresis loop for the developed FE model and experimental results are quite similar except for the slipping behavior which is due to the complexity of the interactions among the various CBP connection elements. All these validation results suggest that the adopted modeling techniques can be applied with a high degree of confidence for further investigation.

Figure 5: Validation of FE model using cyclic loading

### 3 PARAMETRIC STUDY

Once validated, a total of 12 FE models are developed for the parametric study to understand the behavioral insights of the CBP connections under combined axial load and biaxial bending. These models consider different practical values for three critical column base connection parameters such as base plate thickness, base plate yield strength and anchor rod diameter. Since no symmetric plane is available when the specimen is subjected to biaxial bending, a full model is considered to simulate the behavior of the CBP connection. Details of the test matrix and development of the bidirectional loading protocol are described in the subsequent sections.

#### 3.1 Parametric analysis cases

The three critical parameters of the analytical investigation are selected from the literature review conducted by Grauvilardell et al. [1] as well as the previous parametric study done by Trautner and Hutchinson [20] where they categorized different parameters of CBP connection into low, medium, and high category. Based on these studies, three critical parameters with variable ranges are considered in this study. Table 4 provides the details of the simulation matrix considered in this parametric study where the bold numbers indicate the variable values of different parameters. Each of the cases considered only one variable to understand its effect on the base plate connection considering PR-01 as the base model.

Parameter	Specimen ID	Parameter Values						
		Base Plate Thickness (mm)	Base Plate Yield Strength (Mpa)	Anchor Rod Dia (mm)	No. of Anchor Rod	Embedment Length (mm)	Grout Thickness (mm)	Axial Load Ratio
Base Model	PR-01	<b>25</b>	<b>350</b>	<b>20</b>	<b>4</b>	<b>500</b>	<b>25</b>	<b>0.2</b>
Base Plate Thickness	PR-02	<b>16</b>	350	20	4	500	25	0.2
	PR-03	<b>20</b>	350	20	4	500	25	0.2

### 3.2 General features of the FE models

All the developed FE models of the parametric analysis cases have similar geometric and material properties. ASTM A992 Grade 50 W250x73 column section (typical interior first story column) having 2000 mm length (2/3rd of typical first story height of SMRFs) is designed according to the requirements of CSA S16-19 [21]. The column is designed considering yield strength ( $F_y$ ) of 345 MPa and modulus of elasticity ( $E$ ) of 200 GPa and the cross-section is selected to prevent local buckling criteria as well as its capacity to ensure its effectiveness before the failure of the base plate connection. A rectangular base plate of 407 mm x 407 mm, welded together with the column, having different thicknesses and yield strength is selected for the study. Anchor rods of different sizes are designed using yield strength and modulus of elasticity of 790 MPa and 200 GPa, respectively following the requirements of CSA S16-19 [21] and CSA A23.3-19 [22] to prevent any type of failure in the concrete by pullout or breakout strength. The nut and washers are selected according to standard geometry for the specific anchor rod. A concrete foundation of 1220 mm x 1220 mm is designed to support all types of loading. Non-shrink grout having 64 MPa compressive strength of various thickness is also considered between the pedestal and the base plate. All the FE models developed for the parametric analysis study have the same configuration of mesh size, geometric imperfection, tie contact, and interaction properties as the validated full FE model. Anchor rods, nuts and washers and concrete material properties of the developed FE models are also the same as the validated model.

### 3.3 Bidirectional lateral loading protocol

A bidirectional symmetric lateral loading protocol is developed for the numerical investigation in pursuance of evaluating the effect of biaxial bending on the exposed CBP connection. This cyclic loading protocol is developed for a four-story steel frame building following the concepts discussed in Krawinkler [23] and Elkady [17]. The loading protocol covers a wide range of story drift ratios starting from 0.375% amplitude up to amplitude of 4% radians in the column's strong axis direction as shown in Figure 6(a). It also covers story drift ratio ranging from 0.25% to 2% amplitude in the column's weak axis direction as shown in Figure 6(b). When combined, it is found that the developed bidirectional loading protocol achieves a maximum drift ratio of 3% in the column's strong axis direction when 2% drift amplitude is reached in the column's weak axis direction as depicted in Figure 6(c). Detail procedure of the developed bidirectional loading protocol is described in Elkady [17].

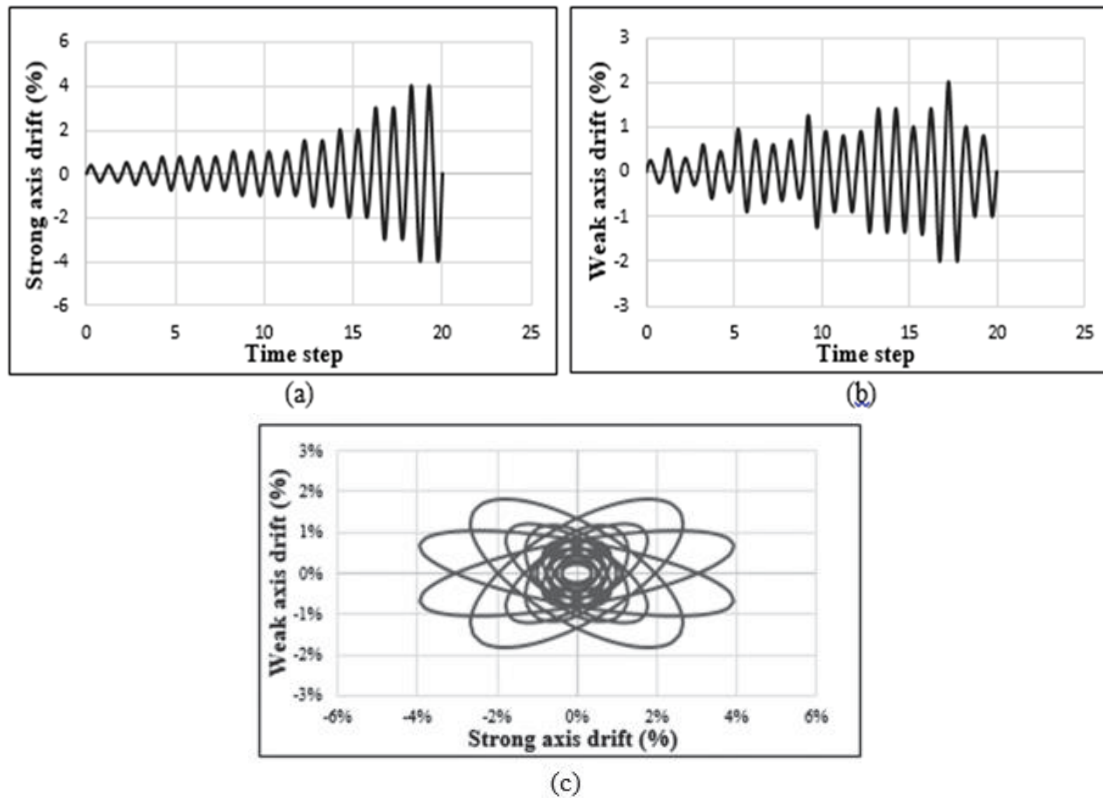

Figure 6: Developed bidirectional symmetric lateral loading protocol: (a) history of strong axis drift ratio; (b) history of weak axis drift ratio; (c) history of strong axis vs weak axis drift ratio

#### 4 RESULTS AND DISCUSSION

The analytical results obtained from the parametric study have been used to further understand the behavior of exposed CBP connections subjected to combined axial load and biaxial bending. Results are scrutinized in terms of moment-rotation curve which is a key output to better understand the connection behavior by defining the rigidity, resistance, and rotational capacity of any connection. Table 5 provides the summary of the results extracted from the FE models.

FE Model ID	Axis	Yield			Ultimate			$K_{\theta(Yield)} / K_{\theta(Ultimate)}$
		M (KN-m)	$\theta \times 10^{-3}$ (rad)	$K_{\theta} \times 10^3$	M (KN-m)	$\theta \times 10^{-3}$ (rad)	$K_{\theta} \times 10^3$

Table 5: Summary of FE model results

#### 4.1 Moment-rotation behavior

For each FE simulation, the hysteretic response in terms of base moment-rotation is plotted as shown in Figure 7 and compared within the various values of the specific parameter considered in the analytical study. Further bilinear moment-rotation curve, considering yield point and ultimate point, is developed for both the strong (x-axis) and weak axis (y-axis) and analyzed separately for convenient visualization. Column plastic moment capacity ( $M_p$ ) is also shown in the same plot (horizontal line) for both strong and weak axis direction. The column base moment ( $M$ ) and base rotation ( $\theta$ ) are computed from the column lateral force and lateral displacement according to Eq. (1) and Eq. (2), respectively.

$$M = F \times H_{col} \quad (1)$$

$$\theta = \left( \Delta_{top} - \frac{F \times H_{col}^3}{3 \times E_{col} \times I_{col}} \right) \times \frac{1}{H_{col}} \quad (2)$$

Where,  $F$  is the lateral force at the column top,  $H_{col}$  is the column height from the base plate,  $\Delta_{top}$  is the displacement at the top of the column,  $E_{col}$  is the modulus of elasticity of the column,  $I_{col}$  is the column's second moment of inertia in the direction of loading.

Figure 7: Moment-rotation hysteresis curve for PR-01 model (a) Strong axis (b) Weak axis

#### 4.2 Effect of base plate thickness

Six different base plate thicknesses (PR-01 to PR-06) are considered with values ranging from 16 mm to 50 mm. For the base model (PR-01), the base plate thickness of 25 mm is considered for the study which is widely used in the construction industry. Figure 8 illustrates the comparison of bilinear moment-rotation curves for various base plate thicknesses. It is observed from Figure 8 that a higher value of base plate thickness increases both the stiffness and the strength of the connection for both strong and weak axis direction. This is plausible since an increase in base plate thickness increases the flexural rigidity as well as bending resistance of the plate. However, it should be noted that the effect of base plate thickness is more pronounced in the strong axis direction compared to the weak axis. A significant increase in the strength of the connection is observed after yielding for each of the simulation cases except for the PR-02 where the base plate thickness is considered as 16 mm. Early yielding of the base plate of lower thickness significantly hinders the strength gain of the CBP connection. As reported in Table 5, the average ratio of yield to ultimate rotational stiffness for various base plate thicknesses is 2.06 and 1.7 in the strong and weak axis direction, respectively. It is also found that the strength of all the base connections with different base plate thicknesses is significantly below the column plastic moment capacity in both the strong and weak axis directions. In brief, as the base plate thickness increases, the strength of the base connection is augmented with the reduction in ductility.

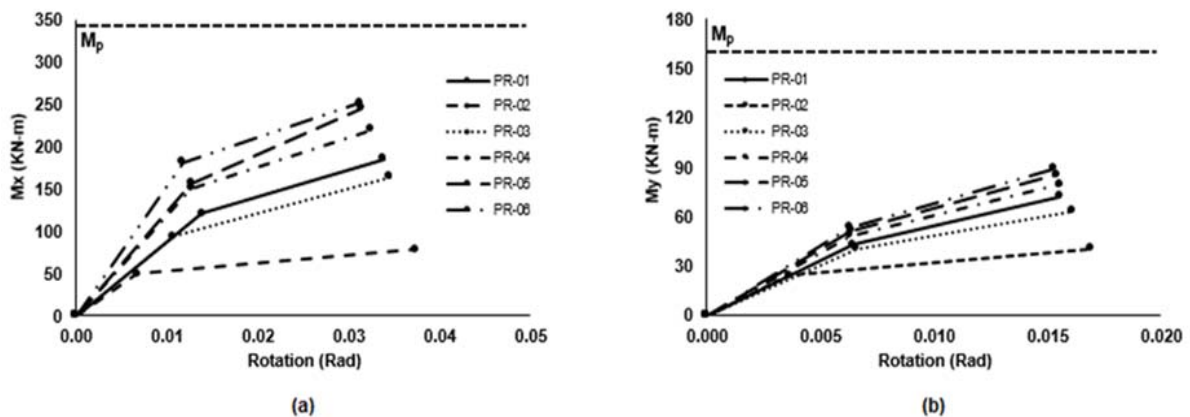

Figure 8: Effect of base plate thickness (a) Strong axis (b) Weak axis

#### 4.3 Effect of base plate yield strength

Different base plate yield strengths of 300, 350 and 400 MPa (PR-01, PR-07 and PR-08) are considered to understand the effect of base plate yield strength on base plate connection behavior. Although base plate yield strength is not considered in the previous experimental study on CBP connections, it is considered in this study due to its contribution on the design of base plate thickness according to AISC Design Guide 1 [8]. The variations in the base plate strengths are considered based on the most commonly used steel grades in industry. It can be seen from Figure 9 and Table 5 that base plate yield strength does not influence the moment-rotation response in the weak axis direction. However, initial stiffness is found to be lower when the base plate yield strength is changed from the base model of 350 MPa in the strong axis direction.

Figure 9: Effect of base plate yield strength (a) Strong axis (b) Weak axis

#### 4.4 Effect of anchor rod diameter

Different anchor bolt diameters ranging from 16 mm to 38 mm (PR-01, PR-09 to PR-12) are selected to scrutinize the moment-rotation behavior of CBP connections. Figure 10 represents the effect of anchor bolt diameter in terms of moment-rotation curves of the base plate connection. It is evident that an increase in anchor bolt diameter increases the initial stiffness as well as the strength in both axes directions. A larger bolt diameter affects the flexibility of the base plate cantilever length by contributing in the base rotation. An increase of 20% is observed for maximum strength in the strong axis direction when the diameter is increased from 20 mm to 38 mm. Conversely, a 6% increment is observed in the weak axis direction for the same configuration. Changes in the initial stiffness are found to be more obvious in the strong axis than the weak axis of the base plate connection. As reported in Table 5, the average ratio of yield to ultimate rotational stiffness is 1.60 and 1.52 in the strong and weak axis direction, respectively.

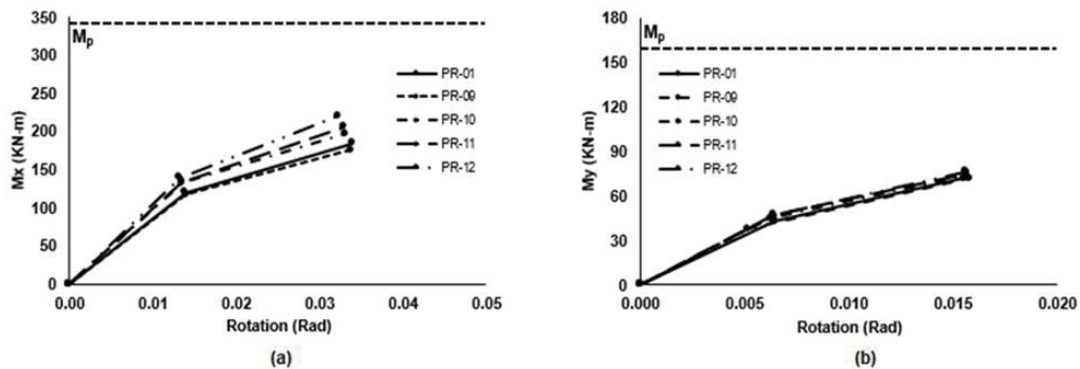

Figure 10: Effect of anchor rod diameter (a) Strong axis (b) Weak axis

## 5 CONCLUSIONS

- Higher value of base plate thickness increases both the stiffness and the strength of the connection for both strong and weak axis directions.
- The effect of base plate thickness is more pronounced in the strong axis direction compared to the weak axis direction.
- Early yielding of the base plate is observed for the thinner (16 mm) base plate of the CBP connection.
- Base plate yield strength has no significant influence on CBP connection within the considered ranges.

- An increase in anchor bolt diameter increases both the initial stiffness and strength in strong and weak axis directions.
- For different anchor rod diameters, changes in the initial stiffness are found to be more obvious in the strong axis than the weak axis of the base plate connection.

### Abstract

*In this present work the geometrical non-linearity in free in-plane vibration of inextensible functionally graded circular arch with uniform cross-section and pinned-pinned at both ends has been studied. For simplification, the complicating effects such as rotary inertia and shear deformation will be ignored. The sixth order differential partial equation of motion has been obtained after the inextensibility assumption. This study is based on Euler Bernoulli theory and Von Karman's assumptions. The kinetic and total strain energies due to the axial strain and bending have been discretized into a series of a finite spatial functions and derived by applying the Hamilton's principle energy. The non-linear algebraic equations were obtained and solved numerically using an approximate explicit method developed previously the so-called second formulation. A numerical results have been obtained to examine the effects of the volume fraction index on non-linear behavior of the arch. Comparison is made with the available results for the case of isotropic homogeneous circular arches: good agreement is obtained.*

**Keywords:** geometrical non-linearity, free in-plane vibration, functionally graded circular arch, uniform cross-section, second formulation.

## 1 INTRODUCTION

Arches have become one of the very important structures elements that are used in many areas such as aeronautics, civil engineering and mechanical engineering due to its ability to transfer loads through the combined action of bending and stretching for in-plane deformations. The equations of free in-plane vibration of an arch are very complex when the complicating effects such as axial extension, shear deformation and rotatory inertia are taken into account. If these effects are neglected, then the equations become much simpler, but the main simplification arises if the arch axis is assumed to be also inextensible.

H. Saffari et al [1] used a finite element technique to obtain the natural frequencies and mode shapes of circular arch in free vibration analysis. The Rayleigh-Ritz method was employed by Laura et al to find the fundamental frequency of arches with various types of cross-section using polynomial functions as a trial function of displacement [2]. G.R. Liu, T.Y. Wu were applied the generalized differential quadrature rule to investigate the free in-plane vibration of inextensible Euler-Bernoulli arches with uniform, continuously varying, and stepped cross-sections. A semi analytical solution for in-plane vibration of circular arch was used by A. Babahammou and R. Benamar [3], [4] to find the linear frequencies and mode shape of arches with various boundary conditions. The results shown a very good agreement with those available in the literature. Recently, the geometrically non-linear in free in-plane vibration of circular arches elastically restrained against rotation at the two ends was investigated by O. Omar et al [5].

Functionally graded material can be defined as a new class of non-homogeneous composite materials made from combination of two different materials. In recent years, a lot of research has been done to study the geometrical non-linearity of the FGM and composite structure based on Benamar's method such as [6]–[10]

The free in-plane vibration of arches made of homogeneous, composite, and FG materials was the interest of numerous researchers such as . Hadi Babaei et al [11] have investigated the large amplitude free vibration of curved beam (shallow arch) resting on elastic foundation. The natural frequencies of a deep circular arch made of FG materials with arbitrary thickness and boundary conditions, have been obtained in [12]. The influence of the temperature, boundary conditions and the material graded index as well as the different geometrical parameters such as the thickness-to-mean radius ratio and the opening angle on the frequency parameters of the FG arches have been investigated by [13]. M. Javan et al [14] have studied a large amplitude thermally induced vibration analysis is investigated for shallow FGM arches under different cases of rapid heating on the top and bottom surfaces. In [15] an analytical solution to study the non-linear thermal bending and buckling of the through-the-thickness FGM shallow arches is presented, taking into account the variation of critical buckling temperature in terms of power law index, geometric parameter and opening angle.

This current work deals with the study of the geometrical non-linearity in free in-plane vibration of a FGM circular arch with uniform cross-section and pinned-pinned at both ends. This theoretical model is based on the Euler-Bernoulli theory and the Von Karman assumptions. The complicating effects such as rotary inertia and shear deformation will be ignored. The kinetic and total strain energies due to the axial strain and bending were discretized into a series of finite spatial functions and derived using Hamilton's principle energy. Then, the non-linear algebraic equations are obtained and solved numerically using an explicit method developed previously, the so-called second formulation. A numerical results have been obtained to

examine the effects of the volume fraction index on the non-linear behavior of the FGM circular arch.

## 2 GENERAL FORMULATION

### 2.1. Non-linear vibration

A functionally graded circular arch made from a mixture of ceramic-metal material with a constant thicknesses is considered in this study. The effective material properties of the FGM circular arch such as Young's modulus  $E(z)$ , and mass density  $\rho(z)$ , with volume fraction index  $p$  are assumed to vary continuously through the thickness of the beam, according to power law form are shown in Fig.1.

The effective of material properties  $P$ , can be expressed as:

$$P = P_m V_m + P_c V_c \quad (1)$$

Where  $P_m$ ,  $V_m$ ,  $P_c$ , and  $V_c$  are the material properties and the volume fraction of the metal and ceramic respectively.

In which  $V_m$  and  $V_c$  are the metal and ceramic volume fractions respectively related by :

$$V_m + V_c = 1 \quad (2)$$

Assuming the power law distribution, the volume fraction can be written with the relation:

$$V_f(z) = \left( \frac{z}{h} + \frac{1}{2} \right)^p \quad (3)$$

Where  $p$  is the volume fraction index,  $0 \leq p \leq \infty$ . When  $p$  is set to zero, the FG arch becomes fully ceramic, when  $p$  is set to infinite, the FG arch becomes fully metal .

Fig 1: Schematic of a FGM circular arch

According to the power law, the young's modulus  $E(z)$  and mass density are  $\rho(z)$  expressed as:

$$E(z) = E_m + (E_c - E_m)V_f(z) \quad (4)$$

$$\rho(z) = \rho_m + (\rho_c - \rho_m)V_f(z) \quad (5)$$

Where  $(E_m, \rho_m)$  are the material properties for metal and  $(E_c, \rho_c)$  are the material properties for ceramic respectively. The physical parameters of ceramic and metal are presented in Table 1.

Table 1 :The physical parameters of ceramic and metal

Materials	Young's modulus $E / Gpa$	Density $\rho / (kg.m^{-3})$
<b>Ceramic</b>	380	3980
<b>Metal</b>	206	7800

The variation the density and Young's modulus along the height of the cross-section is shown in Fig.2, by taking into account several values of the the volume fraction index.

Fig. 2. Variation of the density and Young's modulus through the arch thickness for different values of gradient index p.

In this present study , the complicated effects such as shear deformation and rotary inertia are neglected because the arch is supposed to be thin. The arch axis is supposed to inextensible, the radial displacement  $u$  and tangential displacement  $w$  are related by [16]:

$$\frac{\partial w}{\partial \varphi} = u \quad (6)$$

The sixth order differential equation of motion may be written as:

$$\frac{\partial^6 w}{\partial \varphi^6} + 2 \frac{\partial^4 w}{\partial \varphi^4} + \frac{\partial^2 w}{\partial \varphi^2} + \lambda^2 \frac{\partial^4 w}{\partial t^2 \partial \varphi^4} = 0 \quad (7)$$

$$\lambda_i^2 = \frac{\omega_i^2 R_i^{*4} \int_{-h/2}^{h/2} \rho dy}{\int_{-h/2}^{h/2} E y^{*2} dy} \text{ is the non-dimensional frequency.}$$

$$z_0 = \frac{p(E_m - E_c)}{2(p+2)(pE_c + E_m)} h \quad (8)$$

$$(9)$$

$$z^* = z + z_0$$

$$(10)$$

$$R^* = R + z_0$$

$z_0$  denoted the height of the metal material,  $z$  denoted the neutral axis of isotropic homogenous circular arch,  $z^*$  denoted the neutral axis of the FGM circular arch, of the Where  $R$  denoted the radius of curvature of the geometric median of the arch and  $R^*$  denoted the radius of curvature of the neutral layer.

Considering the arch in a harmonic motion, we put:

$$w(\varphi, t) = W(\varphi) \cos(\omega t) \quad (11)$$

When the form of solution is:

$$W(\varphi) = e^{\Omega \varphi} \quad (12)$$

The characteristic equation may be written as:

$$\Omega^6 + 2\Omega^4 + (1 - \lambda^2)\Omega^2 = 0 \quad (13)$$

The general solution of the differential equation (7) in term of tangential displacement can be written as:

$$W_i(\varphi) = C_1 \sin(\alpha\varphi) + C_2 \cos(\alpha\varphi) + C_3 \sinh(\alpha\varphi) + C_4 \cosh(\alpha\varphi) + C_5(\varphi) + C_6 \quad \text{with} \quad i = 1, \dots, n \quad (14)$$

Where:  $\alpha = \sqrt{\lambda - 1}$ ,  $\beta = \sqrt{\lambda + 1}$  and  $\lambda \geq 1$ .

The pinned-pinned boundary conditions of circular arch in term of tangential displacement may be written as:

$$W_i(\varphi = 0) = W_i(\varphi = \varphi_0) = 0 \quad \left. \frac{dW_i}{d\varphi} \right|_{\varphi=0} = \left. \frac{dW_i}{d\varphi} \right|_{\varphi=\varphi_0} = 0 \quad \left. \frac{d^3W_i}{d\varphi^3} \right|_{\varphi=0} = \left. \frac{d^3W_i}{d\varphi^3} \right|_{\varphi=\varphi_0} = 0 \quad (15)$$

The use of the end conditions and the transfer matrix method leads to a homogeneous system. The determinant of the latest must be set equal to zero to obtain the natural frequencies, determined iteratively by the Newton–Raphson algorithm.

## 2.2. Non-linear vibration

The kinetic energy  $T$  and total strain energy  $V$  of the system presented in Fig. 1 may be written as a sum of the axial energy  $V_a$  and the strain energy due to the bending  $V_b$ . The expression of  $T$ ,  $V_a$  and  $V_b$  are expressed as:

$$T = \frac{R^*}{2} \int_0^{\theta_0} \left[ b \left( \frac{\partial w_i^{(1)}}{\partial t} \right)^2 + \left( \frac{\partial w_i}{\partial t} \right)^2 \int_{-h/2}^{h/2} \rho dy \right] dt \quad (16)$$

$$V_a = \frac{1}{2R^{*3}} \int_0^{\theta_0} \left[ b \left( \frac{\partial w_i}{\partial \theta} + \frac{\partial^3 w_i}{\partial \theta^3} \right)^2 \int_{-h/2}^{h/2} Ey^{*2} dy \right] d\theta \quad (17)$$

$$V_b = \frac{1}{8R^{*3}} \int_0^{\theta_0} \left[ b \left( w_i + \frac{\partial^2 w_i}{\partial \theta^2} \right)^4 \int_{-h/2}^{h/2} E dy \right] d\theta \quad (18)$$

$$V = V_a + V_b$$

Assuming harmonic, the tangential displacement function is expanded in the form of finite basic spatial functions:

$$w_i(\varphi, t) = a_i W_i \sin(\omega t) \quad (19)$$

By replacing  $w_i$  in the expressions for the energies  $T$ ,  $V_a$  and  $V_b$  can be written in the form:

$$T = \frac{1}{2} a_i a_j \omega^2 m_{ij} \cos^2(\omega t) \quad (20)$$

$$V_a = \frac{1}{2} a_i a_j k_{ij} \sin^2(\omega t) \quad (21)$$

$$V_b = \frac{1}{2} a_i a_j a_k a_l b_{ijkl} \sin^4(\omega t) \quad (22)$$

The parameters  $m_{ij}$ ,  $k_{ij}$ ,  $b_{ijkl}$  are the mass tensor, linear and the quadratic non-linear rigidity tensor of the arch in which their expressions are defined as:

$$m_{ij} = R^* \int_0^{\theta_0} b \left( \frac{\partial W_i}{\partial \theta} \frac{\partial W_j}{\partial \theta} + W_i W_j \right) \int_{-h/2}^{h/2} \rho dy d\theta \quad (23)$$

$$k_{ij} = \frac{1}{R^{*3}} \int_0^{\theta_0} b \left[ \left( \frac{\partial W_i}{\partial \theta} + \frac{\partial^3 W_i}{\partial \theta^3} \right) \left( \frac{\partial W_j}{\partial \theta} + \frac{\partial^3 W_j}{\partial \theta^3} \right) \right] \int_{-h/2}^{h/2} Ey^{*2} dy d\theta \quad (24)$$

$$b_{ijkl} = \left\{ \frac{1}{4R^{*3}} b \left[ \int_0^{\theta_0} \left( W_i + \frac{\partial^2 W_i}{\partial \theta^2} \right) \left( W_j + \frac{\partial^2 W_j}{\partial \theta^2} \right) d\theta \int_0^{\theta_0} \left( W_k + \frac{\partial^2 W_k}{\partial \theta^2} \right) \left( W_l + \frac{\partial^2 W_l}{\partial \theta^2} \right) \int_{-h/2}^{h/2} E dy d\theta \right] \right\} \quad (25)$$

The coefficients  $a_i$  are unknowns as well as the frequency  $\omega_i$ . The dynamic behaviour of the conservative system may be obtained by applying Hamilton's principle as defined in equation (27) :

$$\delta \int_0^{2\pi/\omega} (V - T) dt \quad (26)$$

One can obtain the following non-linear algebraic equations:

$$([K] - \omega^2 [M])\{A\} + \frac{3}{2}[B(A)]\{A\} = \{0\} \quad (27)$$

To obtain non-dimensional parameters, ones put:

$$W_i(\varphi) = hW_i^* \left( \frac{\varphi}{\varphi_0} \right) = hW_i^*(\varphi^*) \quad \frac{m_{ij}}{m_{ij}^*} = bR^*h^2, \frac{k_{ij}}{k_{ij}^*} = \frac{b_{ijkl}}{b_{ijkl}^*} = \frac{bh^2}{R^{*3}} \quad (28)$$

Where  $m_{ij}^*$ ,  $k_{ij}^*$  and  $b_{ijkl}^*$  are the non-dimensional generalized parameters given by:

$$m_{ij}^* = \int_0^1 \left( \frac{1}{\theta_0^2} \frac{\partial W_i^*}{\partial \theta^*} \frac{\partial W_j^*}{\partial \theta^*} + W_i^* W_j^* \right) \theta_0 \int_{-h/2}^{h/2} \rho dy d\theta^* \quad (29)$$

$$k_{ij}^* = \left\{ \int_0^1 \left( \frac{1}{\theta_0} \frac{\partial W_i^*}{\partial \theta^*} + \frac{1}{\theta_0^3} \frac{\partial^3 W_i^*}{\partial \theta^{3*}} \right) \left( \frac{1}{\theta_0} \frac{\partial W_j^*}{\partial \theta^*} + \frac{1}{\theta_0^3} \frac{\partial^3 W_j^*}{\partial \theta^{3*}} \right) \theta_0 \int_{-h/2}^{h/2} E y^{*2} dy d\theta^* \right\} \quad (30)$$

$$b_{ijkl}^* = \left\{ \frac{h^2}{4} \int_0^1 \left( W_i^* + \frac{\partial^2 W_i^*}{\theta_0^2 \partial \theta^{2*}} \right) \left( W_j^* + \frac{\partial^2 W_j^*}{\theta_0^2 \partial \theta^{2*}} \right) \theta_0 d\theta^* \int_0^1 \left( W_k^* + \frac{\partial^2 W_k^*}{\theta_0^2 \partial \theta^{2*}} \right) \left( W_l^* + \frac{\partial^2 W_l^*}{\theta_0^2 \partial \theta^{2*}} \right) \theta_0 \int_{-h/2}^{h/2} E dy d\theta^* \right\} \quad (31)$$

By substituting the non-dimensional parameter into equation (28) one obtain the dimensionless non-linear algebraic equations :

$$([K^*] - \omega^{*2} [M^*])\{A\} + \frac{3}{2}[B^*(A)]\{A\} = \{0\} \quad (32)$$

$B_{ijkl}^*$  presents the dimensionless non-linearity tensor,  $K_{ij}^*$  is the dimensionless rigidity matrix,  $M_{ij}^*$  denotes the dimensionless mass matrix and  $\omega^*$  is the dimensionless non-linear frequency. Using the tensorial notation, one put:

$$a_i k_{ir}^* + \frac{3}{2} a_i a_j a_k b_{ijk}^* - a_i \omega^{*2} m_{ir}^* = 0 \quad \text{with} \quad r = 1, \dots, n \quad (33)$$

The called the second formulation [17], it is an approximation which consists to separate the nonlinear term of equation (34) into a terms proportional to  $a_i^3$  and terms proportional to  $a_i^2 \varepsilon_i$  and neglecting terms proportional to  $a_i \varepsilon_i \varepsilon_j$  and terms proportional to  $\varepsilon_i \varepsilon_j \varepsilon_k$  one can write:

$$a_i a_j a_k b_{ijk r} = a_1^3 b_{111 r} + a_1^2 \varepsilon_i b_{11 i r} \quad r = 1, \dots, n \quad (34)$$

After substituting and rearranging, equation (34) may be written in matrix form as:

$$\left( [K_r^*]_R - \omega^2 [M_r^*]_R \right) \{A_r\}_R + \frac{3}{2} [\alpha_r^*]_R \{A_r\}_R = \left\{ -\frac{3}{2} a_r^3 b_{111 r}^* \right\} \quad (35)$$

### 3 RESULTATS AND DISCUSSION

In this present work, the free in-plane vibration of a FGM circular arch made with mixture of ceramic-metal material with uniform section and pinned at the both ends is studied based on multimode approach.

By assuming the material properties in table.1, the material volume fraction p dependence to the variation of the first four in-plane free vibration frequencies of FGM pinned-pinned circular arch are shown in Fig. 2 for radius  $R=60m$ , thicknesses  $h=0.8m$  and an opening angle  $\varphi_0 = 100^\circ$ .

Fig. 2: The material volume fraction p dependence to the variation of the first four in-plane free vibration frequencies of FGM circular arch [18].

The influence of the volume fraction index p on the dimensionless non-linear frequency ratio of pinned-pinned FGM circular arch are presented in Fig.4.

The Fig.2 shows a comparison of the first four linear frequencies of the FGM pinned-pinned circular arch obtained in this present work with the results obtained in [18] as the curvature is constant. Where good agreement is obtained.

The effects of the opening angle of the FGM circular arch with a volume fraction index  $p = 5$  and pinned-pinned ends on the dimensionless non-linear frequency ratios are shown in Fig. 4.

Fig. 3. Influence of the opening angle on the ratio of the dimensionless non-linear frequency ratios to the linear frequency of FGM circular arch beams with volume fraction  $p = 5$ .

Fig. 4. Effect of The material volume fraction  $p$  on the frequency ratio.

The results in Fig. 4 show that the dimensionless non-linear frequency ratios of arch tend increase with increasing the opening angle increases, due to the increased rigidity.

The influence of the volume fraction index  $p$  on the dimensionless non-linear frequency ratios of the FGM arch by considering the pinned-pinned boundary conditions can be clearly shown in Fig. 3.

A quantitative values of the dimensionless non-linear frequency ratios of the FGM circular arch, for various values of the volume fraction index  $p$  and the non-dimensional amplitude of vibration are presented in Table 2. The results are compared with those obtained in [5].

Table 2: comparison of the dimensionless non-linear frequencies ratios for each value of the volume fraction index  $p$  with isotropic homogenous pinned-pinned circular arch [5].

$W_{\max}^*/h$	$\omega_{nl}^*/\omega_l^*$	Present $\omega_{nl}^*/\omega_l^*$						
		Ref [5]	p=0.0	p=0.05	p=0.2	p=1	p=5	p=10
0.08165	1.002004	1.002004	1.002017	1.002048	1.002064	1.001877	1.001867	1.002004
0.46947	1.064259	1.064259	1.064694	1.065658	1.066144	1.60301	1.059994	1.064259
0.857231	1.200968	1.200968	1.202254	1.205100	1.206531	1.189286	1.188324	1.200968
1.24488	1.390340	1.390340	1.392682	1.397860	1.400463	1.368994	1.367231	1.390340
1.63239	1.613943	1.613943	1.617412	1.625076	1.628927	1.582246	1.579621	1.613943

Table 2 shows the dependence of the frequency ratio of the pinned FG circular arch on the amplitude of vibration for various values of the power law index  $p$ . As may be seen in this figure, by increasing the values of the power law index in the range  $[0, 1]$ , the frequency increases. For values higher than  $p=1.0$ , the frequency decreases when  $p$  increases. This may be expected, since when the power index  $p=0.0$  or  $p=\infty$ , the material becomes pure metallic or pure ceramic, respectively, and the non-dimensional frequency corresponds to the isotropic homogenous material case.

## 4 CONCLUSIONS

The geometrical non-linearity in free in-plane vibration of inextensible FGM circular arches. were analyzed based on the Euler Bernoulli theory and the Von Karman geometrical non-linearity assumptions. For simplification, the complicating effects such as rotary inertia and shear deformation will be ignored. The natural frequencies of arch were obtained iteratively using Newton-Raphson algorithm. The kinetic and total strain energy of the arch were reduced discretized then the problem was reduced into a set non-linear algebraic equations using Hamilton's principle energy and spectral analysis and solved numerically by an approximate explicit method the so-called second formulation. A numerical results were obtained to examine the effects of the volume fraction index on non-linear behavior of the FGM circular arch.

### Abstract

*The thermal non-linear vibrational behavior of functional graded beams is analyzed using Euler-Bernoulli beam theory and Hamilton's theorem, combined with spectral analysis. A set of non-linear equations is derived based on the von Kármán deformation-displacement relationship and the properties of the functional graded material are assumed to be temperature dependent and to follow a simple power distribution in the thickness direction. Numerical solutions of the non-linear dynamic equations of functional graded beams are obtained by an approximate method called the second formulation. In addition, numerical examples were performed to highlight the accuracy of the method used in this study, and the results are very consistent with those found in the literature. In the numerical examples, the influences played by thermal environmental conditions and volume fraction index are discussed in detail.*

## 1 INTRODUCTION

Functionally graded materials (FGM) are composed of a mixture of ceramic and metal or a combination of different materials. The FGM ceramic provides a barrier against thermal effects and protects the metal from corrosion and oxidation, and the FGM is hardened and strengthened by the metal component. Currently, FGM has been developed as a general structural element in extremely high temperature environments and has been widely used in electronics, chemistry, optics, biology, medical engineering and many other fields.

Due to the above-mentioned advantageous characteristics, many studies have been conducted on the following topics, which are the static and dynamic behavior of the FGM structure. Xiang and Shi [1] proposed an analytical solution to analyze the thermo-elasticity of FGM beams embedded in piezoelectric layers. Assuming a cantilevered beam, he used the Airy stress function method to obtain an accurate solution. Ebrahimi et al. [2] reported an analytical method to control the vibration of an FGM beam containing two piezoelectric layers. A theoretical model is based on the Kirchhoff's-Love hypothesis, which has a non-linear geometric von-Karman-type deformation. Fu and colleagues [3] studied the non-linear analysis of buckling, free vibration, active control and dynamic stability of functionally graded piezoelectric beams in a thermal environment. Based on Hamilton's principle, a non-linear guidance equation is established. Falsone and La Valle [4] solved the differential equations governing the axial equilibrium and bending in the Euler-Bernoulli and Timoshenko theory of an FGM beam. This analysis is obtained in both cases of material variation in the transverse and axial directions. Kiani et al. [5] studied the thermal buckling of piezoelectric FGM beams, in which the piezoelectric layer is bonded to the surface and subjected to a constant thermal load and tension. Bodaghi and Shakeri [6] analytically studied the free vibration and dynamic response of a cylindrical piezoelectric FGM panel, which is simply supported and subjected to time-dependent explosive pulses. In recent years, a lot of research has been done on free and forced non-linear vibrations. Based on the Euler-Bernoulli beam theory and von Kármán's non-linear kinematics, and using Hamilton's principle, Benamar et al. [7] developed a theory and a method to analyze the vibrational response of isotropic beams. El khouddar et al [8] studied the free and forced non-linear vibrations of laminated composite beams under different boundary conditions, using the Euler-Bernoulli beam theory and the Green-Lagrang non-linearity. From the Euler-Bernoulli beam theory, Chajdi et al [9] examined the forced nonlinear vibrations of an FGM beam with multiple cracks. Based on the Euler-Bernoulli beam theory, Outassafte et al [10], [11] contributed to the geometrically non-linear free vibration of a fixed-ended arch. Currently, many results have been obtained when studying the dynamic mechanical properties of FGM beams, but most of them are based on linear theory. Due to the large displacement of the structure in engineering practice, the geometric non-linearity must be taken into account, otherwise it will lead to serious errors. At the same time, the analysis under thermal loading will affect the non-linear vibration of the FGM structure. Therefore, it is necessary to study the non-linear vibration of the FGM beam under thermal loading in more detail.

In the present work, the problem of geometrically non-linear free vibrations of FGM beams in a thermal environment with fixed ends is studied. In this analysis, the material properties change continuously through the thickness of the beam according to the power law, and change with temperature changes. The Hamiltonian principle is used to establish the governing equation of the beam under thermal load, and the second formula is used to obtain the analytical solution of the non-linear free vibration problem. Important conclusions have been drawn.

## 2 BASIC EQUATIONS

Consider an FGM beam of rectangular cross-section with a length of  $L$  and a thickness of  $h$ . This beam is made of a mixture of ceramics and metals. The coordinate system is shown in Figure 1. The material properties, namely Young's modulus  $E$ , Poisson's ratio  $\nu$ , thermal conductivity  $\kappa$ , and coefficient of thermal expansion  $\alpha$ , depend on temperature and vary with thickness.

Figure 1: Coordinates and geometry of the FGM beam.

The effective material properties  $P$  of the FGM layer, namely the Young's modulus  $E$ , Poisson's ratio  $\nu$ , thermal conductivity  $\kappa$  and coefficient of thermal expansion  $\alpha$ , can be expressed as follows:

$$P(z, T) = P_m + (P_c - P_m) \left( \frac{1}{2} + \frac{z}{h} \right)^k \quad (1)$$

The characteristic  $P$  of the constituent material depends on the temperature and can be written:

$$P = P_0 (P_{-1} T^{-1} + 1 + P_1 T + P_2 T^2 + P_3 T^3) \quad (2)$$

The temperature distribution on the beam is considered as uniform and can reach  $\Delta T = T - T_0$  to deform the beam. Where  $T_0$  is the reference temperature of the beam in the unstressed state.

### 2.1 linear vibration analysis

Considering the mid-plane stretch and ignoring the axial inertia, the equations of motion to control the axial and lateral vibration of FGM beams are often considered in the literature and have been adopted in reference [12]:

$$\frac{\partial N_x}{\partial x} = 0 \quad (3)$$

$$\frac{\partial^2 M_x}{\partial x^2} + \frac{\partial}{\partial x} \left( N_x \frac{\partial w}{\partial x} \right) = I_0 \frac{\partial^2 w}{\partial t^2} \quad (4)$$

$N_x$  and  $M_x$  are respectively the axial internal force and the bending moment acting at the mid-plane of the beam are defined as follows:

$$N_x = A_{11} \frac{\partial u}{\partial x} - B_{11} \frac{\partial^2 w}{\partial x^2} - N_x^T \quad (5)$$

$$M_x = B_{11} \frac{\partial u}{\partial x} - D_{11} \frac{\partial^2 w}{\partial x^2} - M_x^T \quad (6)$$

Where  $I_0$  is the inertia of the beam:

$$I_0 = \int_{-h/2}^{h/2} \rho_f dz \quad (7)$$

Where  $N_x^T$  and  $M_x^T$  are the resultant and the moment of the thermal force, which are calculated using the following relations:

$$N_x^T = \int_{-h/2}^{h/2} E \alpha \Delta T dz, \quad M_x^T = \int_{-h/2}^{h/2} (z - z_0) E \alpha \Delta T dz \quad (8)$$

In equations (5) and (6),  $A_{11}$ ,  $B_{11}$  and  $D_{11}$  are extension-extension, bending-extension and bending-bending coupling coefficients, respectively, which can be evaluated using the well-known classical theory of FGM beams [13]. Their expressions are defined as follows:

$$A_{11} = \int_{-h/2}^{h/2} E dz, \quad B_{11} = \int_{-h/2}^{h/2} E (z - z_0) dz, \quad D_{11} = \int_{-h/2}^{h/2} E (z - z_0)^2 dz \quad (9)$$

The axial equation (1) of equilibrium is then given by :

$$N_x = A_{11} \frac{\partial u}{\partial x} - B_{11} \frac{\partial^2 w}{\partial x^2} - N_x^T = N_{x0} \quad (10)$$

Considering the fixed ends (i.e.  $u = 0$ , at  $x = 0$  and  $L$ ), the integration of Eq (10) along the x-axis leads to:

$$0 = \int_0^L \frac{\partial u}{\partial x} dx = u(L) - u(0) = \frac{1}{A_{11}} \int_0^L \left[ N_{x0} + N_x^T + B_{11} \frac{\partial^2 w}{\partial x^2} \right] dx \quad (11)$$

Also:

$$N_{x0} = \frac{A_{11}}{L} \int_0^L \left[ -\frac{B_{11}}{A_{11}} \frac{\partial^2 w}{\partial x^2} \right] dx - N_x^T \quad (12)$$

By introducing equation (12) into equation (6), the bending moment can be rewritten as follows:

$$M_x = B_{11} \left[ \frac{N_{x0} + N_x^T}{A_{11}} + \frac{B_{11}}{A_{11}} \frac{\partial^2 w}{\partial x^2} \right] - D_{11} \frac{\partial^2 w}{\partial x^2} - M_x^T \quad (13)$$

Taking  $N_x^T$  and  $M_x^T$  as constants along the x-axis, we can obtain the following linear steering equation for the FGM beam by inserting equations (12) and (13) into equation (4).

$$D_{11} \frac{\partial^4 w}{\partial x^4} + (N_x^T) \frac{\partial^2 w}{\partial x^2} + I_0 \frac{\partial^2 w}{\partial t^2} = 0 \quad (14)$$

Equation (14) can be written in a slightly less complicated way, the result is:

$$w'''' + \lambda w'' - \beta^4 w = 0 \quad (15)$$

In formula (15), the new symbol indicates the following functional relationship:

$$\lambda = \frac{N^T}{D_{11}}, \quad \beta^2 = \frac{\omega}{c}, \quad c^2 = \frac{D_{11}}{I_0} \quad (16)$$

Where  $x^*$  is a dimensionless coordinate, which can be written:  $x^* = \frac{x}{L}$ . Equation (15) is an ordinary differential equation of order 4 with constant coefficients whose general solution is given by:

$$w_i(x^*) = A \sin \left( \sqrt{\frac{1}{2}\lambda + \frac{1}{2}\sqrt{\lambda^2 + 4\beta_i^4}} x^* L \right) + B \cos \left( \sqrt{\frac{1}{2}\lambda + \frac{1}{2}\sqrt{\lambda^2 + 4\beta_i^4}} x^* L \right) + C \sinh \left( \sqrt{-\frac{1}{2}\lambda + \frac{1}{2}\sqrt{\lambda^2 + 4\beta_i^4}} x^* L \right) + D \cosh \left( \sqrt{-\frac{1}{2}\lambda + \frac{1}{2}\sqrt{\lambda^2 + 4\beta_i^4}} x^* L \right) \quad (17)$$

i changes from 1 to n, where n is the number of functions.

## 2.2 Non-linear vibration analysis

Using the displacement fields from the Euler-Bernoulli theory and assuming that the FGM beam has large vibration amplitudes, the Von-Karman relation can be written as follows:

$$\varepsilon_{xx} = \frac{\partial u}{\partial x} - (z - z_0) \frac{\partial^2 w}{\partial x^2} + \frac{1}{2} \left( \frac{\partial w}{\partial x} \right)^2 \quad (18)$$

The kinetic energy  $T_e$  of an FGM beam in vibration is equal to:

$$T_e = \frac{I_0}{2} \int_0^L \left( \frac{\partial w}{\partial t} \right)^2 dx \quad (19)$$

The potential energy  $V$  can be written in terms of transverse displacement  $w$  and longitudinal displacement for our beam as:

$$V = \frac{1}{2} \int_0^L N_x \left( \frac{\partial u}{\partial x} + \frac{1}{2} \left( \frac{\partial w}{\partial x} \right)^2 \right) + M_x \left( -\frac{\partial^2 w}{\partial x^2} \right) dx \quad (20)$$

Using the generalized parameterization that corresponds to the transverse displacement of the beam we have [14], [15]:

$$w = a_i w_i(x) \sin \omega t \quad (21)$$

According to Hamilton's principle, the non-linear algebraic equations of the dynamic behavior of the structure are calculated using the tensor notation:

$$a_i k_{iq} + \frac{3}{2} a_i a_j a_k b_{ijkq} - \omega^2 a_i m_{iq} = 0, i = 1, \dots, n \quad (22)$$

To perform a general parametric study, the following dimensionless formulation is used:

$$x^* = \frac{x}{L}, \quad w_i(x) = r w_i^*(x^*), \quad r^2 = \frac{\int_{-h/2}^{h/2} z^2 dz}{\int_{-h/2}^{h/2} dz} \quad (23)$$

$r$  is the radius of gyration of the piezoelectric FGM beam. The numerical solution of equation (22) can be obtained by using the second formula described in [16]. This approximation consists of ignoring the second-order terms provided by the relevant mode. As mentioned in the reference, in the non-linear expression  $a_i a_j a_k b_{ijkq}$  of equation (22), the second order term of  $\varepsilon_i$  will be ignored.

### 3 NUMERICAL RESULTS AND DISCUSSIONS

In this section, the FGM beam is chosen for the material Si3N4 / SUS304, this beam has a length of  $L = 200$  mm and a thickness of  $h = 10$  mm. Table 1 shows the characteristics of Young's modulus  $E$  (in Pa), thermal expansion coefficient  $\alpha$  (in K) and thermal conductivity  $\kappa$  (in W/mK). For the Poisson's ratio  $\nu$  of the FGM layer is assumed to be constant equal to 0.28. It should also be noted that the upper surface of the substrate ( $z = h / 2$ ) is ceramic rich and the lower surface ( $z = -h / 2$ ) is metal rich. In addition, the temperature  $T_m$  of the lower surface of the FGM beam is assumed to be 300K, and the temperature  $T_c$  of the upper surface is variable.

Table 1. Coefficients material properties as a function of temperature for Si3N4 and SUS304.

Materials	Properties	$P_0$	$P_{-1}$	$P_1$	$P_2$	$P_3$
Si3N4	$E_c$ (Pa)	348.43e+9	0	-3.07e-4	2.160e-7	-8.964e-11
	$\alpha_c$ (1 / K)	5.8723e-6	0	9.095e-4	0	0
	$\kappa_c$ (W / mK)	13.723	0	-1.032e-3	5.466e-7	-7.876e-11
SUS304	$E_m$ (Pa)	201.04e+9	0	3.079e-4	-6.534e-7	0
	$\alpha_m$ (1 / K)	12.33e-6	0	8.086e-4	0	0
	$\kappa_m$ (W / mK)	15.379	0	-1.264e-3	2.092e-6	-7.223e-10

Before further investigation of the non-linear behaviors of the FGM beam, the results between the present method and previous work [17] are compared to prove the accuracy of the proposed method. Table 2 lists the dimensionless linear eigenfrequencies ( $\omega_1 L^2 / h \sqrt{\rho_b / E_b}$ ) of the FGM beam considering the clamped-clamped boundary condition when the length-to-height ratio is  $L/h = 100$ . The results of these comparisons, considering the material properties for the upper ( $E_t$  and  $\rho_t$ : ceramic) and lower ( $E_b$  and  $\rho_b$ : aluminium) surfaces are as follows [17]:  $E_t = 380 \text{ GPa}$ ,  $\rho_t = 3960 \text{ Kg} / \text{m}^3$ ,  $E_b = 70 \text{ GPa}$ ,  $\rho_b = 2702 \text{ Kg} / \text{m}^3$

Figure 2: Comparisons of the first five non-dimensional eigenfrequencies of the FGM beam with clamping boundary conditions and for different values of the power index.

It can be seen from Table 2 that the results obtained in this study are in perfect agreement with the results given in the literature, which verifies the effectiveness of the shape function used in this work.

	[17]	8.0672	22.234	43.576	72.008	107.52

Taking into account the material characteristics (see Table 1 [18]), the influence of the thermal load and the volume fraction index on the first three modes of the linear dimensionless eigenfrequency of the FGM beam is studied by considering the boundary condition clamped-clamped. It can be seen from Table 3 that when the temperature of the upper surface of the beam  $T_c$  increases, and when the temperature of the lower surface  $T_m$  remains constant ( $T_m = 300K$ ), the dimensionless eigenfrequency of the beam is stripped, which indicates the temperature-independent material properties have overestimated the stiffness of the structure. As shown in Table 3, in a high-temperature environment, the material properties related to the beam temperature must be considered. In addition, it should be noted that as the volume fraction index  $k$  increases, the frequency decreases due to the fact that the Young's modulus of SUS304 is lower than that of Si3N4.

Table 3. Dimensionless fundamental frequency of the FGM beam under thermal loading with temperature dependent material properties.

Modes	Tc(K)	Volume fraction exponent $k$					
		0	0.2	0.5	2	5	10
1	300	14.930	12.103	10.279	8.094	7.361	7.012
	400	14.162	11.374	9.576	7.433	6.717	6.369
	500	13.353	10.565	8.765	6.632	5.923	5.566
2	300	41.156	33.363	28.335	22.311	20.293	19.331
	400	40.064	32.346	27.369	21.420	19.430	18.473
	500	39.117	31.380	26.388	20.445	18.464	17.497
3	300	80.682	65.405	55.548	43.740	39.783	37.896
	400	79.384	64.224	54.447	42.748	38.829	36.954
	500	78.535	63.306	53.481	41.754	37.836	35.945

Figure 3 shows the influence of the volume fraction  $k$  of the Si3N4 / SUS304 FGM beam on the ratio of non-linear to linear frequency ( $\omega_{NL} / \omega_L$ ), which is a function of the dimensionless vibration amplitude  $W_{max}/r$ . The volume fraction significantly affects the Backbone curve.

On the other hand, when the exponential of the volume fraction diminishes, the frequency ratio increases. All these FGM beams with different volume fractions show typical hardening behavior, i.e., the non-linear frequency increases with increasing vibration amplitude. The effects of uniformly increasing the temperature of the FGM beam with a volume fraction index  $k = 1$  and clamped ends on the relationship between the non-linear to linear frequency are shown in Figure 4. In this example, the temperature of the bottom surface  $T_m$  remains constant ( $T_m = 300$  K), while the temperature of the top surface  $T_c$  varies ( $T_c = 300, 400$  and  $500$  K). The results in Figure 4 show that the curves of the non-linear to linear frequency ratios tend to increase as  $T_c$  increases, and the non-linear effect tends to be higher as  $T_c$  increases. Figure 5 illustrates the effect of simultaneous change in temperature and volume fraction on the non-linear vibration behavior of FGM Si3N4/SUS304 beams. In Figure 5, it is found that increasing the volume fraction ( $k=0, 1$  and  $5$ ) and increasing the temperature of the top surface ( $T_c=300$  and  $500$  K) result in an increase in the ratio of non-linear to linear frequency. It is also interesting to note that as the temperature increases, the effect of the volume fraction exponent  $k$  on the frequency ratio decreases.

Figure 3: Influence of volume fraction  $k$  on the ratio of non-linear to linear frequency of FGM beams with thermal load  $T_c=300$  K.

Figure 4: Influence of the thermal load  $T_c$  on the ratio of the non-linear frequency to the linear frequency of FGM beams with volume fraction  $k = 1$ .

#### 4 CONCLUSIONS

The behavior of clamped FGM beams under free vibration in a thermodynamic environment is studied. The geometrically non-linear vibrational equations are determined in this analysis using an analytical approach based on the Euler-Bernoulli beam model and Hamilton's principle. The effective material properties of FGMs are assumed to be temperature dependent and to follow a simple power distribution in the thickness direction. The effects of volume fraction exposure, thermal loading, and thermal properties of constituent materials on non-linear vibration studies of FGM beams were examined in a parametric study. Numerical results indicate that the volume fraction affects the natural and non-linear frequencies in the ambient temperature fields. The volume fraction has an effect on the non-linear free vibration behavior of an FGM beam, and this effect weakens with increasing temperature. Furthermore, as the temperature increases, the non-linear effect increases, and the relationship between non-linear frequency and non-linear frequency as a function of nondimensional vibration amplitudes increases accordingly.

**Keywords:** Multiple Timescale Spectral Analysis, Background, Resonant.

**Abstract.** *The critical flutter speed of a bridge deck is the result of an eigen value analysis. However, the progressive growth of the response for sub-critical wind velocities, resulting from the buffeting action of the turbulent wind, is also of major concern to the designers. The complete flutter analysis of a bridge structure therefore requires the repeated analysis of the aeroelastic response for various wind velocities, starting from zero (wind off) to the critical flutter speed. In a spectral approach, each of these analyses is typically based on the heavy integration of the power spectral density of the aeroelastic response. It has been recently found that this integration can be facilitated by a background/resonant decomposition as is commonly implemented in a buffeting-only setting. The paper describes a preliminary work showing that this decomposition can be extended to the flutter-and-buffeting configuration. The work is only preliminary since it deals with a single oscillator. However, it shows a massive CPU saving of one to two orders of magnitude, while limiting the error to one percent. This kind of saving is particularly expected to make affordable the analysis of large multi degree-of-freedom structures.*

## 1 INTRODUCTION

The critical flutter speed of a bridge deck corresponds to an aeroelastic instability of the coupled system composed of the bridge and the surrounding air flow [1, 2, 3]. This instability is recognized as potentially very harmful since the famous collapse of the Tacoma-Narrows bridge [4]. Codes and standards [5] take a significant safety margin with respect to this critical wind speed and typically do not allow to overcome 80% of this critical velocity.

Besides, the progressive growth of the response for sub-critical wind velocities, resulting from the buffeting action of the turbulent wind, is also of major concern to the designers [6, 7]. The complete flutter analysis of a bridge structure therefore requires the repeated analysis of the aeroelastic response for various wind velocities, starting from zero (wind off) to the critical flutter speed, or at least to the design wind speed [8]. In a spectral approach, each of these analyses is typically based on the time-consuming integration of the power spectral density (PSD) of the aeroelastic response.

Traditional integration methods struggle to efficiently estimate these integrals because of the significant peakedness of the function in the neighborhood of the natural frequencies. In this paper, we present an extension of the Background/Resonant decomposition (which is commonly applied under the quasi-steady assumption), to aeroelastic analysis, where the stiffness and damping of the coupled system changes with frequency. The study is limited to single degree-of-freedom systems at this stage but constitutes the cornerstone of an extension to multi degree-of-freedom systems, where such an approximation becomes very interesting in terms of computational efficiency.

In the following sections, the mathematical background is presented, then the algorithmic implementation is briefly discussed and the method is illustrated with a few examples. Finally, the perspectives of application to multi degree-of-freedom (MDOF) structures are discussed.

## 2 EXTENSION OF THE BACKGROUND/RESONANT DECOMPOSITION TO THE AEROELASTIC OSCILLATOR

The dynamics of a single degree-of-freedom (SDOF) system subjected to buffeting and aerodynamic loads is governed by

$$m_s \ddot{q}(t) + c_s \dot{q}(t) + k_s q(t) = f_{bu}(t) + f_{ae}(t), \quad (1)$$

where  $m_s$ ,  $c_s$  and  $k_s$  are the mass, viscosity and stiffness of the structural system, and where  $t$  is the time. The loading consists of a buffeting loading  $f_{bu}(t)$  which is here assumed to be characterized as a Gaussian stochastic process and a so-called *unsteady* aerodynamic loading  $f_{ae}(t)$ , which is usually expressed as a convolution of the structural response ( $q(t)$ ,  $\dot{q}(t)$ ) with aeroelastic indicial functions. In the frequency domain,  $F_{ae}(\omega) = [i\omega c_{ae}(\omega) + k_{ae}(\omega)] Q(\omega)$  and the governing equation becomes

$$[-m_s \omega^2 + i\omega c(\omega) + k(\omega)] Q(\omega) = F_{bu}(\omega), \quad (2)$$

where  $c(\omega) = c_s - c_{ae}(\omega)$  and  $k(\omega) = k_s - k_{ae}(\omega)$  gather both the structural and aerodynamic viscosity and stiffness. The later ones can be expressed as a function of Theodorsen's function (flat plate, [9]) or, more generally, as Scanlan's derivatives (e.g. bridge deck [1]).

The power spectral density of the structural response  $q(t)$  is thus obtained by

$$S_q(\omega; U) = \left| [-m_s \omega^2 + i\omega c(\omega) + k(\omega)]^{-1} \right|^2 S_{f,bu}(\omega), \quad (3)$$

and the variance of the response is ultimately obtained by integration of (3),

$$\sigma_q^2(U) = \int_{-\infty}^{+\infty} S_q(\omega; U) d\omega. \quad (4)$$

In a structural design process, this integral has to be computed for several values of the wind velocity  $U$ , which enters in the modeling through  $c_{ae}(\omega)$  and  $k_{ae}(\omega)$  which are expressed as a function of the reduced frequency  $K = \omega B/U$  where  $B$  is a characteristic size of the structural element (deck width). Standard integration schemes based on the trapezoidal rule or Gauss-Lobatto integration schemes [10] do provide an accurate result, they might seem too slow for application in large scale problems or when the bridge stability has to be assessed in a probabilistic manner, which requires many repetitions of the deterministic problem, see Section 5

In the wind engineering community, this type of integral is also encountered in the buffeting-only analysis of structures, i.e. without unsteady forces. The method, implemented in the community by Davenport [11, 12], based on the existing approaches in aeronautics [13], has resulted in the well known Background/Resonant (B/R) decomposition. The use of multiple timescales in the computation of the wind induced response of structures is not new. It has already been used to determine the statistics of non Gaussian responses [14] or of nonlinear aerodynamic loading terms [15]. The general method, based on stretches and rescaling of the frequency bands contributing to the integral has been generalized under the terminology *Multiple Timescales Spectral Analysis* (MTSA) [16].

In the present configuration, under the following assumptions:

- the timescales of the loading and of the system are significantly different. In other words, a distinction is made between the slow dynamics represented by the buffeting loading, and fast dynamics represented by the natural vibrations of the aeroelastic system. The centroid of the power spectral density of the buffeting load shall be substantially lower (5 to 10 times lower) than the natural frequency of the aeroelastic system;
- the structural damping ratio is small, smaller than or of the same order of magnitude as 5%-10%; the quality of the approximation worsens as the damping ratio grows beyond these values;
- the frequency dependent stiffness and damping  $k(\omega)$  and  $c(\omega)$  vary smoothly and moderately in the neighborhood of the resonance peak of the aeroelastic system,

it is actually possible to demonstrate [17], by application of the general concepts of the Multiple Timescale Spectral Analysis [16], that the variance is expressed as a sum of the background and the resonant contributions

$$\sigma_q^2 = \sigma_{q,B}^2 + \sigma_{q,R}^2, \quad (5)$$

where

$$\sigma_{q,B}^2 = \int_{-\infty}^{+\infty} \frac{S_{f, bu}(\omega)}{(k_s - k_{ae}(\omega))^2} d\omega \quad ; \quad \sigma_{q,R}^2 = \frac{S_{f, bu}(\bar{\omega})}{(k_s - k_{ae}(\bar{\omega}))^2} \frac{\pi \bar{\omega}}{2\bar{\xi}} \frac{1}{1 + \frac{1}{2} \frac{\bar{\omega} \partial_{\omega} k_{ae}(\bar{\omega})}{k_s - k_{ae}(\bar{\omega})}}. \quad (6)$$

They are readily interpreted as the aeroelastic extensions of the well known decomposition introduced by Davenport. In this expression  $\bar{\omega}$  represents the resonance frequency of the aeroelastic system; it is defined by

$$\frac{\bar{\omega}^2}{\omega_s^2} = \frac{k_s - k_{ae}(\bar{\omega})}{k_s}. \quad (7)$$

In wind-off conditions,  $k_{ae}(\bar{\omega}; U = 0) = 0$  and  $\bar{\omega} = \omega_s$  is therefore equal to the natural structural frequency. As the wind velocity increases, the natural frequency of the aeroelastic system  $\bar{\omega}$  might drift more or less significantly from  $\omega_s$  depending on the specificities of the aerodynamic stiffness  $k_{ae}(\omega)$ .

### 3 ALGORITHMIC IMPLEMENTATION

This section describes a practical implementation of the algorithm. At this stage, the implemented model is suitable for SDOF models only but its extension to MDOF models is also discussed.

#### 3.1 Algorithm for SDOF structures

The flow-chart of the solution strategy is shown in Figure 1. For a given average wind velocity, the solving process consists of 3 main tasks: the evaluation of the aeroelastic eigen frequency, and that of the background and resonant components. The determination of the eigen frequency of the aerodynamic system relies on an iterative scheme, initiated with the wind-off conditions. Relaxation can be used to improve the convergence of the process. As the wind-off conditions give already an excellent guess of the natural frequency of the aeroelastic system, the convergence is quite straightforward. The resonant component is then evaluated using (6), and Scanlan's formulation for  $k_{ae}(\omega)$ ,  $c_{ae}(\omega)$  and  $\partial_\omega k_{ae}(\omega)$ . The last step is the determination of the background component. Depending on the specificities of  $k_{ae}(\omega)$  and the targeted accuracy, the integration of the buffeting forces according to (6) can be simplified. Indeed, in cases where the background component plays a secondary role,  $\sigma_{q,B} \ll \sigma_{q,R}$ , its accurate determination is no longer a necessity and the denominator in the expression for  $\sigma_{q,B}$  in (6) can be simply replaced by  $k_s^2$ . This leads to a drastic simplification of the computation of the integral since  $\sigma_{q,B}$  then boils down to the usual quasi-static formulation of Davenport. When this assumption can be made —and this is what is done in the rest of this paper—, the background component does not require any integration point, the resonant component just requires one integration point (located at the natural frequency) and the proposed formulation, referred to as MTSA in the sequel, is just based on a single integration point.

All this solving process is embedded in a loop over a range of  $U$ , from wind-off to critical conditions.

#### 3.2 Extension to MDOF structures

Up to now, the use of the background/resonant decomposition for aeroelastic systems was only discussed on SDOF models. For such simple models, the computational load is proportional to the number of wind velocities considered in the analysis. Since the analysis for each wind velocity is rapid, there is no big issue and the process can be repeated for a comfortable number of wind velocities, which allows an accurate evaluation of the transition towards instability on approaching the critical wind velocity. In the case of MDOF models, every single run for a given velocity might turn to be much more expensive. Indeed, if the number of degrees of freedom is large, a very time-consuming operation appears in the algorithm: the projection of the buffeting forces in the modal basis. This is explained by considering that, in a standard linearized model of the buffeting forces, the wind force at each degree-of-freedom is expressed as a linear transformation of the local wind velocity, i.e.

$$\mathbf{F}_{bu}(t) = \mathbf{A}\mathbf{u}(t) + \mathbf{b} \quad (8)$$

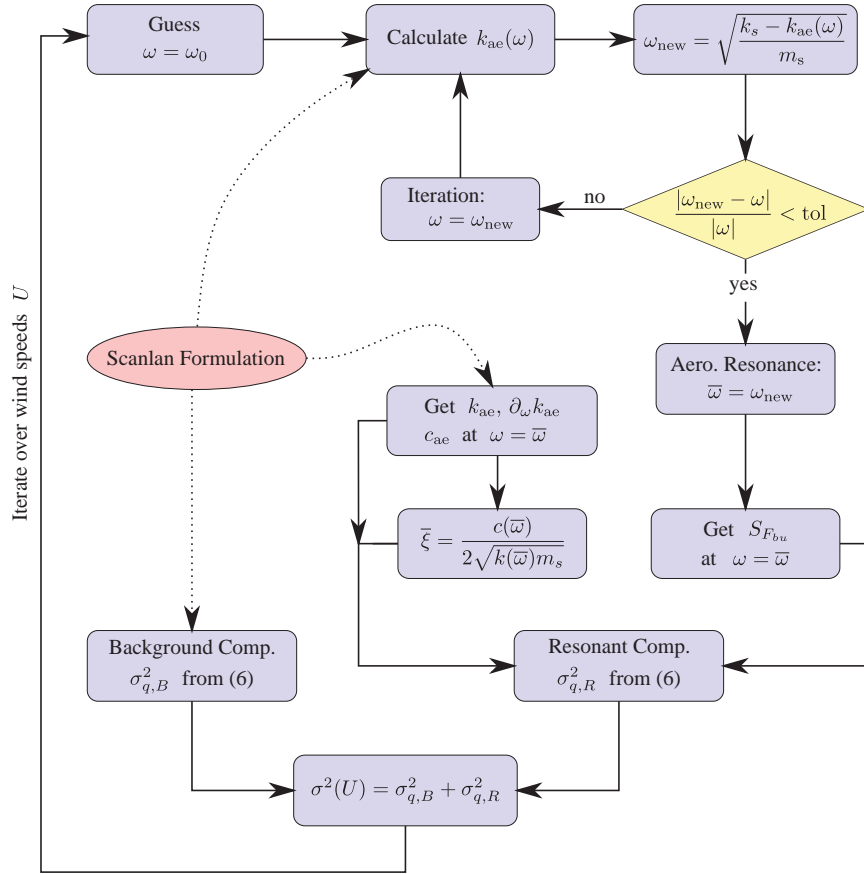

Figure 1: Organigram of the aeroelastic analysis performed with the background/resonant decomposition for evaluating the integral of the response spectra. The solving process is embedded in a loop over the average wind speeds.

where  $\mathbf{u}(t)$  is a column vector containing the fluctuating component of the wind velocities at the nodes of the finite element model, the power spectral density of the buffeting load projected in mode  $i$  reads

$$S_{F_{bu}}^i(\omega) = \phi_i^T \mathbf{A} \mathbf{S}_{\mathbf{u}} \mathbf{A}^T \phi_i. \quad (9)$$

The evaluation of the PSD of the modal forces, including their cross-PSD, is particularly time consuming since it involves the left- and right-multiplication by large matrices.

In short, the computational time for the modal analysis of a large MDOF structure is mostly conditioned by the number of frequencies where the PSD must be sampled, i.e. the number of projections such as (9). As a result, the determination of the variance as the quadrature of the PSD of the structural response (in each mode) is the operation that requires being optimally implemented. Three solutions are studied in the rest of this paper to determine these integrals with various levels of smartness : (i) first, a classical trapezoidal method is implemented; it requires typically a large number of uniformly distributed points to accurately capture the sharp peaks of the spectra, (ii) an adaptative integration scheme is also considered, which is an interesting solution to lighten the computational burden by optimizing the integration mesh, distributing a (smaller) number of points at well chosen locations, (iii) third, a method of integration based on the proposed background/resonant decomposition.

The development of the background/resonant decomposition for spectral aerodynamic analysis is quite straightforward, at least if the modal response is uncoupled. In the latter case, the

analysis is performed mode by mode, and the SDOF model is still applicable provided that the mass, damping and stiffness are replaced by their modal homologue. Cases of structures experiencing modal coupling require however slightly more advanced models [23], but remains in the scope of the approximation that will constitutes the core of the future investigations.

In the next section, these integration methods with uniform and non uniform meshes will be compared with the background/resonant decomposition. A special attention will be paid to the trade-off between number of integration points and accuracy of the results.

#### 4 ILLUSTRATIONS AND EVALUATION OF CPU LOAD SAVING

In this section, the efficiency of the background/resonant decomposition is illustrated on two realistic case studies, namely the Golden Gate bridge and Tacoma Narrows bridge. The aeroelastic behavior of these two structures is characterized by torsional flutter as governing failure mode. The structure behavior is idealized by a SDOF model governed by

$$(-\omega^2 I_s + i\omega(c - c_{ae}(\omega)) + k - k_{ae}(\omega)) \Theta(\omega) = M_b(\omega) \quad (10)$$

where  $I_s$  is the mass moment of inertia per unit length and such that the aeroelastic damping, stiffness, and the buffeting pitching moment are reduced to

$$\begin{aligned} M_{bu}(\omega) &= \frac{qB}{U} \left( \frac{\pi}{2} B A(\omega) \right) W(\omega) \\ k_{ae}(\omega) &= qB^2 \left( \frac{\omega B}{U} \right)^2 A_3^*(\omega) \\ c_{ae}(\omega) &= qB^2 \frac{B}{U} \left( \frac{\omega B}{U} \right) A_2^*(\omega). \end{aligned} \quad (11)$$

The  $A_2^*(\omega)$  and  $A_3^*(\omega)$  coefficients refer to the Scanlan's —or flutter— torsional derivatives (see Figure 2), the admittance  $A(\omega)$  is supposed to be constant and equal to 1 in the following illustrations and  $W(\omega)$  is the spectral representation of the vertical fluctuating component of the wind turbulence. The structural parameters are summarized in Figure 1. For the two test cases, the accuracy and the efficiency of the proposed background/resonant decomposition will be compared to classical integration methods. The trapezoidal scheme is standard, while the adaptative integration scheme is briefly detailed in the Appendix. In each case, the integral in (4) is computed where  $S_q(\omega; U)$  corresponds to  $S_\theta(\omega; U)$ , for these case of torsional flutter. It is also defined by (3) where the aeroelastic stiffness and viscosity are given by (11).

As previously discussed, the number of integration points has a direct impact on the calculation load, and consequently on the computation time: the smaller the number of integration points, the faster the wind flutter analysis. The CPU times are not reported for this simple SDOF structure; they are replaced by the number of integration points which is assumed to give an correct picture of the computational burden for larger problems.

##### 4.1 Golden Gate bridge

Figure 3-a shows the PSD of the torsional degree-of-freedom for a selection of wind velocities. As the wind velocity increases, the resonance peak is shifted to the left and becomes sharper. This is a sign of torsional flutter, i.e. aero-elastic instability by lack of damping. The integral of the PSDs obtained for various wind velocities, i.e. the variance, is used to determine the scaled standard deviation of the angular displacement  $\theta$  shown in Figure 3-b. Each

	Golden Gate	Tacoma
Moment of Inertia $I_s$ [kg.m <sup>2</sup> /m]	$4.4 \cdot 10^6$	$177.73 \cdot 10^3$
Natural frequency $f_s$ [Hz]	0.1916	0.20
Damping Ratio $\xi_s$ [%]	0.5	0.5
Deck width $B$ [m]	27.43	12.0

Table 1: Structural properties of the structures considered in Illustrations 1 and 2.

Figure 2: Flutter derivatives  $A_2^*(\omega)$  and  $A_3^*(\omega)$  of the considered structures .

point of the reference curve was obtained with the trapezoidal integration scheme with a large number (50,000) of integration points. Red dots represents the results obtained with the B/R decomposition while the individual components B and R are also represented to indicate that the instability occurs for this type of cross-section by means of the resonant component. The reference solution and the proposed approximation are in excellent agreement, promising a very low relative error. As shown in Figure 3-c, the damping ratio remains constantly lower than 1% for all wind velocities, indicating that the hypothesis formulated above related to small damping is respected.

In Figure 3-d, the number of integration points required to satisfy a given relative precision is represented for the two usual numerical methods (trapezoidal scheme and adaptative integration) as well as the proposed Multiple Timescale Spectral Analysis approach (background/resonant decomposition). The relative error is calculated with respect to a reference solution obtained from a classical trapezoidal integration method with a mesh of 50,000 points uniformly spaced between 0 and 10 Hz (i.e. 62.8 rad/s). This mesh was kept constant for all considered wind speeds.

The square symbols, associated with the trapezoidal scheme, indicate that this classical integration method requires a minimum of 10,000 integration points to get a relative error of the order of the percent pour all wind speeds. For 1,000 points and below, the error is already way too large and the function is not accurately represented. However, with 1,000 points smartly distributed using an adaptive integration method, the standard deviation is accurately calculated with an error lower than 0.01%. A good compromise can be found around 100 points, where the error is of the order of the percent again. This method reduces the number of integration points required by a factor 100, approximatively. The performance of this adaptive integration method

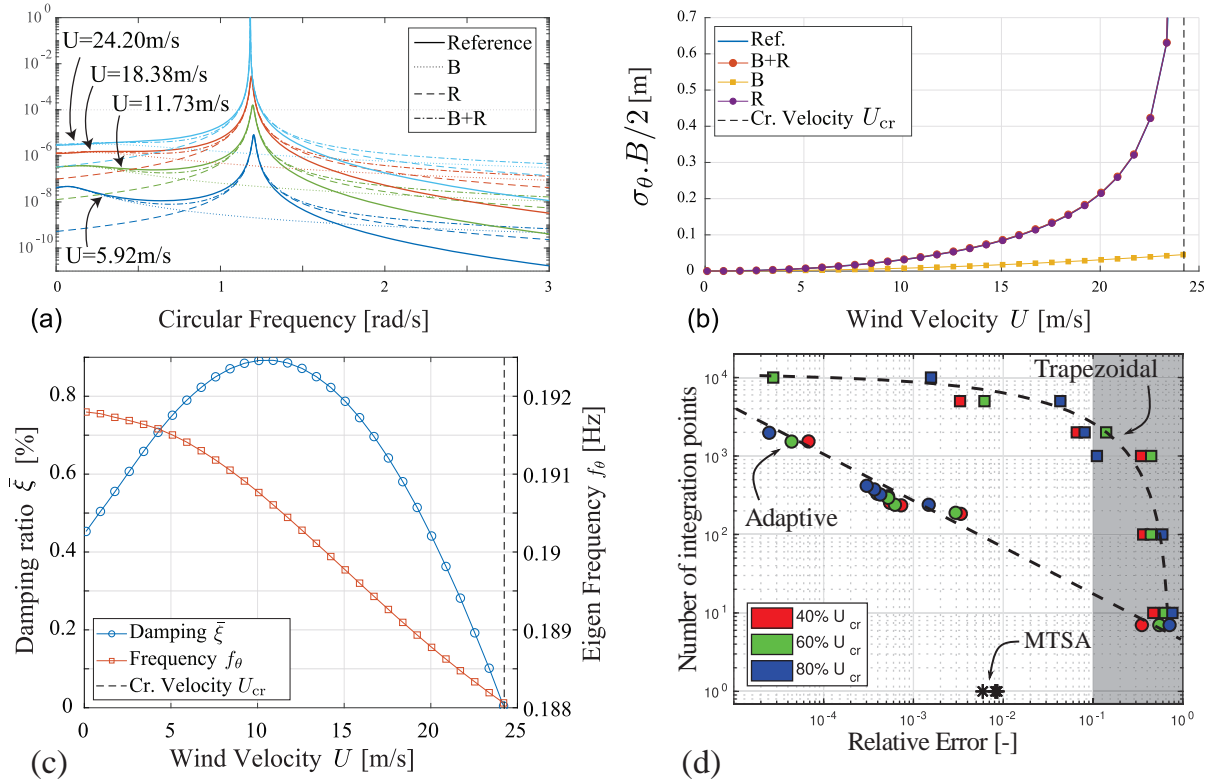

Figure 3: Aerodynamics response under buffeting loads (Golden Gate bridge). (a) PSD and their B and R approximations for different wind velocities. (b) Scaled standard deviations obtained with accurate numerical integration (Reference), background component (B), resonant component (R), and the sum of them (B)+(R). (c) Damping ratio and natural frequency at resonance with respect to avg. wind velocity. (e) Number of integration points required to satisfy a given relative error on  $\sigma_\theta$  for 3 avg. wind velocities and for the three methods discussed (trapezoidal scheme with uniform sampling, adaptive quadrature and the MTSA based B/R decomposition .)

is of course conditioned by the efficiency of the refinement algorithm and also by the parameters passed by the user—for instance the initial mesh. Usage of other adaptive integration scheme than the algorithm presented in the appendix might therefore lead to similar trends but slightly different numbers. The last cluster of points represented in Figure 3-d refers to the B/R decomposition and suggests an error below 1% while being limited a single sampling point, at resonance. This arises from the white noise approximation made in (6). This method appears now to be therefore the best compromise number of points/accuracy.

## 4.2 Tacoma Narrows bridge

The second case study is the Tacoma Narrows bridge. Besides its dangerously low critical velocity of 11 m/s, it behaves very similarly to the Golden Gate bridge such that most of results are globally the same. The output resulting from the aeroelastic analysis are shown in Figure 4.

For this second application the damping related flutter derivative  $A_2^*(\omega)$  is such that the damping ratio at resonance  $\bar{\omega}$  diminishes as  $U$  increases, except at very low wind speeds. The damping ratio remains again below 1% which explains why the quality of the approximation does not drop as the wind velocity increases. The trapezoidal integration scheme, in contrast, fails to capture the sharp resonance peak on approaching the critical flutter speed. More than that, the proposed background/resonant decomposition is even more precise that the damping ratio is small. Because the damping drops as the considered wind velocity approaches the crit-

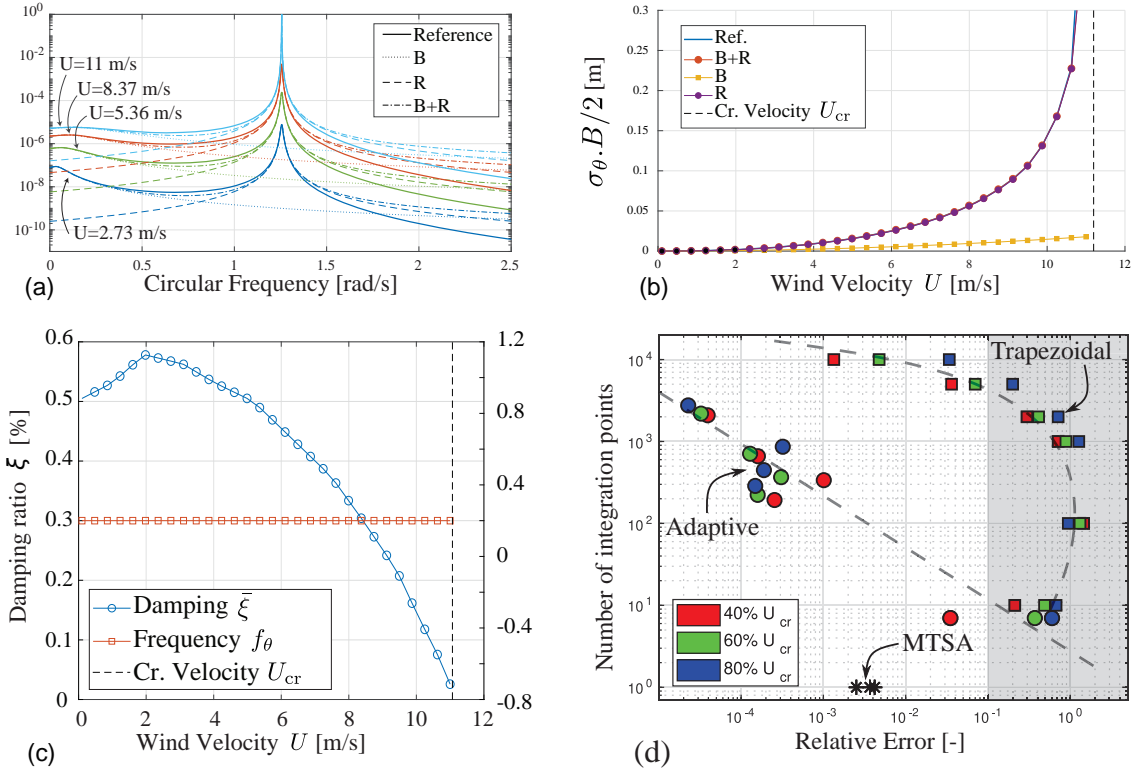

Figure 4: Aerodynamics response under buffeting loads (Tacoma Narrows bridge). (a) PSD and their B and R approximations for different wind velocities. (b) Scaled standard deviations obtained with accurate numerical integration (Reference), background component (B), resonant component (R), and the sum of them (B)+(R). (c) Damping ratio and natural frequency at resonance with respect to avg. wind velocity. (e) Number of integration points required to satisfy a given relative error on  $\sigma_\theta$  for 3 avg. wind velocities and for the three methods discussed (trapezoidal scheme with uniform sampling, adaptive quadrature and the MTSA based B/R decomposition .)

ical velocity, the approximation is even more accurate and appealing as flutter conditions are close. This is unfortunately not applicable to divergence instabilities, where the loss of stiffness is typically accompanied by an increase in damping, see e.g. XXX (bench polimi). Therefore, the approximation should not be recommended for divergence instabilities, particularly close to the flutter conditions.

Regarding the relative error and the integration points, the same 3 tendencies as in the previous applications are observed. A number of 100 integration points are required to accurately integrate the PSD using an adaptive method, and 10.000 points at least should be used if a uniform mesh is used. The MTSA approach provides truly accurate standard deviation with an error lower than 0.5%, slightly lower than in the Golden Gate bridge illustration.

## 5 PERSPECTIVES

The acceleration of the computation of the aeroelastic response of a single degree-of-freedom system could seem ridiculous at the time where the computational power is continuously growing and especially when the multiple mode analysis of large structures has been being available for more than 20 years [18, 19, 20]. We see however two main promising perspectives for this preliminary work.

The first one is immediate and concerns the stochastic stability of the single degree-of-freedom system. Indeed in a probabilistic approach, should it be by means of Monte Carlo simulations [21] or alternatives such as the collocation method or Galerkin approach [22], it is

essential to repeat the solution of the deterministic problem a large amount of times. Any CPU saving is therefore welcome to determine more accurate statistics of the response.

A second perspective of application of the proposed formulation concerns the extension to multi degree-of-freedom systems. They are governed by an equation similar to (I), which reads, in the frequency domain,

$$[-M_s \omega^2 + i\omega C(\omega) + K(\omega)] Q(\omega) = F_{bu}(\omega). \quad (12)$$

The aeroelastic matrices  $M_s$ ,  $C$  and  $K$  combining the structural matrices and aerodynamic unsteady loads might be very large. An analysis in the modal basis is able to drastically decrease the size of the system. The variance of the modal responses in each mode can then be determined with the method proposed in this paper. The main difference with a classical integration of the power spectral densities is that the projection of the buffeting forces in the modal basis is performed for natural frequencies only—or for a very restricted number of points in the most unfavorable case of a large aeroelastic stiffness—and not for the whole set of natural frequencies that a Gauss-Lobatto or trapezoidal integration scheme would require. So the proposed method can be used with very little adaptations as long as modal responses are concerned. Then, the combination of modal responses is necessary to determine structural responses (displacements and internal forces) or, alternatively, equivalent static loads. This requires the estimation of modal correlation coefficients but again, the Multiple Timescale Spectral Analysis has already been used to solve this problem in the buffeting-only case [23] and it is believed that the same extension is possible. Depending on how the eigenmodes of the aeroelastic system are determined, a proper recourse to the smallness of off-diagonal terms might be invoked, similarly to some of the previous results of the authors [24]. All in all, the determination of the response of a single oscillator appears as a major building block for the derivation of a very fast algorithm for the analysis of the aeroelastic response of large bridges. The outlook for future is to make possible the probabilistic analysis of large-scale structures or the rapid parametric analysis of large scale structures (varying the wind incidence, optimization of the aerodynamic deck, etc.).

## 6 CONCLUSIONS

The analysis of an aeroelastic oscillator subjected to low frequency turbulence can be studied by means of background and resonant components, which take a more general form than in the well known case presented by Davenport. They remain simple, however, and offer therefore a straightforward understanding of the response. Beyond this gain in physical insight, the derivation of the two components in an appropriate algorithmic implementation allows to speed up the determination of the stochastic response.

Examples have shown that the number of sampling points is reduced by a factor 10.000 (!) with respect to classical integration method, and by a factor 100 with respect to a smarter adaptive integration technique. This promises massive computational time saving, especially since the projection of the nodal aerodynamic loads vector in modal basis is by far the exhausting operation of the algorithm.

The delicacy of the proposed approximation resides also in the quality of its predictions: in the studied examples, the error committed on the standard deviation is lower than 1% which remains quite accurate when put in perspective to the safety envelope usually taken in civil engineering applications. The approximation method assumes that the damping ratio is small, and this hypothesis is even more respected that the system is close to flutter (except (static) divergence). Therefore the prediction is even more accurate that the resonant peaks are sharp,

as opposed to the trapezoidal integration method with a uniform mesh which struggles to capture accurately the sharpness of the peaks with a reasonable number of points.

These performance are promising for future extensions to probabilistic contexts, or large multiple mode structures, that rely both entirely on the efficiency of the algorithm to be envisaged.

## 7 APPENDIX: THE ADAPTATIVE INTEGRATION SCHEME

The results obtained and presented in this paper are partly obtained with a simple in-house adaptative integration scheme. The algorithm works as follows. First, the domain of integration is divided into segments separated by the integration points. On each segment, the contribution to the integral is computed by means of the trapezoidal rule. These segments are then iteratively refined, if required, until a desired accuracy is reached.

The refinement procedure consists in adding an integration point in the middle of the interval, creating therefore two sub-segments instead of the initial one. The sum of the contribution on the two sub-segments is compared to the contribution along the domain before subdivision. If the relative difference between both is lower than a user-defined threshold, then this domain is not subdivided anymore. This process is continued until no segments requires being divided anymore.

This algorithm performs better when the original distribution of points includes the inflexion points in the function to integrate. This is due to the fact that the break-down condition originates from a concept built on a curvature with a constant sign along the domain. The termination criteria can indeed be too confident in case of a domain with an inflexion point in the middle.

**Keywords:** low frequency, panel, sound transmission loss, elastic mounts, reverberation room

**Abstract.** *Lightweight panels are very common in the building, aerospace and automotive industry, and their acoustic insulation properties are well studied; nevertheless, low frequency noise is inherently difficult to deal with, mainly due to its high penetration. To encounter this issue, several treatments have been proposed in the form of perforated plates, meta-surfaces and acoustic/elastic meta-materials among others. Despite, the continuous attempts, none of the available solutions has indicated an outstanding performance in the low frequency range. On the other hand, boundary conditions of a vibrating panel are known to have an influence on the sound transmission loss (STL). Driven by the recently extended standards to include frequencies as low as 50 Hz, and the academic community debate about the reliability of low-frequency measurements in reverberant chambers, STL improvement in the region of the first panel resonance is investigated in this paper, considering a panel supported on elastic mounts. Following a general vibration isolation approach, the fundamental eigenfrequency of the panel-mount system is reduced and is explicitly selected below the threshold of human hearing. STL predictions are accomplished utilizing a Finite Element (FE) vibroacoustic model that simulates real test room conditions. Compared to the commonly used models of a baffled plate radiating to infinity, this detailed approach allows not only a more accurate calculation of STL but also reveals the potential issues emerging during laboratory measurements.*

## 1 INTRODUCTION

When considering room-to-room noise transmission inside buildings, sources such as electrical appliances, music and movies in neighboring apartments etc., have notable low frequency content. Another significant component of low frequency noise in residential areas is road noise emitted by vehicles, since their engines operate typically at speeds up to 6000 RPM (100 Hz). Therefore, there is an ever increasing demand for noise mitigation solutions in this range, providing an improvement on the residents quality of life but also for compliance with legal requirements [1].

However, the low frequency range approximately below 200 Hz, has been overwhelmingly overlooked in the past when considering applications and we presently lack understanding to properly model the processes governing the sound transfer in this frequency range. Almost exclusively, the focus is on the region of the coincidence frequency of finite partitions. The lack of complete industrial standardization and guidances for such cases, especially below 100 Hz is also a factor. Yet, a large research program on low frequency sound transmission into buildings was conducted by NGI (the Norwegian Geotechnical Institute) between 2010-2016, comprising of laboratory, full scale and numerical testing [2]. The disseminating research findings of the program have been proven very useful, but there are still uncharted areas in this field.

When it comes to acoustic treatment in rooms there are also a lot of misconceptions among the general public. Full scale tests reveal that when noise transmission occurs inside a building, the peaks of the low frequency sound spectrum are of the same order as the fundamental acoustic room-modes [3], leading to a collection of resonances, which compromise the measurements. International standards describe procedures to extend the measurement range down to the 50 Hz one-third octave band [4, 5, 6]. Prescriptions include use of specific source and receiver positions, however the procedure is complex, with the worst case scenario to propose the use of a sufficiently large number of source-receiver combinations as a means to smooth the large spatial variations in measured levels. Moreover, regarding the laboratory geometry, large rooms with volumes  $V > 200m^3$  and specific room size ratios are suggested when low frequency measurements are conducted. Recently, Ayr et al. [7] presented a detailed low frequency qualification procedure for a typical reverberant test room in order to perform sound power measurements, by taking advantage of a room finite element model. Similarly, Løvholt et al. [8] developed a finite element methodology that incorporates a two-way coupled fluid-structure interaction and they compared their numerical results with experimental measurements including low frequency sound transmission of plain walls, and walls with windows. Vorländer and Aretz also worked on room to room acoustic simulations, focusing on the room boundary conditions [9] and the uncertainties of the computational models [10].

As far as the analytic methods are concerned, the acoustic radiation from plates has long been an important subject in structural dynamics and acoustics, thus numerous mathematical models describing the structural response to noise, acoustic fatigue and sound transmission of partitions have been developed. Beranek and Ver, Cremer et al., Ordubadi and Lyon and London [11, 12, 13, 14] derived equations for the unbounded/infinite partitions ("infinite-panel theory") simplifying the problem and later ad hoc corrections were added to enhance the accuracy of the Sound Transmission Loss (STL) formulas. Although, the infinite panel theory can approximate pretty accurately the panel response when high frequency noise mitigation is concerned, it is known that bounded plates vibrating at frequencies below the critical frequency are very much influenced by the presence of their boundaries [15, 16]. Similarly, Kim [17] approached sound transmission through partitions from the standpoint of impedance mismatch. Despite, the merits

of the aforementioned approaches, in low frequency the modal response of the structure affects the transmission properties.

The aim of this contribution is to investigate the effects of elastic mounting in the STL performance, considering a much relevant specific case of single-leaf plasterboard partitions and show how the uncertainties due to practical factors can be diminished with this approach. Namely, the ways that elastic mounting may be incorporated in already existing panels and set circumstances regarding their spatial configuration, as well as, the effectiveness of the damping of the mounts in the mitigation of the first panel resonance. The analysis is conducted via both simple mathematical models and a coupled finite element vibroacoustic model where the room to room sound transmission is described based on the laboratory set-up in SINTEF Building laboratory in Oslo, Norway [8].

The idea of utilizing "soft mounts" to reduce the fundamental frequency of the system delves into the investigation of what constitutes soft mounting. Therefore, a modeling procedure based on certain approximations [18] is formulated in order to provide a projection of the expected level of stiffness that satisfies this terminology and serves the intended purpose. Intuitively, following the general concepts of vibration isolation for the reduction of the eigenfrequency through the reduction of stiffness, supporting an existing panel on elastic mounts, the 'mass law' behavior may be dragged into lower frequencies and the resonant region of the new system panel-mount will be moved below a critical frequency, for example at 20 Hz considering the threshold of human hearing.

To sum up, in Section 2 the theoretical formulation of the three applied methods, are provided together with the FE model describing the room to room transmission. In Section 3 a parametric investigation is presented to reveal the parameters that affect STL of a rectangular panel and finally in Section 4 the conclusions of this work are briefly discussed.

## 2 MATERIALS & METHODS

By defining the transmission coefficient as

$$\tau = \frac{\Pi_t}{\Pi_i} \quad (1)$$

where  $\Pi_i$  is the incident and  $\Pi_t$  the transmitted (radiated) sound power, the STL is expressed as

$$STL = 10 \log_{10} \left( \frac{1}{\tau} \right) \quad (2)$$

A typical form of the STL curve for sound propagation through a thin panel is described in [19]. In the 'mass law' region, the STL is controlled by the mass per unit area of the panel. Specifically, for a thin panel, neglecting stiffness and damping (limp wall):

$$STL = 10 \log_{10} \left[ \frac{\Omega^2 \bar{m}^2}{4(\rho_0 c_0)^2 / \cos^2 \theta_i} \right] \quad (3)$$

where  $\Omega$  is the cyclical frequency of the propagated incident sound waves,  $\theta_i$  is the angle of incidence,  $c_0$  is the speed of sound in air,  $\rho_0$  is the air density and  $\bar{m} [kg/m^2]$  is the mass per unit area of the panel. Although the mass law is very simple and compact, it is only valid for large simple plates because it is derived from the infinite and rigid plate assumption. Therefore, attention should be given when utilized for STL predictions of general finite panels.

Figure 1: (a) Coordinate systems and transmission geometry of a rectangular plate in a rigid baffle. (b) Transmission geometry of the free finite rigid panel.

## 2.1 Sound radiation from a rectangular panel in an infinite rigid baffle

The fluid domain is assumed homogeneous and compressible. The mass density of air and sound speed are noted as  $\rho_0$  and  $c_0$ , respectively. The infinitely large acoustic rigid baffle divides the space into two domains i.e. the excitation domain  $V^-$  and the receiver domain  $V^+$ . The panel is subjected to the incident pressure  $p_i$ , with incidence angle  $\theta_i$  and azimuth angle  $\phi_i$ . Therefore, the excitation domain consists in the incident pressure  $p_i$ , the reflected pressure  $p_r$ , and the re-radiated pressure  $p_{rad}^-$  due to the motion of the finite panel. The receiver domain consists only in the transmitted pressure  $p_t$ , namely the radiated pressure due to the motion of the panel  $p_{rad}^+$ . Assuming that the incident sound pressure  $p_i$  is a harmonic function, we can express it as

$$p_i(x, y, z, t) = P_i e^{-j(\kappa_x x + \kappa_y y + \kappa_z z)} e^{j\Omega t} = \tilde{p}_i(x, y, z) e^{j\Omega t} \quad (4)$$

where  $\tilde{p}_i(x, y, z)$  the time invariable complex amplitude and  $\kappa = \Omega/c_0$  is the wavenumber with

$$\kappa_x = \kappa \sin \theta \cos \phi, \quad \kappa_y = \kappa \sin \theta \sin \phi, \quad \kappa_z = \kappa \cos \theta \quad (5)$$

The reflected pressure by the surface of the panel is then expressed as

$$p_r(x, y, z, t) = P_r e^{-j(\kappa_x x + \kappa_y y - \kappa_z z)} e^{j\Omega t} = \tilde{p}_r(x, y, z) e^{j\Omega t} \quad (6)$$

denoting the opposite direction from the incident wave. Lord Rayleigh [20] determined a relationship expressing the radiated (transmitted) pressure in terms of the structural velocity based on Green's function,

$$p_{rad}^+(\mathbf{r}, t) = p_t(\mathbf{r}, t) = \frac{j\Omega\rho_0}{2\pi} e^{j\Omega t} \int_{-l_x/2}^{l_x/2} \int_{-l_y/2}^{l_y/2} \frac{e^{-j\kappa R}}{R} \frac{\partial w(\xi', \eta')}{\partial t} d\eta' d\xi' \quad (7)$$

where  $R$  referring to Fig.1, is defined as

$$R = |\mathbf{r} - \mathbf{r}_P| = \sqrt{(x - \xi')^2 + (y - \eta')^2 + z^2} \quad (8)$$

and  $\mathbf{r} = (x, y, z)$  is the position vector of a point in the receiver domain while  $\mathbf{r}_P = (\xi', \eta', 0)$  is the position vector of the center of an elemental radiator with surface  $\delta S$  on the panel, having a normal velocity amplitude  $\dot{w}(\xi', \eta')$ . For the local coordinates holds that  $\xi' = \xi - \frac{l_x}{2}$ ,  $\eta' = \eta - \frac{l_y}{2}$ .

Following the calculation of the expression for the transmitted pressure, there are two different ways used to determine the radiated (transmitted) power. The first is to integrate the

intensity on a hemisphere in the far-field enclosing the plate which is followed in this paper, and the latter is to integrate the acoustic intensity over the surface of the vibrating plate. Both approaches require the knowledge of the distribution of the velocity over the plate and they assume a weak coupling between the vibrating structure and the radiated sound field.

Applying the far-field approximation as described in Section A.1, the transmitted intensity  $I_t$  is calculated as

$$I_t(r, \theta, \phi) = \frac{|p_t(r, \theta, \phi)|^2}{2\rho_0 c_0} \quad (9)$$

Then, the transmitted power  $\Pi_t$  comes by integrating the transmitted intensity on a hemisphere in the far field enclosing the plate as

$$\Pi_t = \int_0^{2\pi} \int_0^{\pi/2} I_t r^2 \sin \theta d\theta d\phi \quad (10)$$

while the incident power on the panel is defined as

$$\Pi_i = \frac{|p_i|^2 l_x l_y \cos \theta}{2\rho_0 c_0} \quad (11)$$

## 2.2 Vibration of a panel subject to external pressure

With reference to Fig.1a, the finite-sized flat panel partition is assumed to be rectangular and baffled, with lengths  $l_x$  and  $l_y$  along the  $x$  and  $y$  axes respectively. The panel of thickness  $h$ , is considered homogeneous and isotropic and is modeled as a classical thin plate, implying that the effects of both the rotary inertia and the transverse shear deformation can be neglected. Hereinafter, the equation of motion governing the bending vibration of the plate is given by

$$\begin{aligned} D \left[ \frac{\partial^4 w(\xi, \eta, t)}{\partial \xi^4} + 2 \frac{\partial^4 w(\xi, \eta, t)}{\partial \xi^2 \partial \eta^2} + \frac{\partial^4 w(\xi, \eta, t)}{\partial \eta^4} \right] + \rho h \frac{\partial^2 w(\xi, \eta, t)}{\partial t^2} = \\ = p_i(\xi, \eta, t) + p_r(\xi, \eta, t) + \bar{p}_{rad} - p_{rad}^+ \end{aligned} \quad (12)$$

where  $D = \tilde{E}h^3/12(1 - \nu^2)$  is the bending stiffness of the plate,  $E$ ,  $h$ ,  $\rho$  and  $\nu$  are the Young's modulus, thickness, mass density and Poisson's ratio of the plate, respectively.  $w(\xi, \eta, t)$  is the instantaneous transverse displacement. In order to account for energy dissipation due to structural damping, a complex modulus of elasticity is introduced  $\tilde{E} = E(1 + jn)$ , where  $n$  is the loss factor.

The right hand side must satisfy the velocity continuity at the surface of the panel ( $z = 0$ ). In that case, it holds that  $p_r = p_i$  and also since  $p_t = p_{rad}^+ = -\bar{p}_{rad}$  the right hand side becomes

$$p_i(\xi, \eta, t) + p_r(\xi, \eta, t) + \bar{p}_{rad} - p_{rad}^+ = 2p_i(\xi, \eta, t) - 2p_t(\xi, \eta, t) \quad (13)$$

The so-called "blocked pressure" [17]  $p_b = 2 p_i$ , is the pressure when the incident wave meets a rigid wall.

## 2.3 Free Finite Rigid (FFR) Panel Approximation

In order to replace the infinite panel approximation (limp wall) with a more appropriate reference for finite panels, the free finite rigid (FFR) panel approximation is formulated. In this case it is assumed that the panel is rigid, consisting only in mass and oscillating freely in an infinite rigid baffle but instead has finite dimensions as demonstrated in Fig.1b.

Since the panel is considered rigid, the spatial derivatives of Eq.(12) are eliminated. Also, considering only the blocked pressure  $p_b = 2p_i$  as the forcing pressure and that  $p_i$  are incident plane waves, the equation of motion becomes:

$$\rho h \ddot{w} = 2P_i e^{j\Omega t} \quad (14)$$

The forcing pressure is a harmonic function, therefore the steady-state transverse displacement of the panel can be expressed as

$$w = W(\xi, \eta) q(t) \quad (15)$$

where

$$q(t) = C e^{j\Omega t} \quad (16)$$

For the rigid assumption, the shape function is independent of the position  $(\xi, \eta)$  on the surface of the panel, namely  $W(\xi, \eta) = 1$ . Substituting the solution into Eq.(14) and solving for  $C$  gives:

$$C_{\text{FFR}} = -\frac{2P_i}{\rho h \Omega^2} \quad (17)$$

The transmission coefficient then comes as

$$\tau_{\text{FFR}} = \frac{1}{l_x l_y} \left( \frac{\rho_0}{\pi} \right)^2 \frac{1}{\overline{m}^2} I_{\theta\phi} \quad (18)$$

where  $\overline{m} = \rho h$  is the mass density (mass per surface area) of the panel, and  $I_{\theta\phi}$  is the double integral over a hemisphere in the receiver domain as given in Eq.(A.10).

## 2.4 Simply Supported Plate First Mode Approximation

Analytic solutions for the problem can be found via modal superposition methods, for example as formulated by Roussos [21]. However, in these analytic approaches, past researchers usually avoided to include in their calculations the re-radiated pressure  $2p_t(\xi, \eta, t)$  (often referred to as "fluid loading") of Eq.(13) in order to reduce complexity. According to Roussos [21] neglecting the effect of the re-radiated pressure allows an accurate solution to be obtained over large frequency range, and gives invalid answers only for frequencies near the panel's fundamental resonant frequency.

Since the low frequency range of interest in the present case is exactly the range near the fundamental resonance of the panel, an attempt for a more accurate and usable approximation is formulated in this section, including the effect of fluid loading.

Considering only the 1<sup>st</sup> vibrational mode of the simply supported plate, the spatially dependent amplitude of the transverse displacement  $w(\xi, \eta) = W_1(\xi, \eta, t) e^{-j\Omega t}$  is assumed by the shape function

$$W_1 = C_1 \sin\left(\frac{\pi\xi}{l_x}\right) \sin\left(\frac{\pi\eta}{l_y}\right) \quad (19)$$

the resulting expression for the transmitted (radiated) power  $\Pi_t$  is given by Eq.(A.25). The detailed analysis is presented in Section A.3.

Assuming normal incident waves ( $\theta_i = 0$ ), the incident power is given by

$$\Pi_i = \frac{P_i^2 l_x l_y}{2\rho_0 c_0} \quad (20)$$

leading to the transmission coefficient  $\tau$  as

$$\tau_1 = \frac{1}{l_x l_y} \frac{(16\Omega^2 \rho_0)^2}{|\pi^3 \rho h (\omega_1^2 - \Omega^2) - 16\Omega^2 \rho_0 \frac{e^{-jkr}}{r}|^2} I_{\theta\phi} \quad (21)$$

where distance  $r$  needs to be large enough to satisfy the far-field approximation and  $\omega_1$  is the natural frequency of the 1<sup>st</sup> mode resulting from the homogeneous form of Eq. (12), as

$$\omega_1^2 = \frac{D\pi^4}{\rho h} \left( \frac{1}{l_x^2} + \frac{1}{l_y^2} \right)^2 \quad (22)$$

Expressing the dynamic behavior of the continuous system of the simply supported panel approximated by the 1<sup>st</sup> mode, as a single degree of freedom (SDoF) lumped parameter model (LPM), the corresponding generalized mass and stiffness [22] come as

$$m_1^* = \frac{\rho h l_x l_y}{4} = \frac{\bar{m} l_x l_y}{4} = \frac{m}{4} \quad (23)$$

$$k_1^* = \frac{D\pi^4 l_x l_y}{4} \left( \frac{1}{l_x^2} + \frac{1}{l_y^2} \right)^2 \quad (24)$$

The transmission coefficient is then calculated as

$$\tau_{\text{LPM}} = l_x l_y \left( \frac{4\Omega^2 \rho_0}{\pi^3} \right)^2 \frac{1}{[m_1^* |\omega_1^2 - \Omega^2|]^2} I_{\theta\phi} \quad (25)$$

## 2.5 Lamped parameter model for elastic mounts

The goal is to formulate a straightforward procedure for the investigation of how the bending stiffness of the panel combines with the mounting stiffness in the case where the panel is supported on elastic mounts and how the acoustic performance is affected. In order to do that, the main assumption is that the bending stiffness of the deformable plate is in a way in series with the stiffness of the mounting. Therefore, the resulting stiffness is

$$k_{\text{tot}} = \frac{k_1^* k_0'}{k_1^* + k_0'} \quad (26)$$

When the mounting is very stiff ( $k_0' \gg k_1^*$ ) leads to  $k_{\text{tot}} = k_1^*$ , namely, the case of the simply supported plate is approached. When  $k_0' \rightarrow 0$ , the plate is essentially free floating. Naturally, when the eigenfrequency of the system is reduced along with the total stiffness, the mass considered in the SDof model increases. In this case this variation is neglected for reasons of simplification. As a result, when the considered mounting stiffness  $k_0'$  is of comparative order of magnitude with  $k_1^*$ , there is some deviation between the resulting eigenfrequency of the model and the actual eigenfrequency. However, in cases when  $k_0' \gg k_1^*$  or  $k_0' \ll k_1^*$  the deviation is nullified. Thus the model is used for an estimation of the required stiffness level and guidance for the design of the mounts.

Fig.2, shows the equivalent dynamic SDOF model of the deformable thin panel when it is supported on elastic mounts according to the 'in-series' assumption. This is achieved by utilizing the generalized values of the structure, namely generalized mass and the corresponding

Figure 2: Modelling of a deformable plate on elastic mounts with stiffness  $k'_0$ .

generalized stiffness for the appropriate modes, as calculated from Eqs.(23),(24) for the  $1_{st}$  mode approximation of the simply supported panel.

Since the loss factor ( $n$ ) can represent more accurately the dynamic response of nonlinear systems compared with the damping ratio which is defined on the grounds of the linear single degree of freedom (SDOF) viscous model [23, 24], hysteretic damping is introduced indirectly considering complex stiffness elements as

$$k'_0 = k_0 (1 + jn) \quad (27)$$

$$(28)$$

The STL of the model is then calculated as  $STL = 10 \log_{10} \left( \frac{1}{\tau} \right)$ , where the transmission coefficient  $\tau$  comes as

$$\tau = l_x l_y \left( \frac{4\Omega^2 \rho_0}{\pi^3} \right)^2 \frac{1}{|-\Omega^2 m_1^* + k_{tot}|^2} I_{\theta\phi} \quad (29)$$

## 2.6 3D vibro-acoustic FE model

In addition to the aforementioned analytical methodologies, a 3-D FE coupled vibro-acoustic model was developed on the commercial finite element software package ABAQUS [25]. In the present simulations, the geometry of the SINTEF laboratory [8] is utilized as the computational domain, as shown in Fig.3  $\alpha$  and b. It is noted that the laboratory geometry and the measurement procedure do not follow accurately the proposed from the standards guidance, however, the developed model can be used for room to room sound transmission predictions. The panel is excited by the source located in the left corner of the source room and the incidence and radiated acoustic pressure is extracted from the fluid-structure interface nodes. An arithmetic average is performed by

$$\overline{P}_t = \frac{1}{n} \sum_{i=1}^n |p_{t,i}| \quad (30)$$

$$\overline{P}_i = \frac{1}{n} \sum_{i=1}^n |p_{i,i}| \quad (31)$$

where  $n$  denotes the total number of measuring nodes;  $i$  denotes the node number;  $p_i$  denotes the incidence pressure and  $p_t$  denotes the transmitted pressure. Then the averaged pressures  $\overline{P}_i, \overline{P}_t$  are used to compute the simulated STL by

$$STL = 20 \log_{10} \frac{|\overline{P}_i|}{\overline{P}_t} \quad (32)$$

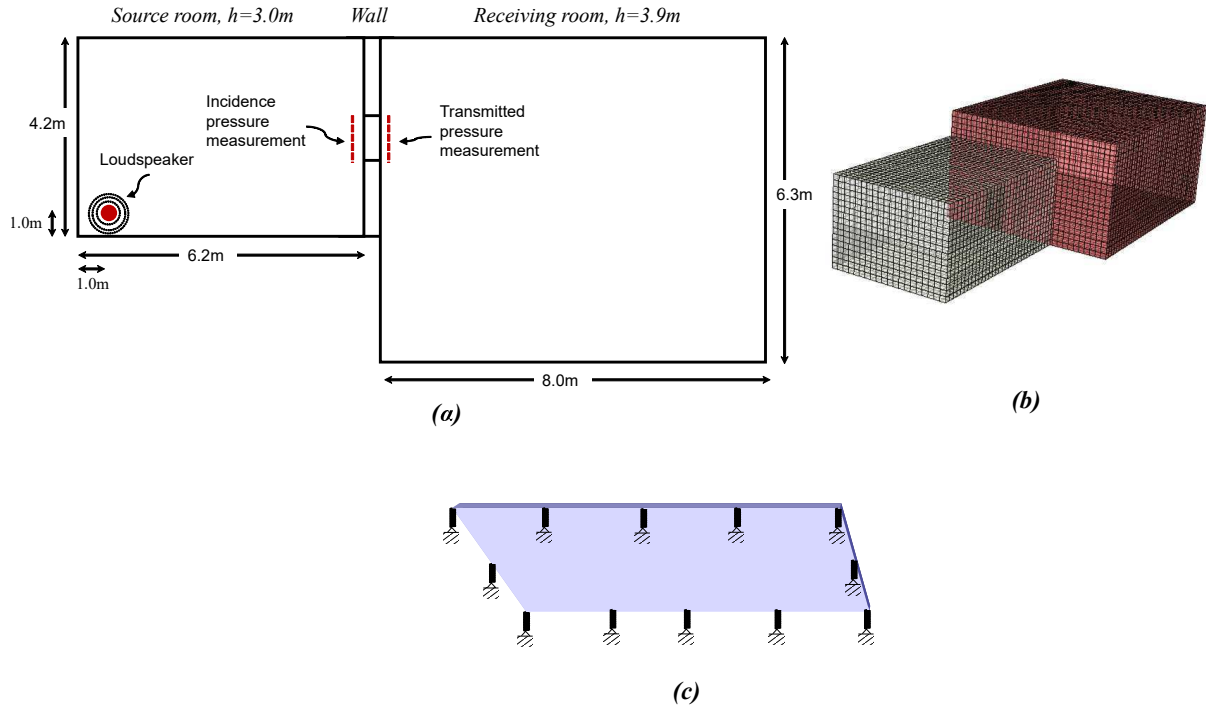

Figure 3: (a) Plan view of the sound laboratory setup used in ABAQUS model. (b) Depiction of the vibro-acoustic model. (c) Positioning of the twelve (12) mounts on the surface of the panel.

The panel is discretized by 20-node quadratic solid hexahedral elements, while the fluid domain is discretized by 20-node quadratic acoustic hexahedral elements. Tie constraints are used to simulate the coupling at the fluid-structure interface, while reflecting boundary conditions were specified to simulate the room conditions. In cases that the plate is supported on elastic mounts, connectors are installed on the required locations with the appropriate properties. Lastly, the discretization of the fluid domain has more than three quadratic elements across the wavelength of interest to increase the accuracy of the computational results [26].

### 3 Numerical Example - Parametric investigation of STL

In this section, the elements that affect STL of a rectangular plate are investigated, especially in case of a single leaf plasterboard partition. Initially, the analytic models proposed in the previous section A  $0.625 \times 1.6m$  rectangular plasterboard is considered, according to real-life masonry applications. The width corresponds to the horizontal distance between the upright supporting beams providing the stable frame of the plasterboard. Typically, the height of such a plasterboard is around 3.2 m, meaning that it can be covered by two pieces with the dimensions consider here. The selected dimensions correspond also to a frontal surface of  $1 m^2$ . The relevant properties of the plasterboard are summarized in Table 1.

Table 1: Plasterboard properties.

$\rho \left[ \frac{kg}{m^3} \right]$	$L_x [m]$	$L_y [m]$	$h [m]$	$E [MPa]$	$\nu [-]$
668	0.625	1.6	$12.5 \cdot 10^{-3}$	2900	0.31

The red dashed line in Fig.4, represents the FFR panel approximation as given by Eq.(18). Intuitively, this approximation should constitute the ideal case regarding the STL of a panel

with finite dimensions and may act as a reference curve for the various comparisons instead of the infinite panel approximation which is invalid in the lower frequency range that is being examined. The yellow line corresponds to the 1<sup>st</sup> mode approximation of the simply supported panel while the blue dotted line is the lumped parameter model as derived from the 1<sup>st</sup> mode approximation. The difference between the two methods is essentially the effect of fluid loading (FL), whereas in the latter model is not included. It is observed that the fluid loading has very little effect on the damping of the first resonance. Thus, the elimination of its participation in the respective models is justified and consists a safe approximation. Lastly, the black dashed line represents the modal superposition method as formulated by Roussos and the grey line with markers shows the STL as calculated from the finite element model. In general a good agreement is observed among all the applied methods.

### 3.1 Mathematical vs Numerical models

Figure 4: Comparison of 1<sup>st</sup> mode, rigid approximations and numerical model.

The objective of the simplified models is to provide a more straightforward and fast prediction of the acoustic performance of the panel along with the ability to extract intuitive and revealing expressions of the main dynamic parameters that govern its frequency response. Since the higher modes have significantly lower modal participation factors in the frequency response than the fundamental mode, they are relatively easily damped. With that thinking, the approximation using only the 1<sup>st</sup> mode is considered appropriate in order to study this low frequency region, and following, the effect of elastic mounting and damping.

### 3.2 Effect of support conditions in STL

A case for the resulting STL frequency response compared to the simply-supported and clamped configurations are presented in Fig.5 $\alpha$ . The total stiffness of the mounting is considered equal to the generalized stiffness of the simply supported panel ( $k = k_1^* = 1.1 \cdot 10^5 \text{ N/m}$ ),

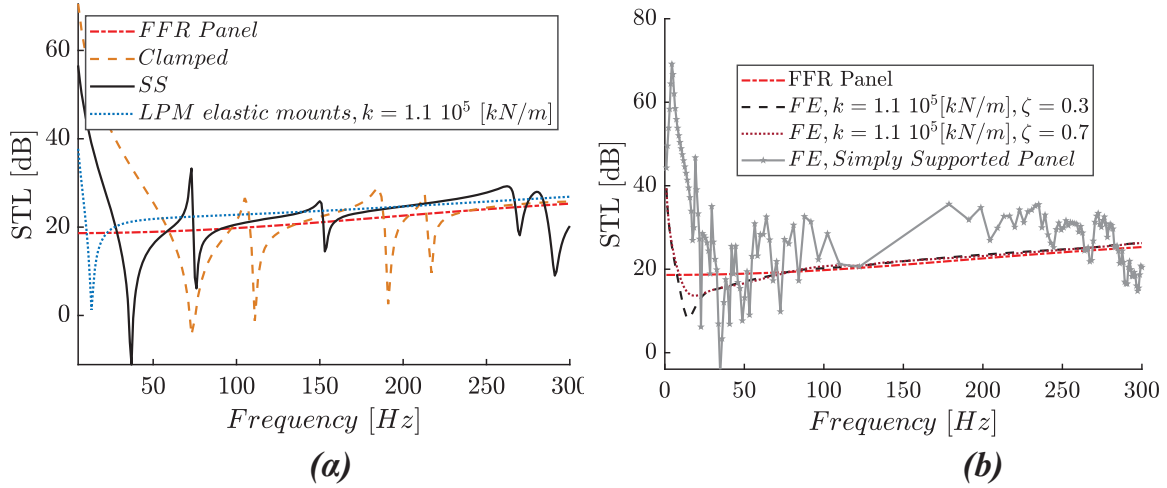

Figure 5: (a) Effect of support conditions in Sound transmission loss (STL). (b) Effect of damping in Sound transmission loss (STL).

while, no damping is considered for the mounts. This choice for the mounting stiffness is based on the Lamped parameter model, described in Section 2.5. Specifically, the total mounting stiffness is selected to drop the  $1_{st}$  resonance below 20 [Hz] and then the estimated stiffness is allocated to the 12 springs of the FE model.

Following the logic of classic vibration isolation, by lowering this frequency enough it can be moved outside the frequency range of interest, e.g. above 20 Hz. However, significantly decreasing this frequency can have certain implications. On one hand, it leads to slightly reduced STL frequency response and on other hand, it may present practical problems including excessive vibration magnitude, possible resonances with other supportive structural elements such as bolts or the frame, or even inadequate rigidity for impact loads. The optimal solution requires a combination that leads to a low enough fundamental eigenfrequency that can be effectively dampend without the need of excessive damping while at the same time is high enough that the overall STL is not significantly reduced and no vibrational implications come into play when the mounting is very soft.

Another purpose of the comparison in Fig.5a is to highlight the deviation of the eigenfrequencies between the simply supported and clamped panels in regards to the uncertainty introduced by this fact in real world installations. Depending on the technique of the installation the exact support conditions may vary between these two cases. However, the inclusion of the soft elastic mounts, eliminates this uncertainty as it produces an explicit, calculated frequency response by design. Additionally, the reduction of the eigenfrequencies alone almost eliminates the participation of the higher modes even without the consideration of any energy diffusive elements besides the structural damping of the panel itself which holds for all three case compared here.

### 3.3 Effect of damping

Further examination considers the effect of damping of the elastic mounts. In order to investigate the effects of damping 12 linear springs were attached to the panel as in Fig.3c. Assuming the same stiffness for the mounts as in the previous case, a comparison is presented in Fig. 5b damping ratios  $\zeta = 0.3$  and  $\zeta = 0.7$ .

The results presented in Fig.5b are meant to demonstrate the expected level of damping in

order to effectively damp the fundamental frequency. As already mentioned, even in cases of low damping the STL response is flattened as the higher eigenfrequencies are very effectively damped while only the first eigenfrequency requires significant damping. How realistic are the actual values of the assumed viscous dampers for high damping ratios is surely a matter of discussion and very much depends on practical factors like the material used for the mounts and spatial considerations of the real world implementation.

Certainly, the positions of the mounts have a significant role on their damping effectiveness. Especially in this case of viscous damping, the velocity amplitude is maximum at the center of the panel and minimum along the edges, therefore a mount positioned at the center would most effectively dampen the fundamental resonance. However, this case would change the dynamic behaviour of the panel and would also require an additional supporting frame along the middle of the panel for example, which is something that is preferably avoided. For this reasons such a modification is not investigated in the current contribution.

## 4 Conclusions

The variation of the support conditions of the panel, between simply supported and clamped, in a real-world implementation affects significantly the eigenfrequencies and therefore the frequency response of the STL.

The term "soft mounts" is approximately defined as the case in which the total stiffness of the mounts is lower than the generalized stiffness of the simply supported panel. When the panel is supported regionally on soft elastic mounts, the values of the eigenfrequencies of the structure are reduced. This has two main consequences:

- The value of the fundamental eigenfrequency can be explicitly defined, depending on the stiffness of the mounts, and be moved outside the frequency range of interest, namely below 20 Hz.
- The contribution of the higher modes is almost nullified without the need of any significant damping in the mounts.

Therefore, the utilization of soft mounts displaces the STL curve towards lower frequencies, providing smooth performance in the entire low frequency range. Additionally, this practice diminishes any uncertainties introduced in the acoustic performance either due to practical support conditions or variations in the rigidity of the panel.

Finally, the analytic models showed good agreement with the developed FE model, indicating that they can be used as a quick tool for the design of soft mounts.

## Appendix

### A.1 Far-field approximation

The distance  $R$  can be written as

$$R = \sqrt{r^2 - 2x\xi' - 2y\eta' + \xi'^2 + \eta'^2} \quad (\text{A.1})$$

where  $r = |\mathbf{r}| = \sqrt{x^2 + y^2 + z^2}$ . In spherical coordinates  $R$  becomes

$$R = r \sqrt{1 - 2 \frac{\sin \theta}{r} (\xi' \cos \phi + \eta' \sin \phi) + \frac{\xi'^2 + \eta'^2}{r}} \quad (\text{A.2})$$

The solution of Eq.(7) is not trivial and has been calculated analytically only for a few cases of boundary conditions. A way around this obstacle comes by utilizing the far field approximation. In the far field we can ignore the weak dependence of the amplitude of the integrand on the position but not the dependence of the phase, namely it holds that

$$\frac{1}{R} \approx \frac{1}{r} \quad (\text{A.3})$$

$$e^{-j\kappa R} \approx e^{-j\kappa r \left[ 1 - \frac{\sin \theta}{r} (\xi' \cos \phi + \eta' \sin \phi) \right]} = e^{-j\kappa r} e^{j\kappa \sin \theta (\xi' \cos \phi + \eta' \sin \phi)} \quad (\text{A.4})$$

Since  $r$  is independent of  $\xi'$  and  $\eta'$ , the corresponding terms in Eq.(7) can be moved outside the double integral, leading to

$$p_t(\mathbf{r}, t) = \frac{j\Omega\rho_0}{2\pi r} e^{j(\Omega t - \kappa r)} \int_{-l_x/2}^{l_x/2} \int_{-l_y/2}^{l_y/2} \frac{\partial w(\xi', \eta')}{\partial t} e^{j\kappa (\xi' \sin \theta \cos \phi + \eta' \sin \theta \sin \phi)} d\eta' d\xi' \quad (\text{A.5})$$

which may be analytically calculated.

## A.2 Free Finite Rigid (FFR) Panel Approximation

Then, the transmitted pressure by considering the far-field approximation, is calculated from the expression

$$p_t(\mathbf{r}, t) = \frac{-\Omega^2 \rho_0 W}{2\pi} \frac{e^{-j\kappa r}}{r} e^{j\Omega t} \int_{-\frac{l_x}{2}}^{\frac{l_x}{2}} \int_{-\frac{l_y}{2}}^{\frac{l_y}{2}} e^{j\kappa (\xi' \sin \theta \cos \phi + \eta' \sin \theta \sin \phi)} d\eta' d\xi' \quad (\text{A.6})$$

where the surface integral is calculated

$$I_{\xi'\eta'} = \frac{8 \sin(\sigma_x) \sin(\sigma_y)}{k^2 \sin^2 \theta \sin 2\phi} \quad (\text{A.7})$$

and

$$\sigma_x(\theta, \phi) = k \frac{l_x}{2} \sin \theta \cos \phi \quad (\text{A.8})$$

$$\sigma_y(\theta, \phi) = k \frac{l_y}{2} \sin \theta \sin \phi \quad (\text{A.9})$$

The transmitted intensity  $I_t$  and consequently the transmitted power, are calculated from Eqs.(9),(10) where  $I_{\theta\phi}$  is defined as

$$I_{\theta\phi} = \int_0^{2\pi} \int_0^{\pi/2} |I_{\xi'\eta'}|^2 \sin \theta d\theta d\phi \quad (\text{A.10})$$

### A.3 Simply Supported Plate - First Mode Approximation

Considering only the 1<sup>st</sup> mode for interpolation of the transverse displacement the derivatives to be substituted in the equation of motion are calculated as

$$\begin{aligned}
 \frac{\partial^2 w(\xi, \eta)}{\partial t^2} &= -\Omega^2 W_1(\xi, \eta) e^{-j\Omega t} \\
 \frac{\partial^4 W_1(\xi, \eta)}{\partial \xi^4} &= C_1 \left( \frac{\pi}{l_x} \right)^4 \sin\left(\frac{\pi \xi}{l_x}\right) \sin\left(\frac{\pi \eta}{l_y}\right) = \left( \frac{\pi}{l_x} \right)^4 W_1(\xi, \eta) \\
 \frac{\partial^4 W_1(\xi, \eta)}{\partial \eta^4} &= C_1 \left( \frac{\pi}{l_y} \right)^4 \sin\left(\frac{\pi \xi}{l_x}\right) \sin\left(\frac{\pi \eta}{l_y}\right) = \left( \frac{\pi}{l_y} \right)^4 W_1(\xi, \eta) \\
 \frac{\partial^4 W_1(\xi, \eta)}{\partial \xi^2 \partial \eta^2} &= C_1 \left( \frac{\pi^2}{l_x l_y} \right)^2 \sin\left(\frac{\pi \xi}{l_x}\right) \sin\left(\frac{\pi \eta}{l_y}\right) = \left( \frac{\pi^2}{l_x l_y} \right)^2 W_1(\xi, \eta)
 \end{aligned} \tag{A.11}$$

Considering the far field approximation for the transmitted pressure and normal incident waves ( $\theta_i = 0$ ), the equation of motion becomes

$$\begin{aligned}
 \left[ D\pi^4 \left( \frac{1}{l_x^2} + 2\frac{1}{l_x^2 l_y^2} + \frac{1}{l_y^2} \right) - \Omega^2 \rho h \right] W_1(\xi, \eta) = \\
 2P_i + \frac{\Omega^2 \rho_0}{\pi r} e^{-jkr} I_{\xi' \eta'}
 \end{aligned} \tag{A.12}$$

where  $I_{\xi' \eta'}$  is the double integral on the surface of the plate

$$I_{\xi' \eta'} = \int_{-l_x/2}^{l_x/2} \int_{-l_y/2}^{l_y/2} W_1(\xi', \eta') e^{jk(\xi' \sin \theta \cos \phi + \eta' \sin \theta \sin \phi)} d\eta' d\xi' \tag{A.13}$$

and the local coordinates  $\xi' = \xi - \frac{l_x}{2}$ ,  $\eta' = \eta - \frac{l_y}{2}$ . For  $\xi'$ ,  $\eta'$  the shape function from Eq.(19) becomes

$$W_1(\xi', \eta') = C_1 \cos\left(\frac{\pi \xi'}{l_x}\right) \cos\left(\frac{\pi \eta'}{l_y}\right) \tag{A.14}$$

The surface integral is then calculated as

$$I_{\xi' \eta'} = C_1 I_{\xi \eta} \tag{A.15}$$

where

$$I_{\xi \eta} = 4\pi^2 l_x l_y \frac{\cos(\sigma_x)}{(l_x k \sin \theta \cos \phi)^2 - \pi^2} \frac{\cos(\sigma_y)}{(l_y k \sin \theta \sin \phi)^2 - \pi^2} \tag{A.16}$$

and  $\sigma_x$ ,  $\sigma_y$  are the same as in Eq.(A.8). Solving (19) for  $C_1$ , the surface integral can be written as

$$I_{\xi' \eta'} = \frac{W_1(\xi, \eta)}{\sin\left(\frac{\pi \xi}{l_x}\right) \sin\left(\frac{\pi \eta}{l_y}\right)} I_{\xi \eta} \tag{A.17}$$

Substituting to equation (A.12), multiplying with  $W_1$  and integrating over the panel surface gives

$$\begin{aligned} \int_0^{l_x} \int_0^{l_y} \left[ D\pi^4 \left( \frac{1}{l_x^2} + \frac{1}{l_y^2} \right)^2 - \frac{\Omega^2 \rho_0 e^{-j\kappa r}}{\pi r} \frac{I_{\xi\eta}(\theta, \phi)}{\sin(\frac{\pi\xi}{l_x}) \sin(\frac{\pi\eta}{l_y})} - \Omega^2 \rho h \right] \dots \\ \dots W_1^2(\xi, \eta) d\eta d\xi = \int_0^{l_x} \int_0^{l_y} 2P_i W_1(\xi, \eta) d\eta d\xi \end{aligned} \quad (\text{A.18})$$

and inserting  $\omega_1$  from Eq.(22) leads to

$$\begin{aligned} \rho h(\omega_1^2 - \Omega^2) \int_0^{l_x} \int_0^{l_y} W_1^2(\xi, \eta) d\eta d\xi = \\ = \left[ 2P_i + \frac{\Omega^2 \rho_0}{\pi} \frac{e^{-j\kappa r}}{r} C_1 I_{\xi\eta}(\theta, \phi) \right] \int_0^{l_x} \int_0^{l_y} W_1(\xi, \eta) d\eta d\xi \end{aligned} \quad (\text{A.19})$$

The two integrals are calculated as

$$\int_0^{l_x} \int_0^{l_y} W_1^2(\xi, \eta) d\eta d\xi = \frac{l_x l_y}{4} C_1^2 \quad (\text{A.20})$$

$$\int_0^{l_x} \int_0^{l_y} W_1(\xi, \eta) d\eta d\xi = \frac{4l_x l_y}{\pi^2} C_1 \quad (\text{A.21})$$

Substituting in Eq.(A.19) and solving the quadratic equation for  $C_1$  leads to:

$$C_1 = \frac{8P_i}{\pi^2 [\rho_0 h \frac{(\omega_1^2 - \Omega^2)}{4} - \frac{4\Omega^2 \rho_0}{\pi^3} \frac{e^{-j\kappa r}}{r} I_{\xi\eta}(\theta, \phi)]} = \frac{32P_i + p_t}{\pi^2 \rho h(\omega_1^2 - \Omega^2)} \quad (\text{A.22})$$

Therefore, substituting in Eq.(A.5) for the transmitted pressure, comes:

$$\begin{aligned} p_t(\mathbf{r}, t) &= \frac{\Omega^2 \rho_0 e^{-j\kappa r}}{2\pi r} C_1 I_{\xi\eta}(\theta, \phi) e^{j\Omega t} \\ \Rightarrow p_t(\mathbf{r}, t) &= \frac{16\Omega^2 \rho_0 I_{\xi\eta}(\theta, \phi) P_i}{r [\pi^3 \rho h(\omega_1^2 - \Omega^2) - 16\Omega^2 \rho_0 \frac{e^{-j\kappa r}}{r}]} e^{-j\kappa r} e^{j\Omega t} \end{aligned} \quad (\text{A.23})$$

The transmitted intensity  $I_t$  is calculated from Eq.(9) as

$$I_t(r, \theta, \phi) = \frac{1}{2\rho_0 c_0 r^2} \left( \frac{16\omega^2 |I_{\xi\eta}| P_i}{|\pi^3 \rho h(\omega_1^2 - \Omega^2) - 16\Omega^2 \rho_0 \frac{e^{-j\kappa r}}{r}|} \right)^2 \quad (\text{A.24})$$

and the transmitted power comes from Eq.(10) as

$$\Pi_t = \frac{P_i^2}{2\rho_0 c_0} \frac{(16\Omega^2 \rho_0)^2}{|\pi^3 \rho h(\omega_1^2 - \Omega^2) - 16\Omega^2 \rho_0 \frac{e^{-j\kappa r}}{r}|^2} I_{\theta\phi} \quad (\text{A.25})$$

where  $I_{\theta\phi}$  is the double integral over a hemispheric surface in the receiver domain

$$I_{\theta\phi} = \int_0^{2\pi} \int_0^{\pi/2} |I_{\xi\eta}|^2 \sin \theta d\theta d\phi \quad (\text{A.26})$$

and  $I_{\xi\eta}$  is defined in Eq.(A.16).

### A.3.1 Lumped Parameter Model

Let us rewrite the transverse displacement as

$$w(\xi, \eta, t) = \sin\left(\frac{\pi\xi}{l_x}\right) \sin\left(\frac{\pi\eta}{l_y}\right) q(t) \quad (\text{A.27})$$

where

$$q(t) = C_1 e^{j\Omega t} \quad (\text{A.28})$$

The kinetic energy of the system is defined as

$$\begin{aligned} T &= \frac{1}{2} \rho h \int_0^{l_x} \int_0^{l_y} \left( \frac{\partial w}{\partial t} \right)^2 d\xi d\eta \\ &= \frac{1}{2} \frac{\rho h l_x l_y}{4} \dot{q}^2(t) \\ &= \frac{1}{2} m_1^* \dot{q}^2(t) \end{aligned} \quad (\text{A.29})$$

and the potential energy as

$$\begin{aligned} U &= \frac{1}{2} D \int_0^{l_x} \int_0^{l_y} \left[ \nabla^2 w(\xi, \eta, t) \right]^2 d\xi d\eta \\ &= \frac{1}{2} \frac{D \pi^4 l_x l_y}{4} \left( \frac{1}{l_x^2} + \frac{1}{l_y^2} \right)^2 q^2(t) \\ &= \frac{1}{2} k_1^* q^2(t) \end{aligned} \quad (\text{A.30})$$

where  $m_1^*$  and  $k_1^*$  are the generalized mass and stiffness of the fundamental, 1<sup>st</sup> mode.

The equation of motion of the equivalent SDOF model is

$$m_1^* \ddot{q} + k_1^* q = f^*(t) \quad (\text{A.31})$$

where the generalized excitation, considering only the blocked pressure, comes as

$$f^*(t) = 2p_i \int_0^{l_x} \int_0^{l_y} W_1(\xi, \eta) d\xi d\eta = \frac{8P_i l_x l_y}{\pi^2} e^{j\Omega t} \quad (\text{A.32})$$

Consequently, by substituting in Eq.(A.31), and since  $k_1^* = m_1^* \omega_1^2$ , the factor  $C_1$  is calculated as:

$$C_1 = \frac{8P_i l_x l_y}{\pi^2} \frac{1}{m_1^* (\omega_1^2 - \Omega^2)} \quad (\text{A.33})$$

**Keywords:** Fan flutter, acoustic reflection, Limit Cycle Oscillation, friction damping, nonlinear complex modes.

**Abstract.** *Fan Blade Flutter is an aeroelastic instability which may occur during the operation of a jet engine, depending on the working conditions of the fan stage. It finds its origins in some various mechanisms, including the impact of the environment of the fan stage, which may play an important role in the stability limits due to acoustic effects. If not properly taken into account, flutter can lead to an anticipated ruin of the fan stage as the fluid keeps on giving energy to the structure. However, nonlinear phenomena may appear at some high vibratory amplitude of the blades, resulting in energy dissipation of the aeroelastic system. Blade roots friction is an example of such a case : by dry-friction dissipation at blade roots, a limitation of the vibratory amplitude may be reached, the so-called Limit Cycle Oscillations (LCO), within the unstable regions of the operating domain predicted with a usual linear structural modelling. By taking these nonlinear effects into account, it is then possible to define more precisely the stability limits of the fan stage. In this paper, we describe a methodology to predict LCO induced by blade roots friction, including acoustic effects on stability. First, assuming a linear behaviour of the structure, the stability limits of the fan stage are described using the cyclic symmetry hypothesis and Computational Fluid Dynamics (CFD). Acoustics effects are taken into account by including the fan inlet environment in the numerical model. Then, a nonlinear structural model of the blade is used to compute nonlinear complex modes in order to check for the presence of a LCO. To do so, a reduced model of the fluid response to the blade movement is used. To sum up, this work intends to establish a methodology to be used in an industrial context for the analysis of the nonlinear stability of the fan stage, including LCO phenomena.*

## 1 INTRODUCTION

Aeroelastic stability of fan blades has been studied for decades. It has become more and more important in the recent years to properly predict when this phenomenon does or does not occur, as the reduction of dry mass in jet engines remains one of the toughest objectives for manufacturers to achieve towards less consuming engines to face environmental issues. Moreover, the current trend for manufacturers which consists in developing designs with greater bypass ratio (hence more flexible blades) and shorter inlets allows fluid-structure interactions to have greater effects on blades movement and potentially on its lifecycle. However, physical mechanisms at the origin of fan blade flutter are still not fully understood despite the research done about it and depends on the operating point of the fan stage, as shown in [1].

In this work, we focus on flutter occurring at 75%-80% speed range near stall boundaries. Various experimental and numerical works relate on the mechanisms causing fan blade flutter in this working range, and two major contributions at its origins have been highlighted. The first one refers to a strong interaction between the shock between tip leading edge and mid-chord of the suction side of the blade and the boundary layer around it [2, 3, 4, 5, 6]. It appears that due to blades vibration and depending on the Inter Blade Phase Angle (IBPA), the shock position may oscillate onto the suction side and be responsible of static pressure fluctuations. In addition, the shock interacts with the boundary layer on the blade surface which may detach behind it. For a periodic motion of the blade, it results in positive (unstable) and negative (stable) aerodynamic work areas onto the blade. This may lead to flutter if the overall aerodynamic work on the blade is positive, meaning that the fluid transfers its energy to the structure. The second mechanism contributing to fan blade flutter in the operating range of interest is due to acoustic interactions between the fan stage and the intake of the engine. Considering a slowly varying intake diameter, acoustic waves may propagate through the intake if the frequency of the perturbation is greater than the characteristic frequency of acoustic propagation  $\omega_{cut-on}$  called *cut-on* frequency. Then, if the fan stage blade generates a perturbation at a frequency  $\omega$  greater than  $\omega_{cut-on}$ , an acoustic wave will propagate through the intake [7]. A reflected wave will occur at the opening of the intake and go back to the fan stage. The phase difference between the wave generated by the fan stage and the one reflected on the intake at the axial position of the stage may cause drastic variation of flutter stability for very narrow operating ranges, yielding the term *flutter bite* [8, 9, 10].

Usually, a linear approach of the structure is sufficient to assess the fan stage aeroelastic stability. Two approaches may be used to do so, as well explained in [11] : the first one consists in neglecting the effects of aerodynamics on the fan stage dynamics and then to assess stability by studying aeroelastic stability of the structural modes of the fan with harmonic motion ; the second one consists in using strong coupling (partitionned or monolithic approaches) to take into account the effects of the fluid onto the structure dynamics. However, if it is sufficient to consider a linear structure to assess stability limits, it is possible to find stable solutions of the aeroelastic system beyond the stability limits predicted with a linear structure by taking into account nonlinear effects. In this study, we are interested in nonlinear effects due to blade-disk dry friction at blade roots. First works about flutter limitation by dry friction between the blade and the disk seem to be attributed to Sinha and Griffin [12, 13]. They showed on small degree of freedom systems that in spite of the presence of negative aerodynamic damping, stable and unstable periodic solutions may arise. Since, many works about this subject have been made and new usefull tools have been developped. As we are dealing with nonlinear autonomous systems, there have been many efforts made in order to define the nonlinear dynamics of such systems by

analogy with the linear modes describing the dynamics of autonomous linear systems. Hence, the notion of *nonlinear normal modes* has been established, describing the dynamics of conservative autonomous nonlinear systems [14, 15] and then extended to nonconservative systems [16]. Other definitions have been suggested in more recent years and are particularly suited to dissipative systems like the one we will study in this paper. Some of these methods are based on frequency approach like the Harmonic Balance Method (HBM) [17, 18]. Decoupled approaches have allowed to find Limit Cycle Oscillations (LCO) of the structure by using the HBM procedure, while modelling aerodynamic effects from Computational Fluid Dynamics (CFD) calculations [19, 20]. More recently, a fully coupled method in the frequency domain has been established [21] in order to find LCO by using harmonic formulation in both flow and structure models, and iterating in a fixed point loop between the two physics.

In this study, a methodology for predicting LCO induced by dry friction of a fluttering rotor blade will be investigated by the means of *nonlinear complex modes* [17]. To do so, a decoupled approach will be used. First, the aeroelastic stability of a rotating fan from a typical modern civil engine will be assessed while considering a linear structure. From those results, a simple model of the acoustic effects on flutter stability will be built and used on a phenomenological model representing a blade with nonlinear dry friction effects at its roots. The purpose of this study is to establish a methodology based on nonlinear complex modes that can be applied to the analysis of an industrial fan stage.

## 2 AEROELASTIC STABILITY WITHIN THE SCOPE OF A LINEAR STRUCTURE

### 2.1 Case modeling and flow solver

For this study, a fan model (18 blades) provided by Safran Aircraft Engines has been used with its intake in order to take account of acoustic interactions between these two elements. Figure 1 shows an illustration of this model. Experimental data showed that the fan stage used with this intake became unstable before surge was reached at 75% speed.

Figure 1: Fan stage model with its intake used for CFD calculations

The mesh used for this model has to be sufficiently dense in the intake to have a good representation of acoustic waves. However, it is of a higher interest to keep the mesh coarse outside of the intake, where a precise representation of the aerodynamic is not required. As a matter of fact, due to the lack of absorbant acoustic boundary conditions, a too high density grid near the external boundaries would lead to unwanted spurious numerical acoustic reflections, which would not have physical meanings. Hence, a coarsening of the mesh has been put in place from the intake to the outside boundaries of the mesh until eventual acoustic waves coming from the intake are sufficiently dissipated by the spatial scheme. Figure 2 shows the boundaries of the mesh and highlights the ratio between the external characteristic dimension  $D$  of the mesh and the intake diameter  $d$  midway between the fan and the intake beginning. This ratio has been set to 30. Since there is no Outlet Guide Vanes (OGV) in the model, same considerations have to be taken for both fan primary and secondary outlets. Mesh coarsening has also been used for these parts of the model.

Figure 2: External mesh boundaries on the left, blade mesh on the right

To build the mesh used in this model, the intake and the fan have been meshed separately with two different meshing tools : *ICEM* for the intake and *Autogrid* for the fan. Hence, we are dealing with a structured mesh of the full model containing about 11M cells, with about 3M cells for the intake and 410000 cells per blade passage.

The solver used to perform both steady and unsteady analysis is the finite-volume *elsA* software developed at Onera [22, 23], which solves in our case 3D compressible (U)-RANS equations. Roe flux difference splitting scheme has been used, with the two equations turbulence model  $k - l$  of Smith. Non reflective boundary conditions have been set upon the external boundaries of the domain with atmospheric sea-level conditions. These conditions are efficient to suppress steady reflections, but are not enough when dealing with unsteady acoustic waves, which justifies the external mesh coarsening. The outflow boundary conditions in primary and secondary outlets is based on radial equilibrium equation for static pressure and allows to select the operating point on the constant 75% speed of the fan characteristic.

As mentionned earlier, the global mesh is built from two meshes that have been merged : the fan, which rotates at 75% speed, and the intake which does not move, both in the fixed frame. Therefore, the stator/rotor interface has to be treated to maintain the flow continuity. While performing steady computations, a mixing plane condition is used, transferring azimuthal

averages of the flow quantities from the intake mesh to the fan one. When dealing with unsteady computations, the mixing plane is replaced with an unsteady interface boundary condition so that acoustic waves may propagate from the fan mesh to the intake mesh. This condition take into account the relative positions of the meshes at the interface at each time step to transfert the information from a cell to its corresponding ones on the other side of the interface. Spatial interpolation is performed when there is no perfect match between the facets of the interface.

## 2.2 Aeroelastic model

As mentioned in the introduction, two approaches may be used to assess the aeroelastic stability of the fan stage. The first one consists in neglecting the impact of the flow on the structure dynamics for the evaluation of aerodynamic forces due to vibrations, while the second one consists in a strong aeroelastic coupling. The approach to be used depends on the case, as the flow may have some impact on the structure dynamics [11]. Even if the second approach may be more precise, it may be computationally expensive to apply, as the first one already gives good insights on the flutter stability while lowering the computationnal costs. In this study, the first approach has been chosen. Strong coupling of the fluid and the structure will be adressed in a future study.

It is assumed for now that the structure is linear and that the vibration is small enough so that aerodynamic forces may be linearized regarding structure movement and velocity. Thus, the aeroelastic stability of the fan may be assessed by considering the aeroelastic stability of each structural eigenmodes separately. Let us consider the equation governing the movement of the linear structure (nonlinear effects due to friction at blade root will be adressed later in this study) :

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{f}_{aero}(\mathbf{x}, \dot{\mathbf{x}}) \quad (1)$$

Solving the eigenvalue problem while considering cyclic symmetry hypothesis for the structure leads to expressing the structure movement in terms of complex modes  $\Phi$  representing rotating waves. It is then possible to express the structure movement in the modal basis  $\Phi$  :

$$\mathbf{x} = \Phi \mathbf{q} \quad (2)$$

By substituing (2) into (1), one can describe the motion of the structure in  $\Phi$  with the complex generalized coordinates  $\mathbf{q}$  [24]. If considering one eigenmode, this leads to the following scalar differential equation :

$$\mu\ddot{q} + \beta\dot{q} + \gamma q = g_{aero}(q, \dot{q}) \quad (3)$$

where  $\mu$ ,  $\beta$ ,  $\gamma$  and  $g_{aero}$  are respectively the generalized mass, generalized dissipation, generalized stiffness and generalized aerodynamic forces.

As we are dealing with stability issues, we consider that the structure is autonomous (*i.e* there is no external forcing and initial conditions). Moreover, we consider that the movement of the structure is small enough so that the generalized aerodynamic forces may be written as a linear function of the structure movement and velocity (respectively represented by  $q$  and  $\dot{q}$ ). Hence, (3) may be written as :

$$\mu\ddot{q} + \beta\dot{q} + \gamma q = A q + B \dot{q} \quad (4)$$

where :

$$g_{aero}(q, \dot{q}) = A q + B \dot{q} ; A, B \in \mathbb{C}$$

Considering harmonic motion ( $q(t) = q_0 e^{j\omega_0 t}$ ), we have :

$$\begin{aligned}
 g_{aero} &= (A + j\omega_0 B) q \\
 &= \left( \left( \operatorname{Re}(A) - \omega_0 \operatorname{Im}(B) \right) + j\omega_0 \left( \frac{\operatorname{Im}(A)}{\omega_0} + \operatorname{Re}(B) \right) \right) q \\
 &= (\gamma_{aero} + j\omega_0 \beta_{aero}) q
 \end{aligned} \tag{5}$$

In (5),  $\gamma_{aero}$  and  $\beta_{aero}$  may respectively be seen as aerodynamic stiffness and aerodynamic dissipation.

The generalized structural dissipation  $\beta$  may be hard to evaluate. Usually, it is convenient to neglect it in order to assess the flutter stability as the approach remains conservative (*i.e* stability limits will be reached sooner than in a more realistic damped system). Hence,  $\beta$  will be omitted in this section. If  $\bar{q}$  denotes the conjugate of  $q$ , the aerodynamic work on one period of harmonic motion may be written as :

$$\begin{aligned}
 W &= \operatorname{Re} \left( \int_0^{\frac{2\pi}{\omega_0}} g_{aero} \bar{q} dt \right) \\
 &= \operatorname{Re} \left( \int_0^{\frac{2\pi}{\omega_0}} (A + j\omega_0 B) q_0 e^{j\omega_0 t} (-j\omega_0 \bar{q}_0 e^{-j\omega_0 t}) dt \right) \\
 &= 2\pi\omega_0 \beta_{aero} |q_0|^2
 \end{aligned} \tag{6}$$

From (4), we may express  $\beta_{aero}$  as an aerodynamic damping term  $\xi_{aero}$  :

$$\xi_{aero} = -\frac{\beta_{aero}}{2\mu\omega_0} = -\frac{W}{4\pi\mu\omega_0^2 |q_0|^2} \tag{7}$$

Flutter occurs when  $\xi_{aero}$  is below zero, meaning that the fluid gives energy to the blade for a blade movement on the considered mode.

### 2.3 Stability computations

Experimental results showed that at 75% speed, the most unstable mode was the 1F2D for the considered fan stage coupled with its intake. Hence, stability analysis has been performed for this mode. In this conditions, acoustic interactions between the fan and the intake are expected as the eigenfrequency of the mode is greater than the cut-on frequency of some acoustic modes. Figure 3 shows a representation of this mode.

In order to analyse the aeroelastic stability of the selected mode, unsteady aerodynamic simulations with prescribed harmonic motion of the row following its 1F2D vibration mode at its eigenfrequency are performed. The simulation are carried out using the Dual Time Stepping (DTS) approach, with 20 dual iterations between each physical timesteps and 192 timesteps per period of vibration. The forward mode is selected (same rotation direction as the one of the fan) to get the largest frequency of perturbation due to vibration in the fixed frame. In these conditions, intake fan acoustic interactions are expected to occur. As a reminder, the perturbation frequency  $f$  generated by the fan stage is  $f = f_{1F2D} + \Omega \times \text{ND}$  ( $\Omega$  is the rotation frequency of the fan and ND the nodal diameter of the forward mode considered). It has to be greater than the cut-on frequency  $f_{cut-on}$  so that acoustic waves can propagate through the intake represented as a cylindrical duct.

Figure 3: Mode shape for 1F2D

Figure 4 shows the stability analysis results for the 1F2D forward mode, where the evolution of  $\xi_{aero}$  is plotted against the normalized mass flow. The red star represents the stability limits measured during experiments. Stability limit is detected sooner with the numerical model than during experiments, as it was expected since the mechanical damping has been neglected. The approach remains conservative (*i.e* numerical results do not predict a stable behaviour of the fan on an experimental unstable operating point).

Figure 4: Evolution of  $\xi_{aero}$  on the constant 75% speed characteristic

For the last period of vibration of the fan, a Discrete Fourier Transform (DFT) has been performed on acoustic variables of interest (density, velocities, static pressure) in the whole domain to check for the presence of acoustic waves in the intake. Results of the DFT of unsteady

static pressure are displayed in Figure 5. The amplitude representation of static pressure shows a peak in the middle of the intake, which highlights the presence of acoustic interferences between the acoustic waves generated by the vibrating fan and the ones coming from the reflection at the inlet level. The phase reveals a two diameter perturbation in the intake, which was expected as the studied structural mode is a two diameter as well.

Figure 5: Discrete Fourier Transform of the unsteady static pressure in the intake : amplitude on the left, phase on the right

Hence, for mode 1F2D at 75% speed, acoustic interactions between the fan and the intake may be observed. The impact of this interaction on flutter stability depends on the reflection rate and the phase lag between emitted and reflected acoustic waves, as mentioned in [9, 10]. Both are functions of the excitation frequency as showed in Bontemps et al. [25]. However, in a context of nonlinear dynamics induced by dry friction, free vibration frequencies of the structure may vary depending on its amplitude of vibration. It is then of interest to have a measure of the sensitivity of  $\xi_{aero}$  against the vibration frequency of the blade to build a model of aerodynamic forces that takes into account acoustic effects on stability.

From the operating point at  $\frac{\dot{m}}{\dot{m}_0} = 0.972$  on the constant 75% speed characteristic, a set of computations with different values of excitation frequency has been made, whose results are displayed in Figure 6.

It can be seen from this figure that excitation frequency has a first order impact on stability for the considered operating point. A sharp drop in stability appears around  $0.87 - 0.9f_{1F2D}$ , which corresponds to the excitation frequency  $f$  equaling the cut-on frequency  $f_{cut-on}$  of the activated acoustic mode in the duct. According to Bontemps et al. [25], this leads to a reflection rate near 100% and quick variations of the phase lag between emitted and reflected acoustic waves onto the fan blades : in other terms, this is where one may encounter the greatest variation of flutter stability due to acoustic effects and frequency shifts. Results displayed in Figure 6 will be used in the next section as a simplified model of acoustic effects on blade stability. We are now going to introduce the phenomenological nonlinear model used for computing LCO.

Figure 6: Evolution of  $\xi_{aero}$  against vibration frequency for 1F2D shape mode

### 3 NONLINEAR APPROACH FOR FINDING LIMIT CYCLE OSCILLATIONS

#### 3.1 Phenomenological model

The phenomenological model that has been used to represent a blade with dry friction at its root is represented in Figure 7. It is made of three distinct parts : the blade, its root, and the disk. Dry friction nonlinearities are considered between the blade root and the disk. Relative motions authorized between the different parts are rotations. Let us define  $X, Y$  and  $Z$  the axis of the rotating frame. We assume that there is no rotation of the parts around the  $Y$  axis. Hence, we define :

- $\theta_{1,x}$  as the angle of rotation of the disk around  $X$  ;
- $\theta_{1,z}$  as the angle of rotation of the disk around  $Z$  ;
- $\theta_{2,x}$  as the angle between  $Z_{root}$  (axis of the local frame attached to the root) and  $Z$  ;
- $\theta_{2,z}$  as the angle of rotation of the blade root around  $Z_{root}$  ;
- $\theta_{3,x}$  as the bending angle between  $Z_{root}$  and  $Z_{blade}$  (axis of the local frame attached to the blade) ;
- $\theta_{3,z}$  as the angle of rotation of the blade around  $Z_{blade}$ .

Moreover, we consider that the section of the blade containing its center of gravity is at a height  $H_G$  of its root ( $H_G \gg e$  where  $e$  is the characteristic dimension of the root thickness). Lastly, we consider that the center of gravity of the blade is not aligned with its center of torsion, but is located at a distance  $a$  of it. In that way, when we will consider the modes of the blade with sticking conditions between the blade root and the disk, we will not have pure plunging or twisting modes, but modes with the contributions of those two pure motions.

We are now going to derive the equations of motion of the blade-root-disk system using lagrangian formalism. Some assumptions need to be made first concerning the movement of the

Figure 7: Phenomenological model of a bending-torsion blade with dry friction at blade root

system. We consider that the disk is motionless in the rotating frame due to its high stiffness (in comparison to those of the root and the blade). Moreover, the root is supposed to rotate only along the  $X$  axis due to its high longitudinal dimension in comparison to its thickness. Hence, we have  $\theta_{1,x} = \theta_{1,z} = \theta_{2,z} = 0$ . The system dynamics is then described by the three variables left :  $\theta_{2,x}, \theta_{3,x}, \theta_{3,z}$ . Let us define the variable  $q$  as the vector containing the generalized coordinates of the system  $q = (\theta_{3,x}, \theta_{3,z}, \theta_{2,x})^T$ . We consider at last that we have small perturbations (*i.e*  $\theta \ll 1$ ). For now, the system is assumed to be in vacuum. The Lagrange equations are :

$$\frac{d}{dt} \frac{\partial \mathcal{L}}{\partial \dot{q}} - \frac{\partial \mathcal{L}}{\partial q} = \mathcal{Q} \quad (8)$$

where  $\mathcal{Q}$  is the generalized non conservative torque (here, due to blade root friction), and :

$$\mathcal{L} = \mathcal{T} - \mathcal{V}$$

In these equations,  $\mathcal{T}$  is the kinetic energy, while  $\mathcal{V}$  is the potential energy of the system. Let us denote respectively (1), (2) and (3) the disk, the root and the blade. Then, we have :

$$\mathcal{T} = \mathcal{T}_2 + \mathcal{T}_3$$

with :

$$\mathcal{T}_2 = \frac{1}{2} J_{2x} \dot{\theta}_{2x}^2 \quad (9)$$

$$\mathcal{T}_3 = \frac{1}{2} \left( m_3 v_G^2 + \Omega_3 \cdot \left( \bar{\bar{I}}_{G,3} \cdot \Omega_3 \right) \right) \quad (10)$$

$J_{2x}$ ,  $m_3$ ,  $v_G$ ,  $\Omega_3$  and  $\bar{\bar{I}}_{G,3}$  are respectively the moment of inertia of the blade root around  $X$ , the mass of the blade, the velocity of the center of gravity of the blade in the laboratory frame

of reference, the angular velocity vector and the moment of inertia tensor of the blade expressed at its center of mass  $G$ .

By calculation, we have at first order :

$$v_G^2 = a^2 \dot{\theta}_{3z}^2 - 2 a H_G \dot{\theta}_{3z} (\dot{\theta}_{2x} + \dot{\theta}_{3x}) + H_G^2 (\dot{\theta}_{2x} + \dot{\theta}_{3x})^2 + a^2 (\dot{\theta}_{2x} + \dot{\theta}_{3x})^2 \theta_{3z}^2$$

Since small perturbations are considered ( $\theta \ll 1$ ), it seems reasonable to neglect the last term of this equation, which is of higher order than the other terms :

$$v_G^2 = a^2 \dot{\theta}_{3z}^2 - 2 a H_G \dot{\theta}_{3z} (\dot{\theta}_{2x} + \dot{\theta}_{3x}) + H_G^2 (\dot{\theta}_{2x} + \dot{\theta}_{3x})^2 \quad (11)$$

Under the assumption that the blade has symmetry properties around its center of torsion on the section containing the center of mass, the moment of inertia tensor of the blade is written as follow :

$$\bar{\bar{I}}_{G,3} = \begin{pmatrix} J_{2x} & 0 & 0 \\ 0 & J_{3y} & 0 \\ 0 & 0 & J_{3z} \end{pmatrix} \quad (12)$$

The angular velocity vector of the blade is written :

$$\Omega_3 = \begin{pmatrix} \dot{\theta}_{2x} + \dot{\theta}_{3x} \\ 0 \\ \dot{\theta}_{3z} \end{pmatrix} \quad (13)$$

Hence, we have :

$$\begin{aligned} \mathcal{T} = & \frac{1}{2} J_{2x} \dot{\theta}_{2x}^2 + \frac{1}{2} m_3 a^2 \dot{\theta}_{3z}^2 - m_3 a H_G \dot{\theta}_{3z} (\dot{\theta}_{2x} + \dot{\theta}_{3x})^2 + \frac{1}{2} m_3 H_G^2 (\dot{\theta}_{2x} + \dot{\theta}_{3x})^2 \\ & + \frac{1}{2} J_{3x} (\dot{\theta}_{2x} + \dot{\theta}_{3x})^2 + \frac{1}{2} J_{3z} \dot{\theta}_{3z}^2 \end{aligned} \quad (14)$$

For the potentiel energy of the system, some rotational stiffnesses are considered between each part. Hence, it may be written as follow :

$$\mathcal{V} = \frac{1}{2} C_{23z} \theta_{3z}^2 + \frac{1}{2} C_{23x} \theta_{3x}^2 + \frac{1}{2} C_{12x} \theta_{2x}^2 \quad (15)$$

Using equations (14) and (15) in (8) leads to the following three degree of freedom system :

$$I \begin{pmatrix} \ddot{\theta}_{3x} \\ \ddot{\theta}_{3z} \\ \ddot{\theta}_{2x} \end{pmatrix} + C \begin{pmatrix} \theta_{3x} \\ \theta_{3z} \\ \theta_{2x} \end{pmatrix} = \mathcal{Q} \quad (16)$$

with :

$$I = \begin{pmatrix} m_3 H_G^2 + J_{3x} & -a m_3 H_G & m_3 H_G^2 + J_{3x} \\ -a m_3 H_G & m_3 a^2 + J_{3z} & -a m_3 H_G \\ m_3 H_G^2 + J_{3x} & -a m_3 H_G & m_3 H_G^2 + J_{2x} + J_{3x} \end{pmatrix} \quad (17)$$

and :

$$C = \begin{pmatrix} C_{23x} & 0 & 0 \\ 0 & C_{23z} & 0 \\ 0 & 0 & C_{12x} \end{pmatrix} \quad (18)$$

$\mathcal{Q}$  is a nonlinear torque due to the presence of a friction force between the blade root and the disk. In this approach, the nonlinear friction torque is simply modelled using the following regularized form of the Coulomb law, which will be helpfull to derive the jacobian of the nonlinear algebraic system that will be solved in the next subsection :

$$\mathcal{Q} = \begin{pmatrix} 0 \\ 0 \\ -e \mu N \tanh \left( p \frac{\dot{\theta}_{2x}}{e \mu N} \right) \end{pmatrix} \quad (19)$$

The evolution of the nonlinear torque is plotted in Figure 8. As it can be seen, a  $p$  parameter allows to choose the slope of the nonlinearity : the nonlinear force asymptotically approaches the Coulomb law as one chooses a high value for  $p$ .

Figure 8: Evolution of the nonlinear torque against the movement of the blade root

Now that the equations of the nonlinear dynamics of the system have been written, we are going to use nonlinear complex modes in order to analyse the occurrence of LCO for the blade-root-disk system.

### 3.2 Nonlinear complex modes

The notion of nonlinear complex mode [17] has been introduced to characterize the nonlinear dynamics of nonconservative autonomous systems. Its formulation is built by analogy with

linear complex modes, as the eigenvalues of such a system may be written in the form :

$$\lambda = \beta + j\omega$$

Let us take the general equation of movement of a structure in presence of some dry friction nonlinear force :

$$\mathbf{M} \ddot{\mathbf{x}} + \mathbf{C} \dot{\mathbf{x}} + \mathbf{K} \mathbf{x} + \mathbf{f}_{nl}(\mathbf{x}, \dot{\mathbf{x}}) = 0 \quad (20)$$

We suppose the solution of this differential equation being in the following nonlinear complex mode form :

$$\mathbf{x}(t) = \mathbf{a}_0 + \sum_{k=1}^{N_h} e^{-k\beta t} (\mathbf{a}_k \cos(k\omega t) + \mathbf{b}_k \sin(k\omega t)) \quad (21)$$

Two time scales may be seen in equation (21) : the first time scale is due to the  $\beta$  term, which may be defined as the dissipation of the nonlinear complex mode by analogy with linear complex mode ; the second time scale is due to the  $\omega$  term. We suppose that the time scale associated to  $\omega$  is much faster than the one associated to  $\beta$  (i.e  $\omega \gg \beta$ ). Moreover,  $\beta$  is supposed to be the same for each harmonic. Defined in that way, the main difference between nonlinear complex modes and linear complex modes is the presence of multi-harmonic content in the nonlinear case.

By the means of a Galerkin procedure, one may rewrite the nonlinear differential equation of the structure into an algebraic one. To do so, a scalar product must be chosen. The scalar product that we consider is the inner product of square integrable functions defined as :

$$\forall f, g \in \mathcal{C} \left( 0; \frac{2\pi}{\omega} \right)^2, \langle f|g \rangle = \frac{\omega}{\pi} \int_0^{\frac{2\pi}{\omega}} f(t) \overline{g(t)} dt \quad (22)$$

Let us consider the Fourier basis functions  $1, \cos(k\omega t), \sin(k\omega t) \forall k \in \{1; N_h\}$ . By reinjecting (21) into the equations of motion and applying the inner product (22) with the Fourier basis functions, the dynamics of the nonlinear system may be described by the following algebraic equation in residual form :

$$\mathcal{R}(\mathbf{X}, \omega, \beta) = \mathbf{Z}(\omega, \beta) \mathbf{X} + \mathbf{F}_{nl}(\mathbf{X}, \omega, \beta) = 0 \quad (23)$$

where the multi-harmonic stiffness matrix  $\mathbf{Z}$  is :

$$\mathbf{Z} = \begin{pmatrix} 2\mathbf{K} & & & & \\ & \mathbf{Z}^1 & & & \\ & & \ddots & & \\ & & & \mathbf{Z}^k & \\ & & & & \ddots \\ & & & & & \mathbf{Z}^{N_h} \end{pmatrix} \quad (24)$$

and :

$$\mathbf{Z}^k = \begin{pmatrix} \mathbf{K} + ((k\beta)^2 - (k\omega)^2) \mathbf{M} - k\beta \mathbf{C} & k\omega \mathbf{C} - 2k^2 \beta \omega \mathbf{M} \\ - (k\omega \mathbf{C} - 2k^2 \beta \omega \mathbf{M}) & \mathbf{K} + ((k\beta)^2 - (k\omega)^2) \mathbf{M} - k\beta \mathbf{C} \end{pmatrix} \quad (25)$$

To perform the scalar product and derive (23), the hypothesis  $\omega \gg \beta$  has been used to neglect the amplitude variation of  $\mathbf{x}$  due to the dissipation  $\beta$  during a period  $\frac{2\pi}{\omega}$ . Hence, orthogonality properties may be used to derive the scalar product of the equation of movement with the Fourier basis functions.

In (23), the unknowns are  $\mathbf{X}$ ,  $\omega$  and  $\beta$ . As the system is autonomous, there are two more unknowns in the system than there are equations, which means that we are dealing with a rectangular system. By adding two more equations, it is possible to make it square. The first equation may be seen as a constraint equation, while the second one as a phase equation. By considering arc-length continuation [26] and a zero phase for an arbitrary harmonic  $k$  and degree of freedom  $q$ , these two equations may be written as :

$$\begin{cases} \mathcal{R}_{arc}(\mathbf{X}, \omega, \beta) = \|\mathbf{X} - \mathbf{X}_0\|^2 + \|\omega - \omega_0\|^2 + \|\beta - \beta_0\|^2 - \Delta s^2 = 0 \\ \mathcal{R}_{phase}(\mathbf{X}, \omega, \beta) = \mathbf{b}_{k,q} = 0 \end{cases} \quad (26)$$

where  $\Delta s$  is the arc-length radius.

A Newton-Raphson procedure is used to solve (23) and (26) simultaneously. Thus, an evaluation of the nonlinear forces in the frequency domain has to be done. Since there is no direct analytical expression of  $\mathbf{F}_{nl}(\mathbf{X}, \omega, \beta)$ , an Alternating Frequency-Time (AFT) method is used, as described in [27]. As previously, under the hypothesis that two different time scales are considered, a periodic movement of the structure is assumed during a pseudo-period  $\frac{2\pi}{\omega}$ , which means that the decrease due to  $\beta$  when performing the AFT method is neglected [17]. It is then assumed that the decrease of the nonlinear forces is the same than the one of the movement.

To get a full branch of nonlinear complex mode, the computation needs to be initialized. To do so, the system is set with small amplitudes of vibration so that the linear sticking case is a good approximation of the solution. Then, the first solution is searched in a subspace of the solutions of (23) at a distance  $\Delta s$  from the linear sticking case with the Newton-Raphson procedure. When converged, the computed solution is stored on one hand and replaces  $(\mathbf{X}_0, \omega_0, \beta_0)$  on the other hand. The next solution is predicted using secant predictor [28]. It is then computed with the Newton-Raphson procedure and so on.

### 3.3 Fluid modeling

We are here interested in taking into account aerodynamic effects on the nonlinear complex mode computation. First, let us consider the asymptotic case when there are sticking conditions between the blade root and the disk (*i.e.*  $\theta_{2,x} = 0$ ). Under the hypothesis that the modal basis of the full blade model used in *elsA* and the phenomenological model are equivalent on the considered bending mode, we assume that we may transfer the aerodynamic damping computed in aeroelastic computations to the equivalent bending mode of the phenomenological model. From (16), we write the movement equation in sticking conditions where  $\theta_{2,x} = 0$  :

$$I_{stick} \begin{pmatrix} \ddot{\theta}_{3x} \\ \ddot{\theta}_{3z} \end{pmatrix} + C_{stick} \begin{pmatrix} \theta_{3x} \\ \theta_{3z} \end{pmatrix} = 0 \quad (27)$$

with :

$$I_{stick} = \begin{pmatrix} m_3 H_G^2 + J_{3x} & -a m_3 H_G \\ -a m_3 H_G & m_3 a^2 + J_{3z} \end{pmatrix} \quad (28)$$

and :

$$C_{stick} = \begin{pmatrix} C_{23x} & 0 \\ 0 & C_{23z} \end{pmatrix} \quad (29)$$

Solving the eigenvalue problem associated to (27) allows to find the modal basis  $\Phi$  of the system in sticking conditions. It is possible to switch from physical base to modal basis using :

$$\begin{pmatrix} \theta_{3x} \\ \theta_{3z} \end{pmatrix} = \Phi \begin{pmatrix} q_{bend} \\ q_{torsion} \end{pmatrix} \quad (30)$$

When switching equation (27) to modal basis in sticking conditions, we have :

$$\mu \begin{pmatrix} \ddot{q}_{bend} \\ \ddot{q}_{torsion} \end{pmatrix} + \gamma \begin{pmatrix} \dot{q}_{bend} \\ \dot{q}_{torsion} \end{pmatrix} = 0 \quad (31)$$

with :

$$\mu = \Phi^T I_{stick} \Phi = \begin{pmatrix} \mu_{bend} & 0 \\ 0 & \mu_{torsion} \end{pmatrix} \quad (32)$$

and :

$$\gamma = \Phi^T C_{stick} \Phi = \begin{pmatrix} \gamma_{bend} & 0 \\ 0 & \gamma_{torsion} \end{pmatrix} \quad (33)$$

Under the assumption that we may use the aerodynamic damping previously computed, a damping modal matrix is added to (31) in the form :

$$\mu \begin{pmatrix} \ddot{q}_{bend} \\ \ddot{q}_{torsion} \end{pmatrix} + \begin{pmatrix} 2\sqrt{\mu_{bend}\gamma_{bend}}\xi_{aero} & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} \dot{q}_{bend} \\ \dot{q}_{torsion} \end{pmatrix} + \gamma \begin{pmatrix} q_{bend} \\ q_{torsion} \end{pmatrix} = 0 \quad (34)$$

Going back in the physical basis gives :

$$I_{stick} \begin{pmatrix} \ddot{\theta}_{3x} \\ \ddot{\theta}_{3z} \end{pmatrix} + D_{stick} \begin{pmatrix} \dot{\theta}_{3x} \\ \dot{\theta}_{3z} \end{pmatrix} + C_{stick} \begin{pmatrix} \theta_{3x} \\ \theta_{3z} \end{pmatrix} = 0 \quad (35)$$

with :

$$D_{stick} = \Phi^{-T} \begin{pmatrix} 2\sqrt{\mu_{bend}\gamma_{bend}}\xi_{aero} & 0 \\ 0 & 0 \end{pmatrix} \Phi^{-1} \quad (36)$$

where  $\Phi$  is the eigenvectors matrix of the system with sticking conditions. Since aerodynamic efforts are applied only on the blade, we make the assumption that  $\theta_{2x}$  will not be affected by aerodynamic damping. Hence, we may use the aerodynamic dissipation matrix  $D_{stick}$  in the full model as :

$$I \begin{pmatrix} \ddot{\theta}_{3x} \\ \ddot{\theta}_{3z} \\ \ddot{\theta}_{2x} \end{pmatrix} + D \begin{pmatrix} \dot{\theta}_{3x} \\ \dot{\theta}_{3z} \\ \dot{\theta}_{2x} \end{pmatrix} + C \begin{pmatrix} \theta_{3x} \\ \theta_{3z} \\ \theta_{2x} \end{pmatrix} = \mathcal{Q} \quad (37)$$

with :

$$D = \begin{pmatrix} D_{stick} & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad (38)$$

Nonlinear complex modes may now be computed as in the previous subsection from (37) by taking into account fluid effects. It is at last assumed that the aerodynamic damping only affects the first harmonic of the nonlinear complex mode : as higher-harmonic content is expected to be much lower than the fundamental content, we may suppose that it does not affect aerodynamic forces. The multi-harmonic stiffness matrix can be expressed as follow :

$$\mathbf{Z} = \begin{pmatrix} 2C & & & \\ & \mathbf{Z}^1 & & \\ & & \ddots & \\ & & & \mathbf{Z}^k & \\ & & & & \ddots & \\ & & & & & \mathbf{Z}^{N_h} \end{pmatrix} \quad (39)$$

with :

$$\mathbf{Z}^1 = \begin{pmatrix} C + (\beta^2 - \omega^2) I - \beta D & \omega D - 2\beta\omega I \\ -(\omega D - 2\beta\omega I) & C + (\beta^2 - \omega^2) I - \beta D \end{pmatrix} \quad (40)$$

and  $\forall k \neq 1$  :

$$\mathbf{Z}^k = \begin{pmatrix} C + ((k\beta)^2 - (k\omega)^2) I & -2k^2\beta\omega I \\ 2k^2\beta\omega I & C + ((k\beta)^2 - (k\omega)^2) I \end{pmatrix} \quad (41)$$

In (40), note that the aerodynamic dissipation matrix  $D$  depends on the free frequency  $\omega$ , meaning that acoustic effects are taken into account.

## 4 NUMERICAL RESULTS

### 4.1 Model identification process

The model derived in the previous section has been used to compute nonlinear complex modes. It should be noticed that in the formulation of  $I$ , all of the terms may be extracted from any FEM model of blade. In this case, the values have been extracted from the blade model used previously in the aeroelastic computations. The remaining terms to choose are those in  $C$ . To do so, let us remind that the nonlinear behaviour of the system is bounded by two asymptotical linear cases respectively defined by sticking or sliding conditions between the blade root and the disk. Hence, rotational stiffnesses have been set so that the eigenfrequencies of the phenomenological blade-root-disk system on asymptotical cases match the eigenfrequencies of the model used for aeroelastic computations on the same asymptotical cases. Table 1 sums up the values that have been used for the phenomenological model. Eigenfrequencies and eigenvectors of the asymptotical linear cases are reported in Table 2.

### 4.2 Nonlinear analysis in vacuum

Results for a branch of nonlinear complex mode are displayed in Figures 9 and 10. The evolutions of free frequency and modal nonlinear damping expressed as  $\frac{\beta}{\omega}$  against the amplitude of the first harmonic of  $\theta_{3x}$  are plotted in the first one. Trajectories in the configuration space of the dynamics of the system during a pseudo-period are plotted in the second one. The trajectories of Figure 10 match the dots of Figure 9.

Parameter	Value
$m_3$	4.3
$H_G$	0.27
$a$	$-\text{chord} \times 0.15$
$J_{3x}(\times 10^{-6})$	159114
$J_{3z}(\times 10^{-6})$	28120
$J_{2x}(\times 10^{-6})$	217
$C_{23x}$	119500
$C_{23z}$	40000
$C_{12x}$	110000
$e$	0.02
$\mu$	0.1
$N$	200000
$p$	123078
$N_h$	15

Table 1: Numerical values of the phenomenological model

Asympt. case	$f$	$\theta_{3x}$	$\theta_{3z}$	$\theta_{2x}$
Sticking	$f_{1F2D}$	-0.919	-0.395	0.

Table 2: Eigenfrequencies and eigenvectors of the asymptotical linear cases

Figure 9: Nonlinear complex mode of the phenomenological model in vacuum

Figure 10: Nonlinear dynamics of the system in the configuration space

The nonlinear behaviour of the system dynamics changes as expected with increasing levels of  $\theta_{3x,1}$  (*i.e* increasing levels of vibration energy). A frequency shift is observed in Figure 9, from the frequency of the linear sticking case to the frequency of the linear sliding one. This frequency shift was expected, as blade root friction may be seen as the liberation of a degree of freedom which reduces the stiffness of the system, thus the free frequency. As  $\theta_{3x,1}$  increases, one may see when nonlinearities start to have a significant impact on the system dynamics, as sharp changes may be observed on the nonlinear damping and free frequency.

It can be seen in Figure 10 the effects of friction nonlinearities onto the system dynamics. Starting in sticking conditions (deep blue curves), the system dynamics evolves along a straight line as the system is nearly linear. With increasing levels of friction nonlinearities (from deep blue to deep red), one may observe an opening and a curvature of the generalized coordinates trajectories. A phase difference between the generalized coordinates appears, leading to hysteresis cycles of the system dynamics. Such cycles are typical of systems with dissipation due to friction nonlinearities.

The system dynamics has been characterized with nonlinear complex modes in vacuum. The previously derived simplified fluid representation is going to be added to the system, using numerical results of the first section.

### 4.3 Nonlinear analysis with simplified fluid representation

In this study, we are interested in predicting LCO with nonlinear complex modes while taking into account flutter instability and changes in acoustic effects due to frequency shifts. To do so, the methodology derived in subsection 3.3 and the results exposed in Figure 6 will be used. A spline has been created to characterize the evolution of  $\xi_{aero}$  with respect to the frequency of vibration. In that way, the evolution of  $\xi_{aero}$  is in regards to  $f$ , and the jacobian may be analytically derived easily. Figure 11 illustrates the spline used for computations.

Figure 11:  $\xi_{aero}$  spline implemented in the computation of the nonlinear complex mode

It should be noticed that Figure 11 differs from 6 : the points have been shifted to a lower level in the latter so that we are in presence of negative aerodynamic damping when the system is stuck and vibrates at  $f = f_{1F2D}$ . This shift, which is artificial, has been applied so that the

system may be unstable in absence of friction nonlinearities. The methodology can then be tested to assess the presence of LCO when taking into account aerodynamic effects. Another way to proceed would have been to compute the dependance of  $\xi_{aero}$  against  $\omega$  on a operating point beyond the stability limit computed previously. It is assumed that it would have produced similar results. A nonlinear complex mode has been computed when the system is initialized on the unstable bending mode. Numerical parameters have been kept the same as the case in vacuum. Results are displayed in Figure 12.

Figure 12: Nonlinear complex mode of the phenomenological model with fluid modeling

Since there is no more information on  $\xi_{aero}$  for values of  $f$  under  $0.77f_{1F2D}$ , the computation has been interrupted for this value of  $f$ . It can be seen that qualitatively we have the same trends for  $f$  and the nonlinear damping as in the case in vacuum, in spite of small discrepancies. What must be noticed is that there is a point on the nonlinear complex mode where the nonlinear damping equals zero, which highlights the presence of a LCO on this point. By using a direct Fourier transform, it is possible to display the dynamics of the system in the state space on the LCO, as shown in figure 13. Finally, it may be seen in Figure 12 that the evolution  $\xi_{aero}$  follows the evolution of the free frequency with increasing values of amplitude, as implemented from Figure 11.

Figure 13: LCO computed by the means of nonlinear complex modes

## 5 CONCLUSIONS

This study has detailed a methodology to assess flutter stability of a fan stage while taking into account friction nonlinearities at blade root. An approach including the use of nonlinear complex modes and stability results from CFD calculations has been developed. It has been tested on a simple three degrees of freedom system that represents a blade-root-disk assembly. It allows to find a dry friction induced LCO while the system is aeroelastically unstable when no friction occurs. Moreover, the sensitivity of the aerodynamic damping to acoustic reflections in the inlet of the engine has been taken into account. The next step would be to apply this methodology in an industrial context, with a typical design of modern civil fan stage. However, some aspects that have been neglected in this study will have to be taken into account. Firstly, assumptions have been made for aeroelastic computations : the effects of the flow on the structure dynamics for the evaluation of aerodynamic forces due to vibration have been neglected. For structures as fan blades, which may be rather large and flexible for modern designs, these assumptions may not be totally realistic. Hence, it will be taken into account in a further study. Concerning the fluid modeling in the nonlinear complex mode computation, it has been chosen to add linear modal fluid effects only on the first harmonic of vibration. However, with increasing levels of energy, the nonlinear shape deformation may change sufficiently so that it has an impact on the flow. Hence, some data exchanges may have to be done between the nonlinear complex mode computation and the CFD based aeroelastic calculations to converge on each physics more accurately.

## 6 ACKNOWLEDGEMENT

The present study has been done thanks to the support of Safran Aircraft Engines.

### Abstract

*The objective of this current work is to study the geometrical non-linearity in free in-plane vibration of stepped circular arch. The first part has been devoted to the study of the linear vibration of stepped arch. The sixth order differential partial equation of motion has been obtained after the inextensibility assumption. For simplification, the complicating effects such as rotary inertia and shear deformation will be ignored. The natural frequencies of arches have been obtained iteratively using Newton-Raphson algorithm, and compared with the available in the literature. The study of the geometrical non-linearity is based on Euler Bernoulli theory and Von Karman's assumptions. The kinetic and total strain energies have been written in each interval of the arch and discretized into a series of a finite spatial functions then derived using Hamilton's principle energy. The problem is reduced into a set of non-linear algebraic equations solved numerically using an approximate explicit method developed previously the so-called second formulation. Consequently, an analysis has been performed in the neighborhood of the first mode, based on the multimode approach, to obtain the stepped circular arches frequency ratio dependence on the maximum vibration amplitude.*

**Keywords:** geometrical non-linearity, free in-plane vibration, stepped circular arch, second formulation, multimode approach.

---

## 1 INTRODUCTION

For a long time, the circular arches are considered one of an important structural element which have large applications in many fields, such as mechanical engineering, civil engineering. Due to the practical importance of the arches, many authors have been studied the static and dynamic behavior of these structures. The challenge today is to find a structure that offers high strength, stability and durability by optimizing the material used in their manufacture. For this reason, the stepped arches are considered. The authors of [1]–[3] used the polynomial co-ordinate functions and Rayleigh-Ritz method to find the fundamental frequency of in-plane vibration of arcs of with thicknesses varying in a discontinuous fashion. In reference [4] an exact solution of the equation of in-plane free vibration of circular arch with uniform cross section has been used to study the free in-plane vibration of a stepped circular arch, the numerical solution have been obtained using ANSYS and performed with the experiments. Using a systematic approach X. TONG et al [5] investigated the free and forced In-plane vibration of circular arch with variable cross-section. The differential quadrature methodology has been presented by the author of [6] to study the free in-plane vibration of circular arches with varying cross-section under a various type of boundary conditions. Recently, the geometrical non-linearity in free and forced vibration of three type of multi- stepped Euler-Bernoulli beams based on single mode approach has been analyzed by El Hantati et al in references [7] and [8].

In this current paper, the geometrically non-linear in free in-plane vibration of a stepped circular arches will be presented. The complicating effects such as rotary inertia and shear deformation will be ignored. Using the inextensibility assumption, the two coupled differential partial equations are reduced to sixth order differential partial equation. The theoretical model is based on the Euler–Bernoulli beam theory and the von Karman geometrical non-linearity assumptions. Harmonic motion is assumed and expended into a series of finites spatial functions. The use of Hamilton’s principle energy, reduces the problem into a set of non-linear algebraic equations solved numerically using an approximate method the so-called second formulation developed in [9] leading to frequency ratio dependence on the maximum vibration amplitude.

## 2 GENERAL FORMULATION

In this study, homogenous stepped circular arches are considered as shown in Fig. 1. Where  $E$  denoted young’s modulus,  $I(\theta)$  is second moment of area,  $A(\theta)$  is the cross section,  $\mu(\theta)$  is the mass per unit length, and  $R$  the radius of the circular. The complicated effects such as shear deformation and rotary inertia are neglected because the arch is supposed to be thin [2].  $u_i$ ,  $w_i$  are respectively radial and tangential displacement of the arches, when the arch axis is supposed to inextensible, radial and tangential displacements are related by [10] :

$$\frac{\partial w}{\partial \varphi} = u \quad (1)$$

Whereas the bending moment  $M(\theta, t)$ , the shear force  $T(\theta, t)$  and the normal force  $N(\theta, t)$  of arch can be expressed as:

$$M(\theta, t) = \frac{-EI(\theta)}{R^2} \left( \frac{\partial^3 w}{\partial \theta^3} + \frac{\partial w}{\partial \theta} \right) \quad (2)$$

$$T(\theta, t) = \frac{-1}{R^3} \frac{\partial}{\partial \theta} \left[ EI(\theta) \left( \frac{\partial^3 w}{\partial \theta^3} + \frac{\partial w}{\partial \theta} \right) \right] \quad (3)$$

$$N(\theta, t) = \frac{1}{R^3} \frac{\partial^2}{\partial \theta^2} \left[ EI(\theta) \left( \frac{\partial^3 w}{\partial \theta^3} + \frac{\partial w}{\partial \theta} \right) \right] + \mu(\theta) R \frac{\partial^3 w(\theta, t)}{\partial \theta \partial t^2} \quad (4)$$

Fig.1: Two stepped arches ( $\eta = h_1/h_2$ ): (a) symmetric stepped arch, (b) unsymmetric stepped arch.

The sixth order differential equation of motion may be written as:

$$\frac{\partial^6 w}{\partial \varphi^6} + 2 \frac{\partial^4 w}{\partial \varphi^4} + \frac{\partial^2 w}{\partial \varphi^2} + \frac{\mu R^4}{EI} \frac{\partial^4 w}{\partial t^2 \partial \varphi^4} = 0 \quad (5)$$

Considering the arch in a harmonic motion, we put:

$$w(\varphi, t) = W(\varphi) \cos(\omega t) \quad (6)$$

If this form of solution is allowed:

$$W(\varphi) = e^{\Omega \varphi} \quad (7)$$

Then it is possible to arrive at this characteristic equation:

$$\Omega^6 + 2\Omega^4 + (1 - \lambda^2)\Omega^2 = 0 \quad (8)$$

Where  $\lambda_j^2 = \frac{\mu R^4 \omega_j^2}{EI_j}$  is the non-dimensional frequency.

The general solution of the differential equation (2) in term of radial displacement in each step of arch can be expressed as:

$$W(\theta) = \begin{cases} W_1(\theta) \rightarrow ]0, \theta_1[ \\ W_j(\theta) \rightarrow ]\theta_{j-1}, \theta_j[ \\ W_{n+1}(\theta) \rightarrow ]\theta_n, 1[ \end{cases} \quad (9)$$

$$W_{ji}(\varphi) = a_j \sin(\alpha_j(\varphi - \varphi_{j-1})) + b_j \cos(\alpha_j(\varphi - \varphi_{j-1})) + c_j \sinh(\alpha_j(\varphi - \varphi_{j-1})) + d_j \cosh(\alpha_j(\varphi - \varphi_{j-1})) + e_j(\varphi - \varphi_{j-1}) + f_j \quad (10)$$

Where:  $\alpha_j = \sqrt{\lambda_j - 1}$ ,  $\beta = \sqrt{\lambda_j + 1}$  and  $\lambda_j \geq 1$

The clamped-clamped boundary conditions of circular arches in term of tangential displacement may be written as:

$$W_{1i}(\varphi = 0) = W_{1i}(\varphi = 1) = 0 \quad \frac{dW_{1i}}{d\varphi} \Big|_{\varphi=0} = \frac{dW_{(n+1)i}}{d\varphi} \Big|_{\varphi=1} = 0 \quad (11)$$

$$W_{1i} \Big|_{\varphi=0} + \frac{d^2 W_{1i}}{d\varphi^3} \Big|_{\varphi=0} = W_{(n+1)i} \Big|_{\varphi=1} + \frac{d^2 W_{(n+1)i}}{d\varphi^2} \Big|_{\varphi=1} \quad (12)$$

The compatibility condition of at the steps of arches may be expressed as:

$$W_{ji}(\varphi = \varphi_i) = W_{(j+1)i}(\varphi = \varphi_i) \quad \frac{dW_{ji}}{d\varphi} \Big|_{\varphi=\varphi_i} = \frac{dW_{(j+1)i}}{d\varphi} \Big|_{\varphi=\varphi_i} \quad (13)$$

$$W_{ji} \Big|_{\varphi=\varphi_j} + \frac{\partial^2 W_{ji}}{d\varphi^3} \Big|_{\varphi=\varphi_j} = W_{(j+1)i} \Big|_{\varphi=\varphi_j} + \frac{\partial^2 W_{(j+1)i}}{d\varphi^2} \Big|_{\varphi=\varphi_j} \quad (14)$$

$$M_{ji}(\theta_i, t) = M_{(j+1)i}(\theta_i, t) \quad T_j(\theta_i, t) = T_{(j+1)i}(\theta_i, t) \quad N_i(\theta_i, t) = N_{(j+1)i}(\theta_i, t) \quad (15)$$

The position of the variation section can be obtained using the Gauss–Lobatto–Chebyshev points:

$$\varphi_i = \frac{1}{2} \left[ 1 - \cos \left[ \frac{(i-1)\pi}{(N-1)} \right] \right] \quad (16)$$

The use of the compatibility conditions corresponding to each step, the end conditions and the transfer matrix method [11] leads to a homogeneous system. The determinant of the latest must be set equal to zero to obtain the natural frequencies, determined iteratively by the Newton–Raphson method [12]

The corresponding dimensionless frequencies  $\lambda_i$  for stepped arches are given respectively in Tables 1 and 2, the results are compared with those of available in the literature.

The corresponding radial  $u_i$  and tangential  $w_i$  displacements of arch are plotted respectively in Fig. 2 and 4. the tangential and radial displacements are projected into a Cartesian coordinate to plot the corresponding first four mode shapes of stepped circular arches in Fig.3.

**Fig.4:** The first tangential and radial displacement  $W$  and  $V$  of symmetrical stepped arch for various values of  $\eta$ .

In Fig. 4, the corresponding first tangential and radial displacement  $W$  and  $U$  of symmetrical stepped circular arch are plotted for various values of  $\eta$  where  $\varphi_1/\varphi_0 = 0.3$  and  $\varphi_2/\varphi_0 = 0.7$

### 3 NON-LINEAR FORMULATION

The expressions of the kinetic energy  $T$ , the axial strain energy  $V_a$  and the bending strain energy  $V_b$  for the system in Fig. 1 can be written as:

$$T = \frac{R}{2} \left( \mu_1 \int_0^{\varphi_1} \left[ \left( \frac{\partial w_1^{(1)}}{\partial t} \right)^2 + \left( \frac{\partial w_1}{\partial t} \right)^2 \right] dt + \dots + \mu_{N+1} \int_{\varphi_N}^{\varphi_{N+1}} \left[ \left( \frac{\partial w_{N+1}^{(1)}}{\partial t} \right)^2 + \left( \frac{\partial w_{N+1}}{\partial t} \right)^2 \right] dt \right) \quad (17)$$

$$V_a = \frac{E}{2R^3} \left( I_1 \int_0^{\varphi_1} \left( \frac{\partial w_1}{\partial \varphi} + \frac{\partial^3 w_1}{\partial \varphi^3} \right)^2 d\varphi + \dots + I_{N+1} \int_{\varphi_N}^{\varphi_{N+1}} \left( \frac{\partial w_{N+1}}{\partial \varphi} + \frac{\partial^3 w_{N+1}}{\partial \varphi^3} \right)^2 d\varphi \right) \quad (18)$$

$$V_b = \frac{E}{8R^3} \left( A_1 \int_0^{\varphi_1} \left( w_1 + \frac{\partial^2 w_1}{\partial \varphi^2} \right)^4 d\varphi + \dots + A_{N+1} \int_{\varphi_N}^{\varphi_{N+1}} \left( w_{N+1} + \frac{\partial^2 w_{N+1}}{\partial \varphi^2} \right)^4 d\varphi \right) \quad (19)$$

Assuming harmonic, the displacement function is expanded as a series of  $N$  basic spatial functions:

$$w_{ji}(\varphi, t) = a_i W_{ji} \sin(\omega t) \quad (20)$$

Where  $a_i$  are the basic functions contributions coefficients. Using a generalized parameterization  $T$  and the usual summation convention defined in [10] and [9] The kinetic energy  $T$ , the axial strain energy  $V_a$  and the bending strain energy  $V_b$  of the arch can be expressed as:

$$T = \frac{1}{2} a_i a_j \omega^2 m_{ij} \cos^2(\omega t) \quad (21)$$

$$V_a = \frac{1}{2} a_i a_j k_{ij} \sin^2(\omega t) \quad (22)$$

$$V_b = \frac{1}{2} a_i a_j a_k a_l b_{ijkl} \sin^4(\omega t) \quad (23)$$

To obtain non-dimensional parameters, ones put:

$$W_i(\varphi) = h W_i^* \left( \frac{\varphi}{\varphi_0} \right) = h W_i^*(\varphi^*) \quad (24)$$

$$\frac{m_{ij}}{m_{ij}^*} = \mu_1 R^3 h_1^2, \frac{k_{ij}}{k_{ij}^*} = \frac{b_{ijkl}}{b_{ijkl}^*} = \frac{EI_1 h_1^2}{R^3} \quad (25)$$

Using Hamilton's principle as defined in equation (12):

$$\delta \int_0^{2\pi/\omega} (V - T) dt \quad (26)$$

One can obtain the following non-linear algebraic equations:

$$([K^*] - \omega^{*2} [M^*]) \{A\} + \frac{3}{2} [B^*(A)] \{A\} = \{0\} \quad (27)$$

Where  $M_{ij}^*$  denotes the dimensionless mass matrix  $K_{ij}^*$  is the dimensionless rigidity matrix and  $B_{ijkl}^*$  is the dimensionless non-linearity tensor. Using the tonsorial notation, one put:

$$a_i k_{ir}^* + \frac{3}{2} a_i a_j a_k b_{ijk r}^* - a_i \omega^{*2} m_{ir}^* = 0 \quad \text{with} \quad r = 1, \dots, n \quad (29)$$

The called the second formulation, it is an approximation which consists to separate the nonlinear term of equation (29) into a terms proportional to  $a_i^3$  and terms proportional to  $a_i^2 \varepsilon_i$  and neglecting terms proportional to  $a_i \varepsilon_i \varepsilon_j$  and terms proportional to  $\varepsilon_i \varepsilon_j \varepsilon_k$  one can write:

$$a_i a_j a_k b_{ijk r} = a_i^3 b_{111r} + a_i^2 \varepsilon_i b_{i11r} \quad r = 1, \dots, n \quad (31)$$

After substituting and rearranging, equation (29) can be written in matrix form as:

$$([K_r^*] - \omega^2 [M_r^*]) \{A_r\}_R + \frac{3}{2} [\alpha_r^*] \{A_r\}_R = \left\{ -\frac{3}{2} a_r^3 b_{111r}^* \right\} \quad (32)$$

### 3. NUMERICAL RESULTS

Based on the multimode mode approach, the results obtained here are given for C-C stepped circular arches in the neighborhood of the first mode shape.

The Fig. 4 and 5 show the effect of the variation in the cross-section on the dimensionless frequency ratio dependence on the maximum vibration amplitude.

**Fig.4:** Backbone curve of symmetric stepped circular arch for  $\eta = 1.25$  and  $1.4$

**Fig.5:** Backbone curve of symmetrical C-C stepped arch with  $\varphi_1/\varphi_0 = 0.3$ ,  $\varphi_2/\varphi_0 = 0.7$  and various values of  $\eta$ .

The non-linear frequency ratio versus the non-dimensional vibration amplitude curves of an unsymmetric and symmetric stepped circular arches clamped at both ends are shown respectively in Fig. 4 and 5 for the first non-linear mode shape by taking into account various values of  $\eta$ . The hardening type of geometrical non-linearity can be clearly observed.

**Fig.5:** The associated first normalized non-linear tangential displacement, non-linear curvature and non-linear shearing force of a C-C symmetric stepped circular arch for various vibrations level.

**Fig.5:** The associated first normalized non-linear tangential displacement, non-linear curvature and non-linear shearing force of symmetric stepped circular arch for various vibrations level.

The amplitude dependent normalized first nonlinear mode shape, the corresponding curvature and shearing force of unsymmetric and symmetric stepped circular arches are plotted respectively in Fig. 5 and 6 for various vibration amplitudes.

#### 4 CONCLUSIONS

The geometrical non-linearity in free in-plane vibration of inextensible stepped circular arches were analyzed based on Euler Bernoulli theory and the Von Karman geometrical nonlinearity assumptions. For simplification, the complicating effects such as rotary inertia and shear deformation were ignored. The natural frequencies of arch were obtained iteratively using Newton-Raphson algorithm, and compared with those available in the literature. The linear modes shapes were plotted and used as a basic function on non-linear analysis. The kinetic and total strain energy were written in each interval of the arch and discretized into a set of non-linear algebraic equations. Using the Hamilton's principle energy and spectral analysis, the problem was reduced into a set of non-linear algebraic equations solved numerically by an approximate explicit method the so-called second formulation. Based on the multimode approach, the effects of the variation of the cross section area on non-linear behavior of the arches were studied. The first non-linear deflections, curvatures and shearing forces curves were plotted.

### Abstract

*The response of the seat-type abutment-backfill system under a dynamic excitation and its contribution to the structural system of the entire bridge is usually ignored in practice in Europe, since the designers prefer providing joint gap sizes larger than the required for the design earthquake. In the high seismic hazard areas of the US, various versions of Caltrans Guidelines prescribe a relatively simple way to account for the abutment – backfill interaction. However, the design of Caltrans abutments is based on the ‘fully sacrificial’ approach, wherein the backwall ‘shears off’ at an early stage, while in other countries the detailing of the deck-abutment interface is such that a plastic hinge forms at the base of the backwall which is detailed for ductile behaviour. In all cases, if assessment of the bridge safety beyond the design earthquake is sought (e.g. in fragility analysis), it is essential to properly account for the response of the bridge when the end joint is closed.*

*This paper focuses on seat-type abutments with backwall hinging. In a practical context, a ‘simple’ model in this case consists of a spring-gap element that models the entire abutment-backfill system, while a ‘complex’ model includes explicit modelling of the abutment using beam-column elements, and of the backfill behind it using one or multiple soil springs. For dynamic response-history analysis, dashpots are also needed for modelling radiation damping. The issues of the number and the arrangement of the spring-dashpot systems and their nonlinear constitutive laws are addressed herein and several configurations are studied. SAP 2000 is used for analysing a typical overpass bridge with seat-type abutments and joints in both the longitudinal and transverse directions, for a number of spectrum compatible records. A series of pushover analyses of the ‘complex’ model are also carried out; their output can be used to define the (single) spring properties of the simple model. Interesting conclusions are drawn, both with regard to the spring configuration and to the difficulties in combining the various nonlinear elements in SAP 2000.*

## 1 INTRODUCTION

While in integral abutment bridges it is now customary to model the stiffness of the backfill soil (and indeed the forthcoming new Eurocode 8-2 makes mandatory to model the effect of interaction between soil and abutments in such bridges), in the case of seat-type abutments this interaction is usually ignored in practice. In a number of European countries, designers prefer to provide end joint gaps substantially larger than the expected seismic displacement of the deck under the design earthquake, so that the joint remains open and the contribution of the backfill can be ignored. In various versions of Caltrans' Guidelines [1], which are implemented in the high seismic hazard regions of the US, seat-type abutments backfill systems in straight bridges are taken into account in a simplified way. Specifically, in the longitudinal direction, the simplified recommendations of the current Caltrans are based on the work of Shamsabadi et al. [2], which, in turn, is based on large-scale abutment tests at UCLA. For the transverse direction a nominal spring stiffness is suggested; this stiffness is not directly correlated to the actual stiffness of the shear keys or the abutment-backfill system, but it is simply meant to suppress unrealistic (?) response modes that would emerge in the transverse direction in the case of a completely unrestrained deck end [1]. Modelling of seat-type abutments is reviewed in the reports of Aviram et al. [3] and the more recent one by Omrani et al. [4], where there are also practical guidelines for modelling in SAP 2000 and OpenSees, respectively. However, Caltrans and the aforementioned reports refer to the 'fully sacrificial' backwall approach, i.e. a backwall that 'shears off' almost immediately after gap closure.

In this paper, the behaviour of seat-type abutment-backfill systems with hinging backwall and exterior shear keys is examined using 'simple' models consisting of one spring-gap element at each end that models the entire abutment-backfill system, and 'complex' models including explicit modelling of the abutment using beam-column elements, and of the backfill behind it using one or multiple soil springs. For a real bridge selected as a case study, in the longitudinal direction, nonlinear static analyses of various configurations of this system are conducted and are compared with a similar backwall-backfill system designed following the 'fully sacrificial' approach. In both the longitudinal and transverse directions, nonlinear response history analyses for different levels of seismic action are carried out to investigate the feasibility of the aforementioned configurations and their effect on the response of the entire bridge. The effect of the joint gap size is also investigated herein and several conclusions are drawn, regarding the importance of accounting for the deck-abutment-backfill interaction and the modelling challenges that it poses.

## 2 OVERVIEW OF THE CASE-STUDY BRIDGE

The studied bridge (called T7) is an actual overpass of Egnatia Motorway in northern Greece, designed by a German firm and overall representative of modern bridge design practice in Europe. It is a three-span concrete structure, designed for earthquake according to the 2000 Greek national seismic code (EAK2000), very similar to the then current draft of Eurocode 8-2. The total length of the bridge is 99 m, consisting of a 45 m central span and two 27 m outer spans, while the longitudinal slope of its axis is equal to 7%. The deck consists of a 10 m wide prestressed concrete box girder section with a continuously changing cross section along the length of the bridge. The two piers of the bridge have a circular cross section, with a diameter of 2 m and are monolithically connected to the deck; their clear heights are 5.94 m and 7.93 m (Fig. 1).

Figure 1: (a) Longitudinal section of the bridge, (b) Pier section, (c) Section close to pier

The deck is supported on seat-type abutments (Fig. 2), which include backwall, wingwalls, and external shear keys, through two elastomeric bearings with dimensions (mm) equal to  $350 \times 450 \times 136$ . The total heights of the abutments are equal to 5.63 m and 5.71 m, while the height of both backwalls is 2.45 m. The deck is separated from the seat-type abutments with joints of 100 mm in the longitudinal direction and 150 mm in the transverse direction.

Figure 2: Section at the abutment

The piers, as well as the abutments, rest on surface footings (due to the relatively firm soil). The pier footings are  $9.0 \text{ m} \times 8.0 \text{ m} \times 2.0 \text{ m}$ , while the abutment footings are  $12.0 \text{ m} \times 4.5 \text{ m} \times 1.5 \text{ m}$ . The soil in the bridge area mainly consists of moderately stiff clay formations, corresponding to soil class C according to Eurocode 8 [5]. In the absence of measured data, a shear wave velocity  $V_s = 300 \text{ m/s}$  was assumed for modelling the properties of clay, while its specific weight was taken as  $\gamma = 20 \text{ kN/m}^3$ .

### 3 FINITE ELEMENT MODELLING OF THE BRIDGE

#### 3.1 Modelling of concrete members

The bridge was modelled using the broadly used SAP 2000 software [6] as shown in Fig. 3. The prestressed deck is deemed to remain elastic during the seismic event and it was modelled as a non-prismatic section, varying along its length, to take into account its changing shape along the longitudinal axis. The inelastic behaviour expected to develop at the bridge piers was modelled with plastic hinges at both ends of each pier (monolithic connection to the deck). SAP 2000 uses a moment-rotation curve for its plastic hinge elements, which was defined on the basis of the pertinent moment-curvature diagram. The length of the plastic hinges was calculated as the weighted average of two relationships available for piers [7], [8]:

$$L_{pl} = 0.08L_s + 0.022d_{bl}f_y \quad (1)$$

$$L_{pl} = 0.6D \left[ 1 + \frac{1}{6} \min \left( 9; \frac{L_s}{D} \right) \right] \quad (2)$$

where  $L_{pl}$  is the calculated plastic hinge length,  $L_s$  is the shear span of the pier,  $d_{bl}$  is the diameter of the longitudinal bars,  $f_y$  is the yield strength of concrete and  $D$  is the diameter of the pier. A weighting factor of 0.7, is selected for relationship (2) since it was derived from numerous experimental results and was specifically created for circular columns, whereas relationship (1) is recommended for general use.

Figure 3: Finite element model of the bridge

Moment-curvature ( $M-\phi$ ) curves are obtained at every pier end, using the section analysis software AnySection [9] for the axial load  $N_{G+0.3}$ . The constitutive models of the materials used in section analysis were the model by Mander et al. as adapted by Paulay & Priestley [7] for confined concrete, the nonlinear model of EN1992-1 [10] for unconfined concrete and the model of Park and Sampson [11] for reinforcing steel. To define the (apparent) yield point,

the  $M-\phi$  curves were bilinearised by adopting the criteria of 15% strength drop and equality of areas under the “exact” and the bilinear curve (equal energy absorption).

The horizontal shear behaviour of the (common) elastomeric bearings was considered bilinear, while in the other directions the bearings are considered to respond linearly. All the relevant stiffnesses, namely initial and post-yield horizontal shear stiffness ( $K_{h,el}$  and  $K_{h,pl}$ ), flexural stiffnesses ( $K_{bx}$  and  $K_{by}$ ) and axial stiffness ( $K_v$ ) were calculated according to [12].

Soil-structure interaction at the foundations of the piers and the abutments of the bridge was taken into account, utilising equivalent linear springs at the bases of the respective beam-column elements of the model. The stiffness values of these springs were calculated according to Mylonakis et al. [13].

The seat-type abutment-backfill system was modelled in detail, as its behaviour is the main focus of this study. This ‘complex’ (in a practical design context) abutment-backfill model is depicted in Fig. 4. It consists of separate beam-column elements which represent the stem wall and the backwall, while the behaviour of the backfill soil was modelled using multiple pairs of springs and dampers (Kelvin-Voigt elements) distributed along the height of the stem wall and the backwall. A moment-curvature ( $M-\phi$ ) curve was derived from AnySection for the expected plastic hinge at the base of the backwall, while the estimated length of this plastic hinge was calculated from the relationship of Biskinis [14], developed for concrete walls:

$$L_{pl} = 0.1L_s + 0.2h \quad (3)$$

A gap element was placed between the top of the backwall and the end of the deck; several initial gap sizes were used, to investigate the effect of the gap size on the response of the bridge. The constitutive models used for the springs and dashpots representing the backfill soil are described in the next section.

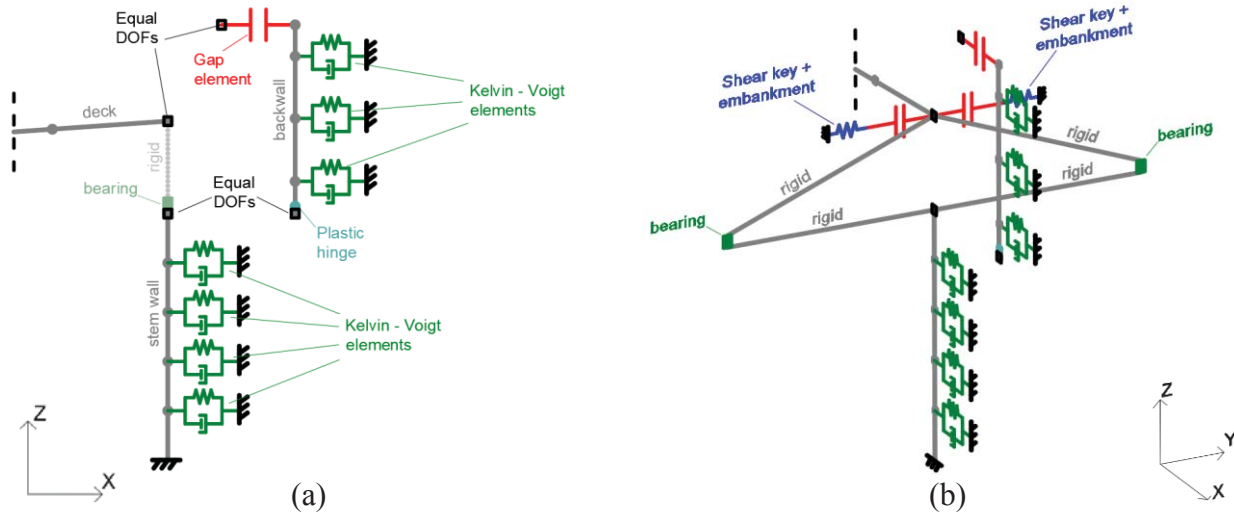

Figure 4: (a) Longitudinal section and (b) 3-d view of the ‘detailed’ abutment-backfill model

### 3.2 Modelling of the backfill soil behaviour

The radiation damping and the hysteretic behaviour of the backfill soil in the longitudinal direction are modelled with the use of multiple spring-dashpots along the abutment, each of which consists of a viscous damper and a nonlinear spring (called “nonlinear link element” in SAP 2000) placed in parallel, as shown in Fig. 4. The effect of the number of these pairs and their position in the abutment-backfill was investigated through a series of non-linear static (pushover) analyses.

The closed-form relationship recently proposed by Khalili-Tehrani et al. [15] was adopted as the backbone curve of the nonlinear backfill springs. This relationship is based on the log-spiral hyperbolic (LSH) model proposed by Shamsabadi et al. [16], which was verified against large-scale experiments on backwall – backfill systems with different types of soil. The relationship is given by:

$$F(y) = f_\delta \frac{a_r y}{\hat{H} + b_r} \hat{H}^n \quad (4)$$

where  $f_\delta$  is a function of the wall – soil interface friction angle,  $a_r$  and  $b_r$  express backfill capacity and wall displacement at capacity, respectively, and  $\hat{H}$  is the normalised value of the wall height.

The above hyperbolic relationship and its parameters were derived from a calibration of multiple experimental results, which were conducted using a 1.7m high backwall specimen, pushed horizontally against backfill of various soil types, considering it a typical sacrificial backwall with almost no shear resistance, i.e. designed to break almost immediately after gap closure, as per the relevant Caltrans provisions [1] (also found in older Caltrans guidelines). As a result, the behaviour of the abutment – backfill was governed by the passive pressures of the backfill soil developing uniformly along the height of the wall. However, in the studied bridge, the backwall is designed to form a plastic hinge at its base. Consequently, after gap closure, it does not shear off but it has a predominantly flexural response, and the backfill soil near the top of the wall deforms more than at its base. Therefore, in the longitudinal direction, the abutment was modelled with separate frame elements representing the stem wall and the backwall, while the backfill soil was modelled with multiple springs to better capture the differing soil deformation along the backwall height.

For the implementation of (4), a dense granular backfill soil, typically suggested by the pertinent codes/guidelines (e.g. [1]) is considered, with  $\phi = 40^\circ$ ,  $c = 0$ ,  $\gamma = 20\text{kN/m}^3$ , soil strain at 50% of the ultimate stress  $\varepsilon_{50} = 0.0035\text{m}$  (according to Shamsabadi et al. [16] for a similar type of soil),  $\nu = 0.35$  and ultimate deformation equal to  $0.05H_{bw} = 0.1225\text{m}$ , where  $H_{bw}$  is the height of the backwall; the value of  $0.05H_{bw}$  is a common estimation of ultimate deformation for granular backfill soil, derived from large-scale experiments [15], [16].

The nonlinear link provided by SAP 2000 is a multilinear one, hence the previously calculated hyperbolic curve was converted to a quadrilinear approximation. Furthermore, to capture the full-range behaviour of the system, a final descending branch was added to this quadrilinear curve, based on a linear approximation of experimental descending branches for granular soils found in Cole & Rollins [17]; both curves are presented in Fig. 5. In the absence of other options, the compression-only “Concrete” hysteresis model, available in SAP 2000, was adopted as the hysteresis rule of the nonlinear backfill springs.

Last, the dashpot coefficient of the viscous dampers was estimated based on the work of Mylonakis et al. [13] which refers to footings rather than backwalls; so an adjustment was made (as also done in [18]) to account for the fact there is no soil above the backwall. The estimated dashpot coefficient was found to be equal to 13.5 MN s/m.

Figure 5: Backfill hyperbolic force-deformation curve according to Khalili-Tehrani et al. [15] and its multilinear approximation made herein

In the transverse direction, it is considered that the external shear keys of the bridge are practically rigid and remain elastic (which was indeed the case here), and the abutment-backfill system was modelled as a pair of p-y springs which represent the bridge-embankment interaction in the transverse direction, according to the model of Xie et al. [19]. This model, which was derived from multiple 3-D continuum finite element analyses of abutment-backfill models verified against the recorded response of Painter Street Bridge during the 1992 Petrolia earthquake, provides closed-form relationships for the calculation of the ultimate embankment capacity at top of the 3D embankment in the transverse direction ( $\Sigma p_{ult,T}$ ), the value of the embankment displacement that corresponds to 50% of  $\Sigma p_{ult,T}$  ( $y_{50,T}$ ) and the value of the transverse secant stiffness at  $y_{50,T}$  ( $K_{s,T}$ ). However, no relationship for the calculation of the embankment displacement at  $\Sigma p_{ult,T}$  or the estimation of the stiffness when the displacements are larger than  $y_{50,T}$  is provided in [19]. In view of this, it was assumed that the full force – deformation curve in the transverse direction is a bilinear one and that the slope of the second branch of this bilinear curve is equal to about 20% of  $K_{s,T}$ . The bilinear curve that was finally derived is shown in Fig. 6, using the same backfill soil properties which have already been described for the longitudinal direction.

Figure 6: Embankment bilinear force-deformation curve in the transverse direction, based on the model of Xie et al. [19]

## 4 NONLINEAR ANALYSIS OF THE BRIDGE

### 4.1 Nonlinear static (pushover) analysis of the abutment-backfill system

In order to investigate the rather complex inelastic behaviour of the abutment-backfill system in the longitudinal direction, before integrating it into the entire bridge model, multiple pushover analyses of different configurations of the system in the longitudinal direction were conducted. The main goals of these analyses were to define the importance of the contribution of the backfill soil after gap closure, to investigate the effect of the number and the positions of soil springs and dashpots and, finally, to compare the behaviour of backwalls which form a plastic hinge at their base with that of ‘fully sacrificial’ (Caltrans type) backwalls which ‘shear off’ as soon as the joint gap closes.

The first issue to be addressed is whether the contribution of the lower part of the backfill, i.e. the area behind the stem wall, should be taken into account. In order to investigate the influence of this area, two additional analyses were conducted; one of the abutment alone, without any contribution from the backfill, and one with the lower part of the backfill considered. The respective models are shown in Fig. 7b and 7c. and the resistance curve (i.e. base shear vs displacement at the top of the backwall) is depicted in Fig. 8 and compared with the model which has springs along the entire height of the abutment (Fig. 7a). It is clear that the contribution of the examined part of the backfill is negligible and hence, in the following analyses, only the part of the backfill behind the backwall is considered. This result is anticipated, since the very high stiffness of the stem wall results in little deformation of the springs attached to it, consequently leaving them almost inactive.

Figure 7: Longitudinal abutment model: (a) with backfill soil springs behind the entire abutment (b) with backfill soil springs behind the stem wall, (c) without backfill soil springs

Figure 8: Resistance curve of the abutment with backfill soil springs behind the stem wall, behind the entire abutment and without backfill soil springs

The next issue addressed was the effect of the position and the number of the backfill springs along the height of the backwall. Some of the configurations explored are depicted in Fig. 9; note that in the multiple spring configurations the influence area of each spring is the same. From the resulting resistance (pushover) curves in Fig. 10, it is clear that the number of the springs does not affect the abutment-backfill behaviour significantly, while for 3 springs or more, hardly any difference is observed in the pushover curves, except for the descending branch that follows the failure of the backwall. This difference is caused by the way that the strength drop of the backwall is modelled in the software due to different discretisation of the frame element of the backwall in each case, since the backwall element is divided at each of its connections with the springs; namely, the shorter an element is, the more it is capable of capturing an abrupt strength drop [20]. However, in the case that a single spring is used, placing it at the top of the backwall seriously overestimates the maximum strength of the backfill by almost 60%. It is stressed here that the springs do not contribute to the response of the system in the same way; the closer a spring is to the top of the backwall, the earlier it reaches its maximum strength (Fig. 11), due to the hinging at the base.

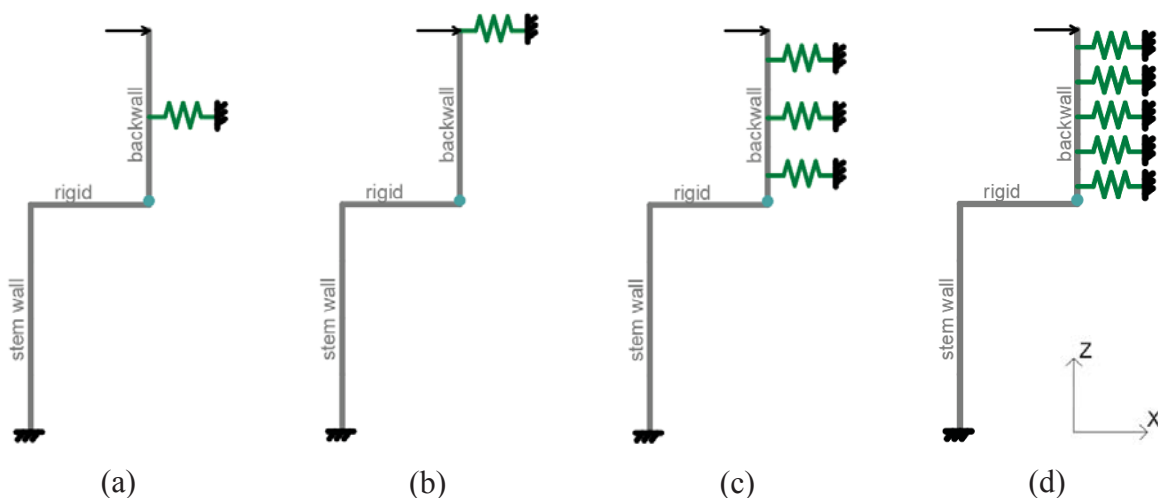

Figure 9: Longitudinal abutment model with: (a) a single backfill soil spring in the middle of the backwall, (b) a single backfill soil spring at the top of the backwall, (c) 3 springs along the height of the backwall, (d) 5 springs along the height of the backwall

Figure 10: Resistance curves for various numbers of distributed backfill soil springs along the height of the backwall and for a single spring at the top of the backwall

Figure 11: Axial forces developed at the backfill soil springs during the pushover analysis of the abutment-backfill system in the case of 3 used springs along the height of the backwall (Fig. 9c)

The case of the ‘fully sacrificial’ backwall with no shear resistance that shears off right after the gap closure with a lateral force applied at its top, was also examined with the use of a backwall model with a roller support at its base, as shown in Fig. 12a. As seen in Fig. 12b, in this case each of the backfill soil springs contributes equally to the response of the system, meaning that a model which consists of a single spring would be enough for modelling the behaviour of the entire abutment-backfill system adequately. The maximum contribution of the backfill soil springs in the case of the ‘fully sacrificial’ backwall is larger by 15% than in the case that the backwall yields and eventually fails in flexure. The ‘fully sacrificial’ backwall has also higher initial stiffness but it develops its maximum strength at a smaller displacement (Fig. 13). These results can be attributed to the fact that in the case of the ‘fully sacrificial’ backwall every spring along the backwall height is activated simultaneously from the beginning, contrary to the case of the backwall with the plastic hinge at its base.

Figure 12: (a) Longitudinal backwall model with no shear resistance ('fully sacrificial') and 3 backfill soil springs along its height, (b) axial forces developed at the backfill soil springs during the pushover analysis of the 'fully sacrificial' backwall-backfill system in the case of 3 used springs along the height of the backwall (Fig. 12a)

Figure 13: Total contribution of the backfill soil springs in the pushover analyses of backwall with plastic hinge formed at its base and 'fully sacrificial' backwall

#### 4.2 Nonlinear static (pushover) analysis of the bridge model

Having compared the spring configurations that represent the abutment-backfill system, nonlinear static (pushover) analyses of the entire T7 bridge model were conducted, for both the 'fully sacrificial' backwall case and the backwall with a plastic hinge formed at its base. Simple spring configurations (such as a single nonlinear spring for the case of the 'fully sacrificial' case) and more complex models, including detailed modelling with nonlinear beam-column elements representing the abutment and nonlinear springs along the height of the backwall, which represented the backfill soil were used. Five longitudinal joint gap sizes, namely 0 cm, 2.5 cm, 5 cm, 7.5 cm and 10 cm were explored, to study the influence of the gap size. The results are given in Fig. 14 and Fig. 15. The total base shear after gap closure is 23.5% and 30% larger than in the case without gap closure for the 'fully sacrificial' and the backwall with a plastic hinge at its base, respectively.

Figure 14: Resistance curves of the entire bridge with 'detailed' abutment-backfill model and backwall with plastic hinge at its base in the longitudinal direction, for various joint gap sizes

Figure 15: Resistance curves of the entire bridge with single spring according to Khalili-Tehrani et al. [15] representing a 'fully sacrificial' backwall in the longitudinal direction, for various joint gap sizes

The effect of simple or complex modelling of the abutment-backfill system can be seen in Fig. 16, where both the detailed and the single-spring model are used to derive resistance curves for the bridge, and these are compared with the detailed (multi-spring) model and the reference case where the abutment-backfill system is ignored (which is the situation prior to gap closure). It is clear (and expected) that when the single spring is defined from the analysis of the abutment-backfill system, the detailed and the simple model produce practically identical curves; however, when the single spring is based on the Khalili et al. [15] model, which corresponds to the case of a shearing-off backwall, the simple model overestimates the strength of the system for the reasons discussed earlier in the paper. Regarding the effect of gap size, the contribution of a shearing-off backwall and a backwall that forms a plastic hinge at its base were very similar for all examined joint gap sizes.

Figure 16: Comparison of the resistance curves of the entire bridge in the longitudinal direction, modelled with 'detailed' and 'simple' (single spring) model representing either a 'fully sacrificial' backwall and a back-wall with plastic hinge at its base, for joint gap size equal to 7.5 cm.

#### 4.3 Nonlinear response history analysis

The nonlinear dynamic response of the bridge was studied to better understand its overall dynamic behaviour and to identify modelling issues that should be further addressed. For the dynamic response history analysis, the bridge is subjected to a set of artificial accelerograms scaled to various levels of intensity, multiples of the design seismic action (0.16g, 0.32g and 0.48g, considering soil class C according to Eurocode 8, but assuming that  $T_D = 4s$  instead of  $T_D = 2s$  suggested by EC8, as a more representative value of high seismicity regions [21], [22]). In the longitudinal direction, 3 pairs of nonlinear spring and dashpots are used to represent the backfill, while in both directions separate gap elements are used.

The issue of modelling the joint gap was one of the focuses of the investigation. In SAP 2000, gaps are modelled with a separate element, which has zero stiffness when it is open and a user-defined stiffness value when it is closed. The latter value is difficult to define in a way such as to avoid numerical instabilities and to appropriately capture the force transfer between the elements which are adjacent to the gap during response history analysis; this is known from the literature [23] and has also been observed in the analyses conducted for the present work. According to Kim & Shinozuka [23], the stiffness of the gap element should not be larger than 1000 times the stiffness of the adjacent elements in order to avoid numerical instabilities. After conducting preliminary response history analyses of the examined bridge model, it was found out that the response quantities are significantly different when the gap element stiffness is equal to 100 times the stiffness of the adjacent elements or lower from those for gap element stiffness 1000 times the stiffness of the adjacent elements or larger. It was decided to set the gap stiffness equal to 1000 times the initial stiffness of the adjacent elements. However, in a nonlinear analysis, the stiffness of the adjacent elements varies with time, and numerical stability is not achieved in every response history analysis. Moreover, the existence of the gap element results in large analysis duration which becomes even larger as the level of the input ground motion increases and, most importantly, the time step at which the base of the backwall yields is very different even for very small differences in the gap element stiffness or the considered initial gap. The use of a nonlinear spring with a backbone curve that starts with a zero slope would be an alternative solution to avoid all the aforementioned prob-

lems. This solution was indeed utilized in the nonlinear *static* analyses with the ‘simple’ single-spring model; however, in the *dynamic* response history analyses with SAP 2000, it could not be implemented, since no compression-only hysteresis model provided by the software is compatible with such a backbone curve.

Some results of the analyses in the longitudinal and the transverse direction are plotted in Figures 17 and 18. In both directions, the deformation of the upper backfill-soil spring, the bearing deformation and the plastic rotations of the pier are depicted for various gap sizes and for the three selected levels of earthquake intensity. In the longitudinal direction, the derived backwall plastic rotations are also shown.

Figure 17: Longitudinal direction: Effect of gap size on: (a) the maximum deformation of the upper backfill spring, (b) the maximum bearing deformation, (c) the maximum pier plastic rotation and (d) the maximum backwall plastic rotation for 3 levels of ground motion

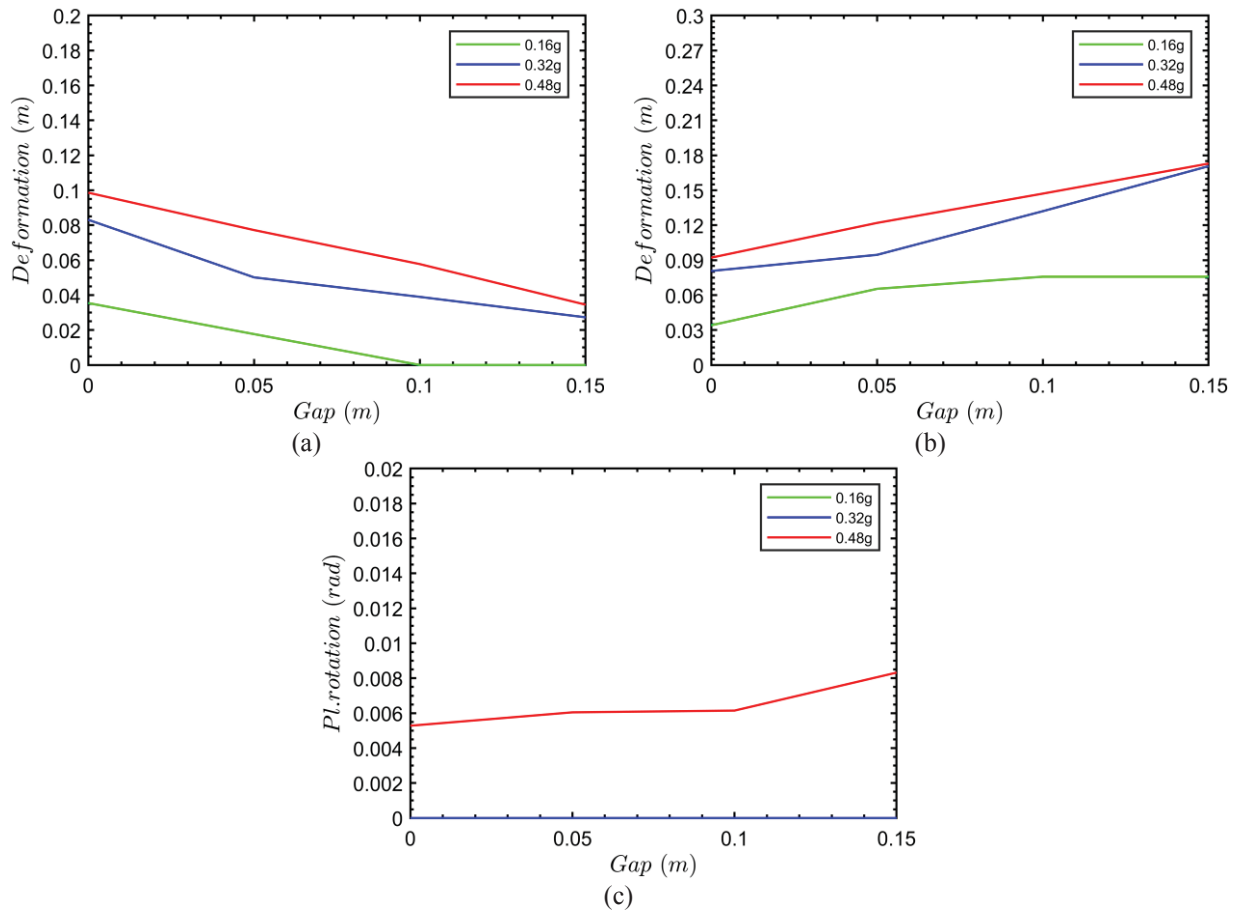

Figure 18: Transverse direction: Effect of gap size on: (a) the maximum deformation of the spring that models the shear key and the embankment resistance, (b) the maximum bearing deformation and (c) the maximum pier plastic rotation for 3 levels of ground motion

The results indicate the importance of accounting for the abutment-backfill system in both directions and the fact that small gap sizes may alter the response of the entire bridge significantly, mainly in cases of high seismic intensities. As expected, the abutment-backfill system is activated more when the gap size is small, and this emerges as beneficial for the piers and the bearings which sustain less damage. Bearings are affected more than piers, particularly in the transverse direction, where an initially closed gap results in approximately 50% decrease of the bearing deformation with respect to 15 cm gap, for ground motion equal to twice the design earthquake. Longitudinal gap sizes larger than 7.5 cm (which is close to the 10 cm gap selected by the designer of the actual bridge), do not make any noticeable difference compared to larger ones, since the displacements in the longitudinal direction are smaller than the largest examined initial gap sizes even for the highest examined level of ground motion.

## 5 CONCLUSIONS

Various configurations of a seat-type abutment-backfill model in the longitudinal and the transverse directions were studied, focusing on an existing overpass designed according to modern code provisions. From both the static and the dynamic (response history) analyses, it emerged that the performance of the bridge improved and that the response of its various components was different when the abutment-backfill system was taken into account, highlighting the importance of modelling this system. Specifically:

- ‘Hinging’ and shearing-off (‘fully sacrificial’) backwalls behave differently when the joint gap closes, hence their modelling should account for this. Abutment-backfill systems with shearing-off backwalls present higher initial stiffness and strength than the ones with ‘hinging’ backwalls; this occurs at the cost of early backwall damage, whereas they reach their strength peak at smaller displacements.
- A single nonlinear spring with a properly defined constitutive law based on passive pressures developing on the backfill is sufficient for modelling the shearing-off system. On the contrary, it is not appropriate for a ‘hinging’ backwall, where the nonlinear behaviour at its base differentiates the response of the entire abutment-backfill system. In this case the single-spring model must be based on the pushover curve derived from the analysis of the abutment-backfill component of the bridge, as described in this paper.
- Modelling the nonlinear behaviour of the backfill soil behind the stem wall of a seat-type abutment is not required, at least in the common case that the stem walls is much stiffer than the backwall, since that part of the soil barely deforms.
- The location of the springs that represent the backfill soil affects the calculated response of the abutment-backfill system, while their number also has some influence. For common backwalls of around 2 m height, use of three springs suffices.
- Modelling the gap element separately, which is necessary for response history analyses with the ‘detailed’ abutment-backfill model, is prone to cause numerical instabilities and/or long computation time. Use of constitutive law with an initial flat slope is clearly preferable, but is not available in all software packages.
- The bearings and the piers are generally relieved as the gap size is made smaller and hence the abutment-backfill system is activated; this occurs at the cost of increased response of the abutment-backfill system that may cause damage to the more critical component of this system.

### Abstract

*In a system of soil-structure interaction, in railway lines particularly, the difference in rigidity at the area of interaction ground-pillar or ground-bridge generates a bending moment at the ends of the structure during the passage of high-speed trains. To analyze the phenomenon and its influence on the response of the work, a more realistic schematization of the studied system is necessary. Although the introduction of rotary springs at the ends of the deck enhances the choice of the appropriate analysis model, most of the contributions reported do not consider this effect. In the present work, an analytical approach to analyze the dynamic response of railway bridges especially those with the ballasted track is investigated. The idea of the proposed model is based on analyzing the continuity effect of the ballasted track (rails and ballast) on the dynamic response of railway bridges, with taking into account an axial force that models the effect of prestressing, ballast interface, axial displacement, force braking. The analytic solution is based on Hamilton's principle, two dynamic case studies of a simply supported and simply supported partially clamped Euler-Bernoulli beam are presented. The results revealed that the compression force presents an additional stiffness which affects the critical velocity and the continuity of the track modeled by rotational springs at the beam's end, so as it increases the dynamic response decreases.*

**Keywords:** Resonance; Force axial; Ballasted track; Partially clamped beam.

## 1 INTRODUCTION

Nowadays, high-speed train plays an important role in the public transportation strategy of the states. Thus, vertical acceleration in the platform of short or long railway bridges in high-speed lines is still a matter of concern. As dynamic analyzes and experimental tests have shown that vertical acceleration is responsible for this result, these analyzes were carried out by the European Railway Research Institute (EERRI) [1]. So from this, we conclude that the deck vertical acceleration is among the most important specifications required for the design and evaluation of short railway bridges, which have been identified as  $3.5m/s^2$  for ballast tracks [2]. Therefore, the development of precise models working to respect this acceleration factor has become important in applications. So the dynamic performance of railway bridges is playing an increasingly important role in public transportation systems due to the extensive construction of new high-speed lines and the use of old high-speed lines. The regular and repetitive nature of the wheel loads that make up the railway bridges can stimulate resonance situations in these structures. For this latter, it is necessary to continuously modernize the railway infrastructure and especially the bridge structures. Even the axle loads of modern trains are not greater than the forces transmitted in older vehicles, higher design speeds can lead to the occurrence of resonance phenomena. Resonance in a railway bridge occurs when the excitation frequency of the periodic loading of a train approaches a natural frequency of the bridge. In this case, the loads enter the bridge in phase with the natural vibrations of the structure, resulting in a progressive increase in the vibration response of the deck.

In the reported works, Mesuros et al. [3] based on an analytical approach, analyzed and studied the free vibration response of simply and elastically supported beams under moving constant and moving loads, in which the conditions of resonance and cancelation are proved. Resonance vibrations have been observed on railway bridges subjected to high-speed trains. An elementary theoretical model of a bridge has been studied using the integral transformation method, which provides an estimate of the amplitudes of the free vibration. Besides, the analysis gives the critical speeds at which resonant vibration can occur. They are caused by two main reasons: the repeated action of axle loads and the high speed itself [4]. Moreover, it is reported in a work that generally consists of studying the effect of the continuity of the ballasted track on the dynamic response of simply supported railway bridges to assess the influence of the track components and its continuity on the response to the acceleration of the bridge under the passage of railway convoys [5-6].

Additionally, some authors have investigated the effect of axial load on natural frequencies and modal shapes with various types of uniform beam boundary conditions with a concentrated mass at the tip [7]. Some authors investigate the vibration and stability of an infinite Bernoulli-Euler beam on an elastic foundation of the Winkler type when the system is subjected to a static axial force and a moving load with constant or harmonic amplitude variation [8]. The present study takes into account the fact of an axial force that models the effect of prestressing, ballast interface, axial displacement, force braking, and so on. This same idea was discussed by Zhong et al. [9] in which they studied and analyzed the effect of prestressing on the dynamic responses of bridges.

A study that presents a methodology for the comprehensive analysis of railway transition zones (for example, near bridges), which includes: an advanced measurement technique that uses a DIC (Digital Image Correlation) device to measure the dynamic displacements of the rails at multiple locations along the track in transition zones [10]. Also, the authors of this work carried out an experimental study on the problem of the degradation of the railways in the transition zones towards the railway bridges, by numerous measurements on the ground [11].

For this reason, in this study, the interest is to analyze the continuity of the ballasted track in the maximum dynamic response of the bridge (acceleration, displacement) due to rail traffic as a criterion of ballast stability in the case of a ballasted track with taking into account an axial force for the two models, simply supported (SS) beam and simply supported partially clamped (SSPC) beam.

## 2 BASIC ASSUMPTIONS AND PROBLEM FORMULATION

In this section, as cited previously, to understand the track's continuity effects in the dynamic response of a simply supported bridge, the studied bridge is modeled by an E-B simply supported partially clamped beam, as shown in Fig. 1, which connected in its end's by two rotational springs with a constant stiffness  $K_r$ , and an axial Force  $K_s$  is presented which simulate the effect of prestressing, ballast interface, axial displacement, force braking.

Figure 1: Simply supported partially clamped beam.

By neglecting the damping ratio, the problem of dynamic vibrations of the system can be expressed by Hamilton's principle which is

$$\delta \int_{t_1}^{t_2} (U - T - W) dt = 0 \quad (1)$$

Which  $U$ ,  $T$  and  $W$  are the potential energy, the kinetic energy, and the work of the external forces and defined as

$$U = \frac{1}{2} EI \int_L \left( \frac{\partial^2 v}{\partial x^2} \right)^2 dx + \frac{1}{2} \int_L k_s \left( \frac{\partial v}{\partial x} \right)^2 dx \quad (2a)$$

$$T = \frac{1}{2} \rho A \int_L \left( \frac{\partial v}{\partial t} \right)^2 dx \quad (2b)$$

$$W = \int_L p(x, t) v dx + W_{r,0} \left( \frac{\partial v}{\partial x} \right) + W_{r,L} \left( \frac{\partial v}{\partial x} \right) \quad (2c)$$

With  $v(x, t)$  is the vertical displacement,  $k_s$  is the axial force,  $EI$ ,  $\rho A$  and  $p(x, t)$  are the bending stiffness, the mass per unit length, and the force acting in the structure are assumed to be constant whereas the vehicle-bridge interactions are neglected, then the moving load model HSMA-A is chosen here, which is expressed as follows:

$$p(x, t) = \sum_{k=1}^N P_k \left( H \left( t - \frac{d_k}{c} \right) - H \left( t - \frac{d_k + L}{c} \right) \right) \delta(x - ct + d_k) \quad (2d)$$

The loads presented through Dirac delta function acting along  $(x_v = ct - d_k)$ , where  $c$  is the constant train speed,  $d_k$  is the distance when  $t = 0$  from the  $k$ th to the entrance of the beam,  $N$  is the total number of axle loads,  $P_k$  the value of the  $k$ th load,  $H$  is the Heaviside function and  $L$  stands for the beam length.

$W_{r,i}$   $i = 0, L$  are the general work done by the moments at the boundary sections  $x = 0, L$ , and the moment at these sections are obtained by

$$M_{r,0} = -\frac{\partial W_{r,0} \left( \frac{\partial v}{\partial x} \right)}{\partial \left( \frac{\partial v}{\partial x} \right)}, \quad M_{r,L} = \frac{\partial W_{r,L} \left( \frac{\partial v}{\partial x} \right)}{\partial \left( \frac{\partial v}{\partial x} \right)} \quad (3a)$$

Where  $W_{r,0} \left( \frac{\partial v}{\partial x} \right) = -\frac{1}{2} K_r \left( \frac{\partial v}{\partial x} \right)_{x=0}^2$ ,  $W_{r,L} \left( \frac{\partial v}{\partial x} \right) = -\frac{1}{2} K_r \left( \frac{\partial v}{\partial x} \right)_{x=L}^2$  (3b)

With  $K_r$  is the stiffness of the rotational springs which are identical in this present model, in the same context, the strain energy due to internal axial forces  $N$  and the strain energy produced by the shear force  $V$  is neglected according to the Euler-Bernoulli beam theory. Introducing Eqs. (2) and (3) into Eq. (1) and integrating by parts lead to Eq. (4):

$$\int_{t_1}^{t_2} \left\{ \int_L \left( EI \frac{\partial^4 v}{\partial x^4} - k_s \frac{\partial^2 v}{\partial x^2} + m \frac{\partial^2 v}{\partial t^2} - p \right) \delta v \, dx - \left[ V - k_s h^2 \frac{\partial v}{\partial x} \right]_0^L \delta v - [M - M_r]_0^L \delta \theta \right\} dt = 0 \quad (4)$$

With  $M$ ,  $V$  are the total bending moment and the total shear force defined by

$$M = EI \frac{\partial^2 v}{\partial x^2}; \quad V = EI \frac{\partial^3 v}{\partial x^3} \quad (5)$$

With  $m = \rho A$ .

As the variations  $\delta v$ ,  $\delta \theta$  must vanish at the  $t_1$  and  $t_2$  according to Hamilton's principle, the partial differential governing equation of the system is given by

$$EI \frac{\partial^4 v}{\partial x^4} - k_s \frac{\partial^2 v}{\partial x^2} + m \frac{\partial^2 v}{\partial t^2} = p(x, t) \quad (6a)$$

With the pertaining boundary conditions

$$\left( EI \frac{\partial^3 v(x, t)}{\partial x^3} - k_s \frac{\partial v(x, t)}{\partial x} \right) \delta v_{x=0}^L + \left( EI \frac{\partial^2 v(x, t)}{\partial x^2} - M_r \right) \delta \frac{\partial v^L}{\partial x_{x=0}} = 0 \quad (6b)$$

As mentioned in the Eqs. (6b), it is evident that the beam affected by the presence of the moments ( $M_{r,0}, M_{r,L}$ ) due to the rotational springs and the axial force, were ( $M, V$ ) are the total moment and the total shear force in the considered beam.

As mentioned in the introduction, the interest is to analyze the continuity of the ballasted track in the maximum peak bridge dynamic response (acceleration, displacement) due to the rail traffic as a criterion for the ballast stability in the case of ballasted track. However, as the

frequency band should range from 0 to 30Hz in the dynamical analysis, this is as a reason which allows this limitation of the frequency range, why we use the mode superposition method for solving the equation of motion Eq. (6a), which the general solutions expressed as follows

$$v(x, t) = \sum_{i=1}^{N_m} \Phi_i(x) q_i(t) \quad (7)$$

Where  $\Phi_i$  is  $i$ th the mode shape which depends on the boundary conditions, and  $q_i$  is the time functions response of the beam and  $N_m$  stands for the number of the considered modes.

## 2.1 Simply supported partially clamped beam

As known for a simply supported beam, the mode shape is a sinusoidal function and following the same procedure, attaching the simply supported beam with two rotational springs introduce end moments at the supports. Fig.1 shows the model of a simply supported beam leaning on identical rotational spring with identical rotational stiffness which is constant and equal to  $K_r$ .

From the eq. (7) which is the vertical deflection of the beam, by using the equations 6(a) and 6(b) the mode shapes and the frequency equation of the uniform simply supported partially clamped beam, the frequency equation is given by

$$\frac{4k^2(r_1L)(r_2L)}{\sqrt{\Delta}L^2} (\cosh(r_1L)\cos(r_2L)-1) + k(r_2L)\cos(r_2L)\sinh(r_1L) - k(r_1L)\cosh(r_1L)\sin(r_2L) - \left( \frac{16k^2k_b + (\sqrt{\Delta}L^2)^2}{8\sqrt{\Delta}L^2} \right) \sin(r_2L)\sinh(r_1L) = 0 \quad (8)$$

With

$$\Delta = \left( \frac{k_s}{EI} \right)^2 + \frac{4m\omega_i^2}{EI} ; r_1 = \sqrt{\frac{\sqrt{\Delta} + \frac{k_s}{EI}}{2}} ; r_2 = \sqrt{\frac{\sqrt{\Delta} - \frac{k_s}{EI}}{2}} ; k_b = \frac{k_s L^2}{EI} ; k = \frac{K_r L}{4EI} \quad (9)$$

The parameters  $k$  and  $k_b$  are the ratio of the rotational stiffness of the rotational springs to the flexural rigidity of the beam, and the ratio of the axial force to the flexural rigidity of the beam, respectively.

The stiffness and flexural strength of the abutments should be analyzed in detail for each particular structure. Nevertheless, from the retrofit studies performed by the authors on real

cases, it can be concluded that stiffness and flexural strength of abutments will be usually railway structures [1].

As shown in equation (8), if we neglected the influence of the axial force ( $k_b = 0$ ), the equation becomes

$$2k^2 \cosh(rL) \cos(rL) - 2k^2 + krL \sinh(rL) \cos(rL) - krL \cosh(rL) \sin(rL) - \frac{(rL)^2}{4} \sinh(rL) \sin(rL) = 0 \quad (10).$$

Which is the same frequency equation founded in [14] with the root  $rL = rL(k)$  and  $rL = \pi \sqrt{\frac{\omega_i}{\omega_{ss}}}$ .

The analytical model shape expressed as follows

$$\psi_i(x) = B_i \left( b_1 \left( \cosh \left( r_1 L \frac{x}{L} \right) - \cos \left( r_2 L \frac{x}{L} \right) \right) + \sin \left( r_2 L \frac{x}{L} \right) \right) + \left( b_1 \left( \cosh \left( r_1 L \frac{x}{L} \right) - \cos \left( r_2 L \frac{x}{L} \right) \right) + \sin \left( r_2 L \frac{x}{L} \right) \right) \quad (11a)$$

$$\text{Where } B_i = - \frac{b_1 (\cosh(r_1 L) - \cos(r_2 L)) + \sin(r_2 L)}{a_1 (\cosh(r_1 L) - \cos(r_2 L)) + \sinh(r_1 L)} \quad (11b)$$

$$\Phi_i(x) = \frac{\psi_i(x)}{\max(\psi_i(x))} \quad (11c)$$

$$\text{And } \eta_1 = \frac{4k}{(r_1 L)_i} ; \eta_2 = \frac{4k(r_2 L)_i}{(r_1 L)_i^2} ; x_1 = \left( \frac{(r_2 L)_i}{(r_1 L)_i} \right)^2 ; a_1 = \frac{\eta_1}{1+x_1} ; b_1 = \frac{\eta_2}{1+x_1} \quad (11d)$$

Finally, introducing the Eqs. (7) and (12c) into the Eq. (6a) and multiplying by the  $j$ th mode  $\Phi_j(x)$  with integration over the length of the beam  $L$ , the  $i$ th modal equation of motion is obtained by using the orthogonality conditions, and by introducing a modal damping ratio  $\xi_i$ , the modal damped equation of motion is expressed as:

$$\ddot{q}_i(t) + 2\xi_i \omega_i \dot{q}_i(t) + \omega_i^2 q_i(t) = \frac{1}{M_i} \sum_{k=1}^N \left( H \left( t - \frac{d_k}{c} \right) - H \left( t - \frac{d_k + L}{c} \right) \right) P_k \Phi_i(ct - d_k) \quad (12)$$

Where  $M_i$  is modal mass associated to the  $i$ -th mode

$$M_i = m \int_0^L \Phi_i^2(x) dx = \rho A \int_0^L \Phi_i^2(x) dx \quad (13)$$

$\omega_i$  Represents the  $i$ th circular frequency in  $rad/s$ .

## 2.2 Free vibration of simply supported partially clamped beam

As can be seen, the mode shape (Eq.11) composed by symmetric and axisymmetric modes, we used this expression, if we neglected the damping effect, the solution of the equation of motion of simply supported partially clamped beam for each value of  $r_j L = r_j L(k, k_b)$   $j = 1, 2$  subjected to moving load can be derived as follows

$$\begin{aligned} \frac{q_i(t)}{q_{st}} = B_i & \left[ \frac{\eta_1}{1+x_1} \frac{(\cosh(O_{i1}t) - \cos(\omega_i t))}{1+K_{i1}^2} + \frac{(\sinh(O_{i1}t) - K_{i1} \sin(\omega_i t))}{1+K_{i1}^2} - \frac{\eta_1}{1+x_1} \frac{(\cos(O_{i2}t) - \cos(\omega_i t))}{1-K_{i2}^2} \right] \\ & + \left[ \frac{\eta_2}{1+x_1} \frac{(\cosh(O_{i1}t) - \cos(\omega_i t))}{1+K_{i1}^2} - \frac{\eta_2}{1+x_1} \frac{(\cos(O_{i2}t) - \cos(\omega_i t))}{1-K_{i2}^2} + \frac{(\sin(O_{i2}t) - K_{i2} \sin(\omega_i t))}{1-K_{i2}^2} \right] \quad 0 \leq t \leq L/c \end{aligned} \quad (14)$$

Where  $q_{st}$  is the static solution which is

$$q_{st} = \frac{P}{\omega_i^2 m \int_0^L \Phi_i^2(x) dx} \quad (15)$$

$$\text{And } O_{i1} = \frac{(r_1 L)_i c}{L}; O_{i2} = \frac{(r_2 L)_i c}{L}; K_{i1} = \frac{O_{i1}}{\omega_i}; K_{i2} = \frac{O_{i2}}{\omega_i} \quad (16)$$

The speed parameters  $K_{i1}$  and  $K_{i2}$  are defined by the ratio of the load frequencies,  $O_{i1}$  and  $O_{i2}$  the simply supported partially clamped beam circular frequency  $\omega_i$ ,  $c$  is the speed of the moving load,  $B_i$ ,  $\eta_1$ ,  $\eta_2$  and  $x_1$  are defined in the Eq. (11d),  $(r_1 L)_i$  and  $(r_2 L)_i$  are the roots of the frequency equation correspond to the  $i$ th mode, which is equal in the case of axial force is neglected ( $k_b = 0$ ).

To understand the effect of the axial force in the case of free vibration of a simply supported partially clamped composite beam, as derived in [3] by using the analytical mode shapes of the considered beam, the amplitude of the  $i$ th modal response of the beam after the passage of a unit constant load  $P$  at a constant speed  $c$  in the so-called free vibration phase normalized by the static solution is computed by [3]

$$R_i = \frac{1}{q_{st}} \sqrt{\frac{\dot{q}_i(t=L/c)^2}{\omega_i^2} + q_i(t=L/c)^2} \quad (17)$$

Where  $q_i(t=L/c)$  and  $\dot{q}_i(t=L/c)$  are the initial conditions for the free vibration phase correspond respectively to the  $i$ th modal deflection of the beam and its derivative  $t = L/c$  dur-

ing the forced vibration phase,  $0 \leq t \leq L/c$ . Analytical expressions of these quantities are derived in Eq. (14). Then as can be observed, this equation at  $t = L/c$  is only dependents on the parameters  $k$  which is the ratio of the stiffness of the rotational springs to the flexural stiffness of the beam, the beam length  $L$  and its flexural stiffness  $EI$ , the two no dimensional speed  $K_{i1}$  and  $K_{i2}$  which are defined in the Eq.(16) and the  $k_b$  which is the ratio between of the axial force and the beam bending stiffness.

### 3 NUMERICAL RESULTS

In this section, two cases study is presented, dynamic response of simply supported beam and dynamic response of partially clamped beam, to investigate the effect of the continuity of the ballast track and the axial force in the dynamic response of the aforementioned structure.

#### 3.1 Simply supported beam

the dynamic response of a simply supported and simply supported partially clamped beam is analyzed, the Vinival Bridge [13] is a simply supported, single-track bridge, the main mechanical properties are cited in the Table. 1, in which these properties schematize the total properties of the bridge (include the mass of the track superstructure), the height of the ballast in this bridge is computed by  $h_b = 0.52m$ , then the dynamic response of the bridge under the circulation of High-Speed Load Model-A (HSLM-A) is presented and the maximum dynamic response takes place at mid-span section [14], as noted in the Eurocode and accounting for modes with natural frequencies below  $30Hz$ , Fig .2 shows the maximum vertical acceleration in terms of the circulating velocity in the range  $[140,310]km/h$  every  $1km/h$ . The maximum vertical acceleration reaches  $6.16m/s^2$  and occurs when the train HSLM-A2 crosses the bridge at  $220km/h$  which corresponding to the fourth resonance of the first bending mode. For these reasons, in the following section, the dynamic response of the bridge will be accounted for by the passage of the train A2.

From Table.1, the main properties are calculated considering the mass and the inertia of the track superstructure which is composed of rails, sleepers, and ballast.

Length $L(m)$	9.70
Mass per unit length, $kg/m$	9754
Natural frequency, $f_{0b}(Hz)$	12.8
Modal damping ratio, $\xi(\%)$	2

Table1: mechanical properties of the considered bridge [13]

Besides, the axial force has the following value:  $k_s = 5.37MN$  (18)

The dynamic response of the bridge under the load model HSLM-A2 is evaluated in the time domain with taking into account the first mode of vibration (allow the Eurocode criterion), the figs. 2 (a) and 2(b) show the vertical acceleration and displacement of the bridge at mid-span section, The blue line in the two figures shows the variation of the acceleration and displacement without taking into account the effect of axial force, and the red line shows the variation of the acceleration and displacement with taking into account the axial force with the mentioned value (Eq. 18). From this figure, it can be concluded that critical speed increases as the axial force are introduced, which explain that the axial force such as bracing force, axial displacement introduces a remarkable stiffness (additional stiffness) to the structure which increases the critical velocity, and the displacement amplitude of vibration decreases, especially in the vicinity of resonance at the critical speed  $220 km/h$  which corresponding to a fourth resonance of the first bending mode.

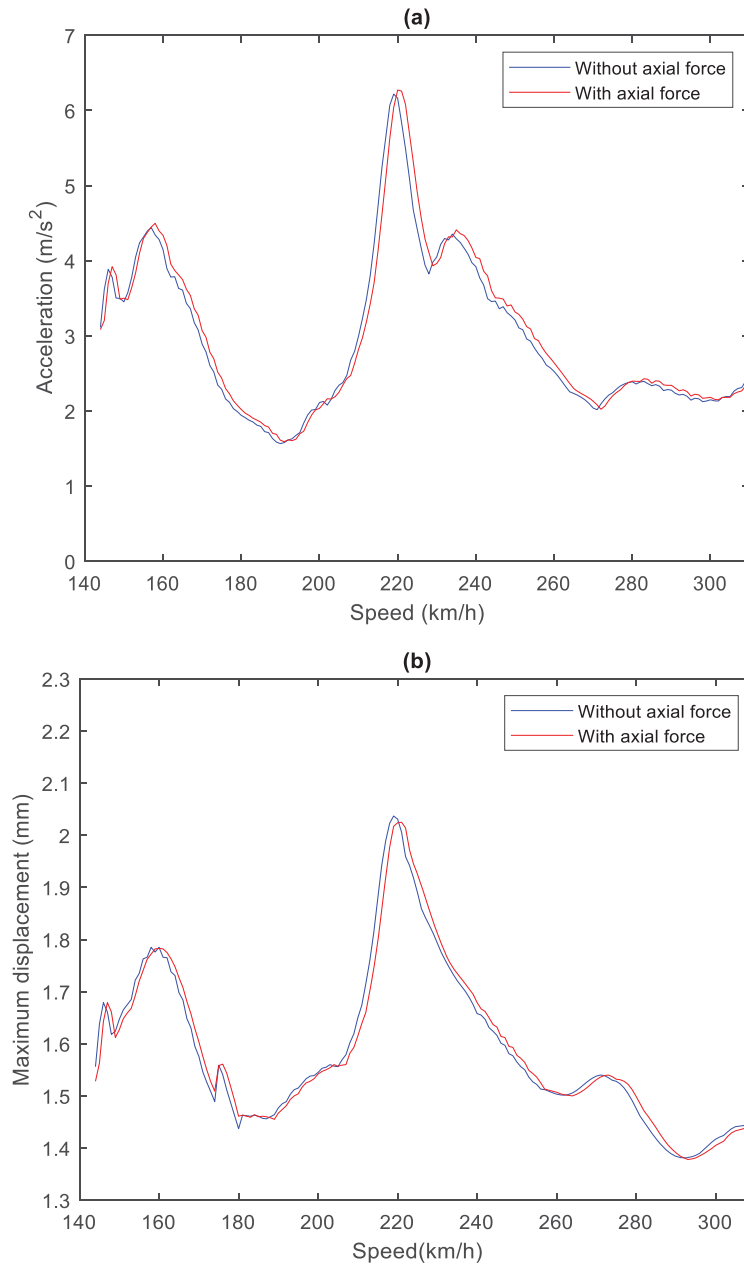

Figure 2: Dynamic response of the beam at mid-span section as a function of the speed of HSLM-A2  
(a) Acceleration, (b) displacement.

### 3.2 Simply supported partially clamped beam

In the following part, as cited in the literature remarkable scientific contributions focused to study the effect of ballast in the response of simply supported bridge, but as the continuity of track introduces a moment of resistance at the beam ends an influence can occur, it is important to study this effect by modeling the bridge as a partially clamped beam schematized by two identical linearly rotational springs attached to the beam ends, to ensure this continuity of the track.

As demonstrated in Eq. (17) the normalized amplitude of the free vibrations of the simply supported partially clamped beam depends on two parameters  $(k, k_b)$ , which represent the effect of the rotational springs and the effect of the axial force. Figure 3 represents the first modal response amplitude of the simply supported partially clamped beam as a function of the speed parameters  $K_{11}$  (Eq. 16)  $k=1.1$ , which represents the ratio between the stiffness of the rotational springs and the beam bending stiffness and which means that the fundamental frequency of the partially clamped beam increases by 50%, with the value of  $k_b$  in the range  $[0, 5k_b]$ . The value  $k_b$  is calculated by using the value of axial force (Eq.18) which corresponds to the value  $k_b = 0.1255$ .

Figure 3: First modal response amplitude vs the speed parameters.

Then as shown in Fig.3, in the case of free vibration of simply supported partially clamped beam, as the ratio  $k_b$  increases, the speed parameters  $K_{11}$  increases which correspond to an increase in the critical speed.

In the case of forced vibration, due to higher modes have frequencies above  $30\text{Hz}$ , the response of the beam is computed from the contribution of its first bending mode, the Figs. 4(a) and 4(b) represent the displacement and acceleration of the simply supported partially clamped beam at the mid-span section of the bridge under the circulation of HSLM-A2 for circulating velocities in the range  $[150, 350]\text{km/h}$  in steps  $1\text{km/h}$ , this wide range of velocities permits the occurrence of a second resonance of the fundamental bridge frequency. Then, from this figure, in comparison with the section (3.1) for a simply supported beam, the critical speed corresponds to  $v_c = 220\text{km/h}$  which theoretical is  $v_{i=1,n=4}^{\text{Res}} = \frac{f_{ss}D}{4} = \frac{12.8.19}{4}.3.6$  [15-16], where  $f_{ss}$  is the fundamental frequency of the SS beam,  $i$  the model number,  $n$  the resonance number and  $D=19\text{m}$  is the characteristic distance of the train HSLM-A2, corresponds to the fourth resonance of the fundamental mode. In the same context, by fixing the value  $k=1.1$ , the fundamental frequency of the beam is changed, due to the rotational spring's stiffness and corresponds to  $\omega_1 = 1.5\omega_{ss}$  which leading to  $f_1 = 19.2\text{Hz}$  the value  $k_b = 0$ . Also, as it can be seen, for  $k_b = 0$  the maximum acceleration reaches the value  $5.21\text{m/s}^2$  which corresponding to a critical velocity  $v_c = 1.5v_{i=1,n=4}^{\text{Res}} = 330\text{km/h}$ , for  $k_b = 5 \times 0.1255$  the acceleration is attained  $5.24\text{m/s}^2$  which corresponding to the critical velocity  $v = 333\text{km/h}$ , the thing explains that for a fixed value  $k=1.1$ , the peak of resonance increases as the ratio  $k_b$  increases. Also, for the displacement, we can conclude that as the ratio  $k_b$  increases the displacement amplitude decreases, and critical velocity increases. Then, this is the same conclusion found in section (3.1) which indicates that the axial force introduces an additional stiffness and independent of the boundary conditions of the beam.

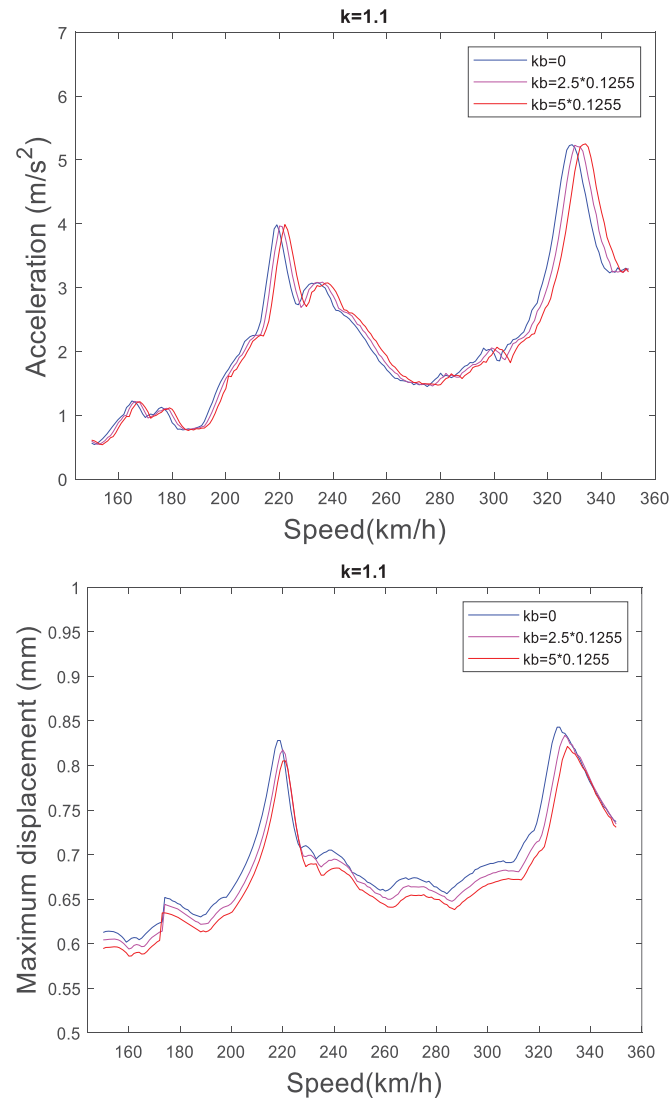

Figure 4: Dynamic response of the beam at mid-span section as a function of the HSLM-A2  
(a) Acceleration, (b) displacement; effect of  $k_b$ .

Figure 5: Acceleration as a function of the stiffness ratio  $k$ .

Another parameter that should be also analyzed is the effect of the rotational stiffness due to the rotational springs located at the beam ends, Fig. 5 represents the variation of the acceleration at the mid-point section of the simply supported partially clamped beam under the passage of HSLM-A2 at the critical velocity, as a function of the ratio  $k$  for a fixed value of the ratio  $k_b = 0.1255$ , from this figure we conclude that as the stiffness ratio  $k$  increases, the vertical acceleration decreases, which means that the continuity of track as its rigidity increases the vertical acceleration decreases independent of the influence of the axial forces.

#### 4 CONCLUSION

To summarize, the dynamic response of a simply supported uniform beam and a simply supported partially clamped beam have been studied, with take into account the axial forces and the continuity of the track effects, the results indicate that the axial forces introduce an additional stiffness which modifies the critical velocity and the continuity of the ballast affects largely only the vertical acceleration of the bridge.

### Abstract

*The use of design spectra is common practice in earthquake engineering design as opposed to wind-resisting design. Nonetheless, previous research has identified ways to map such technique to study wind effects on structures. The present investigation introduces a novel framework to deal with the dynamic performance of infrastructure subject to thunderstorm downbursts. It builds on recent developments that demonstrate that spectral analysis is applicable to wind engineering given various equivalences developed to quantify random loading generated through non-synoptic wind environment. The new framework is tested on a benchmark building via a simplified model, which demonstrates its validity. In this framework, the dynamic response of the multi-degree-of-freedom (MDOF) system subjected to non-stationary wind can be obtained assuming that the first mode of vibration is dominant when the mechanical properties of the structure and aerodynamic characteristics of the thunderstorm downburst are identified.*

**Keywords:** Wind design spectrum, Wind-excited response, Thunderstorm downburst, Non-stationary wind, Multi-degree-of-freedom system

---

## 1 INTRODUCTION

The potentially destructive effect of thunderstorm downbursts on structures raises concerns amongst societies for the safety and serviceability of infrastructure. The recorded highest microburst wind reached up to 150 mph, which is in the range of an EF3 tornado [1] with potentially severe damage to the buildings. The peak velocity of such events locates between 30m and 100m above the ground [2, 3], hence covering the height of critical civil engineering infrastructure. The study of the wind actions and damages on structures induced by the downburst outflows becomes crucial for the current wind engineering design.

Various researchers in the past have discussed the downburst wind load and the dynamic response of structures, see for example [4-9]. However, they acknowledge that the transient properties and limited measurements of this complex phenomena make its study uncertain and challenging, starting from the characterisation of the unsteady wind load. Considering the limited experimental measurements of the thunderstorm downburst, the wind field of these typical characteristics has been simulated through hybrid models [5, 6, 10], based on the theoretical velocity profiles. The state of the art is therefore limited to specific yet disperse techniques to estimate wind loading of thunderstorm downbursts.

The short duration and instantaneous properties of the downburst outflow lead to similarities with earthquake loads which are generally evaluated by the response spectra technique [11-13] – widely used in the past to deal with random vibrations, where the structural performance was combined with the inter-storey displacement and roof displacement ductility of the buildings. The proposed framework merges the response spectral technique applied in earthquake engineering with a refined characterisation of wind loads [14, 15]. It revisits the originally developed wind design spectra [16, 17] for the structural vibrations of regular buildings subjected to stationary wind to enhance that basic methodology to study non-stationary wind events.

## 2 MATHEMATICAL FRAMEWORK UNDERPINNING WIND DESIGN SPECTRA

Martinez-Vazquez [17] dealt with the wind design spectra for regular prismatic buildings subjected to stationary wind. The method requires the generalisation of force exerted by wind, structural mass, and stiffness, as well as the characterisation of partially correlated wind fields and its interaction with bluff bodies, to then apply classic spectral techniques for generating design spectra. The design spectra could be used to analyse MDOF systems via modal analysis, which unfolds the response of the oscillators (implicit in the design spectra) to capture the contribution of higher-order modes. The following paragraphs describe how the original formulation by Martinez-Vazquez [17] was tailored to thunderstorm downbursts.

The method departs from establishing the physical relationship between force and acceleration as established by Newton's Second Law on a vertical slender structure – see Eq. (1)-(2). The relationship enables the spectra of the input acceleration induced by the wind on a MDOF system, to be determined. The force spectrum being the scaled wind power spectrum.

$$S_F(z, n) = q^2(z) S_{\tilde{u}'}(z, n) \quad (1)$$

$$S_A(z, n) = \left( \frac{q(z)}{m} \right)^2 S_{\tilde{u}'}(z, n) \quad (2)$$

In these equations,  $S_F$  is the force spectra;  $S_{\tilde{u}'}$  is the power spectra for reduced horizontal fluctuating velocity component  $\tilde{u}'$ , i.e.,  $n S_{\tilde{u}'}(z, n) = \frac{18f}{[1+27f]^{5/3}}$ , where  $f = nz/\bar{U}_{max}(z)$  [18] and  $\bar{U}_{max}$  is the maximum value of the slowly varying mean velocity;  $S_A$  is the input acceleration spectra, i.e., the acceleration imparted by the wind to the structural system;  $m$  is the mass

of the structure excited by the wind force;  $n$  is the frequency of gust wind;  $z$  is the height above the ground;  $q$  is a force factor, expressed as,

$$q(z) = c_D \rho A \bar{U}_{max}^2(z) [1 + 0.5 \bar{I}_u(z)] \bar{I}_u(z) \quad (3)$$

In Eq. (3),  $c_D$  is the drag coefficients,  $\rho$  is the air density,  $A$  is the air exposed to wind,  $\bar{I}_u$  is the slowly varying mean turbulence intensity. It needs to note that the force factor is purely induced by fluctuating turbulence where the fluctuating force  $f' = 0.5 c_D \rho A (2 \bar{U} u' + u'^2)$ . In this case, The second-order term of the fluctuating turbulence,  $u'^2$ , is replaced by  $\sigma_u u'$  to simplify the calculation process, i.e.,  $2 \bar{U} u' + u'^2 = (2 \bar{U} + u') u' \approx (2 \bar{U} + \sigma_u) \sigma_u \tilde{u}' \approx (2 \bar{U} + I_u \bar{U}) I_u \bar{U} \tilde{u}'$ .

Considering the spatial correlation of wind gusts on MDOF system, the normalized cross spectra proposed by Davenport [19] is adopted, given in Eq. (4).

$$\chi(z, n) = \exp \left\{ - \frac{n}{1/2 [\bar{U}_{max}(z_i) + \bar{U}_{max}(z_j)]} \sqrt{(C_y \Delta_y)^2 + (C_z \Delta_z)^2} \right\} \quad (4)$$

In Eq. (4),  $\Delta_y$  and  $\Delta_z$  are the horizontal and vertical distances between two points,  $i, j$ , located at coordinates  $\{y_i, z_i\}$  and  $\{y_j, z_j\}$  respectively.  $C_y$  and  $C_z$  are non-dimensional decay constants along with the horizontal and vertical directions, in this case, assumed equal to 10.  $\bar{U}_{max}(z_i)$  and  $\bar{U}_{max}(z_j)$  represent the maximum value of the slowly varying mean velocity at height  $z_i$  and  $z_j$ , respectively. In this case, we adopted the suggested shape function for the vertical velocity profile of horizontal wind suggested by Wood, et al. [20].

It follows that, by combining the spectra of input acceleration given in Eq. (2) with the cross spectra of the horizontal turbulence component given in Eq. (4), the cross-spectrum of the input acceleration can be obtained, see Eq. (5).

$$S_{A_{ij}}(z_i, z_j, n) = \frac{1}{m^2} q(z_i) q(z_j) \sqrt{S_{\tilde{u}'}(z_i, n) S_{\tilde{u}'}(z_j, n)} \frac{1}{A^2} \chi(z_i, z_j, n) \quad (5)$$

The integration of Eq. (5) across the area exposed to wind flow, contributes to the power spectral density of the generalised input acceleration  $S_{cu}(z_i, z_j, n)$ , given in Eq. (6).

$$S_{cu}(z_i, z_j, n) = \iint_A \phi(z_i) \phi(z_j) S_{A_{ij}}(z, n) dy_i dy_j dz_i dz_j \quad (6)$$

In Eq. (6),  $\phi(z)$  represents the fundamental modal shape at height  $z$  above the ground. This provides the acceleration inputted to a system, therefore the variance of the overall spectral response can be obtained by passing the signal through the transfer function, as shown in Eq. (7). The integration of this equation can be done in two parts, to separate the background and resonant response components. This is expressed in Eq. (8) and Eq. (9) [15]. In this model, we adopt the transfer function with varying frequency ratio for wind excitation given in units of acceleration, i.e.,  $J(n) = \frac{1}{\sqrt{[1 - (n/n_0)^2]^2 + 4\xi^2(n/n_0)^2}}$  ( $n$  is the frequency of the wind,  $n_0$  is the natural frequency of structures,  $\xi$  is the damping ratio) - derived by Martinez-Vazquez [16].

$$\sigma_a^2 = \int_0^\infty |J(n)|^2 S_{cu}(z_i, z_j, n) dn \quad (7)$$

$$\sigma_{a,b}^2 = \int_0^\infty S_{cu}(z_i, z_j, n) dn \quad (8)$$

$$\sigma_{a,r}^2 = S_{cu}(z_i, z_j, n_0) \int_0^\infty |J(n)|^2 dn \cong \frac{\pi n_0 S_{cu}(z_i, z_j, n_0)}{4\xi} \quad (9)$$

Furthermore, the design spectra of the output acceleration can be evaluated by the square root of the sum of the background component (see Eq. (8)) and the resonant component (see Eq. (9)). Therefore, the design spectra for vertical MDOF system are defined as Eq. (10).

$$S_a = \sqrt{\sigma_a^2} = \sqrt{\sigma_{a,b}^2 + \sigma_{a,r}^2} \quad (10)$$

### 3 ESTIMATION OF WIND DESIGN SPECTRA

The input variables of the wind design spectra are investigated based on the building dimensions with the width of 20m, the aspect ratio of 10, and the ratio between chord and width of 1. The damping ratio of this building is 0.025 and the assumed height of peak velocity of downburst wind is 50m. The reference velocity at 10-metre height above the ground is set as 25m/s. Then, the overall design spectra of the output acceleration with varying  $\bar{U}_{max,10}$  is shown in Figure 1 (a) with varying natural period,  $T$ . According to the properties of the structures, it is reasonable to assume that the investigating range of the natural frequency changes from 0.1Hz to 10Hz and the corresponding range of the natural period varies from 10s to 0.1s. When the natural frequency of the structure matches 0.2, the overall design spectra of the output acceleration at 50m/s is about 5 times higher than the counterpart at 25m/s. When the natural frequency reduces to 0.1, the ratio of the overall design spectra at 50m/s and 25m/s is around 5.4.

The dimensions of the structure are also non-negligible, shown in Figure 1(b) for the aspect ratio,  $H/W$  and Figure 1(c) for the ratio of  $L/W$ . The descending dimensions of the structures relative to the structural width can lead to higher design spectra for both ratios of  $H/W$  and  $L/W$ , since lower structures have higher natural frequency with high acceleration. For the natural frequency of 0.2, the ratio of the design spectra when  $H/W = 1$  and  $H/W = 10$  is around 4.2. The ratio of these decreases to 4.0 for the natural frequency of 0.1. Similarly, the ratio of the design spectra when  $L/W = 0.4$  and  $L/W = 2$  is around 5.1 and 5.0 for  $n_1 = 0.2$  and  $n_1 = 0.1$  respectively. This tendency demonstrates that when the natural periods of the structures increase from 5 to 10, the effects of the input parameters mitigate.

A slight influence of the height of peak velocity can be observed in Figure 1 (d), since the height of peak velocity approaching the top of the building can increase the velocity at the top of the building. Therefore, the reference velocities of the downburst outflow and the dimensions of the structures are important parameters for the design spectra of the output acceleration.

## 4 DYNAMIC RESPONSE OF CAARC TALL BUILDING

### 4.1 CAARC tall building

The CAARC benchmark building is utilized in this section for the validation of the wind design spectra. The CAARC building was experimentally analysed in five different laboratories and has been regarded as a standard prototype of the tall building to study on the dynamic analysis [21]. The dimensions of the building are shown in Figure 2. The natural frequency of the building is 0.2Hz along the x and y direction. The fraction of the critical damping equals 0.01 and the mass per unit volume of the building is  $160 \text{ kg} \cdot \text{m}^{-3}$ . The turbulence intensity at the top of the building is around 10.57% and a linear relationship of the turbulence intensity with varying height is assumed, where the turbulence intensity at height of 0.5H is around 13.34%.

Figure 2: The dimensions of the CAARC benchmark building.

## 4.2 Application of wind design spectra and validation

The CAARC building was assumed as a uniform cantilever structure with a series of single-degree-of-freedom (SDOF) oscillators. This building is equally divided into 18 elements with 19 nodes in the vertical directions of the domain, i.e.,  $z_i = (i - 1) \times 9.89m, i = 1, 2, \dots, 19$  starting from 5m to 183m (see Figure 2). In running a modal spectral analysis (where the proposed design spectra fit), the dynamic displacement response,  $\sigma_d$  (rms of dynamic displacement), can be obtained by using Eq. (11). In addition, the static displacement response of the structure can be obtained with Eq. (12) which is the ratio of the first modal static force (Eq. (13)) and the first modal stiffness  $k_1 = 4\pi^2 n_1^2 m_1$ .

$$\sigma_{1d}(z) = \phi_1(z) \frac{L_1 S_a}{m_1 (2\pi n_1)^2} \quad (11)$$

$$d_{1s}(z) = \frac{\bar{f}_1(z)}{k_1} \quad (12)$$

$$\bar{f}_1(z_i) = c_D \times 0.5 \rho W \bar{U}_{max}^2(z_i) \sum_1^i \left[ \int_{z_i}^{z_{i+1}} \alpha^2(z) \phi_1(z) dz \right] \quad (13)$$

In these equations,  $\phi_1$  is the first modal amplitude at height  $z$  and can approximately take the form  $\phi_1(z) = (z/H)^\psi$  with  $H$  representing the vertical dimension of structures. The constant  $\psi$  is taken as 1 in this case since a frame structure with large columns and shear bracings is considered [22]. Further variables  $n_1$ ,  $m_1$  and  $L_1$  represent the first natural frequencies, first modal mass,  $m_1 = \int_0^H m_l(z) \phi_1^2(z) dz$  (where  $m_l$  is the structural mass per unit height), and first modal excited masses,  $L_1 = \int_0^H m_l(z) \phi_1(z) dz$ , respectively. In Eq. (13),  $i$  represents the  $i$ -th number of recorded velocity time history and  $\alpha(z) = \bar{U}_{max}(z)/\bar{U}_{max}(z_i)$  which is the non-dimensional vertical shape profile of horizontal wind. Finally, the peak displacement response can be obtained by  $d_{1T}(z) = d_{1s}(z) + \sigma_{1d}(z)$ .

The displacements at the top of the building calculated from the wind design spectra are shown in Table 1. In Eq. (4), the correlation function in both vertical and transverse directions of the windward surface of the building is considered. The results from the design spectra combined with the partially correlated function only in vertical direction are also demonstrated in Table 1, where the oscillation amplitude of the displacement at the top of the building in  $x$

direction, i.e., 0.351m, is larger than 0.328m since the correlation in the transverse direction is considered as full correlation, that is the same consequences as the displacement response in y-direction where the counterpart is 0.206m which is higher than 0.196m. Higher correlation can cause higher displacement amplitude of the oscillation. The peak displacements calculated from the simulated wind field using time series analysis methods, i.e., the Newmark method (M1) and interpolation of excitation method (IOE, M2) (detailed in Chopra [23]), are illustrated in Table 1, where the results are slightly higher than those from the wind design spectra.

Direction	Design spectra for thunderstorm downburst					Num. Int. (M1)	Num. Int. (M2)
	Davenport's coherence (vertical and horizontal)			Partial correlated (vertical only)		Partial correlated (vertical only)	
	Static	Dynamic	Total	Dynamic	Total	Total	Total
x	0.200	0.128	0.328	0.151	0.351	0.435	0.434
y	0.112	0.084	0.196	0.094	0.206	0.244	0.243

Table 1: Lateral displacements at the top of the building (Unit: metre).

## 5 CONCLUSIONS

This paper presents a newly developed design spectra technique in the frequency domain subjected to thunderstorm downburst which attempts to extend the successful performance-based design philosophy to wind engineering application. The investigation for the input parameters of the design spectra illustrates that the design spectra of the output accelerations significantly rise with the increasing velocities of the downburst outflow, and obviously mount with the decreasing aspect ratio and cross-sectional ratio of the buildings. The consistent comparison between the results of the wind design spectra in frequency domain and the equivalent numerical simulation in time domain for the benchmark tall building enable design spectra technique to be developed, assuming that the displacement response is mainly reflected on the first mode. This technique identifies the mechanical properties of the structure and aerodynamic characteristics of the outflow winds, which enable to obtain the structural performance for MDOF oscillators. Further validations of the proposed design spectra by using the finite element method will be carried out.

### Abstract

*Tapered beams like structures are widely used in many fields including mechanical and civil engineering, such as high-rise buildings, robot arms, etc. The objective of this paper is to study the geometrically nonlinear free and forced transverse vibrations of tapered beams with a constant width and a linearly varying depth. The theoretical model is based on the Euler-Bernoulli beam theory and the Von Kármán assumptions for geometrical nonlinearity. The motion is assumed to be harmonic and the transverse displacement function of the nonlinear beam is expanded as a series of linear modes, determined by solving the linear problem in terms of Bessel functions satisfying the boundary conditions. The discretized expressions for total beam strain and kinetic energies are derived, and by application of Hamilton's principle, the problem is reduced to a non-linear algebraic system solved using a previously developed approximate method (the so-called second formulation). The effect of the linear variation of depth on the non-linear behaviour of the beam is examined and then illustrated. Using the single-mode approach, the non-linear dynamic behaviour of the tapered beam is studied in the forced case. The effects of the excitation level of the applied harmonic force are investigated and illustrated for various scenarios.*

**Keywords:** tapered beam, transverse vibrations, nonlinear vibrations, forced vibrations

---

## 1. INTRODUCTION

In civil engineering, aeronautics or mechanical engineering, the beams used are commonly non-uniform. This type of beams are often subjected to free or forced vibrations, especially in some applications such as aircraft wings or steel structures. Many works have been devoted to the dynamic behaviour of tapered beams under different boundary conditions and both the Euler-Bernoulli and Timoshenko beam's theory have been used.

The literature review may go back to [1], in which Sanger exposed a general solution in terms of Bessel function of order  $n$  for a range of beams, for different classical boundary conditions as a fixed end, a simply supported end, etc. Goel studied in [2] the transverse vibrations of tapered beams with elastically restrained ends, as well as the effect of a concentrated mass at the free end of a cantilever tapered beam. Craver et al. [3] examined the free vibrations of Euler Bernoulli tapered cantilever beams, elastically restrained at an arbitrary position over its length, using the straight search and bisection method. Abrate [4] gave simple formulas for predicting the fundamental frequencies using one term Rayleigh-Ritz approximations. De Rosa and Auciello [5] investigated a tapered beam of linearly varying width and depth and with rotational and translational springs at both ends using the false position method. In order to solve the natural frequencies of the free vibration of beams with variable flexural rigidity and mass density, Yong Huang and Xian-Fang Li presented in [6] a new approach based on Fredholm's integral equations. S.M. Abdelghany et al. [7] investigated the case of non-uniform circular Euler-Bernoulli beam vibrations using the differential transformation method. Fatemeh Sohani and H. R. Eipakchi [8] studied the flexural vibrations of Euler Bernoulli and Timoshenko beams with an arbitrary varying cross-section using on the perturbation technique.

Despite the large literature devoted to the dynamic behaviour of tapered beams, only few authors have considered the effect of geometrical non-linearity. This effect was studied by L. S. Raju et al. in [9], for a tapered beam of rectangular cross-section with two types of linear taper, one corresponding to the width and the other to the depth. The study was based on Galerkin's method. The analysis of the non-linear behaviour of Timoshenko tapered beams with linear variation in width and depth has been carried out by Minmao Liao and Hongzhi Zhong [10], based on the differential quadrature method. Kumar et al. [11] investigated large amplitudes of free vibrations of axially functionally graded tapered beams under different boundary conditions, taper profiles and material properties. The principle of minimum total potential energy was applied in the static case while Hamilton's principle was used in the dynamic analysis.

The present work is focused on the study of geometrically non-linear free and forced vibrations of tapered beams and constitutes a continuation of the work previously initiated by Benamar et al. [12]–[22] in the perspective of a contribution to a non-linear modal analysis theory of free and forced vibrations of structures. The purpose of this paper is to study the geometrically nonlinear free and forced transverse vibrations of tapered beams with a constant width and a linearly varying depth. The theoretical model is based on Euler-Bernoulli's beam theory and the Von Kármán geometrical nonlinearity assumptions. The motion is assumed to be harmonic and the transverse displacement function of the nonlinear beam is expanded as a series of the linear modes, determined by solving the linear problem in terms of Bessel functions and the boundary conditions. The discretized expressions for total beam strain and kinetic energies are derived, and by applying Hamilton's principle, the problem is reduced to a non-linear algebraic system solved using an approximate method (the so-called second formulation). The effect of the linear variation of depth on the non-linear behaviour of the beam is

examined and then illustrated. Using the single-mode approach, the non-linear dynamic behaviour of the tapered beam is studied in the forced case. The effects of the excitation level of the applied harmonic force are investigated and illustrated for various scenarios.

## 2. GENERAL FORMULATION

### 2.1 Linear formulation

This study concerns a non-uniform fully-clamped tapered Euler-Bernoulli beam subjected to transverse vibrations. A thin rectangular cross-section tapered beam of a constant width and a linearly varying depth, denoted by beam (a) is considered.

Figure 1: Coordinates system for the tapered beam studied.

Setting that  $h_{(x)} = h_0 \left( 1 - \alpha \left( \frac{x}{L} \right) \right)$ , where  $h_{(x)}$  and  $\alpha$  present the depth of the beam and the taper ratio equal to  $1 - \frac{h_L}{h_0}$ . The area and inertia functions are given as follows:

$$S(x) = h_{(x)} \times b_0 \quad (1)$$

$$I(x) = \frac{h_{(x)}^3 \times b_0}{12} \quad (2)$$

The equation of motion of the tapered beam in the case of free transverse vibrations can be expressed as in [23]:

$$\frac{\partial^2}{\partial x^2} \left\{ EI_{(x)} \frac{\partial^2 w_i}{\partial x^2} \right\} + \rho S_{(x)} \frac{\partial^2 w_i}{\partial t^2} = 0 ; \quad x \in [0, L] \quad (\text{For } i = 1, 2, \dots, 10) \quad (3)$$

Where  $E$ ,  $\rho$  and  $t$  are respectively the Young's modulus, the density of the beam material and time.  $w$  presents the transverse displacement function of  $x$  and  $t$ , supposed to be separated into two functions  $w(x, t) = W(x) \times \varphi(t)$ . By substituting  $\xi = 1 - \alpha \left( \frac{x}{L} \right)$  in the equation of motion (6), leads to the formulation previously stated in [23]:

$$\xi^2 \frac{d^4 W_i}{d\xi^4} + 2(n+2)\xi \frac{d^3 W_i}{d\xi^3} + (n+2)(n+1) \frac{d^2 W_i}{d\xi^2} - \frac{\beta_i^4}{\alpha} W_i = 0 \quad (4)$$

Where:

$$\beta_i = \sqrt[4]{\frac{\rho S_0 \omega_i^2 L^4}{EI_0}} \quad \text{and } n=1 \quad (5)$$

The eigenvalue parameter is denoted by  $\beta_1$ . The solution of Eq. (4) presents the linear modes form given in [23] as follows:

$$W_i(\phi) = \frac{1}{\phi} (A_i J_1(\phi) + B_i Y_1(\phi) + C_i I_1(\phi) + D_i K_1(\phi)) \quad (6)$$

Where  $\phi = (2\beta_1 \sqrt{\xi}) \alpha^{-1}$

In equation (6)  $A_i, B_i, C_i$  and  $D_i$  present constants that can be determined from the boundary conditions,  $J_1$  and  $Y_1$  are Bessel functions of the first and second kinds in order 1,  $I_1$  and  $K_1$  are the modified Bessel functions of first and second kinds in order 1.

After setting  $x^* = x/L$  for  $x^* \in [0, 1]$ , the beam end conditions are given by:

The end conditions at the left side:

$$W_i|_{x^*=0} = \frac{dW_i}{dx^*}|_{x^*=0} = 0 \quad (11)$$

The end conditions at the right side:

$$W_i|_{x^*=1} = \frac{dW_i}{dx^*}|_{x^*=1} = 0 \quad (12)$$

The substitution of equation (6) into equations (11 and 12) leads to four equations, expressed in the following forms:

$$A_i J_1(\phi_0) + B_i Y_1(\phi_0) + C_i I_1(\phi_0) + D_i K_1(\phi_0) = 0 \quad (13)$$

$$A_i J_2(\phi_0) + B_i Y_2(\phi_0) - C_i I_2(\phi_0) + D_i K_2(\phi_0) = 0 \quad (14)$$

$$A_i J_1(\phi_L) + B_i Y_1(\phi_L) + C_i I_1(\phi_L) + D_i K_1(\phi_L) = 0 \quad (15)$$

$$A_i J_2(\phi_L) + B_i Y_2(\phi_L) - C_i I_2(\phi_L) + D_i K_2(\phi_L) = 0 \quad (16)$$

Where  $\phi_0 = \frac{2\beta_1}{\alpha}$  and  $\phi_L = \frac{2\beta_1}{\alpha} \sqrt{1-\alpha}$ .

The satisfaction of equations (13-16) leads to an homogeneous system which can be expressed by the following matrix form:

$$\begin{bmatrix} J_1(\phi_0) & Y_1(\phi_0) & I_1(\phi_0) & K_1(\phi_0) \\ J_2(\phi_0) & Y_2(\phi_0) & -I_2(\phi_0) & K_2(\phi_0) \\ J_1(\phi_L) & Y_1(\phi_L) & I_1(\phi_L) & K_1(\phi_L) \\ J_2(\phi_L) & Y_2(\phi_L) & -I_2(\phi_L) & K_2(\phi_L) \end{bmatrix} \times \begin{Bmatrix} A_i \\ B_i \\ C_i \\ D_i \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \\ 0 \\ 0 \end{Bmatrix} \quad (17)$$

The non-trivial solutions corresponding to the natural frequencies are derived from equation (17), solved iteratively by the Newton-Raphson method. Then the constants  $A_i, B_i, C_i$  and  $D_i$  are determined by the usual classical algebra procedure.

## 2.2 Non-linear formulation

### 2.2.1 Free vibration

The kinetic energy  $T$  of the tapered beam can be presented in the following form:

$$T = \frac{\rho}{2} \int_0^L S(x) \left( \frac{\delta w}{\delta t} \right)^2 dx \quad (18)$$

The total strain energy  $V$  is the sum of the strain energy due to bending and the axial strain energy due to the non-linear stretching forces induced by the large deflections, respectively denoted by  $V_f$  and  $V_a$  and written as follows:

$$V = V_f + V_a \quad (19)$$

$$V_f = \frac{1}{2} \int_0^L E I(x) \left( \frac{d^2 w_i}{dx^2} \right) \left( \frac{d^2 w_j}{dx^2} \right) dx \quad (20)$$

$$V_a = \frac{1}{2} \frac{N_x^2}{E} \int_0^L \frac{dx}{S(x)} \quad (21)$$

Where  $N_x$  presents the non-linear axial stretching forces in the beam, which may be written in the form reported in [9]:

$$N_x = \frac{E}{2} \cdot \frac{\int_0^L \left( \frac{dw_i}{dx} \right)^2 dx}{\int_0^L \frac{dx}{S}} \quad (22)$$

The dynamic behaviour of the system is studied by applying Hamilton's principle, stated formally as:

$$\delta \int_0^{\frac{2\pi}{\omega}} (V - T) dt = 0 \quad (23)$$

Assuming a harmonic motion, the transverse displacement can be written as:

$$w(x, t) = a_i W_i(x) \sin(\omega t) \quad (\text{For } i = 1, 2, \dots, n) \quad (24)$$

In which  $W_i(x)$ ,  $a_i$  and  $\omega$  present the linear mode, the basic function contribution coefficients and the associated frequency.

After Substituting equation (24) in the expressions for the kinetic energy, the axial deformation energy due to non-linear stretching forces and the deformation energy due to the bending, one gets:

$$T = \frac{1}{2} \omega^2 a_i a_i (\cos(\omega t))^2 m_{ij} \quad (25)$$

$$V_a = \frac{1}{2} a_i a_j a_k a_l (\sin(\omega t))^4 b_{ijkl} \quad (26)$$

$$V_f = \frac{1}{2} a_i a_i (\sin(\omega t))^2 k_{ij} \quad (27)$$

Where  $k_{ij}$ ,  $b_{ijkl}$  and  $m_{ij}$  denote the matrix of the stiffness due to  $V_f$ , the non-linearity tensor due to  $V_a$  and the mass matrix attributable to  $T$ . Equation (23) is extended by adding equations (25, 26 and 27) into it, which can be expressed in the following form:

$$2a_i k_{ir} + 3a_i a_j a_k b_{ijk r} - 2\omega^2 a_i m_{ir} = 0 \quad ; \quad r = 1, \dots, n \quad (28)$$

Equation (28) can be expressed in a matrix form as follows:

$$2[K]\{A\} + 3[B(\{A\})]\{A\} - 2\omega^2 [M]\{A\} = 0 \quad (29)$$

In which  $(k_{ir}), (m_{ir}), (a_j, a_k, b_{ijkl})$  and  $(a_i)$  are converted into  $[K], [M], [B(\{A\})]$  and  $\{A\}$ . Setting some dimensionless parameters as below:

$$\frac{W_i(x^*)}{W_i^*(x^*)} = h_0; \frac{\omega^2}{\omega^{*2}} = \frac{EI_1}{\rho S_1 L^4}; \frac{M_{ij}}{M_{ij}^*} = \rho S_1 h_0^2 \quad (30, 31, 32)$$

$$k_{ij} = \frac{EI_1 h_0^2}{L^3} k_{ij}^*; b_{ijkl} = \frac{EI_1 h_0^2}{L^3} b_{ijkl}^* \quad (33, 34)$$

After substituting the dimensionless parameters in equation (29), this later becomes:

$$[K^*]\{A\} + \frac{3}{2}[B^*(\{A\})]\{A\} - \omega^{*2} [M^*]\{A\} = 0 \quad (35)$$

In order to determine the frequency ( $\omega$ ) and the column vector of the contribution coefficients  $\{A\}$ , which represent the unknowns of equation (35), the so-called second formulation had been used. This method was previously developed by EL KADIRI et al. in [16].

### 2.2.2 Forced vibrations

To study the non-linear forced vibrations, the tapered beam is supposed to be excited by a concentrated harmonic force. The dynamic behaviour of this beam is then studied using Hamilton's principle including the forcing term, and can be expressed as in ref[18]:

$$\delta \int_0^t (V - T + F) dt = 0 \quad (36)$$

The concentrated harmonic force applied at the point  $x_0$  can be written as in[14]:

$$F_i^c = F^c \cos(\omega t) w_i(x_0) = f_i^c \cos(\omega t) \quad (37)$$

Where the dimensionless force  $f_i^{c*}$  can be written as:

$$f_i^{c*} = \frac{L^3}{EI_1} F^c w_i^*(x_0) \quad (33)$$

The mathematical development of equation (36) obtained after substitution of equations (25, 26, 27 and 37), as well as the dimensionless parameters can be given as follows:

$$[K^*]\{A\} + \frac{3}{2}[B^*(\{A\})]\{A\} - \omega^{*2} [M^*]\{A\} = \{F^{c*}\} \quad (32)$$

Equation (32) was solved using the single mode approach, previously applied by AZRAR et al [14]. This approach consists of using only the predominant mode. The predominant mode and the contribution coefficients are denoted by "i" and "a<sub>i</sub>", leading to the following equation:

$$1 + 3 a_i^2 \frac{B_{iiii}^*}{K_{ii}^*} - \frac{f_i^{c*}}{a_i K_{ii}^*} = \left( \frac{\omega_{nl}^*}{\omega_1^*} \right)^2 \quad (34)$$

Where  $\omega_1^* = \frac{K_{ii}^*}{M_{ii}^*}$ .

### 3. NUMERICAL RESULTS AND DISCUSSION

#### 3.1 Free vibration

The beam investigated in this study is a tapered beam of a constant width, A linearly varying depth and IS characterised by a taper ratio equal to  $\alpha = 0.8$ . The first four eigenvalues of this tapered beam are compared to those of [23] for two end conditions: a tapered beam clamped at the both sides denoted by C-C, and a tapered beam simply-supported at the both sides denoted by S-S. The results of this comparison are summarised in table 1.

Table 1: The first four eigenvalues of tapered beams for different end conditions. The taper ratio

$$\alpha = 0.8 \text{ and } \frac{S(x)}{S_1} = \left(1 - \alpha \left(\frac{x}{L}\right)\right)$$

		Mode index				
		1	2	3	4	5
CC	Present work	11.84165331	32.47545622	63.51175681	104.8670264	156.5532995
	Ref [23]	11.8417	32.4755	63.5118	104.867	156.554
	Rel Diff	3E-04	1E-04	6.7999E-05	2.51307E-05	4E-04
SS	Present work	4.91976	21.34448781	47.48198199	83.82160776	130.436039
	Ref [23]	4.91976	21.3445	47.482	83.8216	130.436
	Rel Diff	5.51534E-05	-5.71158E-05	-3.79301E-05	9.2612E-06	2.98946E-05

$$Rel\ Diff = \left[ \frac{|Present\ work - Ref[23]|}{Present\ work} \right] \times 100$$

The comparisons made in Table (1) show an excellent agreement, with a relative difference not exceeding 0,0004% for the whole range of frequencies considered.

In the nonlinear free vibration case, the tapered beam investigated remains characterised by the same taper ratio and clamped at the both ends. Figure (2) shows the amplitude dependence of the non-linear frequency parameter on the maximum vibration amplitude.

Figure (2) Backbone curve of the tapered beams studied, corresponding to the first nonlinear mode.

Figure (3): The normalized first non-linear mode of the tapered beam for different amplitude values

Figure (4): The Non-linear curvature distribution associated to the normalized first non-linear mode for different amplitude values

It may be seen in the backbone curve given in Figure (2) that increasing the maximum non-dimensional amplitude  $W_{\max}^*$  results in an increase the non-linear to linear frequency ratio, which is characteristic of a non-linearity of the hardening type. In addition, the bending moment distribution associated to the non-linear mode shows that the assumption of neglecting the geometrical non-linearity may be misleading. For instance, the non-linear bending moment of the tapered beam at the right end with a contribution coefficient  $a_1 = 1$  is 248.84, while the linear bending moment predicted by linear theory is 237.21, which corresponds to a percentage correction of 4,9%. For  $a_1 = 1.5$ , the non-linear bending moment equals 392.41, while the linear bending moment is 355.81, resulting in a percentage difference of 10,28%. For a contribution coefficient  $a_1 = 2$ , the non-linear and linear bending moments are equal respectively to 553.71 and 474.42, which corresponds to percentage correction of 16,71%.

### 3.2 Forced vibration

The fully-clamped tapered Euler-Bernoulli beam is excited by a concentrated force located at the middle. The generalised forces calculated in Table (2) shows that the first mode remains predominant, which justifies use of the approximate theory developed in [16] for the determination of the non-linear frequency response curve in the neighbourhood of the first mode (NLFRF). The following Table illustrates the type of results obtained.

Table 2: Percentage of generalized forces exciting the first five symmetric modes of tapered beams excited by a concentric force located at the middle of it.

	Modes				
	1	3	5	7	9
$ F^c w_i^*(x_f) $	18,41	9,20	0,35	9,98	16,32

Using the single-mode approach, an investigation of the dynamic behaviour of the tapered beam was carried out in the vicinity of the predominant mode. The response curves were plotted for the tapered beams shown in Figure (1), which was excited by a concentric harmonic force. Five scenarios was investigated in which the excitation level varied in the following way  $[F^c=10^n]$ (for  $n=0,1,2$  and 3).

Figure (5): Nonlinear frequency response functions, based on the single mode approach, for the tapered beam subjected to four levels of excitation.

Figure (5) shows the effect of the geometrical non-linearity in the case of forced vibrations, with the jump phenomenon region commonly found in non-linear vibrations. The hardening behaviour is also visible, as well as the non-proportional progression in the frequency response with the excitation intensity.

#### 4. CONCLUSION

Geometrically non-linear transverse vibrations of tapered beams were studied analytically using the Euler-Bernoulli beam theory and Von Karman nonlinearity assumptions. The solution of the linear problem was obtained for a tapered beam of a constant width, a linearly variable depth and a taper ratio equal to 0.8. The linear modes obtained were used as basic functions in the analysis of non-linear vibrations. To solve the non-linear algebraic system derived via application of Hamilton's principle, a previously developed approximate method, called the second formulation, was applied. A comparison was made between the result obtained from the numerical method used here and those obtained using the transfer matrix method. This comparison shows an excellent agreement since the relative difference does not exceed 0.0002 %. Then, the non-linear dynamic behaviour of tapered beams subjected to free vibrations was examined and illustrated by the backbone curve, nonlinear modes and curva-

ture distributions, in which the hardening behaviour can be clearly observed. Using the single-mode approach, a study of the dynamic behaviour of the tapered beams in the forced case was carried out in the vicinity of the predominant mode. The effect of the force level was examined and illustrated for four excitation levels. The results illustrate the effect of geometrical non-linearity with the hardening type behaviour and the instable regions in which the jump phenomena can occur.

**Keywords:** Powder Snow Avalanche, Impact, Dynamic Magnification, Power Transmission Towers, Pylons, RAMMS

**Abstract.** *Tall structures play an important role in the economic well-being of mountainous regions. They serve to distribute hydroelectric energy (power line transmission towers), generate tourist income (cableway pylons) and protect important infrastructure from natural hazards (trees). It is not uncommon for these structures to be destroyed by the air-blast of a powder avalanche. In this paper we investigate the shock response spectra of an asymmetric steel structure subjected to powder avalanche impact. We perform a spectral analysis of measured accelerations in the in-plane (avalanche flow) and cross-plane (normal to avalanche flow) directions. The structural eigenfrequencies in each direction are likewise calculated using a simple finite element model consisting of three-dimensional beam elements. Mode superposition is then used to reconstruct the measured accelerations, velocities and displacements in order to identify the magnitude and duration of the powder avalanche loading. From the analysis we find that the powder avalanche must contain high-frequency, short-duration blasts ( $f > 2$  Hz) of moderate magnitude ( $p \approx 1$ -10 kPa). High frequency blasts are also present in the cross-plane, transverse flow direction. This result, however, does not exclude the existence of longer duration blasts, which, because of the frequency mismatch, cannot excite the measurement pylon. It appears the high-frequency content of the cloud attenuates to endanger low-frequency structures ( $f \approx 1$  Hz) such as trees at the lateral edges of the flow, or hanging cables located well above the core. The shock response of a specific structure therefore depends on its location relative to the avalanche core, depending on how the blast-structures dissipate in time and space. Because the powder cloud contains a wide range of blast frequencies, tall structures are vulnerable to the action of the powder cloud, even if they are located well outside the avalanche core.*

## 1 INTRODUCTION

A longstanding problem in natural hazards engineering has been to predict the action of snow avalanches on power transmission towers and pylons. These are thin, tall structures, that are exposed to both the impact of the dense avalanche core and powder cloud (Figs. 1 and 2). The avalanche core is composed of clumps and clods of compacted snow with bulk densities reaching  $500 \text{ kg/m}^3$  or even higher (Fig. 3). The avalanche core is primarily a surface flow governed strongly by terrain and slope properties (steepness, roughness, vegetation, gullies, channels, etc) [1]. Although engineers can often position transmission towers and pylons outside the reach of the flow core, exploiting natural terrain features such as elevated ridges and knolls, they are nonetheless subjected to the wind blast of the airborne powder cloud.

Figure 1: Left: The front of a powder snow avalanche. Photograph taken at the Swiss experimental avalanche dynamics site in 2003. The avalanche is moving at a speed between 40-50 m/s. Note the turbulent billow and cleft structures an indication of velocity fluctuations. Right: A powder avalanche overturned this power transmission mast in January 2018. The mast is located in the runout zone of the Val Barcli avalanche track, Zerne, Switzerland. The conductors are still attached to the mast which appears to be severely damaged near the foundation. Note the mangled and twisted truss elements near the foundation suggesting a multi-dimensional loading. The photograph appeared in the newspaper Engadiner Post, January 24th, 2018. The transmission line belongs to the Engadiner Kraftwerke AG (EKW).

The powder cloud consists of suspended ice-dust; it is created when both dense particles and ice-dust are ejected from the avalanche core into the surrounding air, often quickly and to great heights [1]. The suspended dust remains airborne while the larger particles eventually return back to the core. The difference in particle sizes thus leads to a natural separation between the core and cloud. The cloud is created from the core and during the formation phase is continually supplied with mass and momentum from the core. It can reach significant speeds. More importantly, once airborne the flow of suspended ice-dust is free from the terrain and will essentially travel in the initial direction defined by the core/cloud momentum exchange. Thus, while the core is a surface flow, the cloud is an inertial, airborne flow. At formation the flows are combined, but the flows can separate, flow in different directions and velocities and therefore can inundate larger areas.

Figure 2: An avalanche displaced and tilted this cableway mast in East Tirol, Kals, Austria. The mast itself was not damaged and could be brought back into an upright position. The picture appeared in the Dolomitenstadt.at online magazine on November 21, 2019.

Transmission towers and pylons are vulnerable to the action of the powder cloud. For one, because the powder cloud applies wind loadings at significant heights above the ground. The primary purpose of these structures is to carry cables above ground. They are designed for vertical loads and horizontal wind loads. As such, heavy, cable supporting sub-structures are often located well above the ground, Fig. 2. Mass is therefore not equally distributed over the height, but often concentrated near the top of the structure. This makes masts and pylons particularly vulnerable to dynamic loads. If this mass is excited by the avalanche impact, large internal stresses can be generated by the external loading. Another problem is that the cables between towers can also be impacted by the powder cloud. That is, the towers can escape the powder blast, but the cables are often subjected to pressures larger than the wind load. The impact of the cables creates internal stress/deformation waves that propagate back and forth between the towers, with a magnitude and frequency dependent on the elasticity and cross-sectional mass of the cables [2]. This leads to concentrated, dynamic loads on the towers, again at some distance above the ground. Thus, powder avalanches can both directly and indirectly produce dynamic loads on tall tower-type structures (Fig. 4).

The purpose of this paper is the following. We first would like to identify the duration and magnitude of powder avalanche impact loadings on tall, thin structures. This information is the prerequisite for performing a dynamic structural engineering analysis for both man-made structures as well as natural structures such as trees [3]. We do this by back-calculating measured accelerations on a tall, asymmetric structure with known cross-section and material properties. For this purpose we develop a simple three-dimensional finite element beam model. Thus, we are able to approximate both longitudinal and transverse loadings arising from the powder cloud

Figure 3: Flowing avalanche core  $\Phi$  and powder cloud  $\Pi$ . Avalanche dynamics models predict the movement of the core and cloud in general terrain. The core contains granular mass in the form of clumps of snow. The cloud contains suspended ice-dust. The layers are not separate, but overlaid and mixed. The height of the core is defined by the location of the highest clump of snow; that is, it includes saltating particles at great heights in the powder cloud. A splashing front exists at the front of the avalanche.

impact. We perform a modal analysis to identify the duration, location and magnitude of the blast [4]. We then apply a mixed flowing/powder avalanche model to calculate the destruction of the mast to demonstrate the important contribution of the dynamic powder blast to overall avalanche loading. Clearly, the primary objective of this paper is to underscore the necessity of including both (internal) inertial forces and (external) impulsive forces when calculating the response of tall structures to powder avalanche impact.

## 2 ACCELERATION MEASUREMENTS and FE-MODAL ANALYSIS

Acceleration measurements on the 20 m high, tubular steel pylon at the Swiss Vallée de la Sionne test site are used to determine the duration and intensity of powder loadings [5, 6]. The width of the pylon is approximately  $w = 0.6\text{ m}$ , with bevelled edges; in the direction of avalanche flow the pylon is 1.6 m long. Accelerometers are fixed on the pylon at four heights (3.8 m, 7.8 m, 12.3 m, 16.3 m) and measure accelerations in both the longitudinal (avalanche direction) and transverse (perpendicular to flow) directions. The pylon is fixed rigidly to the ground via a concrete sub-structure and can be considered a fixed-end cantilever. Because of internal stiffness elements and variable section thickness (1-3 cm), the moments of inertia can vary with height somewhat. Values at the midsection are stated here,  $I_Y = 0.0042\text{ m}^4$  and  $I_Z = 0.0125\text{ m}^4$ . The flexural rigidity of the pylon is subsequently a factor 3 lower in the transverse direction. The modulus of elasticity and density for steel are applied in the analysis,  $E = 200\text{ GPa}$  and  $\rho = 8000\text{ kg/m}^3$ , respectively.

Measured accelerations in the transverse and longitudinal directions are depicted in Fig. 5. The measurements reveal (1) Within six seconds the pylon was struck by a series of short duration blasts lasting less than a fraction of a second, between 0.25 s and 0.50 s. (2) Higher accelerations are measured in the transverse (less stiff) direction, (3) the magnitude of the accelerations at the highest location (16.3 m) reach 10  $g$  in the transverse direction and 4  $g$  in the

Figure 4: We consider two loading cases: 1) The avalanche core and cloud directly impacts the mast. 2) The mast is outside the reach of the core and cloud and the avalanche impacts only the cables, causing pull and collapse forces on the mast. The avalanche impacts the mast in transverse  $Y$ -direction producing bending moments around the  $X$ -axis. The  $X$ -direction runs parallel to the cable. Cable impact induces pulling forces  $T_X(t)$  in the  $X$ -direction and collapse forces  $T_Z(t)$  in the  $Z$ -direction. These induce bending moments around the  $Y$ -axis. A third loading case is when both the mast and cables are struck by the avalanche.

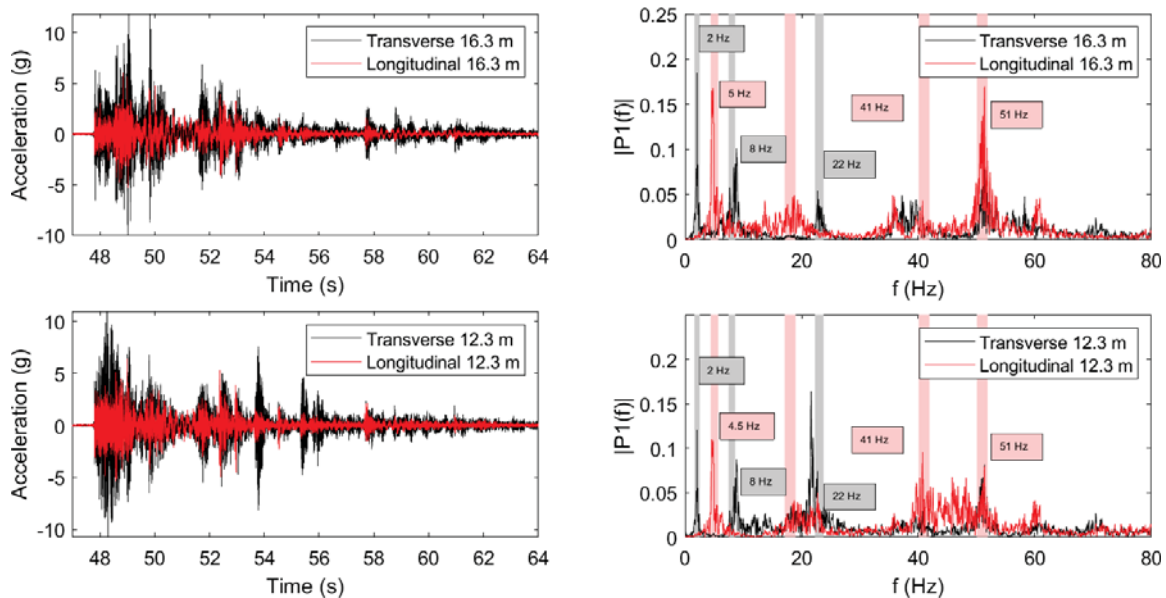

Figure 5: Left: Measured accelerations at heights 16.3 m and 12.3 m in the transverse (black) and longitudinal (red) directions. Right: Frequency analysis of the measured accelerations. The three lowest eigenfrequencies in longitudinal direction are 5 Hz, 18 Hz and around 40 Hz; in the transverse direction 2 Hz, 8 Hz and 18 Hz.

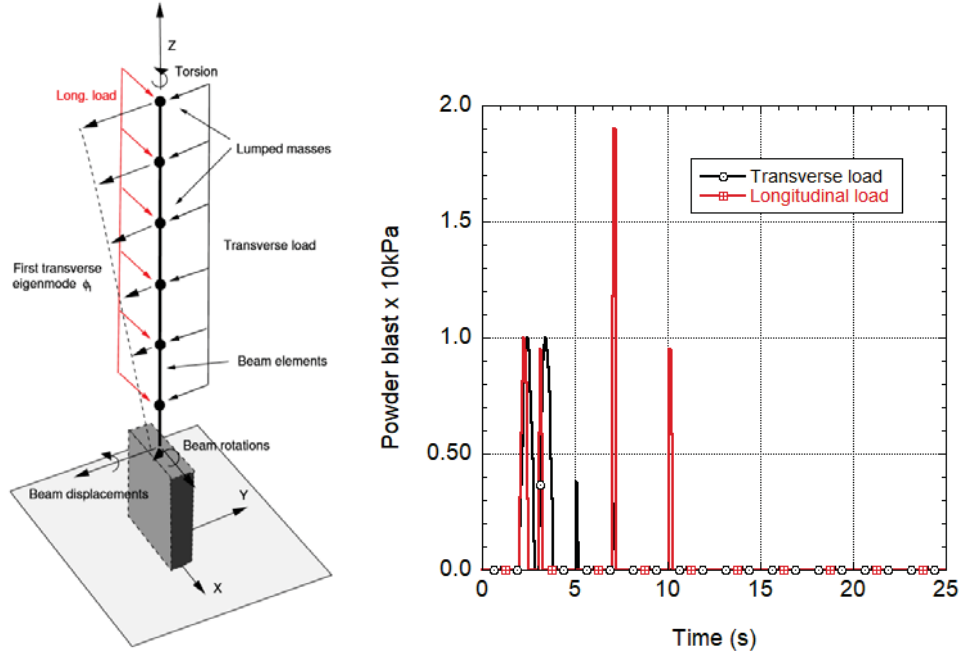

Figure 6: Left: Three-dimensional finite element beam model displaying the transverse and longitudinal directions. The finite element model is used to determine the eigenmodes of the structure. Right: A powder loading is applied to the structure as a series of random pulses.

longitudinal direction and finally (4) the intensity of the blast is clearly highest at or near the avalanche front.

We performed a discrete Fourier transform using the standard fast Fourier transform (FFT) algorithm [7] to identify the eigenfrequencies. Figure 5 shows raw data streams and its according FFTs without applying any data filtering. Likewise, we developed a simple finite element model consisting of three-dimensional beam elements to model the pylon structure (Fig. 6). The finite element model consisted of 7 elements, 8 nodes (48 DOFs). We calculated all  $n = 48$  eigenvalues ( $\omega_n$ ) and eigenvectors ( $\phi_n$ ) using MAPLE [8]. Measured and calculated eigenfrequencies are presented in Table 1.

Mode no.	Longitudinal $X$ -direction	Transverse $Y$ -direction
	Eigenfrequency $\phi_z$ (Hz)	Eigenfrequency $\phi_y$ (Hz)
	Measured/FE	Measured/FE
1	5.0 / 5.1	2.0 / 1.9
2	18.0 / 18.5	8.0 / 8.8
3	41.0 / 41.5	18.0 / 21.3

Table 1: Longitudinal and transverse eigenfrequencies of the impact pylon.

The orthogonality properties of the eigenvectors can be used to uncouple the general equations of motion to arrive at a series of  $n=3$  differential equations in the longitudinal and transverse directions [4],

$$M_n \ddot{Y}_n + C_n \dot{Y}_n + K_n Y_n = P_n(t) \quad (1)$$

where

$$M_n \equiv \phi_n^T m \phi_n \quad K_n \equiv \phi_n^T k \phi_n \quad P_n \equiv \phi_n^T p(t) \quad (2)$$

are the generalized mass (FE mass matrix  $m$ ), stiffness (FE stiffness matrix  $k$ ) and load (FE load vector  $p(t)$ ). The damping  $C_n$  is determined using the usual method of assigning a damping ratio for each mode  $n$ . For the mode-superposition method we took the three lowest eigenfrequencies in the longitudinal and transverse direction and therefore solved a system of six ordinary differential equations to find the dynamic response. Higher frequencies were not included in the analysis.

We matched the experimental results by selecting short duration blasts arranged randomly over the six second interaction time. The load  $p(z, t)$  acted over the entire pylon height. The magnitude of the load did not change between the longitudinal and transverse directions  $p_0 = 5$  kPa. The avalanche core was assumed to act only on the lower region of the pylon ( $h < 5$  m). The measurements appear to be strongly damped and we selected an appropriate damping ratio for each mode.

In order to capture measurements it was necessary to apply several high-frequency blasts of duration  $0.25 \text{ s} \leq \Delta t \leq 0.5 \text{ s}$  (Fig. 6). We applied these loads homogeneously over the entire height. The blasts must be applied in both flow and cross-flow directions. The fact that the pylon structure is asymmetric, and therefore has two dissimilar first bending mode eigenfrequencies, is helpful to quantify the frequency content and blast magnitude in both directions. For the blast loading we found the frequency content and intensity to be similar (Fig. 7).

It would be entirely wrong to conclude the powder cloud contains *only* turbulent structures of duration 0.25s to 0.50s (2Hz - 4Hz). These pulses exist at the eigenfrequency of the pylon, and therefore the pylon reacts to them. Lower frequency (longer duration) pulses could exist in the cloud, but the pylon would not react to them. These pulses would therefore not be seen in the measurements.

Of considerable importance is the fact that we applied significant core loadings to the structure at the same time as the powder blast. The magnitude of the acceleration response, however, was not dominated by the magnitude of the long-duration core load ( $p = 60$  kPa), rather by the short duration of the powder blast, especially in the transverse direction. Using the model it was possible to obtain similar accelerations in both the longitudinal and transverse directions, at different heights. Clearly, the comparison between the measurements and model results could be optimized to obtain the exact magnitude and load timing. We show that with a relatively simple load model a reasonable and good quantitative fit to the experiments can be achieved. Remarkable is the model prediction of the three lowest eigenfrequencies in each direction.

Finally, we note that we applied the powder blasts over the entire pylon. Only in this way could we match the measured accelerations. This result indicates that the pulses have considerable height (20m) in the  $Z$ -direction, larger than the pulse wavelength in the  $X$ - and  $Y$ -directions. Vorticity in the cloud must therefore not be distributed equally in all directions.

### 3 RAYLEIGH ANALYSIS with AVALANCHE DYNAMICS SIMULATIONS

To reinforce the idea that the duration and magnitude of the powder blast contributes a large part to the total structural load, we performed a simple Rayleigh analysis, using a method developed by Wolf [9]. In this section we investigate two of the largest snow avalanches ever recorded at the Swiss Vallée de la Sionne test site. These are the avalanches of the 10th of February and 25th February, 1999. Both avalanches are documented in the SLF internal report No. 732 entitled *Lawinendynamik-Versuchsgelände Vallée de la Sionne-Arbaz, Wallis. Schlussbericht Winter 1998/1999*. These avalanches clearly impacted the pylon structure with a significant core loading.

We construct an equivalent one-dimensional model of the mast (Rayleighs method) given by

Figure 7: Results of the FE mode-superposition analysis. Transverse (black) and longitudinal (red) accelerations. a)  $z = 16.3$  m. b)  $z = 12.3$  m. The calculations are damped with first mode damping ratios of  $\xi_n = 0.02$ .

the dynamic equation

$$M\ddot{u}(t) + Ku(t) = P(t) \quad (3)$$

where  $M$ ,  $K$  and  $P$  are the effective mass, stiffness and loading values. The deformation at the top of the structure  $z = H$  is  $u(t)$ . For this simple analysis we neglect structural damping. We use the analytical function (see [4])

$$\psi(z) = 1 - \cos \frac{\pi z}{2H}. \quad (4)$$

to model the bending displacement. The effective mass and loading are then found,

$$M = \int_0^H m(z) (\psi(z))^2 dz \quad P(t) = \int_0^H p(z, t) \psi(z) dz. \quad (5)$$

The mass distribution of the steel structure is given  $m(z)$ ; the external avalanche loading  $p(z, t)$ . The effective bending stiffness (flexural rigidity  $EI(z)$ ) is given by

$$k_b = \int_0^H EI(z) \left( \frac{d^2\psi}{dz^2} \right) dz \quad (6)$$

which we modify to include foundation effects according to the procedure of Wolf [9],

$$K = \frac{k_b}{\left[ 1 + \frac{k_b}{k_x} + \frac{k_b H^2}{k_\theta r^2} \right]} \quad (7)$$

where the parameters  $k_x$ ,  $k_b$  and  $r$  characterize the foundation stiffness. The dimensions of the pylon (width 0.6 m, length 1.6 m, avg. plate thickness 25 mm) were used to approximate the flexural rigidity of the tubular steel structure  $EI = 3.5$  GNm<sup>2</sup>. This also provided the approximate mass per running height of the pylon ( $m = 550$  kg/m). We considered a soil strength of  $k_x = k_x = 75$  MN/m. This produced a vibration frequency  $\omega = 12.2$  rad/s ( $f = 1.95$  Hz), in good agreement with the finite element model and the acceleration measurements. The natural vibration frequency of the pylon on an absolutely rigid foundation is  $\omega = 25.0$  rad/s ( $f = 4$  Hz).

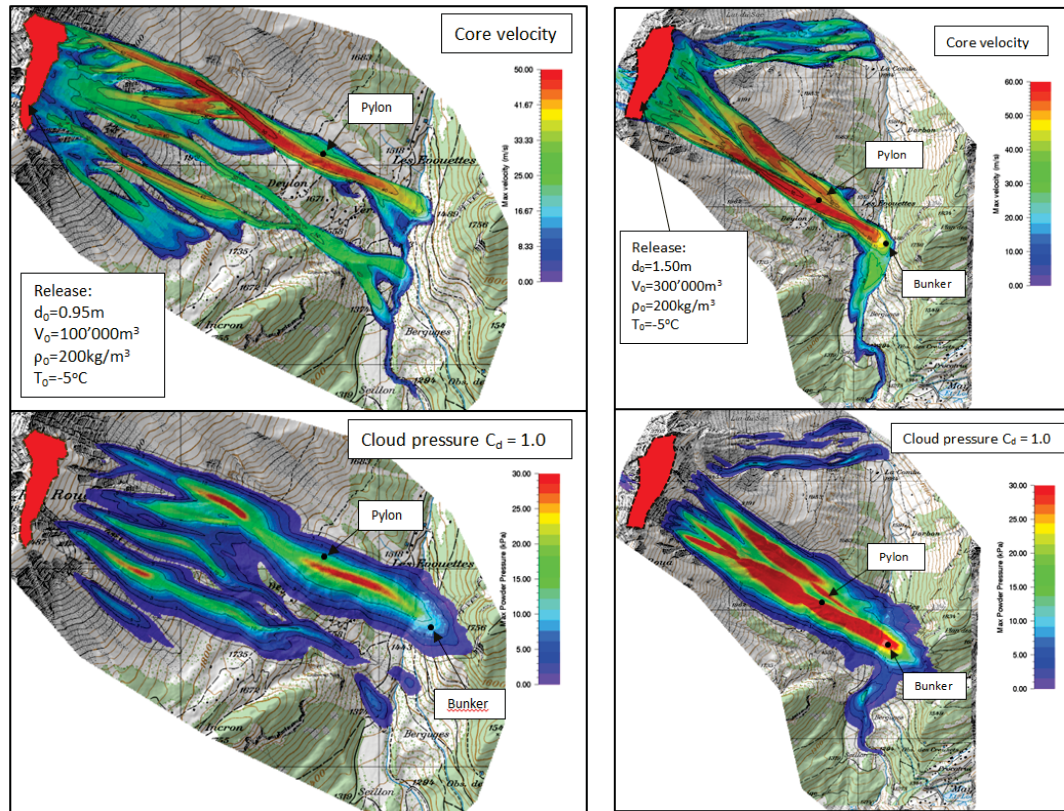

Figure 8: Vallée de la Sionne, 1999. Calculated core velocities and powder cloud impact pressures (**RAMMS**) for two large powder avalanches that occurred on 10.2.1999 and 25.2.1999. The calculated pressures are around 35 kPa ( $C_d = 1$ ).

We first simulated the avalanche events with the **RAMMS** software [10] to determine the core and powder cloud loadings (Fig. 8). An overview of the simulation results is contained in Table 2. Pre- and post event photogrammetric measurements were used to derive the mass balance of both avalanches. The location and extent of the release zones are also defined according to the photogrammetric measurements. The fracture depths  $d_0$  and release volumes  $V_0$  likewise correspond to the experimental observations.

The calculated avalanches reach peak leading-edge velocities of 60 m/s (10.2.1999) and 80 m/s (25.2.1999), close to the observed values (see report). The calculated runout distances correspond to the observations. The avalanche of 25.2.1999 inundated the forested area behind the bunker with pressures large enough to knock down trees (observed and calculated). The powder pressure of the 25.2.1999 avalanche is considerably higher than the avalanche of 10.2.1999. This is in large part due to the fact that the core of 25.2.1999 avalanche impacted the mast directly, whereas the core of the 10.2.1999 avalanche flowed past the pylon on the orographic right side, reducing the magnitude of the calculated powder pressures. This fact suggest large transverse loadings on the structure for the second avalanche. The calculation results were used to construct core and cloud loading that are shown in Fig. 9. Note that the core of the 25.2.1999 avalanche struck the mast at a higher level as it flowed on the deposits of the 10.2.1999 avalanche.

The first surprising result of the Rayleigh analysis is that the powder avalanche load contributes significantly to the effective avalanche loading in both the longitudinal and transverse directions (Fig. 10). The effective loading of the 25.2.1999 avalanche is a factor 5 times larger

Vallée de la Sionne February 1999	10.2.1999	25.2.1999
Release height $d_0$ (m)	0.98/0.95	1.50/1.50
Measured release volume $V_0$ (m <sup>3</sup> )	104'000/105'650	316'000/315'125
Release temperature $T_0$ (°C)	-5	-5
Release density $\rho_0$ (kg/m <sup>3</sup> )	200	200
Snowcover gradient $\Delta h_\Sigma$ (cm/100m)	5	5
Temperature gradient $\Delta T_\Sigma$ (°C/100m)	0.5	0.5
Calculated erosion volume (m <sup>3</sup> )	607'300	1'265'000
Calculated core mass to cloud (t)	33'110	75'100
Cloud deposition volume (m <sup>3</sup> )	74'000	167'000
Measured deposition volume (m <sup>3</sup> )	760'000	1'710'000
Calculated deposition volume (m <sup>3</sup> )	786'950	1'747'125

Table 2: Mass balance of Vallée de la Sionne avalanches February 1999. The size and location of the release zone are taken directly from the experimental report. The total measured deposition volume is compared to the calculated deposition volume which is the sum of the simulated release, erosion and powder cloud deposition volumes.

Figure 9: Calculation model of the VDLS pylon for two avalanches (10.2.1999 and 25.2.1999) in 1999. The second avalanche destroyed the pylon. The two loadings produce two different effective loadings  $P_{\text{eff}}(t)$ .

than the avalanche of 10.2.1999 – although the pressure loading from the core and cloud vary only by a factor two. This is due in part to the stronger powder cloud pressure of 25.2.1999, but also due to the fact that the core load is elevated 4 m from the base of the pylon. For the avalanche of 25.2.1999 the effective loading increases from  $P_{\text{max}} = 150$  kN to peak impact pressures of  $P_{\text{max}} = 300$  kN; that is, the effective loading essentially doubles. Note that the duration of the core and powder loadings differ - the core loading is of longer duration (15s) than the powder loading ( $< 1$  s). The Rayleigh analysis effectively quantifies the effect of the loading elevation.

Another interesting result of the Rayleigh analysis is that the elastic limit ( $2000 \mu\epsilon$ ) is reached because of the transverse impact. Strains from the transverse loading are approximately 4 times higher than from longitudinal loading ( $500 \mu\epsilon$ ), see Fig. 10c. The calculated accelerations in the transverse direction have a higher order of magnitude than the experimental measurements ( $15 g > 5 g$ ), but are also longer lasting, suggesting a more intense impact.

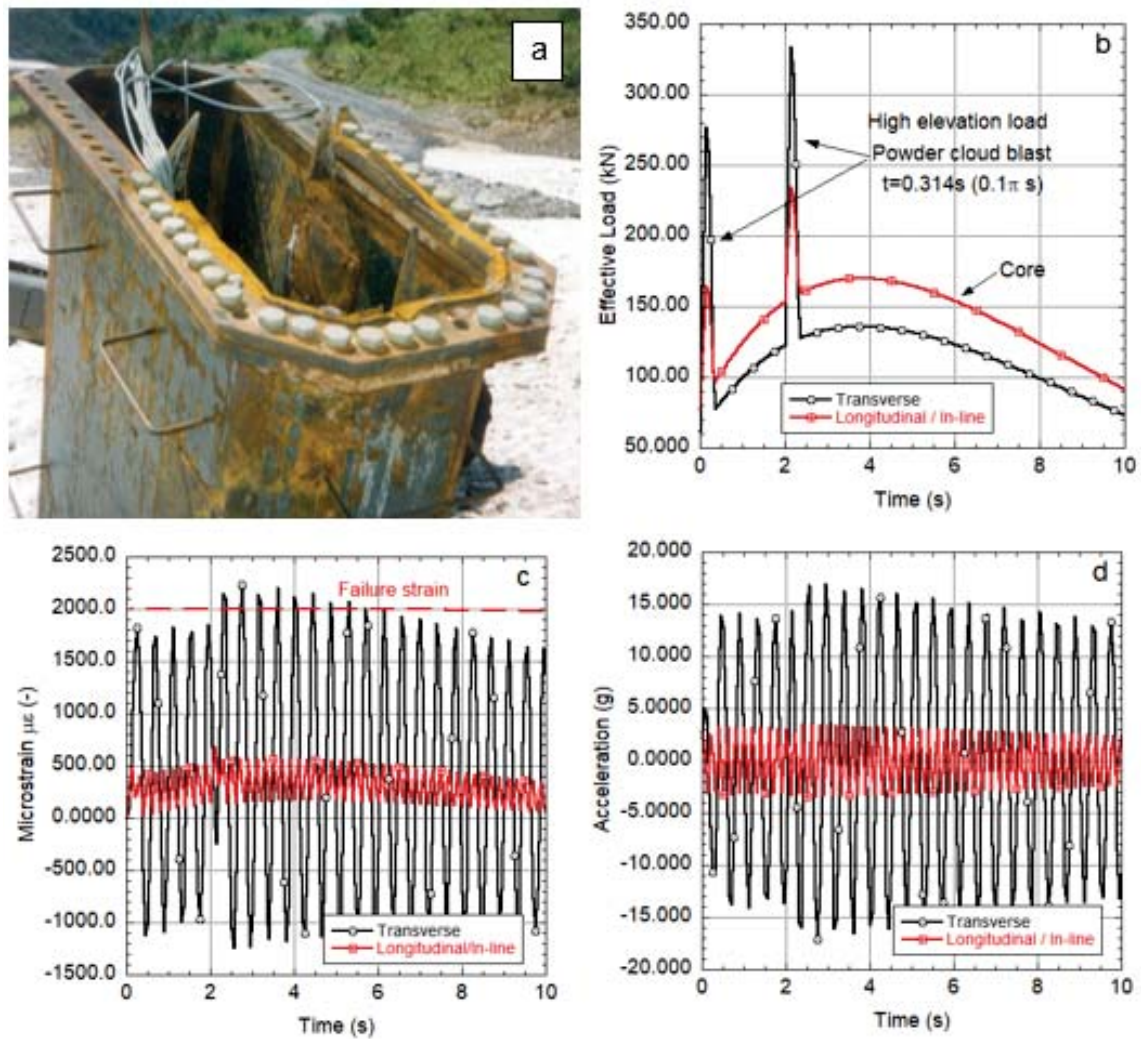

Figure 10: Results of Rayleigh analysis for the two observed avalanches with a loading duration of  $\pi$ s. a) Calculated microstrains for avalanche of 10.02.1999. b) Calculated effective load of 10.02.1999. c) Calculated microstrains for avalanche of 25.02.1999. The powder cloud loading excites the inertial forces such that the failure strains are reached. d) Calculated effective load of avalanche 25.02.1999.

## 4 CONCLUSIONS

We began our work with an analysis of measured structural accelerations induced by powder avalanche impact of a 20 m high cantilever pylon. In the measurements we could clearly identify the first three bending frequencies of the pylon in both the longitudinal and transverse directions. These eigenfrequencies could be reproduced using a simple finite element beam model. Because the pylon cross-section is a rectangular tube (1.6 m x 0.6 m, with some internal stiffening elements), the first mode eigenfrequencies differed in the longitudinal (5 Hz) and transverse (2 Hz) directions. Avalanche impact of the pylon induced accelerations reaching 10 *g* in the transverse direction (pylon top) and smaller accelerations in of 2 *g* in the stiff longitudinal direction. The significance of these results is twofold.

Firstly, a mode superposition analysis reveals that to reproduce the measured accelerations it is necessary to apply short duration blasts with duration times of approximately 0.25 s to 0.50 s. This corresponds to loading frequencies of 2 Hz to 4 Hz. At present it is not possible to model the exact timing of the blasts, but it appears there can be several within the first 10 s of the avalanche passage. It is not possible to conclude that the powder cloud contains structures only of this duration. The pylon reacts to these loading frequencies because they are near the eigenfrequencies of the pylon. It is entirely possible for the cloud to contain many different frequencies. Secondly, the powder blasts appear to be stronger than considered in the transverse direction. These transverse loadings arise as the avalanche head passes to one side of the structure. The lateral blasts are significant, especially for asymmetric structures which reduce the impact area in the longitudinal direction (in this particular case 0.6 m), but increase the length of the structure (in this particular case 1.6 m) in order to increase the flexural rigidity in the line of attack. The primary conclusion of this part of the paper is that inertial effects and dynamic magnification factors must be considered when designing pylon type structures against powder avalanche impact. Presently, this is not performed in avalanche engineering.

In the second part of the paper we performed a Rayleigh analysis of the pylon. That is, we reduced the finite element model to a single degree of system, modelling the response of the structure using only the first bending mode. In this analysis the mass, flexural rigidity and loading distributions are reduced to scalar (effective) quantities by assuming a specific deformation in the *z*-height direction. With this simple modelling approach, it was possible to obtain the eigenfrequencies in the longitudinal and transverse directions, but not with the accuracy of the finite element model. We simulated two large powder avalanches that occurred at the test site during the avalanche winter of 1999, on the 10.02.1999 and 25.02.1999. The second avalanche was so extreme, that it destroyed the pylon. Our analysis reveals that the transverse loading played a significant part in the structural failure, as we could only generate microstrains above the plastic limit (2000  $\mu\epsilon$ ) from this loading case. The first avalanche appeared to stress the pylon up to only 50% of its capacity. Of interest is the fact that the effective loading of the avalanche core contributed only 50% of the total effective loading. Moreover, the short duration powder loading, because it hits the pylon at the right frequency some distance above the ground contributes a significant part of the total effective loading.

Finally, there is considerable empirical evidence that the duration of the powder blast increases with distance from the avalanche core, where the powder cloud is formed. Trees have eigenfrequencies of approximately 1 Hz and would easily survive short duration powder blasts in the 2 Hz to 5 Hz range. This result suggests that the blast frequency of the cloud is continually changing in time and space. The powder cloud contains a wide spectrum of turbulent wavelengths that would excite tall structures. As the cloud turbulence dissipates, we expect

longer duration blasts which would blow-down tree stands. This fact would explain why trees in the runout zone of avalanches (and on the sides of avalanche tracks) are especially vulnerable to the action of the powder cloud. This fact motivates our interest in understanding both the production and decay of vorticity in powder avalanches. For shear flows with varying in space and time vorticity an intermediate model was recently proposed where the governing equations are obtained by depth-averaging the Euler equations without assuming potential flow [12, 13, 14].

### Abstract

*The main objective of this work is to study the geometrically non-linear free vibration of stepped beams carrying multiple masses. These beams are studied on the basis of the Euler-Bernoulli beam theory and the Von Karman geometrical nonlinearity assumptions. The discrete expressions for the beam total strain and kinetic energies are derived. By applying Hamilton's principle, the problem is reduced to a non-linear algebraic system solved by an approximate method (the so-called second formulation). A parametric study is performed to explore the effect of non-linearity on the dynamic behaviour of stepped beams with several added masses. The free vibration case is discussed by considering three types of stepped beams which differ in the cross-section type.*

**Keywords:** Stepped beam, transverse vibrations, nonlinear vibrations, free vibrations

## 1 INTRODUCTION

Stepped beams are commonly encountered in practical structures and extensively used in many domains, including mechanical and civil engineering, such as high-rise buildings, robot arms, etc. These structures, often subjected during their lifetime to transverse vibrations, may contain concentric elements that can be assimilated to point masses or to linear or rotational springs. Considerable work has been done to study the dynamic behaviour of these types of beams by means of linear theory, making the analysis relatively easy, but leading to inaccurate results when the beams are subjected to large vibration amplitudes. In such situation, non-linear analysis is needed to obtain with accuracy the deformation of the beam for each amplitude level considered. A review of the literature goes back to Naguleswaran who presents an overview of the existing studies performed to analyse stepped beams using linear approaches[1]. El Hantati[2], [3] presents a literature review of works related to non-uniform beams in the case of linear and non-linear vibrations. A significant number of studies have been conducted on the dynamic response of single and multi-mass beams, using linear and non-linear analyses for both free and forced vibrations. These studies have been mostly reported in an extensive literature review presented by Fakhreddine[4]. Regarding non-uniform beams with concentric masses, many studies have been carried out to analyse their response to free and forced vibrations, considering both the Euler-Bernoulli and the Timoshenko beam theories. Karami[5] investigated free vibrations of arbitrary non-uniform Timoshenko beams with their concentrated mass and rotary inertia and resting on elastic supports based on the differential quadrature element method. Based on the same method, Torabi et al. studied in [6] free vibrations of a non-uniform cantilever Timoshenko beam with multiple concentrated masses. Kohan et al. [7] studied a non-uniform beam carrying a concentrated masses and supported by linear and rotational springs at both sides. The analytical formulation exposed in this work was based on the Ritz method and the orthogonal polynomials within the framework of the first order shear deformation beam theory. Jong-Shyong[8] used the continuous-mass transfer matrix method to investigate free vibrations of a multi-step Timoshenko beam axially loaded and carrying arbitrary concentrated elements. K.Torabi et al [9] investigated multiple-stepped Bernoulli Euler and Timoshenko beams, carrying concentrated masses with rotary inertia at arbitrary points based on the same method. Yusuf Yesilce[10] studied free vibrations of a Timoshenko multiple-step beam under axial load, carrying a number of intermediate lumped masses and rotary inertias based on the Differential transform method and numerical assembly technique. Farghaly and El-Sayed presented in [11] parametric studies for an axially loaded stepped Timoshenko beam carrying several attachments. All of the aforementioned studies were carried out assuming linearity and none of them took into account the effect of geometrical non-linearity. This work, which is a continuation of the work previously carried out by Benamar et al.[12]–[19], is intended to contribute to a non-linear modal analysis of structural vibration by studying the geometrically non-linear free vibration of stepped beams carrying multiple masses using the Euler-Bernoulli beam theory and the Von Karman geometrical nonlinearity assumptions. The beam total strain and kinetic energies are presented as discrete expressions and then derived. By applying Hamilton's principle, the problem is reduced to a non-linear algebraic system solved by an approximate method previously applied to similar problems (the so-called second formulation) [16]. A parametric study is performed to explore the effect of non-linearity on the dynamic behaviour of stepped beams with several added masses. The free vibration case is discussed by considering three types of stepped beams which differ in the cross-section type.

## 1- General formulation

### 1.1 Linear formulation

The current study deals with the three homogeneous Euler-Bernoulli multi-step beams shown in Figure (1), characterised by a thin rectangular cross-section. The first beam rectangular cross-section (a) varied in breadth, the second beam (b) varied in depth, and the third beam (c) varied in both. For the remainder of the work, the beams examined are fully clamped, with a concentrated mass at the middle, and subjected to transverse vibrations.

Figure 1: Three representative cases of the stepped beam.

Each of the beams shown in Figure 2 carries a concentric mass in the middle. They are also partitioned into three uniform cross-section parts and are subjected to transverse vibrations.

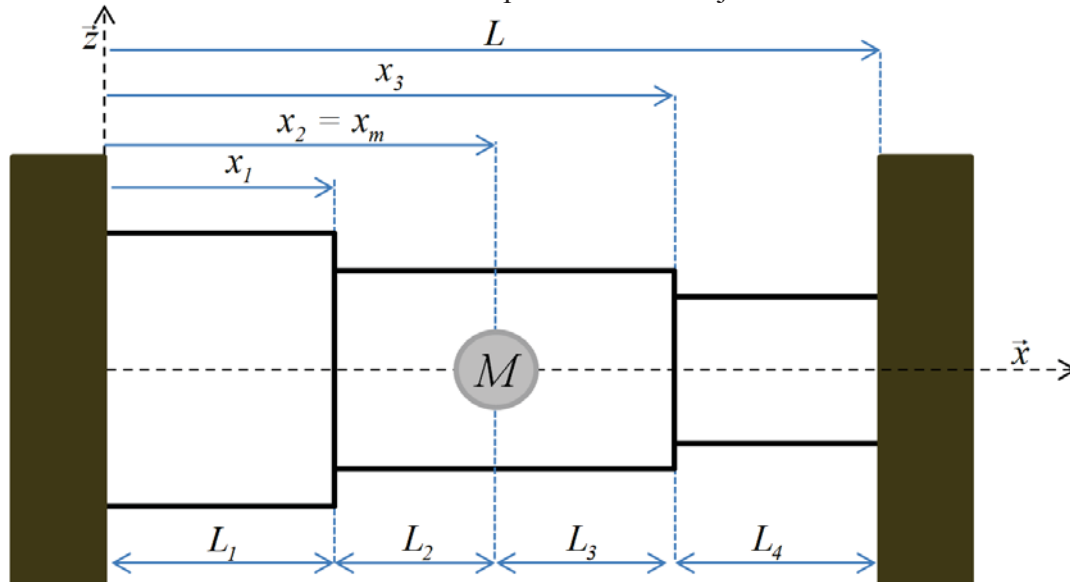

Figure 2: The coordinate system for a multi-stepped beam.

The transverse free vibration in each span is governed by the following equation:

$$\frac{d^4 W_i(x)}{dx^4} - \beta_i^4 W_i(x) = 0 \quad ; x \in [0, L] \text{ (For } i=1, 2, \dots, 12) \quad (1)$$

Where

$$\beta_{ij}^4 = \omega_i^2 \frac{\rho_j S_j}{E_j I_j} \text{ (For } j=1, 2 \text{ and } 4) \quad (2)$$

After putting the parameters of equation (1) into a non-dimensional form, Equation (1) can be written in the following form:

$$\frac{d^4 W_i(x^*)}{dx^4} - \beta_i^4 W_i(x^*) = 0 \quad ; x^* \in [0 \ 1] \quad (3)$$

Where

$$x_j^* = \frac{x_j}{L}; R_j^* = \frac{L_j}{L} \quad ; \quad z_j = \frac{\beta_{ij}}{\beta_{i1}}; u_j = \frac{S_j}{S_1}; v_j = \frac{I_j}{I_1} \quad (4)$$

Each step of the beam is characterized by a ratio of sections, moments of inertia and eigenvalue parameters which are denoted by (  $u_j, v_j$  and  $z_j$  ).

The solution of Eq. (1) presents the linear modes form which can be expressed at each span as:

$$W_i(x^*) = \begin{cases} W_{ij}(x^*) \rightarrow \{x_{j-1}^* \leq x^* \leq x_j^*\} \\ \dots \\ \dots \end{cases}$$

$$W_{ij}(x^*) = A_j \cosh(\beta_{ij} L(x^* - x_{j-1}^*)) + B_j \sinh(\beta_{ij} L(x^* - x_{j-1}^*)) + C_j \cos(\beta_{ij} L(x^* - x_{j-1}^*)) + D_j \sin(\beta_{ij} L(x^* - x_{j-1}^*)) \quad (5)$$

In equation (5), the constants  $A_j, B_j, C_j$  and  $D_j$  can be solved from the compatibility conditions and the boundary conditions.

The boundary conditions at the left side:

$$W_{i1}(x^*) \Big|_{x^*=0} = 0 \quad ; \quad \frac{dW_{i1}(x^*)}{dx^*} \Big|_{x^*=0} = 0 \quad (6,7)$$

The boundary conditions at the right side:

$$W_{i4}(x^*) \Big|_{x^*=1} = 0 \quad ; \quad \frac{dW_{i4}(x^*)}{dx^*} \Big|_{x^*=1} = 0 \quad (8,9)$$

The compatibility conditions at each change in the cross-section are given by:

$$W_{ij}(x^*) \Big|_{x^*=x_j^*} = W_{ij+1}(x^*) \Big|_{x^*=x_j^*} \quad (10)$$

$$\frac{dW_{ij}(x^*)}{dx^*} \Big|_{x^*=x_j^*} = \frac{dW_{ij+1}(x^*)}{dx^*} \Big|_{x^*=x_j^*} \quad (11)$$

$$EI_j \frac{d^2 W_{ij}(x^*)}{dx^{*2}} \Big|_{x^*=x_j^*} = EI_{j+1} \frac{d^2 W_{ij+1}(x^*)}{dx^{*2}} \Big|_{x^*=x_j^*} \quad (12)$$

$$EI_j \frac{d^3 W_{ij}(x^*)}{dx^{*3}} \Big|_{x^*=x_j^*} = EI_{j+1} \frac{d^3 W_{(j+1)i}(x^*)}{dx^{*3}} \Big|_{x^*=x_j^*} \quad (13)$$

The compatibility conditions for an attached mass with a rotary inertia are given by:

$$W_{ji}(x^*) \Big|_{x^*=x_m^*} = W_{(j+1)i}(x^*) \Big|_{x^*=x_m^*} \quad (14)$$

$$\frac{dW_{ji}(x^*)}{dx^*} \Big|_{x^*=x_m^*} = \frac{dW_{(j+1)i}(x^*)}{dx^*} \Big|_{x^*=x_m^*} \quad (15)$$

$$\frac{d^2 W_{ji}(x^*)}{dx^{*2}} \Big|_{x^*=x_m^*} = \frac{d^2 W_{(j+1)i}(x^*)}{dx^{*2}} \Big|_{x^*=x_m^*} + J_j \omega^2 \frac{dW_{ji}(x^*)}{dx^*} \Big|_{x^*=x_m^*} \quad (16)$$

$$\frac{d^3 W_{ji}(x^*)}{dx^{*3}} \Big|_{x^*=x_m^*} = \frac{d^3 W_{(j+1)i}(x^*)}{dx^{*3}} \Big|_{x^*=x_m^*} - \frac{M_j \omega^2 W_{ji}(x^*)}{EI} \Big|_{x^*=x_m^*} \quad (17)$$

Non-trivial solutions corresponding to the natural frequencies are derived by stating that the determinant of the homogeneous system obtained from the boundary and compatibility conditions vanishes. The transcendental equation obtained is solved iteratively by the Newton-Raphson method and the constants  $A_j, B_j, C_j$  and  $D_j$  are determined by classical algebra.

### 2.3. Non-linear formulation

#### 2.2.1 Free vibration

The kinetic energy  $T$  of the beam is given by:

$$T = \frac{\rho}{2} \int_0^L S(x) \left( \frac{\delta w(x^*, t)}{\delta t} \right)^2 dx + \frac{I}{2} M_c \left( \frac{\delta w(x_m^*, t)}{\delta t} \right)^2 \quad (18)$$

The total deformation energy  $V$  is the sum of the deformation energy due to bending and the axial deformation energy due to the non-linear stretching forces induced by the large deflections, respectively denoted by  $V_f$  and  $V_a$  and written as follows:

$$V = V_f + V_a \quad (19)$$

$$V_f = \frac{I}{2} \int_0^L E I(x) \left( \frac{d^2 w_i}{dx^2} \right) \left( \frac{d^2 w_j}{dx^2} \right) dx \quad (20)$$

$$V_a = \frac{I}{2} \frac{N_x^2}{E} \int_0^L S(x) dx \quad (21)$$

Where  $N_x$  present the non-linear stretching forces in the beam. The dynamic behaviour of the system is studied by applying Hamilton's principle, stated formally as follows:

$$\delta \int_0^{2\omega} (V - T) dt = 0 \quad (22)$$

Assuming that the system has a harmonic motion, the transverse displacement can be written as:

$$w(x,t) = a_i W_i(x) \sin(\omega t) \quad (\text{For } i = 1, 2, \dots, n) \quad (23)$$

The linear modes, the basic function contribution coefficients and the associated frequency are denoted by  $W_i(x)$ ,  $a_i$  and  $\omega$ . After Substitution of equation (23) into equations (18, 20 and 21), the expressions for the kinetic energy, the axial deformation energy and the bending strain energy can be written as follows:

$$T = \frac{1}{2} \omega^2 a_i a_i (\cos(\omega t))^2 m_{ij}; \quad (24)$$

$$V_a = \frac{1}{2} a_i a_j a_k a_l (\sin(\omega t))^4 b_{ijkl}; V_f = \frac{1}{2} a_i a_i (\sin(\omega t))^2 k_{ij} \quad (25,26)$$

Where  $k_{ij}$ ,  $b_{ijkl}$  and  $m_{ij}$  denote the stiffness tensor due to  $V_f$ , the non-linearity tensor due to  $V_a$  and the mass tensor attributable to  $T$ . Equation (23) is extended by adding equations (24 and 26) into it, which leads to the following new form:

$$2a_i k_{ir} + 3a_i a_j a_k b_{ijkr} - 2\omega^2 a_i m_{ir} = 0 \quad ; \quad r = 1, \dots, n \quad (28)$$

Equation (28) can be expressed in a matrix form as follows:

$$2[K]\{A\} + 3[B(\{A\})]\{A\} - 2\omega^2 [M]\{A\} = 0 \quad (29)$$

In which  $(k_{ir})$ ,  $(m_{ir})$ ,  $(a_j a_k b_{ijkl})$  and  $(a_i)$  are the general terms of the matrices  $[K]$ ,  $[M]$ ,  $[B(\{A\})]$  and  $\{A\}$ . Setting the dimensionless parameters as follows:

$$\frac{W_i(x^*)}{W_i^*(x^*)} = h_0; \frac{\omega^2}{\omega^{*2}} = \frac{E I_1}{\rho S_1 L^4}; \frac{M_{ij}}{M_{ij}^*} = \rho S_1 h_0^2 \quad (30,31,32)$$

$$k_{ij} = \frac{E I_1 h_0^2}{L^3} k_{ij}^*; b_{ijkl} = \frac{E I_1 h_0^2}{L^3} b_{ijkl}^* \quad (33,34)$$

After substitution of the dimensionless parameters, Equation (29) becomes:

$$[K^*]\{A\} + \frac{3}{2}[B^*(\{A\})]\{A\} - \omega^{*2} [M^*]\{A\} = 0 \quad (35)$$

In order to determine the frequency  $\omega$  and the column vector of the contribution coefficients  $\{A\}$ , which are the unknowns of equation (35), the so-called second formulation, previously developed by EL KADIRI et al. in [16], is used to solve equation (35).

## NUMERICAL RESULTS AND DISCUSSION:

### 1.2 Free vibration:

In order to validate the numerical method mentioned above using the available data, the results corresponding to a uniform beam carrying a point mass at the middle are compared to those obtained in [20], where the section ratios of the 1<sup>st</sup> and 2<sup>nd</sup> steps, designated by  $u_1$  and  $u_2$ , are equal to  $u_1 = u_2 = 1$  and the mass magnitude  $M_c = 1$

$W_{\max}/r$	Present work	Reference [20]	Rel Diff[20]
0.4	1.0035	1.0034	0.01%
0.8	1.0142	1.0137	0.05%
1	1.0221	1.0213	0.08%
2	1.0851	1.0814	0.34%

Table 1:  $\left(\omega_{NL}/\omega\right)$  for clamped beams, in which a concentrated mass is located at its middle with  $r = \sqrt{I/S}$ .

The results show an excellent agreement, with a relative difference not exceeding 0,34%. The cases considered in all figures below are for three stepped beams with two cross-section changes and carrying a concentrated mass at the middle as shown in figure (1). The mass magnitude  $M_c = 1$ , the cross-section ratios at the 1st and 2nd step  $u_1$  and  $u_2$  equal to  $u_1=0.8$  and  $u_2=0.6$ . The three beams keep the same ratios  $u_1$  and  $u_2$ , but each of them is expressed differently. The figures below show the effect of the cross-section variations on the frequency ratio.

Figure (3): Backbone curves of the three stepped beams studied, corresponding to the first nonlinear mode.

Figure (4): The normalized first non-linear mode of beam (a) for different values of  $a_1$ .

Figure (5): The non-linear curvature distribution of beam (a) associated to the normalized first non-linear mode for different values of  $a_1$ .

Figure (6): The normalized first non-linear mode of beam (b) for different values of  $a_1$ .

Figure (7): The non-linear curvature distribution of beam (b) associated to the normalized first non-linear mode for different values of  $a_1$ .Figure (8): The normalized first non-linear mode of beam (c) for different values of  $a_1$ .Figure (9): The non-linear curvature distribution of beam (c) associated to the normalized first non-linear mode for different values of  $a_1$ .

beam	Curvature		
	Non-linear theory	Linear theory	percentage correction %
a	49,33	61,43	19,69
b	54,18	81,44	33,47
c	58,56	70,12	19,74

Table 2: The percentage correction between the curvatures estimated at the right end via the linear and nonlinear theories for  $a_1=2$ .

The backbone curves in Figure (3) show that by increasing the maximum non-dimensional amplitude  $W_{\max}^*$ , the frequency ratios also increase. Also, the hardening effect of non-linearity is more accentuated in beam (b) compared to the other. It can be noticed that the geometrical non-linearity is not only related to the section ratio but also to the way it varies. For instance, the results obtained from Table (2) show that the percentage correction of the linear and non-linear bending moment of beam (a) at the right end with a contribution coefficient

$a_1=2$  is 19.69%, and remains higher than the two others, where the percentage correction of beam (c) and beam (a) are respectively 19.74% and 19.69%. Once more, these results reveal that the assumption of neglecting geometrical non-linearity for the same beam can be misleading.

## 2 CONCLUSION

The geometrically non-linear transverse vibrations of multi-stepped fully clamped beams carrying masses at the middle was studied analytically based on the Euler-Bernoulli's beams theory and the Von Karman's nonlinearity assumptions. The solution of the linear problem was obtained for the stepped beams considered. After determining the linear mode shapes, these were employed as basic functions for non-linear vibration analysis. To solve the non-linear algebraic system, the approximate method called the second formulation was applied. A comparison was performed between the result obtained from the numerical method used in the present work and those of Reference [18]. This comparison showed an excellent agreement. Then, the non-linear dynamic behaviour of multi-stepped beams in the free vibration case was examined by considering three types of fully clamped multi-stepped beams carrying masses at the middle. The results were illustrated by backbone curves, amplitude dependent non-linear modes and curvatures, showing a clear hardening non-linear behaviour. The assumption of neglecting the geometrical non-linearity is also illustrated and discussed.

### Abstract

*During the last few years, different methodologies have been developed for the analysis of the structural seismic response, such as the performance-based design, the systems of energy dissipation, seismic isolation. Based on these efforts, a number of devices, known collectively as protection systems have emerged. They are divided into three types of systems: passive, active, and semi-active. Passive systems dissipate energy through friction, viscous fluid dampers, and inelastic behavior of the material, among others. On the other hand, active control systems can be implemented by applying time varying forces to counteract those imposed by the excitation. which can be active, passive, semi-active, active, etc.*

*This paper presents the response of the structure when it enters the nonlinear range and is being controlled by the Viscous Damper. To obtain the nonlinear response of the structure system through numerical simulation are used the Methodologies of ASCE 7-10 and ASCE 7-16. To examine the behavior of the structures and the application of each methodology, simulations using concrete frames of 5, 7 and 11-story buildings were performed. The models were subjected to the horizontal components of different earthquakes, for the ASCE 7-10 were used three earthquakes, for the ASCE 7-16 were used seven earthquakes. These seismic records are subjected to a matching process to obtain records that match the corresponding building code design spectrum for a high seismic risk zone. The history displacement and acceleration results were compared with those obtained with the uncontrolled structure with nonlinear behavior.*

## 1 INTRODUCTION

During the last three decades, a number of modern mechanical devices have been proposed to reduce the structural response of buildings to environmental loads. These devices, which are known collectively as protective devices, include viscoelastic dampers, viscous fluid dampers, frictional dampers, tuned-mass dampers, and base isolation systems. The devices themselves and their design methodology are referred to as passive control systems [1]. On the other hand, the highest level of sophistication in seismic protection is provided by the active control systems [2]. There is an intermediate alternative between passive and fully active control systems: they are referred to as “semi-active systems” [3, 4, 5, 11, 12]. The passive systems dissipate the seismic energy through friction in special devices, the inelastic behavior of sacrificial elements, etc. The passive systems have the important advantage that they do not require external energy for their operation.

On the other hand, research on fragility curves in structures with control system incorporated have been developed Taylor and Dike [13], Cundumi and Laboy [6], and among others.

This can be achieved by incorporating control systems to reduce displacements, acceleration and forces among seismic events. Incorporating control systems as an alternative for the design of new structures and the rehabilitation of existing structures is becoming more popular among building codes. Some examples of this Code include the Colombian Code NSR-10 [16], ASCE 7-10 and ASCE 7-16 (American Society of Civil Engineers) [17, 18], the Eurocode [30], and the Chilean Standard NCh [27].

This paper only presents the result abstained for two frames. The frames used were subjected to acceleration at the base by using three earthquakes [16] and seven earthquakes [17]. To obtain the maximum drift, displacement time histories, acceleration time histories, hysteresis, etc. for each one of the frames the program ETABS [19] and programs utilizing Mathlab applications was developed. The amount of damage was quantified by using HAZUS parameter [14, 15], where the damage index was obtained based on the ratio between the maximum displacement and the story height.

Finally, a series of Figures and Table are presented for each frame analyzed in order to represent the difference between using three [17] and seven [18] seismic records.

## 2 EQUATION OF MOTION AND DAMPER FORCE

It is well known that the equations of motion of a structure modeled as a multi-degree of freedom system and subjected to a base acceleration of  $\ddot{x}_g(t)$  at all its supports is:

$$[M]_{n \times n} \{\ddot{x}(t)\} + [C]_{n \times n} \{\dot{x}(t)\} + [K]_{n \times n} \{x(t)\} = -[M]_{n \times n} \{E\} \ddot{x}_g(t) \quad (1)$$

where  $[M]$ ,  $[C]$  y  $[K]$  are the mass, damping and stiffness matrix respectively, the vectors  $\{\ddot{x}(t)\}$ ,  $\{\dot{x}(t)\}$ ,  $\{x(t)\}$  are the acceleration, velocity and displacement of each dynamic degree of freedom of the structure,  $\{E\}$  is the vector of influence coefficients, and  $n$  is the number of degrees of freedom.

When a viscous fluid damper is incorporated in the structure, the damping matrix change. The force-displacement response of a velocity-dependent dashpot-type device is primarily a function of the relative velocity between each end of the device.

$$[M]_{n \times n} \{\ddot{x}(t)\} + [C + C_d]_{n \times n} \{\dot{x}(t)\} + [K]_{n \times n} \{x(t)\} = -[M]_{n \times n} \{E\} \ddot{x}_g(t) \quad (2)$$

The ideal force output of a viscous fluid damper can be expressed as is presented in equation (3).

$$F_d(t) = C_o |\dot{x}(t)|^\alpha \operatorname{sgn}(\dot{x}(t)) \quad (3)$$

where  $F_d$  is the damper force,  $C_o$  is the damping coefficient for the device,  $\dot{x}(t)$  is the relative velocity between each end of the device,  $\operatorname{sgn}$  is the sign um function that in this case defines the sign of the relative velocity term, and  $\alpha$  is the velocity exponent for the device which may take values in the range of about 0.25 to 2 (see reference [10]). The case  $\alpha=1$  correspond to a linear viscous damper in which the damper force is proportional to the relative velocity. When  $\alpha$  smaller than 1 the device is called a nonlinear viscous damper. Values of  $\alpha$  larger than 1 (also a nonlinear damper) have not been used often in practical applications.

The viscous damping ratio in the first mode should be estimated as [7]:

$$\beta_{v1} = \frac{\sum_j (2\pi)^{a_j} T_1^{2-a_j} \lambda_j C_j f_j^{1+a_j} \Delta_{roof}^{a_j-1} \phi_{rj}^{1+a_j}}{8\pi^3 \sum_i \left( \frac{\omega_i}{g} \right) \phi_{i1}^2} \quad (4)$$

where  $\lambda_j$  is a dimensionless parameter given by Equation 14 of Ramirez et al. [10] and all other terms have been defined by Whittaker et Al [7].

### 3 NUMERICAL PROCEDURE AND EXAMPLE

As an initial step, two concrete frames are established for two different buildings, Type I frame is five (5) levels with cover consisting of beams and columns with three lights ranging in length between 4m and 5m with a total height per story of 3m, on the other hand, the type II frame consists of seven (7) levels with cover and four lights ranging in length between 5m and 6m with total height per story of 3m, as shown in the Figure 1.

Figure 1: Types frames.

Once the two types of frames are defined to be designed, the next step is to build the design spectrum, where two types of spectrum with different characteristics belonging to a particular area were established, for this, the Colombian earthquake resistant code (NSR-10) was used. establishing the city of "Santiago de Cali" as the area to study because it is an area of high seismic threat, for the spectrum, different couples of results were taken depending on the importance level of the structure and of the type of soil, for the Type I design spectrum, a type "D" soil was used, corresponding to rigid soil profiles with a group III of importance equivalent to "Community care buildings". For the Type II design spectrum, a type "C" soil was used, corresponding to soft soil profiles or formed by soft rock, with a group IV of importance equivalent to "Essential buildings" such as clinics. Based on this data, the rest of the coefficients belonging to the construction of the design spectrum. The Table 1 presents the definitive characteristics for each type of spectrum.

DESIGN SPECTRUM COEFFICIENTS							
ESPECTRUM	SOIL GROUP	Aa	Av	Fa	Fv	IMPORTANCE GROUP	I
Type I espectrum	D	0,25	0,25	1,3	1,9	III	1,25
Type II espectrum	C	0,25	0,25	1,15	1,55	IV	1,5

Table 1: Design spectrum coefficients.

Once the spectrum coefficients are defined, it gives way to calculate and graph the two types of spectrum "Type I" and "Type II", therefore, the maximum expected spectrum "MCEr" is calculated, as indicated by the American regulations, multiplying by 1,5 the accelerations obtained in the previous calculated designs spectrum. Figure 1 shows the design spectrum.

Figure 2: Design spectrum.

For the load assessment of the two frames, an afferent width of 3m was assumed, a 10cm slab and an additional dead load corresponding to walls with an equivalent value to  $2\text{kN/m}^2$ , on the other hand, a live load was assumed for each story equivalent to  $2,5\text{kN/m}^2$  and  $0,5\text{kN/m}^2$  for the cover, therefore, the respective load assessment is obtained. The Table 2 presents the load assessment.

LOAD ASSESSMENT			
FRAME	STOREYS	WD [ $\text{KN/m}^2$ ]	WL [ $\text{KN/m}^2$ ]
Type I	1 - 5	4,4	2,5
Type I	Cover	2,4	0,5
Type II	1 - 7	4,4	2,5
Type II	Cover	2,4	0,5

Table 2: Load Assessment.

After obtaining the load assessment, it gives way to carry out the pre-dimensioning and design of the different structural elements for the two frames, thus obtaining the following dimensions. The Table 3 presents the model dimensions.

MODEL DIMENSIONS					
ESPECTRUM	TYPE FRAME	BASE COLUMN (cm)	HEIGHT COLUMN (cm)	BASE BEAM (cm)	HEIGHT BEAM (cm)
Group III - Soil D	I	40	40	40	40
Group IV - Soil C	II	55	55	55	50

Table 3: Model dimensions.

The code ASCE 7-16 specifies that, for both the design spectrum and the MCER, at least seven (7) seismic records must be selected, each of these records must be escalated to the design spectrum as the MCER, the average of the seven (7) seismic records should not stay below both spectrums mentioned above. For this, the procedure called "Matching" is carried out using the SeismoMatch software [23], where a damping of 5% is determined and the period of

vibration of the structure is specified by the design spectrum and the MCER. next up, the seven (7) seismic records to analyze. The Table 4 presents the seven (7) seismic records.

<b>SEISMIC RECORDS</b>			
<b>NAME</b>	<b>YEAR</b>	<b>MAGNITUDE</b>	<b>PGA [g]</b>

Kobe	1995	6,9	0,34
Kocaeli	1999	7,4	0,35
Loma Prieta	1989	6,9	0,37
Northridge	1994	6,7	0,57

Table 4: Seven seismic records.

On the other hand, the code ASCE 7-10, specifies that, for both the design spectrum and the MCER, three (3) seismic records must be selected, unlike the standard ASCE 7-16, Each seismic record must be analyzed independently, analyzing the maximum values obtained for each record, without averaging the results of the three records among themselves. Since the objective is to compare the behavior in each frame for both seven (7) and three (3) registers, of the seven (7) mentioned above, three records are chosen to perform the respective calculations and analysis based on the ASCE 7-10. The Table 5 presents the three (3) seismic records to analyze.

<b>SEISMIC RECORDS</b>			
<b>NAME</b>	<b>YEAR</b>	<b>MAGNITUDE</b>	<b>PGA [g]</b>
Friuli	1976	6,4	0,35
Loma Prieta	1989	6,9	0,37
Northridge	1994	6,7	0,57

Table 5: Seven seismic records.

Once the seismic records, design spectrum and dimensions mentioned above are defined, the modeling is carried out using the ETABS Software [19], where four (4) structural models are defined, and each one of the frames are evaluated by the method given by each code. Next up, the four (4) models to analyze. The Table 6 presents the model types.

<b>MODEL TYPES</b>			
<b>MODEL</b>	<b>FRAME TYPE</b>	<b>ESPECTRUM</b>	<b>METHOD</b>
I	I	Group III - Soil D	ASCE-16
II	I	Group III - Soil D	ASCE-10
III	II	Group IV - Soil C	ASCE-16
IV	II	Group IV - Soil C	ASCE-10

Table 6: Model types.

After assigning each model with different properties, it gives way to define the energy dissipaters, in this case, the viscous dampers were modeled as non-linear elements “Link” of the “Damper - Exponential” type, the dampers are located in the external lights of each frame.

Next up, the distribution and selection of the dampers to be analyzed in each frame. The Figure 3 shows the Damper's location and selection.

Figure 3: Damper's location and selection.

Each of the dampers are assigned a value of ( $\alpha = 0.3$ ), on the other hand, the damping “C” is included, which is generated by the damper, plus the contribution of the stiffness of the strut connecting the damper, depending on the stiffness value on the diagonal is assigned a metal profile equivalent to that value. Next up, the properties for each damper depending on the model to be analyzed. The Table 7 presents the viscous dampers properties.

VISCOUS DAMPERS PROPERTIES					
FRAME TYPE	ESPECTRUM	METHOD	PROFILE	STIFFNESS [KN/m]	DAMPING [KN*(s/m) <sup>Cexp</sup> ]
I	Group III - Soil D	ASCE-16	W8X24	200000	100
I	Group III - Soil D	ASCE-10	W8X31	250000	100
II	Group IV - Soil C	ASCE-16	W8X35	290000	100
II	Group IV - Soil C	ASCE-10	W8X35	290000	100

Table 7: Viscous dampers properties.

Once each model has been defined with their respective properties for each damper, we proceed to run each of the models in order to analyze the behavior of each of these under the different methods established by the ASCE-10 and ASCE-16 codes. Since the code establishes that when designing a structure with energy dissipaters, said structure must be evaluated against different seismic records. When a structure is exposed to a seismic loading, the structure presents displacement generated by the force, the displacement is in function with the height, that is why the displacement at the maximum point of the structure is analyzed, in this case on the cover, due to this, the maximum displacements generated by each historical record are analyzed in order to analyze said displacements and see if these values are optimal for the structure.

Then the seismic record is shown as in function of the time for the cover displacement in each one (1) of the four (4) models. The Figure 4 shows the cover displacement for Model I and Model II.

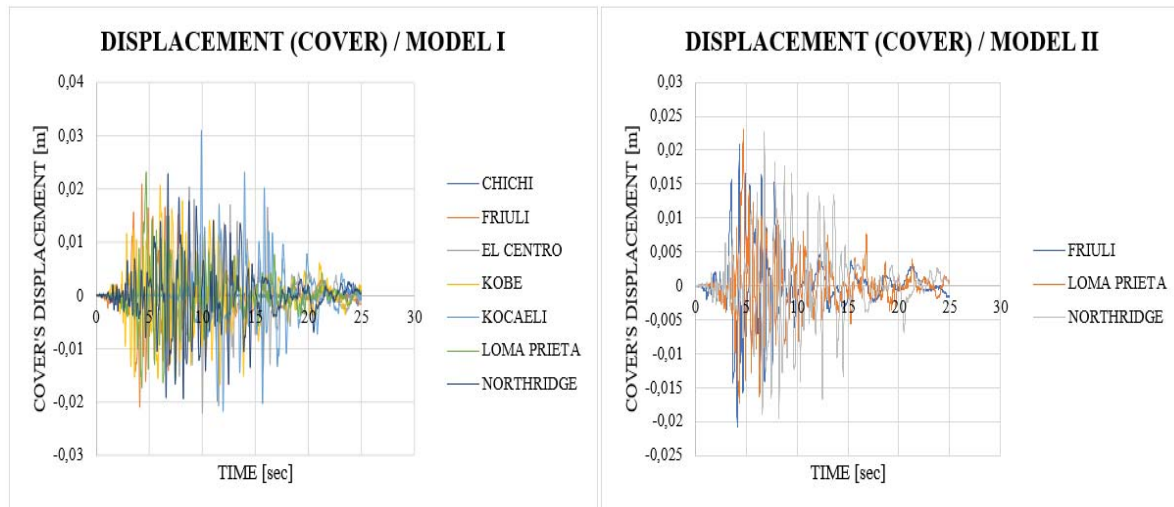

Figure 4: Cover displacement (MI - 7 seismic records vs MII - 3 seismic records).

With regard to “Model I” in Figure 4, it presents a maximum displacement on the cover equivalent to 0,031m corresponding to the seismic record “Kocaeli”, however, the average of the seven (7) seismic records presents a maximum displacement of 0,02m, on the other hand, the “Model II” presents a maximum displacement on the cover of 0,023m corresponding to the “Loma Prieta” seismic record. The Figure 5 shows the cover displacement for Model III and Model IV.

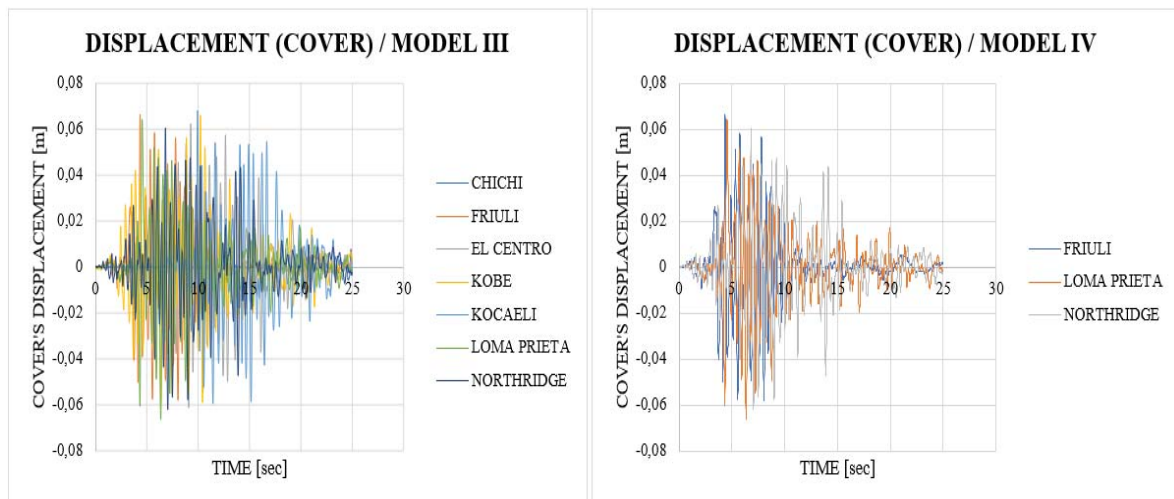

Figure 5: Cover displacement (MIII - 7 seismic records vs MIV - 3 seismic records).

It is observed that in Figure 5, the “Model III” presents a maximum displacement on the cover equivalent to 0,068m corresponding to the seismic record “Kocaeli”, however, the average of the seven (7) seismic records presents a maximum displacement of 0,057m, on the other hand, with regard to the “Model IV” this presents a maximum displacement on the cover of 0,066m corresponding to the “Loma Prieta” seismic record.

The Table 8 presents the maximum cover displacements for each model.

DISPLACEMENT (COVER)		
MODEL	METHOD	MAXIMUM DISPLACEMENT [m]
I	ASCE-16	0,02
II	ASCE-10	0,023
III	ASCE-16	0,057
IV	ASCE-10	0,066

Table 8: Maximum displacement.

Once the maximum displacements on the cover have been found, the corresponding drifts to each model is reviewed in order to analyze if these meet the requirements for design, based on the Methodology "HAZUS" a moderate damage is established for armed concrete frames, for the "Type I" frame with a total height of 15m, a target drift of 0,58% is assigned, on the other hand, for the "Type II" frame with a total height of 21m, a target drift of 0,54% is assigned as presented in the following table. The Table 9 presents the target drifts.

TARGET DRIFTS	
FRAME TYPE	DRIFTS [%]
I	0,58
II	0,54

Table 9: Target drifts.

Based on the aforementioned, the same gantry is compared under the methodologies specified in each code. The Figure 6 shows the maximum story drifts for Model I and Model II.

Figure 6: Maximum story drifts (MI - 7 seismic records vs MII - 3 seismic records).

As it can be seen in Figure 6, both models are below the target drift, on one hand, “Model I” presents a maximum equivalent drift to 0,32% corresponding to the “Chichi” seismic record, however, the average of the seven (7) seismic records shows a maximum drift of 0,25%, on the other hand, the “Model II” presents a maximum drift of 0,24% corresponding to the

“Loma Prieta” seismic record. The Figure 7 shows the maximum story drifts for Model III and Model IV.

Figure 7: Maximum story drifts (MIII - 7 seismic records vs MIV - 3 seismic records).

In Figure 7, for the “Model III” it is observed that the “Chichi” seismic record exceeds the target drift with an equivalent value to 0,56%, however, the average of the seven (7) seismic records presents a maximum drift of 0,45%, on the other hand, the “Model IV” presents a maximum drift of 0,47% corresponding to the “Loma Prieta” seismic record.

The Table 10 presents the maximum drifts for each model.

MAXIMUM STORY DRIFTS			
MODEL	METHOD	DRIFT [%]	TARGET DRIFT [%]
I	ASCE-16	0,25	0,58
II	ASCE-10	0,24	0,58
III	ASCE-16	0,45	0,54
IV	ASCE-10	0,47	0,54

Table 10: Maximum story drifts.

Therefore, considering the MCEr registers, the force-displacement relationship is analyzed in different dampers located on the first and last story. Next up, the Figure 8, 9, 10 and 11 show the dampers hysteresis cycle with different location in each frame.

Figure 8: Model I hysteresis cycle.

Figure 9: Model II hysteresis cycle.

Figure 10: Model III hysteresis cycle.

Figure 11: Model IV hysteresis cycle.

Finally, the results of the progressive accumulation of the shear forces in each story are presented, which are reflected in the same base, next up, the seismic record is shown as in function of the time for the base shear in each one (1) of the four (4) models. The Figure 12 shows the base shear results for Model I and Model II.

Figure 12: Base shear (MI - 7 seismic records vs MII - 3 seismic records).

With regard to “Model I” in Figure 12, it presents a maximum base shear with a value equivalent to 408,8kN corresponding to the seismic record “Kocaeli”, however, the average of the seven (7) seismic records presents a maximum shear at the base with a value of 300,3kN, on the other hand, the “Model II” presents a maximum base shear with a value of 351,9kN corresponding to the “Loma Prieta” seismic record. The Figure 13 shows the base shear results for Model III and Model IV.

Figure 13: Base shear (MIII - 7 seismic records vs MIV - 3 seismic records).

It is observed that in Figure 13, the “Model III” presents a maximum base shear with a value equivalent to 1851,5kN corresponding to the “Loma Prieta” seismic record, however, the average of the seven (7) seismic records presents a maximum base shear with a value of 1407kN, on the other hand, with regard to "Model IV" this presents a maximum base shear of 1851,7kNm corresponding to the seismic record "Loma Prieta".

The Table 11 present the maximum base shear values for each model.

BASE SHEAR		
MODEL	METHOD	BASE SHEAR [KN]
I	ASCE-16	300,3
II	ASCE-10	351,9
III	ASCE-16	1407
IV	ASCE-10	1851,7

Table 11: Base shear.

## 4 CONCLUSIONS

This paper presented the analysis and result for two concrete frame buildings with passive controllers incorporated using the methodologies ASCE 7-10 (three seismic record) and ASCE 7-16 (seven seismic records). The response of the hysteresis cycle, time histories displacement, acceleration, and base shear were compared for each analysis and corresponding frame. The differences between the two methodologies of the maximum responses obtained were presented in detail in section 3.

The results obtained in the numerical simulations for the frames presented in this article, show in Table 8 differences in the maximum displacement of 15% in the two frames using both methodologies, the displacement results obtained are lower with the methodology of the ASCE 7-16. Similarly, Table 10 presents difference percentages of less than 5% for the maximum drifts, registering the lowest values with the ASCE 7-16 methodology.

### Abstract

*Urban areas with a significant number of buildings designed without earthquake resistant concepts may undergo high losses following major earthquakes. However, an adequate design is the direct result of a comprehensive knowledge of the seismic hazard. In Italy, for example, the seismic zonation was completed in recent years, thus a significant number of buildings lack adequate lateral capacity. For this reason, preventive assessment of their vulnerability and expected damage is crucial.*

*This paper presents the vulnerability assessment of two reinforced concrete buildings designed for gravity loads and representative of the Pescara Province in the Abruzzi Region (Central Italy). Geometrical and structural characteristics of the buildings are initially derived from an existing database based on structured interviews with local technicians. The two buildings are then modeled using a simulated design approach following two different buildings codes. Nonlinear dynamic analyses are carried out in order to derive a suite of fragility curves for different damage states. These curves may be used to predict the expected damage following earthquakes of increasing intensities and plan mitigation strategies.*

## 1 INTRODUCTION

The European Union is actively trying to enhance the understanding of disaster risk by laying out a shared approach for loss assessments [1]. Italy committed to this effort by developing a National Risk Assessment (NRA) [2] which considered all potential disaster risks. Among potential risks, seismic risk induces the second highest loss of lives, especially in the Euro-Mediterranean Region.

A commonly agreed definition of seismic risk is the combination of hazard (H), vulnerability (V) and exposure (E) [3], see Eq. 1:

$$R = H \cdot V \cdot E \quad (1)$$

Hazard relates to the probability of occurrence of an earthquake of a specified intensity in a defined period of time. Vulnerability relates to the potential damage undergone by the asset under assessment (e.g., a building) in the occurrence of the earthquake. Exposure relates to the potential losses (e.g., economic and social) caused by the building's damage.

Among the three aspects of Eq. 1, the vulnerability definition has proven to be the most challenging task, as it requires not only an extensive knowledge of all buildings under assessment, but also a detailed evaluation of their seismic response. The complexity of the task is further increased when dealing with large scale assessments. For these reasons, the concept of “minimal fragility portfolio” has been recently developed [4–6], which focuses on defining a reasonable number of buildings typologies that are representative of the whole built environment. By focusing on the derivation of fragility curves (which relates the probability of exceeding pre-defined damage states for increasing intensities [7]) only for these typologies, the time needed to perform large scale assessments is significantly reduced while keeping a sufficient level of accuracy.

In this paper, an existing database for Italian residential buildings is used to define two reinforced concrete (RC) building typologies that are representative of the Pescara province, Central Italy. These buildings have been modeled using a simulated design approach [8] in order to perform non-linear dynamic analyses (NLDAs). Outputs of these analyses have been used to derive a suite of fragility curves for defined damage states.

## 2 CASE STUDY DEFINITION

The Abruzzo Region, Central Italy, is among the areas with the highest seismic risk in Italy, as showed by the extensive losses in the aftermath of the L'Aquila 2009 [9] and Central Italy 2016-2017 [10] earthquakes.

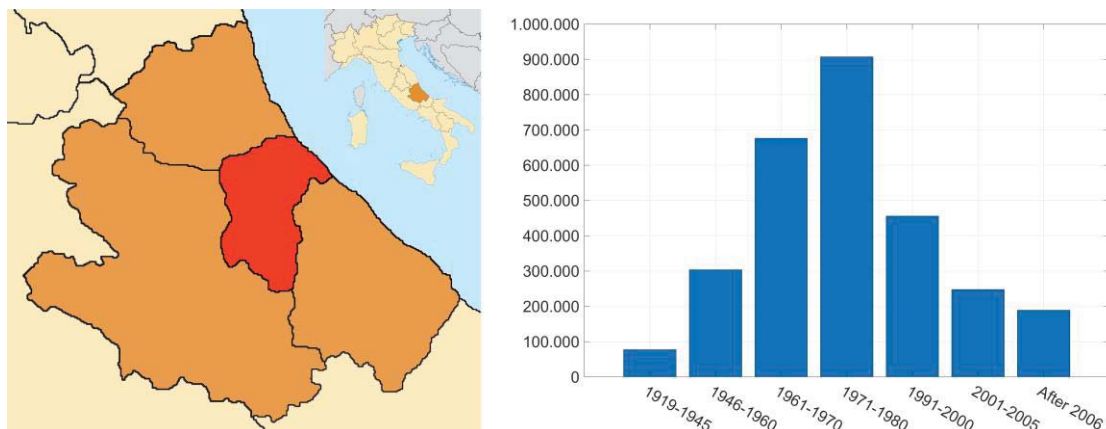

Figure 1. (left) Map of Italy with Abruzzo Region and Province of Pescara highlighted and (right) number of RC buildings in Italy per different construction periods.

In the Abruzzo Region, the Province of Pescara spreads from the coast to the inner mountain areas, see Figure 1a, with the highest population density in the former. The coastal area has been fully included in the seismic zonation in 2003 [11] while the majority of RC buildings in Italy has been built between 1961 and 1980 (source: Census data [12]). For this reason, RC buildings in Pescara were designed considering only gravity loads (GLD) thus making them prone to damage even in the occurrence of earthquakes with moderate intensity.

To collect information on RC buildings in the Pescara Province, the database provided by the CARTIS project [13] has been used. The CARTIS project has been collecting data on the geometrical and structural features of residential buildings in Italy since 2014. The data collection is performed by filling a structured form through interviews with local technicians. The experience and knowledge of the technician ensure that collected data are accurate.

CARTIS data are freely accessible through the pgAdmin platform (<https://www.pgadmin.org/>). For RC buildings, the parameters provided in Table 1 are available.

Parameter
<b>Main resisting system</b>
<b>Number of stories</b>
<b>Construction period</b>
Seismic joints
<b>Unidirectional frames</b>
<b>Ground floor infill walls</b>
Soft story upper floors
Presence of SAP slabs (or similar)
Regularity in plan
Regularity in elevation
Roof material
Roof spread
Structural strengthening

Table 1. Parameters available in the CARTIS database for RC buildings (in bold, those used for the relevant typologies definition).

Parameters of Table 1 in bold have been used to determine the most relevant typologies for the Pescara Province, whose characteristics are listed in Table 2.

ID	Main resisting system	No. of Stories	Construction Period	Design Type	Unidirectional frame	Ground floor infill walls	Regularity in plan
A	Frames with exposed beams and non-sturdy infill walls	4-6	1946-1960	GLD	Yes	Regular configuration	Regular
B	Frames with exposed beams and non-sturdy infill walls	4-6	1971-1980	GLD	Yes	Regular configuration	Regular

Table 2. Characteristics of relevant RC building typologies for the Pescara Province based on CARTIS data.

### 3 MODELING APPROACH

#### 3.1 Design codes, geometry, loads and material properties definition

To model the buildings listed in Table 2, a simulated design approach [8] has been used. Following this approach, the design loads, material properties, and construction details have been determined based on the codes in use at the time of the construction. More specifically, R.D.L. 1939 [14] and D.M. '72 [15] have been used for RC typologies A and B, respectively. In addition, as both typologies were designed for gravity loads and the only load combination used is the sum of dead ( $G$ ) and live ( $Q$ ) loads. This design type does not change for increasing number of stories, the focus has been put on the six-story buildings. The 4 and 5-story buildings have been subsequently derived by taking the upper 4 and 5 stories, respectively.

At first, the buildings' layout is assumed, as no geometrical information was provided by the CARTIS data. The assumed plan layout is derived by existing studies that analyzed buildings of the same period [14,15] and is shown in Figure 2. In the inner frames, beams are present only in the X direction, thus making the Y direction less resistant to lateral forces. Each story is 3 m height, for a total height of 18 m.

Figure 2. Assumed plan layout (dotted, the bond-beams in the Y direction).

As for the design loads, the R.D.L. 1939 does not provide any value, therefore they had to be assumed based on the experience. On the other hand, the D.M. '72 refers to another code for the definition of  $G$  and  $Q$  [16]. Design loads for Building A and B are assumed equal and are listed in Table 3, divided between story levels 1-5 and 6 (i.e., roof), infills and stairs.

Load type	Story 1-5 [KN/m <sup>2</sup> ]	Story 6 [KN/m <sup>2</sup> ]	Infills [KN/m]	Stairs [KN/m <sup>2</sup> ]
G	6.4	6.1	5.5	5.3
Q	2	1	-	4

Table 3. Assumed design loads.

The material properties for the concrete and the steel reinforcement are assumed based on the codes provision and are listed in Table 4 and Table 5, respectively.

Concrete					
Building A			Building B		
$R'_{bk}$	250	[kg/cm <sup>2</sup> ]	$R'_{bk}$	250	[kg/cm <sup>2</sup> ]
$\sigma_c$	77.8	[kg/cm <sup>2</sup> ]	$\sigma_c$	85	[kg/cm <sup>2</sup> ]
$\tau_{b0}$	4	[kg/cm <sup>2</sup> ]	$\tau_{b0}$	5.3	[kg/cm <sup>2</sup> ]
$\tau_{b1}$	14	[kg/cm <sup>2</sup> ]	$\tau_{b1}$	16.9	[kg/cm <sup>2</sup> ]

Table 4. Assumed material properties for concrete.

Building		Steel Reinforcement			
A		Longitudinal (carbon)		Transversal (mild)	
		$\sigma_y$	[kg/cm <sup>2</sup> ]	2000	$\sigma_y$ [kg/cm <sup>2</sup> ]
B		Longitudinal (FeB44K)		Transversal (FeB32K)	
		$\sigma_y$	[kg/cm <sup>2</sup> ]	2600	$\sigma_y$ [kg/cm <sup>2</sup> ]

Table 5. Assumed material properties for steel reinforcement.

$R'_{bk}$ ,  $\sigma_c$ ,  $\tau_{b0}$ , and  $\tau_{b1}$  are the concrete compressive strength, permissible stress, and shear strength without/with reinforcement, respectively.  $\sigma_y$  is the steel permissible stress at the yielding of longitudinal and transversal reinforcement. Mild and carbon steel are associated to carbon percentages of 0.15-0.25% and 0.4-0.6%, respectively.

### 3.2 Finite element modeling

The vulnerability analysis of Building A and B is performed through a Finite Element Method (FEM) approach. The FEM modeling has been performed in OpenSees [17] using the pre/post processor STKO [18], as shown in Figure 3.

Figure 3. Graphical user interface of STKO.

Beams have been modeled as lumped plasticity elements combining a section based on so-called “phenomenological” laws and two plastic hinges of finite length at both ends with fiber section [19,20]. By combining these sections, it is possible to reduce the model complexity while describing its behavior with high accuracy [21]. Assumed phenomenological laws are different between the two buildings as they are based on the rebars type. Building A adopts smooth rebars, therefore the phenomenological law proposed by Verderame et al. (2018) [22] is assumed. On the other hand, Building B adopts corrugated bars, therefore the phenomenological law based on the Ibarra et al. (2005) [23] model with Haselton et al. (2008) [24] predictive equation is assumed.

Columns have been modeled as fiber sections using the *Concrete01* [25] and *Steel02* [26] model for the RC and steel, respectively. The length of plastic hinges at both ends has been determined based on modern code provisions [27].

To correctly evaluate the seismic behavior of existing buildings, different material properties than those listed in Table 4 and Table 5 are assumed, in order to consider the aging effect. For the RC compressive strength,  $f_c$ , mean values provided by Masi et al. (2014) [28] have been used, which derived from a large scale in situ survey. For the steel yielding strength,  $f_y$ , values provided by the open-access software Stil ([http://www.reluis.it/index.php?option=com\\_content&view=article&id=199&Itemid=136&lang=it](http://www.reluis.it/index.php?option=com_content&view=article&id=199&Itemid=136&lang=it)) have been used [29]. In addition, the elastic modulus,  $E_s$ , of Building A has been modified to consider the bond-slip that may occur with smooth bars. Assumed values for the structural modeling are listed in Table 6.

Building	Concrete				Steel			
A	$f_c$	18	[MPa]	$f_y$	350	[MPa]	$E_s$	175000 [MPa]
B	$f_c$	20	[MPa]	$f_y$	470	[MPa]	$E_s$	206000 [MPa]

Table 6. Assumed values for the concrete and steel in the structural modeling.

Infills and stairs have not been modelled but have been considered only as loads.

## 4 VULNERABILITY ANALYSIS

### 4.1 Seismic input

The ground motions selection is crucial when performing NLDAs as they must be representative of the seismic hazard in the area under assessment [30] and the number must be sufficient to capture all possible damage states. In this paper, the ground motion selection proposed by Paolucci et al. (2020) [31] has been used. This selection includes 125 unscaled input motions have been determined for soil category A (rock) using the L'Aquila hazard spectra (Abruzzo Region, close to the Pescara Province) as target.

### 4.2 Engineering Demand Parameter and Damage states

The maximum interstory drift ratio (IDR) in both horizontal directions is assumed as Engineering Demand Parameter (EDP) to determine the building's damage. Damage is classified according to the European Macroseismic Scale EMS-98 [32] and varies from D0 (no damage) to D5 (destruction or complete collapse). IDR values are associated to EMS-98 damage states by using the ranges proposed by Masi et al. (2015, 2021) [33,34] for medium and high-rise ( $\geq 3$  stories) GLD RC buildings, that are listed in Table 7.

Damage State	IDR (%)
D0 (none)	< 0.1
D1 (slight)	0.1 - 0.25
D2 (moderate)	0.25 - 0.5
D3 (substantial to heavy)	0.5 - 1.0
D4 (very heavy)	1.0 - 2.5
D5 (destruction)	> 2.5

Table 7. Assumed relationships between IDR values and EMS-98 damage states.

### 4.3 Fragility curves definition

Selected ground motions have been applied on both horizontal directions thus obtaining 250 PGA-IDR values, which relate the maximum Peak Ground Acceleration of the considered ground motion to the maximum IDR among all story levels. Then, fragility curves are derived using the formulation proposed by FEMA 2018 [35], see Eq. 2.

$$P(D_k|PGA) = \Phi \left[ \frac{1}{\beta_{D,Dk}} \cdot \ln \left( \frac{PGA}{PGA_{Dk}} \right) \right] \quad k = 1, \dots, 5 \quad (2)$$

where  $P(D_k|PGA)$  is the probability of exceeding the  $k$ -th damage state,  $D_k$ , given a PGA value,  $\Phi$  is the Gaussian cumulative distribution function,  $\beta_{D,Dk}$  and  $PGA_{Dk}$  are the logarithmic standard deviation and median value, respectively.

Obtained fragility curves for Building A and B are shown in Figure 4. As previously mentioned, 4 and 5-story buildings have been derived by the 6-story by taking the four and five upper stories, respectively.

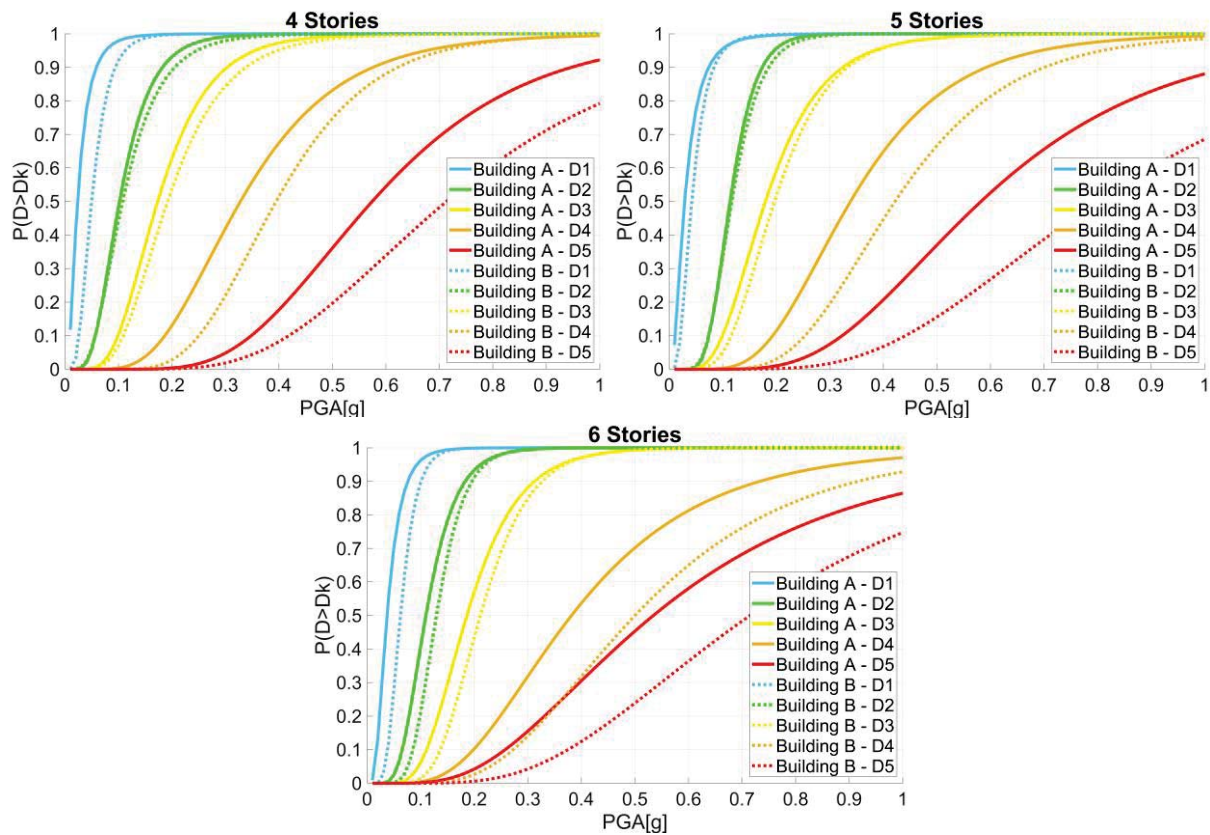

Figure 4. (clockwise) Fragility curves for 4-story, 5-story and 6-story Building A (designed with R.D.L. 1939) and Building B (designed according to D.M. '72).

Observing the graph, it is possible to note that fragility curves of the 4 and 5-story buildings do not significantly differ, while the 6-story buildings is significantly less vulnerable. This is possibly due to the fact that 4-story and 5-story buildings are both considered as “medium-rise”, while the 6-story building is included in the “high-rise” category [36]. Then, Building B is consistently less vulnerable than Building A, thus noting how the evolution of codes is associated to an increase in the seismic performance.

## 5 SUMMARY AND CONCLUSIONS

This paper has presented the vulnerability analysis of two RC building typologies that are representative of the built environment in the Pescara Province, Central Italy. Main characteristics of the typologies have been derived by an existing database of Italian residential buildings. Then, buildings have been modeled through a simulated design approach, also considering the aging effects.

A suite of ground motion records has been used to perform NLDAs whose outputs were used to derive fragility curves for five damage states. Obtained fragility curves show medium-rise buildings have a higher fragility than high rise ones. Finally, the evolution of the building code is associated to an increase in the seismic performance.

**Keywords:** Singular Matrix, Combined Periodic and Stochastic Excitations, Moore-Penrose Inverse Matrix, Nonlinear System, Statistical Linearization.

**Abstract.** *A new technique is proposed for determining the response of multi-degree-of-freedom nonlinear complex multi-body systems with singular parameter matrices subject to combined periodic and stochastic loads. The singular parameter matrices are due to adopting redundant coordinates for modeling the system governing equations of motion. Considering that the system response has a periodic as well as a stochastic component, a harmonic balance method-based scheme is used for treating the deterministic component, followed by the application of the generalized statistical linearization method, in conjunction with an averaging treatment to account for the stochastic component. The validity of the proposed technique is demonstrated by pertinent numerical examples.*

## 1 INTRODUCTION

When the problem of formulating the governing equations of motion of multi-degree-of-freedom (MDOF) dynamical systems is considered, the minimum number of independent coordinates is used. Nevertheless, for several classes of complex multi-body systems and also systems subject to constraints [1, 2], a redundant coordinates modeling is often connected with solution treatments of reduced computational cost [3, 4, 5]. However, this yields singular matrices in the system governing equations of motion. Therefore, several techniques have been developed recently for conducting stochastic response analyses pertaining to systems exhibiting singular parameter matrices; see, indicatively, [6, 7, 8, 9, 10, 11]. This is achieved by resorting to the theory of generalized matrix inverses.

In this paper, a Moore-Penrose (M-P) generalized matrix inverses framework is adopted for determining the response of MDOF nonlinear systems with singular matrices subject to combined periodic and stochastic excitations. To this end, the harmonic balance method is combined with the statistical linearization methodology for systems with singular matrices [12, 13]. Specifically, since the system excitation consists of a periodic and a stochastic component, the corresponding response also has a periodic and a stochastic part. Therefore, a solution treatment based on the harmonic balance method is used for the former, whereas the latter is treated by resorting to the generalized statistical linearization method. Combining the two methods results in the formulation of a coupled system of algebraic equations, which is solved iteratively by invoking the generalized matrix inverse theory [14]. Overall, the proposed technique consists a generalization of the framework developed in [15] to account for systems with singular matrices. Its validity is demonstrated by pertinent numerical examples.

## 2 MATHEMATICAL FORMULATION

The governing equations of motion of an  $l$ -DOF nonlinear system are given by

$$\mathbf{M}_x \ddot{\mathbf{x}} + \mathbf{C}_x \dot{\mathbf{x}} + \mathbf{K}_x \mathbf{x} + \Phi_x(\mathbf{x}, \dot{\mathbf{x}}, \ddot{\mathbf{x}}) = \mathbf{f}_{d,x}(t) + \mathbf{Q}_x(t), \quad (1)$$

where  $\mathbf{x}$  denotes an  $l$  dependent coordinates vector,  $\mathbf{M}_x$ ,  $\mathbf{C}_x$  and  $\mathbf{K}_x$  are, respectively, the  $l \times l$  mass, damping and stiffness matrices, and  $\Phi_x(\mathbf{x}, \dot{\mathbf{x}}, \ddot{\mathbf{x}})$  represents the  $l$  vector of the nonlinearities, which are of the polynomial kind for simplicity. Further,  $\mathbf{f}_{d,x}(t)$  represents the periodic component of the excitation, whereas  $\mathbf{Q}_x(t)$  is a zero-mean Gaussian stochastic excitation. Considering that the system of Eq. (1) is subject to a number of constraint equations of the form  $\mathbf{A}\ddot{\mathbf{x}} + \mathbf{E}\dot{\mathbf{x}} + \mathbf{L}\mathbf{x} = \mathbf{F}$ , where  $\mathbf{A}$ ,  $\mathbf{E}$ ,  $\mathbf{L}$  and  $\mathbf{F}$  denote, respectively,  $m \times l$  matrices and an  $l$  vector, Eq. (1) is recast into

$$\bar{\mathbf{M}}_x \ddot{\mathbf{x}} + \bar{\mathbf{C}}_x \dot{\mathbf{x}} + \bar{\mathbf{K}}_x \mathbf{x} + \bar{\Phi}_x(\mathbf{x}, \dot{\mathbf{x}}, \ddot{\mathbf{x}}) = \bar{\mathbf{f}}_{d,x}(t) + \bar{\mathbf{Q}}_x(t). \quad (2)$$

In Eq. (2),  $\bar{\mathbf{M}}_x$ ,  $\bar{\mathbf{C}}_x$  and  $\bar{\mathbf{K}}_x$  denote the augmented  $(l + m) \times l$  mass, damping and stiffness parameter matrices, which have the form [7]

$$\bar{\mathbf{M}}_x = \begin{bmatrix} (\mathbf{I}_l - \mathbf{A}^+ \mathbf{A}) \mathbf{M}_x \\ \mathbf{A} \end{bmatrix}, \quad \bar{\mathbf{C}}_x = \begin{bmatrix} (\mathbf{I}_l - \mathbf{A}^+ \mathbf{A}) \mathbf{C}_x \\ \mathbf{E} \end{bmatrix}, \quad \bar{\mathbf{K}}_x = \begin{bmatrix} (\mathbf{I}_l - \mathbf{A}^+ \mathbf{A}) \mathbf{K}_x \\ \mathbf{L} \end{bmatrix}, \quad (3)$$

where  $\mathbf{I}_l$  denotes the  $l \times l$  identity matrix, and “+” represents the M-P matrix inverse operation. Further, the augmented  $(l + m)$  vector of the system nonlinearities, and the corresponding periodic and stochastic  $(l + m)$  vectors of the excitation are given by

$$\bar{\Phi}_x = \begin{bmatrix} (\mathbf{I}_l - \mathbf{A}^+ \mathbf{A}) \Phi_x \\ \mathbf{0} \end{bmatrix}, \quad \bar{\mathbf{f}}_{d,x}(t) = \begin{bmatrix} (\mathbf{I}_l - \mathbf{A}^+ \mathbf{A}) \mathbf{f}_{d,x}(t) \\ \mathbf{F} \end{bmatrix}, \quad \bar{\mathbf{Q}}_x(t) = \begin{bmatrix} (\mathbf{I}_l - \mathbf{A}^+ \mathbf{A}) \mathbf{Q}_x(t) \\ \mathbf{F} \end{bmatrix}. \quad (4)$$

A detailed derivation of Eqs. (2)-(4) is found in [7, 12].

Next, considering that the MDOF system in Eq. (2) is subject to combined deterministic and stochastic loads, it is assumed that the corresponding response also consists of a periodic and a stochastic component, namely  $\mathbf{x}(t) = \mathbf{x}_s(t) + \mathbf{x}_d(t)$ . Further, assuming that the stochastic excitation is modeled as a zero-mean Gaussian process, ensemble averaging Eq. (2) yields

$$\bar{\mathbf{M}}_{\mathbf{x}}\ddot{\mathbf{x}}_d + \bar{\mathbf{C}}_{\mathbf{x}}\dot{\mathbf{x}}_d + \bar{\mathbf{K}}_{\mathbf{x}}\mathbf{x}_d + \mathbb{E}[\bar{\Phi}_{\mathbf{x}}(\mathbf{x}_s + \mathbf{x}_d, \dot{\mathbf{x}}_s + \dot{\mathbf{x}}_d, \ddot{\mathbf{x}}_s + \ddot{\mathbf{x}}_d)] = \bar{\mathbf{f}}_{d,\mathbf{x}}(t), \quad (5)$$

which consists of a periodic and a stochastic response component too. In the ensuing analysis, first, the harmonic balance methodology is used in conjunction with the concept of the generalized inverse matrix for treating the deterministic component in Eq. (5). Then, the stochastic component of the system is treated by applying the generalized statistical linearization [12, 13].

## 2.1 Application of the harmonic balance method for treating the periodic component of the response

Assume that  $\bar{\mathbf{f}}_{d,\mathbf{x}}(t)$  in Eq. (4) is modeled as a monofrequency function of period  $T = \frac{2\pi}{\omega_d}$ . Then,  $\bar{\mathbf{f}}_{d,\mathbf{x}}(t) = \bar{\mathbf{f}}_{d1,\mathbf{x}} \cos(\omega_d t) + \bar{\mathbf{f}}_{d2,\mathbf{x}} \sin(\omega_d t)$ , where  $\bar{\mathbf{f}}_{d1,\mathbf{x}}$  and  $\bar{\mathbf{f}}_{d2,\mathbf{x}}$  are the constant coefficient  $(l + m)$  vectors, and thus, the deterministic response of the system in Eq. (5) becomes  $\mathbf{x}_d(t) = \mathbf{x}_{d1} \cos(\omega_d t) + \mathbf{x}_{d2} \sin(\omega_d t)$ , where  $\mathbf{x}_{d1}$ ,  $\mathbf{x}_{d2}$  are constant  $l$  vectors. Next, applying the harmonic balance method yields the overdetermined system of equations

$$\mathbf{P}\mathbf{u} = \mathbf{v}, \quad (6)$$

where the  $2(l + m) \times 2l$  matrix  $\mathbf{P}$ , and the  $2l$ - and  $2(l + m)$  vectors  $\mathbf{u}$ ,  $\mathbf{v}$  are given by

$$\mathbf{P} = \begin{bmatrix} \bar{\mathbf{K}}_{\mathbf{x}} - \omega_d^2 \bar{\mathbf{M}}_{\mathbf{x}} & \omega_d \bar{\mathbf{C}}_{\mathbf{x}} \\ -\omega_d \bar{\mathbf{C}}_{\mathbf{x}} & \bar{\mathbf{K}}_{\mathbf{x}} - \omega_d^2 \bar{\mathbf{M}}_{\mathbf{x}} \end{bmatrix}, \mathbf{u} = \begin{bmatrix} \mathbf{x}_{d1} \\ \mathbf{x}_{d2} \end{bmatrix}, \mathbf{v} = \begin{bmatrix} \bar{\mathbf{f}}_{d1} - \frac{2}{T} \int_0^T \mathbb{E}[\bar{\Phi}_{\mathbf{x}}] \cos(\omega_d t) dt \\ \bar{\mathbf{f}}_{d2} - \frac{2}{T} \int_0^T \mathbb{E}[\bar{\Phi}_{\mathbf{x}}] \sin(\omega_d t) dt \end{bmatrix}. \quad (7)$$

The solution of the system in Eq. (6) leads to the computation of the deterministic component of the response. In this regard, utilizing the generalized matrix inverses theory implies [14]

$$\mathbf{u} = \mathbf{P}^+ \mathbf{v} + (\mathbf{I} - \mathbf{P}^+ \mathbf{P}) \mathbf{y}, \quad (8)$$

which, in essence, corresponds to a family of solutions, since  $\mathbf{y}$  is an arbitrary  $2l$  vector. However, the matrix  $\bar{\mathbf{M}}_{\mathbf{x}}$  in the diagonal entries of matrix  $\mathbf{P}$  in Eq. (7) ensures that the columns of the latter are independent of each other or, equivalently, that matrix  $\mathbf{P}$  has full column rank. Therefore, it holds that  $\mathbf{P}^+ = (\mathbf{P}^* \mathbf{P})^{-1} \mathbf{P}^*$ , and thus, Eq. (8) attains a unique solution corresponding to the deterministic response component of the system in Eq. (2).

## 2.2 Application of the statistical linearization method for treating the stochastic component of the response

The stochastic component  $\mathbf{x}_s(t)$  of the system response is treated by resorting to the generalized statistical linearization methodology for systems with singular parameter matrices [12, 13]; see also [16, 17, 18, 19, 20, 21, 22, 23] for a broader perspective, as well as several examples pertaining to application of the method. First, the difference between the systems in Eqs. (2) and (5) is formed,

$$\bar{\mathbf{M}}_{\mathbf{x}}\ddot{\mathbf{x}}_s + \bar{\mathbf{C}}_{\mathbf{x}}\dot{\mathbf{x}}_s + \bar{\mathbf{K}}_{\mathbf{x}}\mathbf{x}_s + \tilde{\Phi}_{\mathbf{x}}(\mathbf{x}_s, \mathbf{x}_d) = \bar{\mathbf{Q}}_{\mathbf{x}}(t), \quad (9)$$

where  $\tilde{\Phi}_{\mathbf{x}}(\mathbf{x}_s, \mathbf{x}_d) = \bar{\Phi}_{\mathbf{x}}(\mathbf{x}_s + \mathbf{x}_d, \dot{\mathbf{x}}_s + \dot{\mathbf{x}}_d, \ddot{\mathbf{x}}_s + \ddot{\mathbf{x}}_d) - \mathbb{E}[\bar{\Phi}_{\mathbf{x}}(\mathbf{x}_s + \mathbf{x}_d, \dot{\mathbf{x}}_s + \dot{\mathbf{x}}_d, \ddot{\mathbf{x}}_s + \ddot{\mathbf{x}}_d)]$  is the zero-mean vector of the system nonlinearities. Then, the linear equivalent system to Eq. (9) is written as [12, 16]

$$(\bar{\mathbf{M}}_{\mathbf{x}} + \bar{\mathbf{M}}_e)\ddot{\mathbf{x}}_s + (\bar{\mathbf{C}}_{\mathbf{x}} + \bar{\mathbf{C}}_e)\dot{\mathbf{x}}_s + (\bar{\mathbf{K}}_{\mathbf{x}} + \bar{\mathbf{K}}_e)\mathbf{x}_s = \bar{\mathbf{Q}}_{\mathbf{x}}(t). \quad (10)$$

Subsequently, the error function, which is defined as the difference between Eqs. (9) and (10), is formed and minimized by adopting the mean square minimization criterion [12, 13, 16]. In this regard, the elements of the  $(l + m) \times l$  matrices  $\bar{\mathbf{M}}_e$ ,  $\bar{\mathbf{C}}_e$  and  $\bar{\mathbf{K}}_e$  are given by pertinent closed form expressions; more details are found in [13].

Since the nonlinear vector  $\tilde{\Phi}_{\mathbf{x}}(\mathbf{x}_s, \mathbf{x}_d)$  depends on the deterministic and stochastic components of the response, the elements  $m_{ij}^e, c_{ij}^e, k_{ij}^e$  of matrices  $\bar{\mathbf{M}}_e$ ,  $\bar{\mathbf{C}}_e$  and  $\bar{\mathbf{K}}_e$  are also time-dependent. Nevertheless, the slowly varying over a period  $T$  of oscillation components of  $\bar{\mathbf{M}}_e$ ,  $\bar{\mathbf{C}}_e$  and  $\bar{\mathbf{K}}_e$  are approximated by their average over  $T$  [15, 24], i.e.,  $\bar{\mathbf{M}}_e \approx \bar{\mathbf{M}}_e^{av}$ ,  $\bar{\mathbf{C}}_e \approx \bar{\mathbf{C}}_e^{av}$  and  $\bar{\mathbf{K}}_e \approx \bar{\mathbf{K}}_e^{av}$ ; indicatively,  $\bar{\mathbf{M}}_e^{av} = \frac{1}{T} \int_0^T \bar{\mathbf{M}}_e dt$ . This provides with an approximation to the system in Eq. (10), given by the equivalent system

$$(\bar{\mathbf{M}}_{\mathbf{x}} + \bar{\mathbf{M}}_e^{av})\ddot{\mathbf{x}}_s + (\bar{\mathbf{C}}_{\mathbf{x}} + \bar{\mathbf{C}}_e^{av})\dot{\mathbf{x}}_s + (\bar{\mathbf{K}}_{\mathbf{x}} + \bar{\mathbf{K}}_e^{av})\mathbf{x}_s = \bar{\mathbf{Q}}_{\mathbf{x}}(t). \quad (11)$$

Further, the response statistics of the equivalent system in Eq. (11) are determined by employing a frequency domain approach. In this regard, the frequency response function matrix of the system in Eq. (11) is derived and used in conjunction with the generalized input-output relationship for systems with singular parameter matrices, i.e.,  $\mathbf{S}_{\mathbf{x}}(\omega) = \boldsymbol{\alpha}_{\mathbf{x}}(\omega) \mathbf{S}_{\bar{\mathbf{Q}}_{\mathbf{x}}}(\omega) \boldsymbol{\alpha}_{\mathbf{x}}^T(\omega)$ , for determining the response power spectrum  $\mathbf{S}_{\mathbf{x}_s}(\omega)$  [13]. Finally, the second order response statistics of the equivalent system in Eq. (11) are computed by [16]

$$\mathbb{E}[\mathbf{x}_s^2(i)] = \int_{-\infty}^{\infty} \mathbf{S}_{\mathbf{x}_s(i)\mathbf{x}_s(i)}(\omega) d\omega, \quad i = 1, 2, \dots, l. \quad (12)$$

Eq. (12) in conjunction with the generalized input-output relationship for systems with singular parameter matrices, as well as Eq. (8), constitute a coupled nonlinear system of equations to be solved for determining the system response. For its solution, the following iterative procedure is used: *i.* The nonlinear vector  $\tilde{\Phi}_{\mathbf{x}}(\mathbf{x}_s, \mathbf{x}_d)$  in the governing equations of motion is set equal to the null vector and the deterministic response  $\mathbf{x}_d$  is obtained. *ii.* The variance of the stochastic response  $\mathbf{x}_s$  is derived by using the generalized input-output relationship in conjunction with Eq. (12). *iii.* Using step (ii.), Eq. (8) leads to the derivation of the deterministic response, which, in turn, results in calculating the values  $\bar{\mathbf{M}}_e^{av}$ ,  $\bar{\mathbf{C}}_e^{av}$  and  $\bar{\mathbf{K}}_e^{av}$ . *iv.* Steps (ii.) and (iii.) are repeated until reaching satisfactory accuracy for the response variance.

### 3 NUMERICAL EXAMPLE

In this example, the 2-DOF system in Fig. 1 is considered, where mass  $m_1$  is connected to the foundation by a nonlinear damper and a nonlinear spring of forces  $c_1 \dot{q}_1(1 + \varepsilon_1 \dot{q}_1^2)$  and  $k_1 q_1(1 + \varepsilon_2 q_1^2)$ , respectively. Further,  $q_i$  denotes the displacement of the  $i$ -th mass, and  $\varepsilon_1, \varepsilon_2$  the magnitude of the nonlinearities. In addition, mass  $m_2$  is connected to  $m_1$  by a linear spring of stiffness  $k_2$  and a linear damper of damping coefficient  $c_2$ . The system is excited by a combination of a stochastic force  $Q_1(t)$ , which is modeled as a Gaussian white noise stochastic process with spectral density  $S_0$ , and a deterministic force of the form  $f_{d2,1} \sin(\omega_d t)$ . The following set of parameter values is considered:  $m_1 = m_2 = 1$ ,  $c_1 = c_2 = 0.2$ ,  $k_1 = k_2 = 1$ ,  $S_0 = 10^{-2}$  ( $0 < \omega < 2\pi$ ),  $f_{d2,1} = 0.4$ ,  $\omega_d = \pi$  and  $\varepsilon_1 = \varepsilon_2 = 10$ .

Figure 1: A 2-DOF nonlinear system subject to periodic and stochastic excitations.

Figure 2: The nonlinear system of Fig. 1 modeled by employing an additional redundant coordinate.

Next, considering the redundant coordinates vector  $\mathbf{x}^T = [x_1 \ x_2 \ x_3]$ , the 2-DOF system of Fig. 1 is decomposed into its partial subsystems, as shown in Fig. 2. The system constraints equation is formed (see section 2), where  $\mathbf{A} = \begin{bmatrix} 1 & -1 & 0 \end{bmatrix}$ ,  $\mathbf{E} = \mathbf{L} = \mathbf{0}_{1 \times 3}$  and  $F = 0$ . Thus, the parameter matrices defined in Eq. (3) are determined, and the  $(l + m)$  vectors in Eq. (4) are computed. For the application of the harmonic balance method, the system response is decomposed into its stochastic  $\mathbf{x}_s$  and deterministic  $\mathbf{x}_d$  components, and ensemble averaging the expression for  $\bar{\Phi}_{\mathbf{x}}$  yields

$$(\mathbb{E}[\bar{\Phi}_{\mathbf{x}}])^T = \left( c_1 \varepsilon_1 (\dot{x}_{d,1}^3 + 3\dot{x}_{d,1} \sigma_{x_{s,1}}^2) + k_1 \varepsilon_2 (x_{d,1}^3 + 3x_{d,1} \sigma_{x_{s,1}}^2) \right) \begin{bmatrix} 0.5 & 0.5 & 0 & 0 \end{bmatrix}. \quad (13)$$

Then, taking into account that the  $8 \times 6$  matrix  $\mathbf{P}$  has full rank (see Eq. (7)), the overdetermined system in Eq. (6) leads to a uniquely defined periodic response component. Next, the iterative scheme in section 2.2 is employed to solve the coupled set of algebraic equations formed by Eqs. (12) and Eq. (8), and thus, to derive the variance of the stochastic response. The scheme is initialized by using  $\bar{\mathbf{C}}_e^{av} = \mathbf{0}$ ,  $\bar{\mathbf{K}}_e^{av} = \mathbf{0}$  and  $x_{d1} = x_{d2} = 0$ . The stochastic and deterministic components are derived based on the criterion  $\left| \frac{\bar{\mathbf{C}}_{e,j+1}^{av} - \bar{\mathbf{C}}_{e,j}^{av}}{\bar{\mathbf{C}}_{e,j}^{av}} \right| < 10^{-5}$  and  $\left| \frac{\bar{\mathbf{K}}_{e,j+1}^{av} - \bar{\mathbf{K}}_{e,j}^{av}}{\bar{\mathbf{K}}_{e,j}^{av}} \right| < 10^{-5}$ , as well as a similar criterion for  $x_{d1}, x_{d2}$ . The iterative scheme is applied until reaching satisfactory accuracy for the response displacement and velocity variances. Finally, considering that  $\mathbf{x}(t) = \mathbf{x}_s(t) + \mathbf{x}_d(t)$  and successively ensemble and temporal averaging the expression  $\mathbf{x}_d(t) = \mathbf{x}_{d1} \cos(\omega_d t) + \mathbf{x}_{d2} \sin(\omega_d t)$  implies

$$\langle \mathbb{E}[x_i^2] \rangle = \sigma_{x_{s,1}}^2 + \frac{x_{d1,i}^2 + x_{d2,i}^2}{2}, \quad \langle \mathbb{E}[\dot{x}_i^2] \rangle = \sigma_{\dot{x}_{s,1}}^2 + \frac{\omega_d^2 (x_{d1,i}^2 + x_{d2,i}^2)}{2}, \quad i = 1, 2, 3, \quad (14)$$

where  $\langle \cdot \rangle$  denotes the temporal averaging operation.

Eq. (14), in conjunction with the results of the iterative scheme above yield  $\sigma_{x_1}^2 = 0.0705$ ,  $\sigma_{\dot{x}_1}^2 = 0.0704$  and  $\sigma_{x_3}^2 = 0.0617$ ,  $\sigma_{\dot{x}_3}^2 = 0.1098$ . Finally, applying the standard solution framework proposed in [15] for deriving the system response variance yields  $\sigma_{q_1}^2 = 0.0705$ ,  $\sigma_{\dot{q}_1}^2 = 0.0704$  and  $\sigma_{q_2}^2 = 0.0617$ ,  $\sigma_{\dot{q}_2}^2 = 0.1098$ . Clearly, comparing the results above, it is seen that the herein proposed framework is in total agreement with the standard approach in [15].

## 4 CONCLUSIONS

In this paper, the response of multi-degree-of-freedom nonlinear systems with singular parameter matrices subject to combined stochastic and deterministic excitations has been determined by resorting to a generalized inverse matrix-based approach. Singular matrices appeared due to a redundant coordinates formulation of the system governing equations of motion. The

latter is associated with solution frameworks of reduced computational cost for certain classes of complex multi-body systems and/or systems with constraints. In this context, considering that the system excitation consists of a periodic and a stochastic component, the corresponding response has been decomposed in two parts, namely a periodic and a stochastic. Then, the system response has been determined by utilizing the generalized matrix inverses theory, in conjunction with the harmonic balance method and the generalized statistical linearization method for systems with singular parameter matrices. The validity of the proposed technique has been demonstrated by pertinent numerical examples.
